
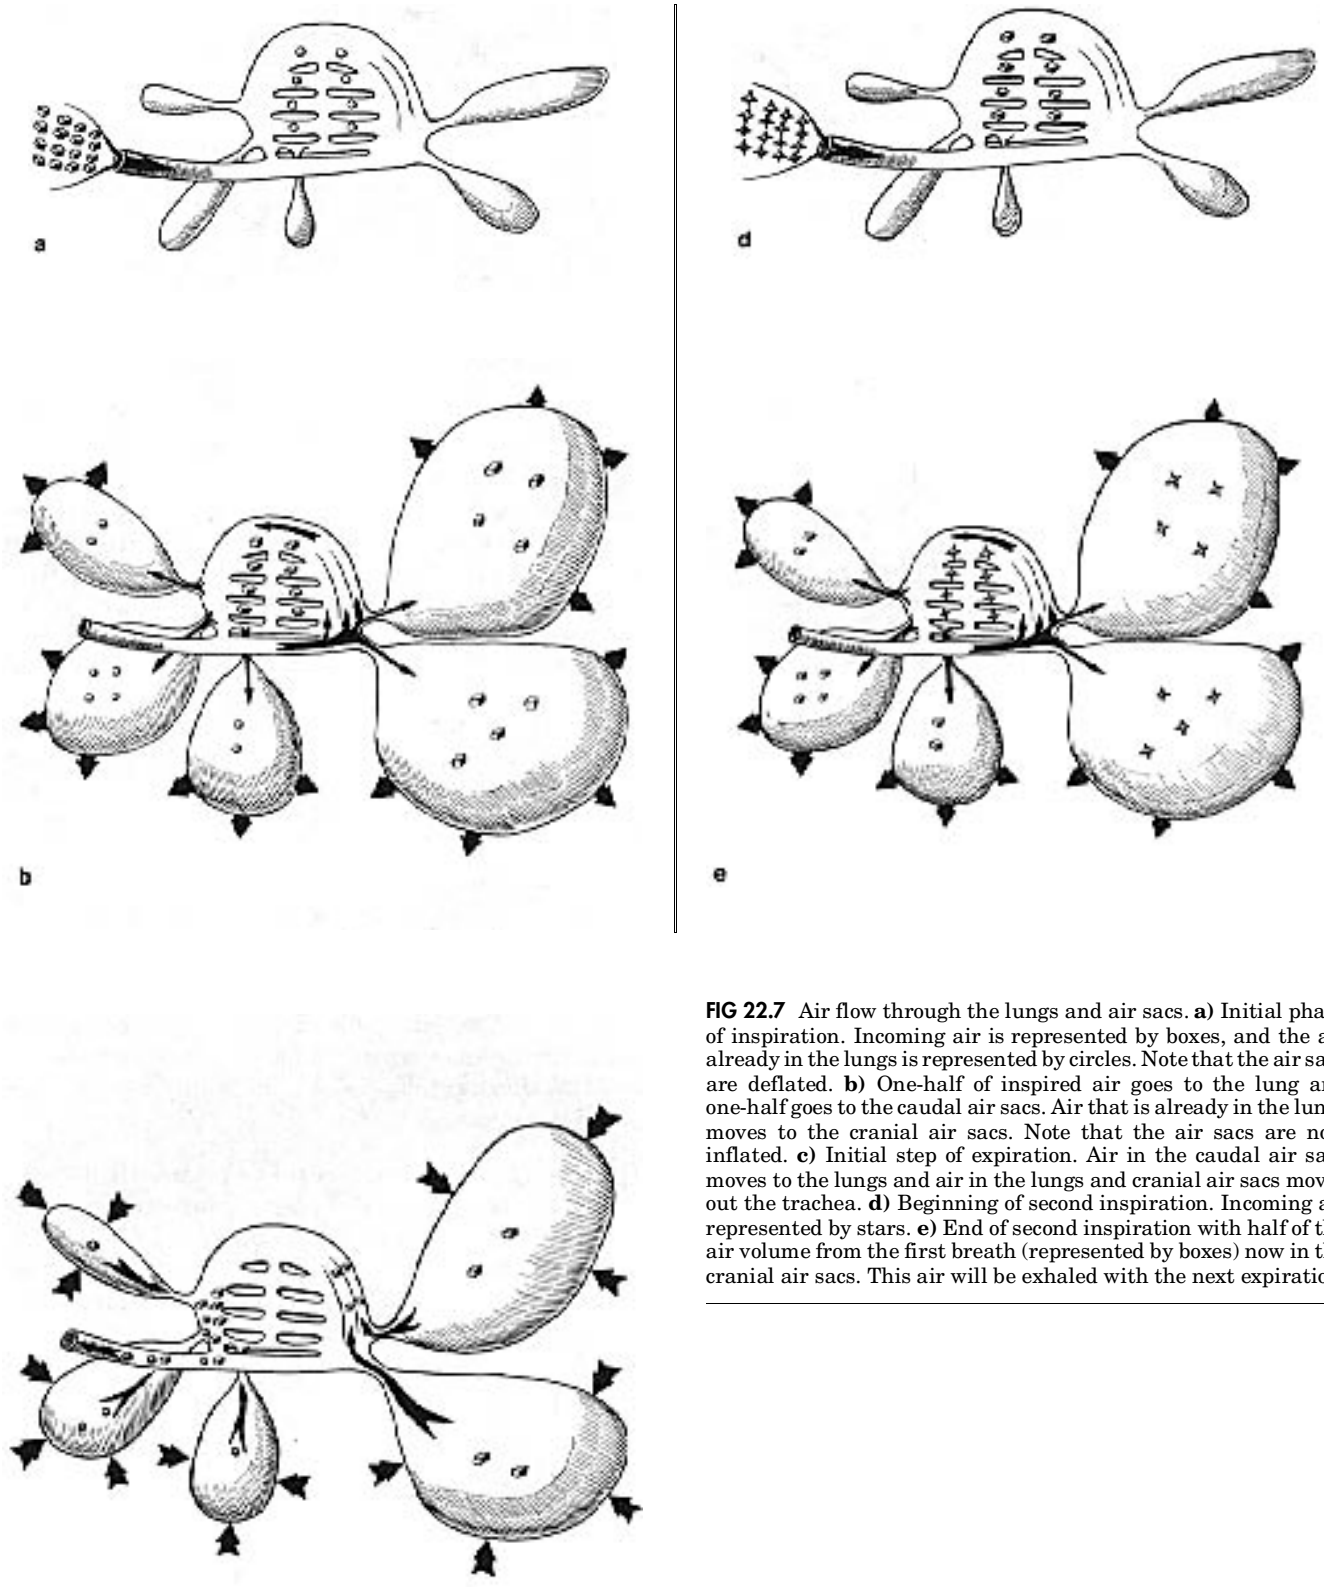

FIG 22.7 Air flow through the lungs and air sacs. **a)** Initial phase of inspiration. Incoming air is represented by boxes, and the air already in the lungs is represented by circles. Note that the air sacs are deflated. **b)** One-half of inspired air goes to the lung and one-half goes to the caudal air sacs. Air that is already in the lungs moves to the cranial air sacs. Note that the air sacs are now inflated. **c)** Initial step of expiration. Air in the caudal air sacs moves to the lungs and air in the lungs and cranial air sacs moves out the trachea. **d)** Beginning of second inspiration. Incoming air represented by stars. **e)** End of second inspiration with half of the air volume from the first breath (represented by boxes) now in the cranial air sacs. This air will be exhaled with the next expiration.

Diagnostic Techniques

Auscultation

The sinuses, trachea, lung, thoracic air sacs and abdominal air sacs can be auscultated using a pediatric stethoscope. Audible sounds on inspiration generally correlate with upper respiratory tract disease, while sounds on expiration are more commonly associated with lower respiratory tract diseases.[35,53,59] Because air moves through the lungs continuously and the air capillaries do not collapse and expand to the same degree as alveoli, a "smacking" sound characteristic of pneumonia in mammals does not occur in birds (Figure 22.8). However, mild respiratory lesions may be associated with audible respiratory sounds, while auscultation may be normal in patients with severe air sac pathology. Placing a thin towel around the bird and ascultating through the towel will actually enhance the clinician's ability to detect respiratory sounds.

With bacterial, fungal and parasitic diseases, harsh sounds may be heard on auscultation when air moves through narrowed parabronchi. Air sac pathology is best detected by placing the stethoscope along the lateral and dorsal body wall. An increased respiratory rate, particularly with dyspnea, is indicative of respiratory tract pathology, and harsh sounds may indicate chronic air sac or parabronchi pathology.[65] Use of a small amount of wing flapping (exercise) serves to increase respiratory rate and accentuate pathologic sounds. The amount of time for the bird to return to normal respiration (respiratory recovery time) is usually under two minutes even in obese birds. Prolonged respiratory recovery time is an indication that further diagnostic tests are necessary.

Imaging

Radiography and endoscopy (with biopsy and culture) are the most effective diagnostic techniques for avian respiratory disease. Radiographically, generalized air sacculitis may be recognized by the appearance of air sac lines on lateral radiographs. Radiographic interpretation of the avian respiratory tract is different from mammals. Interstitial patterns, air bronchograms and atelectasis do not occur in avian radiography.[54] Radiographs are usually of little value in diagnosing acute sinus infections but may be of value, particularly with respect to documenting involvement of bones in the head, with chronic inflammatory processes. Rhinography and sinography are helpful in the diagnosis of upper respiratory tract problems (see Chapter 12).[54]

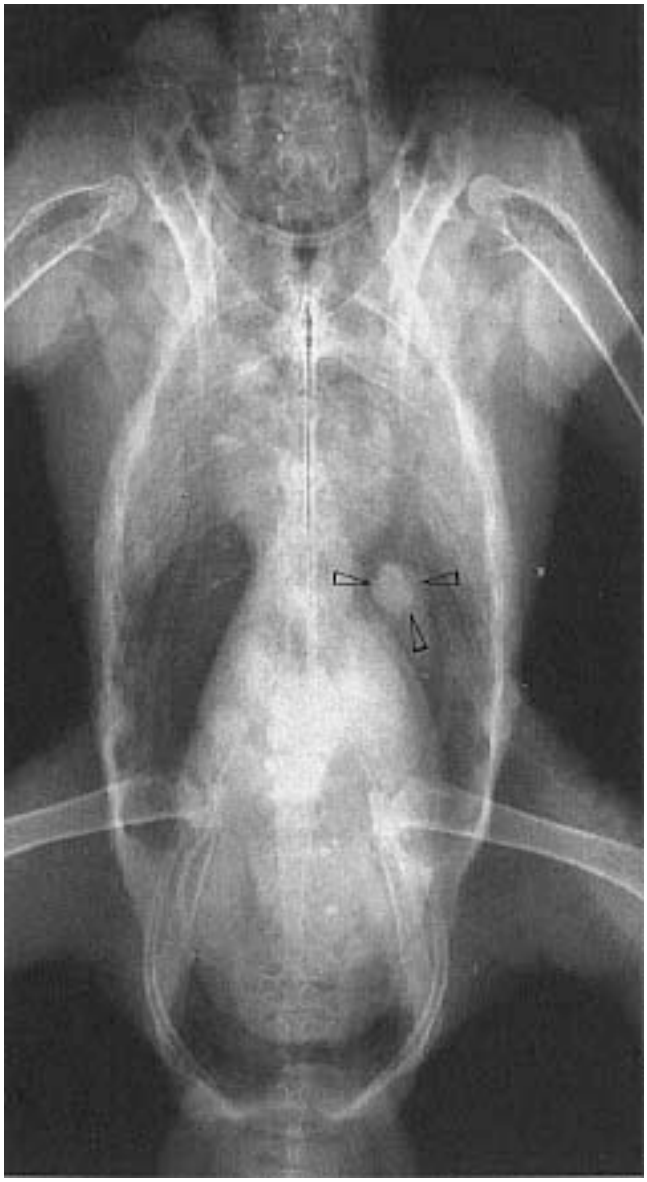

FIG 22.8 A Blue and Gold Macaw was presented with progressive dyspnea of one month's duration. The bird had stopped eating and was depressed for two days before evaluation. Radiographs indicated a soft tissue mass in the left thoracic air sac region (arrows). The only change that could be detected by auscultation was decreased lung sounds. Endoscopy revealed a granulomatous mass and diffuse air sacculitis. The mass was surgically removed and the bird responded to therapy with broad-spectrum antibiotics.

The ventrodorsal view should be used to assess the subtle disorders of the lung and air sacs. Radiographically, soft tissue masses are commonly associ-

ated with upper respiratory signs, pneumonia and air sacculitis (Figure 22.8).[54] On a lateral radiograph, the trachea of normal toucans and mynah birds deviates ventrally, which should not be misinterpreted as a displacement caused by a soft tissue mass. In many ducks, the male has an enlargement on the left side of the syrinx (syringeal bulla) that is not found in the female.

Sample Collection

The minimum database for respiratory problems includes cytology of samples collected from the affected area, a CBC, biochemistries, radiographs and, when indicated, endoscopy.

A sinus aspirate is important in determining the cause of sinusitis. There are several techniques that allow for minimal sample contamination and maximum microbial and cytologic examination. A patient must not move during this procedure or severe damage to the globe of the eye can occur (see Chapter 10). Aspiration of the right and left infraorbital sinuses is needed for diagnostic procedures in some passerines.[44] Samples collected from the rostral portion of the choanal slit may provide some useful information on the organisms present in the respiratory passages. Samples collected from the caudal choanal slit are of little diagnostic value with respect to the sinuses or nasal passages.

Tracheal Lavage

Tracheal lavage is indicated when pathology of the trachea or lower respiratory system is suspected. The procedure is relatively simple but requires general anesthesia in most avian patients.[40] A normal wash should be low in cellularity with a minimum of pulmonary macrophages or inflammatory cells.[13]

Increased numbers of heterophils, pulmonary macrophages and other inflammatory cells in the lavage fluid are clinically important.[13] In a severely dyspneic bird, a large-gauge hypodermic needle or a respiratory catheter placed in the abdominal air sacs will help the patient breathe while the procedure is performed.

An intratracheal wash is performed by placing the bird in dorsal recumbency and passing a sterile, soft plastic or rubber tube (eg, Rob-nel catheter) through the glottis into the trachea, ending near the syrinx (just caudal to the thoracic inlet). A sterile saline solution (0.5 to 1.0 ml/kg body weight) is infused into the trachea and reaspirated in the sterile syringe attached to the tube.[40]

A sterile endotracheal tube may be placed within the trachea prior to inserting the lavage tube to prevent sample contamination as the lavage tube is passed through the oral cavity. Tracheal swab samples for microbiology evaluation may be taken by passing a small sterile cotton swab directly into the trachea.

A transtracheal lavage can be performed by sterilely placing an 18 to 22 ga Teflon indwelling catheter through the skin and into the trachea. The bird is held parallel to the floor and fluid is instilled and immediately removed. This procedure can be performed in some patients without anesthesia.

Endoscopy

An endoscope may be used to diagnose respiratory problems associated with the trachea, air sacs or lungs. Small-diameter, rigid or flexible endoscopes can be inserted to the syrinx in some birds. A 1.9 mm endoscope easily passes to the syrinx in a 200 g parrot while a 1.7 mm scope will not reach the syrinx in a cockatiel.

Endoscopic evaluation of the air sacs can be performed on both the right and left side of the patient. The caudal surface of the lung, which normally appears pale pink and spongy, may also be observed during this procedure (see Chapter 13).

Diffuse air sacculitis, recognized endoscopically as vascularized, transluscent, thickened air sacs, commonly occurs with chlamydiosis, some viral diseases, poor air quality, bacterial infections and localized fungal infections. Granulomatous air sacculitis is difficult to resolve without surgery.

Air Sac Diagnostics

Cultures or biopsies of the air sacs can best be obtained using endoscopically guided procedures. Specially designed brushes are commercially available that will transverse the length of a sterile channel in the endoscope, eliminating the problem of coordinating the position of a separate endoscope and sample collecting device (see Chapter 13). Feather picking over the air sacs may be an indication of irritation that requires further investigation. The lung can also be biopsied using an endoscope (see Chapter 13).

A cytologic sample can be collected from the air sacs by passing a tube through an endoscopic cannula, lavaging with sterile LRS and immediately reaspi-

rating. Sterile cotton swabs may be used to obtain samples for bacterial or fungal cultures using the same technique.[40]

Lung Biopsy

Lung biopsies may be diagnostic in some cases of toxin inhalation and microbial or parasitic infections. This procedure does create the potential for localized pulmonary hemorrhage and should be performed with minimal trauma to the lungs (see Chapter 13).[41]

The approach to the lung can be achieved through either the caudal thoracic air sac or via an intercostal approach through the third intercostal space. Approaching through the caudal thoracic air sac provides the best view of the caudal aspect of the lungs while the intercostal approach is used to access the dorsolateral portion of the lung. In experimental pigeons, mild to moderate pulmonary hemorrhage occurred at the biopsy site using a 2.7 Fr (best biopsy sample but more severe hemorrhage) or 5 Fr biopsy forceps. The procedure is not without risk and should be considered only when other diagnostic techniques are ineffective or when a biopsy is necessary to determine and initiate life-preserving therapy.[41]

Aerosol Therapy

The use of a therapeutic solution that has been atomized into a fine mist is effective in treating upper respiratory tract infections.[66] Humidification, vaporization and nebulization are three types of aerosol therapy that have been used successfully to treat avian respiratory problems.

If the relative humidity of the environmental air is low, then humidification of inspired air may improve the efficiency of the mucociliary blanket.[66] In the clinical setting, humidification is used in conjunction with a therapeutic agent but can be prescribed without additives for home treatment. Any source of cool, moist air could be used.

Vaporization is a form of aerosol therapy that utilizes cool or warm mist to deliver topical medications to the mucous membranes.[66] Vaporized particles are large and do not reach the lower respiratory system. Eucalyptus-based products, available as over-the-counter medications for human vaporizers, may cause mucosal irritation in birds and should not be used.

Nebulization can be used to augment systemic therapy of some respiratory tract diseases. Nebulization can help maintain proper hydration of the respiratory epithelium, break up necrotic debris and deliver antimicrobial agents to the upper respiratory tract and portions of the lower respiratory tract. Nebulization therapy is indicated in birds exhibiting sinusitis, rhinitis, pharyngitis and bronchitis. Depending on the agents delivered, nebulization can be used three to four times per day for 10 to 15 minutes for each session. Therapy should be continued for three days after all clinical signs have been resolved.

The equipment needed for nebulization therapy includes an air compressor or some source of O_2, an enclosed chamber and an infant (human) nebulizer. The most important piece of equipment is the air compressor. An inexpensive reliable unit is commercially available,[a] which should satisfy most nebulization requirements. At least two sizes of nebulization chambers should be maintained, one for larger patients and one for small birds. It has been shown that nebulization can be used to deliver antimicrobial agents to the lungs and some portions of the air sacs if the particle size is less than 0.5 microns in diameter.

All medications delivered to birds by nebulization are used empirically and should be based at least on results obtained from culture and sensitivity (Table 22.5). Mucolytic agents should be used only with infections localized to the sinuses and trachea. Amphotericin B, gentamicin, polymyxin B and tylosin have been found to be poorly absorbed from the respiratory epithelium, and these agents are used principally for their local effects. However, penetration of nebulized antibiotic particles into avian lung parenchyma and onto air sac surfaces may be effective.

The addition of DMSO to the nebulization solution was found to increase the local and systemic concentration of nebulized tylosin.[40] However, the systemic effects of inhaling DMSO have not been evaluated. Nebulized tylosin required one hour to reach therapeutic concentrations in the air sacs and lungs of pigeons and quail.[67]

Other therapeutic agents that have been reportedly used for nebulization therapy in birds include acetylcysteine, sodium tris-EDTA, levamisole phosphate and corticosteroids.[12] The use of immunosuppressive drugs such as corticosteroids in nebulization therapy should be avoided. Acetylcysteine may be added to

nebulization therapy for upper respiratory diseases in which the exudates can be physiologically removed, but it should not be used for lower respiratory treatment because of a bird's inability to rapidly remove exudates from the air sacs.

TABLE 22.5 Medications Commonly Used in Nebulization Therapy[5]

Drug	Dosage
*Amphotericin B	100 mg in 15 ml saline
Chloramphenicol succinate	200 mg in 15 ml saline
Erythromycin	200 mg in 10 ml saline
*Gentamicin	50 mg in 10 ml saline
*Polymyxin B	333,000 IU in 5 ml saline
Spectinomycin	200 mg in 15 ml saline
Sulfa dimethoxine	200 mg in 15 ml saline
*Tylosin	100 mg in 10 ml saline, 1 g in 50 ml DMSO
*Amikacin	50 mg in 10 ml saline
Enrofloxacin	100 mg in 10 ml saline

These drugs may also be delivered by transtracheal injection.
*Poorly absorbed from the respiratory epithelium; provides primarily topical therapy.

Specific Respiratory Diseases

Table 22.6 lists the most common etiologic agents associated with respiratory diseases in birds (see Figure 22.11).

Nutritional Disorders

Hypovitaminosis A has been associated with hyperkeratosis, abscessation of the palatine salivary glands and other oral salivary glands and respiratory lesions in psittacine birds (see Color 8.).[56,68] Improving a bird's diet and providing oral vitamin supplementation and parenteral administration of vitamin A will prevent and eliminate nutritional deficiencies, support ill patients and speed recovery time in patients with respiratory infections. It should be noted that with the widespread use of formulated diets, hypovitaminosis A is less commonly encountered than it was a decade ago.

TABLE 22.6 Selected Etiologic Agents of Avian Respiratory Disease

BACTERIAL
- *Chlamydia psittaci*
- *E. coli*
- *Mycoplasma*
- *Pseudomonas*
- *Klebsiella*
- *Salmonella*
- *Mycobacterium avium*
- *Proteus*
- *Haemophilus*
- *Bordetella avium*
- *Pasteurella*
- *Streptococcus*
- *Staphylococcus*

NUTRITIONAL
- Vitamin A deficiency
- Iodine deficiency
- Obesity
- General malnutrition

TOXIC
- Polytetrafluroethylene gas
- Formaldehyde
- Quaternary ammonium
- Creosote
- Chlorinated biphenyl
- Carbon monoxide
- Cigarette smoke
- Naphthalene
- High ammonia
- Airborne particulate matter
- Zinc

VIRAL
- Adenovirus
- Paramyxovirus
- Laryngotracheitis virus
- Influenza virus
- Infectious bronchitis virus
- Avian poxvirus

PARASITIC
- *Sternostoma* (tracheal mites)
- *Cytodites* (tracheal mites)
- *Cyathostoma*
- *Syngamus*
- *Sematospiculum* (nematode)
- Cryptosporidia
- *Trichomonas*
- Coccidia (systemic)
- Hematozoa
- *Knemidokoptes* (scaly face mites)
- *Sarcocystis*

FUNGAL
- *Aspergillus*
- *Candida*
- *Mucor*
- *Cryptococcus*

Infectious Organisms

Chlamydia psittaci and *Mycoplasma* spp. are obligate intracellular organisms with a predilection for respiratory epithelium and have been implicated in cases of rhinorrhea, infraorbital sinusitis and inflamed choanae.[34,73] Both organisms may persist as low-grade upper respiratory tract infections. This is particularly common in birds that are treated with immunosuppressive, over-the-counter antibiotics.

Mycoplasma spp. have been proposed as causes of upper respiratory and ocular infections in cockatiels and budgerigars, although documented cases are rare (see Color 22.2 and Chapter 38).[27,30,36] *C. psittaci* and *Mycoplasma* spp. organisms are difficult to isolate and can cause similar clinical signs, which complicate a definitive diagnosis. These organisms have also been isolated from tissues of clinically asymptomatic birds.[65] Birds with suggestive clinical signs frequently respond to treatment with tetracyclines, tylosin or spectinomycin. These drugs are rarely effective against microbial organisms other than *Chlamydia* or *Mycoplasma* spp.

Bacteria

Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, *Pasteurella multocida*, *Yersinia pseudotuberculosis* and *Salmonella* spp. are gram-negative bacteria frequently isolated from birds with respiratory tract infections (Color 22.1).[55,63] Gram-negative bacterial infections cause a mucopurulent or thick serous drainage in comparison to the rhinorrhea (clear nasal discharge) associated with uncomplicated *C. psittaci* infections (see Chapter 33).

Serous nasal discharges may result from foreign bodies, allergies, uncomplicated viral, bacterial, fungal or chlamydial infections and with developmental defects or injuries that block the normal drainage of the sinuses into the oral cavity. With most infectious agents, the discharge will turn rapidly from serous to mucopurulent.

Pathogenic gram-positive bacteria commonly associated with respiratory infections include strains of *Streptococcus* spp. and *Staphylococcus* spp.[30] *Mycobacterium tuberculosis* was recovered from the nasal cavity and infraorbital sinuses of a Red-lored Amazon Parrot (Color 22.10).[5]

Under most circumstances, *Streptococcus* spp. and *Staphylococcus* spp. would be considered normal bacterial flora. However, pure isolates of *Staphylococcus* spp. and *Streptococcus* spp. have been associated with respiratory and intestinal tract infections.[30] Common nonpathogenic bacteria isolated from the respiratory tract of psittacines include *Bacillus* spp., *Corynebacterium* spp. and *Lactobacillus* spp. (see Chapter 33).[3,65] Upper respiratory infections caused by spirochetes have been seen in cockatiels. This organism can be demonstrated on wet mount smears (see Chapter 10).

Mycotic Organisms

Systemic avian mycotic infections can be difficult to treat. *Aspergillus* spp. are ubiquitous fungal organisms and are common pathogens in the respiratory system of immune-incompetent birds.[42,55] African Grey Parrots, cockatoos, Amazon parrots, raptors, penguins, turkeys, swans and other waterfowl (see Chapter 37) seem to be more susceptible than most psittacine species to this mycotic infection (see Chapter 35). Birds with a history of stress, unsanitary conditions or malnutrition and birds affected by oil spills or other toxins are most susceptible.[61,65] Infections may be acute, chronic or associated with mycotic tracheitis.[29,33] Mycotic granulomas may be found in the nasal cavity, oropharynx, glottal opening, tracheal bifurcation (syrinx), lungs or air sacs.[42,55,62,65]

Clinical signs with acute mycotic tracheitis include dyspnea (mild to severe) and a white discharge originating from the glottis (Color 22.16).[41,55] Fungal hyphae may be seen cytologically in specimens taken from the choana or trachea. Tail-bobbing and peracute severe respiratory distress are common with chronic lower respiratory tract involvement if the passages from the air sacs to the lungs is occluded.[65] Secondary infections may occur on organs in contact with infected air sacs, which might include the liver, kidneys, intestinal serosa and gonads (see Chapter 35). *Candida* spp. infections originating in the oral pharyngeal cavity may extend into the proximal trachea and infraorbital sinuses resulting in varying degrees of dyspnea.[14,39,62] Infected birds may temporarily respond to antibiotics (alleviation of secondary bacteria) but fail to recover. In these cases, samples from the affected area should be evaluated by cytology and culture for the presence of fungal pathogens.

Although not common in psittacine birds, a few cases of respiratory cryptococcosis have been described.[15,23,32,69] Affected birds were depressed with severe dyspnea and were unresponsive to treatment. Necropsy findings indicated gelatinous myxomatous material in the nasal cavity, infraorbital sinus and air sacs.[61]

Rhinosporidiosis is most frequently associated with waterfowl from estuary habitats.[11,17] These and other less common saprophytic fungi have been associated with rhinitis and sinusitis.[11]

Trichosporon beigelli (trichosporonosis), *Absidia* sp. (mucormycosis) and *Nocardia asteroides* (nocardiosis) have been isolated from the lungs and air sacs of birds with respiratory signs.[9,19,47,70]

Parasites

Disseminated cases of trichomoniasis may involve the upper respiratory system, trachea and air sacs causing dyspnea and respiratory distress.[58] In the oropharynx and ventral choanal surface, lesions may appear as white or yellow caseous nodules or ulcers[61] (see Chapter 36).

The tracheal mite, *Sternostoma tracheacolum* may cause severe respiratory signs in finches and canaries. Symptoms include vocalization changes, a characteristic clicking during respiration, tail-bobbing and dyspnea.[50] Severe cases lead to weakness and death. The mite may be present in any location of the

respiratory system. Transtracheal illumination may be helpful in diagnosing infections. The identification of eggs in mucus from the trachea is diagnostic (see Chapter 36).

Gapeworms (*Syngamus trachea)* inhabit the trachea and glottis area of an infected bird. Clinical signs include dyspnea and changes in vocalization. Visualization of large, bright-red helminths that are in a Y-configuration in the glottal opening are indicative of infection.[2] The earthworm is the primary vector for *Syngamus trachea*, and infections occur following ingestion of the worm. This parasite most often infects ground-dwelling species, usually in zoo and aviary situations.

Sarcocystis falcatula is a coccidian parasite with an obligatory two-host life cycle.[16,21] This parasite causes an acute, fulminating, hemorrhagic, interstitial pneumonia.[16] The clinical presentation may range from respiratory distress and severe dyspnea to peracute death with no premonitory signs (Color 22.11; see Chapter 36).

Systemic microfilaria, trematodes, nematodes and cryptosporidia are other parasites that have been documented in the respiratory system of companion birds.[2,38] These parasites may be incidental findings on necropsy or may cause varying degrees of upper or lower respiratory distress.

Inhalation Toxicosis

Birds are sensitive to inhaled toxins and have historically been used as sentinel animals to detect toxic levels of poisonous gases. Clients should be educated with respect to the adverse effects that fumes from common household compounds can have on their companion birds. The clinical changes following inhalation of household fumes may include irritation of mucous membranes, conjunctivitis, rhinitis, dyspnea or peracute death (see Chapter 37).

Cigarette Smoke

Passive exposure to cigarette smoke is a common cause of primary respiratory problems in birds as well as a common complicating factor in other respiratory illnesses. Exposure to cigarette smoke can cause a mixture of clinical problems including conjunctivitis, sinusitis, air sacculitis, rhinitis and dermatitis. Diagnosis and treatment of respiratory disease in birds that are exposed to cigarette smoke are difficult, if not impossible. In many cases, complete cessation of all respiratory signs occurs from several weeks to several months after the bird is removed from an environment contaminated with cigarette smoke.

Rhinitis and Sinusitis

Rhinitis may be caused by chemical, bacterial, fungal, chlamydial or viral pathogens. Precipitating environmental factors may include cigarette smoke, excessive powder down, dust from organic debris (bedding, flooring substrate), nutritional deficiencies and inappropriate use of antibiotics, all of which may damage the mucosa of the upper respiratory tract allowing pathogens to colonize. South American Psittaciformes that are exposed to the dander of cockatoos and cockatiels may develop a severe allergic pneumonitis. Antibiotics should be used with caution in mild undiagnosed rhinitis. Prolonged or inappropriate use can predispose the patient to secondary bacterial or fungal infections.

A seasonal occurrence (primarily winter months) of serous nasal discharge, mild sneezing and erythromatous nostrils has been described in some Psittaciformes (particularly South American species) maintained in cold, dry northern environments.[5] Similar lesions are seen when the heat or air conditioning systems are first turned on, which might suggest the accumulation of debris or respiratory irritants (stale gases) in the duct system. These birds can frequently be maintained with conservative therapy by increasing humidity, as long as the discharge remains serous and no pathogens are demonstrated. Birds are susceptible to influenza-A virus and could, theoretically, be infected through exposure to diseased members of the household (see Chapter 32).

Miscellaneous Conditions

Choanal Atresia

An African Grey Parrot chick with bilateral serous nasal discharge starting at four days of age was found to have choanal atresia (Figure 22.9). Fluids introduced into the nasal cavity did not enter the mouth and a rhinogram (nasal sinus contrast study) indicated that there was no communication between the nasal passage and the choanal slit (see Figure 12.42). Endoscopy of the choanal slit and surrounding structures revealed an intact membrane covering the choana at the level of the palate. All other oral structures were normal. Similarly, an Umbrella Cockatoo with a three-year history of intermittent serous to mucopurulent oculonasal discharge was found to have a deformed hard palate with no choanal slit. The roof of the mouth was flat and bony,

FIG 22.9 An African Grey Parrot was presented with a life-long history of serous to mucopurulent nasal discharge that was unresponsive to antibiotics. Fluid introduced to the nasal cavity would not pass into the oral cavity, and endoscopy and rhinography were used to document choanal atresia (courtesy of Cheryl Greenacre).

with papillae scattered randomly. Sterile saline introduced into the nostrils would not pass from the nares to the oral cavity. Contrast media placed in the nares stopped abruptly at the level of a thickened palate, confirming the diagnosis of choanal atresia (see Figure 12.43).[31]

Proliferative Nasal Granulomas (Rhinoliths)

Proliferative nasal granulomas have been documented in numerous psittacine species, but are particularly common in African Grey Parrots.[18] Pathogenic organisms isolated from these granulomatous growths included *E. coli*, *Enterobacter* spp., *Pseudomonas* spp. *Klebsiella* spp., *Aspergillus* spp. and *Candida* spp. Malnutrition and poor air quality play principal roles in initiating this lesion.

Upper respiratory disease, wheezing, sneezing and insufflation of the infraorbital air sacs on expiration can be early clinical changes associated with the accumulation of debris in the nares. Subtle lesions can best be detected by examining the area around the operculum using magnification. It is best to remove accumulating necrotic debris by probing and flushing before it accumulates and alters the architecture of the nares or sinus passages (see Chapter 41).[14] Recurrence is common unless dietary and management changes are made in conjunction with aggressive parenteral, topical and nebulization therapy.

Advanced lesions require removal of granulomatous tissue, frequently resulting in a large tissue defect (atrophic rhinitis; Figure 22.10). Given the vascularity of the affected area, manipulation of the affected tissue must be augmented with magnification.

Sunken Eye Sinusitis

A syndrome characterized by periorbital depression (sunken sinus syndrome) has been described as a sequela to sinusitis in macaws, conures and emus. Progressive collapse of the epithelium into the infraorbital sinus around the eye is typical (Color 22.1). Gram-negative organisms have been isolated from the infraorbital sinuses and choana of affected birds. The pathogenesis of this lesion is unclear. Ocular pathology or radiologic changes consistent with bone involvement are uncommon.

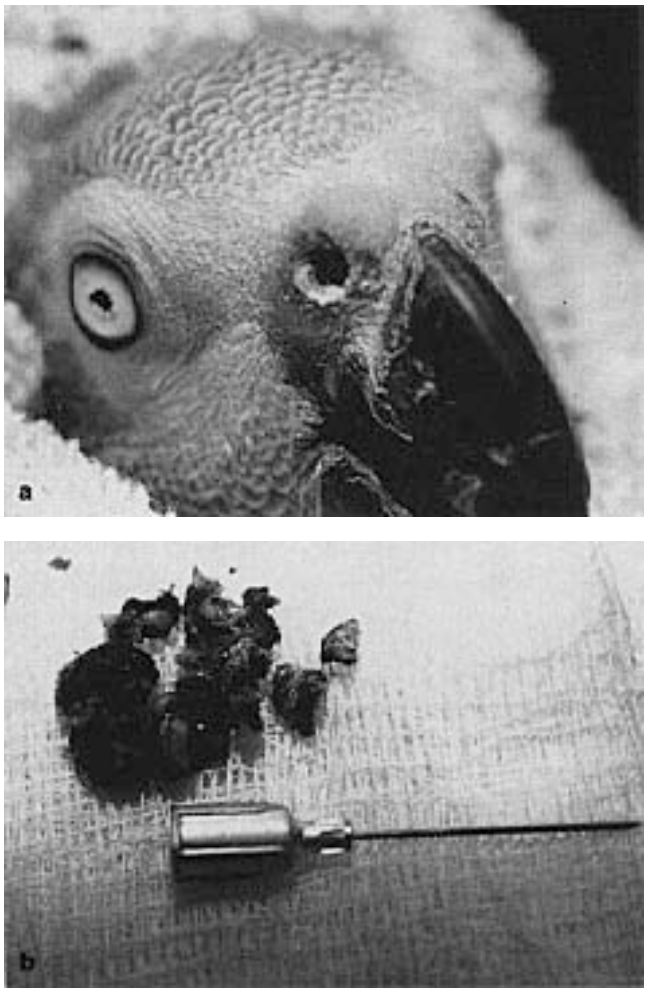

FIG 22.10 **a)** Proliferative nasal granuloma and advanced atrophic rhinitis in an African Grey Parrot. Note the enlargement of the nostril, absence of the operculum and swelling of the perinasal tissues. **b)** Necrotic material that was removed from the nostril of this bird.

Upper Respiratory Disease

Clinical Presentation

Dyspnea, rhinorrhea, purulent nasal discharge, periocular swelling, voice change, open-mouthed breathing, coughing, sneezing

Diagnostic Techniques

History
External examination of nares, choana, pharynx, larynx and trachea for hyperkeratosis, mites, granulomas
Palpation of neck and thoracic inlet, transillumination of trachea
Choanal Gram's stain and culture
Transtracheal wash, suction, cytology
Sinus flush and culture
Radiographs
Endoscopy

Rhinitis

1. Bacteria
2. Fungi
3. Reovirus
4. Parasites
5. Malnutrition
6. Chlamydia
7. Toxins

Sinusitis

1. Bacteria
2. Fungi
3. Hypovitaminosis A
4. Papilloma
5. Chlamydia
6. Mycoplasma
7. Toxins

Tracheitis

1. Amazon Tracheitis Virus
2. Avian Pox
   a. *Agapornis* Pox
   b. Psittacine Pox
   c. Amazon Pox
   d. Budgerigar Pox
3. Parasites
4. Malnutrition
5. Chlamydia
6. Toxins

Laryngitis

1. Herpesvirus
2. Poxviruses
3. Haemophilus-like organisms
4. Hypovitaminosis A

Lower Respiratory Disease

Clinical Presentation

Coughing, dyspnea, open-mouthed breathing, tail-bobbing, low exercise tolerance, depression

Diagnostic Techniques

History
Auscultation of lungs and air sacs
Radiography
Laparoscopy
Culture, flush or biopsy
Visualize lungs and air sacs

Nonrespiratory Diseases with Respiratory Signs

1. Ascites: liver disease, renal disease, neoplasia
2. Hemocoelom: trauma, vitamin K deficiency
3. Malnutrition
4. Obesity
5. Goiter
6. Cardiomyopathy: heart failure
7. Paramyxovirus, herpesvirus, reovirus
8. Hemochromatosis
9. Egg-related peritonitis

Foreign Body Inhalation

Parasites

Air Sacculitis

1. Bacteria
2. Fungi
3. Canary pox
4. Paramyxovirus
5. Chlamydia
6. Mycoplasma

Pneumonia

1. Bacteria
2. Fungi
3. Virus
4. Mycobacterium
5. Parasite (Sarcocystis)
6. Toxin

Respiratory Abscess

1. Bacteria
2. Fungi

Allergy

FIG 22.11 Differential diagnoses of upper and lower respiratory disease.

It has been suggested that this lesion may occur because a vacuum develops within the infraorbital sinus due to blockage of small diverticuli secondary to the host's inflammatory response to infectious agents. Once an infection is resolved and the sinus pathways are patent, the collapsed sinus should return to normal. Within a flock of one hundred six-month-old emus, two birds developed this syndrome, suggesting a low prevalence of the problem in a given population (see Chapter 48).

Foreign Body Inhalation

The inhalation of foreign bodies (seeds, granulomatous plaques, splinters and toys) occasionally occurs in companion birds.[54] The acute onset of mild to severe dyspnea in an otherwise healthy bird is a suggestive finding (Color 22.8). A thorough endoscopically assisted examination of the nares, choana, glottis, trachea and syrinx is helpful in the diagnosis of foreign body inhalation. Tumors, granulomas, abscesses and papillomas (glottis and choana) may cause varying degrees of dyspnea.[18]

The methods chosen to remove a foreign body will depend on the size of the patient. In birds weighing over 300 g, an endoscope can be used to suction or guide grasping forceps in the removal of some foreign bodies. Once the foreign body is localized, a 30 ga needle can be passed through the trachea distal to the mass to prevent it from moving further down the trachea. Some foreign bodies that cannot be removed by grasping may be flushed out of the trachea by holding the bird upside down and infusing fluids through a small tube placed in the trachea or through a transtracheal needle passed caudal to the mass. In some smaller birds, the distance to the syrinx can be estimated and marked on an appropriate-sized tube. The tube is then passed blindly to this predetermined level and suction is applied to remove accumulated debris.[48] If all other methods of removal fail, a tracheotomy is necessary (see Chapter 41).

Proliferative Tracheitis

Dyspnea, rales, pseudomembranous tracheitis, conjunctivitis and sinusitis have been described as clinical signs associated with proliferative tracheitis in psittacine birds. A herpesvirus with group-serologic relations to the infectious laryngotracheitis virus (ILT) has been shown to cause this lesion in *Amazona* spp (Color 22.7).[28] Swabs of the glottis and proximal trachea for cytology culture and viral isolation are necessary for diagnosis. Antiviral therapy utilizing acyclovir may be helpful along with supportive therapy and antibiotics.[65] This disease is rarely reported in the USA, and has been described only in smuggled or recently imported Amazon parrots (see Chapter 32).

Air Sacculitis

Bacterial and fungal organisms are commonly associated with acute and chronic air sac infections.[62] The air sacs are poorly vascularized and have no clearance mechanism (mucociliary blanket), which complicates the treatment of air sacculitis. Air sac infections are best treated aggressively with therapeutic agents that are chosen based on culture and sensitivity. Surgical debridement may be necessary to resolve air sac infections that result in the formation of masses.

Subcutaneous Emphysema

Subcutaneous emphysema can occur following damage to any air sac system but is most common with damage to the cervicocephalic, abdominal or caudal thoracic air sacs (Figure 22.12). Trauma, malnutrition and infectious agents have been implicated as causes of subcutaneous emphysema (see Chapter 41). In addition, the cervicocephalic air sac may distend as a result of rhinitis, which causes occlusion of the nasal passage or damage to the outflow tracts. The resulting lesion looks clinically like subcutaneous emphysema as the air sacs progressively inflate with each successive expiration.

When the air is removed with a needle, the sac will deflate but will typically reinflate with subsequent respiratory cycles. Initially, these problems can be managed by wrapping the area with a loose, self-adherent bandage. If the problem persists, long-term management can be achieved by inserting a Teflon stent in the dorsal wall of the air sac that allows air to escape. In some cases, the damage to the sac will repair itself and the stent can be removed. In other cases, the stent must remain in place permanently (see Chapter 41).

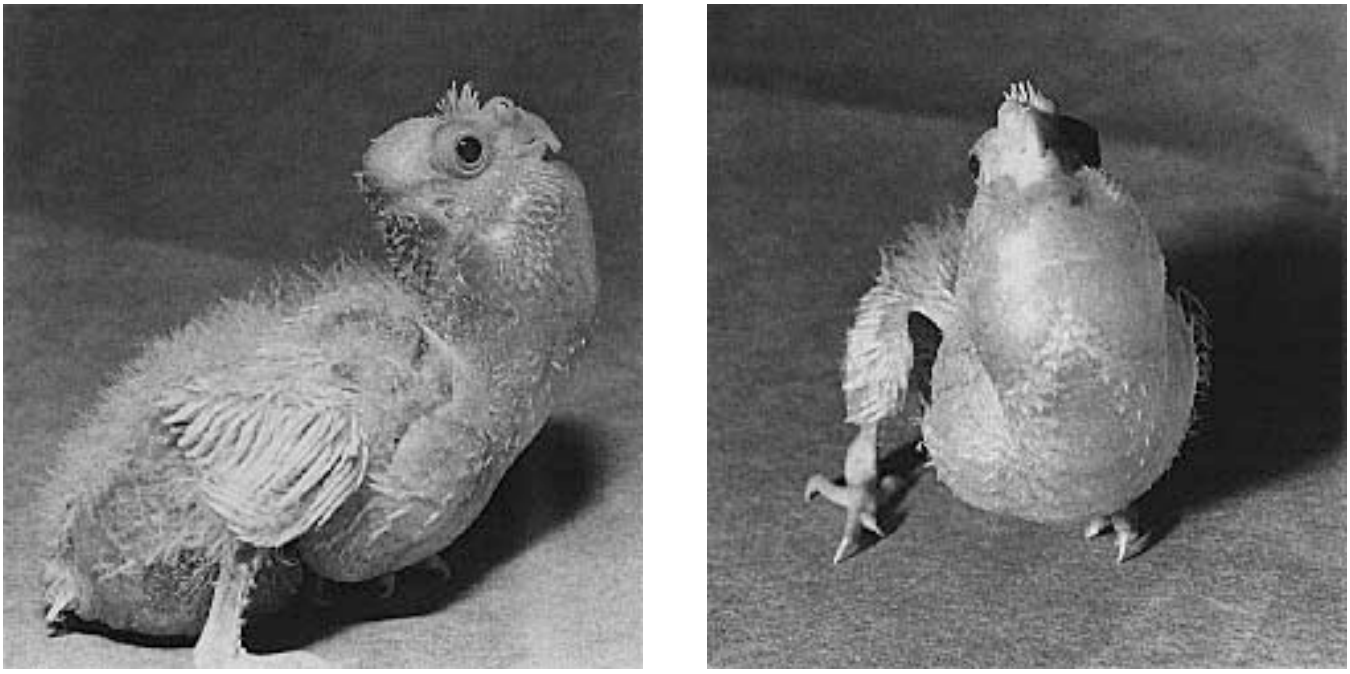

FIG 22.12 Hyperinflation of the cervical air sacs in a cockatiel. The etiology was not determined. The bird was successfully managed by making an incision into the air sacs allowing them to deflate. The rents were kept open for ten days and the problem resolved.

CHAPTER

23

ENDOCRINOLOGY

J. T. Lumeij

The endocrine system of birds consists of the hypothalamic-hypophyseal complex, the gonads, pancreatic islet cells, adrenal glands, thyroid glands, parathyroid glands, ultimobranchial glands and the endocrine cells of the gut. All these organs release hormones into the bloodstream, which act on target tissues by interacting with receptors on the surface of the cell (peptide hormones) or within the cytoplasm or nucleus of the cell (steroid hormones).

Although endocrinopathies in birds do occur, endocrinology is a subject that is frequently unfamiliar to the avian practitioner. Endocrine system abnormalities may be more frequently diagnosed as practitioners expand their working knowledge of normal avian endocrinology, and appropriate clinical diagnostic tests can be used to document endocrine abnormalities.

A clinical presentation that suggests an endocrine disorder must always be confirmed before treatment is begun. Confirmation of the diagnosis may be difficult once replacement therapy is initiated, and improper or inadequate endocrine therapy can be fatal. Obesity is a good example of a clinical sign that is often misdiagnosed as an endocrine disorder (hypothyroidism) in birds, but is nearly always caused by malnutrition and lack of exercise instead. Feather abnormalities have also been reported in association with endocrine disorders without supporting evidence for an etiology. Polydipsia and polyuria can be of endocrine origin, but may also be psychogenic in origin. Psychologic factors and generalized organic diseases can profoundly affect endocrine function. Suppression of gonadotropin synthesis and reproductive failure may occur with environmental stress, and there can be an inadequate production of vitamin D in chronic renal failure leading to renal secondary hyperparathyroidism. Occasionally, failure of a target organ to respond to hormones may mimic endocrine disease (eg, nephrogenic diabetes insipidus, pseudohyperparathyroidism).

Furthermore, in man, domestic mammals and possibly also in birds, a number of endocrine syndromes may develop in association with tumors of non-endocrine origin, which form hormones that have a biological activity similar to the natural hormones (eg, paraneoplastic syndromes, ectopic hormone production).

This chapter will provide a review of normal endocrine function in birds (mostly based on gallinaceous species)[28,29,93,101] and discuss reported endocrinopathies in birds and some physiologic phenomena of clinical importance. Because there is a strong tendency among veterinarians to extrapolate knowledge of small animal endocrinology to birds, differences between avian and canine endocrinology will be highlighted.

Therapeutic measures are not given for diseases that have not been reported in birds. Guidelines for specific treatments of all endocrine abnormalities can be found in human and veterinary textbooks of internal medicine.[26,109]

The Hypothalamus and Pituitary Gland

Anatomy and Physiology

The hypothalamus is a relatively small structure that occupies about three percent of the total brain volume and forms a large portion of the ventral diencephalon. Various neural cell clusters can be recognized in the hypothalamus. Anteriorly, the most prominent are the preoptic nucleus, supraoptic nucleus and paraventricular nucleus. The infundibular nucleus and the medial posterior hypothalamic nucleus are found in the posterior or tuberal hypothalamus (see Chapter 28).

The hypophysis or pituitary gland is intimately connected to the hypothalamus. The pituitary gland consists of an adenohypophysis and a neurohypophysis (pars nervosa, neural lobe). In birds, the adenohypophysis can be divided into the pars distalis (anterior pituitary gland) and the pars tuberalis. The pars distalis forms the bulk of the adenohypophysis and is situated ventral to the neurohypophysis. Two distinct cell types can be distinguished in the cephalic and caudal part of the pars distalis, which therefore are referred to as the cephalic lobe and caudal lobe, respectively. A functional pars intermedia, which occurs in mammals, is not present in birds. The neurohypophysis can be divided into the pars nervosa (equivalent of posterior pituitary gland), the infundibular stalk and the median eminence.

The hypothalamic peptidergic neurons control pituitary gland function, whereby a variety of internal and environmental factors exert their influence by afferent neural stimuli and circulating hormone concentrations (eg, negative feedback). The hypothalamus is extensively innervated by ascending and descending afferent fibers from the rest of the central nervous system. Efferent fibers run to the pars nervosa and the median eminence of the neurohypophysis.

The supraoptic and paraventricular nuclei form the neurohypophyseal hormones, mesotocin and vasotocin, which are transported by axoplasmic flow and stored in depots in the neural lobe. The axons converge into a distinct bundle that is called the supraoptico-(neuro)hypophyseal tract. Axons terminating at the median eminence discharge their chemotransmitters into a portal system of blood vessels, which drain into the anterior pituitary gland.

Neurohypophyseal Hormones

Avian neurohypophyseal hormones, arginine vasotocin (AVT) and mesotocin (MT), are similar to the mammalian antidiuretic (arginine vasopressin, AVP) and oxytocic (oxytocin) hormones, respectively. The major effect of AVT in birds is to reduce urine production. This is accomplished by decreasing the glomerular filtration rate through constriction of the afferent arterioles of reptilian-type nephrons, and by increasing the permeability of collecting ducts of mammalian-type nephrons. AVT is released in response to plasma osmolality changes, which are registered by peripheral and central osmolality receptors. Dehydration and infusion of hypertonic solutions cause AVT release, while infusions of hypoosmotic glucose solutions depress plasma AVT concentrations below the detectable limit (<0.5 fmol/ml).

Injections of both AVT and oxytocin increase intrauterine pressure in birds, and a large increase in blood AVT concentration has been observed shortly before oviposition.

Plasma concentrations of AVT can be measured by means of an AVP radioimmunoassay that has been validated for AVT in avian plasma.

Adenohypophyseal Hormones

Adenohypophyseal hormones are either glycoproteins or polypeptides. The glycoprotein hormones are luteinizing hormone (LH), follicle stimulating hormone (FSH) and thyroid stimulating hormone (TSH; thyrotropin). They consist of two subunits: α and β.

The β subunit is the same for all three hormones, while the α subunit is hormone-specific.

The adenohypophyseal polypeptide hormones are growth hormone (GH; somatotropin), prolactin- and proopiomelanocortin (POMC)-derived hormones such as adrenocorticotrophic hormone (ACTH) and β-melanocyte stimulating hormone (α- and β-MSH), β- and τ-lipoprotein (β- and τ-LPH), β-endorphin and encephalin.

LH is secreted mainly from the caudal lobe, while TSH is secreted in the cephalic lobe. The secretion site for FSH is undetermined. Prolactin is secreted in the cephalic lobe, while GH is secreted from the somatotrophic cells in the caudal lobe. The POMC-derived hormones, ACTH and α-MSH, are secreted in the corticomelanotrophic cells of the cephalic lobe. This differs in mammals in which MSH is produced in specific cells in the intermediate lobe.

Both LH and FSH stimulate ovarian steroid synthesis and are essential for ovarian function in birds. During the ovulatory cycle, plasma FSH concentration shows little change. However, approximately five hours before ovulation, a rise in plasma LH concentration can be observed. Plasma LH concentration is low during egg laying, incubation and care for the chicks. An increase in LH secretion occurs toward the end of the chick-rearing period to prepare the hen for the next laying cycle.

In males, LH stimulates Leydig cell differentiation and testosterone synthesis, while FSH promotes Sertoli cell differentiation and spermatogenesis. A seasonal pattern of gonadal function that is regulated by daylight length has been described in birds. In male Japanese quail, a rise in plasma LH and FSH concentrations followed by increases in testicular size and gonadal steroid synthesis can be observed when the animals are transferred from 8 to 20 hours of daylight. After 50 days of being exposed to long daylight periods, the birds become refractory to photostimulation. Gonadotrophin synthesis is negatively influenced (suppressed) by other factors, such as aggressive encounters, nutritional deficiencies and the stress of restraint.

A chicken LH radioimmunoassay (RIA) can be used to measure plasma LH in other birds. The RIA for mammalian FSH can be used to measure plasma concentrations of avian FSH.

TSH increases the number of colloid droplets in thyroid cells, stimulates the uptake of iodide by the thyroid and stimulates the release of thyroxine (T_4). A human TSH RIA has been used to detect immunoreactive TSH in plasma of Japanese quail.

Avian GH has effects both on growth and on the short-term control of metabolism. Growth in chicks is markedly depressed after the administration of anti-GH antibodies. GH mobilizes stored lipids and increases free fatty acids, which are then available as an energy source. Lipogenesis is decreased. Muscle glycogen is increased and glucose utilization is reduced. GH seems to spare carbohydrates from use as a precursor for lipid synthesis.

An RIA for chicken GH is capable of detecting this hormone in many avian species (see hormonal involvement in avian growth and development).

In birds, prolactin is known to affect reproduction and osmoregulation. Effects on growth and metabolism have been suggested. In pigeons and doves, prolactin stimulates the production of crop milk. Just before the eggs are to hatch, there is a prolactin-induced proliferation and sloughing of mucosal cells in the crop sac. These cells are then regurgitated to feed the young during the first eight to eleven days of life. In other avian species, prolactin induces broodiness and suppresses ovarian function directly and indirectly via the hypothalamus. Prolactin is released after infusion of hypertonic NaCl solutions, and reduced urine flow occurs following the administration of prolactin.

Plasma prolactin concentrations can be measured by means of a homologous or heterologous RIA.

ACTH stimulates corticosterone and aldosterone production by the avian adrenal cortical (interrenal) cells.

At present, the unavailability of an ACTH RIA for avian plasma is an obstacle to studying the hypothalamic-hypophyseal-adrenocortical axis in birds, and plasma concentrations of corticosterone must be used as an indicator of plasma ACTH concentration. In ptarmigan (grouse), feather pigmentation has been shown to be influenced by MSH.[43]

Hypothalamic Releasing or Inhibiting Hormones or Factors

The hypothalamic-hypophysiotropic factors are released from the median eminence and are transported to the anterior pituitary gland via the portal blood vessels. If the chemical structure of these hypothalamic chemotransmitters is known they are called

hormones, and when the chemical structure is unknown, they are called factors. These chemotransmitters can have a stimulating or an inhibiting action on the release of the trophic anterior pituitary hormones and hence are called releasing or inhibiting hormones or factors.

The secretion of gonadotropin (LH and FSH) is controlled by LH releasing hormone (LHRH) which differs slightly from its mammalian counterpart. Both mammalian and avian LHRH stimulate avian LH secretion both *in vivo* and *in vitro*. LHRH cell bodies are located in the periventricular preoptic nucleus and in the tuberoinfundibular neurons.

The secretion of TSH is under stimulatory hypothalamic control. The hypophysiotropic factors regulating pituitary TSH release are somatostatin and thyrotropin releasing hormone (TRH), which are also physiologic regulators of GH secretion in birds.

GH release from the adenohypophysis is under hypothalamic control by TRH, growth hormone releasing factor (GRF) and somatostatin (somatotropin release inhibiting factor; SRIF), which inhibits GH secretion. Somatostatin is also formed in the avian pancreas.

Contrary to the situation in mammals, prolactin is under stimulatory hypothalamic control. The identity of avian prolactin releasing factor (PRF) remains undetermined.

The secretion of ACTH in birds is presumably under control of corticotrophin releasing factor (CRF).

Hormonal Involvement in Avian Growth and Development

A number of hormones play a major role in the control of growth. These include GH, T_4 (3,5,3',5' – tetraiodothyronine), T_3 (3,5,3' – triiodothyronine) and the sex steroids. The effect of GH on growth is via mediating factors: insulin-like growth factors (IGF) I and II (somatomedins), transforming growth factors (TGF), epidermal growth factors (EGF) and nerve growth factors (NGF).[81] Insulin appears to be available for the embryo all throughout chicken ontogeny, and the gene is expressed before the pancreas differentiates.[88] Plasma concentrations of GH are first detectable on day 17 of chicken embryo development, and responses to injection of GH releasing factor or thyrotropin releasing hormone are not observed until three weeks into incubation.[81]

Three variants of chicken GH have been observed. It has been postulated that some variants are more specific than others for the distinct activities of GH (eg, growth promotion, lipolysis, inhibition of glucagon-induced lipolysis). Independent control of synthesis and release of the variants of GH may exist. Mammalian and avian GH preparations have both lipolytic and antilipolytic activities; fish GH has no lipolytic effect, yet exerts full antilipolytic effect. This has been regarded as tentative evidence for the existence of two types of GH receptors: a GH receptor that does not recognize fish GH ("lipolytic" receptor) and a GH receptor that recognizes mammalian, avian and fish GH ("antilipolytic" receptor).

In chickens, plasma concentrations of GH are highest from hatching up to eight weeks of age, and then decline to reach a low, relatively static level.

Diseases in Relation to the Hypothalamic-Hypophyseal Complex

Although in recent decades major advances have been made in the elucidation of hypothalamic-hypophyseal control of endocrine function in birds, relatively little has been reported with regard to diseases related to the hypothalamic-hypophyseal complex (HHC).

Considering the large number of diseases associated with the HHC in man and domestic animals, and the similarity of the HHC between mammals and birds, it is to be expected that a number of hypothalamic diseases that hitherto have not been reported in birds will be reported in the future.

Diseases may be caused by hypo- or hypersecretion of one or, more commonly, several of the hypothalamic or pituitary hormones. These alterations in secretion may be caused by tumors that are primary or metastatic, benign or malignant, pituitary or parapituitary, or by granulomatous lesions, congenital lesions or trauma. In addition to causing endocrine abnormalities, space-occupying lesions may cause neurologic signs due to pressure on surrounding nerve tissue.

When a diagnosis of hypothalamic disease is based on circulating concentrations of hypothalamic or hypophyseal hormones, it should be considered that primary hypofunction of a target organ will result in hypersecretion of the trophic hormone. This makes it possible to distinguish between a primary disorder of the gland or a disorder of the gland secondary to pituitary dysfunction or a hypothalamic disorder (tertiary dysfunction).

Examples from mammalian medicine of hyperpituitarism include Cushing's syndrome (ACTH), precocious puberty or infertility (gonadotrophin), amenorrhoea in women and infertility in men with galactorrhea (prolactin), hyperthyroidism (TSH), gigantism (GH before puberty) and acromegaly (GH after puberty). Examples of hypopituitarism include dwarfism, secondary hypothyroidism, adrenocortical insufficiency and hypogonadism. An example of a disease associated with a disorder of the hypothalamus or posterior pituitary gland is cranial (central) diabetes insipidus, which is caused by insufficient secretion of antidiuretic hormone.

Dwarfism

Dwarfism has been reported in various avian species such as the fowl,[46] pheasant,[2] Black-headed Gull[42] and Great Crested Flycatcher.[67] Dwarfism is sex-linked recessive in the fowl.[46] Sex-linked dwarf growing chicks have lower concentrations of somatomedin C (insulin-like growth factor, IGF - I) and T_3, whereas GH and T_4 are increased, probably due to a decreased negative feedback effect on GH secretion. The dwarfism is not caused by a defective release mechanism of GH because both TRH and GRF stimulate the release of GH to a greater degree in dwarfs then in normal chickens. In normal chickens, GH and TRH stimulate hepatic 5'-monodeiodination activity (conversion of T_4 to T_3). This conversion does not occur in dwarfs. A lack of GH receptors could be a sufficient cause for deficiencies in IGF-I and T_3 production in dwarfs.[50]

Diabetes Insipidus

In birds, the main physiologic regulator of body water balance is the octapeptide, arginine vasotocin (AVT). Both arginine vasotocin and the mammalian counterpart, arginine vasopressin (antidiuretic hormone, ADH), produce antidiuresis in birds, but the former is considerably more potent.

Diabetes insipidus has been reported to occur in chickens and might also occur in other avian species. The principal clinical signs of this disease are polyuria and polydipsia (PU/PD) (see Color 8).

Water deprivation test can be used in dogs to distinguish between the causes of PU/PD. The principle of the water deprivation test is to determine whether endogenous ADH is released in response to dehydration and whether the kidney responds to this stimulus. With this test, differentiation between central diabetes insipidus, nephrogenic diabetes insipidus, primary (psychogenic) polydipsia and hyperadrenocorticism is facilitated. For healthy racing pigeons, it has been established that a urine osmolality of at least 450 mOsm/kg can be expected after 24 hours of water deprivation, which typifies the normal concentrating capacity of the kidneys. In avian patients with PU/PD in which urine osmolality does not increase in response to water deprivation, administration of exogenous ADH or AVT can be used to differentiate between central diabetes insipidus and other causes of PU/PD.[1] A water deprivation test using plasma AVT concentration has recently been developed for use in birds. Plasma AVT concentrations were measured before and during a 72-hour period of water deprivation. It was concluded that an AVT concentration > 2.2 pg/ml after 24 hours of water deprivation is indicative of a normal AVT release from the neurohypophysis in the pigeon.[61]

Pituitary Tumors in Budgerigars and Cockatiels

Chromophobe adenomas and carcinomas of the pituitary are common in budgerigars (see Chapter 25). In a review of 497 tumors in budgerigars, 156 were either chromophobe adenomas or carcinomas;[85] however, in other reports, the incidence of these tumors was considerably lower.[12] Variations in the reported incidence of pituitary tumors might be caused by the fact that these tumors are easily overlooked during a routine gross necropsy. The pituitary gland is easy to isolate and should always be evaluated. The mandible is removed with the bird in dorsal recumbency. The medial ridge of the sphenoid bone can be broken away with forceps, after which the pituitary will be found lying in the sella turcica of the sphenoid, just posterior to the optic chiasm. The normal pituitary gland from a budgerigar is about 2 mm in diameter,

CLINICAL APPLICATIONS

Pituitary gland tumors should be suspected in clinical cases with:

- PU/PD
- Reproductive failure
- Feather dystrophy
- Pigmentation abnormalities
- Obesity
- Stupor
- Blindness
- Convulsions
- Uni- and bilateral exophthalmos
- Hyperglycemia.

If these signs are present and a bird dies, the pituitary gland should be submitted for histopathology.

while the diameter can be 7 mm if a pituitary tumor is present. Pituitary tumors have been associated with a ten-fold weight increase of the pituitary gland.[8,12,82]

These tumors may be infectious in nature, which could also explain the variation in the reported incidence of disease. Homologous transplantation of pituitary tumors from budgerigars has been reported, and renal adenocarcinomas occurred in ten percent of the birds.[84] Avian leukosis virus antigen has been demonstrated in budgerigars with kidney tumors.[69] A causal relationship between renal tumors in budgerigars and avian leukosis virus, however, has yet to be demonstrated. Pituitary tumors have also been reported in an *Agapornis* spp.[91] and in two cases in the fowl.[15]

Recently, pituitary adenoma and pituitary adenocarcinoma with metastasis to the liver have been reported in cockatiels.[19,106]

Reported clinical signs of pituitary tumors in budgerigars and cockatiels are related to hormonal imbalance (eg, polyuria, polydipsia, reproductive failure, obesity and feather structure and pigmentation abnormalities) and to compression of surrounding nervous tissue (eg, stupor, blindness, uni- or bilateral exophthalmus, convulsions). Although it has been suggested that the PU/PD is caused by hyposecretion of AVT (diabetes insipidus), hypersecretion of ACTH (Cushing's disease, secondary hyperadrenocorticism), TSH (hyperthyroidism) or GH have not been excluded.

Hyperglycemia and obesity occurred in birds with subcutaneous transplants of pituitary tumors.[84] The obesity was characterized by an accumulation of adipose tissue beneath the skin of the breast and abdomen as well as in the peritoneum and mesentery. The liver was often enlarged, and histologic sections revealed an accumulation of fat in hepatic cells.

In budgerigars with large tumor transplants, blood glucose concentrations exceeded 1000 mg% with one value reaching 1768 mg%. At necropsy, the thyroids, adrenal glands and pancreas were normal.

Calcium Metabolism

Anatomy and Physiology

Calcium metabolism in birds is under the control of three major hormones: parathyroid hormone (PTH), calcitonin (CT) and 1,25 dihydrocholecalciferol ($1,25(OH)_2D_3$), the active metabolite of vitamin D_3 (Figure 23.1). Other hormones, however, also alter calcium metabolism, and the amounts of calcium and vitamin D in the diet have profound effects.

Parathyroid Hormone

PTH is secreted by the paired parathyroid glands, which consist of cranial and caudal lobes and can be found caudal to the thyroid glands. In the chicken, the left parathyroid gland is not in contact with the thyroid gland, while on the right side the cranial lobe lies next to the thyroid gland. In companion birds, the parathyroids are normally visible as light-colored areas at the caudal end of the thyroid glands (see Anatomy Overlay). The main tools that have been used for studying parathyroid function in birds have been parathyroidectomy and the use of heterologous (usually bovine) PTH. Currently, a sensitive radioimmunoassay for avian PTH is not available and avian PTH (1-84) or PTH (1-34) is also not commercially available. Heterologous and homologous PTH may act differently in birds.

PTH is secreted in response to hypocalcemia. The primary target organs of PTH are the kidney and bone. Calcium excretion in the urine is decreased by increasing tubular reabsorption of calcium, while circumstantial evidence suggests that calcium resorption from bone is increased. During the egg-laying cycle, PTH functions in the resorption of medullary bone. Under the influence of PTH, renal tubular secretion of phosphate is increased, while decreased tubular reabsorption may occur. The net result is a phosphate diuresis and a decrease in plasma phosphate.

PTH regulates vitamin D by stimulating 1-hydroxylase activity and inhibiting 24-hydroxylase activity in the renal cortex, thereby enhancing the production of the key calcium-regulating hormone $1,25(OH)_2D_3$. Furthermore PTH acts together with $1,25(OH)_2D_3$ to increase calcium absorption from bone.

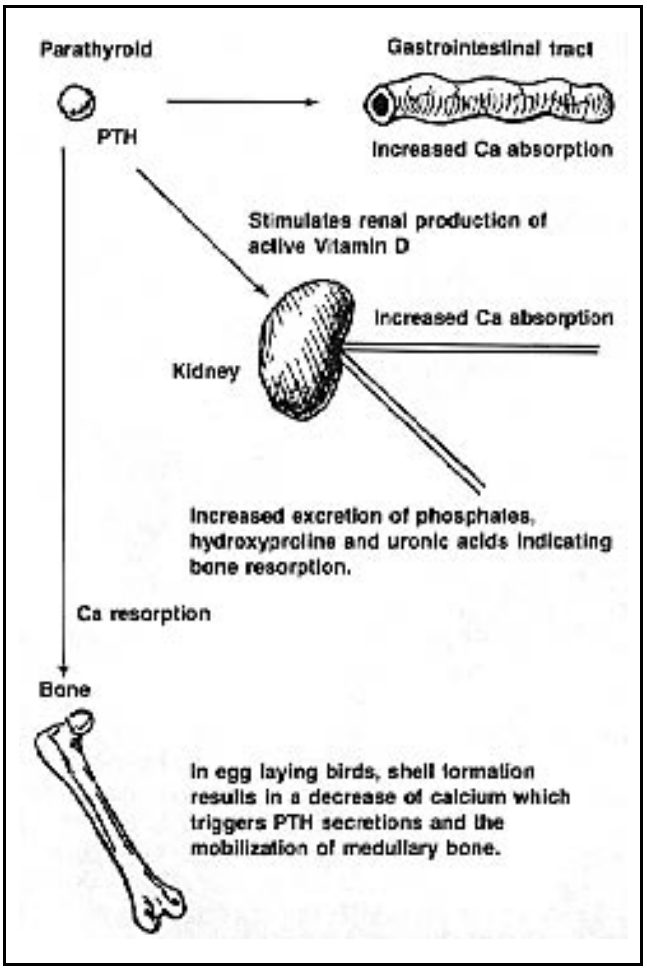

FIG 23.1 Control of calcium metabolism. The parathyroid gland secretes PTH, which increases calcium absorption from the gastrointestinal tract, increases calcium absorption by the kidney and causes calcium resorption from the bone.

Calcitonin (CT)

CT is secreted by the C cells of the ultimobranchial glands. In chickens, the left gland lies caudodorsal to the caudal lobe of the parathyroid gland, while the right ultimobranchial gland lies more caudally and is separate from the caudal lobe of the parathyroid gland. In chickens, the ultimobranchial glands are found in association with the parathyroid tissue; in pigeons, they are found in association with thyroid tissue.

The chromatographic profile of the biologic activity of cultured ultimobranchial glands from embryonic chickens resembles that of purified salmon CT. Furthermore, chicken and salmon CT exhibit immunological identity, which makes it possible to measure avian CT by radioimmunoassay with antibody raised against synthetic salmon CT.[20]

In contrast to its action in mammals, CT does not induce a hypocalcemia in normocalcemic birds. It appears, rather, to control hypercalcemia and to protect the skeleton from excessive calcium resorption.[5] The mode of action is through decreasing calcium resorption from bone.

Vitamin D_3

Vitamin D_3 (cholecalciferol) is converted from its precursor, 7-dehydrocholesterol, under the influence of ultraviolet (UV) light. It has been suggested that this process occurs in birds when the oil of the uropygial gland is spread over the feathers and irradiated by UV light before the vitamin is orally ingested during preening. The mechanism of conversion in birds that lack a uropygial gland has not been proposed. The photolysis reaction converts 7-dehydrocholesterol to pre-vitamin D_3, which is in equilibrium with both its precursor and with vitamin D_3. The next step occurs mainly in microsomal fractions of liver cells and is the formation of 25-hydroxycholecalciferol. The second and more important step in the activation of D_3 occurs in mitochondria of cells in the renal cortex, and involves the conversion to 1,25-dihydroxyvitamin D_3 [1,25-$(OH)_2D_3$], which is regarded as the key calcium-regulating hormone. When body demands for calcium are low, the major hydroxylation product of $25(OH)D_3$ is $24,25(OH)_2D_3$. There is evidence from studies in mammals that the latter inhibits the secretion of PTH.

Other hormones that stimulate the production of $1,25(OH)_2D_3$ are prolactin and estrogen.

The main role of the active metabolite of vitamin D_3 is to elevate plasma calcium and inorganic phosphorus by increasing small intestinal absorption of these minerals in conditions whereby the plasma concentrations of one of these minerals are too low to sup-

CLINICAL APPLICATIONS

Activities of the parathyroid hormone:

- Decreased renal excretion of calcium
- Increased calcium resorption from bone
- Resorption of medullary bone (egg laying)
- Increased renal excretion of phosphate
- Increased production of active D_3.

Activities of calcitonin and vitamin D_3:

- Calcitonin decreases calcium resorption from bone.
- Vitamin D_3 increases intestinal absorption of calcium and phosphorous
- In conjunction with the parathyroid, vitamin D_3 mobilizes calcium and phosphorous from bone.

port normal mineralization of bone. Therefore, lack of vitamin D_3 in young birds leads to rickets. In addition, $1,25(OH)_2D_3$ acts together with PTH to mobilize calcium and phosphorus from the skeleton when hypocalcemia occurs.

Vitamin D_2

Because ergocalciferol (vitamin D_2) is more rapidly metabolized and excreted than cholecalciferol (vitamin D_3), the antirachitic properties of the former are 10 to 40 times less than those of vitamin D_3, despite the equal rate of initial uptake by the target tissues.

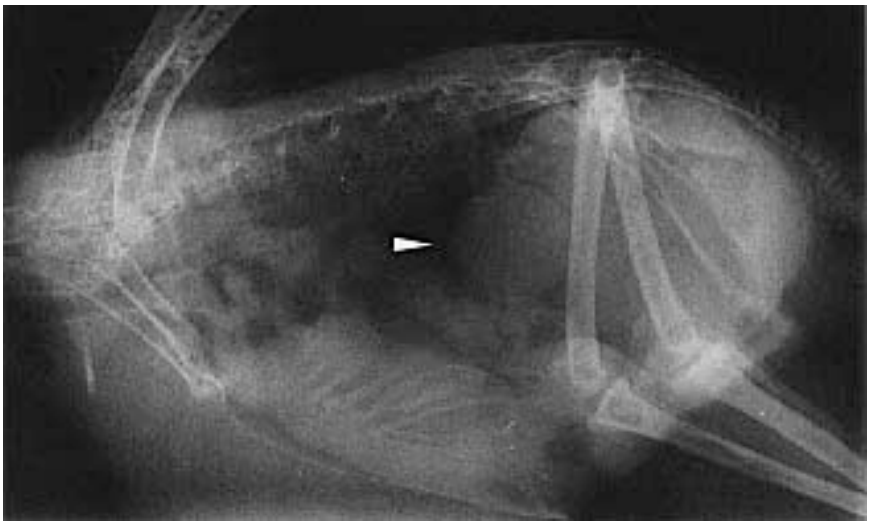

FIG 23.2 Lateral radiograph of a sexually mature Mexican Red-headed Amazon Parrot hen. Note the spherical mass (arrow) cranioventral to the kidneys, representing a solitary large ovarian follicle. Pre-ovulatory bone deposition is apparent in the medullary cavity of the appendicular skeleton (courtesy of Marjorie McMillan).

Calcium in Reproductive Physiology

Two independent physiologic phenomena related to calcium metabolism are seen in hens during reproduction. These normal changes should not be misinterpreted as pathologic.[89]

- ***Estrogen-induced Hypercalcemia:*** About four days before female pigeons are due to ovulate, the blood calcium concentration rises from a normal value of about 2.2 mmol/l (9 mg/dl) to a value of over 5.0 mmol/l (20 mg/dl) at the time of ovulation. This rise is caused by an increase in the protein-bound calcium, secondary to the estrogen-induced transport of yolk proteins to the ovary as calcium complexes. The concentration of ionized calcium remains constant.

- ***Physiologic Marrow Ossification:*** During egg-laying, there is a large increase in the quantities of calcium and phosphorus that are retained from the diet and deposited in the medullary bone. This medullary bone may completely fill the marrow cavity of long bones, particularly those in the limbs (Figure 23.2). This period of bone deposition coincides with increased osteoblastic activity. When the hen starts to secrete the eggshell, the medullary bone is resorbed by osteoclastic activity. Calcium is deposited in the eggshell as calcium carbonate, and the phosphorus is excreted from the body. Normal medullary bone deposits should not be mistaken for a pathologic condition radiographically. The precise details of the hormonal mechanism by which the supplies of calcium from the gut and from the skeleton are regulated in relation to the requirements for shell formation are not fully understood.

Relation Between Total Calcium and Protein in Avian Plasma

The plasma calcium concentration is normally about 2.0-2.8 mmol/l (8-11.2 mg/dl), depending on the species. About one-third of plasma calcium is protein-bound and is biologically inactive. Total calcium concentration is markedly influenced by plasma protein concentrations. The ionized fraction is important with regard to deposition of calcium salts and excitability of nervous tissues. For technical reasons, most laboratories determine only total calcium. Hence, total plasma calcium should be evaluated in conjunction with plasma protein concentrations.

In man and in dogs, there are significant linear relationships between calcium and albumin, and calcium and total protein. In these species, adjustment formulas have been derived for serum total calcium on the basis of the concentrations of albumin and total protein. Recently, a significant correlation was found between total calcium and albumin concentration in the plasma of 70 healthy African Grey Parrots. Approximately 14% of the variability of calcium was attributable to the change in the concentration of plasma albumin (R^2=0.137).[59] A correction formula was derived on the basis of the concentration of albumin:

Adjusted Ca (mmol/l) = Ca (mmol/l) - 0.015 albumin (g/l) + 0.4

A significant correlation was also found between total calcium and total protein concentration in 124 plasma samples of Peregrine Falcons. About 42% of

the variability in calcium was attributable to the change in the plasma total protein concentration. The correlation between calcium and albumin was significant, but significantly smaller than the correlation between calcium and total protein. Only 11% of the plasma calcium concentration was attributable to a difference in concentration of albumin. An adjustment formula for plasma calcium concentration in the Peregrine Falcon was derived on the basis of the total protein concentration.[62]

Adj. Ca (mmol/l) = Ca (mmol/l) - 0.02 Total Protein (g/l) + 0.67

Application of a correction formula in African Grey Parrots and Peregrine Falcons is indicated when extremely low or extremely high plasma protein concentrations are detected. It should be stressed that the correction formulas mentioned above are based on total protein and albumin determinations with specific analytic methods. For total protein, the biuret method is used with human protein as a standard, and albumin is calculated from total protein and plasma protein electrophoresis on cellulose acetate membranes.[59a]

Diseases in Relation to the Metabolism of Calcium and Phosphorus

Hyperparathyroidism

Hyperparathyroidism is a condition whereby there is an increased secretion of PTH. In man primary hyperparathyroidism may occur from hyperplasia, adenoma or carcinoma of the parathyroid gland. The most common presentation is a renal disorder due to recurrent renal calculi (nephrocalcinosis). The second most common presentation is bone disease (osteitis fibrosa generalisata), while the third mode of presentation is related to hypercalcemia. Pseudohyperparathyroidism is a condition characterized by hypercalcemia caused by the release of hormone-like substances from nonendocrine tumors; however, with neoplasm, hypercalcemia may also occur from widespread skeletal deposits of metastatic tumors, with associated increased osteoclastic activity. Contrary to the situation in man and domestic mammals, primary hyperparathyroidism and pseudohyperparathyroidism have not been documented in birds. Because adenoma and carcinoma of the avian parathyroid gland do occur,[36] it is likely that primary hyperparathyroidism will be reported in the future.

Secondary nutritional hyperparathyroidism is commonly reported in birds secondary to a calcium-deficient diet (see Chapter 3).

Diets that contain only seeds or only meat are deficient in calcium. Fruits and most vegetables are also calcium deficient. Nonetheless, many pet food retailers continue to market so-called "complete parrot foods," which consist only of seeds (mainly sunflower seeds). Affected birds have a low or normal plasma calcium concentration, a normal plasma phosphate concentration and increased AP activity. In young birds, rickets or rachitis is seen as a result of calcium-deficient diets, while in adult birds osteomalacia will occur.

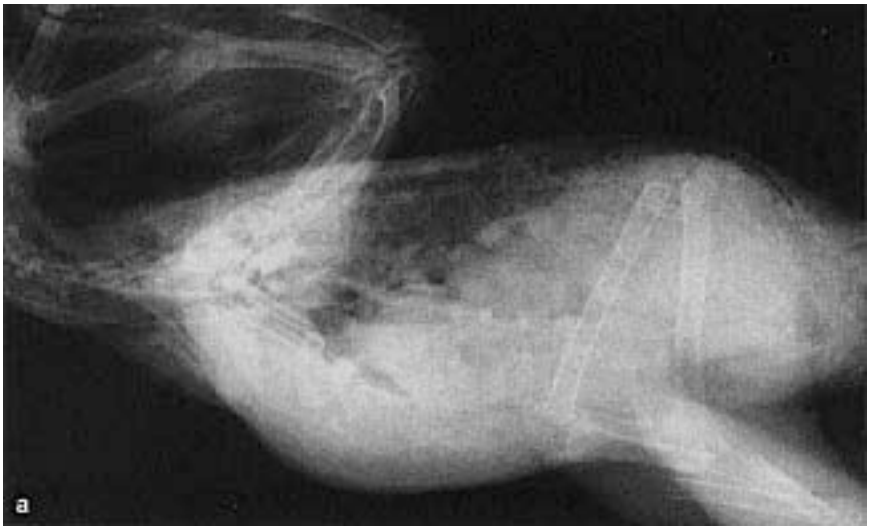
Secondary hyperparathyroidism due to a renal disorder is well known in mammals and possibly occurs also in birds. In chronic renal disease, failure of the conversion of 25-hydroxycholecalciferol to 1,25-dihydroxyvitamin D_3 [1,25-$(OH)_2D_3$], the key calcium-regulating hormone, will result in reduced intestinal absorption of calcium. Under these circumstances, a high plasma phosphate concentration may be seen due to decreased tubular secretion of phosphate. Plasma AP activity will be increased.

Tertiary hyperparathyroidism is known in man as a pathologic extension of the secondary form when adenomas develop in the previously hyperplastic glands and there is accompanying hypercalcemia due to autonomous PTH secretion. This condition has not been reported in birds.

Rickets

Rickets or rachitis is a metabolically induced bone disease in growing animals. Painful deformities occur throughout the skeleton, particularly in the proximal tibiotarsus, the head of the ribs and sometimes the costochondral junction. The skeleton and the beak (rubber beak) become soft and pliable. Rickets can be caused by inadequate dietary intake of calcium, phosphorus or vitamin D_3 or by an improper calcium:phosphorus ratio. With calcium and vitamin D deficiencies, the resulting hypocalcemia induces enlargement of the parathyroid gland (nutritional secondary hyperparathyroidism). Consistent parathyroid gland changes are not typical with a phosphate deficiency or excessive calcium intake. Histologically, it is possible to differentiate between rickets caused by vitamin D deficiency, hypocalcemia and hypophosphatemia/calcium excess.[53-55]

Tachypnea and polycythemia have been observed in birds with rickets, presumably because of poor rib strength and infolding of ribs.[48] Affected birds died of right ventricular failure, often accompanied by ascites.



Osteomalacia (Osteodystrophy)

In mature birds, calcium deficiencies will result in parathyroid enlargement and PTH-induced activation of osteoclastic activity, which eventually can result in complete demineralization of medullary bone, followed by cortical bone (Figure 23.3). The resorbed osseus tissue can be replaced by fibrous tissue (osteodystrophia fibrosa). The cortical bone can become so thin that spontaneous fractures may occur, especially in the vertebrae, ribs, tibiotarsus, tarsometatarsus and femur. The fractures are typical for demineralized bone and are called "greenstick fractures." The beak becomes soft and pliable. Plasma calcium concentrations remain generally normal until the end stage of the disease, when tetanic convulsions may be observed. Although calcium deficiencies accompanied by pathologic fractures seem relatively common in psittacine birds, nutritional osteodystrophia fibrosa is rarely diagnosed. A possible explanation might be that histologic examination of bones is not often performed.

Osteoporosis

To a certain degree, osteoporosis (cage layer fatigue) is physiologic during egg production. Osteoporosis is characterized by the progressive reduction of bone mass. It is the most important skeletal disease in

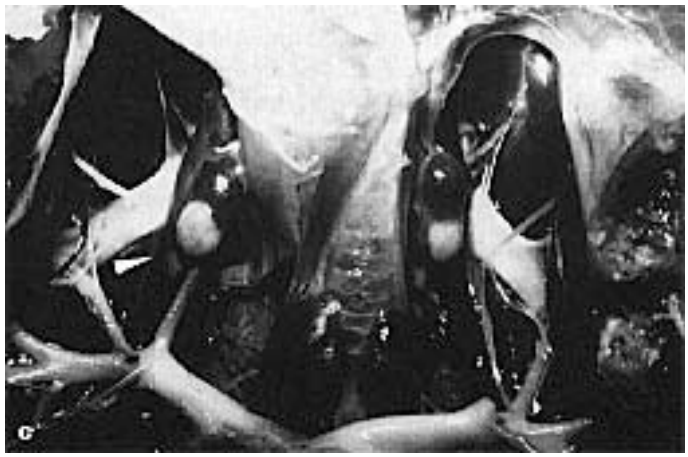


FIG 23.3 An adult female Amazon parrot was referred for evaluation of bilateral tibiotarsal fractures after flying into a wall. The hen had a three-year history of egg laying and had recently laid her second egg of the year. The bird appeared to have head tremors, was unable to stand and both wings were drooping. The diet consisted of a sunflower seed and peanut mix. **a,b)** Radiographs indicated multiple fractures, decreased bone density and soft tissue densities in the abdomen. **c)** At necropsy, the parathyroid glands were dramatically enlarged (arrow), and the abdomen was filled with flocculent debris. Histopathology indicated egg-related peritonitis, parathyroid hyperplasia and severe osteoporosis suggestive of secondary nutritional hyperparathyroidism.

chickens used for egg production and is restricted to birds kept in enclosures. Etiologic factors may be immobilization, which is a well known cause for osteoporosis in man, and marginal nutritional calcium deficiency, which can alter the physiologic osteoporosis from high egg production into severe osteoporosis with associated clinical signs. Affected birds are found paralyzed in their enclosures, and have skeletal deformities and enlarged parathyroid glands. Paralysis may be explained by spinal cord compression due to fractures in the thoracic spine and possibly by hypocalcemia, although the latter has not yet been demonstrated.

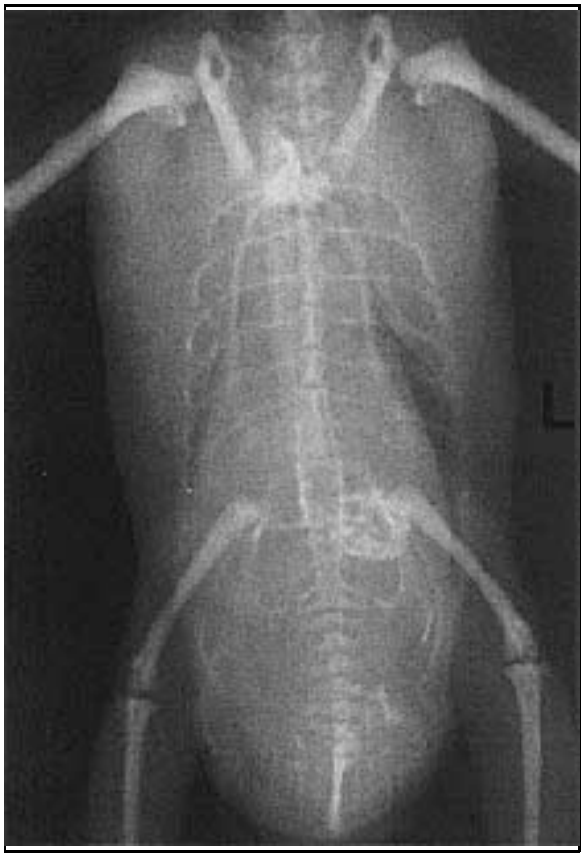

FIG 23.4 Radiographs of a budgerigar hen with increased endosteal bone formation and a distended abdomen secondary to oviductal enlargement. These findings are suggestive of hyperestrogenemia (courtesy of Marjorie McMillan).

Hypervitaminosis D_3

Oversupplementation of the diet with vitamin D_3 (>4 million IU/kg diet) causes dystrophic calcification of kidney tubules. Calcium nephropathy can also occur when birds are raised on diets containing 3% calcium instead of the normal 0.6% (see Chapters 3, 31).

Hypocalcemia Syndrome in African Grey Parrots

Hypocalcemia characterized by seizures has been described in raptors and African Grey Parrots. A unique feature of this syndrome in African Grey Parrots is that demineralization of the skeleton to maintain normal calcium levels does not occur. Hypocalcemia is an important problem to consider in an African Grey Parrot that repeatedly falls off its perch. Administration of parenteral calcium and sufficient dietary uptake of calcium resolves clinical signs. A dietary calcium deficiency is suspected, but not confirmed as the etiologic agent. In a recent study it was shown that African Grey Parrots have significantly lower calcium, albumin and total protein concentrations compared to Amazon Parrots; however, the significantly lower mean and median values for plasma calcium in African Greys could be explained only partially by the difference in albumin-bound calcium.[59] The higher incidence of hypocalcemia in African Grey Parrots might therefore be associated with lower plasma concentrations of free calcium.

Polyostotic Hyperostosis

In female budgerigars, polyostotic hyperostosis (Figure 23.4), which resembles physiologic marrow ossification is often seen in association with ovarian tumors. The condition can also be induced by stilbestrol implantation.[86] Physiologic marrow ossification and polyostotic hyperostosis may be related, and the latter may be a pathologic exacerbation of a physiologic phenomenon caused by hyperestrogenism. Hyperestrogenism has also been associated with abdominal hernias (Figure 23.5).

FIG 23.5 A mature budgerigar hen was presented with a progressively enlarging abdominal mass, weight loss and a reduced fecal output despite a normal appetite. Radiographs indicated polyostotic hyperostosis and an abdominal hernia suggestive of hyperestrogenemia.

The Thyroid Glands

Anatomy and Physiology

The thyroid glands in birds are paired organs that lie on each side of the trachea in the thoracic inlet. A connecting isthmus is absent. The thyroids are in close contact with the common carotid artery, just distal to the origin of the subclavian artery and common carotid artery from the brachiocephalic trunk (see Anatomy Overlay). Blood supply is from the cranial and caudal thyroid arteries that originate from the common carotid artery. Venous return is through the thyroid veins, which empty into the jugular vein. Except for doves and pigeons, the avian thyroid gland lacks calcitonin cells, which are located in the ultimobranchial glands.

The thyroid lobes are composed of follicles surrounded by a single layer of epithelial cells enclosed by a basement membrane. The height of the epithelial cells is dependent on the secretory rate and may vary from flat to columnar. The follicles contain a proteinaceous material called colloid, which is mainly thyroglobulin, the storage form of the thyroid hormones.

The basement membrane is in contact with the blood vessels, while the opposite cell membrane faces the colloid. The basement membrane is the site of TSH-stimulated iodide uptake from the plasma and secretion of thyroid hormone into the plasma. The cell membrane facing the colloid is the site of thyroglobulin synthesis, oxidation and organification of iodide onto tyrosine residues of preformed thyroglobulin such as of 3-monoiodotyrosine (MIT) and 3-5-diiodotyrosine (DIT). MIT and DIT residues are coupled to form 3,5,3',-triiodo L-thyronine (T_3) and 3,5,3',5'-tetraiodo L-thyronine (thyroxine, T_4).

Compared to the thyroid gland in mammals, the avian thyroid produces more T_4 than T_3.[3] It is T_3 that is the principally active hormone,[108] produced mostly by extrathyroidal 5'-monodeiodination of T_4 in liver and kidney. The activity of the 5'-monodeiodination enzyme is hormonally controlled by hypothalamic hormones (TRH, GRF) and GH.[50]

Pathology

Histologic examination of the thyroid gland is a useful and reliable means of differentiating between various thyroid disorders.

In primary hypothyroidism, there is a loss of follicles resulting either from thyroiditis or atrophy, while in secondary or tertiary hypothyroidism, the thyroid follicles are distended with colloid and the lining epithelial cells become flattened. The colloid is uniformly dense with complete or nearly complete absence of resorption vacuoles at the periphery of the colloid.

In hyperthyroidism, a diffusely hyperplastic epithelium may be observed, with little or no colloid present and possibly with lymphocytic infiltration.

In endemic goiter (caused by iodine deficiency), the thyroid gland is diffusely enlarged because of cellular hyperplasia as a result of TSH stimulation. The accumulation of thyroglobulin occurs because poorly iodinated thyroglobulin is relatively resistent to digestion by endogenous proteases. Some thyroid areas may atrophy with concomitant fibrosis.[44]

In thyroiditis, lymphocytic infiltration is present. Lymphocytic cells are often so numerous that they dominate the microscopic structure of the gland. Secondly, there is some proliferation of thyroid epithe-

lium. The pathologic changes result in considerable destruction of the thyroid. Lymphocytic infiltration of the thyroid gland is also a common finding with leukosis in chickens, and it may be difficult to differentiate autoimmune thyroiditis from leukosis.

Amyloidosis of the thyroid gland is characterized by amyloid deposits in interfollicular tissue and is often associated with tuberculosis or other chronic infections, especially in Anseriformes.

Normal thyroid histology is also dependent on the stage of plumage development. Increased thyroid activity can be observed in molting pigeons: the height of the thyroid epithelium increases and colloid is resorbed from the follicles.[100]

Thyroid Disorders

Diseases of the thyroid gland may be accompanied by thyroid enlargement (goiter), hyperfunction or hypofunction. Functional disorders may be primary, secondary or tertiary, depending on the location of the lesion (thyroid gland, pituitary gland or hypothalamus, respectively). Only goiter has been adequately documented in birds and may be caused by neoplastic disease or by iodine deficiency. Hypothyroidism has been documented in chickens, pigeons and one parrot, and it has been suggested that hyperthyroidism may be induced by exposure to iodide-containing disinfectants. Thyroiditis occurs frequently in birds,[112] but clinical signs associated with this condition have not yet been reported.

Thyroid Tumors

Thyroid neoplasia is rare in birds. Most thyroid enlargements represent thyroid hyperplasia caused by iodine deficiency. Adenomas and adenocarcinomas have been reported in budgerigars,[12] a Scarlet Macaw and some other birds from zoological collections (see Chapter 25).[83,102] Thyroid adenomas and adenocarcinomas have been reported in chickens.[15,33] Leukotic changes have also been documented in chickens.[42]

Clinical signs associated with thyroid enlargement include regurgitation and dyspnea. Like thyroid tumors in man and domestic mammals, it is to be expected that some avian thyroid tumors will have autonomic hormone production and will cause hyperthyroidism; however, no reports are available in birds.

Goiter in Budgerigars

The most frequent clinical disease of the thyroid gland in birds is goiter in budgerigars, caused by feeding an iodine-deficient diet (usually seed mixtures).[12,49,83] Goiter has occasionally been seen in chickens[33] and other avian species,[12] but is a well known and distinct clinical entity in the domestic pigeon. In budgerigars with goiter, clinical changes are limited to regurgitation and dyspnea caused by gland pressure on the trachea and esophagus (see Color 19). Specific signs of hypothyroid function are absent. Circulatory problems may occur due to compression of the heart and great vessels. The size of the glands can exceed 10 mm compared to a normal size of about 2 mm, while the weight can show a 100-fold increase (normal weight = 3 mg). If the glands are cystic they may weigh 1000 mg and be palpable at the thoracic inlet. Radiographically, a dorsal or ventral displacement of the trachea may be visible.

Goiter can be prevented by placing a bird on a complete formulated diet. The dietary requirement of iodine is about 20 μg per week for a 35 g budgerigar. Affected animals can be treated with a 0.3% Lugol's solution in the drinking water (1 drop per 20 ml water): first week, daily; second week, three times a week; then once weekly.

Goiter in Domestic Pigeons

Goiter can occur in domestic pigeons on an iodine-deficient diet. Certain breeds (eg, White Carneaux) are more susceptible than others.[44] Soybeans and fat-rich corns (like maize) may increase the iodine demand

CLINICAL APPLICATIONS

Clinical findings of thyroid enlargement in budgerigars

- Obesity
- Regurgitation
- Dyspnea
- Dorsal displacement of trachea (radiographs)
- Ventral displacement of trachea (radiographs)
- Circulatory problems

Clinical findings of goiter in pigeons

- Lethargy
- Obesity
- Palpable mass (thoracic inlet)
- Reduced fertility
- Reduced hatching rate
- Unhealthy squabs
- Myxedema
- Dystrophic feathers

and potentiate goiter.[99] Clinical signs in adult pigeons are different from those in budgerigars and include lethargy, obesity and a palpable thyroid gland in the thoracic inlet. Affected birds show a reduced fertility, reduced hatchability and reduced viability of squabs. Signs of hypothyroidism may include a puffy appearance of the facial skin (myxedema) and abnormal feather development. Tail and wing feathers that are too long and narrow or structural defects in the contour feathers may give the bird a ruffled appearance and an irregular or failing molt. Dyspnea accompanied by a respiratory stridor occurs only in severe cases. Although supporting data is not available clinical signs suggest that contrary to the situation in budgerigars, iodine-deficient goiter in White Carneaux Pigeons is accompanied by hypothyroidism.

Hypothyroidism

Primary hypothyroidism is a well recognized disorder in birds. In chickens, it occurs as a hereditary autoimmune disorder.[18,92] Low levels of thyroid hormones have also been associated with a malabsorption syndrome.[77] Experimentally induced hypothyroidism is associated with growth retardation, mental retardation and defective plumage development (fringed and elongated feathers with loss of barbules and color). Chickens with genetic hypothyroidism have low T_4 concentrations, obesity, rather silky plumage, delayed sexual development or delayed maturity (Figure 23.6).[17]

In man and dogs, various non-thyroidal illnesses have been shown to favor the formation of T_3 to protect the body from the catabolic state that accompanies many of these diseases. This phenomenon has been designated the "low T_3 syndrome," though affected subjects remain euthyroidic.[52] The same mechanism seems likely in birds.[23] For this reason, measurement of plasma T_3 is of doubtful value for the diagnosis of primary hypothyroidism and could even lead to false conclusions. The measurement of T_4 would seem to be the most logical choice for evaluating birds; however, even plasma T_4 concentrations can be influenced by drugs, handling, bleeding,[107] food intake, environmental temperature,[108] increased plasma corticosterone concentration[23] and infections with *Eimeria maxima*.[22] Normal plasma T_4 concentrations in birds are about one-fifth to one-tenth those characteristic for mammals.[50] In many birds, resting plasma thyroxine concentrations are below the detection limit of the assay.[110]

Thyroid abnormalities have been frequently reported as a common cause of disease in companion and aviary birds; however, the only support for these statements has been a low plasma T_4 when compared with a reference interval established in a single random blood sample.[75,76] Reports of hypothyroidism are therefore questionable at best (Figure 23.7). Documentation that a low plasma T_4 level is caused by primary hypothyroidism requires a TSH stimulation test to rule out other causes for a decreased T_4 concentration.

A TSH test has been reported for chickens,[107] Psittaciformes[56,110] and racing pigeons.[63] Low T_4 levels were documented in a Hyacinth Macaw that responded to L-thyroxine therapy. For evaluation of thyroid function in racing pigeons, blood samples should be collected before and between 4 and 24 hours after administration of 0.1 IU of TSH.[a] If a dose of 1 IU per pigeon is used, samples can be collected up to 32 hours later. In healthy individuals, at least a 2.5-fold increase will be observed over basal T_4 concentrations using these doses and sampling times.[63] The TSH stimulation test can also be used in other avian species using 1 IU/kg. A diagnosis of hypothyroidism should not be based on low baseline thyroxine concentrations or on a "favorable response to administration of thyroxin."[71-75] A diagnosis is based on suggestive clinical signs, especially defective plumage development, in conjunction with failure to respond to TSH.

FIG 23.6 A mature, obese Amazon parrot was presented with an asymmetric, ulcerative periabdominal mass. Biopsy indicated a lipoma. Obesity and lipoma formation are frequently discussed as signs of hypothyroidism in companion birds; however, affected birds can rarely be shown to have hypothyroidism by determination of T_4 levels following TSH stimulation. Thyroxine supplementation should be used only in birds with documented cases of hypothyroidism (courtesy of Tom Tully).

If secondary and tertiary hypothyroidism occur in birds, these disorders can probably be diagnosed by performing stimulation tests with both TRH and TSH and by measuring of plasma TSH and thyroxine concentrations.

Hyperthyroidism

Hyperthyroidism or thyrotoxicosis results from oversecretion of thyroid hormones. It is clinically characterized by an increased metabolic rate. In man, it may result from diffuse hyperactivity of the gland (Graves' disease) or as a result of a single hyperplastic nodule (toxic adenoma). Rarer causes are increased TSH secretion from the pituitary gland, ectopic TSH producing tumors, metastatic thyroid carcinoma and ovarian teratoma containing thyroid tissue. The administration of iodides may also induce hyperthyroidism (Jod-Basedow phenomenon), but in these cases the gland is already abnormal.

Two Fairy Blue Penguins developed signs of hyperirritability after the use of iodide-containing disinfectants, and the disease was classified under the term hyperthyroidism.[37,78,79] The histology of the thyroid glands of the affected birds, however, was that of colloid goiter (large follicles with flattened epithelium). Furthermore, it is not likely that excessive amounts of iodide will induce hyperthyroidism. Exposure to excessive amounts of iodide paradoxically may lead to goiter or even hypothyroidism. In normal humans, a small but significant decrease in thyroid hormones with a compensatory rise in serum TSH concentration occured after excessive dietary intake of iodine. This suggests that the inhibitory effects of iodides on the serum concentrations of the thyroid hormones are probably partially overcome by the increased TSH secretion. Iodide-induced goiter, hypothyroidism or both in subjects with normal underlying thyroid function is uncommon. Most patients who develop disease have received large quantities of iodides for a long period of time.[13] In the author's opinion, the affected penguins should be classified as "iodide goiter" and not "hyperthyroidism."

FIG 23.7 An adult Blue and Gold Macaw was evaluated for a chronic feathering problem that had been diagnosed as hypothyroidism. The bird was on an all-seed diet and was restricted to a dark corner of the house. The bird had numerous pin feathers and thin, poorly formed mature feathers. Clinicopathologic, radiographic and TSH stimulation findings were within normal limits. The bird responded to a change in diet and daily exposure to unfiltered sunlight.

Thyroiditis

Various forms of thyroiditis have been described in man. Etiologies include pyogenic organisms, viruses and autoimmune phenomena (Hashimoto's thyroiditis). Clinical signs are variable and may be associated with goiter hyper- or hypothyroidism. Thyroiditis was reported in a large variety of avian species, including an Amazon parrot. At necropsy, 36.9% of avian thyroid lesions were of an inflammatory nature.[112]

In an obese strain (OS) of chickens, circulating thyroglobulin autoantibodies have been shown to be the cause of spontaneous thyroiditis accompanied by hypothyroidism.[17,18] Clinical signs included obesity, silky plumage, delayed sexual development or lack of maturity, thyroid glands that were either smaller or larger than normal and low plasma thyroxine concentrations. Another line of chickens (described as delayed amelanotic, DAM) with similar thyroid abnormalities has been reported.[92] Neonatal bursectomy decreased the incidence and severity of chronic thyroiditis in OS and DAM line chickens.[51] Because neonatal bursectomy, and not thymectomy, prevents the occurrence of the disease, it is likely that the disease is caused by an immunologic response to free particulate fractions of thyroid rather than by antibodies that react with thyroglobulin.[25]

The Use of Thyroid Hormone in Non-thyroidal Disorders

Thyroid hormone has been frequently recommended for the treatment of obesity in birds. However, no controlled studies have been performed to demonstrate the effectiveness of this treatment. Most studies with physiologic doses of thyroid hormone in man have failed to show any significant effect on weight

reduction. Physiologic replacement of thyroid hormone in a euthyroid individual is compensated for by suppression of the hypothalamic-pituitary-thyroid axis with no net hormonal effect. Pharmacologic doses of thyroid hormone sufficient to raise the basal metabolic rate to a hypermetabolic state undoubtedly result in increased weight loss. If caloric intake is not carefully controlled, however, predominantly fat-free tissue may be lost during treatment. The weight loss may be readily and rapidly reversed after discontinuation of therapy.

The occurrence of toxic effects is unavoidable when pharmacologic doses of thyroid hormone are used. In man, cardiovascular complications were seen in 20% of patients treated with pharmacologic doses. In obese birds without proven hypothyroidism, thyroid hormone therapy can be dangerous and should not be used in lieu of providing a well balanced diet and adequate exercise.

Thyroid hormone can induce molt in a number of species. The molt is more pronounced after administration of a single dose compared with daily administration of small doses equal to the sum of the single dose. A decreasing sensitivity to thyroxine-induced molt is seen in guineafowl, pigeons, gallinaceous birds, waterbirds, Passeriformes and birds of prey. A number of members of the latter orders either do not molt in response to excess thyroid hormone or show only slight molting of small feathers in response to large or even sublethal doses of the hormone.

The Adrenal Glands

Anatomy and Physiology

The right and left avian adrenal glands are yellow organs located craniomedial to the kidneys (see Color 21). The glands receive blood from branches of the renal artery, while the adrenal veins drain into the caudal vena cava. The microanatomy of the avian adrenal gland differs from that of mammals in that the avian adrenal gland is not clearly divided into an outer cortex and inner medulla. In birds, cortical and chromaffin tissue are intermingled. Chromaffin tissue accounts for about 25% of adrenal tissue and can be divided by means of cytochemistry into two types of chromaffin cells: those releasing epinephrine and those releasing norepinephrine.

Cortical or interrenal cells are arranged in numerous cords composed of a double row of cells. The cords radiate from the center of the gland and loop against the inner surface of the connective tissue capsule. The arrangement of specific cell types along the cords results in some structural zonation with two zones: a subcapsular zone that produces aldosterone and a more extensive inner zone that produces corticosterone. The zonation is the most distinct when corticotrophic stimulation is suppressed or enhanced. The major function of the avian adrenal cortical cells is to produce glucocorticoid and mineralocorticoid hormones, of which corticosterone is the most important corticoid hormone in birds. Aldosterone production is considerably less.

In avian embryos, other corticosteroids like cortisol and cortisone are also synthesized. These compounds decrease in concentration around hatch and are absent in the adrenals of chickens and ducks older than two weeks.[68,96] The embryonic avian adrenal gland is also a site of sex steroid synthesis.[96] The secretion of corticosterone is regulated by ACTH, which is released from the corticomelanotropic cells from the cephalic lobe of the adenohypophysis in response to hypothalamic CRF. Glucocorticoids exert a negative feedback at the level of the hypothalamus and hypophysis. The hypothalamic-hypophyseal adrenal (HPA) axis has been reviewed by Bayle.[7]

Corticosterone is essential for survival in times of stress and regulates intermediary metabolism and hemodynamic functions. It also has mineralocorticoid activity. Corticosterone balances the production and action of biologically active substances produced during stress (ie, catecholamines, prostaglandins). If left unchecked, the stress-induced release of these compounds would lead to shock. Plasma corticosterone concentrations can reliably be determined using an RIA.

In free-ranging Mallard Ducks living in coastal estuaries and alkaline lake environments, corticosterone functions as an important mineral-regulating hormone. Under these circumstances, it acts simultaneously on three target organs: the small intestine, the nasal salt glands and the kidney. A specific increase in extracellular sodium concentration, an increase in the concentration of an associated anion or an increase in extracellular osmolality activates the hypophysiotropic reflex to cause a release of ACTH.[45,97]

This response is in marked contrast to that seen in birds that do not possess functional nasal glands and cannot tolerate hyperosmotic drinking water. In these birds, as in most mammals, glucocorticoids do not function as mineral-regulating hormones and sodium does not act as a secretogogue for ACTH release.

The regulation of aldosterone secretion in birds and mammals is probably similar. Renin is released from the juxtaglomerular cells of the kidney in response to low plasma sodium concentration or reduced blood volume. The renin acts on circulating angiotensinogen to form angiotensin I, which is converted to angiotensin II. Aldosterone secretion is stimulated by angiotensin II. Angiotensin II appears to stimulate aldosterone synthesis by acting directly on the steroidogenic cells rather than by stimulating the release of ACTH from the adenohypophysis.[45] In contrast to mammals, birds do not release aldosterone in response to elevated extracellular potassium concentrations.[45]

Angiotensin II has been shown to be a potent dipsogen in a variety of birds. However, carnivorous birds that ingest most of their water requirement with food, show a much lower sensitivity to angiotensinogen II. In quail, daily water consumption parallels a pattern of change in plasma angiotensin II. Furthermore, the inhibition of endogenous angiotensin II by captopril or by the receptor antagonist Saralasin, decreases natural water intake in quail. In the xerophilous budgerigar, daily patterns of water intake and plasma concentrations of angiotensin II are not parallel.[95]

Adrenocortical Disorders

Both over- and underproduction of either glucocorticoid (Cushing's syndrome and Addison's disease, respectively) or mineralocorticoid hormones (aldosteronism and hypoaldosteronism) have been reported in man and domestic animals. Although adrenal lesions have been described on postmortem examinations in a high percentage of birds (27% in one study involving psittacine birds), a clinical diagnosis of spontaneous adrenal disease has never been documented. The use of the ACTH stimulation test, dexamethasone screening test and dexamethasone suppression test as reported for dogs[26] should prove useful for the diagnosis of both hypoadrenocorticism and hyperadrenocorticism in birds. The optimal dose for ACTH and sampling times for determination of plasma corticosterone (not cortisol) concentrations have been established for a number of avian species.

Hyperadrenocorticism (Cushing's syndrome)

Spontaneous hyperadrenocorticism has not been reported in birds, but the effects of exogenous glucocorticoids have been well documented. In man and domestic mammals, Cushing's syndrome occurs most commonly in patients receiving glucocorticoids. Hyperadrenocorticism can occur as a result of a primary tumor of the adrenal gland, a pituitary tumor that hypersecretes ACTH, or ectopic ACTH secretion from a nonpituitary tumor. Both of the latter conditions induce bilateral adrenocortical hyperplasia due to continuous ACTH secretion.

Pituitary and adrenal tumors have been reported in birds, and it is not unlikely that a number of these patients were in fact suffering from hyperadrenocorticism. The following conditions have been reported: bilateral adrenal adenoma and adrenal cortical hyperplasia in budgerigar,[8] unilateral adrenal adenoma in a budgerigar,[12] unilateral adrenocortical carcinoma in a pigeon,[33] adrenal carcinoma with metastasis in the liver,[12] and adrenal gland neoplasia in a variety of avian species.[39] An adrenal cortical tumor in an 18-month-old leghorn hen with marked signs of virilism was reported[15] as well as an adrenal cortical adenoma.[16]

Furthermore, a number of stressful situations can increase adrenal size as a result of continuous stimulation by ACTH. Heterotopic adrenal tissue may occur in the ovary, and both cortical and medullary tumors have been tentatively identified in this site.[15]

Hypoadrenocorticism

Adrenalectomy in birds results in renal loss of NaCl and death from hyponatremia and hyperkalemia. Affected birds can be maintained with high NaCl intake or corticosterone injections.

In dogs, the ACTH-stimulation test is used to evaluate adrenocortical function. In adrenocortical insufficiency, administration of ACTH will not lead to an increase in plasma cortisol, while in hyperadrenocorticism, an exaggerated response may be seen. In all avian species studied, corticosterone, and not cortisol, is considered to be the major glucocorticoid; therefore, cortisol is not a valid parameter to evaluate adrenocortical function in birds.

It has been demonstrated that Mallard Ducks consuming petroleum-contaminated food (South Louisiana crude oil) developed structural damage to the

mitochondria of the inner zone cells in the adrenal cortex and had decreased circulating corticosterone concentrations.[32] Adrenocortical testing procedures using corticosterone have been reported in Psittaciformes,[57,104,110] raptors[111] and pigeons.[60] In pigeons, ACTH testing was accomplished by taking blood samples before and at 60 or 90 minutes after stimulation with 50 μg of ACTH[b] or at 30, 60, 90 or 120 minutes after stimulation with 125 μg of ACTH. In healthy individuals, a 10- to 100-fold increase over baseline corticosterone concentrations and absolute concentrations in the range of 2.2 to 15 μg/dl should be considered normal for post-stimulation samples.

The Use of Corticosteroids in Non-endocrine Disease

Glucocorticoids are widely used in human and veterinary medicine for their beneficial effects in a wide variety of diseases, especially those in which inflammation is severe or in which immunologic-induced disease is involved. Occasionally, glucocorticoids are used to reduce hypercalcemia induced by certain types of neoplasms (renal excretion is increased and intestinal absorption reduced). The adverse effects of glucocorticoids should always be considered before they are administered. The clinician has to consider whether the disease is serious enough to warrant long-term glucocorticosteroid therapy.

The majority of knowledge on the effects of corticosteroids on immunity is derived from experimental work on small rodents and rabbits, although some work has also been performed in birds. In mammals the antibody-forming cells ("bone marrow-derived" or "bursa-equivalent" [B-] lymphocytes and plasma cells) are relatively resistant to the suppressive effects of these agents, while thymic-derived (T-) lymphocytes, and therefore cell mediated immunity, are affected.

Pharmacologic concentrations of corticosterone in birds can cause involution of the cloacal bursa, thymus and spleen, resulting in suppression of both humoral and cell-mediated immunity.[35] Corticosterone in the diet causes a dose-dependent lymphopenia in chickens and an increase in susceptibility to viral infections.[35] A single intramuscular injection of dexamethasone or prednisolone in racing pigeons was found to cause lymphopenia.[34] Lymphopenia occurs within a day after glucocorticoid administration,[35] but leukocyte numbers apparently recover.[21] There is a proportional increase in granulocytes that occurs with the lymphopenia. It has been suggested that this may increase the resistance to bacterial infections through enhanced phagocytosis.[21,35] However, studies in mammals have shown that corticosteroids inhibit neutrophil, macrophage and monocyte migration, chemotaxis, diapedesis, interferon production, processing of antigens, phagocytosis and intracellular killing.[6,27,65]

In man, monocytes are more sensitive to functional suppression by steroids than neutrophils, which may impact the formation of granulomas. Granulomatous hypersensitivity diseases are responsive to glucocorticoid therapy, while tuberculosis and certain fungal diseases associated with granuloma formation are prone to exacerbation and relapse following glucocorticoid therapy. Stress-related aspergillosis is common in oil-contaminated waterfowl.[30,31,87] Aspergillosis has been observed in racing pigeons and budgerigars as a complication of long-term administration of glucocorticosteroids (Westerhof I, unpublished).[84] Aspergillosis in recently captured free-ranging birds may be related to stress-induced hypercorticosteronism with associated suppression of monocyte function (Figure 23.8).

A dose-dependent increase in the excretion of coccidial oocysts can be observed after administration of dexamethasone in infected pigeons.[38]

Glucocorticoids (Corticosteroids)

The anti-inflammatory activities of therapeutically used glucocorticoids (Table 23.1) have been assessed in mammals.[4]

Appropriate dosages for glucocorticoids in birds have not been fully established and are currently being investigated. Dosage guidelines are based on data in mammals.

TABLE 23.1 Activity of Glucocorticosteroids Used in Mammals

Glucocorticoid	Equivalent Dose (mg) Based on Anti-inflammatory Potency	Mineralocorticoid Potency
Cortisone	25	2+
Hydrocortisone (cortisol)	20	2+
Prednisone	5	1+
Prednisolone	5	1+
Methylprednisolone	4	0
Triamcinolone	4	0
Flumethasone	1.5	0
Dexamethasone	0.75	0
Betamethasone	0.6	0

Mineralocorticoid activity is an undesired side-effect in some glucocorticoid drugs. Cortisone and cortisol (hydrocortisone) have the highest mineralocorticoid activity and are the corticosteroids of choice for replacement therapy after adrenalectomy or in (iatrogenic) hypoadrenocorticism. Supplemental administration of the mineralocorticoid, fludrocortisone, is suggested in these cases.

The cortisol dosage for replacement therapy is about 0.5-1 mg/kg daily. Cortisol is also indicated when stressful procedures are undertaken in patients who have been receiving long-term treatment with corticosteroids and are suffering from iatrogenic secondary hypoadrenocorticism or iatrogenic hyperadrenocorticism-like disease.

Prednisolone is the agent of choice for anti-inflammatory immunosuppression and antineoplastic therapy to reduce the severity of negative feedback at the hypothalamus-hypophyseal level. Anti-inflammatory doses of prednisolone are 0.5-1.0 mg/kg. Immunosuppressive and chemotherapeutic doses are 2-4 mg/kg prednisolone daily. Corticosteroids are used as chemotherapy for lymphoreticular neoplasia because of their antimitotic effects on lymphoid tissue.

Dexamethasone is the steroid of choice for reducing cerebrospinal edema. Dosages used in mammals are 2 mg/kg TID until improvement occurs.

Cortisone and prednisone must be metabolized in the liver to form cortisol (hydrocortisone) and prednisolone, respectively. Therefore, prednisone and cortisone are not effective when applied topically.

In clinical situations where long-term glucocorticosteroid therapy is indicated, appropriate consideration should be given to exacerbations of subclinical infections (eg, viral, bacterial, mycotic or parasitic) or induction of iatrogenic secondary hypoadrenocorticism or iatrogenic hyperadrenocorticism-like disease. Local corticosteroid therapy should be considered in ophthalmic and dermatologic conditions, and alternate-day therapy should be considered in long-term systemic corticosteroid therapy to reduce these side-effects. However, the clinician should be aware that high or even toxic blood levels of steroids can occur following topical application.

With daily glucocorticosteroid therapy, short-acting agents are used to simulate the normal physiologic corticosterone cycle. Short-acting glucocorticosteroids are administered in man in the morning when endogenous glucocorticoid concentrations are highest. This induces the most profound negative feedback on ACTH secretion. Low levels late at night release the pituitary from feedback inhibition and permit secretion of ACTH. When the same total amount of glucocorticosteroids is given in divided doses, a greater incidence of complications, particularly suppression of the HPA axis, is to be expected. A nocturnal rise in plasma corticosterone concentrations has been demonstrated in pigeons[47] and chickens,[9] with the acrophase towards the end of the scotoperiod, which is suggestive of an increase of the secretion of corticotrophin (ACTH) at night. There is, however, some controversy about the exact timing of the acrophase in chickens.[28] Considering these findings, it seems logical to administer glucocorticoids in the morning hours in diurnal birds. The situation might be reversed in nocturnal birds.

FIG 23.8 A mature Moluccan Cockatoo male was presented for feather dystrophy and progressive inspiratory dyspnea of several weeks' duration. Endoscopy of the trachea revealed a proliferative mass occluding the majority of the lumen. The bird was euthanatized. At necropsy, an aspergilloma was detected in the mid-cervical area of the trachea. The only other gross lesion was bilateral adrenal hypertrophy (three to four times normal size) suggestive of chronic stimulation by ACTH. Blood collected from the bird during the initial evaluation was positive for PBFD virus by DNA probe testing.

Corticosteroid therapy in severe inflammatory diseases is best divided into several doses through the day. Once the desired effects are reached, the regimen should be tapered down to the least toxic dose. The divided daily dose is given in a single daily dose in the morning and gradually decreased to the minimal effective dose. Whenever glucocorticosteroid therapy has to be given for periods over two weeks, alternate-day therapy should be considered. The daily dose is doubled and given every other day, while the dose on the "off" day is gradually decreased to zero. The use of nonsteroidal anti-inflammatory drugs can be used on the "off" days during the tapering period.

Whenever long-term glucocorticoid therapy is discontinued, gradual tapering of glucocorticoid dosage is indicated.

Iatrogenic Hyperadrenocorticism-like Disease

Exogenous glucocorticoids cause hyperphagia while reducing growth and body weight in birds. There is a marked increase in fat deposition (lipogenesis) and a concomitant increase in protein catabolism. Cholesterol levels increase, and true lipemic conditions may develop as a result of glucocorticoid injections. Furthermore, gluconeogenesis is increased (production of blood glucose at the expense of muscle and adipose tissue) and hence plasma glucose concentrations are elevated. Steroid diabetes may be induced with accompanying glucosuria. Hepatic glycogen is increased. Calcium absorption from the intestinal tract is reduced after administration of betamethasone and cortisol. Corticosterone increases the glomerular filtration rate which, together with glucosuria, may be recognized as polyuria and polydipsia.

Iatrogenic Secondary Hypoadrenocorticism

Glucocorticoids exert a negative feedback influence at the hypothalamo-hypophyseal level and suppress basal and stress-induced corticosterone release. Failure of the adrenal gland to respond to stress factors may result in adrenocortical insufficiency. Many stressors are known to induce corticosterone secretion in birds: extreme environmental temperatures, handling, immobilization, anesthesia, infection, frustration, fear, housing, noise, food and water deprivation and hypovitaminosis A. Adrenocortical failure and shock may occur in birds exposed to one or more stressful situation following iatrogenic glucocorticoid administration. Sustained suppression of the HPA axis is common in human patients who have received the equivalent of 30 mg prednisone per day for more than one week. Exposure to high doses over a prolonged period of time may lead to HPA axis suppression for up to one year. It has been shown in pigeons that short-term, high-dose glucocorticoid therapy produces only transient suppression of the HPA axis (Westerhof I, unpublished). An ACTH stimulation test can be performed to evaluate the integrity of the HPA axis. Replacement therapy is indicated in stressed birds with hypoadrenocorticism.

Stress Marks

A common disorder of developing feathers is the symmetrical development of stress marks or hunger traces. These represent a segmental dysplasia in the barbs and barbules. Stress lines can be easily identified by holding the spread wing or tail feathers against a light and looking for bilateral symmetrical lines perpendicular to the feather shaft (see Color 24). These lesions represent a period of malnutrition or stress while the feathers were developing. They can also be induced by a single injection of a glucocorticoid. Administration of glucocorticoids strongly suppresses growth and increases protein catabolism,[24] and these lesions probably reflect a short period of decreased amino acid available to the developing feather. Chronic malnutrition and chronic stress in birds with developing feathers will result in more severely affected feathers.

Adrenomedullary Disorders

Pheochromocytoma (Chromaffinoma)

A benign or malignant tumor of chromaffin tissue may cause hypersecretion of epinephrine or norepinephrine, which in man is known to lead to hypertension and associated symptoms such as profuse sweating and cardiac irregularities. A pheochromocytoma of the adrenal gland in a 14-week-old broiler pullet has been reported.[15] The bird died suddenly. The only obvious abnormality was an enlarged left adrenal gland measuring 15 mm in diameter.

Endocrine Control of Feather Formation

A basic knowledge of endocrine control of feather formation should direct the clinician away from using endocrine abnormalities as a repository for disturbances in feather formation of unknown etiology. Three basic factors have been discussed in feather formation: the feather-forming tissue itself, the neurohumoral factors in the absence of which the feather-forming tissue is unable to fulfill its specific morphogenetic function, and finally the environmental factors, especially the variation in daylight length, which controls the neurohumoral factors.[100] Neural control of feather formation has been demonstrated by growth retardation of feathers when denervation occurs. The metabolic processes that underlie feather formation are regulated by the thyroid and the gonads.

The development of embryonic, juvenile and adult plumage has three phases: the production of germ

cells, their proliferation and development and the renewal of feathers. The first phase can occur in the absence of thyroid hormone. The presence of thyroid hormone, however, is essential for the growth, differentiation of structure and formation of feather pattern. The importance of thyroid hormone for feather formation is generally similar in young and mature birds. In some birds, this thyroid dependence affects the rate of feather growth and formation of vane structure and in others, it affects the pigmentation and development of feather pattern.

In thyroidectomized birds, the lower parts of the feather are underdeveloped, while in hyperthyroidism, these parts develop most vigorously. In hypothyroidism, the vanes of the feathers are narrower and there is a partial reduction of the barbs. In a number of fowl breeds, hypothyroidism is accompanied by partial or complete replacement of black eumelanin by brown pheomelanin, while in hyperthyroidism eumelanin pigmentation is enhanced. The black pigment can be formed in the bird's body at only a certain concentration of thyroid hormone.

Molting is possible only as the result of complex hormonal influences. Molting occurs during a period of depressed sexual activity. It can be suppressed by sex hormones or induced by administration of progesterone (see Chapter 24).

When the duration of light is decreased, or a long period of artificial daylight is suddenly replaced by a short one, sexual activity declines or ceases and molting begins. Numerous experiments in birds of various species have provided similar results. Short periods of daily light associated with declining sexual activity are needed for the proliferation of feather germ cells and renewal of plumage. Sudden transition to darkness after prolonged exposure to lengthened periods of daily light produces vigorous molting in various birds.

It should be remembered that many avian species must be exposed to natural photoperiods to allow a normal hypothalamic-pituitary control of the molting process. Improper photoperiods may be an important cause of feathering disorders in companion birds kept indoors. Additionally, normal feather development requires that appropriate nutrients for feather development are available in appropriate quantities.

An increase in thyroid gland activity during molting does not cause molting but rather is a response to the body's increased requirements of thyroid hormone in connection with the development of new feathers. However, thyroid hormone administration in some species will accelerate the molting process.

In some birds (eg, Galliformes, Passeriformes, Anseriformes), feather color and pattern vary with the age, gender and season, and these characteristics are governed by hormonal influences of the gonads. In these birds, the adult plumage, unlike the juvenile plumage, develops under the influence of at least two endocrine glands. In contrast, the plumage of Fringillidae may or may not differ by gender. In these birds the plumage does not change under influence of plasma concentrations of sex hormones but is governed by the autosome: sex chromosome ratio and cannot be overridden by hormonal imbalance. The influence of sex hormone in the former group in each feather-forming process is realized only at a definitive level of metabolism that is maintained by thyroid hormone (female plumage does not develop in thyroidectomized birds given estrogen). When the bird is adequately saturated with thyroid and sex hormones, the feathers that develop should be termed the thyro-sexual type. Under conditions of hypothyroidism or athyreosis, the feathers that develop are uniform in structure and should be termed the athyreoid type of plumage (and consequently also asexual, juvenile type).

The male plumage is potentially an attribute of both genders, and the female hormones play the principal role in gender differences in the plumage of Galliformes and Anseriformes. When a rooster, drake or cock pheasant is castrated, no changes are produced in the pattern of its plumage. Neutered females, however, develop male-type plumage after molting. When a castrated rooster or a neutered hen undergoes an ovarian transplant, female-type plumage develops.

Diabetes Mellitus

Spontaneous diabetes mellitus has been reported in a variety of granivorous avian species, including the domestic pigeon. One case of spontaneous diabetes mellitus has been reported in a raptor.[103] Budgerigars and cockatiels frequently develop diabetes mellitus. The most striking clinical signs are PU/PD and loss of weight despite a good appetite. A tentative diagnosis can be made by demonstrating glucosuria while a

definitive diagnosis can be made by finding persistent hyperglycemia.

There are some striking differences between birds and mammals with respect to pancreatic control of carbohydrate metabolism. The insulin content of the pancreas of granivorous birds is about one-sixth that of mammalian pancreata, while the glucagon content is about two to five times greater. Circulating plasma concentrations of glucagon are 10 to 50 times higher in birds than in mammals. In mammals, pancreatectomy results in diabetes mellitus. Reported effects of pancreatectomy in birds are controversial. However, recent experiments performed on granivorous birds indicate that surgical extirpation or destruction of the pancreas with cytotoxic agents leads to hypoglycemic crisis and death. The few reported pancreatectomies performed on carnivorous birds have always led to diabetes mellitus.

It is generally accepted that glucagon is more effective in granivorous birds, which exhibit a marked insulin insensitivity. The limited data available on spontaneous diabetes mellitus in granivorous birds suggest that in these species diabetes mellitus is not caused by an insulin deficiency. Birds of prey may be more insulin-dependent than granivorous birds.[103]

There are several case reports of successful treatment of spontaneous diabetes mellitus in birds with daily injections of insulin using dosages comparable to those used in dogs. These reported "successful treatments" of diabetic birds (disappearance of clinical signs) are surprising, considering the relative insulin insensitivity that has been reported to occur in a variety of avian species.

Plasma insulin and glucagon concentrations have been established in three birds with hyperglycemia.[58] It is not clear whether these determinations were accurate. In all cases, insulin concentrations were similar to controls. Glucagon concentrations on the other hand were extremely high or extremely low. This suggests that the hyperglycemia may have been from varying etiologies.

TABLE 23.2 Control of Carbohydrate Metabolism

	Birds (granivorous)	Mammals
Pancreas	Low insulin High glucagon	High insulin Low glucagon
Plasma glucagon	High	Low
Pancreatectomy	Varies (hypoglycemia)	Diabetes mellitus

When speculating on causes of diabetes mellitus in birds, the possible role of the diabetogenic hormones should be considered. Glucocorticoids, epinephrine, glucagon and growth hormone can all induce hyperglycemia and impaired glucose tolerance. Overproduction of these hormones may occur with tumors of the hormone-producing cells or paraneoplastic syndromes ("ectopic" hormone production).

In man, hyperglucagonemia may be associated with bacterial infections, trauma, congestive heart failure, azotemia and functioning tumors of the α-cells of the islets of the pancreas or of the gastrointestinal tract (eg, glucagonoma).[10,72]

Most avian pancreatic carcinomas are the result of secondary invasion usually via serosal implantation on the duodenal loop of tumors arising in the female reproductive tract.[15] The histology can be most misleading because in the pancreas there is often an appearance of gradation and continuity between epithelium and tumor cells. An islet cell adenoma that was identified as an α-cell adenoma has been described.[15] No clinical information on this bird was available.

An islet cell carcinoma has been diagnosed in one case of diabetes mellitus in a parakeet. The cellular origin of the tumor was not identified, but it was suggested that it could be an α-cell tumor.[80] This also may have been a case of a paraneoplastic syndrome. In man, pancreatic islet cell tumors are a well known site of ectopic ACTH production, which can cause an associated Cushing's syndrome.[70] Pancreatic islet cell tumors are also associated with ectopic GH secretion,[70] which can cause diabetes mellitus in dogs.[26] Unfortunately, no endocrine studies were performed in this particular parakeet. Glucagon-like immunoreactivity has been reported from extracts of certain parts of the avian small intestine.[90]

The normal avian pancreas contains extremely high levels of somatostatin (produced in the D-cells of the islets). This compound depresses glucagon secretion (and to a lesser extent insulin and avian pancreatic polypeptide secretion), and it might be hypothesized that elevated glucagon concentrations could be caused by decreased release of somatostatin (SRIF). The hypothesized triggering mechanism for a diminished release of SRIF, however, is not clear.

In intact female dogs, progesterone-induced GH overproduction with subsequent insulin resistance accompanied with hyperinsulinemia can cause diabetes mellitus. The disease can occur spontaneously

during diestrus or as a complication of treatment with medroxyprogesterone acetate. The data available on plasma insulin concentrations in birds with hyperglycemia/glucosuria suggest that the cases were not caused by insulin resistance because insulin concentrations in the birds were similar to controls. Overproduction of GH, therefore, was an unlikely cause of diabetes mellitus in these birds, but might be a cause of diabetes in other birds.

Hyperglycemia was reported in budgerigars with subcutaneous transplants of pituitary adenomas in combination with slightly elevated GH activities.[84]

A cockatiel was reported with what seemed to be subnormal glucagon concentrations and normal insulin concentrations.[58] It is possible that the low glucagon concentration was a response to a hyperglycemia induced by another unknown factor (steroid diabetes caused by primary, secondary or iatrogenic hyperadrenocorticism or ectopic ACTH production).

The association of Cushing's syndrome with carcinoma is the most common ectopic endocrine syndrome in man. Neoplasms associated with this syndrome include lung carcinoma (oat cell and small round cell), pancreas carcinoid and islet cell carcinomas, medullary carcinomas of thyroid and neoplasms derived from the neural crest (pheochromocytoma, neuroblastoma, paraganglioma, ganglioma) (see Color 25). Numerous cases suggest that any carcinoma may induce an ectopic endocrine syndrome. The current theory is that POMC is probably produced in small quantities by all normal nonendocrine tissues. Immunoreactive POMC is found in large quantities in extracts of carcinomas. Some carcinomas metabolize POMC to biologically active ACTH, producing the so-called ectopic ACTH syndrome.[70] Renal carcinomas and pancreatic carcinomas have been seen in association with hyperglycemia in birds, and a paraneoplastic syndrome involving POMC-derived ACTH with subsequent hyperadrenocorticism cannot be excluded.

The single case of diabetes mellitus reported in a raptorial bird was associated with markedly vacuolated B-cells indicative of excessive stimulation.[103] Further findings were four fluid-filled cysts on the kidneys and mildly enlarged adrenals. Histology revealed chronic multifocal lymphocytic interstitial nephritis. The liver had variable-sized, randomly scattered foci of lipidosis.

The pathogenesis of diabetes mellitus in birds remains unclear.

Polyuria/Polydipsia (PU/PD)

A variety of diseases that cause PU/PD in birds has been defined, but the pathophysiologic mechanisms and etiology are not always clear. The minimal database for an avian patient with PU/PD should include dietary history, social and behavioral history, vaccination status (paramyxovirus in pigeons) and recent medications (eg, corticosteroid therapy), urinary glucose, plasma glucose, urea, uric acid, AST, bile acids, total calcium, total protein, protein electrophoresis and HAI-titer for paramyxovirus in pigeons. Diseases that are known to cause PU/PD in other animals, but that have not been diagnosed in birds, are hyperthyroidism, hyperadrenocorticism and hypercalcemia associated with (pseudo)hyperparathyroidism.

Determining the reproductive history is important in hens with PU/PD. Birds with egg-related peritonitis may have previously laid eggs and then stopped because of the egg-related peritonitis. These birds may have a swollen abdomen in association with PU/PD.

Polyuria/Polydipsia Syndrome in Pigeons Feeding Squabs

Pigeons feed their young crop milk during the first 7 to 11 days after hatching, at which time the squabs are fed regurgitated grains. The parent birds and the squabs often develop PU/PD for a couple of days during the transition period. When the parents and squabs are separated from each other, PU/PD continues in the adult birds but subsides in the squabs.

The observed PU/PD in the parent birds may be caused by a decrease in the circulating concentrations of prolactin. Apart from being essential for the production of crop milk, it has been shown that prolactin has an influence on water and electrolyte regulation in birds. Experimental administration of prolactin to Mallard Ducks results in a decreased urine production. In chickens, an increase in plasma prolactin concentrations has been observed after infusion of hypertonic saline and with dehydration.

When water intake is restricted in these birds, the PU/PD stops immediately, indicating that the body is capable of correctly concentrating urine.

TABLE 23.3 Some Conditions Associated with Polyuria/Polydipsia

- Dietary-induced polyuria
- Excitement or nervousness
- Apparent psychogenic polydipsia
- Medications (corticosteroids, diuretics, progesterones)
- Toxins (eg, gentamicin)
- Nephrogenic diabetes insipidus
- Diabetes insipidus
- Diabetes mellitus
- Renal glucosuria
- Pigeons feeding squabs
- Paramyxovirus (racing pigeons)
- Liver disease
- Renal disease
- (Hypercalcemia?)
- (Hyperadrenocorticism?)
- (Hyperthyroidism?)
- Hypervitaminosis D_3
- Elevated dietary sodium
- Excess dietary protein
- Excessive fruit consumption

Renal Glucosuria

Glucosuria is not always associated with hyperglycemia, and the two should occur together to warrant a diagnosis of diabetes mellitus. Glucosuria without hyperglycemia in man is associated with the Fanconi syndrome, which is caused by inherited or acquired damage to the proximal convoluted tubules of the kidney.[105] Glucosuria without hyperglycemia has been observed in an African Grey Parrot.

Apparent Psychogenic Polydipsia

Some avian patients may develop psychogenic polydipsia that results in polyuria. A water deprivation test may be useful in documenting a primary polydipsia or compulsive water drinking. In these patients, water restriction results in disappearance of the clinical signs. It seems that psychogenic polydipsia should be added to the list of behavioral problems that can be encountered in companion birds.[64]

Paramyxovirus Infection in Racing Pigeons

When a pigeon strain of paramyxovirus serotype-1 infects an unvaccinated flock of pigeons, about 80% of the birds will develop severe PU/PD, which can last for several months and then gradually resolve. The pathophysiologic mechanism for these clinical changes has not been defined.

CHAPTER

24

DERMATOLOGY

John E. Cooper
Greg J. Harrison

The condition of the skin and feathers of a bird provides a clinical window to the nutritional plane and environmental conditions to which the patient is exposed. Additionally, systemic diseases (hepatic, renal, pancreatic, gastrointestinal, hematopoietic) can alter the condition of the integument. These changes are frequently detected by observant owners and should be carefully evaluated by the veterinarian. In addition to responding to systemic abnormalities, the feathers and skin are subject to a group of organ-specific diseases.

The unique structure and adaptations of the avian integument have long attracted interest.[26,32,67] The avian integument consists of the skin, scales, feathers, four sets of glands, beak, cere, nails and foot pads. Some species (particularly Galliformes) have highly adapted integumentary appendages that are used for defense or mating rituals. These include wattle, ricti, ear lobes, comb (chickens); dewlap, snood (turkeys); casque (cassowaries); shields (coots and gallinules); knob (goose) and various modifications of the head plumage into crests and bristles. Through selective breeding the comb of the red junglefowl has been modified into dozens of unique shapes, sizes and colors. These unfeathered appendages are particularly susceptible to traumatic injuries and infectious agents. Not all skin appendages are found in any one bird. The only common elements are skin, beak, nails and feathers, which vary in pigmentation, shape, texture, function, location and number, depending on evolutionary adaptations.

Anatomy and Physiology of the Avian Integument

The epidermis of birds consists of three layers including the basal (germinative) layer, intermediate layer and outer cornified layer. The germinative layer is thin (two to four cells thick) in the feathered areas of the body and may be much thicker and interdigitate with the dermis in unfeathered areas of the legs and feet.[26] Striated muscles located in the epidermis move the skin.

The dermis is divided into superficial and deep layers, with the former containing loosely arranged layers of collagen in interwoven bundles and the latter containing fat, feather follicles, smooth muscles that control movement of the feathers and large blood vessels and nerves that supply the dermis and epidermis.[32] A complex mechanoreceptor system (Herbst's corpuscles) occurs in various parts of the avian body including the integument, bones, tendons, muscles, joints and vessels.

The skin overlying the head, extremities and sternum is firmly attached to underlying skeletal structures. Over the remainder of the body, the skin is loosely attached to the underlying muscles. The areas with the most subcutaneous tissues include the dorsal cervical, midline, axillary and groin regions. Footpads are present in many birds, primarily terrestrial species (Figure 24.1). The feet of some birds indigenous to areas with inclement weather are covered with feathers or contain projections (spikes) to facilitate movement in ice and snow.

During the breeding season, many avian species will develop a thickening and increased vascularization of the skin on the ventral abdomen called a brood patch. Depending on the species, one or both genders may develop this brood patch, which should not be mistaken for a featherless, hyperemic skin lesion.

Birds lack sweat glands and most of the skin over the body is thin, dry and inelastic. The feet and, to varying degrees among species, the legs are covered with thick scales. The skin is glandless except for the uropygial (preen) gland, glands of the ear canal and pericloacal glands. The uropygial gland is involved in maintaining feather condition in those species that have this structure. The presence or absence of these

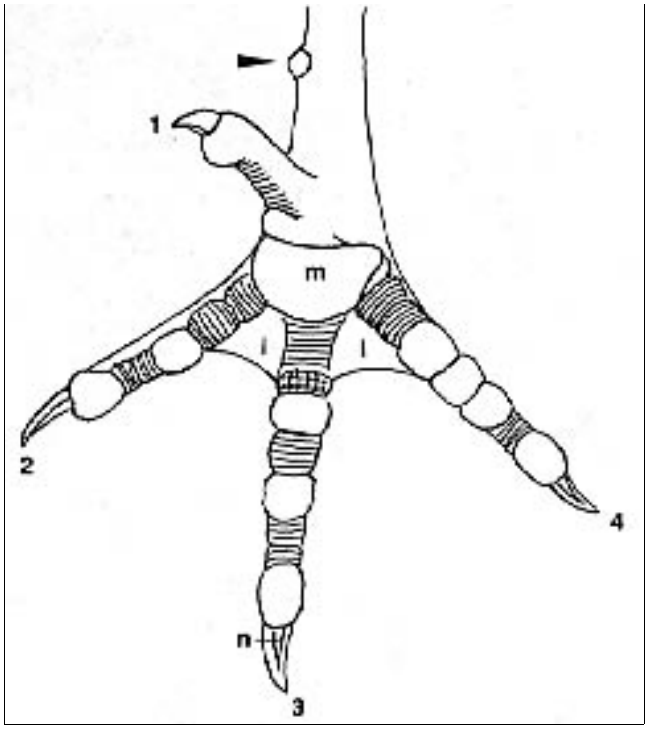

FIG 24.1 Well developed footpads are common in terrestrial birds. Digits 1, 2, 3 and 4 from the right foot of a gallinaceous bird. The interpad spaces are shaded and the digital pads are unshaded. Metatarsal pads (m), interdigital web (i), nail (n) and metatarsal spur (arrow) (modified from Lucas and Stettenheim[32]).

glands varies widely among species. Pericloacal glands secret mucus.[28]

The feathers serve a protective function and the unfeathered areas of the integument (cere, beak, face, legs and feet) are common sites for primary skin disease (poxvirus, *Knemidokoptes* spp.). The skin is capable of dissipating some heat through evaporative cooling but the lack of sweat glands makes birds particularly sensitive to hyperthermia. The functional capacity of the evaporative cooling mechanism may be adversely affected by an essential fatty acid deficiency.[35]

Some birds maintain feather quality through dusting, sunning or bathing. "Anting," or the intentional allowing of ants to cover the body, may serve a grooming role in some species. Other species, most notably cockatoos, have specialized feathers (powder down) that produce a fine keratin debris that is involved in maintaining feather condition. Presence of this normal keratin debris should not be confused with a pathologic condition. Additionally, the exsheathed portion of the keratin shaft from a developing feather should not be confused with dandruff. Retention of the sheath is common in birds with systemic disease

and these birds may be pruritic or appear hypersensitive when stroked.

Cere

The wax-like cere is composed of keratinized skin at the base of the upper beak. Many Anseriformes lack a cere and their nostrils are located in the tip of the soft beak (see Figure 46.7). The cere is affected by a number of conditions, and its appearance can change with the health of the bird. In raptors, the cere may change from bright yellow to pale yellow based on the quantity of carotenoids in the diet.

Brown hypertrophy of the cere may occur in male budgerigars, presumably due to changes in the ratio of sex hormones, and is frequently associated with testicular tumors (Color 24.18). The discolored hyperkeratotic material can be moistened and gently peeled away or removed by scraping or rasping.[3] Hyperkeratosis and flaking of the skin around the cere may be pronounced in malnourished birds. Some hypertrophy is normal in reproductively active hens.

Beak

The beak (rostrum) consists of the bones of the upper (maxilla) and lower (mandible) jaws and their horny covering (rhamphotheca). The beak (or bill) functionally replaces the lips and teeth of mammals and varies in function, shape, size and length among species. The bone underlying the rhamphotheca is covered by periosteum. The periosteum is covered by the dermis and epidermis. The dermis of the beak does not appear to be divided into layers as it is in the skin, but rather is a single layer of dense connective tissue.[32]

The consistency of the rhamphotheca varies among species. It is horny and firm in Psittaciformes, but soft and pliable in Anseriformes. The rhamphotheca can be viewed as the stratum corneum of the beak, and the dermis is well vascularized and connected to the periosteum of the underlying bone. Trauma or necrosis of the dermis will frequently result in a lesion that induces a beak deformity (inability of the damaged area to regrow) (Figure 24.2).

The beak, nails and spurs grow continuously and are worn down by digging, eating or chewing hard objects (Figure 24.3). The beak is used as a tool, weapon and as a tactile exploratory organ for food discrimination, plumage care, nest-building and feeding of the young.

FIG 24.2 Depending on the severity and location of a beak injury, defects in the rhamphotheca can be permanent or they can heal. In this case, a traumatic beak wound in a Great-billed Parrot has been repaired with cyanoacrylic resin (arrows) (courtesy of Louise Bauck).

The beak is modified to rip (raptors), tear or crush (psittacine birds), sift (flamingos) or probe for food (avocets). The beak of some gallinaceous birds is serrated and resembles teeth in both form and function. The buccal surface of the upper beak of some Psittaciformes has a number of rasp-like ridges (Figure 24.4). These are believed to function in holding nuts, filing down fruits and maintaining a sharp edge on the lower beak.[28]

The skin and beak of birds are sensitive to heat, cold and various degrees of pressure. Cutting the beak of a goose will elicit an increase in blood pressure, heart rate and respiratory rate and initiate a tear flow (pain response).[28] Herbst's corpuscles found in the tip of the beak may serve a tactile function that is independent of the tongue and eyes in the exploration for and sorting of food.

Birds that use the beak to search, catch or select food have a well developed "bill tip organ" that can be recognized as papillae that originate in the dermis and end in crater-like structures at the distal tip of the beak.[28] The location and degree of development of the bill tip organ vary among species. In parrots, the organ is best developed in the lower beak (Figure 24.5). The upper beak in Psittaciformes can be viewed as a probe that is used to move items over the bill tip organ in the lower beak. Granivores that obtain food by pecking (Columbiformes and Passeriformes) do not appear to have this organ. The bill tip organ should be presumed to be extremely sensitive,

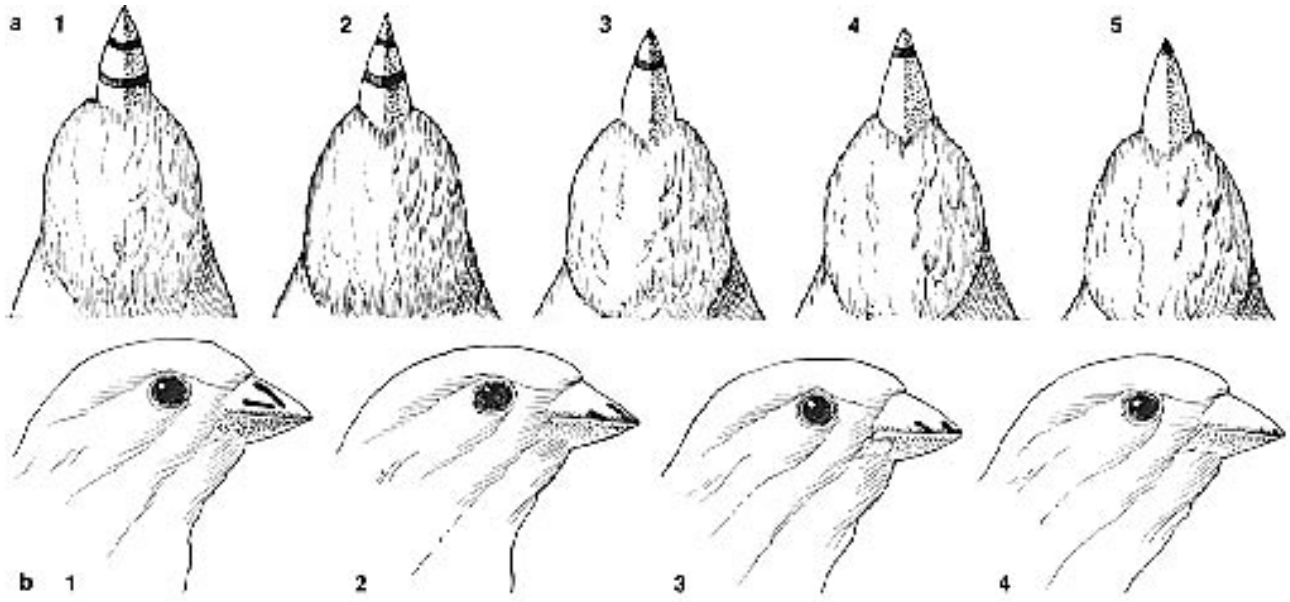

FIG 24.3 Based on beak migration patterns, the clinical progression of rhamphothecal hyperkeratosis secondary to malnutrition must involve dysfunction of multiple growth plates. **a)** Lines were placed on the dorsal rhinotheca to demonstrate the rostral migration of the upper layer of the rhinotheca during growth. Note that the dorsal plates migrate straight to the tip. 1) Marks were placed on the beak and evaluated at: 2) two weeks, 3) one month, 4) two months and 5) ten weeks. **b)** Marks were placed on the lateral rhinotheca to demonstrate the difference in migration of the lateral and dorsal plates of the beak. Note that the lateral plates migrate in a curvilinear fashion toward the cutting edge of the rhinotheca. 1) Marks were placed and evaluated at 2) one month, 3) six weeks and 4) two months (modified from Lüdicke[33]).

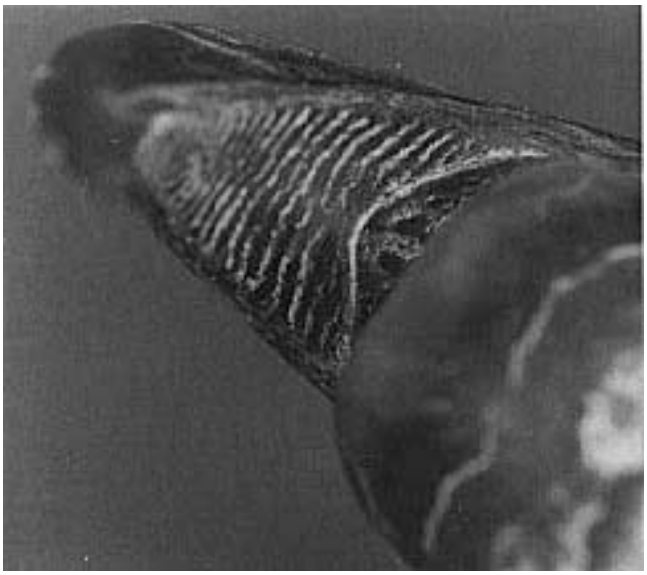

FIG 24.4 Ridges on the occlusal surface of the upper beak of some psittacine birds are believed to function in holding food and sharpening the edge of the lower beak.

which should be considered when manipulating the tip of the beak.

The horny tissue of the beak is generated from two locations. The hard outer horn is produced by the epidermis and grows toward the rim (cutting surface). A softer keratin that surrounds the papillae of the bill tip organ originates from the keratinized epidermis (Figure 24.3).[28] The beak should remain in proper condition without trimming in birds that are maintained on a formulated diet supplemented with fresh fruits and vegetables, exposed to adequate periods of sunlight, allowed to bathe regularly and provided with hard woods to chew.

Any companion bird that requires repeated beak trimming should receive a thorough diagnostic evaluation to detect the underlying management, nutritional or systemic abnormality that is causing excessive beak growth or improper beak wear. Overgrowth of the lower beak may lead to occlusion of the openings to the bill tip organ and a loss of function. To improve the sensory capacity of the bill tip organ, the lower beak should be included in routine grooming activities if the beak is overgrown.

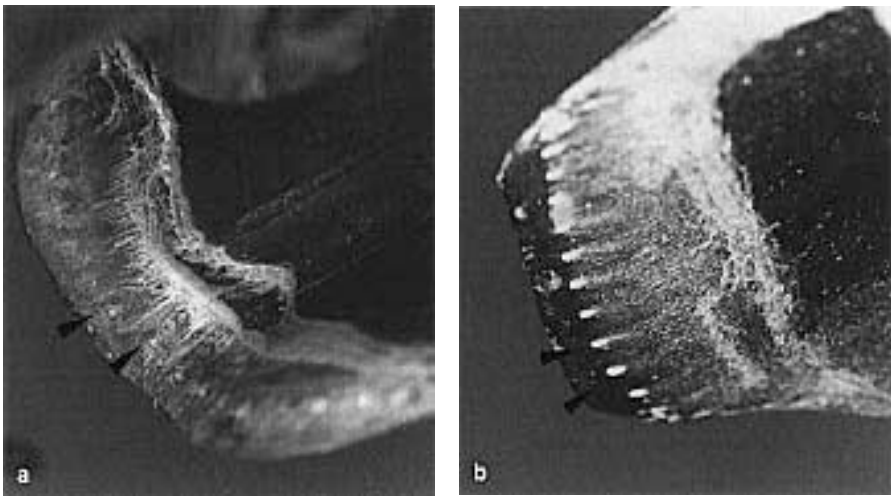

FIG 24.5 **a)** The bill tip organs are barely visible on the occlusal surface of an overgrowing lower beak in a Hyacinth Macaw. **b)** After trimming, the bill tip organs are distinct (arrows).

The recently hatched neonates of most bird species have a small pointed eminence on the dorsal surface of the upper beak (egg tooth) that is used during the hatching process to penetrate the shell (see Color 30). The egg tooth regresses in Galliformes, Psittaciformes and Passeriformes during the first week of life. Some birds, megapodes for example, lack an egg tooth; these neonates are believed to use the feet to kick their way out of the egg.

Abnormalities of the beak are caused by:

- Malformation (often due to nutritional disorders)
- Primary viral infection
- Overgrowth (associated with a high-protein diet in some frugivorous birds, believed to be secondary to malnutrition or organopathy [liver] in many species)
- Fracture or puncture (usually traumatic).

Color changes in the beak of some species (toucans, lorikeets) may be associated with malnutrition or systemic disease. Bacterial or fungal infections of the beak are usually secondary to injuries that result in damage to the horny layer of the beak[3] (see Chapter 42). Bragnathism and scissors beak occur commonly in some neonatal psittacines (see Chapters 30 and 42). A discussion of the diseases of the beak is provided in Chapter 19.

Skin

Developing dermal cells (keratinocytes) undergo a metamorphosis from a cuboidal to squamous nature, and in the process lose cellular organelles, produce lipids and fibrous proteins (keratin) and finally dehydrate and lyse.[62] Although avian skin is noted for its paucity of glands, it has been suggested that the lipid production by the keratinocytes (a function unique to birds) makes the entire skin an oil-producing holocrine gland.[37,44] The lipids produced by the keratinocytes are combined with oils secreted by the uropygial gland to form a thin film that is deposited over the feathers.[62] In poultry, lipid production has been found to be higher in thin skin that must be kept supple than in thicker skin that is relatively rigid.

In combination, lipids from the keratinocytes and uropygial gland secretions are believed to waterproof the feathers, inhibit the growth of bacteria and fungi and maintain proper moisture content and pliability of the feathers.[37] It can be theorized that the severe and generalized feather pathology associated with systemic diseases (eg, organopathy, malnutrition) is a result of improperly functioning keratinocytes.

Patagia

Skin may be reflected into flat, membrane-like structures (patagia) in areas where the wings, legs, neck and tail join the body.[32] The wing has four patagia: the propatagium (wing web), where the neck and wing join the thorax; the postpatagium, formed at the caudal angle of the wrist; the metapatagium, at the caudal junction of the wing and the thorax; and the alular patagium, at the interspace between the alula and the metacarpi (hand) (Figure 24.6). A cervical patagium is located anterior to the shoulder in the angle between the neck and the scapula.

A similar structure is formed by the skin connecting the knee to the prolateral region of the paralumbar area (knee web). This is a transitory structure that is formed when the leg is in certain positions. It is called a web to differentiate it from a patagiam, which is always present regardless of the position of the limb.[32] A groin web may be formed by the skin extending from the sternal region to the medial surface of the thigh (Figure 24.6).

Patagia and webs represent sites of major skin flexion and can be used clinically for subcutaneous injec-

tions or tattooing. These anatomic areas as well as the ventral tail region appear to be frequent sites for the occurrence of ulcerative dermatitis.

Uropygial Gland

The uropygial gland is a bilobed gland located at the base of the tail dorsal to the pygostyle. The gland is absent in many Columbiformes, Amazon parrots and other Psittaciformes. This holocrine gland opens to the outside through a caudally directed nipple that is frequently surrounding by a tuft of feathers (Figure 24.7). Its secretions are spread by preening (grooming) and are considered to serve a waterproofing

FIG 24.7 The uropygial gland is located on the dorsal surface of the bird at the base of the tail (arrow). The opening to the gland is frequently surrounded by a tuft of feathers (open arrow).

function. Additional secretions from the skin and the uropygial gland are believed to suppress the growth of microorganisms. Uropygial gland secretions contain vitamin D precursors that are spread through the feathers, converted to an active form following exposure to ultraviolet light and ingested with subsequent preening activity.

Abnormalities associated with the uropygial gland include neoplasm (primarily squamous cell or adenocarcinoma), abscessation and impactions. A presumptive diagnosis of uropygial gland abnormalities can be based on microbiological culture and cytologic examination of exudate, an aspirate or a biopsy.

Impacted glands are frequently discussed in the literature but appear to be uncommon clinically. The gland is normally swollen and appears as though it may need expressing. In some birds, hyperkeratotic plugs may form in the gland. These cases will generally respond to removal of the plug and improving the bird's diet. An African Grey Parrot with widespread feather loss and a cystic uropygial gland failed to

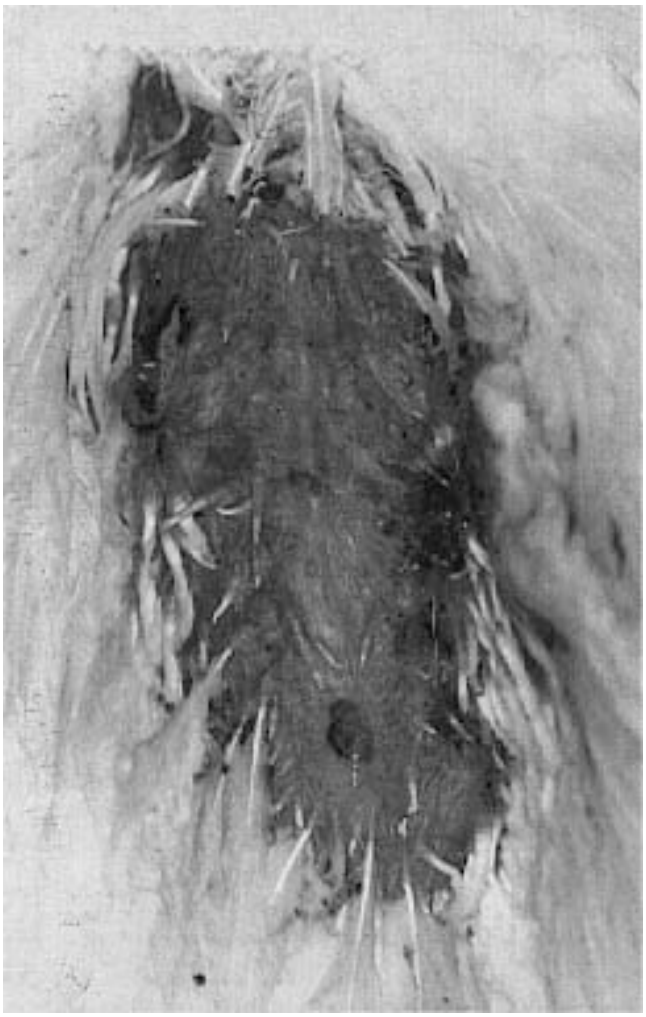

FIG 24.8 The body is divided into areas that contain feather tracts (pterylae) and areas that do not contain feather tracts (apteria). The division between feather tracts is evident on the back of this lutino cockatiel with pruritic dermatitis (courtesy of Louise Bauck).

respond to extensive treatment that included laser therapy, but recovered three months later after a deficient diet was corrected.[32] Uropygial gland rupture has been described in Gentoo Penguins and in free-living seabirds in Europe (Cooper JE, unpublished).[34]

Surgical extirpation of the gland may be necessary if neoplasia occurs (see Chapter 41). In ducks, removing the gland will cause the birds to lose the ability to waterproof their feathers. In other birds, removal of the gland seems to have few clinically detectable effects.[32]

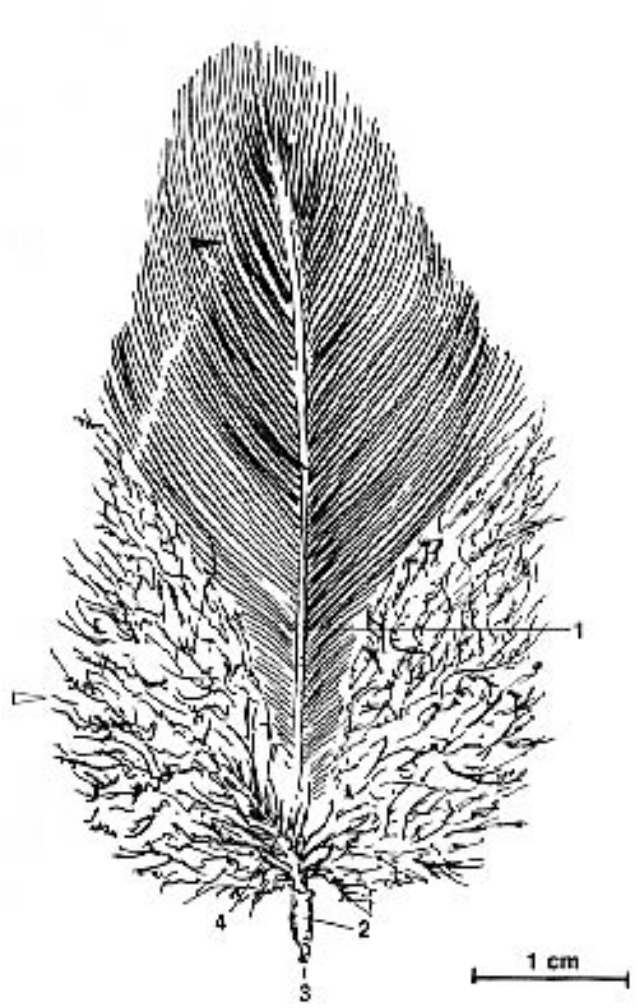

FIG 24.9 Anatomy of a contour feather: 1) rachis 2) calamus 3) posterior umbilicus and 4) afterfeather. The pennaceous portion of feather (arrow) and plumaceous portion of feather (open arrow) are also evident. The rachis and calamus form the shaft. The pennaceous and plumaceous portions of the feather form the vane (modified from Lucas and Stettenheim[32]).

Feathers

The three principal functions of the feathers are flight, insulation and waterproofing. Feathers may also function in courtship, defense (color mimicking) and aggressive territorial behaviors. In most birds, the body is divided into areas that contain feather tracts (pterylae) and areas that do not contain feather tracts (apteria) (Figure 24.8). The location of feather tracts varies among avian families. By originating from tracts rather than being scattered randomly over the body, feathers can smoothly overlap each other and conform to the natural contours of the

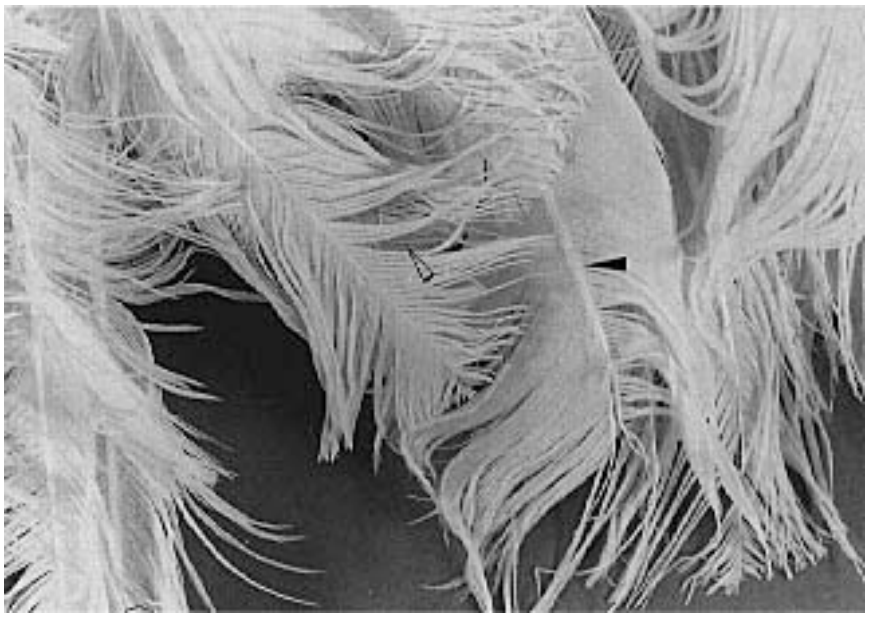

FIG 24.10 Damaged feathers in a malnourished cockatoo. These lesions are frequently blamed on an enclosure of insufficient size. The central shaft of the feather is called the rachis (arrow). The barbs (open arrow) branch from the rachis. The barbs are connected to each other by the barbules. Where the barbs are connected, the barbules are intact. Those that are not connected have damaged barbules.

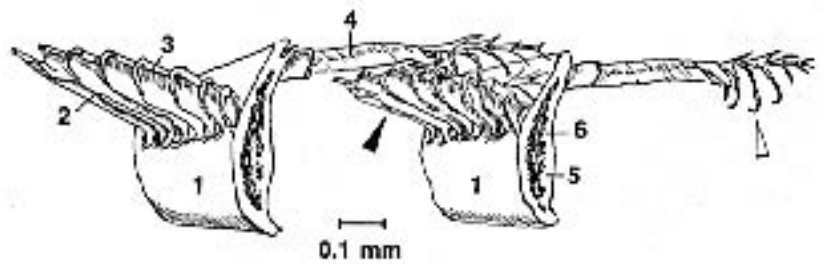

FIG 24.11 The 1) cut end of two barbs showing the interlocking nature of the barbules (arrow). The 2) posterior barbules contain 3) ridges that connect with the hooks (open arrow) found on the 4) anterior barbules. This interlocking mechanism makes the feathers waterproof and improves their insulating capacity. 5) Cortex and 6) pith (modified from Lucas and Stettenheim[32]).

body. The spaces between the tracts can facilitate the clinical evaluation of the skin. A single featherless region and its underlying integumentary components is called an apterium.

Terms used to describe parts of a feather are listed in Table 24.1.

The feather is composed of a long, central tapering shaft that is divided into the hollow base (quill, calamus) and an angular central shaft (rachis) (Figure 24.9). Barbs branch from both sides of the rachis, and barbules branch from both sides of the barbs (Figure 24.10). The anterior, middle and posterior portions of the barbule vary in structure. The anterior and middle barbules contain barbicels (hooks), which are missing in the posterior barbules. The posterior barbules contain ridges, to which the anterior barbicels are attached in a zipper-like fashion.

A feather appears as a unified sheet of tissue because of the interlocking barbules that hold the barbs together to form the vane on either side of the feather shaft. The interlocking nature of the barbules serves to waterproof the feathers, forming a type of thatched roof (Figure 24.11). The interlocking barbules also serve to improve the insulating capacity of the feathers and create an aerofoil to facilitate flight (see Chapter 8).

The feathers can be characterized based on the structure of the rachis, barbs and barbules, and are divided into ten feather types.[32]

- **Contour feathers** represent the predominant feathers that cover a bird's body. They are the largest feathers and have a well developed shaft, pennaceous and plumulaceous components of the vane and an afterfeather.
- **Coverts** are the small contour feathers that are found in rows on the wing and tail.
- **Remiges** are large, stiff, well developed feathers found in the wing and are principally responsible for flight. These feathers are generally asymmetric in form and have an entirely pennaceous vane. The remiges that arise from the periosteum of the metacarpus are called primaries, and those that arise from the periosteum of the ulna are called secondaries. The primaries are counted from proximal to distal (digits), while the secondaries are counted from distal (carpus) to proximal (elbow) (Figure 24.12). The number of primary and secondary feathers varies among species.
- **Rectrices** are large flight feathers found in the tail. They are structurally similar to the remiges. Tail feathers are counted from the center laterally.

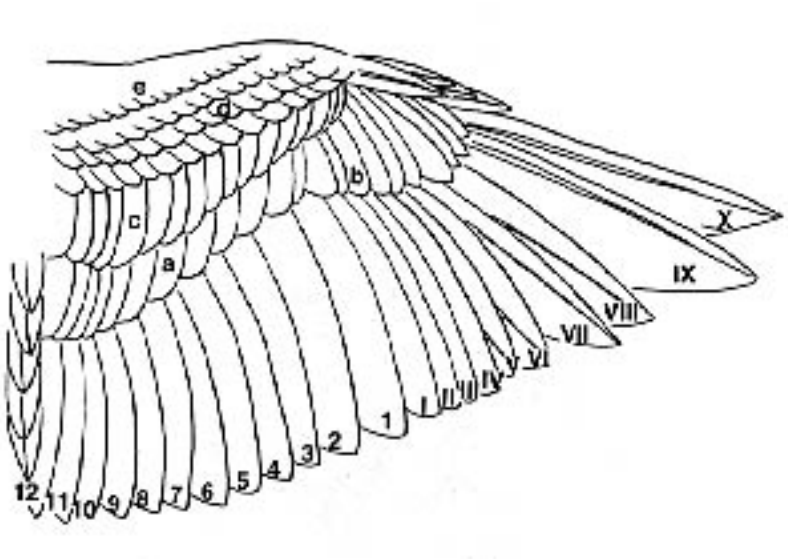

FIG 24.12 Dorsal view of the feathers of the wing: primaries (Roman numerals); secondaries (numbers). a) greater secondary coverts b) greater primary coverts c) median secondary coverts d) lesser secondary coverts and e) marginal coverts (modified from Lucas and Stettenheim[32]).

- **Downs** (juvenile and definitive) are small, fluffy, wholly plumulaceous feathers with a short or absent rachis. Natal downs are present at or soon after hatching and are replaced during the first molt. Definitive down feathers occur on various parts of the body as part of the adult plumage. They are evenly distributed in parrots and waterfowl, confined to tracts in gallinaceous birds and sparse or absent in some pigeons and passerines.
- **Powder down** are specialized down feathers that disintegrate and produce a powder (keratin) that is spread through the feathers during preening. They are found throughout the body among the down and contour feathers. African Grey Parrots, cockatiels and cockatoos have the most abundant powder down feathers. Birds with damaged powder down feathers frequently have soiled-appearing feathers, suggesting their involvement in the maintenance of normal feather condition.
- **Semiplumes** have a long rachis and entirely plumulaceous vane. They occur in feather tracts of their own or are found along the margins of contour feather tracts. They provide insulation.
- **Hypopnea** (afterfeathers) are structures attached to the underside of a feather at the superior umbilicus. They may consist only of barbs or have a shaft and plumulaceous barbs.
- **Filoplumes** are fine, hair-like feathers with a long rachis and a tuft or barb on the tip. They generally accompany contour feathers in most species. They are believed to serve a proprioceptive function.
- **Bristles** are characterized by a stiff, tapered rachis with no barbs except at the proximal end. They are usually found around the mouth, nostrils and eyes and are believed to serve a sensory function.

The feather follicles are formed by invaginations of the skin. The follicular wall has an abundant supply of sensory nerve fibers, and the papillae, pulp and feather muscles are also well innervated.[32] Smooth muscles at the base of the feather follicles help maintain body temperature by increasing or decreasing the elevation of the feathers from the skin.

Herbst's corpuscles at the base of feather follicles are believed to detect subtle ground vibrations and changes in air current. Changes in

TABLE 24.1 Common Terms Used to Describe Portions of a Feather

Calamus	The short, tubular, unpigmented end of the mature feather that is inserted into the feather follicle and is thus present below the skin level.
Rachis	The long, solid, tubular portion of the shaft above the skin. It is a thickened continuation of the calamus external to the skin margin. The rachis contains pith, which is composed of air-filled keratinized epithelial cells surrounded by a solid keratinized outer cortex.
Shaft	The longitudinal central axis of a feather that is composed of the calamus and rachis. The calamus and proximal portion of the rachis are vascularized in the developing feather (pin feather).
Vane or vexillum	The portion of the feather that extends to either side of the rachis and is composed of the barbs and their associated structures. The vane is either plumulaceous (soft, downy) or pennaceous (compact and closely knit) depending on the individual type of feather.
Pulp	The mesodermal component of the growing feather consisting of vascular connective tissue. The pulp regresses as the feather grows and is absent in the normal mature feather.
Pulp caps	Keratinizing epidermis that covers the distal extremity of the pulp. As the pulp regresses, the keratinized caps remain and are visible as horizontal bars crossing the lumen of the calamus.

TABLE 24.2 Feather Coloration as a Result of Pigments and Structural Features

Pigments

- Melanins
  Alone, dull. When combined, create black, brown, reddish brown, yellow, red, purple and chestnut red-appearing colors. These pigments make feathers more dense and resistant to wear.
- Carotenoids
  Bright red, orange, yellow. Cannot be synthesized and must be derived from ingested plants. Carotenoids have growth-promoting properties and impart a green color.
- Carotenes and xanthophylls
  Xanthophylls are more readily absorbed from food than carotenes. Yellow = lutein.
- Porphyrins
  Red and brown, true green.

Structured Color

- Due to the physical separation of the components of white light reflecting from or passing through the feather:
  Iridescent colors change with the angle of view; eg, blue.
  Noniridescent colors do not change with the angle of view (eg, green, purple and violet).

electroencephalographic activity following the removal of feathers suggest that it is a painful procedure.[16] Clinically, the removal of a feather will frequently stimulate movement in an anesthetized bird at the same anesthetic plane that can be used to perform surgery.

Feather Color

The color of feathers is determined by two factors: the pigments that are deposited at the time of development, and structural features of the feather that alter the absorption or reflection of light (Table 24.2). These structural features of the feather can be inherent in the development of the feather or can be induced by materials that are placed on the feathers after development. If a feather reflects all wavelengths of light, it appears white; if it absorbs all wavelengths of light, it appears black. Dark-colored feathers appear to be more durable than light-colored ones.

The pigmentation of feathers may serve to absorb or repel heat (light), warn predators, act as a camouflage or function in mating displays. The capacity of the barbs and barbules to scatter and reflect varying wavelengths of light causes the iridescent glow of the feathers. Blue colors are created by the barbs interacting to reflect blue light while allowing other wavelengths of light to be absorbed by darker melanin granules. Green colors may be created by pigments, or more commonly through the combination of blue (from structural characteristics) and yellow pigments.

Colors tend to be brightest and boldest on the exposed surfaces of the feathers and paler on the ventral surface. Some red coloration in the appendages of birds is caused by vascularization and not pigment disposition. Pinching the tissue and observing for blanching can be used to determine if an area is vascularized.

The normal iridescent glow of the feathers may be induced in part by lipids derived from the keratinocytes. This "glow" is frequently absent in birds with clinical abnormalities and returns as a bird responds to therapy. The sheen of dark feathers has been suggested to be caused by the fat-soluble red and green pigments that are either synthesized by the bird (melanins and porphyrins) or absorbed from food (carotenes and xanthophylls).[44]

It is interesting to note that abnormally colored feathers may return to normal without a molt. This is particularly common in cockatiels with feathers that are stained yellow secondary to chronic biliverdinuria (liver disease) (see Color 8). As birds respond to therapy for hepatitis, these feathers will return to a normal white coloration, presumably because biliverdin-laden, keratinocyte-produced lipids are replaced with lipids that do not contain biliverdin.

Yellow or red pigments derived from the uropygial gland can be spread on the feathers where the pigment remains bright until it fades due to oxidation from exposure to air and light. In a healthy bird, feathers maintain their bright pigmentation through the addition of newly synthesized oils during preening. These mechanisms for imparting color to a feather would allow changes in feather pigmentation to occur without a bird undergoing a molt.[32] Birds receiving higher fat diets would be expected to produce a lipid-rich, keratinocyte-derived uropygial gland secretion that may enhance the color and sheen of the feathers.

In poultry, a lack of pigmentation (achromia) has been associated with dietary deficiencies in lysine, folic acid and iron.[63] Lysine deficiency has not been found to alter the pigmentation of cockatiel feathers but deficiencies of choline or riboflavin will cause abnormal pigmentation (see Chapter 31). Both melanism and albinism have been reported in a variety of captive and free-ranging species.

Peach-faced Lovebirds may develop red patches on their normally green plumage, and both diet and blood parasites have been suggested as a cause of

this condition. Abnormal yellow, red and pink feathers may be noted in Amazon parrots and African Grey Parrots, and it has been suggested that these are associated with hepatopathies, renal dysfunction or systemic disease. Psittacine beak and feather disease has been implicated in some cases of the abnormal occurrence of red feathers in African Grey Parrots.[29] Excess dietary levels of beta carotene can cause a similar feather change.

Molt

Soft keratin structures (skin, comb, wattles, cere) undergo constant replacement through the sloughing of the outer cornified layer (Figure 24.13). Old or damaged outer layers of hard keratin structures (rhamphotheca and metatarsal spurs) are replaced through normal wear. The thick, horny heel pads on the back joints of woodpecker, toucan and barbet neonates are molted at fledging. In cases of malnutrition or systemic disease, hyperkeratotic layers of the rhamphotheca can accumulate and be peeled off with a blunt instrument.

Molting is the process whereby the growth of a new feather causes the shedding of an old feather. The single generation of feathers that occurs as a result of a molt is collectively known as plumage. At any one time, a bird may have feathers derived from more than one molt. This is because some molts involve all of the feather tracts, while others involve only certain tracts or specific feathers. Collectively, the feathers present on the body at one time, regardless of when they first appeared, are called the feather coat.

A new feather that is still enclosed in a feather sheath is called a pin feather (Color 24.5). The physical characteristics and appearance of the feather are controlled by factors that affect the development of the feather at the edge of the epidermal collar. Any infectious agent or systemic abnormality that alters the nutrients or blood supply available to the developing feather will alter its appearance. Additionally, damage to the epidermal collar will be manifested clinically as an abnormal feather.

Feathers grow from the base and mature in an upward and outward fashion (Figure 24.14). The developing feather is composed of the outer epidermis and the inner pulp. The barb ridges, rachis and hyporachis are formed by the epidermis as it grows longitudinally. Lateral growth from a basal layer forms the keratinized sheath.

Once a new feather has been stimulated to grow in the follicle, the molting process is purely mechanical

FIG 24.13 The epidermis of birds is normally replaced on a constant basis. Excessively dry, flaky skin can be an indication of malnutrition or organopathies. In this cockatoo, a heavy molt and sloughing of sheets of the epidermis were induced by changing the bird from a wild-bird seed to a formulated diet.

and is strictly dependent on the developing generation of feathers; thus, the pattern of molt should be defined based on the *developing* feathers (which control the molt cycle) and not on the *shedding* of a feather (which has nothing to do with the molt unless the feather has been mechanically removed).

Molting Periods

The molting process can be divided into periods. The first molt occurs shortly after hatching and involves the replacement of the natal down, resulting in the second plumage (the first plumage would be the natal down). A parrot in its second plumage appears smaller than an adult because the feathers are reduced in length and width at this stage of development. The second molt in a juvenile leads to the third plumage, which is a divided process with many second and third generation feathers being present at the same time. The third molt occurs with the growth of the fourth generation of feathers, which should

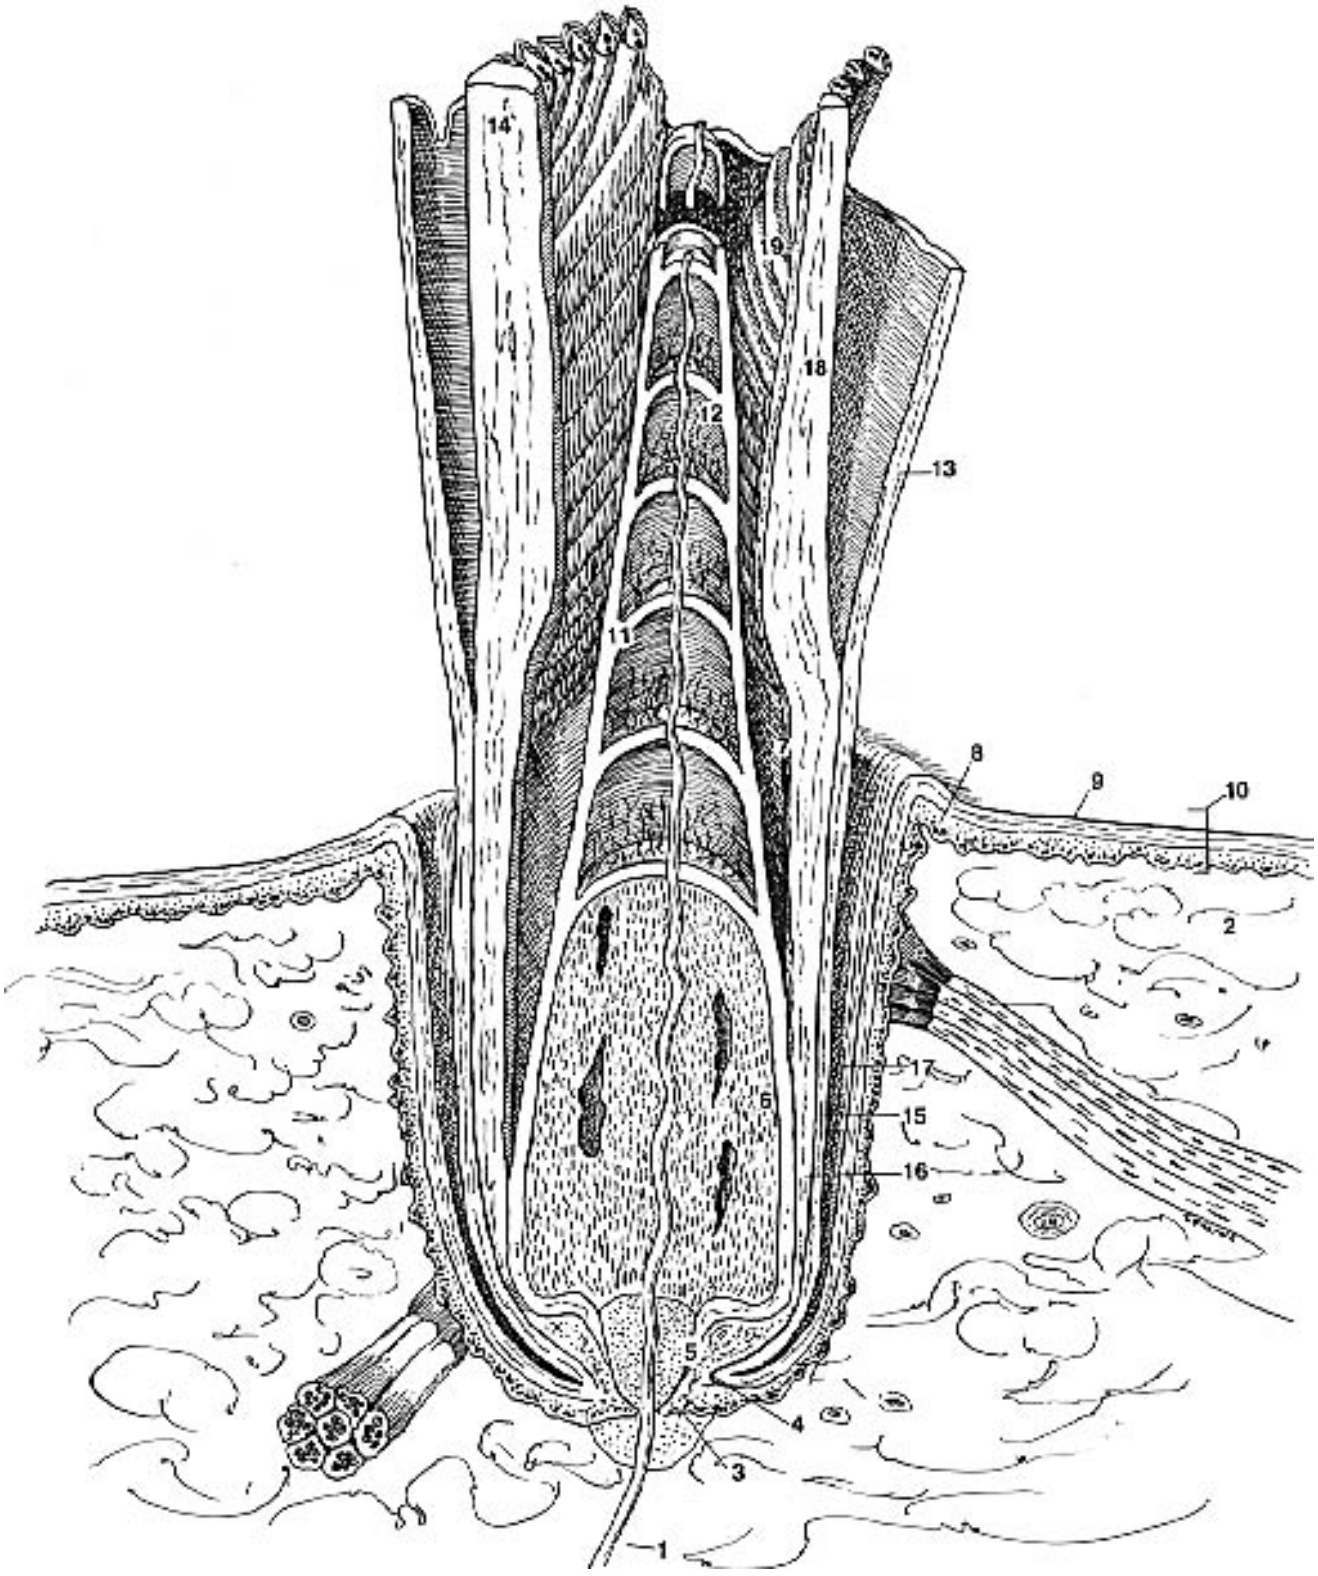

FIG 24.14 Illustration of the layers of feather development: 1) nutrient (axillary) artery 2) dermis 3) inferior umbilicus 4) epidermal collar 5) dermal papilla 6) pulp 7) calamus 8) germinative layer 9) corneous layer 10) epidermis 11) pulp cap 12) remnant of the axillary artery 13) degenerating feather sheath 14) rachis 15) intermediate follicular epithelium 16) basilar follicular epithelium 17) sheath follicular epithelium 18) hyporachis and 19) barb of vane (modified from Lucas and Stettenheim[32]).

result in the development of mature plumage in a normal bird. Malnutrition may cause the adult plumage to be incomplete or abnormal.

The molting process in adult birds occurs on a cyclic basis. A molt cycle is defined as the period that runs from the appearance of a plumage to the appearance of its replacement. The cycle length for most birds is one year; however, some species will molt throughout the year, while others will molt annually or several times a year during distinct periods. Large Psittaciformes may have a two-year molt cycle. Powder down feathers are shed continuously. Most authors theorize that replacement of the adult plumage is synchronized with the gonadal cycles and will be longer or shorter than one year based on reproductive activity; however, molting may be more dependent on photoperiod. Domesticated birds that reproduce year round under artificial lighting conditions may not undergo the seasonal molt that would be expected to occur in their free-ranging conspecifics.

In general, the molting process of the flight and tail feathers starts with the proximal primaries on both wings and progresses until about half of the primaries are replaced. The secondary feathers are then molted in a distal to proximal progression. The body feathers begin to molt after the wing feathers are actively being replaced. The tail feathers are replaced from the central feathers outward. By having a progressive molt, birds are able to continue flying while the feathers are being replaced. In some waterfowl and seabirds, all of the flight and tail feathers are replaced at one time, and these birds go through a period of flightlessness. Penguins molt randomly.

Malnutrition can impact the speed of molt and the health of the developing feathers. The molt period increases a bird's metabolic rate and demand for protein. Birds that are on diets that contain insufficient energy or protein might undergo a partial molt of shorter than normal duration.[5,65]

Companion and aviary birds may have abnormal molts caused by unnatural lighting conditions, malnutrition and environmental or disease-related stress factors. Many companion birds will have a new generation of feathers on the head and neck, with several generations of old feathers on the wings and body (Figure 24.15).

Molting has been suggested to be an autonomous process within the feather papillae, which may be triggered by seasonal changes. If the physiology of the papillae were to change in preparation for feather growth, it might become increasingly sensitive to certain secretions (thyroid hormone, sex hormones) that could then potentiate the growth of a new feather.[32]

FIG 24.15 A malnourished African Grey Parrot with light brown feathers (arrows) in place of the normal slate gray feathers. The bird was placed on a formulated diet and the newly developing feathers are correctly pigmented (open arrows).

The occurrence of a cyclic rather than systemically controlled molt seems clinically feasible given that all the feathers do not molt at the same time from all locations. The feathers appear to molt in sections starting with the head, neck and thorax, followed by the wing and tail feathers. The molt in each anatomic location may occur at varying times, and some pterylae may undergo several plumage replacements before any feathers are molted from another area.

Control of Molt

The control of molting is extremely complex and only partially understood. The process probably involves a combination of hormonal, seasonal, nutritional and local (feather follicle) factors. The effects of individual hormones on the molt cycle appear to vary widely among avian genera, and information derived from studies in one species should be cautiously applied when evaluating clinical abnormalities in another species.

Specifically, the precise role that thyroid hormone plays in the molting process appears to vary among species. This hormone may affect the shape, structure, formation of pigment, color patterns and rate of growth of feathers. In fowl, administration of thyroid hormone may induce a molt in seven or eight days. If the thyroid is removed, feather formation on the body stops but the molt of wing feathers will continue, suggesting that their replacement is not controlled by thyroid hormone. Administration of high concentrations of thyroxine will increase the speed of the molt cycle. These findings suggest that thyroid hormone is important in initiating a molt; however, other studies indicate that progesterone and prolactin can induce a molt without a change in circulating levels of thyroid hormone.[32]

In a study of King Penguins, it was found that thyroxine levels rose significantly (five times resting levels) during the molting period, and corticosterone levels increased at the end of the molt.[5] In other studies, it has been demonstrated that thyroid activity (as measured by thyroidal uptake of radioactive iodine) did not differ appreciably between molting and nonmolting hens. These apparent conflicts in experimental findings may suggest that research protocols, no matter how effectively conceived, may not accurately reflect the natural mechanism of molting.

Feather formation is prevented by circulating estrogens. Progesterone will stimulate feather growth in follicles that are already replacing a feather but will not stimulate feather development. Molts are sluggish and prolonged in fowl exposed to 12 to 14 hours of light. The effect of photoperiod on normal molt in companion birds that originate from widely varying geographic regions is undetermined. In studies in poultry, plasma prolactin, growth hormone and LH levels decrease, and testosterone and thyroxin levels increase, during the molt. Molting activity can be induced by high doses of medroxyprogesterone, decreased exposure to light or administration of thyroxine or prolactin.[24] Luprolide has been found to decrease the size of the ovary, elevate circulating testosterone levels and induce a molt.[37a]

The nervous system may serve as a mediator between the rhythmic environmental events (principally photoperiod) and the hormonal activities of the thyroid and gonads that all combine to facilitate molting. Birds that are stressed by handling during a molt may lose more feathers than birds that are in a relaxed atmosphere. Some birds are able to release feathers when being restrained (fear or stress molt).

General Diagnosis and Therapy

Investigation of Dermatologic Disease

Integumentary diseases can be broadly classified as being caused by infectious or noninfectious agents (Table 24.3). In many cases, dermatologic lesions are secondarily infected with bacterial or fungal agents, and the identification of microbial agents from cultures of the skin does not necessarily implicate these organisms as the precipitating cause of the lesions.

Using a dermatology examination form is a concise way to consistently evaluate and record integumentary lesions. Making drawings or taking photographs is an effective method of recording the precise location and the effects of therapy on skin lesions. By using a standardized form and evaluation system, avian veterinarians and dermatologists can more effectively quantify and compare their findings, which will ultimately lead to improved clinical description, diagnosis and treatment of skin and feather diseases.

The predilection to develop certain types of integumentary diseases may vary among species (Table 24.4). The diagnostic evaluation used for avian dermatologic diseases is similar regardless of the etiology (Table 24.5). The evaluation of feather and skin lesions, particularly in small birds, can be facilitated by the use of a magnifying loupe. Inflammation of the skin can occur as a result of trauma, chemical irritation, bacterial, fungal, viral or parasitic agents. Pericloacal inflammation may be associated with the accumulation of excrement.

Cytology, culture and biopsy are indicated in cases of dermatitis. Cultures should be obtained by removing

TABLE 24.3 An Etiologic Approach to Integumentary Diseases

Infectious	Non-infectious
Viral	Traumatic
Mycoplasmal	Chemical/toxic
Chlamydial	Nutritional
Bacterial	Hormonal
Fungal	Developmental/genetic
Protozoal	Irradiation
Metazoal (parasitic)	Neoplastic
	Immune-mediated
	Behavioral
	Allergic

TABLE 24.4 Common Integumentary Diseases by Order

Passeriformes
- Poxvirus
- *Knemidokoptes* infection
- Papillomatosis (pedal)
- Damaged nails and beak
- Constricted feet and digits
- Hyperkeratinization associated with malnutrition
- Bacterial dermatitis (often secondary to above)
- Loss of feathers around the head and neck - malnutrition
- Dermatophytes
- Trombiculid mites

Galliformes
- Poxvirus
- *Knemidokoptes* infection
- *Dermanyssus* and *Ornithonyssus* infection
- *Echidnophaga gallinacea*
- "Bumblefoot" syndrome
- Contact dermatitis
- Malnutrition
- Skin tumors
- Xanthomatosis
- Viral (Marek's disease, reticuloendotheliosis)
- Genetic
- Enlarged sternal bursa

Anseriformes
- Malnutrition
- "Bumblefoot" syndrome
- "Wet feather"
- Vesicular dermatitis and photosensitization
- Leech infestation

Raptors
- Malnutrition
- Poxvirus
- "Bumblefoot" syndrome
- Gangrene of wing
- Tuberculosis
- "Blain" (bursitis of carpus)
- Damaged nails and beak

Columbiformes
- Poxvirus
- Feather defects associated with PMV infection
- Salmonellosis
- Neoplasia including melanomas

Ratites
- Poxvirus
- Malnutrition

any scabs, moistening the culturette in the sterile transport media and rolling the tip over the lesion. Moistened swabs will yield better results than dry ones, and it is important that the swab be plated as soon as possible after collection. A quick and inexpensive diagnostic technique in practice is to apply a microscope slide to the affected area and to examine it cytologically (see Chapter 10). Skin biopsies are most diagnostic if collected from the center and the periphery of the lesion.

TABLE 24.5 Dermatology Database

Systemic
- Physical examination
- CBC, AST, LDH, UA, bile acids, CPK
- DNA probe for PBFD virus
- DNA probe for polyomavirus
- Gram's stain of feces
- Fecal examination for parasites
- Radiographs
- Thyroid levels - TSH test

Specific Integumentary Examination
- Microscopic (operating or dissecting) examination of feather for parasites
- Cytology of pulp cavity (bacterial and fungal)
- Bacterial and fungal cultures of feather pulp
- Histopathology of biopsy specimens (skin and follicle)
- Electron microscopy of feather sections

General Therapy for Integumentary Lesions

In most cases, the therapy for feather and skin abnormalities caused by a number of factors is similar, with modifications necessary only to resolve specific disease agents. These general therapeutic considerations include:

- Correcting any nutritional deficiencies by administering parenteral multivitamins, minerals (trace minerals) and placing the bird on a formulated diet supplemented with some fruits and vegetables.
- Removing the bird from all exposure to aerosolized toxins that may accumulate on the feathers and skin and cause irritation (eg, cigarette smoke, kerosene fumes, cooking oils).
- Ensuring that the bird has frequent exposure to sunlight, and that a regular bathing program is instigated.
- Identifying and correcting any behavioral abnormalities that are causing over-grooming (feather picking).

Skin lesions should be kept clean, and creams, lotions or solutions can be used to moisturize and sooth dry, irritated skin and reduce pruritus and discomfort. Any medications placed on a wound should either kill specific target microorganisms or protect healing tissue. Ointments and oily compounds interfere with normal feather function and should be avoided (Color 24.3). Some commonly used lavage agents, povidone iodine compounds for example, are effective in controlling bacteria, but may also impair healing by destroying fibroblasts and white blood cells (see Chapter 40).[64] Hydrophilic compounds are often of value in birds but should not be used on large open

wounds where they may potentiate dehydration and electrolyte imbalance.

Aloe vera gel, human skin softeners with a vanishing cream base, nystatin-neomycin sulfate ointment[a] (for pruritic lesions and moist dermatitis) and silver sulfadiazine cream[b] (for moist dermatitis and burns) are particularly effective topical medications. A mixture of Penetran and aloe vera may relieve severe pruritus in some cases (see Chapter 18). This therapy should be discontinued or the solution should be diluted further if a bird becomes depressed or lethargic. If a bird does not improve within 48 hours of initiating therapy, the preparation should be considered ineffective and discontinued.

If an infectious agent is identified, specific antimicrobial therapy should be initiated. In some cases of severe ulcerative dermatitis, surgical debridement and primary wound management may be necessary; however, surgery should not be considered until all other therapeutic modalities have failed to resolve the lesions over a six-month treatment period. Peeling, flaking skin and heavy molts are common for prolonged periods (up to a year) when a diet change is initiated in a malnourished bird.

Lesions should be evaluated regularly (generally on a weekly basis) to determine if prescribed therapy is effective. Trimming the tip of the beak to prevent a bird from self-mutilating or applying a neck brace is justified only as a last resort.

Specific Etiologies of Generalized Dermatopathies

Viral Diseases

Dystrophic feathers may occur in birds infected with PBFD virus, polyomavirus, adenovirus and a parvo-like virus (waterfowl). Dermatologic lesions may occur with poxvirus, papillomavirus and herpesvirus infections (see Chapter 32).

Young birds are most susceptible to PBFD virus, which is characterized by the progressive appearance of dystrophic feathers after a molt (Colors 24.7, 24.13). The disease progression can be acute or chronic depending on the age and species of bird. A diagnosis of PBFD is made by demonstrating viral antigens or nucleic acid in affected tissues. DNA probes are available that can be used to detect the virus in circulating white blood cells (see Chapter 32).

Avian polyomavirus (budgerigar fledgling disease) causes feather pathology in some affected budgerigars and occasionally in large Psittaciformes (see Chapter 32).

"French moult" is a descriptive term used to describe feather dystrophy in young psittacine birds, primarily budgerigars.[1] The classic clinical changes include premature molting of the wing and tail feathers and associated hemorrhage and poor plumage (see Color 32). Affected young birds are termed "runners" because they are usually incapable of flying. Feather changes characteristic of "French moult" can be caused by PBFD virus, polyomavirus or both (Color 24.7). It should be noted that any factor (infectious or noninfectious) that damages the epidermal collar can result in a gross lesion resembling that induced by PBFD virus or polyomavirus (see Color 32).

There is no specific treatment for French moult. Techniques that are discussed in the lay literature, including dietary additives and careful selection of breeding stock, are probably futile. Good hygiene is advisable, and birds should be purchased from sources that test free of PBFD virus and polyomavirus (see Chapter 32).

Poxvirus can cause skin lesions in most avian species and may retard wound healing. Uncomplicated lesions are characterized by the formation of nodules on the unfeathered skin. Skin lesions should be kept clean and dry to prevent secondary bacterial or fungal infections (see Chapter 32).

Cutaneous papillomas may occur on the head, neck, beak commissure, feet or uropygial glands. Some of these lesions have been associated with papillomavirus or herpesvirus while others are of undetermined etiology. Therapy is generally limited to removal of the masses in birds in which they cause problems. A herpesvirus has been associated with "feather dusters," and adenoviral folliculitis has been reported in lovebirds (see Chapter 32).

Parasites

Wasps, bees or other stinging insects will occasionally attack birds causing characteristic hyperemic swellings (Color 24.17). Most affected birds heal with no therapy; however, in severe cases steroids may be

indicated to reduce inflammation. The likelihood of a bird being stung can be reduced by removing uneaten soft foods (particularly fruits) from the enclosure and destroying wasp nests found near the aviary.

Flies, mosquitoes and gnats can cause severe dermatitis on the face, feet and legs, particularly in birds raised in warm coastal areas (see Color 26). Lesions are most common in Amazon parrots and macaws, but can occur in any species. The flies that commonly parasitize cattle and deer can induce small bleeding ulcers on the unfeathered areas of the body (Color 24.17).

Ants (especially fire ants) can be a nuisance to nesting birds. If necessary, five per cent Sevin dust can be used in the nest box to prevent chicks from being eaten alive. Many affected chicks die, and those that survive may have localized necrotic areas that are secondarily infected with *Staphylococcus* spp. Topical application of antibiotic and steroid lotions or creams can be used to reduce swollen or hyperemic lesions. Ant bites also may cause localized necrosis that results in defects in the webs of the feet in waterfowl (Figure 24.16). Some helminths and mites can cause dermatitis (see Chapter 36).

A sarcoptid mite infection was described in a Grey-cheeked Parakeet with feather loss and flaking skin on the head and trunk. Severe pyogranulomatous dermatitis was associated with a sarcoptic mite infection in a Green-winged Macaw. The bird did not respond to ivermectin therapy.[55] Generalized alopecia and thickening of the calamus occurred in a Red-fronted Parakeet infected with *Knemidokoptes* spp. (see Chapter 36).

Mites are more likely to be a primary cause of dermatitis on the head than are lice. Control of ectoparasites, whether on the head or elsewhere, must be undertaken with caution. Only those parasiticidal agents that are licensed or recommended for use in birds should be applied, and such therapy must be accompanied by other measures to exclude the parasites.

In subtropical and tropical areas, the sticktight flea (*Echidnophaga gallinacea*) can be a problem on many species of birds.[10] This is a sessile flea, and large numbers may attach to the skin of the head, especially around the eyes, and cause anemia (see Color 8). This parasite can be controlled with the topical application of a pyrethrin-based product.

FIG 24.16 Defects in the interdigital webs in a duck secondary to multiple fire ant bites.

Bacterial and Fungal Diseases

There have been remarkably few studies on the bacterial flora of the avian skin other than in poultry and birds of prey.[39] Surprisingly, fungi have attracted more attention, and several surveys on the fungal flora of free-ranging birds have been reported. In one study, 6000 fungi were recovered from the feathers, nests, pellets, droppings and organs of 92 species of free-ranging birds.[23] Several of the fungi isolated were potential pathogens and a number were keratinolytic.

Many authors have suggested theories to explain the apparent paucity of primary skin infections in birds, including a high body temperature, which might inhibit the growth of some organisms, and keratinocyte-derived lipids that may inhibit certain pathogenic bacteria or may provide appropriate nutrients for competitive autochthonous flora.[54] Bacterial and fungal infections of facial skin are usually secondary to trauma or possibly a contact dermatitis. Avian skin abscesses are rare but can be found following wounds or in association with feather cysts. Treatment is routine with surgical drainage or removal.

Although frequently discussed, documented cases of bacterial folliculitis in birds are rare. The pulp can be examined for the presence of bacteria by making impression smears or by culturing the pulp cavity (Figure 24.17). Bacterial pathogens that have been implicated in folliculitis include *Staphylococcus* spp., *Aeromonas* spp. and *Mycobacterium* spp.[13,44,60] Dermatitis of the head and body was associated with mycobacteriosis in an Amazon parrot.[14] *Staphylococ-*

FIG 24.17 A macaw was presented with dystrophic feathers. Numerous developing feathers were frayed, and the pulp cavities were split and contained dried blood and developing feather components. The pulp cavity of birds with this type of presentation should always be examined cytologically, and cultures should be submitted for bacterial and fungal isolation. The diet should be carefully evaluated in these cases.

cus spp. are frequently isolated from exudative ulcerative skin lesions of the patagial area (Color 24.23). The importance of staphylococci in the occurrence of these lesions has not been defined. Secondary fungal agents may also be recovered from these lesions.[18]

Trichophyton spp. (*flavus*) have been associated with scaly, crusty lesions of the wattle, comb and legs in gallinaceous birds (see Color 8). *Trichophyton* spp. and *Microsporum gypseum* have been reported as a cause of dermatitis of canaries and budgerigars, respectively.[27] A vesicular dermatitis was reported in chickens following the ingestion of *Cladosporium berbarum* fungus.[47]

Aspergillus spp. have been associated with skin and feather lesions, particularly in pigeons. Affected feathers are generally dry, have yellow spots and are scaly.[66] Candidiasis has been associated with skin and feather lesions in gallinaceous birds.[30,66]

Mucor circinelloides was recovered from three pigeons experiencing severe feather picking and self-mutilation problems. *Rhizopus arrhizus* was isolated from a lovebird, *Penicillum chrysogenum* from a parrot, *A. candidus* from a cockatiel and *A. phoenicis*, *P. cyclopium* and *M. circinelloides* from parakeets that were mutilating feathers. The birds in these cases responded favorably to fungicidal therapy, suggesting that the fungus was involved in the feather picking behavior. The use of STA (3 g salicylic acid, 3 g tannic acid and 100 ml ethyl alcohol) applied biweekly is particularly effective in controlling integumentary fungal infections.[66]

Nutritional Factors

The ability of avian skin to resist infections and to heal properly is related to many factors, the most important of which is the nutritional status of the bird. Malnutrition, particularly hypovitaminosis A, is suggested by the smoothing of the normally papillary surface of the plantar surface of the feet (see Color 8).

Hyperkeratosis of the feather sheath may occur as a result of malnutrition or in association with some infectious agents that affect the developing feather (eg, PBFD virus, polyomavirus). In affected feathers, the sheath on the developing feather is retained, resulting in a bird that appears to have an excess number of pin feathers. The precise effects that malnutrition and organopathy (particularly hepatopathy) have on the quality and pigmentation of feathers remain undetermined; however, their role is suggested clinically by the frequency of abnormal plumage in birds fed marginal diets and with hepatopa-

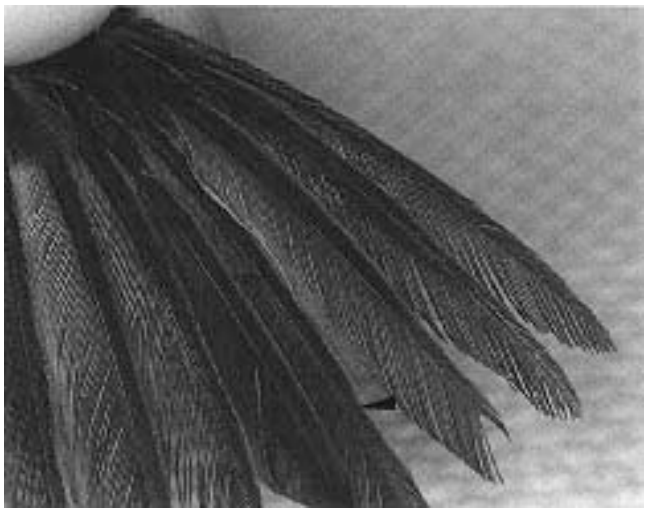

FIG 24.18 A grackle that had been fed a baby cereal diet was presented for weakness and poor feather formation. The feather barbs were not connected properly, making the vanes appear like they contained holes. The bird was placed on a formulated diet and molting activity started within several weeks. The newly developing feathers were properly formed (arrow).

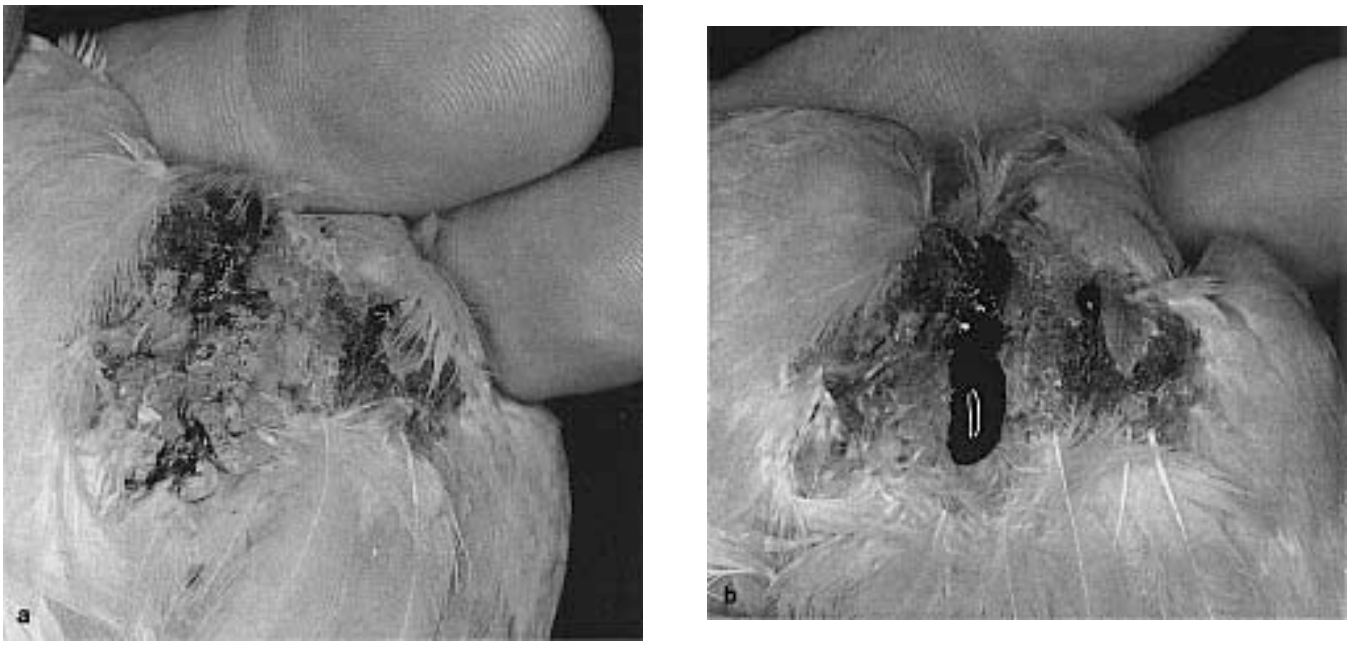

FIG 24.19 **a)** Chronic ulcerative dermatitis in the cervical patagium and interscapular area of a canary. **b)** The skin was extremely dry and brittle, and the least flapping motion would cause spontaneous tears and hemorrhage. The etiology of these lesions was not determined, but the bird responded to bandaging, a diet change, frequent exposure to sunlight and keeping the wounds clean with dilute chlorhexidine solution.

thies (Figure 24.18). Further, many generalized feather abnormalities will resolve when a bird is placed on a proper diet or when an organopathy is effectively treated.

A malnutrition-induced loss of feathers on the back of the head and neck is believed to occur in canaries. Affected birds are usually egg-laying females and also may show decreased fertility and produce weak chicks. Dietary changes will usually resolve the lesions.

Nonspecific Dermatopathies

Many minor scratches and cuts (that are not caused by animal bites) require no medical attention, especially if they are in the non-feathered areas of a healthy bird. If a severe wound occurs, the feathers can be trimmed or pulled from the periphery of a lesion to prevent the accumulation of necrotic debris. Most companion and aviary birds do not pick at skin injuries (see Chapter 16).

Burns occasionally occur in companion birds (Color 24.1, 24.2) Treatment should include debridement and topical antimicrobial agents (see Chapter 15). A "stress-related" dermatitis has been reported in lovebirds, cockatoos and budgerigars. *Staphylococcus* spp. are frequently recovered from these birds, and topical drying agents and antibiotics may be effective therapy.

Chronic Ulcerative Dermatitis (CUD)

Chronic ulcerative dermatitis is characterized by septic, edematous and hyperemic ulceration and exudation of the skin (Figure 24.19). Chronic ulcerative dermatitis has been associated with tumors (lipomas, squamous cell carcinomas and papillomas), abscesses, unhealed wounds, hernias, mycobacteriosis, diabetes, nephritis, hepatitis and giardiasis. Biopsies should always be performed on proliferative, chronic skin lesions to determine if they are neoplastic in origin.

Giardiasis and hypovitaminosis E seem to be associated with ulcerative dermatitis in lovebirds and cockatiels (Color 24.24). The precise nutrients that may be missing in the diet have not been defined, but these birds are frequently fed seed-based diets with or without the addition of fruits and vegetables. Many cases of CUD will improve when a bird is placed on a balanced, formulated diet and provided with adequate exposure to sunlight. Complete resolution may not occur for several months after these management changes are initiated.

Propatagial CUD

Lovebirds, cockatiels, Grey-cheeked Parakeets and occasionally Amazon parrots and cockatoos may develop chronic ulcerative dermatitis involving the metapatagium or propatagium (Color 24.23). Lesions may also be noted in the proventer and in the interscapular regions of the body. The lesions appear to be extremely pruritic. Outbreaks of ulcerative dermatitis affecting patagial membranes have been described. In one outbreak, 60% of the lovebirds in a flock were affected, and the progression of the disease suggested an infectious agent.[49]

Treatment for propatagial CUD should include metronidazole for giardiasis (if identified), administration of parenteral vitamin E, removing the feathers from the periphery of the lesion and placement of a figure-of-eight bandage to prevent mutilation. Secondary bacterial or fungal infections should be treated with appropriate topical medications.

Surgical debridement and primary wound closure may be necessary if the lesions do not heal in five to six weeks. Radiosurgery should not be used to debride or control hemorrhage associated with these lesions. Birds with long-term or severe lesions will replace the normally elastic patagial tissue with scar tissue, which may make the bird more susceptible to future lesions.

CUD in Other Regions of the Body

Ulcerative dermatitis of the proventer region may occur in heavy-bodied birds (African Grey and Mealy Amazon Parrots) that have had improper wing trims. A bird that attempts to fly from a high perch and has no lift may land on its sternum, resulting in a bruise or open wound over the cranial portion of the keel. These damaged tissues seldom become infected although cellulitis of the area is common (see Color 8).

The skin wounds should be treated as discussed under general therapy for integumentary lesions, and several of the clipped primary and secondary feathers from each wing should be removed to stimulate replacement of the feathers. These new feathers will provide the bird with the necessary lift to prevent further injury. In severe cases, necrotic portions of the keel must be surgically removed. Supportive care is successful in most minor cases and the lesions generally resolve in six to nine weeks.

Birds with chronic ulcerative dermatitis in the caudal aspect of the postventer region may be presented with a history of blood-tinged excrement. Feathers adjacent to and covering the skin lesion may be stained with blood. This lesion is common in malnourished birds and may begin when a bird with an improper wing clip lands on a hard surface. The impact of the tail with the ground causes a hyperextension of the rectrices and places excessive pressure on the tight skin of the proventer region (Figure 24.20).

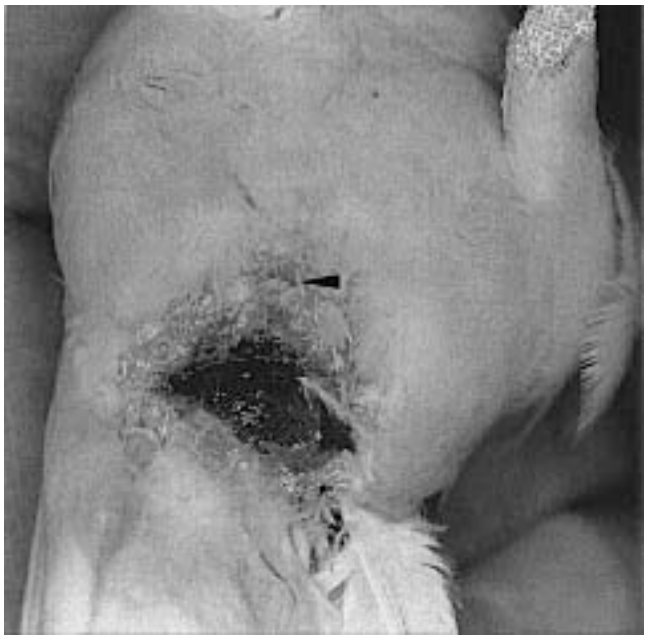

FIG 24.20 A mature cockatiel on an all-seed diet was presented for evaluation of bloody diarrhea. An ulcerated lesion was noted in the postventer region. Bilateral ulcerative lesions of the metapatagium were also present. Pruritic skin lesions and ulcerative dermatitis in cockatiels appear to be associated with primary malnutrition or giardiasis. In this case, giardia could not be documented and the bird responded to a change in diet. The tail feathers were transected to reduce the pressure on the postventer skin. The lesions were cleansed daily with chlorhexidine solution and were coated with live yeast derivatives twice a day. Cloaca (arrow).

Disorders Affecting the Feet and Legs

Skin on the legs may be damaged by bands (rings) or, in the case of falconers' birds, by badly fitted leather jesses. Secondary bacterial infections of skin wounds can occur and impair healing, particularly when a foreign object is constantly in contact with the wound. The application of a self-adherent wound dressing (see Chapter 16) will keep the wound clean and moist and permit regular visual inspection.[8]

Pox lesions on the feet and legs are characterized by dry, brown plaques. Other viral infections appear to be rare, but a herpesvirus has been implicated in skin lesions in Mallard Ducks and cockatoos (see Chapter

Dermatology

Color 24.1
A goose sustained severe burns on the unfeathered portions of the face, feet and legs after being trapped in a yard fire. The wounds were debrided and flushed repeatedly with copious amounts of sterile saline solution.

Color 24.2
Burns on the legs and feet of a goose were cleaned and treated with silvadene cream TID. This photograph, taken two weeks after the initial burns, shows a healthy bed of granulation tissue over the burns, and the bird healed with no complications.

Color 24.3
A mature, male budgerigar with dermatitis was presented for progressive shivering and depression. The bird had been treated with an over-the-counter, oil-based antibiotic. The oil-laden feathers had lost their insulation ability, causing the bird to lose excessive amounts of body heat. The oil was removed with repeated washing in warm dishwashing detergent, and the bird was placed in an incubator (94°F) to dry.

Color 24.4
A proliferative skin mass on the abdominal wall of a cockatoo with PBFD virus. The mass had histologic features characteristic of a papilloma. Part of the diagnostic evaluation for any proliferative skin mass should be a biopsy to rule out neoplasm.

Color 24.5
Normal primary pin feathers (blood feathers) in a developing Moluccan Cockatoo neonate.

Color 24.6
Feather cyst in a budgerigar. The cyst was surgically removed and the bird had no further complications.

Color 24.7
Primary feathers removed from a pionus parrot with PBFD virus. The infection was confirmed by DNA probe testing of whole blood and by histopathologic evaluation of dystrophic feathers. Note the constricted calamus, areas of necrosis and hyperkeratotic feather sheaths. This bird was exposed to PBFD virus when infected neonates from another collection were introduced to the nursery. The fact that part of the distal feather is normal indicates that there was no damage occurring to the follicular epithelium when this part of the feather was developing.

Color 24.8
Feather cysts are common in canaries, particularly the Norwich, Crested, Crest-bred and new color canaries that have "double-buff" soft feathers. In severely affected birds, feathers emerge in all directions (courtesy of Patricia Macwhirter).

Color 24.9
Split section of a feather cyst showing the accumulation of cellular debris in multiple follicles (courtesy of John Cooper).

Color 24.10
Straw-feather disease has been described in canaries and a few other Passeriformes and is believed to be genetic in origin. There is incomplete development of the feather barb and barbules and there may be retention of the feather sheath in some affected feathers (courtesy of Louis Filippich).

Color 24.11
Segmental discoloration, black lines or transparent areas across the vane of a feather are called stress marks and indicate a dysfunction of the epidermal collar at the time the feather was developing.

Color 24.12
Magnified view of stress marks in a developing feather (courtesy of John E. Cooper).

Color 24.13
Necrotic, dystrophic contour feathers on the body of an adult Umbrella Cockatoo with chronic PBFD virus. Note the dystrophic growth, areas of necrosis and constriction of the feather shaft at its interface with the edge of the epidermis.

Dermatology

Color 24.14
Knemidokoptes spp. infections are most common in budgerigars and passerine birds, but may also occur in other birds, such as this Sulphur-crested Cockatoo. This bird responded to topical ivermectin therapy, but did have some post-infection feather loss and damage to the eyelids.

Color 24.15
Knemidokoptes spp. may cause severe proliferation and deformity of the beak. Note the skin on the face is also infected.

Color 24.16
A mature Yellow-collared Macaw was presented for severe depression. The head was covered with normal feathers but the remainder of the body was featherless. Several areas of self-mutilation were present including both feet and legs and the cervical patagium. An etiology could not be determined for this bird's self-mutilation.

Color 24.17
Hyperemic, indurated masses secondary to wasp stings in a Blue and Gold Macaw.

Color 24.18
Brown hypertrophy of the cere in a male budgerigar. This syndrome is believed to be caused by imbalances in the ratio of sex hormones.

Color 24.19
A mature Amazon parrot was presented with an acute onset of picking at the feet and legs. This photograph was taken several hours following the onset of the picking behavior and is characteristic for the acute phase of the Amazon foot necrosis syndrome. The cause of this bird's problem could not be determined, but it responded to general dermatologic therapy.

Color 24.20
A Golden Eagle was presented with severe bilateral swelling of the metatarsal pads. One pad was ulcerated, and a thick, greenish-yellow discharge was present in the center of the mass. The necrotic material was surgically removed from both feet and the wounds were packed with antibiotic-impregnated gel foam. A healthy granulation bed was produced within three weeks of initiating therapy, and walking bars that were stabilized in a tarsometatarsal cast were used to allow the bird to ambulate without placing pressure on the plantar surface of the foot.

Color 24.21
A mature cockatiel hen was presented for severe feather picking. The bird had removed most of its feathers from the axillary and leg regions. *Giardia* sp. was diagnosed by examining a fresh wet mount fecal sample. The bird responded to therapy with metronidazole.

Color 24.22
Knemidokoptes spp. mites have caused proliferative yellowish-colored lesions on the foot of a canary. The bird was presented with a shifting leg lameness.

Color 24.23
Chronic ulcerative dermatitis in the ventral propatagium of a mature cockatiel hen. Note that the feathers are melanistic. This bird had biliverdinuria and responded to a dietary change and therapy for liver disease. The feathers returned to normal color with subsequent molts.

Color 24.24
A lovebird was presented for progressive feather picking. The bird would scream as it picked at the tissues of the chest, back and wings. Ulcerative lesions were present on the cranial edge of both propatagial membranes. *Staphylococcus* spp. and *Candida* spp. were isolated from the wounds, but they were considered secondary pathogens. The bird responded to therapy for chronic ulcerative dermatitis (and wing splinting), but many of the feather follicles had been destroyed and the bird remained featherless in some areas.

Color 24.25
Necrotic digits in adult passerine birds are commonly caused by fibers that wrap around the toe. Diagnosis usually requires examining the proximal edge of the affected digit under a dissecting or operating microscope.

32).[70] Proliferative, hyperplastic lesions on the feet of canaries and mynahs have been associated with abrasions, aging and malnutrition. A condition involving cracking of the feet that is responsive to high doses of biotin has been documented in flamingos, ratites and waders (see Color 48) (Greenwood A, unpublished).

Keratomas that appear clinically as digit-like projections composed of hyperkeratotic scales have been described in some species. These callus-like growths may predispose a bird to bumblefoot (see Chapter 43). Virus-induced papillomas are common on the feet of finches in Europe.[2]

"Bumblefoot" or pododermatitis has been reported in many species of birds but is a particular clinical problem in captive birds of prey, Galliformes, Anseriformes, waders, penguins and many Psittaciformes (Color 24.20). In Psittaciformes and Passeriformes, most lesions are believed to be the result of malnutrition, which causes the skin of the foot to become dry and hyperkeratotic. Hepatic dysfunction may also be involved in some cases. Penetrating wounds or bruising of the feet may be predisposing factors in raptors and Anseriformes (see Chapter 16).[8]

A "constricted toe syndrome" has been described in a number of Psittaciforme neonates (see Color 30). The fibrous band can be surgically excised to correct the problem (see Chapter 41). Other causes of ischemic necrosis of the feet or legs may include entangled fibers, hairs, bedding material, leg bands, strings, jesses, dried skin, frostbite or ergot poisoning (Color 24.25).

Pruritic, ulcerative lesions have been described on the feet and legs of Amazon parrots (particularly Yellow-naped and Double Yellow-headed Amazon Parrots). The lesions start with a bird chewing at the feet and legs followed by the formation of hyperemic lesions, sometimes within minutes of the initial pruritic episode. An ulcerative dermatitis occurs as the bird continues to chew on the feet and legs (Color 24.19). Characteristic histopathologic findings associated with this syndrome include ulcerative dermatitis that may contain coccoid bacteria and fungi. The role that the bacteria or fungi play in the pathogenesis of this syndrome is undetermined. Immune-mediated and allergic reactions with secondary involvement of autochthonous skin flora have been proposed as etiologies for these lesions (see Chapter 33).

Staphylococcus spp. are frequently isolated from the lesions, but the birds will usually not respond to antibiotic therapy alone. The syndrome appears to be more common in the spring (suggesting a seasonal allergen), and many affected birds belong to cigarette smokers. In these latter birds, the lesions may spontaneously resolve when the clients stop smoking or wash their hands before handling the birds. Other cases will respond to a change in diet, frequent exposure to sunlight and a topical antimicrobial cream containing steroids. Topical steroids should be applied with caution to prevent toxicity.

Atarax and oral antibiotics were found to be effective in some cases.[21] Seasonal recurrence of the lesions may be prevented by the oral administration of prednisolone about one month prior to the time that lesions typically occur.

A hydroactive dressing can be used to facilitate healing of these wounds. Initially, the bandage may require daily changing. The frequency of bandage changes can be reduced as the wound becomes less exudative. Once granulation tissue forms at the edge of the ulcers, scabs should be removed and the lesions should be kept clean to facilitate healing (see Chapters 15, 16).

Some reports detail the use of thyroid supplementation as a therapeutic regimen for foot necrosis syndrome; however, thyroid levels were not determined in the treated birds and the indiscriminate administration of thyroxine, can cause fatal toxicity (see Chapter 23).

Diseases of the Feathers

The appearance of malformed, broken, bent, dirty, stained or unusually colored feathers should be considered abnormal. Feather conditions can be divided into two main groups: those affecting normal feathers and those in which abnormality of the feather is the primary feature. A simple method to determine if a feather problem occurs during or after development is to remove an affected feather (it should be examined cytologically, microscopically and possibly histologically) and evaluate the growth of the new feather over the next one to three weeks. There are three possibilities with respect to the new feather:

- The feather does not regrow (suggests a systemic or follicular abnormality)

TABLE 24.6 Common Pathologic Terms Used in Avian Dermatology

Term	Definition
Acanthosis	Hyperplasia of the stratum germinativum
Acantholysis	Lack of cohesion between epidermal cells, leading to formation of clefts, vesicles and bullae
Atrophy	Decrease in size of a tissue or organ – in dermatology usually refers to thinning of the epidermis
Ballooning degeneration	Intracellular accumulation of fluid (edema)
Depigmentation	Loss of (melanin) pigmentation
Dyskeratosis	Prematurely cornified cells with eosinophilic cytoplasm and small dark nuclei
Excoriation	Secondary ulceration that may occur following self-inflicted trauma
Hyperkeratosis (hyperkeratinization)	Increased thickness of the stratum corneum
Hyperplasia	Thickening of the epidermis
Hypopigmentation	Reduced (melanin) pigmentation
Melanosis	Dark appearance due to increased melanocyte activity and deposition of melanin
Parakeratosis	Retention of pyknotic nuclei in the cells of the stratum corneum, usually associated with defective keratinization
Spongiosis	Extracellular accumulation (edema) causing separation of epithelial cells
Telangiectasis	Persistent vasodilation: skin does not blanch when compressed with a microscope slide

TABLE 24.7 Incidence of Histologic Lesions in a Group of 213 Feather Biopsies[60]

Diagnosis	Number of Affected Birds
PBFD virus	32
Suspect PBFD virus	20
Normal skin and feathers	26
Inactive feather follicle - no lesion	22
Epidermal atrophy	6
Staphylococcus dermatitis	3
Other pyodermas	17
Suspected bacterial pulpitis	9
Dermatomycosis	3
Sarcoptic mange	1
Hypersensitivity reaction	78
Trauma	46
Drug eruptions	2

- The feather regrows but is not normal (suggests a problem in the feather follicle or organopathy)
- The feather regrows normally (suggests that the feathers are being damaged after development, eg, feather chewing, enclosure trauma).

Biopsy and histopathology are indispensable for diagnosing the cause of feather lesions. Some common descriptive terms that may be needed by the clinician to interpret the results of pathology reports are listed in Table 24.6. The results of 213 feather biopsies from a group of Psittaciformes are listed in Table 24.7.[60]

Stress Marks

Translucent lines across the vane of a feather are frequently referred to as stress marks (Color 24.12). These abnormalities represent segmental dysplasia that occurred in the developing barbs and barbules and represent a brief period of dysfunction in the epidermal collar (Figure 24.21). These marks can be induced by the administration of exogenous corticosteroids, suggesting that they are truly "stress" marks. Restraint, illness, a brief period of food deprivation or exposure to environmental extremes should be expected to induce these lesions. Deficiencies of arginine (curled wing feathers), riboflavin (clubbed down feathers) and pantothenic acid, niacin and selenium (poor feathering) are nutritional causes of poor feather structure in poultry.[63]

Preening

Much of a bird's day is spent in feather preening, a natural process for maintaining feather condition. Feather preening appears to be innate, but occasionally a hand-raised neonate will have poor quality feathers or an excess number of pin feathers because of an improper preening response. These birds should be taught to preen the feathers by gently breaking the sheaths while encouraging the bird to pick at an area with its beak. Some wear of the feathers should be considered normal. Over-preening (feather picking) occurs when what is a normal part of feather maintenance becomes a pathologic condition (see Chapter 4).

Some birds may molt feathers on a seasonal basis from the ventral abdomen and lower legs (developing a brood patch). Damage to the feathers of the breast, abdomen and legs during the breeding season may indicate reproductive frustration. Seasonal feather picking associated with breeding activity is usually temporary and no specific therapy is necessary or warranted unless the feather loss is persistent or involves areas other than the lower abdomen.

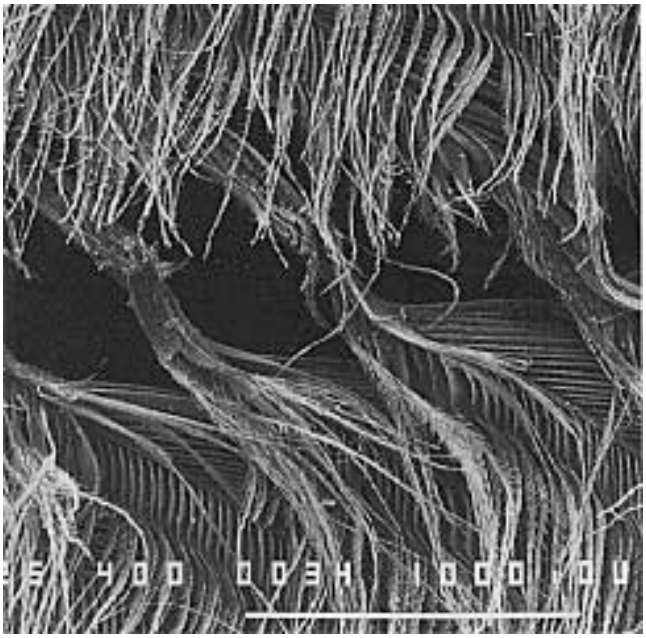

FIG 24.21 Scanning electron micrograph of a feather with segmental dysplasia (stress marks). Note that the barbs and barbules that were present in the epidermal collar at the time the stress occurred are improperly formed (courtesy of John Cooper).

Feather Picking

Feather picking occurs when a bird damages its feathers or skin (or the feather and skin of a companion). Feather picking is a condition of captivity. With the importance of the feathers for thermal regulation and flight, severe, self-induced feather damage would be life-threatening to a free-ranging bird. Clinically, feather picking is characterized by the loss or damage of feathers on the body and neck with normal feathers on the head (Figure 24.22). Feather picking induced by a companion is characterized by loss or damage of feathers around the head and neck. Male cockatiels will occasionally over-preen the orange face patch of the hen.

Feather picking can become an obsessive behavior with a bird progressively damaging all or part of the accessible plumage, leading to abnormalities in normal feather development and molt. Self-mutilation is characterized by over-preening and subsequent damage to the skin or muscle. Mutilation of the skin can cause, or occur secondary to, chronic ulcerative dermatitis.

Many feather-picking or self-mutilating birds are considered to be pruritic, which is difficult to document. Over-preening and scratching an area with the nails is suggestive. Inflammation or irritation associated with internal pathology, including that caused by infectious agents, has been suggested as a precipitating factor for feather picking.[19] Organopathy, toxins, malnutrition, bacteria, viruses, fungi, parasites (blood or intestinal), boredom, anxiety, lack of sleep, psychosis and undesired contact with strangers or family pets (dogs or cats) have all been implicated in cases of self-mutilation.[55] Feather loss on the neck of lories and Hyacinth Macaws has been attributed to contact with conifers.

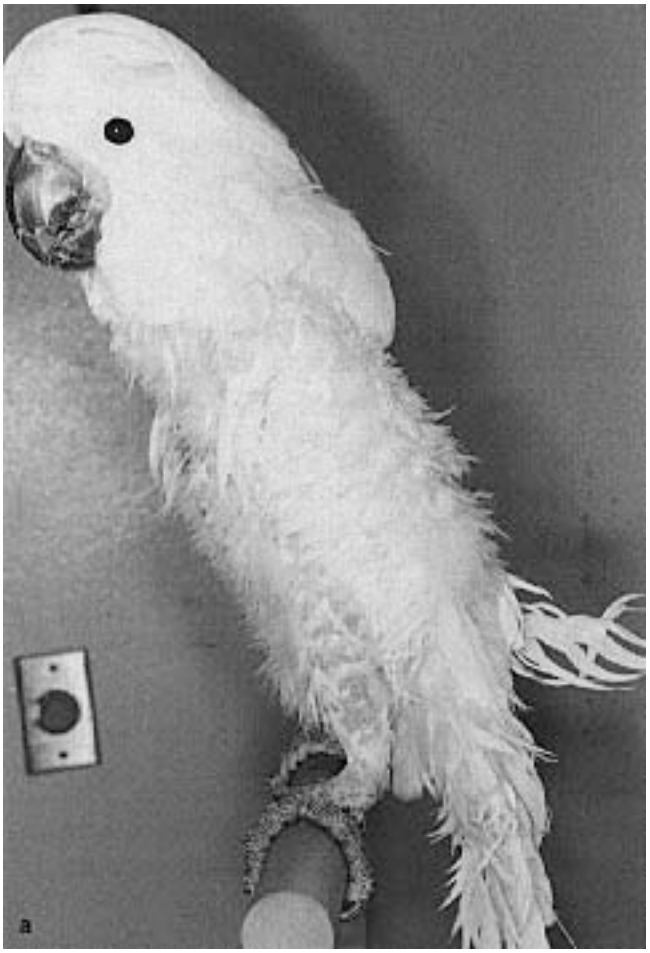
Mutilation is a commonly discussed problem in poultry and has been associated with improper management, crowding and malnutrition. In humans, hepatopathies have been associated with pruritus, and many self-mutilating birds have clinical changes suggestive of liver disease.[21]

Some birds may be mutilated by other birds (canaries, finches, conures, cockatoos). In colony-breeding flocks, reducing the number of birds in the enclosure, increasing the number of hiding places and nest boxes or removing the offending birds may be necessary for control. Cockatoos may occasionally overpreen a mate, but more commonly a male bird will kill its mate with no previous indication of aggressive behavior (see Chapter 2).

Examination of the Feather-picking Bird

Feather-picking birds should be approached in a systematic fashion.[7,19] A diagnosis of psychologically induced self-mutilation should be reserved for patients in which no cause for the problem can be identified by physical examination, complete blood count (CBC), serum chemistries, feather pulp culture and cytology, skin lesion culture and cytology, radiographs, endoscopy and direct microscopic examination and biopsies of affected feathers. If no etiology can be determined for the over-preening, then behavioral abnormalities should be considered.

There is an apparent species' predilection to feather-picking behavior. African Grey Parrots appear to be particularly prone to feather picking, perhaps as a result of their sensitive natures or need for a highly stimulated environment. Spoiled, improperly socialized, hand-raised birds of any species may also be prone to self-mutilation. Cockatoos and conures frequently develop feather-picking behavior for which an etiology cannot be conclusively identified, necessitating a diagnosis of psychologic feather picking. By comparison, idiopathic feather picking in budgerigars and cockatiels is rare. In these species, feather picking associated with ulcerative dermatitis of the patagial membranes is most common (Color 24.21).



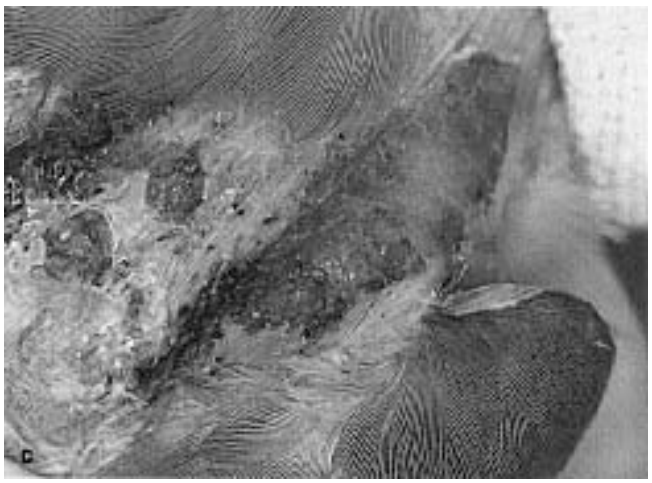


FIG 24.22 **a)** Feather picking is characterized by normal feathers on the head and neck, with damaged feathers at other locations where over-preening can occur. **b)** With chronic feather picking, the follicles may be permanently damaged, and feather regrowth cannot occur. **c)** In severe cases of self-mutilation, a bird may actually induce wounds in the skin or muscle.

Treatment of Feather Picking

Once initiated, feather picking can become habitual and continue even though the precipitating cause is no longer present. Chronic feather picking can result in sufficient damage to the follicles to prevent any future feather growth (Figure 24.22). Therapy for self-mutilation of undetermined etiology should be considered effective if the destructive behavior can be reduced. Complete cessation of self-mutilation is rare.

In a retrospective study of 106 feather-picking cases, 31 had no change on follow-up examination; resolution of the problem occurred in 20 cases; 21 showed some improvement; and 34 were lost to follow-up. Amazon parrots and cockatiels appeared most likely to respond to treatment. Excluding birds with confirmed PBFD virus infections, treatment of other feather abnormalities with an etiology that was determined by the minimum database was generally successful. Idiopathic cases of feather picking were less likely to respond to therapy.[60]

Occasionally, a bird will self-mutilate as a result of sexual frustration. Some of these birds will stop mutilating when placed in a breeding situation; however, others will continue self-mutilation activities and may also over-preen a mate. Assuming that idiopathic self-mutilation is a result of some undetectable neurosis, it would be considered unwise for these birds to be added to a breeding collection where they may pass on genes that will predispose their progeny to the same problem.

There are probably as many recommended therapies for the feather-picking bird as there are avian veterinarians. Any underlying medical problems should be identified and corrected. Various foul-tasting substances are frequently applied to the feathers in an unsuccessful attempt to modify the picking behavior. This procedure only masks clinical signs and should not be considered therapeutic. Treatment for feather picking should include the correction of organopathies, specific therapies for folliculitis (bacterial or fungal), improving the diet, removing exposure to cigarette smoke, providing frequent exposure to fresh air and sunlight, providing an 8- to 14-hour photoperiod that varies naturally with the seasons, and behavioral modification (see Chapter 4). If these therapies are determined to be ineffective over a two-month period, then mood-altering drugs may be necessary.

Where feather picking is determined to be psychological (a failure in the ability to diagnose a cause for the problem), a video recorder may be helpful in documenting a bird's behavior in its normal environment. Identifying the specific factors that induce the feather-picking behavior (separation anxiety, a tormenting pet, an unliked child, an abusive adult) can guide the clinician in making specific recommendations to correct the behavior and resolve the problem (see Chapter 4). Striving to improve the human-animal bond may be the most effective therapy in these cases.

Some problems with separation anxiety can be corrected by leaving tape recordings of family activities or a radio or TV playing in the family's absence. With some birds, the addition of new toys or moving an enclosure to a different location will be a stress factor that induces feather-picking, while with other birds these moves are positive and help to keep a bird mentally stimulated. A bird that is properly socialized and adapted early in life to changes in daily routine is less likely to develop emotional problems due to separation anxiety when changes occur later in life.

If psychological feather picking cannot be stopped with behavior modification, drugs may be necessary. Mood-altering drugs that have been suggested for use in feather-picking birds include tricyclic antidepressants and antihistamines (hydroxyzine hydrochloride,[c] 2 mg/kg oral). These therapeutic agents are frequently discussed but are rarely effective. Hormonal therapies including thyroxine, testosterone and medroxyprogesterone have also been suggested for some cases of feather picking; however, all of these agents have undesirable side-effects and should be used only to treat specifically identified problems.[21] Medroxyprogesterone acetate may be effective in stopping some sexually related behavioral disorders including feather picking, aggressiveness and masturbation; however, the drug can have severe side-effects including obesity, polydipsia, polyuria, glucosuria and liver disease.[51]

Ongoing studies suggest that haloperidol[d] may be effective in some feather-picking cases.[31] This drug is used to control hyperactive and impulsive behavior in humans. The dose being used in cockatoos is 0.08 mg/kg orally SID. It takes two days to stabilize the dose. Side-effects include loss of appetite, incoordination and vomiting. If there are no side-effects and a bird is still picking, the dose can be increased in 0.01 ml increments every two days. The maximum dose should not exceed two times the initial dose.

Successful treatment is generally reported within two to three days when the bird stops over-preening or self-mutilating and begins to play, sing and interact with the client.[31] There is also a haloperidol decanoate (50; 100 mg/ml) injectable repositol for IM administration. Dosed at 1-2 mg/kg, the patients respond for up to 14 to 21 days. Both administration forms have to be used continually unless the initiating cause of the feather picking can be corrected. Clinical experience suggests that Moluccan and Umbrella Cockatoos, Quaker Parakeets and African Grey Parrots may respond to a lower dose (half that used for other birds).

Feather damage can be prevented by beak trimming or, as a last resort, by applying restrictive collars (Figure 24.23). These procedures only suppress the clinical signs and do not address the underlying problem.

Endocrine-related Feather Disorders

In poultry, hypothyroidism causes black, brown and yellow feathers to become red, longer and more pointed and to have less pennaceous barbules than

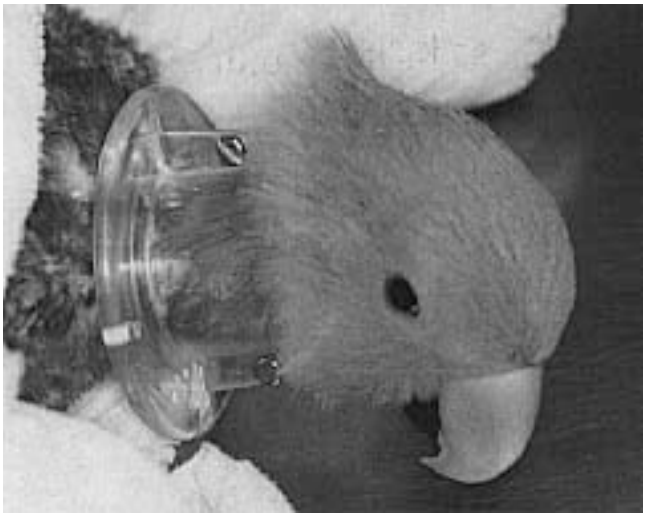

FIG 24.23 Collars should be used only in cases of severe self-mutilation that cannot be diagnosed and resolved with specific therapy (courtesy of Louise Bauck).

normal. The feather vanes have a fringed or lacy appearance. Hypothyroidism has been shown to delay wound healing in pigeons.[53] Documented cases of hypothyroidism in companion birds are rare. It should be noted that some species of birds that are deficient in iodine will have a TSH response test that suggests hypothyroidism (see Chapter 23).

In a Scarlet Macaw with reported hypothyroidism, clinical signs included nonpruritic feather loss, mild nonregenerative anemia, mild leukocytosis and heterophilia, hypercholesterolemia, sparse feathers, a history of no molting for over a year, and obesity with fat deposits on the lower abdomen and under the skin of the legs. Although no feather measurements were obtained, photographs of this bird suggest that contour feathers lacked width and were shorter than normal. This bird responded favorably to treatment with 0.02 mg/kg (20 μg/kg) L-thyroxine orally BID.[40]

There are no documented cases of feather abnormalities resulting from hyperadrenocorticism or hypoadrenocorticism in birds although both conditions would be expected to occur. Hyperkeratotic dermatitis and feather loss were reported in a macaw that had histologic evidence of adrenal gland degeneration. This bird was on a poor diet and had staphylococcal abscesses of the occipital bone, bacteremia and bilateral pododermatitis.[41] It is likely that the adrenal gland degeneration in this bird was secondary to other medical problems and was not the primary cause of the noted lesions.

Hyperestrogenism is associated with pruritic hair loss in mammals. Hyperestrogenism has been associated with proliferation of endosteal bone in birds, but has not been associated with feather lesions (see Chapter 23). Up to 60% of the male canaries in some flocks may develop baldness that is responsive to a change in the level of nutrition provided.

Inactive Feather Follicles

A feather follicle is normally inactive between molts. Persistent generalized inactivity of the feather follicles should be considered abnormal. In one study, many birds with inactive follicles had abnormal bacterial populations, elevated CPK activity and toxic heterophils. Some birds had a leukocytosis and elevated calcium levels; a few of these cases responded to antibacterial therapy. Epidermal atrophy accompanied chronic inactive feather follicles, hyperkeratosis and follicular atrophy in some birds.[55]

Cysts

Cutaneous cysts are characterized by an epithelial wall surrounding keratinaceous contents. Epidermal cysts have been described in the dermis and subcutis of budgerigars (Color 24.6) If the orifice of the feather follicle is occluded from a traumatic or infectious episode, keratinaceous debris will accumulate in the follicle resulting in a follicular cyst (Color 24.9). These lesions are particularly common in canaries. Therapy is excisional (see Chapters 41 and 43). Feather cysts have been reported to occur in free-ranging birds.[11]

Polyfolliculitis

Pruritic polyfolliculitis and dermatitis that may be caused by a virus have been described in lovebirds and budgerigars. Lesions appear to be particularly common in the feather tracts of the tail and dorsal region of the neck. The newly emerging feathers have short, stout quills with retained sheaths. Some of these birds have been histologically diagnosed with PBFD virus infections, whereas others have not been shown to be infected (Figure 24.24).

Histologically, polyfolliculitis is characterized by the appearance of multiple feather shafts from the same follicle with a thin layer of epidermis separating the shafts. Chronic inflammation occurs beneath the pulp cap, and the feather sheath is thickened. In some cases, large, keratin-filled cysts may also be

noted. Therapy with broad-spectrum antibiotics and corticosteroids is palliative at best.[50]

Other Feather Abnormalities

Bleeding occurs if the protective keratin sheath of a developing feather (pin or blood feather) is injured or the feather is dislodged from the follicle. Hemorrhage can be severe, particularly in birds with coagulopathies. Experimentally, developing feathers that are removed can be rotated and reinserted and will continue to grow. In the clinical setting, it is best to remove damaged pin feathers (see Chapter 15).

Neonates kept in areas with low humidity may have dystrophic feather growth characterized by failure of the developing feather to exsheath. The lesions will usually resolve when the humidity is increased (and the affected feathers are removed).

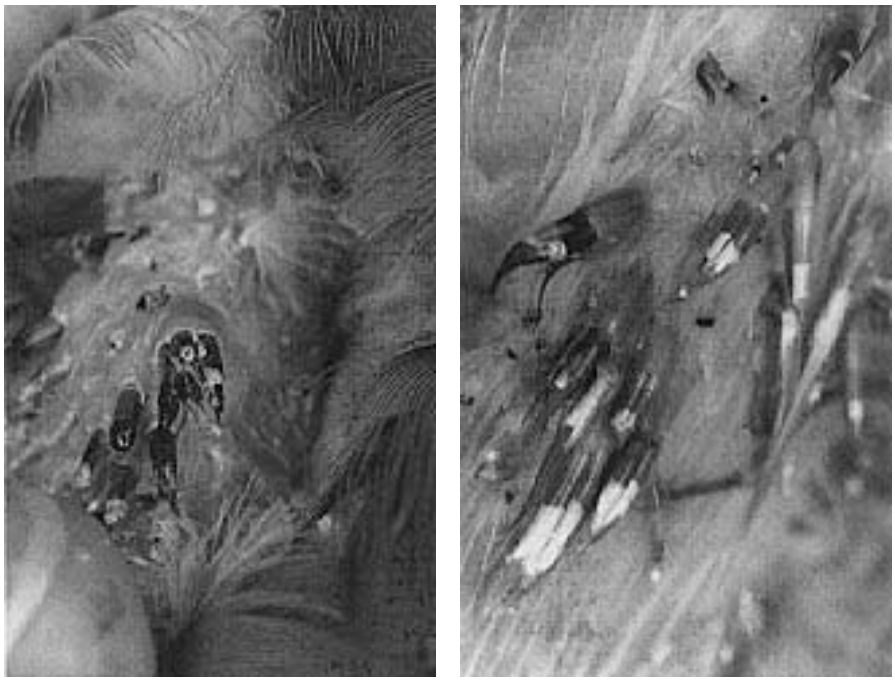

FIG 24.24 Clinical appearance of polyfolliculitis in twolovebirds. Both birds had progressive syndromes that could not be resolved. An etiologic agent could not be detected by histopathology in either case.

CHAPTER

25

ONCOLOGY

Kenneth S. Latimer

Neoplasia is an abnormal, uncontrolled, progressive proliferation of cells in any tissue or organ. Classification of neoplasms is based upon general tissue origin (epithelial vs. mesenchymal), specific cell lineage and whether the neoplasm is benign (-oma) or malignant (sarcoma or carcinoma). Classification of some neoplasms as benign or malignant may require knowledge of the biological behavior of the neoplasm.

The majority of the veterinary medical literature has reported the incidence, gross appearance and microscopic characteristics of neoplasms of domesticated birds, especially poultry.[20,22,23,101,109] Furthermore, the study of retroviral-induced neoplasia in poultry has advanced medical knowledge of retroviral molecular biology, as well as that of neoplasm development, growth and metastasis.[91,101] Similar information concerning neoplasms of captive and free-ranging birds is almost nonexistent. One ultrastructural survey of various budgerigar neoplasms failed to disclose retroviral particles, but sampling errors are a known complication of such studies.[52] More recently, papillomaviruses have been demonstrated as the etiologic agents of cutaneous papillomas in African Grey Parrots, Chaffinches and Bramblings.[73,87,94,96]

Reports of neoplasia are extant for captive as opposed to free-ranging birds,[5,6,7,12,15,49,51,83,102,108] especially budgerigars, where the overall incidence of neoplasia ranges from 16.8% to 24.2%.[12,15,51] In a veterinary diagnostic laboratory with a diverse avian caseload, budgerigars accounted for 69.7% of all psittacine neoplasms and 41% of all avian neoplasms recorded. The overall incidence of neoplasia approximated 3.8% in all avian submissions.[108]

Compared to free-ranging birds, neoplasia is reported more frequently in companion and aviary birds because such birds are observed closely for abnormalities, have a longer life span and may have a genetic predisposition to neoplasia through inbreeding. Little is known, however, concerning the etiology, predisposing factors, development, biological behavior or treatment of neoplasms in companion and aviary birds. As more cases of avian neoplasia are studied and reported, our clinicopathologic knowledge will increase and treatment regimens will improve.

This chapter is written to provide a systems approach to avian neoplasia, with an emphasis on neoplasms of companion, aviary and free-ranging birds. Information is presented to assist the clinician in understanding the complexities and treatment of avian neoplasms (see Table 25.1). Lesions that mimic neoplasia also are discussed briefly. Lastly, the cytologic and histologic features of various neoplasms are presented to assist veterinary pathologists in the diagnosis of these neoplasms (see Table 25.2).

Integumentary System

Neoplasms of the integumentary system are common and account for 12% to 70% of all avian neoplasms.[6,12,15,108] Of the various neoplasms reported, lipomas and fibrosarcomas are observed most frequently.

Adipose Neoplasms and Masses

Neoplasms associated with fatty tissue and lipid deposition in companion birds include lipoma, myelolipoma, liposarcoma and hibernoma. Lesions that mimic these neoplasms include xanthomas and lipogranulomas. Definitive diagnosis of each of these neoplasms or masses requires histopathologic examination of surgical biopsy specimens (Figure 25.1).

- ***Lipoma:*** Lipomas are benign proliferations of well differentiated adipocytes (lipocytes) that may exhibit slow-to-rapid, progressive growth over time. Lipomas are the most frequently observed neoplasm of companion birds, with a reported incidence of 10% to 40% in budgerigars.[143] Besides budgerigars, lipomas may be observed frequently in Rose-breasted Cockatoos (galahs) and Amazon parrots.[98,143] Obesity, advancing age, species of bird and high-energy diets appear to be predisposing factors for tumor development. Based upon clinical observations, a genetic predisposition to lipoma development may exist in budgerigars.

Lipomas usually arise in the subcutis of the sternal or abdominal skin, but may also be observed on the wings, back, neck, legs or near the uropygial gland.[6,12,15,30,49,51,69,72,86,102,108,127] In addition, lipomas may occur in the thoracoabdominal cavity (arising from thoracic or mesenteric fat, ovary, ventriculus and liver) or in association with skeletal muscle.[12,40,102,108,127] Tumor size typically ranges from 0.3 to 4.0 cm in diameter (Color 25.2).

FIG 25.1 A 15-year-old Amazon parrot was referred for evaluation of a tumor. A previous veterinarian had advised euthanasia. A large, pendulated, ulcerative mass was present on physical examination. The bird was in overall good condition, and abnormal clinicopathologic findings were limited to a mild heterophilia (18,000/μl). Cytology of a fine-needle aspirate revealed an accumulation of necrotic debris and reactive macrophages. The mass was surgically incised, and a piece of wood was found penetrating the esophageal wall. The granuloma was surgically removed, the esophageal defect was repaired and the surgical site was managed as an open wound. A mass should be considered of neoplastic origin only with the cytologic or histologic identification of suggestive cells.

Lipomas occur as single or multiple masses. Affected birds may be presented for diagnosis of a visible skin or subcutaneous mass or abdominal distention. Large tumors may interfere with leg movement, perching or flight. On palpation, lipomas are usually well defined and soft; the overlying skin is freely mobile.[143]

Grossly, excised lipomas appear soft, round-to-multilobulated and pale yellow. On cut surface, they are thinly encapsulated and fatty. Histologically, lipomas appear as thinly encapsulated masses composed of lobules of well differentiated adipocytes. Scattered

blood vessels are also present. Central necrosis may be present in larger masses, especially those neoplasms that grow rapidly or are subjected to trauma.

Dietary changes and increased exercise are frequently curative in early cases and should be implemented prior to surgery to reduce the size of the mass. Because lipomas are often accompanied by body fat that may interfere with caudal air sac volume, exercise programs should be initiated with care, especially in tachypneic patients. Surgical excision is necessary if the tumor is causing clinical problems that are not resolved with diet change and increased exercise.[25,30] Lipomas may be vascular; therefore, attention to hemostasis through the use of bipolar radiosurgery is important. Feeding formulated diets should prevent goiter and may also reduce the likelihood of a bird developing lipomas. Non-specific use of thyroxine should be avoided, and treatment of lipomas in the absence of hypothyroidism is not an indication for thyroxine administration.[66,113]

- ***Myelolipoma:*** Myelolipomas are composed of adipose and hematopoietic tissues that may arise in the subcutis of the trunk, wings and legs. Occasionally they may occur in the liver or spleen. The outward appearance is similar to a lipoma.

- ***Liposarcoma:*** Liposarcomas are malignant, fatty neoplasms composed of lipoblasts and immature adipocytes. These neoplasms are firm on palpation, poorly encapsulated, highly vascularized and usually arise in the subcutis of the sternum or uropygial gland area.[102] Infrequently, liposarcomas may present as poorly demarcated nodules in the thoracoabdominal cavity, liver or skeletal muscles.[47,108] Liposarcomas are locally invasive, have the potential to metastasize and may arise in a multicentric pattern. Multicentric origin or widespread metastasis is typical.[47]

  Histologically, neoplastic cells appear spindle-like, stellate, round or polyhedral. Cell nuclei are round to oval and contain multiple nucleoli. The cytoplasm stains lightly eosinophilic or contains variably sized vacuoles. Larger vacuoles may cause peripheral nuclear displacement. Mitotic figures may be present but are not numerous. The presence of lipid within the cytoplasmic vacuoles may be demonstrated by fat-soluble stains, such as oil red O or Sudan IV, applied to frozen tissue sections. Alternatively, osmicated tissue specimens may be processed routinely and stained with hematoxylin and eosin. In these latter tissue sections, osmicated lipid will appear brown-black.

- ***Hibernoma:*** A hibernoma is a rare benign tumor of brown fat origin. A subconjunctival hibernoma was successfully excised from a two-year-old male white goose. The neoplasm involved the ventrolateral aspect of the right sclera and protruded through the palpebral fissure, interfering with eyelid closure.[89]

  Histologically, neoplastic cells stained faintly eosinophilic, appeared foamy, had central-to-paracentral nuclei and had a voluminous cytoplasm containing numerous, fine vacuoles and birefringent eosinophilic material. The neoplasm was well vascularized and contained a delicate stromal framework. Lipid was demonstrated within the cytoplasmic vacuoles by oil red O staining.[89]

- ***Xanthoma/Xanthomatosis:*** The term xanthoma means "yellow mass." An xanthoma is not a true neoplasm, but an inflammatory intumescence resulting from the accumulation of lipid-laden macrophages, giant cells, free cholesterol and variable degrees of fibrosis. Xanthomas occur frequently in gallinaceous and psittacine birds, appearing as yellow, single-to-multiple, discrete subcutaneous nodules or diffuse thickenings of skin that may be featherless, ulcerated or hemorrhagic (Color 25.15).[25,143] These masses may occur anywhere on the skin or overlie other neoplasms, especially lipomas (Color 25.2).[143] Infrequently, xanthomas may have a periarticular arrangement or involve the oral cavity.[60,111]

  Although the precise etiology of xanthoma formation is unknown, various theories have been proposed including high-lipid diets or ingestion of toxic fat-soluble substances (such as aromatic chlorinated hydrocarbons) that might incite inflammation and trauma.[25,98,117,143] Cellular infiltrates, lipid accumulation and fibroplasia give rise to the nodular or tumorous appearance of these lesions. Unresectable or multiple skin xanthomas may respond to irradiation (low-energy X-rays; 20 to 30 Gy) or hyperthermia.[143] Dietary restriction of oily seeds may be beneficial in the medical management of xanthomatosis.[34]

Connective Tissue Neoplasms and Masses

Connective tissue neoplasms (fibrosarcoma, fibroma, myxosarcoma and myxoma) arise from the proliferation of fibroblasts or undifferentiated mesenchymal cells, which frequently assume a spindle-like appearance. These neoplasms contain a collagenous or mucinous stroma. Cellular morphology, mitotic index

and biological behavior are used to classify these neoplasms as benign or malignant.

In chickens, connective tissue neoplasms can arise following infection with specific strains of avian leukosis or sarcoma virus.[101] The etiology of similar neoplasms in aviary and free-ranging birds is unknown.

- ***Fibrosarcoma:*** Fibrosarcoma is a malignant neoplasm of fibroblast or mesenchymal cells, which possess the ability to produce collagen fibers. Fibrosarcomas occur commonly in budgerigars, cockatiels, macaws and parrots.[7,25,49,108,110,143] Fibrosarcomas may constitute 3 to 14% of all neoplasms in budgerigars.[143]

  Clinically, fibrosarcomas are firm, single-to-multiple, broad-based, relatively immobile nodules or masses. Superficial fibrosarcomas may be covered by an intact-to-ulcerated epidermis accompanied by hemorrhage and secondary bacterial infections. Fibrosarcomas commonly arise from the soft tissues of the wing, leg, head, beak, cere and trunk (Color 25.1, 25.5, 24.19).[6,11,12,15,72,75,102,108,110] They also may arise in the viscera and deep tissues including thoracoabdominal cavity, spleen, liver, mouth, tongue, syrinx, lung, small intestine, proventricular wall, testes and ovary (Figure 25.2).[12,27,102,108] These neoplasms are locally invasive and may eventually metastasize, especially to the abdominal cavity, lungs, liver, kidney, heart base and bone (Figure 25.3).[12,102,108,110,143] Intra-abdominal neoplasms also have been observed enveloping bowel loops and adhering to the pancreas.[82,127] These neoplasms have been reported as neurofibrosarcomas based upon cellular arrangement or pattern, but a neural origin has not been demonstrated.

- ***Fibroma:*** A fibroma is an uncommon benign neoplasm composed of well differentiated fibroblasts distributed within a collagenous matrix. Fibromas are firm on palpation and may arise almost anywhere, but usually involve a firm mass in the skin and subcutaneous tissues of the wing, leg, face, beak, neck or sternum.[12,32,69,72,143]

- ***Myxoma and Myxosarcoma:*** These neoplasms are of fibroblast or mesenchymal cell origin, but possess abundant mucinous stroma. These rare neoplasms may arise wherever connective tissue exists including the foot pad, cranium, leg, kidney, commissure of the beak and within the thoracic cavity.[15,108] Clinically, these masses may appear soft on palpation and gelatinous on cut surface. In myxosarcomas, neoplas-

FIG 25.2 A ten-year-old Amazon parrot was presented with a one-year history of a progressive swelling of the head and face (see Color 25.1). Physical examination revealed numerous masses throughout the body that were confirmed by radiographs. Histopathology indicated an invasive fibrosarcoma involving the soft tissues and bones of the head (courtesy of Jane Turrel).

FIG 25.3 An adult female dove was presented with a soft tissue swelling involving the right scapulohumeral region. Radiographically, a large, uniform, soft tissue mass with osteolysis involving the humoral head and diaphysis was noted. The increased medullary bone density was considered normal for a laying hen. Cytology of a fine-needle aspirate confirmed fibrosarcoma (courtesy of Marjorie McMillan).

tic cells appear to be more numerous and contain plump nuclei. Metastasis may occur, but is infrequent to rare.

- ***Reactive Fibroplasia:*** Granulation tissue exemplifies healing by second intention. Granulation tissue may be highly vascular and proliferative with variable degrees of inflammation. Grossly, granulation tissue may have a proliferative or neoplastic-like appearance. Cytologic specimens often contain a pleomorphic population of immature fibroblasts that mimic neoplasia. Inflammatory cells may be admixed with blood. Histologically, tissue architecture is a differentiating feature of the lesion wherein blood vessels are oriented at right angles to the surface of the lesion, while fibroblasts are oriented parallel to the surface of the lesion. Marked, proliferative fibroplasia with granuloma formation also may be observed in the ceca of gallinaceous birds, especially pheasants, infected with *Heterakis isolonche* (see Color 14). In such instances, nematode-induced reactive fibroplasia may be difficult to distinguish from neoplasia.[57,62]

Epithelial Neoplasms and Cysts

- ***Papillomas and Papilloma-like Lesions:*** Cutaneous papillomas are observed occasionally in domestic, captive and free ranging birds.[4,6,11,15,46,73,98] Multiple papillomas most frequently originate from the skin of the eyelids, at the junction of the beak and face, and on the feet and legs. The anatomic location of these benign neoplasms may interfere with vision, prehension of food or perching if the lesions are severe (Color 25.17). Histologically, these lesions consist of folds of hyperplastic stratified squamous epithelium over a fibrovascular stroma. Cutaneous papillomas are viral-induced, at least in African Grey Parrots, Chaffinches and Bramblings (Color 25.10) (see Chapter 32).[73,87,96]

- ***Squamous Cell Carcinoma:*** Squamous cell carcinoma is observed most frequently in chickens but has also been described in captive and free-ranging birds in the skin of the head, eyelids, neck, chest, wings or around the beak (Color 25.9).[6,7,15,29,49,59,108,135,142] Grossly, these neoplasms appear as multiple, raised masses with central craters or ulceration (Color 25.7). Multiple neoplasms usually are present, involving both feathered and unfeathered areas of the skin. An interesting recent study indicates that these neoplasms originate as elevated keratin-filled cysts that subsequently ulcerate and flatten. Some lesions may subsequently resolve as dermal scars.[59]

Histologically, these dermal squamous cell carcinomas are characterized by epidermal ulceration and infiltration of the subjacent dermis by squamous cells. These cells are scattered singly or arranged in nests and cords. Infiltration of underlying skeletal muscle is rare. Laminated keratin pearls may be observed within epithelial cell cords in companion and free-ranging birds.[108] The etiology of multifocal, dermal squamous cell carcinoma of chickens has not been determined.

- ***Uropygial Gland Adenoma and Adenocarcinoma:*** Uropygial gland neoplasms occur sporadically in captive birds, especially budgerigars and canaries.[6,102,108] On physical examination, the uropygial gland may appear enlarged, ulcerated and hemorrhagic (Color 25.11). Neoplasia must be distinguished from adenitis, which usually requires histologic examination. Partial or complete removal of the affected gland is recommended (Figure 25.4).

- ***Feather Folliculoma:*** Feather folliculomas occur primarily in canaries and budgerigars.[18,108,149] These neoplasms may appear as discrete, mobile, single or multiple dermal nodules that may ulcerate or hemorrhage (see Color 14). Microscopically, these lesions appear multilobulated and are lined with irregular, hyperplastic, basaloid cells that exhibit feather formation. Basal cells are arranged in barb ridges and undergo abrupt squamous differentiation in the center of the mass, forming laminations of free keratin.[108,149]

- ***Miscellaneous Basal Cell Tumors and Cutaneous Cysts:*** All of these neoplasms present as discrete skin nodules. Basal cell tumors are composed of sheets, nests or cords of basaloid epithelial cells. This cell population does not exhibit terminal cellular or structural differentiation.[5,25,108]

Intradermal cystic lesions occasionally are observed in captive and free-ranging birds. Histologically, these lesions often appear cystic as a result of glandular differentiation or keratin production. Those benign neoplasms that exhibit glandular differentiation are cystadenomas.[67] Cystic lesions with keratin production are classified on the basis of gradual or abrupt keratinization. Gradual keratinization is observed with epidermal inclusion cysts, follicular cysts and intracutaneous cornifying epitheliomas.[88,108,130] Those cystic lesions with abrupt keratinization include trichoepithelioma and pilomatrixoma.[88,108]

Miscellaneous Neoplasms

- ***Cutaneous Lymphosarcoma:*** Cutaneous lymphosarcoma is observed in chickens as a manifestation of

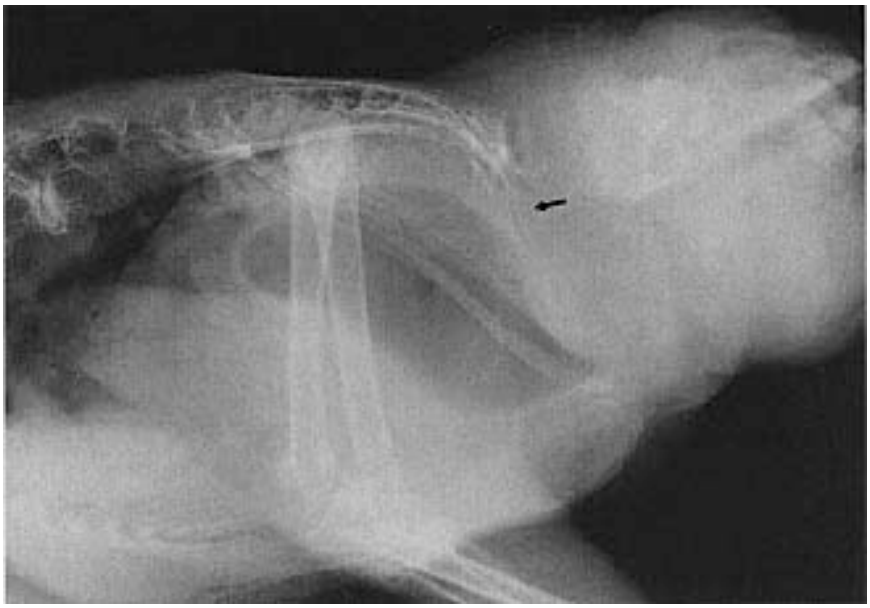

FIG 25.4 A 36-year-old macaw was presented for evaluation of a progressive mass over the dorsal spine and straining to defecate. On physical examination, a large mass was noted in the area of the uropygial gland and dried excrement had accumulated around the vent. Tenesmus was noted during the physical examination. Radiographs indicated a large mass that had invaded the synsacrum and was displacing the cloaca ventrally. The histopathologic diagnosis was adenocarcinoma of the uropygial gland (courtesy of Jane Turrel).

Marek's disease and may occasionally occur in captive and free-ranging birds.[9,100,105] Neoplastic lymphocytes may exhibit multifocal to diffuse follicular and perifollicular infiltration, producing numerous skin nodules that may ulcerate along feather tracts.[20,98] In psittacine birds, cutaneous neoplasms may develop under the skin of the face or neck, often in association with generalized or systemic lymphosarcoma.[9]

- ***Mast Cell Tumor:*** Mast cell tumors have been reported in three owls and a chicken.[99,124,139] In owls, mast cell neoplasms usually are associated with the skin of the eyelid or auditory meatus, but may also be observed in the mouth.[124,139] Generally, animal species with a higher circulating basophil count have fewer tissue mast cells, which may explain the rarity of mast cell tumors in avian species. Mast cell tumors appear grossly as raised-to-spherical, pink-to-red, dermal or submucosal masses. In some instances, neoplastic margins may be indistinct or the neoplasm will demonstrate marked local tissue invasion.[124,139] Attempted surgical excision of a mast cell tumor was unsuccessful in one owl.[124]

Respiratory System

The avian lung serves as a metastatic site for many neoplasms including fibrosarcoma, adenocarcinoma, hemangiosarcoma, malignant melanoma, mesothelioma and osteosarcoma (Figure 25.5).[12,78,81,102,108,127] In contrast, primary neoplasms of the avian respiratory system are rare in species other than chickens.

- ***Lymphosarcoma and Hemangiosarcoma:*** Chickens with Marek's disease (Marek's lymphoma) often have herpesvirus-induced pulmonary lymphoid tumors.[109] Multicentric hemangiosarcomas of chickens also may originate in the pulmonary parenchyma.[74,129] Hemangiosarcomas occur in fowl infected with retrovirus and are discussed under the circulatory system.

- ***Papilloma:*** Laryngeal papillomas are observed occasionally in psittacine birds, especially Amazon parrots and macaws.[36,55,102] Papillomas also may occur within the nares and choanal area.[36,55] Clinically, laryngeal papillomas may cause dyspnea. These lesions may be surgically excised, but will recur if excision is incomplete.[102]

- ***Bronchiolar Adenoma and Adenocarcinoma:*** A bronchiolar adenoma has been reported in a parrot.[108] The neoplasm appeared as a large, lobulated, adenomatous nodule within a major bronchus. A bronchiogenic adenocarcinoma has been reported in a quail, but histologic features of the neoplasm were not described.[49]

- ***Fibrosarcoma:*** A solitary pulmonary fibrosarcoma has been described in a cockatiel. Due to the absence of other neoplastic nodules, primary pulmonary origin was suggested.[27]

- ***Ectopic Pulmonary Ossification:*** Ectopic pulmonary ossification may be confused radiographically with pulmonary metastasis. This subject is discussed below (bone proliferation resembling neoplasia; musculoskeletal system).

- ***Ultimobranchial Cyst:*** Ultimobranchial cysts develop from branchial pouch remnants following embryogenesis. A large ultimobranchial cyst has been observed in the lower neck of a lorikeet. The thyroid gland was displaced by this mass. Histologically, the neoplasm was lined by squamous epithelium and contained laminated keratin material and desquamated cells within the cyst lumen.[108]

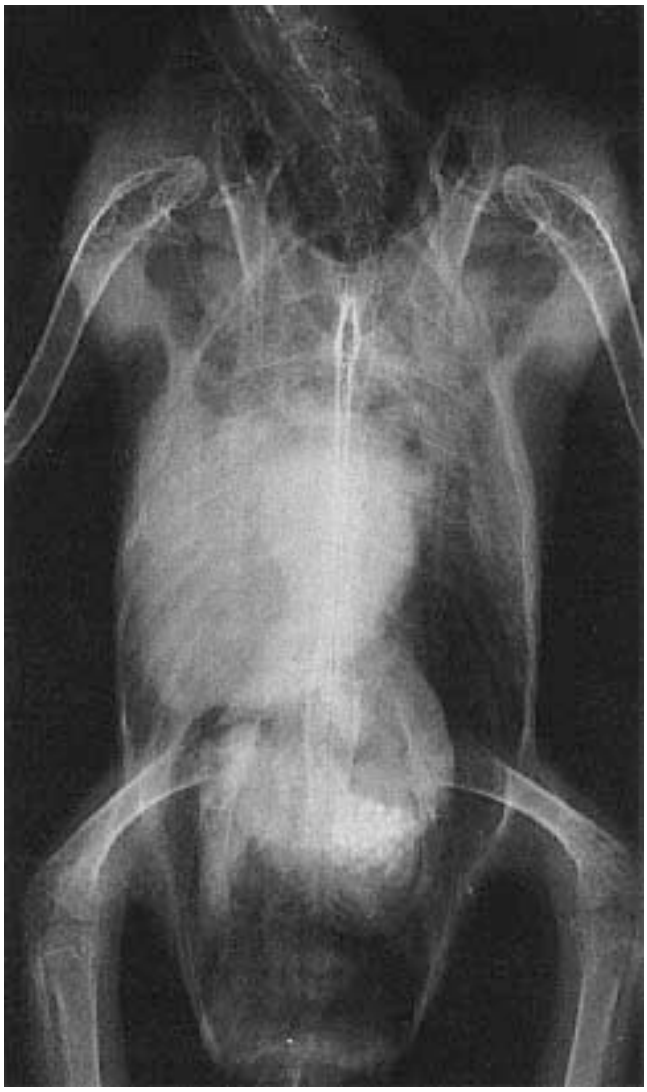
Circulatory System

Vasoformative neoplasms originate from endothelial cell proliferation with subsequent formation of irregular vascular channels and spaces filled with blood (or rarely with lymph). These neoplasms may form wherever endothelium exists; however, preferred sites of origin are apparent. Vasoformative neoplasms are classified as benign (hemangioma, lymphangioma) or malignant (hemangiosarcoma, lymphangiosarcoma).

Vasoformative neoplasms must be distinguished from non-neoplastic conditions such as vascular malformations (arteriovenous fistulas and aneurysms), hematomas, excessively vascularized granulation tissue or other neoplasms with a rich blood supply.[84,88] Definitive diagnosis requires histopathology.

In chickens, vasoformative neoplasms may arise as a sequela to avian leukosis virus, subgroup F infection. These virus-induced neoplasms may progress from benign growths to fibrosarcoma-like neoplasms, analogous to Kaposi's sarcoma in human beings.[42] In contrast, reports of vasoformative neoplasms in captive and free-ranging birds are sporadic and of undetermined etiology.[14,72,85, 102,108,127,143]

On gross inspection, hemangiomas and hemangiosarcomas may appear as single-to-multiple; variably-sized; pink, red or blue-black nodules (blood blisters), swellings or multiloculated masses within the skin or abdominal viscera.[22,74] Internal neo-



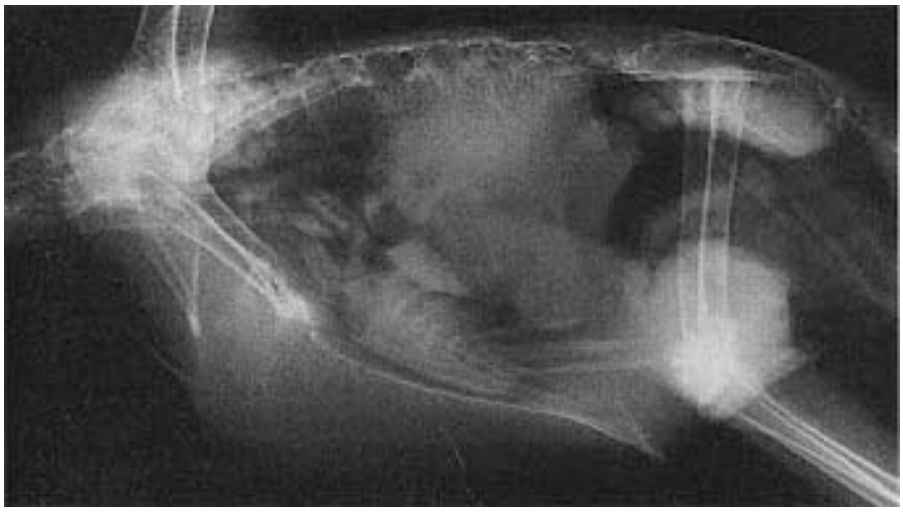


FIG 25.5 Radiographs of a four-year-old female African Grey Parrot indicated a large, soft tissue mass in the right thoracic area. Histopathology revealed a renal tubular adenocarcinoma with metastasis to the lung, liver and myocardium (see Color 25.13).

plasms may present as primary abdominal distention from tumor mass or secondary abdominal distention from hemorrhage (hemoperitoneum). Vasoformative neoplasms may hemorrhage spontaneously or following minor trauma (palpation) resulting in anemia or exsanguination.[19,25,98]

- ***Hemangioma:*** Cutaneous hemangiomas often arise within subcutaneous tissues of the dorsum of the neck, wing or legs.[15,25,102] Feather follicles also may be involved.[25] Abdominal hemangiomas may arise in the spleen, liver, kidney or testicular capsule. These latter neoplasms may cause abdominal distention by tumor mass or hemorrhage (hemoperitoneum).[22,49,102] External hemangiomas, particularly on the wing tips, are subject to trauma and may bleed profusely.

  Cytologic aspirates of hemangiomas are of limited diagnostic value and generally consist of blood. Endothelial cells are rarely observed. Erythrophagocytosis, hemosiderin-laden macrophages and hematoidin crystals may be observed if concomitant hemorrhage is present. Hemosiderin is an iron pigment derived from erythrocyte catabolism. This pigment appears globular and blue, golden-brown or greenish-black in Romanowsky-stained cytology preparations. Hematoidin, a hemoglobin breakdown product, appears as small, bright-yellow, parallelogram-shaped crystals that are observed most frequently within the cytoplasm of macrophages. Hematoma, hemangioma and hemangiosarcoma may be difficult or impossible to distinguish cytologically.

  Histologically, hemangiomas are composed of variably-sized vascular spaces and channels that are lined by flattened endothelium. Occasional solid areas of plump endothelial cells also may be observed. Vascular spaces typically contain blood, plasma or fibrin thrombi. On rare occasions, immature hematopoietic precursor cells may be adherent to the endothelium.

- ***Hemangiosarcoma:*** Hemangiosarcomas may arise singly or in a multicentric pattern. These neoplasms often arise in the skin, liver, lungs, spleen, muscle, mesentery, kidney, heart, oviduct, bone or synovium.[19,49,74,102,108,127,128,129,143] Hemangiosarcomas that develop in the distal diaphysis of long bones may exhibit aggressive osteolysis and surface hemorrhage (Figure 25.6).[143] Hemangiosarcomas may metastasize to distant tissues including lung, liver or myocardium.[102,143]

  Cytologic aspirates are similar to those described for hemangiomas; however, widely scattered pleomorphic endothelial cells may be present. These endothelial cells usually appear polyhedral-to-spindle-shaped with round-to-oval nuclei and dark-blue, occasionally finely vacuolated, cytoplasm. Aspiration sites may hemorrhage profusely.

  Histologically, vascular spaces in hemangiosarcomas are lined by plump endothelial cells with hyperchromatic nuclei. Mitoses may be observed. Neoplastic cells often dissect surrounding structures and exhibit vascular invasion. Secondary hemorrhage is common.

- ***Lymphangioma:*** Birds possess lymphatic channels but they appear less well developed than corresponding structures in mammals. Lymphangiomas are benign neoplasms wherein endothelial cells form lymphatic channels. These neoplasms are extremely rare in all species, especially birds. Lymphangioma has been reported in the mesentery and spleen of a rhea and budgerigar, respectively.[72,102] However, the budgerigar neoplasm closely resembled an hemangioma.[102]

  Histologically, these neoplasms consist of vascular channels lined by flattened epithelium and filled with lymph. Lymph appears as a homogeneous, light-pink substance.

Musculoskeletal System

Neoplasms of Smooth and Striated Muscle

Neoplasms originating from striated or smooth muscle that are benign or malignant are observed occasionally in captive and free-ranging birds. Muscle neoplasms presumably arise from embryonic remnants of myotomes, from pluripotential cells of embryologic structures or from neoplastic transformation of myoblasts during degeneration or repair processes.[88] Generally, smooth muscle neoplasms are reported about twice as frequently as striated muscle tumors. Furthermore, malignant neoplasms are reported twice as frequently as their benign counterparts.

- ***Leiomyoma:*** Leiomyomas are benign neoplasms that generally are nodular and may arise from smooth muscle of the gastrointestinal or female reproductive tract, especially the oviduct. Other sites of origin include smooth muscle trabeculae within the spleen or smooth muscle associated with vessels or

FIG 25.6 A dove was presented with lameness and a large swelling of the metatarsal area. Radiographically, the mass involved proliferation of soft tissues and osteolysis resulting in a pathologic fracture. The histologic diagnosis was hemangiosarcoma (courtesy of Jane Turrel).

ducts in the pancreas.[15,102,108] Leiomyomas usually exhibit slow growth and may be associated with abdominal distention, gastrointestinal or reproductive tract obstruction, or organ displacement.

Cytologic aspirates and imprints are sparsely cellular, containing only scattered free nuclei or a few spindle cells with elongate nuclei. Histopathology reveals a uniform population of elongate cells arranged in broad, interlacing bands. These cells have cigar-shaped nuclei and eosinophilic cytoplasm. Mitoses are observed infrequently.

- ***Leiomyosarcoma:*** Leiomyosarcomas are the most common muscle neoplasm reported in captive and free-ranging birds.[15,102] They may arise from smooth muscle in any location, but usually arise from splenic smooth muscle trabeculae.[12,15,102] Other sites of origin include crop, intestinal tract, trachea, pancreas, oviduct, ventral ligament of the oviduct, vas deferens and testicular capsule.[12,15,25,102,133] Leiomyosarcomas may be locally invasive. Metastasis is a late and infrequent event, but has been documented to involve the liver, spleen, thoracic cavity and bone marrow.[15,119]

Cytologic imprints of leiomyosarcomas may contain free nuclei and a pleomorphic but sparse population of spindle cells. Distinguishing leiomyosarcomas from fibrosarcomas may be difficult cytologically. Grossly, excised neoplasms appear firm, pink, poorly delineated and unencapsulated. Microscopically, leiomyosarcomas are hypercellular with spindle cells arranged in sheets, interlacing bundles or whorls. Neoplastic myocytes have plump often pleomorphic nuclei, occasional nucleoli and variable amounts of eosinophilic cytoplasm.

- ***Rhabdomyoma:*** Rhabdomyomas are benign neoplasms of striated muscle and are the rarest muscle neoplasm reported in captive birds. Reported sites of origin include the wing, tongue and eyelid.[12,15,108] These neoplasms may be solitary or multinodular, blending with surrounding skeletal muscle.

  Cytologic aspirates are unrewarding except for possible fragments of striated muscle cells. Histologically, rhabdomyomas are composed of cells ranging from a fibroblast appearance to multinucleated cells. Most cells have distinct fibrillar cross striations. Some cells may appear vacuolated and have high glycogen content demonstrated by diastase-labile, periodic acid Schiff (PAS)-positive granules.[88]

- ***Rhabdomyosarcoma:*** Rhabdomyosarcomas are of skeletal muscle origin and frequently present as irregular, elevated, lobulated, relatively firm subcutaneous swellings of the wing or shoulder that limit the use of the wing.[12,15,51,102] Because these neoplasms blend with surrounding skeletal muscle, they are immobile or firmly attached on palpation. Less frequently, neoplasms will arise from other sites such as the dorsal lumbar musculature.[107] Metastasis to the abdominal cavity and liver was reported in one bird.[107]

  Cytologic studies of rhabdomyosarcomas have not been reported. Microscopically, the neoplasms are composed of a pleomorphic population of fusiform-to-elongated cells. Anisokaryosis may be prominent with plump oval-to-elongated nuclei. Some elongated or "strap cells" will retain cross striations typical of skeletal muscle cells. Phosphotungstic acid hematoxylin (PTAH) staining may facilitate identification of these cross striations.

Neoplasms of Cartilage and Bone

Neoplasms arising from cartilage and bone are observed occasionally. Osseous neoplasms usually arise from the long bones, while cartilaginous neoplasms often arise on the foot. Cytology may suggest the

presence of mesenchymal neoplasia by demonstrating a pleomorphic population of spindle-to-polyhedral cells and possible matrix material; however, histopathology is required to determine whether the neoplasm originates from cartilage or bone and to determine whether the neoplasm is benign or malignant.

- ***Chondroma:*** Chondromas are reported occasionally in captive and free-ranging birds, especially of the order Anseriformes.[108] Grossly, these neoplasms may be single or multiple. They often arise on the plantar surface of the foot pad where they may be subjected to trauma with subsequent hemorrhage and ulceration of the overlying epidermis.[108] Other sites of origin of chondromas include the cranium (especially in canaries) and proximal humerus (Figure 25.7).[108]

  Histologically, these neoplasms consist of nodular, encapsulated foci of developing chondrocytes separated by connective tissue septa. Variable amounts of sulfated mucopolysaccharide matrix and lacunae may be observed.

- ***Chondrosarcoma:*** Chondrosarcomas are very rare in comparison to chondromas. A chondrosarcoma has been reported involving the metatarsal-phalangeal joint of a ruffed grouse; however, the histologic appearance of the lesion is similar to a multilobular chondroma.[25,127]

FIG 25.7 A mature cockatiel from an aviary flight was presented with a mass that had been progressing in size for a year. The mass was fluid-filled (serosanguinous), and cytologic evaluation of the fluid was nondiagnostic. The mass was excised and the cranium formed the base of the mass. The bird recovered uneventfully. Histopathology indicated a bone cyst. Trauma was considered the most likely cause (courtesy of Tom Tully).

- ***Osteoma:*** Osteomas are observed infrequently in birds compared to osteosarcomas. Osteomas may originate from the cranium, scapula, tarsometatarsus, plantar foot pad and elbow joint.[6,12,49,51,108] Histologically, osteomas are small, well encapsulated nodules composed of disorganized bony trabeculae and are attached to adjacent bone.[108] Surgical excision is the treatment of choice.

- ***Osteosarcoma:*** Osteosarcomas occur 3.5 times more frequently than osteomas and usually originate from the proximal or distal portion of long bones including the radius, humerus, femur, tibiotarsus and tarsometatarsus (Figure 25.8).[5,6,12,51,72,81,102,108] Less frequent sites of origin include the ribs, phalanges, cranium, orbit and coccyx.[6,102,108] Osteosarcomas may metastasize widely to such sites as the lungs, liver, kidney, ovary, mesentery and other bones (Color 25.16).[81]

  Histologically, osteosarcomas are composed of polyhedral-to-spindle mesenchymal cells that produce osteoid. Bony trabeculae may be present but disorganized. Scattered islands of cartilage, fibrous connective tissue, and myxomatous matrix also may be present.[108] Scattered mitotic figures may be observed.

Bone Proliferation Resembling Neoplasia

Radiographically, skeletal hyperostostosis is recognized by increased medullary bone density, increased bone thickness and deformities involving one or multiple long bones. The differential diagnosis for increased medullary opacity of long bones includes osteopetrosis, polyostotic hyperostosis, metastatic neoplasia, hypertrophic osteopathy and metabolic bone disease.

- ***Osteopetrosis:*** Osteopetrosis is defined as marked subperiosteal proliferation of bone resulting in loss of medullary space, increased bone thickness and deformity. Osteopetrosis in chickens occurs sporadically and is caused by leukosis/sarcoma virus infection. Depending upon the strain of virus, osteopetrosis may be experimentally induced within one to three months of virus inoculation with a disease frequency of 60-100%.[125,126]

  Histologically, decalcified sections of bone demonstrate marked proliferation of porous subperiosteal bone. Osteoclast numbers are normal, but a marked increase in osteoblastic activity exists.[109,125,126]

- ***Ovarian and Oviductal Neoplasms and Cysts:*** Cystic ovaries, oviductal carcinoma and ovarian neoplasms may induce generalized or localized bone formation in companion birds.[5,12,132] Increased medullary bone density is apparent on survey radiographs. Histologically, the increased medullary density is the result of formation of bone spicules throughout the marrow cavity.

- ***Ectopic Pulmonary Cartilage and Bone:*** Ectopic pulmonary cartilage and bone formation may be observed in the lung parenchyma of chickens, especially broilers.[16,109,150] The incidence varies with the strain of bird, suggesting a genetic predisposition to this condition. This condition probably represents abnormal embryonic induction of mesenchyme or germ cells displaced from adjacent bronchi during development.[150] Alternatively, osseous or cartilaginous metaplasia also may explain the development of this condition. Histologically, nodules of cartilage or bone are present within the pulmonary parenchyma.[109,150]

Ectopic pulmonary ossification has been observed in an Orange-winged Amazon Parrot and a Senegal Parrot. Survey radiographs in both birds detected multifocal opacities throughout the lung fields, suggesting deep mycosis or metastatic neoplasia. Lung biopsy specimens, however, contained only small foci of osseous tissue within the parenchyma.

Urogenital System

Neoplasms of the urogenital system are reported frequently, especially in budgerigars. In a recent survey, urogenital tumors accounted for 12.5% (7.3% renal and 5.2% genital) of all neoplasms in a diverse avian population.[108] Surveys in budgerigars indicate an 11.2 to 66.0% incidence of urogenital neoplasia.[7,12,15,92] Testicular neoplasms of captive and free-ranging birds are approximately three times as common as ovarian and oviductal neoplasms. This observation may be explained partially by the presence of bilateral testes in the male but only one functional ovary and oviduct in the normal hen.

Larger neoplasms may cause abdominal distention or respiratory embarrassment. Some renal, testicular, ovarian and oviductal neoplasms may cause unilateral or bilateral leg paresis or paralysis with difficulty or inability to perch.[12,51,92] This occurs because the nerves of the sacral plexus pass through the mid portion of the kidney where they are subject to compression or infiltration by neoplastic cells. Lastly, gonadal neoplasms may be associated with various paraneoplastic syndromes such as feminization or

FIG 25.8 A nine-year-old Sulphur-crested Cockatoo was presented with a left limb lameness. An initial radiograph (left) indicated osteolysis of the distal femur that was diagnosed as osteomyelitis. A second radiograph (middle) taken seven weeks later indicated increased soft tissue swelling and osteolysis. A biopsy was non-diagnostic. A third radiograph (right) taken three months after initial presentation indicated a pathologic fracture with marked osteolysis. The histologic diagnosis was anaplastic sarcoma.

masculinization and localized or polyostotic hyperostosis (Figure 25.9).[5,6,12,92,102,132] Feminization or masculinization is most apparent in budgerigars where the male's cere may change from blue to brown, or the female's cere may turn from brown to blue (see Color 24).[6,12,102]

Renal Neoplasms

Renal neoplasms are observed occasionally in free-ranging and captive birds, especially budgerigars. Renal neoplasms usually occur unilaterally, but may occur bilaterally, and presenting complaints generally include an inability to perch or ambulate.[12,51,102,108] Abdominal enlargement and articular gout also may occur.[12]

The etiology of renal neoplasms is obscure, but they may originate from embryonal nests in the avian kidney. In poultry, renal neoplasia is usually a sequela to avian leukosis virus infection.[101]

Renal neoplasms are difficult to manage surgically. Renal carcinomas may aggressively invade adjacent muscle and bone. Because the kidneys are located in the renal fossae, neoplasms are difficult to isolate and excise (Figure 25.10). The sacral plexus passes through the mid portion of the kidney and is subject to trauma. Finally, the kidneys are highly vascular and marked hemorrhage is expected. Treatment of renal neoplasms using radioisotope implants appears promising, but will require further evaluation.[143]

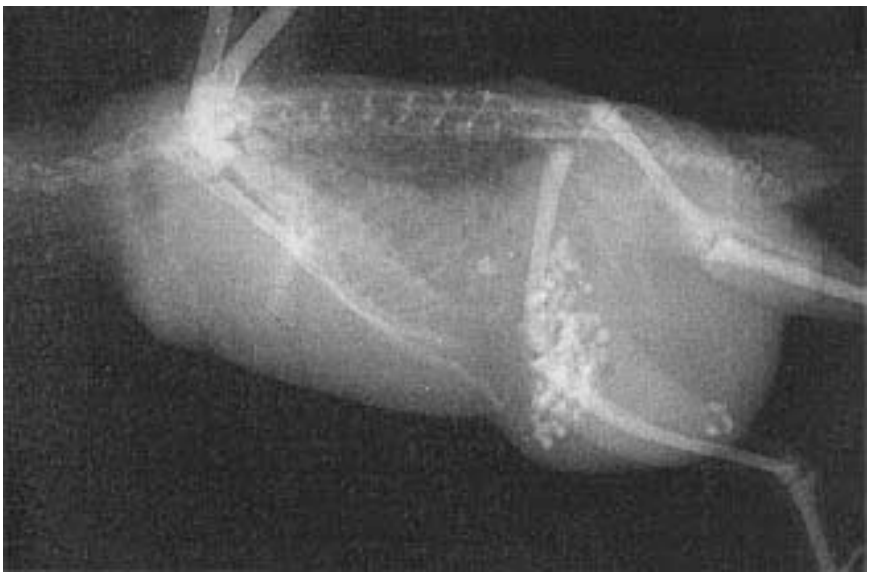

FIG 25.9 A five-year-old male budgerigar was presented because of a change in cere color (from blue to pink), abdominal distention and unilateral leg paresis. Radiographs indicated a large soft-tissue opacity in the abdomen and polyostotic endosteal hyperostosis of the long bones. The clinical and radiographic findings were highly suggestive of a gonadal tumor. Histopathology confirmed a sertoli cell tumor, which was probably secreting low levels of estrogen (courtesy of Jane Turrel).

- ***Renal Carcinoma:*** Renal carcinoma is the most frequently observed renal neoplasm in captive and free-ranging birds.[7,12,41,49,69,71,85,102,108,144] Renal adenocarcinomas may infiltrate adjacent muscle and bone with extension into the spinal canal. Distant metastasis to the liver and oviduct may occur, but is unusual (Color 25.13).[69,71]

  Affected kidneys contain large, pale, multilobulated masses. Histologically, these neoplasms are composed of vesicular epithelial cells arranged in sheets, nests, cords or tubules. Epithelial cells may be cuboidal to columnar, especially those cells involved in tubular formation. Fibrovascular stroma may be prominent. A few multinucleated cells and scattered mitoses may be observed within the neoplasm.[102,108]

- ***Renal Adenoma:*** Renal adenomas are benign neoplasms that are observed infrequently compared to renal adenocarcinomas.[7,49,85] Although gross enlargement of a portion of the kidney is apparent, the microscopic appearance of the tissue may be unremarkable-to-subtle in comparison to the normal kidney. Epithelial cell cytoplasm may be slightly more basophilic. Compression of adjacent normal parenchyma occurs as the neoplasm slowly enlarges.

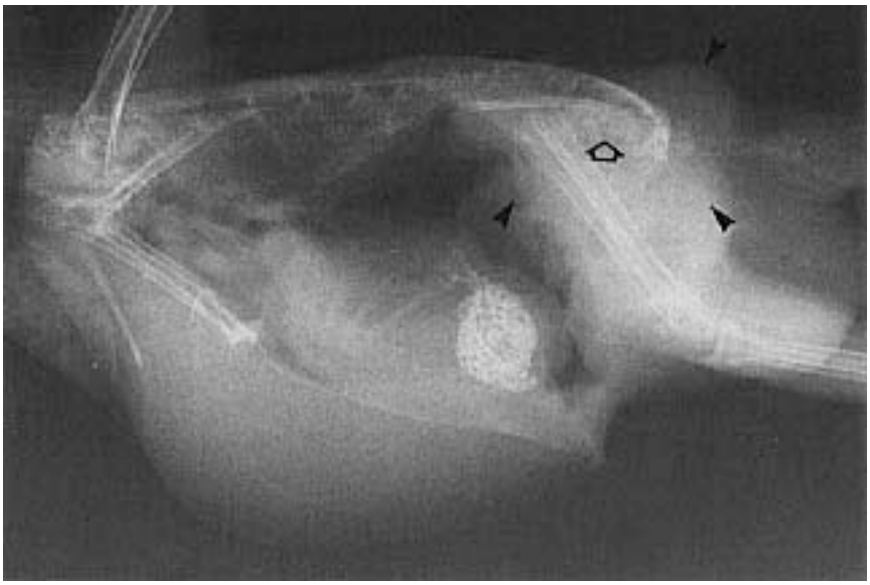
- ***Embryonal Nephroma:*** Embryonal nephroma (nephroblastoma, Wilms's tumor) has been observed most commonly in chickens infected with leukosis (sarcoma) virus. In chickens, these neoplasms usually are unilateral but may arise bilaterally.[23,101,109] In captive and free-ranging birds, these neoplasms are observed occasionally, especially in budgerigars.[12,15,102] The literature suggests they are more frequent than adenomas but less common than adenocarcinomas. These neoplasms are believed to arise from the metanephric blastema.[88]

  On gross inspection, embryonal nephromas cannot be distinguished from renal adenocarcinomas. Histologically, epithelial cells are arranged in solid masses of variably-sized tubules or cords. Characteristic features include the formation of tubules and glomerulus-like structures. Variable quantities of mesenchymal stroma may be present, which further undercores the embryonal nature of the neoplasm.[88,102] Rare metastasis to the liver and

spleen may occur, but is poorly documented.[15]

Testicular Neoplasms

Testicular neoplasms are usually unilateral, but may occur bilaterally. With unilateral neoplasms, atrophy of the contralateral testis may be observed. In rare instances, a collision tumor may be observed in which two or more cell lines are involved in the neoplastic process.[12] Cytologic studies have not been performed on avian testicular neoplasms. Definitive diagnosis of the following neoplasms is dependent upon histopathologic examination. Orchiectomy is the treatment of choice but must be initiated early for a successful outcome.



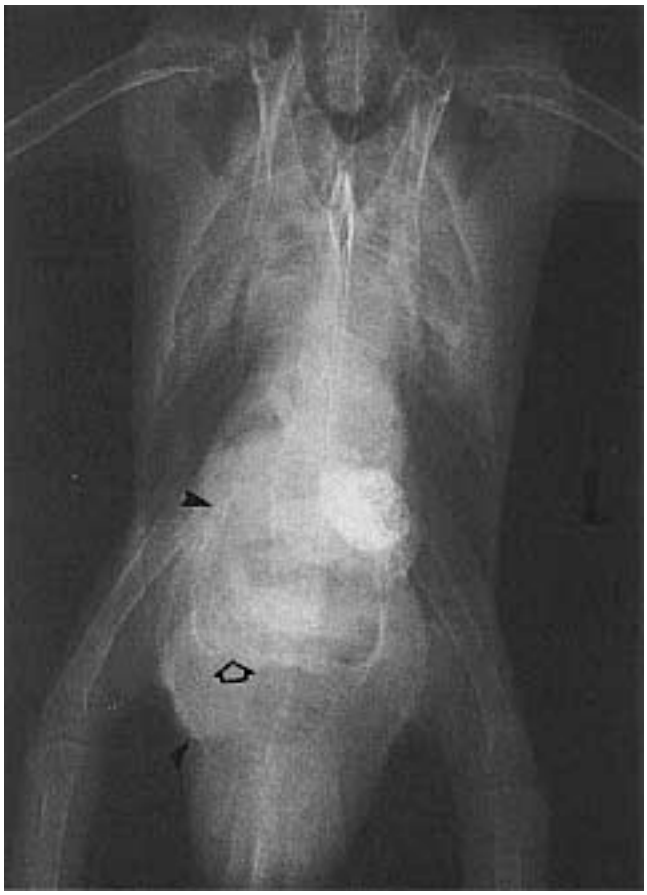


FIG 25.10 A Quaker Parakeet was presented for evaluation of a pericloacal and abdominal swelling. Radiographs indicated a renal mass that had invaded the synsacrum, causing osteolysis cranially and sclerosis caudally. The mass extended dorsally to the synsacrum and ventrally into the abdomen. The histopathologic diagnosis was renal carcinoma (courtesy of Jane Turrel).

- ***Sertoli Cell Tumor:*** Sertoli cell tumor is one of the most frequent testicular neoplasms encountered in captive and free-ranging birds.[5,12,49,51,53,102,108] These cells constitute a portion of the intratubular gonadal stroma, secreting testicular fluid and nourishing developing spermatids. If neoplastic Sertoli cells are synthesizing estrogen, feminization may be present. This phenomenon is most noticeable in male budgerigars in which the cere color changes from blue to brown (Figure 25.11).[12]

  Neoplastic testes appear as enlarged, pale, firm, nodular masses. Neoplasms may have a pink tinge secondary to central necrosis and hemorrhage. Variably sized, fluid-filled cystic spaces also may be present.[53,108] Serosal metastases are unusual but may occur.[108]

  Histologically, Sertoli cell tumors are composed of sheets, lobules and islands of cells. Cells within seminiferous tubule remnants may palisade. Individual neoplastic cells are elongate with round-to-oval basal nuclei. Cytoplasm is abundant, eosinophilic, and occasionally vacuolated. The mitotic rate is variable. A delicate-to-dense fibrovascular stroma is present.[53,108]

- ***Seminoma:*** Seminomas are neoplasms of germ cell origin. These tumors also occur frequently in captive and free-ranging birds.[5,12,44,49,51,54,85,102,108,141] The most common clinical signs include dyspnea, lethargy, anorexia, ascites and abdominal enlargement (occasionally with a palpable intra-abdominal mass).[44] Seminomas infrequently may be associated with signs of feminization in budgerigars.[12]

FIG 25.11 A mature male budgerigar was presented with a progressive growth and discoloration of the cere. Brown hypertrophy of the cere is frequently encountered in older budgerigars with gonadal neoplasms. The hypertrophied tissue can be moistened with skin-softening creams and gently peeled away.

Neoplastic testes appear large, white-to-gray, firm and oval. Small cystic spaces also may be present. Occasionally, adherence to the kidneys, ureters and dorsal body wall may be observed.[44,108] Seminomas are generally considered benign; however, metastasis to the liver may occur, presumably as a late event.[5,49,54,102]

Histologically, seminomas are composed of pleomorphic germinal epithelial cells arranged in sheets, nests and irregularly shaped tubules. Seminiferous tubules may be filled, distended or disrupted by neoplastic cells. Nests and tubules of neoplastic germ cells are separated by thin bands of connective tissue. Individual cells are round-to-polygonal and exhibit anisocytosis. Nuclei are large and round with hyperchromatic, coarsely clumped chromatin and indistinct nucleoli. Multinucleated tumor cells and bizarre mitotic figures may be observed frequently.[44]

- ***Interstitial Cell Tumor:*** Interstitial (Leydig) cell tumor is the least frequently reported gonadal stromal testicular neoplasm of birds.[12,102,108] Neoplastic testes appear enlarged, fleshy, and occasionally cystic.[12,108] The contralateral testis may be atrophied (Color 25.4).[12]

  Microscopically, interstitial tumors have a dense fibrovascular stroma that divides the neoplasm into lobules. Individual neoplastic cells are large and polyhedral, containing eccentric nuclei and vacuolated eosinophilic cytoplasm.[108] The vacuolated cytoplasm is a reflection of steroid hormone (testosterone) production.

- ***Miscellaneous Testicular Neoplasms:*** Lympho- sarcoma (Marek's disease, Marek's lymphoma) is the most frequent testicular neoplasm of chickens. This neoplasm is herpesvirus-induced.[20,109]

  The testicular capsule or testis may be the site of origin for hemangioma, fibrosarcoma and leiomyosarcoma.[102,108] Both carcinoma and leiomyosarcoma have been reported to arise from the epididymis and vas deferens, respectively.[12] Teratomas also may arise in the testis and are discussed under neoplasms of the nervous system.[23,63,112]

Ovarian and Oviductal Neoplasms

Ovarian neoplasms are reported more frequently than neoplasms arising from the oviduct. Clinical signs may include abdominal distention, ascites, dyspnea, intra-abdominal mass and leg paresis or paralysis. Usually the left leg exhibits paresis or paralysis initially, but both limbs ultimately may be affected. Paraneoplastic syndromes that may be observed in conjunction with ovarian and oviductal neoplasms include localized exostosis or polyostotic hyperostosis.[5,132]

Ovarian neoplasms are classified histologically according to cell lineage. Granulosa cell tumors are gonadal stromal neoplasms that originate from supportive tissues and are the most common type of ovarian neoplasm. Ovarian carcinomas are of epithelial cell origin and comprise the second most frequent classification of ovarian neoplasia. Dysgerminomas are germ cell tumors that are analogous to seminoma in males. This neoplasm is very rare and has been reported only in poultry and budgerigars.[7,23] Oviductal neoplasms are also described, and most of these tumors are of epithelial cell origin. Ovariectomy or salpingectomy is the treatment of choice.

- ***Granulosa Cell Tumor:*** Granulosa cell tumors are the most frequently reported ovarian neoplasm in captive and free-ranging birds.[12,28,49,51,102,108] These gonadal stromal neoplasms appear as large, pale, nodular masses. Central necrosis and hemorrhage may be present and impart a pink color to the neoplasm.

  Histologically, these neoplasms are composed of islands of epithelial-like cells separated by fibrovascular stroma. Cells may form tubules or palisades around blood vessels. Individual neoplastic cells have cytoplasmic vacuoles. Plump, theca-like cells may be scattered throughout the neoplasm.[108]

- ***Ovarian Carcinoma:*** Ovarian carcinomas or adenocarcinomas are the second most frequently reported neoplasm originating in the ovary.[12,28,31,51,102,108,134,145] These neoplasms may appear

as large, firm, cystic, multilobulated-to-pedunculated masses.

Limited cytologic study of one ovarian cystadenocarcinoma in a budgerigar demonstrated putative neoplastic cells in abdominal effusion fluid.[28] A few large epithelial cells were observed that had oval nuclei, prominent nucleoli and abundant blue cytoplasm. Anisocytosis and occasional mitotic figures also were observed.[28] Histologically, ovarian carcinomas are composed of epithelial cells arranged in nests, cords, tubules and cysts. Foci of epithelial cell proliferation are separated by connective tissue septa. Papillary projections of epithelial cells may protrude into the cysts. Cystic spaces may contain a homogeneous eosinophilic secretory product. The mitotic rate is variable.

Ovarian carcinomas may metastasize to the mesentery, intestinal serosa, liver, lung, pancreas, muscle and bone.[31,134,145]

- ***Miscellaneous Ovarian/Oviductal Neoplasms:*** Stromal tissues of the ovary are infrequent sites of origin for lipomas and fibrosarcomas.[12,108] Teratomas also may originate in the ovary and are discussed under neoplasms of the nervous system.[23]

  The oviduct and ventral ligament of the oviduct occasionally are the sites of origin of leiomyomas and leiomyosarcomas.[102,108]

- ***Oviductal Dysplasia, Adenomatous Hyperplasia, Adenoma and Adenocarcinoma:*** Studies of reproductive tracts from turkey hens suggest a progression of oviductal lesions in the development of neoplasia.[13] Preneoplastic changes include epithelial dysplasia and adenomatous hyperplasia. With time, these lesions may progress to oviductal adenoma and adenocarcinoma.[12,13,15,49,108,132] Oviduct adenocarcinomas may metastasize to abdominal serosal surfaces.[15]

  Grossly, oviduct adenomas and adenocarcinomas may appear as firm nodular masses. Carcinomatosis, if present, will appear as multiple, small white nodules on serosal surfaces. Polyostotic hyperostosis is a rare paraneoplastic syndrome associated with oviductal adenocarcinoma.[132]

  Histologically, oviductal adenomas and adenocarcinomas are composed of sheets, nests, cords and tubules of cuboidal-to-elongate epithelial cells. Fibrovascular stroma is variable, but fibroplasia is more intense with adenocarcinomas.

- ***Carcinomatosis:*** Carcinomatosis is the seeding of the thoracoabdominal cavity with neoplastic cells that subsequently proliferate, forming variably sized white nodules. Carcinomatosis may be observed with ovarian and oviductal adenocarcinomas, intestinal adenocarcinoma, pancreatic adenocarcinoma, mesothelioma and undifferentiated adenocarcinoma (Figure 25.12).[15,31,56,77,85,108,127,134] The pattern of metastasis may be governed partially by serosal membranes within the body cavity.[77] Both disseminated mycobacteriosis and egg-related peritonitis of hens may mimic neoplasia clinically and at necropsy. Both cytology and histopathology can confirm the presence of carcinomatosis.[77]

FIG 25.12 Carcinomatosis secondary to an anaplastic pancreatic carcinoma in a mature cockatiel (see Color 25.6) (courtesy Cheryl Greenacre).

Digestive System

Oral Cavity

- ***Papilloma:*** Papillomas are composed of proliferative squamous epithelium with a fibrovascular stroma. Oral papillomas are occasionally encountered, especially in psittacine birds, and may involve the oropharyngeal, choanal or laryngeal regions of the pharynx.[24,36,55] Papillomas may undergo malignant transformation to squamous cell carcinoma.

- ***Squamous Cell Carcinoma:*** Squamous cell carcinomas are second to papillomas in frequency and may involve the oral cavity and tongue.[3,33,72] These carcinomas appear as ulcerative-to-cauliflower-like, painful lesions or masses that are associated with inappetence, dysphagia, regurgitation, halitosis and frequent head shaking.[3,33,143] The differential diagnosis for this lesion should include oral neoplasia, hypovitaminosis A, trauma, candidiasis or protozoal infection (trichomoniasis).

  Cytologic examination may demonstrate a pleomorphic population of epithelial cells, but squamous cell hyperplasia and squamous cell carcinoma may be difficult or impossible to distinguish. Histologically, squamous cell carcinomas are composed of sheets, nests and cords of pleomorphic epithelial cells that infiltrate adjacent tissues. Anisocytosis, anisokaryosis, dyskeratosis and intercellular bridges usually are observed. Keratin pearl formation and adenoid patterns are observed less frequently. The mitotic rate is variable. Squamous cell carcinomas may be accompanied by inflammation and a scirrhous reaction. Local infiltration of surrounding tissues is common, but metastasis is rare.

- ***Miscellaneous Neoplasms:*** Miscellaneous oral neoplasms include a mast cell tumor in an owl and a fibrosarcoma in a budgerigar.[102,124] These neoplasms are discussed in detail under the integumentary system. Mucinous adenocarcinoma of the tongue also has been described in an owl (Figure 25.13).[45]

Esophagus and Crop

- ***Squamous Plaque:*** Squamous plaques are focal or multifocal thickening of stratified squamous epithelium that may be accompanied by dysplastic change. This lesion has been described as an "epithelioma" in the crop of a pigeon.[108] Squamous plaques are caused by chronic irritation and may undergo neoplastic transformation.

FIG 25.13 Radiographs of the head of an Umbrella Cockatoo indicate the extent of a sublingual mass. Granulomatous response is considered a precursor to some oral tumors (see Color 25.20).

- ***Papilloma:*** Papillomas account for the vast majority of neoplasms observed on the mucosal surfaces of the esophagus and crop, especially in psittacine species.[24,36,55,108] Papillomas may undergo malignant transformation.

- ***Squamous Cell Carcinoma:*** Squamous cell carcinoma of the crop has been observed in a budgerigar and an Amazon parrot.[15,90] The most detailed description is given for the Amazon parrot.[90] Grossly, the esophageal wall was thickened (Figure 25.14). The neoplasm was circumferential with a dry, white, cauliflower-like surface (Color 25.8). Microscopically, the neoplasm was composed of aggregates of pleomorphic squamous epithelial cells that extended into the submucosa.

- ***Leiomyosarcoma:*** A multifocal leiomyosarcoma has been reported to originate in the crop wall of a budgerigar. The only clinical sign attributed to this neoplasm was difficulty in swallowing.[102]

Proventriculus and Ventriculus

Neoplasms of the proventriculus are approximately twice as common compared to neoplasms of the ventriculus. Adenocarcinomas are most commonly ob-

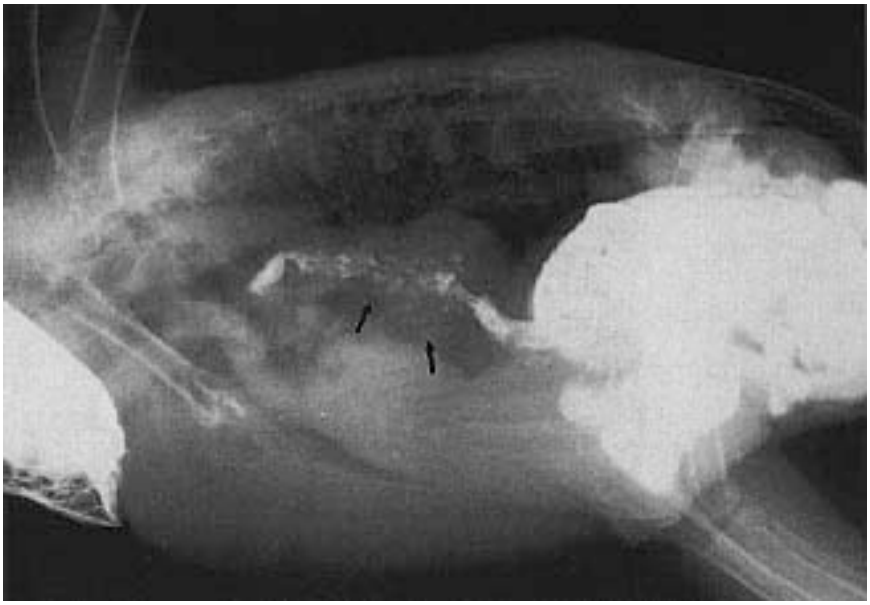

FIG 25.14 An esophagram of an adult Amazon parrot indicated an irregular mucosal filling pattern in the distal esophagus suggestive of a mass (see Color 25.8) (courtesy of Jane Turrel).

served and often arise from the junction of these two organs.

- ***Proventricular Carcinoma:*** Proventricular carcinoma is the most frequent neoplasm observed in this organ.[79,80,104,108,123,143] These neoplasms are more common in psittacine species, especially Grey-cheeked Parakeets.[79,104,123]

On gross inspection, proventricular carcinomas appear as ulcerated, thickened, raised or depressed lesions. Clinically, gastrointestinal bleeding, as determined by observation of melena, anemia or a positive fecal occult blood test, should alert the clinician to the possibility of gastrointestinal neoplasia. Severe bleeding, hypovolemic shock or exsanguination may occur.[79,104] Proventricular carcinomas may exhibit rare transmural extension with serosal metastasis to the ventriculus, intestine and pancreas or hematologic metastasis to the spleen, liver, lungs and heart base.[79,108]

Microscopically, these neoplasms are composed of columnar-to-cuboidal-to-squamous epithelial cells arranged in a tubuloacinar pattern. Individual cells have vesicular nuclei and eosinophilic-to-basophilic cytoplasm. Mitotic figures may be observed frequently. Many neoplasms are associated with a scirrhous reaction. The luminal surface of the neoplasm is often ulcerated, while deep margins of the neoplasm exhibit invasion of the muscularis.[79,104,108] Periodic acid-Schiff (PAS) and alcian blue staining may help differentiate proventricular and ventricular carcinomas. Proventricular carcinoma cells and the secretory product are strongly PAS-positive and stain dark pink. In contrast, the koilin secretory product of ventricular epithelial cells is alcian blue-positive and appears bright blue.[79,104]

- ***Ventricular Carcinoma:*** Ventricular carcinomas are infrequent in comparison to proventricular carcinomas but the clinical signs are similar (Figure 25.15).[79,104] These neoplasms have not been reported to metastasize. Microscopically, the appearance of ventricular carcinoma is similar to proventricular carcinoma except secretory cells are PAS-negative. The koilin secretory product is strongly alcian blue-positive. A single ventricular adenoma has been reported in a parrot but the neoplasm was not characterized.[49]
- ***Papillomas:*** Papillomas are reported to occur within the proventriculus and ventriculus.[24,55] They are apparently more common in the ventriculus.[55]
- ***Proventricular Adenoma:*** A proventricular adenoma has been observed in a teal. On gross examination, the proventriculus was spherical instead of fusiform. The luminal surface was covered by a hemorrhagic, fibrillated, plaque-like mass. Histologically, the mass was composed of tubuloacinar structures lined by one-to-four layers of short, columnar epithelial cells. Cellular nuclei were centrally located, vesicular and had a small nucleolus. Cellular cytoplasm was basophilic. Few mitotic figures were observed and fibrovascular stromal tissue was minimal. Hemorrhage and necrosis were present near the luminal surface.[8]

Intestine

Although rare, some neoplasms originating in the small intestine have been reported. Intestinal neoplasms can best be managed by surgical excision and intestinal anastomosis if the lesions are diagnosed early, if metastasis has not occurred and if the site can be adequately exposed.

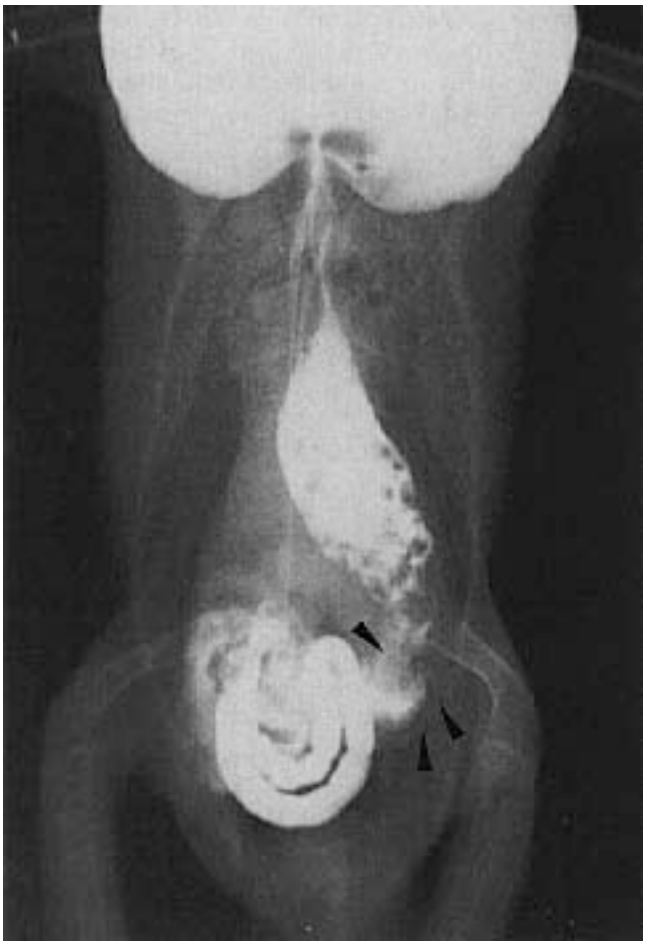

FIG 25.15 A six-year-old male budgerigar was presented with a history of regurgitation and weight loss. Radiographs taken 30 minutes after the administration of barium sulfate indicated filling defects in the proventriculus (consistent with ingesta) and an indistinct and irregular mucosal pattern in the lateral wall of the ventriculus (arrows) (consistent with neoplasm) (courtesy of Jane Turrel).

- ***Leiomyosarcoma:*** Primary intestinal leiomyosarcomas have been observed in budgerigars. Metastatic lesions were not observed.[15,133]

- ***Intestinal Carcinoma:*** Intestinal carcinoma has been reported in a budgerigar, duck and gull.[15,49,72] Metastatic foci were observed within the lung, liver and spleen.[72]

Cloaca

Cloacal neoplasms and masses, including papillomas, adenocarcinomas, and adenomatous polyps and hyperplasia are observed most commonly in psittacine birds, especially Amazon parrots.[35,37,49,51,55,65,102,136]

- ***Cloacal Papilloma:*** Cloacal papillomas are recognized frequently in psittacine birds.[37,55,65,102,136] Cloacal papillomas and bile duct carcinoma may show concurrent development, especially in Amazon parrots.[55,65] Grossly, cloacal papillomas appear as broad-based, pink-to-red, proliferative-to-ulcerative masses. They may closely resemble granulation tissue (see Color 19). Major clinical signs associated with cloacal papillomas are straining, bleeding from the vent and cloacal prolapse. A viral etiology has been suggested for these neoplasms, but has yet to be confirmed.[136]

  Histologically, cloacal papillomas are composed of hyperplastic epithelium over a base of fibrovascular stroma. The epithelium may vary from 10- to 50-cell layers in thickness. Depending upon the biopsy site, epithelial cells may exhibit a transition from columnar to squamous morphology. Epithelial cells on the luminal surface may contain basophilic intracytoplasmic mucin granules that can be demonstrated by alcian blue and mucicarmine staining.[136]

- ***Cloacal Carcinoma:*** Cloacal carcinomas are observed infrequently compared to papillomas.[49,51,102,136] Histologically, these neoplasms contain a more pleomorphic epithelium, characterized by dysplasia and bizarre mitoses.[136] Transmural cellular invasion and penetration of the cloaca may be associated with sclerosing fibroplasia.[51,102]

- ***Cloacal Adenomatous Polyp or Hyperplasia:*** Histologically, these lesions are characterized by epithelial cell hyperplasia resulting in a visible mass.[35,102] It seems reasonable that a progression of cloacal lesions occurs, ranging from hyperplasia to neoplasia (usually benign papillomas). Furthermore, cloacal papillomas may rarely undergo malignant transformation to adenocarcinomas.

Hepatic Neoplasms

Both primary and metastatic neoplasia occur in the liver. The most frequent primary hepatic neoplasms are hepatocellular carcinoma and bile duct carcinoma. Conditions that must be differentiated from neoplasia include hepatic nodular hyperplasia, bile duct hyperplasia and biliary cysts (see Color 20).

- ***Cholangiocarcinoma:*** Cholangiocarcinoma (cholangiocellular carcinoma, bile duct carcinoma) originates from bile duct epithelium. This is the most frequent hepatic neoplasm reported in captive and free-ranging birds (lymphoid neoplasms are most common in gallinaceous birds).[1,2,5,49,50,72,102,103,108,147,148] Specific clinical signs are infrequent, although emaciation, weakness, hepatomegaly, ataxia, trembling

and seizures have been observed.[2,50,148] Some neurologic signs are suggestive of hepatoencephalopathy.

On gross inspection, the hepatic parenchyma contains numerous, variably sized, firm, white-to-tan nodules. Histologically, these neoplasms consist of columnar-to-cuboidal epithelial cells arranged in ribbons, cords, tubules or ducts. Infiltration of the hepatic parenchyma is apparent. A few mitotic figures may be observed. In some neoplasms, a scirrhous reaction may be present.[1,2,50,148]

Cholangiocarcinomas may exhibit vascular invasion with subsequent widespread metastasis to the lungs, brain, kidney, pleura and serosa of the ventriculus.[1,43,72,102,147,148] There is no available treatment for cholangiocarcinoma.

- ***Cholangioma:*** Cholangiomas are of bile duct epithelial origin and are rare in comparison to cholangiocarcinoma.[49,108] Cholangiomas may occur as single or multiple, firm nodules. Histologically, they appear as epithelial-lined tubular structures with a dense fibrous stroma.[108]

- ***Bile Duct Hyperplasia:*** Bile duct hyperplasia is observed with some frequency in psittacine birds with liver disease. Bile duct hyperplasia is often seen concurrently with hepatic fibrosis and hepatocellular lipidosis. The gross and microscopic appearance of some livers may mimic cholangiocarcinoma. The etiology of bile duct hyperplasia is often undetermined; however, ingestion of mycotoxin-contaminated feed should be considered in the differential diagnosis (see Chapter 20).

- ***Biliary Cyst:*** Biliary cysts are reported infrequently in birds.[95] Such cysts are generally congenital and may be intra- or extra-hepatic. Biliary cysts may be observed in conjunction with polycystic kidneys.

- ***Hepatocellular Carcinoma:*** In captive and free-ranging birds, the incidence of hepatocellular carcinoma is superseded only by cholangiocarcinoma.[12,43,51,108] Birds with hepatocellular carcinoma frequently present in a debilitated state with enlargement of one liver lobe. Abdominal enlargement may be apparent on physical examination.

  Antemortem liver lobe enlargement may be confirmed by radiography, ultrasound, endoscopy or laparotomy. Postmortem confirmation of liver lobe enlargement is made by visual inspection at necropsy. Neoplasms may vary in size and color, ranging from light tan to a more normal red-brown. Microscopically, these neoplasms are composed of cords of hepatocyte-like cells with effacement of normal tissue architecture. Bizarre-to-multinucleated hepatocytes may be observed. Variable numbers of mitotic figures are present.[43,108]

  Metastases are rare, but when they occur the lungs are usually involved.[43,147] Partial or full hepatic lobectomy may be attempted to excise these neoplasms.

- ***Hepatocellular Adenoma:*** Hepatocellular adenoma (hepatoma) is poorly documented in birds, having been reported in a cissa, guineafowl, hornbill and mynah bird.[49,72,131,147] The multiple nodules within the hepatic parenchyma of the mynah bird were associated with osseous metaplasia and extramedullary hematopoiesis. These nodules probably represented hepatic nodular hyperplasia.[131]

- ***Nodular Hyperplasia:*** Nodular hyperplasia of the liver may be viewed as attempted parenchymal regeneration following injury. Nodular hyperplasia is usually an incidental finding at necropsy in birds with evidence of chronic liver disease.[64] The gross appearance of these pale nodules may be mistaken for hepatocellular adenoma or adenocarcinoma. The most common associations with nodular hyperplasia are mycotoxin exposure and iron-accumulating hepatopathy.

- ***Miscellaneous Hepatic Neoplasms:*** Miscellaneous neoplasms described in the liver include malignant lymphoma, fibrosarcoma, hemangioma, hemangiosarcoma and lipoma.[12,64,102,108,109] Myelolipomas also may arise within the hepatic parenchyma. Furthermore, the liver may be involved in hematologic neoplasia, which can be difficult to distinguish from extramedullary hematopoiesis.

Pancreatic Neoplasms

Most pancreatic neoplasms reported in birds arise from the exocrine pancreas, especially ductular structures. These neoplasms may be single or multiple. Neoplasms arising from the endocrine pancreas are rare.

- ***Pancreatic Adenoma:*** Pancreatic adenomas occur in psittacine birds, especially Amazon parrots, macaws and budgerigars.[15,49,56] In Amazon parrots, pancreatic adenomas may be associated with internal papillomas or may be observed as incidental findings at necropsy.[56]

  On gross inspection, multifocal pancreatic adenomas usually are observed associated with ductular struc-

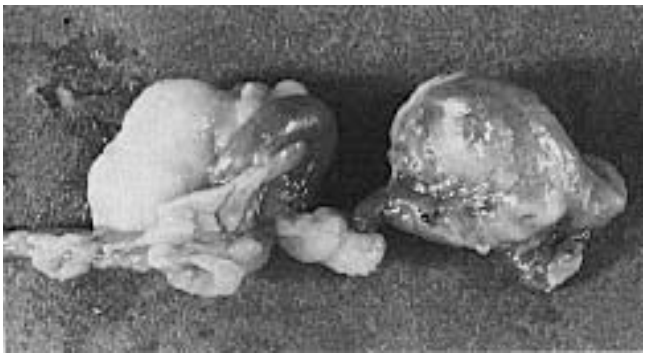

FIG 25.16 Pancreatic carcinoma with involvement of the serosal surface of the intestines in a cockatiel (see Color 25.6) (courtesy of Cheryl Greenacre).

tures. Intraductal neoplasms may cause local distention of affected ducts with concurrent compression atrophy of the adjacent pancreatic parenchyma.[56]

Histologically, these neoplasms are composed of proliferating columnar epithelial cells arranged in cords or papillary projections. Epithelial cell proliferation may be accompanied by fibroplasia.[56]

- ***Pancreatic Adenocarcinoma:*** Pancreatic adenocarcinoma may be observed in various species of birds including psittacines, doves, Anseriformes and ratites.[49,56,72,108,137] These neoplasms occasionally may be quite large, envelop bowel loops and result in abdominal effusion.[137] They are not amenable to treatment (Figure 25.16).

Histologically, adenocarcinomas are composed of a pleomorphic population of epithelial cells that infiltrate or dissect local tissues. Metastasis may occur, usually by serosal seeding.[56] Pancreatic adenocarcinoma should be a diagnostic consideration when carcinomatosis is observed (Color 25.6).

Endocrine System

The endocrine system is composed of widely distributed tissues, glands and organs. The endocrine system, in conjunction with the nervous system, maintains homeostasis by the ability to synthesize, store and release various hormones. These hormones are distributed via the blood to effector cells, tissues or organs where their biological effect is mediated. Neoplasms usually affect only one endocrine cell type. Rarely, neoplasia will involve two or more different endocrine cell lines, a condition called multiple endocrine neoplasia. Evidence suggests that multiple endocrine neoplasia occurs in birds as well as in mammals.[49]

Pituitary Gland

Pituitary neoplasms are the most frequently reported endocrine neoplasm in birds and there is no effective treatment for them.[10,12,102,121]

- ***Pituitary Adenoma:*** Pituitary adenoma is the most frequently reported endocrine neoplasm of birds, especially budgerigars.[10,12,15,39,49,102,108,121] These neoplasms often originate from proliferation of chromophobe cells in the anterior lobe. Because of the anatomic location of the pituitary gland, expansive neoplasms follow the path of least resistance, compressing the hypothalamus and optic chiasm. Neurologic signs resulting from compression include incoordination, poor perching or posture, somnolence, seizures and convulsions, and visual impairment including blindness associated with dilated, fixed pupils.[10,12,39,102,108,121] Unilateral or bilateral exophthalmos may result from neoplastic cell infiltration along the optic nerve(s).[121]

Pituitary adenomas also may be associated with polydypsia and polyuria.[10,12,39,102] The mechanisms of polydypsia and polyuria have not been investigated in birds, but may be caused by decreased antidiuretic hormone (ADH) concentrations or by over-production of adrenocorticotrophic hormone (ACTH). Compression of the posterior lobe of the pituitary decreases ADH transport and storage with subsequent diuresis. Excessive production of ACTH might cause adrenal cortical hyperplasia with excess corticosterone secretion and steroid-induced diuresis.

Pigment changes such as alterations in feather coloration pattern and cere color have been reported in a cockatiel and budgerigar; however, hormonal changes were not investigated.[10,39]

Necropsy usually reveals a mass in the location of the pituitary that compresses the overlying hypothalamus. Microscopically, these neoplasms are composed of round-to-cuboidal cells arranged in sheets or sinusoidal patterns containing a delicate fibrovascular stroma. Cells have round nuclei, stippled chromatin and variable quantities of cytoplasm. In chromophobe adenomas, the cytoplasm stains poorly. Mitoses are infrequent and a remnant of the pars distalis may be apparent.[88]

- ***Pituitary Carcinoma:*** Pituitary carcinomas are rare neoplasms in birds, but have been reported and characterized in two budgerigars.[121] Neoplastic cell invasion of the brain and formation of retrobulbar masses have been observed, along with distant metastasis to the liver and kidney. Histologically, these neoplasms are highly cellular and may contain foci of necrosis and hemorrhage. Confirmation of metastasis supports the presumptive diagnosis.

Pineal Gland

Neoplasms of the pineal gland are rare. These expansive neoplasms may displace or compress adjacent neural tissue resulting in neurologic deficits. Because of their anatomic location, surgical excision of pineal gland neoplasms is virtually impossible.

- ***Pineoblastoma:*** A pineoblastoma has been described in a cockatiel.[151] Clinical signs included polydypsia, depression, right-sided head tilt and inability to grasp objects with the right foot.

  Necropsy examination disclosed a grey suprathalamic mass extending into the right ventricle and compressing the right occipital lobe and thalamus. Microscopically, the mass consisted of sheets, cords and fewer palisades of round cells with round-to-oval nuclei, stippled chromatin and lightly basophilic cytoplasm. A delicate fibrovascular stroma was present. Occasional mitotic figures were observed throughout the mass.

- ***Pinealoma:*** Pinealoma has been reported in two chickens and a dove.[22,108,138] The neoplasm apparently was an incidental finding in one chicken from a flock exhibiting increased mortality and trembling.[138] The neoplasm in the dove was a serendipitous discovery during postmortem assessment of cranial trauma.[108]

  On microscopic examination, the mass was encapsulated, cellular and displaced cerebellar folia and extended deeply between them. The mass had a lobular architecture, with some lobules containing single layers of ciliated columnar-to-pseudostratified-columnar epithelium. Neoplastic cells contained round-to-oval nuclei exhibiting mild anisokaryosis. Mitotic figures were observed occasionally.

Thyroid Gland

Enlargement of the thyroid glands may be observed with hyperplasia or neoplasia. Signs of thyroid gland enlargement may include dyspnea and a distinctive squawk on vocalization.[6,12,118] Their anatomic location near the thoracic inlet precludes palpation of masses unless glandular enlargements are extreme.[6] Thyroid hyperplasia can be managed medically. Theoretically, thyroid neoplasia can be managed surgically, but diagnosis and extirpation of intrathoracic lesions are difficult.

- ***Thyroid Hyperplasia:*** Thyroid hyperplasia (goiter) may be associated with iodine-deficient diets, ingestion of goitrogenic plants such as *Brassica* species, exposure to iodine-containing disinfectants or excessive dietary iodine.[88,115] Thyroid hyperplasia is manifested by bilateral glandular enlargement. Colloid-distended follicles may result in glandular enlargements reaching 20 mm in diameter.[12] Because of improved diets for companion birds, thyroid hyperplasia is reported less frequently than three decades ago.[6,12,15,118]

  On gross necropsy examination, the thyroid glands are bilaterally enlarged and may appear cystic. Histologic sections of thyroid gland contain large, irregular follicles that are lined by columnar epithelium and distended with light-pink colloid. Papillary projections of epithelium may protrude into the lumen of some follicles (see Chapter 23).

- ***Thyroid Adenoma:*** Thyroid adenomas are usually unilateral but may occasionally cause bilateral glandular enlargement. These neoplasms usually represent incidental necropsy findings in birds.[12,15,49,108]

  Histologically, thyroid adenomas are poorly characterized in birds. Most thyroid adenomas appear as nodules of encapsulated glandular tissue.

- ***Thyroid Carcinoma:*** Thyroid carcinomas are rare and poorly characterized in birds.[12,49,102] Thyroid gland enlargement may be unilateral or bilateral. Dyspnea may be a presenting complaint.[102] Histologically, thyroid carcinomas may appear nodular, poorly encapsulated and invasive. These neoplasms are highly vascular.

Adrenal Gland

In contrast to mammals, avian adrenal glands have no distinct cortex or medulla. Both interrenal (cortical) and enterochromaffin (medullary) cells are intermingled throughout the gland.[109] Adrenal neoplasms are rare in captive and free-ranging birds and have not been studied in detail. When enlargement of the adrenal glands is observed at necropsy, a primary consideration is adrenal gland hyperplasia.

- ***Adrenal Adenoma:*** Adrenal adenomas arise from interrenal (cortical) cells and have rarely been re-

ported in birds and generally are not associated with clinical signs of disease.[15,49,108]

Histologically, affected adrenal glands are replaced by a lobulated mass of tubuloacinar tissue. Epithelial cells appear pale with foamy cytoplasm and centrally located nuclei. Mitotic figures are uncommon.[108]

- ***Adrenal Carcinoma:*** Adrenal carcinoma was described in a Mountain Duck that was depressed and had leg paralysis.[43]

The adrenal gland neoplasm was unilateral and composed of a pleomorphic population of polyhedral-to-elongated cells arranged in a frond-like pattern. Marked anisocytosis and anisokaryosis was apparent, including the presence of tumor giant cells. Mitoses were observed infrequently. Neoplastic cells infiltrated adjacent nerves.[43]

- ***Pheochromocytoma:*** A single pheochromocytoma has been reported in a Mouflon, but clinical, necropsy and histologic findings were not discussed.[49]

Endocrine Pancreas

- ***Islet Cell Carcinoma:*** The islets of Langerhans constitute the endocrine portion of the pancreas. These scattered islets are composed of a diverse aggregation of alpha, beta and delta cells that secrete glucagon, insulin and gastrin, respectively. Islet cell neoplasms may be secretory or non-secretory. Secretory islet cell neoplasms may have diverse clinical presentations.

An islet cell carcinoma has been reported in a budgerigar with hyperglycemia.[116] The neoplasm was presumed to be of alpha cell origin and associated with glucagon hypersecretion and diabetes mellitus, but this assumption was not proven. It must be noted that in health, birds have higher glucose values than mammals. In stressful situations, avian blood glucose values may temporarily approach or exceed 700 to 800 mg/dl. Therefore, persistent and dramatic hyperglycemia must be present to confirm a diagnosis of avian diabetes mellitus.

Histologically, this islet cell carcinoma consisted of nests and lobules of pleomorphic, pale-staining cells with vesicular nuclei and a moderate mitotic index. The neoplasm was poorly circumscribed and contained a delicate fibrovascular stroma. Both compression and invasion of the adjacent exocrine pancreas were observed.[116]

Chemoreceptor Neoplasms

Chemoreceptors, in concert with the parasympathetic and sympathetic nervous systems, regulate blood pH, pCO_2 and pO_2. These neoplasms are very rare in birds. A carotid body tumor has been reported in a parakeet, but no details of the neoplasm were presented.[15]

Nervous System and Eye

Nervous system and ocular neoplasms apparently are infrequent in birds with the exception of pituitary adenomas in budgerigars and malignant lymphoma (leukosis) in chickens.[48,49,121]

Central Nervous System

Neoplasms of the central nervous system may represent an interesting incidental finding at necropsy or may be related to profound neurologic deficits from compression and infiltration of neural tissue, obstruction of cerebrospinal flow, or secondary edema, hemorrhage or necrosis. These neoplasms have a poor prognosis, and effective treatment regimens have yet to be developed (Color 25.14). The discussion below is confined to those neoplasms recently reported in birds.

- ***Astrocytoma:*** An astrocytoma is a differentiated neoplasm of astrocytes that exhibits slow but progressive growth. These neoplasms usually arise in the cerebral hemispheres, thalamus, brainstem, cerebellum or spinal cord.[88] A single astrocytoma has been reported in a duck with neurologic signs (especially circling).[108] At necropsy, a lobulated mass was identified in the base of the cerebellum. Histologically, the neoplasm was lobulated and unencapsulated with large globular cells in a fibrillar network.[108] The tumor description suggests a gemistocytic astrocytoma.

- ***Glioblastoma:*** A glioblastoma is an undifferentiated neoplasm of astrocyte origin. These neoplasms grow rapidly, infiltrate surrounding neural tissue, and are very destructive. A glioblastoma has been described in a budgerigar with weakness, incoordination, inability to perch properly, tremors of the wings and rigidity of the legs.[106] Gross brain lesions were not observed at necropsy. Microscopically, a circumscribed mass occupied a large area of the diencephalon and mesencephalon. Neoplastic cells were pleo-

Oncology

Color 25.1
A ten-year-old Amazon parrot was presented with a one-year history of progressive swelling of the head and face. Numerous masses were palpable throughout the body, and their occurrence was confirmed by radiographs (see Figure 25.2). Histopathology indicated an invasive fibrosarcoma involving the soft tissues and bones of the head (courtesy of Jane Turrel).

Color 25.2
A six-year-old budgerigar was presented with a large, featherless mass involving the ventral abdomen. The mass interfered with the bird's ability to fly and perch. Cytology indicated a lipoma with xanthomatosis of the skin overlying the mass (note the yellowish, thickened skin). The tumor and associated xanthoma were surgically excised (courtesy of Jane Turrel).

Color 25.3
A four-year-old African Grey Parrot was presented with a history of anorexia, weight loss and depression. The bird did not respond to supportive care. Hepatomegaly and splenomegaly with raised white nodules in the liver were noted at necropsy. Histopathology revealed an accumulation of lymphoid cells in the nodules, consistent with a diagnosis of lymphosarcoma (courtesy of Jane Turrel).

Color 25.4
A five-year-old male budgerigar was presented for abdominal distention and left limb paresis. The bird did not respond to supportive care. Necropsy findings included seasonal testicular (t) hypertrophy (which should not be confused with neoplasm) and a renal mass (arrow). The renal mass was histologically identified as a renal carcinoma (courtesy of Jane Turrel).

Color 25.5
A five-year-old budgerigar was presented with a rapidly growing firm mass on the dorsal surface of the wing. Cytology indicated a pleomorphic population of spindle cells suggestive of fibrosarcoma. The mass was limited to the soft tissue of the wing and did not involve the underlying bones. The case was managed by amputating the affected wing (courtesy of Jane Turrel).

Color 25.6
An adult female cockatiel was presented for weight loss and a distended abdomen. On physical examination, the bird was bright, alert and responsive, and weighed 91 g but was severely emaciated as detected by pectoral muscle atrophy. The abdomen was severely dilated and had a fluid consis tency. Abdominocentesis was used to collect 10 mls of fluid that was used for cytologic evaluation. The fluid had the characteristics of a modified transudate and contained cells suggestive of neoplasm. The bird did not respond to supportive care. At necropsy, 20 mls of fluid were removed from the distended abdomen. A large mass was filling the space between the descending and ascending duodenum that is normally occupied by the pancreas. The histologic diagnosis was multicentric, anaplastic pancreatic carcinoma with carcinomatosis of the serosal surfaces of the abdomen and the tunica muscularis of the intestines (courtesy of Cheryl Greenacre).

Color 25.7
A captive Blue Jay was presented with a crusty, hemorrhagic, poorly defined mass on the wing. The lesion first appeared as a non-healing wound that progressively enlarged over a period of several months. Biopsy of the lesion revealed a squamous cell carcinoma (courtesy of Jane Turrel).

Color 25.8
A 50-year-old Amazon parrot was presented with a history of dysphagia, regurgitation and weight loss of several months' duration. Histopathology of the mass confirmed a squamous cell carcinoma (see Figure 25.14) (courtesy of Jane Turrel).

Color 25.9
A two-year-old Umbrella Cockatoo was presented with epiphora and an ocular mass. The mass was debulked and the histologic diagnosis was squamous cell carcinoma. The tumor margin was irradiated with a strontium-90 ophthalmic probe (courtesy of Jane Turrel).

Color 25.10
A three-year-old cockatoo was presented with bilateral foot lesions characterized by depigmented, scaly, hard, thickened skin. The lesions were suggestive of a viral-induced papilloma. If not associated with any specific dysfunction, lesions such as these can remain untreated (courtesy of Jane Turrel).

Oncology

Color 25.11
A mature, male cockatiel was presented with a several-month history of poor generalized feather condition and feather loss around the uropygial gland. A raised, firm, uropygial gland mass was evident. Cytology of the mass revealed multiple mitotic figures. The mass was surgically removed and the histopathologic diagnosis was adenocarcinoma.

Color 25.12
A four-year-old female cockatiel on an all-seed diet was presented with a three-month history of a progressively enlarging abdominal mass. On presentation, the ventral surface of the mass was dragging on the ground and the bird was having trouble ambulating. The bird weighed 128 g. Note the rotund appearance of the pelvic musculature. This bird responded to a change in diet and increased exercise over a three-month period, followed by surgical excision of the mass that was half its original size at the time of surgery.

Color 25.13
A four-year-old female African Grey Parrot was presented for removal of a fibrosarcoma from the left dorsal humerus. Surgery was complete and uneventful. The bird was presented one year later with lethargy, anorexia, ataxia and severe dyspnea. Radiographs indicated a large, soft tissue mass in the cranial thorax. Cytology of a fine-needle aspirate indicated ovoid cells with large, eccentric nuclei suggestive of a neoplasm. The bird did not respond to supportive care. Histopathology revealed a renal tubular adenocarcinoma with metastasis to the lung, liver and myocardium. Interestingly, the bird's mate died from adenocarcinoma two years earlier.

Color 25.14
A four-year-old Blue-fronted Amazon Parrot was presented for an acute onset of depression and apparent blindness. The only abnormal physical examination finding was mild ataxia. Radiographs of the abdomen were unremarkable. Blood lead and zinc levels were normal. A mild heterophilia (19,000 cells/μl) was the only abnormal clinicopathologic finding. EEGs indicated diffuse cerebral inflammation. The bird would maintain weight and condition with supportive care but would deteriorate when the supportive care was stopped. After two months the bird was euthanatized. The ventral surface of the brain was nodular in appearance. The histopathologic diagnosis was meningioma.

Color 25.15
A two-year-old female cockatiel was presented for feather picking associated with the right carpus. A diffuse, firm, yellow mass was noted in the carpal region on physical examination. The appearance of the lesion was suggestive of xanthoma, and the demonstration of vacuolated macrophages, lipids and cholesterol crystals in a fine-needle aspirate from the mass was confirmatory. The xanthoma was surgically excised.

Color 25.16
A mature Amazon parrot was presented with a non-weight-bearing lameness of one week's duration. Radiographs indicated a fracture of the mid-diaphyseal tibiotarsal bone. During surgery for placement of an IM pin, it was noted that the bone did not appear normal and a biopsy was performed. Surgical recovery was unremarkable. The biopsy report indicated osteosarcoma, and the client chose to have the bird euthanatized. Inset shows the dissected bone, which had healed from the pathologic fracture, with the pin in place.

Color 25.17
An adult Indian Ring-necked Parakeet was presented with a three-month history of a proliferating mass involving the cere and left periocular area. Note the defect in the rhamphotheca, indicating inflammation of the germinative layers of the beak. The masses were surgically removed. Histopathology was suggestive of a papilloma.

Color 25.18
A mature budgerigar was presented with progressive dysphagia, and a disfiguring oral lesion was noted on physical examination. Histologic lesions were consistent with adenocarcinoma.

Color 25.19
A four-year-old budgerigar was presented with a rapidly growing, necrotic mass of the upper beak. The mass was interfering with the bird's ability to eat, and the owners chose euthanasia. Histologic evaluation indicated the mass was a fibrosarcoma (courtesy of Jane Turrel).

Color 25.20
A ten-year-old Umbrella Cockatoo was presented for dysphagia, weight loss and poor feather formation. On physical examination, a large, pendulated, ulcerative sublingual mass was identified. The bird had dystrophic feathers and was positive for PBFD virus by DNA probe testing of whole blood. Cytology of a fine-needle aspirate of the oral mass was suggestive of a giant cell granuloma. Radiographs of the head indicated the extent of the sublingual mass (see Figure 25.13).

morphic and numerous multinucleated giant cells were observed.

- ***Oligodendroglioma:*** This neoplasm originates from oligodendroglial cells. These neoplasms usually arise in the cerebral hemispheres. Microscopically, they are composed of small cells with round, hyperchromatic nuclei arranged in a honeycomb pattern.[88] A single "glioma" has been reported in the left cerebral hemisphere of a budgerigar, but microscopic characteristics of the neoplasm were not reported.[6]

- ***Choroid Plexus Papilloma:*** These benign neoplasms originate from the choroid plexus epithelium, usually in the fourth ventricle at the cerebropontine angle.[88] A choroid plexus papilloma has been observed in a budgerigar with blindness, exophthalmos and seizures.[102] A visible mass was not observed at necropsy; however, the tumor was apparent in tissue section. This neoplasm arose from the choroid plexus of the fourth ventricle. Rows of columnar cells were arranged in irregular papillary projections, small rosettes and contorted cysts. Neoplastic cells were columnar with round-to-oval, basal nuclei.

- ***Neuroblastoma and Ganglioneuroma:*** These neoplasms are derived from primitive neuroepithelial cells that differentiate toward neuroblasts (neuroblastoma) or neurons (ganglio-neuroma).[88] Ganglioneuromas have been reported in chickens where they may arise in the nervous system, gastrointestinal tract, ovary, muscle or heart.[23] These neoplasms are composed of ovoid, pyramidal or irregular neurons scattered among Schwann cells and fibrous stroma. Ganglioneuromas are usually benign, but may be malignant.

- ***Vascular Neoplasms:*** The most common vascular neoplasms observed in the central nervous system are hemangiosarcoma and hamartoma. A hamartoma is a benign tumor-like nodule composed of an overgrowth of mature cells. A hamartoma-like lesion has been reported in the brain of an 11-week-old budgerigar. Microscopically, the lesion was composed of blood-filled spaces within the neuropil that compressed adjacent tissue.[12] Vasoformative neoplasms are frequently observed in chickens; however, brain involvement has not been reported.[74,129]

- ***Teratoma:*** Grossly, these primordial germ cell neoplasms, which may be large and cystic, have been observed in chickens and ducks.[21,23,38,58,61,63,68,76,112] Teratomas have diverse sites of origin including the brain, pineal gland, testis, ovary, kidney, orbit, cranium, thoracoabdominal cavity and retroperitoneal space. Teratomas arising within the cranial vault may cause neurologic deficits such as head tilt, circling and facial nerve paralysis.[68,76]

  The microscopic appearance of these neoplasms is quite striking, containing a mixture of tissue types derived from two or three germ cell layers. The differentiated tissues may include cartilage, bone, fat, keratin cysts, smooth muscle, epithelium, neural cells and melanocytes.

- ***Lymphosarcoma:*** Lymphosarcoma of the central nervous system may be classified as a primary or secondary disease. Primary lymphosarcoma originates in the CNS, while secondary lymphosarcoma represents a metastatic event. Evidence exists for both of these presentations of lymphoid neoplasia in birds, although metastatic neoplasia is more common.[9,49] Most instances of CNS lymphosarcoma occur in poultry and are viral-induced.[20,101] Lymphosarcoma is discussed in detail under the hemolymphatic system.

- ***Meningioma:*** Meningiomas originate from neural crest cells or mesenchymal cells in contact with neural crest cells. Microscopically, meningiomas are often characterized by whorls of crescent-shaped cells.[88] Meningiomas have been reported in chickens, but have not been characterized in detail.[23]

Peripheral Nervous System

Peripheral nervous system neoplasms arise in nervous tissues other than the brain and spinal cord. Localized neoplasms may be amenable to surgical excision based upon their location, size and proximity to vital structures.

- ***Schwannoma:*** These neoplasms previously have been reported as neurolemmomas or neurofibroma, the latter term being a misnomer.[88] Schwannomas may arise from Schwann cells or perineural cells of the peripheral nerve sheaths in any location including unspecified peripheral nerves, cranial nerves, sciatic plexus, gastrointestinal tract, testis, pineal gland, kidney, skin, muscle and spleen.[17,23,85,108]

  Grossly, these neoplasms appear as single-to-multiple nodular masses or varicose thickenings of the nerve sheath. Histologically, fusiform cells are arranged in interwoven bundles, whorls or palisade arrangements. Specific diagnosis relies upon observation of the associated nerve of origin.[17,88]

- ***Malignant Schwannoma:*** Malignant schwannomas (neurofibrosarcoma is a misnomer) also originate

from Schwann cells or perineural cells. These neoplasms have greater cellularity, marked anaplasia, an increased mitotic rate and may metastasize. Malignant schwannomas have been reported to occur in Canada Geese, but histologic studies have failed to demonstrate a neural origin.[82,127] Therefore, those neoplasms should be classified as fibrosarcomas instead of malignant schwannomas.

- ***Lymphoid Neoplasia (Lymphosarcoma):*** Marek's disease in chickens is often associated with leg paralysis secondary to ischiatic nerve infiltration by neoplastic lymphocytes. Affected nerves appear thickened. Microscopically, the lymphoid infiltrates may vary from small lymphocytes and plasma cells to lymphoblasts.[20] The former infiltrates appear inflammatory, while the latter infiltrates clearly are neoplastic.

Ocular Neoplasms

The following discussion is concerned with primary and metastatic intraocular neoplasms of birds. Neoplasms involving the eyelids, conjunctiva and orbit are discussed under appropriate organ systems and will not be considered here (Figure 25.17).

Intraocular neoplasms in birds may be associated with blindness, hyphema or aqueous flare. Some neoplasms, such as malignant lymphoma, may be visualized occasionally by ophthalmoscopy. Because the avian eye is reinforced by scleral ossicles, buphthalmos is not expected. In contrast, exophthalmos occurs with some frequency and usually indicates a retrobulbar space-occupying lesion or extension of malignant ocular neoplasia into the retrobulbar area. In birds, exophthalmos has been associated with various retrobulbar neoplasms including malignant lymphoma, pituitary adenoma and adenocarcinoma, malignant intraocular medulloepithelioma, intraocular rhabdomyosarcoma, undifferentiated carcinoma, teratoma, and glioma.[15,23,48,51,100,105,121,122]

- ***Lymphosarcoma:*** Lymphosarcoma (malignant lymphoma) involving the iris, ciliary body and choroid is observed most frequently in chickens with Marek's disease.[48] When visualized, these neoplasms may appear as yellow-to-white proliferative masses. Most occurences of ocular lymphoid neoplasia represent metastatic lesions.

- ***Rhabdomyosarcoma:*** Intraocular rhabdomyosarcomas have been reported in two chickens.[48] These neoplasms may have arisen from the ciliary muscles, which are striated in birds. One neoplasm extended into the retrobulbar space. The other neoplasm replaced the iris, ciliary body and choroid.

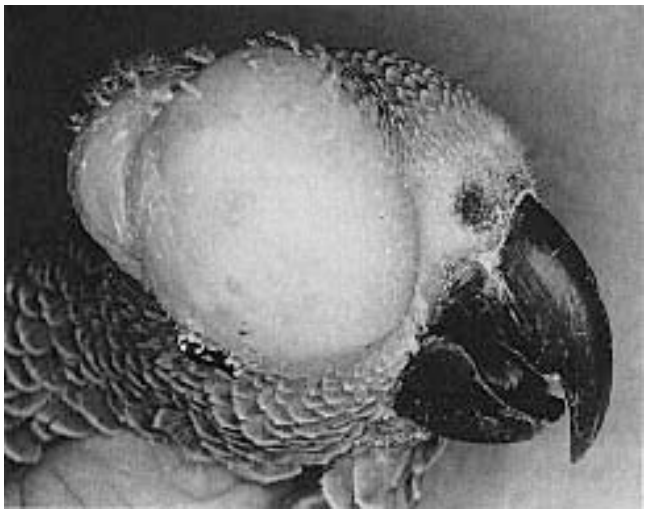

FIG 25.17 A mature African Grey Parrot was presented with a space-occupying mass involving the right periorbital area and globe. The mass was surgically removed in conjunction with enucleation. The mass reappeared two years later and the bird was euthanatized.

- ***Malignant Medulloepithelioma:*** Intraocular medulloepitheliomas are primitive neoplasms that originate from the optic cup epithelium[88] and have been described in two cockatiels.[122] The neoplasms were composed of tall columnar neuroepithelial cells with well defined limiting membranes. These cells were arranged in nests, sheets and rosettes. Foci of necrosis also were observed. Neoplastic cells extended into the retrobulbar spaces, infiltrating the optic nerve and adjacent skeletal muscle.

- ***Malignant Melanoma:*** Metastatic ocular malignant melanoma has been reported in a Pintail Duck in association with multiple neoplasms involving adrenal gland, skin, liver, skeletal muscle, heart, lung, kidney, brain and bone.[72]

Hemolymphatic System

The hemolymphatic system encompasses those tissues and organs that are involved in leukocyte, erythrocyte and thrombocyte production. The bone marrow produces thrombocytes, erythrocytes and most of

the leukocytes with the exception of lymphocytes. Lymphocyte production occurs within lymphoid tissues, which can be divided into primary and secondary lymphoid tissues. The thymus and bursa of Fabricius are the primary lymphoid tissues. The secondary lymphoid tissues are more diverse and, depending upon the species of bird, include the spleen; conjunctival, nasal and bronchial-associated lymphoid tissues; cecal tonsils, Peyer's patches, Meckel's diverticulum and other gut-associated lymphoid tissues; lymph nodes and lymphoid aggregates distributed throughout the body.[109] The majority of the lymphocytes are produced in the secondary lymphoid tissues.

Clinical signs related to hemolymphatic neoplasia are variable and vague including lethargy, anorexia, weight loss, lameness, swellings, dyspnea, loose droppings and petechial-to-ecchymotic hemorrhages. Death often occurs from organ dysfunction secondary to infiltrative disease.

Lymphoid Neoplasia

Lymphoid neoplasia is the most common form of hemolymphatic neoplasia occurring in domestic, captive, and free-ranging birds.[9,20,49,70,72,97,108,146] This form of neoplasia may originate from the peripheral lymphoid tissues as lymphosarcoma (malignant lymphoma) or in the bone marrow as leukemia.

Lymphoid neoplasia of poultry has been studied extensively. In chickens, lymphoid neoplasms may be induced by herpesvirus or retrovirus infections. Herpesvirus infection causes Marek's disease. In this disease, early lymphoid infiltrates may appear inflammatory and consist of a mixture of small lymphocytes, plasma cells and lymphoblasts. Following neoplastic transformation, lymphoid neoplasms appear more progressive and are composed of lymphoblasts. In contrast, lymphoid leukosis is caused by retroviral-induced neoplastic transformation of B-lymphocytes. The presentations of Marek's disease and lymphoid leukosis may differ considerably.[20]

Lymphoid neoplasia of free-ranging and captive birds has not been studied in detail. A recent pathologic survey subclassified avian lymphoid neoplasia as plasmacytoma or fibrifying, lymphoblastic, lymphocytic or mixed-cell lymphosarcoma.[108] However, the prognostic importance of these subclassifications has not been demonstrated and requires further clinicopathologic study.

Currently, there is no effective treatment for avian lymphoid neoplasia. Radiation therapy may be palliative.[100] Combination chemotherapy with vincristine sulfate, prednisone and chlorambucil appears promising but requires more clinical research.[93]

- ***Lymphosarcoma:*** Lymphosarcoma (malignant lymphoma) is defined as any lymphoid neoplasm that originates in the peripheral lymphoid tissues. This form of lymphoid neoplasia is commonly observed in birds and is characterized by the formation of white-to-yellow tissue discolorations or sarcomatous masses.

  Lymphosarcoma usually presents as a disseminated multisystemic disease that can involve all tissues of the body, including bone marrow.[9,20,97,108,146] The abdominal viscera often are involved (visceral leukosis), especially the liver, spleen and kidney (Color 25.3). Occasionally, lymphosarcoma may show tissue tropism with multiple neoplasms being observed in one tissue such as skin.[9] The rarest presentation of lymphosarcoma is the presence of a single, localized neoplasm. This presentation was documented as a single neoplasm at the optic chiasm of a cockatiel.[9]

  A presumptive diagnosis of neoplasia may be apparent after physical examination by observing swellings of the skin or retrobulbar masses.[9,100,105] Abdominal enlargement and hepatomegaly also may be present. In addition, soft tissue masses, hepatomegaly or osteolysis may be detected or confirmed radiographically.[100,105] A complete blood count may be beneficial in diagnosing lymphoid neoplasia by detecting lymphocytosis and demonstrating variable numbers of immature (neoplastic) lymphocytes in the blood film.[9] The latter finding is termed a "leukemic blood picture" and indicates hematogenous dissemination of the neoplasm.

- ***Lymphoid Leukemia:*** Lymphoid leukemia originates in the bone marrow and disseminates to various body tissues. This presentation of lymphoid neoplasia is rare compared to lymphosarcoma.[93] Birds with lymphocytic leukemia may have anemia, thrombocytopenia and marked lymphocytosis. Lymphocytes in blood smears may be well differentiated or blastic. Bone marrow aspirates contain innumerable lymphocytes. Sarcomatous masses are not observed in tissues at necropsy; however, hepatosplenomegaly may be prominent. Infiltration of various tissues by neoplastic lymphocytes is observed microscopically.

- ***Thymoma:*** Thymoma is a localized form of lymphoid neoplasia that is confined to one or more thymic lobes. Histologically, thymomas may present as lymphocytic or epithelial masses.

Thymoma has been observed in two budgerigars.[15,152] Only one neoplasm has been described in detail and presented as a palpable mass on the right side of the base of the neck.[152] Histologically, the neoplasm was an epithelial-type thymoma, consisting of aggregates of small lymphocytes and epithelial cells encased in a dense fibrous stroma. The epithelial cells had a "clear cell" morphology.

Nonlymphoid Neoplasia

Nonlymphoid hematologic neoplasia is observed most frequently in chickens infected with certain strains of leukosis (sarcoma) retroviruses.[101] Some strains of virus are associated with the development of granulocytic leukemia (myelocytomatosis) or erythremic myelosis (erythroblastosis).

- ***Granulocytic Leukemia:*** Granulocytic leukemia is the unregulated proliferation of granulocytes. In chickens, this disease (myeloblastosis) is caused by retrovirus infection; the etiology in captive and free-ranging birds has not been identified.[101]

  Granulocytic leukemia in birds is sometimes associated with the formation of sarcomatous masses called myelocytomas. These lesions are analogous to chloromas in mammals. More commonly, tissue infiltration by neoplastic granulocytes results in hepatosplenomegaly. Microscopically, the neoplastic cells appear either blastic (myeloblastosis) or exhibit heterophilic (myelocytic) differentiation.[108] Differentiation is appreciated more readily, however, in blood and bone marrow smears as opposed to histologic sections.

- ***Erythremic Myelosis:*** Erythremic myelosis is the unregulated production of erythrocyte precursors. This form of leukemia is caused by retrovirus infection in chickens and has been called erythroblastosis.[101]

  An erythremic myelosis-like syndrome has been described in conures.[114] Most of these birds appear weak and have a history of spontaneous hemorrhage. Histopathology has documented acute and chronic hemorrhages within various tissues in conjunction with erythrocyte proliferation in the bone marrow, hepatic sinusoids and splenic red pulp.[114] Although the evidence occasionally appears supportive of erythremic myelosis, marked extramedullary erythropoiesis cannot be excluded. In comparison to mammalian erythrocytes, avian erythrocytes have a very short life span (20 to 25 days). Following acute and ongoing hemorrhage, intense extramedullary erythropoiesis could occur, especially with concurrent recycling of iron from internal hemorrhage. Therefore, the conure bleeding syndrome will require further hematologic characterization before it can be classified absolutely as erythremic myelosis.

TABLE 25.1 Specific Treatment Concerns of Neoplasms*

Lipomas	Frequently recur following excision
Liposarcomas	Locally invasive and metastatic
Xanthomas	Excise localized masses, amputate limb if deeper tissues involved, irradiation (see text)
Fibrosarcomas	Generally unrewarding, locally invasive, if in extremeties amputate ASAP
Hemangioma	Highly vascularized and must be excised with great care
Hemangiosarcomas	Frequently recur after surgical excision, amputate affected limb
Leiomyosarcoma	Must excise before metastasis occurs
Rhabdomyomas	Radical excisions necessary, margins difficult to define
Rhabdomyosarcomas	Radical excision before metastasis, bleed extensively
Chondromas/sarcomas	Difficult to remove without extensive damage to surrounding tissues
Osteosarcomas	Remove affected bone or limb; endoscopy, radiology and biopsy to check for metastasis
Renal adenocarcinomas	Generally considered untreatable, radioisotopes hold some promise
Embryonal nephroma**	Non-reported, difficult to remove because of underlying sacral plexus

*Surgical excision is the treatment of choice for all tumors that are not listed.
**All renal tumors are difficult to excise because of potential damage to sacral plexus.

TABLE 25.2 Cytologic and Histologic Differentiation of Integumentary and Connective Tissue Neoplasms and Masses

Mass	Cytology	Histopathology
Lipoma	Abundant free lipid, some intact adipocytes	See text
Myelolipoma	Hematopoietic precursors, differentiated hematopoietic cells, free lipid and intact adipocytes	Hematopoiesis (particularly heterophils) mixed with mature adipose tissue
Liposarcoma	Free lipid, scattered polyhedral cells with cytoplasmic vacuoles similar to xanthomas	See text
Xanthoma	Vacuolated macrophages, multinucleated giant cells, lipids, cholesterol clefts (appear as parallelograms with notched corners), rarely fibroblasts	Lipid-laden macrophages, multinucleated giant cells, cholesterol clefts, varying fibroplasia[117]
Fibrosarcoma	Pleomorphic spindle cells, multinucleated tumor giant cells, similar to reactive fibroplasia	Pleomorphic to spindle-shaped cells, plump nuclei, eosinophilic fibrillar cytoplasm, cells in bundles, sheets, whorls, mitotic figures may be numerous
Fibromas	Sparsely cellular, similar to fibrosarcomas, reactive fibroplasia	Compressed fibroblasts, dense collagenous stroma cells in sheets, swirls, or interlacing bundles
Myxoma/sarcoma	Viscous aspirate, free nuclei, spindle cells (singular or clusters)	Spindle cells in loose collagen matrix, alcian blue-positive mucinous ground substance, rare mitotic figures
Papilloma	See text	See text
Squamous cell carcinoma	See text	See text
Basal cell tumors	See text	See text
Cutaneous lymphosarcoma	See text	Neoplastic lymphocytes in the dermis or pulp cavity
Mast cell tumors	Round cell population with fine, purple cytoplasmic granules that may obscure nuclear detail (Romanowsky stain)	Uniform population of round cells, central round-to-oval nuclei and abundant eosinophilic cytoplasm, metachromatic granules (Giemsa stain)

Cytology based on fine-needle aspirates unless otherwise noted. The presence of lipid in cells and the background of the smears may be indirectly demonstrated by new methylene blue staining (fat- and aqueous-based stains do not mix). Histopathology is usually necessary to definitively diagnose the type of tumor.

CHAPTER

26

OPHTHALMOLOGY

David Williams

In general, the techniques of evaluating the avian eye are similar to those used in mammals. However, the small size of the eye in companion birds and the striated sphincter muscle of the avian iris necessitate modified procedures to visualize the posterior segment of the eye.

Each ophthalmologist has a particular pattern for ophthalmic examination. The key to effective evaluation is to develop a logical, consistent use of the same pattern of examination for each eye.

Before a bird is agitated by restraint, the eyes should be evaluated from a distance, noting whether the bird will fixate on moving objects, whether both pupils are the same size and whether there are any obvious abnormalities in the periorbital area (Figure 26.1). Vision can be difficult to evaluate because birds can feel slight air movements created by an approaching hand. The detailed examination requires adequate restraint, and a darkened room will calm the bird and improve the illumination provided by a focal light source.

Many disease processes affect the external eye and periorbita. Ocular discharge, conjunctival hyperemia or periorbital swelling can be an indication of a primary ocular disorder or may occur secondary to sinusitis or facial dermatitis (see Chapter 24). Some larger Psittaciformes may inflate a portion of their periorbital sinus as an aggressive gesture, creating a transient swelling in the periorbital region (Color 26.7). This swelling should not be mistaken for periorbital disease. Collapse of the anterior chamber may occur in an otherwise normal eye following a period of head restraint or lateral recumbency during anesthesia. Normal anterior chamber depth is rapidly regained.

Examination of the anterior segment can be performed with a bright pen light, a binocular loupe, an operating microscope, an ophthalmoscope set on +20 diopters or, ideally, a slit lamp (Figure 26.2). Key features to evaluate are the clarity of the cornea, the aqueous, the lens and the color and vascularization of the iris. Aqueous flare, as seen in uveitis, can be detected by looking for scattering of a slit light beam that is passing through the anterior chamber (Colors 26.25, 26.26). Pupillary light reflexes can be determined, but because the avian iris is under conscious control, rapid changes in pupil diameter according to

FIG 26.1 Normal periocular area in a Grey-cheeked Parakeet. The eye should be open with a bright, shiny appearance. The lid margins should be evenly colored, dry and symmetrically shaped.

FIG 26.2 A slit lamp is ideal for examining the anterior segment of the avian eye. The lamp can also be used to facilitate evaluation of oral and dermatologic lesions (courtesy of David Williams).

the degree of alertness of the animal can make evaluation difficult.

Retinal examination is difficult in many birds because of the small size of the eye and the lack of response of the avian iris to conventional parasympathomimetic mydriatics. Mydriasis can be accomplished by intracemeral injection of d-tubocurarine or by the frequent use of a freshly prepared topical 3 mg/ml solution of crystalline d-tubocurarine in 0.025% benzilonium chloride over a fifteen-minute period.[5,56] A more practical approach may be the topical use of commercially available neuromuscular blocking agents commonly used for intravenous injections. The most useful regime in raptors has been found to be vecuronium bromide solution (4 mg/ml) topically every five minutes for fifteen minutes (see Chapter 18).[53]

FIG 26.3 Indirect ophthalmoscopy in a cockatiel to evaluate the fundus. A 28 diopter lens is particularly useful but results in an inverted image that requires some practice to interpret (courtesy of David Willaims).

With or without mydriasis, the easiest way to view the fundus is to start with the direct ophthalmoscope at the +20 dioptre setting, and with the instrument close to the bird's eye, change the dioptre setting gradually back to zero. This will bring the pleated pecten into view. It is then possible to focus on the avascular retina at the posterior of the eye. An indirect ophthalmoscope is excellent (Figure 26.3), although an expensive binocular all-pupil model is needed if adequate mydriasis is not achieved. A 28 or 40 dioptre lens is useful to obtain a good field of view in the small avian eye. A 90 dioptre lens used with a slit-lamp provides excellent visualization of a large area of the fundus.

Ancillary Tests for Evaluation of the Eye

Further testing can be used to confirm or refute the presence of suspicious lesions detected by gross observation. Corneal ulcerations can be detected by staining with fluorescein dye. The Schirmer Tear Tests can be used on birds, although normal data for psittacine birds have not been published. Conventional 6 mm-wide Schirmer tear test filter paper strips have been found to be difficult to insert in the lower conjunctival sac of the smaller Psittaciformes; thus trimming these to 4 mm is more useful. This also gives a higher reading of wetted strip length than the 6 mm-wide filter strips, with which the Schirmer tear test results are rarely over 3 in clinically normal

birds. To date, Schirmer tear test readings have been found to be 8 ± 1.5 mm in the larger Psittaciformes such as the African Grey Parrot, and 4.5 ± 1 mm in smaller species such as lories and conures.

The difference in tear production between species is presumably related to the size of the orbit and lacrimal gland tissue. These interspecies differences make it difficult to provide standard normal data for all Psittaciformes. With unilateral problems, comparison between the affected and the unaffected eye may be useful. A normal bird of the same species, ideally an enclosure mate, can also be used for comparative purposes.

Tonometry is possible in birds, but little normal data has been published. The simple indentation Schiotz tonometer cannot be used in smaller birds because of its large footplate, which covers the cornea and sclera in all but the largest avian species. However, the portable Tonopen applanation tonometer is ideal for use in birds. One study indicates that this instrument provided reproducible readings in birds with corneal diameters over 9 mm. Some readings in birds with corneal diameters as small as 5 mm were reliable.[40] This tonometric examination of 275 birds (39 species) showed intraocular pressures in normal eyes of between 9.2 and 16.3 mmHg. Among 14 species of psittacine birds, values were found to be 14.4 ± 4.2 mmHg with a sample size of 74 birds.

Avian periorbital and external eye disease is frequently associated with infectious agents. A consistent technique for sample collection should be used to increase the validity of the sample. The best diagnostic bacteriologic samples can be obtained by inserting a sterile swab moistened in transport medium into the upper conjunctival fornix and rubbing it from side to side two or three times. The upper fornix is the preferred site for collecting culture samples because there is less contamination from environmental organisms than in the lower fornix. Conjunctival scrapings can be stained with a modified Wright's stain for general cytology. A Giemsa stain can be used to detect chlamydial elementary bodies (see Chapters 10, 34).[14]

Anatomy of the Eye

An understanding of the anatomy of the avian eye (Figures 26.4-26.7) and how it differs from the mammalian eye is vital when differentiating between the normal and abnormal.[24,46,52,68,77]

As an overview, the avian eyelids are mobile, the lower more so than the upper. The meibomian glands are absent, but a lacrimal gland (varying in size between species) is present, inferior and lateral to the globe. The Harderian gland acts as a second lacrimal gland at the base of the nictitating membrane (Figure 26.5). The nictitating membrane actively moves over the cornea during blinking and in the menace response (Color 26.1). It has an unusual muscular arrangement; it is drawn across the eye by the pyramidal muscle originating in the posterior sclera and loops over the optic nerve through a sling formed by the bursalis muscle (quadratus muscle.) Inferior and superior nasolacrimal puncta at the medial canthus drain lacrimal secretions into the nasal cavity (Color 26.2).

The orbit is open, but, because the globe occupies the vast majority of the space, the rectus and oblique muscles are not well developed, and torsional movements of the globe are limited in many species to between two and five degrees. A key point in the anatomy of the avian orbit is the close proximity of the tightly packed orbit with the infraorbital diverticulum of the infraorbital sinus (Figure 26.5). Sinusitis and enlargement of this diverticulum will

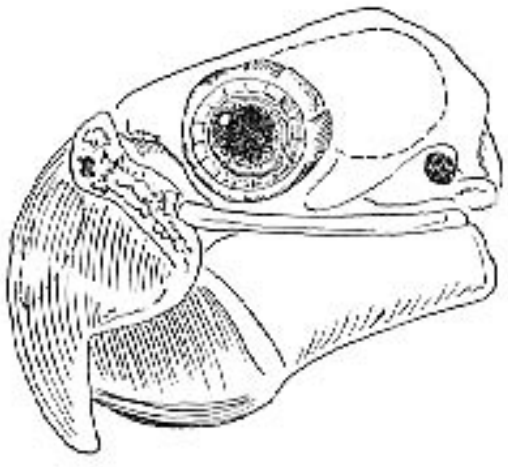

FIG 26.4 Relative size of the globe to the skull.

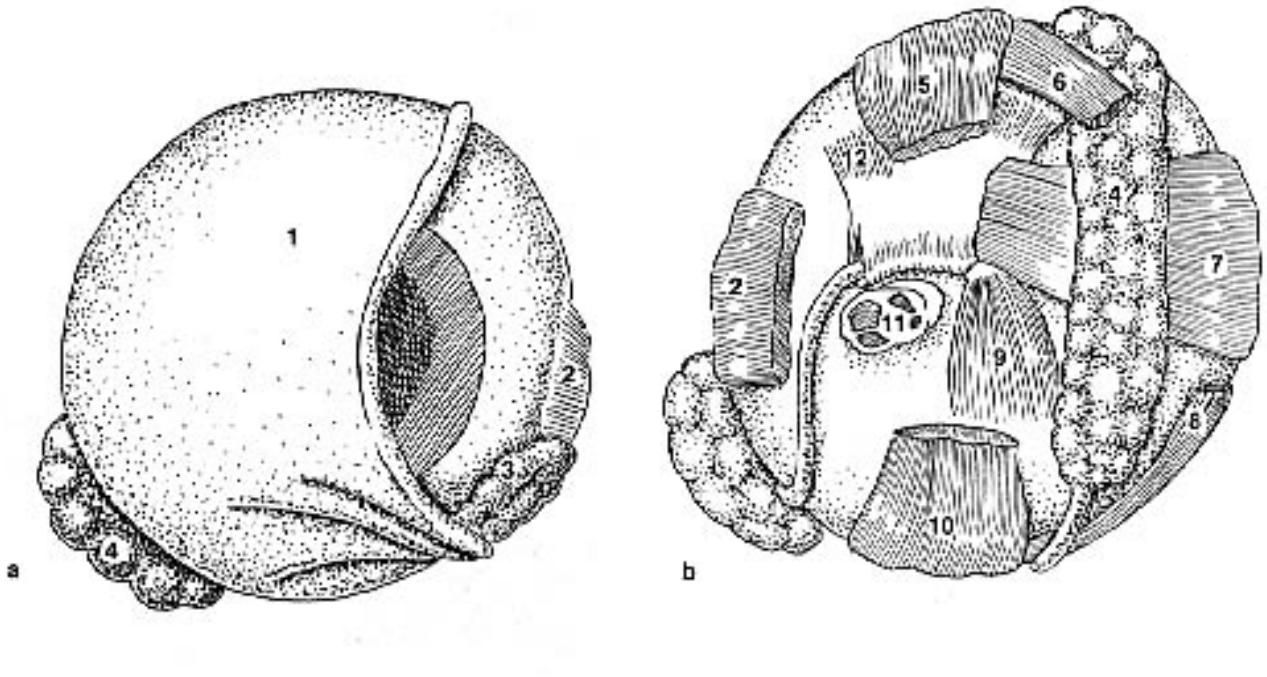

FIG 26.5 **a)** Anterior and **b)** Posterior view of the avian globe. 1) Nictitating membrane 2) M. lateral rectus 3) lacrimal gland 4) gland of nictitating membrane 5) M. dorsal rectus 6) M. dorsal oblique 7) M. medial rectus 8) M. ventral oblique 9) M. pyramidalis 10) M. ventral rectus 11) optic nerve and 12) M. quadratus (modified from Martin[46]).

therefore lead to periorbital or orbital compression and signs of periorbital swelling, conjunctivitis and sometimes intraocular disease (Color 26.16).

In most birds, including Psittaciformes, the globe is anterio-posteriorly flattened, with a hemispherical posterior segment. It is rounded in some diurnal birds and tubular in owls (Figure 26.6). The sclera immediately posterior to the cornea contains scleral ossicles, and through its full circumference, the sclera has a support of hyaline cartilage (Figure 26.7). The avian cornea is similar to that of mammals except that it is considerably thinner, and unlike mammals, it has a Bowman's layer. The thickness of the cornea varies depending on the size of the bird. The anterior segment is relatively shallow compared with the posterior segment, with some anatomic differences noted between species. Owls have an unusually deep anterior chamber (Color 26.21).

The iris is thin and contains striated dilator and constrictor muscles. Varying chromatophores create the different iris colors noted with age, gender and species of some birds. In some white cockatoo species, for example, the iris is dark brown in the adult male and reddish pink in the adult female. Immature cockatoos of both genders have black irides. In the Moluccan Cockatoo, however, the male has a black iris and the female has a dark brown iris, and in most black cockatoo species and in the Goffin's Cockatoo, there is no gender difference in eye color. Young Blue and Gold Macaws have a dark iris that lightens in the first two to three years and then turns yellow as the bird ages. African Grey Parrots have dark muddy-grey irides as young birds, which turn yellowish-grey and then silver as they mature.

Pupillary light reflexes do occur in birds but their interpretation is complicated by the fact that voluntary constriction and dilation of the pupil is possible, even in the absence of retinal stimulation. Clinically, the complete separation of the optic nerves prevents the elicitation of a consensual pupillary light reflex. The iridocorneal angle is well developed in all birds and drains the aqueous fluid, as in mammals. The lens is soft and is almost spherical in nocturnal birds, or has a flattened anterior face in diurnal species including companion birds. An annular pad lies under the lens capsule in the equatorial region, and can be separated from the center of the lens during cataract surgery.

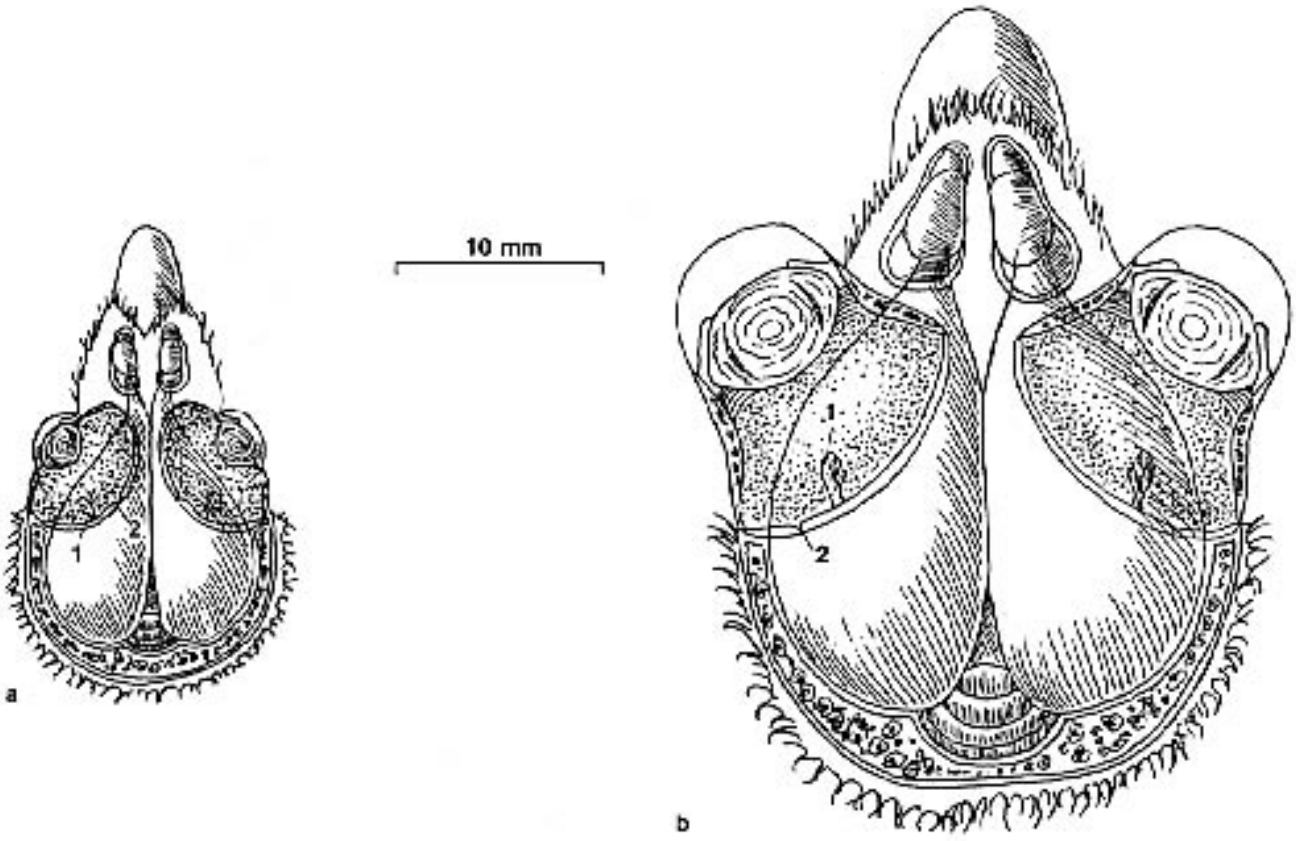

FIG 26.6 **a)** In diurnal birds, like this chickadee and most companion birds, the lens has a flattened anterior surface, whereas **b)** in noctural birds, like this Great Horned Owl, the lens is almost spherical. 1) pecten 2) fovea (modified from Martin[46])

The color of the fundus varies considerably among species; however, all species have a pecten, a comb-like black or brown projection of choroidal tissue that extends into the vitreous (Color 26.35). Recent work has shown that small, regular torsional movements of the eye sweep the pecten through the relatively fluid vitreous. Blood vessels in the pecten disperse a serum filtrate that extends to the peripheral retina.[62] The pecten is thought to provide oxygen and nutrients to the inner portion of the retina. Most species, including Psittaciformes and Passeriformes, have indistinct fovea. Many raptors have one and some diurnal raptors and hummingbirds have two foveae. Macaws have a particularly distinct foveal area that can be evaluated fundoscopically. It is suggested that in bi-foveate birds, one fovea serves for near vision and the other accommodates long-range vision. Birds can distinguish colors and in most cases have excellent visual acuity. Because a bird's sight is so important behaviorally, it is critical that ophthalmologic problems are accurately diagnosed and rapidly resolved.

Ophthalmic Disorders

Lids and Periorbita

One of the most common ocular presentations in large psittacine birds is periorbital disease secondary to upper respiratory infection, particularly chronic rhinitis and sinusitis (Figure 26.8) (see Chapter 22). As stated above, the close proximity of the infraorbital sinus to the orbit predisposes it to physical displacement when the sinus diverticulum is enlarged. In some cases, cellulitis or abscessation occur from spread of organisms from the sinus cavity. Antibiotics alone are rarely efficacious in these cases; flushing the sinus and, in some cases, more aggressive surgical debridement is required (see Chapter 41).

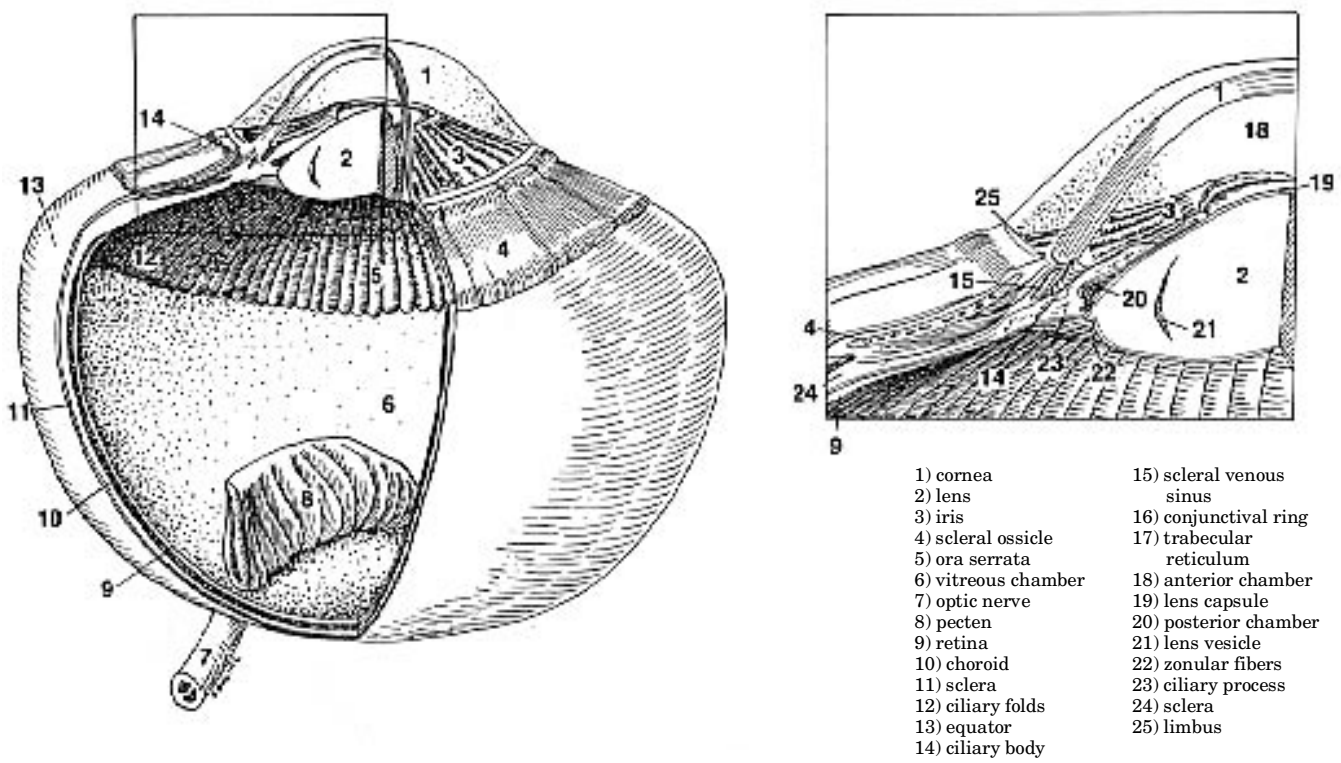

FIG 26.7 Three-dimensional representation of the avian eye; enlarged view of the interior of the eye.

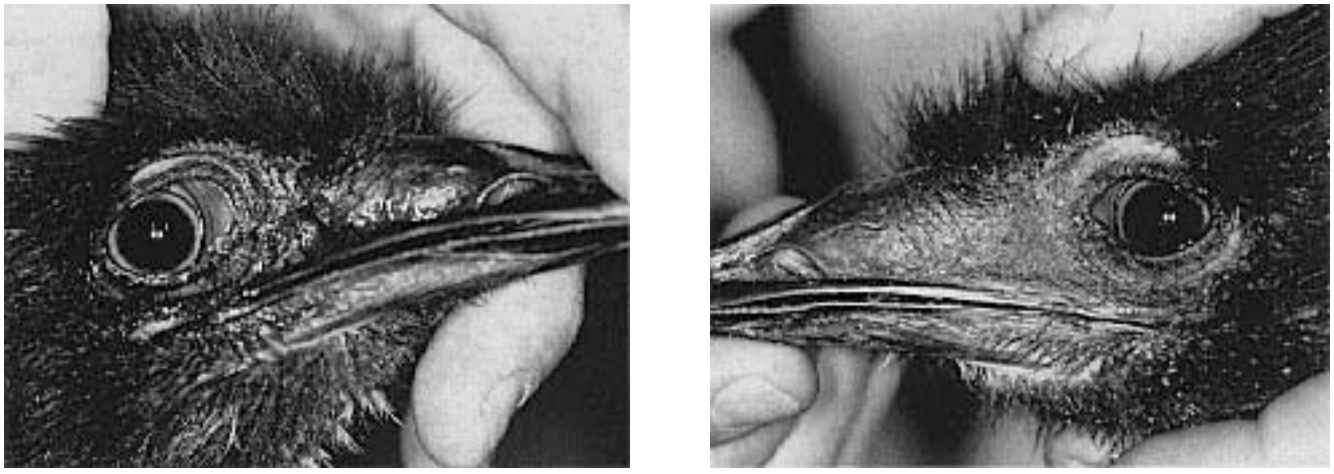

FIG 26.8 An emu (left) was presented with a history of chronic sinusitis. A serous to mucoid oculonasal discharge was noted on physical examination. The sinus was retracted into the skull ("sunken sinus syndrome"). This condition has been most frequently reported in macaws but may also occur with sinusitis in other avian species. Antibiotics were curative (see Chapter 22). A normal emu (right) is shown for comparison (courtesy of Tom Tully).

Poxvirus

Avian poxvirus may cause lesions in or around the eyes in a number of species (see Chapter 32). The initial changes include a mild, predominantly unilateral blepharitis with eyelid edema and serous discharge starting about 10 to 14 days post-infection (Color 26.8). As the disease progresses, ulcerative lesions on the lid margins and at the medial or lateral canthus develop; these can become secondarily infected, giving rise to a mucopurulent discharge and transient ankyloblepharon (Color 26.9). The lids be-

come sealed shut with a caseous plug or with dry crusty scabs, which fall off within two weeks.[50]

Clinical lesions provide a tentative diagnosis. An infection can be confirmed through histopathologic identification of eosinophilic intracytoplasmic inclusion bodies (Bollinger bodies) in scabs or scrapings of periocular ulcers.[27,34]

Poxvirus infections may cause keratitis and, less commonly, anterior uveitis. The keratitis can be mild with corneal clouding or severe with ulceration that progresses to panophthalmitis and rupture of the globe. Keratitis may lead to permanent corneal lid scarring. Cicatricial changes in the lid margins can lead to entropion, ankyloblepharon or deformities of the lid edge, resulting in keratitis from corneal abrasion or environmental exposure. These patients may need corrective surgery (lid retraction) or can be placed on life-long therapy with ocular lubricants.

Many affected psittacine birds, particularly Amazons, pionus parrots and mynah birds, have residual problems that cause more important pathology than the primary ocular and periocular lesions. In one study, 46% of the Amazon parrots and pionus parrots with poxvirus had post-infection ocular abnormalities.[35] Eyelid and corneal lesions are most severe if poxvirus lesions are secondarily infected with bacteria or fungus. Treatment of poxvirus lesions should include topical antibiotic ophthalmic ointments to reduce the incidence of these sequelae. Systemic antibiotics may also be required in severely affected birds. Early eye lesions should be flushed with dilute antiseptic solutions. Once scabs have formed they should not be removed. It may be beneficial to soften scabs with hot or cold compresses soaked in nonirritating baby shampoo. It has been reported that prophylactic vitamin A supplementation of exposed birds decreases the severity of infection[36] (see Chapter 18). The importance of subclinical hypovitaminosis A in the progression of the disease has not been determined.

Hypovitaminosis A

Hypovitaminosis A is less prevalent today than a decade ago; however, it may still be seen as a complicating factor in ocular diseases. Xerophthalmia is said to be the classic sign of hypovitaminosis A in many avian species, but the most common ocular change in psittacine birds is mild periorbital and conjunctival swelling with some discharge (Color 26.14). These signs can be subtle. Hypovitaminosis A should be considered in cases of unexplained ocular discharge or swelling.

Nasal discharge, sneezing, crusted nares, dry oral membranes and palatine and choanal abscesses are highly suggestive of primary hypovitaminosis A, particularly in Amazon parrots. Response to injectable vitamin A or oral beta carotene supplementation suggests the involvement of a deficiency in the disease process.[42,63]

Lovebird Eye Disease

A severe and often fatal systemic disease with periocular lesions as the presenting sign has been reported in lovebirds. Generalized depression is accompanied by blepharitis and serous ocular discharge, followed by hyperemia and edema of the periorbita with a mucopurulent ocular discharge. Affected birds are often attacked by enclosure mates and usually die within a few days of the onset of ocular signs. The disease is most commonly seen in the Peach-faced mutations, and it is in these birds that the lesions are most severe.

No definitive isolation of an infectious agent has been achieved, but an adenovirus-like particle has been demonstrated in renal tissue by electron microscopy. Conjunctival inclusions have been found in some affected birds.[32,36] The histologic lesions reported in one case included proliferative inflammatory reaction of the subconjunctival tissue with lymphoid cell infiltration and concurrent atrophic changes in conjunctival epithelium. Conjunctival edema with minimal cellular infiltrates were characteristic in other cases. The disease occurs most frequently immediately after shipping or introduction into a new aviary, suggesting that stress may be involved in initiating pathologic changes. Symptomatic therapy that includes isolation of affected birds in a stress-free environment and administration of antibiotics has been suggested.

CLINICAL APPLICATIONS

- Sinusitis frequently causes ocular disease because of the close proximity of the infraorbital sinuses and the globe.
- Hypovitaminosis A may cause mild periorbital swelling.
- Lacrimal sac masses present as mobile swellings anterioventral to the medial canthus.
- Pupillary light reflexes are difficult to interpret because birds can voluntarily constrict and dilate the pupil.

Ophthalmology

Color 26.1
A three-month-old Blue and Gold Macaw was presented with a two-week history of serous nasal discharge. Note the accumulation of debris on the feathers of the face. The nictitating membrane, which moves over the cornea during blinking and in the menace response, is normal. This bird's rhinitis was caused by exposure to cigarette smoke.

Color 26.2
An Umbrella Cockatoo was presented with a two-month history of unilateral discharge. Note the moist, discolored feathers on the face. The nasolacrimal duct in this bird was occluded and was opened by repeated flushing with warm, sterile saline.

Color 26.3
Depression and hyperemia of the face and eyelids in a gallinaceous bird with sinusitis and pneumonia.

Color 26.4
Periocular dermatitis in an Amazon parrot from southern Florida. These lesions, frequently encountered in birds in outdoor aviaries, are believed to be caused by biting insects.

Color 26.5
a) Gross proliferative lesions caused by *Knemidokoptes* sp. infection in a budgerigar. **b)** *Knemidocoptes* spp. are most frequently associated with beak and cere lesions but can also cause lesions in the periorbital tissues (courtesy of the Unit for Continuing Veterinary Education in London and John E. Cooper).

Color 26.6
A mature cockatiel was presented for diarrhea and weight loss of five days' duration. The bird had partial paresis of the eyelid, mild conjunctivitis and was unable to bite. Partially hulled seeds were common in the bottom of the enclosure. *Giardia* spp. were detected in a fecal smear. The bird responded to treatment with metronidazole and vitamin E.

Color 26.7
An Amazon parrot with a transient periorbital sinus inflation. This inflation is believed to be secondary to stressful events and is not indicative of a pathologic problem.

Color 26.8
Scarring of the palpebral margin secondary to a poxvirus infection (courtesy of David Williams).

Color 26.9

Ophthalmology

Color 26.10
A budgerigar with conjunctivitis, epiphora and chemosis of seven to ten days' duration. The etiology is unknown but the clinical presentation is similar to that described with conjunctivitis in cockatiels. In this case, topical application of enrofloxacin resolved the chemosis within four days (courtesy of R. Korbel).

Color 26.11
Subconjunctival granuloma in an Amazon parrot. Chemotic conjunctivitis in this bird was not ameliorated with topical or systemic tetracycline and enrofloxacin treatment. Ziehl-Neelsen staining of the granulomatous conjunctival tissue revealed *Mycobacterium* spp. The conjunctiva was surgically removed (courtesy of R. Korbel).

Color 26.12
An adult Arcuna was presented with a two-week history of progressive depression and weight loss. The bird had a bilateral, serous ocular discharge and preferred to keep the eyes shut. *Thelazia* spp. were noted on physical examination. The bulk of the nematodes was removed with copious flushing (LRS), and the bird was successfully treated with topical ivermectin.

Color 26.13
Conjunctivitis in an ostrich caused by flukes (*Philophthalmus* sp.). This bird was housed in an area that contained a waterfowl pond. Most infected birds are housed in low-lying, damp areas.

Color 26.14
Hypovitaminosis A in psittacine birds can cause dysplastic lacrimal gland lesions (courtesy of David Williams).

Color 26.15
Cockatiel conjunctivitis frequently responds to therapy with tetracyclines (courtesy of Louise Bauck).

Color 26.16
Infraorbital sinusitis in a 2.5-year-old Indian Hill Mynah. Surgical removal of caseous masses followed by treatment with enrofloxacin and vitamin A successfully resolved the lesion (courtesy of R. Korbel).

Color 26.17
A four-year-old female budgerigar was presented with a three-week history of progressive ocular swelling and ataxia. The bird died shortly after presentation. Abscesses present in the infraorbital sinuses also involved portions of the calvarium.

Color 26.18
An eight-year-old African Grey Parrot was presented with a twelve-day history of progressive upper respiratory disease. This was the only companion bird in the household, but the bird had been boarded at a pet retailer two months before the onset of clinical signs. The client also had a flu-like disease. Chlamydia was detected by using a fecal antigen test, and the bird responded to doxycycline therapy. Note the rhinolith in the left naris.

Pasteurella spp. septicemia and gram-positive cocci have been associated with conjunctivitis in lovebirds. A poxvirus has been described in Masked and Peach-faced Lovebirds.[43]

Periorbital and Orbital Abscesses

Periorbital disease with exophthalmos or strabismus is most likely to be caused by an abscess of the orbit or lacrimal gland. In some cases, periorbital neoplasia, either primary or secondary, can cause similar clinical changes. Periorbital abscesses generally result from chronic upper respiratory tract infection and sinusitis. They are most often seen in cockatiels, and can occur in any position in the orbit (Color 26.11). Early treatment of sinusitis reduces the incidence of these lesions. Surgical debridement of the abscesses with concomitant systemic antibiotics is the only effective treatment. Lacrimal sac abscesses must be differentiated from periorbital abscesses. The lacrimal sac masses present as mobile swellings at, or immediately anteroventral to, the medial canthus. Early dacryocystitis can sometimes be treated by expressing the inflammatory debris through the lacrimal punctum. More severe cases with firm, necrotic debris require cannulation and regular flushing with antibiotic solutions as dictated by bacteriologic culture and sensitivity. Surgical removal is not recommended because of the potential for scarring and long-term nasolacrimal drainage problems.

Periorbital Swelling of Neoplastic Origin

Any primary tumor arising in the periorbital or retrobulbar area can cause swelling with or without globe displacement.[7] The periorbital area in birds appears to be a particularly common area for cutaneous manifestations of lymphoreticular neoplasia,[13] represented clinically by periorbital swelling, globe displacement and feather loss.[61,65] Exophthalmia or posteriorly directed strabismus may be noted.

Exophthalmos and globe deviation have been reported secondary to optic nerve glioma, orbital round cell sarcoma,[2,26] and some advanced cases of pituitary chromophobe tumors in budgerigars.[69] Other less common causes of retrobulbar masses include *Mycobacterium* spp.,[79] *Aspergillus* spp. granulomas and disseminated cryptococcosis.[25]

Hyperplastic Periocular Lesions

Proliferative and hyperplastic periorbital lesions are most commonly seen in budgerigars and canaries in response to *Knemidokoptes* spp. infections. Pitted or honeycombed, scaly and crusting lesions are easily noted in the periorbital area as well as on the beak, vent and legs (Color 26.5). The periorbital lesions seldom cause problems even though they may be quite severe. Ivermectin can be used topically.

A potential differential diagnosis would include vitamin A deficiency, which can lead to periorbital epithelial hyperplasia and hyperkeratosis, but hypovitaminosis A lesions rarely achieve the size or proliferative extent seen with knemidokoptes. Periorbital papilloma-like virus infection in an African Grey Parrot resulted in hyperplastic parakeratotic epithelial proliferations.[33] Other periorbital papillomas have been described without viral isolation.

Other Periocular Dermatoses

Any dermatosis (eg, allergic, bacterial, fungal) can potentially affect the periorbital skin and occur in the periorbital region (Color 26.4). It should be noted that many periorbital dermal lesions appear to be exceptionally pruritic and that self-trauma can complicate the initial lesions.

Congenital Deformities

Although rare in birds, congenital eyelid abnormalities do occur and are a surgical challenge to correct. Partial agenesis of the upper eyelid, which was surgically corrected by creating a new lateral canthus at the point at which normal upper eyelid would be found, has been reported in a raptor.[37]

Cryptophthalmos (fusion of the eyelid margins) has been reported in four cockatiels[11] in which dramatically reduced or absent palpebral fissures were described without other ocular abnormalities (Color 26.20). Reconstructive surgery was uniformly unsuccessful. Behaviorally, the birds appeared normal because some vision was possible through one or both eyes. Corneal dermoids have been reported in one goose, in which feathers grew out of the aberrant dermal tissue on the lateral aspect of the globe.[12] Microphthalmia and maldevelopment of ciliary body, retina and pecten, as well as retinal dysplasias and congenital cataracts have been described in raptors.[10] The lacrimal ducts did not drain properly in an Umbrella Cockatoo with choanal atresia, resulting in a chronic ocular discharge (Figure 26.9). Ectropion with secondary exposure keratitis has been seen in cockatiels. This lesion can be resolved with a lateral canthoplasty (see Chapter 41).

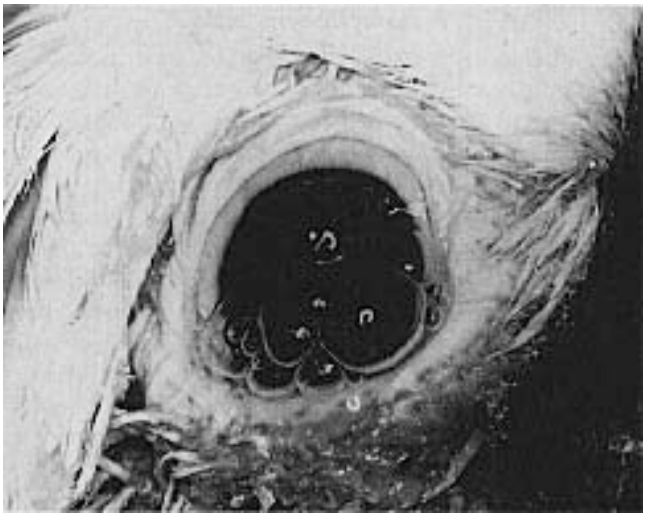

FIG 26.9 A mature Umbrella Cockatoo was presented with a lifelong history of ocular nasal discharge. Physical examination indicated the lack of a choanal slit and an abnormally formed infundibular cleft, preventing normal lacrimal drainage. The periorbital tissue was moistened with a serous ocular and nasal discharge. Note the bubbles in the ocular fluids suggesting that air was exiting the lacrimal duct.

Conjunctiva

Differential Diagnosis of Conjunctivitis

Conjunctivitis can be classified clinically into three groups. The first are those caused by strictly local factors, such as localized conjunctival infection or foreign bodies. The second are those in which conjunctivitis is a manifestation of periorbital or orbital disease. These are mainly related to sinusitis (see Chapter 22). The third group are those in which conjunctival hyperemia is caused by a septicemia. Almost any organism causing systemic infection can result in conjunctivitis. A careful examination of the bird for upper respiratory disease is mandatory in determining the cause of ocular discharge or conjunctival hyperemia (Color 26.10). Exposure to cigarette smoke, chemical fumes and other aerosolized environmental toxins should always be considered in the differential diagnosis of conjunctivitis, with or without signs of upper respiratory disease.

Various infectious agents have been implicated in conjunctivitis, but mere isolation of a bacteria or protozoan does not imply that it is the cause of the disease. The conjunctival flora of captive exotic birds has been surveyed (Table 26.1).[80] Bacteria was isolated from the upper conjunctival fornix of 71% of the psittacine birds tested. *Staphylococcus* sppp. or *Corynebacterium* spp. were isolated from 86% of the birds. Gram-negative bacteria were recovered from 14% and fungi, from 9% of these clinically normal birds. In another study, 41% of ocular samples were sterile and 50% of the isolates were gram-positive cocci.[82]

TABLE 26.1 Avian Conjunctival Flora

Family	Gram + Isolates	Gram- Isolates	Fungal Isolates
Anseriformes	36/68 (56%)	30/68 (44%)	2/27 (11%)
Coraciiformes	3/3 (100%)	0/3 (0%)	0/2 (0%)
Falconiformes	17/18 (94%)	1/18 (6%)	4/11 (36%)
Piciformes	6/7 (86%)	1/7 (14%)	1/5 (20%)
Psittaciformes	44/51 (86%)	7/51 (14%)	5/55 (9%)
Rheiformes	6/18 (33%)	12/18 (67%)	2/5 (40%)
Falconiformes	17/18 (94%)	1/18 (6%)	4/11 (36%)

Adapted from Wolf DE, et al: J Am Vet Med Assoc 183:1232-1233, 1983.

The incidence of gram-positive, gram-negative and fungal organisms was determined in a group of 117 birds by swabbing the conjunctiva. The birds sampled were clinically asymptomatic and were housed in zoos or pet shops. *Staphylococcus* spp. or *Corynebacterium* spp. were recovered from 85 of 97 birds in which bacterial organisms were recovered. *Chlamydia* spp. was not identified by cytologic evaluation of conjunctival scrapings in any of the birds.

In one study of domestic ducks, *E. coli* was isolated from the eyes of a majority of clinically asymptomatic ducklings, suggesting that neonatal conjunctival flora are derived from intestinal flora (Color 26.24).[16] The isolation of gram-negative bacteria from the eye or conjunctiva should be considered abnormal except in Anseriformes and Rheiformes, where gram-negative bacteria are considered autochthonous flora. *Haemophilus*-like bacteria have been reported to cause conjunctivitis in cockatiels.[19]

Chlamydia psittaci is a frequent cause of keratoconjunctivitis in Australian parakeets[23] and of conjunctivitis without other signs in pigeons and finches. In these cases, treatment with topical oxytetracycline is effective. Clinical chlamydiosis in Psittaciformes is generally associated with conjunctivitis, diarrhea and polyuria.

Mycoplasma spp. are important causes of conjunctivitis in pigeons and are suspected in many cases of conjunctivitis in cockatiels. Ocular discharge and conjunctivitis may be the only presenting signs. Other affected birds may develop rales, nasal discharge and sneezing. Unilateral conjunctivitis (one-eyed cold) in pigeons is frequently associated with mycoplasma but can also be caused by chlamydia or salmonella.

Cryptosporidial conjunctivitis has been described in pheasants[66] and ducks.[48] A case of blepharitis and conjunctivitis in a goose yielded *Actinobacillus suis*,[45] while *Mycobacterium avium* was isolated from a conjunctival granuloma in an ostrich.[31]

The presence of foreign bodies in the fornix, or behind the third eyelid, may be a cause of conjunctival irritation and should be suspected in cases of unilateral conjunctivitis that are not responsive to antibiotics. In one study, 7% of the free-ranging Red-shouldered Hawks had grass florets lodged behind the third eyelid.[49] In companion birds, millet seeds, seed husks and feathers have been associated with a foreign body conjunctivitis.

Cockatiel Conjunctivitis

Cockatiels are frequently presented with a conjunctivitis from which no infectious agent can be isolated. Clinical signs involve blepharitis and serous ocular discharge, progressing to conjunctival chemosis and inflammation with hyperemic conjunctiva protruding in front of the eye. These signs are seen much more frequently in white or albino mutations than in birds of normal gray color (Color 26.15).

The lesions are often associated with upper respiratory tract infection, and *Mycoplasma* spp. and *Chlamydia* spp. have been suggested as agents. Isolating mycoplasma requires specialized techniques, and diagnostic samples should be sent in specific media to qualified laboratories. Many cockatiels with conjunctivitis are not systemically positive for *Chlamydia* spp., shedding some doubt on the importance of this organism in the cockatiel syndrome.[3]

Treatment with topical antibiotics often ameliorates the signs but recurrences are common. Systemic tetracycline is often curative but should be combined with symptomatic treatment of the inflamed periorbita. Antibiotic ophthalmic ointments may be used or the eyes can be sprayed with tylosin (l:10 dilution in sterile water) or lincomycin and spectinomycin. The problem seems to follow familial lines, suggesting that affected birds should not be used in breeding programs. In some cockatiels, the conjunctivitis is associated with partial lid paresis and reduced jaw tone (Color 26.6). Many of these birds have giardiasis and respond to treatment with metronidazole and vitamin E. A similar condition has been noted in budgerigars, and again, the etiologic agent has yet to be identified.[41]

Parasitic Conjunctivitis

A number of nematode and trematode parasites can occasionally cause conjunctival irritation in a wide variety of avian species (see Chapter 36). *Oxyspirura mansoni* is a nematode that has been associated with conjunctival irritation and pruritus in cockatoos, mynahs and other avian species. This nematode can enter the lacrimal duct and may cause transient epiphora if present in large numbers. Small numbers of nematodes can be manually removed or flushed out of the lower conjunctival sac. Heavy parasite burdens must be treated with a single topical dose of ivermectin.[74] This nematode has an indirect life cycle. Nematode eggs are passed through the nasolacrimal duct, swallowed and passed in the feces, where they are consumed by cockroaches (*Pycnoscellus* spp.). When a bird eats the cockroach, the mature nematode larvae escape into the crop, move up the esophagus and enter the nasolacrimal duct to reach the eye. Companion birds maintained in indoor environments are less likely to be infected. *Thelazia* spp. are reported to cause conjunctivitis in birds but are more common in mammals (Color 26.12).[8]

Trematode flukes of the genus *Philophthalmus* have been reported as a cause of conjunctivitis in many avian species (Color 26.13). The degree of irritation was sufficient in one group of ostriches to cause the birds to show persistent lacrimation, irritation and loss of condition. Repeated applications of topical carbamate powder eliminated the flukes.[29]

Cornea

Treating Corneal Ulcers and Keratitis

Most corneal problems seen in Psittaciformes are epithelial erosions secondary to trauma or keratitis secondary to lid abnormalities. Fluorescein dye will stain denuded stroma indicating the presence of an ulcer. In subtle lesions such as Amazon punctate keratitis, an ultraviolet Wood's lamp can be used to augment the detection of fluorescein retention. Keratitis can be difficult to resolve, but, as a rule, topical antibiotics and corneal bandaging techniques provide a sterile environment and time for corneal epithelium to heal (Color 26.22). By extrapolation from other species, anticollagenases should be used in deep ulcers, especially in hotter climates, where corneal melting may be a cause of rupture of the globe. Acetylcysteine can be applied by spray every few hours without having to restrain the bird. A temporary tarsorrhaphy created by placing one or two horizontal mattress sutures of 4-0 or 6-0 nylon

provides a corneal "bandage." This is preferable to a third eyelid flap because the muscular action moving the third eyelid can cause the suture to pull through. The use of a hydrated collagen shield to provide a medicated corneal bandage has not been reported in birds but may be useful in selected cases. Chronic corneal erosions may occur in older birds. To provide a suitable surface for reattachment of the epithelium, devitalized epithelium can be removed with a dry cotton-tipped applicator or by using a punctate or grid keratotomy.

Mynah Bird Keratitis

Corneal erosions may be noted secondary to capture and transport in many imported companion birds. The majority of these heal by corneal epithelial migration within 48 hours. Mynahs appear to be especially prone to handling-related keratitis. In one study, 96% of birds examined immediately after shipping were found to have corneal scratches.[36] Blepharospasm or some degree of conjunctival hyperemia is a characteristic finding. Many of these lesions regress spontaneously in a few weeks, but some may lead to corneal scarring and permanent opacity. Some birds develop a chronic keratoconjunctivitis with conjunctival masses, severe geographic corneal ulceration and corneal vascularization. Systemic aspergillosis is found in many chronically affected birds, suggesting an immunosuppressed condition. Acyclovir-responsive herpesvirus lesions have been suggested as complicating factors in some affected birds.

Amazon Punctate Keratitis

A transient keratitis with a characteristic subtle punctate appearance has been reported in Central American Amazon parrots. Lesions are bilateral, and the presenting signs are normally blepharospasm and a clear ocular discharge. The keratitis normally starts in the medial cornea. In 50% of the birds, lesions progress to cover the cornea but resolve generally within one to two weeks. The lesions are transiently fluorescein-positive. A small minority of birds develop more serious lesions with deep corneal ulceration and anterior uveitis, manifesting either as a flare and "muddiness" of the iris or as a more severe inflammation with fibrin clots and synechiae (Color 26.27). Some birds develop concomitant sinusitis. The use of topical antibiotics or antivirals has not been found to significantly alter the outcome of the disease.[36]

Amazon parrots from northern South America have also been reported with a chronic keratitis. There are fewer cases reported in this group of birds, but the incidence of long-term corneal scarring is higher.

Treatment of more severely affected birds, such as those with intraocular lesions, includes topical and systemic antibiotics. Topical corticosteroid to control intraocular inflammation can reduce the healing of concurrent corneal ulceration; topical non-steroidal anti-inflammatories such as indomethacin or flubruprofen may be more appropriate in these cases.

Uvea

Uveitis in raptors is most commonly seen as a sequel to intraocular trauma[57] and is characterized by aqueous flare, hypopyon and fibrin clots in the anterior chamber, iridal hemorrhages or gross hyphema. The latter was reported to be the most common ophthalmologic finding in injured raptors in one survey.[58] Uveitis can occur following rupture of the crystalline lens[1,54] or secondary to severe extraocular disease in conditions such as poxvirus infection. One case of bilateral intraocular inflammation with concomitant staphylococcus septicemia in a lovebird has been reported.[6] Uveitis has been reported in psittacine birds with reovirus infection in which histopathologic changes suggested disseminated intravascular coagulopathy. Hypopyon and hemorrhage, sometimes with fixed dilated pupils (atypical for uveitis where miosis is more common), are characteristic ocular signs. Birds that recover may have synechiae (Color 26.28).[17]

Clinical signs of uveitis vary, reflecting the diversity of inflammatory states in the eye. Active inflammation may be mild, with increased levels of aqueous proteins causing a flare that reduces the clarity of iris detail and pupil margin. More severe cases may be characterized by accumulation of pus or hemorrhage in the anterior chamber. Subtle signs including a darkened iris or more obvious lesions including posterior synechiae or organized fibrin clots in the anterior chamber suggest a past episode of anterior segment inflammation. Glaucoma is seen secondary to traumatic uveitis in raptors,[58] and has been diagnosed without concurrent ocular disease in a canary. If the eye appears painful, enucleation or evisceration is the only treatment (Figure 26.10) (see Chapter 41).

Lens

Cataract and lens luxation can occur in birds. Both conditions can be treated surgically in suitable cases. Cataracts are seen relatively frequently[39] and have a

FIG 26.10 Although evisceration or enucleation can be disfiguring, these procedures may be life-saving in cases of severe infections or neoplasms.

wide variety of causes, although in the majority of cases the etiology is unknown. Senile cataracts have been described in macaws (Color 26.30).[18]

There is clear evidence for familial cataracts in Yorkshire and Norwich Canaries (Color 26.31).[72] A fully penetrant autosomal recessive gene is responsible for the condition. In affected canaries, the cataracts were mature with lens-induced uveitis and posterior synechiae formation (Color 26.32). In one affected bird, lens resorption had taken place. Lens removal by the irrigation-aspiration technique was unsuccessful in these birds. Patients requiring cataract removal should be referred to a veterinary ophthalmologist.

Because of the small size of the avian eye, conventional extracapsular cataract extraction techniques are generally difficult. In small birds, soft lenses can be removed through a 26 ga needle. Phacoemulsification is the technique of choice for avian cataract removal in patients with eyes large enough to accommodate the phacoemulsification probe.[38] The extracapsular technique can be used in intumescent or resorbing cataracts where the lens material can be aspirated or flushed from the anterior chamber (Color 26.34).[55] An intracapsular technique has been used for removal of an anteriorly luxated lens in an owl.[9] In eight aging macaws with senile cataracts, the lens was disrupted and removed with an irrigation aspiration technique, resulting in vision in 77% of the eyes.[18] Post-operative treatment with 17% maxitrol was considered an indispensable part of the therapy. Topical medications, particularly steroids, must be applied cautiously to small birds to prevent intoxication.

Trauma in wild raptors is likely to be a frequent cause for lenticular opacification, and because other intraocular damage may be present, care should be taken in assessing the bird for cataract surgery (Color 26.34). Assessment should include full evaluation of the bird physically, neurologically and, of course, ophthalmoscopically. Ideally, ultrasonic evaluation of the posterior segment should be made to avoid operating on an eye with a concurrent retinal detachment. An electroretinogram gives useful data on retinal function and is suggested prior to surgery in some cases.[30]

Miscellaneous Eye Conditions

Retinal Diseases

The difficulties in examining the posterior segment of the avian eye, especially in small companion birds, have delayed investigations into retinal disease in these species. The pioneering work of Casey Wood in the early part of this century on the normal avian fundus has not been surpassed even with the advances in ophthalmoscopic instrumentation and the growing interest in avian ophthalmology.[81]

Nevertheless, some reports of retinal disease in birds have found their way into the literature. Wood himself noted a high prevalence of posterior segment inflammatory lesions in captive raptors, and other authors have confirmed his findings.[28,56,58] Lesions include pigmentary deposits on the otherwise unpigmented peripheral retina, focal scarring, pre-retinal membranes, vitreal opacities and gross inflammatory disease of the entire posterior segment (Color 26.35). Many of these lesions in free-ranging birds may be caused by trauma with hemorrhage that causes vitreal scarring and contraction. Posterior segment bleeding may result from choroidal vessels, a damaged ciliary body, or even in some cases, rupture of the pecten.

Toxoplasmosis has been suggested as a cause of retinal lesions in raptors (see Chapter 36). This report, however, was based on identifying seropositive birds in a population where the seroprevalence is unknown.[28] Toxoplasmosis was confirmed as a cause of retinitis and blindness in canaries. Toxoplasmosis was diagnosed in a group of canaries with crusty ocular lesions, white lesions in the vitreous humor and, in most cases, collapse of the globe. Several of the infected birds had neurologic signs characterized by circling and head tremors. High latex agglutination antibody titers to *T. gondii* were seen in five of the seven affected birds. Histologically, *T. gondii*

tachyzoites were demonstrated in the detached and intact retina, the lens and in exudate in the vitreous humor.[76]

Retinal detachment can occur through trauma, but idiopathic bilateral detachments have been noted in pheasants unassociated with mechanical damage.[67] Retinal dysplasia has been diagnosed in raptors,[21,60] and a retinal degeneration of unknown origin was reported in a parakeet.[75]

Intraocular Tumors

Intraocular tumors are rare in birds. Malignant intraocular medulloepithelioma has been reported in two-year-old cockatiels in which, after enucleation for presumed bacterial panophthalmitis and orbital cellulitis, tumor masses grew rapidly in the orbit.[70] An intraocular adenocarcinoma has been reported in a budgerigar.[22]

Neurophthalmology and Central Blindness

Blindness in birds may be caused by opacity of the visual media, retinal lesions or central neurologic disease. In cases where no obvious ocular cause of blindness can be observed, an electroretinogram can be used to differentiate between retinal or central lesions.[47]

Causes of central blindness may include cataracts, neoplasia or encephalitis that may be localized or related to systemic disease. Heavy metal toxicities can result in blindness, but the visual changes are only one of a number of multifocal nervous signs. Space-occupying brain lesions, particularly pituitary adenomas, can cause visual deficits from pressure being placed on the optic chiasm. One large survey of 50 chromophobe pituitary tumors reported central blindness in a number of birds with associated neurologic and endocrine signs.[4,69]

Defects of cranial nerves III, IV and VI are somewhat difficult to appreciate in birds because there is relatively little torsional movement of the globe within the orbit. Horner's syndrome was suggested as a diagnosis in one bird in which a unilateral ptosis and mild miosis ameliorated by topical phenylephrine was noted.[78]

- ***Evaluating the Blind Bird:*** Determining if visually defective birds are sound for release can be difficult. Some birds such as owls perform well with one eye, while releasing a one-eyed diurnal falcon to the wild might be considered unwise. Many companion birds can survive remarkably well with little or no vision, as has been noted with cockatiels with cryptophthalmos[11] and Bobwhite Quail with dense bilateral cataracts;[44] however, blindness can be very debilitating in some smaller Passeriformes where flying from perch to perch is behaviorally important.

Enucleation

Enucleation is frequently necessary in birds because of trauma, non-responsive inflammation or tumors. Enucleation is difficult because of the large size of the avian eye and the tight fit of the globe into the orbit. For further information on enucleation and other ophthalmic surgeries, see Chapter 41.

Ophthalmology

Color 26.28
Tawny Owl with uveitis. Examination with a slit lamp showed that the white glistening of the eye was caused by hypopyon and not a corneal lesion. Resolution with topical steroid medication was slow and several synechiae remained. No etiologic agent could be identified (courtesy of David Williams).

Color 26.29
An adult male cockatiel was presented with a three-week history of ocular discharge and scratching of the face. A severe panophthalmitis was noted on physical examination. The bird's WBC count was 22,000. A conjunctival scraping revealed numerous gram-negative bacteria, both free and within conjunctival cells. The bird was placed on systemic and ophthalmic antibiotics. Cultures indicated *Pseudomonas* spp. The eye did not respond to therapy, and enucleation was performed six days after initial presentation.

Color 26.30
Cataract in an Eclectus Parrot. The periorbital feather loss is probably secondary to the bird's rubbing the area because of reduced vision in the eye (courtesy of David Williams).

Color 26.31
Inherited cataract in a Norwich Canary. Note also the polycoria probably subsequent to senile iridal atrophy (courtesy of David Williams).

Color 26.32
Cataract and posterior synechiae in a thirteen-year-old canary. Phitisis bulbi with wrinkling of the lid margins are also evident (courtesy of R. Korbel).

Color 26.33
Cataract in a mynah bird with posterior synechiae. In this case, the contralateral eye was unaffected, the bird's behavior was normal and surgical removal of the cataract was not attempted (courtesy of K.C. Barnett).

Color 26.34
Cataract in a Harris Hawk. Note the scintillating appearance of the cataract, indicating some resorption. The iris ectropion is believed to be a congenital anomaly and not reflective of a uveitis. Extracapsular cataract extraction was performed and the bird regained vision in the eye (courtesy of David Williams).

Color 26.35

CHAPTER

27

CARDIOLOGY

J. T. Lumeij
Branson W. Ritchie

The avian heart is divided into four complete chambers and is located midway in the thoracic cavity in an indention in the sternum parallel to the long axis of the body.[50,91] The right atrioventricular (AV) valve is a simple muscular flap devoid of chordae tendineae, while the left bicuspid AV valve is thin and membranous. Both the aortic and pulmonary valves are membranous and tricuspid as in mammals. The left ventricle is heavily walled and is about two to three times thicker than the right. The right ventricle works as a volume pump and responds rapidly to an increased workload by dilation and hypertrophy.[48] Rigor mortis in a normal heart always results in complete emptying of the left ventricle. Rigor mortis may not occur if severe degenerative disease of the myocardium is present.[31]

In contrast to mammals, in which the lungs are situated on either side of the heart, the apex of the avian heart is covered ventrally by the cranial portion of the right and left liver lobes (see Color 14). The normal pericardial sac is clear and in contact with the epicardium circumferentially and the mediastinal pleura dorsally (see Color 13). A normal bird should have a small quantity of clear to slightly yellow fluid in the pericardial sac (see Color 14). The muscle fibers in the avian heart are five to ten times smaller than the muscle fibers in mammals, and their internal structure is simple, lacking the T-tubules found in mammals. The small surface area precludes the need for a complex T-tubule system for excitation to occur. The heart is normally even in color and is deep reddish-tan (see Color 14). In neonates, the heart is normally a lighter pink color and may appear pale.

Birds have a proportionately larger heart (1.4 to 2 times larger), higher pulse rate, higher blood pressure and a slightly lower peripheral resistance to blood flow than is found in mammals. These factors contribute to the enhanced circulatory and oxygen transport systems that are necessary to sustain flight. The increased cardiac output requires a higher arterial pressure to produce higher blood flow rates. High blood pressure is a predisposing factor to aneurysm and aortic rupture in male turkeys of hypertensive strains.[53,54] On a body weight basis, smaller birds in general have a bigger heart than larger birds. Systolic blood pressure ranges from 108 to 220 mm Hg depending on the species.

The aorta in birds is derived embryologically from the right fourth arterial arch and right dorsal aorta and therefore the ascending aorta curves to the right and not to the left as in mammals. This structure can be clearly seen radiographically on a ventrodorsal projection. Blood is returned to the heart from the peripheral circulation by the left and right cranial caval veins and a single caudal caval vein. Most of the myocardial blood supply comes from deep branches of the right and left coronary arteries.

Evaluating the Avian Heart

Electrophysiology[87]

The electrocardiogram (ECG) reflects the differences in conduction that occur between the avian and mammalian heart. Electrical impulses that precede mechanical contraction of the myocardium are generated in the sinoatrial (SA) node. Because the rate of depolarization of the cells of the SA node is higher than that of any other cardiac muscle cell, the SA node functions normally as the cardiac pacemaker. The SA node is located between the entrance of the right cranial vena cava and the caudal vena cava into the right atrium. Electrical impulses are transported along ordinary muscle fibers in the interatrial septum to the atrioventricular (AV) node. The P-wave in the ECG depicts this part of the electrical conduction (ie, depolarization of the atria).

The AV node is located in the caudoventral part of the interatrial septum or the caudodorsal part of the interventricular septum. Electrical conduction is delayed in the AV node, which facilitates filling of the ventricles before they contract. Delay of conduction in the AV node is depicted by the PR-segment in the ECG. The AV node is continuous with the AV bundle branches into right and left crura as it courses into the interventricular septum. The AV bundle electrically separates the atria from the ventricles by penetrating the fibrous tissue. The AV node in birds also gives rise to the right AV ring that encircles the right AV opening and controls the activity of the right muscular AV valve. There are also fibers running to the truncobulbar node at the base of the aorta.

The AV bundles and their branches consist of Purkinje fibers. Electrical conduction in Purkinje fibers is about five times faster than in normal cardiac muscle cells and hence the conduction system plays an important role in regulating myocardial contraction. After transmission of the electrical impulses through the ventricular conduction system, all areas of the ventricles are activated in a coordinated fashion. Depolarization of the ventricles is depicted by the QRS complex in the ECG.

Birds have a mean electrical axis that is negative, while the mean electrical axis in dogs is positive. This difference can be explained by the fact that in birds, the depolarization wave of the ventricles begins subepicardially and spreads through the myocardium to the endocardium, while in the dog, depolarization of the ventricles starts subendocardially. The parasympathetic nervous system (via the vagus nerve) and the sympathetic nervous system (via the cardiac nerve) synapse on the SA node.

Diagnostic Methods

Primary heart diseases should be included in the differential diagnosis when avian patients are presented with lethargy, periodic weakness, dyspnea, coughing and abdominal swelling (ascites). Any drugs that the patient has received, potential exposure to toxins and concurrent diseases should always be evaluated when determining if the heart is abnormal. Arteriovascular disease was noted in 199 of 1726 mixed avian species necropsied in one zoological collection.[13] Cardiac-induced ascites appears to be less common in Psittaciformes than in Galliformes and Anseriformes.

Auscultation of the avian heart is difficult and the information that can be gained is limited. Subtle murmurs are easiest to detect when birds are under isoflurane anesthesia and the heart rate is de-

creased. Auscultation of the heart can best be performed on the left and right ventral thorax. Pleural or pulmonary fluid accumulation may cause muffled lung sounds or rales when a bird is auscultated over the back between the shoulder blades.

Mild stress, such as occurs in the veterinary examination room or following restraint, may cause a bird's heart rate to increase substantially (two to three times normal). Exercise, age, climatic conditions, stress factors, drug exposure, toxins, diet, percent body fat and blood pressure can all alter the avian heart rate. As a rule, the heart rate in a bird that is being restrained is higher than the heart rate obtained in the same bird if the rate had been determined using telemetry. A stress-induced increase in heart rate should resolve several minutes after the stressing factors are removed.

Diagnostic aids that have proven to be effective in evaluating cardiac diseases include CBC, plasma chemistries (eg, AST, LDH, CPK), cytologic examination of pericardial or peritoneal effusions, plasma electrolytes, blood culture, radiographs (including contrast studies such as nonselective angiocardiography), electrocardiography, cardiac ultrasonography (echocardiography) and color flow doppler. CPK activity from cardiac muscle origin (CPK-MB isoenzyme) was significantly higher in ducklings with furazolidone-induced cardiotoxicosis when compared to controls.[99a]

Imaging

Radiographic detection of cardiovascular abnormalities may be difficult, although an enlarged cardiac silhouette or microcardia can often be visualized. Radiographic detection of an enlarged cardiac silhouette with muffled heart sounds is suggestive of pericardial effusion. An increased cardiac silhouette with normal heart sounds is suggestive of dilative heart disease.

Electrocardiography (low voltage in pericardial effusion) and ultrasonography may demonstrate free pericardial fluid. Microcardia is indicative of severe dehydration or blood loss that has resulted in hypovolemia (Figure 27.1). Other radiographic changes that suggest cardiac disease include congestion of pulmonary vessels, pulmonary edema, pleural effusion, hepatomegaly and ascites.

Non-selective angiocardiography with rapid sequence serial radiographs has been used to confirm impaired cardiac function in a racing pigeon (Figure 27.2).[57] This technique has also been used to rule out cardiovascular shunt as the cause of severe dyspnea and hypoxia in a Blue and Gold Macaw. The procedure is performed by injecting a bolus dose of contrast medium into the catheterized basilic vein.[95]

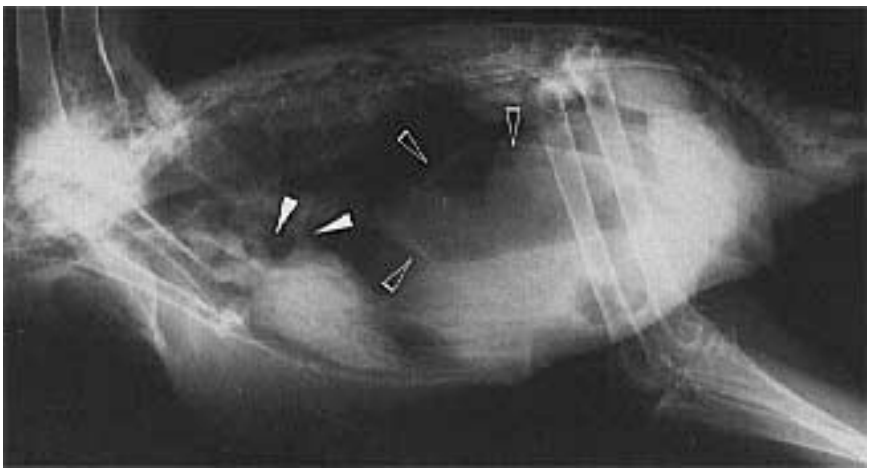
Of the imaging techniques, echocardiograms generally provide the most diagnostic information. Echocardiography was used successfully to detect valvular endocarditis on the aortic valve of a four-year-old female emu suspected of cardiac disease. Staphylococcus was isolated from the vegetative lesion, which was seen as a large mass using this technique.[70] In small birds, the echocardiographic image of the heart is best obtained by sweeping through the liver. Color flow doppler was used to demonstrate mitral regurgitation and right-sided heart failure in a mynah.[76]

Electrocardiology

Using a capillary electrometer, Buchanan[8] was the first to describe the form of the electrocardiograms in birds. She discovered that "when the mouth is to the acid (+) and the legs to the mercury (-)" the mean deflection of the QRS-complex in birds is negative and not positive as in mammals. In 1915 the first electrocardiogram of a pigeon made with a string galvanometer was published;[49] leads were connected to the neck and abdomen.

It was demonstrated in 1949 that the negative mean electrical axis of ventricular depolarization in birds occurs because the depolarization wave begins subepicardial and then spreads through the myocardium towards the endocardium.[51] Sturkie[83-92] pioneered the use of clinical electrocardiography in birds and described the normal ECG of the chicken using standard bipolar limb leads. Of all avian species, both normal and abnormal ECGs of chicken and turkey have been best characterized. Details of the ECG of gulls,[51] buzzards,[21] parakeets and parrots[101] have also been published.

Despite its great clinical applicability, electrocardiography has received relatively little attention from companion and aviary bird practitioners. This might be due to the scarcity of electrocardiographic reference values in companion birds. To the authors' knowledge these values have been established only in racing pigeons, African Grey Parrots and Amazon



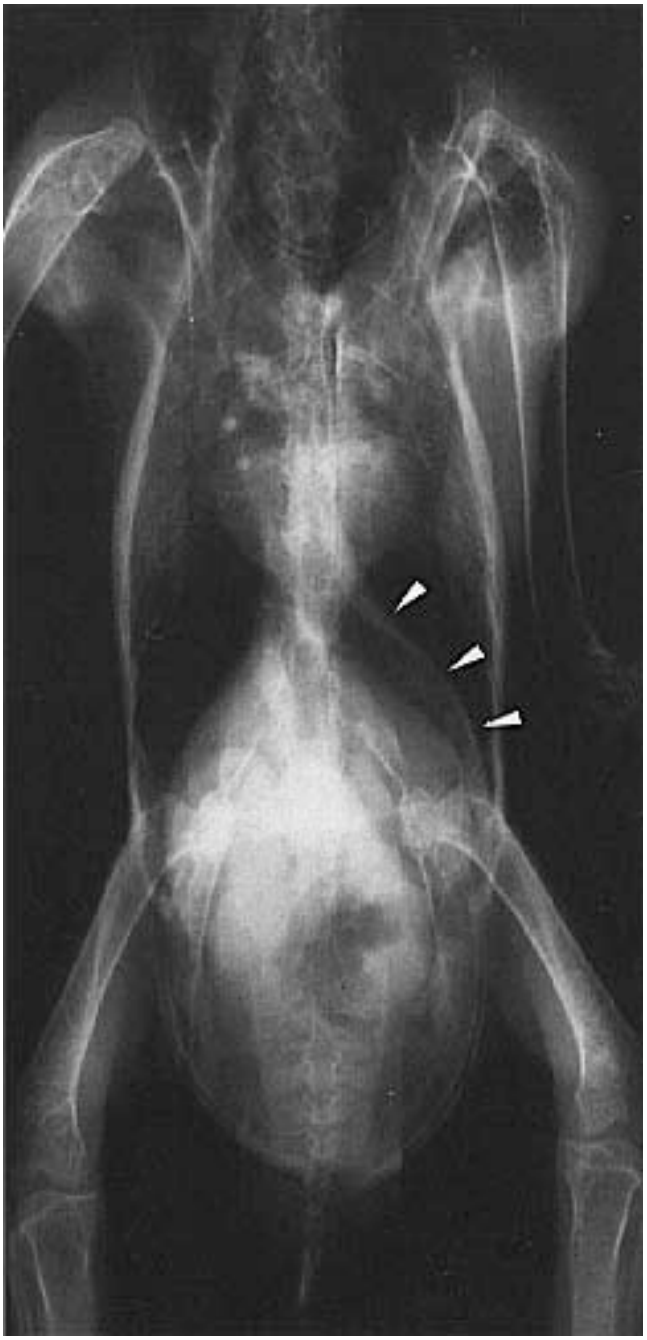


FIG 27.1 An adult Umbrella Cockatoo was presented for severe depression. The eyes were glazed and partially closed, the ulnar vein refill time was two seconds, and the skin on the toes would stay elevated for several seconds when pinched. All these findings were suggestive of severe dehydration. The lateral radiograph indicated microcardia (indicative of dehydration) and gaseous distention of the proventriculus (open arrows), which is common in birds that are anesthetized or are severely dyspneic. The pulmonary arteries and caudal vena cava are also visible (arrows). The VD view shows the gas-filled proventriculus (arrows).

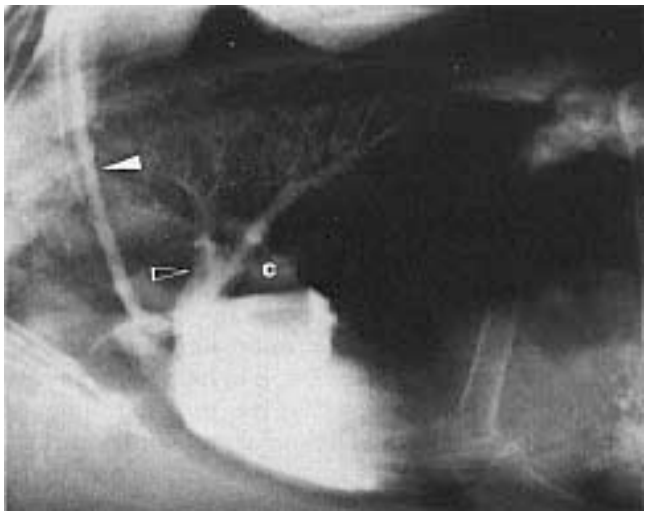

FIG 27.2 Angiography can be used to evaluate impaired cardiac function. A single rapid intravenous bolus of contrast agent was administered via a catheter into the cutaneous ulnar vein of a normal Green-winged Macaw. Images were made with a rapid film changer at six films per second. The axillary vein (arrow), cranial vena cava (c), cardiac chambers and pulmonary arteries (open arrows) are clearly visible. Note that contrast media is also present in the kidneys (courtesy of Marjorie McMillan).

TABLE 27.1 Normal Electrocardiograms in Selected Birds*

Parameter		Racing Pigeon	African Grey Parrot	Amazon Parrot
Normal heart rate		160-300	340-600	340-600
Normal heart rhythms		Normal sinus rhythm Sinus arrhythmia Second degree AV block	Normal sinus rhythm Sinus arrhythmia Ventricular premature beats Second degree AV block	
Normal heart axis		-83° to -99°	-79° to -103°	-90° to -107°
Normal measurements in lead II	P-wave duration Amplitude	0.015-0.020 s 0.4-0.6 mV	0.012-0.018 s 0.25-0.55 mV	0.008-0.017 s 0.25-0.60 mV
	PR-interval	0.045-0.070 s	0.040-0.055 s	0.042-0.055 s
	QRS complex duration R amplitude (Q)S amplitude	0.013-0.016 s 1.5-2.8 mV	0.010-0.016 s 0.00-0.20 mV 0.9-2.2 mV	0.010-0.015 s 0.00-0.65 mV 0.7-2.3 mV
	ST-segment	Very short or absent Elevation 0.1-0.3 mV No ST depression		
	T-wave	Always discordant to the ventricular complex		
		0.3-0.8 mV	0.18-0.6 mV	0.3-0.8 mV
	QT-interval Unanesthetized Anesthetized	0.060-0.075 s	0.039-0.070 s 0.048-0.080 s	0.038-0.055 s 0.050-0.095 s

*Criteria for the normal electrocardiogram in racing pigeons (n=60), African Grey Parrots (n=45) and Amazon parrots (n=37). Measurements are derived from ECGs recorded at 200 mm/s and standardized at 1 cm = 1 Mv. Reference values (inner limits of the percentiles $P_{2.5}$ - $P_{97.5}$ with a probability of 90%) modified from Lumeij[56] and Nap, et al.[67]

parrots (Table 27.1).[56,67] Other reports involve only a limited number of birds.

Electrocardiography may be useful for detecting cardiac enlargement from hypertrophy of any of the four cardiac chambers. Electrocardiography is indispensable for the diagnosis and treatment of cardiac arrhythmias and is also useful in monitoring changes in electrolyte concentrations during the treatment of metabolic diseases that alter electrolyte balance. When evaluating cardiac enlargement it is best to compare the electrocardiographic findings with those of cardiac imaging techniques.

The electrocardiogram may be of help in evaluating and diagnosing some of the diseases that cause vague signs of weakness, fatigue, lethargy, fever, collapse or seizures. Metabolic, cardiac, neurologic and systemic diseases that produce toxemia can cause one or all of these clinical changes. The electrocardiograph may be used also to monitor heart rate and rhythm in an anesthetized patient. Because the myocardium is very sensitive to hypoxia, the electrocardiogram can serve as a reliable indicator of the oxygenation of the bird (see Figure 27.15). The clinician should realize, however, that cardiac pathology can occur without electrocardiographic changes.

The Electrocardiograph and Recording of the ECG

Regardless of the type of electrocardiograph used, it must be able to run electrocardiograms at a paper speed of at least 100 mm/s. Avian heart rates are so rapid that inspecting and measuring the tracing is less accurate at slower speeds. For routine ECGs, the machine is standardized at 1 cm = 1 mV. When dealing with ECGs with a low voltage, the sensitivity of the machine should be doubled. If the complexes are so large that they exceed the edge of the tracing paper, the sensitivity should be halved. The calibration and the paper speed should always be marked on the electrocardiogram together with the date, time, name and case number of the patient.

The electrocardiogram can be recorded in an unanesthetized racing pigeon that is restrained in an upright position, while in parrots, isoflurane anesthesia is recommended. When comparing anesthetized and unanesthetized parrots, only the median heart rate and QT-interval were found to be significantly different ($P < 0.05$) (Table 27.1).[67]

A Mingograph 62 electrocardiograph (Siemens-Elema AB) with a paper speed of 25, 100 or 200 mm/s was used by the primary author to establish the reference values listed in Table 27.1. It is easiest to perform an ECG on a bird in dorsal recumbency, but

right lateral or ventral recumbency is equally effective. Needle electrodes placed subcutaneously are superior to alligator clips for use in avian patients.[a]

Lead I in birds is nearly isoelectric. The lead II electrocardiogram in Figure 27.3 is a recording of electrical currents generated during the depolarization and repolarization of the heart. The P-wave signifies that the atria have depolarized, causing contraction and ejection of their complement of blood into the ventricles. The PR-segment indicates the short delay in the atrioventricular node that occurs after the atria contract, which allows complete filling of the ventricles before ventricular contraction occurs. The depression of the initial part of the PR-segment is related to large atrial repolarization forces. In dogs, this is caused by right atrial hypertrophy and is called auricular T-wave or T_a-wave.[5,24,96] In racing pigeons, this phenomenon is seen in 83% of healthy individuals and depicts the repolarization of the atria.[56] A "T_a-wave" is also normal in some gallinaceous birds.[6]

In parrots, a slight indication of a T_a-wave may occasionally be noted.[67] The (Q)RS-complex represents ventricular depolarization and contraction with the ejection of blood into the aorta and pulmonary artery. The Q-wave is the first negative deflection, the R-wave is the first positive deflection and the S-wave is the first negative deflection following the R-wave. When there is no R-wave, the negative deflection is called a QS-wave. The largest wave in the QRS-complex is depicted with a capital letter, (ie, Rs or rS). The ST-segment and T-wave depict the repolarization of the ventricles. In clinically asymptomatic racing pigeons and parrots, the ST-segment is often very short or even absent, the S rising directly into the T-wave ("ST-slurring"). When the ST-segment is present, it is often elevated above the baseline (maximum 0.3 mV elevation in the racing pigeon). In mammalian species, these changes are associated with cardiac disease (ie, left ventricular hypertrophy),[5,12] but the cause of ST-slurring in birds remains undetermined.

The duration (measured in hundredths of seconds) and amplitude (measured in millivolts) of the complexes can be measured. When the machine is standardized at 1 cm = 1 mV each small box on the vertical is 0.1 mV. When the electrocardiograph is recorded at a paper speed of 100 mm/s, each small box on the horizontal is 0.01 s and when the ECG is recorded at 200 mm/s, each small box represents 0.005 s. The determined values can be compared with reference values (Table 27.1).

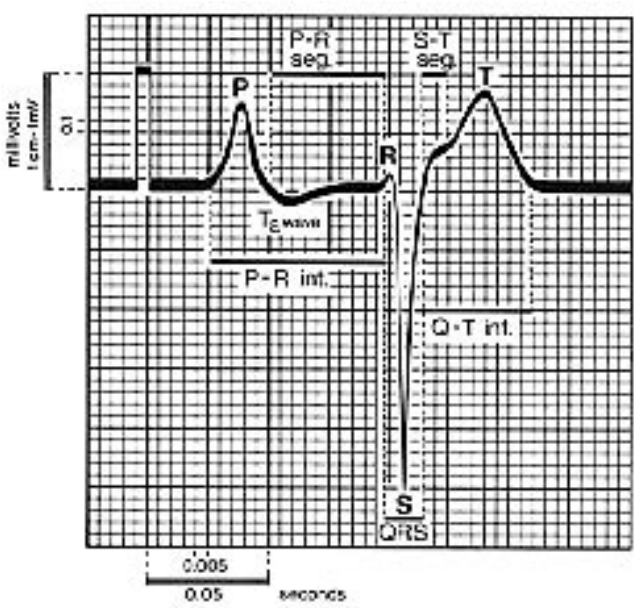

FIG 27.3 Schematic representation of a normal lead II electrocardiographic complex of a racing pigeon. Paper speed 200 mm/s, 1 cm = 1 mV (courtesy of J. T. Lumeij. Reprinted with permission[56]).

ECG Leads

The vector in the frontal plane of the electrical current that is generated during ventricular depolarization is called the mean electrical axis. The various lead systems were developed to measure the direction and force of the cardiac vector accurately. Each lead has a positive and a negative pole. If an electrical impulse is traveling in the direction of a lead's negative pole, a negative deflection results and vice versa (Figure 27.4). If the vector runs perpendicular to a lead, that lead will record either no deflection or an equal number of positive and negative forces. This is called an isoelectric lead. Bailey's hexaxial lead system is most widely used in veterinary electrocardiography (Figure 27.5). [5,24,96] It combines the three bipolar limb leads (I, II and III) from Einthoven's

CLINICAL APPLICATIONS

ECGs can be used to:

- Diagnose primary heart disease
- Monitor therapy of heart disease
- Evaluate cardiac effects of systemic abnormalities
- Monitor anesthesia
- Establish a cardiac database for the subclinical patient

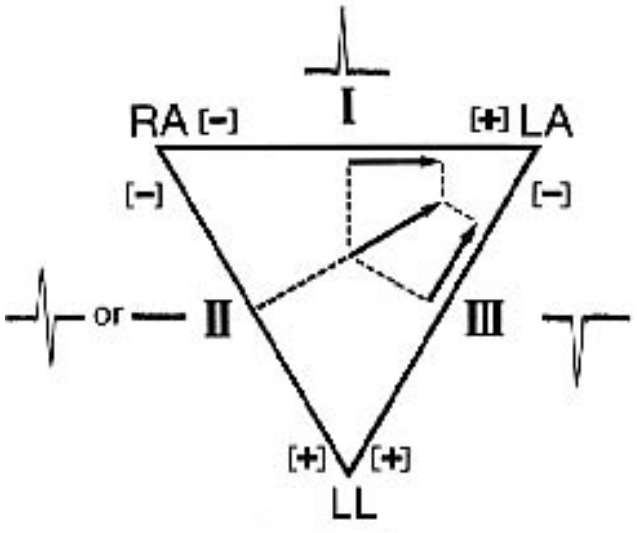

FIG 27.4 If an electrical impulse is traveling in the direction of a lead's negative pole, a negative deflection results and vice versa. If the vector runs perpendicular to a lead, that lead will record either no deflection or an equal number of positive and negative forces. This is called an isoelectric lead (see Figure 27.8).

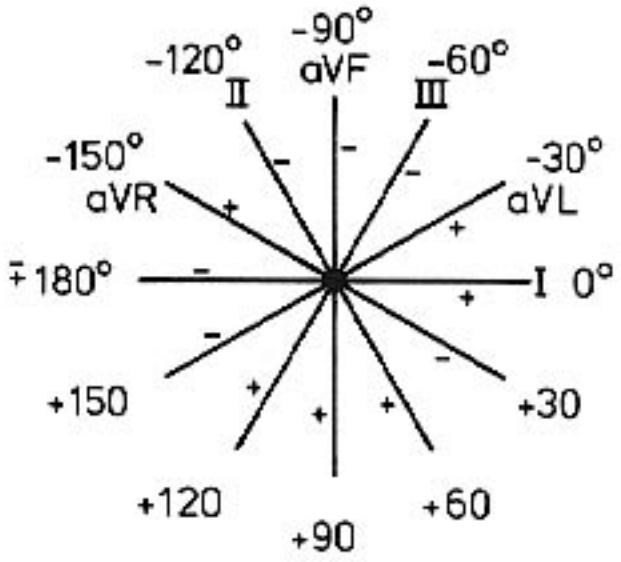

FIG 27.5 Bailey's hexaxial system. The three leads from Einthoven's triangle (I, II, III) and the three unipolar leads (aVR, aVL, aVF) can be redrawn exactly at the same length and polarity by passing each lead through the center point of the triangle. This produces a hexaxial system and angle values can be assigned to both the positive and negative pole of each lead. Now there are six leads, with a positive and a negative pole, and each pole has an angle value. This six-lead system is used for determining the mean electrical axis of ventricular depolarization.

triangle with the augmented unipolar limb leads (Figure 27.6).

The electrodes are attached to the right wing (RA), the left wing (LA) and the left limb (LL). The right hind limb (RL) of the bird is connected to the ground electrode.

- In lead I, RA is the negative pole and LA the positive pole.
- In lead II RA is the negative pole and LL is the positive pole.
- In lead III LA is the negative pole and LL is the positive pole.

In theory, these three leads form an equilateral triangle. The three leads can be redrawn exactly at the same length and polarity by passing each lead through the center point of the triangle. This produces a triaxial system, and angle values can be assigned to both the positive and negative pole of each lead.

The augmented (machine-induced increase in signal strength) unipolar leads (aVR, aVL, aVF) provide three more leads (Figure 27.6). An augmented unipolar lead compares the electrical activity of the reference limb to the sum of the electrical activity at the other limbs. The augmented vector leads are right arm (AVR), left arm (aVL) and frontal plane (aVF); "a" = augmented, "V" = vector, "R" = right arm, "L" = left arm and "F" = frontal (represents the left leg).

In lead aVR, RA is the positive pole and the negative pole compares LA and LL. In lead aVL, LA is the positive pole and the negative pole compares RA and LL. In lead aVF, LL is the positive pole and the negative pole compares RA and LA. Now there are six leads, with a positive and a negative pole, and each pole has an angle value. This six-lead system is used for determining the mean electrical axis of ventricular depolarization (see Figure 27.5).

Interpretation of the ECG

Electrocardiograms should be read in a systematic manner. There are four important steps in the process of interpreting an ECG (Figure 27.7).[5,96]

Determination of Heart Rate

All recording paper has a series of marks at the top or bottom of the paper. These marks are spaced so that they are three seconds apart at a 25 mm/s paper speed. To estimate heart rate per minute, the number of complexes that occur in three seconds are

counted and multiplied by 20. A second method of determining heart rate per minute is to count the number of small boxes from S-wave to S-wave and divide into 1500 (there are 1500 small boxes per minute at 25 mm/s paper speed).

Determination of Heart Rhythm

- Is the heart rate normal or abnormal for the species (bradycardia or tachycardia)?
- Is the heart rhythm regular or irregular?
- Is there a P-wave for every QRS-complex, and is there a QRS-complex for every P-wave?
- Are the P-waves related to the QRS-complexes?
- Do all the P-waves and all the QRS-complexes look alike?

Determination of Mean Electrical Axis

To determine the heart axis, the mean wave of electrical activity in the frontal plane that occurs when the ventricles depolarize is measured. The procedure for a rough estimation of the axis is simple and involves three steps (Figure 27.7):

- Find an isoelectric lead.
- Use the six-axis reference system chart and find which lead is perpendicular to the isoelectric lead (see Figure 27.5).
- Determine if the perpendicular lead is positive or negative on the tracing and examine the angle value on the six axis reference system. Compare these values with reference values (Table 27.1).

When all leads are isoelectric it is not possible to determine the heart axis and the heart is "electrically vertical" (Figure 27.8). The heart axis can be precisely determined by graphing leads II and III. Alternatively the heart axis can be calculated from the vectors of ventricular depolarization in leads II and III (in Figure 27.9 named **a** and **b** respectively) using Bailey's hexaxial system (see Figure 27.2).[67] The angles β and τ are known (60° and 30°, respectively).

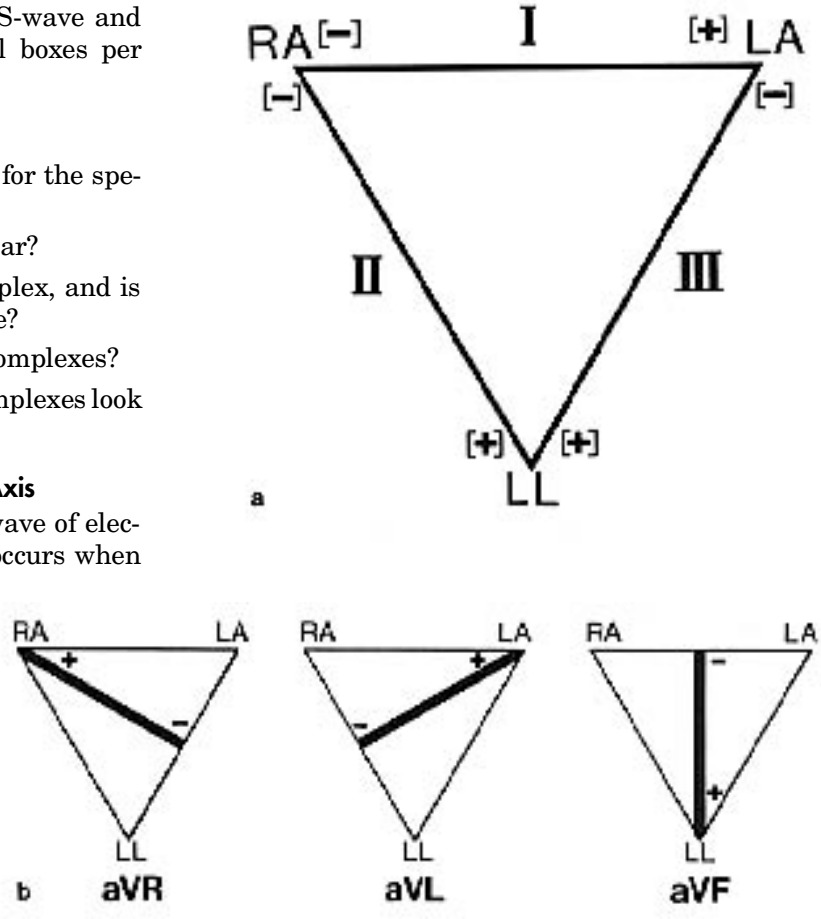

FIG 27.6 **a**) Einthoven's triangle depicts the three bipolar limb leads I, II and III. The electrodes are attached to the right wing (RA), the left wing (LA) and the left limb (LL). The right hind limb (RL) of the bird is connected to the ground electrode. In lead I, RA is the negative pole and LA the positive pole. In lead II, RA is the negative pole and LL is the positive pole. In lead III, LA is the negative pole and LL is the positive pole. The three leads form in theory an equilateral triangle. **b**) The augmented unipolar leads (aVR, aVL and aVF) provide three more leads. In lead aVR, RA is the positive pole and the negative pole compares LA and LL. In lead aVL, LA is the positive pole and the negative pole compares RA and LL. In lead aVF, LL is the positive pole and the negative pole compares RA and LA (courtesy of J. T. Lumeij).

Then:

$b = p \cos \beta$

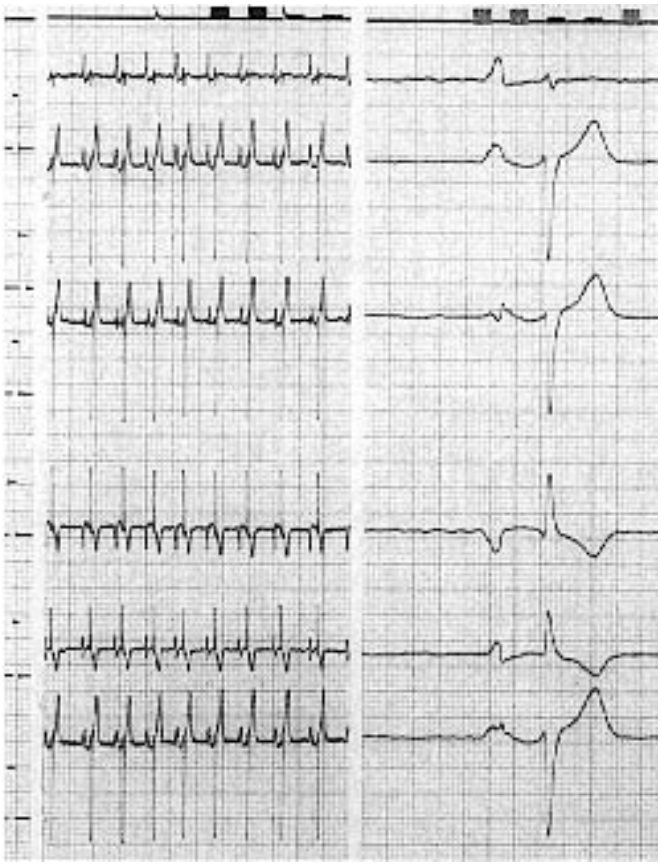
$q = p - a = [b/\cos \beta] - a$

$\tan \tau = h/q$

$h = q \tan \tau = q \tan (90 - \beta) = q \cot \beta$

$\tan \alpha = h/a = [q/a] \cot \beta = (\{[b/a] \cos \beta\}\text{-}1) \cot \beta$

Thus, α can be calculated from known parameters and the mean electrical axis can be determined. The calculations have been computerized by the primary author to facilitate the determination of the mean electric axis.[67]



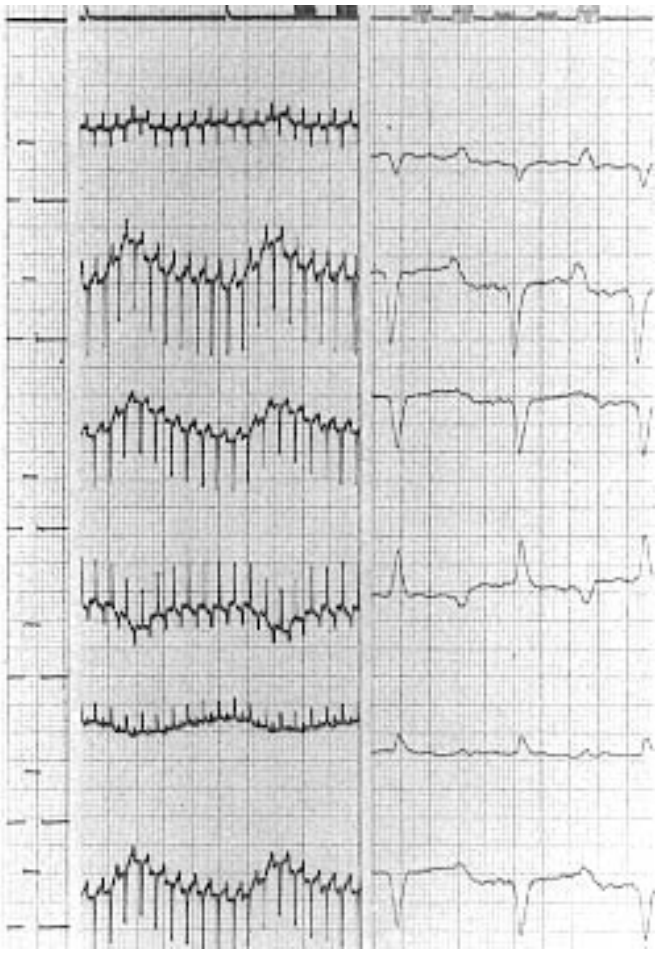


FIG 27.7 Normal pigeon electrocardiogram. From top to bottom: leads I, II, III, aVR, aVL, aVF. 1 cm = 1 mV. Paper speed 25 mm/s and 200 mm/s (courtesy of J. T. Lumeij).
Heart Rate: 250 (SS-interval is six boxes at 25 mm/s paper speed)
Rhythm: Sinus arrhythmia (the first two SS intervals are not equidistant)
Axis: -90° (The vector of ventricular depolarization is isoelectric in lead I. In the six-axis reference system (see Figure 27.5) lead aVF is perpendicular to lead I. The ventricular depolarization vector is negative in lead aVF. Angle value on the six-axis ref. chart is -90°)
Measuring: P-wave = 0.02 s, 0.4 mV. PR-interval = 0.06 s. QRS-complex = 0.015 s, 1.9 mV. ST-segment = 0.1 mV elevated, ST-slurring. T-wave discordant and positive in lead II, 0.8 mV. QT-interval = 0.07s.
Electrocardiographic Diagnosis: Normal pigeon electrocardiogram.

Representative ECG of an African Grey Parrot, with six simultaneously recorded leads. From top to bottom: leads I, II, III, aVR, aVL and aVF. Paper speed 25 mm/s and 200 mm/s, 1 cm = 1 mV (courtesy of J. T. Lumeij).
Heart Rate: 540
Rhythm: Normal sinus rhythm
Axis: -105° (leads I and aVL are closest to being isoelectrical. Leads aVF and II are perpendicular to these respective leads and negative. The heart axis is midway between -120° and -90°)
Measuring: P-wave = 0.015 s, 0.5 mV, slight 'P on T phenomenon'. PR-interval = 0.05 s. QRS-complex = 0.015 s, QS 1.3 mV. T-wave discordant 0.18 mV. QT-interval = 0.06 s
Electrocardiographic Diagnosis: Probably a normal electrocardiogram. The axis is borderline compared to reference values for the African Grey Parrot, but no other abnormalities can be identified.

In mammals, right axis deviation occurs when the vector of ventricular depolarization has moved clockwise on Bailey's six-axis reference system from a positive value (eg, +40° to +100° in dogs) toward the right side of the body. With left axis deviation, the vector moves counterclockwise toward the left side of the body. In mammals, right axis deviation is seen with enlargement of the right ventricle, while left axis deviation is seen with hypertrophy of the left ventricle.

Deviations in mean electric axis in birds are confusing because the normal heart axis is negative (except for some strains of chickens). More cases of left and right axis deviation in birds, and their associated clinical and pathologic changes, need to be determined before the importance of these electrocardiographic findings can be ascertained (Figures 27.10, 27.11, 27.12).

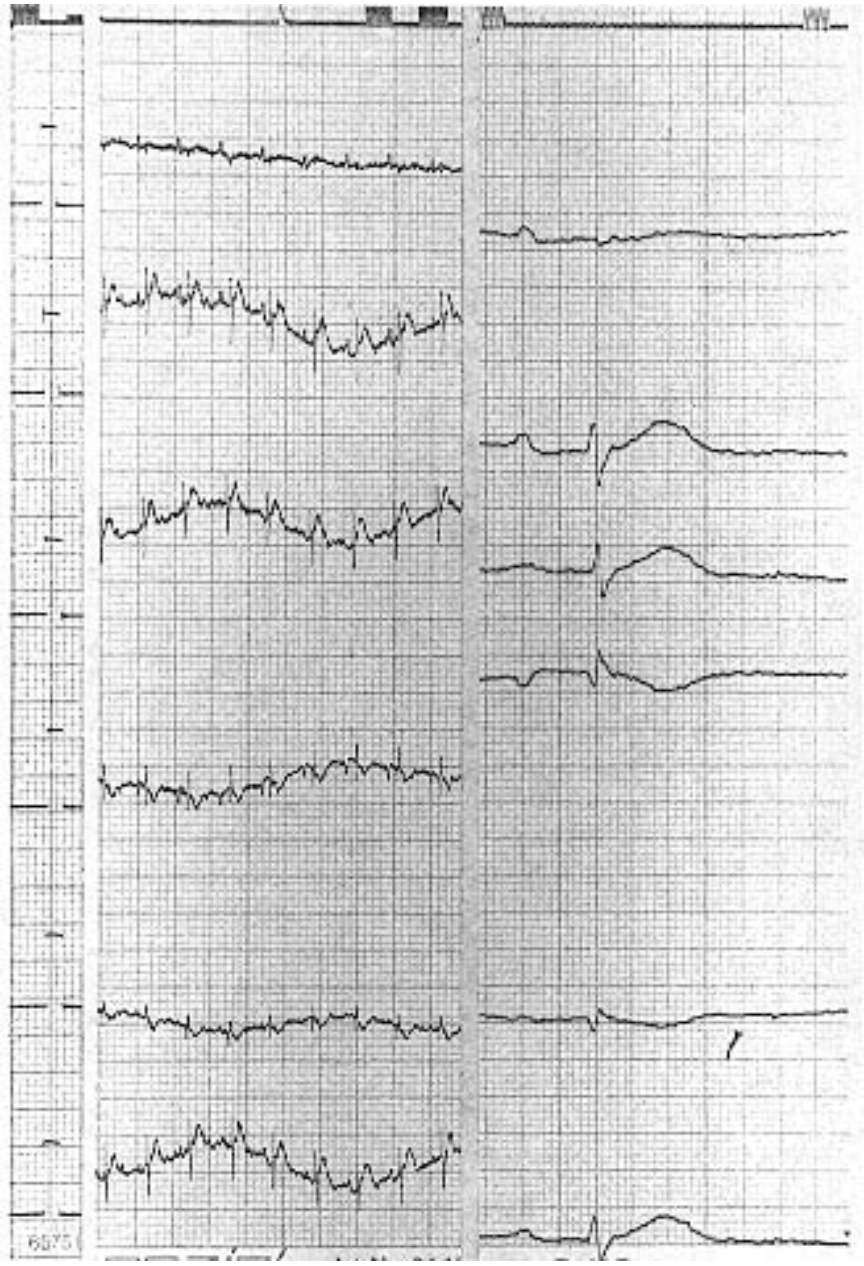

FIG 27.8 Electrically vertical heart in an African Grey Parrot. From top to bottom: leads I, II, III, aVR, aVL and aVF. 1 cm = 1 mV; paper speed 25 mm/s and 200 mm/s. This bird was presented with dyspnea and seizures. The heart axis is indeterminate because all leads are isoelectric. Radiographs indicated a dilated proventriculus. Myocarditis has been reported as a possible component of neuropathic gastric dilatation of psittacine birds (courtesy of J. T. Lumeij).[97]

Measuring

All measurements are made on the lead II rhythm strip. Measurements include the amplitude and the duration of the different electrocardiographic complexes (see Figure 27.3). The values found should be compared with the reference values (Table 27.1).

- ***P-Wave:*** With right atrial hypertrophy the P-wave becomes tall and peaked (P pulmonale), and with left atrial hypertrophy the P-wave becomes too wide (P mitrale). There is an increased number of P waves with tachycardia. P pulmonale has been associated with dyspnea induced by aspergillosis or tracheal obstruction. A tall, wide P-wave is suggestive of biatrial enlargement and is common with influenza virus in gallinaceous birds.
- ***PR-Interval:*** In the normal pigeon ECG, a T_a-wave can be seen in the PR-segment, indicating repolarization of the atria. A small T_a may occur also in some asymptomatic parrots. This finding is considered normal and should not be interpreted as a sign of right atrial hypertrophy as it is in the dog.
- ***QRS-Complex:*** Two measurements are made on the QRS-complex. The duration is measured from the beginning of the R-wave to the end of the S-wave. The second measurement is the amplitude of the S-wave, measured from the baseline downwards. Low voltage ECGs occur often in birds with pericardial effusion (Figure 27.13). A QRS-complex that is too wide or too tall indicates left ventricular hypertrophy (Figure 27.14). Prominent R-waves are suggestive for right ventricular hypertrophy[17,41,59] and it might be that a R_1-R_2-R_3 pattern is comparable to an S_1-S_2-S_3 pattern in dogs (see Figure 27.12)
- ***ST-Segment:*** The ST-segment in the avian electrocardiogram is often short or absent. When present, it may be elevated above the baseline, which should *not* be interpreted as a sign of left ventricular hypertrophy, myocardial hypoxia, myocarditis or hypocalcemia as it is in the dog.[5,24,56,67,96]
- ***T-Wave:*** In the normal avian ECG, the T-wave is always in the opposite direction to the main vector of the ventricular depolarization complex, and always positive in lead II. When the T-wave changes its

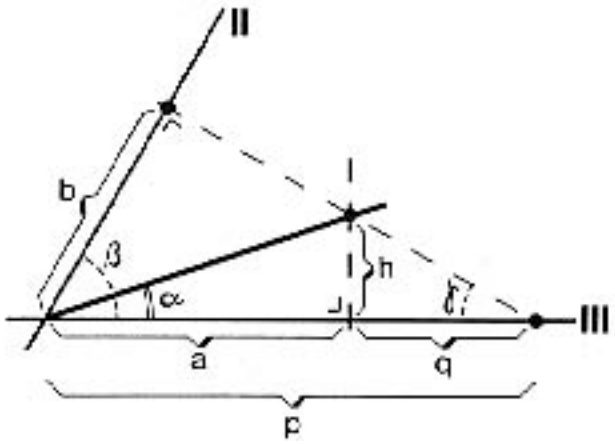

FIG 27.9 Mathematical derivation of the mean electrical axis of ventricular depolarization in the frontal plane. Known parameters are the vectors in lead II and III (named b and a, respectively, and the angles β and τ (60° and 30°, respectively), α can be derived using the formulae described in the text (courtesy of J. T. Lumeij. Reprinted with permission[67]).

polarity, it suggests that myocardial hypoxia is occurring (Figure 27.15). The same is true for a T-wave that progressively increases in size (eg, during anesthesia). T-wave changes may also occur in association with electrolyte changes (eg, increased T-wave amplitude with hyperkalemia).[3]

- ***QT-Interval:*** Prolongation of the QT-interval might be associated with electrolyte disturbances like hypokalemia and hypocalcemia. In African Grey and Amazon parrots, the QT-interval was significantly ($P < 0.05$) prolonged during isoflurane anesthesia (see Table 27.1). The effects of various diseases and compounds on the heart are listed in Table 27.2.

Arrhythmias

Sinus Arrhythmias

The normal rhythm of the heart is established by the SA node. A normal sinus rhythm does not vary in rate from beat to beat. An increase in vagal activity may decrease the heart rate, while a decrease in vagal activity may increase the heart rate. Heart rate may increase during inspiration and decrease during expiration and hence the S-S interval may not be equidistant. The associated rhythm is called sinus arrhythmia.

Sinus arrest is an exaggerated form of sinus arrhythmia and can be diagnosed if the pause is greater than

TABLE 27.2 Cardiovascular Effects of Selected Conditions or Agents[6,17,18,28,30,32,39-41,43,46,53,54,60, 61,64,83-93]

Condition/Agent	Rhythm	SA node	AV node	ECG Changes
Dilated cardiomyopathy	Atrial arrhythmia Ventricular arrhythmia			Increased R-wave Negative T-wave Mean axis 0° to - 170°
E. coli septicemia (Galliformes)				Elevated P-waves Elevated T-waves Elevated S-waves Elevated R-waves
Halothane	Decreased heart rate		First degree AV block	Increased PR-interval
Hyperkalemia (ducks)				Elevated T-waves
Hypokalemia	Sinus arrhythmia Sinus bradycardia VPCs	SA block	Incomplete AV block AV junctional PC	
Influenza virus (Galliformes)	Ventricular tachycardia VPCs		Decreased conduction	Increased ST-segment Increased TP-interval Increased PR-interval Increased RS-interval
Newcastle disease virus (Galliformes)	Ventricular arrhythmias		Decreased conduction	Fusion T- and P-waves Increased T-waves
Thiamine deficiency	Sinus arrhythmia Sinus bradycardia Sinus arrest VPCs			Decreased ST-segment
Vitamin E deficiency	Sinus arrhythmia Sinus bradycardia Sinus arrest VPCs			Decreased PR-interval Elevated ST-segment

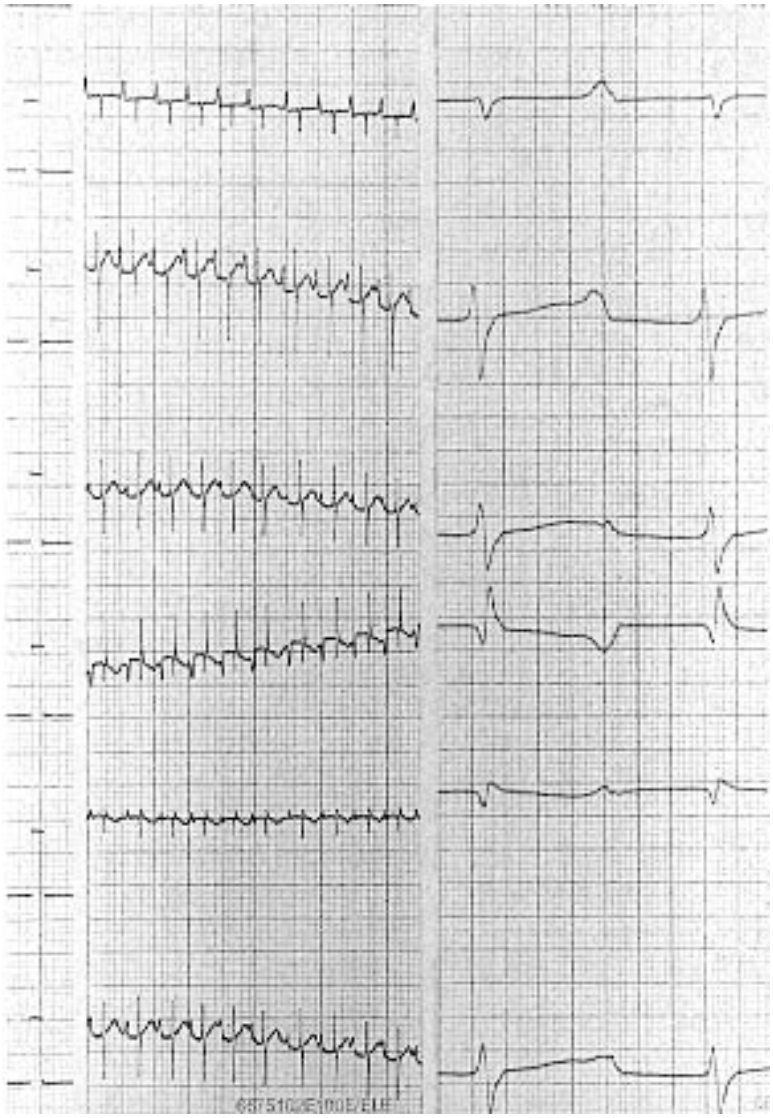

FIG 27.10 *History:* ECG of a 37-year-old African Grey Parrot with congestive heart failure. From top to bottom: leads I, II, III, aVR, aVL and aVF. 1 cm = 1 mV; paper speed 25 mm/s and 200 mm/s.
Heart Rate: 320
Rhythm: Sinus arrhythmia
Axis: -150° (The vector of ventricular depolarization is isoelectric in lead III. In the six-axis reference system [Figure 27.5], lead aVR is perpendicular to lead III. The ventricular depolarization vector is positive in lead aVR. The angle value on the six-axis reference chart is -150°)
Measuring: P = 0.4 mV, 0.025 s. PR-interval = 0.09 s. QRS-complex = 0.02 s, R = 0.6 mV, QS = 0.9 mV, T = 0.2 mV and QT = 0.11 s.
Electrocardiographic Diagnosis: Widening of P-wave (P-mitrale), widening of the QRS-complex and axis deviation are all indicative of left atrial and ventricular enlargement. An increase in the amplitude of the R-wave has been associated with right ventricular failure in chickens.
Clinical Findings: This bird was presented with severe dyspnea and inability to perch. Radiographs revealed cardiohepatomegaly and ascites. Ultrasonography confirmed the presence of ascites, but no free pericardial fluid could be seen. A liver biopsy was performed because of elevated bile acids (220 μmol/l). Histologic examination revealed fibrotic changes, possibly secondary to chronic liver congestion (right-sided heart failure). Treatment of the congestive left and right heart failure with furosemide 1 mg/kg BID and digoxin 0.045 mg/kg SID resolved the clinical signs within ten days (courtesy of J. T. Lumeij).

twice the normal S-S interval. A sinoatrial block occurs when an electrical impulse from the sinoatrial node fails to activate the atria. The pauses are exactly twice the S-S interval. A continuous shifting of the pacemaker site in the SA node or the atrium, and hence a continuously changing configuration of the P-wave, is called wandering pacemaker. Sinus arrhythmia, sinus arrest, sinoatrial block and wandering pacemaker have been reported in association with normal respiratory cycles and are considered physiologic in birds.[4a,39,67,99]

Sinus bradycardia can be induced by vagal stimulation and can be converted by the administration of atropine. Various anesthetics (eg, halothane, methoxyflurane, xylazine and acepromazine) have been reported to cause sinus bradycardia, when atropine is not given simultaneously. Hypothermia, which may accompany long-term anesthesia, may potentiate this arrhythmia.[1,37,58,63]

Pathologic conditions that may induce sinus bradycardia and sinus arrest include hypokalemia,[85,90] hyperkalemia,[3] thiamine deficiency,[11] and vitamin E deficiency.[88] The conduction abnormalities (SA block, AV block) caused by potassium deficiencies can be corrected by administering atropine, suggesting that potassium increases vagal tone to the SA and AV nodes.[87]

Several toxins have been reported to induce bradycardia, including, organophosphorus compounds and polychlorinated biphenyls.[43] Reflex vagal bradycardia may occur when pressure is exerted on the vagus nerve by neoplasms, and space occupying lesions impinging on the vagal nerve should be considered when unexplained atropine responsive bradycardia is seen. One case of sinoatrial arrest in an African Grey Parrot, which was associated with syncopal attacks, was seen at the primary author's clinic. The underlying disorder could not be determined (Figure 27.16).

If the sinoatrial node is sufficiently depressed by vagal stimulation, another part of the conducting system may take over the pacemaker function and escape beats may occur. When an electrical impulse originates

below the SA node in the atria the configuration of the P-wave will be abnormal, but positive in lead II. When an electrical impulse originates in fibers near the AV node (junctional beat), the P-wave may be absent or negative in lead II, indicating retrograde conduction (Figure 27.11). With ventricular beats the ectopic focus is localized in the fibers of the ventricle. The QRS complex is usually abnormal (but may be normal) and is unrelated to the P-wave. Atrioventricular nodal escape rhythm has been reported in ducks with sinus bradycardia induced by hyperkalemia.[3]

Atrial Arrhythmias

Atrial tachycardias may be seen as a result of pathologic conditions of the atrium. Sinus tachycardia (two times normal) has been reported in chickens infected with avian influenza virus.[64] When the heart rate is rapid, the P-wave may be superimposed on the T-wave (P on T phenomenon). This phenomenon has been recorded in 16% of normal Amazon parrots and in six percent of African Grey Parrots.[67]

When (paroxysmal) supraventricular tachycardia is associated with valvular insufficiency, digoxin therapy is indicated. It is imperative to differentiate between junctional tachycardia (presence of negative P-waves due to retrograde impulse conduction) and ventricular tachycardia/atrioventricular dissociation (presence of normal P-waves that are usually not followed by a QRS complex; no retrograde impulse conduction to the atrium), because administration of digoxin may potentiate ventricular fibrillation in birds with ventricular arrhythmias.

Atrial fibrillation occurs when electrical impulses are generated in the atrium in a rapid and irregular way, and the atrium is in a state of permanent diastole. Impulses reach the AV node in a high frequency and at irregular intervals, and hence the ventricular rhythm is irregular. The ECG is characterized by the absence of normal P-waves, normal QRS complexes (which may have an increased amplitude and duration because of ventricular hypertrophy) and irregular S-S intervals. Instead of the normal P-waves,

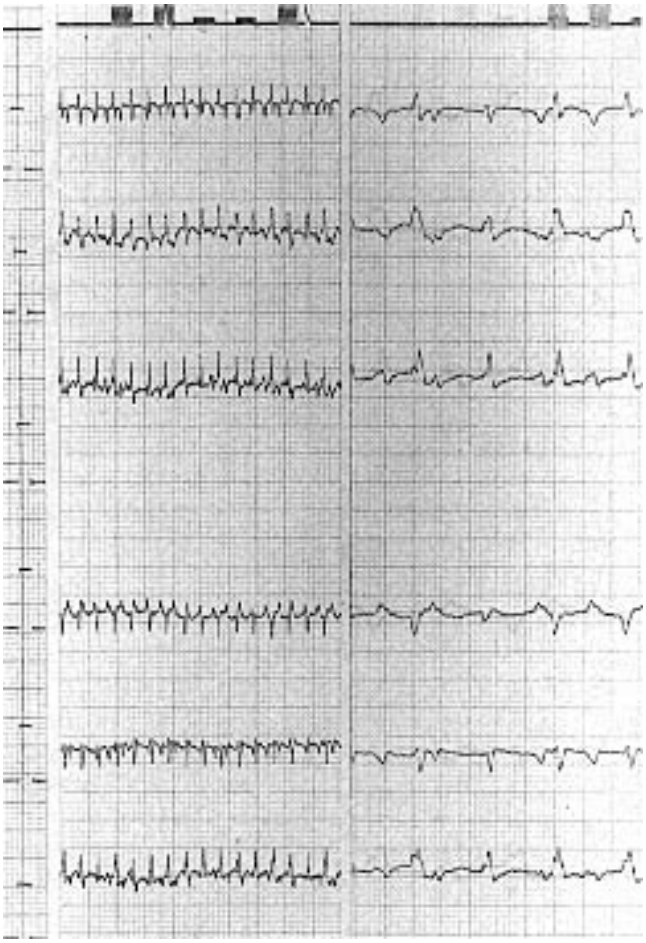

FIG 27.11 *History*: ECG of a 13-year-old African Grey Parrot with congestive heart failure and atherosclerosis. From top to bottom: leads I, II, III, aVR, aVL and aVF. 1 cm = 1 mV; paper speed 25 mm/s and 100 mm/s.
Heart Rate: Atrial rate 640, ventricular rate 480.
Rhythm: Complete AV-block with ventricular escape rhythm. (5 P-waves can be seen in lead I of the 100 mm/s ECG strip as negative deflections evenly spaced at 0.09 s. In this strip there are 4 ventricular complexes spaced at 0.12 s)
Axis: +80° (see below).
Measuring: P-wave negative in lead I and II. Bizarre ventricular complexes.
Electrocardiographic Diagnosis: Severe loss of function of the cardiac conduction system. Negative P-wave in lead I and II is indicative of retrograde conduction from ectopic focus in the atrium or AV-node. An idioventricular rhythm that is less than the atrial rhythm is characteristic for complete AV-block. Although there is dissociation between atrial and ventricular rhythm, the condition is not called atrioventricular dissociation because the ventricular rate is slower than the atrial rate. AV-dissociation is a form of ventricular tachycardia with a ventricular rate higher than the atrial rate. Bizarre ventricular complexes which are wide and positive in lead II are indicative of a focus in the ventricular wall, which acts as the pacemaker for the escape rhythm. The heart axis of +80° is therefore not indicative of ventricular hypertrophy.
Clinical Findings: This bird was presented with a two day history of dyspnea and anorexia. Radiographs indicated a marked haziness of the peritoneal cavity and a poorly defined cardiohepatic silhouette. The bird died on the second day of hospitalization. Post mortem examination revealed severe cardiomegaly, ascites and atherosclerosis of large arteries. Pulmonary edema was present also (courtesy of J. T. Lumeij).

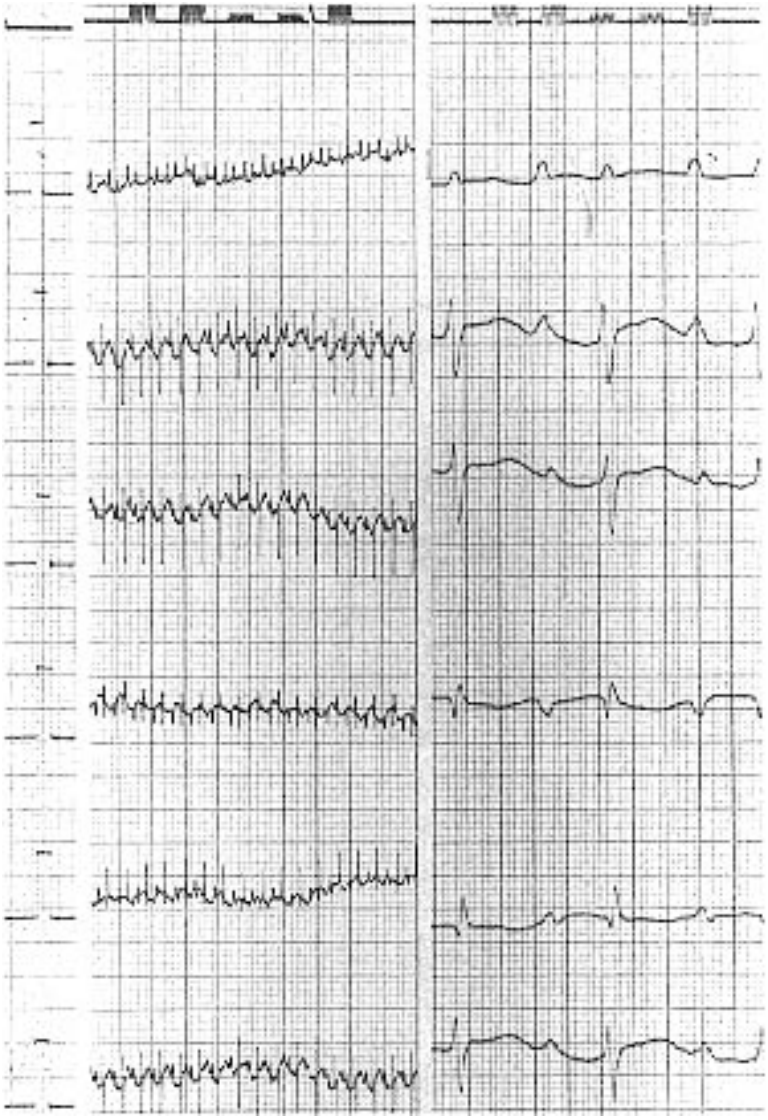

FIG 27.12 *History*: ECG of three-year-old African Grey Parrot with pericardial effusion and ascites. From top to bottom: leads I, II, III, aVR, aVL and aVF. 1 cm = 1 mV; paper speed 25 mm/s and 200 mm/s.
Heart Rate: 480
Rhythm: Normal sinus rhythm
Axis: -30° to -60°
Measurements: P-wave = 0.015 s, 0.6 mV. QRS-complex = 0.015 s, R = 0.6 mV, QS = 0.6 mV. T-wave = 0.3 mV. QT-interval = 0.065s
Electrocardiographic Diagnosis: P pulmonale and prominent R-waves in leads I, II and III. Heart axis shift to -45°±15°. These changes are consistent with right ventricular failure.
Clinical Finding: This bird was presented with dyspnea. Radiographs indicated an enlarged cardiac silhouette and ascites. Abnormal clinicopathologic findings included hypoproteinemia (25 g/l) and hypoalbuminemia (6 g/l). Postmortem findings included pale and enlarged kidneys (might explain proteinuria and hypoproteinemia). The pericardial sac contained a large amount of clear yellow fluid, which was also present in the peritoneal cavities. The endocardium, myocardium and epicardium were grossly normal. Renal failure, with secondary hypoalbuminemia, ascites and pericardial effusion, was considered to be the primary disease in this case. Right ventricular failure will develop before left ventricular failure because the weaker right ventricle is less able to compensate for the additional strain induced by pericardial effusion. Both P pulmonale and increased R-waves in lead II have been associated with right ventricular failure in birds (courtesy of J. T. Lumeij).

baseline undulations (F-waves) may be seen on the ECG.[4,24]

Atrial flutter is characterized by the regular occurrence of symmetrical P-waves, which appear to be saw-toothed. Usually the ventricles respond with some degree of atrioventricular block. The condition has never been reported in birds but artifacts from shivering, thermal polypnea, bucopharyngeal flutter and 60 cycle interference can be confused with atrial flutter. Atrial premature contractions, atrial fibrillation and atrial flutter are usually associated with serious atrial dilatation due to valvular insufficiency. Atrial fibrillation associated with left atrial enlargement due to mitral valve insufficiency has been reported in a Pukeko with congestive heart failure.[4] Digoxin is considered the treatment of choice for atrial fibrillation, but the prognosis should be guarded because of the presence of marked cardiac pathology.[4,24]

Ventricular Arrhythmias

Supraventricular tachycardias may originate from the sinoatrial node (sinus tachycardia), atrium (atrial tachycardia) or junctional area (junctional tachycardia). Differentiation between sinus tachycardia and atrial tachycardia may be accomplished by measuring the P-P interval. This interval is perfectly equidistant in atrial tachycardia but may be irregular in sinus tachycardia due to vagal effects. Junctional tachycardias can be diagnosed by the presence of inverted P-waves in lead II. The most common cause of sinus tachycardia is nervousness. But it is likely that stress, pain and other known causes of sinus tachycardia in dogs (eg, electrocution) may also precipitate the condition in birds.

Ventricular premature contractions (VPCs) are characterized by QRS complexes that are unrelated to the P-waves. Two, three or four and more premature contractions of the atria, junctional area or ventricle in a row, are called a pair, run and tachycardia respectively. Bigeminy is a rhythm characterized by alternating normal beats and premature contractions, while in trigeminy two normal beats are followed by one premature contraction.

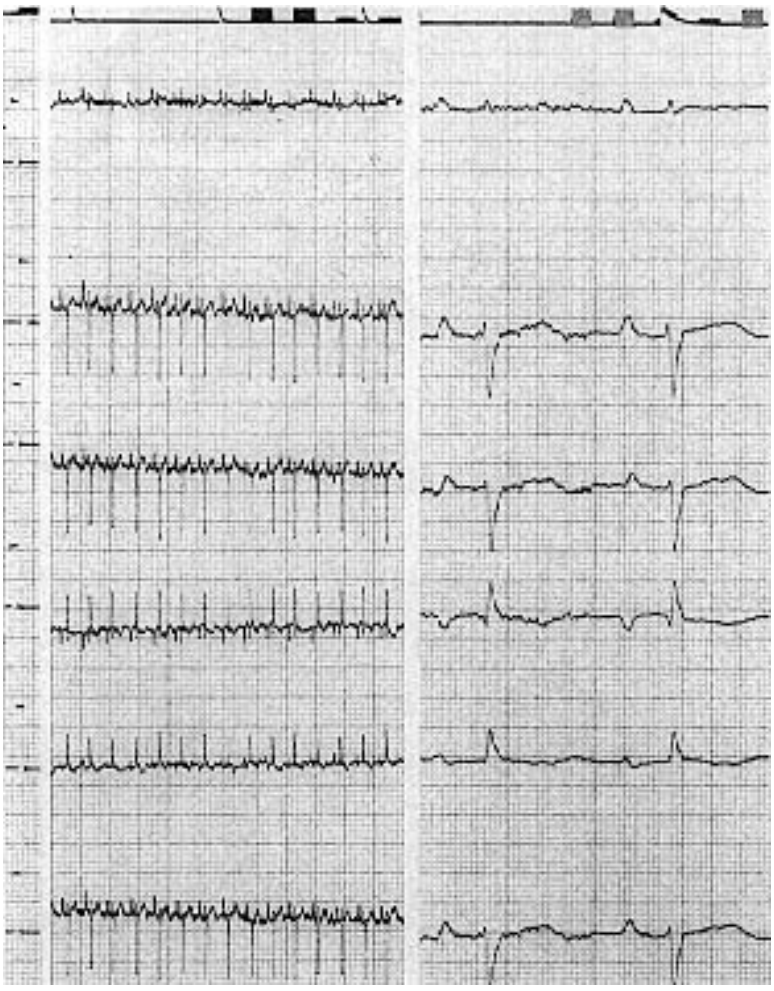

FIG 27.13 Low voltage ECG caused by pericardial effusion in a pigeon. From top to bottom: leads I, II, III, aVR, aVL and aVF. 1 cm = 1 mV; paper speed 25 mm/s and 200 mm/s.
Heart Rate: 375 (SS-interval four boxes at 25 mm/s paper speed).
Rhythm: Sinus tachycardia.
Axis: -90° (see Figure 27.7).
Measuring: P-wave = 0.015 s, 0.3 mV. PR-interval = 0.04 s. QRS-complex = 1 mV, 0.015 s. ST-segment normal. T-wave discordant, positive in lead II, 0.2 mV. QT-interval = 0.075 s.
Electrocardiographic Diagnosis: Sinus tachycardia, shortening of the PR-interval and low voltage QRS-complexes. Possibly pericardial effusion. The PR-interval varies inversely with heart rate, and in general is shorter when the heart rate is rapid. Pericardial effusion is the cardiovascular disease entity most often associated with low voltage complexes. Serofibrinous pericarditis was diagnosed in this bird at necropsy (courtesy of J. T. Lumeij).

Ventricular premature contractions in birds have been associated with hypokalemia,[85,90] thiamine deficiency,[11] vitamin E deficiency,[88] Newcastle disease and avian influenza viruses,[60,64] myocardial infarction due to lead poisoning[80] and digoxin toxicity.[63] The rhythm may be regular or irregular in birds with ventricular tachycardia. Positive P-waves can be identified in lead II at a lower frequency. Ventricular capture beats (normal P-QRS complexes in between abnormal PVCs) and ventricular fusion beats (a QRS-complex intermediate between a normal P-QRS complex and a bizarre QRS-complex that is formed by the simultaneous discharge of the ectopic ventricular focus and the normal AV node) are characteristic of ventricular tachycardia.

A special form of ventricular tachycardia is atrioventricular dissociation. In this condition, the atrial and ventricular rhythms are independent of each other, whereby the atrial rate is lower than the junctional or idioventricular rate. Runs of multiple VPCs, ventricular tachycardia or a bigeminal rhythm have been reported in birds with Newcastle disease or avian influenza virus infections.[64]

VPCs, ventricular tachycardia and ventricular fibrillation may occur during periods of hypoxia and with the use of halothane (Figure 27.17). Changes in the configuration of the T-wave should alert the clinician that myocardial hypoxia is present and more severe ECG abnormalities are imminent.

Atrioventricular Node Arrhythmias

Conduction disturbances in the atrioventricular node may lead to various gradations of atrioventricular (AV) heart block. When the impulse through only the AV node is delayed, first degree AV block is present. In second degree AV block some impulses do not reach the ventricles, but the majority of P-waves are followed by a QRS-complex. Third degree AV block or complete heart block is characterized by independent activity of atria and ventricles, whereby the frequency of the atrial depolarizations is higher than the ventricular depolarizations.

First-Degree Heart Block

First-degree heart block has been reported as the result of the administration of various anesthetics such as halothane[63] and xylazine,[58] whereby the PR-interval may increase to three to four times its normal value. The condition is associated with severe bradycardia. Atropine may be used to prevent or reverse the condition.[58]

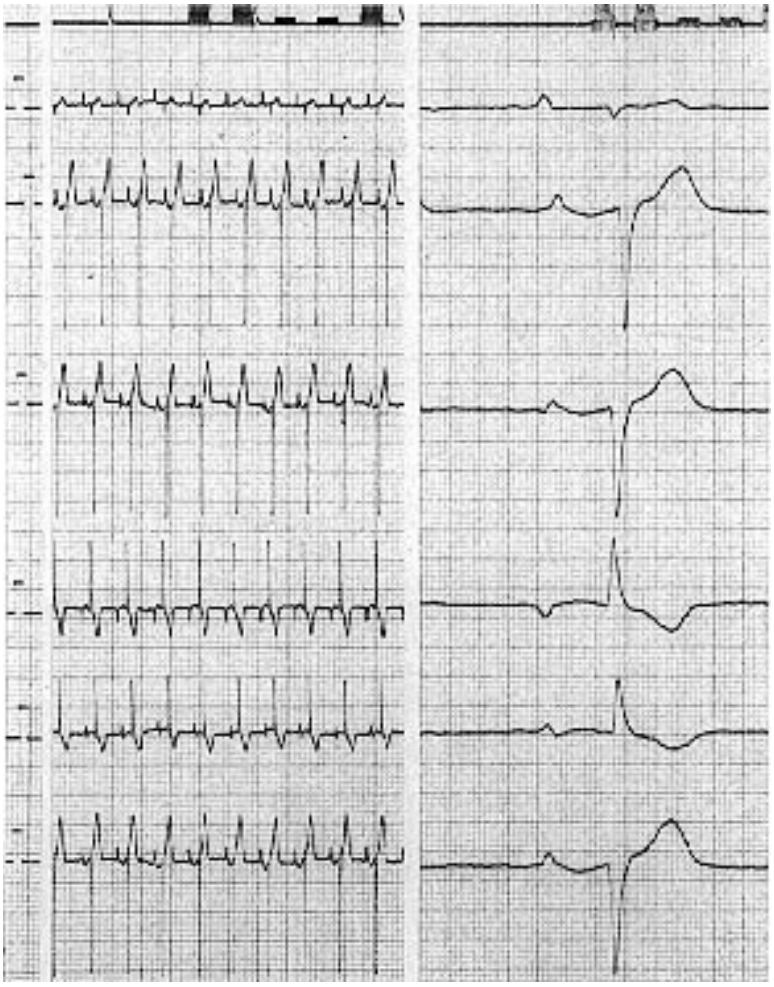

FIG 27.14 Ventricular hypertrophy in a pigeon. From top to bottom: leads I, II, III, aVR, aVL and aVF. 0.5 cm = 1 mV; paper speed 25 mm/s and 200 mm/s.
Heart Rate: 250.
Rhythm: Normal sinus rhythm.
Axis: -100°.
Measuring: P-wave = 0.5 mV (0.25 cm at 0.5 cm = 1 mV), 0.015 s. PR-interval = 0.06 s. QRS-complex = 0.02 s (4 boxes at 200 mm/s), 4.2 mV (2.1 cm at 0.5 cm = 1 mV). ST-segment = 0.2 mV elevated. T-wave = 1.4 mV. QT-interval = 0.08 s.
Electrocardiographic Diagnosis: QRS complexes are too wide and too tall, which is suggestive of ventricular hypertrophy. Nonselective angiocardiography was performed in this pigeon. Rapid sequence serial radiographs showed impaired ventricular function (courtesy of J. T. Lumeij).

Second-Degree Heart Block

Second-degree atrioventricular block Mobitz type 1 (Wenckebach phenomenon) has been reported as a physiologic phenomenon in five percent of trained racing pigeons[56] (Figure 27.18) and is seen occasionally in asymptomatic parrots[67] and raptors.[4a] In this form of AV block the PR-interval lengthens progressively until a ventricular beat is dropped. In a study with racing pigeons, second-degree AV block was observed in 24% of subclinical birds. It should be noted, however, that in the latter study the birds were restrained in a mechanical device during recording of the ECG. The birds had been in the device for one to two hours before ECGs were made and some of them were nearly asleep.[99]

Second-degree AV blocks that can be corrected with atropine have been described in several avian species. This stimulatory effect of atropine on the avian heart suggests that this agent functions, as it does in mammals, to decrease parasympathetic tone to the SA and AV nodes.[63] Complete AV dissociation has been documented in a parakeet.[101]

Third-Degree Heart Block

Third-degree AV block is characterized by a slow ventricular (escape) rhythm. The ventricular complexes may have a normal configuration or may be idioventricular depending on the site of ventricular impulse formation. The condition should be differentiated from atrioventricular dissociation and ventricular tachycardia whereby there is also no relation between P-waves and QRS-complexes, but wherein the ventricular rate is higher than the atrial rate.

Complete AV block with an idioventricular rhythm (auricular rate 300 and ventricular rate 200) has been seen in chickens with hypokalemia.[85] Complete AV block with an atrial rate of 640 and a ventricular rate of 480 was diagnosed at the primary author's clinic in an African Grey Parrot with severe cardiomegaly, ascites and atherosclerosis (see Figure 27.11).

Intraventricular Conduction Disturbances

Intraventricular conduction disturbances such as left bundle branch block and right bundle branch block and the Wolf-Parkinson-White (WPW) syndrome have not been reported in birds. In the latter condition, an accessory pathway bypasses the AV node and conducts atrial impulses directly to the ventricles, which result in a shortened PR-interval and bizarre QRS-complexes.

There are no reports on the clinical use of antiarrhythmic agents in avian medicine, and appropriate veterinary or human textbooks should be consulted for further information.

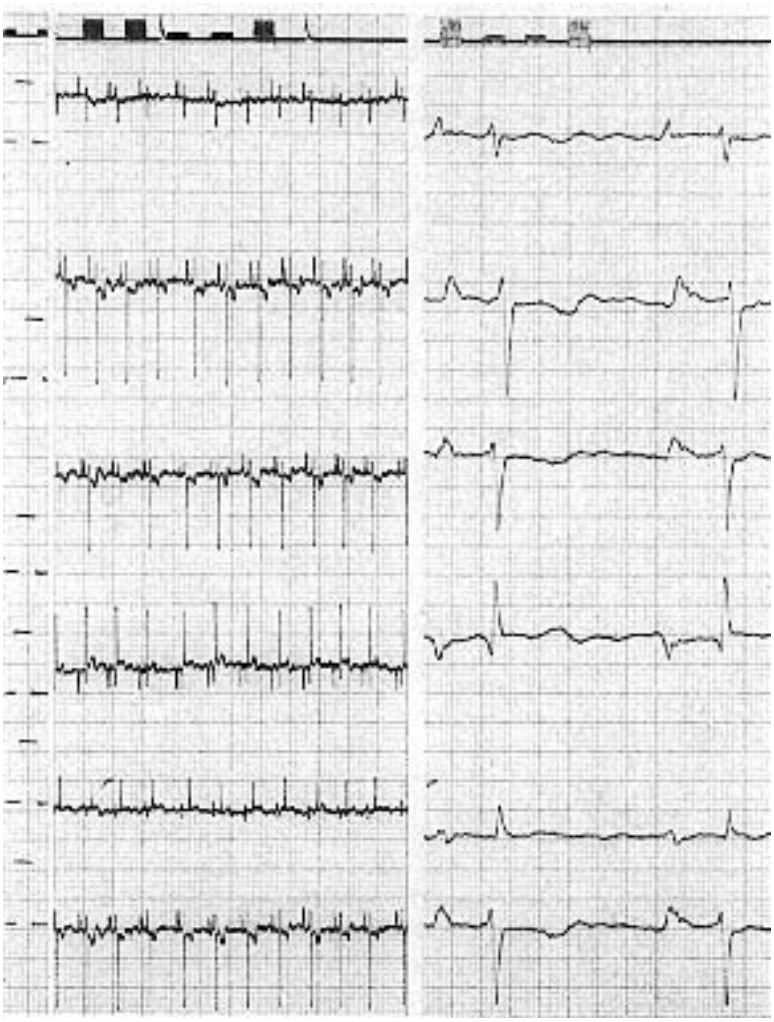

FIG 27.15 Electrocardiographic effects of myocardial hypoxia in a pigeon. From top to bottom: leads I, II, III, aVR, aVL and aVF. 1 cm = 1 mV; paper speed 25 mm/s and 200 mm/s.
Heart Rate: 300 (SS-interval is 5 boxes at 25 mm/s paper speed).
Rhythm: Sinus arrhythmia.
Axis: -94° (see Figure 27.7).
Measuring: P-wave = 0.015 s, 0.4 mV. PR-interval = 0.05 s. QRS-complex = 0.015 s, 1.7 mV. ST-segment = 0.1 mV depressed. T-wave concordant and negative in lead II, 0.2 mV. QT-interval = 0.07 s.
Electrocardiographic Diagnosis: Myocardial hypoxia. In this patient hypoxia was caused by a local mycotic tracheitis causing an inspiratory stridor and severe dyspnea. ST-depression and reversal of the T-wave during anesthesia are suggestive of myocardial hypoxia (courtesy of J. T. Lumeij).

Effects of Anesthesia

General anesthesia is typically associated with a time-related and progressive decrease in heart rate and a corresponding decrease in blood pressure. Methoxyflurane and halothane are both cardiac depressants that sensitize the heart to catecholamines. Halothane, methoxyflurane and ketamine have been reported to cause a decrease in heart rate in some birds and an increase in heart rate in others.[1,37] Xylazine, acepromazine and hypothermia have all been associated with bradycardia. Atropine can be used to increase the heart rate.

With halothane and methoxyflurane, respiratory and cardiac arrest routinely occur at the same time, and recovery from an anesthetic-induced cardiac arrest is rare. With isoflurane, respiratory arrest typically occurs several minutes before cardiac arrest. Birds with severe arrhythmias induced by an overdose of isoflurane may recover with appropriate intermittent partial pressure ventilation.

The increased PR-interval, first-degree AV block, decreased heart rate and conduction disturbances that occur with halothane anesthesia can be potentiated by the hypothermia that accompanies long-term anesthesia.[1] With severe hypothermia, the heart rate may decrease to less than 100 bpm with the PR-interval increasing to three to four times its normal value.[63]

Cardiovascular Diseases

Congestive Heart Failure

Pathogenesis

Congestive heart failure is a clinical syndrome that can be defined as the compensated condition associated with fluid retention that results from a sustained inadequacy of the cardiac output to meet the demands of the body. The causes of congestive heart failure are numerous and include endocardial, epicardial, myocardial and combined diseases. The condition should be differentiated from other causes of fluid retention (see Chapter 19). A diagnosis may be especially difficult in constrictive pericarditis because the heart is not enlarged radiographically (*pericarditis fibrinosa in organisatione* that may lead to *pericarditis adhaesiva*).

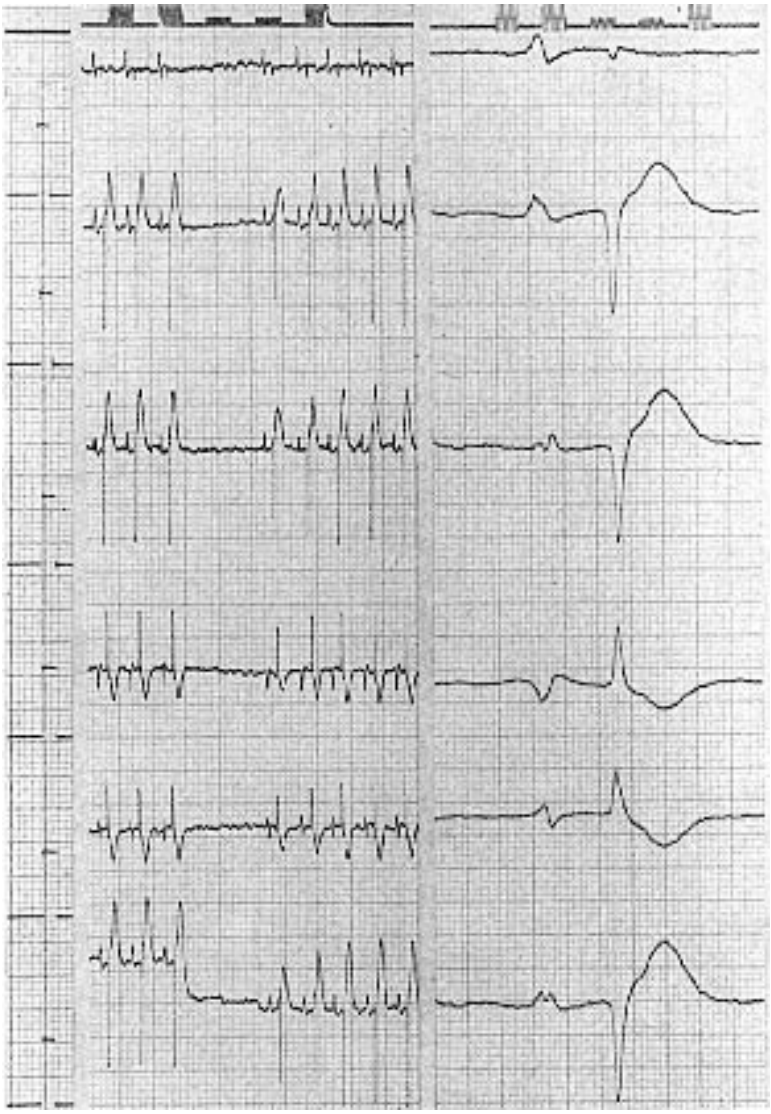

FIG 27.16 *History*: ECG of a 22-year-old African Grey Parrot with syncopal attacks. From top to bottom: leads I, II, III, aVR, aVL and aVF. 1 cm = 1 mV; paper speed 25 mm/s and 200 mm/s.
Heart Rate: 240.
Rhythm: Sinoatrial arrest.
Axis: -90°.
Measuring: P-wave = 0.02 s, 0.35 mV. PR-interval = 0.06 s. QRS-complex = 0.013 s. QS = 1.5 mV. T = 0.9 mV. QT-interval = 0.07 s.
Electrocardiographic Diagnosis: Sinus bradycardia and sinoatrial arrest. P mitrale indicative of left atrial enlargement. Repolarization changes in the ventricle are depicted by increased amplitude of the T-wave and prolongation of the QT-interval. Sinoatrial arrest and elevated T-waves are suggestive of hyperkalemia. Causes for sinoatrial arrest in birds include excessive vagal stimulation, thiamine deficiency, vitamin E deficiency and poisoning with organophosphorus compounds. The combination of P mitrale and sinoatrial arrest suggest a pathologic condition of the atrium such as atrial fibrosis or dilatation.
Clinical Findings: This bird was presented with short periods (several seconds) of syncope for several hours, two to three times a month. The bird was normal between attacks. Radiographs were unremarkable. Clinicopathologic abnormalities included leukocytosis with a left shift, hyperglobulinemia, and increased activity of AST. Potassium and calcium levels were normal. The sinoatrial arrest was considered to be a possible explanation for the observed syncopal attacks. The tentative diagnosis was bacterial/chlamydial myocarditis (courtesy of J. T. Lumeij).

The pathophysiology of congestive heart failure involves both backward failure and forward failure. Backward failure involves increased atrial and venous pressure due to a failing ventricle, while forward failure involves decreased renal blood flow resulting in sodium and fluid retention. In response to low blood volume, renin is released from the juxtaglomerular cells of the kidney. Renin acts on circulating angiotensinogen to form angiotensin I, which is converted to angiotensin II. Angiotensin II stimulates aldosterone synthesis. Aldosterone causes sodium and fluid retention.[94] Both mechanisms ultimately result in increased venous and capillary pressure, so that more fluid escapes by transudation in the interstitial spaces. The process is cumulative, ultimately leading to death from the local effects of fluid accumulation. (Compensated) congestive heart failure should be differentiated from (uncompensated) cardiogenic shock, which is characterized by acute cardiac dysfunction resulting in reduced arterial pressure and reduced tissue perfusion, without fluid accumulation in tissues.

Pulmonary edema predominates in isolated left ventricular disease. Systemic edema with hepatomegaly and ascites will predominate in isolated right ventricular disease, or when both ventricles are affected.

Left ventricular disease will result in increased pulmonary venous and capillary pressure. The active pulmonary constriction that occurs is known to cause an increase in pulmonary artery pressure and right ventricular failure in man. Atrial fibrillation, which is seen in left ventricular disease, presumably as a result of fibrotic changes disturbing the process of activation in the left atrium, is another contributing factor to the development of right heart failure. Closure of the left atrioventricular valves in man is dependent on the presence of atrial systole, perhaps through the effect of atrial relaxation. The resulting valvular insufficiency leads to pulmonary hypertension.

In birds, the right AV valve (muscular flap) thickens along with the right ventricle in response to an increased workload, and it has been postulated that this predisposes birds

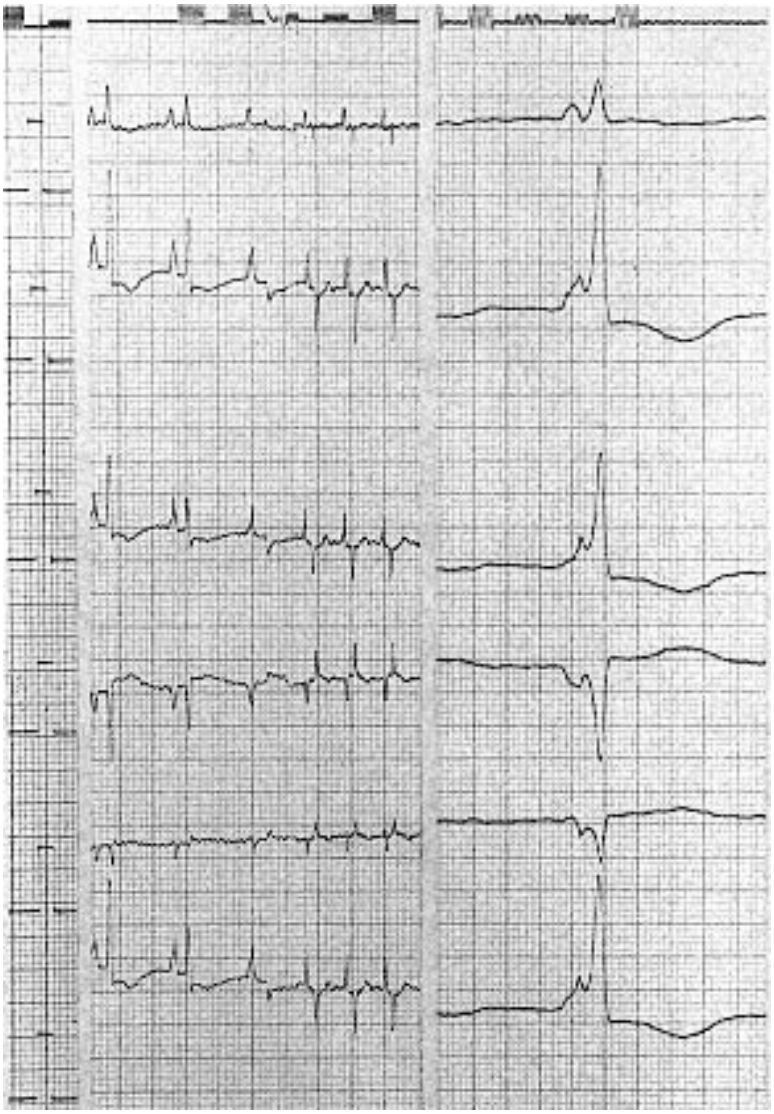

FIG 27.17 ECG of a Blue and Gold Macaw recovering from halothane anesthesia. From top to bottom: leads I, II, III, aVR, aVL and aVF. 1 cm = 1 mV; paper speed 25 mm/s and 200 mm/s. The 25 mm/s strip shows two idioventricular beats followed by a ventricular fusion beat and three normal P-QRS-T complexes. The 200 mm/s strip shows a bizarre QRS-complex caused by a discharge from an ectopic ventricular focus with a negative repolarization (T) wave. Halothane sensitizes the heart to adrenalin-induced arrhythmias (courtesy of J. T. Lumeij).

to right AV valvular insufficiency and right-sided heart failure.[48]

Clinical Findings

Heart enlargement with a thin left ventricular wall has been reported as a common occurrence in mynah birds.[22] In one study, 12 of 12 mynah birds had an abnormally thin left ventricle and ascites. The predominant clinical sign in affected birds was dyspnea (see Table 27.3). The heart lesions were associated with liver fibrosis and end-stage iron storage disease.[20]

In another report, an 11-year-old mynah was presented with dyspnea, polyuria and depression. Radiographs indicated cardiohepatomegaly and ascites. Echocardiography indicated biatrial enlargement, distended hepatic vessels and ascites. Color-flow doppler indicated a mitral regurgitation and right sided heart failure. The animal responded to treatment with furosemide (2.2 mg/kg) and digoxin (0.02 mg/kg). Repeated echocardiography indicated a decrease in the size of the heart and liver.[76] Changing to a diet low in iron and vitamin C may have been helpful in resolving these lesions. Congestive heart failure complicated by atrial fibrillation due to mitral valve insufficiency has been reported in a Pukeko.[4] A number of ECGs of parrots with congestive heart failure have been documented by the primary author (Figures 27.10, 27.11, 27.19).

Spontaneous turkey cardiomyopathy (STC), and ascites associated with right ventricular failure (ARVF) in broilers have been well documented. The high incidence of cardiovascular failure in meat-type poultry is probably the result of genetic selection for rapid growth and high breast meat yield, with no attention to cardiovascular health and stress resistance. The practice of inbreeding certain species of companion birds for color or size variations could have a similar effect.

Ascites associated with right ventricular failure seems to be associated with the oxygen demand placed on the body. Ascites associated with right ventricular failure was first described at high altitudes, but it also occurs at low altitudes and is most common in rapidly growing broiler chicks, with an increased incidence in cold weather. The following pathophysiologic mechanism has been suggested for AVRF.[48] The relatively higher oxygen demand causes a hypoxemia, which in turn induces a polycythemia. With polycythemia, the blood is more viscous and more difficult to pump through the lungs. The increased workload results in right ventricular dilatation and hypertrophy. The resulting insufficiency of the right ventricular valve leads to RVF, with associated liver congestion and ascites. Right ventricular failure and ascites have also been reported as a result

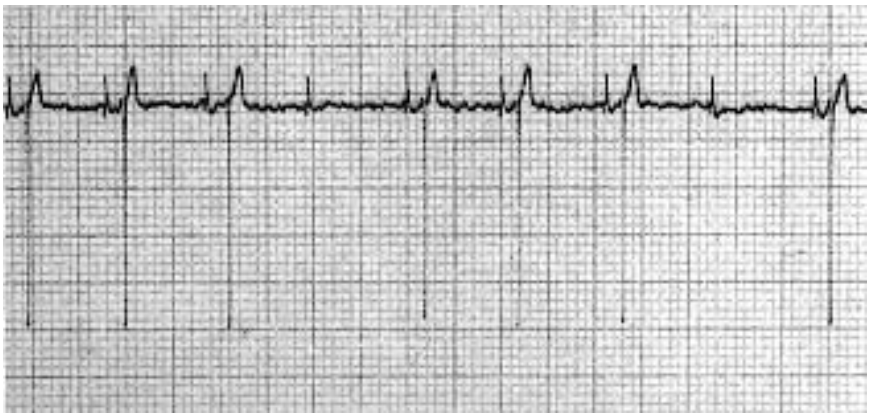

FIG 27.18 Normal lead III from a pigeon electrocardiogram showing Wenckebach block. The PR-interval becomes prolonged just prior to the omission of a QRS-complex.

of sodium toxicity. A moderate increase in dietary sodium for one week may cause congestive heart failure.[48a]

Treatment

Once congestive heart failure has been diagnosed, the prognosis for long-term survival is guarded, because a specific therapy is not available. A significant prolongation of life, however, can be achieved by providing timely symptomatic treatment. Treatment of congestive heart failure in birds can best be accomplished with the loop diuretic furosemide. The dosage must be adjusted for the individual bird, but 1-2 mg/kg SID or BID is a general starting point. Response to therapy should be rapid and can be best monitored by weighing the patient daily to establish the degree of fluid loss. Dosages should be tapered down to the minimal effective dose, but continuous therapy is required to prevent recurrence of fluid retention.

Side effects of furosemide administration include hypovolemia and hypokalemia. The latter is especially important when diuretics are used together with cardiac glycosides, because these drugs may also lower plasma potassium concentrations. Hypokalemia may increase the frequency of rhythm disturbances induced by cardiac glycosides.

Cardiac glycosides are indicated in congestive heart failure, especially when accompanied by atrial fibrillation. Ventricular tachycardia may be a contraindication because digitalis may induce ventricular fibrillation in these cases. Cardiac glycosides increase the contractility of the heart muscle and delay conduction through the atrioventricular node that can be seen by prolongation of the PR-interval on the electrocardiogram. Arterial pressure, cardiac output and stroke volume are increased, while venous pressure is decreased. A decrease of the heart rate can be seen due to improvement of the circulation and parasympathetic (vagal) stimulation. Signs of toxicity include cardiac arrhythmias and gastrointestinal signs.

Any type of arrhythmia may result from digoxin poisoning. Digoxin therapy should be discontinued immediately if arrhythmias develop, and a lower dose regimen should be established. Diuretic-induced hypokalemia may precipitate digoxin-induced arrhythmias. Only limited information is available with regard to digoxin therapy in birds. Digoxin appears to have varying effects among different avian species and the therapeutic index is low. Digoxin pediatric drops, rather than digoxin tablets, should be used in birds to improve the accuracy of dosing. A dose of 0.02 mg/kg daily was considered safe and produced satisfactory plasma levels of digoxin in parakeets and sparrows.[35] A daily dose of 0.01 mg/kg successfully reduced right ventricular enlargement and ascites in chickens.[2] A dose of 0.05 mg/kg/day was considered safe and produced adequate blood plasma levels in Quaker Conures (Monk Parakeet).[100]

Recently, angiotensin converting enzyme (ACE) inhibitors, which reduce the formation of angiotensin II, have gained considerable popularity for the treatment of congestive heart failure in man.[10,15,74,79,81] These drugs, including captopril and enalapril, reduce plasma volume by interfering with the renin-angiotensin-aldosterone system, and should be used in combination with a diuretic. There are no reports of the use of these drugs for the treatment of congestive heart failure in birds, but it has been shown that inhibition of endogenous angiotensin II concentrations in quail by captopril can decrease natural water intake.[94]

Vegetative Endocarditis

Endocarditis of the aortic and mitral valves may cause vascular insufficiency, lethargy and dyspnea. Valvular endocarditis is most common in birds with chronic infections (eg, salpingitis, hepatitis and bumblefoot) and has been reported in a large variety of avian species including Galliformes,[7,31,69,73] Anseriformes,[7,36] eagle,[44] emus,[70] curassow,[73] flamingo and a Blue and Gold Macaw.[42] Frequently implicated bac-

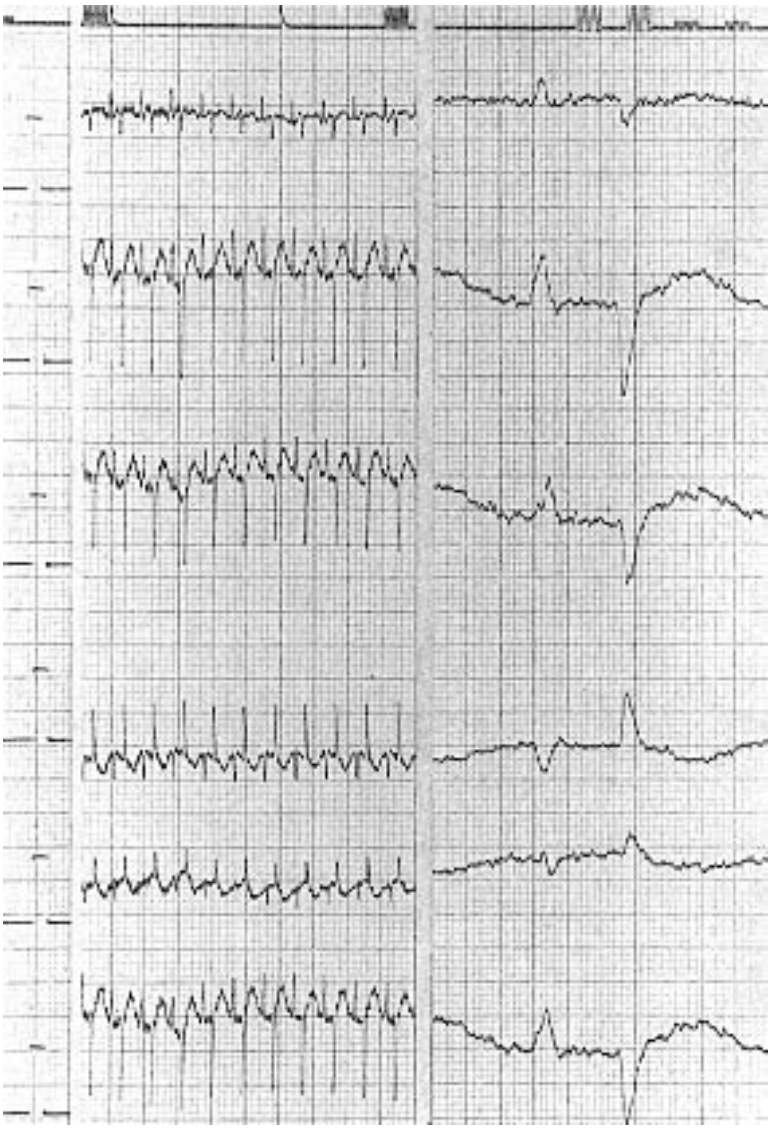

FIG 27.19 ECG of a 12-year-old Amazon parrot with congestive heart failure. From top to bottom: leads I, II, III, aVR, aVL and aVF. 1 cm = 1 mV; paper speed 25 mm/s and 200 mm/s.
Heart Rate: 320.
Rhythm: Normal sinus rhythm.
Axis: -110° (In this series of leads there is no true isoelectric lead. The two leads that are closest to being isoelectric are lead I [0.4 mV negative] and lead aVL [0.3 mV positive]. Lead aVF is perpendicular to lead I and negative and lead II is perpendicular to lead aVL and negative. The heart axis is slightly more negative than the average between -120° and -90° because the positive value of lead aVL is slightly more than the negative value of lead I.)
Measurements: P-wave = 0.7 mV, 0.02 s. PR-interval = 0.065 s. QRS-complex = 0.02 s, QS = 1.3 mV. T discordant, 0.5 mV. QT-interval = 0.1 s.
Electrocardiographic Diagnosis: P pulmonale and P mitrale are indicative of biatrial enlargement. Widening of the QRS-complex and lengthening of QT-interval are indicative of left ventricular enlargement. Axis deviation to -110°.
Clinical Findings: This bird was presented with dyspnea of at least four months' duration. The dyspnea had become progressively more severe for the few days before evaluation. Radiographs indicated cardiohepatomegaly. Ultrasonography revealed ascites and dilation of the hepatic veins. Total protein and protein electrophoresis were normal. Unsuccessful treatment with oxygen, gavage feeding, furosemide and digoxin was attempted. Postmortem findings confirmed cardiohepatomegaly and severe ascites. Histologic examination of the liver revealed fibrosis that was thought to have occurred secondary to right ventricular failure (courtesy of J. T. Lumeij).

TABLE 27.3 Clinical Signs Associated with Heart Disease

Congestive Heart Failure	Arrhythmia
▪ Dyspnea	▪ Asymptomatic
▪ Coughing	▪ Dyspnea
▪ Weakness	▪ Coughing
▪ Syncope	▪ Weakness
▪ Cachexia	▪ Syncope
▪ Reduced exercise tolerance	▪ Sudden death
▪ Sudden death	
▪ Edema and ascites	

teria include streptococci, staphylococci, *E. coli*, *Pasteurella, Pseudomonas aeruginosa* and *Erysipelothrix rhusiopathiae*. In pigeons, trichomoniasis has been reported as a cause of valvular endocarditis.[31]

Lesions consist of yellow irregular masses on any of the heart valves. The disease is associated with bacteremia, and thromboembolisms may occur throughout the vasculature.[31,36,69,70] Secondary lesions have been described in the liver, CNS, spleen, heart, lungs, kidneys, ischiatic artery and external iliac artery (Figure 27.20).[36,70]

Any alteration in blood flow through the heart could predispose a bird to endocarditis. The initial damage to the heart valves that induces vegetative endocarditis is usually unknown. Factors that have been associated with endocardial or valvular lesions include chronic bacterial septicemia, frostbite, congenital lesions (that alter blood flow) and degenerative myocarditis.[4,36,44,70,98]

Clinical Findings

Valvular endocarditis and vascular insufficiency are frequently associated with lethargy and dyspnea, although the clinical presentation can vary. A six-year-old Blue and Gold Macaw was presented with anorexia, tachypnea, mild dyspnea and weight loss. A mild systolic murmur, which could best be auscultated over the left pectoral muscles, was noted on physical examination. *Enterobacter cloacae* was isolated from the blood in pure culture. Vegetative endocarditis of the left AV valve was diagnosed (Figure 27.21).[42]

Erysipelothrix rhusiopathiae was recovered from mitral and tricuspid valve lesions of a subclinical seven-year-old female swan that was found dead in her enclosure.[36]

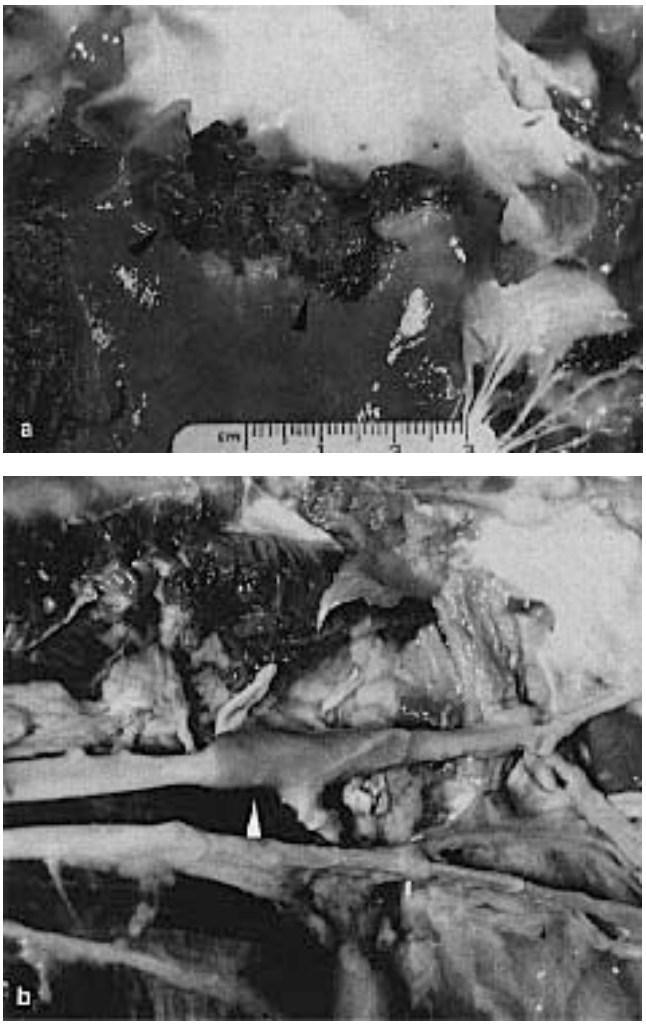

FIG 27.20 A four-year-old emu with a six-week history of lethargy, anorexia and inability to stand had a mild systolic murmur. Abnormal clinical pathology findings included an elevated AST (6000 IU/l) and anemia (PCV=27%). Electrocardiography revealed a heart rate = 120, P-wave = 0.3 mV, PR-interval = 150 mS, R-wave = 0.15 mV, S-wave = 1.3 mV, QRS-complex = 40 mS, mean electrical axis = -90°. Echocardiography indicated a large mass on the aortic valve. **a)** Staphylococcus was isolated from vegetative endocardial lesions (arrows). **b)** Ischemic infarcts were found in several large muscle masses, and a thrombus was present in the left external iliac artery (arrow) (courtesy of John Randolph, reprinted with permission[70]).

A six-year-old curassow was presented with lethargy and a cool edematous left leg. Radiography revealed cardiomegaly and enlargement of a brachiocephalic artery. Abnormal clinicopathologic findings included heterophilia (60,000/l with toxic changes), and elevated plasma activities of LDH and CPK (4108 IU/l and 6,692 IU/l, respectively). Staphylococcus-induced lesions were found on the left AV valve. Septic thrombi were present in the left brachial artery.[73]

Myocardial Diseases

Congenital Heart Disease

A list of common avian heart diseases and some of their etiologies are listed in Table 27.4. Chicken embryos are classic experimental animals to study teratologic effects of drugs on the heart. Various cardiovascular malformations can experimentally be induced, especially intraventricular septal defects. Spontaneous cardiovascular malformations like duplicitas cordis, multiplicatis cordis, ectopia cordis have been reported.[31] Intraventricular septal defects are common, while foramen ovale persistence is of little clinical importance. Intraventricular septal defects are usually functionally closed, but in two percent of cases the condition is associated with congestive heart failure. Blood is shunted from left to right, which leads to right ventricular failure and ascites secondary to valvular insufficiency.

Acquired Diseases

In mammals, myocarditis can occur secondary to many common viral, bacterial, mycotic and protozoan infections. Cardiomyopathy has been associated with thyroid diseases, anemia, malnutrition, metabolic disorders, parasitic infections, pancreatitis, toxemias and neoplasia.[24] The pathogenesis of cardiomyopathy and myocarditis in birds is similar to that described in mammals.[31] The liver and myocardium can be sites of excessive iron storage in birds with hemochromatosis. Experimental *E. coli* infections have been shown to cause myocarditis and pericarditis with marked electrocardiographic changes, including left axis deviation.[32]

Fowl plague has been associated with myocardial lesions in a variety of avian species.[60] Myocarditis has been reported as a component of neuropathic gastric dilatation in psittacines.[97] Sarcocysts (muscle cysts containing bradyzoites, the asexual generation of *Sarcocystis* spp.) have been reported in the myocardium of a variety of avian species.[23,55,66] A number of idiopathic degenerative conditions of the myocardium have been reported in gallinaceous birds.

Spontaneous turkey cardiomyopathy (STC, round heart disease, cardiohepatic syndrome) in turkey poults one to four weeks of age is characterized by marked dilatation of the right ventricle with extreme thinning of the ventricular wall. [75] Generally, ascites, hydropericardium and liver congestion are present.[41,75] Although the major increase in heart size is caused by the right ventricular dilatation, there is also an increase in total mass of both ventricles, with

TABLE 27.4 Some Common Causes of Heart Lesions in Birds

Pericarditis	**Myocarditis**
Listeria	*Listeria*
E. coli septicemia	*E. coli* septicemia
Chlamydia	*Pasteurella*

Reovirus (Galliformes)	Polyomavirus
Concurrent respiratory disease	Avian serositis virus
Cardiomegaly	*Sarcocystis*
Polyomavirus	Neuropathic gastric dilatation
Hemochromatosis	Selenium and vitamin E deficiencies
Epicarditis	**Hydropericardium**
Salmonella	Polyomavirus
Pasteurella	Reovirus (Galliformes)
	Furazolidone toxicity
	Genetics

a relatively greater increase in the left.[40] Lungs are generally congested and edematous.[75] Although the etiology of STC is unknown, it is clinically associated with rapid growth and hypoxic conditions (eg, low oxygen levels in the incubator and poor ventilation).[47,47b] Lesions induced by feeding ducklings, chicks and turkey poults furazolidone (300 ppm of feed) are indistinguishable from those described with STC.[18,47,72]

FIG 27.21 Valvular endocarditis on the left atrioventricular valve (arrows) from a Blue and Gold Macaw (courtesy of Ramiro Issaz, reprinted with permission[42]).

Myocardial degeneration (round heart disease) of unknown etiology has been described in backyard poultry. The morbidity is very low, but mortality may reach 50%. Lesions consist generally of an enlarged and yellowish heart. A few affected birds may have an excess of gelatinous fluid in the pericardial sac or peritoneal cavity.[69,75] The disease should not be confused with STC.

Vitamin E and selenium deficiencies are well known as causes for cardiomyopathy in gallinaceous birds.[78] Selenium and vitamin E deficiencies have also been suggested as causes for myocardial and skeletal muscle degeneration in ratites less than six months old that died after a brief period of depression (see Chapter 48). Histologic lesions in the heart of these birds were similar to those reported in poultry with vitamin E and selenium deficiencies.[71] Vitamin E and selenium deficiencies have also been suggested as causes of myocardial degeneration in cockatiels. Affected birds typically have increased activities of SGOT and CPK, decreased heart tone and an increase in pericardial fluid.[38]

Various benign and malignant primary myocardial tumors arising from connective tissue or from muscle have been reported occasionally (see Chapter 25).[31]

Ruptures of the myocardium may occur secondary to degenerative, inflammatory or neoplastic conditions of the myocardium or aneurysms of the myocardial vessels (see Color 48).[31] Myocardial infarctions may result from embolisms originating from valvular endocarditis or heavy metal poisoning.[80,86] In White Carneaux Pigeons, myocardial infarcts have been reported after ulceration and embolism of atheromas in the aortic trunk.[31]

All conditions that lead to cardiomyopathy or myocarditis may result in increased myocardial irritability and cardiac arrhythmias that can be detected by ECG. Radiographs may reveal cardiomegaly (Figure 27.22). Electrocardiography has been shown to be effective for diagnosing both spontaneous and furazolidone-induced cardiomyopathy.[40,46] Characteristic changes include a right axis deviation from negative to positive, ie, from an average of -85° (range -60° to -120°) to an average of 70° (range 32° to 95°).[41] The amplitude of the P-wave is increased and the T-wave is negative in leads I, II and III. Similar ECG findings have been reported in psittacine birds with cardiomyopathy.[63]

Treatment of myocardial disease should be aimed at the primary cause. Furthermore, symptomatic treat-

ment is indicated. Digoxin can be used when cardiac output is diminished due to myocardial disease, but is contraindicated when persistent ventricular arrhythmias are present. Digoxin treatment should be discontinued if the severity of an arrhythmia increases.

Epicardial and Pericardial Diseases[31]

Pericardial effusion is a common finding in birds. The accumulated fluid may be a result of cardiac or systemic disease and may be of an inflammatory or noninflammatory nature (see Color 14). Pericardial effusion may be part of generalized ascites. Transudates can occur with congestive heart failure and hypoproteinemia. Exudates may be present in a variety of infectious diseases. Fibrinous pericarditis is most common and may lead to adhesions of the epicardium to the pericardium and to constrictive heart failure (see Color 14). A serofibrinous pericarditis may occur in conjunction with a variety of bact-erial (eg, *E. coli*, *Streptococcus* spp., *Listeria, Salmonella*) and viral (eg, reovirus in Galliformes, polyomavirus infections in Psittaciformes) diseases, and can also be seen in chlamydiosis and mycoplasmosis. Occasionally tuberculous or mycotic pericarditis can be encountered. *Pericarditis urica* may occur in birds with visceral gout (see Color 21). Hemopericardium may be the result of puncture of the epicardium by a foreign body, iatrogenic puncture of the heart, cardiac tumors, rupture of the left atrium or myocardial rupture.

Pericardial effusion may eventually result in heart failure. When a pericardial effusion develops rapidly, the circulatory system will not have time to compensate for the reduced cardiac output, and acute death occurs from cardiac tamponade.

Diagnostic techniques that may be of use in diagnosing pericardial effusion include radiography, electrocardiography, ultrasonography and endoscopy (Figure 27.23). Enlargement of the cardiac silhouette on radiographs may be caused both by cardiomegaly and pericardial effusion, and other techniques are needed to differentiate between these conditions. Ultrasonography is a useful method to demonstrate a pericardial effusion. Electrocardiography may reveal a low voltage ECG. Marked changes in the electrocardiogram, including left axis deviation, have been reported in *E. coli*-induced pericarditis and myocarditis in chickens.[32]

FIG 27.22 An adult male duck was presented for dyspnea, coughing and syncope. The clinical signs were exaggerated by mild exercise. Radiographs indicated severe cardiomegaly. ECG and ultrasound diagnostics were refused. Other radiographic findings included a large amount of grit in the ventriculus and irregular mineral densities in the medullary canal of the femurs.

Fluid for bacteriology, cytology and clinical chemistries can be collected from the pericardial sac, using endoscopy (see Chapter 13). Treatment for pericardial effusion should be both symptomatic and aimed at treating the underlying condition (eg, antibiotics in bacterial pericarditis). Symptomatic treatment can be attempted with furosemide. If sufficient quantities of nonserosanguinous pericardial fluid cannot be removed by conventional means to avoid the occurrence of cardiac tamponade, then it is necessary to create a surgical window in the pericardium.[24] This technique was used successfully in an African Grey Parrot presented with congestive heart failure and idiopathic pericardial effusion.

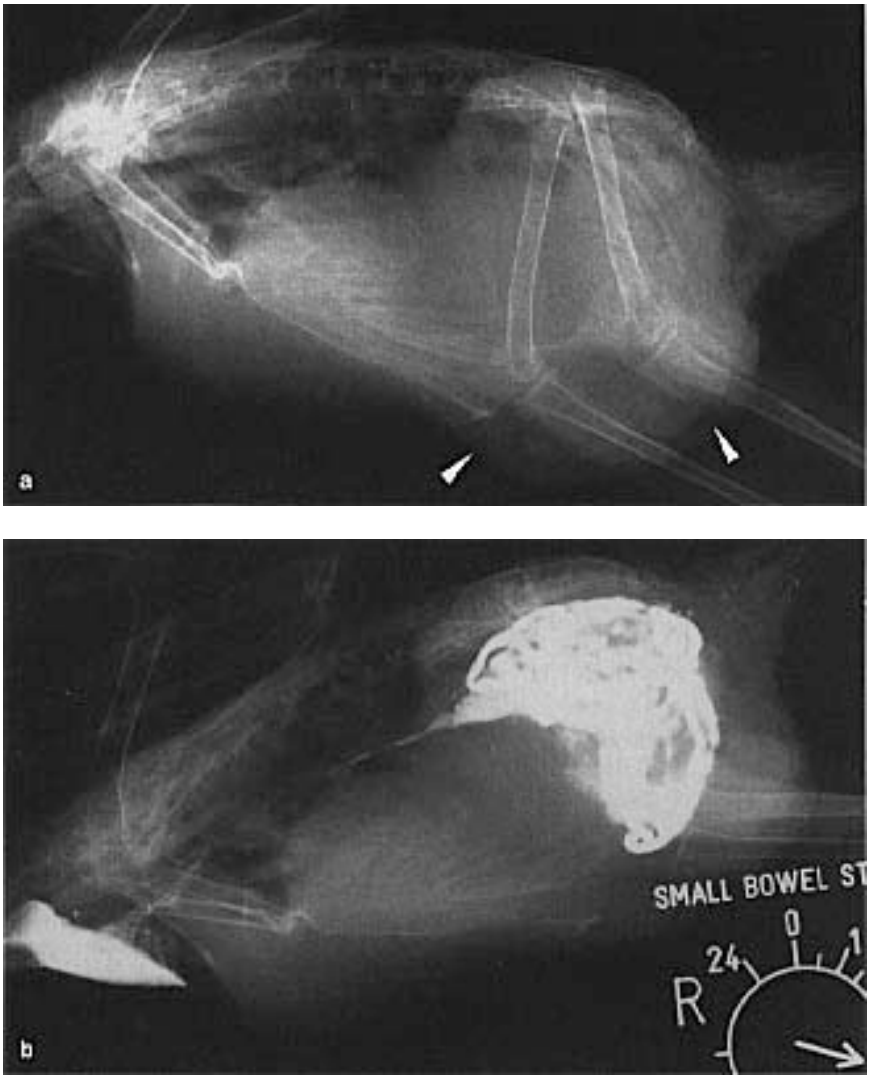

FIG 27.23 An adult Amazon parrot was presented for emaciation (254 g), a swollen abdomen and passing whole seeds. The referring veterinarian diagnosed NGD based on survey radiographs and clinical findings. Survey radiographs indicated a diffuse soft tissue density in the thorax and abdomen. Note the distension (arrow) of the abdominal wall. A barium contrast study indicated that the proventriculus was being displaced dorsally, and the intestinal tract was being displaced dorsally and caudally by an abdominal mass (suspected to be the liver). The heart was also considered to be enlarged, and the nondistinct edge of the cardiac silhouette was suggestive of pericardial effusion. Ultrasound confirmed pericardial effusion and hepatomegaly.

Atherosclerosis

Atherosclerosis can be defined as a diffuse or local degenerative condition of the internal and medial tunics of the wall of muscular and elastic arteries. The degenerative changes include proliferation of smooth muscle cells, deposition of collagen and proteoglycans and deposition of cholesterol (esters).[45] Calcium deposits may sometimes be encountered. The lesions can macroscopically be identified by thickening and yellow discoloration of the arterial wall (see Color 14).

Atherosclerosis has been reported in many avian orders, but Psittaciformes (parrots)[27,45] and Anseriformes (ducks and geese)[27] appear to be particularly susceptible. Amazon parrots seem to be specifically prone to atherosclerosis, and age appears to be a risk factor.[45] Ciconiiformes (flamingos, herons, storks), Falconiformes (vultures, falcons, eagles), Galliformes (pheasants, turkeys, fowl), Gruiformes (cranes), Columbiformes (pigeons), Cuculiformes, Coraciiformes, and Piciformes (toucans) are moderately susceptible. Atherosclerosis has also been seen in other species such as ostriches, penguins, cormorants, free-ranging owls, and various Passeriformes, including birds of paradise.[27,62,65] In a retrospective study involving 12,072 companion and aviary birds, atherosclerosis was detected in 53 birds of six orders (Table 27.5).[45]

Pathogenesis

In man, atherosclerosis of the coronary arteries is a major source of morbidity and mortality in affluent societies, and elevated serum lipids (cholesterol, triglycerides, low-density lipoproteins), hypertension and exposure to cigarette smoke are important risk factors.

The accumulation of pathogenic material in the arterial wall has been explained by the insudative theory.[14] Normally a transfer of plasma proteins occurs through the arterial wall with subsequent removal from the outer coats by lymphatic vessels. During this process of permeation, fibrinogen and very low density lipoproteins are selectively entrapped in the connective tissue of the arterial wall. Their presence stimulates reactive changes that give rise to the production of atherosclerotic lesions. Variations in vascular permeability and arterial blood pressure can explain the preference of atherosclerotic lesions for certain areas of the arterial system.

TABLE 27.5 Retrospective Study of Avian Atherosclerosis[45]

Order	Number Affected	Anatomic Location
Psittaciformes	43	aorta (34) myocardial vessels (8) brachiocephalic trunk (7) splenic arteries (5) pulmonary artery (3)
Falconiformes	6	aorta (6) minor lesions in other vessels
Piciformes	1	aorta
Passeriformes	1	aorta
Strigiformes	1	aorta
Struthioniformes	1	mesenteric artery

In man, systemic hypertension is known to accelerate atherosclerotic diseases and atherosclerotic lesions are often seen in high pressure areas of the arterial system. Atherosclerosis in the pulmonary arteries is rare and seen only with pulmonary hypertension.

In birds, atherosclerotic lesions are usually found in the brachiocephalic trunk and abdominal aorta (Figure 27.24). Lesions in the internal carotid arteries also occur with some frequency. Atherosclerotic lesions in the coronary artery are not as common in birds as in man, but have been reported.[45] Atherosclerotic lesions have not been described in the brain, and lesions in the pulmonary artery are rare.

The risk factors associated with development of atherosclerosis in birds have been insufficiently studied; however, at least three of the risk factors that occur in humans (ie, obesity, high-fat diets and exposure to cigarette smoke) frequently occur in companion birds. In one study of birds from a zoological collection, the incidence of atherosclerosis was higher in females and carnivores than in males and granivores.[65] Free-ranging turkeys from colder environments have a higher incidence of atherosclerosis than birds from warmer environments, suggesting that cold stress may play a role in the pathogenesis of this disease.[54]

FIG 27.24 Atherosclerosis can be macroscopically identified by thickening and yellow discoloration of the arterial wall. Note the irregular margins to the great vessels in this 20-year-old rosella.

In one study, 86% of the Amazon parrots with atherosclerosis were over five years;[45] however, in another study an age or species predilection to atherosclerosis among zoo and aviary birds was not found to occur. Atherosclerosis and congestive heart failure should be considered in any geriatric patient with lethargy, dyspnea, coughing or abdominal swelling (ascites).[65]

Marek's disease virus infections of arterial smooth muscle cells induce an altered lipid metabolism that can result in the accumulation of phospholipids, free fatty acids, cholesterol and cholesterol esters.[26,34] White Carneaux Pigeons that are genetically predisposed to atherosclerosis are extensively used in studies of this disease.[77]

Clinical Changes

Clinical signs associated with atherosclerosis are caused by decreased blood flow through the affected vessels and plaque-induced thrombi that cause vascular accidents.

Clinical signs of atherosclerosis are rarely reported in birds, and the condition is often associated with sudden death; however, subtle and intermittent signs that include dyspnea, weakness and neurologic signs may be present. Regurgitation from an undocumented cause is common. Blood chemistry may reveal elevated plasma cholesterol. Radiologic examination may reveal an increased density and size of the right aortic arch. Nodular densities cranial to the heart may be caused by large arteries with atherosclerotic changes that are seen end on.[45]

Galliformes and Anseriformes may die acutely from dissecting aneurysms that result in aortic rupture secondary to hypertension and atherosclerosis. The abdominal aorta and aortic arch are the two vessels that are most frequently affected. In some species, males tend to have more severe lesions in the abdominal aorta, while females most frequently develop lesions in the aortic arch.

Atherosclerosis was diagnosed at necropsy in a seven-year-old female Blue-fronted Amazon with a two-month history of regurgitation and stupor. Lesions were noted over the entire length of the aorta and brachiocephalic trunk. The lumen of the carotid arteries were reduced up to 95%. Lesions were noted also in the small arteries in the epicardium, myocardium and the renal artery. Clinicopathologic findings were unremarkable. Radiographs indicated a prominent aortic arch and pulmonary vein.[45]

Atherosclerosis involving the aorta, brachiocephalic trunk and axillary arteries was described in an 18-year-old male African Grey Parrot with weight loss, dyspnea and rhinitis. A concomitant respiratory bacterial infection was also present.[45]

Coronary atherosclerosis was documented in 75% of the birds that were necropsied in one zoological collection. The most severe vascular lesions occurred in birds that also had thyroid abnormalities.[65] A few birds, including an ostrich and a hornbill with atherosclerosis, showed signs of chronic weakness prior to death. Lesions in parrots have been described most frequently in the aorta and its major branches.[13]

Aortic Rupture

Aortic rupture in turkeys is a condition associated with fatal hemorrhage from a ruptured aorta. The disease is especially common in male turkeys between 6 and 24 weeks of age with the highest mortality seen between three and four months. The location between the external iliac and ischiatic arteries is the most common site, but the aorta may rupture at another site just dorsal to the heart. In turkey hens a rupture of the left atrium may occur. The precise etiology is unknown, but the disease is associated with hypertension, degenerative changes of the aorta wall (atherosclerosis, qv), copper deficiency and high levels of protein and fat in the diet (see Color 48). Similar lesions may be induced in turkeys by ingestion of the sweet pea (*Lathyrus odoratus*).[48,75]

NEUROLOGY

R. Avery Bennett

Companion and aviary birds frequently develop clinical signs associated with the central or peripheral nervous system. These changes may include depression, blindness, opisthotonos, head tilt, circling, tremors, ataxia, convulsions, paresis and paralysis. Neurologic changes in birds may occur from primary or secondary diseases including genetic abnormalities, neoplasms, metabolic diseases, malnutrition, exposure to toxins, trauma and bacterial, viral, fungal or parasitic infections.

In a retrospective study of avian patients with neurologic disorders, the clinical signs most frequently observed were seizures, ataxia, paresis, paralysis, intention tremors, circling, head tilt, nystagmus, abnormal mentation and visual deficits. General supportive care for patients in this study included antibiotic therapy, fluid support, parenteral vitamin therapy and gavage feeding for nutritional support. The two most common etiologies were lead toxicity and hypocalcemia/vitamin D_3 deficiency. Many other neurologic problems resolved with general supportive care and vitamin supplementation.[87]

Diagnostic tests that may be of value in determining the etiology of neural lesions, as well as the prognosis for recovery in some cases, include CBC, biochemistries, specific tests for detecting levels of toxins, radiographs, electroencephalograms, electromyograms, auditory evoke potentials, CT scans and MRI. Some of these diagnostic techniques require specialized equipment, but their efficacy in diagnosing neurologic diseases in birds has been documented. Many of the advanced neurologic diagnostic tests are available at veterinary colleges, and case referral should be considered when one of these techniques is needed to evaluate a patient.

Neuroanatomy[69]

Meninges

As in mammals, birds have three meninges: pia mater, arachnoid and dura mater. The subarachnoid space contains cerebrospinal fluid that may be collected from the cisterna magna; however, birds have a large venous sinus located dorsal to the cisterna that is easily damaged during a spinal tapping procedure and, if disrupted, will cause severe hemorrhage.

Brain

The brain of birds is agyric, with virtually no convolutions (Figure 28.1). The vallecula arises near the rostral end of the median fissure and extends caudad. The sagittal eminence is a prominence medial to the vallecula. The lateral ventricles are displaced dorsally by the large corpus striatum.[83] The olfactory bulbs are pointed at the rostral extent of the brain, and the olfactory center of the brain is rather underdeveloped.[28] The cerebral cortex is also underdeveloped (being two to three cell-layers thick, <1 mm); however, when compared with mammals, the corpus striatum is well developed and is considered the main center for association in birds (Figure 28.2). Consequently, instincts dominate avian behavior, which may account for some of the self-mutilation that occurs in companion birds. Birds have no corpus callosum nor septum pellucidum.

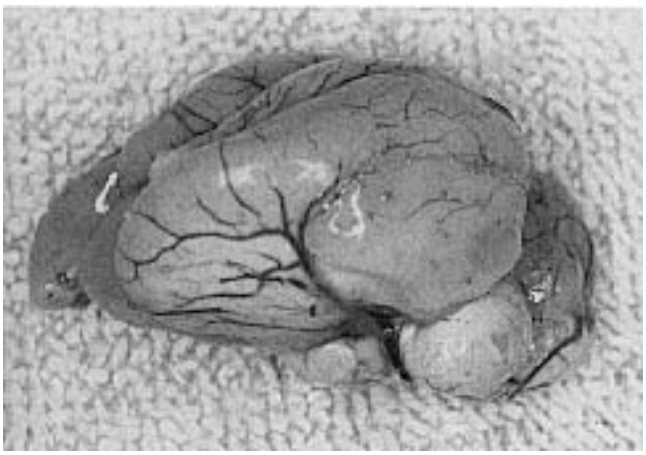

FIG 28.1 The brain of birds is agyric with virtually no convolutions.

The diencephalon is the location of the pineal body, which lies dorsal and medial between the caudal aspects of the cerebral hemispheres. It is composed of secretory cells, which resemble rudimentary photoreceptors. The nonmyelinated axons are responsive to light. The pathway for stimulation courses from the optic nerve to the cranial cervical ganglion, which has axons to the pineal body. Interestingly, these axons are still responsive to light even if the bird's eyes are removed and the cranial cervical ganglion is removed. The pineal body is involved in reproduction, migration and circadian rhythms. Its secretions exert their effect on the hypothalamus. The hypothalamus is located caudal (or ventral) to the optic chiasm.

Midbrain

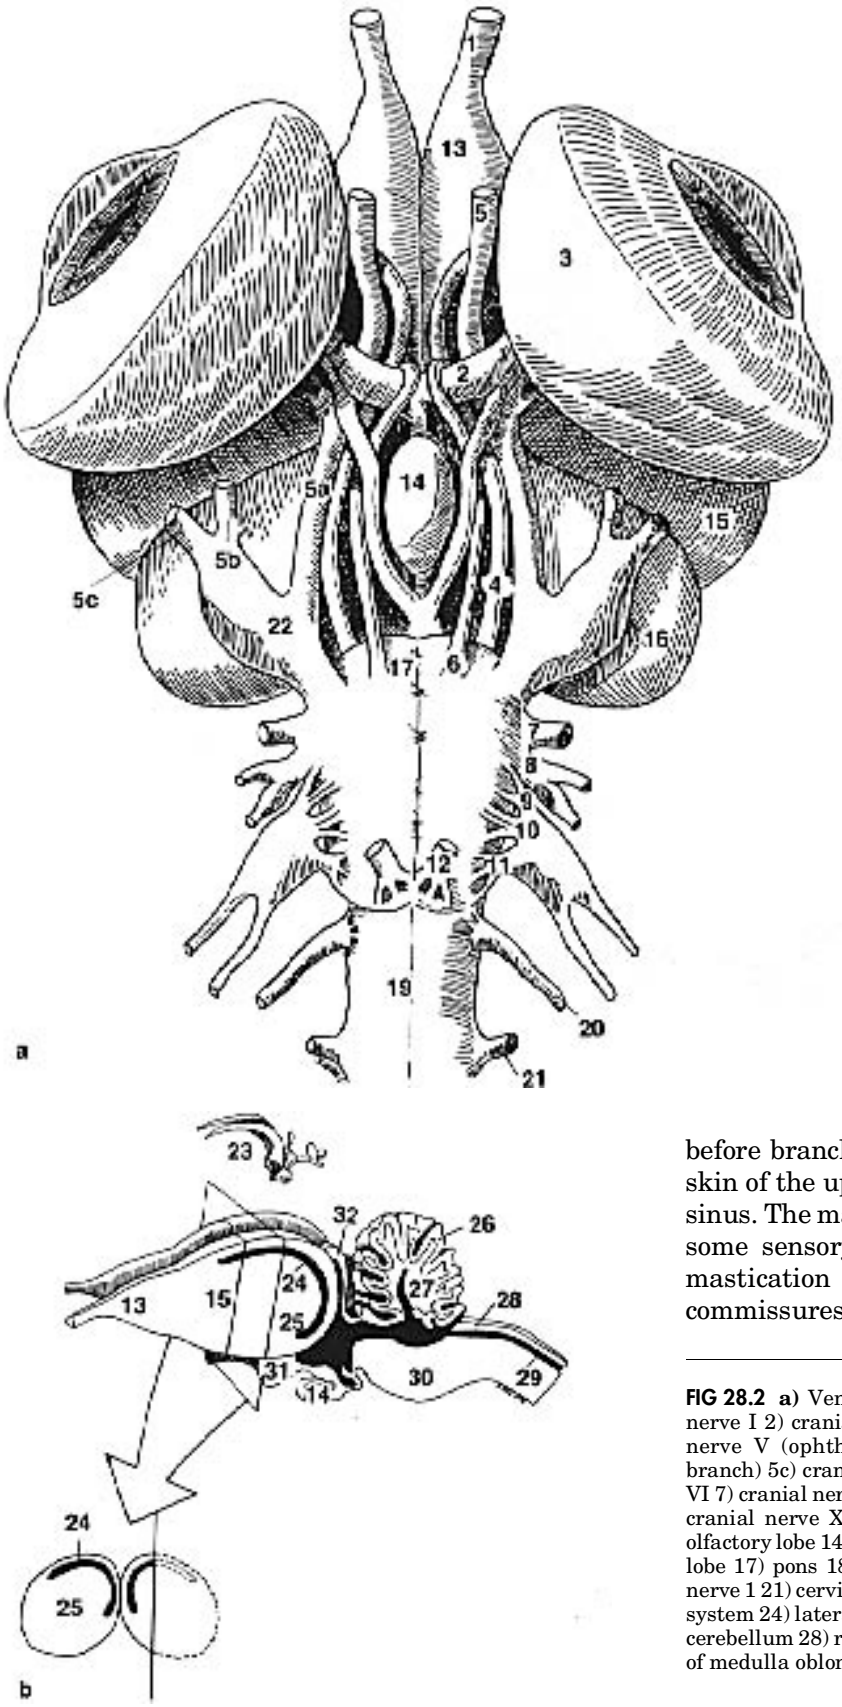
The midbrain is the location of the optic tectum. The avian optic lobes are massive and responsible for the well developed, though monocular, vision of most birds (Figure 28.2). The optic tectum is equivalent to the rostral colliculus of mammals and birds have no caudal colliculus. Cranial nerves III and IV exit from the midbrain. Large motor afferent, efferent and optic fiber systems originate, decussate and terminate in the mesencephalon and myelencephalon. There is complete decussation of tectospinal (motor) and rubrospinal (modulation) tracts in the midbrain, while the tracts of the pons and medulla do not decussate.[1]

Cerebellum

As in mammals, the cerebellum is the center for coordination of movements and is correspondingly large. It has a single median lobe with transverse sulci and is divided into three main lobes (not four as in mammals) by the fissura prima and fissura secunda, which are deeper transverse sulci. Smaller transverse sulci divide it into ten primary lobules. Each lobule is believed to be responsible for coordination of a specific part of the body. For example, lobules II and III control leg coordination. The lateral flocculus (lobule X) with the paraflocculus (lobule IX) are located at the rostral aspect. The rostral and caudal cerebellar peduncles attach the cerebellum to the medulla. There may also be a cerebellar peduncle.

Pons

The pons is poorly developed and is present only as a broad band of fibers at the rostral portion of the medulla oblongata. There is no pyramid as found in mammals. Cranial nerves V through XII arise from the medulla.



Cranial Nerves

The cranial nerves of birds correspond to those found in mammals (Figure 28.3). The olfactory nerve (CN I) is sensory and passes through a single hole in the skull (the olfactory foramen) rather than a cribriform plate. The optic nerve (CN II) is sensory and large in order to accommodate the visual acuity birds require. It is usually more than half the diameter of the spinal cord. The oculomotor nerve (CN III) is motor to the dorsal, ventral and medial rectus muscles and the ventral oblique muscle of the eye. It also supplies the muscles of the eyelids. It has parasympathetic fibers to the gland of the third eyelid, the choroid, the iris and the pecten (triangular pleated membrane extending forward from the optic disc). The trochlear nerve (CN IV) is motor to the dorsal oblique muscle of the eye.

The trigeminal nerve (CN V) contains both sensory and motor fibers. The ophthalmic branch is sensory and consists of two components. The dorsal component innervates the upper eyelid and the skin of the forehead. The ventral component is sensory to the nasal cavity and upper beak. The maxillary branch is sensory and innervates the upper eyelid before branching to supply the lower eyelid, palate, skin of the upper beak, nasal cavity and infraorbital sinus. The mandibular branch is motor but may have some sensory fibers. It innervates the muscles of mastication and the skin and the mucosa at the commissures of the beak.

FIG 28.2 **a)** Ventral and **b)** lateral view of the brain. 1) cranial nerve I 2) cranial nerve II 3) eye 4) cranial nerve IV 5a) cranial nerve V (ophthalmic branch) 5b) cranial nerve V (maxillary branch) 5c) cranial nerve V (mandibular branch) 6) cranial nerve VI 7) cranial nerve VII 8) cranial nerve VIII 9) cranial nerve IX 10) cranial nerve X 11) cranial nerve XI 12) cranial nerve XII 13) olfactory lobe 14) pituitary gland 15) cerebral hemisphere 16) optic lobe 17) pons 18) medulla oblongata 19) spinal cord 20) cervical nerve 1 21) cervical nerve 2 22) trigeminal ganglion 23) ventricular system 24) lateral ventricle 25) corpus striatum 26) arbor vitae 27) cerebellum 28) roof of medulla oblongata 29) central canal 30) floor of medulla oblongata 31) optic chiasm and 32) pineal body.

The abducent nerve (CN VI) is motor to the lateral rectus muscles and muscles of the third eyelid. The facial nerve (CN VII) is motor with a small sensory component and parasympathetic fibers. It is not involved in taste as in mammals, but supplies the hyoid and the cutaneous neck muscles. The vestibulocochlear nerve (CN VIII) has separate ganglia for the vestibular and the cochlear nerves. The glossopharyngeal nerve (CN IX) is sensory and motor. Cranial nerves IX, X, XI arise from a row of small roots. Cranial nerves X and XI combine in a common ganglion. The lingual branch of the glossopharyngeal nerve receives sensory input from taste fibers.

The pharyngeal branch has fibers that join with the vagus nerve to innervate the larynx and trachea. The esophageal branch courses along the neck with the jugular vein, supplying the esophagus. The vagus nerve (CN X), CN XI and jugular vein course down the neck in a common sheath to the level of the nodose ganglion. The spinal accessory nerve (CN XI) is enclosed with the vagus and supplies the superficial muscles of the neck. The hypoglossal nerve (CN XII) and CN IX innervate the tracheal muscles. The former has a lingual branch that innervates the tongue muscles and a syringeal branch that courses to the syrinx and tracheal muscles.

Spinal Nerves

Because birds of different species have varying numbers of vertebrae, spinal nerves are numbered by the vertebra caudal to it in numerical order regardless of whether it is cervical, thoracic, lumbar, sacral or coccygeal. In discussions of plexuses, it is customary to refer to the roots making up the plexus by the ordinal number of their cranial to caudal location (Figure 28.4). The lumbar spinal cord contains a dorsal gelatinous structure (glycogen body), which is nestled in a deep cleft between the dorsal columns.[83]

The brachial plexus is formed by ventral branches of three to five spinal nerves. The ram communicans lateralis and medialis connect the second to the third nerve roots and the fourth to the fifth roots (if present). These are sympathetic nerve fibers. The sec-

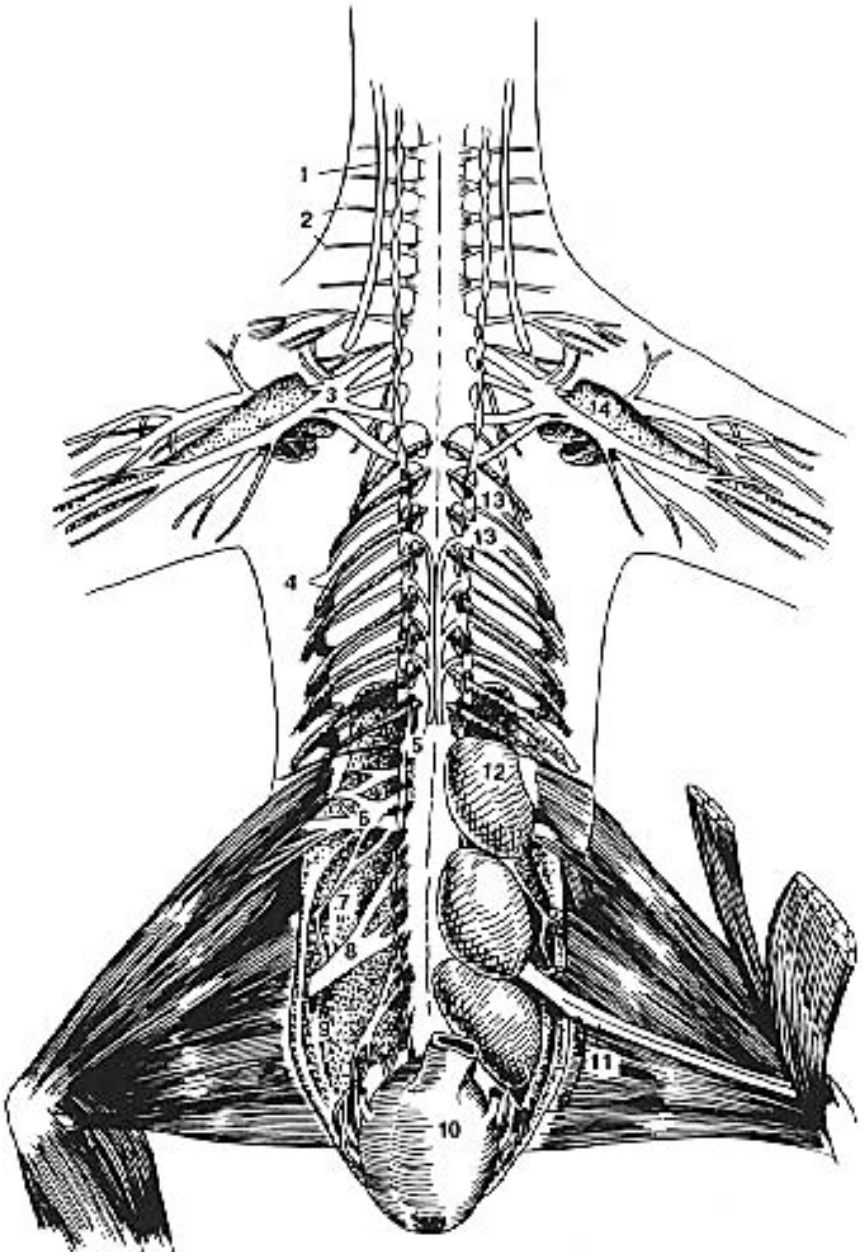

FIG 28.4 Ventrodorsal view of the spinal nerves and autonomic nervous system. The right kidney has been removed to show their relationship with the lumbar plexuses. 1) vagus 2) cervical spinal nerves 3) brachial plexus 4) thoracic spinal nerves 5) greater splanchnic nerves 6) lumbar plexus 7) obturator nerve 8) sacral plexus 9) pudendal plexus 10) cloaca 11) ischiatic nerve 12) cranial division of kidney 13) autonomic ganglion and 14) humerus.

ond through fourth roots give off rami musculares to innervate the neck muscles. The nerves arising from this plexus innervate the muscles of the wing.

There are three nerve plexuses in the lumbosacral region (lumbar, ischiatic and pudendal). These nerve roots lie embedded in the foveae of the pelvis surrounded by the kidneys (see Anatomy Overlay). All three plexuses are connected to the sympathetic chain. The lumbar plexus is composed of three to four nerve roots (the last two lumbar and first sacral roots). It innervates the cranial thigh muscles and the muscles of the body wall. The obturator nerve, femoral nerve, cranial gluteal nerve and saphenous nerve arise from this plexus.

The ischiatic plexus or sacral plexus is usually made up of six sacral nerve roots, but occasionally four, five or seven roots. The first root arises with the last root of the lumbar plexus. The roots combine to form the ischiatic nerve, which is the largest nerve in body. This nerve should be faintly striated and a loss of striations is suggestive of an inflammatory process. The caudal gluteal nerve also arises from the sacral plexus.[83]

The pudendal plexus is formed by five thin coccygeal nerve roots and supplies the cloaca and tail.

Neurologic Examination

Two of the primary objectives in performing a neurologic examination are to determine if the neuropathy is focal or diffuse, and to localize focal lesions. The examination should be performed in a consistent, logical manner that starts with a complete history (see Chapter 8). Neuropathies are particularly common secondary to trauma, exposure to toxins and malnutrition. Subtle changes in cranial nerve function and abnormal reflexes are difficult to appreciate and interpret in birds. Assessment of segmental reflexes may be difficult in avian patients, making evaluation of muscle tone, strength and atrophy an essential part of the neurologic examination.

Neurologic evaluation of neonates is particularly difficult, and making a "side-by-side" comparison with a "normal" clutchmate is the best way to detect subtle changes. Useful tests include evaluation of the feeding response, menace reflex, use of wings to balance, vocalization, perching ability, pain perception and hopping response.[65]

Mental Status

The patient's mental status and level of consciousness should be evaluated. Any personality changes reported by the owner should be noted. The bird's ability to perform normal activities and its awareness of its surroundings should be assessed. Clients may indicate that the bird acts sleepy, dull, uneasy, nervous, anxious, aggressive or dizzy. It is difficult to differentiate between seizures and syncope based on the history; however, either may suggest an intracranial lesion. Seizures may be characterized by ataxia, disorientation and falling off a perch followed by tonic clonic convulsions.

Cranial Nerves

An evaluation of the cranial nerves may help localize a focal brain lesion (individual nerves involved) or a generalized encephalopathy (several nerves involved). Olfaction (CN I) is difficult to assess because birds have a poor sense of smell; however, most normal birds will react negatively to noxious odors (eg, alcohol pledget). Birds with CN I dysfunction may exhibit an altered appetite or feeding response.

An ophthalmic examination is essential for detecting neurologic abnormalities (see Chapter 26). Failure to avoid obstacles may indicate vision impairment. Bilateral blindness without ocular lesions may indicate neoplasm, abscess or granuloma formation in the brain.[97] The menace reflex can be used to evaluate CN II and VII; however, depending on the circumstances, the absence of a menace response does not always indicate dysfunction of these cranial nerves. The pupillary light response evaluates CN II and III. Because there is complete decussation of the optic nerves at the chiasm, birds do not have a consensual pupillary light response. [68]

Birds have some degree of voluntary control of pupil size because of skeletal muscles in the iris.[28,68] Excited birds will voluntarily dilate and constrict their pupils. The presence of anisocoria may indicate dysfunction of CN III or a sympathetic neuropathy. Normal eye movements require the coordination of CN III, IV, VI and VIII as well as the cerebellum and brain stem.[87] The presence of nystagmus or strabismus may indicate an abnormality in this system (vestibular). A fundic examination may be performed with the aid of d-tubocurarine. Its action on the avian pupil may be to inhibit the iris constrictor muscles allowing the myoepithelial dilator action to dominate.[68] In some birds, intracameral injection of 0.045-0.09 mg d-tubocurarine chloride produces mydriasis within five minutes without systemic effects.[68]

Cranial nerve V is responsible for facial sensation, movement of the mandible and blinking of the eyelids. Diminished beak strength may indicate an abnormality in CN V. Eye blink involves both CN V and VII. A defect in CN VIII will cause deafness or a head tilt toward the affected side. Cranial nerves IX through XII are involved in normal tongue movement, swallowing and beak strength. Dysfunction is manifested by dysphagia. Deviation of the tongue or atrophy of its muscles is observed with damage to CN XII.

Loss of normal physiologic nystagmus may occur with bilateral CN VIII lesions or with severe brain stem lesions.[87] Altered consciousness is usually an accompanying sign with brain stem lesions. Abnormal, spontaneous nystagmus may result from vestibular lesions. Strabismus may indicate vestibular system dysfunction or a lesion in CN III, IV or VI.[87]

Horner's syndrome may occur with intracranial lesions or with a lesion in the cervical sympathetic tract or the brachial plexus.[87]

Locating Lesions

Reflexes are evaluated to help determine if a lesion is central (upper motor neuron) or peripheral (lower motor neuron). Wing droop, inability to fly and diminished or absent pain perception may be present with either central or peripheral lesions. Pain perception in the wing requires intact peripheral nerves and the cervical spinal cord. Wing withdrawal is a segmental reflex that is present with intact peripheral nerves, but does not require an intact cervical spinal cord. A spinal cord lesion should cause hyperreflexia; however, hyperreflexia is difficult to distinguish from normoreflexia.

In most situations, it is sufficient to determine if a reflex is present or absent. Weakness in the legs, knuckling over and an inability to grasp perches with the feet may be observed with either upper motor

neuron lesions or lower motor neuron lesions. The patellar reflex is difficult to assess in birds; however, the withdrawal reflex is also a segmental reflex and should be intact with lesions affecting only the spinal cord.[87]

Conscious proprioception requires an intact peripheral and central nervous system. A lesion in either will result in the bird knuckling over. The vent response is a segmental reflex, and the sphincter should be responsive to stimulation if a spinal cord lesion is present and the nerve roots are not affected. A crossed extensor reflex generally indicates a lesion in the spinal cord with a loss of normal central inhibitory pathways.

With cervical spinal cord lesions, dysfunction of the wings, legs and cloaca may be observed while head function and cranial nerves appear normal (Figure 28.5). Weakness in the wings and legs with intact leg and wing withdrawal and vent response would be indicative of a cervical spinal cord lesion. Lesions affecting the thoracolumbar spinal cord will cause leg and cloacal dysfunction without affecting the head, cranial nerves or wings. Cloacal sphincter hypertonia, incontinence and soiling of the vent without signs of head, wing or leg dysfunction are indicative of a lumbosacral spinal cord lesion.

Loss of pain perception indicates a poor prognosis for recovery.[87] It is crucial to differentiate pain perception from withdrawal reflex. Because withdrawal of a stimulated extremity is a segmental reflex and does not require an intact spinal cord for a normal response, movement does not indicate the patient is able to feel the stimulus. Some type of conscious recognition of the stimulus must be identified (eg, vocalization, attempting to bite or escape behavior). This part of the examination is generally reserved for last so that the painful stimulus does not influence the patient's response to other segments of the neurologic examination.

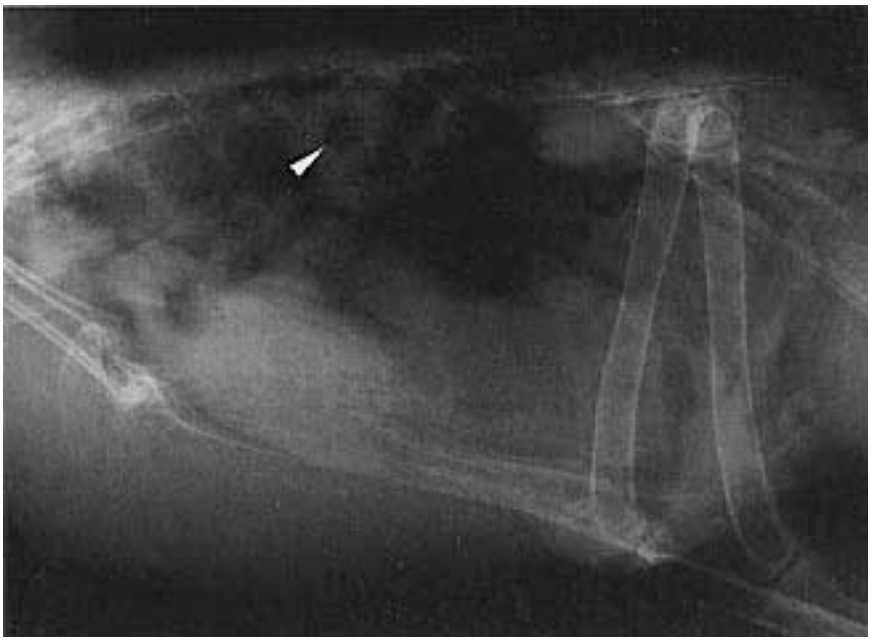

FIG 28.5 A mature Amazon parrot was presented for emergency evaluation after being bitten by a dog. The bird had several large puncture wounds in the thorax. The bird was recumbent, and a deep pain response could not be elicited from either pelvic limb. Radiographs indicated a puncture wound through the lung (arrow) with an increased soft tissue density (blood) in portions of the lung parenchyma. The bird was placed on broad-spectrum antibiotics and steroids. A deep pain response was noted five days after the initial injury, and the bird slowly improved with a complete return to normal function over a three-month period.

Diagnostic Techniques

The results of the neurologic examination will suggest which diagnostic tests should be performed. A CBC and serum chemistry profile are indicated if an infectious or metabolic neuropathy is considered. Laparoscopy and organ biopsy may be indicated to further define metabolic neuropathies. Serum for viral diseases or chlamydiosis, and blood levels for heavy metals are indicated in some cases. Radiographs are indicated if spinal trauma or heavy metal intoxication is suspected. TSH stimulation test may be helpful if hypothyroidism is suspected. Electromyograms, nerve conduction velocities, spinal evoked potentials and nerve or muscle biopsies are helpful in evaluating neuropathies.

Electrodiagnostics

Electrodiagnostic studies are used commonly in mammals for localizing neurologic lesions and aiding in prognostic assessment. When available, electrodiagnostic techniques are valuable in avian patients for distinguishing between a neuropathy and a myopathy, localization of

neurologic lesions and determining the prognosis for return to normal function.

Electromyogram (EMG)

Diseases of motor neuron cell bodies, ventral nerve roots, nerve plexuses, peripheral nerves, neuromuscular junctions and muscle fibers may alter the electromyogram (EMG), which is a recording of the electrical activity in striated muscle.[27] Normal activity consists of insertion potentials, motor unit potentials and spontaneous waves, which occur infrequently. When the electrode is inserted into the muscle, the intrafascicular nerve branches and muscle fibers are stimulated, creating a brief burst of electrical activity, which ceases immediately after the electrode stops moving. If the electrode is moved, insertional activity will again be recorded. Large positive waves are occasionally observed. If the electrode is inserted coincidentally near a motor endplate, a low continuous level of electrical activity will be recorded with an auditory component sounding like a distant beach surf. Motor unit potentials occur during involuntary muscle contraction or when a motor nerve is stimulated (an M response). The M response has two phases and represents the sum of the electrical activity of all of the muscle fibers in that motor unit.

Fibrillation potentials, positive sharp waves, myopathic potentials and reinnervation potentials are abnormal EMG recordings. Prolonged insertional activity due to muscle hyperexcitability occurs six to ten days following peripheral nerve injury, then gradually decreases. Fibrillation potentials are mono- or biphasic and occur five to seven days following denervation. These spontaneous, repetitive action potentials from muscle fibers, not produced by nerve impulses, occur because of the instability of the cell membrane at the endplate. Fibrillation potentials increase for several weeks after denervation, then decrease as muscle atrophy and fibrosis occur. They stop if reinnervation occurs.

Positive sharp waves are generally associated with denervation, but may be observed with primary myopathies. They are characterized by an initial positive deflection followed by a slower negative potential with a "dive bomber engine" auditory component. They may be single or multiple. Myopathic potentials are generally indicative of a primary myopathy but may be observed with fibrillation potentials following denervation. They are continuous discharges with varying amplitude, duration and frequency with a waxing and waning auditory component sounding like an attacking then retreating dive bomber. As reinnervation occurs, motor unit potentials are initially low amplitude and polyphasic but become larger than normal motor unit potentials and are an indicator of a good prognosis for recovery.

Nerve conduction velocities (NCV) can provide information regarding delayed transmission along a nerve as well as the location of a peripheral nerve lesion. A nerve stimulator is used to generate an M response at two different locations along the course of a peripheral nerve. The distance between the sites is divided by the latency difference in the two M responses to determine the velocity with which the impulse travels along the nerve (m/s). Where there is a peripheral neuropathy such as demyelination, the velocity is slow and the M responses are polyphasic and prolonged. If the nerve has been transected, the stimulation distal to the site will produce an M response, while stimulation of the site proximal to the lesion will not.

Standard EMG equipment may be used to evaluate H-wave and F-wave reflexes. The H-wave reflex evaluates both the afferent and efferent pathways. A peripheral site is stimulated and sensory impulses are carried to the spinal cord, where the alpha motor neurons are activated and discharged, resulting in a compound muscle section potential. The F-wave reflex is evaluated by stimulating the peripheral nerve with a lower intensity than that required to cause an H-wave production, activating the motor neuron to generate an efferent impulse. The H-wave and F-wave reflexes are used in combination to evaluate nerve root avulsion.

Signal-averaging capabilities are required for somatosensory-evoked potentials, spinal-evoked potentials and motor-evoked potentials. Somatosensory-evoked potentials correspond clinically to the presence or absence of pain perception. They may be utilized to determine if failure to react to a painful stimulus is the result of other more painful injuries, stoicism or denervation. This procedure is performed by stimulating a peripheral nerve and recording the response in the cervical spinal cord or cerebral cortex. It is important to recognize that these evoked potentials evaluate sensory, not motor nerve function. A response may persist after permanent loss of motor function.

Spinal-evoked potentials are utilized to determine the location of a spinal cord lesion. Stimuli are applied to peripheral nerves and the responses are recorded by an electrode inserted near the spinal

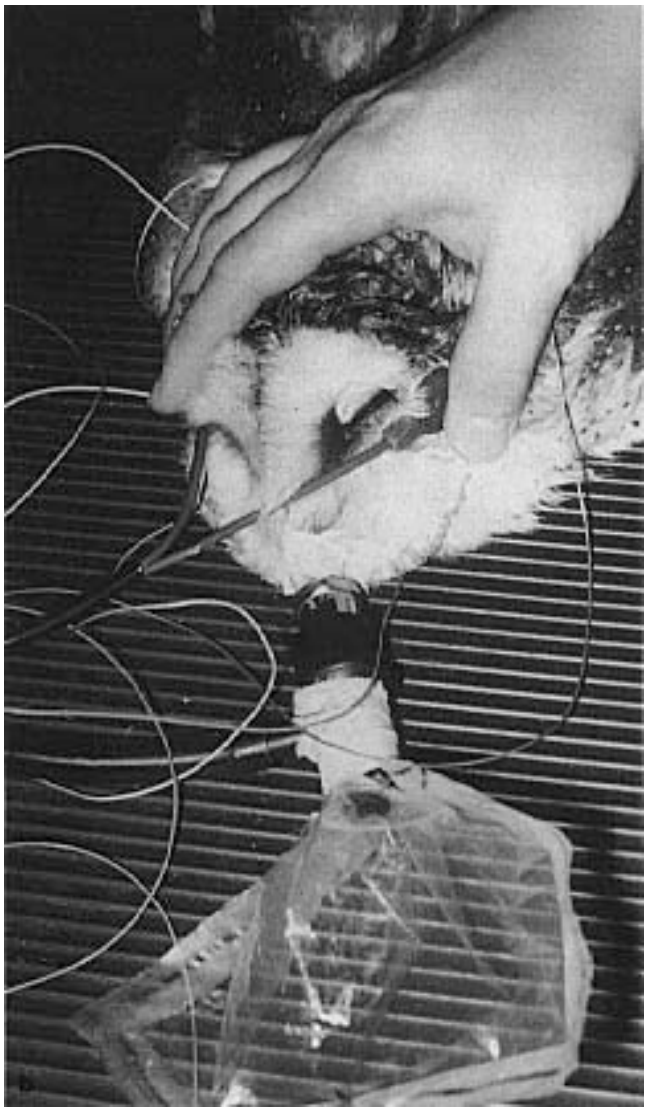

FIG 28.6 **a)** A Barn Owl was presented with a progressive head tilt and ataxia. Physical examination revealed a discharge of necrotic debris from the right ear canal that contained gram-negative rods. **b)** Auditory-evoked potentials indicated a centralized inflammatory disease (see Color 14).

cord. They can discretely evaluate the sensory pathway of a focal segment of spinal cord such that loss of response cranial to a specific vertebra identifies the location of the lesion. Spinal-evoked potentials also evaluate only sensory function. Motor-evoked potentials are capable of evaluating motor function, but techniques are not well established for animal use. They are currently being evaluated for safety, effects of anesthetics and correlation with injury.

Electroencephalograms

Electroencephalograms (EEG) are continuous recordings of the electrical activity of the cerebral cortex. They vary with head size, environment, restraint techniques and state of consciousness of the patient. They may be beneficial in monitoring progress in response to brain lesions or injury. Auditory-evoked potentials evaluate the brainstem response to auditory stimuli. They may be used to assess hearing ability and brainstem function (Figure 28.6).

Neuropathies

Nutritional

Hypovitaminosis E and Selenium Deficiency

Deficiencies of vitamin E and selenium have been reported to cause a wide variety of clinical signs and pathologic lesions in birds of all ages. In a survey of central nervous system lesions from animals in a zoological collection, birds had a higher incidence of disease than mammals, and encephalomalacia histologically compatible with hypovitaminosis E was the most common lesion observed.[130]

Vitamin E is a fat-soluble vitamin and depletion of body stores occurs slowly in adult birds, while young birds may develop clinical signs associated with acute deficiency. In young birds, hypovitaminosis E may cause encephalomalacia, exudative diathesis or muscular dystrophy. Encephalomalacia results in ataxia, head tilt, circling and occasionally convulsions and is particularly common in hatchling budgerigars.[51] Exudative diathesis and muscular dystrophy (white muscle disease) occur also with deficiency of vitamin E or selenium. The myositis associated with hypovitaminosis E may cause clinical changes difficult to distinguish from neurologic signs.

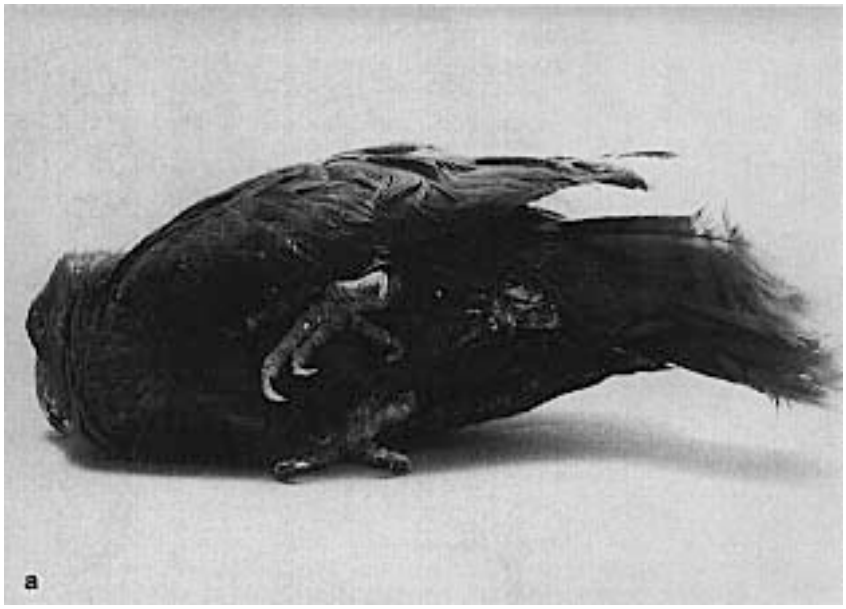

FIG 28.7 **a)** A two-year-old domestically raised Eclectus Parrot was presented with a one-month history of progressive difficulties in ambulating. At presentation, the bird was recumbent and had stiff, nonmotile thoracic and pelvic limbs, but was bright, alert and responsive. The muscle masses associated with all limbs were atrophied and firm. **b)** EMG findings included fibrillation potentials and positive sharp waves suggestive of denervation. Histopathology indicated severe, progressive, generalized muscle fibrosis of undetermined etiology.

Clinical signs associated with vitamin E and selenium deficiencies include tremors, ataxia, incoordination, abnormal head movements, reluctance to walk and recumbency. [14,63] Postmortem findings suggestive of encephalomalacia include cerebellar edema or hemorrhage (petechia) with flattening of the convolutions.[14] Histologically, there is edema, interruption of vascular integrity with associated capillary hemorrhage and hyaline thrombosis, and cerebellar demyelination with degeneration and necrosis of neurons.[14] Focal or multifocal poliomyelomalacia of the spinal cord may also occur.[40,63] Diagnosis of hypovitaminosis E is frequently presumptive based on clinical signs, history and gross and microscopic pathology. Hypovitaminosis E and selenium deficiency should be considered with pathologic lesions of demyelination and malacia in birds with vague clinical signs or in birds that are found dead in their enclosures with no premonitory signs.

Muscular dystrophy is characterized by light-colored streaks in the muscle fibers (Figure 28.7). Early histologic changes include hyaline degeneration, mitochondrial swelling, loss of striations and central migration of the nucleus.[14] In more chronic cases, muscle fibers are disrupted transversely and macrophages are present engulfing debris from necrotic myocytes.

This deficiency has also been incriminated as the etiology of cockatiel paralysis syndrome. This condition appears to occur most frequently in lutino cockatiels infected with *Giardia* sp. or *Hexamita* sp. Vitamin E- and selenium-responsive neuropathies have been reported in a variety of other species including Blue and Gold Macaws, Severe Macaws, Eclectus Parrots and African Grey Parrots.

Clinical signs include slow or incomplete eye blink due to paresis of the lower eyelid, weak jaw muscles, paresis of the tongue, poor digestion with passage of partially digested food, diminished playful activity, hyperactivity, clumsiness and weak grip, low-pitched and weak vocalization, delayed crop-emptying, spraddle leg, death of young in nest, weak hatchlings,

increased dead-in-shell, increased egg binding that is not responsive to vitamin A and calcium supplementation and decreased fertility. Cockatiels and other psittacine birds showing these clinical signs have responded to vitamin E and selenium supplementation and antiprotozoal therapy. In one study, treatment of giardiasis resulted in an increase in serum vitamin E levels from a deficiency state into the normal range.[49]

A selenium-responsive progressive ascending paralysis in fledgling mocking birds fed a commercial cat food has been reported.[85] Necropsy findings were suggestive of a viral encephalitis; however, clinical signs were similar to vitamin E- and selenium-responsive paralysis in cockatiels. All affected birds responded to parenteral administration of selenium followed by oral vitamin supplementation. Other species of birds being raised at this facility were not affected.

Vitamin E deficiency also occurs in piscivorous birds fed an unsupplemented diet of frozen fish (especially smelt). In birds of the family Ardeidae (herons and bitterns), the deficiency manifests initially as fat necrosis accompanied by steatitis. In pelicans, myodystrophy predominates.[105]

Supplementation with injectable and oral vitamin E is the recommended treatment; however, the patient may or may not respond depending on the severity of damage. Muscular dystrophy may resolve with supplementation, but encephalomalacia rarely responds to therapy. [14]

Hypovitaminosis B_1 (Thiamine)

Clinical signs of hypothiaminosis include anorexia, ataxia, ascending paralysis and opisthotonos.[51] Opisthotonos ("star-gazing") may result from paralysis of the anterior muscles of the neck resulting in pseudohypertonus of the muscles of the dorsal aspect of the neck (see Color 48). Histologically, thiamine deficiency causes a polyneuritis with myelin degeneration of peripheral nerves. Adrenal hypertrophy and edema of the skin are also characteristic of thiamine deficiency. Affected birds generally respond within hours of oral or parenteral administration of vitamin B_1. A response to treatment provides a presumptive diagnosis. Administration of thiamine is a useful adjunct to therapy in many nonspecific neurologic disorders.

Hypovitaminosis B_2 (Riboflavin)

Curled toe paralysis occurs in poultry and is seen in nestling budgerigars with riboflavin deficiency (see Color 48). Other signs include weakness, emaciation in the presence of a good appetite, diarrhea, walking on the hocks with toes curled inward and atrophy of leg muscles. Chicks fed a deficient diet may develop clinical signs as early as 12 days of age.[61] Histologically, a demyelinating peripheral neuritis is observed with edema of the nerves (especially the ischiatic and brachial nerves). There is Schwann cell proliferation and swelling, perivascular leukocytic infiltration and segmental demyelination accompanied by accumulation of osmophilic debris in the cytoplasm of Schwann cells.[61] Gliosis, chromatolysis in the spinal cord and degeneration at the neuromuscular endplate may also be observed. Treatment involves administration of oral or parenteral riboflavin and diet correction; however, many of the changes are irreversible, especially in chronic cases.

Hypovitaminosis B_6 (Pyridoxine)

Neurologic signs associated hypovitaminosis B_6 are characteristic, with the bird exhibiting a jerky, nervous walk progressing to running and flapping the wings. The bird then falls with rapid, clonic tonic head and leg movements. These convulsions are severe and may result in death due to exhaustion.[51]

Hypovitaminosis B_{12} (Cyanocobalamine)

Deficiency in a Nanday Conure was reported to cause subacute, multifocal white matter necrosis.[51]

Traumatic

Concussion Lesions

Concussive head trauma is fairly common in free-ranging as well as companion and aviary birds. Head trauma may occur at night when a panicked bird flies into an enclosure wall or if birds fly into windows or mirrors. Injured birds may remain on the bottom of the enclosure and exhibit depression, head tilt, circling or paresis of a wing or leg. Blood may be present in the mouth, ears or anterior or posterior chamber of the eye. Anisocoria and delayed pupillary light response may be present and convulsions may occur if the bird is disturbed.

Fractures of the skull or scleral ossicles may be detected radiographically. In some cases, a bruise might be visualized on the head that is the result of meningeal hemorrhage seen through the cranium. Blood actually leaks into bone and is not subdural (see Color 14).[51] If the vessels in the neck are rup-

tured, the pneumatic spaces in the skull may fill with blood obscuring evidence of trauma. It is very rare for hemorrhage to occur within the brain parenchyma. Unconsciousness with a loss of normal physiologic nystagmus indicates a brainstem lesion with a poor prognosis.[88]

Treatment is supportive and involves maintaining the bird in a dark, quiet, cool area with no disturbances. Dexamethasone appears to be the most important therapeutic agent. The prognosis is guarded-to-poor if the bird is convulsing.

Compressive Lesions

Pigmented calvarium is characterized by a yellow discoloration (hemosiderin) in the skull, especially the pneumatic spaces of the temporal bones. These pneumatic cavities help regulate CSF pressure. There is no definitive correlation as yet between this condition and neurologic signs. Inflammation of the frontal bone was reported as a cause of opisthotonos and depression with violent convulsions. [51] Jugular stasis occurs secondary to thyroid enlargement and results in increased intracranial pressure. Hydrocephalus and intracranial masses cause compressive injury to the brain or spinal cord. With hydrocephalus, the cortex over the lateral ventricles has a "blister-like" appearance at necropsy.[84] Imaging techniques (CT or MRI) and EEG studies may be helpful in diagnosing these conditions.

Spinal Abnormalities

Spinal fractures may be the result of injury or metabolic bone disease and may cause compression of the spinal cord. Tumors may affect the spinal cord by direct invasion or compression. MRI, CT scans and scintigraphy are useful imaging modalities for identifying these lesions, which may not be visible with plain radiographs, especially in the acute phase.

The junction of the fixed synsacrum with the more flexible portion of the thoracolumbar spine is a location susceptible to mechanical stress and vertebral subluxation. In broiler chickens, a congenital defect of the vertebral facets of T_6 and T_7 allows ventral displacement of T_7, producing spondylolisthesis and varying degrees of spinal cord compression.[148] In a King Penguin, spondylolisthesis was believed to be the result of trauma because no articular defects were observed.

The intervertebral discs of birds differ from those of mammals. They consist of a fibrocartilaginous central region surrounded by a "C"-shaped synovial cavity that extends around the dorsal and lateral margins of the disc. A fibrocartilaginous, wedge-shaped meniscus protrudes into the joint cavity from the dorsal and lateral margins.[37] This zygapophyseal joint has hyaline cartilage with an intervening synovial cavity. With intervertebral disc rupture, this meniscus is driven into the spinal canal along with the fibrocartilaginous disc material (see Color 14).

In a Black Swan, cervical intervertebral degenerative joint disease and spondylosis caused spinal cord compression and associated neurologic signs. In mammals with spondylosis, ventral and lateral osteophyte formation result in osseous bridging between adjacent vertebrae, while dorsal and dorsolateral osteophyte formation, as occurred in this swan, are rare. Spondylosis is believed to be the result of degenerative changes in the annulus fibrosis and intervertebral disc as a result of continuous heavy stress. In birds, the joints between vertebral bodies are synovial and in this swan, noninflammatory, degenerative changes were associated with the spondylosis. The degeneration, rupture and atrophy of the synovial-lined, fibrous intervertebral meniscus may have been involved in the pathogenesis of this disease.[57]

Dexamethasone and forced rest are the only recommended therapies for birds with spinal lesions. Myelography and spinal surgery have rarely been performed in birds. Naloxone and thyrotropin releasing hormone are beneficial in mammalian patients with spinal cord trauma, but their effects in avian patients are unknown.

Peripheral Nervous System

Trauma

Concussive peripheral nerve trauma occurs as a result of long bone fractures or impact trauma. The level of nerve injury (eg, neurapraxia, neurotmesis, axonotmesis or complete transection) determines the prognosis. In many instances, nerve dysfunction is transient; however, as in the case of brachial plexus avulsion, the damage may be permanent.

Brachial plexus avulsion occurs most commonly in traumatized free-ranging birds (Figure 28.8).[34,46] Clinically, there is evidence of denervation of the affected wing including lack of pain perception, paralysis with loss of withdrawal reflex and atrophy of the muscles of the affected wing and the ipsilateral pectoral muscles. Signs of Horner's syndrome may be present including ptosis and a dropped "horn" on the affected side of "horned" owls such as Screech and

FIG 28.8 **a)** An immature Red-tailed Hawk was found down and unable to fly near a highway. A severe wing droop was present and radiographs indicated a fractured coracoid. The wing was placed in a figure-of-eight bandage and the fracture healed without complication. When the bandage was removed, the bird still had a severe wing droop, no deep pain and muscle atrophy involving most of the palpable muscle masses. **b)** At necropsy, swelling (arrows) and discoloration were present in the brachial plexus suggestive of an avulsion-type injury.

Great Horned Owls. Because of the skeletal muscle in the avian iris, miosis is not a consistent feature of Horner's syndrome. Interruption of the sympathetic pathway from T_1 and occasionally T_2 segments results in these clinical signs.

A long bone fracture may or may not be associated with peripheral nerve injuries. It may be difficult to determine the level of nerve injury in birds presented with clinical signs associated with a unilateral peripheral neuropathy involving one extremity. Typically, birds with neurapraxia improve clinically within two to four weeks, while those with axonotmesis and neurotmesis (as with avulsion injury) would not.[34] EMG and spinal-evoked potentials can help determine the degree of injury. If these are not available, it is prudent to treat with supportive care for approximately one month, with weekly evaluation for signs of improved neurologic function.

Abdominal Masses

Compressive peripheral nerve trauma generally occurs secondary to an expanding mass that applies pressure to the nerve (see Figure 25.10). Because the pelvic nerves pass through the renal parenchyma, tumors or infection of the kidneys can damage the nerves (see Color 21). Ovarian tumors, if very large or invasive, have also been reported to damage these nerves. Of 74 budgerigars with abdominal tumors, 64 had paresis of one or both legs.[104] Paresis is usually unilateral in the early stages and is accompanied by abdominal distention.

Renal adenocarcinomas occur more commonly in males than females and the incidence is higher in psittacine than passerine birds (see Color 25). The most common sign is a unilateral leg paresis progressing to paralysis. Affected birds may demonstrate an abdominal lift. The paresis may become bilateral, but systemic signs usually develop before the contralateral limb is affected. The bird may have a palpable abdominal mass with polydypsia and polyuria. Grossly, these tumors are 1 to 2.5 cm in diameter, irregular, ovoid, globular, white or off-white with cysts or necrotic foci. They may metastasize to the liver (see Color 25).

The biologic behavior, clinical signs and gross appearance of embryonal nephromas are similar to renal adenocarcinoma. They usually contain more cysts and necrotic foci and are less frequently associated with paralysis. They occur in younger birds (three to five years old). Ovarian adenocarcinomas and granulosa cell tumors usually cause anorexia, weight loss and diarrhea, but can invade the kidneys and compress the pelvic nerves. If these tumors cause paralysis, the patient is likely to show an abdominal lift.

All of these tumors are associated with a poor prognosis. Excision may be attempted but if neurologic signs are present, the neoplasm is generally not amenable to resection. These tumors cause a peripheral neuropathy with a loss of withdrawal reflex not observed with a spinal cord lesion.

Egg binding or internal trauma associated with oviposition may result in hemorrhage and swelling around the area of the pelvic plexus, causing a transient paresis or paralysis secondary to neurapraxia.

Circulatory Disturbances

Both peripheral and central neuropathies have been associated with diminished circulation. Atherosclerosis occurs with some degree of frequency in birds. Most commonly, no clinical signs are associated with this condition, and affected birds are simply found dead in their enclosure. In some cases, however, neurologic signs may be observed. Atherosclerosis of the carotid arteries has been described as a cause of ischemia and cerebral hypertension.[22,51,64]

Neurologic signs associated with atherosclerosis include a sudden onset of blindness, ataxia, paresis and seizures. A Blue-fronted Amazon Parrot, which had a 90 to 95% reduction in lumen diameter in one carotid artery and a 60 to 70% reduction in the other due to atherosclerosis, presented with clinical signs of regurgitation once daily, an "aura-like" behavior and holding the right leg in front of the body while going into a semiconscious state. Another Blue-fronted Amazon Parrot with progressive hind limb paresis was found to have severe atherosclerosis at necropsy.[64]

Signs ranging from blindness and ataxia to opisthotonos and seizures have been associated with cerebrovascular accidents and ischemic infarction.[22,46,51,130] MRI, CT scans and EEG may be useful in diagnosing these lesions.

Primary Neoplasms of the Nervous System

Glioblastoma multiforme, choroid plexus tumors, Schwannomas and astrocytomas, pineal body tumors, undifferentiated sarcomas and hemangiomas have been described in the nervous system of companion birds.[51,116,118,140] Clinical signs vary with the location of the neoplasm. Imaging with MRI or CT may be useful in determining the location of the mass; however, all neural tumors are associated with a grave prognosis. Phenobarbital for control of seizures and dexamethasone to decrease cerebrospinal fluid production (thus, intracranial pressure) may provide symptomatic relief.

Pituitary adenoma or pituitary chromophobe adenoma occurs in young (four years old), predominantly male budgerigars with a two to three percent prevalence. These tumors arise from chromophobe cells and may or may not be functional, secreting tumors. The avian pituitary gland secretes LH, FSH, TSH, ACTH, growth hormone, melanocyte stimulating hormone (MSH) and prolactin (in Columbiformes). These tumors are reported to cause a classic clinical syndrome described as somnolence with occasional convulsions, uncoordinated wing-flapping and clonic leg twitches, followed by unconsciousness.[51] Clinical signs are usually the result of compression of the brain and cranial nerves. Incoordination, tremors and inability to perch have also been reported.[91] Polydipsia and polyuria, cere color change, feather abnormalities and obesity may occur with functional tumors. Exophthalmos, visual deficits, lack of pupillary light response and mydriasis may be present also.[97,140]

A tentative diagnosis may be confirmed with contrast-enhanced CT scanning of the skull. Because clinical signs are primarily related to compression of the brain and not to adrenal hypersecretion, therapy with o,p'-DDD is not generally indicated.[140] Radiation therapy is effective in treating human and canine pituitary tumors and may be efficacious in birds. A report suggests that this tumor is transmissible; however, this theory has not been confirmed.[54]

Metabolic Neuropathies

Hepatic Encephalopathy

Birds with severe liver disease may demonstrate signs of hepatic encephalopathy. Hepatic lipidosis, mycotoxicosis, hemochromatosis and vaccine-induced hepatopathy have been reported to cause clinical signs of depression, ataxia, diminished conscious proprioception and seizures (see Color 20).[98,110,135,146] With hepatic encephalopathy, these signs usually occur shortly after eating when the blood levels of neurotoxins absorbed from the gastrointestinal tract (and not properly processed by the liver) are high. Various compounds are believed to contribute to the clinical signs associated with hepatic encephalopathy including ammonia, glutamine, glutamate, alpha ketoglutarate, aromatic amino acids, methionine, mercaptans and short chain fatty acids.[18] In addition, abnormal neurotransmitters, alterations in the blood-brain barrier, alterations in neuroreceptors, al-

tered cerebral sensitivity and hypoglycemia contribute to the development of clinical signs associated with hepatic encephalopathy.

Postprandial blood ammonia concentrations may be elevated and can be determined using a conspecific control bird.[135] In a Toco Toucan with hepatic encephalopathy, the three-hour postprandial blood ammonia level was 350 μg/dl, while the conspecific control was only 86 μg/dl. Ammonia tolerance tests may be beneficial in diagnosing some cases; however, a parallel test should be performed on an asymptomatic bird of the same species. Serum bile acids assays are a more reliable and safer test of hepatic function.

Treatment should be directed toward the underlying cause of hepatic failure. Lactulose syrup and a low-protein, high-carbohydrate, high-quality protein diet with a vitamin supplement may provide symptomatic relief while the underlying hepatopathy is corrected.[135] Neomycin sulfate may decrease the formation of ammonia by reducing the quantity of gram-negative bacteria in the colon.

Hypocalcemia

A syndrome characterized by opisthotonos, tonic extension of the limbs and convulsions has been described in young (two- to five-year-old) African Grey Parrots.[43,53,95,101,122,123] Initially, an affected bird may only seem uncoordinated and fall from its perch. The frequency gradually increases, seeming to be precipitated by some external stimulation. Eventually, seizure activity is pronounced and may become constant or prolonged. Serum calcium levels are below 6.0 mg/dl with concentrations as low as 2.4 mg/dl reported. It has been shown that parathyroidectomized birds begin to have seizures when the serum calcium concentration falls below 5.0 mg/dl.[127] Birds demonstrating only intermittent incoordination may still have normal serum calcium levels. This condition has also been observed in Amazon parrots and conures.[122]

At necropsy, the parathyroid glands of affected African Grey Parrots are grossly enlarged, presumably in response to the low serum calcium concentrations (see Color 14). Parathyroid hyperplasia and degeneration are prominent histologic findings. Vacuolation of the cells of the adrenal glands is a consistent feature and may be an indication of stress. There is no skeletal demineralization present in this syndrome.[122] In most birds with signs of nutritional secondary hyperparathyroidism, serum alkaline phosphatase activity is increased; however, this change has not been found to occur with the hypocalcemia syndrome in African Grey Parrots.[53]

The etiology and pathogenesis of this condition remains speculative. Affected birds are usually wild-caught and are maintained on a diet deficient in calcium and vitamin D_3 (usually a whole-seed diet). It appears that these birds are not able to mobilize body calcium stores (as occurs in cows with "milk fever"). Vitamin A deficiency may also play a role, as hypovitaminosis A has been shown to inhibit osteoclast activity.[123] It has been postulated that a virus that affects parathyroid function is the cause of this problem; however, attempts to demonstrate viral particles using electron microscopy have failed. Another hypothesis suggests that there is increased renal excretion of calcium.[95,122]

Diazepam may be used as an anticonvulsant, but birds generally rapidly respond to the parenteral administration of calcium gluconate. Seizure activity would be expected to cease well before serum calcium levels return to normal.[53] Corticosteroids should not be used in these patients because they increase urinary excretion and decrease intestinal absorption of calcium.

Once the serum calcium concentration has returned to within normal limits, the patient should be placed on a proper diet with calcium and vitamin supplementation. Foods such as dairy products should be encouraged, while those high in fat such as seeds should be eliminated. Serum calcium concentration should be evaluated periodically (every two to four months) to determine if alterations in therapy are indicated. The prognosis for full recovery appears to depend on the severity of damage to the parathyroid glands. If the condition is detected before complete

CLINICAL APPLICATIONS

- The corpus striatum is well developed and is considered the main center for association in birds; consequently, instincts dominate avian behavior, which may account for some of the self-mutilation that occurs in companion birds.
- Birds are ten to twenty times more susceptible than mammals to acetylcholine inhibitors found in organophosphate and carbamate pesticides. Young birds and males are also more susceptible.
- Because withdrawal of an extremity following stimulation is a segmental reflex that does not require an intact cervical spinal cord for normal response, movement does not indicate the patient is able to feel the stimulus.

degeneration of the glands has occurred, the prognosis is favorable.

Because it appears that these birds cannot mobilize body stores of calcium, long-term prevention of recurring problems requires that birds receive adequate levels of calcium in proper balance with phosphorus, as well as sufficient levels of vitamins A, D_3 and E.

Hypoglycemia

Hypoglycemia may occur as a result of starvation or malnutrition, hepatopathy, endocrinopathies and septicemia. Blood glucose less than 150 mg/dl (or half the species' normal value) may be an indication of hypoglycemia.[146] Seizure activity usually occurs once the blood glucose level falls below 100 mg/dl. Therapy should consist of 1.0 ml/kg IV of a 50% dextrose solution for acute relief of clinical signs, while the underlying cause of the problem is being determined and corrected. Dextrose solutions (>2.5%) should be administered intravenously with caution because they are hypertonic and may cause tissue damage if perivascular leaking occurs. Dextrose will compromise a patient's acid-base balance and should not be used in dehydrated birds.

Seizures and Idiopathic Epilepsy

Seizures in birds can have numerous etiologies and various clinical presentations (Table 28.1). A typical seizure may consist of a short period of disorientation with ataxia followed by falling to the enclosure floor as a result of the loss of the ability to grip the perch (Figure 28.9). The bird may remain rigid or have major motor activity for a few seconds or a few minutes. Voiding may or may not occur. The postictal phase is variable.

TABLE 28.1 Common Causes of Seizures in Birds

- Nutritional (Calcium, phosphorus and vitamin D_3 imbalances, vitamin E and selenium deficiencies, thiamine deficiency, hypovitaminosis B_6)
- Metabolic (Heat stress, hypocalcemia, hypoglycemia, hepatic encephalopathy)
- Toxic (Heavy metals, insecticides)
- Infectious (Bacterial, fungal, viral or parasitic)
- Traumatic
- Neoplastic
- Hypocalcemic (African Grey Parrots)
- Hypoglycemic (Raptors)

Idiopathic Epilepsy

Idiopathic epilepsy is used as a diagnosis when other causes of seizures have been ruled out. A syndrome of idiopathic epilepsy has been described in Red-lored Amazon Parrots that has been suggested to have a genetic basis.[124] Seizures of undetermined cause occur with some degree of frequency in Greater Indian Hill Mynahs as well. Mild to severe seizure activity may occur in these birds with signs ranging from "periodic trance-like states" and "stiffening up" to grand mal-type seizures.

Diazepam can be used to temporarily interrupt seizure activity.[125,126,146] Long-term phenobarbital at a dose of 4.5-6.0 mg/kg PO BID titrated to effect, appears to be beneficial in reducing the frequency and severity of seizures in these birds.[124] Blood phenobarbital concentration should be determined approximately one month after institution of therapy to evaluate the dosage. Owners should be advised that the therapy does not "cure" the condition, and they should keep a calendar recording seizure activity and severity.

The use of electroencephalograms in diagnosing epilepsy is difficult in any species of animal. The knowledge of normal electroencephalogram patterns for avian species is limited as is the availability of the equipment and trained personnel to make and evaluate the EEG. Even in species where EEG patterns indicative of epilepsy are established, it is recognized that between seizures, the EEG may be normal.[146]

Lafora Body Neuropathy

Lafora body neuropathy has been reported as a cause of fine, continuous myoclonus in one cockatiel and weakness, anorexia and dyspnea in another cockatiel.[1,9,11] This disease is characterized by the formation of glycoprotein-containing cytoplasmic inclusion bodies within neurons. This accumulation of glycoproteins is believed to be the result of a defect in intracellular metabolism. In humans, the condition is known as familial progressive myoclonic epilepsy. It has also been diagnosed as a cause of spontaneous convulsions or epilepsy in beagles, miniature poodles and basset hounds. The inclusions may be found in other organs including the liver, heart, skeletal muscle and sweat glands. In the affected cockatiel, Lafora-like particles were identified diffusely throughout the liver.[9,11]

FIG 28.9 A mature Umbrella Cockatoo that was maintained in a dark room on a wild-bird-seed diet was presented for an acute onset of convulsions. The bird was severely depressed and was unable to stand. Note the poor general condition of the feathers. The bird did not respond to supportive therapy. Necropsy findings included microhepatia, hypertrophy of the parathyroid glands and enlarged adrenal glands.

Xanthomatosis

The etiology of xanthomatosis is unknown but it seems to develop as a response to deep inflammation (see Chapter 25). The clinical manifestation is thick yellow skin usually in the area of the sternum and ventral abdomen. Xanthomatosis may affect the brain where it appears in association with blood vessels.[51]

Toxic Neuropathies

Heavy Metals

Lead and zinc poisoning are the most common causes of toxicity in birds (see Chapter 37).[92] In addition to common sources of lead contamination, chronic exposure to automobile exhaust has been shown to contribute to the cumulative lead concentrations in body tissues.[88]

Clinical signs associated with lead intoxication are dependent on the amount ingested and the chronicity of the intoxication. Lead adversely affects all body systems by inhibiting enzyme activity and protein formation.[100] Nervous, digestive and hematopoietic systems are most affected. Neurologic changes suggestive of plumbism include lethargy, depression, weakness, ataxia, paresis, paralysis, loss of voice, head tilt, blindness, circling and seizures.

Lead intoxication causes a demyelination of the vagus nerve and a block of presynaptic transmission by competitive inhibition of calcium. Demyelination produces the clinical signs associated with peripheral neuropathy. Lead encephalopathy is the result of diffuse perivascular edema, increases in cerebrospinal fluid and necrosis of nerve cells.[100]

Histologically, neurologic lesions associated with plumbism include neuronal degeneration with shrunken, angular, basophilic neurons of the cerebral cortex and edema of Virchow-Robin spaces and leptomeninges.[59,106] Vacuolation of the neuropil of the cerebral cortex, optic lobes and medulla may be present. Gross and microscopic neurologic lesions may be absent, even in birds with neurologic signs.[32]

Botulism (Limber Neck)

Botulism in birds is usually the result of ingestion of the exotoxin of *Clostridium botulinum* type C. Occasionally *C. botulinum* type A and type E are involved. The organism is an anaerobic, spore-forming bacillus. Spores are present in the soil of many wetlands and are numerous in marsh areas with a history of the disease. The spores are environmentally stable, can survive in the soil for years and are resistant to heat and chemical disinfectants.

Botulism is uncommon in companion birds, but occurs with some degree of frequency in waterfowl. Decaying organic matter provides adequate substrate for development of the clostridial spores. The toxin can persist for months under alkaline conditions (pH 9). Intoxication occurs following ingestion of contaminated food such as necrotic tissue (plant or animal) or dipterous maggots and other invertebrates. Maggots concentrate the toxin without being affected. Birds eat the toxin-laden maggots and disseminate the disease. It is generally the larval stages of blowflies and fleshflies (Calliphoridae and Sarcophagidae) that are found in high concentrations on decomposing carcasses and carry the greatest concentrations of toxin.[39] In an outbreak in pheasants,

20,000 maggots were collected from one carcass, each containing $4x10^4$ mouse MLD of type C toxin/g of maggots. It has been estimated that one ounce of type C toxin could kill the entire population of the United States.[95]

The toxin interferes with the release of acetylcholine at motor endplates causing signs of peripheral neuropathy. All peripheral nerves, including cranial nerves, are affected. The classic clinical sign is a limber neck resulting from paralysis of the cervical musculature. Most birds exhibit hindlimb paresis first, which is characterized by sitting on their sternum with legs extended behind their body.[12] Paralysis of the wings followed by loss of control of the neck and head are observed in the terminal stages. Green diarrhea with pasting of the vent are also common with botulism.[12,39,48] Inconsistent clinical findings with botulism are chemosis, swelling of the eyelids and nictitans, ocular discharge and hypersalivation.[12,48]

Gross and histologic examination generally fail to reveal any lesions. In some cases, maggots may be observed within the proventriculus, and some birds have a pericardial effusion.[12,48] The toxin can be detected in stomach contents, serum or plasma. The mouse protection test is used to provide an antemortem diagnosis in most cases. Mice are challenged with the serum of an affected bird and control mice are left untreated while others receive antitoxin. A positive diagnosis is made if only unprotected mice die. This test is accurate approximately 75% of the time.[48,62] In an outbreak where toxin was not detected in serum, the toxin was recovered from the spleen and liver.[39]

Therapy is primarily supportive. Cathartics, laxatives and drenches are used to flush unabsorbed toxins through the gastrointestinal tract. Tube-feeding provides nutritional support for birds that are unable to eat and drink. Antitoxin may be administered intraperitoneally, but it is not commercially available and its benefits are equivocal.[12,48,72]

Efforts should be made to prevent exposure of birds to maggots and other sources of botulism toxin. Ponds and lakes should not be used for disposal of carcasses and organic debris. They should be dredged periodically, and a fountain or other means of aeration should be provided.

Pesticides

The United States Environmental Protection Agency has registered 36 different organophosphate and 46 carbamate compounds such as carbaryl (Sevin dust), dursban (chloropyrifos), diazanon, malathion, dichlorvos and methyl carbamate.[113] Both of these compound classes are acetylcholinesterase inhibitors that bind to and subsequently inactivate acetylcholinesterase causing an accumulation of acetylcholine at the postsynaptic receptors. Organophosphate bonds are considered irreversible, while carbamate bonds are slowly reversible (spontaneous decay in several days). Acetylcholine is the neurotransmitter found at autonomic ganglia (both sympathetic and parasympathetic); postganglionic parasympathetic nerves affecting smooth muscle, cardiac muscle and exocrine glands; and at neuromuscular junctions of the somatic (skeletal muscle) nervous system.[72,119]

Birds are 10 to 20 times more susceptible to these acetylcholine inhibitors than mammals. Young birds and males are also more susceptible.[94] The development of clinical signs is dependent on the concentration of the pesticide, the route and proximity of exposure, the amount of ventilation, the species of bird and its physical condition.[72] Exposure in companion birds is generally accidental or the result of inappropriate use of insecticide products. The most common route of exposure is inhalation.

Two types of neuropathy and corresponding clinical signs have been described related to toxicosis with acetylcholinesterase inhibitors.[72] Acutely, clinical signs are related to excessive stimulation of acetylcholine receptors. Signs include anorexia, crop stasis, ptyalism, diarrhea, weakness, ataxia, wing twitching and muscle tremors, opisthotonos, seizures, bradycardia and prolapse of the nictitans.[72,94,113,119] Bradycardia and dyspnea with crackles and wheezes may occur as the toxicosis progresses. Respiratory failure is usually the cause of death and results from increased mucus secretion, bronchoconstriction and paralysis of respiratory musculature.

The second type of neuropathy is an organophosphate ester-induced neuropathy, which is not associated with an inhibition of acetylcholine.[73] The onset of clinical signs is delayed (7 to 21 days after exposure) and is the result of a symmetric distal primary axonal degeneration of the central and peripheral nervous systems, with secondary myelin degeneration. Clinical signs include weakness, ataxia, decreased proprioception and paralysis.

Diagnosis of acetylcholinesterase inhibition is usually based on clinical signs and a history of exposure

to these compounds. Cholinesterase assay may be performed on blood, plasma, serum or brain tissue. A decrease in acetylcholinesterase of 50% from normal is considered diagnostic.[73] Normal avian plasma cholinesterase levels are reported to be greater than 2000 IU/l. A new cholinesterase test requires only 0.01 ml of serum and results may be available in five minutes.[113]

Intoxication is best treated with atropine, pralidoxime chloride (2 PAM) and supportive care (see Chapter 37).[119]

The exact mechanism of action of organochloride insecticides, such as DDT, is unknown, but clinical signs are usually neuromuscular, resulting from either stimulation or depression of the central nervous system.[11] There is no known antidote for organochloride intoxication. Birds with seizures or other signs of CNS stimulation should be tranquilized or lightly anesthetized with a long-acting agent such as phenobarbital. In cases of CNS depression, stimulants may be beneficial. Cathartics, activated charcoal and general supportive care should be provided as necessary (see Chapter 37).

Therapeutic Agents

Dimetridazole was commonly used to treat trichomoniasis, giardiasis and histomoniasis. Toxicity results in birds with increased water consumption (increased intake of drug). Convulsions, wing flapping and opisthotonos have been reported in budgerigars, goslings, pigeons and ducks. Histologically, large clear spaces are present around blood vessels, neurons and glial cells. Neurons have a pyknotic nucleus and eosinophilic cytoplasm. Dimetridazole is no longer commercially available in the United States.

Metronidazole toxicity has been reported in dogs and cats, but not in companion birds. Clinical signs relate primarily to the vestibular system and include ataxia, incoordination, proprioceptive deficits, nystagmus, depression, paresis, tremors and seizures. Treatment involves limiting further absorption of the drug (eg, absorptives, emetics and cathartics), fluid therapy to increase renal excretion, control of seizure activity and supportive care.

Other Neurotoxins

Many plants are toxic to the nervous and digestive systems. Generally, birds are more resistant than mammals to plant-derived toxins (see Chapter 37).

Citreoviridin and tremorgens are two types of mycotoxins that primarily affect the neural system. Fusariotoxins and ochratoxins also produce nervous disorders. A syndrome characterized by cervical paresis in free-ranging Sandhill Cranes has been associated with mycotoxicosis.[107]

Domoic acid poisoning was diagnosed as the cause of death in Brown Pelicans and Brandt's Cormorants exhibiting neurologic signs. Twenty-seven of 39 affected birds died within 24 hours.[153] Domoic acid is a neurotoxin produced by marine diatoms. It is an excitatory toxin that binds to both pre- and postsynaptic kainate receptors in the brain, resulting in continuous depolarization of neurons until cell death occurs. It was theorized that this epornitic was caused by the ingestion of contaminated anchovies, which had fed on the diatoms.

Infectious Neuropathies

Fungal

The nervous system may be a secondary site for aspergillosis lesions that may cause ataxia, opisthotonos and paralysis. In infected birds, yellowish, mycotic nodules may be grossly visible within the brain or spinal canal. Fungal granulomas may compress or invade peripheral nerves and cause unilateral or bilateral paresis or paralysis (see Color 21).[47] Spinal aspergillosis has been diagnosed in several penguins at the San Francisco Zoological Gardens. Fungal elements are usually detected histologically (see Chapter 35).

Dactylaria gallopava has been reported in Grey-winged Trumpeter Swans and gallinaceous birds. The organism is present in wood chips and bark litter. Infections characterized by encephalomyelitis occur following the inhalation of fungal spores. *Cladosporius* (*Exophiala*) and *Mucomyces* have also been reported to cause meningoencephalitis.[31]

Parasitic

Toxoplasma

Toxoplasma gondii infections are reported primarily in Galliformes and Passeriformes with lesions involving the brain and skeletal muscles. Cats are the only host known to excrete infectious oocysts.[36] Considering avian species, it would seem that raptors are

most likely to become infected because they prey on the same types of animals as cats. Although toxoplasmosis has been reported in raptors, they appear to be more resistant to infection than other birds.[36,78]

Clinical signs include anorexia, pallor, diarrhea, blindness, conjunctivitis, head tilt, circling and ataxia. Infection may occur from ingestion of coprophagic arthropods or food and water supplies contaminated with feces from infected cats. Encapsulated cysts (round or oval) are found in the brain histologically. A definitive diagnosis is made using a latex agglutination serum test or immunohistochemical staining of affected tissues. There is variation among avian species with respect to the antibody response generated against *Toxoplasma* sp. Chickens do not develop antibodies, while raptors, pigeons, canaries and finches have been shown to develop positive agglutination antibody titers.[36,70,144] In experimentally infected raptors, cysts were found in the brain and muscles (skeletal and cardiac) even when no clinical abnormalities were noted.

In canaries and finches, toxoplasmosis has been shown to cause loss of myelinated axons in the optic nerve resulting in blindness and conjunctivitis.[144] Tachyzoites could be demonstrated in the detached and intact retinae, lenses and exudate from the vitreous humor. Focal, disseminated, chronic inflammation with accumulations of tachyzoites characterized the histologic findings in the brains (see Chapter 36).

Sarcocystis

Sarcocystis spp. infect a broad range of hosts in several orders of birds. Infection in birds is reported to be less common than in mammals; however, infection has been reported in over 60 species of birds, with Old World psittacines apparently more susceptible (see Chapter 36). Unlike many other species of *Sarcocystis, S. falcatula* schizonts can persist in avian tissues for up to 5.5 months.[36] It is believed that cockroaches and flies may be transport hosts for the parasite.[26,52] Raptorial species may become infected by ingestion of prey containing the encysted organism.[1,36]

Histologically, the organisms are elongated, spindle- or banana-shaped, and grouped into packets within a spherical- to spindle-shaped cyst. Granulomatous inflammation consisting of macrophages and lymphocytes forming nodular and diffuse aggregates is associated with these cysts. With electron microscopy, characteristic polar rings and micronemes may be discernable.[58]

Schistosomiasis

Granulomatous encephalitis caused by the blood fluke *Dendritobilharzia* sp. has been reported in swans.[77,147] Neurologic signs included head tilt, circling, weakness and extension of the head and neck. Granulomas containing macrophages, giant cells, lymphocytes and occasional heterophils and fibroblasts were identified within the cerebrum and cerebellum of affected birds. Ova of the parasite were identified within these lesions. Adult flukes were identified within the blood vessels in one bird. Adult schistosomes usually live within veins; however, those of the genus *Dendritobilharzia* live within arteries. Adults have little host-specificity.

Baylisascaris sp.

Baylisascaris procyonis is the ascarid of raccoons and is a zoonotic organism that can cause fatal meningoencephalitis in humans. Over 40 species of mammals and birds have been shown to develop clinical cerebrospinal nematodiasis following infection.[4,5,68,99] Free-ranging birds are infected by ingesting raccoon feces, while companion birds may become infected by ingestion of food contaminated with parasite eggs. The eggs may remain viable and infective in the environment for years.

Clinical signs are nonspecific and include depression, ataxia and torticollis. The onset may be acute or chronic, possibly related to the number of larvae involved. Prolonged migration of a single larva within the brain could produce chronic, progressive signs. Treatment with ivermectin has been completely ineffective.[5]

Gross lesions are generally absent. Edema of the brain and spinal cord, encephalitis, encephalomalacia, eosinophilia around sections of larvae, degenerative foci with heterophils in the neuropil, perivascular cuffing and glial cell proliferation are observed histologically.[4,5,38,67,99] In some cases, a cross section of the parasite may not be observed as the larvae migrate even after host death.[99]

Filaria

Chandlerella quiscali is a filariid nematode of grackles that has been reported to cause cerebrospinal nematodiasis in emus.[7] Gnats are the vectors for natural infection. The gnat is ingested and the larvae migrate into the brain or spinal cord and then into the lateral ventricles of the cerebrum where they mature and produce microfilaria. Affected emu chicks demonstrated torticollis, ataxia, recumbency

and death. Circulating microfilaria were not detected (see Chapter 36).

Viral Neuropathies

The following viral diseases of birds have neurologic clinical or histologic abnormalities as part of their pathophysiology; most produce lesions in other systems as well. Only their effects on the nervous system will be discussed here. For a more complete discussion of these viruses, see Chapter 32.

Paramyxovirus

Paramyxoviruses (PMV) 1, 2, 3 and 5 have been isolated from companion birds, and groups 1 and 3 have been associated with lesions of the central nervous system.[75] Pigeon paramyxovirus causes a nonsuppurative encephalitis similar to that described with Newcastle disease virus.[129]

Clinical signs associated with PMV-1 in companion birds are variable depending on the virulence of the strain and the species of bird affected. In some cases, the only signs may be acute death and high mortality. Other signs are associated with abnormalities of the respiratory, digestive and nervous systems.[23,24,30] Neurologic signs including depression, hyperexcitability, ataxia, incoordination, torticollis, head tremor, opisthotonos, muscle tremors and unilateral or bilateral wing or leg paresis or paralysis occur more commonly in older birds and with chronic infections.[24,30] Some birds clench their feet while others lose control of the tongue and their ability to grip with the beak.[23]

All reflexes are depressed but neurologic signs are exacerbated by excitement. Seizures and running movements are often observed just prior to death. Neurologic signs generally persist in birds that survive the acute infection.[142]

At necropsy, there may be petechiae on the surface of the cerebrum and cerebellum.[23] Histologically, central nervous system lesions are commonly observed in the cerebellum, brainstem, midbrain and spinal cord. Neuronal degeneration, gliosis, endothelial cell hypertrophy and lymphocytic perivascular cuffing characterize the lesions.[30,114]

Lymphoplasmacytic meningoencephalitis outbreaks have been described in *Pionus* species and *Neophema* species from a quarantine station. These deaths were caused by an unclassified hemagglutinating virus that morphologically resembles paramyxovirus.[82,84] The disease produced high morbidity and moderate mortality. Muscle tremors, circling, ataxia, torticollis, weakness, depression, paresis and paralysis were the major clinical signs.

A yellowish periventricular discoloration was the only abnormal gross brain lesion noted. Histologically, there was lymphoplasmacytic perivascular cuffing adjacent to the ventricles, within the choroid plexus and around the central canal of the spinal cord, sometimes accompanied by edema of the neuropil. Some ependymal cells and few subependymal glial cells had equivocal eosinophilic Cowdry type A inclusions. On electron microscopy, these contained virions compatible with paramyxovirus.

Neuropathic Gastric Dilatation

There is strong evidence that neuropathic gastric dilatation is caused by a virus (possibly a paramyxovirus). Anorexia, regurgitation, changes in fecal consistency, weight loss, pectoral muscle atrophy and depression are presenting clinical signs.[55,64,90,139,151] The clinical signs of this disease primarily relate to the gastrointestinal system, with central and peripheral neurologic signs occurring only occasionally.[64,150] However, the main histologic lesions involve the nervous system.

Creatine kinase is an enzyme released from damaged nerves and muscles. It has been reported that some birds with neuropathic gastric dilatation have elevated serum CK levels; however, an elevation of serum CK activity is not specific for this disease and may occur with septicemia, neuropathies and myopathies.[60]

Microscopic lesions generally involve the brainstem, the ventriculus and the proventriculus. Multifocal lymphocytic encephalitis with lymphocytic perivascular cuffing, gliosis and neuronophagia characterize the brainstem lesions.[55] Asymmetric lymphocytic poliomyelitis, lymphocytic perivascular cuffing and gliosis are present in the spinal cord. Multifocal lymphocytic leiomyositis with smooth muscle degeneration and fibrosis are common in the ventriculus and proventriculus.

There is a general loss or depletion of myenteric ganglion cells (myenteric ganglioneuritis). The ganglia of gastric and duodenal myenteric plexuses demonstrate round cell accumulations (lymphocytes, plasma cells, macrophages). Intranuclear and intracytoplasmic eosinophilic inclusion bodies have been described within the perikaryon of the celiac ganglion and myenteric plexus.[90] Virus particles associ-

ated with the inclusions have been morphologically similar to paramyxovirus particles.

Avian (Picornavirus) Encephalomyelitis

This picornavirus has been associated with gastrointestinal and neurologic signs in Galliformes, Anseriformes and Columbiformes.[8,51,89,132,133] Only one serotype is recognized but strains vary in neurotropism. Clinical signs include depression, ataxia, paresis or paralysis and severe, but fine head and neck tremors. Neurologic signs occur only in birds less than 28 days of age.[51] No characteristic gross lesions are noted at necropsy. Neuronal degeneration with lymphocytic perivascular cuffing and gliosis in the brain and spinal cord characterize the disease histologically.[89]

Polyomavirus (Budgerigar Fledgling Disease)

Although not the primary lesions, tremors of the head, neck and limbs, incoordination and ataxia have been associated with polyomavirus in infected birds. Histologically, large, slightly basophilic intranuclear inclusion bodies can be identified in the cerebellar ganglionic layers.[88,91,131]

Reovirus

Reovirus is commonly reported in imported birds and primarily affects African Greys, cockatoos and other Old World Psittaciformes. Clinical signs include uveitis, depression, emaciation, anorexia, incoordination, ataxia, paresis and diarrhea. Histologically, multifocal necrosis of the liver is present. This is not a neurotropic virus, and the paresis or paralysis is the result of vascular thrombosis of the extremities.

Togaviridae

Viral encephalitis caused by a number of togaviruses has been reported in numerous species of birds. Clinical signs include depression, ruffled feathers, decreased appetite, dyspnea, profuse hemorrhagic diarrhea (in emus), ataxia, muscle tremors, weakness, unilateral or bilateral paresis or paralysis, torticollis and death. At necropsy, the cerebral hemispheres may be softened. Histologically, lesions include nonsuppurative encephalitis, patchy neural necrosis, cerebral vasculitis, leukocytic perivascular infiltrates, microgliosis, meningitis, neuronal degeneration and myocardial necrosis.[121] These changes have a rostral distribution contrary to most avian viral encephalitides. Vaccines are available and appear to be beneficial in outbreaks.[15,51,56,21,121,138]

Marek's Disease

This lymphoproliferative disease is caused by a herpesvirus. Peripheral nerve dysfunction occurs secondary to lymphoid infiltrates. Often birds display a spraddle-leg paralysis with one leg extended forward and the other back. Grossly, the ischiatic nerves appear enlarged with a loss of striations and a gray discoloration. In a study of neoplasms of budgerigars, many birds with abdominal tumors also had evidence of infection with avian leukosis virus; however, similar findings were not confirmed in another study.[43,104]

Encephalomyelitis in Lorikeets

Encephalomyelitis was described in free-ranging Australian lorikeets.[102] Affected birds demonstrated a progressive bilateral paralysis with clenched feet. Perivascular macrophage infiltrates, vascular endothelial cell proliferation, gliosis, neuronal necrosis and neuronophagia were observed in the brainstem and spinal cord of affected birds. Edema of the ischiatic nerve was also a feature. A viral or protozoal etiology has been suggested.

Duck Viral Enteritis

Duck viral enteritis is primarily a concern where feral populations of ducks mingle with captive birds. Clinical signs include photophobia, ataxia, seizures, penile prolapse, lethargy, hemorrhagic diarrhea and serosanguinous nasal discharge. The most notable finding at necropsy is hemorrhagic bands on the small intestine (see Color 14).

Duck Viral Hepatitis

Duck viral hepatitis is caused by a picornavirus. Clinical signs include lethargy, seizures, opisthotonos and death. Ducklings suffer the highest mortality, and Muscovy Ducks appear to be resistant to infection with this virus. At necropsy, the liver, spleen and kidneys are enlarged with petechial hemorrhages. It is recommended to vaccinate breeders before the onset of laying.

Bacterial Neuropathies

Listeriosis

Listeria monocytogenes is a small, gram-positive, nonsporulating, motile rod that is frequently confused with a hemolytic *Streptococcus* sp. The organism is ubiquitous and can survive for years in the environment. Intracranial infections cause opisthotonos, ataxia and torticollis (Figure 28.10).[29] Brain lesions consist of microabscesses with heterophil and giant cell infiltrates, diffuse gliosis, meningeal hyperemia, degeneration of Purkinje cells and perivascular cuffing (see Chapter 33).

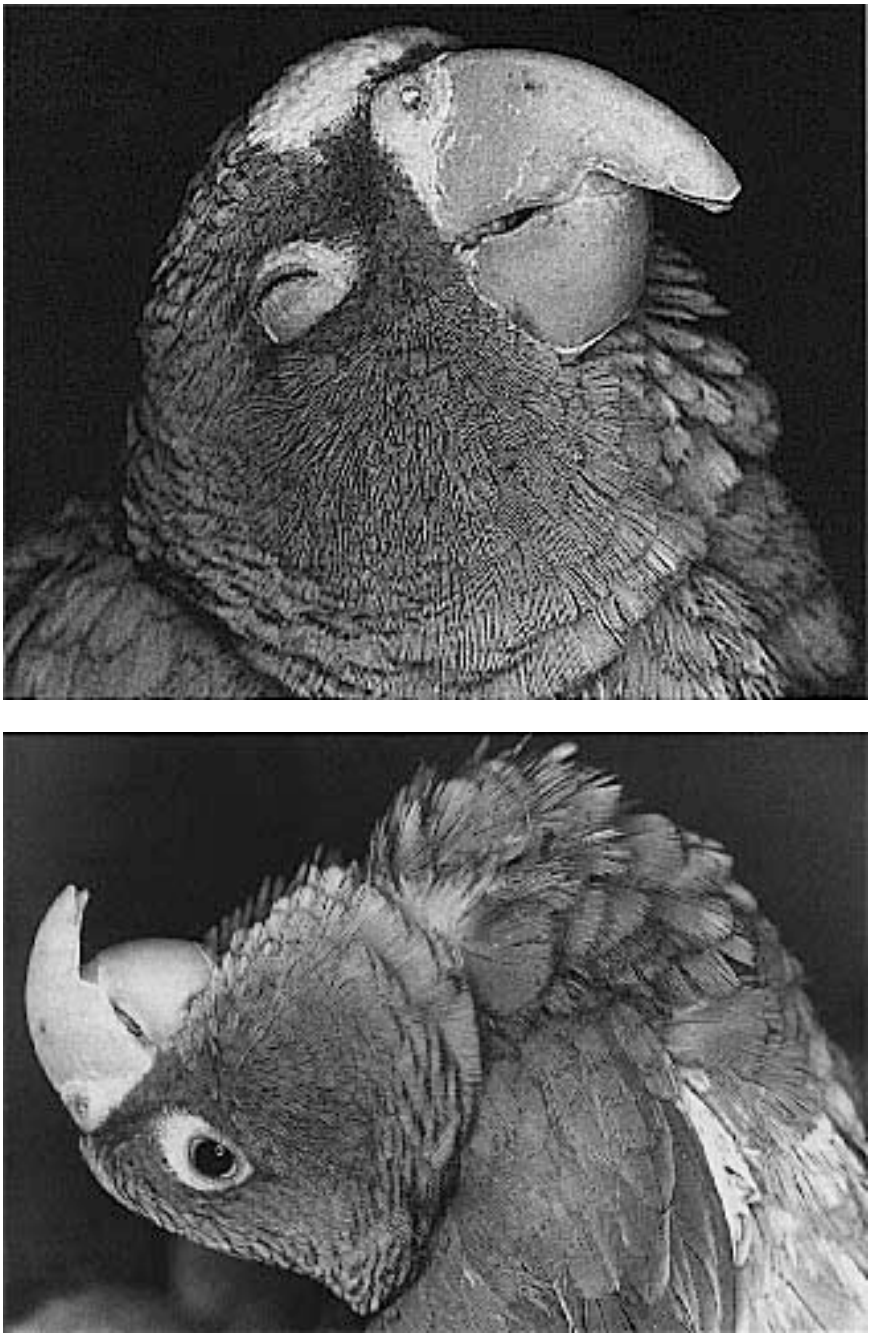

FIG 28.10 An adult Amazon parrot was presented with a history of progressive depression, weight loss and ataxia. When undisturbed, the bird would exhibit repeated periods of opisthotonos with shifting phase nystagmus. Abnormal clinicopathologic findings included WBC=26,000 (toxic heterophils), PCV=26, total protein=7.5 and CPK=1200. The bird did not respond to supportive care. Histopathology indicated a severe perivascular cuffing with neuronal necrosis of undetermined etiology.

Chlamydiosis

Occasionally, *Chlamydia psittaci* will cause neurologic signs in birds that survive the acute respiratory or gastrointestinal phase of the disease. Signs include seizures, torticollis, tremors and opisthotonos (see Chapter 34).[88]

Granulomas

Avian tuberculosis can cause neurologic signs if the granulomas occur intracranially or adjacent to peripheral nerves.[51,108] Osteomyelitis caused by mycobacterium may produce a lameness that could be misinterpreted as a neuropathy. Abscesses, granulomas, encephalitis, myelitis and meningitis may be caused by any bacterial organism. *Salmonella, Streptococcus, Staphylococcus, Pasteurella multocida, Mycoplasma* and *Clostridium* spp. have been isolated.[19,46,51,73] Clinical signs depend on the location and extent of the lesions.

Otitis

Otitis media and interna in companion birds may cause neurologic signs. Otitis interna produces a head tilt and circling toward the affected side (see Figure 28.6). If the infection progresses, other cranial nerves and the midbrain may become affected.

Congenital Abnormalities

The incidence of developmental abnormalities of the avian nervous system is not well established. Studies in poultry suggest that meningocoele and other related anomalies result from early malformation and forking of the neural tube during embryonic development.[79] In turkeys, hydrocephalus, shortened beaks and absence of the terminal digits have been linked to an autosomal recessive semilethal gene.[103] In laboratory animals, virus infections, certain chemicals and malnutrition (hypovitaminosis A, hypervitaminosis A, hypovitaminosis B_{12} and B_6 and

zinc deficiency) may cause hydrocephalus. The chemotherapeutic agent cyclophosphamide and alkaloids from the plant *Veratrum californicum* cause hydrocephalus, microphthalmia, meningocoele, encephalocele, cebocephaly and cyclopia in chick embryos. Other cephalic and cerebral abnormalities have been induced by petroleum distillates, phenylmercuric acetate, tellurium and 6 amino-nicotinamide.[10,66] Hydrocephalus of unknown etiology has been described in psittacine birds. [51,145]

CHAPTER

29

THERIOGENOLOGY

Kim L. Joyner

Theriogenology in mammals includes obstetrics, genital diseases and reproductive physiology. Theriogenology in birds includes these topics as well as egg anatomy, physiology and incubation. With the rising interest in captive propagation for avicultural and conservation purposes, modern avian theriogenology also includes veterinary and avicultural techniques designed to maintain optimal production. Many factors, including complex reproductive behaviors, affect avian reproduction. Avian clinicians can serve the avicultural community by developing a thorough understanding of the avicultural techniques, anatomy, physiology, nutrition and behavior necessary to maintain long-term reproductive health for individual pairs and the flock.

Reproductive disorders occur with surprising frequency but can be difficult to diagnose because the cloaca serves as the endpoint of the gastrointestinal, urinary and reproductive systems in birds. In 24 avian orders, an 8.9% prevalence of reproductive disease was described in necropsy specimens.[84] The most commonly affected companion bird species was the budgerigar, although this observation was probably skewed by biased sampling in this particular study. Domestic poultry that have been genetically selected for productivity traits are probably more susceptible to reproductive disorders than companion bird species. Poultry hens have been reported to have a reproductive disease prevalence of 27.5% and 53.3%[155,159] with senility, malnutrition and infectious agents being the most often incriminated causes of disease. The most common infectious agent affecting the reproductive tract of laying hens appears to be *E. coli*.[159] Reproductive disease in hens is frequently multifactorial, complicating diagnosis and therapy. Additionally, more than one type of reproductive disorder is often present; however, because of the common pathogenesis of many of these disorders, preventive and therapeutic considerations are generally similar irrespective of the etiology.

Female Reproductive Anatomy and Egg Formation

Ovary

The normal reproductive tract of a mature hen consists of a left ovary and oviduct. The right ovary and oviduct are present in embryonic stages, but these tissues normally regress before hatching in most species (Color 29.10). In some species and individuals (raptors), these organs may be vestigial or functional post-hatching. The left ovary is located at the cranial end of the kidney and is attached to the abdominal wall by the mesovarian ligament. In young birds the ovary is flattened, in an inverted "L"-shape. It has nearly inappreciable folds and resembles a piece of fat (see Color 13). As birds mature and the gyri become more prominent, small primary oocytes give the ovary a cobblestone appearance (Color 29.24). This process occurs by about 25 weeks of age in Blue and Gold Macaws (see Color 13).[171] Ovarian tissue can be more or less melanistic, especially in cockatoos, macaws and some conures. Gonadotropin secretion in maturing hens causes a hierarchy of follicles to develop, giving the ovary the appearance of a cluster of variably sized grapes (Color 29.20). As the breeding season approaches, the follicles undergo a period of rapid growth with the deposition of yolk proteins and lipid produced by the liver. At this point the yellow yolk is clearly visible through the highly vascularized follicular wall. The large follicle is suspended by a stalk. The normal post-ovulatory follicle becomes a thin-walled sac devoid of blood clots.[86] The hypertrophied granulosa cells are metabolically active for several days and may not be reabsorbed until eight to ten days post-ovulation in the chicken, and up to several months in the Mallard Duck.[100] The post-ovulatory follicle is thought to secrete non-steroidal hormones that are involved in oviposition and nesting behavior.[86]

During the non-breeding season, the ovarian follicles normally collapse and exhibit atresia. Two kinds of atresia have been described.[86] Bursting atresia occurs when the follicle wall ruptures and yolk is harmlessly released into the peritoneal cavity where it is absorbed. Invasion atresia involves granulosa and theca cells invading the ovum with subsequent *in situ* yolk absorption. The earliest detectable indication that a large follicle is undergoing normal atresia is the appearance of a vesicular lesion. This vesicle formation continues until the entire follicle is covered. As the largest follicle is absorbed, the smaller follicles will progress similarly.[38] Small follicles can be covered by connective tissue, sometimes leaving a scar-like area (see Color 13). Large follicles may undergo cystic degeneration (Color 29.22).[46,176] If ovulation ceases suddenly due to trauma or stress, then developing follicles may be hemorrhagic and result in regression of the developing follicle. Aging hens can exhibit permanent ovarian involution, which is believed to be a normal physiologic process. Aflatoxicosis can also cause follicular atresia.[52]

Oviduct

Understanding the anatomic divisions of the oviduct and their associated functions is important when discerning pathologic changes in the reproductive tract. During active egg laying, the oviduct enlarges and occupies much of the left abdomen. During the non-breeding season, the oviduct shrinks considerably in length and width. The oviduct of a preovulatory hen is usually thin, straight and uniform in diameter, and can be confused with the laterally tracking ureters (Color 29.19). An ovary and oviduct can regress to a point where it is difficult to determine if a hen has ever been reproductively active.

The oviduct consists of five microscopically distinguishable regions: infundibulum, magnum, isthmus, uterus (shell gland) and vagina (Figure 29.1). Dorsal and ventral ligaments attach the oviduct in the peritoneal cavity.[79] In psittacine birds, the dorsal ligament is clearly visible crossing the cranial division of the kidney (see Color 13).[172] Peristaltic activity in the cranial oviduct and stronger smooth muscle contractions in the uterus and vagina move the ovum down and the sperm up the reproductive tract. Oviduct transit time varies among species and is approximately 24 hours in the chicken. Similar transit times are discussed in companion and aviary birds, with the egg spending varying but proportional times in each section of the oviduct.

The cranial infundibulum consists of a thin, nearly transparent finger-like funnel that engulfs the ovum into an ovarian pouch (see Anatomy Overlay). More distally, the infundibular wall thickens as it becomes tubular. In domestic fowl, the infundibulum is about seven centimeters long, while in the Brown Kiwi it extends the width of the peritoneal cavity to receive oocytes from functional left and right ovaries.[86] Fer-

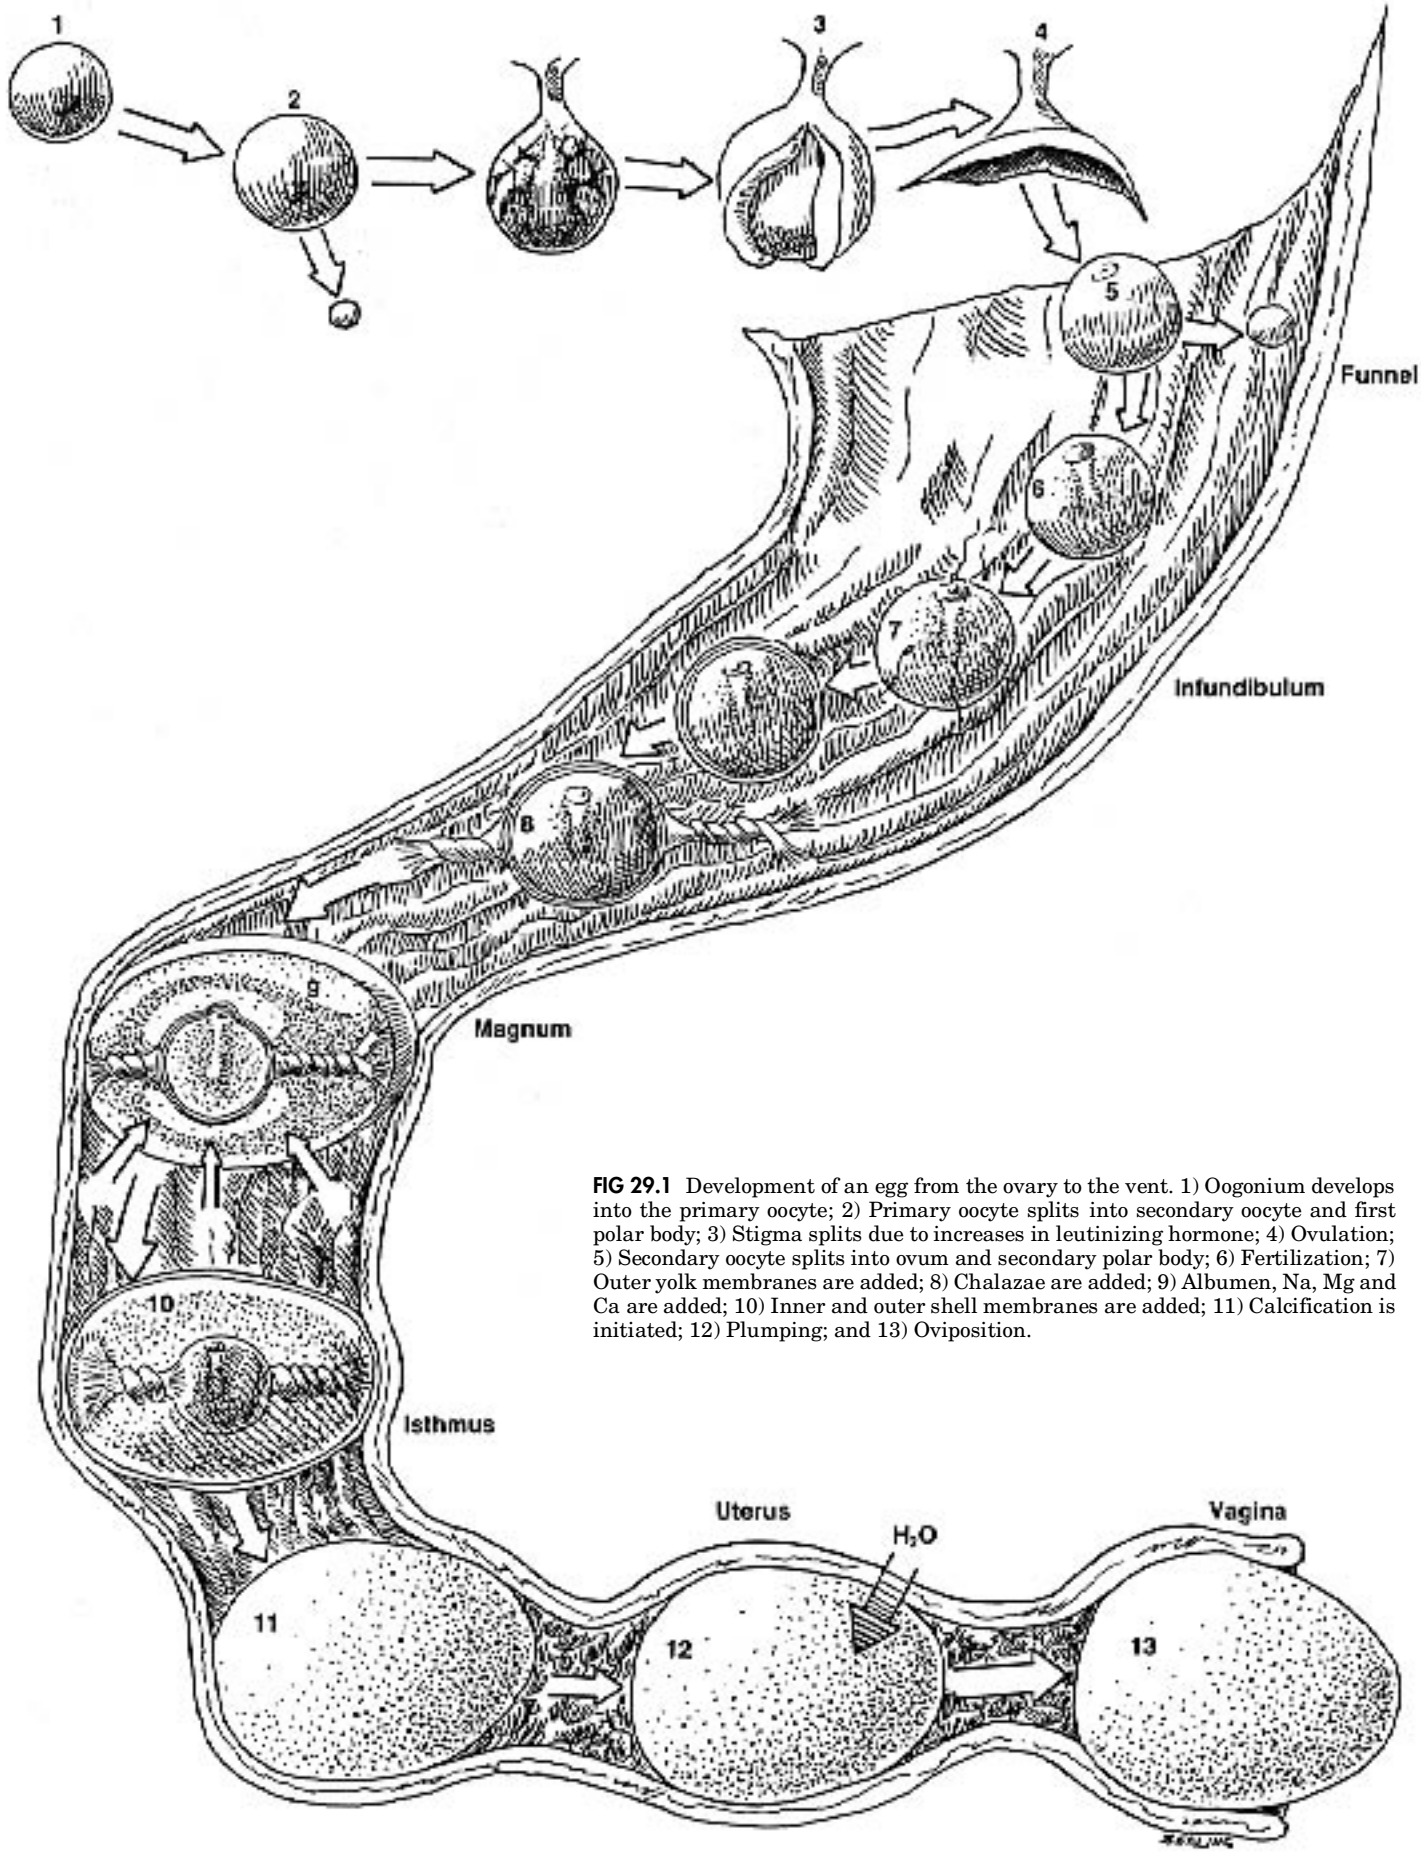

FIG 29.1 Development of an egg from the ovary to the vent. 1) Oogonium develops into the primary oocyte; 2) Primary oocyte splits into secondary oocyte and first polar body; 3) Stigma splits due to increases in leutinizing hormone; 4) Ovulation; 5) Secondary oocyte splits into ovum and secondary polar body; 6) Fertilization; 7) Outer yolk membranes are added; 8) Chalazae are added; 9) Albumen, Na, Mg and Ca are added; 10) Inner and outer shell membranes are added; 11) Calcification is initiated; 12) Plumping; and 13) Oviposition.

tilization occurs in the tubular portion of the infundibulum, where sperm may reside in glandular grooves awaiting the arrival of the ovum. Production of the chalaziferous layer of the albumen and the paired chalazae occurs also in the tubular portion of the infundibulum. Less than an hour later, the ovum exits the infundibulum and enters the highly glandular magnum that is differentiated from the infundibulum by its sudden enlargement in the mucosal folds. It is the largest and most coiled portion of the oviduct and deposits most of the albumen, sodium, magnesium and calcium used in egg development. The egg may remain in the magnum for three hours. Inner and outer shell membranes are added to the developing egg during its one to two hours in the isthmus. The isthmus has less well developed circular muscle and glandular tissue compared to the magnum.

The short uterus has numerous leaf-like lamellae composed of longitudinal folds, consisting of prominent longitudinal muscles and underlying tubular gland cells. This part of the uterus is ovoid in shape and holds the egg during shell deposition. The more cranial aspect of the uterus is difficult to differentiate from the isthmus. The egg remains in the uterus for 20 to 26 hours and receives salts, water, the shell and shell pigment. The uterus is highly vascularized during egg laying and must be carefully manipulated during any surgical procedure to prevent excessive hemorrhage (see Chapter 40 for considerations prior to performing uterine surgery). The egg is oriented in the uterus with its sharp end pointing caudally. In most species the egg is laid in this direction, although in some species the egg turns in the uterus just before oviposition.[86] The S-shaped vagina is the thickest walled portion of the oviduct; it begins at the uterovaginal sphincter muscle and terminates in the cloaca. The vagina is distinguishable by its numerous thin folds of mucosa. In juvenile chickens and some Anseriformes, the vagina is separated from the cloaca by a membrane that deteriorates at sexual maturity.[86] The vagina does not contribute to the formation of the egg, which passes through the vaginal lumen in seconds during normal oviposition. Along with the uterus, the vagina contributes to the muscular expulsion of the egg. Cranes that are disturbed during oviposition may retain an egg in the vagina for four days, followed by a normal egg delivery (Gee GF, unpublished).

Gallinaceous hens can store sperm in the spermatic fossulae (sperm host glands) at the uterovaginal junction and the glandular grooves and tubular glands of the infundibulum. Other species may have only one set of these glands. Sperm located in these glands remain fertile for 7 to 14 days in the chicken and for 40 to 50 days in the turkey.[79] Anecdotal evidence suggests that sperm can remain viable for over a week in psittacine species.

Female Hormonal and Physiologic Factors

Primary oogenesis begins in the embryo when secondary oocytes are formed. Meiosis is arrested until adult life when follicles become active and grow in three phases, the first of which can last months to years.[75] This long initial stage represents the resting pre-nuptial period that occurs in all species. Stage two lasts about 60 days in the domestic hen, and during this period some yolk is deposited in vacuoles within the oocyte. This stage corresponds with ovarian regression that occurs in the non-breeding season in free-ranging species. Stage two growth in nondomestic species is influenced by luteinizing hormone (LH) and follicle stimulating hormone (FSH), which are both produced by the adenohypophysis under the control of the hypothalamus. Stage three involves rapid yolk deposition and normally occurs in free-ranging birds only when a mate is present. Courtship and nest-building activity seem to precede stage three follicular development, which terminates with either normal follicular atresia or ovulation.

Developing ovarian follicles consist of concentric layers of yolk, the oocyte, perivitelline lamina, granulosa cells, basal lamina and theca. Ovarian thecal and interstitial cells produce estrogen while the granulosa cells produce progesterone. Increasing concentrations of circulating estrogen stimulate an LH surge that is responsible for the continuation of meiosis two hours before ovulation. At this time, LH causes extrusion of the first polar body, the follicular wall ruptures and ovulation occurs. Extrusion of the second polar body occurs in the infundibulum, and the ovum is formed. The remaining granulosa cells of the ruptured follicle are under the control of LH and prolactin. These cells continue to produce progesterone, which inhibits further ovulation and induces behavioral and physiologic changes associated with incubation and brood care. During this time, the ovary and accessory reproductive tissues, such as the oviduct and comb, regress. Broody behavior is accompanied by the development of a brood patch in some species. Prolactin secreted by the anterior pituitary stimulates the production of "crop milk" in both genders of Columbiformes. In some avian species, pro-

lactin levels are usually higher in the parent providing the majority of the care.

In photoperiodic species, day length changes may terminate reproduction; however, in most species a photorefractory state develops that is controlled at the level of the hypothalamus.[42] Long day length as a stimulus is blocked, and serum gonadotropin and gonadal steroid hormones decrease to minimum levels. Photorefractoriness is then terminated by shorter daylight periods. This change often corresponds to a surge in reproductive behavior in the fall in some species. Circadian rhythms are also involved in the photoperiodic control of synthesis and release of FSH and LH.

Domestic hens are continuous layers (indeterminate layers) and under optimum conditions are reproductively active year round. Hormonal mechanisms controlling continuous egg production have been artificially induced through selective breeding. In contrast, free-ranging birds lay one or more eggs in a clutch and then terminate egg production to begin incubation. The onset of reproductive activity is influenced by increasing photoperiod in temperate climates.[79] Photoperiod is less important in equatorial birds where day length is similar all year. Photoperiodic pathways are controlled by light passing through the eye via the optic nerve to the hypothalamus, and by light passing through the spongy calvarium stimulating the hypothalamus or pineal body. Photoperiod also affects the time of ovulation and oviposition. In poultry, the maximum effect of photostimulation occurs when birds are provided 12 to 14 hours of light; however, normal egg production can occur when hens receive 12 to 18 hours of light. Because reproductive activity continues even when hens are placed in continuous darkness, other factors also control egg laying.[79]

Hypothalamic control of reproduction is influenced by environmental factors other than light, especially in periodic breeders of equatorial climates. In arid-dwelling species, such as the budgerigar and Zebra Finch, the rostral pituitary is constantly stimulated by the hypothalamus to release gonadotropins except when inhibited by negative external conditions such as drought. During these dry conditions when food would be scarce, the hypothalamic secretions suppress reproductive activity.

Ovulation in the domestic hen occurs shortly after oviposition allowing a 24 hour lay interval. In psittacine birds, the laying interval is generally two days.[4] In most Passeriformes, lay intervals are 24 hours, but they can extend up to four to five days in the Andean Condor and up to 44 days in the Brown Kiwi.[86] It is not clear whether transit time in the oviduct, a delay in ovulation or both are responsible for longer lay intervals.

Several hormones secreted by the follicle affect the oviduct. Progesterone in large doses may inhibit ovulation or, if given 36 hours before expected ovulation, will induce follicular atresia.[75,79] If given 2 to 24 hours pre-ovulation, progesterone can induce a preovulatory surge of LH and premature ovulation. The dose and critical period for exogenous progesterone administration appear to vary among species and experimental designs. The extrapolation of any data collected in gallinaceous birds should be applied to companion bird species with caution. If progesterone is used to prevent egg laying, it should be administered when a complete clutch has been laid. Premature administration can cause an abnormal ovulatory process that may lead to soft-shelled eggs, mummification, peritonitis and death (Harrison GJ, unpublished). In general, the seasonal hypertrophy of the oviduct in free-ranging birds is dependent on estrogen secreted from the ovary. Progesterone and prolactin also interact with estrogen in stimulating the growth and secretory activity of the oviduct. In the oviduct, estrogens influence the synthesis of oviductal proteins, oviduct growth and the formation of tubular glands. Androgens in estrogen-primed birds influence the synthesis of proteins in the oviduct and in conjunction with estrogen initiate medullary ossification.

Ovum transport in the oviduct is primarily accomplished by contractions of the oviduct in response to a stretch stimulus. Prostaglandins, which contract the smooth muscle of the oviduct and vagina, may also influence egg transport and expulsion.[79] Arginine vasotocin released by the posterior pituitary stimulates uterus contractility *in vitro*, but it is not clear what role it plays in oviposition. The effect of oxytocin, also produced by the posterior pituitary, in inducing premature oviposition may be mediated *in vivo* by prostaglandins. It is likely that oviposition is a complicated process involving neurohypophyseal hormones, prostaglandins and hormones of the pre- and postovulatory follicles. Oviposition may last from seconds to hours depending on the species. Before expulsion of the egg can occur, the abdominal muscles and cervix must relax.

The thecal cells of the pre-ovulatory follicle and the ovarian stromal interstitial cells (homologous with the interstitial Leydig cells of the testis) produce androgens.[75] Sexual behavior and secondary sexual characteristics are influenced by androgens in the female and may become apparent depending on the stage of ovarian regression or growth. Examples of androgen-controlled characteristics include comb growth, bill growth and aggressive male-type behavior (territoriality).

LH levels increase in female cockatiels when they start nest-searching behavior and reach their highest levels during egg laying.[116] LH levels decline during incubation, hatching and chick-raising, but increase again in both genders if a second clutch of eggs is laid. In male cockatiels, LH levels are highest during nest inspection and are lowest during egg laying. Prolactin levels increase in both genders during egg laying, peak during incubation and then decline to a resting level.

Calcium Metabolism

High levels of circulating calcium are needed for shell formation. Estrogen increases total plasma calcium by increasing the production of blood calcium-binding proteins.[5] During the laying process in psittacine birds, the calcium levels can become extremely high, reaching levels of 30 mg/dl.[82] However, increased blood calcium levels alone are insufficient for shell formation because hens can deplete the entire blood calcium in 8 to 18 minutes during the time the egg is in the uterus. Increased intestinal absorption and bone mobilization of calcium are needed to constantly replenish blood calcium. Laying hens will preferentially consume calcium-rich diets. This has also been observed in reproductively active psittacine hens. For psittacine birds, it is recommended that laying hens be offered at least 0.3% calcium (1:1 or 2:1 ratio with phosphorous) in their diet to prevent bone mobilization, but no more than 1% to ensure that egg shells are not excessively thick.[142] For continuous layers, higher levels of dietary calcium (up to 3.34% in turkey hens) are necessary for maximum egg production and hatchability.[109] In domestic fowl, most of the egg shell calcium is obtained from the intestine, and bone calcium is used only when blood calcium levels are low.

Bone calcium does serve as a source of calcium for shell development in hens that lay eggs during morning hours when food intake and subsequent intestinal absorption of calcium is decreased.[79] Calcification of the medullary spaces of the long bones, particularly the femur and tibia, occurs in female birds approximately ten days before egg formation (see Figure 15.16). In budgerigars, the primary sites of medullary calcification are the humerus and femur.[149] If insufficient calcium is consumed, cortical bone will be mobilized. At some point in the mobilization process, calcium deficiency causes a reduction in FSH secretion that stops the laying process. High-fat, low-calcium diets exacerbate a calcium deficiency by decreasing calcium absorption from the intestines. Increased activity and concentrations of renal and circulating Vitamin D_3 occur prior to and during egg laying. In budgerigars, it is theorized that polyostotic hyperostosis in non-laying females results from aberrant estrogen metabolism. Affected budgerigar hens have been shown to have normal ovaries and no evidence of hormone-secreting tumors or other endocrine diseases. The liver is responsible for inactivating estrogens, and it has been suggested that impaired liver function may be responsible for this disease.

Other Metabolic Changes

Hematogenic changes associated with egg laying include a slight increase in white blood cell count, packed cell volume, total serum solids and total protein. Total serum solids and total protein are increased because of a need for protein for calcium transport as well as from the estrogen-controlled liver synthesis of lipid and proteins produced during yolk formation (Table 29.1). Alkaline phosphatase levels may also increase due to estrogen stimulation. This has been shown to occur in budgerigars with estrogen implants.[149] Alkaline phosphatase levels were also shown to be elevated in egg-laying cockatiels and pigeons.[57]

TABLE 29.1 Typical Hemogram of Normal Laying Cockatoo Hen

	Values	Change from Non-laying Status
WBC	15-18 x 10^3/mm^3	Increased
PCV	48-55%	High range of normal
Total protein	4 - 6.5 gm/dl	Increased
Calcium	15-20 mg/dl	Increased
AP	>500	Increased

Egg Structure and Physiology

The avian egg is made of concentric layers of tissue that originate from different portions of the oviduct (Figure 29.2). Each component of the egg is responsi-

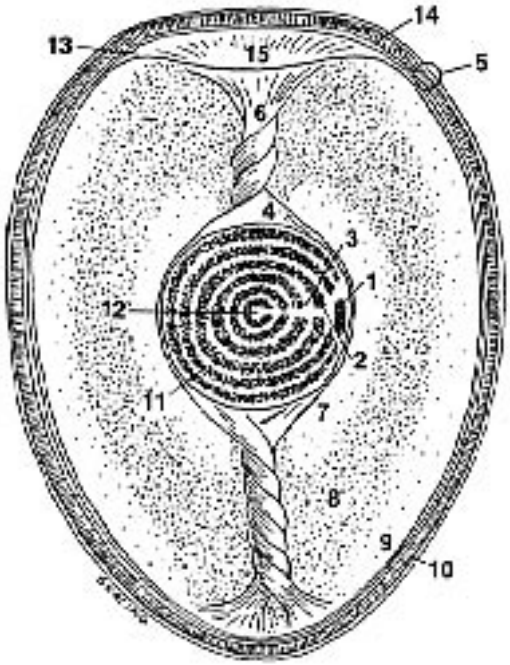

FIG 29.2 Components of an egg: 1) blastoderm before fertilization, 2) disc of latebra 3) neck of latebra 4) chalaziferous layer 5) shell (testa) 6) chalazae 7) internal layer of thin albumen 8) thick outer albumen 9) external layer of thin albumen 10) cuticle 11) vitellus aureus 12) center of latebra 13) internal shell membrane 14) outer shell membrane 15) air space (modified from Stoodley).[165]

ble for various physiologic functions needed to support the growing embryo (Figure 29.3) (Table 29.2).[79,86] Understanding normal egg anatomy allows the clinician to recognize abnormalities and instigate appropriate therapeutic or preventive measures to resolve embryonic death problems and female reproductive disorders.

The germinal disc is a small, circular, opaque white spot on the surface of the yolk that contains cytoplasm and the oocyte (Color 29.1). The yolk is classified as either "white" or "yellow" and is layered in strata that are visible when stained with potassium dichromate.[49] The yolk is 50% solids, 99% of which are proteins.[86] Maternal antibodies (IgG) are present in the yolk. These antibodies are absorbed by the chick and provide waning passive immunity until it becomes immunocompetent. The concentration and longevity of specific immunoglobulins in psittacine egg yolk are not known. It has been demonstrated that vaccinated hens pass anti-PBFD virus antibodies to their chicks and that these antibodies wane to undetectable levels between 30 and 45 days of age.[134]

The yolk is surrounded by layers of membranes, collectively called the vitelline membrane. The normal yolk is various shades of yellow (depending on the diet and species of hen), firm, intact and separate from the albumen. The albumen is made of the chalaziferous layer, chalazae, and inner, middle and outer layers. The outer clear and inner layers are thinner than the middle layer, which can be macroscopically distinguished (see Figure 29.2). Although less viscous than the yolk, the middle layer of albumen is quite viscous, which makes it appear as a whitish-clear gel. It remains adhered to the yolk through the chalazae and albumen ligaments. At the blunt end of the egg the two shell membranes separate from each other, forming the air cell. The outer layer is adhered to the testa layer of the shell and the inner layer is attached to the dense portion of the albumen. The outermost surface of the egg is covered by a thin, sometimes waxy, cuticle. Microscopic pores in the egg shell allow for passive diffusion of oxygen,

TABLE 29.2 Embryonic Structures and Their Physiologic Function

Structure	Function
Shell	Physical protection, protects embryo from microorganisms, transpiration, regulate evaporation, source of calcium carbonate for bone formation.
Shell membrane (outer and inner)	Transpiration, protects embryo from microorganisms.
Air cell (between two shell membranes)	Transpiration.
Albumen	Nutrition, protects embryo from microorganisms
Chalazae (thick strands of albumen)	Stabilization and centralization of the yolk.
Yolk	Nutrition, maternal antibodies.
Vitelline membrane (yolk sac membrane)	Protects embryo from microorganisms.
Germinal disc	Infertile - blastodisc; Fertile - blastoderm.
Positive development	No embryo, only extra-embryonic structures.
Blastoderm without embryo	No embryo, only extra-embryonic structures, including blood islets and some vessels.
Chorioallantoic membrane	Transpiration, metabolism, waste collection, calcium transfer (shell to embryo).
Amnion	Structure around embryo, provides protective fluid environment, muscles gently rock embryo for five to twelve days of incubation, protein source (albumen drains into amnion, which embryo drinks late in incubation).
Cuticle	Regulates evaporation, protects embryo from microorganisms.

carbon dioxide and water during embryo development (see Color 48).

The shell thickness, size, shape and pigmentation vary depending on the species of bird, and a certain amount of individual variation occurs intraspecies (Figure 29.4). Hens that produce precocial young generally have larger, thicker-shelled eggs. Larger eggs usually have thicker shells. This can be clearly noted with conure eggs that have thinner shells than their somewhat close relatives, the macaws. Eggs may be conical, spherical, oval or cylindrical in shape. Cockatoos have more spherical-shaped eggs than macaws. In most species, the egg has a blunt end, which contains the air cell and is the point of exit for the emerging chick (Color 29.18). Other eggs, like those of ratites, are almost spherical. Psittacine eggs are generally smooth, but depending on the species, may be glossy (such as in macaws), greasy, chalky, powdery, ridged or pitted.

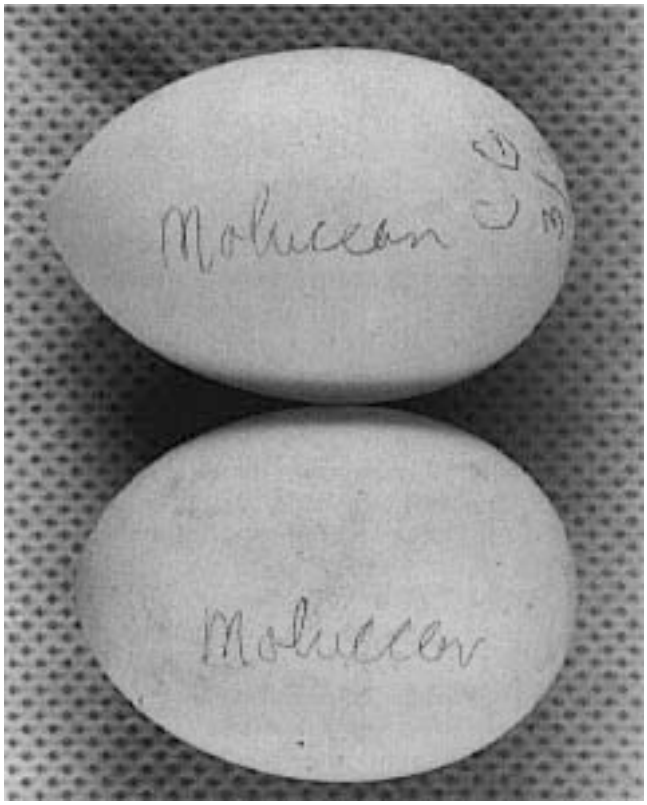

FIG 29.4 Egg morphology and size vary dramatically among species and individuals in the same species. Normal eggs from two different Moluccan Cockatoo hens illustrate the difference in egg shape. The egg is normally passed with the pointed end caudally. A soft pencil is nontoxic and can be used to mark eggs for record-keeping purposes.

Most avian embryology has been investigated in domestic species, but embryogenesis is thought to be similar for all species (Color 29.1 to 29.13).[12,55]

Male Reproductive Anatomy

The paired testes are located within the body cavity ventral to and near the cranial border of the kidney and the abdominal air sac (see Anatomy Overlay). The testis is attached to the body wall by the mesorchium and is encapsulated by two fibrous coats. Occasionally, one testis may be larger but both should be functional in mature birds.[86] The author has noted testes of unequal size on numerous occasions in young and mature psittacines, the importance of which is unknown. The bilateral testes are not al-

ways symmetrically located within the body cavity. One can be located more caudally than the other. Dimensions, color and shape can vary, not only by age but also among species. During the resting stage, most testes are small, yellow-white and bean-shaped. In young birds, the testes can appear flattened and pointed when compared to the rounded shape of the mature testicle. Melanistic testes, like melanistic ovaries, can occur in some species of Psittaciformes (Golden Conure, Blue and Gold Macaw, some cockatoos), Passeriformes and Piciformes (Keel-billed Toucans). Under hormonal control the testes can increase in size by 300- to 500-fold (Figure 29.5).[168] The increase in size appears to be proportionally greater in finches and Columbiformes than in Psittaciformes (Harrison GJ, unpublished). Vascular supply increases during reproduction, resulting in a more prominent pattern of blood vessels on the testicular serosal surface. During the breeding season, yellowish testes may turn white, while melanistic testes may change from black-grey to grey-white.[86] The testes normally atrophy during periods of sexual inactivity; however, the testes never become as small as they were in the prenuptial stage.

Convoluted seminiferous tubules comprised of germ (spermatogonia) and Sertoli cells make up the bulk of the testes and are responsible for spermatogenesis. Leydig cells, also called interstitial cells, produce male androgens and occupy the interstitial spaces between the tubules. Melanistic cells responsible for the color of the testicles are found in the same location. Mature spermatozoa exit via straight tubules into the rete testis, which connects the testis to the cranial aspect of the epididymis. The rete testis is not present in all birds. The epididymis, considered vestigial in birds, lies along the dorsomedial aspect of the testes and is concealed from view during laparoscopic examination, even during the breeding season when it enlarges considerably. In some species of birds, the epididymis is connected throughout its length by tubules to the rete testis.[86] Spermatozoa exit the epididymis and enter the ductus deferens, which forms a zigzag tubule running parallel with the ureter just medial to the kidneys. The ductus deferens is under hormonal control and is more convoluted during the breeding season. In the nonbreeding season, it blends indistinguishably with the ureter and kidneys. The ductus deferens penetrates the dorsal wall of the urodeum, which functions as a receptacle for sperm. The last two to three millimeters of the ductus deferens project into the urodeum forming a papilla. In passerine birds and budgerigars, the caudal end of the ductus deferens forms the seminal glomus, which enlarges during the breeding season to form a prominent projection in the cloacal wall for the storage of sperm.[85] This prominence allows passerines to be easily sexed during the breeding season. Birds that do not have this structure have little sperm storage capacity. Proctodeal glands develop to varying degrees in birds and undergo hypertrophy in response to increases in steroid sex hormones.[117]

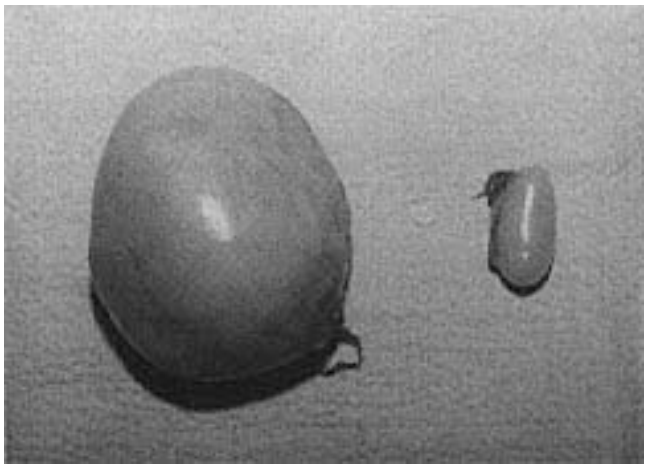

FIG 29.5 The testicle of a normal bird can increase substantially in size during the breeding season. In this Eclectus Parrot, the right testicle was of normal size and enlargement of the left testicle was caused by a seminoma (courtesy of Kim Joyner).

The ejaculatory papillae (terminal projectory papillae of the ductus deferens), paracloacal vascular bodies, cloacal folds and the phallus are involved with male copulation and are variably developed in avian species. The cloacal lymph folds and paracloacal vascular bodies contribute to the lymphatic erection of either cloacal or phallic tissue, and release a lymph-like transparent transudate when engorged.[80] Although not all avian species have been adequately studied, it is known that ratites, tinamous, Anseriformes, some members of the family Cracidae and one Passeriforme, the Black Buffalo Weaver, have phalli that are intromittent (inserted into the female).[11,86] Other species have phalli that may become engorged during copulation, but semen transfer occurs by direct cloaca-to-cloaca contact without intromission.

The phallus, if present, is located ventrally in the proctodeum. Dysfunction or disease of the phallus can cause reproductive failure. Psittacine birds do not have a phallus, and copulation is accomplished by an eversion of the cloacal wall, which contains the slightly raised papilla that transfers semen to the everted orifice of the oviduct.[106] Determination of

gender can be accomplished by identifying the seminal papilla in the male of many cockatoos but not in Amazon parrots and macaws (Harrison GJ, unpublished).

Semen

In domestic fowl, spermatozoa undergo maturation and become fully fertile in the ductus deferens. The transient time required for sperm to pass from the testes to the distal ductus deferens is estimated to be from one to four days. Seminal plasma that is formed in the efferent and connecting ductules of the epididymis and ductus deferens accompanies the spermatozoa. Seminal plasma composition can vary among species but is similar in concentration and constituents in the budgerigar and domestic fowl.[145] In most birds, semen is stored in the ductus deferens. In Passeriformes, semen is also stored in the seminal glomus, which is the enlarged terminus of the ductus deferens. A lymph-like fluid, called "transparent fluid," originates in the proctodeum and mixes with the semen during ejaculation. The function of this fluid is uncertain, but it does contain blood clotting agents that are deleterious to the spermatozoa.[86]

In Passeriformes, spermatozoa are of the complex type, which can be differentiated from the simple type of sperm found in other birds by their predominantly spiral structure.

Semen can be collected from birds for artificial insemination, to evaluate its reproductive potential, to detect disease and to distinguish species or subspecies.[154] The consistency of normal semen ranges from that of water to that of heavy cream. Watery semen may indicate high volumes of transparent fluid in the sample. Normal semen is light white to milky, and brown, green or red discoloration may be due to fecal contamination or cloacal hemorrhage from over-exuberant semen collection. Production of fertile eggs is the best indicator of sperm viability, but determining sperm count and motility can be used to estimate function (Table 29.3).[45] One million sperm are required for optimal fertility in the domestic fowl.

Sperm concentration can be determined by mounting semen on a hanging drop slide, use of a spermatocrit or direct counting in a hemocytometer. In those species with higher sperm concentrations, dilution with artificial insemination semen extender may be necessary prior to evaluation. Motility is estimated as the percentage of spermatozoa moving in a forward motion as seen under high magnification. Live-dead counts using an eosin-nigrosin stain make it possible to evaluate the concentration of live sperm. Live-dead counts, computer-assisted measurement of spermatozoal swimming speed and metabolic rates of semen can also be used to determine semen quality.

TABLE 29.3 Volume and Concentration of Ejaculates from Selected Birds [21,69,80,106,147]

Bird	Sperm Concentration	Ejaculate Volume
Chicken	1.7-3.5 billion/ml	500-1000 μl
Budgerigar	9.5-11.3 billion/ml	3.5-13 μl
Pheasant	10 x 10^9/μl	50-250 μl
Large Psittaciformes	9-10 million/ml	50-100 μl
Emu	4.4 billion/ml	1200 μl

Male Hormonal and Physiologic Factors

In the male, FSH and LH exert gonadotrophic properties similar to those described in the hen. FSH initiates the growth of seminiferous tubules and results in increased spermatogenesis. LH promotes development of the testosterone-producing cells of Leydig. Testicular growth is approximately logarithmic until half of the ultimate size is attained.[42] Higher levels of testosterone are then responsible for male sexual behavior. Testosterone increases spermatogenesis and growth of accessory reproductive organs, such as the epididymis and cloacal gland. Testosterone also causes manifestation of secondary sexual characteristics such as comb growth, plumage and

FIG 29.6 Male cockatoos will frequently attack and sometimes kill their hens. This behavior can occur in pairs that have been stable and producing young for years. The precise cause of these attacks is unknown, but they are most common in the early part of the breeding season. Males generally become reproductively active earlier than the females, and a hen's failure to respond to a soliciting male may facilitate an attack. In this cockatoo hen, most of the beak and a part of the skull had been removed by the male.

bill color, structure of feathers, vocalizations and reproductive behavior. Specific reproductive behavior affected by testosterone, and probably mediated by other hormones, includes territorial aggression, courtship, copulation, nest building, incubation and care of the young. Testosterone levels are highest in many species at the time of establishment and defense of territory, courtship and nesting activity.[42] Substantial field observations suggest that the testes become functional earlier than the ovaries, and that coordination of the reproductive effort is mediated by environmental and photoperiodic stimulation in the female.[42] As in the hen, prolactin, progesterone, estrogen and androgens are all involved with incubation and brood care. This complex control of the reproduction cycle may account for breeding failures and mate aggression in captive Psittaciformes (Figure 29.6).

Female Reproductive Disorders

Egg Binding and Dystocia

Two of the most common clinically recognized reproductive disorders seen in avian species are egg binding and dystocia. Egg binding is defined as the failure of an egg to pass through the oviduct at a normal rate. Most companion bird species lay eggs at intervals greater than 24 hours, and individuals within a species may vary by more than one day from the normal oviposition rate.[4] Variability in egg transit times makes it difficult to determine when a problem is occurring.

Dystocia defines a condition in which the developing egg is in the caudal oviduct and is either obstructing the cloaca or has caused oviduct tissue to prolapse through the oviduct-cloacal opening. Egg movement through the oviduct can stop at various locations. The most common anatomic areas for problems to occur are the caudal uterus, vagina and vaginal-cloacal junction.

The pathogenesis of egg binding in a particular case can be multifactorial. The pubic bones are not fused in birds, and pelvic deformities seldom play a role in dystocia. Common causes of dystocias are oviduct muscle dysfunction (calcium metabolic disease, selenium and vitamin E deficiencies), malformed eggs, excessive egg production, previous oviduct damage or infection, nutritional insufficiencies, obesity, lack of exercise, heredity, senility and concurrent stress such as environmental temperature changes or systemic disease.[62,66,140,160] Dystocia can also result from breeding birds out of season, egg production in virginal hens and a persistent cystic right oviduct (Color 29.20).[72]

Abnormally prolonged presence of an egg in the oviduct causes a multitude of complications in the hen (Figure 29.7). The severity of these complications depends on the species, the bird's previous health, the cause of egg binding, the egg's location in the oviduct and the time elapsed since egg development began. An egg lodged in the pelvic canal may compress the pelvic vessels and kidneys, causing circulatory disorders and shock.[140] An impacted egg may cause metabolic disturbances by interfering with normal defecation and micturition, inducing ileus and renal dysfunction.[66] Pressure necrosis may occur to all three layers of the oviduct wall and lead to rupture.

Clinical Signs

Budgerigars, canaries, finches, cockatiels and lovebirds most frequently have problems with dystocia.[141] This is probably because the presentation of a palpable egg for more than a few hours in small birds is generally more serious than it is in larger birds. The patient's clinical signs will depend on the severity of the complications. Generally, the hen appears depressed, has an abnormally wide stance, is reluctant to fly or perch and may show persistent wagging of the tail and straining movements of the abdomen. Canaries often exhibit drooped wings. Rear limb paresis or paralysis may occur. Egg-related peritonitis, septicemia, leg injuries and abdominal neoplasia show similar clinical signs (Color 29.27). Any depression can lead to anorexia, which further compromises the bird's condition.

Hens with dystocia frequently present with depression and secondary complications that require emergency therapy. A complete history including information of past breeding activity and the diet "consumed" will often suggest a pathogenesis. A thorough but rapid physical examination can also establish contributing factors such as obesity, concurrent disease or a malformed egg. Dystocias are most critical in passerines and other small birds, many of which can survive only a few hours without aggressive therapy.[66] Initially the therapeutic plan is to stabilize the patient (see Chapter 15) with an emphasis being placed on correcting the most likely etiology for the dystocia.

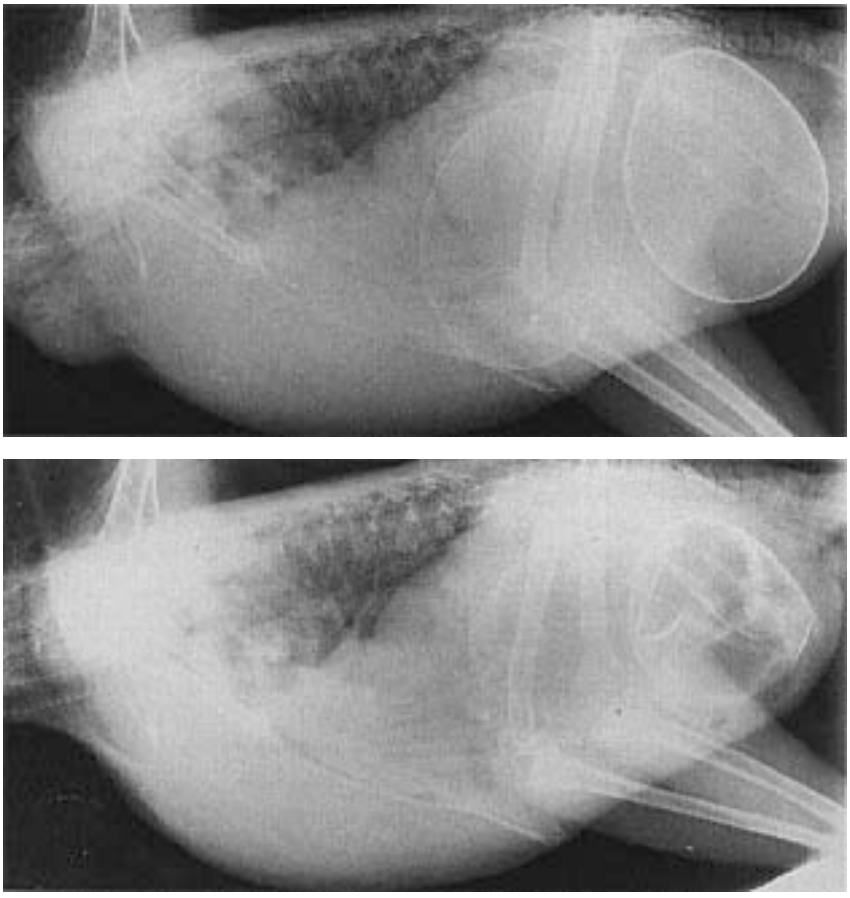

FIG 29.7 An Amazon parrot hen was presented for depression, a hunched stance and tenesmus. A firm palpable mass was present in the caudal abdomen. Radiographs revealed two calcified eggs. The caudal egg could not be located through the cloaca. The contents of the eggs were removed by ovocentesis, and the eggs were collapsed. Radiographic appearance of the collapsed eggs. The hen's attitude improved immediately and she began eating normally. The fragmented egg shells were passed two days after they were collapsed.

The severity of the dystocia, and speed of correction that will be required, can be partially estimated by the level of depression. Careful abdominal palpation and a cloacal examination are required to determine the egg's position in the reproductive tract. In smaller birds the displaced ventriculus may make palpation of an egg difficult. Soft-shelled eggs, shell-less eggs or eggs located cranial to the uterus can also be difficult to palpate. Suspected egg masses must be differentiated from palpable hernias, lipomas or ascites. Radiographs are a useful confirmatory tool but may not delineate a shell-less egg. Radiographically identifying more than one egg in various stages of development is common.

Therapy

The most important consideration in initiating therapy for dystocia is to establish a physiologic normal state. Attempts to remove the egg are secondary to stabilizing a patient in shock. In minimally depressed patients with few complications, the egg will usually pass if the hen is provided with supplemental heat, injectable calcium, selenium, vitamin E, vitamin D_3 and easy access to food and water.[56] Others require subcutaneous or IV fluids, rapidly acting steroids to combat shock, antibiotics to treat sepsis or peritonitis and injectable vitamins and minerals to address further nutritional deficiencies. Prolapsed oviductal or cloacal tissues should be moistened and cleaned with warm, sterile saline washes and water-based antiseptic ointments, such as chlorhexidine. Lubricating tissues surrounding the egg or the cloaca or vagina itself may be of some help to egg expulsion.

The bird should be placed in an incubator at 85 to 95°F with an inflow of heated, moisturized air. If the egg is not expelled within a few hours, then a prostglandin injectable product (dinoprost tromethamine) can be administered IM or applied topically to the oviductal tissue. This compound appears to be superior to oxytocin because it has the combined effect of inducing uterine contraction while relaxing the uterovaginal sphincter (see Chapter 18).[73] Prostaglandin or oxytocin should be used only in cases where the uterus is thought to be intact and no adhesions to the oviduct are suspected. A hen receiving these agents must be able to withstand the increased contractions of the oviduct and abdomen that occur following the administration of oxytocin. Clinical signs

of oxytocin response include tail pumping, panting, abdominal contractions and elimination of the egg. Increasing and repeated doses of oxytocin can be given if initial injections have no effect. Experimental use of prostaglandins and arginine vasotocin in domestic species has shown that injections of either of these drugs may result in oviposition.[144,157] Arginine vasotocin likely causes the release of prostaglandins from the uterus. Clinical use of vasotocin in reptiles suggests that this drug may be of some value in birds (0.01 to 1.0 mg/kg BW) (Lloyd M, personal communication). It has been shown that uteri are more sensitive to vasotocin than to oxytocin.[97] Complications of oxytocin or vasotocin use include oviduct rupture.

If medical therapies fail to elicit oviposition, then more aggressive approaches that require manual manipulation of the patient may be necessary. Massaging the abdomen or cervix may help stimulate egg passage or relax the cervix so that the egg can be passed. The egg itself can be digitally manipulated caudally for expulsion (Color 29.30). The use of warmed water-soluble solutions or ointments (saline with methyl cellulose) to lubricate the urodeum or vagina is equivocal. Gentle, persistent, caudally directed pressure on the egg may supplement weakened muscular contractions and loosen any recently formed adhesions. Only gentle traction should be used to prevent rupture of the oviduct. As long as the bird remains stable, repeated attempts at digital egg removal should continue. The cervix can be dilated by using a speculum to insert a blunt probe that is advanced in gentle, twirling motions (Figure 29.8). Eggs may be fertile and viable and should be incubated following expulsion. Digital manipulation and contracting therapy should not be used if one suspects ectopic eggs, uterine torsion, uterine rupture, or uterine constrictions due to adhesions (mucosal adhesions to the egg or the opposite uterine wall or serosal adhesions to other abdominal structures).

Ovocentesis

If the bird's condition is deteriorating or if an inappropriate period of time has passed since the dystocia was first noted, then more aggressive therapy such as ovocentesis must be considered. Ovocentesis is performed by aspirating the contents of the egg with a large needle (18 ga).[141] Preferably the egg is manipulated with the use of a speculum so that it is observable and tapped through the cloaca.[2] If this is not possible, the egg is brought in juxtaposition to the abdominal wall so that other organs are not damaged during a transabdominal aspiration procedure. Following aspiration of the egg contents, the egg can be gently collapsed (Figure 29.9). The risk of tearing the oviduct and producing peritonitis does exist but appears to be minor (see Chapter 48). The shell fragments and remaining contents of the egg should pass within several days (see Figure 29.7). Fragments that are visible through the cloaca can be gently removed. Some clinicians advocate flushing the uterus post-oviposition with an iodine, chlorhexidine or saline solution to help remove egg fragments and to decrease the incidence of metritis.[56] A Brunswick feeding catheter (3 to 5 Fr) can be placed through the cervix for this procedure (Figure 29.10). A course of broad-spectrum antibiotics, chosen based on the results of a Gram's stain collected from the uterus and confirmed as the correct choice by culture and sensitivity, is also recommended.

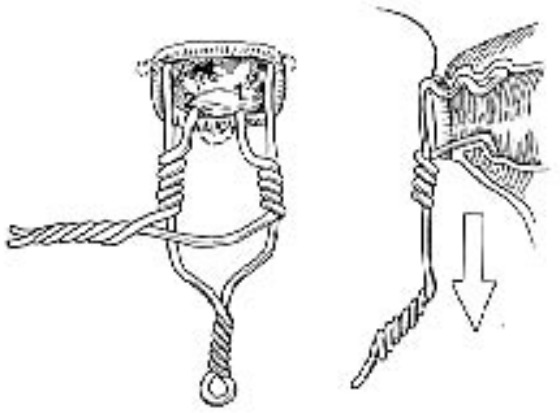

FIG 29.8 A speculum can be used to facilitate evaluation of the cloaca and removal of eggs. 1) opening of the ureter and 2) vaginal opening.

If the egg is lodged in the caudal oviduct or cloaca and the survivability of the egg is critical, then an episiotomy may be beneficial in delivering the egg.[141] A laparotomy may be necessary to remove egg material or to perform a hysterectomy in cases where the uterus is ruptured or severe adhesions exist. Soft-shelled eggs located cranial to the uterus or ectopic eggs also require surgery.[104,140]

Many hens with dystocia will attempt to lay another egg. Administration of medroxyprogesterone will stop ovulation, but there are side effects and its use is controversial. Following medroxyprogesterone administration, eggs already present in the proximal oviduct may continue to descend, complicating the

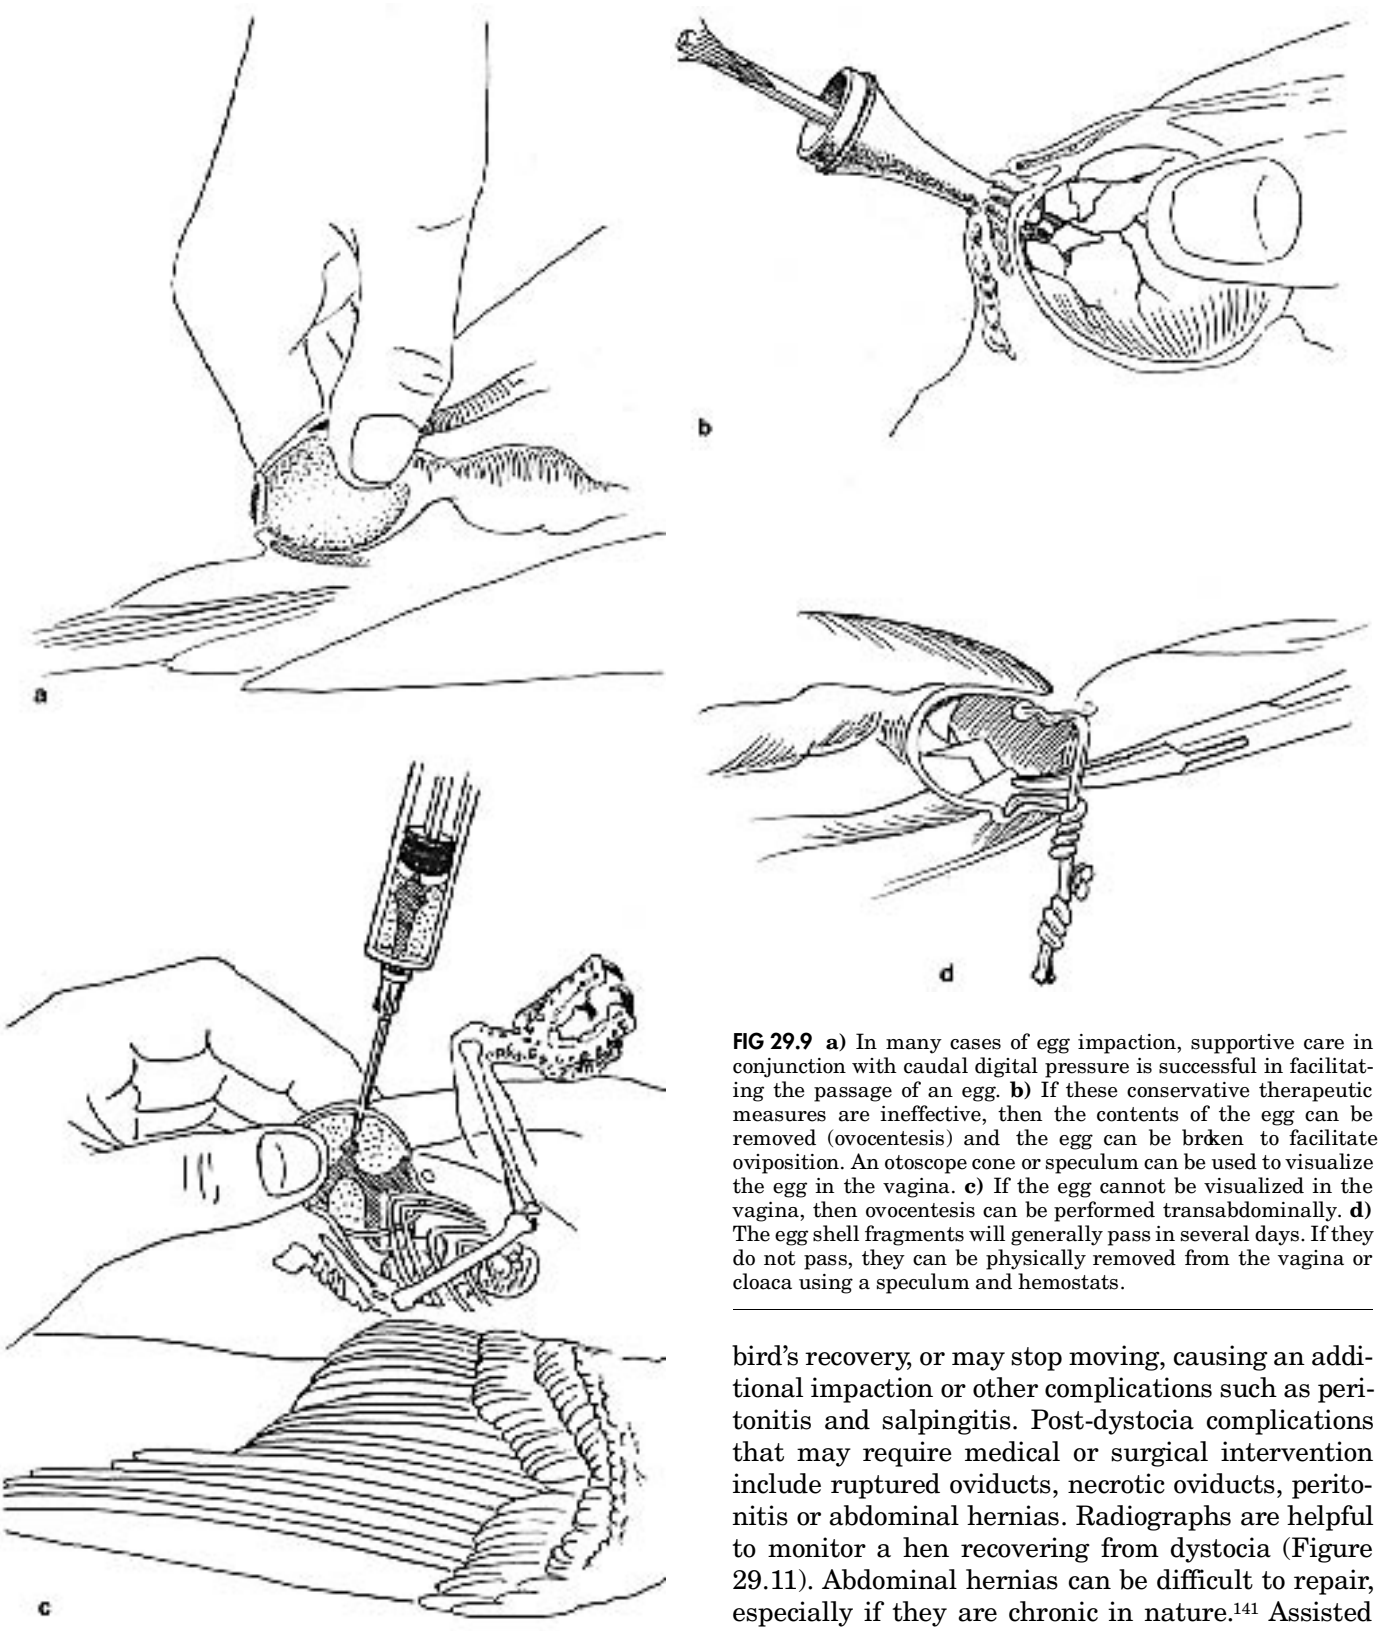

FIG 29.9 **a)** In many cases of egg impaction, supportive care in conjunction with caudal digital pressure is successful in facilitating the passage of an egg. **b)** If these conservative therapeutic measures are ineffective, then the contents of the egg can be removed (ovocentesis) and the egg can be broken to facilitate oviposition. An otoscope cone or speculum can be used to visualize the egg in the vagina. **c)** If the egg cannot be visualized in the vagina, then ovocentesis can be performed transabdominally. **d)** The egg shell fragments will generally pass in several days. If they do not pass, they can be physically removed from the vagina or cloaca using a speculum and hemostats.

bird's recovery, or may stop moving, causing an additional impaction or other complications such as peritonitis and salpingitis. Post-dystocia complications that may require medical or surgical intervention include ruptured oviducts, necrotic oviducts, peritonitis or abdominal hernias. Radiographs are helpful to monitor a hen recovering from dystocia (Figure 29.11). Abdominal hernias can be difficult to repair, especially if they are chronic in nature.[141] Assisted oviposition may cause a flaccid cervix, allowing reflux of feces and urine into the uterus. Daily flushing and Gram's staining of the uterus to monitor pro-

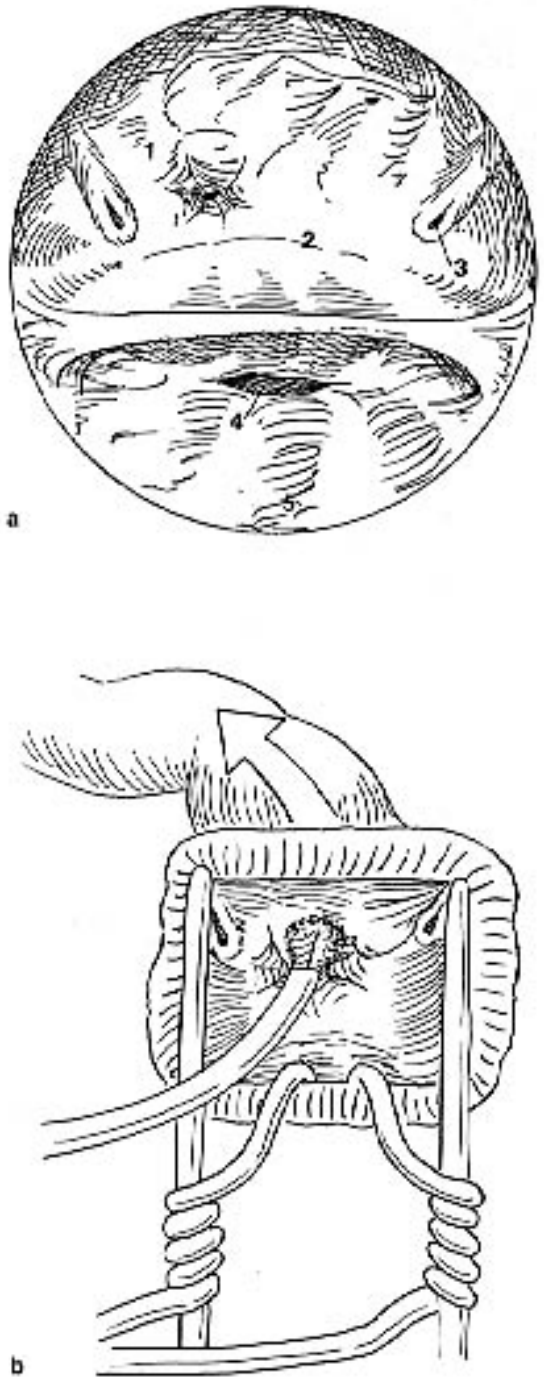

FIG 29.10 **a)** Caudal to cranial view of the normal cloacal anatomy of a hen: 1) vaginal opening, 2) urodeum, 3) opening of ureter, 4) rectal opening and 5) coprodeum. **b)** Post-dystocia flushing of the uterus with chlorhexidine or sterile saline may reduce the occurrence of salpingitis.

gress following the removal of an egg appears to reduce the occurrence of metritis (Harrison GJ, unpublished).

Prolapsed Oviduct and Cloaca

Prolapse of the oviduct may occur secondary to normal physiologic hyperplasia and egg laying or as a sequela to dystocia (particularly in canaries and budgerigars) (Color 29.31 and 29.32).[6] Excessive contraction of the abdominal muscles, perhaps exacerbated by poor physical condition and malnutrition, may cause these prolapses.[14] Usually the uterus protrudes through the cloaca, often together with a partial prolapse of the vagina and cloaca. Distal portions of the oviduct may also prolapse, and frequently an egg is present (Color 29.30). Oviduct prolapses have been associated with deformed, soft-shelled and shell-less eggs.[84] Timely, aggressive therapy is needed to prevent devitalization of uterine tissues and secondary infections. All exposed tissue must be kept as moist as possible and cleaned thoroughly with sterile saline solution. Topical steroid preparations containing antibiotics or dimethyl sulfoxide gel can be used to reduce swelling so that prolapsed tissues can be replaced. If no egg is present, tissue replacement is accomplished by gently guiding the tissues through the cloaca with pressure from a lubricated swab or thermometer. Repeated replacement of tissues may be required, as prolapses often recur. Stay sutures placed in the cloaca or percutaneous retention sutures may prevent further prolapsing while uterine tissues regress in size, abdominal tissues regain structural integrity and the hen has a chance to regain normal muscle tone and strength.[104,139] The prognosis for birds with uterine prolapses is good as long as they are treated immediately.[66]

If an egg is present in the prolapsed tissue, it must be removed before the tissue is replaced in the abdomen (Color 29.31). Digital manipulation or implosion of the egg as discussed under dystocia may be effective. Chronically displaced tissue that contains eggs or egg material may require surgical debridement due to adhesions and shell abnormalities. In severe cases of uterine damage and necrosis, a partial or complete hysterectomy may be necessary, but is best delayed until the bird's condition is stable (see Chapter 41).[141]

Salpingitis and Metritis

Salpingitis may occur from air sacculitis, pneumonia, liver disease or retrograde infections of the lower

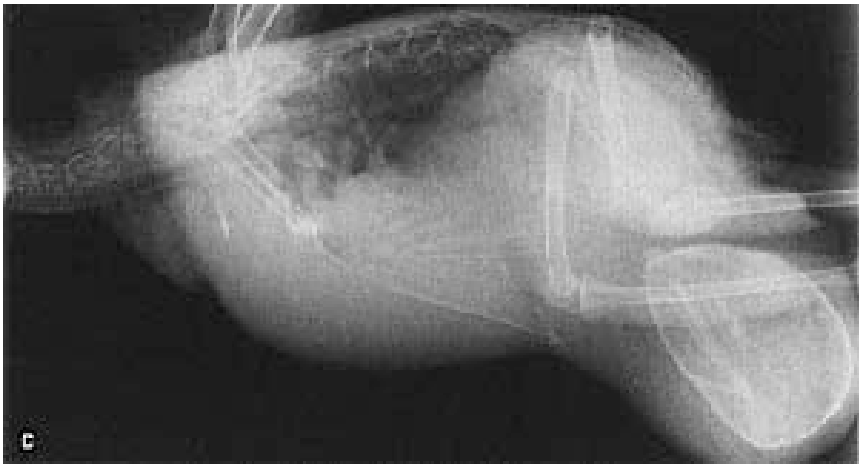

FIG 29.11 **a)** An adult Amazon parrot hen was presented for evaluation of a ventral abdominal mass. **b,c)** Radiographs indicated a herniated egg and a second abnormally formed egg in the dorsal abdomen. Surgical correction of the hernia and a salpingohysterectomy were recommended but refused. **d)** Additional radiographs taken eight weeks after the initial presentation indicated that the herniated egg was being resorbed, and that the second egg was increasing in density.

Egg Incubation

From the poster of Cockatiel Embryonic Development, reprinted with permission. Posters are available from the University of California, ANR Publications, 6701 San Pablo Avenue, Oakland, CA 94608-1239.

Color 29.1

a) The unincubated fertile egg has a distinct ring consisting of a white peripheral region (area opaca) surrounding a clear central region (area pellucida). **b)** The same area in the unincubated infertile egg is small in size, lacks cellular organization and looks like a small piece of cotton on the surface of the yolk. The diameter of the fertile blastodisc is four to five times that of the same area in an infertile egg.

Color 29.2

Unincubated egg with a large blood spot indicative of bleeding from the follicle during ovulation.

Color 29.3

Incubated fertile egg showing two common types of first-day failures. Neither shows development of embryonic structures. **a)** Eggs with positive development fail before blood formation, while **b)** eggs with blastoderm without embryo continue cell division until blood-forming stages. Blastoderms without embryos can be seen during candling, when a blood ring is usually present. Positive developments and blastoderms without embryos may vary in size depending on the length of incubation.

Color 29.4

A profile shot of a yolk 48 hours after the onset of incubation showing a bleb that represents the embryonic area. This bleb can also be seen by candling.

Color 29.5

Cockatiel egg at approximately three days of incubation (embryo stage 17). The heart and major blood vessels of the yolk sac are visible. The embryo has turned to its left side.

Color 29.6

Cockatiel egg at approximately 4.5 to 5 days of incubation (embryo stage 24). The subdivisions of the brain, the developing pigmented eye, increased yolk sac circulation, developing wing, leg buds and the allantois (arrow) are visible.

Color 29.7

Embryo removed from an egg at 4.5 to 5 days of incubation. The divisions of the brain are pronounced. The limb buds and tail fold are prominent.

Color 29.8

Normal cockatiel embryo approximately six days of incubation (embryo stage 28-29). The characteristic cockatiel-shaped head shows prominent mid-brain divisions. There is further development of the eye, including appearance of the choroid fissure (arrow). Outlines of the digits can be seen on the developing wings and legs.

Color 29.9

Normal embryo at approximately 7 to 7.5 days of incubation (stage 31). The egg tooth, beak and scleral papillae of the eye are evident. The limbs are developing and the bones are beginning to calcify. The first feather follicles can be seen.

Color 29.10

Normal cockatiel embryo approximately nine days of incubation (embryo stage 35). A prominent egg tooth and early development of the upper beak are evident. Scleral papillae in the eye form a complete ring. The head shape is square with a less prominent mid-brain. Note the feather formation on the dorsal body surface and calcification in the long bones and toes.

Theriogenology

Color 29.11
Normal embryo at 12 to 13 days of incubation illustrates features unique to cockatiels. The lower beak is shorter than the large square upper beak. Note the serrations on the inner surface of both beaks. The scleral papillae can no longer be seen as the eyelid is now nearly closed. Calcification of the characteristic psittacine toes and growth of sparse feathers are evident.

Color 29.12
Normal cockatiel embryo at approximately 16 to 17 days of incubation (stage 42). The eyelids are closed, the beak is enlarged and the egg tooth and toenails are almost completely formed. The yellow pigmentation of the skin reflects the metabolism of fat. The extremities may appear pinker than illustrated.

Color 29.13
Normal cockatiel chick at hatching (18 days of incubation). The yolk sac is completely resorbed and the umbilicus is sealed. Hatchlings would not be expected to appear as hyperemic as illustrated.

Color 29.14
The appearance of a blood spot in this egg indicates that the egg was fertile. The development of a blood ring is characteristic for early embryonic death (courtesy of Kim Joyner).

Color 29.15
Day ten of incubation in a Black Palm Cockatoo egg. Note the centrally located embryo with the developing blood vessels and the small air cell (arrow) (courtesy of Kim Joyner).

Color 29.16

Color 29.17
Day 12 of incubation in an Eclectus Parrot egg (courtesy of Kim Joyner).

Color 29.18
a) Day 21 of incubation in a Military Macaw egg. Note the development of the air cell (arrow) and the still prominent blood vessels. **b)** Day 26 of incubation in the same egg. The shell is pipped and the blood vessels are collapsing as the bird switches from chorioallantoic to pulmonary respiration (courtesy of Kim Joyner).

uterus, vagina or cloaca. In Passeriformes, salpingitis has been associated with impaction of the oviduct and egg-related peritonitis.[85] Foreign bodies such as wheat grains located in the oviduct can cause metritis and salpingitis.[132] Excessive abdominal fat has been associated with many cases of salpingitis in domestic fowl.[127] The etiologic agent most frequently isolated from birds with salpingitis is *E. coli*.[132] Other bacteria such as *Mycoplasma gallisepticum*, *Salmonella* spp. and *Pasteurella multocida* can affect other organ systems simultaneously with the salpinx. In raptors, *E. coli* and *Streptococcus* spp. have been described as causes of salpingitis.[32] Ascending infections from the cloaca induced by copulation, inappropriate treatment for egg binding or uterine prolapse may induce salpingitis.[66]

While salpingitis is most common in adult hens, it can also occur in young birds.[132] Salpingitis reportedly occurs less frequently than oophoropathies, obstruction of the oviduct and ectopic ovulation in a variety of avian species.[84] Depression, anorexia, weight loss and abdominal enlargement can occur with salpingitis. A discharge from the cloaca may also occur. Acute salpingitis in poultry is characterized by an enlarged, dark red oviduct with involvement of the infundibulum.[155] The lumen may contain cream-colored, slimy fluid or cheesy, yellowish fibrinous exudate. The oviduct may be thin-walled or decreased in length (common with Newcastle disease virus or infectious bronchitis virus).[13,19] Congestion may be the only grossly observable change, although salpingitis may not be recognized macroscopically.[119] Bacteriologic and histologic examinations are necessary to establish a diagnosis.

Cockatiel hens that have a history of egg laying followed by mild depression and weight loss may have a low grade salpingitis or focal egg-related peritonitis (Harrison GJ, unpublished).

Metritis is a localized problem within the uterine portion of the oviduct. It can be a sequela to dystocia, egg binding or chronic oviduct impaction. Bacterial metritis is often secondary to systemic infections.[141] Metritis may affect shell formation or uterine contractility or cause infections in embryos (embryonic death) or neonates (weak chicks). Metritis can also cause egg binding, uterine rupture, peritonitis and septicemia. Coliforms, especially *E. coli*, are frequently implicated. Coliform metritis may be complicated by poor diet, and death rates are highest in hens during the ovulatory and egg-laying period.[62]

In more advanced cases, birds may be depressed and have an enlarged abdomen and a palpable turgid uterus. Radiographs often reveal indistinct abdominal detail with a diffuse increase in soft tissue density. Ultrasound has been used in ostriches.[69] An affected ostrich hen may have a history of erratic production, malformed or odoriferous eggs or a sudden drop in production. An odoriferous cloacal discharge may occur, and the WBC may range from 20,000 to 100,000 mm^3. Metritis and salpingitis are treated aggressively with parenteral antibiotics, supportive care and therapy for shock (see Chapters 15 and 18). In non-responsive cases, a laparotomy may be necessary to remove necrotic tissue, inflammatory exudates or egg material. The oviduct may be flushed directly with lactated Ringer's solution (with or without antibiotics) by placing an IV fluid tube or soft catheter into the vagina.[62] Visualizing placement of the tube can be augmented by use of a cloacal protractor (see Figure 29.10).

Oviduct Impaction

Impaction of the oviduct is often a sequela to salpingitis (most frequently), metritis or egg binding. One study found that impactions were nearly always associated with obvious salpingitis in older birds.[84] Impactions may occur from excess secretion of mucin and albumen associated with cystic hyperplasia or inspissated egg material in the magnum. Soft-shelled, malformed or fully formed eggs can impact in the distal oviduct. Cockatiels, canaries and budgerigars are frequently affected, and the condition has been documented in raptors and an African Grey Parrot.[6,14,35,66,83,85] Clinical changes are not always obvious and may include a cessation of egg production, progressive loss of condition and alternation between constipation and diarrhea. Chronic deterioration is particularly common if concurrent peritonitis or salpingitis is present. The abdomen may be diffusely or unilaterally (usually left side) enlarged, birds may be reluctant to fly or walk and periodic anorexia may occur.[66] Radiology can be helpful in some cases, but many oviduct impactions can be diagnosed only through endoscopy or exploratory laparotomy or at necropsy. Impacted oviducts may contain obvious egg material, gray or yellow purulent material, calcareous deposits or albumen. Diffuse peritonitis with adhesions can also occur with oviduct impactions. Treatment consists of parenteral antibiotics and in most cases, surgery to clean, repair or remove necrotic portions of the oviduct.[3,66]

Oophoritis

The ovary can reflect the general health of a mature hen because many infectious diseases and physiologic abnormalities cause retrogressive changes in this organ.[127] Endoscopic evaluation of the female reproductive tract should include the ovum as well as the ovary. The normal ovary with mature follicles has yellow, turgid ova (Color 29.21). When diseased, the ovum can be wrinkled, black, enlarged, firm or hemorrhagic. In addition, abnormal yolk may appear coagulated or "cooked" and flake off onto the ovary or into the abdominal cavity.[155] Adhesions may exist between follicles and the follicles may be slightly stalked.[159] Pullorum disease of domestic fowl is characterized by discolored, pedunculated and inspissated ova. Other bacteremias may cause congestion, distortion and atresia of the follicles.[132] Peritonitis commonly occurs with oophoritis.

Clinical signs of oophoritis include depression, anorexia, chronic wasting and sudden death. Therapy includes supportive care and parenteral antimicrobial agents as dictated by the etiologic agent.

Parasites

Eggs may contain adult ascarids that probably enter the oviduct from the cloaca due to reverse peristalsis.[74] Flukes (*Prosthogonimus ovatus* and related trematodes) inhabit the oviduct of Anseriformes and Galliformes. Heavy infections may cause soft-shelled or shell-less eggs, resulting in salpingitis.[87] Adult flukes less than 1 cm long may be passed in the eggs. Prevention involves the control of aquatic snails and dragonflies that serve as intermediate hosts.

Cloacal Problems

Cloacitis, cloacal strictures, cloacal liths and chronic prolapse of the cloaca can interfere with egg laying and copulation (Figure 29.12). These conditions may in turn result from traumatic egg laying. The cloaca may become chronically impacted with an egg, resulting in severe cloacitis and abdominal adhesions.[84] Feathers, fat and abdominal lipomas may occlude the vent, inhibiting reproductive ability.[139] Both medical and surgical approaches are helpful in treating cloacal problems (see Chapter 19). It is interesting to note that the cloaca prolapses normally in the Vasa Parrot during the breeding season.

In some cases, cloacal papillomas may interfere with copulation and semen transport (see Color 19). Painful lesions in the cloaca may also discourage individuals from mating; however, healthy chicks can be produced by breeding pairs of psittacine birds where one or both adults have mild to moderate cloacal papillomatosis.[107] The etiology of these lesions is unknown and it is recommended to exclude birds with this condition from a breeding aviary. Affected birds in a collection should be isolated from unaffected birds. Affected parents may or may not produce affected offspring, but regardless, chicks from affected parents should be hand-raised in isolation. Results from various treatment regimes for cloacal papillomatosis vary.[139,180] A diet low in fat and high in fresh fruit and vegetables with high vitamin A or beta carotene was considered useful in resolving cloacal papillomatosis and cloacal adhesions in one case.[178]

Cystic ova (reported in budgerigars, canaries and pheasants) may be single or multiple and may be noted during laparoscopy in apparently healthy psittacine hens (Color 29.22).[66,84] Ovarian tumors and cystic hyperplasia of the oviduct can occur secondarily.[14,66] The etiology of this condition and its clinical importance are unknown, but a primary endocrine disturbance is suspected because this lesion is frequently associated with hyperostosis.[6] In affected birds, dyspnea, altered movement and diffuse distention (ascites) of the abdomen are common.[132] Although not always palpable, abnormal ova may be firm, soft, fluctuating or pedunculated. Cysts may rupture, so palpation should proceed carefully. Radiographs may show a diffuse soft tissue density near the cranial lobe of the left kidney. Endoscopically, the ovary may be enlarged with many thin-walled cysts full of straw-colored fluid. Respiratory distress may be eliminated by transabdominally aspirating cystic

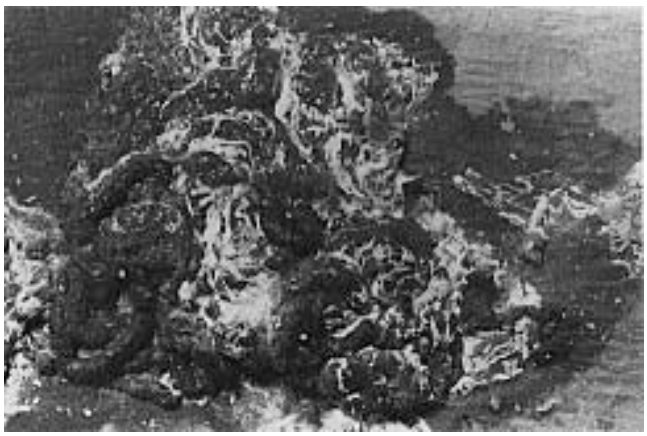

FIG 29.12 Voluminous stools are common in hens that are preparing to lay or that are incubating a clutch of eggs. Similar quantities of feces may be produced by birds with cloacal pathology that interferes with the normal passage of excrement.

fluid with a needle and syringe.[132] Cystic ovaries were successfully treated in two budgerigars with oral testosterone.[14] Removal of the ovaries, although technically difficult, may be the only long-term treatment.

Cystic Hyperplasia of the Oviduct

Most reports of cystic hyperplasia of the oviduct are in budgerigars and domestic fowl.[14] The entire oviduct is dilated with a white or brown mucoid fluid, white or creamy masses or occasionally secondary cysts (Figure 29.13). Cysts also can occur secondary to improper formation of the left oviduct (possible degeneration during embryonic development) or from adhered lips of the infundibulum.[127] The ovary in affected hens may also have cystic changes suggesting an endocrine abnormality. Progressive abdominal distention, ascites and respiratory distress are the most common clinical changes. Palpation and radiographs may reveal the distended oviduct. Abdominal paracentesis may be attempted either for diagnosis or for relief of respiratory distress. Laparotomy will provide a conclusive diagnosis. Hormonal therapy with testosterone may prove effective in resolving the immediate problem, but a hysterectomy may be necessary to prevent future problems.

If a rudimentary right oviduct (or ovary) exists, it may also become cystic (Color 29.20).[86,127] Cysts are of walnut size, contain watery or milky fluid and are situated near the cloaca in domestic fowl.[119] Small cysts may go undetected, but large cysts may place pressure on abdominal organs. Egg binding has occurred secondary to a fully developed right oviduct in a budgerigar.[72] The hen was depressed and thin and had a distended abdomen. Successful bilateral hysterectomies were performed to remove the egg-filled left oviduct and the right oviduct that contained a walnut-sized cyst with gelatinous fluid.

Neoplasia

In one study, neoplasia of the reproductive tract accounted for up to 4.3% of all reproductive disorders.[84] Budgerigars often have neoplasia in the ovary or oviduct.[14] Ovarian neoplasia has been reported less frequently in other Psittaciformes. Ovarian and oviduct neoplasia occur more commonly in gallinaceous birds[155,159] and occasionally in waterfowl and have been reported in a free-ranging Great Tit and a Mauritius Kestrel.[31,120]

Presenting signs are similar to those seen with cystic ovaries or oviduct impactions.[66] In small birds, ascites and peritonitis can produce clinical changes similar to those associated with reproductive neoplasias. Ovarian tumors can be very large and represent up to one-third of the body weight. Egg retention,[141] concurrent cysts,[6] ascites and herniation are common sequelae to reproductive tract neoplasias. Changes in secondary sex characteristics (cere color change in the budgerigar) may also occur. Radiographs can be helpful, although an enlarged ovary or oviduct creates an image similar to that seen when uncalcified eggs are present. A confirmatory diagnosis requires exploratory laparotomy and histopathologic examination of biopsy samples. Lymphomatosis is suggested by cauliflower-like growths of the ovary in domestic fowl.[119] A variety of other tumor types have been reported including adenocarcinomas, leiomyomas, leiomyosarcomas, adenomas[119] and granulosa cell tumors. Excisional surgery is the traditional therapy, although prognosis for long-term recovery is poor.

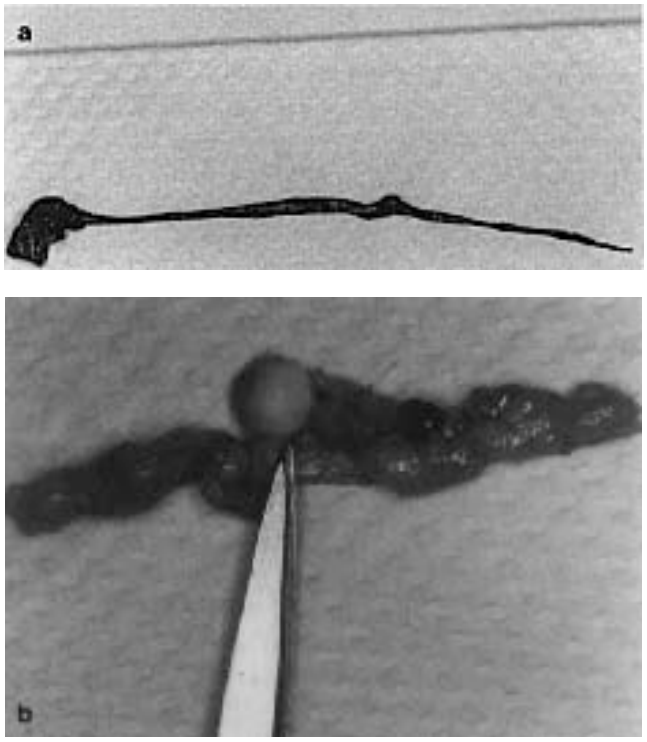

FIG 29.13 **a)** Normal oviduct from a cockatiel (cranial is to the left) **b)** and an oviduct from a hen filled with creamy masses and a mummified egg.

Ectopic Eggs and Non-septic Peritonitis

Egg material may gain access to the abdomen through ectopic ovulation and discontinuous or ruptured oviducts (Color 29.25). Ectopic ovulation occurs when the infundibulum fails to engulf an ovum. It

may be caused by reverse peristalsis of the oviduct, which occurs during normal egg laying, or by trauma to the oviduct that interferes with normal function.[141] Restraining or stressing a hen during egg laying has been incriminated as a cause of ectopic ovulation.[132] Ectopic ovulation is thought to occur frequently, and in one study it was the most common reproductive disorder (28.6%) described in necropsy specimens from nine avian orders.[84] Peritonitis may or may not develop from ectopic ovulation. If present, it can occur in either a septic or non-septic form. Yolk itself only causes a mild histiocytic response and if free of pathogens will gradually be reabsorbed by the peritoneum.[102]

Depending on the location of rents in the oviduct, completely or partially shelled eggs may be deposited in the abdomen. Ruptured oviducts can result from acute and chronic oviduct impaction, including egg binding, cystic hyperplasia, neoplasia and salpingitis. Large, misshapen eggs may cause uterine disintegration and rupture resulting in ectopic eggs.[182]

Ectopic eggs have been reported in Passeriformes and Psittaciformes.[141] Uncomplicated ectopic ovulation may go unnoticed for a protracted period of time. Abdominal distension, a penguin-like stance and weight loss may be the only clinical changes. Free yolk in the abdomen may be absorbed and systemic antibiotics may be needed until the abdomen clears itself of yolk. The condition may recur if predisposing factors are still present. Excessive accumulations of egg material or fully formed eggs should be removed surgically. Damaged oviduct tissue should be repaired or removed.

Cockatiel hens with a history of egg laying frequently present with gradual weight loss, intermittent depression and ascites. If the abdominal fluid is sterile (rules out septic peritonitis), these birds will frequently respond to therapy that includes dexamethasone and medroxyprogesterone acetate.[140] The dose of medroxyprogesterone varies with the size of the bird (150 g [0.05 mg/g]; 150 to 300 g [0.04 mg/g]; 300-700 g [0.03 mg/g]; 700 g [0.025 mg/g]; Umbrella Cockatoo [0.018 mg/g]). Some hens may not cease egg laying activity with the administration of medroxyprogesterone alone and require administration of testosterone as well (Harrison GJ, unpublished). Scientific investigations are necessary to determine the pathogenesis of ascites in these hens and what role the empirically derived therapeutic regime plays in resolving this problem.

Egg-related Septic Peritonitis

Peritonitis is the most frequent cause of death associated with reproductive disorders.[84] It may not be a single disease but part of several syndromes, including ectopic ovulation, ruptured oviducts and salpingitis. It is theorized that it may be the cause instead of the result of a ruptured oviduct.[14] It is uncertain which component of the egg is most important in inducing peritonitis but it is likely to be the yolk that is secondarily contaminated with bacteria. Frequently, hens that have been hysterectomized behave as if they have ovulated but do not develop egg-related peritonitis. Experimentally, egg yolks from other hens can be placed near the infundibulum of a laying hen and the yolk will be delivered normally. Peritonitis was never induced by the yolk (Ringer RK, unpublished). In another study, 87% of hens with ectopic ovulation also had egg-related peritonitis (Color 29.28).[84] In domestic fowl, fatal peritonitis can occur alone.[129] The peritoneum is commonly congested and edematous and appears lusterless; adhesions may be present. Peritonitis appears to be described most frequently in cockatiels, budgerigars, lovebirds, ducks and macaws.[141]

Presenting clinical signs include sudden death, abdominal swelling, respiratory distress, depression, anorexia and cessation of reproduction. The hemogram may show a severe inflammatory response. Radiology, abdominocentesis and laparotomy are helpful diagnostic aids. Septic peritonitis leading to severe debilitation, sepsis and death can occur if the yolk is contaminated with bacteria. Egg yolk in the peritoneal cavity is thought to be a predisposing factor to septic peritonitis.[155] Turbid yellow, green or brown yolky fluid or cheese-like yellowish masses of inspissated yolk material in the abdomen are indications of ectopic ovulation or a ruptured oviduct. Peritonitis may lead to secondary infection of other abdominal organs, and in advanced cases, extensive adhesions may form in the abdomen. Egg-related pancreatitis may cause temporary diabetes mellitus, especially in cockatiels.[141] A temporary stroke-like syndrome has been described in cockatiels with yolk peritonitis, possibly due to yolk emboli. Aspirin may be used as an anticoagulant in cases where yolk emboli are suspected (1 tablet/30 cc water, 0.5 cc/kg PO TID). The etiologic agent of egg-related peritonitis is often coliforms, especially *E. coli*.[129] In cockatiels, *Yersinia pseudotuberculosis* and *Staphylococcus* spp. have also been reported in association with egg-related peritonitis.[84]

Treatment consists of antibiotics, steroids to reduce inflammation and supportive care (heat, fluids, nutritional supplements). Long-term antibiotic therapy may be necessary and diet correction is advised. Most cases resolve with medical therapy alone, but early diagnosis is essential. If surgery is required to remove egg material or perform abdominal irrigation, the patient should be stabilized first with supportive care and antibiotics.

Chronic Egg Laying

Chronic egg laying occurs when a hen lays eggs beyond the normal clutch size or has repeated clutches regardless of the existence of a suitable mate or breeding season. Humans, inanimate objects (stuffed animals, enclosure toys) or birds of another species may act as substitute mates and stimulate excessive egg laying. This problem is particularly common in hand-raised hens that are imprinted on humans. The chronically reproductively active female may exhibit weight loss from constant regurgitation and feather loss or mild dermatitis around the cloaca in association with masturbatory behavior. Removing eggs from the hen effectively induces a form of double clutching and can facilitate the problem. The continuation of egg laying is ultimately hormonally controlled. The most domesticated psittacine birds, cockatiels, lovebirds and budgerigars, are notorious chronic egg layers. Perhaps the high incidence of problems in these species indicates a lack of hormonal balance in controlling egg laying that has occurred due to selective pressures designed to make birds produce continually in a variety of environmental situations.

Hens on a completely nutritious diet can continuously lay eggs for years without deleterious effects. In most cases, however, malnutrition and the progressive stress and physiologic demands of egg laying ultimately will compromise the hen. Calcium deficits lead to abnormal egg production, reduced oviduct inertia and generalized muscular weakness. Egg binding is common in hens that chronically lay eggs. Behavior modification can be attempted to stop the laying cycle (see Chapter 4). The stronger the environmental stimulus to cease egg laying activity, the better. Diminishing exposure to light to only eight to ten hours a day should interrupt the hormonal cycle, and egg laying should cease. Objects stimulating masturbatory behavior or sexually oriented regurgitation should be removed, although many birds will continue reproductive behavior despite this environmental change. Nest boxes and possibly enclosure mates should be removed. Changing the location of the enclosure may also be helpful. Owners may discourage reproductive behavior by decreasing the amount of time spent with a hen until egg laying ceases.

Medical therapy is designed to correct any nutritional imbalances or reproductive tract abnormalities. Mineral and vitamin supplements should be given parenterally and added to the diet. Caloric intake with adequate protein levels should be increased. Medroxyprogesterone injections can be used to interrupt the ovulatory cycle. Depression, polyuria, weight gain, liver damage, immunosuppression and occasionally diabetes mellitus (especially in cockatiels) can occur with use of medroxyprogesterone. Egg laying may be stopped from two weeks to several months following therapy and repeat injections are often necessary. Some patients experience no problems, while others experience continual or permanent side effects. Dangerous spikes in drug concentrations can be prevented by implanting a progesterone pellet that allows for continual drug delivery.[61] Despite behavioral and medical therapy, affected hens may continue to lay eggs. The long-term solution in these cases is a salpingohysterectomy (see Chapter 41).

Over-production

Maximal safe levels of egg production and chick care have not been determined for companion bird species. Dietary and environmental conditions in different aviaries would be a factor in determining safe production levels. Free-ranging psittacine hens may produce only one, at the most two, clutches per year. Egg production in excess of two clutches a year would thus be considered unnatural. Many captive psittacine birds (particularly Blue and Gold Macaws, cockatoos and Eclectus Parrots) routinely produce four clutches of eggs per year with no apparent side effects; however, continued levels of unnatural clutch production may lead to reproductive tract disease or other disorders precipitated by poor body condition. Over-producing hens may be thin and in poor feather condition, have poor muscular tone and be unable to quickly involute the uterus after egg laying has stopped. To ensure the long-term health of a reproductively active hen, egg production should be limited to two clutches a year in birds exhibiting medical problems secondary to excessive egg production.

Anatomic Abnormalities

Congenital atresia of the oviduct has been described in domestic fowl and is one of the causes of egg-related peritonitis. Oviduct discontinuity can occur due to degeneration of part of the Muellerian duct during embryonic development.

Normally, only the left ovary is present in birds, except in Falconiformes and Kiwis,[86] where both ovaries are frequently present.[84] Persistence of the right ovary has been reported in corvidae, ducks, swans, a Funereal Cockatoo, owls and grouse without mention of the presence of a right oviduct.[84,86] The author has repeatedly seen right ovaries in young macaws and cockatoos and once in a mature Golden Conure, all without evidence of a functional right oviduct. In these birds, the right ovary appeared vestigial as has been reported in other cockatoos and owls.[84] A right ovary and oviduct were present at necropsy in a mature Scarlet Macaw that died from complications of egg impaction in the left oviduct (Color 29.20) (Ritchie BW, unpublished). In domestic fowl, about 90% of enlarged right ovaries are the result of damage to the left ovary. Occasionally, fertile eggs can result from ovulatory activity from the right ovary.[86]

All early embryos have bilateral oviducts. After the first trimester of incubation, growth of the right oviduct appears to be inhibited. Persistent right oviducts without right ovaries (although they could have been rudimentary and overlooked) have been described in penguins and budgerigars.[72,84] Right oviducts, occasionally paired with right ovaries and oviductal orifices, have been reported in domestic fowl.[151] The incidence is highest in inbred strains, probably due to hormonal imbalances or abnormal genes that affect growth and differentiation of the Muellerian duct.[113] Functional right oviducts have been reported in the domestic fowl, occasionally associated with cystic changes.[86,119,127,151] A fully developed cystic right oviduct has also been observed in a budgerigar. Some domestic fowl with bilateral reproductive tracts can lay two eggs a day, and this unusual condition has also been reported in a duck. A functional-appearing right oviduct that is not altering the health of a companion bird can remain intact.

Abnormal Eggs

Dietary problems, environmental factors and reproductive tract abnormalities can all result in the production of abnormal eggs. Soft-shelled eggs may be an incidental occurrence or may indicate an underlying nutritional or medical disorder. Nutritional deficiencies of calcium and vitamins A and D_3 have been associated with soft-shelled eggs. Therapy consists of both parenteral and oral nutritional supplements.

Oviduct pathology may also cause abnormal egg production. Suggestive abnormalities include thin-shelled eggs, irregular external calcium deposits, or overly thick-shelled eggs. Uterine infections may cause rough-shelled eggs, which can be corrected by flushing the uterus with appropriate antibiotics (Harrison GJ, unpublished). Organochloride pesticides (DDE) cause egg shell thinning by inhibiting deposition of calcium by the shell gland.[30,126,131] Contaminated free-ranging birds in captive breeding projects may have reproductive abnormalities for many years due to the residual activity of these poisons and the long-term storage of these chemicals in body fat.

Domestically bred birds may be exposed to chemical toxins that may cause abnormal eggs through contaminated feed and agricultural spraying. In fact, it is legal to divert contaminated feeds from human food production into food used for animals, directly or by dilution, if the process of manufacturing or cooking will depredate the pesticide to "safe" levels.[50]

Metritis, ectopic ovulation and ovarian disease may cause yolkless, small or sterile eggs that appear grossly normal. Inconsistent transient times of the egg passing through the oviduct may cause abnormally sized eggs due to deposition of differing amounts of albumen. A slow passage time of a preceding egg may allow for double ovulation to occur and result in a double-yolked egg.[62] This occurs with some frequency in domestic fowl but has also been observed in psittacine birds. The problem is usually self-limiting. Hatchability is decreased in moderately abnormal eggs, but these eggs may still produce normal chicks.

Blood clots (meat spots) are described in poultry eggs in association with hemorrhage at ovulation or at other locations in the reproductive tract (Color 29.2). Shell color, yolk color and the odor of an egg can be influenced by diet, hereditary factors and microbial contamination. Some drugs and environmental toxins may cause abnormal egg production, resulting in early embryonic death or weak chicks. Examples include crude oil, exhaust fumes, nicotine, chlorinated hydrocarbons and certain antibiotics (furazolidone).[121]

Male Reproductive Disorders

Toxins

Numerous toxins can affect spermatogenesis in mammals. Reduced spermatogenesis has been reported in Japanese quail exposed to mercury.[174] Copper fungicides in feed have been found to suppress spermatogenesis and induce testicular atrophy.[148] Cystic testicular degeneration occurs in ducklings given feed with furazolidone.[185]

Anatomical Abnormalities

Cyclic seasonal testicular atrophy occurs in many species (up to 500-fold in Passeriformes). Following the correct environmental stimuli, the testicles can undergo hypertrophy in preparation for breeding. Because of the seasonal change in testicular size, pathologic cases of atrophy can be difficult to diagnose (see Color 25). Serial laparotomies may be indicated to evaluate changes in testicular size. Testicular atrophy can be caused by orchitis as a result of trauma or genital infection or can be due to progressive infertility. Malnutrition, toxicity or bacteremia may also cause testicular degeneration. Affected birds may demonstrate a lack of libido or be infertile. Therapy is limited to addressing infectious or behavioral problems. If fibrotic or infiltrative changes have occurred, spermatogenesis may be permanently altered.

Testes can be abnormally joined at their anterior ends, which may not prevent spermatogenesis.[119] Testicular hypoplasia may be attributable to congenital or hereditary conditions. Similarly, true agenesis may occur, causing parts of the genital tract to be absent (monorchidism).

Orchitis

A variety of bacteria can cause orchitis in birds, including *E. coli*, *Salmonella* spp. and *Pasteurella multocida*.[132] Infections may originate from prolapsed or ulcerated phalli, renal obstruction, cloacitis and septicemia. Clinical signs are similar to those expected for any generalized infection. Antibiotics may be helpful in resolving the active infection but may not prevent or reverse infertility.

Neoplasia

Testicular tumors commonly occur in older budgerigars but can also be found in larger Psittaciformes and other birds.[14] A seminoma of the testes was reported in a Collared Turtle Dove[133] with progressive emaciation for several months before death. The author diagnosed a seminoma in an Eclectus Parrot that died suddenly with an enlarged left testicle that occupied much of the left peritoneal cavity (see Figure 29.5). The surface of the testicle was smooth, which is typical of primary tumors. This bird had a long history of aggressive behavior (atypical for the species) toward numerous hens. It was theorized that hormonal imbalances associated with this tumor were responsible for the behavioral changes.

Sertoli and interstitial cell tumors have been described in birds (see Chapter 25).[47] Lymphoproliferative diseases, such as leukosis, can also affect the testes resulting in infertility.[99] Regardless of the tumor type, testicular neoplasias can involve one or both testes. Unilateral paresis, progressive weight loss and abdominal enlargement are typical clinical signs. Affected birds may have reduced secondary sex characteristics and become more feminine in nature (cere of the male budgerigar turning from a blue to brown color). Metastasis from testicular tumors usually affects the liver.[14] Surgery may be successful if the tumor is easily approached and unilateral and the cock is in good health. Long-term prognosis is guarded due to the possibility of metastasis.

Phallic Prolapse

Birds with large phalli may develop partial or complete prolapses, which are frequently secondary to trauma, infection or extreme weather fluctuations.[69] Infections may be secondary to mucosal irritation (over-exuberant mating or vent sexing) or fecal contamination. The phallus may become enlarged and ulcerated. In geese, *Neisseria* spp. have been isolated from erosions of the phallus, oviduct and cloaca and are believed to be sexually transmitted.[118] Occasionally, a prolapsed phallus will revert preventing evaluation of secondary infections. In severe cases of phallic prolapse, the birds may be severely depressed, anorectic and disinterested in copulation. Permanent infertility is a common sequela. In ostriches, frostbite and necrotizing dermatitis may occur secondary to a prolapse.

Exposed tissue should be thoroughly cleaned with a sterile saline solution, carefully debrided and cov-

FIG 29.14 Environmental factors that would make a pair of birds feel insecure should always be considered when evaluating a lack of breeding success. The design and location of the nest box, enclosure and aviary are all critical factors to consider. This male Sulphur-crested Cockatoo with fertile eggs was eliciting proper nest box defense behavior in response to an intruder.

ered with antibiotic cream. Topical DMSO may help reduce swelling, making replacement of the phallus easier and more permanent. Daily therapy and cloacal mattress suture may be necessary to prevent recurring prolapses (see Chapter 41). Systemic antibiotics should be considered due to the possibility of ascending urogenital infections. If large areas of necrosis are present, then surgery is necessary to debride the wound. Nodular ejaculatory papillae have been described as abnormal in pigeons.[11]

Behavioral Abnormalities

Reproductively active males and females (particularly budgerigars and cockatiels) may exhibit masturbatory behavior or excessive regurgitation. These are normal reproductive behaviors that may become pathologic in birds that are isolated. Cockatiel cocks incubate the eggs, and a single male may spend much of the time on the enclosure floor mimicking incubation activities. Removing the bird from its enclosure for long periods of time (with available food and water sources) or changing the enclosure or enclosure location may stop this behavior. In other cases, displaced reproductive behavior may occur in males housed with females. In these cases, the male is often "imprinted" on humans and cannot complete the reproductive cycle with its own species. Exchanging mates may prove helpful, but usually these males should be removed from the breeding program. Human imprinting can also occur in females, and in both genders behavioral abnormalities due to improper imprinting may not be obvious. Indeed, lack of pair-bonding, lack of egg production or infertility may be the only signs associated with the use of hand-raised imprinted birds in a breeding program. The interaction of a chick with its parents and nesting conditions may be critical for successful reproduction in some species (see Chapter 4).

Under-production

Establishing the existing level of production is the first step to managing a breeding pair. This includes calculating levels of fertility, hatchability and chick fledging rates. Average clutch sizes have been reported for many species of birds;[4,43] unfortunately, clutch size can vary among individuals and within genera. Under-production is particularly important with endangered species where maximum production is critical to ensure the survival of the species.

If production from a breeding pair does not approach the average, then medical, physical or behavior problems should be addressed. Correction of any medical or physical abnormalities, such as clipping overgrown feathers near the cloaca, dieting overweight birds or treating birds for localized infections can be instituted. The diet should be carefully analyzed and any deficiencies should be corrected. Environmental deterrents to breeding may be determined by using a video camera to observe the pair's daily behavioral patterns. Some changes that may be necessary include re-pairing birds, improved enclosures, different nest boxes, varied diet, altered climate, different lighting or reducing aviary disturbances induced by humans, other birds or vermin (Figure 29.14).

Endocrine manipulation for improving reproductive success in birds has been studied with marginal success. The dependence of the avian endocrine system on environmental stimuli makes clinical manipulation of the avian reproductive system difficult. Specific behavioral manifestations of endocrine abnormalities have been treated medically, such as testosterone injections in timid male Eclectus Parrots, but such therapy is experimental in nature and long-term use can cause testicular atrophy.

Testosterone has been suggested to induce singing in male canaries but can cause serious side effects. Male canaries that do not sing are usually sick or malnourished. PMSG (gonadotrophin serum) administered to canary hens induced defeathering and vascularity of the brood patch and accelerated reproductive tract development with accompanying increased incidences of egg binding and oviposition on the enclosure floor.[164] In another study, PMSG administration stimulated reproductive activity in birds maintained in both long and short daylight cycles.[163]

Birds that consistently fail to produce should be removed from the breeding program.

Artificial Insemination

Artificial insemination (AI) has been used successfully in cranes, cassowaries, raptors, gamebirds, Anseriformes, Columbiformes, Galliformes and some psittacine species, including budgerigars, a cockatiel and Hispaniolan Amazon Parrots.[45,60,146] This technique may be beneficial in endangered species, especially when a limited number of individuals of a species is available. Problems with incompatible pairs, poor fertility due to physical or behavioral difficulties and large distances between individuals housed at different breeding facilities may be resolved using AI.

Collection Technique

Successful collection techniques include cooperation, massage and electroejaculation. Cooperative AI requires human-imprinted males that are encouraged to copulate and deposit semen in or on a suitable receptacle.[16] This technique is extensively used in raptor breeding.[173,184] Using imprinted birds requires a tremendous amount of time and effort and may not be possible in all species.[17] Semen may also be collected during or after natural copulation or through the use of dummy mounting devices and artificial vaginas.[11] Semen collected with these techniques is usually free from contamination.

The massage collection technique requires two people, one to restrain the bird and the other to collect the semen. The inner thigh, ventral abdomen, tail, vent and synsacral area are stroked. The tail is positioned dorsally and with continued stroking pressure is placed laterally on the cloaca to encourage ejaculation. Even without ejaculation, semen can be expressed from the cloacal region with this technique. Contaminated semen samples often contain feces and urine and should be discarded. Contamination can be reduced by fasting the birds and evacuating the cloaca before semen collection. Visualization of semen volumes in small Psittaciformes can be augmented using a strong light source. Massage has been used successfully in poultry, Casuariiformes, Anseriformes, Columbiformes, Falconiformes, Gruiformes, Passeriformes and Psittaciformes including budgerigars, Hispaniolan Amazon Parrots, Maroon-bellied Conures and Monk Parakeets.[11,21,45,78,147]

Five to fifteen μl of semen could be artificially collected from budgerigars twice weekly using a modified massage technique where the semen is collected by simply applying pressure on both sides of the cloaca to empty the contents of the seminal glomus. Hispaniolan Amazon Parrot males were collected three times a week during the months corresponding with the natural breeding season although semen yields remained high in one individual for several months after the normal breeding season. In Hispaniolan Amazon Parrots, paired and unpaired males yielded statistically similar semen volumes, sperm motility and sperm concentrations. Collection of semen from males paired with reproductively active hens did not affect their breeding performance.

Electroejaculation under anesthesia is not a common method for collecting avian semen although it has been successfully used with a variety of birds including waterfowl, domestic fowl,[91] psittacine birds[58] and pigeons.[11] Electroejaculation may cause semen samples to be expelled with feces and urine.[11] This technique, however, can be attempted if massage and cooperative techniques fail. Electroejaculation was successful in 95% of mature pigeons when used in conjunction with a cloacal retractor.[10] A combination of massage and electrostimulation was used to collect semen from macaws, cockatiels and Amazon parrots.[58]

The volume and sperm concentration of semen varies among species (see Table 29.3).[45] Semen volume can be increased by multiple collections in a week. Excessively frequent collection can cause cloacal irritation, swelling and hyperemia of the vent. Adding diluent to the semen may help preserve sperm viability in low-volume samples.[45] Semen should be evaluated before and after any storage or preservation and before insemination. The phallus, anal gland secre-

tions, urine, feces and transparent fluid can all interfere with semen collection and viability.

Higher fertility levels are achieved when semen is used for insemination immediately following collection. Uncontaminated semen in chickens can be stored for 1.5 days and still result in 37% fertility.[95] Short-term storage requires temperatures near freezing and protection from drying and contamination. Diluents should be used when semen is stored for more than one hour. Commercially available poultry diluents have been used successfully in non-domestic species.[21,78] Long-term semen storage requires cryopreservation using either glycerol or dimethylsulfoxide (DMSO) as a cryoprotectant. Glycerol must be removed prior to insemination using dialysis. Frozen-thawed semen has proven to be viable in Sandhill Cranes, American Kestrels, Peregrine Falcons and budgerigars.[20,124,146,152] Modifications in cryopreservation methods and fluids may be necessary when handling semen of other avian species.

Insemination Technique

Cooperative techniques may be used to inseminate females that are encouraged to respond to handlers allowing semen to be deposited in the cloaca or oviduct.[184] Massage techniques involve manual stimulation, eversion of the cloaca and placement of the semen via a tube, straw or catheter through the cloaca into the vagina. Anatomical structures can be better visualized using speculums and specially designed cloacal retractors.[10] Deep vaginal insemination results in the best fertility levels; however, with frequent and timely inseminations fertile eggs can occur when semen is deposited in the cloaca.

Fertile eggs were produced by budgerigar hens using five to ten µl of fresh semen or 40 µl of frozen-thawed dialyzed semen placed by cannula into the oviduct two hours post-oviposition. Determining when to inseminate is crucial for fertilization to occur. It is best to inseminate every other day after the first egg in a clutch is laid or after each egg is laid.[184] The frequency of insemination is governed by the species, sperm concentration, durability of the sperm, method of insemination and ovulation patterns. Hispaniolan Amazon Parrots were successfully inseminated before egg laying started but fertile eggs were not laid until insemination procedures were discontinued.

Initiating egg laying usually requires behavioral stimulation provided by the presence of a mate. Female budgerigars were successfully inseminated only after they began laying when stimulated by the presence of a vasectomized male.[146] Vasectomized cocks show normal male sexual behavior, including courtship and copulation. Hispaniolan Amazon Parrot hens begin egg laying when housed separately but adjacent to males.

Non-disease Factors Affecting Reproduction

Gender

The most common cause of reproductive failure in companion birds is pairing of two birds of the same gender. Several techniques for determining the gender of birds have been described. The appropriate method to use depends on the species, age of the bird and the information to be derived from the procedure.

Physical Characteristics

Many species of birds are sexually dimorphic, with visual characteristics that distinguish males from females. The degree of dimorphism varies with species and may not always be obvious. Even with monomorphic species, subtle differences may exist that allow determination of gender. With most monomorphic species, definitive gender differentiation requires laboratory or laparoscopic procedures.

With birds of prey, the female is generally 30% larger than the male, although some size overlap occurs in the intermediate weight ranges.[188] In other groups of birds, the male is generally heavier and has a larger frame than the female. Head size as well as bill breadth, length and depth are often greater in males. Differences in beak size are usually obvious in toucans but may require calipers to appreciate in smaller species. The majority of psittacine birds are monomorphic although there are many exceptions (Table 29.4).

In dimorphic birds, feather color, iris color and bill characteristics typically differentiate hens from cocks.[43,64,101,158,167] These secondary sexual characteristics become more obvious as birds reach reproductive maturity. Immature birds typically have color patterns similar to adult females. Feather shape and length may also be different. For instance, male Racket-tailed Parrots have much longer central

retrices than females, and male Princess Parrots have a spatula extension at the end of the ninth primary feather. In general, red to brown iris color is more common in female cockatoos; however, this technique is not always reliable, especially in Moluccan, Rose-breasted, Bare-eyed, Goffin and immature cockatoos. At maturity, wild-type (green) male budgerigars have lavender to dark-blue ceres while females have light-blue to tan or brown ceres. Gender determination based on cere color may not be effective in inbred color mutations. The White-fronted Amazon is clearly sexually dimorphic. Males have numerous red secondary wing coverts while females have few to none.

Vent Sexing

Gender can be determined in most Galliformes, Anseriformes, some game birds, ratites and some species of Cracidae by looking for the phallus on the wall of the cloaca. In Columbiformes and Passeriformes, which have prominent papillae of the ductus deferens, gender can be determined if these structures can be visualized using general anesthesia and a cloacal protractor.[10] The clitoris is located at the same location as the phallus, and differentiating the phallus from the clitoris can be difficult in chicks and immature cocks (see Chapters 46 and 48).

Determining the distance between the pelvic bones (gapped in females, close together in males) has been discussed as a method of gender determination. The distance between the pelvic bones increases in postovipositional females but may narrow considerably in the months following oviposition. In larger psittacine birds, this is an unreliable method of gender determination. Some practitioners feel that this is a reliable method for gender determination in mature lovebirds.

Behavioral Characteristics

Behavioral characteristics generally vary with gender; however, birds can develop homosexual pair bonds with one bird behaving more like a hen than the other. Males are generally more aggressive and are responsible for territorial defense. The songs of the male finch, canary and cockatiel differentiate them from females. With some free-ranging psittacine species, the hen incubates while the male is perched nearby as a sentry. Depending on the cycle of incubation and the age of chicks, the hen may join the male in inter- and intraspecific territorial confrontations. In cockatiels and some other species of psittacines, the male shares in incubation duties.

Observing copulation in species in which the male completely mounts the female may indicate a successful pair bonding. Complete mounting is typical of raptors, waterfowl and Passeriformes. In New World Psittaciformes, copulation occurs side by side, and homosexual pairs have been observed precisely mimicking this procedure. The male usually places one foot on the caudal tail region of the female and has the more dorsally placed tail during cloacal contact. It is theorized that females exhibiting masturbatory or courtship behavior with inanimate objects, other species of birds or humans will often lay eggs. If no eggs are produced, it may indicate that the bird is a cock, but some masturbating hens have been known to wait twelve years after the onset of this behavior before laying an egg.

Laparoscopic Sexing

Although subject to error when used in young birds with undifferentiated gonads, laparoscopic examination is a definitive method of gender determination when performed by an experienced practitioner (see Chapter 13). Its major advantage over other gender determination techniques is that it allows for direct inspection of abdominal structures, especially reproductive organs, for evidence of disease or dysfunction. Its disadvantage is that it is an invasive procedure that requires anesthesia.

Laboratory Methods

Genetic determination of gender in birds is considered the most reliable of the available noninvasive techniques. One method employs feather pulp as a source of chromosomes. After culturing, staining and careful examination, the gender chromosomes can be identified in most species. The disadvantage of this technique is the difficulty of collecting an adequate number of growing feathers that will produce a viable culture that is not contaminated. Other problems include overnight mailing and a lag time in obtaining results, as only one laboratory[a] offers this service commercially in the United States.

Determination of gender can also be accomplished by evaluating differences in the DNA composition between males and females. A small volume of red blood cells is necessary for this procedure, and advantages include easy and relatively non-traumatic sample collection and a long sample shelf life without refrigeration. Lag time in obtaining results is a disadvantage, as only one laboratory[b] offers this service in the United States.

TABLE 29.4 Examples of Sexual Dimorphic Differences in Psittacines*

Species	Male	Female
Budgerigar	Cere lavender to dark-blue	Cere pink-brown to light-blue
Cockatiel	Lacks barring, bright yellow face and cheek patch	Tail and flight feathers have barring on underside
Malee Ring-necked Parrot, Adelaide Rosella, Red-rumped Parrot, Bourke's Parrot	Lacks barring when mature	Barring on underside of wings
Red-rumped Parrot	Red rump patch	Green rump patch, paler
Scarlet-chested Parrot	Scarlet breast	Green breast
Regent Parrot, Superb Parrot	Yellow feather patches	Green throughout
Princess Parrot	Spatular extension on the end of the ninth primary flight feather, coral beak	Lacks spatular extension, brownish beak
Red-bellied Parrot	Red belly	Scattered red feathers on green belly
King Parrot	Red head feathers	Green head feathers
Red-winged Parrot	Blue crown feathers, bright yellow-green underparts, black shoulder mantle, coral bill, orange-red iris	Duller green feathers, pale-brown iris
Duchess Lorikeet	Red side rump patch	Yellow side rump patch
Fairy Lorikeet	Blue rump patch	Yellow side rump patch
Josephine's Lory	Red lower back	Green lower back
Whiskered Lory	Red face-crown and crown	Green face-crown and crown
Cacatua spp.	Brown to black iris	Red to reddish-brown iris
Eclectus Parrot	Green	Red and purple
Pesquet's Parrot	Red spot behind eye	No red spot
Grey-headed Lovebird	Grey head, neck and breast	Green head, neck and breast
Ring-necked Parakeet	Colored ring around the neck	No ring
Mueller's Parrot	Red beak	White beak
White-fronted Amazon Parrot	Red alula and primary covert feathers	Slight to no red in primary covert feathers
Mountain Parakeet	Yellow forehead, lores, cheeks and throat	Green forehead, lores, cheeks and throat
Mexican Parrotlet	Blue lower rump and underwing coverts	Yellow-green lower rump and underwing coverts
Pileated Parrot	Red forehead	Green forehead
African Grey Parrot	Red vent and rump feathers	Grey tips on red feathers or mostly grey

* Not all members within a genus will portray the listed sexual differences. One representative species is listed for each genus. Differences are usually observable only in mature species.)

Fecal steroid assays have been used to determine gender in birds.[8] Steroid hormone levels including estrogens and androgens (mostly testosterone) are measured by radioimmunoassay, and an estrogen/testosterone ratio is used to estimate the sex of the bird. An individual bird's production of steroid hormones varies with age and sexual activity and leads to some overlap in the estrogen/testosterone ratios. Commercial laboratories[c] claim high accuracy, although no blind studies have been performed to validate the test. One recent report suggests that fecal sex steroid determination in most parrots is not effective, especially in small birds.[7] This technique of gender determination requires that a bird be sexually mature.

Sexual Maturity

In birds, the female is the heterogametic gender (ZW), and the gender of the embryo is determined prior to ovulation and not at fertilization as occurs in mammals. Males are homogametic (ZZ). Sex differentiation occurs in the developing embryo during the first trimester of development. Secondary sexual characteristics under hormonal control may be obvious before functional sexual maturity is achieved.

The age of sexual maturity varies greatly between species. For example, Zebra Finches and captive Japanese Quail are sexually active by two months of age. By comparison, the Fumar begins breeding at about eight years of age.[86] Many smaller Passeriformes begin breeding in the first or second spring after hatching. In larger Psittaciformes (Amazon parrots, African Grey Parrots, large cockatoos and macaws),

viable eggs can be produced when the birds reach three to six years of age. Pionus and smaller cockatoos and macaws may be sexually mature by two to four years. Lories and lorikeets produce young at two to three years, conures at one and one-half to two years, and budgerigars, lovebirds and cockatiels at six months to one year of age.[107] Initial clutches of eggs may be infertile in young birds due to immaturity of reproductive tissues or reproductive inexperience.

Environment

Light

The most important factor for reproductive stimulation of free-ranging birds in mid to high latitudes is day length. Neuroendocrine systems control the annual development of the reproductive system with sufficient precision to assure that young will be produced when trophic resources are optimal. Lengthening photoperiods elevates LH secretion, which is the primary reproductive hormone. The effect of photoperiod on certain species of captive companion birds has been partially studied, and this information may be applicable to other related species.

Female budgerigars have been found to lay eggs when exposed to male vocalizations even when kept in continuous darkness.[71] Male song appears to be a strong factor for successful oviposition, but a dark nest box is also important. Photoperiod can have a direct effect on male vocalizations, which in turn stimulates the female reproductive cycle. In poultry, the onset of sexual maturity is affected by lighting.[40]

Climate

High environmental temperature combined with high humidity increases the physiological stress on birds and can decrease reproductive activity. An ambient temperature greater than 27°C induces a state of thermal stress in pullets[67] and decreases egg production, feed consumption and feed efficiency. Increases in humidity appear to have less effect on reproductive activity than increases in dry bulb temperature. Temperature extremes have been shown to decrease semen production and cause thinner egg shells. The use of misters in hot weather can alleviate this problem.

Rainfall triggers courtship behavior in male Zebra Finches. Juvenile finches may form pair bonds before the rainy season so that they are ready for breeding when rain occurs. Finches are thought to maintain testicular function throughout the year, making rapid reproduction post-rainfall possible.[179] Cold temperatures inhibit Zebra Finch reproduction.

Season

Effects of environmental conditions on reproduction may be similar in captive birds and free-ranging birds; however, heavily domesticated species like canaries, budgerigars and finches react differently than their free-ranging conspecifics.[179] For larger Psittaciformes, insufficient information has been collected to make comparisons between the reproductive characteristics of free-ranging and captive birds. In Central America, free-ranging Yellow-naped Amazon Parrots have been found to produce eggs as early as December and can have eggs hatch as late as April. Conures in the same area have roughly the same cycle although in both species, the majority of eggs hatch in January (dry, cooler weather). Budgerigars in Australia breed throughout the year, but in each geological or ecological area only produce young for a set number of months each year.[189]

Individual pairs of a particular species have the capacity to re-nest if necessary to account for yearly changes in environmental conditions as well as to adjust to geographic or ecologic changes in a region. This same adaptability may be expressed in captivity.

Egg production was monitored for one year at a large Psittaciforme breeding facility in California.[169] Amazon parrots were found to breed during a 17-week period from early March to early July. Blue and Gold Macaws had the longest breeding season, with eggs being produced year round, although egg numbers decreased in September and November. Rose-breasted Cockatoos had the shortest season, which lasted nine weeks from late winter to early spring. Amazon parrots bred at a time when the mean high temperature and humidity was highest (87.9°F and 44.4% RH), as opposed to the cockatoos, which bred with a mean high temperature of 79°F and RH of 27%. Blue and Gold Macaws bred during the broadest range of temperature and humidity.

The Amazon parrots quit producing when day length began to decrease and did not breed again until day length had increased considerably. Blue and Gold Macaws could breed in both increasing and decreasing light. Cockatoos produced only during periods of increasing day length. It could not be determined from this study if temperature, humidity, day length, a combination of all three or other unrecorded factors controlled reproduction. All three of the evaluated species originate from temperate climates and are

probably affected by other factors as well as day length. In Hyacinth Macaws in a Florida aviary, eggs are produced between May and October.

Mate Presence

In cockatiels, mate access is essential to ensure nesting behavior.[156] Increases in LH levels necessary for oviposition occurred only in females given full mate and nest box access. Visual, but not auditory, isolation of mates did not negatively affect cockatiel reproduction in one study.[190] Testicular development was found to be greater in starlings when males were housed with females. In other species, sufficient photoperiods will induce testicular development regardless of whether a female is present.[179]

Separating a pair during the non-breeding season may not affect reproductive success in a subsequent season, and mates will usually reunite, especially if they have previously been reproductively successful. Mate retention has been found to be associated with greater reproductive success than mate replacement in a variety of species that naturally separate in the non-breeding season.

Orange-winged Amazon Parrots in one study were stimulated to breed by separating them from their self-selected mates for three months and then placing them into enclosures with nest boxes that permitted them to "chew" an entrance hole into the nest box.[111] In addition, these "enriched pairs" were given fruit instead of a complete crumble diet and were exposed to water misters on alternate days. The reproductive success in these birds was better than in a control group, but no one factor could be identified as being responsible for the increased egg production.

Mate Selection

In some monogamous birds, such as California Quail and Turtle Doves, forced pairing of mates can result in successful breeding. In other species like cockatiels, forced pairing was found to result in decreased reproductive activity.[190] In some species, force-pairing may result in increased mate aggression.

Specific mate characteristics may affect mate acceptance and the strength of the pair bond. Rather startling is the fact that leg band color is important in determining mate preference in finches. This is just one indication that color of feathers and beaks, which often changes seasonally, can be an important reproductive stimulant. External physical characteristics of birds can be dependent on health and nutrition as well as environmental cues that influence the production of hormones responsible for secondary sex characteristics.

Aggressive mates can inhibit reproduction by preventing the opposite sex from eating or through direct physical abuse. Aggressive behavior is most noteworthy in cockatoos and is seen occasionally in Eclectus Parrots. Male cockatoos, even in long-term successful pairs, may suddenly attack and sometimes kill their mates. The beak, eyes, skull, feet and cloaca are most commonly traumatized.

Old World Psittaciforme males completely mount the female during copulation, and male aggression may occur from failures in proper copulatory behavior. Evidence suggests that males become sexually active before hens, which may precipitate the aggressive behavior. If a free-ranging male cockatoo becomes aggressive, the hen is able to escape to prevent serious injury.

Lighting, food and the presence of other birds may induce aggressive behavior. As a solution, male cockatoo flight feathers are often clipped, and the nest box is provided with a lower "escape" hatch so that the female cannot be trapped within the nest box. Males should be introduced into the hen's enclosure by being placed within a smaller enclosure. After mate acceptance, the male can be released into the female's enclosure. In the case of Eclectus Parrots, females are more aggressive than males, although they rarely seriously injure a mate. Excessively aggressive males or timid females should be removed from the breeding program.

Mate Pair-bonding

Pair-bonding refers to the behavioral acceptance that exists between a compatible hen and cock and is evident in all successful pairs, although considerable species and individual variation exists. Strong territorial defense coordinated between the male and female, such as lunging at the front of the cage with upraised wings in macaws and tail-fanning with crown and nape feather ruffing in Amazon parrots, are examples of proper pair-bonding (Figure 29.15). Other behaviors include mutual preening (see Chapter 4), feeding, nest box inspection and copulation (see Color 8). Homosexual pairs may also bond and exhibit these same behaviors.

Evaluating a breeding pair through the aid of video recorders will help identify causes of behavior-induced infertility. Some copulatory efforts may be handicapped by physical, medical or behavioral abnormalities. Abbreviated copulatory efforts may nor-

FIG 29.15 Using a video camera to observe a pair of birds' daily behavior can help determine if an effective pair bond exists and may help identify environmental factors that are inhibiting breeding. These strongly pair-bonded Green-winged Macaws are displaying proper territorial defense behavior in response to an intruder.

mally precede successful copulation. Birds should be allowed to choose their own mates to increase the likelihood of pair-bonding.

Mate Vocalization

Male auditory signals stimulate female reproduction in several species. In turn, males will maintain spermatogenesis longer when paired with sexually active females. Budgerigars may be the only avian species in which an auditory stimulus promotes ovarian development and ovulation.[22] Isolation of budgerigar pairs both visually and auditorially from other budgerigars will cause reduced reproductive behavior.[22] A similar effect has been hypothesized in macaws, Amazon parrots, cockatoos and African Grey Parrots (Harrison GJ, unpublished).

Social Interaction

The presence of other breeding birds is a reproductive stimulus in highly social and colony breeding species. Social birds such as budgerigars should be housed within hearing, if not visual, range of the same species to stimulate successful reproduction.

Social behavior varies during the breeding season in some species. For example, some parrots will feed only in pairs during the breeding season while cockatoos will interact daily with other pairs and feed in larger groups. Free-ranging populations of Zebra Finches are highly social until courtship behavior begins.

In captivity, housing similar species near each other may reinforce the pair bond and strengthen endocrine controls by eliciting territorial defense behavior. In contrast, excessive territorial defense may waste energy and interfere with pair interactions that are critical for reproductive success. Monitoring of a pair's behavior and analysis of enclosure diagrams in multiple-pair and multiple-species aviaries will help define proper housing for each species and individual pair.

Human Interaction

Human interference can affect reproduction. Circulating levels of prolactin are easily altered by stressful events; stress is one method used to discourage incubation in egg-producing turkeys.[38] Aviary disturbances and handling birds near the breeding season may disrupt endocrine control of the reproductive cycle or disturb the birds so that mating is not initiated or completed, incubation is interrupted, eggs are damaged or chicks are cared for improperly. Successful territorial defense appears to have a positive effect on reproduction, and males that feel they have defended their nest from humans may be more reproductively active. Although evidence is rather anecdotal, barren pairs have been induced to breed by disturbing, handling or relocating the pairs. Some species of birds are withdrawn and display fear as opposed to aggression when approached by humans, indicating improper territorial defense. These pairs may be more productive once conditioned to human activity or if placed in an isolated, protected area. Annual physical exams can be performed on properly conditioned birds and do not appear to negatively affect reproduction.

Nests

Availability and acquisition of a proper nest site and nesting material may be a strong environmental stimulus for breeding particularly in male cockatiels and finches.[77,110,179] In fact, LH surges that stimulate reproduction and spermatogenesis may be induced

because of male defense behavior and not because of the presence of a female. Starling males that did not defend their nest boxes were found to have similar LH levels to males without a nest box.[51] The relationship of the perch to the nest box hole (perch ten cm below the hole) played a significant role in reproductive success in budgerigars.[23] This phenomenon may be applicable to considerations of nest box design in other species as well.

Birds are generally classified as being either determinate or indeterminate layers. Determinate layers will lay only a set number of eggs in a clutch regardless of whether any egg is removed or destroyed. Indeterminate layers will continue to lay until they "recognize" the correct number of eggs. Prolactin is released from the pituitary gland in response to the incubating bird's physical contact with eggs in the nest. The concentration of prolactin, which is responsible for regression of the ovary and incubation behavior, was found to increase gradually in cockatiels that were incubating eggs.[112] These cockatiels were also found to be able to continue to lay additional eggs if previous eggs were removed from the nest. In turkeys, follicular atresia occurs when egg incubation starts.[38]

Applying these principles to companion birds, it is logical that if birds are thought to be indeterminate layers, eggs should be removed before incubation starts if production of more eggs is desired. The longer incubation is allowed to proceed the more complete the ovarian regression would be, which would make a hen less likely to lay another clutch. Budgerigars are believed to be determinant layers.

Territory

In finches, males with a breeding territory had larger testes with a longer functional period than males that were photo-stimulated without a breeding territory.[42] The presence of sexually active females may also affect the influence of breeding territory in stimulating male reproductive activity. The male's reproductive condition appears to be more easily synchronized by environmental cues than does that of the female. Female reproductive performance appears to be more affected by captivity than does that of males. The presence of a sexually active male probably has a positive effect on females in many species, even though the effect may not be recognizable because of the lack of stimulation in the female from other cues.

Enclosures

Enclosure design can affect reproduction. Some species of birds appear to breed better in flights as opposed to flight enclosures. The actual dimensions may be important, but longer, wider and higher enclosures may not always be better, as a larger enclosure may represent a territory that a pair feels it cannot adequately defend. Enclosure design in general and nest position, including whether it is within the enclosure, how high it is and whether it is open or obscured by walls, may all influence a pair's feeling of security (see Chapter 2).

Reproductive Experience

Previous reproductive activity may decrease the requirement for environmental cues to stimulate breeding. This has been shown to occur in budgerigars and is suspected in Orange-winged Amazon Parrots.[18] Mate familiarity increases reproductive success in cockatiels,[190] and mate retention throughout successive breeding seasons has been correlated with greater reproductive success in monogamous birds. Mate familiarity may improve pair coordination, decrease aggression between mates and increase male reproductive behavior.[39]

Hand-raising neonates may result in imprinting on humans or a lack of early environmental "learning," which may affect future reproductive success. Imprinting often appears stronger in males than in females. Hand-raised cockatiel hens were more likely to lay eggs (and more of them) than parent-raised birds; however, eggs were often laid on the floor of the enclosure. Pairs with hand-raised male cockatiels were less likely to inspect nest boxes or produce fertile eggs.[116] The behavioral deficits of hand-raising can be attenuated by successful and repeated breeding experience. Imprinting on the wrong species is common in birds and has been reported to occur when Rose-breasted Cockatoo chicks are foster-raised by Major Mitchell's Cockatoos.[143] During fledging, chicks are thought to imprint on habitat, which will later control nest site selection.

Nutrition

Low dietary calcium levels (0.056% to 0.3%) have been shown to cause a complete cessation of egg laying in gallinaceous birds. Decreased energy intake causes decreased LH levels followed by ovarian atresia. Low-sodium diets also result in cessation of egg laying. Zinc-rich diets decrease feed intake and

may directly decrease egg laying by altering metabolism and endocrine functions.

Psittacine birds being fed largely seed diets should be expected to consume low levels of vitamin A, D_3 and E as well as other nutrients (see Chapters 3 and 31). Vitamin E deficiency can cause reduced spermatogenesis in domestic fowl and Coturnix Quail. Vitamins A and D_3 are needed for proper reproductive gland secretions and calcium metabolism, respectively. Over-nutrition may precipitate infertility by either mechanically blocking the cloaca or reducing successful ovulation. Abdominal fat and lack of condition may contribute to oviduct inertia and egg-laying problems. Amazon parrots, Scarlet Macaws and Rose-breasted Cockatoos are commonly obese and should be carefully monitored to prevent weight-related infertility. Fat can accumulate in pendulous folds near the cloaca and crop, often differentiating into lipomas (see Color 8). Subcutaneous fat deposits over the coxofemoral and flank regions are more subtle indications of excessive energy intake.

The availability of certain food items and not simply energy consumption may be one of the many stimulants needed to begin or strengthen reproductive activity. Aviculturists can mimic naturally occurring variations in food availability by reducing food intake and variability in the non-breeding season and then dramatically increasing the quality, quantity and variety of foods before the breeding season. The success of this method is equivocal but suggests the need for further study.

In White-crowned Sparrows, consumption of green wheat enhanced photo-stimulated ovarian growth. Testicular growth was not affected.[41] It was not shown if the ovarian stimulatory effects of green leaves were ecologically significant or if specific substances in the green plants induced the change.

Aflatoxins and mycotoxins in feed have been shown to reduce egg production and cause infertility. Thiotepa, although mutagenic, teratogenic and carcinogenic in large doses, proved in one experiment to be a safe, effective temporary chemosterilant when fed to free-ranging male Red-winged Blackbirds.[128]

Physical and Medical Characteristics

Adequate exercise is important to reproductive success and decreases the likelihood of reproductive disorders, such as egg-binding. Any physical abnormality or medical condition affecting mobility, balance, the cloacal region or the reproductive tract can cause infertility or decreased reproductive success. Heavy cloacal feathering, such as in Rose-breasted Cockatoos and fancy pigeon breeds, may prevent copulation resulting in infertility. A female Golden Conure with an abscessed preen gland repeatedly attacked her mate when he attempted copulation. The pair laid fertile eggs three weeks after the abscess was resolved. Medications, especially certain antibiotics, can cause infertility or decreased or abnormal egg production. For example, testosterone injections in males can cause infertility, and an entire season of reproduction can be interrupted after the use of injectable doxycycline therapy.[162] These changes may have been due to the stress of restraint and injection; however, similar cessations of reproductive activity have been noted following the administration of doxycycline in other psittacine species (Harrison GJ, unpublished).

Inbreeding

Males inherit fertility and semen quality characteristics. Some mating behavior is learned and some is inherited. Inbreeding may lead to infertility or decreased production due to genetically controlled physical or behavioral deficits. Lethal and sub-lethal genes that are more frequently expressed during inbreeding can cause decreased hatching rates. Genetic selection for large body types (budgerigars and turkeys) may cause a physical inability to breed.

General

Frequently, the positive environmental factors that stimulate breeding and the negative factors that prevent it cannot be discerned. Successful captive breeding depends on establishing environmentally enriching conditions that stimulate reproductive activity.

In environmentally stimulated cockatiels, the period from ovarian development to first oviposition was independent of environmental conditions.[110] In pair-bonded cockatiels, a combination of diet, photoperiod, light intensity, ambient temperature and misters increased breeding activity. It was found that changing from a low-quality to a high-quality diet was not necessary to elicit a strong reproductive response. Of the remaining four factors it could not be determined if a non-stimulatory period was necessary or if the presence of any or all of the four factors was necessary to induce breeding.

Free-ranging populations of budgerigars were found to have minimal requirements for reproduction, including correct ambient temperature, day length and

water and food availability.[179] Captive budgerigars have similar requirements, which include sufficient food and water, a nest box with an opening at least ten cm below the nest box hole, combination of loud and soft warbles from the males and, in some cases, exposure to short photoperiods before the breeding season. Budgerigars are strongly stimulated by the vocalizations of other pairs.

Canaries respond principally to photoperiods, with low ambient temperatures causing a delay in egg laying.[179] Inducing reproductive activity in canaries requires exposure to a sequence of short photoperiods to abolish photorefractoriness followed by increasing day length to 14 hours of light. Providing a nest pan is not a prerequisite for ovulation and egg-laying in canaries but improves egg production.[182] In reproductive success in canaries, the presence of a male or male vocalizations plays only a modifying role compared to photoperiod.

Natural Incubation

Natural incubation is a behavior under hormonal control that can be externally affected by many factors. Improper parental incubation can lead to a complete lack of egg development, arrestment of embryo development, late embryo death or abnormal or weak chicks at hatch. Additionally, many species such as macaws tend to be rather nervous in captivity and are notorious for breaking eggs. Minor punctures and hairline cracks can cause the death of a developing embryo. Foster parents or artificial incubation can be used in pairs with incubation problems. Failures in incubation can also originate from embryo-related problems, diet or environmental factors. In a group of Hyacinth Macaws, natural incubation of the eggs and chick-raising did not occur until the diet contained 15% fat and 2.5% fiber with limited seeds and nuts (Harrison GJ, unpublished). Studying pertinent egg information and performing thorough diagnostic procedures can help determine the cause of some of these incubation failures.

Information Collection

The attending veterinarian should review existing records concerning the parent's reproductive and medical history and fate of any eggs or chicks. Developing an accurate and consistent record-keeping system and regularly scheduling on-site visits will help identify factors that could explain incubation failures (see Chapter 2).

Reproductive information from each pair including numbers of eggs per clutch, number of clutches per year, time of day eggs are laid, previous fertility and hatchability statistics, causes of egg failure and chick survivability will all help in evaluating a collection. To get a true fertility rate for a pair, one must necropsy all eggs as soon as possible after they are determined to be dead.

Fertility

Documenting if an egg is infertile or was fertile and died in early incubation is the first step in investigating egg problems. Eggs that are fertile but were not incubated or that failed to develop past two to five days of incubation will generally appear infertile when candled. These eggs should be opened to determine if they were fertile. Fresh, infertile eggs have a well organized small blastodisc, which in domestic species can be easily differentiated from the large, sometimes cottony or doughnut-shaped fertile blastoderm (Color 29.1). Old, addled or infected eggs in which fertility cannot be determined should not be included in fertility calculations. Additionally, any misshapen, mis-sized or otherwise abnormal eggs that are discarded should not be used in calculating fertility rates. The preferred method would be to include these eggs, as they can be fertile, or to calculate a separate fertlity rate for abnormal eggs. Hybrid eggs should also be discounted, as they may have decreased fertility. Fertility rates can be calculated by finding what percentage of the total number of eggs laid were fertile. Undetermined eggs should not be included.

Fertility rates can be useful for discerning problems within a flock or individual pair. Infertility can be a result of behavioral, environmental, nutritional and medical problems (Table 29.5). Factors that should be considered include age of the birds, time the pair has been together, time the pair has been in the aviary, enclosure type, enclosure location, production of eggs in the past, past fertility and hatchability, hybrids, inbreeding, date of lay, environmental parameters (temperature, humidity, day length, rainfall) and behavioral characteristics of the pair. Fertility within an aviary should be evaluated on an individual pair and species basis within an aviary. Fertility rates of free-ranging birds may vary among species due to natural physiological processes. Fertility is normally reduced in older birds, in younger birds and at the beginning and end of a breeding season. Infertility in these cases may be a natural occurrence and not an indication of disease.

Domestic poultry have been genetically selected to produce high fertility rates of approximately 95%.

TABLE 29.5 Causes of Infertility

- **Behavioral:**

Immaturity, pair incompatibility, normal species differences, normal occurrence as part of clutch, sexual inexperience, lack of early learning, aviary disturbances, lack of social interaction, excess social interaction, homosexual pairs, lack of pair-bonding, asynchronous breeding condition, improper imprinting, infrequent matings.

- **Environmental:**

Incorrect photoperiod, incorrect nest box design or nesting materials, incorrect enclosure design, lack of visual barriers, excessive rain, insufficient rain, temperature, humidity, availability of correct foods, loose or incorrect perches.

- **Medical:**

Obesity, age (young or old breeders), inbreeding, vent feathers, drug therapy (causing vitamin deficiency or direct, decreased fertility), previous hormonal therapy (testosterone injections), musculoskeletal, neuromuscular or other disease (causing pain, paresis, ataxia, weakness, decreased muscle tone or incoordination), neurologic disease (causing paresis, ataxia, lack of muscle control), reproductive tract disease, nutritional deficiencies or excesses, systemic disease, parasitic disease leading to malnutrition, cloacal abnormalities, abnormal cloacal pH, possible thyroid deficiency, toxins (pesticides, chemicals, mycotoxins).

The fertility rates of most free-ranging companion birds have not been determined, although in some species studies have indicated that fertility can be quite high. Captive companion and aviary birds have the potential for similar fertility rates but more commonly the rates are lower, probably due to a combination of environmental and dietary factors.[92] Free-ranging macaws do not necessarily nest and produce offspring each year. This cyclic production is probably related to environmental factors and not due to disease-related infertility. Aviculturists should establish their own fertility rates and standardize data so that comparisons can be made among similar aviaries.

Hatchability

Hatchability rates are determined from eggs that were known to be fertile. Including infertile eggs in hatchability statistics will artificially lower hatchability rates and confuse diagnostic efforts. Hatchability rates are calculated by finding the percentage of fertile eggs that successfully hatched. "Successfully hatched" may or may not include chicks that were weak and died soon after hatching from pre-nursery-associated problems. Hatchability rates can be calculated for individual pairs, separate clutches, different species, eggs incubated naturally, eggs incubated artificially and eggs that had various kinds of physical problems or that were manipulated during incubation or hatching. The more precise the hatchability statistic, the more diagnostic the information that is provided (Figure 29.16).

In domestic fowl, the hatchability of naturally and artificially incubated fertile eggs approaches 85 to 90%. With companion and aviary birds, this figure may be much lower, and ranges from 8% to 100% have been discussed.[29,92] Lower hatchability rates are probably due mostly to improper parent or artificial incubation techniques Aviculturists should be encouraged to develop their own standards for hatchability and then strive annually to improve their level of success.

The number of lethal or chromosomal abnormalities reported in companion bird species is low when compared to domestic species. Evaluating fertility and hatchability statistics from parents and sisters of breeding males may help identify lethal or semi-lethal genes in some family trees. Breeding tests may

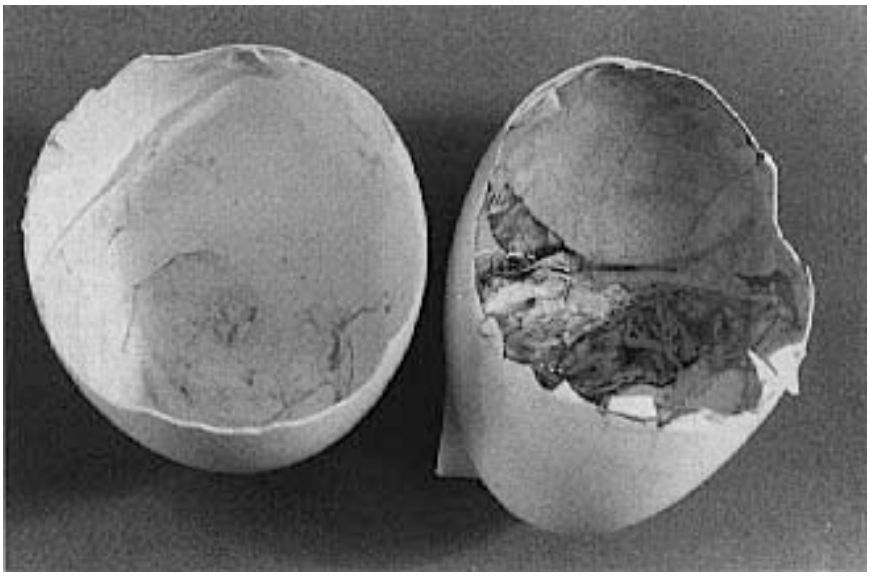

FIG 29.16 Complete and accurate hatching records can be indispensable in helping a veterinarian identify reproductive or neonatal problems. The egg on the left was from a normal unassisted hatch, and the chick from this egg was strong and developed normally post-hatching. The egg on the right was from a difficult hatch that required assistance. Note the retained blood within the membranes and excrement in the egg. The chick from this egg had intermittent problems with depression and slowed gastric emptying times for the first week of life.

TABLE 29.6 Causes of Death or Abnormalities in Embryos[92]

FIRST TRIMESTER
- Egg handling
  - Eggs stored too long
  - Eggs stored under incorrect conditions
  - Incorrect egg fumigation or sanitation (dirty hands)
  - Excessive vibrations (jarring)
  - Rapid temperature change
- High temperature in early incubation
- Incubation faults
  - Temperature, humidity, turning
  - Cooling after development has begun
  - Suffocation due to incorrect ventilation
- Inbreeding
- Chromosome abnormalities
- Egg-transmitted infectious diseases
- Parenteral nutritional deficiencies
- Abnormal or aged sperm
- Idiopathic developmental abnormalities
- Drugs, toxins, pesticides
- Cracked eggs
- Small holes in eggs

SECOND TRIMESTER
- Parenteral nutritional deficiencies
  - Riboflavin, vitamin B_{12}, folic acid, biotin, manganese, pyridoxine, pantothenic acid, phosphorous, boron, linoleic acid, vitamin K, vitamin D
- Secondary vitamin deficiencies
  - Antibiotic therapy destroying vitamin-producing flora
  - Diet imbalances, inadequate food intake
- Viral diseases
- Bacterial infections
- Fungal infections
- Egg jarring or shaking in the first trimester
- Incubator faults
  - Incorrect turning, temperature, humidity and ventilation
- Inbreeding resulting in lethal genes

THIRD TRIMESTER
- Malpositions
  - Inadequate or incorrect turning
  - Abnormal egg size or shape
  - Incorrect incubator temperature
- Incubator faults
  - Poor incubator ventilation
  - Egg cooling early in incubation
  - Inadequate or incorrect turning
  - Incorrect temperature
  - Incorrect humidity
- Incorrect hatcher temperature or humidity
- Long storage time pre-incubation
- Infectious disease
- Nutritional deficiencies
  - Vitamin A, D, E, K, pantothenic acid, folic acid
- Lethal genes
- Chromosomal abnormalities
- Idiopathic developmental abnormalities

be required to establish whether such genes are sex-linked or autosomal, dominant or recessive.

Parental Factors

The medical history of each parent should be examined to identify factors that may affect fertility and hatchability. Table 29.6 lists factors associated with embryonic death according to the stage of incubation (first to third trimester). A pair with persistent fertility or hatchability problems should be completely evaluated by performing physical examinations, complete cloacal examinations, cloacal and choanal cultures, Gram's staining and culturing of uterine samples (many uterine problems are anaerobic), complete blood counts, serum chemistries, radiographs, exploratory laparoscopies and evaluation of sperm. Exposure to toxic compounds, either directly or in the food or water, should be considered. Behavioral problems including lack of pair-bonding, inconsistent parental incubation and egg trauma in the nest may also cause hatchability problems.

Diet

Diets should be analyzed for adequate levels of protein, fat, carbohydrates, calorie content, minerals, fiber, calcium and vitamins and for the presence of aflatoxins. Total caloric intake and food selection behavior for each individual bird should be evaluated. Nutritionally deficient hens can produce eggs, but the low level of nutrients may prevent the eggs from hatching. The age of embryonic mortality will usually depend on the degree and type of deficiency or toxicity.

Severe hypovitaminosis A causes a complete cessation of egg production. Partial hypovitaminosis A may cause circulatory collapse and embryo death and has been suggested as a cause of egg binding. Vitamin E deficiencies can cause lethal rings in which the embryo is seen surrounded by a ring of separated tissue. Vitamin D_3 deficiencies can cause small eggs with poorly calcified shells. Ultraviolet light exposure may improve hatchability in these cases while excess D_3 may lead to a complete cessation of egg production. Embryonic hemorrhage is common with deficiencies in vitamins E and K. Vitamin K is also involved with calcium transport, and vitamin K deficiencies can mimic the clinical signs associated with hypocalcemia.

Calcium-deficient eggs exhibit reduced hatchability, poor shell calcification, embryos with rickets and excessive loss of water and weight during incubation. The calcium/manganese ratio regulates the rate of hatching, and imbalances of these minerals may cause early or late hatching. Given the wide variability in the types of food (and thus the composition of these foods) consumed by free-ranging birds of different species, it is not surprising that a single commercially available diet cannot meet the needs of all captive companion birds. For example, free-ranging

Hyacinth Macaws that feed on high-fat nuts may require nutrients contained in these foods for successful reproduction and embryo health. It is speculated that breeding third and fourth generations of companion bird species will result in higher fertility and hatchability rates in birds fed commonly available commercial diets (see Chapters 3 and 31).

Environmental Factors

Perches should be stable enough for breeding, and nest boxes of suitable size should be easily accessible (see Chapter 2). Nest box size and shape and bedding material should be evaluated. The microclimate of the nesting area, including temperature and humidity, is important for proper incubation and is adversely affected by soiled bedding and improper nest box design. Cultures from bedding material may help identify infectious agents. Ambient temperature, humidity and to a lesser degree rainfall, wind and barometric pressure may affect the success of parental incubation.

Pre-incubation Factors

Non-incubated, fertile eggs will not develop if held at 55°F to 75°F. Cockatiel eggs stored at 55°F and 60% relative humidity did not show decreased hatchability until after three to four days of storage.[33] Eggs can be incubated for two days, removed and placed at 55°F, and placed back in an incubator without a decrease in hatchability. These temperature manipulations are convenient for shipping eggs and for synchronizing hatching times.

Parents may not initiate incubation until more than one egg is laid. Under natural conditions, the failure of a parent to incubate the first egg when temperatures are not within safe preincubation ranges can result in the death of the egg. Exposure of eggs to temperatures that are higher than 55 to 75°F but below optimal incubation temperatures can cause death of the embryo. Parent behavior, climate and nest box characteristics may be responsible for lack of development or deaths in embryos during the first and last third of development.

Artificial Incubation

Hatchability of artificially incubated eggs is frequently lower than naturally incubated eggs.[36] Eggs that have been naturally incubated for the first five to ten days may have higher hatchability levels than eggs that are artificially incubated for the entire developmental period (Figure 29.17). The fact that different hatchability rates exist between natural and artificially incubated eggs highlights the need for a wider dissemination of information on successful incubation protocols.[1,24,33,53,65,81,122,165,166,184]

Many aviculturists prefer to use foster parents rather than artificial incubators, particularly during the first week to ten days of incubation. Foster parents must exhibit broodiness and be accepting of the shape, size and color of the foster eggs (see Chapter 6). Bantam and Silkie chickens have been used successfully to foster eggs from many psittacine species. The number of eggs under each foster parent should not exceed the number that the hen can adequately incubate.

Incubation Requirements

Important incubation factors include temperature, humidity, air flow in the incubator and hatcher, egg position during incubation, the angle for egg turning and the number of times per day the egg is turned. Incubator temperature and humidity affect the incubation period, and published incubation periods may vary with different incubation parameters (Table 29.7). Substantial research is necessary to establish the optimal incubator parameters for companion bird species. Most psittacine eggs are incubated at 99.1° to 99.5°F (37.3°

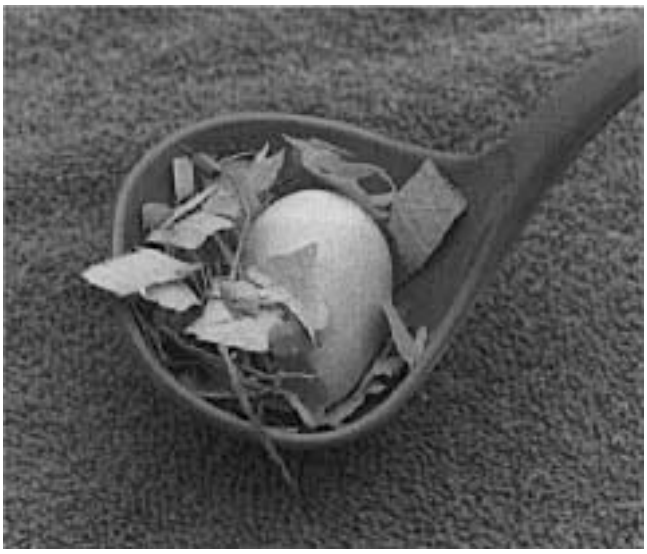

FIG 29.17 A plastic soup ladle makes an ideal tool for removing eggs from the nest. It has smooth edges and a long handle and can be easily sterilized between uses (courtesy of Apalachee River Aviary).

to 37.5°C) and 80° to 82°F (26.7° to 27.8°C) wet bulb, and hatched at 98.5°F (36.9°C) and 88° to 90°F (31.1° to 32.2°C) degrees wet bulb. Lower incubator humidities and higher hatcher humidities have also been described (Jordan R, unpublished). Research involving fertile cockatiel eggs determined that 99.5°F (37.5°C) with 56% relative humidity and 98.4°F (36.9°C) with 67% relative humidity were optimal settings for incubation and hatching, respectively.[33]

Temporary shifts in temperature (as long as not excessively hot or cold) probably have no effect on hatchability. Such fluctuations are common when the incubator door is opened and the eggs are candled. It is best to turn off the fan when the incubator door is opened. Daily temperature and humidity charts should be maintained for each incubator. Individual incubators may have hot or cold spots that affect hatchability, and placing numerous thermometers at different locations within an incubator can help to identify these areas. Thermometers and hygrometers should be calibrated frequently to make certain that they are accurate.

A 2°F excess in temperature during the first few critical days of incubation can result in embryonic death.[122] Increasing or decreasing the incubation temperature by 1.4°C caused poor hatchability and increased the incidence of abnormalities in cockatiel chicks.[33] Chicks produced by higher than optimal incubation temperatures were small, weak and dehydrated and frequently had umbilical openings and exposed yolk sacs. Scissor beaks, curled toes and wry necks were also common. Slightly higher temperatures will further increase mortality, and temperatures approaching 104°F (40°C) will kill all embryos.

Marginally lower-than-optimum temperatures may cause a delay in hatching. Temperatures that are constantly a degree or so lower than optimum have been shown to cause an increased number of "late dead" embryos, and if hatching occurs, chicks are weak with large, soft bodies and unabsorbed yolk sacs. Some chicks may be ataxic post-hatching. Hatching may occur several days later than expected. Low humidity results in lower egg weight, larger air cell size and small dehydrated chicks, possibly due to inadequate calcium mobilization for bone development.

Chicks from eggs incubated at high humidities may have excessive amounts of fluid, including residual albumen, that may obstruct the nostrils causing asphyxiation. Eggs should be turned at least five to eight times a day for at least two-thirds of the incubation period. More frequent turning, up to 24 times a day, may improve hatchability in Psittaciformes or with embryos suspected to have a lack of vigor or delayed development. Eggs should be positioned on their sides with the round or air-cell end slightly elevated. Poultry eggs tilted or placed in a horizontal position were found to have an increased incidence of malposition of embryos.[76]

Still-air incubator temperature requirements are usually higher than forced-draft incubators. Placing incubators in a room that maintains a relatively cool (70-80°F; 21-26°C), dry (50-60% relative humidity), environment is ideal. Extreme temperature and hu-

TABLE 29.7 Incubation Periods for Psittacine Species Common in Aviculture

Species	Incubation Period (days)	Pip to Hatch Interval (hours)

midity fluctuations (5°F or 5% relative humidity) in the incubation room should be avoided. Incubator ventilation, sanitation, abnormal vibrations, improper mechanized egg turning, inaccurate thermometers, inaccurate hygrometers and placement of incubators near walls and windows can all affect incubator function.[89] Incubators with horizontal grill-type turners may be too rough for sensitive embryos. Excessive jarring and shaking, particularly during the early stages of development, can result in embryo death or malformation. Improper egg position and faulty egg turning during development may result in malpositions and incomplete closure of the ventral body wall.

Hatchers should be evaluated in a manner similar to incubators (Figure 29.18). The success of the sanitation program and the presence of microbial contamination can be estimated with cultures of the incubator surfaces, water trays, egg trays, and incubator room floor, shelves and instruments.

Incubation Preventive Techniques

Prevention of most incubation problems involves correcting the three most common causes for decreased hatchability in artificially incubated eggs: improper temperature, humidity and egg turning.[89] Accurate record-keeping is mandatory for identifying hatching-related problems. A protocol for carefully evaluating incubator performance and stability should be followed.[89] Pre-conditioning incubators a month prior to breeding season and evaluating daily fluctuations in temperature and humidity in the incubator room and in the incubators may help identify problem areas. The egg-turning mechanism should be checked periodically to confirm that it functions at the correct time interval, maintains the necessary egg angle and does not excessively vibrate the eggs. Excessive vibrations have been associated with reduced hatchability.[184]

Bacterial and fungal agents infrequently cause problems in psittacine eggs, but occasionally a contaminated incubator, hatcher or incubator room can cause high egg losses. Water trays should be removed and disinfected daily and should be filled with distilled water. In the non-breeding season incubators should be dismantled, and non-sensitive parts should be thoroughly cleaned with a glutaraldehyde solution followed by a long period of air drying. Disinfecting incubators with formalin and potassium permanganate is extremely dangerous and cannot be recommended.

FIG 29.18 Plastic strawberry baskets with a section of small plastic mesh in the bottom make ideal hatching containers. They are safe, have no sharp edges and can be easily sterilized between uses. This hatching basket contains the perfectly opened egg from a Greater Sulphur-crested Cockatoo chick (courtesy of Apalachee River Aviary).

Periodic culturing of newly hatched chicks, eggs and incubator surfaces will indicate if bacterial contamination is occurring. A sterile contact tape can be used to culture nursery surfaces and eggs. An open microbiological agar plate can be placed in an incubator to determine what bacteria are present in the air. Incubators can be tested for the presence of PBFD virus or polyomavirus by taking swabs for DNA probing.

The incubator room should be kept scrupulously clean to prevent particulate matter from contaminating egg shell surfaces. Clothes and shoes worn around other birds should be removed or covered before entering the incubation area. Hands should be thoroughly washed with a disinfectant or gloved before handling eggs. Problems associated with incubation are listed in Table 29.8.

Eggs are relatively resistant to bacterial invasion, but eggs that may have been contaminated with infectious agents should be incubated separately from non-contaminated eggs. Feces and dried particulate matter can be gently sanded off the egg surface, although over-exuberant sanding should be avoided.

Chlorine dioxide foam may be a safe sanitizing agent for contaminated eggs,[125] or eggs can be washed with a warmed iodine solution (104°F) or immersed in warm water baths (110°F) for up to five minutes. Bacterially contaminated eggs can be dipped into a cold water antibiotic solution by warming the eggs to 37°C, and placing them in cold water (4°C) containing 1000 μg/ml of gentamicin solution.[161] Psittacine eggs should not be incubated with eggs from other species.

Monitoring the Embryo

Candling

A candling program allows one to follow developmental progression of an embryo and detect any abnormalities that may occur. Chicken eggs can be used for practice. Periodic candling will ensure the removal of non-developing eggs as soon as they are identified. This increases the likelihood that the cause of an embryo's death can be determined and reduces the possibility of an infected egg contaminating the incubator. Daily candling will improve an individual's ability to recognize developmental stages of the various species.

Initial candling of psittacine eggs should occur no later than six to seven days into incubation. The eggs should be handled with care to prevent sudden jarring or chilling from inducing embryonic death or malformation.[175] Shortly after oviposition, an egg may not have an air cell; this develops as the egg cools and the internal volume is reduced. It is during this initial cooling process that surface contaminants can be drawn into the egg. Eggs can be marked for identification using a #2 pencil (see Figure 29.4). Candling between the seventh and tenth day of incubation will indicate if an egg is fertile and whether it is developing normally. After the initial candling, eggs can be evaluated every two or three days if desired, and should be examined at least once just before transfer to the hatcher.

Candling naturally incubated eggs should be considered; however, the disadvantages of disturbing the adults and eggs must be weighed against the possible advantages of identifying eggs that need manipulation or intervention for hatching to occur. Candling to determine if the egg is fertile (five to seven days post-laying) followed by evaluation just prior to the expected date of pipping will usually be sufficient for evaluating parent-incubated eggs.

Extended flashlight type candlers may not satisfactorily illuminate eggs when ambient light is present, and more specialized tools may be required (Figure 29.19).[103] High intensity lights (heat) may injure embryos during early development.

TABLE 29.8 Chick Abnormalities Caused by Incubation Problems

Abnormalites	Possible Causes
Early hatch, thin, excessive vocalizations	Small eggs, species differences, high incubator temperature, low incubator humidity, high incubator or hatcher temperatures (bloody navels).
Late hatch	Large eggs, old parents, eggs stored too long pre-incubation, low incubator temperature, inbreeding.
Sticky chicks, albumen present	Low incubation temperature, high incubation humidity, incorrect turning, very large eggs.
Dry chicks, stuck to shell	Low humidity during egg storage, incubation or hatching, incorrect turning, cracked eggs, poor shell quality, high incubator temperatures.
Small chicks	Small eggs, low humidity during egg storage or incubation, high incubator temperature, high altitude, thin or porous shell, tetracycline used in hen.
Weak chicks	Variety of causes including incorrect humidity and parental malnutrition.
Umbilicus fails to close with varying degrees of unretracted yolk sac	Incorrect incubation temperature, low hatcher temperature, high hatcher humidity, parental malnutrition, omphalitis (can be caused by contamination or incorrect incubation temperature), inadequate ventilation.
Short, wiry down (species dependent)	Nutritional deficiencies, toxins (eg, mycotoxins), high incubation temperature first two trimesters.
Dwarf embryos, stunting in growing chicks	Egg contamination, heredity, parental malnutrition, possible hypothyroidism.
Short beak, missing beak, face, eye or head abnormalities	High incubator temperatures early first trimester, lethal genes, idiopathic developmental abnormalities, parental nutritional deficiencies (eg, niacin), low oxygen early first trimester, sulfa drug use in hen, insecticides, herbicides, excess dietary selenium, nicotine, viral.
Red hocks	Prolonged pushing on shell during pipping and hatching, parental vitamin deficiencies, thick shells, high incubator humidity, low incubator temperature.
Musculoskeletal or neurologic abnormalities	Incorrect incubation temperature (curled or crooked toes, splayed legs), low incubation temperature (bent necks, nervous disorders), high incubation temperature (ataxia, star gazing), low humidity, unsuitable hatching substrate, sulfa drug use in hen, insecticides (scoliosis, lordosis).

- ***Candling Data:*** Candling helps identify the degree of egg shell thinning, egg shell cracks, blood rings, meat spots, membrane and blood vessel integrity, heart rate, stage of development, development progression, air cell size and shape, and yolk size, color and shape (Colors 29.14 to 29.16). Candling later in incubation helps to evaluate malpositions, chick movement, size, shape and location, and internal pip-to-hatch interval (Colors 29.17, 29.18). Lack of embryo vitality can be recognized by poor vessel integrity, decreased movement and retarded development. Embryo death in early incubation results in cessation of development, blood rings and loss of membrane and vessel integrity. Late embryo death is somewhat harder to recognize due to the natural opaqueness of the developing embryo, but lack of

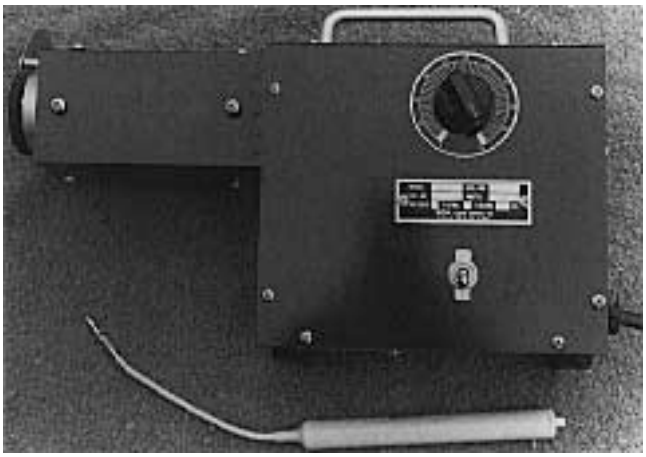

FIG 29.19 Small utility lights (below) can be used to perform basic candling tasks in dark areas, but have limited application for performing in-depth diagnostic evaluation of an egg. It is best to use a commercial candler (above) when detailed information on the developmental state of an egg is required (courtesy of Apalachee River Aviary).

vessel integrity and movement are indicative of late incubation deaths.

Egg Weights

Eggs should be weighed when they are candled, and weight loss rates can be recalculated throughout the incubation cycle. Air cell dimensions can be evaluated to provide an estimate of weight loss. Eggs from most Psittaciformes should lose an average of 12% to 13% of their weight from the beginning of incubation to the point of transfer to a hatcher. An additional 3% of weight should be lost during pipping.[24,81,130] Desired egg weight loss can be determined using a variety of mathematical formulas.[24,68,81,130] Egg weight loss is affected by egg shell porosity, air circulation, altitude, temperature and humidity.[24,26] Egg weight loss rates can be used to detect incubation problems and can also be used to manipulate the humidity or egg to ensure proper weight loss.

Egg Necropsy

Every egg that fails to develop or that dies should be necropsied. ("Breakout" refers to opening eggs for diagnostic purposes.) Candling cannot distinguish very early embryonic deaths from infertile eggs, and the presence of fertility is an important criteria when proceeding with a diagnostic program in avian reproduction. All data relating to the egg should be reviewed prior to necropsy. The veterinarian should be able to identify various embryologic structures and understand the physiological purpose of each structure that might be related to embryo death (see Table 29.2, Figures 29.2, 29.3).[1,44,55,135,137]

Necropsy should be performed on eggs or chicks as soon after death as possible to prevent rapid autolysis from destroying valuable information; however, one should always make certain that an embryo has stopped developing before initiating a necropsy. The majority of eggs for necropsy will fall into two distinct age groups: embryonic death at three to five days of incubation and death perihatching.[135] Early embryonic mortality is common with improper incubation temperature, jarring, inbreeding and chromosomal abnormalities. Deaths at the end of incubation are usually associated with hatching, and the stressful period of switching from allantoic to pulmonary respiration. Factors including improper incubation humidity, temperature and turning are thought to be the leading causes of late embryonic death in psittacines. Mid-incubation deaths occur in poultry embryos when the hen is fed a diet deficient in proteins, minerals or vitamins.

- ***Technique:*** All eggs should be candled before necropsy to determine the best point for entering the egg. This also permits the correlation of candling with necropsy findings. Eggs should be weighed and measured, and external shell characteristics (egg shape, egg size, external calcium deposits, cracks or thinning) should be noted. Pip marks should be evaluated for turning direction, location and size. Chicks normally pip counter-clockwise from the round end of the egg. The egg necropsy should be performed under sterile conditions until cultures have been taken of embryonic fluids and tissues.

The egg is opened over the air cell with sharp-blunt scissors. Shell membranes are examined for abnormalities and then carefully peeled back to expose the internal egg contents (Color 29.36). When exposed, the albumen and amnion can be cultured and visible microbial growth may be noted (Color 29.37). The chorioallantoic membrane (CAM) normally adheres to the inner shell membranes after the first trimester

CLINICAL APPLICATIONS

Egg Weight Formulas — Weight loss trend to pip:

([laid weight] - [current weight]) ÷ (# days incubated) = (average daily weight loss)

(average daily weight loss) x (total incubation period prior to pip) ÷ (laid weight) = (decimal percentage)

(decimal percentage) x 100 = (weight loss trend to pip)

(laid weight) = (species specific coefficient^{81}) x (length egg in mm x breadth^2)

of development. Adhesions of the embryo to the CAM are abnormal. Eggs that are not necropsied shortly after death may develop adhesions or sticky membranes. Late-term embryos have anatomical differences from adults, but are similar to young chicks.[114]

Internal egg membranes and structures should be evaluated before being altered by manipulation or culture techniques. A ruptured yolk sac can obscure the necropsy field. Color, size and location of the albumen, yolk and allantois is recorded. Presence and characteristics of the circulatory tree are observed. Abnormal odors should be noted.

Enlarging the hole over the round end of the egg is performed by careful removal of egg shell fragments with thumb forceps. If a small chick or no chick is identified, the contents of the egg can be carefully poured into a sterile container (Color 29.38). If a well developed chick is present, the position of the air cell with respect to the egg, orientation of the embryo as a whole within the egg, position of the head, beak and neck in relation to the body and position of the beak in relation to the air cell should be evaluated (Color 29.34).

Different malpositions have various success rates for hatching in domestic species, and many can hatch unassisted (Table 29.9). Although only six malposition classifications are traditionally discussed, there is an almost endless variety of malpositions that can occur, some of which are very subtle and require close inspection.

Psittaciformes appear to have different malpositions than domestic species.[28,29] Frequently the head appears on an even plane with the right wing, and the entire body may be rotated such that the spine is on a horizontal plane with the short axis of the egg. The significance of this malposition is not known. Common causes of malpositions include turning problems, incorrect position in the incubator, oxygen deprivation, excess CO_2, lack of embryo vigor and delayed development.[37]

If a chick can be seen in the egg, it should be weighed, measured and staged according to standards.[55] Remaining albumen, chorioallantoic membrane blood vessels and ruptured yolk or allantoic contents may adhere to the shell once the chick is removed. If size permits, the chick should have a full necropsy performed, being careful to keep the yolk sac membrane intact. Special attention should be given to the hatching muscle for size, edema and hemorrhage. Other gross evaluations, including skin color and hemorrhage, musculoskeletal deviations, internal hemorrhages and contents of the mouth, nares, crop and esophagus, should be made. The liver may be hemorrhagic from exuberant kicking, especially if a chick was malpositioned (Color 29.39).

The hatching muscle (Muscularis complescus) is a primary storage site for lymph in the embryo and is normally enlarged perihatching. Lungs are evaluated for evidence of air intake or for the presence of fluid, although this differentiation usually requires histopathology. Tissues should be fixed in formalin for histopathologic evaluation. Eggs can be frozen for future analysis of toxic substances.[96]

At hatching, a chick's weight, activity, vocalizations, body measurements and degree of yolk sac retraction and the presence of any abnormalities should be recorded. Monitoring chick growth rates, food intake, behavior and development progression can help detect any subtle problems that may occur.

Microbiology of Eggs

External egg structures prevent but do not stop microorganisms from entering the egg. Bacteria located in an egg could suggest environmental contamination that occurred after embryonic death. If the ne-

TABLE 29.9 Classic Malpositions of Chick Embryos

Malposition 1:	Head between the thighs. Failure of the chick to lift and turn its head to the right in the middle of the last trimester. Completely lethal. Incidence increased by high incubation temperature.
Malposition 2:	Head in the small end of the egg. Chick is upside down in the egg. Hatchability reduced by 50% in domestic species. Incidence increased by incubator egg position and low temperature.
Malposition 3:	Head is under the left wing. Chick rotates its head to the left as opposed to the right. Usually lethal. Incidence increased by incubator egg position, temperature and parental malnutrition.
Malposition 4:	Beak is away from the air cell. Upward turned aspect of maxilla and egg tooth is not near the air cell; however, the rest of the embryo is normally positioned. Slightly reduced hatchability. Incidence increased by incubator egg position.
Malposition 5:	Feet over head. Usually lethal.
Malposition 6:	Head is over the right wing. Normally the head is under the right wing in domestic species. Psittacines may normally hold the head in the same plane as the wing. Reduces hatchability slightly in domestic species. Incidence may be increased by parental malnutrition.

cropsy is performed immediately following embryonic death, finding bacteria in the embryo can indicate bacteremia or an infected ovary or oviduct in the hen. Bacterial contamination of an egg usually originates from the atmosphere, the nesting area or the surface of the cloaca.[25]

In poultry, reducing microbial loads in nest shavings does not increase hatchability, although it does decrease bacterial contamination in dead or dying eggs. With duck eggs, however, hatchability and chick hatch weight could be increased by having clean eggs (not visibly soiled).[82a] Generally, egg infection is not caused by environmental contamination although the type and concentration of bacteria in the nest box can definitely increase the likelihood of an egg infection. Eggs with hairline cracks, pinpoint punctures and thin shells are more prone to colonization by microorganisms. Reduced cuticle deposition, which occurs in older birds, does not affect hatchability except in extreme instances, but will affect the number of dead or dying eggs that are bacterially contaminated.

Egg structures are affected by bacteria in different ways. The source of persistent egg infections may be identified by culturing the hen's cloaca, nest box contents, the exterior egg shell, albumen, yolk and embryonic tissues. Gram-positive bacteria occur mostly on the surface of the egg, and the insides of contaminated eggs contain mostly gram-negative bacteria.[15] Chicks that are infected in the egg usually die with macroscopic yolk lesions (coagulated yolk and yolk sac hemorrhages) (Color 29.39). In other cases, embryos may die before the production of macroscopic changes in the yolk and a histological examination is necessary to establish the presence of an infection.[63]

Egg Therapeutics

Treatment of bacterially infected eggs is possible although preventing infections is more effective. Medical intervention should be attempted only in those cases where the embryo is at risk of dying. Perpetuation of weak genetic lines in companion birds may be exacerbated by assisting in the hatching of troubled eggs.

Pre-incubation

Defects in egg shells can be repaired by using sparing amounts of Elmer's glue, surgical glue or paraffin. Thick or excessively large applications of these substances can retard air exchange or create difficulty for the chick during hatching. It has been suggested that large defects can be covered with egg shell remnants from other eggs, although the prognosis for these eggs should be considered poor.[165] Tremulous air cells resulting from trauma or weak shell membranes may indicate blastoderm shock and ruptured shell membranes. Eggs with tremulous air cells usually have reduced hatchability but should not be discarded because embryos may develop and hatch normally.[90] These eggs should be hand-turned as should all eggs with suspected shell or membrane defects.

Incubation

Manipulation of eggs before the point of hatching should be limited. The most frequently used techniques are designed to change the weight loss of an egg. Eggs can be moved to higher or lower humidity incubators based on weight loss. Eggs can also be gently sanded or have small holes placed in them over the air cell to increase weight loss. Paraffin can be used to partially cover the egg to reduce weight loss although no more than 60% of the area above the air cell or total air cell surface should be coated.[26] Sealing a large portion of the air cell may decrease oxygen intake and cause the embryo to invert within the egg. Eggs that have had their shell altered should be hand turned to keep the sealant intact and to reduce chances of damaging the shell. Irregular or weak vascular patterns may be corrected by increasing the turning frequency (Thormahlen M, unpublished).

Injecting sterile lactated Ringer's solution into severely dehydrated eggs has proven successful in some cases.[26] Injection of sterile water into the small end of the egg (albumen) during the first half of incubation led to addled eggs in one study[150] but was of benefit if given later in incubation. Replacement volumes to be given are calculated from egg weight deficits. Injecting antibiotics (piperacillin 200 mg/ml, 0.02 ml for macaw eggs, 0.01 ml for cockatoo eggs) into bacterially contaminated eggs has been attempted with some success.[108] If done properly, injecting gentamicin into the albumen was not found to lower hatchability.[27]

Small dental drills or needle puncture holes can be used to make a pathway for delivering injections into either the small end of the egg or over the air cell. Holes should be resealed with paraffin or glue. Preincubatory egg injections with 2.4 mg of tylosin and 0.6 mg of gentamicin was successful in eliminating *Mycoplasma meleagridis* from turkey poults.[105] Ap-

propriate drugs, dosages, site of inoculation and timing of inoculation for companion bird species have not been determined, and egg injections should be avoided except in special cases.

Late Incubation

As the expected hatch date approaches, the egg should be candled frequently to monitor changes in the configuration of the air cell. As the chick develops, the head comes to lie under the right wing, with the tip of its beak directed towards the air cell.[122] When the air cell drops and enlarges, the hatching process has begun and a chick begins the transition from chorioallantoic circulatory respiration to pulmonic respiration. As the circulation to the allantois no longer has the capacity to meet the embryo's needs for gas exchange, the chick begins to move its head to the air-filled end of the egg. This stage of hatching can be observed only by candling. Some chicks will begin to vocalize during this period. The CO_2 level in the embryo rises causing the neck muscles to twitch, and the embryo will penetrate the membrane into the air cell. At this point, the embryo begins to breathe air, and the patent right-to-left cardiovascular shunts close.[122] The muscle twitching also occurs in the abdominal musculature initiating retraction of the yolk sac into the coelomic cavity.[122] As the chick becomes more active and depletes the oxygen in the air cell, its carbon dioxide level increases to 10%, producing even stronger muscle contractions of the neck until the beak creates a puncture in the shell.[122] At this point the chick is breathing room air and vocalizations can be heard. External embryo structures such as the yolk sac or enlarged allantois can be accidently ruptured during the pipping process.

Once eggs have started to pip and are transferred to the hatcher, they should be left undisturbed. As it hatches, the chick alternates between jerking head movements, which continue to chip the shell, and prolonged muscle contractions of the neck and back, which straighten the neck and force the body to rotate slightly counterclockwise. When these muscles relax, the head is in a new position, and additional jerking movements chip a different portion of the shell. During this process, called cutting out, the chick rotates within the shell 360°, cracking the shell circumferentially (see Figure 29.16). Eventually, the chick will push off the top of the shell and emerge. In most cases the process proceeds normally and a healthy chick emerges.

The average incubation period and pip-to-hatch interval of each species varies (see Table 29.7) and eggs that deviate from these average values can successfully hatch without assistance. Premature intervention in the hatching process can cause embryonic death. Proper intervention at the correct time can definitely result in a hatched chick that would have otherwise died. The amount of assistance required is difficult to determine but it is generally best not to rush the hatching process, but to gently assist each stage as necessary. Pip-to-hatch intervals are 36 to 48 hours in most species and hatching times of less than 24 hours and greater than 80 hours usually indicate a problem.[54] Chicks that pip one-fourth to one-half of the egg and then stop for an extended period of time, or that reverse direction and return to the pip site, usually require assistance.[68]

Eggs that lose an abnormal amount of weight or contain a malpositioned chick can hatch, although hatchability is generally reduced. The timing and degree of intervention is dictated by the recession of active blood vessels, yolk sac retraction and extent of delayed hatching. A weak chick may also require assistance with hatching. Weak chicks will emit faint and infrequent vocalizations. These chicks may be normally positioned and may have appropriately entered the air cell; however, if the hatching process is delayed, the embryo may be in jeopardy.

Chicks can be safely removed from their eggs if the yolk sac and blood vessels have retracted. In general, chicks that have made one quarter of a turn during pipping can usually be safely removed from the egg. Chicks can bleed to death or rupture their yolk sacs if removed prematurely, although in some cases minor bleeding and a partially unabsorbed yolk sac must be accepted to remove a chick before death occurs. Candling or dampening the inner shell membrane with sterile water will help elucidate the position of unretracted blood vessels. Once chicks pip internally, it is important that they have an unoccluded path for air intake. Malpositioned chicks or chicks with delayed albumen ingestion may need egg shell fragments removed and fluid cleared from their nares.

If drawdown fails to occur, little can be done to assist the chick. The transition from allantoic respiration to breathing air is delicate and timely. Forcing the process will result in the death of the chick. If internal pip has occurred but external pip does not, a small hole can be safely created in the air cell to provide a source of fresh air. If there are no signs of external pip after 36 hours from drawdown, a breathing hole should be created. The breathing hole need only be a few milli-

meters in diameter and can be created using a bur with or without magnification depending on the size of the egg.

To perform an ovotomy, the egg is candled and the air cell identified and marked with a soft pencil. The shell over the air cell is cleaned with dilute chlorhexidine or povidone iodine. It is important to keep the ovotomy site totally over the air cell where there are relatively few blood vessels in the outer shell membrane. If the shell is opened over any other area of the egg, severe, life-threatening hemorrhage may occur. Vessels that are regressing take on a ghostlike appearance and are often only partially filled with blood.

If, after providing a breathing hole, external pip still does not occur, the shell should be removed over the air cell. This procedure is usually performed 48 hours after drawdown or early on the scheduled hatch date if it is accurately known.[81] Using a bur, the shell is removed without disrupting the outer shell membrane, which lies directly below and attached to the shell. A circular area of shell 0.5 to 1.5 cm in diameter should be removed, depending on the size of the egg. Once the shell has been removed, the outer shell membrane should be moistened with saline on a cotton-tipped applicator. Once moistened, the membrane becomes translucent, making it easy to identify any vessels that might need to be coagulated using bipolar radiosurgical forceps. After the vessels are coagulated, the membrane can be opened with the bipolar forceps revealing the chick within the air cell.

If the chick has entered the air cell, there will be a small nick in the inner membrane through which the beak has penetrated allowing respiration. The inner membrane is generally moister and more translucent than the outer shell membrane, except in the area where the beak has penetrated. In this region, the vessels retract and the membrane will usually appear dry and white. The inner shell membrane is delicate and highly vascular. The membrane should be carefully manipulated to prevent tearing. The entire exposed inner shell membrane will rapidly desiccate and should be kept moist by adding drops of warm, sterile saline or lactated Ringer's solution. Small quantities of fluids should be used to keep the chick from drowning. If the membrane is opaque, it is not properly hydrated.

At this point the position and status of the chick may be assessed. A major cause of late embryonal death is suffocation caused by occlusion of the nares by the inner shell membrane. The bipolar forceps may be used to coagulate the vessels around the site of membrane penetration followed by the creation of a small circular defect in the membranes. Removing this tissue allows the chick to breathe and prevents the membranes from occluding the nares.

For a successful hatch to occur, there must be an increase in CO_2 within the air cell to stimulate the chick to struggle, which ensures retraction of the yolk sac and the break out from the egg. The hole created in the shell can be partially sealed to allow this increase in CO_2 to occur. A stretchable, wax type test tube sealant can be used to effectively seal the hole created in the shell. The edges should be smoothed out and the egg returned to the incubator. An alternative solution is to place the egg in a small plastic bag with moistened sterile gauze. The bag can be partially sealed to allow an increase in CO_2 to develop, and the moistened gauze will ensure adequate humidity.

Chicks that are slightly malpositioned may create an external pip below the air cell. Strong chicks will continue to move their head toward the air cell creating additional external pips along the way. Appearance of more than one external pip may be an indication that the chick is malpositioned and may need assistance. If the pip is properly located, the egg should be returned to the incubator with the pip up. If the pip is on the opposite end of the egg from the air cell, it is likely that the chick is inverted and will need major assistance. If the pip is close to, but not within the air cell, intervention is indicated (see Chapter 41).

Embryo Extraction

The time period between external pip and hatching varies with species, shell thickness, incubation regimen, genetics and the strength of the chick. These factors make it difficult to determine when intervention is indicated. Embryos that enter the air cell prematurely may defecate inside the shell causing a compromise in the normal metabolic management of waste (see Figure 29.16).

When sufficient time has passed that the risk of fecal contamination is high or if the chick appears to be weakening based on decreased vocalizations and movements, the hole in the shell and shell membranes should be enlarged to allow gentle extraction of the chick's head and neck. The chick should be grasped by the beak and gently pulled out of the shell to allow visual inspection of the yolk sac (Figure

29.20). If the inner shell membranes have not adequately retracted, the yolk sac will still be visible, (incompletely absorbed). If no feces are found, the chick is gently replaced and the egg is sealed to allow hatching to proceed. The chick should be re-evaluated every one to three hours for the presence of feces. If the chick appears weak, oral administration of 5% dextrose solution may be beneficial. This can be alternated with lactated Ringer's solution to provide additional electrolytes. Since embryos are very susceptible to drowning, it is best if the solution can be placed into the esophagus or ingluvies using a 1 mm diameter silicone catheter or metal feeding tube. Excessive quantities of fluid should be avoided to prevent the accumulation of fluids in the allantois, which may increase the potential for membrane ruptures or delayed yolk sac absorption.

Once feces are observed within the shell, the chick should be removed. The chick is gently extracted with care taken to control hemorrhage from any unretracted vessels. The major attachment of the chick to the shell is in the area of the umbilicus where the vessels of the inner shell membrane attach to the yolk sac and umbilicus. The chick is extracted to a point where these vessels are visible and a vascular clip can be easily applied. The vessels are transected using radiosurgery and the chick is completely removed from the shell.

Aggressive hatching assistance is indicated for inverted chicks to prevent their dying of hypoxia or drowning. The earliest indication that a chick is inverted is an external pip at the small end of the egg. In approximately one of three inverted chicks, the air cell will have drawn down far enough to supply the chick with air. This is beneficial as the key to saving inverted embryos is providing air and enough time to allow retraction of the yolk sac. A breathing hole should be created over the air cell, which will change the pressures within the egg and allow the embryo to slide down into the large end of the egg and the air cell to migrate to the small end of the shell.[81] The original pip site should be enlarged, with care taken not to damage the vessels within the membranes. If bleeding occurs it should stop in ten seconds. Sustained bleeding of chorioallantoic membranes can be stopped by applying pressure with sterile swabs or with the careful and specific application of a chemical coagulant such as silver nitrate. Experimentally, excessive bleeding can be controlled by placing injectable vitamin K sparingly on the bleeding CAM. Dehydrated chicks can be given fluids orally or subcutaneously while still in the egg. A small amount

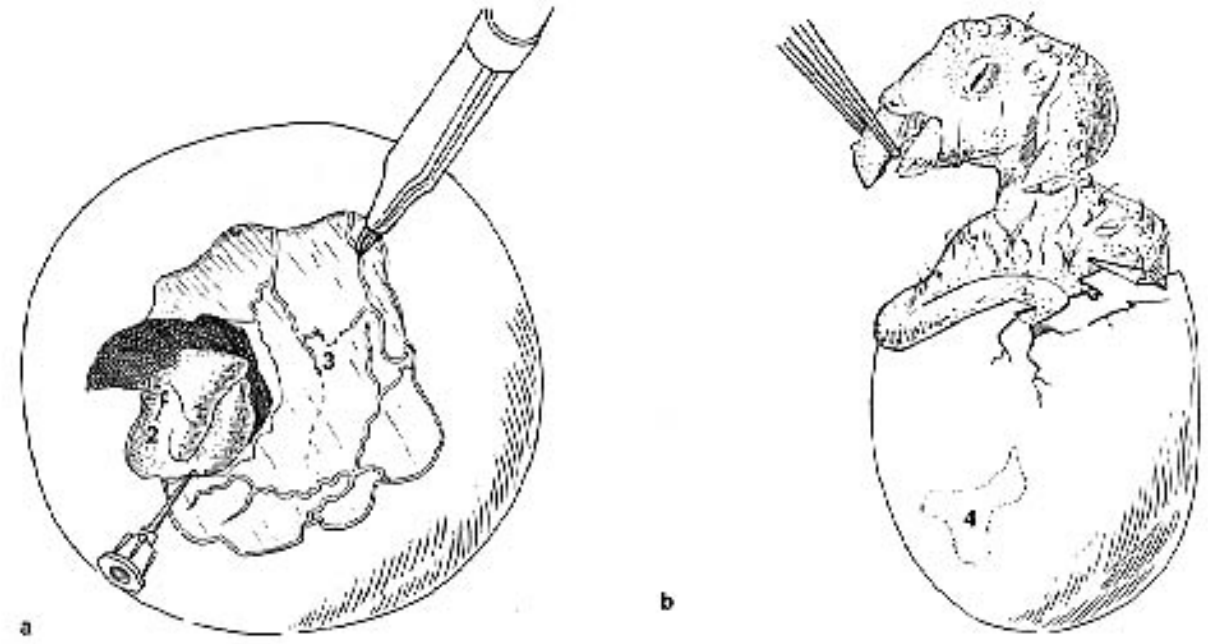

FIG 29.20 **a)** Assisting with the hatching procedure can be a life-saving procedure in some situations. The most important factor is to ensure that the chick's nostrils are clear of the shell membranes so that it can breathe. The avascular membranes can be gently teased away from the nostrils using a hooked needle. Radiocautery is used as needed to control bleeding. **b)** Smooth, plain pick-ups can be used to grasp the beak across the egg-tooth to elevate the head and evaluate the progresion of yolk sac absoption. If the yolk sac is not absorbed, the head should be replaced, the end of the egg should be partially covered with parafilm and the egg should be returned to the hatcher. If the yolk sac is absorbed, the chick can be removed. 1) egg tooth, 2) nare, 3) receding vessels and 4) ghosted yolk sac (modified from Stoodley).[165]

Theriogenology

Color 29.19
Normal left melanistic ovary in a mature Umbrella Cockatoo hen (open arrow). The cranial, middle and caudal divisions of the kidney are clearly visible. The inactive ovary is found in its normal location at the cranial medial border of the cranial division of the kidney. The right and left adrenal glands (arrows), the ischium (i), the pubis (p) and the ureter (u) are also visible.

Color 29.20
A 25-year-old Scarlet Macaw hen was referred with a history of egg binding that had supposedly been resolved with a hysterectomy. The hen was losing weight, regurgitating and had a distended, painful abdomen. An exploratory laparotomy indicated peritonitis and a fibrous constriction of the bowel. A side-by-side intestinal anastomosis was performed, but the bird did not recover. Necropsy findings included an abdominal egg yolk (arrow) and a fully developed left oviduct (open arrow). The abnormal development of a right ovary (also present here) can predispose a hen to reproductive problems.

Color 29.21
Infectious salpingitis with secondary infection of the ovary. A normal follicle (arrow) is seen adjacent to degenerating, hemorrhagic follicles (open arrows). The lungs (l) are also visible (courtesy of R. Korbel).

Color 29.22
A 23-year-old Amazon parrot hen was presented with a history of progressive abdominal swelling and weight loss. Cytology of fluid collected by abdominocentesis revealed a modified transudate. Radiographs indicated a diffuse soft tissue opacity in the intestinal peritoneal cavity that was pushing the ventriculus cranially. The bird did not respond to supportive care. The ovary (arrow) was reddish-brown, enlarged, firm and contained numerous hemorrhagic follicles. Histopathology indicated cystic follicular degeneration and bacterial hepatitis.

Color 29.23
Grayish-yellow, nodular follicles in a gallinaceous hen with a Marek's disease virus-induced ovarian neoplasm (courtesy of R. Korbel).

Color 29.24
a) Ovary and oviduct from a normal 22-month-old ostrich hen. Note the size of the oviduct and suspensory ligament. **b)** Close-up view of the ovary showing several follicles that are beginning to mature (courtesy of Brett Hopkins).

Color 29.25
A reproductively active Sun Conure was found dead in the nest box. The bird was in excellent overall condition and had delivered a normal fertile egg two days prior to presentation. The liver was enlarged, friable and congested. Histopathology indicated acute gram-negative bacterial hepatitis. Several active ovarian follicles (arrow) and the size of the oviduct (open arrows) in a reproductively active hen are evident.

Color 29.26
An Amazon parrot hen was presented for necropsy following several days of anorexia, depression and straining to defecate. A firm mass was present in the caudal abdomen. Necropsy indicated the retention of an egg (open arrow) in the caudal portion of the uterus. The degree of dilatation and hyperemia of the uterus (arrow) are evident. Histopathology indicated bacterial salpingitis.

Color 29.27
An Umbrella Cockatoo hen was presented with a three-day history of depression following the delivery of its first egg of the season. Radiographs indicated a granular, soft tissue opacity in the intestinal peritoneal cavity that was pushing the proventriculus and ventriculus cranially. Clinicopathologic changes included WBC=35,000 (toxic heterophils), AST=1500, LDH=1200 and calcium=8 mg/dl. An exploratory laparotomy indicated diffuse peritonitis with adhesions throughout most of the abdominal cavity. The bird was euthanatized. At necropsy, necrotic, brown, fibrous, peritonitis-related material was located on most of the abdominal organs.

Color 29.28
Egg-related peritonitis in an Amazon parrot hen with chlamydiosis. The bacterial peritonitis was considered to have occurred secondary to the chlamydial infection.

Theriogenology

Color 29.29
Typical presentation of an impacted egg. In this conure, the excessively large egg was lodged in the caudal uterus and vagina. The egg was removed by performing ovocentesis through the cloaca and collapsing the egg.

Color 29.30
a) An impacted egg in the cloaca of a budgerigar. Note the vagina (arrow). **b)** The egg could be seen through the vent and was removed by performing ovocentesis and gently removing the fractured portions of the eggshell.

Color 29.31
A mature cockatiel hen was presented with a one-day history of depression and tenesmus. The client became extremely concerned when blood was noted in association with a mass protruding from the cloaca. The hen had a prolapsed uterus that contained an egg. The egg was removed and the uterus was coated with a steroid-containing antibiotic ointment and was gently replaced in the cloaca with a moistened cotton-tipped applicator. Retention sutures were placed on both sides of the cloaca. These sutures were removed two days later, and the hen had no further problems.

Color 29.32
Mild prolapse of the vagina in the immediate post-oviposition period (courtesy of Kim Joyner).

Color 29.33
a) A necropsy should be performed on every egg that fails to hatch. In this case, a Moluccan Cockatoo embryo pipped three days earlier than expected. The embryo was properly positioned, but the excessively large embryo was preventing the development of a normal air cell. **b)** Hyperemia in newly hatched chicks is characteristic of dehydration or septicemia. In this excessively large (32 g) Moluccan Cockatoo embryo, the hyperemia was believed to have been caused by struggling in the egg and anoxia.

Color 29.34
Malposition 2 in an Umbrella Cockatoo chick. Note that the head is positioned at the pointed end of the egg opposite the air cell (courtesy of Kim Joyner).

Color 29.35
Soft-shelled eggs with depigmentation from a gallinaceous hen with salpingitis (courtesy of R. Korbel).

Color 29.36
During an egg necropsy, the membranes should be gently peeled away using fine-tipped forceps to ensure that all underlying structures are examined (courtesy of Kim Joyner).

Color 29.37
Fungal infection in a macaw egg. Note the proliferative growths on the eggshell membranes (courtesy of Kim Joyner).

Color 29.38
Examination of a dead-in-shell embryo should be performed sterilely to allow the collection of diagnostic culture samples. In this case, the egg has been opened and its contents have been placed in a sterile petri dish for further evaluation. The partially autolyzed, 20-day-old embryo and the yolk sac are easily distinguishable. Note the blood-tinged fluid, indicative of hemolysis.

Color 29.39
A dead-in-shell Eclectus Parrot embryo with hemorrhage of the liver and a ruptured yolk sac. These are common findings in embryos from bacterially contaminated eggs. Note the well developed pipping muscle that is a major storage site of lymph in the developing embryo.

of air (depending upon the size of the egg) may be injected into the egg through the original pip site to infiltrate under the membrane and expand it in any areas not trapped by the shell.

The egg should then be returned to the incubator with the pip site elevated at a 45° angle. Air should be injected through the pip site every two hours for the first day. On the second day, the pip site should be enlarged. The membranes should be left dry allowing the shell to separate from the membranes more easily. During the second and third days, the membrane should be gently and very gradually torn around the pip site allowing vessels to retract between manipulations. Eventually, as the shell is removed from the small end of the egg, the yolk sac should be visualized to determine if it has retracted. Once the end of the shell and its associated membranes are removed and the yolk has retracted, the chick will usually emerge without further assistance.

Altricial birds have a relatively small yolk sac at hatching because the parent birds begin to feed the hatchlings almost immediately. Conversely, precocial birds have a relatively large internal yolk sac because they leave the nest soon after hatching. Over the subsequent several days they learn to select food items by observing the parent birds. During this time period, they maintain their nitrogen balance with the aid of the residual internalized yolk sack. The internalized yolk sac of altricial birds comprises five to ten percent of their total body weight and of precocial birds is 12 to 25%. Additionally, altricial birds use their internalized yolk sac faster than precocial birds.

Unabsorbed yolk sacs are best left unattended and allowed to fully retract. This may require leaving a chick in the egg for several hours longer than normal so that the shell protects this fragile sac. Small umbilical protuberances can generally be ignored although the chick should be handled carefully until the umbilicus is sealed. Frequent application of disinfectants such as iodine solutions will prevent infections of the umbilicus and yolk sac. Larger protuberances can be carefully placed into the abdomen with the aid of a swab dipped in a water-based sterile ointment. The umbilicus is then sutured or surgically sealed with glue.

Surgical ligation and removal of the yolk sac may be needed in cases with a persistent or very large external yolk sac (see Chapter 48). Chicks that require amputation of the yolk sac can survive but have higher mortality levels. The chick is anesthetized with isoflurane to prevent traumatic injuries to the yolk sac and a hemostatic clip is applied to the umbilicus between the chick and the yolk sac. Two sutures (8-0 to 10-0) are placed to aid in closure of the umbilical opening with care taken to place them shallow enough to avoid penetrating umbilical vessels. The hemostatic clip is outside the body and an occlusive dressing is applied to protect the umbilicus. Occasionally, herniation of intestinal contents can occur through the umbilical opening while the chick is still within the egg. The prognosis is poor in these cases, although surgical resolution of the hernia should be attempted. Exteriorized tissues should be adequately cleaned with sterile saline and kept moist with the application of ointments if necessary. Umbilical openings can be surgically enlarged if necessary to replace herniated intestines (see Chapter 41).[68]

Appreciation is extended to G. J. Harrison and R. Avery Bennett for detailing the surgical aspects of assisted hatches.

CHAPTER

30

NEONATOLOGY

Keven Flammer
Susan L. Clubb

Care of pediatric patients is becoming an important segment of avian medicine as legislation and economic factors continue to restrict the importation of wild-caught psittacine birds. Because most birds entering the pet trade come from domestic sources, it is to the advantage of avian practitioners to become knowledgeable in avicultural and pediatric medicine.

Birds may be classified according to their state of maturity at hatching. Precocial birds such as pheasants, ostriches and waterfowl are covered with down and are able to see, walk and feed themselves at hatching. Altricial species such as psittacine birds, song birds and pigeons are helpless at hatch. Most altricial birds are born naked with their eyes closed and depend totally on their parents for food and warmth. Neonates lack a fully competent immune system and are more susceptible to disease than older birds. Because they are helpless, the conditions under which they are maintained, the diet they are fed and the amount of parental care they receive all have a profound influence on their health.

Genetics, incubation and nutrition all affect the early survivability and growth of the chick. A chick with a poor start may develop clinical problems much later in life.

Options for Raising Birds

Chicks can be raised by their parents, by avian foster parents or by humans (hand-raised). Each of these options has particular advantages and disadvantages.[9,18]

Parent-raising

Allowing the parents to raise their own offspring has some advantages if the parents provide adequate care. It saves the considerable labor associated with hand-feeding, and parent-raised chicks usually develop faster (Figure 30.1). Parent-raised birds may also acquire species-specific behavioral traits that may be lacking in hand-raised chicks. For example, hand-raised Thick-billed Parrot chicks failed to show normal flocking behavior, suggesting that parent-raised chicks may be more desirable for reintroduction programs. Roudybush found that compared to parent-raised birds, hand-raised male cockatiels inseminated females less frequently, and hand-raised females laid more eggs but often failed to lay them in the nest box.[30] This work has not been repeated in other psittacine species. It is known that hand-raising does not prevent normal breeding behavior, and many aviculturists believe that hand-raised chicks are better adapted to captivity and will breed sooner than chicks raised by other means.

There are disadvantages to leaving nestlings with the parents. Captive parents do not always provide optimal care and may traumatize, fail to feed, improperly feed or abandon chicks, especially if there are disturbances in the aviary (Color 30.9). The chicks may also be exposed to diseases carried by the parents. Chicks that are parent-raised beyond the pin-feather stage are also more difficult to tame and are less suitable as pets. Many aviculturists elect to hand-raise the larger, more expensive psittacine birds. Parent-raising is most often used with small, highly productive species such as cockatiels, lovebirds and budgerigars where the cost of hand-raising is difficult to recover upon sale of the bird.

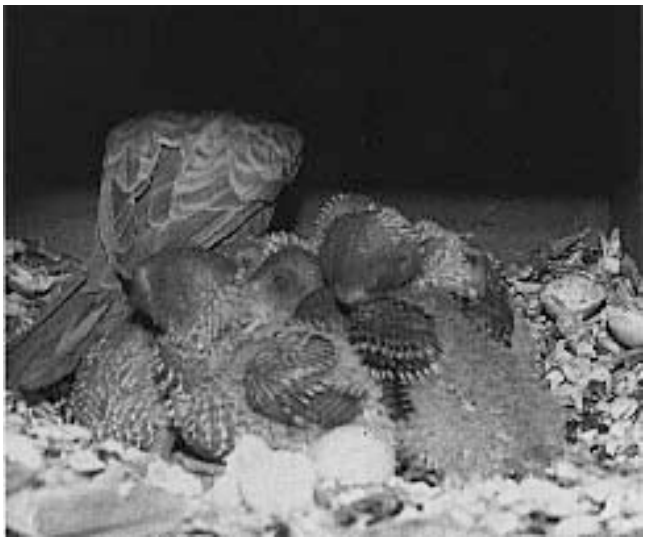

FIG 30.1 Allowing parents to raise neonates saves time and would be indicated for any offspring being considered for breeding or reintroduction to the wild. Hand-raised birds may make better pets (courtesy of Deanna Shafar).

Fostering

Fostering refers to moving eggs or babies from one nest to another. Some bird species (eg, Society Finches and canaries) make excellent foster parents and will feed neonates from species other than their own. Fostering is necessary when chicks are from neglectful or abusive parents or when there are large differences in the sizes of the chicks or between the times the eggs hatch. Fostering may also be used to increase production by removing eggs from a productive pair, which will stimulate them to lay more eggs. In most cases it is desirable to foster eggs rather than chicks, and the foster nest should have eggs or chicks of a similar age. Society Finches may foster chicks of any age. Fostering may spread disease, and the medical histories of both sets of parents should be established before considering cross-fostering.

Hand-raising

Aviculturists may hand-raise birds for the following reasons:

- To produce a tame bird that will socialize with people.
- To increase production by encouraging a pair of birds to lay additional clutches.
- To raise offspring hatched from artificially incubated eggs.
- To save sick or abandoned offspring.
- To reduce the burden of parental care on a compromised parent.
- To prevent or reduce the transmission of diseases from the parents to the neonate.

The disadvantages of hand-raising include the intensive labor required to feed birds and the threat of disease outbreaks that can occur when multiple nestlings from different pairs are concentrated in a nursery. Hand-raised birds seldom gain weight as quickly in the initial week of growth as parent-raised chicks; however, they usually compensate later and wean at a normal weight.

Problems Associated with Parent-raised Birds

Nestling birds are most likely to have medical problems during the first week of life, at fledging and at weaning. Monitoring the condition of parent-raised offspring in the nest box can be difficult. Semi-domesticated species such as budgerigars, cockatiels, finches and lovebirds may tolerate repeated evaluation and handling of their offspring. Larger psittacine birds are usually protective of the nest box, and the aviculturist should establish a routine of examining the nest box daily to condition the birds to this procedure. Nest boxes should be constructed with a small door that can be used for viewing the chicks and examining the eggs. A fiberoptic light and mirror may be helpful.

Chicks receiving adequate parental care will have food in their crops and yellowish-pink skin (Color 30.3). Chicks that have empty crops, act listless and are cool to the touch are receiving inadequate care and should receive immediate attention. These chicks may be hypothermic, hypoglycemic, dehydrated or have bacterial or yeast infections. The solution to many of the problems associated with parent-raised neonates is to remove them for hand-raising. Care of the critically ill neonate is described in the section on hand-raising.

Parental Problems

Parenting is a learned process and captive birds do not always make ideal parents, especially with the first few clutches. Parents may eat, traumatize or abandon the eggs or the chicks. Some parents never learn to provide adequate care; others may learn to provide improved care with subsequent clutches. Disturbances in the aviary will increase parental problems. Most psittacine birds lay eggs every two to three days and start incubation when the first egg is laid. Highly productive species such as cockatiels may lay an additional clutch before fledging chicks from the previous lay. These adults may remove the feathers from the chicks in an attempt to encourage them to leave the nest.

Nestling Problems

A healthy nestling will interact with the parents and elicit feeding activity by displaying a food-begging behavior. Any factor that decreases the vigor of the chicks (disease, cold, competition) can decrease their chances of being properly fed. Often the older and more vigorous chicks will compete most efficiently for food and parental attention, causing younger chicks to be neglected and undernourished.

Environmental Problems

Nestlings in a hot, cold or damp nest box may be stressed, fail to beg for food or be abandoned (Figure 30.2). Improper nest material may be ingested or inhaled or may support the growth of bacteria and fungi. Rats, snakes and other predators may consume nestlings or disturb the parents and prevent regular feedings. Disturbances of the nest box may cause parents to neglect or traumatize chicks.

Injuries

Nestlings may be injured by their parents, other nestlings or improper nest box construction (eg, exposed nails, slippery nest material). Poor nutrition can cause metabolic bone disease and make the chicks more susceptible to fractures. Many of the larger psittacines are territorial and may traumatize the nestlings when defending the nest. To prevent these injuries, the nest box can be equipped with a sliding door over the entrance hole to exclude the parents from the nest box while chicks are being examined. Chicks may also traumatize each other, most frequently injuring the beak, face and wing tips.

Infectious Diseases

Microbial infections (gram-negative bacteria, chlamydia, viruses and yeast) and internal parasites (eg, giardia and trichomoniasis) are frequent causes of mortality in nestling birds (Figure 30.3). Common sources include adult birds (which may be asympto-

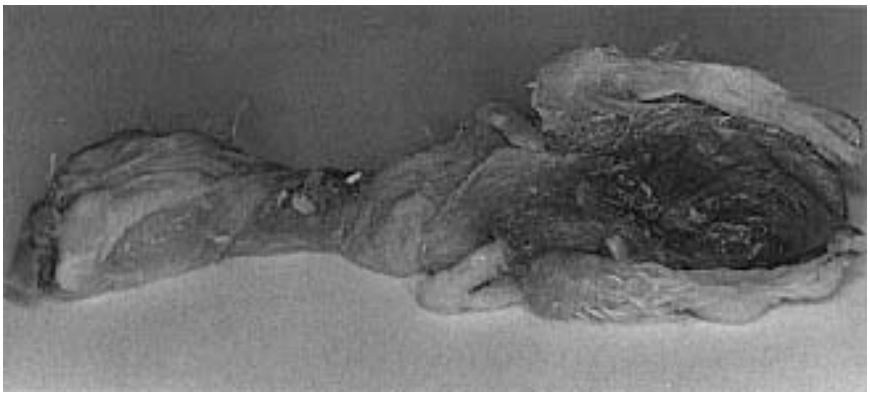

FIG 30.2 Chicks may be abandoned in the nest if the parents are inexperienced, if insufficient types and quantities of food are available, if the neonate does not properly beg for food, or if the nest box is cold, hot, damp or infested with vermin. Chicks that are being raised by the parents should be observed daily, if the parents will allow it, to ensure they are receiving proper care. Neonatal mortalities may indicate disease or management-related problems within the collection that can be identified by postmortem examination.

FIG 30.3 Any neonate or embryo that dies should be submitted for necropsy and histopathologic evaluation. This is particularly true of incubated eggs. These deaths may indicate underlying bacterial or viral infections in the flock. Note the egg tooth and membrane covering the ear in this 28-day-old Moluccan Cockatoo embryo.

matic carriers) and contaminated food, water or nest material. Ill nestlings should be pulled for hand-feeding and appropriate treatment. These birds should be raised separately from other neonates and should not be fed by the same person who cares for the other birds in the nursery. If this is not possible, *some* microbial infections can be treated by offering medicated food to the parents who will then feed it to the nestlings. Fortunately, adult birds are often less selective of their diet while feeding offspring and may accept foods that they would ordinarily refuse. Parents preferentially feed nestlings soft, moist food, which should be offered fresh two to three times daily. Only highly susceptible microbial infections can be treated by offering medicated food to the parents, because it is difficult to achieve adequate antibiotic concentrations in the chick by using this technique (see Chapter 17). It is also possible that a parent could feed toxic amounts of the antimicrobial agent to the chicks. Viral infections such as polyomavirus and beak and feather disease virus (PBFD) can also affect parent-raised chicks.

External Parasites

Red mites (*Dermanyuss gallinae*), Northern fowl mites (*Ornitysluss sylvarium*), fire ants, Africanized bees and mosquitos can infest the nest box and cause discomfort, anemia and even death of chicks. Mites can be controlled by dusting the birds with 5% carbaryl or pyrethrin powders and spraying the cage and nest box with 5% carbaryl or 5-10% malathion. Adding a small amount of 5% carbaryl powder to the nest material will aid in control, but care should be taken in areas where insect vectors (eg, cockroaches) might carry *Sarcocystis* sp. If cockroaches enter the nest box and die from the insecticide, they may be eaten by either the parents or nestlings and subsequently transmit *Sarcocystis* sp.[9] Control of other pests is described in Chapter 2. Insecticides should be used only if indicated by the infestation of a parasite. They should not be used prophylactically.

Hand-raising Birds

Husbandry and Preventive Medicine

Psittacine chicks are altricial, and as neonates they are unable to thermoregulate, unable to feed themselves and have a poorly developed immune system. Consequently, diet and environmental conditions have a profound impact on health. When faced with a neonatal health problem, it is essential for the clinician to carefully evaluate the environmental conditions, hygiene practices and feeding methods in the nursery. Books are available on hand-feeding practices and it is beyond the scope of this chapter to completely discuss all aspects of hand-raising. The purpose of this section is to introduce the avian veterinarian to the most important factors to consider when investigating neonatal health problems (Table 30.1). Possibly one of the most overlooked factors in raising healthy psittacine chicks is providing them with ample rest periods in which they are not disturbed between feedings.

Nursery Design

Careful design can increase the function of the nursery and aid in disease prevention. The nursery should be separated from any contact with adult birds, and the aviculturist should take steps to prevent disease transmission from the adult flock. It is best to have separate caretakers for the adults and the babies. If this is impossible, the aviculturist should shower and change clothes between caring for adults and young. It is advantageous to have several potential nursery rooms in case there is a disease outbreak. If possible, valuable or endangered species should be raised in a room separate from common species that have a high incidence of infectious diseases (eg, budgerigars, cockatiels, lovebirds and conures). The nursery room(s) should have adequate

TABLE 30.1 Guidelines for Nursery Management

1. Every nursery should have a separate room where sick birds can be isolated. This room should not share air flow with the primary nursery. Nestlings showing signs of disease should be immediately moved from the primary nursery and isolated.
2. If a baby leaves the nursery for any reason and is exposed to other birds, it should not be returned to the primary nursery.
3. A nestling should never be added from another facility.
4. The same people should not care for both the adults and the neonates, unless special precautions are taken to avoid disease transmission.
5. Visitors, especially people who own birds, should be restricted from entering the nursery. People can act as mechanical vectors of infectious agents.
6. Ideally, every bird that is sold should be tested for microbial diseases, PBFD virus and polyomavirus before shipment.
7. Thorough cleaning of nursery facilities and equipment is better than partial cleaning followed by the use of disinfectants. Disinfectants are toxic, and exposure to the nestlings should be minimized (both direct contact and fumes).
8. Proper feeding practices can minimize problems.
   a. Use a proven diet and constantly evaluate growth by assessing development and comparing weight gains with a growth chart.
   b. Store dry nestling diet in a cool, dry, rodent-free area. Opened food containers should be stored in the freezer.
   c. Feeding formula should be carefully measured and mixed, and the temperature checked before feeding.
   d. Mix food fresh for each feeding. Do not store mixed food in the refrigerator and feed it at a later time.
   e. Use an individual syringe for each nestling.
   f. Never feed a bird and place the syringe back in the feeding formula.

temperature control and be self-contained with a large sink for washing hands and feeding utensils, a scale for weighing birds, a coffee-maker or hot plate for heating water or food and simple shelves for holding the brooders and enclosures. The room should be kept uncluttered to allow easy and complete cleaning, and the walls should be covered or painted with a durable, non-porous surface that can be easily disinfected. In areas where power outages are common, an alarm or back-up electrical system should be considered. An evacuation and emergency plan is best designed prior to a disaster.

Age at Time of Removal from the Nest

For most species, nestlings less than two to three weeks of age are easiest to adapt to the hand-feeding process. Older birds may be fearful of people and more difficult to feed, while younger chicks more readily accept hand-feeding but must be fed more frequently. Chicks hatched from artificially incubated eggs must be hand-raised or fostered from the first day. To help control some diseases, many aviculturists feed only babies hatched from artificially incubated eggs and are careful to exclude parent-hatched nestlings. Several viral infections (eg, PBFD and polyomavirus) that can be egg-transmitted may not be prevented by incubating eggs.[27,28]

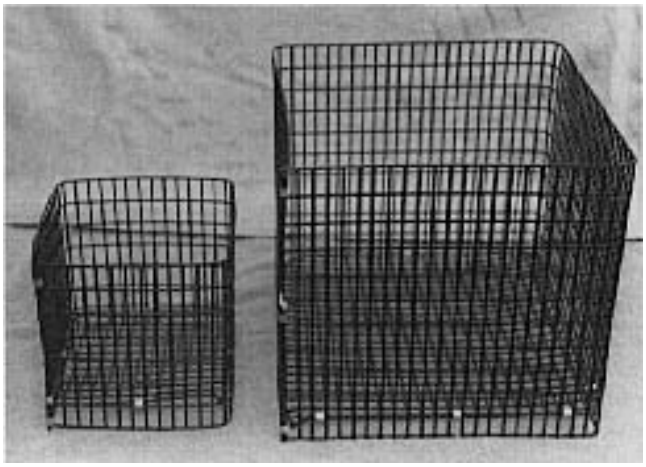
Housing

Chicks should be housed in brooders in order to provide the precise temperature and humidity control required for optimal development of young neonates. Older chicks can tolerate wider temperature fluctuations. Commercially available brooders vary widely in quality and design. Solid state thermostats are more reliable than wafer types, and a back up thermostat should turn the unit off if the temperature becomes too high. Air should be circulated with a gentle fan. Commercial models with powerful fans should be avoided because they can dehydrate the chicks. Inside the brooder the chick should be kept in a small plastic container lined on the bottom with soft, absorbable paper toweling to aid in support and provide security. Slick surfaces can cause leg deformities. Chicks can also be housed in containers with a raised floor made of plastic-coated wire. These units keep the neonates clean and dry by allowing excrement to fall through the wire mesh; however, the mesh must be small enough to prevent the leg (especially the tibiotarsal joint) from extending through the wire. The container should have smooth walls to prevent the chick from entrapping its wings or beak (Figure 30.4).

Partially feathered chicks can be housed in open plastic pans or aquariums if the nursery is properly heated. Fully feathered chicks are capable of flight and should be kept in secure enclosures. Their wing feathers should be clipped after they are fully developed.

Temperature and Humidity

The nestling's age and amount of feathering determine the optimal environmental conditions. The relative humidity for tropical species should be above 50 percent. Temperature should be adjusted for the behavior of the particular bird. Birds that are too hot will pant and hold their wings away from their bodies; those that are too cold will huddle, shiver and may have slow crop-emptying times. Chicks housed at temperatures outside the optimal range will grow more slowly. Some suggested temperatures for psittacine chicks are provided in Table 30.2.



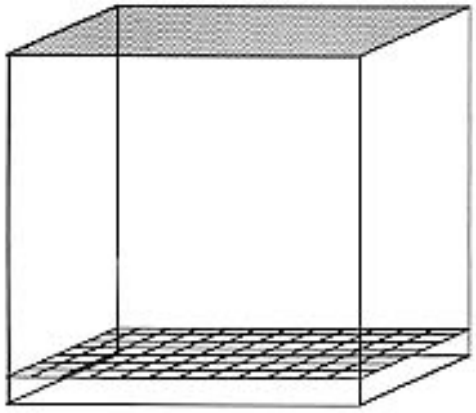


FIG 30.4 Plastic-coated wire baskets with raised floors are excellent for housing psittacine neonates greater than ten days of age. The size of the floor mesh can be varied to accommodate different sized chicks. This enclosure design keeps the neonates clean and dry, and can be placed inside most commercially available brooders (courtesy of Apalachee River Aviary).

TABLE 30.2 Suggested Ambient Temperature Ranges for Psittacine Chicks

Recent hatchlings	92-94°F
Unfeathered chicks	90-92°F
Chicks with some pin feathers	85-90°F
Fully feathered chicks	75-80°F
Weaned chicks	68-75°F

The actual temperature should be adjusted according to the needs of the individual chick.

Substrate

The substrate on the floor of the "nest" should absorb moisture from the droppings, provide firm footing and not cause major digestive problems if ingested. Cloth diapers or unfrayed cotton woven towels and coated wire screens can be used with few problems. Problem substrates include tissue paper (provides poor traction), soft, crumpled or shredded paper, wood shavings or chips (cause impactions if ingested), sawdust (causes respiratory problems if inhaled), and coarse pelleted bedding (causes GI irritation or blockage if ingested) (Figure 30.5). Substrate consumption may even result in malnutrition.

FIG 30.5 Drop-through, raised floor units are preferable for housing growing chicks in the nursery. If other types of containers are used, the bottom should be covered with cloth diapers or woven cotton towels. Wood shavings, wood chips, cat litter and pelleted bedding can cause respiratory, gastrointestinal or dermatologic problems.

Housing Multiple Chicks

Nestlings seem to grow best if they are housed with their clutch mates; however, chicks should be separated if there are substantial differences in body size, or if a bird becomes ill. Housing birds from different clutches together is discouraged because of the threat of disease transmission. Chicks should be housed individually if there is a disease outbreak in the nursery. Neonates or visitors from another collection should be discouraged from entering the nursery.

Chick Identification

Chicks should be assigned individual identification numbers upon entering the nursery and identified by closed banding or transponder implants when they are large enough. Closed bands are rings that are slipped over the foot at the mid-pin feather stage and become fixed in place over the metatarsus as the foot grows too large for the band to be removed (Figure 30.6).[10,21] Electronic microchip transponders can be intramuscularly or subcutaneously implanted and provide permanent identification.[10] At a minimum, the aviculturist should record the following information in a log book: egg number if artificially hatched, identification of siblings and parents and location of

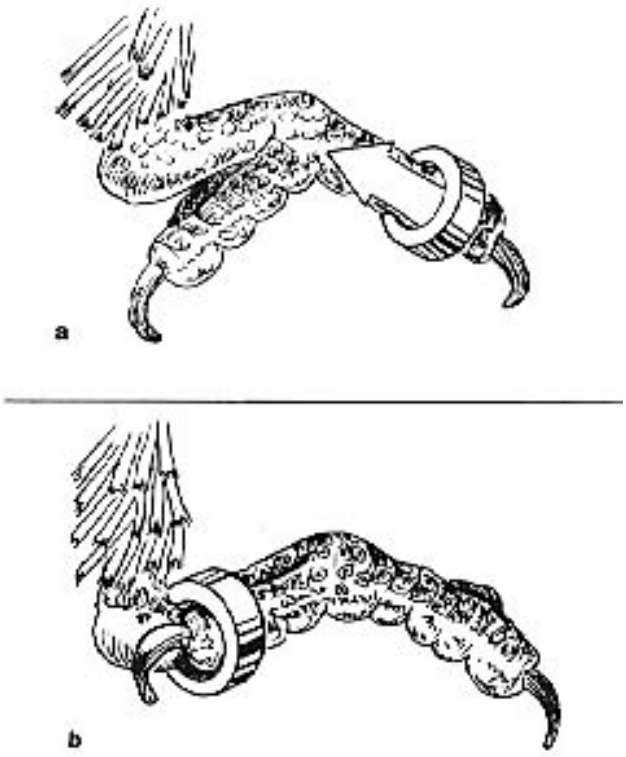

FIG 30.6 Many states require that domestically rasied neonates be closed banded. The band is applied by **a)** placing digits 2 and 3 together facing forward and **b)** slipping the band over the metatarsus. The size recommendations of the manufacturer of various bands should be carefully followed.

the parents' enclosure. Recording the health history of the parents and siblings is also helpful if epidemiologic information is required for disease investigation. Permanent identification is required for international sale of CITES-listed species and shipment into some states.

Diets

Numerous hand-feeding diets are available, and a diet that works for one facility may not work well in another. Apparently, the idiosyncracies of the feeder's techniques and the amount and frequency of feeding influence growth as much as the composition of the diet. Therefore, a *carte blanche* recommendation for a particular diet cannot be made. Manufacturers of commercial diets are listed in Table 30.3 and examples of homemade diets are given in Table 30.4. The major advantages of commercial diets are that they are easier to prepare and have more consistent nutritional content.

Most of the nutritional requirements of psittacine chicks are not known, and the development of successful hand-feeding diets has been based largely on trial and error and extrapolation from the dietary requirements of poultry (Figure 30.7). Some generalizations regarding neonatal nutrition can be made. Investigations in cockatiels[30] and the observations of numerous aviculturists indicate that the protein content should be approximately 18 to 22%, calcium 1%, and calcium and phosphorus should be balanced in approximately a 2:1 ratio. Lists of specific nutrient deficiencies and associated clinical signs are often published for poultry but may not be applicable to psittacine birds. For example, lysine deficiency causes depigmented feathers in poultry but not in cockatiels. Choline deficiency has been shown to be associated with feather depigmentation in cockatiels.[30]

The water content, consistency and temperature of the feeding formula are also important. A diet containing approximately 25 to 30% solids (70-75% water) should be fed to nestlings older than one or

TABLE 30.4 Primate Diet Hand-feeding Formula Used With Success in Some Nurseries

1. Grind primate diet.
2. Mix (by weight)

   Ground primate diet 50%
   Commercial hand-feeding formula 25%
   Dry oatmeal baby cereal 25%
3. Store mixed dry diet in a sealed bag in the freezer.
4. Heat water to approximately 120°F. Add 20 to 25 mls of the heated water to 25-30 gms of the dry mixture. Stir in 1 teaspoon of creamed carrots and 1 teaspoon of mixed baby cereal (from a jar).
5. Mix throughly and feed at a temperature of 102 to 105°F.

FIG 30.7 A three-week-old Blue and Gold Macaw chick was presented with a three-day history of inability to ambulate and the appearance of ulcerations on the abdominal body wall. The bird was being fed a homemade diet. The limbs were soft and pliable. Radiographs indicated osteopenia and pathologic fractures in the humerus and tibiotarsus suggestive of metabolic bone disease (rickets). Note the soft tissue opacity of the abdomen, a relatively normal finding in young chicks. The liver, proventriculus, ventriculus and intestines (the last three of which stay filled with food) generally fill the entire abdominal cavity (courtesy of Marjorie McMillan).

two days.[30] It may be beneficial to feed a more dilute diet for the first day after hatching because the chick will be using the contents of its yolk sac for nutrition. Inexperienced hand-feeders should actually weigh the solid and liquid portions of the diet to ensure a proper dilution is fed. Evaluating a cooked diet according to visual consistency is inaccurate. Cooked starches may cause the formula to appear thick even though the percentage of solids is very low. The food should be warmed to 101°-104°F and the temperature measured with an accurate thermometer. The instructions provided with commercial diets should

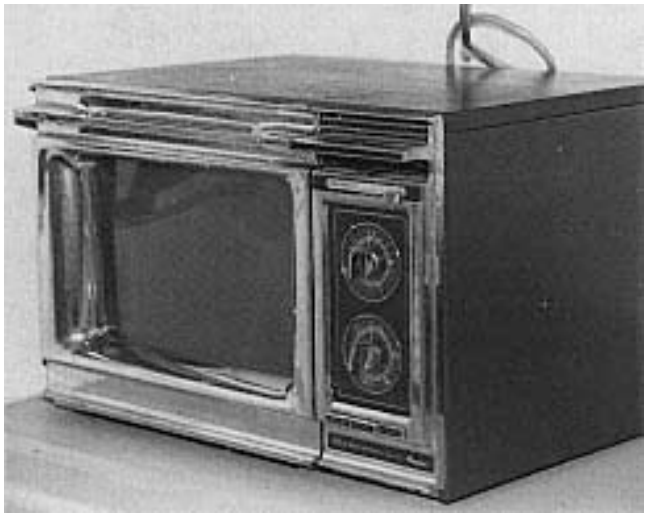

FIG 30.8 Coffee makers and hot plates are better for heating water for formula for neonates than microwave ovens. Microwave ovens tend to create super hot spots in the formula that can cause full-thickness burns in the crop (Color 30.13).

be carefully followed. Cooler food may be refused, hot food may scald the crop. A hot plate or coffee maker should be used for heating formula. The use of a microwave oven for heating food frequently results in severe crop burns (Figure 30.8).

Feeding Methods

Most aviculturists now use syringes for feeding, although bent spoons or crop tubes are occasionally used. Catheter-tipped syringes are especially popular. Hungry nestling birds display a feeding response that consists of rapid, thrusting head movements and bobbing up and down. These movements can be stimulated by touching the commissures of the beak or pressing lightly under the mandible (Figure 30.9). While the bird is displaying this behavior, the glottis is closed and large amounts of food can be delivered quickly with less fear of passing food into the trachea. If a neonate resists feeding or a feeding response is not displayed, the chance of tracheal aspiration is greater. If a young bird that is not eating on its own refuses to eat for two to three feedings in a row, it may be having a medical problem that should be evaluated. As some birds get older, they display less of a feeding response and are more difficult to feed. This may be an indication that weaning is beginning to occur. If an older bird resists feeding, that feeding should be skipped. The chick may be hungrier and more willing to eat at the next scheduled feeding. A long, soft tube can be used to feed recalcitrant birds. Short tubes should not be used, as they may become detached from the syringe and swallowed.

FIG 30.9 A neonate with an active feeding response will rapidly thrust the head up and down on a syringe. The head should be gently supported to prevent injuries during the feeding process (courtesy of Apalachee River Aviary).

Feeding Amounts and Frequency

Younger birds should be fed more often than older, larger birds. Adequate weight gain and good morphologic development are more important indicators of adequate nutrition than the amount or number of feedings. The amount of food and frequency of feeding depends on the age and development of the chick and the particular diet fed. Birds one to five days old should be fed six to ten times daily; chicks with eyes closed, four to six times daily; chicks with eyes opened, three to four times daily; and birds with feathers emerging, two to three times daily. Chicks less than one week old may benefit from around-the-clock feeding, but it is not necessary to feed older chicks through the night. The last feeding can be given between 10:00 p.m. and 12:00 a.m. and the first between 6:00 and 7:00 a.m. The crop should be filled to capacity and allowed to nearly empty before the next meal. The crop should be allowed to completely empty at least once each day (usually in the morning following the final night feeding). It is important to feed young birds the maximum amounts of food early to stimulate good growth and increase crop capacity. However, excessively large meals in very small birds can predispose them to regurgitation and subsequent aspiration. In these birds, it is best to feed smaller quantities of food on a more frequent basis. Some formulas have higher fiber content that allows for longer periods between feedings and less total food volume per day due to improved feed efficiency.

Weaning

Weaning is a stressful time for both the bird and the hand-feeder. Some birds wean themselves at the appropriate body weight by refusing to be hand-fed, but many others must be encouraged to wean (particularly cockatoos and large macaws).[30] Several weeks prior to the expected age of weaning, the bird should be offered a variety of foods such as corn, cooked vegetables, various fruits, soaked monkey chow, formulated diet, spray millet, hulled seeds and peanut butter and jelly sandwiches. Seeds with hulls and large chunks of food should be avoided because at this stage the bird may consume them whole. Most birds will pick up and play with food long before they actually consume the material. To encourage experimentation, food bowls should be easily accessible and placed at perch height. The presence of an older, self-feeding bird may encourage younger birds to wean more quickly. It is best to accustom a weaning baby to a wide variety of formulated diets and fresh fruits and vegetables. This will make them more likely to accept the varied diets that they may be offered when they leave the nursery. If birds are weaned onto a specific diet, it is important that a new owner continue feeding the same diet until the bird is accustomed to its new surroundings and the diet can be safely changed.

When the bird is at the right weight and development or consuming some solid food, the midday feeding should be gradually eliminated, followed by the morning and then the evening meals. If the bird was fed properly to begin with, weight loss in the range of 10 to 15% of the peak body weight may be expected during the weaning process. If the bird was underweight to begin with, any weight loss may be abnormal. Subclinical illness (especially gram-negative bacterial infections of the alimentary tract) may become apparent during weaning. Clinical signs could include excessive weight loss, slowed crop-emptying times, depression, diarrhea, regurgitation or simply a failure to wean. If problems are noted, weaning should be postponed and the underlying problem diagnosed and treated. If the weight loss is severe, it may be necessary to resume hand-feeding two to three times daily, and weaning should not be re-attempted until the bird has gained adequate weight.

Some birds will resist hand-feeding before they are capable of maintaining adequate body weight on their own. This is especially common in malnourished birds that are stunted in growth but of weaning age. It may be necessary to tube-feed these birds, because forcing them to hand-feed increases the risk of aspiration and causes severe stress.

Hygiene

Careful control of environmental sources of pathogenic bacteria and yeast are essential for maintaining healthy chicks. A diligent, thorough, commonsense approach that includes minimum exposure to harmful chemicals works best. The most important sources of microbial contamination include the food, water supply, feeding and food preparation utensils, other birds in the nursery and the hand-feeder. If microbial infections are repeatedly encountered in a nursery, these areas should be cultured in order to identify and eliminate the source of contamination.

Microbes in the food and water that would have little effect on adult birds can cause life-threatening infections in neonates. Yeast, *Escherichia coli, Klebsiella, Enterobacter* and *Pseudomonas* spp. are common contaminants. To avoid these microbes, the components of the diet should be carefully selected. Most commercial diets are relatively clean. Products intended for poultry, however, may contain high levels of bacterial contamination and should be excluded from the diet.[17] Monkey chow is a common ingredient in homemade diets and can be used successfully if properly stored (Figure 30.10). Yeast and bacterial contamination of any formulated diet can occur if it is improperly stored. Pseudomonas is a frequent contaminant of water taps and bottled water dispensers.

The diet should be mixed fresh before each feeding. As a guide, the standards for cleanliness in a nursery should be higher than the feeders would maintain for themselves. Opened containers of dry baby formula should be stored in sealed containers in the freezer. Powdered baby formula that has been mixed with water should never be stored and fed to babies in subsequent feedings. Hands should be washed between birds or groups of birds to avoid transmitting diseases (Figure 30.11). A separate syringe should be used for each bird and the syringes should be filled in advance. Under no circumstances should a syringe used to feed a bird be dipped back into the food for a refill; this will result in the spread of infectious agents throughout the nursery. The syringes and all implements used for preparing food should be kept clean by disassembling, scrubbing and disinfecting after each use. Quaternary ammonium products containing a detergent are recommended for disinfection since they will cause less drying of the syringe

FIG 30.10 All avian food stuffs should be maintained in sealed containers in cool, moisture-free areas. All rodent, insect or feral bird exposure to the food must be prevented. Several bacterial disease outbreaks in nurseries have been blamed on specific types of manufactured food when, in fact, the outbreaks were the result of careless food handling (eg, wet food or food contaminated by rodent droppings) on the part of the aviculturist (courtesy of Apalachee River Aviary).

FIG 30.11 Nursery hygiene is critical in preventing infectious disease outbreaks. In addition to maintaining the neonates in a clean, dry environment, aviculturists must also make certain they do not serve as sources of infection for their neonates. Part of personnel hygiene involves thoroughly washing the hands before handling any neonate. Hands should also be washed when moving from one group of neonates to the next.

plunger than Clorox.[10] The syringe plunger should be periodically removed and scrubbed to avoid a build-up of food and pathogens. Feeding implements must be thoroughly rinsed to reduce exposure of chicks to residual disinfectants.

New Additions

New additions to the nursery should be placed in separate brooders, fed last and monitored carefully until it is apparent that they are healthy. It is prudent to culture the cloaca of new birds at the time they enter the nursery to diagnose and eliminate potential microbial infections that might spread to other chicks. A cloacal swab can also be submitted to make certain that the neonates are not shedding polyomavirus. Detecting an infectious agent in a newly introduced chick also indicates that the parents and egg incubator should be evaluated. In this manner, chicks can be used to monitor the health of the adult collection. A clinical workup and brief isolation period of all new arrivals to the nursery will help prevent some diseases but will not eliminate all risks. For example, chicks infected with PBFD virus or polyomavirus may not show clinical signs of disease for weeks to months after exposure. Antigen detection tests may be used to identify potential carriers of these diseases[28] (see Chapter 6). Birds from other collections should *never* be brought into a nursery.

Evaluating Nestling Birds

Nestling psittacine birds can be evaluated in the same way as adult birds. A complete history, thorough physical examination and appropriate laboratory tests should be completed. The unique features of neonatal psittacine birds are emphasized in the sections below.

History

Avicultural clients should be asked to prepare a written summary prior to taking a nestling psittacine chick to the veterinarian. The history should include the following:

1. The past breeding and health history of the parents and condition of the chick's siblings.
2. Problems during incubation or hatching if the chick was artificially incubated. (Chicks that have problems hatching frequently grow poorly during the first few weeks of life and may be stunted).
3. Brooder temperature, substrate, hygiene practices (including exposure to any disinfectants) and condition of other birds in the nursery.
4. The type of diet, percent solids content, how the diet is prepared, amount and frequency of feedings and implement used to feed the chick.
5. The identification number and method used to identify the chick.

Body Weight Charts

One of the most valuable tools for evaluating nestling birds is a chart recording daily body weight. Birds should be weighed prior to the morning feeding when the crop and GI tract should be relatively empty (Figure 30.12). At most stages of development, juvenile birds should gain a certain amount of weight daily. Failure to gain this amount of weight is cause for concern. Almost any disorder will affect the weight gain, and lack of a normal weight gain is often one of the earliest signs of problems. Body weight can be compared to weight charts developed from records of morphologically normal birds to access normal development; however, it must be stressed that there is wide natural variation in the normal growth rates of chicks depending on individual body conformation, gender and feeding practices. See Table 30.5 for suggested normal growth rates for selected psittacine species.

FIG 30.12 Chicks should be weighed each day before the morning feeding to monitor growth and to detect problems in an early stage.

Extensive discussion of the normal growth of psittacines has been published.[11,21] Growth is slow for approximately one to four days following hatching and then accelerates logarithmically until a second plateau stage just prior to weaning, when many birds will achieve body weights that exceed their adult weight. During weaning, this extra weight is lost as the bird exercises more and assumes more adult proportions.

Developmental Characteristics

Recording developmental characteristics, such as the date the eyes open, the first appearance of head, wing and tail feathers and any other physical changes will help in assessing the growth of a chick. As a generalization, growth characteristics vary with body size, and larger species develop more slowly. The growth rate may be as high as 17% a day during the first week. Growth characteristics for a number of psittacine species have been reported.[11] Delayed developmental characteristics usually indicate delayed overall growth and stunting.

Physical Examination

A thorough physical examination is as important in nestlings as it is in adults. During the examination, chilling and stress should be avoided by warming hands, warming the room and keeping handling times to a minimum. Birds with food in the crop should be handled carefully to avoid regurgitation and aspiration. The heart and lungs should be auscultated to detect cardiac murmurs and moist respiratory sounds (Figure 30.13). The eyes and ears should be carefully examined to evaluate normal development and opening. It is normal to have a clear discharge from the eyes when they open. In macaws, the eyes usually open between 14 and 28 days following hatching; in cockatoos, between ten and 21 days;

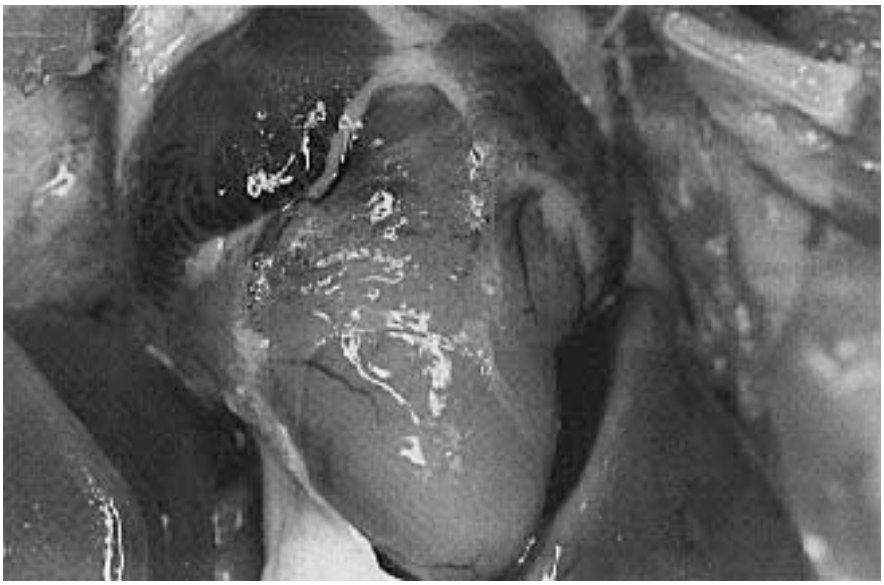

FIG 30.13 A five-week-old Blue and Gold Macaw chick was presented for regurgitation and retarded growth (the younger sibling weighed 120 g more than the patient). The bird was severely dyspneic and depressed. The crop was partially filled with food but peristaltic activity appeared to be normal. Auscultation of the heart revealed a severe murmur. The bird did not respond to supportive therapy. At necropsy, the heart was enlarged and a ventricular septal defect was identified.

FIG 30.14 **a)** An eight-week-old African Grey Parrot was presented with severe torticollis (the top of the head rested on the ground when the bird stood upright). The bird's head had been turned at a 180° angle since hatching. Radiographs indicated a rotational deformity in the cervical vertebrae. A clutchmate was unaffected. Improper incubation parameters, nutritional deficiencies in the hen, infectious diseases, improper chick position in the egg and genetic flaws have all been proposed as etiologies of spinal deformities. **b)** A three-day-old Blue and Gold Macaw chick was presented for severe torticollis. The abnormality was corrected within two weeks of applying a neck brace (courtesy of Martin Orr).

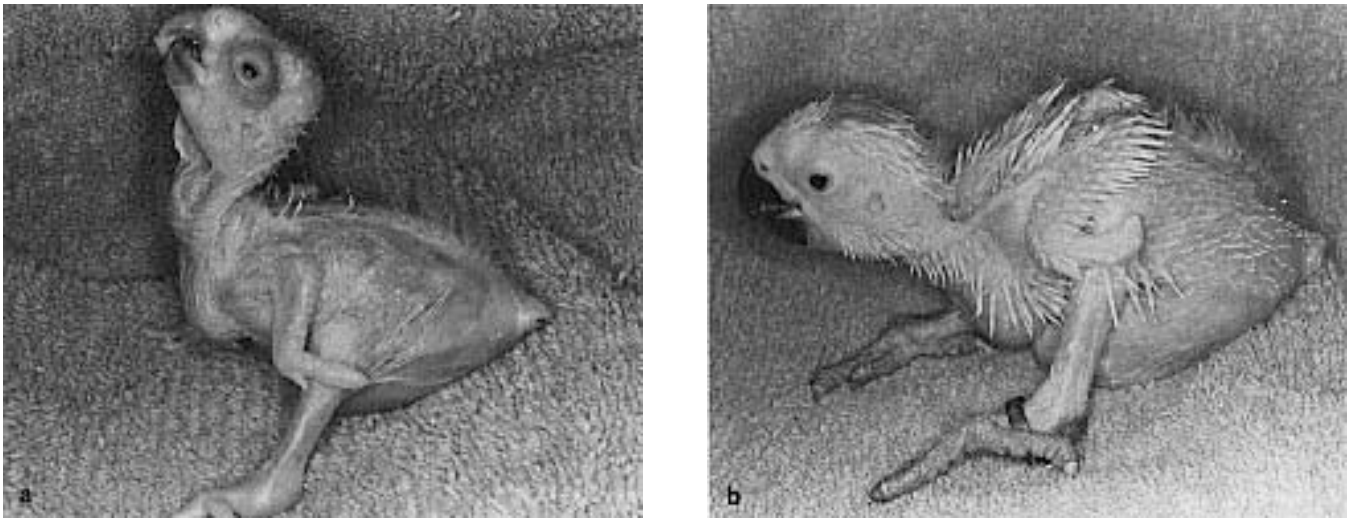

FIG 30.15 Until weaning, neonates like these **a)** two-week-old and **b)** four-week-old Moluccan Cockatoo chicks will stand on their hocks with their abdomen on the ground for support. A normal chick will be bright and alert, with the head raised in response to any activity that may suggest that it is feeding time.

and in Amazon parrots, from 14 to 21 days. The ears are open at hatching in Old World Psittaciformes, and open from ten to 35 days of age in neotropical species. Nestlings can be examined in the same manner as adults but have physical characteristics that differ from adult birds. Particular attention should be paid to body conformation, spine and neck curvature and beak alignment and curvature (Figure 30.14).

Posture

Nestling birds sleep much of the time and are most active when hungry. They may sleep in almost any position, including sprawled with their legs in the air. Until weaning, they sit on their hock joints, rather than up on their feet, using their protuberant abdomen to create a tripod stance (Figure 30.15). Young birds may be uncoordinated and splay their legs when trying to walk. This should be considered normal unless a limb is held consistently in an abnormal position.

Body Conformation

Nestlings have relatively little muscle mass and a large, protuberant abdomen. The pectoral muscles are almost nonexistent. As the bird ages, the muscle mass will increase, but even at weaning they will be thinner than in an adult. Body mass in young nestlings is best assessed by noting the thickness of the muscle and subcutaneous fat covering the elbows, toes and hips. In contrast to adults, nestlings have a very full abdomen because the ventriculus and proventriculus are greatly enlarged at this age.

FIG 30.16 The normal skin of a nestling should be yellowish-pink, supple and warm. A neonate that is being properly cared for by the parents will always have a full crop, as seen in this neonatal Umbrella Cockatoo.

TABLE 30.5 Sample Weight Gains (in grams) of Selected Hand-raised Psittacine Birds and Normal Adults

Age (in days)	0	3	7	14	21	28	35	42	49	Adult

Weight ranges were derived from the weight gain records of birds hand-raised from hatching to weaning. They are provided as suggested ranges only, as growth of an individual chick is dependent on hatch weight, body structure, sex, diet and feeding and husbandry practices. Comparison of data from two successful nurseries has indicated that birds with widely divergent body weights can successfully wean.[10,20] Birds in the lower end of the weight range are more prone to stunting and should be carefully observed. Birds in the upper end of the weight range may shed excess weight at weaning. Data from this table should be combined with observation of the conformation and physical condition of the chick before deciding if an individual is stunted in growth. All weights are given in grams.

Skin

It is important to evaluate both texture and color of the skin. Normal nestlings have yellowish-pink skin with a supple, warm feel (Figure 30.16). Dehydrated nestlings will have dry, hyperemic skin that feels sticky to the touch (Color 30.4). Nestlings with white, cool skin are either hypothermic or moribund and need immediate attention. Some flaking of the skin is normal; excessive amounts of flaking indicate dehydration or exposure to high temperature, low humidity or malnutrition.

Feather Growth

Most psittacine chicks are naked at hatch except for a sparse coating of down (Color 30.1). The first feathers appear on the head, wings, and tail, followed by feather emergence on the rest of the body (Figure 30.17). Gross discrepancies in the pattern of feather development may indicate stunted growth. Feather dysplasia (eg, pinched off feathers, constrictive bands, blood in the rachis) or epilation may indicate polyomavirus, PBFD virus, adenovirus or bacterial folliculitis. Neonates being treated with antibiotics may also have abnormally developed feathers.[28]

Crop

Nestling birds have a greater crop capacity per body weight than adults, sometimes as much as two to three times the adult volume (Figure 30.18). The crop should empty at least once daily; overstretched, damaged and atonic crops will not empty properly. The crop should be palpated for foreign objects and trapped, doughy food, and examined externally for redness or scabs that might indicate a burn or puncture (Color 30.12).

FIG 30.17 Feather growth occurs rapidly in neonatal birds and follows a set pattern that varies among species. In general, feather growth starts with the head, wings and tail, followed by feather emergence on the rest of the body. This figure shows normal pin feather development in the carpus and distal portion of the radius and ulna of a five-week-old Umbrella Cockatoo.

FIG 30.18 The crop capacity of neonatal birds is larger than in an adult when compared on a per weight basis. Neonates should be fed the maximum volume of food that does not over-stretch the crop (courtesy of Apalachee River Aviary).

Droppings

Nestlings often have polyuric droppings. This usually results from the liquid diet they are fed. The fiber content of some formulated diets is higher than homemade formulas, and the droppings from birds fed those diets are less watery and more formed.

Diagnostic Procedures

Clinical Pathology

The clinical pathology of nestling psittacine birds is poorly documented; however, recent publications have established reference intervals for some species.[12-14] In general, nestling birds normally have lower packed cell volumes (20's-30's), lower total protein (1-3 g/dl), and higher white blood cell counts (20,000-40,000) when compared to adults of the same species (see Appendix). Young chicks also have lower plasma concentrations of albumin and uric acid and higher concentrations of alkaline phosphatase and creatine phosphokinase. It is very important to note these age-related differences in hematology so that

misinterpretation of laboratory values does not result in the unnecessary treatment of a normal chick.

Microbiology

Young birds are highly prone to microbial infections and cloacal cultures, and fecal Gram's stains should be routinely evaluated during development. Normal aerobic cloacal flora is gram-positive and consists of *Lactobacillus*, *Corynebacteria*, *Staphylococcus*, nonhemolytic *Streptococcus* and *Bacillus* spp.[16] Common pathogens include gram-negative bacteria and yeast. Many commercial diets contain nonpathogenic brewer's yeast that can be seen on Gram's stains of the crop or feces. Yeast that is contained in the diet should not be budding (an indication that the yeast is alive). Choanal cultures can be used to evaluate the microflora of the upper respiratory tract.

Radiography

The anatomic differences of nestling birds must be considered when interpreting radiographs. The proventriculus and ventriculus are normally much larger than in an adult and may fill most of the abdominal cavity, especially if food is present. Intestinal loops may also be filled with food. Filling of the digestive tract with food reduces the volume of the air sacs. Growth plates in the bones may be open and the general muscle mass will be reduced.

Endoscopy

The techniques and indications for endoscopy are similar to those for adults. An endoscope can be used to identify foreign bodies, inhaled food or aspergillosis in the trachea. Flexible or rigid endoscopes are useful for visualizing the crop when foreign bodies or burns are suspected. The proventriculus and ventriculus are best visualized with flexible scopes passed per os. Great care must be used when scoping the coelomic cavity of nestling birds because the relatively large digestive tract reduces the free space in which the scope can be safely introduced to the air sac. The bird should be fasted for several hours (depending on age) before attempting this procedure. Indications for laparoscopy include surgical sexing, documentation of aspiration or pneumonia and identification of abdominal or thoracic masses not confined to the digestive tract. Nestling birds can be endoscopically sexed as young as six weeks of age.

Common Problems of Neonates

Neonatal Problems

Perinatal Problems

Diagnosis, treatment and prevention of premature hatch, difficult hatch, unabsorbed yolk sac, hemorrhage of the complexus muscle and other developmental problems associated with incubation and hatching are described in Chapter 29. All of these problems may affect the growth and development of the chick (Figure 30.19).

Failure to Absorb the Yolk Sac

The yolk sac is a diverticulum of the intestine and is internalized into the abdomen just prior to hatch. Following hatch, the yolk is normally absorbed and provides nourishment and maternal antibodies during the first days of life. Once the yolk is absorbed, only a small remnant of scar tissue should remain. A common cause of death in artificially hatched chicks during the first week of life is retention of the yolk sac, which may be associated with primary or secondary infections of the navel (omphalo-vitellitis) (Color 30.2). Infections, improper incubator conditions and idiopathic causes can result in a failure of the yolk sac to be absorbed. In a retrospective review of 59 yolk sac cultures at the Denver Zoological Gardens, *E. coli, Proteus, Streptococcus fecalis*, and *Clos-*

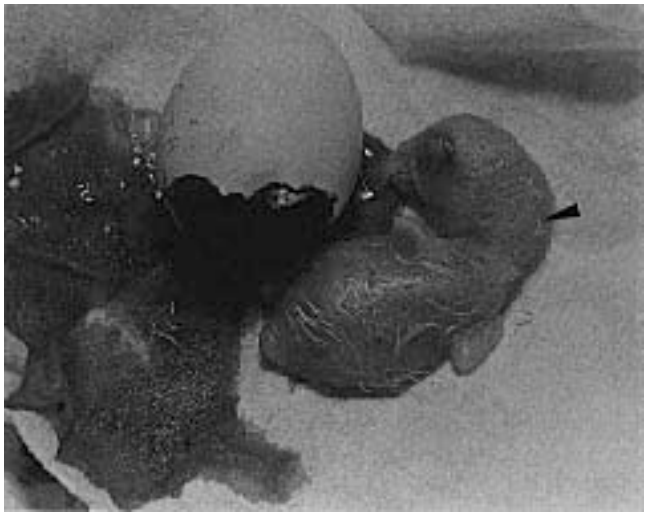

FIG 30.19 A healthy, vibrant neonate should hatch unassisted. The pipping muscle (arrow) located on the dorsal cervical area should not be misinterpreted as an abnormal swelling.

tridium sp. were the most common bacterial isolates associated with yolk-related problems.[6] In pigeons, there is an increased occurrence of omphalitis and bacterial septicemia in eggs that are washed prior to incubation.

Yolk sac infections can occur secondary to infections of the navel if it is poorly internalized prior to hatching. Alternatively, bacteria can multiply in the hatching egg following fecal contamination of the shell. In squab, omphalo-vitellitis may be caused by trichomonas. Affected animals have enormous yolk sacs that are 20 to 40% of the total body weight. The navel may be thickened, prominent and necrotic. Failure of yolk absorption is reported primarily in ratite and waterfowl chicks, but also occurs in companion birds. The normal interval for complete absorption of the yolk varies in different species. Precocial young use the yolk more quickly than altricial neonates. The yolk sac is no longer visible at six days in macaws, is absent in the ostrich in eight or more days and is palpable in emus for approximately seven days. Birds with unabsorbed yolk will have enlarged, doughy abdomens, and the large yolk sac may be visible through the abdominal wall or via radiography (Color 30.10). Dyspnea, exercise intolerance, depression, anorexia and inability to stand have also been reported.[6]

A surgical procedure has been described for removing the yolk sac in ratites and waterfowl.[6] The yolk sac is exteriorized and the yolk stalk and associated vessels ligated close to the jejunal/ilial junction of the small intestine. The body wall and skin are closed in separate layers (see Chapter 48).

Critical Care of the Neonate

Nestling birds have little reserve capacity and sick neonates are often presented in critical condition, regardless of the underlying cause. Ill or abandoned nestlings are frequently hypothermic, dehydrated, hypoglycemic and may be septicemic. Supportive care to correct these physiologic imbalances should be implemented immediately (Table 30.6).

Stunted Growth

Poor development and stunted growth is a common problem in both parent and hand-fed birds. Any factor that interferes with the homeostasis of the chick can alter growth (Figure 30.20). The leading causes of stunting are suspected to be underfeeding, chronic microbial infections and polyomavirus. Other possible causes of stunting include:

TABLE 30.6 Critical Care of the Neonate

1. **Collect samples for diagnostic blood work** and microbiology if this will not compromise the patient.
2. **Correct hypothermia.** Hypothermic neonates may be unresponsive and appear dead. They should be gradually warmed in an incubator set at 92°-95°F and monitored to make sure they do not become hyperthermic. The response to warming can be quite dramatic.
3. **Correct dehydration.** Dehydrated chicks will have sunken facial features, dry, reddened, wrinkled skin and feel sticky to the touch. The preferred route of fluid administration depends on the condition and size of the chick. If the chick is severely depressed and potentially hypovolemic, intravenous lactated Ringer's solution can be given by slow bolus administration at a rate of 10-15 ml/kg. An alternative to IV administration is to place an intraosseus catheter in the tibia using a butterfly catheter for small birds and an indwelling catheter for large ones.[19] If a catheter is used, the fluid deficit plus maintenance (40-60 ml/kg/day) should be replaced in a 48-hour period. Once the hypovolemia is corrected, subcutaneous fluids can be administered between the shoulder blades and into the groin. Lactated Ringer's solution, with or without added dextrose, is the preferred fluid because the lactate will provide some buffering of the metabolic acidosis assumed to occur in most dehydrated birds. Oral fluids can be used in birds that are responsive and are not having problems with crop stasis or regurgitation. Solutions containing dilute complex carbohydrates and electrolytes work best. Jarred baby cereal containing oatmeal, applesauce and bananas diluted 50 percent with water, the juice of boiled rice or commercial human infant fluid replacers have been successfully used as oral fluids.
4. **Correct hypoglycemia.** Chicks that have not been fed and those suffering crop stasis may be marginally hypoglycemic. Psittacine birds rarely seizure because of hypoglycemia; the most common clinical sign is depression. A solution of 2.5-5% dextrose can be added to IV fluids once the hypovolemia has been corrected. Dextrose should not be added to the fluids of a dehydrated neonate to prevent the induction of metabolic acidosis and the movement of fluids out of the intracellular space causing more severe dehydraion. Glucose can also be added to oral rehydration fluids.
5. **Treat the septicemia.** Primary and secondary bacterial infections are very common in nestling birds. If suspected, treatment should begin immediately, because waiting for cultures may be fatal. If the bird is severely depressed or has crop stasis, parenteral antibiotics should be administered via the SC or IM route. They can also be added to IV fluids. The advanced generation penicillins (eg, piperacillin) and cephalosporins (eg, cefotaxime and ceftiofur) have excellent gram-negative activity and are relatively nontoxic. To avoid renal toxicity, the aminoglycosides should not be used in dehydrated patients. If the bird is capable of taking oral antibiotics, enrofloxacin or trimethoprim-sulfa provide good gram-negative bacterial activity. Enrofloxacin has been safely used in many nurseries but should still be used with caution in growing birds because joint abnormalities have been reported in mammals. Trimethoprim-sulfa combinations can cause regurgitation in some birds, especially macaws. Nystatin can be used to treat yeast infections of the alimentary tract (see Chapter 18).

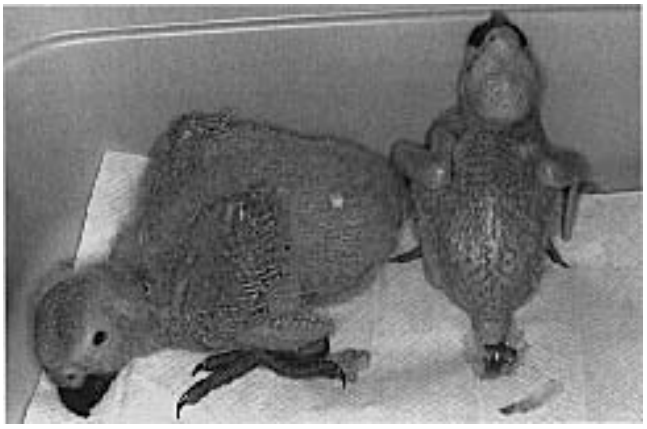

FIG 30.20 The African Grey Parrot (left) and Blue and Gold Macaw chick are approximately the same age. The birds were fed the same diet, which had been used successfully in many other macaw chicks. The cause of stunting in this macaw chick could not be determined. Note the large head compared to the rest of the body.

- Improper feeding: unbalanced nutrition, not feeding enough volume, not feeding frequently enough and feeding a diet with low total solids.
- Poor environmental conditions in early development: low or high temperature, low humidity.
- Diseases: any disease may cause a chick to expend energy fighting the disease, rather than using energy for growth. Clinical and subclinical microbial diseases caused by gram-negative bacteria and yeast are commonly implicated. These organisms may be secondary problems indicating primary viral infections, environmental inadequacies, immunosuppression or malnutrition. Stunted birds may also be infected with polyomavirus or PBFD virus.

CLINICAL APPLICATIONS

Clinical signs of a sick, stunted chick include:

- Subnormal weight gain.
- Reduced muscle mass and subcutaneous fat deposits — thin toes, elbows and hips.
- Mal-proportioned body — head large in proportion to the rest of the body.
- Feather problems: delayed feathering in particular areas, a spiral pattern to the feathers on the back of the head, a "mohawk" pattern in macaw head feathers and excessive numbers of stress marks.
- Chronic, recurrent, microbial infections.
- General illness, including sluggish behavior, dehydration and pale skin color.
- Constant vocalization and begging for food.
- Failure of the palpebral slit to open at the normal time.

- Hyacinth Macaw, Palm Cockatoo and Queen of Bavaria Conure neonates appear to have a higher incidence of stunting than other species, possibly because they have dietary requirements that are not met with commonly used diets. Currently, these species do best when fed high-fiber, high-fat formulated diets throughout development, with the addition of nuts at weaning.

Malnourished birds can often be salvaged by correcting the underlying problems and gradually increasing their plane of nutrition. If the stunting is mild and the cause is corrected early, many birds will wean normally. Moderate stunting may result in a smaller bird with a globose head and slender beak. If the stunting is severe, the bird may survive for a long time without growing but will eventually die. Euthanasia should be considered for nestlings that are confirmed positive for PBFD virus.

Congenital Abnormalities

Congenital abnormalities have been infrequently reported in psittacine chicks. The lack of documented congenital abnormalities could be a result of underreporting, rapid death in embryos with abnormalities or undiagnosed congenital abnormalities in dead neonates. Additionally, the fact that psittacine birds have been domesticated only recently (and thus show a relatively low level of inbreeding) may result in a reduced expression of genes responsible for congenital abnormalities. If the latter were true, one would expect a higher incidence of abnormalities in budgerigars and cockatiels, which have been domesticated longer than other psittacine birds. Reports in the literature would suggest that budgerigars, cockatiels and African Grey Parrots have a greater incidence of congenital deformities than do other psittacine species.[2,5,20] However, this apparent propensity for genetic malformation may simply represent a higher prevalence of these birds in captivity.

Documented cases of congenital abnormalities in psittacine chicks include bilateral anophthalmia in a budgerigar,[2] varying degrees of cryptophthalmus and ankyloblepharon in four cockatiels,[5] congenital extra-hepatic biliary cysts in an African Grey Parrot[26] and familial cataracts in Scarlet Macaws.[24] Skeletal deformities are considered to be the most common congenital abnormalities in psittacine birds,[32] but specific cases rarely have been reported in the literature. Other reported, but poorly documented, deformities include hydrocephalus,[25] and abnormalities of the pelvis, hock, feet, sternum and jaw,[2] stifle and hips,[2,3] tarsus,[3] long bones of the legs[1] and the beak.[4]

A congenital extra-hepatic biliary cyst in an African Grey Parrot was diagnosed by postmortem examination. The neonate was presented with a history of abdominal enlargement since hatch. Radiography and ultrasound indicated marked hepatomegaly.[26] Choanal atresia was diagnosed in an African Grey Parrot and an Umbrella Cockatoo with histories of chronic (four months and four years, respectively) ocular nasal discharge since hatch. The absence of a communication between the sinus passages and glottis was confirmed by endoscopy and positive contrast rhinograms (see Figure 12.42).[20]

Infectious Diseases

Microbial Infections

Microbial infections of the alimentary and respiratory tract are among the most common problems seen in nestling psittacines and are diagnosed by examining Gram's-stained smears and culturing the crop, choana or cloaca. The interpretation of culture results in nestling birds is controversial. Strains of *E. coli, Klebsiella* and *Enterobacter* spp. vary widely in pathogenicity; many cause disease, but some strains can be isolated from completely normal chicks. Some veterinarians believe that gram-negative bacteria and yeast should be treated only if a nestling is showing clinical signs of disease with or without an elevated white blood cell count. Other veterinarians believe all gram-negative bacteria and yeast are potential pathogens and should always be eliminated by antimicrobial therapy. The authors' personal opinions lie in the middle. If only a few organisms are cultured in a healthy nestling, treatment should be delayed unless clinical signs are evident. Mild microbial infections that are asymptomatic at one stage of growth may become symptomatic if the bird is stressed. Infections may be asymptomatic during the growth phase but become symptomatic during the stress of weaning. Because psittacine chicks are relatively easy to medicate prior to weaning, it may be prudent to treat and eliminate mild infections during the growth phase, especially if the hand-feeder is less experienced.

Treatment of microbial infections in nestling birds should be approached in the same manner as in adults (see Chapter 17), with a few special considerations. Medication is more easily delivered via the oral route because nestling birds are fed and handled frequently. If possible, antibiotics should be administered when the alimentary tract is relatively empty. Food in the alimentary tract reduces the absorption of most antibiotics, and calcium in the diet will sig-

TABLE 30.7 Procedures During a Nursery Disease Outbreak

1. **Plan ahead:** Aviculturists should have a plan before an outbreak occurs. As explained below, at least three separate nursery rooms will be required in a disease outbreak. Friends and families can sometimes be enlisted to take birds into their homes and feed them, but it is best if they are trained before they are actually needed.
2. **Isolate clinically ill birds:** At the first signs of illness, a chick should be isolated in a separate room, preferably one with air flow that is separate from the main nursery. Some aviculturists will question why isolation is necessary because the sick bird has already exposed the rest of the nursery to the disease. Sick birds should be immediately isolated because they shed higher quantities of infectious agents than asymptomatic carriers. Isolation of clinically ill birds can greatly reduce the load of infectious material in the nursery.
3. **Do not bring new birds into the nursery:** New hatchlings should go to a separate nursery room to avoid exposure. Ideally, a separate caretaker would be available for these birds.
4. **Maximize good hygiene practices:** If good hygiene practices are not in effect, they should be implemented immediately. Great care should be taken to reduce disease exposure when feeding chicks. If the same feeders must feed ill and healthy chicks, they should shower between groups and wear separate protective clothing in each room.
5. **Determine the cause:** Polyomavirus is the most common cause of nursery outbreaks; PBFD virus, chlamydial, yeast and some bacterial infections can also spread rapidly through a nursery. In some cases, it is best to sacrifice and necropsy an ill nestling to rapidly determine the etiology of the disease problem. This may provide information that can save the other birds. Many microbial infections are secondary to diseases that are difficult to diagnose (such as polyomavirus, PBFD virus and chlamydia).
6. **Treat the birds:** If microbial infections are identified, treatment should be initiated with appropriate drugs. If viral infections are identified, consider euthanasia or isolate sick birds and provide supportive care.
7. **Eliminate the cause:** Find and treat or eliminate asymptomatic disease shedders. Investigate hygiene and feeding practices if microbial infections are confirmed.
8. **Consider all-in all-out procedures:** Consider the primary nursery to be an isolation area. Do not add new birds until all nestlings that were exposed to the disease are moved to another area. This practice is essential with diseases with a long incubation or latency period (eg, polyomavirus and PBFD virus).
9. **Decontaminate the environment:** During the outbreak, clean the facility, brooders and air control system frequently to decrease environmental contamination. At the end of the outbreak, thoroughly clean and disinfect the room before using it as a nursery. If polyomavirus or PBFD virus were encountered, pay particular attention to cleaning the air control system (see Chapter 32).
10. **Do not sell chicks until proven healthy:** As noted above, many diseases (especially polyomavirus and PBFD virus) have a long incubation period. Some birds that are infected early in development will not show clinical signs until weaning. Ideally, neonates should not be sold until they are tested for these two viral diseases.

nificantly reduce the absorption of tetracyclines. However, some oral antibiotics cause local GI irritation (eg, trimethoprim/sulfonamide combinations and doxycycline), and birds will regurgitate unless the drug is administered with a small amount of food. A bird should not be fasted for antimicrobial administration if this will reduce the number of feedings and slow growth. If injectable drugs must be used, the subcutaneous route is preferred, because young nestling birds have little muscle mass and it is difficult (but not impossible) to deliver intramuscular injections. Injections should be carefully given into the pectoral muscle of young chicks, as the sternum is soft and easily penetrated with a needle. To prevent secondary yeast infections, neonates should be screened with fecal Gram's stains, or nystatin should be administered prophylactically. The source of the microbial infection and contributing causes such as malnutrition should be identified and eliminated.

Viral Infections

Nestling birds are prone to viral infections that may be carried symptomatically or asymptomatically by adult birds. These diseases are more completely described in Chapter 32; the salient points in nestlings are described in this section.

Polyomavirus is the most common viral infection described in psittacine nurseries. The onset of clinical signs is usually acute and includes crop stasis, listlessness, regurgitation and vomiting. Hemorrhages may be observed on the skin, and injection sites and broken or plucked feathers will bleed excessively (see Color 32). Most birds are nonresponsive to therapy and die within 24-48 hours. Survivors fail to gain normal weight, are prone to secondary microbial infections and often fail to wean. Feather abnormalities can occur that are grossly similar to those seen with PBFD virus infections. Epilation of all of the large flight feathers of the wings and tail has been observed in older cockatoos. Mortality in the nursery can be widespread or sporadic, depending on the immune status of the chicks and husbandry practices in the nursery. A more common and subtle clinical presentation has been identified. Slow growth, abnormal flora (gram-negative and yeast), beak malalignment, leg deformities and hepatomegaly may be the only clinical signs present (Harrison GJ, unpublished).

Polyomavirus can be controlled in an aviary by testing adult birds and raising neonates from carriers separately from neonates from non-carriers. Neonates can be tested as they are pulled from the nest to determine if they are shedding polyomavirus. Shedders should be raised separately from non-shedders.

Psittacine beak and feather disease also occurs in neonates (see Color 32). Cockatoos and African Grey Parrots are most commonly affected. Clinical signs are most often seen in older, fully feathered chicks just prior or at the time of weaning (Figure 30.21). The onset is subacute and clinical signs include weight loss, listlessness and feather abnormalities. Many neonates showing clinical signs will have reduced red and white blood cell counts. For example, an affected African Grey Parrot with severe bone marrow necrosis had a total white blood cell count of 2000 and a PCV of 4. Idiosyncratic syndromes are seen in some species; loss of only the tail feathers has been observed in *Poicephalus* spp. and lories. The course of disease is often chronic. PBFD virus can be eliminated from a collection by testing adult birds and removing those that are subclinically infected.

FIG 30.21 A group of 14 African Grey Parrots developed PBFD after being exposed to the virus by a hand-feeder who worked in a pet shop where a PBFD virus-infected bird was housed. The neonates were of varied age when exposed to the virus and had different gross presentations of the disease. The two chicks on the right were clutchmates that were about ten days old when exposure to the virus was suspected to have occurred. In these chicks, most of the tail, flight and body feathers were affected. The chick on the left was about five weeks old when exposure occurred, and in this bird, only a few of the flight and tail feathers were initially involved. All of the birds were confirmed to have PBFD virus by immunoperoxidase staining of feather biopsies and by DNA probe detection of PBFD virus nucleic acid in circulating white blood cells. This outbreak indicates the varied clinical signs that occur with PBFD virus infections depending on the age of the bird when virus exposure occurs. It also emphasizes the danger in having individuals that are exposed to other birds (those outside of the closed nursery) having contact with neonates.

Any neonate that is transferred from a facility should be tested negative before shipment. This will protect the aviculturist from allegations that they sold a subclinically infected bird.

Other viral infections are rarely reported in nestling birds. Herpesvirus infection (Pacheco's disease) occasionally causes nursery outbreaks. Poxvirus occurs primarily in lovebirds and imported South American psittacines such as Amazon and *Pionus* parrots. Poxvirus outbreaks may occur in tropical regions (eg, southern Florida) with high bird and mosquito populations (Harrison GJ, unpublished). Poxvirus is also common in free-ranging passerine birds and Columbiformes. The clinical signs and management are similar to those in adults (see Chapter 32).

Diseases of suspected viral etiology are occasionally observed in pediatric patients. Neuropathic gastric dilatation has been described in birds of all ages. Care should be taken when interpreting juvenile bird radiographs since the proventriculus is normally larger than in adults. Avian viral serositis is a neonatal problem characterized by the accumulation of serous fluid in the abdominal cavity (see Color 32).[19] Large amounts of fluid may accumulate and cause severe abdominal distension. Liver, bursal and lymphoid necrosis may also occur. This problem has been suspected to be caused by a togavirus that is related to eastern equine encephalomyelitis virus.

Parasitic Infections

With a few exceptions, internal parasites are an infrequent cause of disease in nestling psittacines in the United States, but are commonly found in countries where parrots are raised in flights with dirt floors. They are also found in finches, zoological avian species and free-ranging birds. Trichomonas and giardia are frequent causes of death in young budgerigars, cockatiels, finches and Columbiformes. Coccidia are commonly recovered from lories, lorikeets, passerines, Columbiformes, and finches; their importance appears to depend on the chick's immune status. *Atoxoplasma serini* is a common cause of mortality in juvenile canaries. The safety of many parasiticidal drugs has not been investigated in nestling birds, and care should be exercised when selecting a treatment regimen. For example, furacin has a low therapeutic index in lory neonates (see Chapter 37).

Disorders of the Alimentary Tract

Pharyngeal and Esophageal Trauma

Damage to the pharyngeal or esophageal wall can occur during metal tube- or syringe-feeding when a nestling lunges against the feeding instrument. This can be prevented by being careful or by use of a soft crop tube when administering food to birds with a strong feeding response, such as macaws. When a puncture occurs, food may be deposited into the subcutaneous tissues and will often migrate caudal to the puncture site (Color 30.8). Liquid food can drain all the way to the base of the crop and be confused with crop contents. If the puncture is in the pharyngeal cavity, food will usually collect in the space ventral to the mandibles. Extravasated food causes a massive inflammatory response and should be treated aggressively and quickly. The bird should be stabilized, and the food pockets surgically opened, curetted and thoroughly flushed (see Chapter 41). Antimicrobial therapy designed for both gram-positive and gram-negative organisms should continue for at least 14 days.

Air in the Crop

Bubbles or filling of the crop with air is usually caused by aerophagia. It occurs most often in stunted birds that beg constantly for food, but has also been observed in young birds of many species (especially cockatiels). Slowly delivering food will contribute to aerophagia because the chick attempts to gulp the feeding formula faster than the food is provided. Some inexperienced hand-feeders will confuse this condition with crop stasis, subcutaneous emphysema and filling of the cervicocephalic air sac. Air is easily distinguished from food or fluid by transilluminating the crop. Visualization of blood vessels in the crop wall can help differentiate between air located in the crop and air located in the subcutaneous space.

Severe aerophagia decreases the amount of food the bird can consume and may contribute to stunted growth. Feeding a nutritious formula at a steady rate will correct the problem in some birds. If aerophagia is persistent, the ingested air can be carefully removed ("burped out") and the bird immediately fed before it can gulp more air. In some cases it may be necessary to tube-feed these neonates.

Crop Stasis

Failure of the crop to empty normally is a common sign of illness in nestling birds. The problem is usually related to generalized gut stasis (often caused by a yeast or gram-negative bacterial infection) rather

than a primary crop disorder, but there are numerous possible etiologies. Food that remains in the crop will ferment and have a sour odor — hence the lay term "sour crop" (Color 30.14).

Causes of crop stasis include:

- Primary crop disorders: foreign bodies, crop infections; crop atony caused by overstretching; crop burns; crop impactions caused by fibrous food, large food chunks (eg, raw carrots) or bedding; and dehydration of food in the crop leading to formation of a concretion or doughy mass.
- Delayed transit time or obstruction of the distal gut: intestinal ileus due to generalized infection, neuropathic gastric dilatation, polyomavirus, GI foreign bodies or hypothermia.
- Cold food.

The motility of a normally functioning crop that is free of infectious agents should not be altered by the consistency of the food. The crop should be examined and gently palpated to determine if it is atonic or burned, or if foreign material or an impaction is present. A CBC, serum chemistries, cloacal culture and radiographs are indicated if the bird has clinical signs of disease. Whole body radiographs can be used to evaluate the distal alimentary tract and barium contrast studies can be used to determine gastrointestinal transit time. The crop can be swabbed or flushed for culture and cytology.

A bird with crop-emptying problems should be fed carefully. The crop should not be overstretched, as this will cause atony and compound the problem. Mild cases of crop stasis caused by a dehydrated food mass or overfeeding can often be solved by administering a small amount of warm water and gently massaging the crop. If the food does not pass in three to five hours, the crop should be emptied and flushed with warm saline. This removes the old food, which acts as a growth media for microbial proliferation. To flush the crop, a lubricated soft feeding tube with an open end is gently passed into the crop, and a small amount of saline is flushed in and out to draw crop material into the syringe. It may be necessary to palpate the tube and direct it toward the food mass and away from the crop wall. When moving or withdrawing the tube, negative pressure on the syringe should be released to make sure the tube does not attach to the crop wall and cause damage. The removal procedure should be accomplished in stages if the bird becomes overly stressed.

Crop stasis caused by generalized ileus is a serious problem that requires immediate attention. Complete stasis may be one of the early signs associated with fatal diseases such as polyomavirus, PBFD virus, septicemia or sarcocystis infection. With these progressive diseases, treatment may not be successful. If the stasis is caused by a microbial infection (yeast, bacteria or chlamydia), intensive medical management may be effective. Treatment consists of antimicrobial therapy targeting the etiologic agent, correcting the dehydration and malnutrition that result from stasis and providing a complex carbohydrate diet to provide energy and gently re-stimulate gastrointestinal motility (Table 30.8).

Crop Burns and Fistulas

Crop burns can occur when excessively heated food is fed or if a bird contacts a heating pad or hot light. Severe burns can result from a single, overly heated meal (eg, greater than 120°F), or by repeated exposure to food that is slightly hot (115°F). Birds will readily accept hot food, and the feeder may not recognize a problem for days to weeks after the burn occurs. If one bird in a nursery has a crop burn, all of the other neonates should be carefully examined to determine if they have also sustained injuries.

The method of treatment depends on the degree of tissue damage and stage of healing. Mild burns result in tissue swelling, erythema and blister formation, and can be treated with antibiotics and topical application of soothing vitamin A and E ointments (Color 30.11, 30.12). The bird should be fed reduced volumes more frequently during the healing process.

Severe crop burns cause greater tissue damage. In the early stages the crop will adhere to the overlying skin; the skin will be hyperemic and the site may be covered with a scab. Eventually the crop may fistulate, and food and water will leak from the crop soiling the bird's chest. Bird owners are frequently puzzled by this odd phenomenon. Crop fistulas are treated by removing the scab, surgically excising the necrotic portion of the skin and crop and then separating and individually closing the crop and skin (see Chapter 41) (Color 30.12). The timing of surgery is important. Birds with this condition are often debilitated and should receive supportive care and enteral alimentation to build their strength prior to anesthesia and surgery. Ideally, the tissues surrounding the fistula should be given as much time as possible to heal before surgery, and the scab should be left in place as long as possible to encourage wound contraction that will reduce the size of the fistula (Color

TABLE 30.8 Treatment for Crop Stasis

1. Empty and flush the crop with LRS using a feeding tube. Repeat every six to twelve hours if the crop does not empty. Digestive enzymes are often beneficial.
2. Give intravenous, intraosseous or subcutaneous fluids. Most birds with crop stasis are dehydrated and require parenteral fluid administration. A Gram's stain of a crop swab can be used to determine the microbial agents that are present.
3. If a generalized microbial infection is suspected, start treatment with a broad-spectrum antibiotic and antifungal drug. Cephalosporins and penicillins are the safest drugs to use; aminoglycosides and sulfas should be avoided due to potential dehydration and renal toxicity. Injectable antibiotics should be used if there is severe stasis because oral antibiotics would not be properly absorbed. Oral antifungals (nystatin) should be used because the parenteral antifungal drugs (eg, amphotericin B) may be toxic. If chlamydiosis is diagnosed, a single SC injection of oxytetracycline or doxycycline IV can be used to initiate therapy, followed by oral doxycycline (see Chapter 17).
4. If the bird has generalized ileus, a motility stimulant such as metoclopramide or D-panthenol can be administered. Response to these stimulants is highly variable.
5. Once the crop starts to partially empty and the bird is stabilized, limited feeding should resume. The bird should be fed a liquid, complex carbohydrate, medium-fiber-content diet until the crop is emptying normally (see Chapter 15). Gerber's oatmeal with applesauce and bananas baby cereal mixed 50:50 by volume with water works well. The bird should be fed less volume, more frequently. As the crop starts to empty normally, the diet that is normally fed should be gradually substituted (provided it is nutritionally adequate). It is important to restore normal feeding as quickly as possible because dilute baby food diets do not provide sufficient nutrition for growth. Subcutaneous fluid administration and antibiotics should continue until the bird is clinically normal.
6. If the crop is overstretched or atonic it is beneficial to apply a "bra" to elevate the crop and facilitate emptying (Figure 30.22). The bra can be constructed from elastic bandage material or baby tube socks and should be applied while the crop is full to make sure it is not too tight. The neonate should be confined to a small container for a few days if it objects to the bra and falls over backwards. Most chicks will eventually accept the bra.
7. Parenteral nutrition would be beneficial in cases of crop stasis; however, at the time of this publication this is still a highly experimental procedure and specific recommendations are speculative at best (see Chapter 15).

30.12). If surgery is attempted before the tissues surrounding the burn have healed, it is difficult to accurately assess the extent of devitalized tissue that must be debrided. Surgical adhesives can be used to close the crop and allow feeding or a pharyngotomy tube can be passed (see Chapter 41). It has been estimated that it takes seven to ten days following a burn to determine the extent of tissue injury.[8]

Large crop defects (greater than one-third the size of the crop) can be difficult to repair. Closure frequently results in a reduced crop capacity. Following repair, the bird should be fed small amounts of food frequently to prevent reflux and aspiration. The amount of food offered can be gradually increased to stretch the crop. If the esophagus was involved, a pharyngotomy tube may be necessary to allow feeding yet protect the wound during healing. An alternative to a pharyngotomy tube is to place a mushroom-tipped jejunal catheter in the crop and tunnel it subcutaneously up the side of the neck. If it is impossible to close the skin over the defect, the wound should be covered with a permeable dressing and allowed to heal as an open wound.

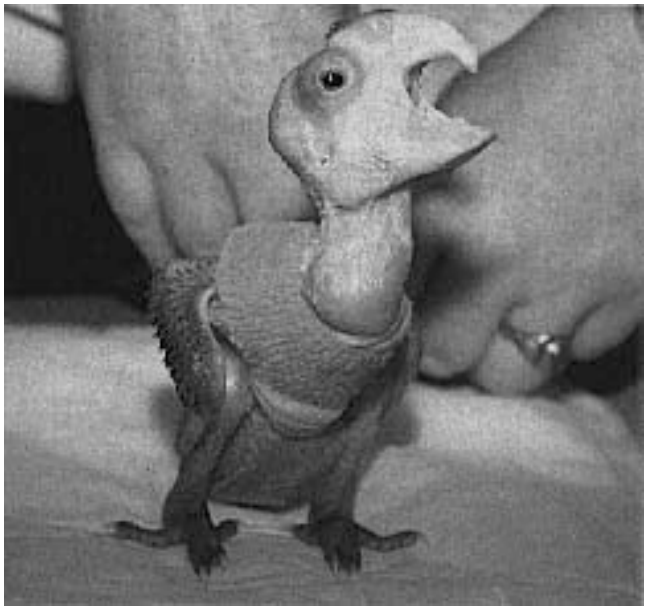

FIG 30.22 In an overstretched, pendulous crop, the distended crop hangs over the thoracic inlet where food cannot enter the thoracic portion of the esophagus. A crop bra can be used to elevate the crop and increase the gravitational forces that encourage food to pass through the thoracic portion of the esophagus and into the proventriculus (courtesy of Kim Joyner).

Regurgitation

Hand-fed birds (especially macaws and African Grey Parrots) commonly regurgitate at weaning, and it is important to differentiate this relatively normal phenomena from a pathologic condition. Causes of regurgitation include overfeeding, crop stasis, alimentary tract infections (especially candidiasis), alimentary tract foreign bodies, blockage of the alimentary tract and use of some drugs such as trimethoprim-sulfa compounds and doxycycline. Treatment consists of correcting the underlying cause.

Foreign Body Ingestion or Impaction

Nestling birds are curious and may ingest foreign objects. Preventing neonates from consuming foreign bodies is far easier than treating them. The feeder should be very selective about the objects the birds are allowed to contact (Color 30.9).

If a consumed foreign object is located in the crop, the bird should be treated immediately to prevent the object from entering the proventriculus. It is much easier to retrieve objects from the crop than the proventriculus, and birds have a remarkable capacity for passing even relatively huge objects such as feeding catheters into the proventriculus. Some objects can be "milked" up the esophagus and retrieved from the caudal oral cavity with forceps. Forceps can also be introduced into the crop to retrieve foreign bodies, with or without the aid of endoscopy. Objects can also be retrieved via an ingluviotomy incision (see Chapter 41).

Objects in the proventriculus or ventriculus can be tolerated for long periods[8] but should be retrieved if they have the potential to erode the stomach wall or can be digested, resulting in toxicity. Foreign bodies may be removed using an endoscope, or forceps can be passed into the proventriculus via an ingluviotomy incision with the aid of air insufflation (via a rubber catheter) (see Chapters 13, 15). The endoscope must be carefully passed to prevent rupture of the thoracic esophagus or proventricular wall.[8] The proventriculus and ventriculus can also be opened surgically as described for adult birds (see Chapter 41).

Proventricular or ventricular impactions caused by grit or bedding material are serious and require urgent attention.[8] Mild accumulation of material in the ventriculus (that does not impede passage of ingesta) can be treated by hydrating the patient and administering laxatives (dioctyl sodium sulfosuccinate or psyllium or digestive enzymes). Psyllium should be limited to no more than one percent of the dry weight of the tubed formula to prevent it from causing an impaction. If this does not work, mineral oil should be administered into the crop, followed 30 minutes later by a large volume of barium sulfate (10 to 15 ml/kg) that may help force the mineral oil through the GI tract by gravitational pressure. The patient should be kept well hydrated with SC fluids due to the hygroscopic nature of barium sulfate. Serial radiographs can be used to evaluate the success of the therapy. If this treatment fails, proventriculotomy (see Chapter 41) or gastric lavage (see Chapters 13,15) can be attempted but are associated with a guarded prognosis.

Intestinal Intussusception

This condition is occasionally reported in macaws and is associated with diarrhea and possibly intestinal hypermotility.[15] In severe cases the ileum may telescope into the colon and protrude through the cloaca. Mild cases are diagnosed radiographically and may respond to antimicrobial and supportive therapy. Severe cases with a visible cloacal prolapse are usually fatal.[8,15] Successful jejunostomy and jejunocloacal anastamosis has been reported.[35]

Disorders of the Respiratory Tract

Upper Respiratory Infections

Nestling birds can pass food through the choanal slit, resulting in clogged nostrils and upper respiratory problems. These can be treated by removing the food plug with a feathered wooden applicator (see Chapter 8) or dull needle, and gently flushing the nares with saline until clear. Microbial infections of the upper respiratory tract are treated in the same manner as in adult birds (see Chapter 22).

Aspiration Pneumonia

Birds may aspirate food during feeding or following regurgitation. Aspiration occurs most often in birds that are reluctant to feed or if the aviculturist introduces food when there is no feeding response. If large amounts of food are inhaled, the bird will die from asphyxiation (see Color 22). Rapid placement of an air sac cannula and aggressive antimicrobial (eg, trimethoprim-sulfa, ketoconazole) and steroid therapy may save the patient, but the prognosis is poor. Some birds respond to such aggressive treatment and die months later due to a chronic fungal infection. If small amounts of food are aspirated, the event may not be noted at the time but the bird may later develop a foreign body pneumonia. An affected bird will show poor weight gain, a persistently elevated white blood cell count and may or may not show respiratory signs. Often, the pneumonia may be noted only by radiology or at necropsy.

Miscellaneous Disorders

Hepatic Lipidosis

In most cases, hand-fed birds gain weight slower than parent-fed birds, and the hand-feeder should be instructed to maintain the maximum weight gain possible. Umbrella Cockatoos, Moluccan Cockatoos

and Blue and Gold Macaws may be an exception to this recommendation. In these species, and possibly others, it is possible to overfeed (especially in the later development stages) and cause massive weight gains and hepatic lipidosis. It has been suggested that multiple deficiencies of fiber, vitamins and minerals and nutritional excesses combine to cause this problem (Harrison GJ, unpublished). Affected birds are usually dyspneic, especially when food in the digestive tract places additional pressure on the respiratory system following feeding (Figure 30.23). The abdomen is usually protuberant and the pale, enlarged liver may be visible through the skin. In these cases, the amount of food fed should be *gradually* reduced and small meals should be fed more often to avoid respiratory distress. Hyperthermia will aggravate the respiratory distress and should be avoided. If identified early, the birds may wean normally, but in severe cases the liver will be massively enlarged and the bird will die. This condition can be prevented by feeding a proven diet and comparing the bird's weight gain to established growth charts. If the bird is normal in body size but substantially heavier than the upper limit on the chart, the possibility of hepatic lipidosis should be considered.

FIG 30.23 A six-week-old Blue and Gold Macaw was presented for a swollen, fluid-filled abdomen and severe dyspnea. The bird was 30% heavier than normal when compared to standard weight charts. The neonate was being fed a homemade formula that consisted of a peanut butter base supplemented with numerous herbs and vitamins. The owners requested euthanasia. On postmortem the bird had large accumulations of fat throughout the abdomen, and the liver was whitish-yellow with a roughened, irregular surface suggestive of hepatic lipidosis.

Hepatomas

Hepatic hepatoma has been described primarily in macaws, and may occur when blunt trauma ruptures the liver and causes hemorrhage.[15] The trauma may occur when the bird is lifted with pressure over the liver or it may simply be idiopathic. Affected birds are pale with extremely low hematocrits and may be saved by repeated blood transfusions within the first few days following the traumatic event.

Gout

Deposition of uric acid crystals in the tissues is called visceral gout and is usually due to end-stage renal disease. Clinical signs include crop stasis and vomiting followed by death. Excess vitamin D_3 results in dystrophic calcification of numerous organs including the kidney, which then may result in gout (see Chapters 3, 21). Macaws seem to be particularly sensitive to excessive dietary consumption of vitamin D_3 and calcium (see Color 21).[33]

Wine-colored Urine

Reddish urine and urates have been described in juvenile African Grey Parrots and some Amazon and Pionus parrots. It can be distinguished from hematuria by a fecal occult blood test. It occurs sporadically with several hand-feeding formulas, and the pigment may be more pronounced on some bedding materials, especially certain brands of paper towels. This condition has not been associated with pathology or other clinical signs.

Musculoskeletal Disorders

Leg Deformities

Orthopedic problems in nestling birds are poorly understood and the causes are believed to be multifactorial. Nutritional deficiencies (especially of vitamin D_3 and calcium), trauma and housing the birds on slippery surfaces are the most common causes. Genetic and incubation abnormalities probably also occur. Polyomavirus may be a common underlying cause (Harrison GJ, unpublished). In general, leg deformities are challenging to repair and the earlier the diagnosis and the younger the bird, the better the prognosis[8,15] (see Chapter 42).

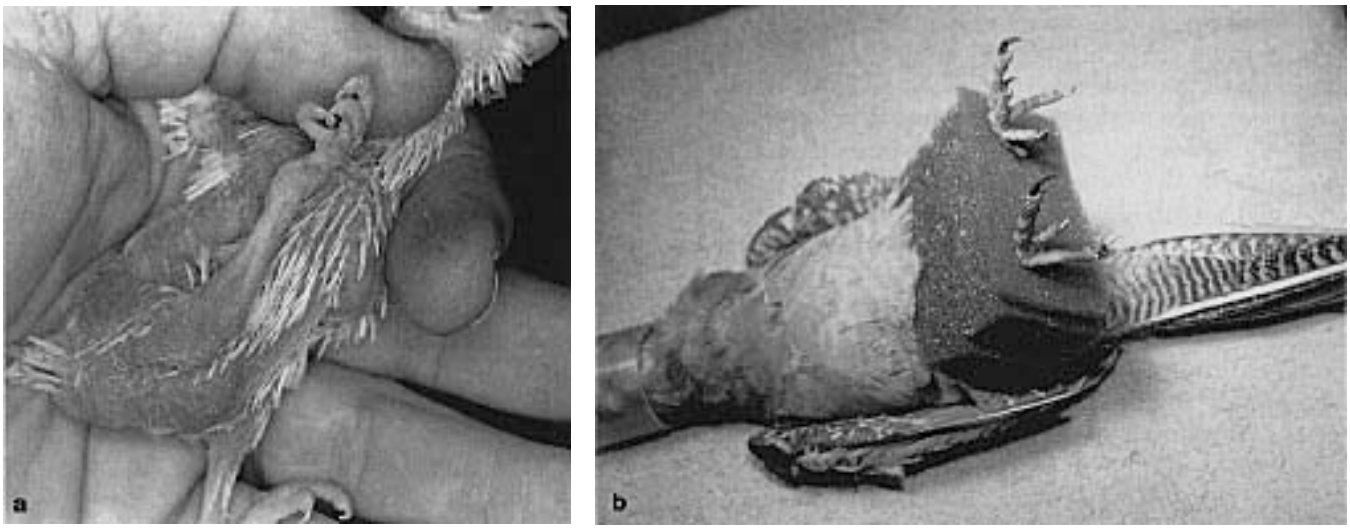

FIG 30.24 **a)** The cause of splay leg in psittacine birds has not been confirmed. Suggested etiologies include nutritional deficiencies, trauma, poor footing, improper incubation and genetic defects. Severe deformities, like the one in this cockatiel chick, are difficult to treat without surgery. **b)** In mild cases that are treated early, splinting or foam rubber hobbles may be effective in correcting the lesion (courtesy of Robert Clipsham).

- ***Spraddle or Splay Leg:*** Birds with this condition will have one or both legs splayed laterally from the hip or stifle (Figure 30.24). Mild deformities can be treated by packing the bird in a deep cup with tissue or towel padding to take pressure off the legs. More severe deformities and those in older birds require a fixation device in addition to packing in a cup. The chick can be taped over a foam rubber pad or sanitary napkin, or placed in a piece of foam with slits cut for the legs. As an alternative, the legs can be hobbled together with elastic tape at the tarsometatarsus and if needed across the tibiotarsus. The hobble sites should be padded with cotton and care should be taken not to tape too tightly. The hobble should be changed every two to four days to allow growth. More severe deformities require more rigid fixation.[8,15] A suspension method of treating this condition has been reported.

- ***Valgus Deformity*** (Bowing of the tibiotarsus with lateral rotation of the femur or tibiotarsus): This is usually caused by premature closure of one side of the growth plate of the proximal or distal tibiotarsus. This causes uneven bone growth and bowing and twisting in the tibiotarsus (Color 30.6). It is a serious condition that may not respond to conservative treatment. Surgically closing the opposite side of the growth plate or periosteal stripping to even out the growth, followed by a dome osteotomy and realignment of the tibiotarsus may be necessary.[15] The osteotomy is repaired with a biplaner KE apparatus. The osteotomy is best performed after the bones have ossified (Figure 30.25). Macaws and cockatoos should be approximately 65-70 days old before attempting an osteotomy procedure.

Toe Malposition

Malposition of digits in neonatal birds is believed to be secondary to malnutrition. Reducing the dietary protein content and slowing the growth of some chicks may aid in correcting the problem.[8] Affected chicks should receive parenteral and dietary vitamins and mineral supplements including vitamins A, D_3, E, B complex, C, K_1, calcium, iodine, selenium, iron, copper and cobalt. Other proposed etiologies include virus infection and improper incubation.

Improving the substrate is also beneficial. The chick should be placed in a smaller, padded environment such as a teacup lined with a towel. This will help diminish the tendency for the legs to splay and the toes to curl. In some patients, this alone may be adequate to correct the condition without splinting.[8] In many cases, taping the affected toes in a normal position is necessary. This condition develops quickly, often in a matter of hours, and when the toes are taped in a normal position, the condition is corrected quickly. Generally, the affected digits should be maintained in the supported position for approximately as long as they were malpositioned (usually a maximum of several days). If the condition is recognized early, corrective measures may be required for only a few hours. This must be monitored closely as deformities can be caused by leaving bandages or splints on too

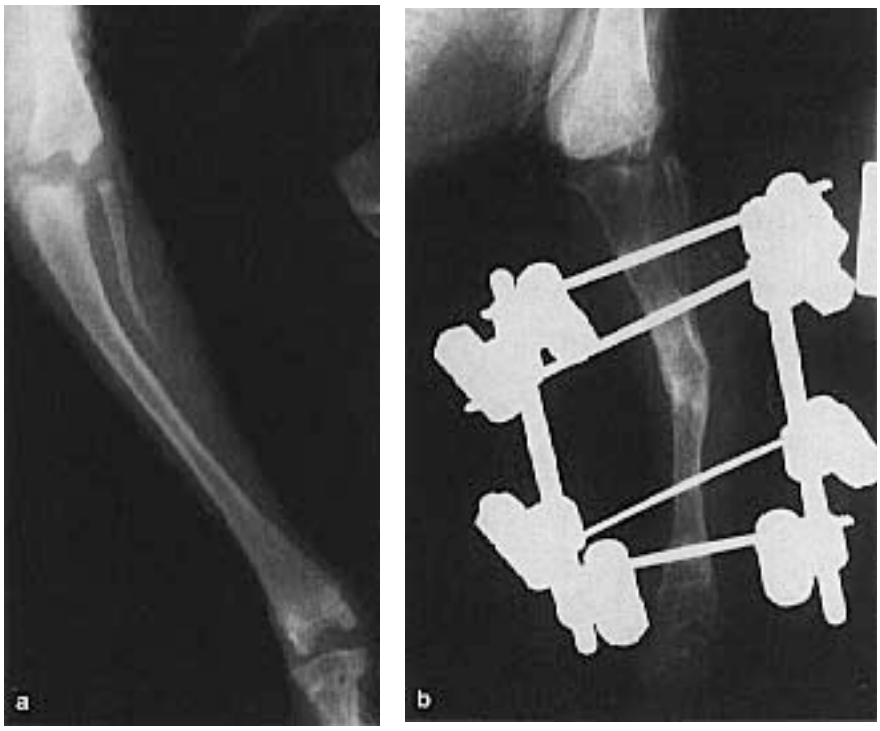

FIG 30.25 **a)** An eight-week-old Moluccan Cockatoo was presented with a valgus deformity of the left tibiotarsus. Radiographs indicated bowing of the tibiotarsus starting in the proximal third of the bone. **b)** The defect was repaired using a dome osteotomy that was stabilized with a bilateral KE apparatus. This radiograph was taken four weeks post-surgery. Note the stable bone union and minimal callus formation suggestive of primary bone repair. The stabilizing pins used in this bird were positive-profile threaded pins that provide maximum strength and tend to form a tight, long lasting pin/bone interface. All of the pins in this bird remained secure and had to be removed by "unscrewing" them from the bone.

long. Additionally, the developing circulatory system and muscle mass of neonates make them more susceptible to edema and pressure necrosis. Their skin is friable and sensitive, so all forms of external coaptation should be adequately padded.[8]

A corrective shoe may be made from a piece of firm material such as thin cardboard or radiographic film. The shoe should be made to properly fit the foot of the affected individual with a notch in the shoe into which each toenail will be placed. Once the shoe is made, the foot is placed in the shoe and each digit is taped into a normal position using very thin strips of masking tape. A hydroactive dressing may be used to make a corrective shoe. The material is cut to fit the foot as described above. The plantar aspect of each toe is placed on the sticky surface of the hydroactive dressing in a normal position. A second piece of hydroactive dressing is applied dorsally to sandwich the toes in place and to maintain reduction. This material is especially appropriate as it is soft, unlikely to cause pressure problems and easy to remove.

Constricted Toe Syndrome

This condition is most commonly reported in Eclectus Parrots, macaws and African Grey Parrots. Any toe may be affected, but the distal phalanx of the outer digits (1 and 4) is most often reported. The lesion consists of an annular ring of constriction that eventually causes swelling and necrosis of the distal segment of the toe (Color 30.7). It appears similar to the lesion induced by wrapping a thread around the toe, but this is seldom the cause. The etiology is unknown but may be related to low brooder humidity[22] or fracture of the digits. Histology usually demonstrates edema and inflammation; microbial infections are rare except as secondary invaders. The condition can be corrected and the digit saved if identified early. If the degree of constriction and swelling of the distal segment is mild, warm water soaks and frequent massage may restore circulation and correct the condition. If a fibrous annular ring is present, it should be carefully incised and accumulated serum and tissue debris gently debrided (see Chapter 41). The toe should be soaked in warm, dilute, povidone-iodine solution and bandaged. A DMSO dressing may reduce inflammation and antibiotic ointments help soften and prevent reformation of the annular ring. If the distal segment is severely swollen or necrotic it should be surgically removed, preferably at a joint proximal to the constricting lesion. Toe constrictions can often be prevented by keeping susceptible species on non-desiccating surfaces and in brooders where the humidity is maintained above 50%. Commercial forced air brooders with rapid air changes tend to desiccate the chicks and should be avoided.

Stifle Subluxation

Stifle luxation or subluxation in both juvenile and adult birds has been reported.[8] This condition may occur when a bird gets a leg caught in the enclosure and struggles to free itself. Idiopathic luxation of the stifles may also occur and appear to be particularly common in cockatiels (Figure 30.26). Rigid fixation of the stifle by applying a KE apparatus to the distal femur and proximal tibiotarsus may fuse the joint

Neonatology

Color 30.1
Psittacine chicks are hatched basically naked with the exception of a sparse natal down. Neonates should be hatched in a warm brooder (94°F), and the feathers should dry shortly after hatching. This neonate exited the egg five minutes before this photograph was taken (courtesy of Apalachee River Aviary).

Color 30.2
A Moluccan Cockatoo egg was presented for evaluation. The embryo internally pipped three days earlier than anticipated and died the day after entering the air cell. The embryo was hyperemic and the yolk sac had not started to absorb. The embryo weighed 32 g (the average weight for chicks from this pair was 22 g) and was considered to be large for the egg (fetal monster). Aerobic and anaerobic cultures of the yolk sac did not indicate the presence of bacteria. There was no histologic indication of abnormalities in any tissues.

Color 30.3
Healthy neonates that are receiving proper care will be bright and alert and have full crops. Development is rapid in large psittacine chicks, like this five-week-old Umbrella Cockatoo. This neonate will grow from a hatching weight of 18 g to its adult size of 600 g in eight to ten weeks.

Color 30.4
Healthy neonates should have yellowish-pink skin with a supple warm feel. Dehydrated nestlings like this Rose-breasted Cockatoo have dry, hyperemic skin that feels "sticky."

Color 30.5
The normal liver of a recently hatched chick may appear large, pale yellow or light red. As the bird matures, the liver becomes its normal brownish-red color and assumes a more proportional size within the abdomen.

Color 30.6
An eight-week-old Moluccan Cockatoo was presented for evaluation of a valgus deformity of the left tibiotarsus. The deformity had first been noticed at one week of age. The defect was managed conservatively by placing the bird in a vertical container; rolled towels positioned around the edges supported the bird in a continuous standing position. Physical therapy was performed on the leg for ten minutes at each feeding. The bird was presented at seven weeks of age for a corrective dome osteotomy (see Chapter 42).

Color 30.7
A three-week-old Eclectus Parrot was presented for swelling of the distal phalanx in several digits. Numerous constrictive le sions were present in the affected digits. Examination of the constrictions with a dissecting microscope failed to demonstrate the presence of constrictive fibers. The defects were repaired surgically and the brooder humidity was increased (see Chapter 41).

Neonatology

Color 30.8
A feeding tube or syringe tip can penetrate the pharyngeal or esophagal wall if a neonate has an over-zealous feeding response or if the feeder has a rough, careless feeding technique. Once the wall has been penetrated, food will be deposited in the subcutaneous tissues causing severe cellulitis. These cases are difficult to treat, but some birds can be saved by early and aggressive therapy that includes surgical debridement, flushing of the involved tissues and systemic antimicrobial therapy. In this photograph, a feeding tube has been placed in the esophagus to demonstrate the location of the periesophageal food.

Color 30.9
A neonatal cockatoo was presented for necropsy after being found dead in the nest several days after hatch. This was the parents' first clutch of eggs. The parents had a broad assortment of soft foods available, including soaked monkey biscuit and mixed vegetables. The baby died from an esophageal and ingluvial impaction after being fed pieces of wood chips and dirt from the substrate in the nest box.

Color 30.10
A 1.5-day-old Umbrella Cockatoo chick died suddenly after failing to thrive (poor feeding response, lethargic). The yolk sac had not started to absorb. The umbilicus was dry and considered to be normal. Bile pigment accumulations were noted on the dorsal surface of the liver. Aerobic and anaerobic cultures of the yolk sac revealed *Streptococcus* spp. Histopathologic findings were limited to mild hepatitis and myocarditis.

Color 30.11
Mild crop burns may be recognized clinically as swelling, erythema and edema of the crop and esophagus.

Color 30.12
In some cases, full-thickness crop and skin burns may cause relatively small fistulas that are easy to repair (see Chapter 41) (courtesy of Elizabeth Hillyer).

Color 30.13
Some burns can result in massive thermal necrosis of the crop and esophagus. In any crop burn, the wounds should be treated conservatively, and surgical correction should be delayed as long as possible for differentiation to occur between damaged and healthy tissue. **a)** In this case the aviculturist noted a hyperemic area in the skin over most of the crop in a six-week-old Umbrella Cockatoo. The bird was placed on smaller feedings provided more frequently to decrease crop stretching. A large scab formed over the crop and caudal esophagus over a ten-day to two-week period. Food began to leak from the caudal-most edge of the scab. The bird's overall condition was excellent, and weight gain had continued normally since the burn had first been noticed. **b)** The scab was removed, revealing the extent of the damage. A healthy bed of granulation tissue was available to facilitate repair. The wound was thoroughly cleansed and the crop was bluntly separated from the skin. The crop and skin were closed in separate layers as described in Chapter 41.

Color 30.14
An eight-week-old Amazon chick was presented for regurgitation, weight loss and anorexia of four days' duration. The chick was the most affected of a group of 12 psittacine neonates that were having varied clinical problems associated with poor weight gain and failure to thrive. Cytologic evaluation of crop samples indicated numerous (30/HPF) budding yeast and gram-negative bacteria (40%). Abnormal clinicopathologic findings included PCV=20, WBC=4000 (numerous toxic heterophils) and TP=2.2. The crop was distended with a doughy, solid mass. The bird died shortly after presentation despite extensive supportive care. Histopathology revealed diffuse gastrointestinal candidiasis and gram-negative bacterial septicemia. The neonates in this nursery were fed from a single syringe with a single food supply that was mixed in the morning and maintained in the refrigerator between feedings.

FIG 30.26 Idiopathic stifle luxation appears to be common in some species of smaller psittacine birds, especially cockatiels. The problem may be congenital, and therapy is usually ineffective (courtesy of Louise Bauck).

and permit limited, but less painful ambulation. The knee should be fixed in a slightly flexed position. Tolerance of the device is variable and it should be left in place for 30-40 days in large birds and 21 days in smaller species. Flunixin can be used for one to three days after placement and removal of the fixation device to reduce pain and inflammation.

Beak Problems

Beak Trauma

Chicks may damage their own or a sibling's beak when they lock beaks and pump against each other, or if they pump against the brooder container.[15] Perlingual wounds are common and should be cleaned daily with a cotton-tipped applicator. Topical amphotericin B cream can be applied if a secondary yeast infection occurs, and antibiotics can be used to control bacterial infections. Occasionally the beak itself is damaged, creating an indentation through the beak wall. The wound should be debrided, flushed with saline, dried, and then filled with a dental acrylic. If the damaged portion of the beak is indented, it should be elevated to the level of the rest of the beak with a bent needle before applying the acrylic patch. The acrylic patch will eventually loosen as granulation tissue fills the wound. Damage and fractures of the tip of the maxillary beak should

FIG 30.27 A ten-week-old Umbrella Cockatoo was presented for lateral deviation of the upper beak. This defect is best corrected early when physical therapy or beak trimming procedures can be effective in resolving the problem. In older birds, like this chick, surgical techniques or implants are necessary to correct the defect (see Chapter 42).

be repaired by applying dental acrylic with or without small pins to stabilize the beak tip. If the germinal center at the base of the beak is damaged, the tip will not regrow and the defect will be permanent. Birds with this condition will require frequent beak trims, as the mandibular beak will continue to grow upward.[15]

Lateral Beak Deviation (Scissors Beak)

Lateral deviation of the upper beak is most often diagnosed in macaws but also occurs in other psittacine birds (Figure 30.27). In most cases, it does not interfere with eating, but it is unsightly. The etiology is unknown and may be multifactorial. Suggested causes include low or unbalanced calcium in the diet, viral diseases, trauma, abnormal pressure applied by the aviculturist during hand-feeding, incubation problems and alterations in the mandibular occlusal surface.

Early recognition is critical for easy and successful correction. If noted early (ie, a few days after hatch), the lower beak should be trimmed in a ramp-like fashion to encourage the upper beak to slide over to the side opposite the curvature. Differences in the height of the occlusal surfaces of the mandibular beak should be corrected, and digital pressure should be applied to the beak two to four times daily to gently push the beak back in position. If the beak is calcified or if conservative therapy fails, a ramp built

from dental acrylic over a stainless steel mesh can be attached to the lower beak to apply pressure to correct the upper beak[7] (see Chapter 42). The acrylic device should be left in place for one to twelve weeks, depending on the bird's age and the severity of the defect. Correction of severe beak deformities in older birds is seldom complete, but substantial improvement can be made.

Mandibular Prognathism

Mandibular prognathism (underbite), in which the upper beak tucks within the lower, is seen primarily in cockatoos (Figure 30.28). Severe prognathism can interfere with self-feeding. The etiology of this condition is unknown. It has been suggested that the parent bird may hook the maxilla during feeding and help extend it, an event that may not occur during hand-feeding.[15] Contraction of cartilaginous extensions of the beak tip may also contribute to the underbite. If the beak is still soft, physical therapy may correct the condition. A finger or loop of gauze can be used at each feeding to apply traction and extend the maxillary beak rostrally. The cartilaginous extensions should be clipped if they are contracted. If the beak is calcified, physical therapy combined with trimming of the lower beak to allow the upper to extend into a notch may help. If this fails, a dental acrylic prosthesis can be applied to the rostral end of the maxillary beak to stretch the maxilla and force it over the mandibular beak[22] (see Chapter 42). The prosthesis can be removed once normal occlusion is achieved.

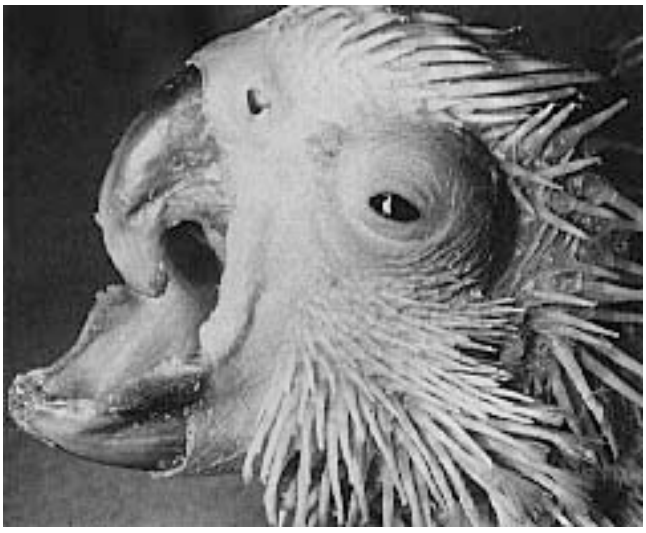

FIG 30.28 A three-week-old Umbrella Cockatoo was presented with severe mandibular prognathism. The problem had been present since hatching, and the aviculturist had been incorrectly told that this was normal and would resolve with age. If corrected from hatching, this problem can be resolved by gently pulling the upper beak forward and placing it over the lower beak for about ten minutes between each feeding. If allowed to progress, as in this cockatoo, repair requires surgical intervention (see Chapter 42).

Compression Deformities of the Mandible of Macaw Beaks

An elongated, shovel-like deformity of the mandible may occur in macaws when the hand-feeder compresses the lateral sides of the lower beak by holding it during feeding or cleaning. If noted before the beak calcifies, it can be corrected by trimming beak tissue from the lateral walls and manually reshaping the lower beak. Once the beak calcifies, it is difficult to repair.

Traumatic Subluxation of the Premaxilla-frontal Joint

Juvenile birds will occasionally subluxate the upper beak when playing or flying. The upper beak will usually be displaced dorsally, and fractures of the premaxilla or frontal bone may be apparent. It is extremely painful, and the bird should be anesthetized while the beak is placed back in a normal position (see Chapter 42). Most birds have been reported to heal well, although some may need to be hand fed for a few days.[8] Antibiotics and anti-inflammatory drugs should be used where indicated.

Integumentary Problems

Feather Stress Bars

Stress bars are horizontal defects in the feathers that occur when there is endogenous release of corticosteroids or when corticosteroids are administered during feather growth (see Chapter 24). A few stress bars in an otherwise normal bird are of only temporary cosmetic concern. Large numbers of stress bars may indicate malnutrition, stunting or a disease problem. Determining the cause of stress bars is often difficult because they represent a problem that occurred when the feather was developing.

Feather Dysplasia

Malformed feathers, feathers that fail to grow, and feathers that are easily epilated are most often caused by polyomavirus or PBFD virus. Hyperthermia, drug reactions and bacterial folliculitis are less common causes.

Occluded Ear Openings

Occlusions of the external openings of the ears are most often seen in macaws, (especially Military Macaws). Macaws are born with a thin membrane covering the ear canal that should start to open between

FIG 30.29 A four-week-old Green-winged Macaw was presented for depression and failure to grow. The bird was being fed a homemade diet with a baby cereal base that was nutritionally deficient. The bird grew normally when placed on a commercial hand-feeding formula. Note the membrane over the ear that has not yet opened.

12 and 35 days of age (Figure 30.29). If the canal fails to open, it should be explored with blunt forceps and an opening surgically created if necessary. If a small hole is found, it can often be enlarged by stretching it with the tips of a pair of hemostats. Occasionally the canal will become infected and fill with inspissated pus. This material should be removed by curettage and flushing, cultured for bacteria and fungus, and the ear treated with appropriate topical and systemic antibiotics. *Pseudomonas* sp. is a common contaminant and ointments containing an aminoglycoside antibiotic should be used until culture results are available.

Eyelid Malformation

Malformation of the eyelids resulting in a narrow aperture is occasionally seen in cockatiels. Several surgical techniques and means of chemical debridement have been attempted with little success.[5] In all reported cases, the aperture closed following treatment. Affected birds can often adapt to this handicap (see Chapter 26).

CHAPTER

31

MALNUTRITION

Patricia Macwhirter

Malnutrition can cause a specific problem or suppress a bird's immune system, decrease response to therapeutic agents, decrease reproductive performance and prolong the period of surgical recovery.

The diet of every avian patient should be carefully evaluated, even if the bird appears clinically to be well nourished. Marginal nutritional inadequacies frequently occur (see Chapter 8), and correcting the diet will improve a bird's general health and its ability to resist infectious diseases. Gastrointestinal malabsorption, hepatitis or renal disease can increase nutrient requirements so that diets that are sufficient in healthy birds may be insufficient for unhealthy birds. Interestingly, free-ranging granivorous birds that are offered both organic (no pesticides) and pesticide-treated grains will preferentially consume the organic foods. Test birds would not eat the pesticide-treated foods until all of the organic grains were gone.

Birds with signs of malnutrition have often developed strong preferences for unbalanced diets. Most seed diets, for example, contain excessive levels of fat and may be deficient in vitamins A, D_3, E, B_{12} and K_1, plus riboflavin, pantothenic acid, niacin, biotin, choline, iodine, iron, copper, manganese, selenium, sodium, calcium, zinc and some amino acids (eg, lysine and methionine).[6]

Birds can be encouraged to accept new foods by offering them first thing in the morning when the appetite is strongest. Favorite items can be withheld until later in the day. New foods may also be mixed with the bird's normal familiar diet. Gradually decreasing the quantity of old food items and increasing the quantity of new foods in the mixture will allow for a smooth transition in the diet. The size of food items offered should be appropriate to the species of bird.[10]

Some birds may be encouraged to eat an unfamiliar food if they can observe its consumption by other birds (Figure 31.1). Converting birds housed in large groups to a new diet is often easier than converting individual birds.[55]

Nutritional requirements vary depending on a bird's species, age, reproductive state, molting status, the external temperature and amount of daily exercise. Formulated diets supplemented with some fresh

fruits and vegetables will improve the nutritional state of birds (see Chapter 3).

While a diet change is occurring, it is important that the bird be carefully monitored for weight loss. Radical, unsupervised changes in the diet can lead to starvation. Most birds will have some degree of diarrhea or polyuria during a diet change. Ketosis was seen in some cockatoos that refused to eat during the transition to formulated diets. Affected birds showed acute weight loss, diarrhea, weakness, lethargy and possible vomition. Ketonuria can be demonstrated by a reagent strip examination of the urine. Therapy should include dextrose, supportive alimentation and placing the bird back on its regular diet. The diet should then be changed gradually to prevent anorexia.

Clinical Conditions Associated with Malnutrition

Avian veterinarians encounter a different type of malnutrition today than was described five to ten years ago. Nutrient deficiencies were historically common, but with the use of formulated diets in combination with vitamin and mineral supplementation, many malnutrition problems noted today are a result of excessive nutrients.[30] In some cases clinical signs believed to be caused by malnutrition are actually complex diseases that involve nutritional, environmental and species-specific factors.

FIG 31.1 A bird that is already adapted to a specific diet can be used to "teach" a reluctant eater to accept a new diet. In this case, a cockatiel is being used to acclimate a parakeet to a formulated food.

Obesity

Obesity is the most common and the most severe malnutrition-related problem recognized in avian practice (see Color 8). Obesity occurs if the energy content of the diet is excessive for the energy demands created by normal metabolic functions and the amount of exercise. In some cases, obesity will be secondary to the over-consumption of food in a bird attempting to consume missing nutrients. However, in most cases, obesity in companion birds is a result of feeding excess quantities of improper foods (eg, cookies, crackers, sweets) or high oil seeds (sunflower, safflower, hemp, rape, niger), a lack of exercise and increased food intake due to boredom (Figure 31.2).

Because companion birds frequently have limited opportunities for exercise, the energy content of their diet needs to be monitored closely. In species prone to obesity, it is important to avoid offering foods that have high caloric densities and to avoid excessive quantities of attractive, palatable food. Fats have twice the caloric density of either carbohydrates or proteins, and foods containing high levels of fats (such as peanuts or sunflower seeds) should be limited. Fresh fruit and vegetables have lower calorie densities than dried foods or seeds and should make up a sizable portion of a low-energy diet. Decreasing caloric intake can also be achieved by restricting feeding times (eg, ten minutes in the morning and evening) rather that offering food ad lib. Ideally, companion birds should be fed pelleted or extruded foods supplemented with small quantities of fresh fruit and vegetables. Some formulated diets may be helpful in controlling obesity and fatty liver problems.[30]

Some species, such as Rose-breasted Cockatoos, Sulphur-crested Cockatoos, Amazon parrots and budgerigars, are particularly prone to becoming obese and may develop secondary lipomas, fatty liver degeneration and heart disease (see Colors 14 and 20). Pancreatitis has been associated with obesity and high fat diets.[40] Hypothyroidism, which can be associated with low dietary iodine, has been correlated with obesity and lipoma formation, particularly in budgerigars. In birds that are confirmed to have hypothyroidism, thyroxine supplementation is recommended (see Chapter 23).[32,44,48]

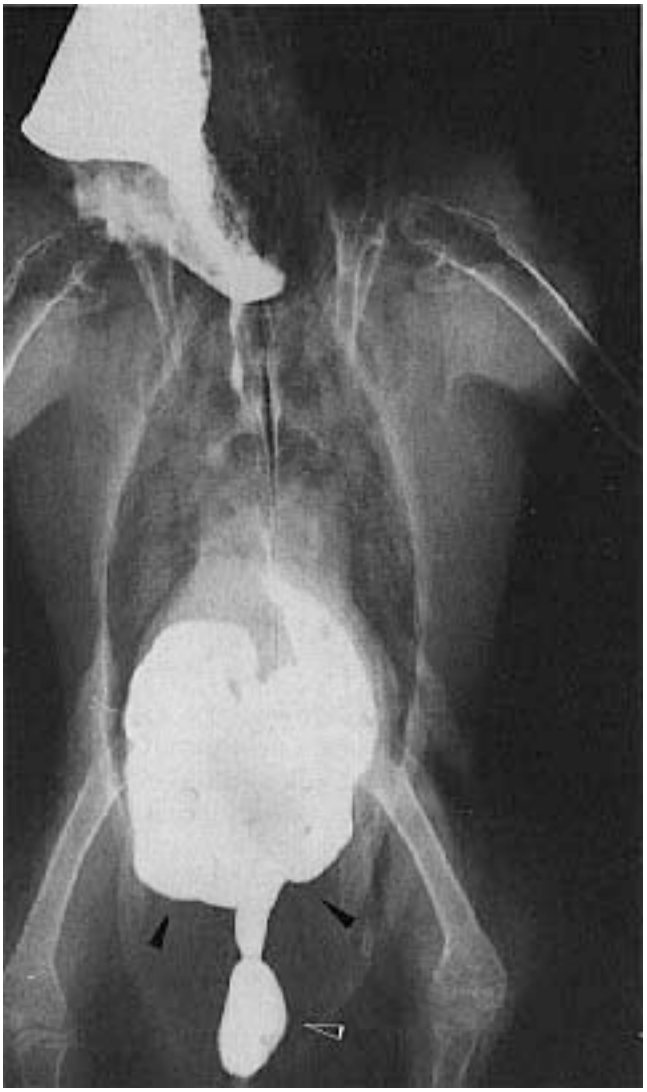

FIG 31.2 A two-year-old female Sulphur-crested Cockatoo was presented with a one-month history of progressive dyspnea (particularly following mild exercise) and abdominal wall masses. The bird was fed a seed diet ad lib and was frequently given treats (eg, crackers, potato chips). Several large pendulated masses were located pericloacally and in the ventral abdominal area. The bird weighed 1050 g. Cytologic evaluation of fine-needle aspirates from a mass was suggestive of adipose tissue. Abnormal clinical pathology findings included lipemic serum and hypercholesteremia. Radiographs indicated a diffuse soft tissue mass in the caudal abdomen. Barium contrast radiography indicated that the mass was displacing the abdominal organs cranially (arrow). Note that the cloaca is being compressed and the colon is oriented in a cranial, rather than its normal right lateral position (open arrow). The bird responded to a diet change (formulated diet, fruits and vegetables and no treats) and increased exercise (an outdoor flight enclosure).

A decrease in photoperiod may induce polyphagia and weight gain in pre-migratory birds. The increased food intake and weight gains appear to be mediated by thyroid hormones, prolactin and gonadotrophins. The role that neurohumoral signals, such as a changing photoperiod, plays in weight regulation in companion birds is unknown.[56] It is common for pre-ovulatory females to have up to a ten percent increase in weight.

Low Body Weight/Poor Growth

Low body weight or poor growth can be the result of inadequate food intake, which in turn can be caused by an insufficient quantity of food, inappropriate diet, unfamiliar food items, infrequent feeding, weaning onto solid foods too early, or loss of appetite, maldigestion or malassimilation of food caused by medical problems.[20]

Poor growth and low body weight occur with nutritionally deficient diets when the energy content of the food is insufficient to meet the energy demands of ongoing metabolic processes.

Low body weight or poor weight gain independent of organopathy can generally be corrected by placing the bird on a high-energy diet (high in fat and carbohydrates). Digestive enzymes and fiber hemicellulose may increase the digestibility and absorbability of the diet. Procedures for calculating daily energy requirements for birds are discussed in Chapter 15. It is important to note that formulas to calculate energy requirements are based on averages, and the nutritional requirements of individual species and individual birds will vary. A bird's clinical response to a particular diet should be carefully evaluated and adjustments should be made as necessary.[42,48]

Diets for Birds with Malabsorption and Diarrheal Syndromes

Parasites, bacterial infections, mycotoxins and pancreatic disease may interfere with the absorption of nutrients from the digestive tract. In addition to correcting the primary problem, these birds need foods that are easily digested and absorbed to facilitate healing of the gastrointestinal tract. Lactose and excessive amounts of green vegetables should be avoided. Diets should be moderately low in fiber and provide easily digested carbohydrate (eg, canary seeds, millet, panicum, corn or hulled oats) and a moderate amount of highly digestible protein. Vitamin and mineral supplementation, particularly of vitamins A and E, may be needed. The addition of digestive enzymes to the diet may be useful (see Chapter 18). In some cases, feeding a small quantity of grit may improve digestion and aid absorption, but should be supplied only in low quantities to prevent gastrointestinal impaction.

Polyphagia

Occasionally birds will overeat fibrous food or grit, causing crop or ventricular impactions. These problems are more likely to occur if young birds are suddenly introduced to new food items (unhulled seeds, particularly). Birds that are exposed to a number of food items at an early age are less likely to overeat infrequently offered foods. Ostriches may eat constantly following relocation, leading to foreign body ingestion and impaction (see Chapter 48).[4]

Feigned polyphagia, in which a bird hulls seeds and appears to be eating but the crop remains empty, may occur in some birds that are very weak or that are offered inappropriate food items. Vitamin E and selenium deficiencies have been suggested as possible causes of this problem.[26] Clients should not rely on the husking of seeds to indicate food intake. Monitoring body weight and fecal output is more effective.

When changed to a formulated diet, older, obese budgerigars and cockatiels may lose weight, yet eat constantly. Obese birds should lose weight slowly to prevent hepatopathies associated with overwhelming fat metabolism. The weight loss can be tempered by adding some millet to the diet. Multivitamin injections and lactulose can be used to suppress progressive hepatopathies in some cases (see Chapter 8).

Polydipsia/Polyuria

Nutritional causes of polydipsia and polyuria include hypovitaminosis A, calcium deficiency, excess protein, hypervitaminosis D_3, excessive dietary salt, dry seed diet, formulated diets or a high percentage of dietary fiber.

Polyuria alone may occur in birds fed moist foods such as fruit, vegetables and semi-liquid diets. Urine or urate color may change from a normal white or cream to yellow or brown when birds are supplemented with B vitamins. Consumption of food dyes, berries and other fruits can also alter the urine color (see Color 8).

Digestive Disorders

White plaques in the mouth or swelling in the salivary ducts may be associated with hypovitaminosis A (see Colors 8 and 13).

Oral paralysis in cockatiels may be related to vitamin E and selenium deficiencies and a malabsorption syndrome secondary to giardiasis.[28]

Nutritional causes of crop impaction include high fiber diets, foreign material ingestion (eg, juveniles eating various substrates such as wood shavings) and excess grit consumption. Cold food, a cold environment or infrequent feeding of large amounts of food may increase the risk of crop impaction in juvenile or debilitated birds. Repeated crop impactions may result in an atonic, pendulous crop. Degeneration of ventricular musculature has been associated with vitamin E and selenium deficiencies and calcinosis due to hypervitaminosis D.[28,52] Crop liths may develop in birds on marginal diets. The etiology is undetermined (see Color 19).

Diarrhea may occur in birds fed low-fiber or high-fat foods, particularly highly processed human foods (eg, cakes, desserts, crackers). Bacteria or parasitic enteritis may occur in birds that eat foods contaminated with excrement. Food and water containers should be positioned so that contamination with droppings will not occur.

Nutritional cases of malabsorption or maldigestion (passing undigested food) include vitamin E and selenium deficiencies (sometimes associated with giardia infection), excess oil in the diet or dehydration. A lack of grit has been frequently discussed as a cause of maldigestion; however, companion birds on formulated diets do not appear to require grit. Studies in poultry indicate that the addition of grit increases the digestibility of feed by as much as ten percent,[14] but similar studies have not been performed in companion birds. Given that obesity is more of a problem than maldigestion in companion birds, increasing the digestibility of a formulated diet that exceeds suggested nutritional requirements is probably unnecessary. Charcoal that is used in some grit mixtures may interfere with the absorption of vitamins A, B_2 and K and contribute to deficiencies of these compounds.

Birds should not be offered grit on an ad libitum basis. If offered free choice, some birds may over-consume grit, leading to crop, proventricular or ventricular impactions. This problem is reported commonly in North America but appears to be uncommon in Australia. The cause for a regional variation in the occurrence of this condition is unknown. Birds showing compulsive grit consumption should be evaluated for hepatopathy, pancreatitis, renal dysfunction and general malnutrition.

There is a difference between grit and crushed shell. Grit is composed of minute stones and commonly

contains silicates and sandstone. Crushed shell is almost entirely composed of limestone (calcium carbonate) and is readily digested by acids in the proventriculus. Crushed shell will provide a source of calcium, and is not effective in aiding in the mechanical breakdown of dietary plant material. Heavy metal toxicity has been associated with feeding crushed shell derived from contaminated sources (oysters raised in polluted waters).

Regurgitation has been associated with feeding high-protein diets to cockatiels.[46]

Respiratory Disorders

Dyspnea (extended neck) and wheezing may be associated with goiter, particularly in budgerigars.[53] Hypovitaminosis A leads to squamous metaplasia of epithelial surfaces causing obstruction of respiratory passages or sinusitis (see Color 8). Dyspnea may be caused by calcium or vitamin D_3 deficiency if severe enough to demineralize bone, causing thoracic or spinal deformities.

Asphyxiation may occur from aspiration of feeding formula into the respiratory tract. This can occur if a tube is accidentally placed in the trachea when attempting crop feeding or if a bird (particularly a weak bird) is fed large amounts or excessively thin formula.

Plumage Abnormalities

Dark, horizontal lines (stress marks) on feathers have been associated with nutritional deficiencies (particularly methionine) and indicate that a release of corticosteroid hormone occurred while the feather was developing. Stress lines are common in neonates that have had a disrupted feeding schedule or in raptors that are molting while in a training period (see Color 24). Molting abnormalities, retained feather sheaths and dry flaking beaks have also been associated with overall nutritional deficiencies (Figure 31.3).

Feather picking may be initiated by dry, flaky, pruritic skin, which in turn can be caused by nutritional deficiencies, particularly deficiencies of vitamin A, sulfur-containing amino acids, arginine, niacin, pantothenic acid, biotin, folic acid and salt. Excessive dietary fat has been incriminated as a possible cause of self mutilation (Figure 31.4).

Deficiencies of minerals such as calcium, zinc, selenium, manganese and magnesium may be associated with brittle, frayed feathers and dermatitis.[29] Arginine deficiency may cause wing feathers to curl upward in chicks. In broilers, pantothenic acid deficiency causes the formation of ragged feathers, while a deficiency in growing cockatiels has been associated with a lack of contour feathers.[46]

FIG 31.3 An 18-month-old Amazon parrot on an all-seed diet was presented for a beak trim. The bird was maintained indoors and had no exposure to sunlight or water for bathing. Horny beak material that is dry and flaky, as well as black discoloration of the feathers are typical of malnutrition. This bird responded to a change in diet and daily exposure to direct (unfiltered through glass) sunlight.

The association between diet and feather pigment has long been recognized by canary breeders. Carotene and xanthophyll pigments, which originate from plant material, are found in fat globules in the feathers and give rise to yellow, orange and red colors (see Chapter 24). Birds lacking a dietary source of carotenoids may develop muted feather or skin colors, while dietary supplementation of carotenoids in birds with suitable genetic backgrounds will result in increased depth of color.

Prolonged feeding of bacon rind and bone marrow has been associated with an oily feather and stool texture (steatorrhea) and an increase in depth of the pink feathers in Rose-breasted Cockatoos. Raptors fed laboratory rats and mice (reduced carotenes) may lose the yellow coloration of their cere, feet and legs that is characteristic in free-ranging birds.[32,38,39] Porphyrins are aromatic compounds synthesized by birds that may produce colors such as red, green or brown. Porphyrins are less sensitive to dietary influences than carotenoids, but both are present in edible blue-green algae, and enhanced feather coloration would be expected in birds fed a diet containing this material.

FIG 31.4 Feather picking and dry, thin, pruritic skin are common signs of malnutrition in Psittaciformes. Note the loss of papillae on the dorsal surface of the feet and toes.

Melanin occurs in granules in the skin and feathers and produces black, brown and red-brown colors. This pigment is derived from tyrosine in an enzymatic reaction requiring copper. Consequently, deficiencies of tyrosine (or other related amino acids) or copper could interfere with melanin production and cause dark-colored feathers to become lighter.[25]

Blue and white are structural colors in feathers. In most cases, their occurrence depends on a scattering of light caused by the structure of the keratin in the spongy layer of the feather rami rather than on the presence of pigments. Essential amino acids that occur in keratin include methionine, histidine, lysine, tryptophan, threonine, isoleucine and valine. It is possible that amino acid deficiencies could alter the structure of keratin and consequently alter feather color. A change in feather color from green to yellow is usually caused by a loss of structural blue color, which may be associated with essential amino acid deficiencies. While this color change is commonly seen in nutritionally deficient Psittaciformes, the exact nature of the deficiency has not been clarified, and it is possible that more than one amino acid could be involved (see Color 24). Lysine deficiency has been discussed as one possible cause of green-to-yellow feather discoloration because many affected birds are consuming all-seed diets that are low in lysine.

Feather color may change from blue to black, green to black or grey to black in birds that are sick or malnourished. These color changes are associated with altered keratin structure in the spongy layer that prevents normal light scattering. When this

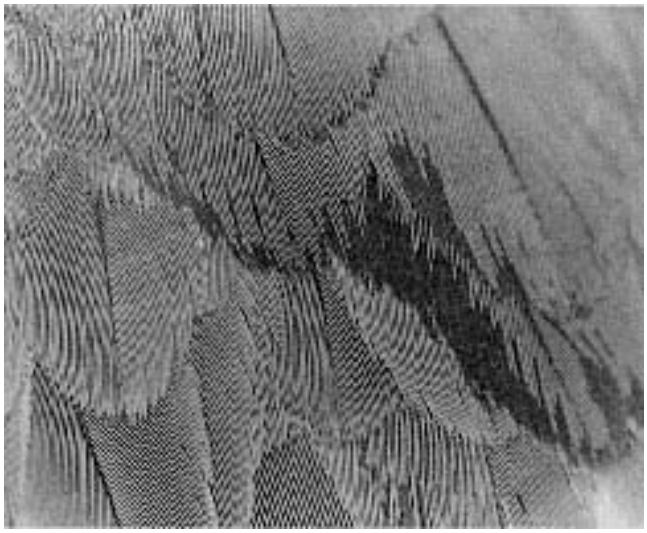

FIG 31.5 Feathers that turn black are an indication of altered keratin structure in the spongy layer of the feather. The black feathers in this Amazon parrot resolved with a change in diet (seeds to formulated diet) and correction of chronic active hepatitis.

occurs, melanin granules in the middle of the feather, if present, would absorb all wave lengths of light, giving the visual effect of black (Figure 31.5).

Nutritionally related alterations in feather color may vary based on the species of bird, specific nutrient deficiency, timing of the deficiency in relation to feather development and the initial color of the affected feathers. While lysine deficiency in chickens, turkeys and quail produces achromatosis, there was no loss of feather color in young cockatiels fed a lysine-deficient diet. However, choline and riboflavin deficiencies produced feather changes in young cockatiels that resembled achromatosis caused by lysine deficiency in poultry.[46] White streaks (usually associated with breakage) in feathers may be associated with a hypovitaminosis B (Figure 31.6).[29]

Skin Changes

Plantar corns and pododermatitis have been associated with biotin and vitamin A deficiencies, particularly in obese birds (Figure 31.7).[29] Edema of subcutaneous tissues has been seen with vitamin E and selenium deficiencies. Exfoliative dermatitis on the face and legs has been associated with biotin, pantothenic acid, riboflavin or zinc deficiency[1] (see Color 48.). If a formulated diet is not available, a diet can be supplemented with multivitamins to compensate for any nutritional deficiencies. Several kiwis in a New Zealand zoo developed a scaly dermatitis over their necks and legs when a multivitamin supple-

FIG 31.6 White streaking in feathers that are normally colored may be associated with a malnutritional deficiency. These feathers are frequently brittle and may break at the site of abnormal coloration.

FIG 31.7 A mature female cockatiel was presented with a complaint of intermittent lameness. The bird was on an all-seed diet with no supplementation and was kept in a small enclosure. The bird weighed 138 g and had severe ulcerative lesions on both metatarsal pads. Changing the diet, increasing the exercise (outdoor flight enclosure) and standard treatment for grade 4 bumblefoot were effective in resolving the lesions.

ment that was routinely included in their diet was omitted. The clinical problem resolved when the multivitamin supplement was again added to the diet.[5] Formulated diets should not be supplemented with vitamin products. Over-supplementation may cause problems with excess vitamin, mineral, fat or protein consumption.

Skeletal and Muscular Disorders

Demineralized, bent bones and pathologic fractures may occur in birds with hypovitaminosis D and calcium, phosphorus or magnesium deficiencies or imbalances.

Airplane wing in waterfowl (rotation of the distal carpi due to heavy, developing feathers being supported by non-rigid, developing bones) may be caused by rapid growth or excessive levels of protein or low levels of calcium (see Chapter 46).[17]

Slipped tendon of the hock (perosis) may occur with manganese, biotin, pantothenic acid or folic acid deficiencies (see Color 8). Obese birds that are not allowed sufficient exercise and birds fed high-mineral diets may be prone to this condition. There is gross enlargement of the tibiometatarsal joint, twisting and bending of the distal tibia and slipping of the gastrocnemius muscle from its condyles. Young gallinaceous birds, cranes and ratites are particularly susceptible to this condition.[34] The author has seen a similar condition in raptors, cockatiels and rosellas. In some cases, surgical correction is possible (see Chapter 46).

Enlargement of the hock, without tendon slipping, may occur with zinc deficiency.

Tibial dyschondroplasia is characterized by uncalcified masses or plugs of avascular hyperplastic cartilage in the proximal metaphyses, particularly of the tibiotarsus. The condition is seen in poultry and ratites. A genetic predisposition along with electrolyte imbalances involving sodium, potassium and chloride are thought to be involved in the development of tibial dyschondroplasia. A relative excess of chloride may increase the incidence of disease.[33]

Neurologic Signs

Seizures or localized paralysis have been associated with salt toxicity and low levels of thiamine, calcium and vitamin E. Leg paralysis has been associated with calcium, chloride or riboflavin deficiency.

Cervical paralysis has been associated with a folic acid deficiency. Jerky leg movements have been associated with pyridoxine deficiency.

Sudden collapse or fainting has been associated with hypoglycemia in raptors or in other species when a bird has not eaten and is acutely stressed. Syncope is characteristic of advanced hypocalcemia in African Grey Parrots.

Behavioral changes including aggressiveness (biting), nervousness, rejection of food and regurgitation occurred in cockatiels placed on a high-protein diet.[46]

Frequently, companion birds that are switched from an unbalanced all-seed diet to a balanced formulated diet will undergo a corresponding change in behavior characterized by decreased biting, screaming and chewing, and increased activity and playfulness.[30]

Reproductive Disorders

Many dietary deficiencies or excesses may result in reduced reproductive performance due to infertility, poor hatchability or nestling deaths. Calcium, vitamin E and selenium deficiencies may be associated with egg binding.

General Ill Health or Sudden Death

Fatty liver infiltration may occur due to high fat diets, fatty acid or B vitamin deficiencies and high-energy diets in exercise-deprived birds (see Color 20). Gout may be a precipitating cause or an end result of systemic diseases (see Color 21). Ascites may be associated with excessive dietary levels of iron in birds susceptible to iron storage disease (hemochromatosis). Atherosclerosis may be associated with diets high in fat and cholesterol (see Color 14).

Aortic rupture has been associated with copper deficiency in poultry and is suspected to occur in ratites (see Color 48).

Immune Response

Adequate levels of both B complex (particularly pantothenic acid and riboflavin) and vitamin E have been shown to improve the body's response to pathogens. In poultry, vitamin C and zinc are involved in T-cell response, and vitamin C stimulates macrophages and helps to counter the immunosuppressant effects of stress. Low vitamin A levels may result in a sub-optimal immune response and have been associated with the occurrence of aspergillosis in psittacines.[3,13]

Deficiencies of Specific Nutrients

When one considers the array of ecological niches to which different species of birds are adapted, it is not surprising that there are major species differences in the ability to metabolize proteins, fats, carbohydrates and other nutrients.

To date, comprehensive nutritional requirements have been established only for domestic fowl. In spite of the absence of complete data for companion birds, anecdotal findings and scientifically supported investigations suggest that general health and reproductive success will be greater in birds fed "balanced" formulated diets supplemented with limited fresh fruits and vegetables compared to birds fed seeds supplemented with fresh fruits and vegetables (Figure 31.8).[30,54]

Research findings and clinical experience suggest that there is considerable interspecies variation in nutrient requirements and in clinical signs of malnutrition. For example, some finches may consume up to 30% of their body weight, budgerigars, 25% of body weight and domestic chickens, 6% of body weight on a daily basis. These differences point to the dangers of extrapolating nutrient requirements, particularly of minerals, from poultry data when the level of food consumption varies dramatically. Requirements will also vary depending on the bird's age and physiologic state, interactions with other dietary components and the presence of concurrent diseases.

Protein and Amino Acids

Protein in the diet is broken down into component amino acids before being absorbed by the intestine.

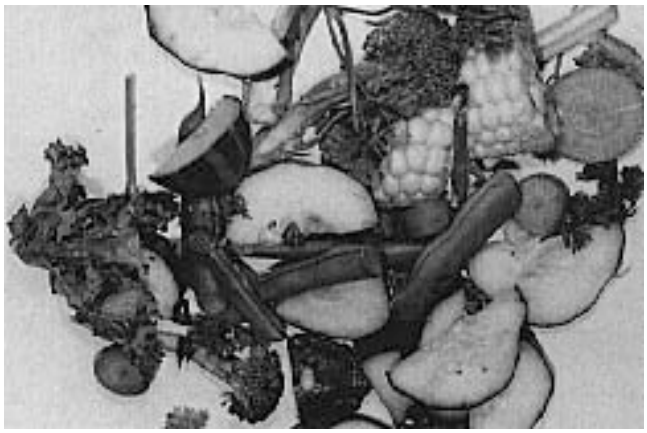

FIG 31.8 Birds appear to be healthiest when supplied a formulated diet supplemented with some fresh fruits and vegetables. Over-supplementation with fresh foods, as is the case with this daily vegetable bowl for a cockatoo, can actually cause malnutrition through insufficient consumption of a formulated diet. For a bird the size of an Umbrella Cockatoo, the formulated diet should be supplemented with the equivalent of several slices of carrot (or dark squash or sweet potato), one-eighth cup of spinach (or broccoli or endive) and several small slices of favorite fruits as a treat.

Amino acids are needed by the body to reconstruct proteins that make enzymes, hormones, muscles, bones and feathers. Birds are uricotelic, ie, the product of protein breakdown is uric acid, which is excreted as a slurry (urates) by the kidneys.

Excess Dietary Protein

Dietary protein requirements vary dramatically between species. Broiler chickens and turkeys have been genetically selected for rapid growth and are fed high protein levels to achieve maximum growth rates. These feeding practices are rarely appropriate in other species. Starter rations for turkey poults or pheasants may contain nearly 30% protein, but young ratites, waterfowl and psittacine birds require much lower levels. Using a high-protein diet in these latter species may result in clinical problems such as airplane wing in ducks, deformed legs in ratites, poor growth rates in psittacine birds and increased susceptibility to disease in all species.

Inappropriate calcium levels in the diet may compound problems caused by excessive dietary protein. A group of macaw neonates being fed a human, high-protein baby cereal with added vitamins and calcium showed suboptimal growth rates. When the protein level in the diet was reduced by adding pureed fruits and vegetables, the growth rate and the chick's general health improved dramatically (see Chapter 30).

Nutritional data collected in juvenile cockatiels indicated that a protein level of 20% was optimal for this species. Levels of 10% produced stunting, poor growth and high mortality; levels over 25% produced transient behavioral changes such as biting, nervousness, rejection of food and regurgitation.[46]

In budgerigars, one study showed that a protein level of 17 to 20% was optimal. Birds on low-protein seed diets increased their food intake and gained weight in the form of excessive body fat. Those on low protein (12%) mash diets lost weight, but some died with their crops packed with food. This finding suggests that the birds unsuccessfully attempted to consume enough food volume to compensate for the protein deficiency. Birds fed high-protein diets were very thin.[55] Other studies in budgerigars indicate that a diet with 2% lysine and 10% protein (13 kcal/kg of body weight) is ideal.[12]

Gout is the deposition of uric acid crystals on body organs (visceral gout), in joints (articular gout) or in the ureters (renal constipation) (see Color 21). High dietary levels of protein and calcium, hypervitaminosis D_3, poor kidney response, dehydration, cold weather and other stress factors work in concert to interfere with the kidney's ability to adequately excrete uric acid.[15,35] Hypervitaminosis D_3 causing renal calcinosis or vitamin A deficiency causing squamous metaplasia of the ureters may exacerbate blockage of the ureters.

Diets for Birds with Renal Disease or Gout

Birds with renal disease or gout should be provided diets that decrease the workload of the kidneys and slow the loss of renal function. These diets should be lower in protein and meet energy needs with non-protein calories. Calcium, phosphorus, magnesium, sodium and vitamin D_3 levels should be reduced to avoid renal mineralization. Vitamin A should be present in adequate amounts to ensure proper function of the mucous membranes lining the ureters. B vitamins should be increased to compensate for losses associated with polyuria.

Protein and Amino Acid Deficiencies

Protein or specific amino acid deficiencies are occasionally encountered in companion birds, particularly in insectivorous birds (softbills). Insectivorous birds require higher protein levels than granivores and generally require live food such as crickets or mealworms. If these insects are reared exclusively on bran, their total body protein may be low, and consequently the level and quality of protein that they provide to birds will also be low. Clinically, insectivores receiving low-protein insects will have a history of recurrent disease problems. Feeding crickets that have been raised on dried dog food or encouraging insectivores to consume artificial diets with appropriate levels of high quality protein prevents the problem.

Many seeds are relatively low in total protein and may also be deficient in some essential amino acids such as tryptophan, methionine, arginine or lysine. Free-ranging, seed-eating birds will frequently eat insects, particularly during the breeding season and when raising young.

Deficiencies of individual amino acids may cause abnormal feathers as well as suboptimal growth and poor breeding performance. Deficiencies of essential amino acids are most likely to occur if birds are fed a diet restricted to one or two individual types of seeds.

Serine, glycine and proline are the most abundant amino acids in feather keratin while methionine, histidine, lysine and tryptophan occur at lower levels. Methionine content of chicken feathers decreases

with age, while that of threonine, isoleucine and valine increases. Lysine deficiencies have been associated with impaired feather pigmentation in poultry, but not in cockatiels.[46]

Methionine deficiency has been associated with stress lines on feathers and fatty liver change. Cystine and methionine act as sources of glutathione, which has a sparing effect on vitamin E.

Fats and Essential Fatty Acids

Fats provide a concentrated source of energy. Linoleic and arachidonic acids are essential fatty acids needed for the formation of membranes and cell organelles. Deficiencies of linoleic acid may be associated with decreased metabolic efficiency, decreased growth, hepatomegaly, increased fat storage, decreased reproduction, embryonic mortality and decreased hatchability. In mammals, lipogenesis occurs mainly in adipose tissue while in birds, it nearly all occurs in the liver. T_3 is believed to be associated with lipogenesis and calorigenesis, especially during migration, while T_4 is associated with reproduction and molt (see Chapter 23).[56]

Lipogenic liver function in birds predisposes them to the occurrence of conditions involving excessive accumulation of liver fats, for example, fatty liver and kidney syndrome in young chickens and fatty liver hemorrhagic syndrome in laying hens (FLHS).[33] Geese that are force-fed cream and not allowed to exercise in preparation for *pate de foie gras* may have a six-fold increase in liver weight with only a two-thirds increase in weight.[24]

Fatty liver syndromes of undetermined etiologies are common in companion birds (see Color 20). In addition to fatty liver, excessive levels of fat in the diet are known to cause obesity, diarrhea and oily feather texture, and to interfere with the absorption of other nutrients such as calcium. Paradoxically, lack of fatty acids can also result in fatty liver infiltration because essential fatty acids are needed for lipid metabolism. Poor growth and reduced resistance to disease also occur with essential fatty acid deficiencies. FLHS in poultry is associated with high carbohydrate, low-fat, selenium-deficient diets given ad lib.

If fats become rancid, essential fatty acids may be destroyed, amino acid availability may be reduced and peroxidases may be produced that interfere with the activities of fat- and water-soluble vitamins (biotin). Rancid foods have been shown to reduce growth and egg production in poultry. Levels of peroxide exceeding 15 mEq/kg were found to be toxic. Changes in the taste or odor of rancid food stuffs did not occur until the peroxide level reached 90 mEq/kg. Rice and oats are particularly susceptible to becoming rancid and are processed for foods through extrusion, rolling or roasting. Many commercial diets contain antioxidants (propylene glycol or ethoxyquin) to prevent foods from becoming rancid. The long-term effect of these products on birds is unknown.

Ventricular erosion may occur in birds fed highly polyunsaturated fatty acids (such as those present in cod liver oil), if the fatty acids are not protected by an adequate dietary level of vitamin E. "Gizzerosine" has been associated with ventricular ulceration in poultry fed heated fish meal. Because of these problems, fish liver oils are not recommended as dietary components in companion birds.[26,49] Soybean oil is a good source of fatty acids that is less likely to spoil.

Atherosclerosis may be induced by diets high in saturated fats and cholesterol. This problem is occasionally seen in aged Psittaciformes and may be associated with long-term feeding of high-oil seeds such as sunflower and safflower (see Chapter 27).[34]

Young cockatiels were able to tolerate fat levels from 1 to 60% of the diet with no effect on growth. However, about half of the birds fed a 60% fat diet developed a necrotic crop infection and died.[46]

Carbohydrates

Carbohydrates are a source of energy in the diet and are readily converted into fats in the liver. Exercise-deprived birds on high-energy diets may develop fatty liver infiltration even though carbohydrates, rather than fats, form the major component of energy consumed.

Clostridial infections, in which gas fermentation occurs along the gastrointestinal tract, have been associated with high-sugar diets in nectivorous birds.[20,23]

Birds have blood glucose levels that are several times higher than those of mammals. Some species, such as penguins and sea birds, are adapted to tolerate long fasting periods during molting, egg incubation or migration. Small companion birds (eg, finches) may collapse from hypoglycemia if they are deprived of food for even short periods. Food restriction prior to anesthesia should not exceed several hours. Raptors that are fed small quantities of food as part of their training program may experience hypoglycemic col-

lapse and may require emergency therapy with oral or parenteral glucose. Glucagon, rather than insulin, is the principal director of carbohydrate metabolism in birds.[56]

Diets for Birds with Hypoglycemia

Birds prone to hypoglycemia should be fed frequently with nutrients that are slowly converted to glucose (a high-protein, high-energy diet). In most cases, hypoglycemia is dietary-induced, and placing the bird on a diet appropriate for that species is all that is required.

Vitamins

Vitamins are a mixed group of organic compounds that are essential for a variety of metabolic processes. Most birds require the same vitamins as mammals with the exception that vitamin D_3 (not vitamin D_2, as in mammals) is the active form of this compound. Exogenous vitamin C is required in fruit-eating birds such as bulbuls, but seed-eating species are generally able to synthesize vitamin C. Debilitated birds may have higher requirements and a reduced ability to synthesize vitamin C, and should be supplemented orally or parenterally.

Birds with vitamin deficiencies may have life-threatening clinical signs (eg, seizuring associated with thiamine deficiency) or simply appear ruffled and in poor condition. Vitamins A, C, E and B complex are all involved with immune responses, and deficiencies in these compounds may increase the severity of infectious diseases.

Antibiotics may induce vitamin deficiencies by interfering with normal intestinal microflora. In most cases, birds given long-term antibiotics should also receive multivitamin supplementation. Protozoan infections such as coccidiosis or giardiasis may interfere with the absorption of vitamins (such as vitamins A or E) from the intestinal tract. Vitamins are sensitive to heat and light, so overheated or outdated commercial foods may be vitamin deficient.

Hypervitaminosis, particularly with fat-soluble vitamins, is becoming increasingly common as clients over-supplement improved, formulated avian diets.

Fat-soluble Vitamins

- ***Vitamin A:*** Vitamin A is formed in the liver from beta carotene. It is involved in mucopolysaccharide biosynthesis and is needed for the formation of normal mucous membranes and epithelial surfaces, for growth, for vision, for the development of the vascular system in embryos, for the production of adrenal hormones and for the formation of red and orange pigments in feathers. Beta carotene and vitamin A, themselves, are colorless. It is their derivatives that are responsible for feather pigmentation. Low vitamin A in the diet may result in a suboptimal immune response.[3]

  Numerous clinical problems may be associated with hypovitaminosis A. Squamous metaplasia of mucous membranes may occur, altering the function of the respiratory, gastrointestinal or urogenital systems. Hyperkeratosis, a related condition, may affect epithelial surfaces (Figure 31.9).[13]

  Small white pustules may be seen in the mouth, esophagus, crop or nasal passages. If squamous metaplasia causes blockage of salivary ducts, small swellings (often symmetrical) may be noted dorsally around the choana, around the larynx and laterally under the tongue or mandibles (see Figure 19.3). White caseous material may accumulate in the bird's sinuses, particularly if hypovitaminosis A is associated with a concurrent sinus infection. Squamous metaplasia may also lead to thickening and sloughing of part of the lining of the syrinx with subsequent partial or complete tracheal obstruction (see Color 8). Xerophthalmia occurs if squamous metaplasia affects the eyes. There may be lacrimation, and caseous material may accumulate under the eyes (see Color 26). In chicks, acute hypovitaminosis A has been associated with weakness, incoordination and ataxia. These symptoms must be differentiated from "crazy chick disease" caused by hypovitaminosis E.

  In mild cases of hypovitaminosis A, particularly in budgerigars, the only clinical signs may be polyuria and polydypsia, but squamous metaplasia may be seen histologically along the gastrointestinal and urinary tracts. Kidney damage and gout may occur if squamous metaplasia causes partial or complete occlusion of the ureters.

  Reduced egg production, egg binding or poorly formed egg shells (pitted) are common in hens with hypovitaminosis A. In cocks, hypovitaminosis A may cause decreased sperm motility, reduced sperm counts and a high level of abnormal sperm.

  Hypovitaminosis A may cause hyperkeratosis of the plantar skin of the metatarsal and digital pads (see Color 8). The normal papillary scale structure is lost and the corneum is thickened. Focal hyperkeratosis (corns) often occurs on the metatarsal pads (see Fig-

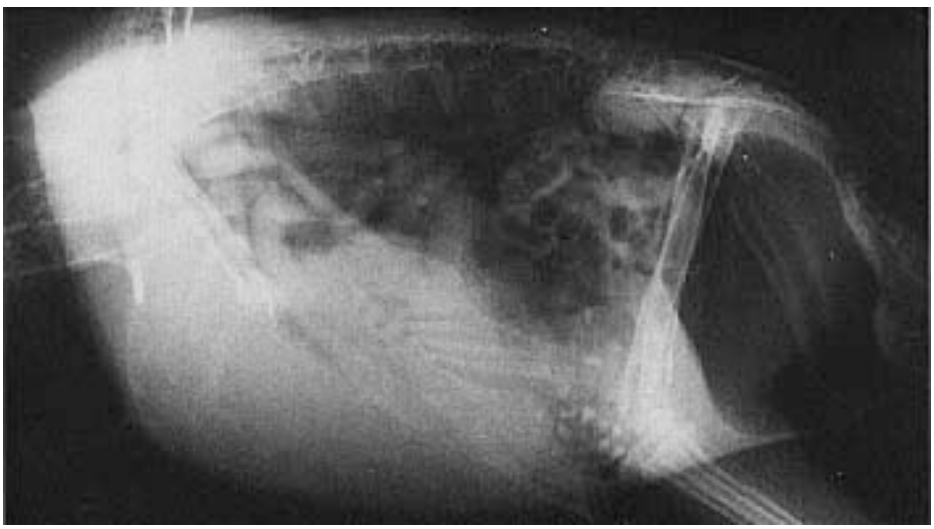

FIG 31.9 An adult female Amazon parrot was presented for severe dyspnea (open-mouthed gasping) and diarrhea. A large, ulcerated pharyngeal mass was evident on physical examination. Radiographic changes included gaseous distension of the crop, gastrointestinal tract and cloaca. The gaseous distension (aerophagia) was related to gasping for air associated with an occluded glottis. The bird did not respond to emergency care. The oval mass was characterized by marked epithelial acanthosis and parakeratosis (see Color 8). The lungs were congested and hemorrhagic. Cystic hyperplasia was evident in the pancreatic ducts. The diagnosis was severe hypovitaminosis A and syringeal granuloma.

ure 31.7). These changes predispose birds to pododermatitis (bumblefoot). Other factors apart from malnutrition are also associated with this condition.[22,27] In young ducks, hypovitaminosis A has been shown to cause retardation of endochondral bone growth.

In a number of avian species, vitamin A levels in the liver of less that 50 IU/gm have been found to correlate with the occurrence of squamous metaplasia elsewhere in the body.[34]

Hypovitaminosis A should be initially treated with parenteral supplementation, which establishes rapid blood levels and does not rely on intestinal absorption. In limited clinical trials, some birds may respond just as quickly to supplementation of the diet with spirulina (Harrison GJ, unpublished). Oral administration in the food and modification of the diet to include natural sources of beta carotene is recommended. Zinc levels in the diet should be sufficient to allow for normal vitamin A function. Liver disease may decrease the bird's ability to store vitamin A.

- ***Vitamin D*** helps to stimulate gastrointestinal absorption of calcium, has a hormonal effect on regulation of calcium and phosphorus excretion in the renal tubules and may be involved in controlling alkaline phosphatase in the blood. An increase in alkaline phosphatase may be an early indication of hypovitaminosis D_3.

Ingested vitamin D precursors are converted to the active form of the vitamin (vitamin D_3 in birds) in the skin. Alternatively, vitamin D precursors in the uropygial gland may be spread on the feathers, activated by UV light and then consumed during preening activities. This process requires natural sunlight or appropriate artificial ultraviolet light. Low levels of calcium in the diet, particularly if associated with high levels of phosphorus, will precipitate hypovitaminosis D_3.[53] If groups of juvenile birds are fed diets low in calcium and vitamin D_3, birds in shady flights may show overt signs of rickets while those in sunny flights will be normal. Hypovitaminosis D_3 can easily occur in birds raised indoors. It is advisable to sup-

plement indoor birds that do not have access to natural sunlight with exogenous vitamin D_3.

Signs of vitamin D_3 deficiency parallel those of calcium deficiency. Adult hens may show thin-shelled or soft-shelled eggs, decreased egg production and poor hatchability. Seizuring or leg weakness may occur due to pathologic bone fractures or if an already low blood calcium level is further exacerbated by metabolic demands of egg laying (Figure 31.10).

Hypovitaminosis D_3 in neonates is characterized by demineralized and easily broken bones. Leg bones will frequently be bent into grossly distorted positions. The sternum may be bent laterally or indented. The spinal column may undergo lordosis or fracture easily, causing pressure on nerves and subsequent paralysis. Radiographically, bones will show poor density and pathologic fractures may be apparent (Figure 31.11).

High levels of vitamin D_3 (>10^6 IU/kg of food compared with recommended levels of around 2000 IU/kg of food) in chickens may cause calcification of renal tubules and arteries, visceral calcinosis, urate nephrosis and visceral gout. Excessive levels of vitamin D precursors may also be toxic. Clinical evidence suggests that young macaws may be particularly susceptible to hypervitaminosis D. Nephrocalcinosis, suspected to be associated with hypervitaminosis D, has been reported in a dove, a toucan, a cardinal and a variety of Psittaciformes (Figure 31.12).[30] Home-

FIG 31.10 Metabolic bone disease is common in birds with hypovitaminosis D_3 and hypocalcemia, as well as in birds consuming diets with low calcium to phosphorus ratios. An 11-week-old African Grey Parrot was presented for limb deformities. The bird was being fed a commercial hand-feeding formula that was rendered ineffective with the addition of oatmeal, strained meat, mashed fruit, baby vegetables and neo-calglucon. Radiographs indicated bending type deformities in the right humerus, pelvis and both femurs and tibiotarsal bones. The case was managed by removing the supplements from the hand-feeding formula.

FIG 31.11 Rickets in a juvenile Blue and Gold Macaw. Note the lack of bone density, bending of the bones and pathologic fractures (courtesy of Marjorie McMillan).

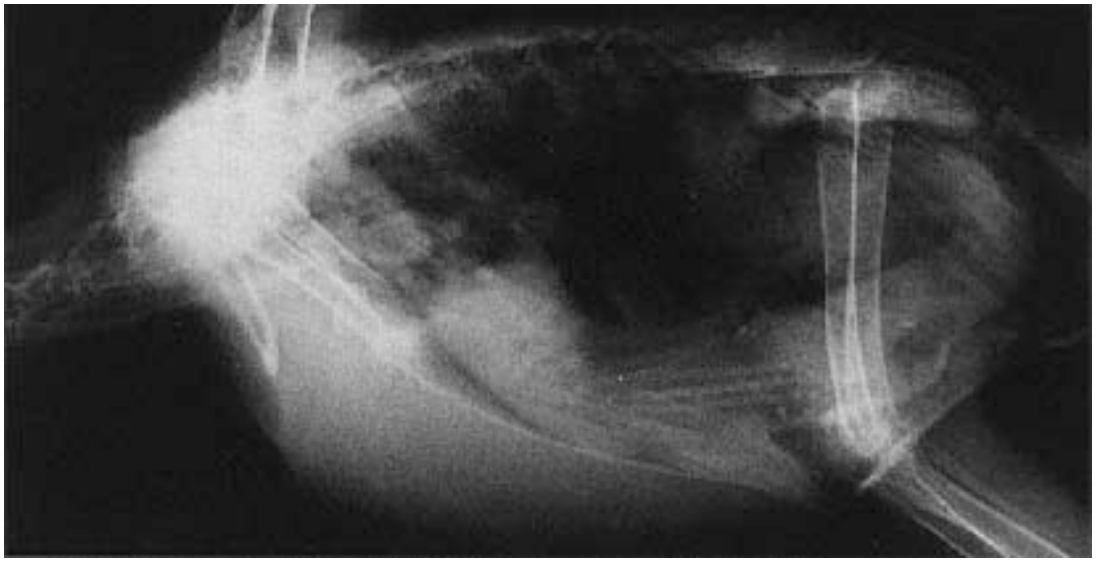

FIG 31.12 An African Grey Parrot was presented for a pre-purchase examination. Physical and clinical pathology findings were unremarkable. The bird was negative for PBFD virus and polyomavirus by DNA probe testing. Radiographs indicated mineral densities in the kidneys. This is a frequent finding in African Grey Parrots and its clinical importance is unknown. However, calcium supplementation and injectable vitamin A and D_3 in a bird with this condition are contraindicated. Note the extensive air sac capacity, which appears to be normal in African Grey Parrots.

made dietary formulas (particularly those for neonates) are likely to contain improper levels of many nutrients.[41,52] Neonatal birds are best fed proven formulas (see Chapter 30).

- ***Vitamin E:*** Vitamin E is an antioxidant that acts to prevent fat rancidity and fatty acid degeneration in foodstuffs, as well as acting in concert with selenium and sulfur-containing amino acids to prevent peroxidative damage to cell membranes. Birds on high-fat diets, particularly if the fat has become rancid, require higher amounts of antioxidants, and consequently are more likely to show signs of vitamin E deficiency than birds on diets low in fat.

  If accompanied by deficiencies in sulfur-containing amino acids or selenium, hypovitaminosis E may result in skeletal muscle dystrophy as well as muscular dystrophy of the heart or ventriculus. Electrocardiographic changes may accompany heart muscle dystrophy. Undigested seed in the droppings may occur with ventricular muscular dystrophy. Degeneration of the pipping muscle may occur in neonates, resulting in decreased hatchability. Exertional rhabdomyolysis or spraddle legs may be associated with vitamin E and selenium deficiencies (see Chapter 48).[11,34]

  Muscle weakness, localized wing paralysis, poor digestion and embryonic and hatchling mortality have been described in cockatiels that responded clinically to vitamin E and selenium therapy. Giardiasis may have been a predisposing factor. Elevated levels of serum creatinine phosphokinase may suggest nutritional myopathy.[28]

  Hypovitaminosis E may cause encephalomalacia in poultry and other species. This condition can be prevented by supplementing the diet with linoleic acid but not arachidonate. *Neophema* parrots fed a dog food that contained a high amount of rancid fat and seed soaked in cod liver oil showed incoordination, abnormal body movements and torticollis. At necropsy, affected birds showed cerebellar demyelination and muscular dystrophy of the heart and skeletal muscle typical of vitamin E deficiency.[8] A similar vitamin E and selenium-responsive syndrome has been reported in Eclectus Parrots in Switzerland.[47]

  Deficiencies in vitamin E and selenium may cause exudative diathesis, which results in edema of ventral subcutaneous tissue in poultry. Hypovitaminosis E is one of a number of dietary factors that has been associated with enlarged hocks in turkeys. Prolonged hypovitaminosis E may cause testicular degeneration in males, and in hens it may result in infertility or early embryonic deaths.

  In mammals, a degenerative disease of fat (yellow fat disease, steatitis) has been associated with hypovitaminosis E. A similar condition has been recognized in birds fed fish with high fat content such as herring, smelt or red meat tuna. Ceroid, a pigment that is

considered pathognomonic for yellow fat disease in mammals, was identified histochemically in the fat from affected birds.[9]

Birds suspected of hypovitaminosis E should receive parenteral supplementation. Mild conditions may respond dramatically to this treatment. In cases where there is irreversible nerve or muscle damage, response is poor (see Chapter 18).

- ***Vitamin K:*** Vitamin K is required for the synthesis of prothrombin. Deficiency of vitamin K results in prolonged prothrombin time and delayed blood clotting. Affected birds may exsanguinate from minor traumatic injuries. Bacterial flora in the intestine are the natural source of vitamin K. Clinical problems associated with bleeding or petechia from pulled feathers may respond to injectable vitamin K, but naturally occurring hypovitaminosis K has not been proven in companion birds.[18] Sulfaquinoxaline has been reported to induce hypovitaminosis K in poultry, and it is possible that long-term antibiotics used in aviary birds could do likewise.

Water-soluble Vitamins

- ***Thiamine (Vitamin B_1):*** Thiamine deficiency may lead to loss of appetite, opisthotonos, seizures and death. Deficiency of thiamine is uncommon in birds on a seed diet because seeds and grains generally contain sufficient thiamine. Thiamine deficiency-induced seizures and neurologic signs may occur in carnivorous birds fed solely on meat or day-old chickens, and in fish-eating birds fed fish containing thiaminase.[17] Free-ranging honey-eaters in urban areas of southern Australia may develop thiamine deficiency during the winter. This is thought to be associated with the planting of exotic ornamental trees that provide inadequate nutrition but encourage the birds to remain in an urban area rather than properly migrate.

  Response to treatment in thiamine deficiency cases can be dramatic. Affected birds will respond within minutes to injectable thiamine. Response to oral thiamine may also be rapid.

- ***Riboflavin (Vitamin B_2):*** In young chicks, riboflavin deficiency causes weakness and diarrhea, but the bird's appetite remains normal. Affected birds have toes curled inward both when walking and resting. The skin is rough and dry. Similar clinical signs thought to be associated with riboflavin deficiency have been reported in young waterfowl, an eagle and ratites (see Color 48).[34] Turkey poults with riboflavin deficiency show poor growth with dermatitis around the face and feet. Cockatiels fed riboflavin-deficient diets failed to incorporate pigment into their primary feathers.[46]

  Older birds are more resistant to riboflavin deficiency than juveniles. Breeding hens fed riboflavin-deficient diets may show fatty infiltration of the liver as well as decreased hatchability of their eggs and increased embryo mortality. Heterophil counts may increase and lymphocyte counts decrease. Primary wing feathers may be excessively long.[36,51] Early treatment with riboflavin will resolve clinical signs; however, in chronic cases permanent nerve damage may occur.

- ***Niacin (Nicotinic Acid):*** Clinical signs of niacin deficiency are fairly nonspecific and include poor feathering, nervousness, diarrhea and stomatitis. Young chickens, turkeys and ducks with niacin deficiency may show enlargement of the hock and bowed legs similar to those seen with perosis, but the gastrocnemius tendon does not slip from the condyles. Chickens showing signs of hysteria have responded clinically to niacin supplementation in the drinking water.[3] Niacin deficiency has not been described in Psittaciformes.

- ***Pyridoxine (Vitamin B_6):*** Chicks with pyridoxine deficiency may show depressed appetites, poor growth, perosis, jerky movements and spasmodic convulsions. As with riboflavin deficiency, heterophil counts may increase while lymphocyte counts decrease.

  Because pyridoxine is involved in amino acid metabolism, signs of deficiency rarely occur unless dietary protein levels are high. In adult chickens, pyridoxine deficiency causes reduced egg production and poor hatchability. Pyridoxine deficiency was suspected in juvenile rheas that developed "goose-stepping" gaits.[16]

- ***Pantothenic Acid:*** Symptoms of pantothenic acid deficiency in chicks are similar to those of biotin deficiency and include dermatitis on the face and feet, perosis, poor growth, poor feathering and ataxia (see Color 48). Severe edema and subcutaneous hemorrhages are signs of pantothenic acid deficiency in developing chicken embryos.[1] Similar signs have also been seen in developing ostrich embryos. High incubator humidity may contribute to this problem. Cockatiels reared on pantothenic acid-deficient diets failed to grow contour feathers on their chests and backs, and many died at three weeks of age. Affected birds had the appearance of feather-picked chicks.[46]

- ***Biotin:*** Natural sources of the vitamin are the same as those for pantothenic acid, and signs of biotin deficiency may parallel those of pantothenic acid: dermatitis on the face and feet, perosis, poor growth, poor feathering and ataxia. Biotin deficiency may also be associated with swelling and ulceration of the foot pads, and biotin-deficient embryos may show syndactylia and chondrodysplastic changes in the skeleton. Fatty liver and kidney syndrome in chickens has been associated with marginal biotin deficiency. Although egg yolk is a rich source of biotin, uncooked egg white contains a biotin antagonist called avidin, and biotin supplementation of a diet containing raw egg white may not correct the deficiency unless the biotin-binding capacity of the egg white has been exceeded. Mycotoxins may also interfere with biotin uptake.

- ***Folic Acid:*** In poultry, folic acid deficiency has been associated with embryonic mortality, deformation of the upper mandible, poor growth, macrocytic anemia, bending of the tibiotarsi and perosis. Folic acid, lysine and iron appear to be needed for the production of feather pigments in colored breeds of poultry. Folic acid is synthesized by bacteria in the digestive tract, so antibiotic therapy, particularly with sulfonamides, could induce a deficiency.

- ***Choline:*** A deficiency of choline caused poor growth and perosis in juvenile turkeys and chickens. In older birds, fatty liver infiltration may occur. Cockatiels reared on choline-deficient diets showed unpigmented wing and tail feathers but no signs of perosis.[46]

- ***Vitamin C:*** Bulbuls and fruit-eating birds may require exogenous vitamin C (ascorbic acid) but in chickens, and probably most species of seed-eating birds, vitamin C is synthesized in the liver. Birds with vitamin E and selenium deficiencies, heat stress, trace element toxicity or parasitic infections would be expected to have an increased requirement and decreased production of vitamin C.[3] In these situations, parenteral supplementation of vitamin C would be indicated. Natural sources of vitamin C include fresh fruits and vegetables (eg, citrus fruits, broccoli, green peppers). High dietary intake of ascorbic acid improves albumen quality and egg shell thickness in chickens. Signs of vitamin C deficiency have not been documented in companion birds.

Minerals

Calcium and Phosphorus

Calcium in the diet is used for bone formation, egg shell production, blood clotting, nerve impulse transmission, glandular secretion and muscle contraction. Phosphorus is important in many body functions including bone formation, the maintenance of acid-base balance, fat and carbohydrate metabolism and calcium transport in egg formation. Separate vitamin D-dependent mechanisms are believed to be responsible for calcium and phosphorus absorption from the intestine.

If calcium utilization exceeds absorption from the intestine over a prolonged period of time, parathyroid hormone excretion will increase and the parathyroid glands will enlarge (see Color 14). This condition, called secondary nutritional hyperparathyroidism (SNH), allows normal blood calcium levels to be maintained. High levels of phosphorus or low levels of vitamin D in the diet may exacerbate SNH. Symptoms of the syndrome may include weakness, polydypsia, anorexia and regurgitation. In breeding hens, SNH may result in decreased egg production, production of soft-shelled eggs, egg binding and fragile bones (see Chapter 23).

Hypocalcemic seizures associated with severe parathyroid enlargement and degeneration occur as a syndrome in African Grey Parrots.[45] Affected birds are generally between the ages of two to five years. Abnormal clinical pathology findings include leukocytosis and hypocalcemia. Calcium levels may be below 6.0 mg/dl and sometimes as low as 2.4 mg/dl. At necropsy, there is no apparent calcium mobilization from bones as would be expected when blood calcium levels decease in normal birds. Affected birds have difficulty in mobilizing calcium from body stores, and should be supplemented constantly with dietary calcium. There has been some undocumented discussion that the syndrome is limited to imported birds, and that some naturally occurring environmental factor may initiate the syndrome. Additionally, the problem may be regional in nature because it appears to be more prevalent on the West Coast, as compared to the East Coast, of the United States.

- ***Diets for Birds with Hypocalcemia:*** Calcium syrup may be used in the drinking water, sprinkled on seeds or soft foods or administered directly. Foods containing high levels of calcium such as bones, cheese or yogurt may be provided. Calcium powder may be sprinkled on soft food. High-fat seeds (eg, sunflower,

safflower) may interfere with calcium uptake from the intestine. Levels of vitamin D_3 in the diet should be evaluated and supplemented if needed.

High-calcium diets are generally required only until normal body reserves are restored. The addition of psyllium to the diet may increase the absorption of calcium.[30] Long-term consumption of high levels of calcium may interfere with manganese or zinc absorption and may result in renal calcium deposition, reduced numbers of glomeruli per kidney and subsequent renal failure.[41] Because of these problems, care should be taken to provide correct supplementation levels. Laying hens and rapidly growing juveniles will require higher levels of calcium than nonbreeding adults.

Hypocalcemic seizures are rare in species other than African Grey Parrots. Occasionally, companion birds on an all-seed diet will be presented with seizuring caused by hypocalcemia. These birds usually respond dramatically (within minutes) to intramuscular calcium and multivitamin therapy.

Because calcium metabolism is closely linked with vitamin D metabolism, many changes caused by calcium deficiency in juveniles are identical to those caused by hypovitaminosis D. Appropriate amounts of calcium, phosphorous and vitamin D are necessary for optimal bone and egg shell formation. The normal calcium to phosphorus ration for chickens is 2:1. It is likely that a similar ratio would be appropriate for most species of birds although specific research data is lacking. Most available commercial seeds are extremely calcium deficient: corn=1:37, millet=1:6, milo=1:14, oats=1:8 and sunflower seeds=1:7. High-fat content in oil seeds may also interfere with calcium absorption from the intestine and exacerbate the problem.[46]

Muscle meat is low in calcium and high in phosphorus with a ratio of 1:20. Carnivorous birds fed an all-meat diet, day-old chicks or pinky mice may show signs of calcium deficiency and SNH. Feeding whole adult mice, older chicks, quail or rats to carnivorous birds should provide better calcium balance. It is important to provide variety in the type of food fed.[38]

Long bone deformities in juvenile birds, particularly ratites, may be associated with high protein, low calcium diets; however, reducing dietary protein and supplementing calcium may not always correct the problem. In these situations, the overall suitability of the diet, including the calcium to phosphorus ratio, the level of magnesium and electrolytes and the energy level in the diet should be evaluated. The birds should be encouraged to exercise more and the rate of weight gain should be reduced (see Chapter 48).

Excess phosphorus consumption can exacerbate SNH. Decreases in egg production, poor egg shell quality and rickets could occur with phosphorus deficiency, but this is unlikely because the mineral is very widely distributed in common food items.

Magnesium

Magnesium is necessary for bone formation, for carbohydrate metabolism and for activation of many enzymes. Its metabolism is closely associated with that of calcium and phosphorus. Deficiencies in young chicks may result in poor growth, lethargy, convulsions and death. Excessive amounts may cause diarrhea, irritability, decreased egg production and thin-shelled eggs.

Iron

Iron is needed for the production of hemoglobin and many enzymes. Iron deficiency may result in hypochromic, microcytic anemia. Normal levels of nonheme iron in the plasma are necessary for feather pigmentation.

- ***Diets for Birds with Anemia:*** Birds with anemia should receive a diet that is high in energy and protein, and be supplemented with B complex vitamins (including B_{12}, pyridoxine, niacin and folic acid), iron, cobalt and copper.
- ***Diets for Birds with Hepatopathies:*** Iron storage disorders have been reported in a variety of non-psittacine species, particularly Indian Hill Mynahs, birds of paradise, hornbills and toucans.[34] In some cases, the disease has been correlated with diets high in iron, and problems with the condition decreased when dietary iron levels were lowered to less than 40 ppm (see Chapters 20, 47).

Liver disease may decrease the absorption and storage of fat-soluble vitamins A and D and inhibit the synthesis of vitamin C necessitating supplementation.[21] Other objectives in designing diets for birds with liver disease include reducing the work load on the liver (fat conversion, gluconeogenesis, deamination and nitrogen conversion), preventing sodium retention and hypokalemia, restoring liver glycogen and minimizing the possibility of hepatic encephalopathy. The diet should contain a readily available energy source such as dextrose or other easily digested carbohydrate. Canary seeds, millet, panicum, corn or hulled oats are relatively high in carbohy-

drate and low in protein and fat. These should be used in preference to sunflower seed, rape or niger, all of which are much higher in fat and protein and lower in carbohydrate. Birds with hepatopathy should be offered a variety of fresh fruit and vegetables that are generally high in easily digestible carbohydrates. These fruits and vegetables should be organically grown to prevent exposing the compromised liver to pesticides. The diet should contain a low level of protein of high biologic value such as chopped hard-cooked egg, cottage cheese or cooked chicken. For carnivorous birds, purine-containing foods (offal) should be avoided. The bird should receive a sufficient volume of food to meet caloric needs (see Chapter 20).

Copper

Copper is necessary for heme synthesis and is an important component of several enzymes including lysyl oxidase, an enzyme involved in the formation of cross-linking in elastin and tyrosine o-diphenol oxidase, which catalyzes the early stages of melanin synthesis. Copper deficiency has been associated with aortic rupture in poultry as well as being associated with increased bone fragility and impaired feather pigmentation. In laying hens, copper deficiency may cause decreased egg production and shell abnormalities including shell-less, misshapen, wrinkled eggs and large eggs with thin shells.

Selenium

In addition to having a vitamin E-sparing effect in the prevention of ventricular myopathy, white muscle disease and exudative diathesis, selenium is also linked with exocrine pancreatic function and the production of thyroid hormones. In young chickens, selenium deficiency causes poor growth and poor feathering, impaired fat digestion and pancreatic atrophy. Similar problems are occasionally seen in companion birds, but a link with selenium deficiency has not been established. Excess dietary selenium (above four ppm) in ducks can impair hatching success and may be teratogenic[37] (see Chapter 48).

Manganese

Manganese is required for normal bone and egg shell formation and for growth, reproduction and the prevention of perosis. Poultry embryos and young chicks with a manganese deficiency develop chondrodystrophia: short, thickened limbs, parrot beak, protruding abdomen and retarded growth. Ataxia may also be noted. Seed diets may be deficient in manganese.

Zinc

Zinc is needed for the formation of insulin and many enzymes in the body. In poultry, zinc deficiency may cause short, thickened long bones, enlargement of the hock, dermatitis and impaired T-cell function. Ducks may develop hyperkeratosis of the feet and oral cavity. Zinc is also necessary for proper function of vitamin A. Patients with hypovitaminosis A must receive adequate levels of dietary zinc for therapy to be successful. Excess levels of zinc may cause pancreatic cell necrosis secondary to interference with cellular protein synthesis.

Iodine

Iodine is needed for the formation of thyroxine and related compounds in the thyroid gland. Iodine deficiency may result in goiter (enlargement of the thyroid glands). The thyroid glands in birds are located in the thoracic inlet and usually cannot be palpated (see Anatomy Overlays).

Clinical signs of goiter are the result of pressure on organs adjacent to the gland. A loud, wheezing respiration with neck extended may occur if there is pressure against the trachea. Crop dilation and vomiting may occur if the goiter obstructs the outlet to the crop. Iodine-deficient budgerigars are particularly prone to goiter (see Color 19). Goiter has occasionally been reported in other species of birds[53] (see Chapter 23).

Birds with goiter must be handled with care. Excessive stress may cause regurgitation and subsequent aspiration of vomitus. Conservative therapy should include the administration of a drop of iodine orally each day. Injectable iodine and dexamethasone may be necessary in more advanced cases. Once stabilized, the bird should be changed to a formulated diet.

Excess dietary iodine has also been reported to induce goiter (eg, birds consuming iodine-based cleaning agents). High levels of iodine may also antagonize chloride, depress growth rates and induce CNS signs. Goitrogens in plants of the genus *Brassica* (eg, broccoli, cabbage or mustard greens) have been implicated as a cause of goiter in mammals; however, companion birds frequently consume these plants with no side effects.

The iodine content of seed depends on the iodine content of the soil on which it is grown. Seed grown in "goiter belt" regions of the world are likely to be deficient. The problem can be eliminated if iodine is

added to the seed. Alternatively and preferably, the birds should be changed to a formulated diet.

Budgerigars with thyroid tumors may have clinical signs identical to those seen with goiter. While goiter will generally respond quickly to iodine supplementation, thyroid tumors will not. It has been suggested that iodine-deficient diets may be associated with signs of hypothyroidism (eg, lethargy, obesity or dermatitis); however, these signs are rarely seen in companion birds with goiter (see Chapter 23).[32]

Potassium

Potassium is the principal cation in intracellular fluid and is required for glucose and protein metabolism. The mineral is widely distributed in food of both plant and animal origin. Symptoms associated with deficiency are unlikely to occur, but in chickens these may include decreased egg production, egg shell thinning, muscle and cardiac weakness, tetanic convulsion and death.

Sodium and Chloride

In poultry, salt deficiency causes weight loss, decreased egg production, small eggs and increased cannibalism. In psittacine birds, it has been suggested that salt deficiency may play a role in some cases of self-mutilation. Sodium deficiency alone may cause a decrease in cardiac output, hemoconcentration, reduced utilization of protein and carbohydrates, soft bones, corneal keratinization, gonadal inactivity and adrenal hypertrophy.

Chloride deficiency in chickens produces dehydration and characteristic CNS signs, in which chicks fall forward with their feet stretched out behind them for several minutes. Tibial dyschondroplasia in meat poultry has been associated with excess dietary chloride. This problem is seen occasionally in young ratites, although the cause has not been clearly defined. Demineralized bone formation was seen in a variety of juvenile Australian parrots fed a homemade mineral block containing apparently adequate calcium and phosphorus levels, but an excess level of salt. The problem stopped when the mineral block was removed.

Excessive amounts of salt may be acutely toxic. Affected birds show intense polydipsia, muscle weakness and convulsions. Ducks are more sensitive to salt intoxication than are poultry. Sea birds have a nasal salt gland that is controlled by the ATPase pump in the gastrointestinal tract, and is used to excrete excessive exogenous salt. Oil contamination may suppress the ATPase pump and cause clinical signs of salt toxicity. The salt gland of sea birds provided fresh water becomes nonfunctional. Prior to release into a marine environment, these birds should receive gradually increasing levels of salt to ensure that their glands are functional.[57]

Water

Water consumption in birds varies dramatically among species and among individuals of the same species. Budgerigars and Zebra Finches (species that evolved in desert regions) have been reported to survive several months without drinking, apparently relying on water derived from metabolic sources.[7] On the other hand, healthy companion birds may consume significant amounts of water daily and become distressed if water is withheld.

Some birds that have not evolved for desert living (eg, canaries), may die if they do not drink water for 48 hours. The addition of any compound to the drinking water can cause these birds to stop consuming water, resulting in a rapid dehydration and death.

CHAPTER

32

VIRUSES

Helga Gerlach

Worldwide movement of birds for the pet market can cause a blending of different populations with the possibility of carrying widely varying microorganisms or antibodies against them. If one group of birds is exposed to another with a latent infection, then a severe disease outbreak can occur. Such latently infected birds create a diagnostic and flock management dilemma. While the carrier birds may be clinically inconspicuous, the virus may propagate at a low level and shed through the feces, urine, respiratory secretions or exfoliated epithelial cells from the feathers or skin. In some cases, latently infected birds may succumb to disease, with the virus replicating very rapidly, and both groups of birds may become sick. Artificial incubation and shipping of eggs has been suggested as a method to protect a given population from introduction of an exogenous virus. However, this concept is flawed because a hen can pass antibodies and some viruses to her offspring while the egg is developing. Infected neonates can cause severe epornitics with high mortality in a nursery situation.

In general, viral infections remain untreatable. Nonspecific supportive care, antimicrobials to prevent secondary bacterial and fungal infections and good nutritional support, including the supplementation of vitamin C, remain the only available therapeutic regimens for most viral infections. Newly emerging concepts in the use of antisense RNA will undoubtedly result in more specific therapies for many infectious diseases (see Chapter 6). Interferon has been suggested for treatment of viral infections. Paramunity inducers have proven effective with some viral diseases.[334,365] Acyclovir has proven to be effective with some strains of avian herpesvirus and may have positive effects in treating poxvirus infections (see Table 32.18). Substantial viral disease outbreaks may be prevented by having a working knowledge of the transmission routes and pathogenesis of a particular virus, by using specific diagnostic tests to detect clinical or subclinical infections, by practicing sound hygiene and by maintaining closed aviaries. Virus adaptation on specific host cells may be difficult to overcome with the routine avian culture systems, and great patience might be necessary when trying adaptation passages (at least ten or more). Continued international cooperation will be mandatory for the expansion of knowledge in the field of avian virology. The application of molecular biology

techniques seems to improve the researcher's ability to diagnose infections and to establish the role that viruses play in the disease process.

Diagnostic Principles

An unequivocal diagnosis of a particular viral infection can be made only through specific laboratory diagnostic methods. Clinical, pathologic and histologic changes are perhaps suggestive of a diagnosis but pathognomonic lesions are rare, and in-depth diagnostic tools are necessary to confirm a virus as a cause of morbidity or mortality in an avian host (Table 32.1). There are several procedures that can be used to confirm the presence of a viral infection: 1) Isolation of the pathogen from the test material; 2) Demonstration of viral particles or inclusion bodies by histopathology; 3) Demonstration of viral antigen (Ag) in infected tissues using viral-specific antibodies (Ab); 4) Demonstration of viral nucleic acid in infected tissues using viral-specific nucleic acid probes; 5) Indirect demonstration of a viral infection by detection of humoral antibodies. A viral disease can sometimes be demonstrated by a rise in antibody titers in paired serum samples.

Viral-specific nucleic acid probes are more sensitive than other techniques and allow the detection of small concentrations of virus as well as the ability to detect the presence of viral nucleic acid before substantial histologic changes may have occurred.

Virus Cultures

Choosing an optimum culture system for avian viruses is difficult. There are over 8,700 avian species, which probably have an equally large number of specifically host-adapted viruses. Primary cell cultures from fibroblasts, kidney or liver cells collected from embryos of the test species normally provide the best chance of isolating a host-adapted virus. Unfortunately, such embryos (which should ideally be free of specific pathogens) are rarely available for the bird species seen in private practice. Cell cultures derived from chickens, ducks and geese are most often used as an alternative choice because of their wide availability; however, these sources of cells have inherent problems. Not every newly prepared cell culture is identical to its predecessor, which may affect virus propagation. If pathogens from heterologous bird

TABLE 32.1 Virus Identification Tests

Immunodiffusion (ID)
The ID is a common, inexpensive method to demonstrate mainly group-specific soluble antigens (primarily IgM). The antigen and antibody diffuse toward each other in an agar gel. Where reactive partners meet, they form a precipitate that is visible as one or several pale lines. This technique is relatively simple and adequately fulfills several objectives. It is, however, relatively insensitive when compared to other techniques. The gel should contain 8% NaCl when testing avian serum (Figure 32.1).

Hemagglutination Inhibition Test (HI)
Proteins present on the surface of some viruses agglutinate erythrocytes from certain avian or mammalian species. By adding antibodies directed against the agglutinating portion of the virus, hemagglutinin activity is neutralized so that hemagglutination cannot take place (hemagglutination inhibition - HI). The HI test recognizes surface antigens (primarily detects presence of IgG).

Virus Neutralization Test (VN)
Test serum is mixed with an antigen. If viral-specific neutralizing antibodies are present in the test serum, and the quantitative ratio is correct, then virus in a sample will be neutralized. Determining that an Ag-Ab reaction has occurred must then be demonstrated by showing that the neutralized virus is incapable of inducing disease in a test system (usually cell culture). Although VN tests can be performed for many viruses, they are time-consuming and require a series of dilutions that consume a large quantity of raw materials and reagents. The VN test is suitable for serotyping depending on the virus species and the type of antibody used.

Complement-Fixation (CF)
Complement is necessary for binding to occur between Ag and Ab. If an Ag-Ab reaction occurs with test material then complement is fixed (used up), and a second reaction with an Ag-Ab indicator system can no longer take place. This system is just as complicated as the ELISA test, which is much more sensitive. Furthermore, commercially available guinea pig complement is inappropriate for use with many bird species. The CF test is generally used for demonstrating group-specific antigens.

ELISA
Antigen or antibody is bound firmly to a plate. A test material is added (can be serum for detecting Ab or tissue samples for detecting Ag). The occurrence of an Ag-Ab reaction is demonstrated by adding a third Ag or Ab that is conjugated with an enzyme. A substrate that is converted by the bound enzyme is added to the system and a color change occurs. This system is highly sensitive and technically simple to operate. However, preparation of the appropriate enzyme conjugate with a correspondingly high degree of specificity is demanding. Nonspecific reactions are frequently observed. Generally, the ELISA recognizes group-specific antigens; however, with the use of monoclonal antibodies, serotypes, biovars or mutants can be demonstrated.

Immunofluorescence (IF)
Antigen or Ab is conjugated with fluorescent dyes. If an Ag-Ab reaction occurs with test material then fluorescence is present after washing off the superplus reagents. Nonspecific fluorescence that complicates interpretation of the test is common. The IF is best suited for demonstration of group-specific antigens.

Radioimmunoassay (RIA)
Either antigens or antibodies are radioactively labelled. The technique itself is essentially similar to that of IF. Although this method is very sensitive, it presents inherent dangers to personnel dealing with radioactive materials as well as creating disposal problems for radioactive waste. Identification of group-specific antigens, serovars or individual antigenic sites is possible with the correct antibodies.

species will grow in non-host cell cultures at all, they often require repeated passages for adaptation to the cells, prolonging the recovery of a virus from weeks to months. Many viral pathogens have never been successfully isolated in cell culture.

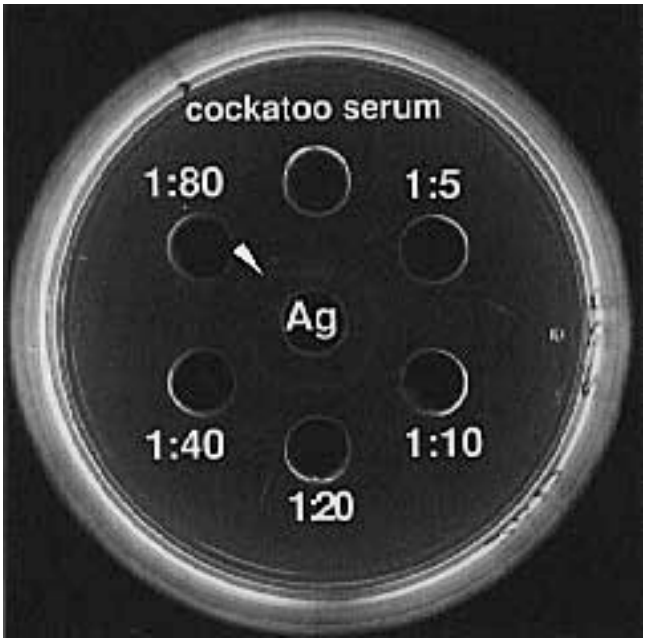

FIG 32.1 Agar-gel diffusion test using serum from an adult psittacine bird three weeks after vaccination with an experimental inactivated PBFD virus vaccine. The initial precipitating antibody titer was 0. The presence of a precipitation line at 1/80 (arrow) indicates that the bird seroconverted following vaccination and produced anti-PBFD virus precipitating antibodies.

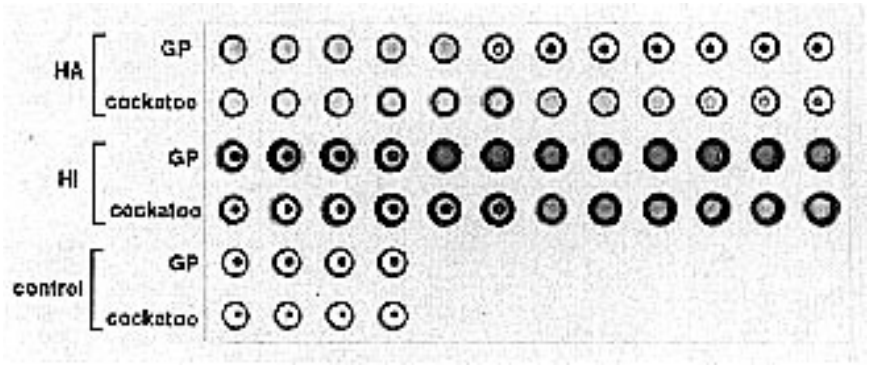

FIG 32.2 Some viruses will cause the agglutination (no button forms) of certain types of erythrocytes. Noted examples of avian viruses that will agglutinate some erythrocytes include PBFD virus, polyomavirus and paramyxovirus. Antibodies to these viruses can be detected by determining if serum from a patient prevents agglutination (the antibodies bind to the hemagglutination site on the RBC and allow a button to form). In this photograph, decreasing dilutions of PBFD virus were used to agglutinate (HA) guinea pig and cockatoo erythrocytes. The point at which the diluted virus will no longer agglutinate the cells (button forms) is the HA titer for the virus. Anti-PBFD virus antibodies could be detected by showing that serum would block (hemagglutination inhibition-HI) the virus from causing agglutination, which allows a button to form (reprinted with permission from Am J Vet Res 52:1991).

In addition to tissue cultures, embryonated eggs have been used to recover avian viruses. In contrast to tissue culture, they offer a complete biologic system with cells of endo-, meso- and ectodermal origin. The flocks from which these eggs are obtained should be free of viruses and virus antibodies in order to allow a particular virus to grow.

Virus Identification

Direct identification of a virus by electron microscopy is possible only with a relatively high concentration of the virus (generally $>10^6$ particles/ml). As a rapid but insensitive survey, fresh tissue samples fixed on grids (stained with osmium or another appropriate stain) can be examined by electron microscopy for the presence of viruses. Viral-specific nucleic acid probes allow the detection of very small concentrations of a virus in infected tissues or contaminated samples (crop washing, feces, respiratory excretions). Analytic methods such as electrophoresis without blot systems (Ab-dependent with blots), chromatography and nucleic acid probes are the most sensitive methods of demonstrating virus. They function independent of Ag-Ab reactions. The recent advances in genetic engineering will certainly have profound effects on virus detection in the future. DNA probes are currently available for detecting polyomavirus and psittacine beak and feather disease virus. Other similar diagnostic tests will ultimately be developed. All other methods of virus identification are based on changes induced by the virus, such as histologically discernible inclusion bodies. Viral-specific antibody preparations can be used to confirm the presence of a virus. Depending on the test objective, either polyclonal or monoclonal antibodies can be used. Monoclonal antibodies are normally used for identifying specific antigen structures and to differentiate between serotypes, subtypes, variants and mutants. Polyclonal antibodies are generally adequate for routine diagnostic tests. The identification of viruses using known antibodies inevitably requires an appropriate system to show that an antigen-antibody reaction has taken place. A test is chosen based on the objective of the test (group-specific antigens, serotyping) and the type of antibody (polyvalent, monovalent, monoclonal) available. Frequently used tests to demonstrate the presence of a virus or antibodies against a virus are listed in Table 32.2.

Indirect Virus Identification

Indirect virus identification techniques require the demonstration of specific antibodies in a patient's serum. To differentiate between Ab's that have been induced by prior exposure to an agent and those caused by a current infection, it is necessary to test two serum samples collected at two- to three-week intervals. A rise or fall in Ab concentrations or a switch from IgM to IgG are indicative of an active infection. Egg yolk (containing IgG) can be used in place of serum for some diagnostic tests.

Serologic cross-reactions caused by closely related antigens or epitopes with an identical structure can cause false-positive results when using indirect virus identification techniques. Precipitating Ab's (as used in the immunodiffusion test) consist primarily of IgM and are present relatively quickly after an infection and are broken down equally rapidly once the pathogen has been eliminated. The immunodiffusion test; therefore, is useful in diagnosing an actively occurring antibody response. It should be noted that not all infected individuals will produce precipitating Ab's.

Test Material

The proper test material for diagnosing viral infections depends on whether antemortem or postmortem samples are available and which viral disease is suspected. Antemortem samples may include feces, skin, organ or feather biopsy, blood or serum, or mucosal swabs from the trachea, cloaca, pharynx or conjunctiva. When flock problems occur, collecting fresh postmortem samples from a recently affected bird is the best way to achieve an accurate diagnosis. Samples for culture should be transported quickly and well cooled in a transport medium containing antibiotics. A relevant anamnestic report is valuable to help guide the laboratory diagnostic efforts.

Avipoxvirus

Members of the Poxviridae family (*Avipoxvirus* genus) cause a variety of diseases in birds. These large DNA viruses (250 to 300 nm) induce intracytoplasmic, lipophilic inclusion bodies called Bollinger bodies (pathognomonic). These inclusion bodies may be identified in affected epithelial cells of the integument, respiratory tract and oral cavity. Many bird species are considered to be susceptible to some strain of poxvirus, and isolates from different bird species have been classified into taxons. Biologic and serologic-immunologic properties for many avian poxviruses have not been determined, and the currently described taxons are probably incomplete.

The genus *Avipox* seems to be restricted to birds. Most of the members of the genus seem to be species-specific, but some taxons appear to be able to pass the species, genus or even family barrier. Although certain poxvirus strains will experimentally infect a variety of host species, cross-immunity may not al-

TABLE 32.2 Characteristic Histologic Lesions and Diagnostic Techniques of Selected Avian Viruses

Virus	Characteristic Lesions	Diagnostic Methods
Adenovirus	Basophilic intranuclear inclusions	Histopathology, serology (AGID)
EEE	Non-suppurative encephalitis, "descending" encephalitis	Histopathology, serology (HI)
Herpesvirus	Basophilic to eosinophilic intranuclear inclusion bodies (Cowdry type A)	Histopathology, virus isolation (Ab titers inconsistent)
Papillomavirus	Hyperkeratotic epidermis, intranuclear inclusions	Histopathology
Polyomavirus	Enlarged cells containing clear basophilic or amphophilic inclusions	Histopathology suggestive, virus isolation, viral-specific DNA probes (detecting shedders and confirming infections), *in situ* hybridization of tissues
PBFD virus	Basophilic intranuclear inclusions in epithelial cells, basophilic intracytoplasmic inclusions in macrophages	Histopathology, viral-specific DNA probes (detecting symptomatic or asymptomatic infections in blood), *in situ* hybridization of tissues
Paramyxovirus		Electron microscopy (EM), serology (HI), viral isolation
Poxvirus	Epithelial ballooning degeneration, intracytoplasmic inclusions (Bollinger bodies) pathognomonic, intranuclear inclusion bodies	Histopathology, viral culture, virus detection in feces by culture or EM
Reovirus	Necrotizing hepatitis, rarely intracytoplasmic inclusions	Virus isolation

Viruses

Color 32.1
A young pionus parrot was confirmed to have PBFD virus by demonstrating viral antigen in infected tissues with viral-specific antibodies and by demonstrating viral nucleic acid in circulating white blood cells using a DNA probe test. This bird was infected as a neonate when the breeder unknowingly added some infected African Grey Parrot chicks to the nursery.

Color 32.2
An Umbrella Cockatoo chick shows the first clinical feather changes associated with PBFD virus a minimum of 34 days after being exposed to the virus. The bird was depressed for two days before necrotic feathers became apparent. All of this bird's primary and secondary feathers were affected within a week after this photograph was taken.

Color 32.3
PBFD virus in older birds is characterized by progressive feather dystrophy and loss that typically starts with the powder down feathers as seen in this Umbrella Cockatoo. The disease then progresses during the ensuing molts to a point where the flight and tail feathers are also involved.

Color 32.4
Scarlet Macaw with the progressive form of PBFD virus causing dystrophic changes in the primary and secondary feathers.

Color 32.5
An experimental PBFD virus vaccine has been shown to be effective in preventing infections in neonates. In this photograph, an infected (right) and a vaccinated, protected African Grey Parrot chick of the same age dramatically illustrate the effects of the PBFD virus on a developing chick.

Color 32.6
PBFD virus antigen and nucleic acid can be demonstrated in infected white blood cells using viral-specific antibodies (shown here) or viral-specific DNA probes. The circulating white blood cells that are brown contain PBFD virus antigen. The other white blood cells in this preparation do not contain viral protein, suggesting that both infected and uninfected white blood cells are present in the circulation (courtesy of Kenneth Latimer).

Color 32.7
Immunoperoxidase staining of a feather from a bird with PBFD virus. Viral antigen is demonstrated in intranuclear (arrow) and intracytoplasmic (open arrow) inclusion bodies (courtesy of Kenneth Latimer).

Color 32.8
a) Large, basophilic intranuclear inclusion bodies are suggestive of avian polyomavirus. Infections can be confirmed only by documenting viral antigen or nucleic acid in suspect lesions using viral-specific antibodies (shown here) or **b)** DNA probes, respectively.

Color 32.9
Early poxvirus lesions on the lid margin of a mynah bird.

Color 32.10
A recently imported Blue-fronted Amazon Parrot was presented with oculonasal discharge. Ulcerative lesions of the lid margins with accumulation of necrotic debris were characteristic for poxvirus. The bird responded to supportive care that included flushing the ocular lesions with sterile saline QID and administration of broad spectrum antibiotics to prevent secondary bacterial infections.

Color 32.11
Beak changes may or may not occur in birds with PBFD virus infections. If they occur, they generally start as palatine necrosis.

Viruses

Color 32.12
Subcutaneous hemorrhage in a Blue and Gold Macaw chick suggestive of a polyomavirus infection.

Color 32.13
A Moluccan Cockatoo was presented with a progressive neurologic disease that started with ataxia and tremors several months before presentation. The bird had an upper respiratory disease about two weeks before the CNS signs were first noted. The bird's feather condition was marginal. DNA probe testing for PBFD virus and polyomavirus were negative. Radiographs were normal. Abnormal clinicopathologic findings included WBC=25,000 (lymphocytosis) and CPK=1500. EEG indicated an inflammatory disease. The bird died despite extensive supportive care. Several milliliters of yellow fluid were collected from the brain cavity at necropsy. The brain was hyperemic. Histopathology indicated basophilic intranuclear inclusion bodies similar to those caused by adenovirus.

Color 32.14
Finding a dilated, thin-walled proventriculus is suggestive of neuropathic gastric dilatation. The diagnosis can be confirmed only by demonstrating characteristic histopathologic lesions including lymphoplasmacytic ganglioneuritis.

Color 32.15
A 25-day-old budgerigar with PBFD virus. The feather lesions caused by PBFD virus are grossly similar to those caused by polyomavirus. French moult may be caused by either the PBFD virus or polyomavirus. Differentiation of these viral diseases requires detection of viral-specific antibodies or viral-specific DNA probe testing.

Color 32.16
Typical fluid accumulation in the abdomen of a Blue and Gold Macaw with avian viral serositis.

Color 32.17
A Blue and Gold Macaw chick was presented for evaluation. The bird was in a comatose state and was the sixth baby from a psittacine nursery to die acutely. The bird had subcutaneous hemorrhages, hepatomegaly and swollen hemorrhagic kidneys, all suggestive of polyomavirus. The bird was confirmed to have avian polyomavirus by identifying suggestive intranuclear inclusion bodies in the liver, spleen, kidneys and heart and by DNA probe detection of viral nucleic acid on a swab taken from the cut surface of the liver and spleen.

Color 32.18
An 18-week-old Blue and Gold Macaw was presented with a one-week history of lethargy and regurgitation. **a)** The abdomen was severely enlarged and filled with fluid. Abnormal clinicopathologic findings included TP=0.7, PCV=19, WBC=3,000. Radiographs indicated ileus with severe bowel loop distension. **b)** Gross necropsy findings included distension of the black, congested intestines. Histopathology indicated multifocal nonsuppurative serosities and lymphocytic proventriculus suggestive of avian viral serositis. The bird's clutch mate died several weeks later with the same lesions.

Color 32.19
A cockatoo that had been exposed to birds with neuropathic gastric dilatation (NGD) was suspected to have the disease based on clinical signs of diarrhea, hypermotility of gastrointestinal tract (as detected by contrast radiography) and weight loss. The bird died acutely. The only gross necropsy lesion was congestion of the gastric vasculature. The bird had histologic lesions consistent with NGD.

Color 32.20

ways be inducible. Further, the *Avipox* genus has a high capacity for recombination, which has been shown to occur between field and vaccine strains of virus when actively infected flocks are vaccinated. Many experimental infections have been performed without determining the strain of virus, which probably adds to confusion about poxvirus epizootiology.

Various *Avipox* spp. demonstrate serologic cross-reactions (VN and ID). Hemagglutinins are not produced. Species differentiation is based on host spectrum, plaque morphology of primary isolates, thermostability, optimal propagation temperature, serology, cross-immunity and ultrastructural characteristics (Tables 32.3, 32.4).

Waterfowlpox probably does not form a uniform group. Therefore, it can be expected that the full protection provided by fowlpoxvirus is not effective in all waterfowl species.

Peacock poxvirus can experimentally infect chickens but not domesticated pigeons and probably not turkeys. However, peafowl vaccinated with fowlpoxvirus were not protected against peacockpox.[16]

Poxvirus lesions have been documented on the feet, beak and periorbitally in numerous Passeriformes.[216,403]

Transmission

Transmission occurs through latently infected birds and biting arthropods in the habitat. In many areas, mosquitoes serve as the primary vectors, and infections are most common during late summer and autumn when mosquitoes are prevalent. Birds of any age are considered susceptible, although young birds are most frequently affected. A mosquito that feeds on an infected bird can retain infectious virus in the salivary glands two to eight weeks. Direct transmission of the virus between birds is linked to traumatic injuries induced by territorial behavior, which allows the virus access to the host through damaged epithelium.

Pathogenesis

Most members of the Poxviridae stimulate the synthesis of DNA in the host's epithelial cells resulting in hyperplasia of the affected epithelium. Avipoxvirus cannot penetrate intact epithelium. Traumatic lesions that may be induced by biting insects (mosquitoes, mites and ticks) can cause sufficient damage to the epithelial barrier to allow viral entrance to the host. Infections may be restricted to the portal of entry, or viremia and subsequent distribution to target organs may occur. The factors that control the type of infection have not been determined; however, it is known that a severe generalized disease occurs only if the infection takes the two-cyclic course (Figure 32.3).

This replication cycle occurs only with pathogenic strains, and the secondary viremia does not occur with nonpathogenic, slightly pathogenic or modified live virus vaccine strains. These strains generally induce an infection restricted to the inoculation site.

Avian poxvirus infections, particularly in a flock situation, can remain latent for years.[155,216] Non-specific stress factors are associated with viral reactivation. It has been suggested that latent poxvirus infections (including vaccine strains) can be egg transmitted (at least in the chicken).[155] Fowlpoxvirus (including vaccine strains) is known to induce a mild immunodepression that potentiates secondary infections.[25]

Clinical Disease and Pathology

Infections induced by poxvirus vary in clinical expression based on the virulence of the virus strain, the mode of transmission and the susceptibility of the host. The course of the disease is generally subacute, and it takes three to four weeks for an individual to recover. Flock outbreaks require two to three months to run their course. Clinically recognized symptoms include:

- ***Cutaneous Form ("Dry Pox"):*** The cutaneous form is the most common form of disease in many raptors and Passeriformes but not in Psittaciformes. Changes are characterized by papular lesions mainly on unfeathered skin around the eyes, beak, nares and distal to the tarsometatarsus. The interdigital webs are most frequently affected in waterfowl and the Shearwater. As lesions progress, papules change

color from yellowish to dark brown and develop into vesicles that open spontaneously, dry and form crusts (Figure 32.4). Spontaneous desquamation may require weeks and occurs without scarring in uncomplicated cases. Pigmented skin will frequently be discolored following an infection. Secondary bacterial or fungal colonization of lesions can substantially alter the appearance and progression of the disease.

In some cases, vesicles may not form and papules become hyperplastic, remaining in the periorbital region, nares, sinus infraorbitalis or on the tongue. These nodules may cause dyspnea (or asphyxia) or dysphagia depending on their location in the oral cavity. This progression is particularly common in the Bobwhite Quail, Canada Goose and Humboldt Penguin.[228] Periorbital lesions may cause blepharitis, symblepharon, keratitis, uveitis and ultimately ophthalmophthisis. Blue-fronted Amazons and Indian Hill Mynahs frequently develop ocular lesions (Color 32.9).[208] In domesticated male turkeys, papular infections may occur in the vent and pericloacal area without involving the cloacal mucosa or phallus. Infectivity levels may approach 75% of the flock. Virus transmission is suspected to occur during collection of semen for artificial insemination.[17]

- ***Diphtheroid Form ("Wet Pox"):*** Poxviral lesions that occur on the mucosa of the tongue, pharynx and larynx (rarely in the bronchi, esophagus and crop) cause fibrinous lesions that are grey to brown and caseous. Disturbing the exudates covering these lesions will induce severe bleeding. Multiple foci that coalesce may prevent a bird from swallowing food or result in dyspnea (or asphyxiation) if the larynx is involved. Oral lesions are frequently seen in Psittaciformes, Phasianiformes, Bobwhite Quail, some Columbiformes and Starlings.[71]

  Cutaneous and diphtheroid lesions may occur in the same bird or either or both types of lesions may be noted in a flock outbreak. The septicemic form can also occur in conjunction with either cutaneous or diphtheritic forms of this disease.

- ***Septicemic Form:*** An acute onset of ruffled plumage, somnolence, cyanosis and anorexia characterize septicemic poxvirus infections. Most birds (mortality rates of 70-99%) die within three days of developing clinical signs. Cutaneous lesions are rare and antemortem documentation of infections is difficult. Septicemic infections are most common in canaries and canary and finch crosses. Canarypox frequently causes a desquamative pneumonia with occlusion of the air capillaries resulting in dyspnea. Clinical signs can last for months, and death may occur by exhaustion. It has been suggested but not proven that the massive cellular proliferation of interstitial mesenchyme induced by the virus can cause neoplastic changes.[160] Postmortem lesions in affected canaries include small pneumonic foci and hemorrhages, as well as fatty liver degeneration and jejunitis.

FIG 32.4 The cutaneous form of poxvirus can cause mild to severe nodular lesions on the unfeathered areas of the face, feet and legs of companion and free-ranging birds of most orders.

- ***Tumors:*** Some Avipoxvirus strains have oncogenic properties. Passeriformes and Columbiformes that survive infections are prone to tumor formation. These rapidly growing, wart-like efflorescent tumors of the skin are generally void of normal epithelium and hemorrhage readily when disturbed. Bollinger bodies are usually present in the neoplastic tissue but viable virus may not be demonstrated. Surgical removal of the skin tumors is an effective therapy.

Specific Poxviral Symptoms

Psittacinepoxvirus infections have been documented in numerous South American parrots and parakeets. *Amazona* spp. and *Ara* spp. are most severely affected. Coryza and ocular lesions are frequently the dominating clinical signs in the genus *Amazona*; however, postmortem findings usually include diphtheroid enteritis or myocardial necrosis. Ocular lesions begin as dry areas on the eyelid that become crusty with exudate, sealing the lids closed. Secondary infections frequently cause keratitis, followed by ulceration, perforation of the globe, panophthalmia and finally ophthalmophthisis. When compared to other Psittaciformes, the unique clinical signs that occur in Amazon parrots are thought to be caused by virulence factors and not differences in virus strains.

Cutaneous lesions coupled with central nervous system signs (CNS) have been described in the Mourning Dove and falcons from the Persian Gulf. Cutaneous lesions in raptorial birds from most regions are relatively mild and self-limiting. In contrast, cutaneous lesions in Persian Gulf falcons were characterized by inflammatory necrotic processes that inhibited feeding. In some of these birds, CNS signs including somnolence, anorexia, opisthotonus, tonic-clonic cramps of the tail muscles and paresis and paralysis of the feet occurred. Histopathology revealed a distinct cribriform state, fresh hemorrhages in the white matter, mild inflammation of the meninges and no distinct inclusion bodies.[212] Mild CNS signs caused by poxvirus have also been described in turkeys.

Poxvirus infections in lovebirds usually cause cutaneous lesions although diphtheroid lesions ("wet pox") have also been described. Skin lesions rarely erupt, and the affected skin appears dehydrated and brownish in color. Ocular lesions characterized by serous conjunctivitis with heavy vascularization are common. The skin of the lower lid and of the facial angular palpebra may be yellow-brown with palpable induration. Serous exudate may become mucopurulent or fibrinous if secondary bacterial or fungal infections occur. Blepharosynechia caused by dried, crusty exudates can occur.[223] Morbidity and mortality in lovebirds may reach 75% of the at-risk population.

A budgerigar poxvirus was isolated from "feather dusters;" however, experimental infections with the isolated virus caused only a mild dyspnea of three to four days duration with no skin or feather lesions.

Poxvirus infections in 10- to 60-day-old ostrich chicks are characterized by small vesicles containing yellowish fluid on the eyelids and face. Lesions become dry and form a scale within six to ten days of forming. Diphtheroid lesions may also occur on the larynx, oral mucosa and the base of the tongue.

CLINICAL APPLICATION

Differential Diagnosis for Pox

Cutaneous Form
- Trauma
- *Trichophyton* spp.
- *Knemidokoptes* spp.

Diphtheroid Form
- Trichomoniasis
- Candidiasis
- Aspergillosis
- Pigeon herpesvirus
- Hypovitaminosis A
- Amazon tracheitis virus

Diagnosis

A definitive diagnosis of poxvirus can be made through the histologic demonstration of Bollinger bodies in biopsy samples of suspect lesions.

Culture is usually necessary to document the septicemic or coryzal forms of the disease. Cutaneous tumors are histologically characterized by a palisade-like arrangement of epithelial cords containing Bollinger bodies. Virus may be intermittently shed in the feces of asymptomatic carriers that may be identified by repeated culturing of feces. Serology is of little value in diagnosing poxvirus infections. Host recovery is primarily a function of cell-mediated immunity, and humoral antibodies are rarely and irregularly produced. If antibodies are present, they can be demonstrated by ID or VN.

Control

Birds that recover from pox should be protected from further disease for at least eight months, but many reports indicate shorter durations of immunity.[216] Cellular immunity is primarily responsible for recovery, and only small amounts of humoral antibodies are produced. Vaccination is the best method for controlling poxviral infections. Taxon-specific vaccines are available for only a few of the avian poxviruses (see Table 32.4 for the known cross immunities, which might be helpful for vaccination). Vaccines are commercially available for psittacine poxvirus, and should be considered to prevent infections in high-risk populations (imported birds, pet shop birds exposed to imported birds, areas with high densities of mosquitoes).[431] The manufacturer's guidelines for vaccination should be carefully followed. Canaries (and crosses) should be immunized with an appropriate vaccine. Only healthy flocks of these birds should be vaccinated. The use of a vaccine in an actively infected flock of canaries and other birds may result in recombination between the field and vaccine virus strains, inducing a severe disease in the entire flock. A new or freshly sterilized needle must be used for each bird to prevent the vaccination procedure from spreading the virus. Canaries should be immune for three to six months following vaccination.

Cutaneous vaccination (wingweb, feather follicle) is normally used in gallinaceous birds. This method of vaccination causes the formation of a typical pox lesion at the site of inoculation. These lesions correlate with immunity, and vaccinated birds should be inspected nine or ten days following vaccination to be certain that lesions have formed. The statistical portion of a group of birds that must properly serocon-

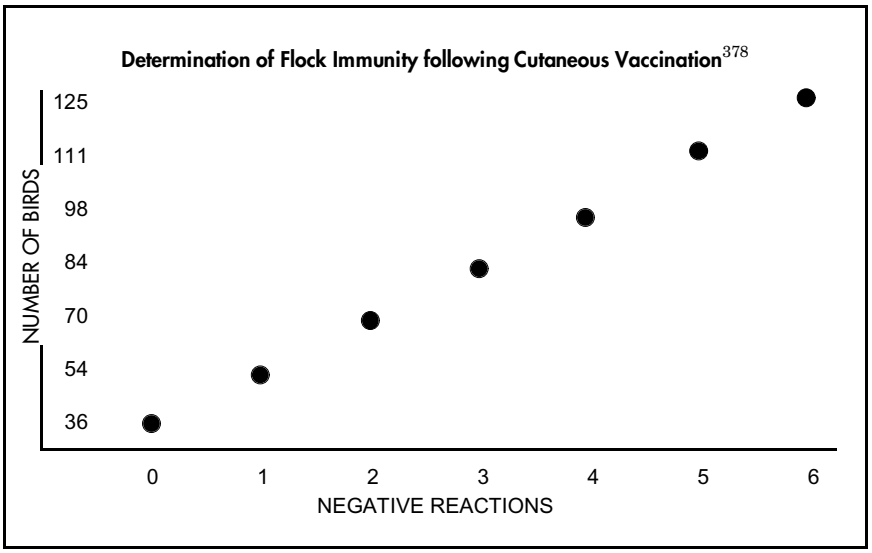

FIG 32.5 Chart for determining the number of successful poxvirus vaccination reactions necessary to ensure flock immunity.

vert in order to impart flock immunity is illustrated in Figure 32.5. For example, the statistical limits for full flock protection for 54 birds is 1.

Fowlpox vaccine has been found to provide protection for ostriches. Vaccination at 10-14 days old is recommended in areas with high densities of mosquitoes.

Herpesviridae

Herpesviridae are 120 and 220 nm diameter, double-stranded DNA viruses. Replication occurs in the nucleus. In some cells, an envelope may be obtained as the virus passes through the cytoplasmic membrane. Herpesvirus is not always restricted to a specifc host or tissue. Crossing over a host- or tissue-specific barrier can alter the pathogenicity of the virus considerably. Herpesviruses primarily infect lymphatic tissue (either B- or T-cells), epithelial cells (skin, mucosa, hepatocytes) and nerve cells. Herpesviridae are considered a phylogenetic old group of viruses and as such are typically well adapted to their hosts. It should be expected that more avian herpesviridae strains will be isolated, adding further confusion to the already tangled classification system. As a group, herpesviruses generally induce latent and persistent infections (for weeks, months, years or lifetime) in an adapted host with irregular periods of recrudescence and shedding. Latently infected birds can remain asymptomatic for years.

Concomitant disease, environmental stressors or hormonal changes have all been associated with induction of disease and activation of shedding. Reactivation does not always lead to clinical disease. Latently infected birds may shed virions via the feces, nasal discharge or desquamated skin (thereby endangering neighboring birds) without developing clinical signs. Virus can be transferred from cell to cell within an infected host with no invasion of the intracellular space, which protects the virus from humoral antibodies and antigen-processing cells. Because humoral antibodies decrease with time, indirect diagnosis of herpesvirus infections by detection of antibodies may give false-negative results. Herpesviruses generally produce Cowdry type A intranuclear inclusion bodies in target cells.

The Herpesviridae family is divided into three subfamilies:

- α-Herpesvirinae (hemorrhagic lesions)
- β-Herpesvirinae (necrotic lesions)
- τ-Herpesvirinae (lytic/neoplastic lesions)

Of the herpesvirus strains isolated from birds, only Marek's disease virus has been officially named. Table 32.5 shows the various herpesvirus taxons (it is questionable whether or not these have the status of a species), their respective subfamilies and the currently documented host spectrum. More detailed investigations may lead to further taxons, particularly with "Pacheco's disease-like" virus strains (the original Pacheco's disease virus has been lost). Table 32.6 shows the immunologic interactions.

Transmission

Transmission routes for avian herpesviruses in companion birds have not been thoroughly investigated. Vertical transmission has been confirmed only with budgerigar herpesvirus and duck plague herpesvirus. Epizootics result in high concentrations of virus being released to the environment. Budgerigars infected experimentally with Pacheco's disease virus shed virus with the feces for 48 hours post-infection. Birds in direct contact (same enclosure) and within

TABLE 32.5 Survey of Avian Herpesviridae

DISEASE	SUSCEPTIBLE SPECIES
Subfamily - α	
Infectious laryngotracheitis	Chickens, pheasants, peafowl, canaries
Amazon tracheitis	Genus Amazona, Bourke's parrot
Duck Plague (syn. Duck virus enteritis)	Ducks, geese, swans
Subfamily - β	
Pacheco's disease virus, "Pacheco's disease-like" virus	All Psittaciformes considered susceptible to varying degrees. At least three different serotypes. Host spectrum of two recent isolates is unknown.
Budgerigar herpesvirus	Budgerigar, pigeon, Double Yellow-headed Amazon
Pigeon inclusion body hepatitis (Esophagitis)	Pigeons, falcons, owls, budgerigar
Pigeon herpes encephalomyelitis	Pigeons
Falcon herpesvirus inclusion body hepatitis	Peregrine Falcon, Prairie Falcon, Common Kestrel, American Kestrel, Merlin, Red-necked Falcon Experimentally susceptible birds (see text)
Owl herpesvirus Hepatosplenitis infectiosa strigum	Eagle Owl, Great Horned Owl, Forest Eagle Owl, Snowy Owl, Striped Owl, Long-eared Owl, Little Owl, Tengmalm's Owl. Experimentally susceptible birds (see text)
Bald Eagle Herpesvirus	Bald Eagle
Lake Victoria Cormorant virus	Little Pied Cormorant
Crane inclusion body hepatitis	Demoiselle Crane, Crowned Crane, Whooping Crane, Sandhill Crane
Stork inclusion body hepatitis	Black Stork, White Stork
Colinus herpesvirus	Bobwhite Quail

"Local" herpesvirus causing papilloma-like lesions on feet	Cockatoo, Macaw
Herpesvirus associated with papilloma	Conures

the same air space (adjacent enclosures) shed virus in the feces 48 hours later than the experimentally infected birds, suggesting an incubation period of 48 hours.

Fecal virus concentrations in clinically affected birds reached levels of up to 10^6 to 10^7 tissue culture infectious dose $(TCID)_{50}$/g of feces. Experimentally infected birds that remained asymptomatic shed virus in the feces for approximately three weeks. Virus concentration in the lungs was 10^6 $TCID_{50}$/g and in the liver was 10^7 $TCID_{50}$/g.[445] These findings would suggest that the gastrointestinal tract (virus excreted from the liver) and the respiratory tract could be the primary points of entrance and release of the virus. Rapid spread through the aviary is common with virulent strains. The acute onset of clinical signs in several members of the flock may occur three to five days after the initial case is recognized.

Pathogenesis

Necrotizing lesions in the parenchymatous organs are characteristic of virulent herpesvirus infections. Hemorrhagic lesions may occur with some strains in various companion and aviary birds. Details on the pathogenicity of herpesvirus infections, particularly with respect to host and tissue specificity, are scarce.

Infectious Laryngotracheitis (ILT)

The herpesvirus responsible for ILT is distributed worldwide and appears to be serologically uniform. It is normally associated with acute disease of the respiratory tract, has a relatively small host spectrum and affects predominantly adult or growing birds older than eight weeks of age. Strain virulence varies widely from apathogenic to highly virulent. Several gallinaceous species (including peafowl and pheasants) have been found to be susceptible. The canary may also be susceptible to ILT as well as to its own herpesvirus strain (Kaleta EF, unpublished).[87,227]

Unlike other herpesviridae, natural transmission is exclusively aerogenic. The virus has an affinity for respiratory epithelium, and viremia does not develop. Occasionally, the virus is recovered from the esophagus and intestine.

Clinical Disease, Pathology and Diagnosis

Virulent strains of ILT cause severe dyspnea, gasping and coughing-like sounds. During inspiration, loud wheezing sounds may occur with the neck extended and the head raised. Expectoration of bloody mucus is common, and infected birds shake their heads to expulse the mucus. In severe cases, bloody fibrin may be discharged. Affected birds become progressively weak and cyanotic and die from asphyxiation. Conjunctival and nasal discharge (mucoid, purulent, rarely hemorrhagic), increased lacrimation and swelling of the sinus infraorbitalis frequently occur. These may be the only clinical signs associated with less virulent strains. A similar clinical picture has

Read as Marek's disease virus (y axis) reacts with individual strain (x axis). Vaccines available are listed as homologous or

been described in canaries. Primary ILT infections may be complicated by bacteria or fungi that colonize the necrotic respiratory epithelium.

Depending on the chronicity of the infection, postmortem findings may include hemorrhagic or fibrinous inflammation of a thickened mucosa of the larynx, trachea and in some cases, the bronchi. Caseous plugs or fibrinonectrotic pseudomembranes may also be noted.

Early histopathology lesions show ballooning degeneration of the mucosal epithelium followed by desquamation and inflammatory infiltrates as disease progression occurs. Prior to the desquamation stage, typical intranuclear eosinophilic inclusion bodies (Seifried's bodies) may be found. Air capillaries occluded with detritus and pneumonia have been occasionally reported.[156]

Immunodiffusion, VN, IF and ELISA can be used to identify isolates. In infected birds, precipitating antibodies can be demonstrated as early as eight to ten days post-infection. The occurence of intranuclear inclusion bodies in the respiratory epithelial cell is indicative, but confirmation of the disease requires virus isolation.

Control

Cell-adapted vaccines that have a considerable residual pathogenicity and may induce vaccinal reaction are available for chickens. Pheasants are considered to be more susceptible to ILT than chickens. Particular caution should be exercised in vaccinating pheasants with these products (this warning is not normally stated in the product insert).[67] Vaccine strains may induce life-long latency with reactivation following immunosuppression events.

Amazon Tracheitis (AT)

Chickens and the Common Pheasant are experimentally susceptible to the Amazon tracheitis virus. The disease that occurs in gallinaceous birds is mild in comparison to the clinical changes in Amazon parrots (see Color 22). The AT virus shares a serologic relationship with ILT and is considered a mutant of this virus. A herpesvirus pathologically similar to the ILT virus has been described in Bourke's Parrots; but no

comparisons between AT, ILT and this virus have been performed.[169,245,433]

The serologic relationship of AT and ILT allows the assumption (partly verified by clinical experience) that AT primarily infects the respiratory epithelium. The virus spreads quickly through an affected flock. Experimentally, clinical signs evolve within three to four days, and peracute death occurs within six days post-infection in the Green-cheeked Amazon.

Clinical Disease, Pathology and Diagnosis

Varying species of Amazon parrots develop similar clinical disease following natural infection. Peracute, acute, subacute and chronic (up to nine months duration) infections have been described. Fibronecrotic ocular, nasal or oral discharges accompanied by open-beaked breathing, rales, rattles and coughing are common. As a rule, the disease in Bourke's Parrots takes a less florid course.

Postmortem findings include serous, mucoid or fibrinous to pseudomembranous rhinitis, pharyngitis, laryngitis and tracheitis. A hemorrhagic inflammation is also possible. Affected birds typically die from asphyxiation caused by blockage of the trachea with fibronecrotic debris. Bronchopneumonia, conjunctivitis, blepharitis, glossitis, ingluveitis and air sacculitis may occur as a result of secondary bacterial and fungal invaders that take advantage of an immunocompromised host.

Histopathologic lesions resemble those induced by ILT. Demonstration of intranuclear inclusion bodies is possible only early in the disease process prior to exfoliation of the affected mucosal epithelium. Pharyngeal or laryngeal swabs submitted for culture are suitable for confirming a diagnosis.

Duck Plague (DP — syn. Duck Virus Enteritis)

Duck plague virus seems to be distributed worldwide with the exception of Australia, and has been documented in free-ranging and captive Anatidae (ducks, geese and swans). DP is caused by a serologic uniform herpesvirus that does not cross-react with other avian Herpesviridae. The disease is characterized by damage to the endothelial lining of vessels resulting in tissue hemorrhage, gastrointestinal bleeding and free blood in body cavities.

Susceptibility varies considerably according to the host species and virulence of the virus strain. Mallards and to a lesser extent, the Common Teal and the Common Pintail, are relatively resistant; however, they do produce antibodies post-exposure and are considered to be important reservoirs of the virus (particularly Mallards). Other Anatidae are considered relatively susceptible.[427]

Intermittent virus shedding in clinically healthy birds has been noted for up to five years. Outbreaks in zoological collections have been linked to free-ranging waterfowl that have access to exhibit ponds. Once infected, the captive birds can maintain the infection in the absence of an open body of water. Vertical transmission occurs, but does not seem to play an important epizootiologic role, perhaps because egg production is severely reduced in clinically affected flocks. Virus stability in water is temperature-dependent (4°C for approximately two months, 22°C for about one month).

Pathogenesis

The DP virus has an affinity for the reticuloendothelial system, propagates preferentially in undifferentiated epithelial cells and causes the destruction of B- and T-lymphocytes. Transovarially infected ducklings die during the first two weeks of life. Survivors are clinically healthy, partially immunotolerant and excrete large quantities of virus up to the sixth month of life. Although DP may occur clinically in only a single individual within a flock, it can also cause the death of 100% of the exposed birds. Climatic factors (heat, cold) are epizootiologically important. Birds (Mallards) with host-adapted strains serve as asymptomatic reservoirs and rarely develop clinical disease, but expose highly susceptible non-indigenous waterfowl to the virus.

Clinical Disease, Pathology and Diagnosis

Peracute death may occur without clinical signs. A more acute course is characterized by polydipsia, photophobia, nasal discharge, serous to hemorrhagic lacrimation, anorexia, cyanosis and greenish, watery (occasionally hemorrhagic) diarrhea. Mature birds generally have a more prolonged course of disease. Many birds swim in circles and are unable to fly. Paralysis of the phallus, convulsions or tremor of the neck and head muscles are occasionally noted. Affected free-ranging waterfowl may sit on the water with neck and head in extreme extension.

Postmortem lesions differ according to species susceptibility, degree of virus exposure and virulence of the infecting strain. Suggestive lesions include petechia and ecchymosis on the epicardium (see Color 14), serous membranes and the large blood vessels of the body; annular hemorrhagic bands on the mucosa

of the intestinal tract; necrosis in the cloacal wall and long parallel diphtheroid eruptions or confluent necrosis in the lower third of the esophagus. Nonspecific lesions include necrotic foci in the liver and hemorrhage of developing egg follicles.[234]

Histopathologic examination reveals eosinophilic intranuclear inclusion bodies (Cowdry A type) in hepatocytes, bile duct epithelial cells and the epithelial cells of the cloacal and esophageal mucosa. In the Muscovy Duck, erosions may be observed in the transition zone between the proventriculus and ventriculus. A definitive diagnosis requires virus isolation. VN is recommended for virus identification and to demonstrate antibodies in the host.

Pacheco's Disease Virus (PDV)

Pacheco's disease virus (PDV) has been described all over the world and is associated with a systemic, in many instances acute, disease that affects the liver, spleen and kidneys.

This disease was first described in parrots from Brazil.[301,380] The affected birds died after eight days of somnolence and ruffled plumage.

Since its initial description, there have been numerous cases of a Pacheco's-like disease induced by a herpesvirus. Susceptibility to PDV seems to be restricted to the Psittaciformes. Naturally susceptible hosts include macaws, Amazon parrots, conures, African Grey Parrots, *Poicephalus* spp., lovebirds, lories of the genus *Eos*, parakeets of the genus *Psittacula*, cockatoos, budgerigars, King Parrots and cockatiels. Patagonian and Nanday Conures are frequently discussed as asymptomatic carriers that intermittently shed virus; however, any bird that recovers from a PDV infection should be considered a carrier.

There are indications that inclusion body hepatitis in Psittaciformes (described and diagnosed as Pacheco's disease) is caused by several herpesviruses that are serologically distinct from the "original" virus.[38] Two serologically distinct herpesviruses (isolated from Blue-fronted Amazon Parrots, African Grey Parrots and a Moustache Parakeet) that induced lesions characteristic of Pacheco's disease have been described.[225] Further investigations are necessary to clarify the relationship between these antigenically distinct strains and to determine the efficacy of currently available monovalent PDV vaccines.

Clinical Disease

PDV generally induces an acute, nonspecific disease characterized by somnolence, lethargy, anorexia, ruffled plumage and intermittent diarrhea, polyuria and polydipsia (Figure 32.6). Biliverdin staining of liquefied feces and urates is indicative of the severe liver necrosis caused by the virus (see Color 8). Sinusitis, hemorrhagic diarrhea, conjunctivitis and convulsions or tremors in the neck, wings and legs have occasionally been described. Many outbreaks are linked to a stressful event such as a change in the environment or the onset of breeding season. Stress factors are thought to induce recrudescence in asymptomatic carriers resulting in virus excretion and an epornitic in exposed birds. In other cases, only a single bird may suddenly die while the rest of the flock remains unaffected. The intensity and course of the clinical disease varies widely according to species susceptibility. Some macaws and *Amazona* spp. are considered highly susceptible, while others in the same group appear to be relatively resistant. Old World Psittaciformes appear to be more resistant to PDV than do New World Psittaciformes.

Pathology and Diagnosis

With peracute or acute disease, birds are in generally good condition at the time of death. A massively swollen, tawny, light-red or greenish-colored liver with subserosal hemorrhages or necrotic foci is common (see Color 20). The spleen and kidneys are also distinctly swollen, and the intestinal mucosa may be hyperemic (Figure 32.7). Histologic lesions include congestion, hemorrhage and coagulative necrosis of the hepatocytes. The term "inclusion body hepatitis" is often misleading, because birds frequently die from massive liver necrosis before an inflammatory reaction occurs. Intranuclear eosinophilic inclusion bodies may be noted in hepatocytes (particularly around necrotic foci), bile duct and renal tubular epithelial cells and in splenic reticular cells. Virus identification is possible by VN, ELISA and IF. Precipitation with the ID is useful as a screening test. The use of monoclonal antibodies allows differentiation between the various PDV serotypes. Antibodies to PDV are difficult to demonstrate and provide no clinically relevant information.

Treatment

Natural immunity can be induced with paramunity inducers. Acyclovir has been shown to be effective for treating at least some strains of PDV. The recommended treatment regimen is to administer the water-soluble powder at a dose of 80 mg/kg TID by

FIG 32.6 The clinical course of Pacheco's disease virus (PDV) depends on the host species. Some birds die peracutely with no clinical signs of disease, while others die following a brief period of depression, ruffled plumage, diarrhea and polyuria. Other species may survive an infection and become asymptomatic carriers. This infected bird died shortly after presentation.

gavage tube. Severe muscle necrosis will occur if the intravenous product is injected IM. If gavage administration is not practical, the powdered acyclovir can be added to the food at a dose as high as 240 mg/kg.[294] Treatment is most effective if started before clinical signs develop. Acyclovir may cause considerable nephrotoxicity, and this drug should be administered carefully in patients with nephropathies. The role that acyclovir may play in inducing asymptomatic carriers has not been determined.

Control

An inactivated PDV vaccine is commercially available in the USA. There have been frequent reports of granulomas and paralysis following the use of this vaccine, particularly in cockatoos (Figure 32.8), African Grey Parrots and Blue and Gold Macaws.[24,103,159,261,323,373] The vaccine is intended for use in high risk patients (import stations, pet shops that handle imported birds). The instructions for use provided by the manufacturer should be carefully followed.

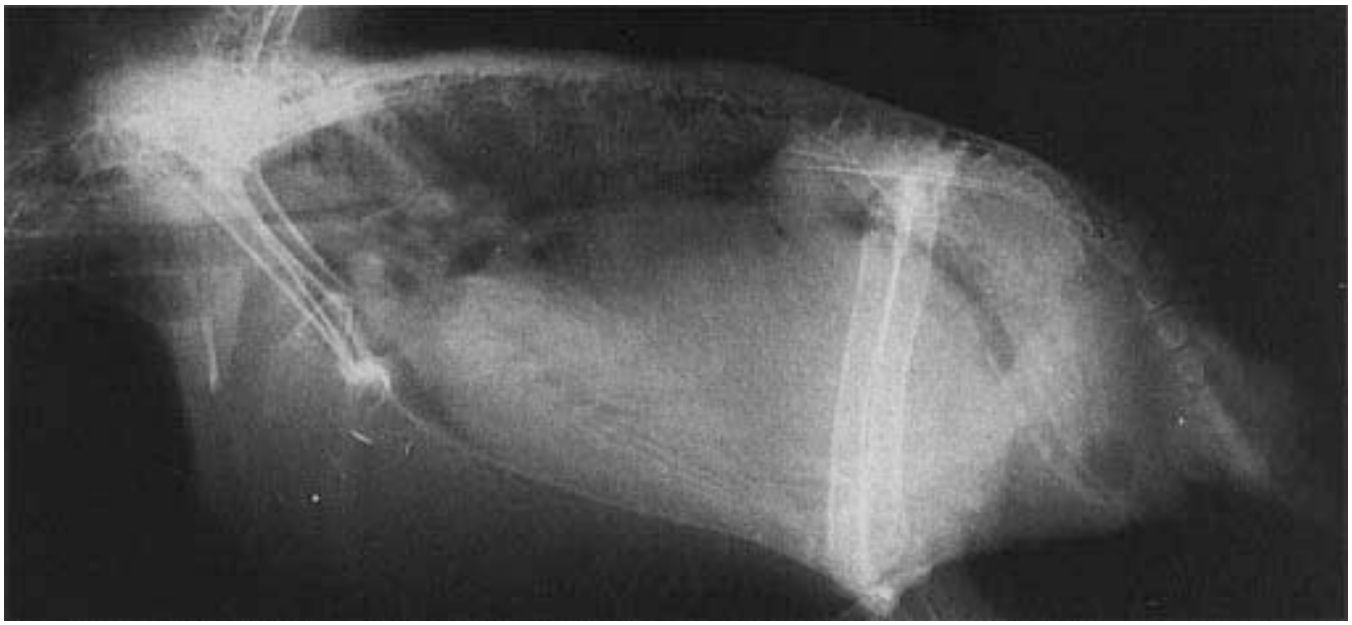

FIG 32.7 A young, recently imported female Blue and Gold Macaw was presented for anorexia, yellow discoloration of the stool and ruffled plumage. A doughy mass was palpable in the caudal abdomen. Abnormal clinical pathology findings included WBC=4000, AST=1200, LDH=980. Radiographs indicated an enlarged liver that occupied much of the abdomen and displaced the proventriculus dorsally and caused the caudal border of the heart to appear indistinct. The bird died shortly after presentation. At necropsy, the liver was enlarged (three to four times normal), mottled, red and had numerous subserosal hemorrhages. Histopathology confirmed the presence of hepatocellular necrosis and intranuclear inclusion bodies suggestive of Pacheco's disease virus.

Budgerigar Herpesvirus

A vertically transmitted herpesvirus has been isolated from the feathers of budgerigars. The virus is occasionally recoverable from parenchymatous organs, blood or feces. Decreased egg hatchability is the principal problem associated with this virus, which is serologically related to the pigeon herpesvirus, but not to Pacheco's disease virus or related strains.

Most isolates of this virus have been from so-called "feather dusters." It is unknown what role, if any, herpesvirus plays in this genetic problem of English Show Budgerigars.

A herpes-like virus was reported in a Yellow-crowned Amazon that died acutely following exposure to budgerigars. At necropsy, the thickened crop mucosa showed parakeratotic lesions with basophilic intranuclear inclusion bodies in the epithelial cells. Cells of the exogenic pancreas revealed degeneration accompanied by the formation of syncytial cells. The peripancreatic fat was necrotic. In addition, chronic hepatitis and proliferation of reticular cells in the spleen were noted. Intranuclear virus particles were present in the crop and pancreas, and enveloped virions with spiked outer membranes (unlike Pacheco's disease virus or ILT virus) were present in the cytoplasm.[245]

Virus isolated in cell culture can be identified using antibodies in the VN or ID tests. In infected flocks of English Standards, breeding should be interrupted to allow hens to develop immunity, which should provide some protection for the chicks.

Inclusion Body Hepatitis in Pigeons (Infectious Esophagitis)

This herpesvirus has a worldwide distribution, and various strains show morphologic, pathogenic and serologic differences (plaque formation in CEF). Small plaque variants are less pathogenic or apathogenic.[207] The large and small plaque-forming viruses may be two different strains.[206] This virus is serologically related to the falcon and owl herpesviruses. The host spectrum of this virus is uncertain, but pigeons and budgerigars are known to be susceptible.[417] Falcons and owls might also be susceptible and could be infected through contact with diseased pigeons. The susceptibility of falcons and owls varies with the species.

Squabs 4 to 16 weeks of age are most susceptible, but any age bird can be infected, particularly if immuno-

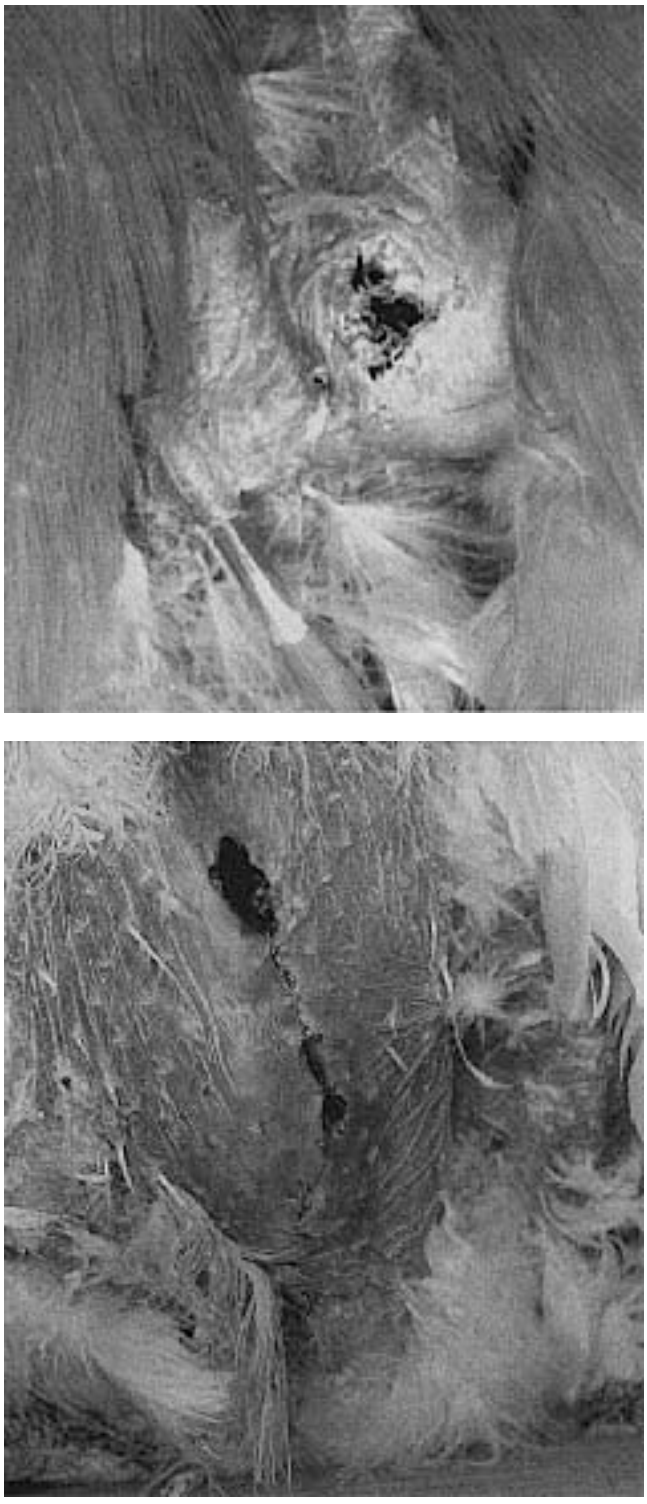

FIG 32.8 Some species of birds (particularly cockatoos) have been found to develop severe granulomas following vaccination with the killed oil-emulsion Pacheco's disease virus vaccine. Birds vaccinated subcutaneously with the oil-emulsion portion of this vaccine were found to develop granulomas suggesting that it is the vaccine adjuvant and not the viral protein that is inducing an unacceptable reaction. Occasionally, birds injected IM (bottom) with the Pacheco's disease virus vaccine can develop severe granulomas and muscle necrosis that require surgical debridement.

suppressed. Annual outbreaks have been described in some flocks. Transmission can occur through contact with contaminated feed or water, through direct contact between mates and through parenteral feeding of offspring.

Clinical Disease, Pathology and Diagnosis

In the flock, morbidity is typically 50%, with a 10 to 15% mortality rate. Serous rhinitis and conjunctivitis are usually the first clinical signs of disease. The nares become occluded, and a grayish-mucoid exudate causes dyspnea. Paresis of the third eyelid is possible. Small diphtheroid foci on the pharynx and larynx (which develop into so-called sialoliths) are indicative of an active infection.[450] Mild diarrhea, anorexia, vomiting and polydipsia may also occur. Affected squabs may die within one to two weeks or slowly recover. Tremors, ataxia and an inability to fly may occur in some birds.[418] Recurring trichomoniasis is common in flocks with endemic herpesvirus.

CLINICAL APPLICATION

Differential Diagnosis for Avian Herpesviruses

Infectious Laryngotracheitis
- Infectious coryza (Haemophilus paragallinarium)
- Mycoplasmosis
- Poxvirus (diphtheroid form)
- Syngamus spp.

Amazon Tracheitis
- Most respiratory diseases
- Avianpox (diphtheroid form)
- Newcastle disease
- Chlamydiosis
- Influenza A virus
- Candida
- Aspergillosis
- Trichomoniasis
- Syngamus spp.
- Hypovitaminosis A

Pacheco's Disease Virus
- Bacterial hepatitis
- Chlamydiosis
- Lead toxicosis
- Salmonellosis
- Paramyxovirus

Inclusion Body Hepatitis of Cranes
- Visceral coccidiosis

Duck Plague Virus
- Macroscopic lesions characteristic
- Influenza virus
- Duck hepatitis virus (ducklings)

Pigeon Herpesvirus
- Poxvirus (diphtheritic form)
- Trichomoniasis
- Chlamydiosis (respiratory form)
- Salmonellosis (liver form)

Pigeon Infectious Paralysis
- Paramyxovirus-1-pigeon
- CNS form of salmonellosis
- Listeriosis

Falcon Inclusion Body Hepatitis
- Many other infectious and non-infectious liver lesions

Hepatosplenitis Infectiosa Strigum
- Mycobacteriosis
- Trichomoniasis
- Candidiasis

Small, grayish-greenish diphtheroid foci on the mucosa of the upper airways, pharynx and occasionally the crop and intestine are characteristic necropsy findings. Air sacculitis, peritonitis, necrotic hepatitis and occasionally necrosis in the kidney, pancreas and spleen are observed. This virus may also induce only necrotic hepatitis.

Histopathology reveals necrosis (liver, kidney, pancreas, spleen) and desquamative lesions of epithelial cells (pharynx, larynx, esophagus). Cells around these lesions contain intranuclear eosinophilic and basophilic inclusion bodies.

The formation of sialoliths is suggestive of an infection, as are high morbidity rates in offspring. The virus may be identified by ID, but strain differentiation requires VN, ELISA or electrophoresis.

Contagious Paralysis of Pigeons (PHEV - Pigeon Herpes Encephalomyelitis Virus)

Pigeon herpes encephalomyelitis virus was first described in Iraq.[277] The distribution of the virus is undetermined. Paramyxovirus-1-pigeon was also present in the initial isolate, and it is uncertain which of the central nervous system signs described were caused by herpesvirus and which were caused by paramyxovirus. Some of the reported neurologic lesions were atypical for those described with paramyxovirus-1-pigeon.[196,333] In Germany, two strains of herpesvirus have been isolated from the brains of pigeons suffering from neurologic disease (Schnee-ganss D, unpublished).

Clinical Disease, Pathology and Diagnosis

Affected birds develop progressive, chronic central nervous signs that start with incoordination and end with an inability to fly and paralysis. Circling and torticollis, which were described in the initial report of the virus[217] have not been observed by other investigators (Schneeganss D, unpublished).

Gross necropsy findings are similar to those described with paramyxovirus-1-pigeon. The meningoencephalitis that is common with paramyxovirus has not been described with PHEV. The Purkinje cells of the cerebellum showed degeneration, lysis and eosinophilic intranuclear inclusion bodies. Paramyxovirus-1-pigeon, salmonellosis and listeriosis are the main rule-outs. A study to describe the pathohistology of PHEV is necessary.

Inclusion Body Hepatitis of the Falcon (FHV - Falcon Herpesvirus)

Falcon herpesvirus seems to be distributed in the northern hemisphere of the Old and New Worlds. The host spectrum is not fully known. There is a close antigenic relationship between FHV and the pigeon and owl herpesviruses. These three viral taxons show a certain independence, particularly with respect to host spectrum and clinical signs (see Table 32.5). Field cases of falcon herpesvirus have been described in the Peregrine Falcon, Common Kestrel, Merlin, Red-necked Falcon, Prairie Falcon and American Kestrel. Experimentally, the African Collared Dove, immature budgerigar, Striated Heron, Lone-eared Owl, Screech Owl, Great Horned Owl and Muscovy Duck have been shown to be susceptible.[254]

The falcon herpesvirus has an affinity for reticuloendothelial cells and hepatocytes. There is no confirmed information on the natural transmission of this virus. It has been suggested that the consumption of infected prey may be involved in transmission. There is no evidence that inhalation of the virus is involved in natural transmission.[131]

Clinical Disease, Pathology and Diagnosis

Generally, an acute disease develops with mild to severe depression, weakness and anorexia. Mortality may approach 100%.[131] At necropsy, light-to-tan colored necrotic foci are seen in the liver, spleen, bone marrow and lymph follicles of the intestine.

Histopathology shows focal or disseminated degeneration and necrosis in the liver, pancreas, lung, kidney and brain. The adrenal, thyroid and parathyroid glands, as well as the ovary, testes and thymus may also be affected. Necrotic foci may be surrounded by parenchymatous cells containing intranuclear (mainly eosinophilic) inclusion bodies. Inflammatory cellular reactions are rare due to the acute nature of the disease and the rapid death of the host.

The clinical signs and gross findings of falcon herpesvirus are nonspecific. Because of the close serologic relationship between pigeon herpesvirus and owl herpesvirus, serologic identification is not possible. Separation of specific proteins using SDS-gel-electrophoresis can be used to differentiate between strains.

Hepatosplenitis Infectiosa Strigum (OHV - Owl Herpesvirus)

Owl herpesvirus has a limited host spectrum and occurs in free-ranging and captive owls.[138] The virus is distributed across Europe, Asia and the United States. Natural infections are mainly seen in owls with yellow- or orange-colored irises including: Eagle Owl, Great Horned Owl, Striped Owl, Long-eared Owl, Snowy Owl, Little Owl, Tengmalm's Owl and Forest Eagle Owl.

Antibodies against OHV have been demonstrated in 24 species of Strigiformes.[205] The American Kestrel, Common Kestrel, Turtle Dove and African Collared Dove can be infected experimentally. Because OHV is serologically related to the pigeon herpesvirus and the falcon herpesvirus, the currently recognized host spectrum may be incomplete.

In contrast to other avian Herpesviridae, OHV affects both epithelial and mesenchymal cells. Virus is excreted from the oral cavity and in urine.[371] Consumption of infected prey should be considered a potential method of transmission. Infection does not take place via the tracheal mucosa. Owl herpesvirus antigen has been demonstrated within the epithelium of feather follicles. Compared with other avian Herpesviridae, the incubation period for OHV is prolonged (seven to ten days) rather than the more typical three to five days.

Clinical Disease and Pathology

Clinical signs including depression, anorexia and weakness may last for two to five days. Infrequently, yellowish nodules the size of millet seeds may develop on the pharyngeal mucosa.[49] These lesions may be secondarily infected with *Trichomonas* spp. In captivity, mortality rates may approach 100%. The demonstration of antibodies in free-ranging owls indicates that birds can survive infections. Leukopenia has been described during active infections.

The necropsy reveals numerous necrotic foci in the liver, spleen and bone marrow.[49] Other suggestive lesions include diphtheroid (frequent) and hemorrhagic (rare) enteritis, diphtheroid stomatitis, esophagitis, proventriculitis and laryngitis (less frequent) as well as single necrotic foci in the lungs and kidneys. Moniliform necrotic nodules may be found along the jugular vein, probably emanating from the remains of thymic tissue.

Necrotic foci in various organs are characterized by a basophilic center with a zone of nuclear debris surrounded by eosinophilic necrotic material. Intranuclear eosinophilic inclusion bodies can be found adjacent to these necrotic areas. Inclusion bodies are rare in natural infections. Amyloidosis has been described in chronic cases.

Diagnosis

The necrotic foci in the liver, spleen, intestine and along the jugular vein should be differentiated from those caused by mycobacteriosis. Although the morphology is strikingly similar, the foci caused by herpesvirus are soft and are not demarcated from the surrounding tissue. In comparison, mycobacteria-induced tubercles are caseous, crumbly and normally well demarcated. Trichomoniasis-induced diphtheroid pharyngitis appears similar to that caused by herpesvirus. Additionally, *Trichomonas* spp. and fungi can be secondary invaders of pharyngeal lesions induced by herpesvirus.

Apparently, owl herpesvirus cannot be transmitted free of cells.[361] This finding would suggest that OHV is a separate taxon from PHV and FHV. It also implies that tissues submitted for virus isolation must contain intact cells (shipped at 4°C as quickly as possible). The bone marrow of the femur is the best tissue to submit for virus isolation.[371] Differentiation of OHV, FHV and PHV requires electrophoresis to delineate strain-specific proteins.

Eagle Herpesvirus

A herpesvirus was isolated from a clinically healthy, free-ranging Bald Eagle nestling.[76] The strain is not related to DPV, herpes simplex, FHV or crane herpesvirus. Eagle herpesvirus was also recovered from a South American eagle (probably a Grey Eagle-Buzzard) that developed lesions similar to those described in owls and falcons.[206]

Lake Victoria Cormorant Herpesvirus

A herpesvirus has been isolated from the blood of a clinically healthy Little Pied Cormorant nestling. This virus was not serologically related to other avian Herpesviridae.[102] Attempts to recover this virus from other Australian birds in the same area were unsuccessful, and it has been suggested that this herpesvirus has a very narrow host range. Chickens, pigeons and budgerigars experimentally infected with the virus did not develop pathologic lesions.

Inclusion Body Disease of Cranes (Crane Herpesvirus)

Crane herpesvirus is probably distributed worldwide (except Australia). There is evidence that infections can be latent and persist for years. To date, disease has been described only in captive birds. Birds maintained by the International Crane Foundation were found to have antibodies to the virus three years before a disease outbreak occurred.[77] Morbidity and mortality were described only in some parts of the premises, and serologic data indicated that susceptibility varied among crane species. The natural host spectrum includes Sandhill, Manchurian, Blue, Hooded, Demoiselle and Crowned Cranes. The Sandhill and Blue Cranes seem to be most susceptible, followed by the Manchurian and Hooded Cranes. The Sarus and Common Cranes seroconverted following infection without developing signs of disease. White-naped Cranes, Demoiselle Cranes and Brolga survived exposure but generally did not seroconvert.[76]

The crane herpesvirus is considered to be a β-herpesvirus with a relatively narrow host spectrum and cytopathology characterized by slowly progressive, lytic lesions within enlarged infected cells and Cowdry type A intranuclear inclusion bodies.[347] Serologically, the crane herpesvirus is closely related to or identical to the Bobwhite Quail herpesvirus.[97]

Clinical Disease amd Pathology

Clinical disease is usually acute, with birds seeking solitude and developing depression, anorexia and diarrhea. At necropsy, the liver, spleen and kidneys are swollen with miliary necrotic foci. Diphtheroid layers develop on the mucosa of the oral cavity, choanal slit and esophagus. Striated hemorrhages can be observed in the upper part of the esophagus. The mucosa of the duodenum, jejunum and colon may be covered with a layer of diphtheroid material. Histopathology reveals necrotic foci, which react basophilic or eosinophilic with hematoxylin and eosin (H & E) stain. Intranuclear eosinophilic inclusion bodies are rare.

Visceral coccidiosis may also cause swelling of various parenchymatous organs in cranes. Giemsa staining can be used to delineate merozoites in infected hosts.

Inclusion Body Hepatitis of Bobwhite Quail (Colinus Herpesvirus)

A herpesvirus was initially isolated from Bobwhite Quail.[200] Nothing is known about the distribution of the virus, but because the Bobwhite Quail is a New World species, the virus would be expected to occur in the United States and Canada. The virus is serologically related to the crane herpesvirus.

Clinical Disease and Pathology

Clinical signs are nonspecific and include ruffled plumage, diarrhea and anorexia. The disease takes an acute course, and death occurs within two to three days of developing clinical signs. None of the birds affected by this virus have been over four weeks old. Gross lesions include hepatomegaly and splenomegaly, both of which contain numerous small yellowish foci. Catarrhal enteritis and ulcers were evident in the jejunum, and a *Clostridium* sp. was isolated from birds with intestinal lesions. Histopathology revealed multiple necrotic hepatic foci with rod-like bacteria at the center, as well as perivascular lymphocytic infiltrates. Lesions described in quail vary from those caused by other members of the avian Herpesviridae. It is thus questionable whether or not infection with a *Clostridium* sp. has caused most of the tissue changes and activation of a latent herpesvirus infection. Conversely, the herpesvirus infection could have triggered the *Clostridium* sp. infection.

Inclusion Body Hepatitis of Storks (Stork Herpesvirus)

A pathogenic herpesvirus that affects White and Black Storks has been described.[198,201] Infections have been described only in Germany, but the virus should be expected to occur in Europe, populated regions of Asia and the African winter quarters. The host spectrum is thought to be restricted, but investigations are incomplete.

The virus is serologically unrelated to other avian Herpesviridae, is cell-associated and can be demonstrated in leukocytes in the presence of humoral antibodies. Cell-free virus can be demonstrated as well. All attempts to recover virus from the feather follicles of White and Black Storks have failed. In addition, attempts to isolate virus from the pharyngeal and cloacal mucosa of viremic storks were not successful (Kaleta EF, unpublished). Studies involving humoral antibodies have indicated that titers vary from negative to positive, year to year and among individuals.

Clinical signs are limited to sudden death. Pathologic lesions consist of small yellowish-white foci in the liver, spleen and bone marrow. There may also be diphtheroid changes in the mucosa of the esophagus, choana and larynx.

Marek's Disease Virus (MDV)

This agent, officially named thetalymphokryptovirus, is distributed worldwide and is the best know avian herpesvirus because of its importance to the poultry industry and its use in comparative oncology research. Marek's disease virus has been shown to have direct and indirect routes of transmission.[53,176,312] Marek's disease is characterized by lymphocytic proliferation in the peripheral nerves that results in varying degrees of paresis and paralysis. The disease is common in gallinaceous species, and suggestive lesions have been reported in Great Horned Owls, ducks, a kestrel and swans. Tumors associated with MDV may occur in any organ but are commonly found in the viscera, skin, eyes, muscle and bones. Enlarged peripheral nerves are a common postmortem finding.

In a Great Horned Owl, lesions suggestive of MDV were associated with paralysis, ataxia, emaciation and formation of enlarged gray-white masses in the splenic, renal, pancreatic and mesenteric tissues. The ischiatic nerves were two to three times normal size. Lymphoblastic cells could be identified in the liver, kidney, pancreas, mesentery, spleen and sciatic nerves.[154a]

Marek's disease virus antigen was demonstrated by an agarose gel diffusion test in the spinal cord and pudendal nerves in a toucan that exhibited a chronic slowly progressive peripheral ataxia with kidney enlargement. The histologic lesions that occurred in this bird were consistent with Marek's disease virus, but a virus could not be isolated (Latimer KS, unpublished).

Gouldian Finch Herpesvirus

An uncharacterized virus suggestive of herpesvirus has been identifed by electron microscopy in clinically affected Crimson Finches, Red-faced Waxbills and Zebra Finches.[74] In a mixed species aviary, Gouldian Finches died from lesions caused by a herpesvirus, while other Passeriformes in the collection remained unaffected. Mortality in Gouldian Finch flocks may reach 70% of the birds at risk.[353,369]

Clinical Disease and Pathology

Listless birds with ruffled plumage develop increasingly severe dyspnea with minimal discharge from the nostrils. Swollen and edematous eyelids and conjunctivae may be sealed with crusts in the lid cleft. Despite severe dyspnea, affected birds may continue

to try to eat, although sometimes unsuccessfully. Death is common five to ten days following the first clinical signs and all Gouldian Finches from one aviary died over a period of two weeks.[74]

Necropsy findings included severe emaciation even though some affected birds continued to eat. Swollen eyelids and conjunctivae, serous discharge in the conjunctival sacs and fibrinoid thickening of the air sacs were the only characteristic findings. Apart from congestion, parenchymal organs appeared normal.

In one outbreak, hyperemic foci and fibrinous deposits were visible on the serosa of the jejunum, the lumen of which was filled with melena-like contents in one bird. The oviduct contained a yellowish fluid with desquamated epithelial cells.[74]

Histopathology is characterized by ballooning degeneration and detachment from the basal membrane of conjunctival and respiratory epithelial cells. The epithelium may be thickened by increased numbers of the ballooning cells. Large, homogeneous, either basophilic or eosinophilic intranuclear inclusion bodies are characteristic. The submucosa may be congested and contain massive diffuse perivascular infiltration with mononuclear cells and few heterophils. The lower respiratory tract and the trachea may have similar but less severe lesions. Cilia may be damaged in affected tracheal mucosa. Hepatocytes are rarely affected.[74]

Other Herpesviruses

A herpesvirus has been described in lovebirds with malformed feathers, but the involvement of this virus in causing the lesions has not been determined.[137]

Papilloma-like lesions thought to be caused by a herpesvirus have been described on the feet of cockatoos (Figure 32.9). Affected birds are usually clinically normal except for the wart-like growths on their feet. Histopathology is consistent with squamous papillomas. The nuclei of affected epithelial cells are homogeneously basophilic with a smudged appearance, and the superficial cells are vacuolated. Electron microscopy has been used to demonstrate virus particles suggestive of herpesvirus. A herpes-like virus was observed by electron microscopy in association with a cloacal papilloma in an Orange-fronted Conure.[118] Squamous papillomas are common with poxvirus and papillomavirus but rather unusual for herpesvirus infections.

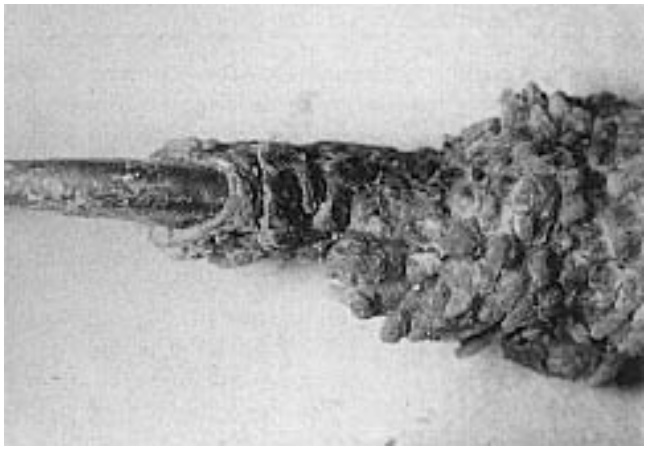

FIG 32.9 An adult Moluccan Cockatoo was presented for evaluation of progressive feather dysplasia. The bird was positive for PBFD virus by feather biopsy (intranuclear and intracytoplasmic inclusion bodies) and by DNA probe (whole blood). The bird also had proliferative (wart-like) growths on several digits. Electron microscopy revealed virus particles suggestive of herpesvirus.

Papovaviridae

The Papovaviridae family of viruses consists of two genera, which vary in virion size, genome size and organization. These two genera are *Papillomavirus*, which is characterized by a 55 nm diameter nonenveloped icosahedral virion with a 7.5-8 kbp circular double strand DNA genome, and *Polyomavirus,* characterized by a 40-50 nm icosahedral nonenveloped virion with a 4.8-5.5 kbp circular double strand DNA genome.[93]

As a group, the papovaviruses tend to cause persistent infections that become active following stressful events.[428] Papillomaviruses are generally associated with the formation of benign skin tumors (warts).[190,298] The first acute, generalized infection associated with a polyomavirus was described in young psittacine birds and was called budgerigar fledgling disease (BFD).[38,39,44] A similar virus has been shown to be associated with high levels of morbidity and mortality in finches (Estrildidae) and in a number of different genera of Psittaciformes. The acute nature of avian polyomavirus infections is most unusual for Papovaviridae, the members of which are classically associated with nonpathogenic subclinical infections and chronic diseases characterized by tumor formation.[428]

Papillomavirus

Papillomavirus has been associated with the formation of benign epithelial tumors (papillomata) on the skin and epithelial mucosa of many mammalian species. The papillomaviruses that infect mammals appear to be species-specific.

Papillomavirus has been associated with proliferative growths on the unfeathered skin of some birds. In addition, clinical and pathologic lesions suggestive of those caused by papillomavirus have been described at various locations along the gastrointestinal tract, particularly in the cloaca (see Color 19). To date, no virus has been associated with these papilloma-like growths in the gastrointestinal tract of Psittaciformes.

Clinical Features

The first demonstration of a papovavirus in a nonmammalian species involved the recovery and characterization of a papillomavirus from proliferative skin masses found on the legs of finches in the family Fringillidae. Virus recovered from these birds was found to be antigenically similar to some types of papillomaviruses documented in humans. Papillomavirus was found to be common in finches, causing proliferative lesions on 330 of 25,000 Chaffinches examined. In contrast, the virus appears to be rare in other avian species.[240,298] Lesions clinically appear as slow-growing, dry, sappy, wart-like epithelial proliferations on the skin of the feet and legs. Severe proliferations can result in the loss of digits or the foot. Histologic changes are typical for papillomas.

A papillomavirus was demonstrated in a Timneh African Grey Parrot with proliferative skin lesions on the head and palpebrae. Histologic evaluation of biopsies from this bird indicated long, thin folds of hyperplastic epidermis, which were moderately acanthotic and parakeratotic. Papillomavirus particles were demonstrated by electron microscopy and by staining with viral-specific antibodies within retained nuclei in the stratum corneum.[190]

Papillomatous lesions have been diagnosed histologically from proliferative growths originating from skin overlying the phalanges, uropygial gland, mandible, neck, wing, eyelids and beak commissure from various Psittaciformes including Amazon parrots, African Grey Parrots, Quaker Parakeets, cockatiels and budgerigars (Figure 32.10). While a viral etiology has been assumed for these epidermal proliferations, virus has not been demonstrated in association with any of these lesions.[318,412]

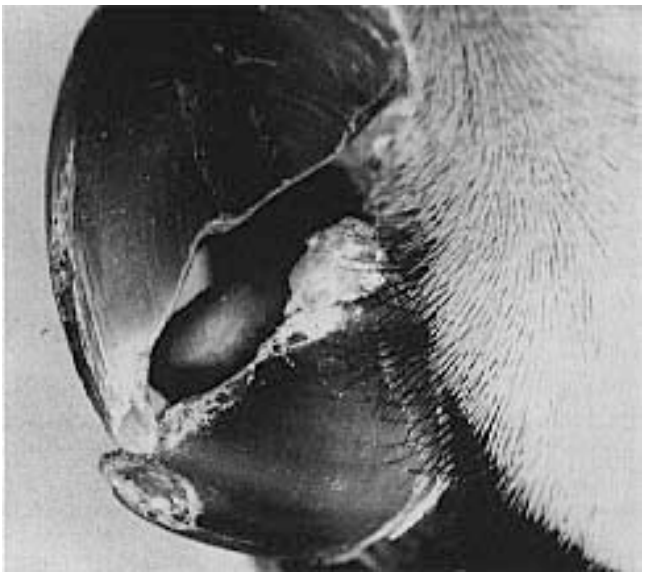

FIG 32.10 A papilloma-like growth at the commissure of the beak in an Alexandrian Parakeet hen. The bird was on a marginal diet and had numerous rhamphothecal and gnathecal defects. The growth was surgically removed. Histopathology indicated long, thin folds of hyperplastic epidermis with acanthosis. This lesion was considered suggestive of a papilloma; however, virus could not be identified histologically.

Histologic lesions suggestive of papillomas have been described at numerous locations along the avian gastrointestinal tract. These papillomatous lesions most frequently occur at the transition between mucosa and cutaneous epithelium in the cloaca. In one study involving 19 species of New World parrots, papillomatous lesions were documented in decreasing frequency in the cloaca, glottis, choanal slit, oropharynx, esophagus, proventriculus and ventriculus. Lesions are commonly reported in Hawk-headed Parrots and Green-winged Macaws, but have also been described in other macaws, African Grey Parrots, *Amazona* spp., caiques, conures, budgerigars, Barraband's Parrot, cockatiels and *Pionus* spp.[65,135,318,399,412]

Clinically, many affected birds may appear normal with no changes in CBC or clinical chemistries. In other birds, intestinal papillomas mechanically interfere with normal physiologic activities (Table 32.7). Cloacal papillomas may cause or mimic recurrent prolapses. Droppings may be loose, causing feathers around the vent to be stained or covered with fecal material. In chronic cases, melena may be noted. Depending on the location and severity of the lesions, some birds with cloacal papillomas are able to breed normally while others may not be able to copulate.

FIG 32.11 A six-year-old Blue-fronted Amazon hen was presented for tenesmus and diarrhea. The bird weighed 425 g and was in overall good condition. Excrement was accumulated on the pericloacal feathers. An irregular pink mass was present on the dorsal mucosa of the cloaca. The area was coated with five percent acetic acid, and the large mass along with several smaller raised lesions on the mucosa turned white. CBC and clinical chemistries were normal. The bird was not found to be shedding polyomavirus using a DNA probe test. These findings were suggestive of cloacal papillomatosis. The mass was removed with staged cauterization using silver nitrate.

Grossly, papillomatous lesions may appear as large, distinct masses or may occur as numerous small, raised lesions covering the mucosa (Figure 32.11). These friable growths may be pink or white and have a tendency to bleed easily when bruised (see Color 19). Acetic acid (5%) will turn papillomatous tissue white, helping to identify suspect lesions.[260,412] Many internal papillomatous lesions are not recognized until necropsy. Suspicious lesions in the oral or cloacal cavity can be viewed directly. Endoscopy is necessary to identify and obtain diagnostic biopsies of suspect papillomatous lesions in the esophagus or proventriculus or high in the cloaca or proctodeum.

Attempts to demonstrate papillomavirus in suspect lesions by electron microscopy, low stringency southern blotting techniques or immunocytochemical procedures have all failed. Attempts to induce lesions in Amazon parrots, macaws and cockatoos using homogenized lesions have also been unsuccessful;[399] however, the disease has features that suggest an infectious agent.[260,412] Chronic irritation of the cloacal mucosa with epithelial cell hypertrophy or hyperplasia could result in a histologic lesion that morphologically resembles those induced by papillomavirus and has been suggested as an alternate cause of these lesions.[135,399] Herpes-like virus particles were described in a cloacal papilloma in a conure.[118] Malnutrition, particularly with respect to vitamin A, has been suggested to potentiate lesions.

TABLE 32.7 Clinical Signs Associated with Internal Papillomatosis

Cloaca	Tenesmus, infertility, recurrent enteritis, hematochezia, flatulence, odoriferous stool, cloacoliths, acid pH
Oral Cavity	Dysphagia, dyspnea, wheezing
Upper GI	GI blockage, anorexia, chronic weight loss, vomiting, dilatation of the proventriculus or ventriculus, passing whole seeds

Histologic examination is necessary to confirm a diagnosis in any suspect lesions. Proliferations of epithelial cells on a fibrovascular stalk are suggestive. The neoplasms may show numerous projections covered by a hyperplastic tessellated epithelium or a non-keratinized columnar epithelium containing some mucous glands. The stroma may show some inflammatory cells. Mitotic figures may be present in the basal cells or upper layers of hyperplastic epithelium.[399] Amazon parrots with papillomatous lesions have been described as having a high incidence of malignant pancreatic or bile duct carcinomas.[135,171] The differential diagnoses for papillomatosis should include the wart-like growths in cockatoos, in which herpesvirus-like particles have been identified, and the tumorous forms of avian pox (skin or oral mucosa).[245]

Therapy

Suggested therapeutic measures for cloacal papillomas have been based on the physical removal of the masses through cryotherapy, radiocautery or surgical excision. These procedures have been performed alone or in combination with the use of autogenous vaccines. None of the proposed therapies is consistently effective, and papillomatous tissue often recurs. The use of autogenous vaccines has been described but is generally not effective.[78,260,352,412] Spontaneous regression of papillomatous tissue has been described.[139,260,412]

With any removal technique, care should be exercised to prevent excessive tissue damage that may result in severe scarring and reduction in the size of

the cloacal lumen. Scarring can result in incontinence, reproductive failure or blockage of the urodeum or proctodeum.

Staged cauterization with silver nitrate sticks may prove to be the easiest, safest and best way to remove papillomatous lesions from the cloaca (see Color 19).[194] Lesions should be exteriorized by inserting a moistened cotton swab followed by carefully rubbing a small area of the lesion with a silver nitrate stick. The silver nitrate should be immediately inactivated with copious fluids to prevent the liquified material from burning unaffected mucosal tissues. The procedure is repeated at two-week intervals until the lesions have been removed.

Epizootiologic evidence has been used to suggest that intestinal papillomas are caused by an infectious agent even though no etiology has been confirmed. Mutual preening and sexual contact have been suggested as methods of transmission. However, other investigations suggest that the disease is not infectious (Clubb, S unpublished). Several large parrot aviaries have had epizootic outbreaks of the disease following the introduction of a clinically positive bird.[260,412] Until further information on the etiology of this disease is available, it is prudent to isolate birds with lesions from the remainder of a collection.

Polyomavirus

Budgerigar fledgling disease (BFD) is caused by the first avian polyomavirus to be characterized (Color 32.15).[85,376] Polyomaviruses that infect various avian hosts appear to be morphologically and antigenically similar; however, the clinical presentation, distribution of lesions and epidemiologic effects of the virus are dramatically different among susceptible species.[38,39,130,175,188]

The capsid antigens from the BFD virus and other polyomaviruses have been shown to be antigenically related. Comparison of nucleic acid from avian and mammalian polyomaviruses indicates that there are similarities; however, the genomes are not identical. Polyomaviruses recovered from several species of Psittaciformes have been shown to be similar by comparing restriction maps of viral DNA and by using viral-specific DNA probes (Color 32.8).[233,281,292,321]

It has been suggested that the avian strains of polyomavirus be placed into the subgenus avipolyomavirus. This is based on the finding that strains of polyomavirus recovered from budgerigars (BFDV-1), chickens (BFDV-2) and Blue and Gold Macaws (BFDV-3) had distinct degrees of tropism.[397] This supports the findings that polyomavirus recovered from budgerigars did not cause disease in experimentally infected Blue and Gold Macaws (Ritchie, BW unpublished). It is suspected that strains from Passeriformes are also different. DNA probes designed to detect polyomavirus from Psittaciformes do not detect some strains of polyomavirus found in passerine birds.

BFDV-2 antibodies could be detected in a flock of clinically healthy broiler chickens in Central Europe that were also infected with infectious bursal disease virus. The role that this immunosuppressive virus played in the pathogenesis of the polyomavirus infection was undetermined.[397]

Transmission

The epizootiology of polyomavirus infections is not fully understood. The factors involved in the duration and induction of viral shedding remain unresolved. Some asymptomatic adults produce persistently infected young, while others have neonates that intermittently may develop clinical signs and die. It has been suggested that persistently infected birds may be immunotolerant as a result of being infected before they are immunocompetent. Some birds are known to shed virus in the presence of high antibody titers. Asymptomatic adults that intermittently shed the virus are thought to be responsible for the persistence, transmission and spread of the virus through various avian populations.[38,39,44,85,105,106] In polyomavirus outbreaks involving 23 different budgerigar aviaries, the onset of disease could be traced to the addition of new, clinically normal breeders.[38,39]

Experimental data and observations with the natural disease suggest that polyomavirus transmission may occur by both horizontal and vertical routes.[38,44,63,188,233] Parents may transmit virus to offspring through the regurgitation of exfoliated crop epithelial cells. Virus can replicate in the epidermal cells of the feather follicles resulting in the presence of virus in "feather dust," which may enter a susceptible host through the respiratory or gastrointestinal tract. Virus has been isolated from lung tissue supporting the possibility of an aerogenous transmission. The presence of virus in the renal tubular epithelial cells suggests passage of virus in the urine. Polyomavirus nucleic acid can be detected in cloacal swabs taken from birds during polyomavirus outbreaks. The recovery of viral DNA from the cloaca

suggests that the virus could be shed from gastrointestinal, renal or reproductive tissues.[292,293]

Seronegative young adult birds will seroconvert when housed adjacent to seropositive breeding birds, implicating indirect transmission of the virus.[63,72,188] Aviary personnel, technicians, veterinarians, pet owners and any aviary equipment should be considered important vectors for this environmentally stable virus.

Findings in support of vertical transmission include the identification of intranuclear inclusion bodies in one-day-old budgerigars and the occurrence of infections when eggs from parents that consistently produce diseased neonates are cross-fostered to parents producing normal young.[38,39,125]

Theoretically, a persistently infected hen could pass maternally derived antibodies, virus or both to its young. The clinical status of the chick could then depend on the level of maternally derived antibodies and the stage of immunocompetency when viral exposure occurs. Chicks that have protective levels of maternal antibodies as well as infections derived from the parents may serve to infect susceptible neonates in the nursery.[105,106] Persistent infections with intermittent shedding and vertical transmission are also suspected to occur in finches and result in early embryonic death.[192,256]

The incubation period is not known. Affected budgerigar fledglings show peak mortality rates between the 15th and 19th day of life. In larger parrots, death may occur from 20 to 140 days of age, with most deaths occurring between 20 to 56 days of age.

Pathogenesis

As a group, polyomaviruses typically reside in a latent state, and infections become patent following periods of suffering from stressors.[428] The age of a bird at the time of viral exposure may be a major factor in the pathogenesis of polyomavirus infections. Budgerigars that die shortly after hatch have more severe and widespread lesions than do birds in which the morbid state is more prolonged.[38] When 11- to 12-day-old chicken embryos are experimentally infected with polyomavirus, the hatched chicks remain normal and produce detectable antibodies by two weeks of age; in contrast, embryos infected at ten days of age are susceptible to the virus and develop pansystemic lesions.[63] It is theorized that persistently infected birds may be those that are infected before they are immunocompetent.[105,106,424]

Field studies have shown that birds that die from avian polyomavirus frequently have antibodies to the virus. These findings, along with the frequent occurrence of glomerulopathy (immune complex induced) have led to the theory that death from avian polyomavirus in large psittacine birds is caused by an immune complex disease;[321] however, Blue and Gold Macaws that were seronegative for avian polyomavirus remained subclinical after being infected with BFD virus. These birds did seroconvert and developed high neutralizing antibody titers (>1:640) indicating that they were susceptible. DNA probe-testing of whole blood indicated intermittent viremia. The experimentally infected birds remained asymptomatic a year after infection, suggesting that other factors may precipitate the formation of immune complexes in field cases (Ritchie BW, unpublished). Further, massive hepatocellular necrosis (with intranuclear inclusion in hepatocytes) is the most frequent histologic lesion in larger psittacine birds that die from avian polyomavirus, and an immune complex theory of avian polyomavirus-induced death does not explain the principal histologic lesion.

The BFD virus can replicate in a variety of target cells of many avian species including chicken embryo cells.[281] The virus appears to require host cells that are dividing and temperatures of at least 39°C. Following the primary viremia, inclusion bodies can develop in most internal organs as well as the skin and developing feathers (Figure 32.13). The highest virus concentration is usually found in the brain. Tissue lesions can be severe and are directly related to the level of morbidity and mortality. The virus has been associated with immunosuppression through its ability to destroy or inhibit the normal development of lymphoid tissue. Infections in adult Estrildidae or Ploceidae have been suggested to be dependent on immunosuppression.[440]

Polyomaviruses in mammals are natural tumor inducers. There has thus far been no association between polyomavirus infections in birds and an increased incidence of tumors, although more in-depth studies are necessary.[38,39,44,63,130,190,281] Some mammalian polyomavirus infections are known to persist by incorporating viral genome into host cell DNA.

Clinical Features

An avian polyomavirus appears to be distributed worldwide, but there are some apparent strain differences. For example in Europe, a more chronic form of the disease is common in budgerigars, while in the United States and Canada an acute form of disease

with high mortality prevails. Most members of the Papovaviridae family have a restricted host range.[281] In contrast, the avian polyomavirus appears to infect a wide variety of Psittaciformes, Estrilidae and Ploceidae including macaws, Amazon parrots, conures, White-bellied Caiques, parrotlets, African Grey Parrots, lovebirds, Ring-necked Parakeets, Eclectus Parrots,[392] Scarlet-chested Parrots, Bourke's Parrots,[311] cockatoos[311,363] and finches.[381,382,440]

- ***Budgerigars:*** The type of clinical disease induced by polyomavirus in budgerigars appears to depend on the age and condition of the bird when exposure to the virus occurs. Neonates from infected flocks may develop normally for 10-15 days and then suddenly die with no premonitory signs. Other infected hatchlings may develop clinical signs, which include abdominal distension, subcutaneous hemorrhage, tremors of the head and neck, ataxia and reduced formation of down and contour feathers.[38,39,72,175,257] Infections have also been associated with decreased hatchability and embryonic death.[125]

  Infected budgerigars may die rapidly once clinical signs develop, and reports on mortality rates vary from 30 to 100% of affected hatchlings. Mortality rates are highest in budgerigars less than 15 days of age. Survivors may exhibit symmetrical feather abnormalities characterized by dystrophic primary and tail feathers, lack of down feathers on the back and abdomen and lack of filoplumes on the head and neck (Color 32.15).[39,44,72,175,281] Birds often die acutely with the crop and gastrointestinal tract full of food. Surviving fledglings frequently have dystrophic feathers (French moult). Developing primary and secondary feathers may break or fall out, resulting in substantial blood loss. Affected birds are unable to fly and are often called runners or hoppers. Similar feather lesions can be caused by the psittacine beak and feather disease (PBFD) virus. In general, feather lesions in budgerigars caused by polyomavirus resolve after several months, while those induced by PBFD virus will continue to progress.

  It has been previously speculated that French moult represents a nonfatal form of BFD;[38,39,175] however, budgerigars with classic French moult lesions are often seronegative for polyomavirus antibodies.[226] In North America and Europe, lesions attributable to French moult are thought to be caused either by the polyomavirus or by the PBFD virus. Investigations in Australian budgerigars have demonstrated that clinical signs associated with French moult are associated with the PBFD virus and not with avian polyomavirus.[38,39,175] Immunohistochemical staining of infected tissues with viral-specific antibodies or DNA probes is required to differentiate between intranuclear inclusion bodies induced by polyomavirus and those caused by PBFD virus.

- ***Other Psittaciformes:*** In larger psittacine birds, polyomavirus infections may cause peracute death with no premonitory signs or acute death after development of clinical changes including depression, anorexia, weight loss, delayed crop emptying, regurgitation, diarrhea, dehydration, subcutaneous hemorrhages, dyspnea and polyuria (Color 32.12).[63,130,190,363] Intramuscular injection sites or damaged feathers may bleed profusely. Neurologic signs characterized by ataxia, tremors and paralysis have been described in some Psittaciformes.[63] Clinical signs are common at the time of weaning, and infected fledglings typically die 12 to 48 hours after developing clinical signs. Infections may occur in both parent-raised and hand-raised neonates.[63,130,190] In one outbreak, mortality rates in exposed neonates ranged from 31 to 41% of the at-risk population.[63] Infected birds that recover are thought to become asymptomatic virus carriers. Infections in adult birds are thought to result in the formation of subclinical carriers with only occasional development of clinical signs. Blue and Gold Macaw neonates experimentally infected with budgerigar fledgling disease virus (derived from cell culture) did not develop clinical signs of infection but did seroconvert, indicating that they were subclinically infected (Figure 32.12) (Ritchie BW, unpublished).

  A chronic form of polyomavirus has also been described and is typified by weight loss, intermittent anorexia, polyuria, recurrent bacterial or fungal infections and poor feather formation.[63,190] Birds that recover appear normal, although some birds have been found to die months later from renal failure.[63] The feather abnormalities that are relatively common with polyomavirus infections in budgerigars have been less frequently described in other psittacine birds.[63,130,190,307]

  In the Eclectus Parrot, transient gastrointestinal stasis, melena and abdominal pain have been described in older chicks. Occult hematuria has been suggested as an indication of a polyomavirus infection in this species.[392] Cloacal swabs from suspect patients can be screened for the presence of polyomavirus nucleic acid using viral-specific DNA probes. Affected birds may have increased activities of LDH, AST and alkaline phosphatase.[63]

FIG 32.12 Blue and Gold Macaw chicks that did not have avian polyomavirus VN antibodies were experimentally vaccinated with a killed vaccine. The vaccinated birds seroconverted and were protected from subsequent infection. Non-vaccinated birds remained asymptomatic following experimental inoculation even though they developed high VN antibody titers, indicating that they had been infected.

In addition to clinical changes in neonates, polyomavirus infections have also been documented in an eight-month-old Splendid Parakeet and in sporadic, acute deaths in fully fledged lovebirds less than one year old.[307,310] An adult Moluccan Cockatoo with neurologic signs was diagnosed as having polyomavirus based on the ultrastructural morphology of inclusion bodies in the brain.[363] An outbreak of polyomaviral disease in an aviary with numerous Psittaciformes resulted in the deaths of an adult Eclectus Parrot, a Painted Conure and 3 of 11 adult White-bellied Caiques. The affected birds were 2 to 2.5 years old and had lesions similar to those seen with polyomavirus infections in psittacine fledglings.[344] These cases suggest that some older Psittaciformes may be susceptible to polyomavirus infections during epornitics.

- ***Finches:*** Lesions suggestive of a polyomavirus infection have been described as a cause of acute mortality in two- to three-day-old fledgling, young adult and mature finches.[98,192,256,440] Affected birds had nonspecific signs of illness 24 to 48 hrs before death.[98,256] In one outbreak, 36 of 70 two- to three-day-old birds died. Many of the fledglings that survived had poor feather development, long tubular misshapen lower mandibles, and fledged several days later than normal young (see Figure 43.13).[256]

Pathology

The gross lesions associated with polyomavirus infections are summarized in Table 32.8 (Colors 32.17, 32.20). Neonates presented for necropsy are usually in excellent overall condition and may have full crops and gastrointestinal tracts, indicating the speed of disease progression. Karyomegaly in various tissues and hepatic necrosis are the most consistent histologic lesions in larger psittacine birds.[38,44,63,130,132,188,190] Other suggestive histologic lesions are listed in Table 32.9. Viral antigen present within inclusion bodies from infected Psittaciformes has been confirmed to be antigenically related to the polyomavirus isolated from budgerigars through the use of fluorescent antibody staining techniques.[130,132,175,440]

Polyomavirus-infected finches may die acutely with no detectable pathology or can have gross and histologic lesions similar to those described for other birds (Tables 32.8, 32.9).[98,188,256,440] Inclusion bodies from some finches have been confirmed to contain polyomavirus antigen by fluorescent-antibody staining techniques.[440]

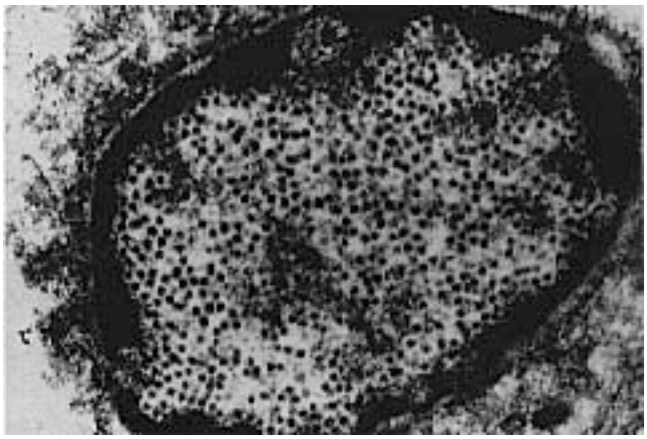

FIG 32.13 Intranuclear inclusion body in the brain of a Ducorps' Cockatoo that died after several days of depression and progressive neurologic signs (ataxia, paresis, paralysis, coma). The inclusion bodies in the brain were confirmed to contain polyomavirus antigen using viral-specific antibodies (immunoperoxidase technique) and polyomavirus nucleic acid using viral-specific DNA probes (*in situ* hybridization). This electron micrograph shows characteristic 50 nm icosahedral viral particles.

TABLE 32.8 Gross Lesions Associated with Polyomavirus Infections

	Budgerigars	Lovebirds	Other Psittaciformes	Finches
Heart	Hydropericardium, cardiomegaly, myocardial hemorrhage		Myocardial hemorrhage, epicardial hemorrhage, pale myocardium	
Liver	Hepatomegaly, yellow-white foci	Pallor, congestion, mottled hemorrhage	Hepatomegaly, red and yellow mottling, friable	Swollen, pallor, mottled hemorrhage
Spleen		Small, pallor	Splenomegaly, friable	Splenomegaly, congestion
GI tract	Intestinal hemorrhage		Intestinal hemorrhage	Serosal or subserosal intestinal hemorrhage
Kidney	Swelling, pallor or congestion, white foci, petechiation		Pallor, swollen	Perirenal hemorrhage
Skin	Subcutaneous hemorrhage, feather dystrophy		Feather dystrophy, petechial hemorrhage, ecchymotic hemorrhage	
Other	Ascites, lung congestion	Increased serosal fluids	Pale skeletal muscle, ascites, serosal and subcutaneous hemorrhage, pallor	

TABLE 32.9 Histologic Lesions Associated with Polyomavirus Infections

	Budgerigars	Lovebirds	Other Psittaciformes	Finches
Heart	Coagulative necrosis, myocardial degeneration, inclusion bodies	Enlarged endothelial cells	Myocarditis, epicardial hemorrhage, inclusion bodies (myocardium)	Myocarditis, inclusion bodies
Liver	Coagulative necrosis, vacuolar degeneration, inclusion bodies	Hepatic necrosis, hemorrhage, inclusion bodies	Hepatic necrosis, inclusion bodies	Kupffer's cell hyperplasia, hepatocellular necrosis, periportal heterophils and lymphocytes, vacuolar degeneration, inclusion bodies (hepatocytes, Kupffer's cells)
Spleen	Lymphatic atrophy, inclusion bodies, (reticulo-endothelial [RE] cells)	Lymphoid depletion, necrosis, inclusion bodies	Karyomegaly of RE cells, multifocal necrosis, inclusion bodies	Macrophage hyperplasia, necrosis, lymph depletion, inclusion bodies
GI Tract	Inclusion bodies (crop, intestines)		Serosal hemorrhage, epithelial desquamation of crop and esophagus, inclusion bodies (esophagus, proventriculus, intestines)	Necrosis and plasma cell infiltrates of lamina propria, enlarged vacuolated epithelial cells, inclusion bodies, mainly enterocytes
Kidney	Focal nephrosis, vacuolar degeneration, inclusion bodies (renal tubular epithelium)	Enlarged endothelial cells, enlarged epithelial cells, karyomegaly of renal tubules	Membranous glomerulopathy, thickened glomerular capillaries, inclusion bodies (glomerulus interstitium, collecting tubules)	Inclusion bodies (endothelium, tubular epithelium)
Skin	Ballooning degeneration (follicular epithelium, lateral and axial plate cells, epidermis) follicular and epidermal hyperplasia, inclusion bodies (epidermis, follicular epithelium, uropygial gland)		Ballooning degeneration and karyomegaly in epithelium of growing feathers, inclusion bodies (follicular epithelium)	
Other	Bone marrow necrosis, lymphatic atrophy, cerebellar lesions (particularly in the Purkinje cells), inclusion bodies (pancreas, adrenals, lung, gonads, brain)		Generalized hemorrhage, bursal medullary necrosis, bone marrow necrosis, inclusion bodies (bone marrow, pancreas, adrenals, skeletal muscle, lungs)	Bone marrow necrosis, inclusion bodies

Diagnosis

Feather lesions in surviving budgerigars cannot be macroscopically distinguished from changes caused by the PBFD virus. Malnutrition can also cause feather lesions, which might be difficult to evaluate clinically. Organ lesions can be induced by a variety of infectious agents, particularly bacteria.

Demonstration of large clear basophilic or amphophilic intranuclear inclusion bodies is considered suggestive of a polyomavirus infection. A confirmed diagnosis requires immunohistochemical staining of suspected lesions using viral-specific antibodies or the detection of viral nucleic acid using polyomavirus-specific DNA probes.[188,292,293,440] The VN can be used to identify virus isolated in cell culture.[281]

Immunodiffusion and virus neutralization techniques have been used to demonstrate polyomavirus antibodies in exposed birds. During outbreaks in mixed psittacine bird collections, infected survivors and asymptomatic birds exposed to them developed anti-BFD virus neutralizing antibodies.[63,188] The prevalence of neutralizing antibodies against BFD virus in aviaries containing cockatoos, macaws, Amazon parrots and conures ranged from 11 to 45%. These titers were found to decrease over a two-month period. The demonstration of waning antibody titers suggests a transient serologic response in exposed birds. Adults from an infected flock that were exposed to diseased birds developed titers and subsequently raised seronegative, clinically normal young.[63,105,106,188,424]

Subclinical carriers that intermittently shed polyomavirus have been thought to maintain high antibody titers in serial serologic assays.[105,424] Based on these suppositions, the demonstration of sustained high antibody titers has been used to screen for polyomavirus carriers;[63,105,106,292,424] however, polyomavirus-specific DNA probes have been used to demonstrate that there is no correlation between the shedding of polyomavirus in excrement and the titers of neutralizing antibodies.[292,293,320]

Viral-specific DNA probes have been used to demonstrate polyomavirus nucleic acid in various tissues including liver, spleen, kidney, cloacal secretions, intestinal secretions, serum and blood. Viral nucleic acid occasionally can be detected in the blood or serum of some infected birds; however, the best antemortem sample for detecting polyomavirus shedders in larger psittacine birds is a cloacal swab. Testing birds twice per year (before and after the breeding season) is recommended to detect intermittent viral shedders.

FIG 32.14 The use of a DNA probe test is the best method to confirm the presence of polyomavirus in postmortem samples. A swab is used to collect a sample from the cut surface of the liver, spleen and kidney.

DNA probes can also be used to detect viral nucleic acid in fresh tissues from birds that are suspected to have died from polyomaviral infections. In suspect cases, duplicate tissue samples can be sent for histopathology as a tentative diagnosis and for DNA probing to confirm a polyomavirus infection. The best sample to submit for postmortem confirmation of polyomavirus is a swab of the cut surface of the spleen, liver and kidney (same swab for all three tissues) (Figure 32.14).

Therapy

In chicks that are hemorrhaging, injection of 0.2-2.5 mg/kg bodyweight of vitamin K IM may be helpful and can increase survival rates favorably, although prognosis in birds with heavy hemorrhaging is poor.

Several immunostimulants have been anecdotally suggested as effective in the treatment of birds with clinical signs suggestive of avian polyomavirus; however, suggested therapies have not been confirmed to

be effective in birds that were documented (liver biopsy) to have an active avian polyomavirus infection.

Control

Polyomavirus virions are small, nonenveloped particles that are resistant to severe environmental conditions, many disinfectants and heat at 56°C for two hours.[44,376,428] Stability of the virus causes a considerable problem in the aviary because persistently infected adult birds can shed virus in their feather dust or excrement. Manual removal of any organic debris followed by the use of appropriate disinfectants is required to prevent or contain outbreaks. Sodium hypochlorite (5%) is thought to be effective against the BFD virus at a concentration of 50 ml/liter of diluent.[93,281] A polyomavirus DNA probe test can be used to screen walls, caging, air circulating ducts and equipment in the home or hospital to determine if this virus is contaminating a bird's environment. This is accomplished by rubbing a swab across the surfaces intended to be evaluated for the presence of polyomavirus nucleic acid.

With the highly infectious nature of avian polyomavirus, particularly to young Psittaciformes, closed breeding operations that do not allow visitors should be encouraged. A cloacal swab of any bird that is being added to a collection should be analyzed during the quarantine period to determine whether a bird is shedding polyomavirus. During an epornitic, birds that are actively shedding the virus can be identified by using DNA probes.[292,293,344] All birds being sold from an aviary should be tested to determine if they are shedding polyomavirus before shipment. Birds also should be tested for viral shedding during the post-purchase examination.

A bird that is shedding polyomavirus could be maintained as a pet if it does not expose other birds, particularly neonates, to the virus. Breeding birds shedding polyomavirus should be separated from the remainder of the collection, and offspring from these birds should be raised separately from birds that are not shedding the virus. Offspring from shedders should also be raised separately from birds that are not shedding the virus. The applicability of killed and recombinant polyomavirus vaccines is being evaluated.

A killed avian polyomavirus vaccine was found to induce virus-neutralizing antibodies in Blue and Gold Macaw chicks that were sufficient to protect them from subsequent challenge. This suggests that a vaccine could be effective in preventing infections (Ritchie BW, unpublished).

Outbreaks of polyomavirus tend to be persistent in budgerigar aviaries that utilize a constant breeding cycle, while the disease appears to be self-limiting in aviaries raising larger Psittaciformes where breeding cycles are discontinuous.[63] High levels of fledgling mortality can be reduced in budgerigar aviaries by stopping the breeding cycle and resting the birds for several months. The exact mechanisms involved in stopping new cases remains undetermined.

Depopulation of budgerigar aviaries experiencing outbreaks followed by restocking with sero-negative birds has been suggested as a method of controlling enzootic infections in this species. It has been suggested that polyomavirus-free budgerigar nestlings can be produced by interrupting the breeding cycle, removing all but the older breeding birds and disinfecting the aviary.[321] This technique has been reported to be successful in some flocks, while in others, infections resume when breeding is initiated.[125] Depopulation is not a practical, nor recommended procedure for controlling polyomavirus in larger Psittaciformes.

Circoviridae

Psittacine Beak and Feather Disease Virus

A chronic disease characterized by symmetric feather dystrophy and loss, development of beak deformities and eventual death was first described in various species of Australian cockatoos in the early 1970's.[315a] Free-ranging Psittaciformes with feather abnormalities suggestive of this disease were noted by Australian explorers at the turn of the century. The disease has been diagnosed in numerous Psittaciforme species in addition to cockatoos. The currently used name, coined by Perry in 1981, is "psittacine beak and feather disease" (PBFD).[316]

This disease has been experimentally reproduced in neonatal budgerigars and Rose-breasted Cockatoos using feather homogenates containing 19-22 nm viral particles, and in neonatal budgerigars, cockatiels, African Grey Parrots and Umbrella Cockatoos using purified concentrated PBFD virions (Color 32.5).[339,443]

The PBFD virus is a 14 to 17 nm icosahedral nonenveloped virion associated with two major proteins that have molecular weights of 27,000 and 23,000

daltons. Virus with similar ultrastructural characteristics, protein composition and antigenic similarities can be consistently recovered from numerous different species of psittacine birds with clinical or histologic lesions of PBFD (Figure 32.15).[339,343,345]

The PBFD virus infecting different hosts is antigenically similar and has sufficiently conserved nucleic acid sequences to allow detection of the virus using viral-specific DNA probes. The virus hemagglutinates erythrocytes from cockatoos and some guinea pigs (see Figure 32.2).[340]

Based on the virion dimension, polypeptide composition and nucleic acid size and experimental conformation, it has been suggested that the etiologic agent of PBFD is a member of a new family of pathogenic animal viruses.[345] The virion size and nucleic acid characteristics described for the PBFD virus are similar to those found for the chicken anemia agent (CAA) and for the apparently nonpathogenic porcine circovirus (PCV).[404] On the basis of these similarities, it has been suggested that these viruses be placed in the same family to be called Circoviridae. Because the PBFD virus does not readily grow in cell culture, nothing is known about its replication mode. The CAA and PCV replicate in the nucleus of the host cells.

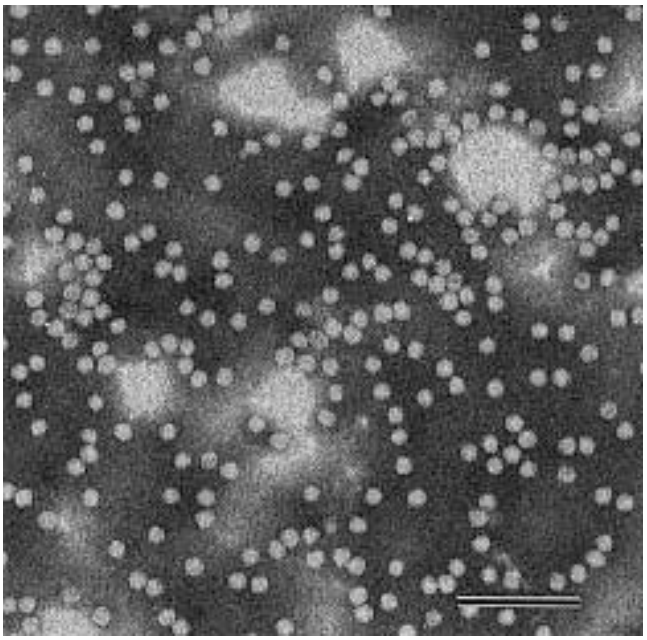

FIG 32.15 High concentrations of PBFD virus can be recovered from dust in rooms where PBFD-positive birds are housed. With the ease with which contaminated dust could be transferred from bird to bird through natural air circulation or through fomites (clothing, hair, skin, caging, nets), it is theorized that contaminated feather dust serves as the major method of environmental persistence and natural transmission of the virus. Areas suspected to be contaminated with PBFD virus can be tested for the presence of virus using viral-specific DNA probes.

TABLE 32.10 Psittaciformes Currently Considered Susceptible to PBFD virus

Sulphur-crested Cockatoo	Triton Cockatoo
Major Mitchell's Cockatoo	Citron Cockatoo
Galah	Goffin's Cockatoo
Little Corella	Vasa Parrot
Long-billed Corella	Blue-fronted Amazon Parrot
Budgerigar	Red-lored Amazon
Cockatiel	Red-vented Cockatoo
Rainbow Lorikeet	Senegal Parrot
Western Rosella	African Grey Parrot
Hooded Parrot	Meyer's Parrot
Malee Ring-necked Parakeet	Black Palm Cockatoo
Port Lincoln Parrot	Red-bellied Parrot
Red-rumped Parrot	Gang-gang Cockatoo
Bourke Parrot	Scarlet Macaw
Eclectus Parrot	Rose-ringed Parakeet
Princess Parrot	Pale-headed Rosella
Peach-faced Lovebird	Golden-shouldered Parrot
Nyassa Lovebird	Northern Rosella
Fisher's Lovebird	Jenday Conure
Masked Lovebird	Green-winged Macaw
King Parrot	Pionus Parrot
Moluccan Cockatoo	
Umbrella Cockatoo	
Indian Ring-necked Parakeet	

A virus that morphologically resembles PBFD virus has been described in pigeons.[134] When compared to PBFD virus, the pigeon circovirus is antigenically unique and has some differences in nucleic acid sequence.[439]

Epizootiology

Histologic or clinically suggestive lesions of PBFD have now been described in 42 species of Psittaciformes. Historically, PBFD was thought to be restricted to Old World and South Pacific psittacine birds, with the white and pink cockatoos being particularly susceptible. However, the disease has been documented in several black cockatoos and New World psittacine birds including Amazon parrots, macaws and pionus parrots (Table 32.10) (Color 32.1). Investigations indicate that the actual host range of the PBFD virus remains largely unknown. Psittacine beak and feather disease has been documented only in Psittaciformes.[139,178,187,309,343]

Epizootiologic studies in one import station in the United States showed that 0.5% of imported Lesser Sulphur-crested Cockatoos, Umbrella Cockatoos, Citron Cockatoos and Moluccan Cockatoos had gross lesions consistent with PBFD, suggesting that these birds had been infected in their country of origin.[187] It is postulated that PBFD has historically been enzootic in free-ranging populations of Old World and

South Pacific psittacine birds, and that the disease has been introduced to other susceptible populations of both free-ranging and captive birds through the worldwide movement of birds for the pet market.[271,273]

In Australia, 75% of the captive Sulphur-crested Cockatoos examined in one veterinary hospital had clinical signs consistent with PBFD. The incidence of the disease in other commonly maintained captive psittacine birds in Australia, including galahs and budgerigars, is thought to be much lower.[316] Psittacine beak and feather disease is reportedly enzootic in free-ranging populations of Sulphur-crested Cockatoos, Rose-breasted Cockatoos, Little Corellas, Major Mitchell's Cockatoos, Crimson Rosellas, budgerigars and Rainbow Lorikeets.[271,272,308,316]

As many as 20% of free-ranging Sulphur-crested Cockatoos have clinical signs of PBFD in any one year. One flock of Sulfur-crested Cockatoos decreased from 120 individuals to 20 over a nine-month period. Many of the dead or dying members of this flock were diagnosed with PBFD. Half of the 20 birds in a free-ranging flock of Crimson Rosellas were found to have PBFD.[273] There does seem to be an increased occurrence of PBFD late in the breeding season in both captive and free-ranging cockatoo populations.[315,316]

Transmission

Susceptible birds can be experimentally infected with the PBFD virus through the combined oral, intracloacal and intranasal routes.[339,443] Psittacine beak and feather disease virus was recovered in the feces and crop washings from various species of psittacine birds diagnosed with PBFD. During the test period, 26% (8 of 31) of the birds screened were found to be excreting PBFD virus in their feces, and 21% (3 of 14) of crop washings were positive for the PBFD virus. While the concentration of PBFD virus demonstrated in the crops of positive birds was low, the possibility of an adult transmitting the virus to neonates during feeding activities that involve the regurgitation of food and exfoliated crop epithelium deserves consideration. Virus that was recovered from the crop may have originated from infected cells located in the crop or esophageal epithelium, or may have been deposited in the crop after swallowing of exfoliated epithelium from beak or oral mucosal lesions. High concentrations of the virus also can be demonstrated in feather dust collected from a room where birds with active cases of PBFD are housed (see Figure 32.13).[342] It has been postulated that the frequent demonstration of PBFD inclusions in tissues of the palate, esophagus, crop, intestines, bursa and liver probably accounts for viral shedding in the feces.[232]

The demonstration of high concentrations of virus recovered from a room where PBFD birds were being maintained implicates contaminated dust from any source as a major vehicle for the environmental persistence and natural transmission of the virus.[342]

Artificially incubated chicks from a PBFD-infected hen consistently develop PBFD suggesting that vertical transmission of the virus occurs. Because viremia has been shown to occur in infected birds, vertical transmission would be suspected.

Several reports suggest the possibility of asymptomatic adults producing progeny with clinical signs of PBFD in successive breeding seasons. These findings suggest a carrier state may exist with vertical or horizontal transmission of PBFD virus from parent to offspring or a genetic predisposition to the disease;[187,316,317,386] however, in most suspected cases of parent-to-offspring transmission, epizootiologic investigations indicate probable exposure to the PBFD virus occurring through sources other than the parents. The widespread use of viral-specific DNA probes to detect subclinically infected birds may provide more information on what role, if any, these birds play in transmitting the virus.

Pathogenesis and Immunity

PBFD is a progressive disease with temporary remission in the occurrence of new lesions in the periods of nonmolting. Irregular photoperiods to which many companion birds are subjected may influence regular molting periods or the lack of them. The lesions of the beak may progress during the intermolt period.[134] It has been suggested that the virus depends on the multiplication of the host cells for its replication.[236] Except for reported recoveries in budgerigars, lorikeets, lovebirds, a pionus parrot and some macaw neonates, the clinically apparent form of PBFD virus is considered fatal (Ritchie BW, unpublished).[306,309,316] Most infected birds survive less than six months to one year after the onset of clinical signs, though some birds have been known to live over ten years in a featherless state. Death usually occurs either from changes induced by secondary bacterial, chlamydial, fungal or other viral agents, or from terminal changes that necessitate euthanasia.[187,316,317,443] Cockatoos with PBFD have been diagnosed with severe cryptosporidiosis infections, which are generally

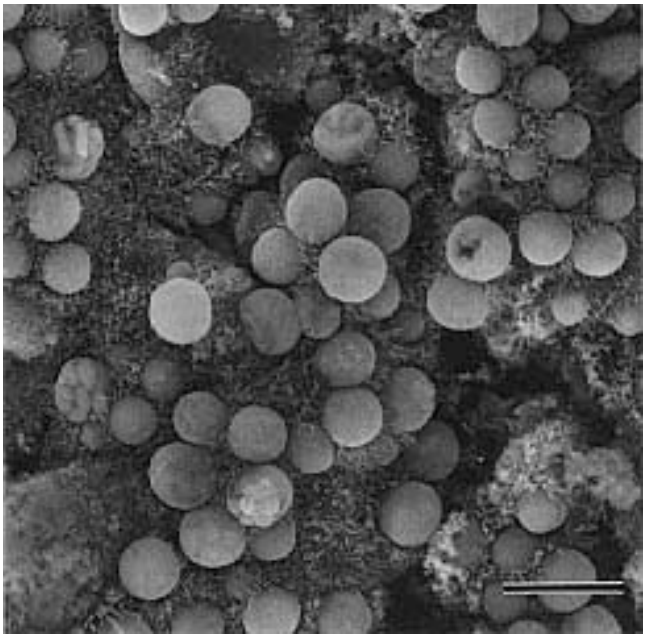

FIG 32.16 Cryptosporidiosis was diagnosed in a group of cockatoos with PBFD virus. In one bird, the infection was severe and extended from the small intestine to the cloaca. In general, cryptosporidiosis occurs only in animals that are immunosuppressed (courtesy of Kenneth Latimer).

considered to occur only in patients with immunodeficiencies (Figure 32.16).[232]

The predilection for birds to die from secondary or opportunistic pathogens has been interpreted to indicate an immunosuppression that is thought to be induced by damage to the thymus and bursa.[187,308,316,386] Only limited work has been performed to document the suspected immunosuppression; however, PBFD patients were found to have low concentrations of pre-albumin and gammaglobulin as indicated by serum electrophoresis.[187] Other investigations with serum electrophoresis in birds with PBFD virus indicated that some birds had hypogammaglobulinemia (usually birds with severe beak necrosis or other clinical abnormalities) and some birds had hypergammaglobulinemia (Ritchie BW, unpublished).

PBFD-positive birds with inclusion bodies located only within the nucleus of infected epithelial cells have been found to spontaneously recover. On the other hand, larger psittacine birds with intracytoplasmic inclusion bodies located in macrophages usually succumb to the disease. Because the macrophage is critical for the initial processing and presentation of viral antigen to the immune system, it can be postulated that the determining factor in whether an infected bird develops a chronic fatal PBFD virus infection, or develops a protective immune response is based on how the body processes the virus before it begins to persist in the cytoplasm of macrophages (see Figure 5.4).[339]

Some birds exposed to the PBFD virus remain clinically normal and develop HI and precipitating antibody titers. In fact, the detection of anti-PBFD virus antibodies in most adult Psittaciformes of a susceptible species suggests that these birds were exposed to the virus at some point in their lives and that the exposure resulted in a subclinical infection with the development of an effective immunologic response (Table 32.11). The factors that determine whether a bird mounts an immune response or is fatally infected could depend on the age at the time of exposure, the presence and levels of maternal antibodies, the route of viral exposure and the titer of the infecting virus.

An age-related susceptibility to the virus has been suggested by some experimental transmission studies. Neonatal budgerigars infected at less than seven days of age were found to develop severe disease, while birds infected at 10 to 14 days were reported to experience lower levels of morbidity, and some remained asymptomatic.[339,443] It was suggested that this age-related susceptibility might be due to the ability of the neonatal bursa to take up particulate matter from the cloaca.[355] Other transmission studies have indicated that the apparent age-related resistance to the virus was due to the birds' not being followed through an appropriate incubation period and may have had nothing to do with an age-related resistance.[339]

Incubation Period

Infected chicks and fledglings may show the first signs of disease during their feather development after replacing the neonatal down. Following experimental infection, the minimum incubation period is 21 to 25 days.[339] The maximum incubation period may be months to years (Figure 32.17).

Rose-breasted Cockatoo chicks experimentally infected with PBFD virus have been reported to develop clinical signs of PBFD approximately four weeks after infection.[443] African Grey Parrot chicks infected at three to eight days of age became depressed by 30 days old and developed progressive feather dystrophy by 33 to 44 days old. Umbrella Cockatoo chicks infected at three to eight days of age became depressed by 40 days old and developed progressive feather dystrophy from 42 to 47 days old.

TABLE 32.11 Information and HI titer of Clinically Normal, PBFD-Negative Birds Naturally Exposed to PBFD Virus

Species	PBFD Virus Exposure	HI titer
Umbrella Cockatoo	PBFD+ mate	1,280
Moluccan Cockatoo	PBFD+ bird in collection	2,560
Moluccan Cockatoo	PBFD+ bird in collection	1,280
Umbrella Cockatoo	PBFD+ bird in collection	80
Umbrella Cockatoo	PBFD+ bird in collection	640
Umbrella Cockatoo	PBFD+ mate	>5,120
Goffin's Cockatoo	PBFD+ mate	2,560
Cockatoo species	PBFD+ bird in collection	160
Cockatoo species	PBFD+ bird in collection	>5,120
Moluccan Cockatoo	PBFD+ mate	2,560

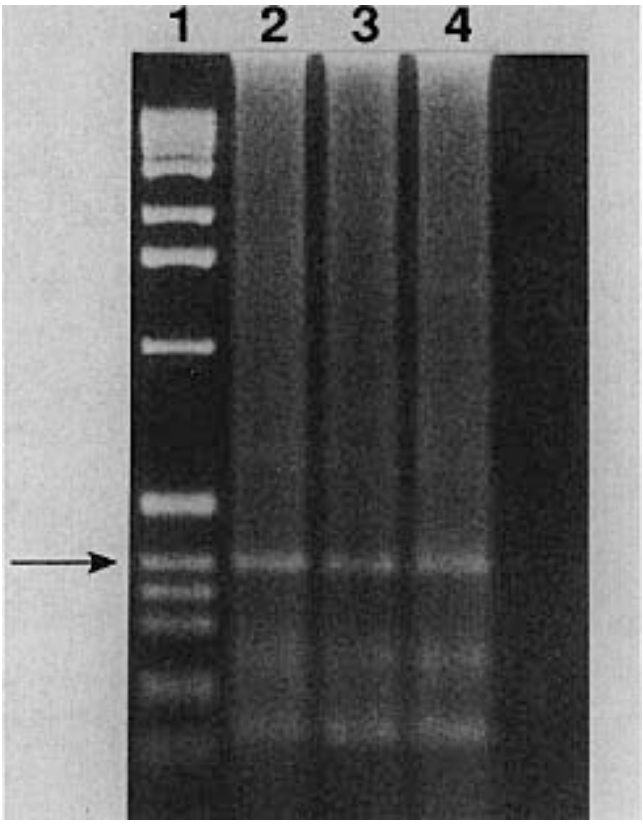
The time variance in developing clinical signs associated with PBFD among different psittacine chicks may be attributed to differences in concentrations of maternally transmitted antibodies, titer of virus in the inoculum or host responses to the virus.[339]

Clinical Disease

It appears that the avian species listed in Table 32.10 are of various susceptibilities; therefore, clinical (and pathological) signs may vary greatly. Generally, PBFD is a disease of young birds (up to three years), but older individuals (up to 20 years of age) may also develop clinical lesions. Older birds that develop clinical signs later in life may have been infected at a young age and remained latently infected.

In some Psittaciformes with pigmented feathers, abnormal coloration has been associated with histologic lesions consistent with PBFD virus infection. This is particularly true in African Grey Parrots, where affected feathers may be red instead of grey.[18,338]

The feather changes, typical lesions of the beak (if present), and more rarely also of the nails, occur symmetrically in most instances. Based on markedly different clinical presentations, peracute, acute and chronic forms of PBFD have been described (Figure 32.18).[315,316] The type of clinical disease appears to be influenced by the age of the bird when clinical signs first appear.



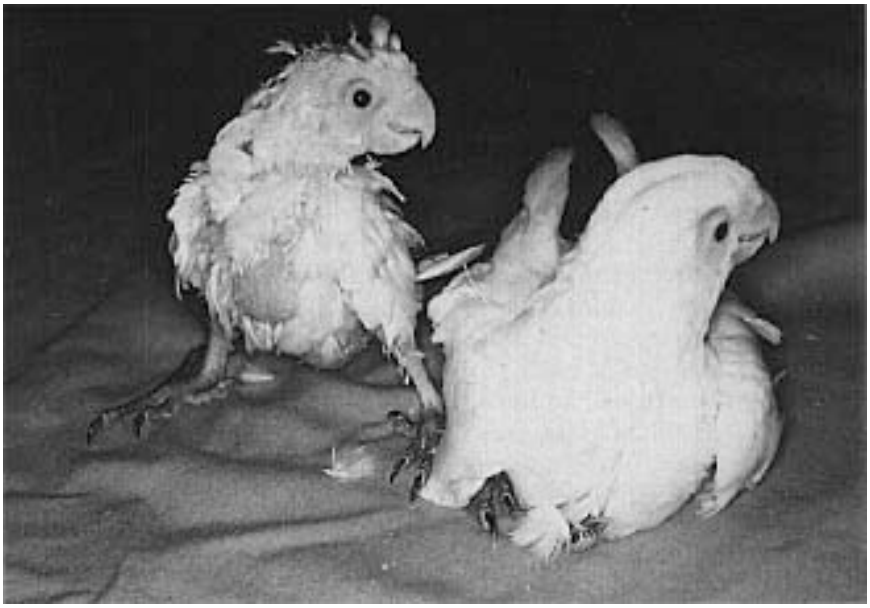


FIG 32.17 Three eggs from a Bare-eyed Cockatoo hen with PBFD virus were artificially incubated. PBFD virus nucleic acid was detected in the blood of all three of the chicks by DNA probe at 20 days of age (lanes 2,3,4; lane 1 is a control). The lane 1 and lane 3 chicks developed clinical signs of PBFD starting at 32 days of age, and infections were characterized by a two- to three-week course of progressive feather changes followed by death. The lane 2 chick (below), shown here with the lane 1 chick, did not develop clinical signs of disease until 80 days of age. Because all three of these chicks were presumably infected by the hen, and all three chicks were blood-positive at 20 days of age, these findings suggest that the time from infection to the development of clinical signs can vary.

FIG 32.18 Some birds can live with PBFD virus for many years. Birds with long-term infections frequently appear bald as feather pathology progresses through successive molts.

Peracute disease is suspected in neonatal psittacines that show signs of septicemia accompanied by pneumonia, enteritis, rapid weight loss and death.[308] Histologic lesions in these cases may be limited. The peracute syndrome appears to be particularly common in young cockatoos and African Grey Parrots. Peracute cases of PBFD may be missed if a complete necropsy and thorough histologic exam are not performed on young of susceptible species that die suddenly.

The acute form of PBFD, commonly called French moult in Australia, is most frequently reported in young or fledgling birds during their first feather formation after replacement of the neonatal down, and chicks as young as 28 to 32 days of age have been described with classic lesions (Color 32.2).[309,315,339] Acute infections are characterized by several days of depression followed by sudden changes in developing feathers, including necrosis, fractures, bending, bleeding or premature shedding of diseased feathers. In some acute cases of PBFD, birds with minimal feather changes may be depressed, develop crop stasis and have diarrhea, followed by death in one to two weeks.[230] Gross feather lesions in the acute form of the disease can be quite subtle with only a few feathers showing dystrophic changes. This clinical picture is particularly common in young Sulphur-crested Cockatoos and lovebirds.[316] In African Grey Parrots a non-regenerative anemia is reported (PCV=14-25%) with typical inclusion bodies in the bone marrow;[391] however, it has not been determined if these changes are caused by the PBFD virus or if they are a result of secondary pathogens. Another observation is the irregular necrosis of the reticular cells in the lymphocytically depleted spleen, which would suggest permanent immunosuppression.

Experimentally infected Rose-breasted Cockatoo neonates became acutely depressed and anorectic approximately four weeks post-infection. Twenty-four hours later, the feathers appeared to lose their luster and became pale and brittle. Subsequently, dystrophic feathers began to appear as the neonates developed their adult plumage.[443] A similar disease progression has been defined for experimentally infected Umbrella Cockatoos and African Grey Parrot chicks (Color 32.5).[339] Chicks that develop clinical lesions while the majority of feathers are still in a developmental stage exhibit the most severe feather pathology. These birds may appear totally normal one day and exhibit 80 to 100% feather dystrophy within a week (Color 32.2).[339] The clinical progression of disease is less dramatic in neonates that develop clinical signs after body contour feathers are mature. In these birds, feather changes may be limited to the still-developing flight and tail feathers.[309,317]

Chronic PBFD is characterized by the progressive appearance of abnormally developed feathers during each successive molt. Gross changes include retention of feather sheaths, hemorrhage within the pulp cavity, fractures of the proximal rachis and failure of developing feathers to exsheathe. Short, clubbed feathers, deformed, curled feathers, stress lines within vanes and circumferential constrictions may also be present (Figure 32.19) (Color 32.3).[309,317,443] Replacement feathers become increasingly abnormal, and if birds live long enough they will eventually develop baldness as the feather follicles become inactive.[309,317,443] Free-ranging birds with severe feather pathology may have an accompanying brownish discoloration of the skin that is thought to occur from exposure of normally sheltered skin to sunlight.[271,309]

The distribution of dystrophic feathers within individual pterylae is variable and depends upon the stage of molt when the bird begins to develop clinical signs. In older birds, the first sign of PBFD is the replacement of normal powder down and contour feathers with dystrophic, necrotic, non-viable feathers that stop growing shortly after emerging from the follicle (Color 32.3). The disease then progresses to involve the contour feathers in most tracts, followed

by dystrophic changes in the primary, secondary, tail and crest feathers (Color 32.4). Primary feathers are usually the last to manifest the disease.[187,309,317,339] It has been assumed that the susceptibility of the powder down feathers is based on their consistent molt pattern, compared to the seasonal molt found in other feather tracts. In contrast to the classic presentation just described, some birds have substantial involvement of the flight, tail and crest feathers, with only minimal changes in the powder down feathers.[187,271,309]

Clinical changes in the beak and oral mucosa of PBFD-positive birds are characterized by progressive elongation, transverse or longitudinal fractures, palatine necrosis and oral ulceration (Color 32.11).[187,309,317] Necrosis of the upper beak progresses proximally to the palatine area and may involve the premaxilla in severe cases. The distal end of the lower beak is less severely involved.[187] If the powder down feathers in cockatoos are dystrophic, the beak may appear to be semi-gloss or gloss black, instead of its normal grey color. The beak may elongate or show transverse delamination or fractures, with or without bacterial or fungal infections in the clefts (see Figure 19.5). Necrosis of the palatine may follow. Likewise, deformities, fractures, necrosis and sloughing of the nails can be seen occasionally.[230]

Classically, beak deformities develop in birds following a protracted course of PBFD where substantial feather changes have occurred; however, some individuals develop severe beak lesions with relatively minor feather pathology, and cracking of the hard corneum at the distal portion of the beak may be the initial complaint requiring veterinary attention.[187,309,317]

Depending on the avian species involved and other factors that remain unresolved, beak changes may or may not be present. In one study involving 22 cockatoos of mixed Asian origin, birds older than one year of age had a lower incidence of beak lesions than did birds that were under one year of age.[187] Beak pathology does not routinely occur with some affected species, while with others, such as the Sulphur-crested Cockatoo, Rose-breasted Cockatoo, Bare-eyed Cockatoo and Moluccan Cockatoo, beak lesions are relatively common.[187,271,309,316,317]

Pathology

Gross feather and beak changes associated with PBFD are described under clinical features. Predominant histologic lesions have been described in the feather shaft, where necrosis and ballooning degeneration of epithelial cells in the epidermal collar and epidermal, basal and intermediate zones of the developing rachis are seen.[187,229,271,309,317] The follicular epithelium may also be necrotic, but this lesion is less commonly reported.[229] Feather sheath hyperkeratosis prevents the feather from exsheathing and results in the terminal clubbing and midshaft constrictions of the developing feather, which are clinically evident.[187] Feather pulp lesions are characterized by suppurative inflammation, including perivascular accumulations of heterophils, plasma cells, macrophages and rarely lymphocytes. Granulomatous dermatitis with vesicle formation was described in a group of infected lovebirds.[305]

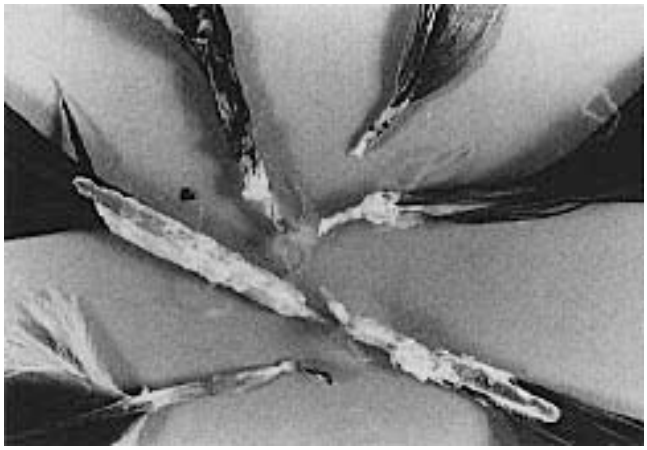

FIG 32.19 Feather lesions suggestive of PBFD virus include retention of the feather sheaths, hemorrhage within the pulp cavity, fractures of the proximal rachis and failure of the developing feather to exsheath; however, it must be stressed that any damage to the follicular epithelium can cause a similar appearing gross lesion. DNA probe testing (whole blood) or feather biopsy is necessary to confirm a diagnosis. Polyomaviral, adenoviral, bacterial and fungal folliculitis can cause similar lesions.

In peracute cases, histologic lesions may be limited to severe bursal or thymic necrosis with the presence of viral-induced inclusion bodies. Feather pathology in these cases may not occur, or may be limited to edema in the follicular epithelium (if present).[187,229,271,306]

Histologic lesions in the beak of PBFD birds are similar to those described in their feathers, including necrosis and hyperplasia of epithelial cells in the basal and intermediate epithelial layers. Hyperkeratosis and separation of the cornified outer layer from the underlying tissues and bone may also be evident, and are often accompanied by secondary necrosis and osteitis of associated tissues.[187,271,306,309]

In birds with beak pathology, necrosis and inflammation of the epithelial lining of the tongue, beak cavity and crop have also been reported.[187,306,317] Secondary gram-negative bacteria and fungi are commonly isolated from beak lesions and may be associated with acute or chronic inflammatory reactions.[187,306,309,316]

At necropsy, internal lesions are variable and differ with age and the type of secondary infection. In young birds, the cloacal bursa may be small with poorly developed folds and the thymus may reveal small lobes with pale necrotic tissue. In mature birds the spleen is frequently small and depleted of lymphocytes, and occasionally necrosis of the reticular cells can be observed. Extracutaneous inclusions demonstrated to be PBFD virus were found mainly in macrophages in the beak, palate, esophagus, crop, nail, tongue, parathyroid gland, bone marrow, Kupffer's star cells of the liver, spleen and thyroid gland. In the intestinal tract inclusion bodies were mainly found in epithelial cells.[232]

Inclusion Bodies

Basophilic intranuclear and intracytoplasmic inclusion bodies have been consistently demonstrated by hematoxylin and eosin staining in sections of the feathers, beak, thymus and bursa taken from birds with clinical signs of PBFD.[187,229,271,306,317] Immunohistochemical staining with viral-specific antibodies was used to confirm that intracytoplasmic basophilic inclusion bodies and some intranuclear inclusion bodies observed in hematoxylin and eosin-stained tissue sections contain PBFD viral antigen (Color 32.7).[232]

Intracytoplasmic inclusion bodies have been reported to be more consistently demonstrated, particularly in early cases, than are intranuclear inclusion bodies.[187,271] Intranuclear and intracytoplasmic inclusion bodies were identified in 23 of 32 birds examined in one study. In this group, intranuclear inclusion bodies were restricted to epithelial cells, and intracytoplasmic inclusion bodies were found only within macrophages.[229] Inclusion bodies have not been demonstrated in feather or beak samples taken from clinically normal birds.[187,271,306,309]

In addition to being localized in the feather and follicle epithelium and lymphatic tissues, PBFD viral inclusion bodies have also been demonstrated by viral-specific antibody staining in the beak, hard palate, bursa, thymus, tongue, parathyroid gland, crop, esophagus, spleen, intestines, bone marrow, liver, thyroid and adrenal glands.[232]

Intracytoplasmic inclusions are thought to originate in epidermal cells and attain their greatest size within macrophages, which engulf these infected cells.[187,229,306,309] It has been postulated that PBFD virus replicates in the nuclei of infected epidermal cells, and inclusions are then released when necrotic cells are phagocytized by macrophage-like cells in the pulp and epidermis;[187,232,309] however, the occurrence of viral antigen within macrophages in the bone marrow and within circulating monocytes suggests that these cells may be directly infected (Color 32.6).

Diagnosis

Feather lesions that appear grossly similar can be caused by PBFD virus and avian polyomavirus. Feather lesions seen with polyomavirus typically resolve after one or two molts whereas PBFD lesions as a rule progress from molt to molt. Dual infections with PBFD virus and polyomavirus do occur. Noninfectious causes of similarly appearing feather lesions include nutritional deficiencies, endocrine abnormalities and drug reactions.

PBFD should be suspected in any psittacine bird with progressive feather loss involving malformed feathers. A tentative diagnosis of PBFD involves the identification of basophilic intracytoplasmic or intranuclear inclusion bodies in the feather pulp or follicular epithelium from birds with clinical signs of dystrophic, nonviable feathers.[187,229,271,306,316] Basophilic intracytoplasmic inclusion bodies are considered diagnostic. Because several viruses may result in similarly appearing intranuclear inclusion bodies, a confirmatory diagnosis of PBFD requires the use of viral-specific antibodies to demonstrate PBFD virus antigen or the use of DNA probes to detect PBFD virus nucleic acid (Colors 32.6, 32.7).[230,341] Viral-specific DNA probes are most sensitive for detecting PBFD virus and can be used on biopsy samples to confirm an infection or on blood samples from a live bird to detect viremia (Color 32.6).

PBFD virus has hemagglutination activity for cockatoo and guinea pig, but not chicken or sheep erythrocytes. The HA test can be used to demonstrate and quantify the amount of virus recovered from PBFD-positive birds. The hemagglutination-inhibition (HI) test was found to provide a rapid, specific technique to assess the immunologic response of psittacine birds to the PBFD virus (see Figure 32.2). Precipitating antibodies can be demonstrated using an agar-gel immunodiffusion test (see Figure 32.1).[340] A suitable culture system for the PBFD virus has yet to be discovered.

The recommended sample to submit for DNA probe detection of active or subclinical (birds that are showing no feather abnormalities) infections is whole anticoagulated blood (0.2 to 1.0 ml of blood in heparin). In addition, in birds that have feather abnormalities, biopsy samples of diseased feathers should be placed in 10% formalin and held for further diagnostic testing should any be needed.

Therapy

Numerous therapeutic trials have been attempted for PBFD virus-infected birds. Recoveries have been reported principally in birds with only intranuclear inclusion bodies. While feather lesions can be tolerated as long as the animal is kept in a controlled environment, beak lesions (also nail lesions) can be painful, particularly when secondarily infected. Euthanasia is suggested under these conditions. Secondary infections should be treated accordingly, and special examinations for cryptosporidiosis might be indicated.[231]

Control

The chicken anemia agent (CAA), which is similar in ultrastructure and DNA composition to the PBFD virus, has been found to be environmentally stable, and infectivity remains unchanged when the virus is heated to 60°C for one hour and following treatment with detergents, enzymes and many commercial disinfectants.[446] While the environmental stability of the PBFD virus is unknown, it would be prudent to consider its stability to be similar to that described for CAA. Psittacine neonates, which seem to be most susceptible to the PBFD virus, should definitely not be exposed to areas that may have been contaminated by feces or feather dust from a PBFD-positive bird.[339,342,443]

A DNA probe for PBFD virus provides the best technique available for controlling infections until a vaccine is available (see Chapter 6). In an effort to reduce the number of cases of PBFD, all birds of a susceptible species should be tested to determine if they are latently infected with the PBFD virus. This is particularly true with respect to breeding birds, birds being sent to pet shops and birds being evaluated during post-purchase examinations. The test is simple, inexpensive and relatively noninvasive.

The DNA probe can also be used to screen walls, caging, air circulating ducts and equipment in the home or hospital to determine if PBFD virus is contaminating these surfaces. The appropriate sample for this test is a swab collected from the test location.

A negative DNA probe test for PBFD virus indicates that viral nucleic acid was not detected in the submitted sample. A positive DNA probe test for PBFD virus indicates that viral nucleic acid has been detected in the submitted sample. A positive test in a bird that has feather abnormalities suggests that the bird has an active PBFD viral infection. A positive blood test in a bird that does not have feather abnormalities may indicate that the bird is latently infected or that it recently has been exposed to the PBFD virus and is viremic. A bird that tests positive and has no feather abnormalities must be retested in 90 days. If the bird is still positive, then it should be considered to be latently infected. A negative test 90 days later would indicate that the viral nucleic acid was no longer detected in the blood and that the bird has probably eliminated the virus.

A companion bird that is diagnosed as a PBFD virus carrier can live a long life when provided a stressor-free environment and supportive medical care. These birds should be restricted from contact with other susceptible birds, particularly neonates. PBFD virus-infected birds should not be maintained in breeding facilities or where they may expose susceptible neonates or adults. Infected birds should be removed from the breeding collection and nursery immediately (see Figure 30.21).

It has been suggested by one author that this disease can be eradicated from a collection by removing patients with clinical signs of disease;[134] however, in the same discussion, this author mentions that the virus may have a two- to three-year incubation period, and that the virus genome can be detected in cells from clinically asymptomatic birds (carrier state). It is obvious that these conclusions are contradictory, and true eradication can be achieved only by testing for carriers.

High HI and precipitating antibody titers can be induced by injecting birds with beta-propiolactone-treated PBFD virus by the intramuscular or subcutaneous routes (Table 32.12). Immunized hens pass maternally derived antibodies to their chicks that offer at least temporary immunity to the virus (Color 32.5).

Because PBFD appears to be restricted in host range to psittacine birds and most of these birds are restricted to enclosures, it is likely that a widespread and continued testing and vaccination program can be used to control this disease in companion birds.

TABLE 32.12 Post-vaccination PBFD Titers

Species	Age	0	21
Moluccan Cockatoo	Adult	640/10	5120/80
Umbrella Cockatoo	Adult	160/1	5120/80
African Grey Parrot	Adult	320/0	5120/80
Moluccan Cockatoo	Adult	160/1	1280/10
Umbrella Cockatoo	Adult	80/0	1280/80
Umbrella Cockatoo	Adult	320/1	2560/80
Umbrella Cockatoo	Adult	80/1	2560/10
Amazon parrot	Adult	320/0	2560/10
African Grey Parrot	Adult	160/0	5120/80
Umbrella Cockatoo	45 days	<40/0	1280/0
Sulphur-crested Cockatoo	45 days	80/0	2560/0
African Grey Parrot	45 days	160/0	5120/0
African Grey Parrot	45 days	80/0	2560/0
African Grey Parrot	30 days	640/0	5120/0
African Grey Parrot	30 days	640/0	2560/0

Hemagglutination inhibition (HI) and precipitating antibody titers before and 21 days after vaccination with B-propiolactone-treated PBFD virus. Titers are listed as HI/precipitating.[340]

Adenovirus

The Adenoviridae family consists of two genera: Mastadenovirus (contains mammalian strains) and Aviadenovirus. The two genera have a distinct group antigen. Most mastadenovirus strains have hemagglutination activity; most aviadenovirus strains do not. Aviadenovirus are divided into three groups according to common group antigens as detected by virus neutralization, growth in cell culture and nucleic acid characteristics.[267,419,449]

Group I: Fowl adenovirus (FAV) consists of 12 serotypes (numbered 1-12) that have been isolated from chickens, turkeys (3 serotypes), pigeons, budgerigars, Mallard Ducks, guineafowl, pheasants, geese (3 serotypes) and Muscovy Ducks.[43,51,264,265,304,449]

Group II: Turkey hemorrhagic enteritis virus, marble spleen disease virus and chicken splenomegaly virus. The common group antigen is distinct from that of group I.

Group III: contains only the virus associated with infectious salpingitis (Galliformes) and a similar virus isolated from ducks (see Color 29). This virus subtype shares some common antigenic sites with group I adenoviruses. This group of aviadenoviruses has hemagglutination activity.

Adenovirus particles are 70 to 90 nm, nonenveloped and contain double-stranded DNA. Virions are icosahedral and are composed of 252 capsomeres arranged in triangular facets with six capsomeres along each edge. There are 240 nonvertex capsomeres (hexons) and 12 vertex capsomeres (penton bases). The latter contain projections (called fibers). Members of Aviadenovirus group III contain one fiber and group I has two fibers (one long and one small). There appears to be a relative relationship between the length of the fibers and the antigenicity of the virus.[109,267]

Adenovirus replicates in the nucleus producing basophilic intranuclear inclusions. The strains have been divided into two subgroups, A and B, on the basis of their cytopathogenicity (the same as with human strains): Subgroup A (eg, FAV 1, FAV 2, FAV 4, FAV 5, FAV 8); Subgroup B (eg, FAV 5, FAV 6, FAV 7, FAV 9, Turkey [TAV] 1, TAV 2,). The differentiation in subgroups A and B may also reflect some differences in pathogenicity. Subgroup A viruses induce refractive, small, roundish inclusions surrounded by a clear halo and tend to cause persistent infections with sporadic disease. Subgroup B viruses induce nonrefractive, irregular, eosinophilic inclusions that fill the nucleus and may cause epornitics, with a tendency not to persist in the host.

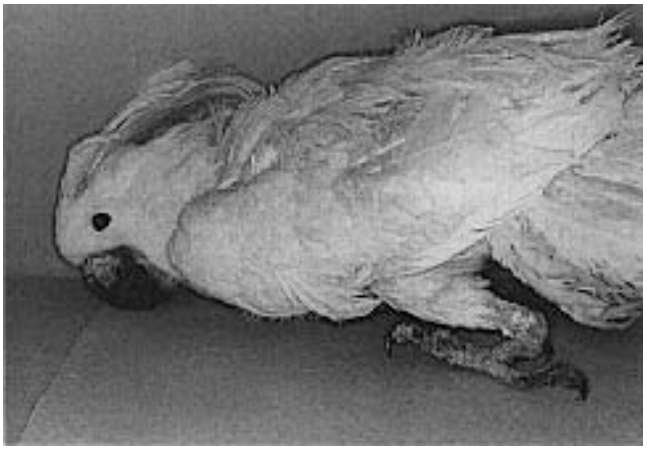
Aviadenovirus are distributed around the world, and many avian species of all age groups are known to be susceptible. Because the isolation of previously uncharacterized aviadenovirus is to be expected, it is likely that the current host range is incomplete.

Transmission

Transmission is known to occur through the oral route, and inhalation is suspected. The virus is excreted mainly in the feces. Latently infected birds experience cyclic changes of the amount of humoral antibodies and virus titers and vice versa. Egg transmission plays a role in the maintenance of infections in a flock. A breeder hen may pass either virus or antibodies to the egg. The primary change in infected eggs is reduced hatchability.

Pathogenesis

Infection with aviadenovirus does not necessarily produce clinical disease, although defined diseases have been characterized, and variability in virulence is known to occur. The factors that govern virulence



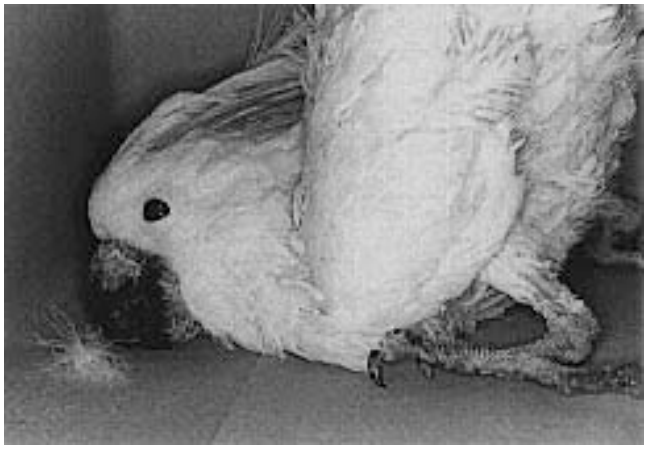


FIG 32.20 A Moluccan Cockatoo was presented with a progressive neurologic disease characterized by ataxia, tremors, head pressing and death. Intranuclear inclusion bodies suggestive of adenovirus were demonstrated by histopathology (see Color 32.13).

have not been conclusively defined; however, in addition to intrinsic damage caused by virus replication in the cells, the structural proteins of the pentons are thought to be directly toxic to host cells. During the lytic cycle of many adenoviral infections, host synthesis of macromolecules (cellular DNA, various proteins, mRNA) stops causing the host cells to die.[177]

Aviadenovirus is generally considered to be an opportunistic pathogen. Identified triggering factors in chickens include immunosuppression caused by infectious bursal disease and the chicken anemia virus.[267] Reoviridae have been implicated as factors in nondomesticated avian species. Some highly virulent strains of aviadenovirus are capable of producing disease alone (hydropericardium syndrome). Aviadenovirus can trigger secondary infections by inducing mild histopathologic lesions without clinical signs. Common microscopic lesions are degeneration of hepatocytes, enterocytes and respiratory epithelial cells. These lesions allow secondary bacteria, fungi and protozoa to enter the host. Parvoviruses that require an adenovirus for replication have decreased *in vitro* growth and pathogenicity.[29,267]

Clinical Disease and Pathology - Group I

Many avian species are known or are suspected to harbor adenovirus. A large number of strains have not been typed and in many instances, the etiologic importance of the virus is unknown. Group I strains have been associated with respiratory signs, anemia, inclusion body hepatitis, intestinal disease, pancreatitis and nephropathies. Histopathologic lesions without clinical signs are also common. The majority of aviadenovirus infections may be latent and subclinical. In other cases, adenoviruses have been isolated or detected by inclusion bodies or electron microscopy from birds with CNS signs (Figure 32.20) (Color 32.13).[143]

Gross lesions are nonspecific including tracheitis, swelling of the liver or kidneys and catarrhal enteritis. Histopathology reveals mononuclear cellular infiltrates in the lamina propria of the trachea, hypertrophy of the mucosal glands and finally loss of the epithelium. Liver lesions vary with the virulence of the strain, but may include vacuolated degeneration of the hepatocytic cytoplasm with lymphocytic infiltration in Glisson's triangles. In more severe cases, hepatocytes show intranuclear eosinophilic inclusions, which increase in size and become basophilic before developing a halo around the inclusion. In the pancreas, irregular necrosis, mainly of the exogenic cells, with and without intranuclear inclusions, has been described.[143] It should be emphasized that in avian species, inflammatory lesions generally develop more slowly than in mammals, and in many cases death occurs prior to inflammation so that hepatitis and enteritis may not occur.

Species-specific Considerations

- ***Guineafowl:*** FAV 1 is the principal isolate and will experimentally cause disease. The main lesion is necrotic pancreatitis, but some respiratory signs (air sacculitis) also occur. Intracerebral infections induce clonic-tonic type CNS signs. Young chicks are highly susceptible. Older birds are more resistant, and disease has been established only by parenteral routes.[304,329,447]

- ***Japanese Quail:*** An adenovirus was isolated from chicks with CNS signs. The strain could not be se-

rologically typed, but nucleic acid analysis showed that it is closely related to FAV 4.[243]

- ***Quail Bronchitis (QB):*** Quail bronchitis virus was first described in 1950 and only Bobwhite Quail (captive and free-ranging) are susceptible.[297] Mortality can reach 90% in young birds up to six weeks of age. Older quail show an age-linked resistance. The virus is serologically related to FAV 1, but nucleic acid sequences are different.[243] These nucleic acid differences might be the cause of an adaptation to Bobwhite Quail, a slow replication in chicken tissue and the failure of vaccination with CELO-type vaccines.

  QB is highly infectious and spreads to young quail mainly through direct contact. Vertical transmission should be expected, although this route has not yet been confirmed.

  Clinical signs include sudden death or signs of respiratory disease, such as tracheal rales, coughing, ballooning skin over the infraorbital sinus, sneezing, increased lacrimation and conjunctivitis. The severity of disease depends on the age of the host, and milder signs may be observed in birds older than three weeks. Gross lesions may not occur or can include catarrhal tracheitis with an excess of clear mucus in the air sacs or pulmonary edema.[143,186,432] Hepatic necrosis has been described.[214] Intranuclear inclusion bodies suggestive of adenovirus may be seen in the tracheal epithelium two to five days post-infection as well as in the epithelial cells of the bronchi. Proliferation of lymph follicles and lymphocytic infiltrations are evident.

- ***Pigeons:*** FAV 8 has been isolated from pigeons, and other reports have suggested infections based on histologic lesions from cases in which virus could not be isolated.[121,265] Virus particles morphologically suggestive of adenovirus have been reported in the nuclei of hepatocytes from pigeons although the typical paracrystalline arrays could not be demonstrated. The adenovirus failed to grow in culture but reovirus was isolated.[120] Pigeon herpesvirus has also been isolated from birds suspected of having adenovirus, suggesting that the role of FAV strains in causing inclusion body hepatitis and inclusion body enteritis in pigeons requires further documentation.[265,411] An FAV strain isolated from pigeons[267] did not cause lesions in chickens following experimental infection.[259]

  Pigeons have been described with clinical signs of anorexia, a "crouching position" for one to two days, ruffled plumage, slimy green droppings, polydipsia, polyuria, watery overload of the crop, vomiting and respiratory distress.[80] At necropsy, affected birds had hepatomegaly and splenomegaly, with the former being friable and mottled. In one case, the only lesion was swelling of the respiratory tract mucosa and in another, hemorrhagic enteritis and ecchymosis in the liver were observed. Histopathologically, liver degeneration or coagulative necrosis with basophilic intranuclear inclusion bodies was the main lesion. The kidneys sometimes showed degeneration of the tubular epithelium. In one case, intranuclear inclusions were also found in the pancreas.

  Six strains of an adenovirus were recovered from these birds, four of which were serologically related to chicken adenovirus, and two of which could not be serologically typed. Interestingly, these strains were isolated from the pigeons with atypical macroscopic lesions.

  A chronic enteritis was described in mainly young pigeons with some adults affected.[36] Diarrhea and lethargy were the main clinical signs. Necropsy lesions were nonspecific. Histopathologically, club-shaped, damaged villi in the duodenum and jejunum became vacuolated, pycnotic and desquamated. Intranuclear inclusion bodies containing adeno-like virus particles (basophilic and in part eosinophilic) may be seen in apical and medial enterocytes. Lymphocytic, heterophilic infiltrates occur in the intestine, liver and other parenchymatous organs.

  Differences in clinical signs and pathology associated with adenovirus infections in pigeons suggest that more than one virus with varied organ affinity may infect these birds. Further studies are needed to elucidate the importance of adenovirus in pigeons.

- ***Goshawk:*** FAV 1 was isolated from a free-ranging Goshawk that experienced clonic-tonic type CNS signs and died shortly after being recovered from the wild. The brain showed neuronal necrosis, satellitosis and proliferation of glial cells.[396] Adenovirus was suspected in a captive American Kestrel with hemorrhagic enteritis and in a Merlin with hepatitis.[379]

- ***Psittaciformes:*** Clinical and histopathologic lesions suggestive of adenovirus infections have been described in several members of the order.

  Pancreatitis and nephropathies have been the two main lesions described in lovebirds. Gross necropsy findings were enlargement of the proventriculus and the duodenum. Acute necrotizing pancreatitis with large basophilic intranuclear inclusion bodies in the

exocrine cells was the main histopathologic lesion. Similar inclusions were described in enterocytes. Adenovirus (serotype not reported) was isolated from Nyassa Lovebirds with inclusions in hepatocytes and splenocytes.[132,143]

Adenovirus-like intranuclear inclusions have also been described in the otherwise normal renal tubular epithelium of clinically normal lovebirds. In other birds, numerous inclusions were associated with tubular necrosis and subacute interstitial nephritis.[246] Renal lesions were also described in Masked Lovebirds with a severe edematous conjunctivitis (30% mortality).[189] The endothelial cells of the conjunctiva and renal epithelium contained inclusion bodies suggestive of adenovirus. Inclusions in the renal tubules have been shown to be located also within the rami ureterici.[280]

Adenovirus-like particles have been connected with acute onsets of mild diarrhea and lethargy in Eclectus Parrots. Hepatitis with subcapsular hemorrhage and enteritis (in some birds hemorrhagic) were the main lesions. Inclusions were evident in hepatocytes and enterocytes together with diffuse inflammatory invasion of the intestinal mucosa. Irregular, discrete interstitial pneumonia and rapid death were also described.[326]

Basophilic intranuclear inclusions were observed mainly in enterocytes of *Pionus* spp. and *Neophema* spp. with persistent torticollis and other CNS signs.[247] Clinical changes were similar to those described with paramyxovirus infections. Lymphoplasmacytic meningoencephalomyelitis and pancreatitis were the main histologic lesions.

Adenovirus was isolated from two budgerigars with individual histories of enteritis and sudden death.[265] An adenovirus epizootic of one year's duration was described in budgerigars, generally adults one to three years old, in Germany. Clinical signs included acute torticollis, opisthotonus, tremor and convulsions. Birds that were able to maintain sufficient orientation to eat and drink usually survived. Gross lesions were unremarkable. Nonpurulent encephalitis, proliferation of glial cells and degeneration and lysis of ganglion cells were the principle histologic lesions. Nonspecific hepatitis with infiltration of mononuclear cells was evident in prolonged cases. Adenovirus was isolated from two affected birds. One isolate was serologically related to FAV 2 and FAV 11, and the other to FAV 4.[107]

Restriction enzyme analysis of the DNA from these isolates revealed similarities to other FAV isolates; however, the budgerigar strains were found to contain unique nucleic acid sequences. Experimental infections resulted in the induction of histopathologic lesions in the absence of clinical disease. Adenovirus-like particles were demonstrated by electron microscopy in large basophilic intranuclear inclusion bodies in the hepatocytes of cockatiels with enlarged necrotic livers.[372]

An epizootic of adenovirus-induced hepatitis has been described in a group of Psittaciformes in a collection of zoo birds.[47] Affected birds included Green-cheeked Amazon, Patagonian Conure, Eastern Rosella, Hyacinth Macaw and a Lesser Sulphur-crested Cockatoo. Hepatitis and enteritis suspected to be caused by adenovirus has been described in Moluccan and Rose-breasted Cockatoos. Adenovirus was described as the cause of acute pancreatic necrosis in an Umbrella Cockatoo.[122,305a,320a]

- ***Waterfowl:*** An epornitic of adenovirus was described in captive Muscovy ducklings in France. Affected animals were lame and emaciated. Birds began to die suddenly at about 35 days of age, and mortality rates averaged 1 to 1.5% of the flock daily for about ten days. A serologically distinct adenovirus was isolated from affected birds.[43] Tracheitis (diphtheroid) accompanied in some cases by bronchitis and pneumonia was described in 10% of two- to three-week-old Muscovy ducklings in another outbreak. Adenovirus-like particles were located within the epithelial cells of the trachea.[37]

Three serotypes of adenovirus have been described in goslings;[449] but virus isolated from the cases did not produce clinical or pathologic lesions in experimentally infected birds. Inclusion body hepatitis was described in goslings with high mortality and adenovirus-like particles in the nuclei of the hepatocytes.[335] Adenovirus-like inclusion bodies have been found in hepatocytes of free-ranging Herring Gulls[235] and the Tawny Frogmouth.[328]

Diagnosis

A definitive diagnosis based on clinical or pathologic changes is not possible. Virus isolation is best achieved from the feces, pharynx, kidneys and liver. Chicken embryo liver or kidney cells and embryonated chicken eggs are suitable for recovering FAV 1 (chickens). Serotypes can be identified using VN or plaque reduction assays. Adenovirus-specific DNA probes have been developed for demonstrating viral

nucleic acid in infected tissues and clinical samples (Niagro FD, unpublished).

Group-specific antibodies can be demonstrated by ID and ELISA. The presence of antibodies indicates that an infection has occurred but does not indicate what part, if any, an Aviadenovirus may have played in a disease process. Histopathology, together with *in situ* hybridization, electron microscopy or virus isolation are necessary for this differentiation. With the number of adenovirus serotypes, a monovalent vaccine would be of questionable value. Vertical transmission and the continuous cycle of viremia followed by antibody production in infected birds makes it exceedingly difficult to produce uninfected offspring.

Group II

The adenovirus that cause hemorrhagic enteritis in turkeys, marble spleen disease (MSD) in pheasants (captive birds only, not documented in free-ranging birds), and chicken adenovirus group II splenomegaly are considered serologically identical;[78,185] however, restriction endonucleases can be used to show that there are genetic differences between the viruses isolated from varying hosts.[78,448]

In the Common Pheasant, MSD virus replicates mainly in reticular cells of the spleen. Young birds are most frequently infected between ten to twelve weeks of age. Acute death may occur without clinical signs or preceded by a brief period of anorexia and dyspnea caused by severe pulmonary edema. Grossly, the spleen may be enlarged two to three times its normal size and is frequently mottled with multiple, grayish, confluent foci. The lung may be congested, edematous and in rare cases, hemorrhagic. Histopathologically, the spleen shows a distinct lymphoreticular hyperplasia with intranuclear inclusion bodies in RES cells (also in liver, lung and proventriculus).[143] Extensive deposits of a slightly fibrinous material (moderately PAS-positive) may be present. These deposits are considered to be amyloid.[185,442] Multiple small foci of necrosis may be present in epithelial and endothelial cells in the lungs.

Suspected adenovirus infections in White and Pearl Guineafowl are characterized by acute pulmonary edema, splenomegaly and ascites. The postmortem and histopathologic findings resemble those seen with MSD and avian adenovirus group II splenomegaly in chickens. Suggestive intranuclear inclusion bodies may be seen in hepatocytes, splenocytes and pneumocytes. Antigen could not be demonstrated by cultural and serologic methods. Pearl Guineafowl experimentally infected with pheasant or turkey group II adenovirus developed lesions that were identical to those described in a natural outbreak.[66]

Diagnosis

The clinical and pathologic signs are suggestive of the disease. The principal rule-outs are various intoxications and reticuloendotheliosis. The virus is difficult to demonstrate in culture (lymphoblastoid B-cells derived from Marek-induced tumors are best for isolation). The agent forms intranuclear inclusion bodies, particularly in splenic cells, and the presence of viral particles consistent with adenovirus can be demonstrated by electron microscopy. Adenovirus-specific DNA probes designed to document infections in Psittaciformes can also be used in pheasants and chickens (Niagro FD, unpublished).

Group III

The natural host of adenovirus group III appears to include various ducks from Europe and Asia that are asymptomatically infected.[30,54] In contrast to other aviadenoviruses, group III strains have hemagglutination activity. Serologic evidence suggests group III strains may also infect turkeys, domesticated geese, Muscovy Ducks, chickens and Cattle Egret.[142,251,267] Like ducks, these hosts appear to become infected without developing clinical or pathologic signs. Adenovirus antibodies were demonstrated in flocks of guineafowl laying soft-shelled eggs. Similar problems occurred when 86-week-old guineafowl were infected orally with EDS 76 strain 127 adenovirus.[141] Experimental birds seroconverted following infection. Virus recovery is necessary for a definitive diagnosis. Cloacal swabs or material from the female genital tract are good diagnostic samples. HI using virus-specific antibodies can be used to confirm the presence of the virus in a cell culture. Group-specific antibodies cross-react with FAV, and the HI test is best suited for demonstrating group III specific antibodies.[279]

Unclassified

Viral particles suggestive of adenovirus have been demonstrated electron microscopically from captive American Kestrels with hemorrhagic enteritis. The antigen does not react with aviadenovirus group II antibodies. Clinical signs include melena, regenerative anemia and high mortality. Gross lesions include

hyperplasia of the white pulp in the spleen and petechiation in the mucosa of the esophagus, colon and coprodeum. Histopathology reveals diffuse hepatocellular necrosis with two types of intranuclear inclusions: eosinophilic Cowdry type A and basophilic Cowdry type B. In addition, disseminated intravascular thrombi and necrosis of the myocardium may be evident.

A disease that clinically mimics MSD has been described in Blue Grouse. Nonenveloped, 100-110 nm viral particles have been observed in the nuclei of splenocytes. The disease has not been experimentally reproduced and it is uncertain if an adenovirus is involved. Clinical signs are lethargy, ruffled plumage, foamy, watery diarrhea and death. Some birds may develop rales or other respiratory signs. At necropsy, the lungs are dark red and firm, and the spleen is enlarged with whitish foci. The lumen of the intestines may be filled with a brownish, liquid material. Histopathology reveals multifocal fibrinoid necrosis, destruction of lymphocytes and reticular cells with basophilic or eosinophilic inclusions within the nuclei of RES cells. In addition to congestion and edema of the lungs, interstitial pneumonia and fibrinous pleuritis may also be noted.[143]

Parvoviridae

The family Parvoviridae consists of nonenveloped, single-stranded DNA viruses of hexagonal morphology with an estimated 32 capsomeres and a size of 19 to 25 nm. Members of the genus Parvovirus are self-replicating, in contrast to the genus Dependovirus, which require helper viruses. Parvovirus replicates in the nucleus of the host cells and depends on rapidly dividing host cells. Avian parvoviruses induce intranuclear inclusion bodies of the Cowdry A type, and form syncytia in cell cultures. Among others, parvovirus has been associated with disease in chickens and enteropathy in turkeys.[218,406]

Goose Parvovirus Infection (Derzsy's Disease)

This virus has been associated with all major goose-farming countries in Europe and Asia. The main host is probably the domesticated goose, but the Canada Goose, Snow Goose and Muscovy Duck are also susceptible. Experimental infection is possible in cygnets of the Mute Swan. The virus is strongly host-specific and requires rapidly dividing cells (DNA synthesis) to replicate. Currently, the virus is considered serologically uniform.

Transmission and Pathogenesis

This virus is highly infectious, and transmission is possible horizontally via oral and nasal routes and transovarially by freshly infected, non-immune breeder geese. Latent infections in adults is epizootiologically important. Non-immune goslings or Muscovy ducklings between 1 to 21 days of age are most susceptible to infection. In older birds (two to ten weeks), infections are characterized by mild, protracted signs or are subclinical and latent. Following entry into the host, virus is distributed to the target organs including the liver, spleen, heart, adrenal gland, thyroid gland and thymus. Therefore, viremia is normally not demonstrable. Virus is shed from the fifth to sixth day following infection, and shedding may persist in some individuals for approximately six months. The intensity, course and mortality rate of the disease is governed by maternal immunity; however, age-related resistance is independent of humoral antibodies beyond the age of four to six weeks. The half-life of the maternal antibodies is between two and one-half to three days.[360]

Clinical Disease and Pathology

Anorexia and polydipsia followed by cessation of water intake are the earliest clinical signs. Goslings appear chilled and occasionally develop conjunctivitis, diarrhea and diphtheroid membranes on the tongue. Somnolence, weakness and giddiness occur prior to death (up to 100% mortality). In older birds that survive, down feathers may fall out, particularly on the neck, wings and back. The skin may be hyperemic and the uropygial gland swollen. The chronic disease is characterized by growth retardation, difficulties in standing or walking and occasionally, convulsions. An accumulation of ascitic fluid may cause a penguin-liked posture. Newly developing feathers may be brittle.[123,143,359]

Clinical and pathologic signs may be influenced by the age and immune status of the host as well as concomitant infections with other goose viruses (see reovirus or "nephroenteritis") or opportunistic pathogens including bacteria, *Mycoplasma* spp. and fungi.

Gross lesions include hepatomegaly with subcapsular petechial hemorrhage and bile congestion together with a small, limp spleen and a highly enlarged thyroid gland. Chronic disease can cause the

formation of serofibrinous fluid in the abdominal cavity. Hemorrhagic fibrinous enteritis, pin head-sized necrotic foci in the pancreas, hemorrhage within the cloacal bursa, degeneration of the myocardium and viscous mucus in the nasal cavity and on the surface of the proventriculus may be noted.[146]

Histopathology reveals a serous hepatitis with necrosis of the hepatocytes and intranuclear inclusion bodies, which can stain eosinophilic or basophilic with HE. Perivascular infiltrations of inflammatory cells occur in prolonged cases and occasionally proliferations of connective tissue occur. Necrosis of the pancreas and edema of the lung are typical of the acute disease. Hyperactive follicular epithelium with a large quantity of cytoplasm and large, lightly colored nuclei are common in the thyroid gland. The follicles are either completely filled with colloid or empty. Bud-like proliferation of the epithelium can be seen at certain sites. There is no interstitial cellular reaction with inflammatory cells. Lesions in the myocardium including degeneration with loss of the striation and interstitial edema, especially around the capillaries, are common with chronic disease. An increase in histiocytes and lymphocytes can be observed in these areas.[146]

Diagnosis

Liver, pancreas and thyroid glands are suitable material for virus isolation. Virus identification can be carried out with VN, ELISA or IF. Latently infected birds can be identified by demonstrating humoral antibodies. Antibodies appear five to ten days following infection and persist for approximately one year. Persistent titers indicate that the animal in question is a carrier or has been exposed.

Clinical signs associated with parvovirus in goslings are similar to those caused by reovirus and nephroenteritis, but the three diseases can be differentiated. Because mixed infections are possible, virus isolation might be necessary to clarify the inciting organisms. Reovirus infection of goslings causes predominantly respiratory signs and changes on the cutaneous mucosa and striated muscles (including heart muscle). Parvovirus infection of the gosling is a hepatic disease (with intranuclear inclusion bodies), small spleen and changes in the thyroid gland. Nephroenteritis of the gosling occurs later in life than the other two diseases and is characterized by hemorrhagic nephritis and enteritis.[123,359,407]

Control

Because maternal antibodies successfully prevent the disease in goslings, vaccination of the breeder geese at least six weeks before the beginning of egg production is recommended. An attenuated strain, which is actually an apathogenic mutant, is available as a vaccine. This strain is effective only when given intramuscularly.[217] Breeding geese without antibody titers should be vaccinated twice. A booster vaccination might be necessary for the second half of the breeding season to prevent hepatitis in goslings hatched late in the breeding season.

Myocarditis and Encephalopathy in Canaries

Myocarditis and encephalitis were described in association with a virus that morphologically resembled parvovirus in three adult canaries from different origins. It is unusal, however, that a parvovirus would cause disease in an adult bird.[168]

The clinical picture was different among affected birds and ranged from sudden death to depression, emaciation and ruffled plumage. Some birds had no gross lesions while others had splenomegaly (three times normal size). Histopathology revealed nonsuppurative myocarditis with intranuclear eosinophilic inclusion bodies. Neurons in the brain stem contained similar inclusions, but there was no inflammatory reaction in the brain. The enlarged spleen of one bird showed increased numbers of macrophages and amyloid deposits.[168]

Hepadnaviridae

The Hepadnaviridae virion is 40 to 60 nm in diameter with an icosahedric, enveloped, symmetric nucleocapsid consisting of one highly immunogenic protein. The virus contains partially double-stranded circular DNA.[368,430]

Closely related taxons of Orthohepadnavirus (formerly hepatitis B virus) have been recovered from humans, ground squirrels, woodchucks and tree squirrels. Related avian taxons (formerly duck hepatitis B group now in the newly formed genus Avihepadnavirus) have been described in the Pekin Duck and domestic goose.[177a] Another strain has been recovered from the Grey Heron. Avihepadnavirus is

strongly host-specific, and infected birds should pose no danger to humans. Avihepadnavirus is less oncogenic than mammalian strains. It has been suggested that avian strains require co-carcinogenic factors to induce neoplasms. One of those hypothetical co-carcinogens could be, for instance, high doses of aflatoxins.[393] Infection with Avihepadnavirus is a triggering factor for clinical and pathologic changes of the new duck syndrome (see Chapter 33).

The Avihepadnavirus are distributed worldwide in commercial duck and goose farms. Generally, infections are subclinical in ducks and geese. Transmission takes place vertically and leads to chronic viremia without the development of humoral antibodies. This pathogenesis is different from human infections in which lesions are partially induced by the elimination of virus-infected cells by the immune system. This mechanism explains why experimentally infected ducks can develop mild hepatic lesions. The Grey Heron strains are different but related to duck and goose strains.

Infected birds with chronic viremia have extremely high viral titers (10^{11} particles/ml serum) so that the virus is directly demonstrable without enrichment procedures.[430] Demonstration of antibodies in birds with vertically derived infections is not possible. Serum and egg yolk are suitable material for diagnosis.

Reoviridae

The family Reoviridae consists of three genera: Orthoreovirus,[176a] Orbivirus and Rotavirus.

Avian Orthoreovirus

Members of the genus Orthoreovirus are divided into mammalian or avian strains. Orthoreovirus virions are nonenveloped, icosahedral, double-capsid particles measuring 75 nm in diameter. The genome is a double-stranded RNA segregated into at least three size classes.[349] The virus replicates in the cytoplasm of the host cells. Avian orthoreoviruses are serologically different, although most strains share a common antigen, which can be demonstrated by immunodiffusion. Hemagglutination activity is not present in avian strains. Because frequent cross-reactions are reported, it seems that avian orthoreovirus strains exist as antigenic subtypes rather than as distinct serotypes.[349] At least 11 of these subtypes have been differentiated.

Avian orthoreoviruses occur worldwide; the current host range include chickens, pheasants, quail, turkeys, ducks, geese, pigeons, birds of prey, Psittaciformes and other companion and aviary birds. Two reovirus strains isolated from Muscovy Ducks were found to be closely related to each other, but did not cross-react with a chicken strain (BIII3). One of the isolated strains was found to be virulent for Muscovy ducklings while the other strain was avirulent.[164]

Transmission

Ingestion of viral particles is probably an important route of infection, but respiratory transmission is also possible. Vertical transmission is epornitically fundamental in chickens and turkeys and has been proven to occur in Muscovy Ducks and domesticated geese. The methods of transmission for many avian reovirus strains are only speculative. Psittacine birds experimentally infected by IM injection were found to shed virus in the feces two days post-infection, with shedding persisting for 15 days. Pigeons infected orally with reovirus were found to shed virus in the feces two to five days post-infection.

Pathogenicity

Orthoreovirus infections are prevalent in many avian species, but their role in the disease process for most hosts is uncertain. Replication of the virus takes place in the intestinal tract, and the role of orthoreovirus in a variety of enteric conditions in poultry has been discussed.[349] The pathogenesis of orthoreovirus infections has not been clearly defined, although strain differences in virulence are known to occur. Many strains may induce latent infections, which may impair the immune system and result in immunosuppression.[350] Chicks infected during the first week of life have a depletion of lymphocytes in the cloacal bursa, hyperplasia of various reticular cells and inhibition of lymphocyte immigration as well as hyperplasia of reticular cells in the spleen (Montgomery, unpublished). The occurrence of cryptosporidiosis in Bobwhite Quail infected with orthoreovirus also suggests an immunosuppressed state.[237,239] Infected chickens develop hypoglycemia presumably caused by lesions in the pancreas.[112,258]

Development of humoral antibodies may provide protection from the disease; however, fecal shedding occurs in persistently infected birds even though antibody titers are present.[112,211]

Clinical Disease and Pathology

- ***Psittaciformes:*** The clinical signs reported in Psittaciformes vary among infected hosts. An infected cockatoo (species not given) and Grey-cheeked Parakeet developed non-specific clinical signs including emaciation, incoordination, labored breathing and diarrhea. Reovirus and *Chlamydia* sp., were recovered from the Grey-cheeked Parakeet. Only reovirus was recovered from the cockatoo.[278] Enteritis, liver congestion, necrosis and in some cases, a swollen spleen are common pathologic changes in African Grey Parrots (mortality up to 100%), Senegal Parrots, Jardine's Parrots, Alexandrine Parakeets (mortality up to 70%), Rose-ringed Parakeets, Hawk-headed Parrots, Rosy-faced Lovebirds, rosellas (up to 69% mortality) and Yellow-fronted Parakeets.[61,62,275,423] Chronic respiratory infections have been described in Amazon parrots (Figure 32.21).[423] African Grey Parrots may develop uveitis, although this is rare in uncomplicated reovirus infections.[61,62] Ophthalmic lesions are characterized by a fixed, dilated pupil and reticular hemorrhages followed by uveitis, hypopyon and fibrous exudates in the anterior and posterior chambers.

  It has been suggested that Old World Psittaciformes are highly susceptible to orthoreovirus, while New World Psittaciformes may be infected but are more resistant to disease.[61] Clinical pathology associated with infections include anemia, leucopenia (with 90-100% lymphocytes), hypoalbuminemia, hyperglobulinemia and increased levels of AST and LDH late in the disease process. In many cases, orthoreovirus is not the only infectious agent involved in a disease process, complicating the interpretation of lesions; however, African Grey Parrots have been infected with isolated virus, fulfilling Koch's postulates.[133]

  Necropsy findings in affected cockatoos, African Grey Parrots and other Psittaciformes include exsiccosis, swollen liver, swollen kidneys with urate depositions and splenomegaly.[61,133] Necrotic foci may be located in the lungs in association with thrombi.

  Histopathologic findings include multifocal coagulative necrosis of the liver and occasionally nephritis with infiltrates of macrophages, heterophils and lymphocytes. Similar infiltrates may be noted in the lamina propria of the intestinum.[278] The spleen is frequently congested with necrosis of the reticular sheaths around blood vessels. Splenic lymphocyte depletion may occur and is probably governed by the chronicity of the infection. The frequent occurrence of thrombi are indicative of a consumptive coagulopathy.[133]

FIG 32.21 Reovirus has been suggested as a cause of chronic respiratory infections in Amazon parrots. Diagnosis requires virus isolation from samples collected from affected respiratory tissues.

- ***Pigeons:*** In infected pigeons, the most frequent clinical signs are diarrhea and dyspnea.[265,370,408] Virus is found mainly in the cloaca, but can occasionally be recovered from the respiratory system. A catarrhal enteritis is a common necropsy finding. A strain isolated from a pigeon liver lesion did not produce recognizable macroscopic or histopathologic lesions following oral inoculation.[161,416] A serologic survey in Belgium and West Germany revealed carriers of antibodies among homing pigeons as 8% and 16%, respectively.[161,416]

- ***Muscovy Ducks and Mullards:*** Mullards are a cross between Muscovy Ducks and Mallards, raised (particularly in France) as table birds because of their fine meat. While Mallards are resistant to the disease, Mullards are highly susceptible. Growth inhibition and impaired development of the plumage has been described in affected three-week-old Muscovy ducklings. In severe outbreaks, up to 90% mortality may occur. At necropsy, pericarditis and air sacculitis of the anterior air sacs are the main findings, frequently accompanied by hyperplasia of the spleen and perihepatitis.[108] A similar disease has been described in Muscovy ducklings between ten days and six weeks of age.[250] Hepatomegaly and splenomegaly with slightly elevated pinhead-sized necrotic foci were consistent lesions. Histopathologic lesions, if present, included coagulative necrosis and a mild lymphocytic infiltration. Experimentally exposed geese, Pekin Ducks and chickens did not succumb to disease.

- ***Geese:*** A reovirus has been found to cause infectious myocarditis in geese.[224] Five- to twenty-one-day-old goslings may develop clinical signs following infection. Older birds appear to be resistant. After an incubation time of three to six days, sudden death or somnolence, anorexia, increased water consumption, mild nasal discharge and conjunctivitis, dyspnea and, more rarely, watery, grayish-white diarrhea can be observed. The body temperature decreases to 38°C. The skin of the beak and feet becomes brownish and peels off. Weakness of the legs caused by myositis and occasionally paresis of the neck musculature or tremors can be observed. Survivors are stunted. Muscovy Ducks were also found to be susceptible. In these birds, the virus replicates in the intestinal tract but does not cause clinical or pathologic lesions.

  At necropsy, besides dehydration, a distinct dilatation and gray discoloration of the heart is seen, as well as pericarditis, catarrhal rhinosinusitis, pulmonary edema, air sacculitis of the thoracic air sacs and dystrophy of the liver.

  Histopathology reveals Zenker's degeneration and necrosis of the myocardium and skeletal muscle, proliferation of the myocardial syncytium, inflammation that is restricted to the subepicardial connective tissue and as pericardial and subendocardial edema. Hemorrhagic interstitial nephritis or coagulative necrosis may also be noted.[150]

- ***Finches (Estrildidae and Ploceidae):*** Clinical signs in finches are associated with enteritis and swelling of the liver, which can be severe enough to be noted through the abdominal skin. At necropsy, disseminated yellowish, greasy or soft foci, which histopathologically represent focal coagulative necrosis, can be observed. Infiltration by monocytes and lymphocytes is seen in the liver, the kidneys and the lamina propria of the intestinal tract. In the spleen, destruction of the reticular cells can be observed as well as ecchymosis in the subcutis, epicardium and other serosal membranes.[150]

Diagnosis

Lesions in ducks and geese can be similar to those caused by parvovirus and nephroenteritis, respectively. Cloacal swabs and samples from the rectum and affected parenchymatous organs are best for viral isolation. Demonstration of viral antigen in affected tissues is possible by IF; however, only positive results provide conclusive evidence because the test is not sensitive enough to demonstrate small numbers of viral particles.

The presence of virus in cell culture can be confirmed by the detection of group specific antigen in the ID test.

Most reovirus strains isolated from Psittaciformes show no serologic relationship with those in gallinaceous birds.[61,275]

Specific antibodies can be demonstrated by ID, but their presence is difficult to interpret because of the frequent occurrence of strains that are not pathogenic. A more than four-fold increase in titer of paired serum samples would be indicative of an active infection, but there might be some doubt as to the importance in a recent disease process.

Control

Commercially available vaccines for poultry are ineffective in Psittaciformes because of antigenic variance among strains. An inactivated vaccine produced from a reovirus recovered from parrots was found to reduce losses associated with an outbreak. Live vaccines designed for use in chickens (viral arthritis) increased survivability (85% survivors if given 100 chicken doses per bird) when used in Muscovy ducklings.[255] Goslings may be provided with passive immunity at hatch by subcutaneous administration of hyperimmune serum.

The use of chlorhexidine in the drinking water (20 ml per gallon of water) was thought to reduce the transmission of reovirus infection in a flock of African Grey Parrots. Long-term use (up to 30 days) may be necessary, and there were no observable side effects from this length of chlorhexidine exposure.[61]

Orbivirus

Orbivirus is a genus of the Reoviridae that depends on insects such as culicoides, phlebotomus and ticks for transmission. An orbivirus has been isolated from a cockatiel and a budgerigar.[174] The cockatiel died suddenly and at necropsy displayed degeneration of the myocardium, a swollen liver and spleen and cloudy air sacs. In the case of the budgerigar, dyspnea, photophobia and ruffled plumage was observed prior to death. Postmortem examination revealed atrophy of the pectoral muscles, catarrhal enteritis and a slightly swollen liver. Experimentally infected budgerigars developed severe greenish diarrhea for four to eight days with no pathologic lesions noted on postmortem examination. Infected birds seroconverted, and reisolation of the virus was possible from the feces.

The viruses isolated from both these birds were serologically related but were distinct from other orbiviruses tested.[174]

Rotavirus

Rotaviruses have more clearly defined outer edges than other Reoviridae, which can be used to differentiate them by electron microscopy. The outer capsid may not be present in noninfectious single-shelled particles. These can morphologically resemble orbivirus and are about 10 nm smaller than the intact virus. The double-stranded genome has 11 segments. During replication within the cytoplasm, some particles appear to bud through ribosome-free areas of endoplasmic reticulum. Virus is released by cell lysis.[270]

Avian rotaviruses are thought to be serologically unique from each other and from mammalian rotaviruses. Only chicken and turkey strains have been classified.[270] Some avian group A rotaviruses agglutinate erythrocytes (human type 0 or guinea pig).

Rotaviruses are distributed worldwide and have been documented in chickens, turkeys, Helmeted Guineafowl, pheasants, ducks, pigeons and lovebirds. Avian strains are resistant to ether, chloroform, sodium deoxycholate, pH 3 and 56°C for 30 minutes.[270,276] The persistence of infectivity in the environment is not known.

Transmission and Pathogenesis

Rotavirus is excreted in the feces in high numbers, and can be transmitted by both direct and indirect contact. Ingestion may be the most important portal of entry. Infections in three-day-old poults suggest egg transmission, which has not been proven. The cross transmissibility between mammalian (including human strains) and avian strains is undetermined.

Rotavirus is a cause of enteritis and diarrhea in a variety of mammalian and avian species. The virus replicates mainly within the enterocytes of the small intestines. Some strains are known to replicate in the colon and cecum. Certain strains prefer the duodenum for replication, while others replicate in the upper portion of the jejunum. The virulence of the strains varies (in ducks they are nonvirulent). Because viral replication causes lysis of the host cell, the intestinal absorption in infected birds is dependent on the number of infected enterocytes. A decrease in the absorption of D-xylosis has been suggested as an indicator of enterocyte damage. Birds that overcome infections develop intestinal immunity via IgA and humoral antibodies (IgG), which are also transferred via egg yolk to the chick. Humoral antibodies do not protect against infection, even in the newly hatched chick.[270,286,357] Cell-mediated immunity is necessary for full protection.[357]

Incubation periods are short (one to three days) in chickens and turkeys. No information is available for companion or aviary birds.[270]

Clinical Signs and Pathology

Infected ducks do not develop clinical or pathologic signs of disease.[400] A short-term (five- to eight-day), self-limiting, transmissible enteritis has been described in the Helmeted Guineafowl.[303] This virus was serologically not related to a bovine strain as other strains were. Pheasants and partridges, especially those infected as chicks, may develop diarrhea and stunting and have increased levels of mortality (up to 30%).[129,408] In infected pigeons, a watery diarrhea may occur.[415] Rotavirus antibodies have been demonstrated in approximately 10% of the pigeons examined. A rotavirus isolated from a lovebird caused the death of a chicken embryo following yolk sac inoculation. The lovebird showed no clinical signs.[128]

Necropsy findings are nonspecific and are restricted to the intestinal tract in uncomplicated cases. The lumen of the intestine is filled with watery fluid and some gas, and the walls may appear pale. Histopathology reveals cellular infiltrates into the lamina propria, vacuolization of the epithelial cells of the villi and loss of enterocytes from the villi.

Diagnosis

Infection with astrovirus and several genera of the Picornaviridae can cause similar clinical signs. The rotavirus causes a shortened disease with a rapid recovery. Survival depends on the titer of infecting virus and the age and species of the host. Because many avian strains have not been grown in cell culture, electron microscopy is still a common method of identification. The contents of the colon and cecae are examined following treatment with fluorocarbon and ultracentrifugation. The demonstration of viral RNA by means of electrophoresis is also possible. Serologic diversity among strains, difficulties in propagating the virus and the widespread occurrence of the virus make the detection of antibodies to the virus difficult to interpret.

Birnaviridae

The virus of the infectious bursal disease is a member of this family. Disease is seen only in chickens. The virus destroys mainly the cloacal bursa of growing chicks causing a passing or (rarely) permanent immunosuppression (refer to textbooks on poultry disase).

Coronaviridae

The family Coronaviridae contains only the genus Coronavirus. Recognized taxons are the infectious bronchitis virus (IBV), turkey coronavirus and at least nine mammalian species. A coronalike-virus isolated from Japanese Quail has not yet been characterized.[302] Isolates from guineafowl and pheasants are serologically different from chicken strains.[124,287] Coronavirus has been reported as a cause of disease in Psittaciformes.[174] An enterotropic IBV was recently recognized as being distinct from other serotypes of IBV.[193]

Coronavirus has a pleomorphic but mainly rounded morphology and is 90 to 200 nm in diameter. It is enveloped with club-shaped surface projections (peptomers) about 20 nm long. It contains a single-stranded RNA.[213] Coronavirus replicates in the cytoplasm of the host cells.

Coronavirus is rather unstable at room temperature and samples for isolation should be stored below -20°C. Shipment of infected material is recommended on dry ice or in 50% glycerol. Lyophilization, preferably in 10% glucose (also for deep freezing), provides adequate stability; however, lyophilized IBV has to be stored in a refrigerator for long-term survival. Coronavirus is sensitive to ether and chloroform, and it is assumed to be sensitive to commonly used disinfectants.[213]

IBV is distributed worldwide and is not antigenically uniform. Chickens are the main host and may develop respiratory signs, interstitial nephritis, visceral gout or egg shell problems with decreased albumen quality. In central Europe, antibodies against IBV have been demonstrated in owls and some Passeriformes.[145]

Coronal enteritis is distributed primarily in turkey-raising countries, and the turkey is the only recognized host.[324]

- ***Pheasants:*** IBV has been isolated from pheasants in Great Britain with some regularity.[124,324] Seven isolates are antigenically closely related, but differ considerably from 12 chicken IBV reference and field strains.

  In adult birds, reduced egg production, poor egg quality, slight to moderate respiratory signs and low mortality associated with egg peritonitis, urolithiasis, visceral gout and swollen kidneys are typical. Mortality is highest in eight- to ten-week-old birds (up to 40%) with renal lesions being conspicuous.[124,241,389] An experimental infection of two-week-old pheasant chicks resulted in a short-term respiratory disease and production of long-term high antibody titers. Virus could not be recovered from the infected birds.[124]

- ***Guineafowl:*** IBV has been recovered from guineafowl with enteritis and hepatopancreatitis.[20,96] Anorexia and high mortality in young birds were common in affected flocks. Emaciation, pancreatitis, enteritis, dehydration and nephritis are common findings at necropsy. Clinical signs may start as early as three days of age. Experimental infections of chicks and guineafowl poults by the intranasal route resulted in mild respiratory distress and polyuria. The virus was characterized as an avian coronavirus but distinct from the Massachusetts serotype.

- ***Psittaciformes:*** Two coronavirus strains have been isolated from parrots (one unspecified species and a Cape Parrot). The two parrot strains appeared to be in the same taxon (which was not related to IBV and several mammalian coronaviruses).[173]

  Preliminary studies indicated that the virus is pathogenic for both chickens and budgerigars. The Japanese Quail proved to be refractory. Principal lesions were associated with necrotic hepatosplenitis. One-day-old chicks were particularly susceptible and died. Older chicks and budgerigars survived at least four weeks in spite of severe lesions in the liver and spleen. Interestingly, the experimental infection was easily established by ocular exposure, and contact spread occurred with both chickens and budgerigars.[173]

- ***Pigeons:*** IBV has been isolated from racing pigeons.[26] The strain was serologically identical to chicken strains in Australia (ie, subtype B). Isolated virus caused respiratory disease in experimentally infected chickens.

  Clinically affected pigeons showed ruffled plumage, dyspnea and excess mucus at the commissures of the beak. Eleven birds died during the first 24 hours following clinical signs. The rest of the flock (size not mentioned) recovered over the next two to three weeks. At necropsy, the birds were in average condition and had recently eaten, but the linings of the crop and esophagus were ulcerated. Mucoid pharyngitis and tracheitis were seen, and the lower intestines contained fluid. Secondary trichomoniasis was probably responsible for part of the lesions in the upper digestive tract.

- ***Ostrich Chicks:*** A coronavirus was identified by electron microscopy in a group of two-week-old ostrich chicks with enteritis.[99] The history revealed weight loss, anorexia, lethargy and weakness. Several affected chicks died. Clinically, two chicks were approximately 5% dehydrated and showed loose droppings. Clinical pathology findings included hypoalbuminemia, low albumin globulin ratio, elevated AST activities, hyperglycemia, hyperkalemia, anemia and normal WBC counts with degranulating heterophils.

  At necropsy, the proventriculus was enlarged, thinwalled and filled with ingesta. The ventriculus was empty. The lower jejunum was filled with a thick brownish paste and had thickened walls. The kidneys were mottled pinkish-white. Both tibiotarsal bones were soft and contained a large band of cartilage extending from the proximal growth plate into the metaphysis. Histopathology revealed hypotrophic villi and crypts of Lieberkühn containing cellular debris in the distal jejunum. Eosinophilic inclusion bodies could be recognized in the apical cytoplasm of enterocytes. The proventricular mucosa was thin and depleted in glands. The moderately swollen hepatocytes revealed increased, clear intracytoplasmic spaces. A pectoral focal myodegeneration, necrosis and mild mineralization was considered to be a nutritional myopathy. The bone lesions were comparable with tibial dystrophy in chickens. The cloacal bursa showed a depletion of lymphocytes. *E. coli*, *Aeromonas* sp. and D-*Streptococcus* sp. were isolated from the intestine and the liver. Unsuccessful therapy included systemic support (fluids, bismuth subsalicylate, tube-feeding and trimethoprim-sulfamethoxazole).

- ***Japanese Quail:*** A coronalike-virus was isolated from Japanese Quail with respiratory signs.[302] The virus replicates in the yolk sac of the embryonated chicken egg and in chicken embryo liver or kidney cells. It was classified as a coronavirus based on morphologic and physicochemical studies. Serologic examinations revealed that the virus is not related to other avian or mammalian strains.

Togaviridae and Flaviviridae (Arbovirus A and B)

These viruses are spheroid, enveloped (lipid-containing) particles, 40 to 70 nm in diameter, with a genome of a positive-sense, single-stranded RNA. The virus replicates in the cytoplasm. Most of the Togaviridae and Flaviviridae isolated from birds are arthropod-borne viral taxons, which implies that they can be transmitted by arthropod vectors and that the virus in question can replicate in the arthropod host. In birds, ornithophilic arthropods are the main vectors. A strict host specificity might be confused with "spill-over" hosts because of a habitat rich in potential arthropod vectors. Only the more important members of the group are described. For other avian arboviruses refer to Ianconescu. [182]

Eastern and Western Equine Encephalomyelitis (EEE, WEE)

EEE (genus Alphavirus of the Togaviridae) is mainly transmitted by *Culiseta melanura*, but may also be transmitted by other mosquitoes (*Aedes* spp. and *Culex* spp.). For WEE (genus Alphavirus of the Togaviridae) the main vector appears to be Culex tarsalis. Both viral taxons are serologically distinct but some cross-reaction does occur. EEE and WEE occur mainly in the Americas, but cases have been reported on other continents. Viral isolates or antibodies against both EEE and WEE viruses have been recovered from more than 60 avian species, with antibody titers being common in various species of birds from aquatic habitats. Rates of infection vary from 25 to 100% depending on the host. Ducklings of *Anas platyrhynchos* are susceptible to natural infection

only during the first 18 days of life, while many gallinaceous birds are always susceptible.

Infections in quail species, pheasant species and many New World finch species are characterized by a short, low-titered viremic phase in which birds remain clinically normal and develop effective antibody titers. The House Sparrow, which has been introduced only recently in the New World, develops a long and high-titered viremia, and chronic carriers may be observed. In addition to the natural host, (the Yellow-crowned Night Heron), the House Sparrow is also considered a reservoir of the virus. EEE and WEE produce cross-reacting antibodies, which may reduce the duration and titer of viremia and result in a rapid antibody response in birds that are immune to one virus and infected with the other.[114,182,346]

Pathogenesis

The virus can be ingested by mosquitoes with the blood of infected hosts from 24 hours post-infection throughout the viremic period (average two to five days) and transmitted to new hosts 7 to 20 days later. The hemagglutinating virus is probably distributed by erythrocytes through the whole body including the brain. Encephalomyelitis mainly develops in young birds.[152] Infections principally occur through insect bites, but horizontal spread following feather picking and other forms of cannibalism have been shown to occur in pheasants. The virus is shed in the feces and occurs in the feather quills. Debeaking, which is not recommended for humane reasons, helps to limit the horizontal distribution of the virus in pheasants.[346]

Clinical Disease, Pathology and Diagnosis

Outbreaks of EEE are seen mainly in pheasants, but also have been documented in ducks, Chukars, turkeys, Whooping Cranes, emus, finches and pigeons. These birds may die peracutely or acutely with mortality of up to 80%, depending on the age. An age-linked resistance has been demonstrated in pheasants beginning at 28 days. Clinical changes in a group of infected Lady Gouldian Finches included severe paresis and dyspnea.[69] Lesions caused by WEE are rare, but are essentially the same as those due to EEE: depression, incoordination, paresis and paralysis, torticollis, tremor, polydipsia and somnolence. Mortality rates in turkeys with ataxia and paralysis is about 6% whereas quail show up to 90% mortality. Clinical chemistry tests reveal anemia with normal numbers of leukocytes. AST, LDH and uric acid values are distinctly elevated. EEE has been associated with the acute onset of depression, profuse hemorrhagic enteritis, anorexia and ataxia, followed by prostration and hyperemesis prior to death in emus.[409]

At necropsy, EEE and WEE lesions are similar (swollen liver, mucoid duodenitis, dehydration) in most species. In the Whooping Crane, a clear yellow fluid is seen in the anterior abdominal air sac, and diffuse necrosis is present in many parenchymatous organs. Pheasants typically develop a neurotropic disease, while lesions in chickens are mainly myocardiotropic.[346] Histopathology reveals a nonpurulent encephalitis with edema, meningitis, perivascular infiltrates, diffuse gliosis (also in the spinal cord) and necrosis in the cerebral cortex.[152] Histologic changes occur principally in the rostral brain with a "descending" tendency, which stands in contrast to other avian encephalitides with a typically "ascending" encephalitis.[346]

In Lady Gouldian Finches, necropsy findings included consolidation in the lungs and a pale liver and kidney. Histologic lesions included hemorrhage, bronchopneumonia and multifocal centrolobular hepatitis (brain was not submitted for histopathology).[69]

Diagnosis

Because EEE and WEE viruses are sensitive to temperature, pH and many solvents, transport of virus for isolation is difficult. Homogenates of blood, liver, spleen and brain are best for virus isolation. The virus can be identified in cell culture by HI, ELISA, radioimmune assay or molecular hybridization. Humoral antibodies can be identified by the same methods; however, IgM can persist longer than IgG and methods for demonstrating IgM should also be used.[140]

Treatment

Administration of hyperimmune serum was not shown to have any effect on mortality levels in infected pheasants.[346] Emus should be treated symptomatically with fluids, vitamins (probably vitamin K) and supportive alimentation.[409]

Control

Control of insects, mites and ticks is important in preventing infections. Sentinel birds (some pheasant chicks) may be used to indicate the presence of infected mosquitos. There is some conflicting evidence on the use of vaccines. Formol-inactivated vaccine for horses (five pheasants per one horse dose) is reported to be efficacious (national legal implications notwithstanding). A formalized bivalent chicken embryo vac-

cine was found to protect only 60% of the experimentally vaccinated birds.[346]

Several recommendations have been made to vaccinate ratites in endemic areas with an inactivated equine EEE vaccine.[b] Neither the efficacy nor safety of this vaccine when used in ostriches has been established. Written permission should be obtained from the insurance carrier of an ostrich before vaccination is carried out. The recommended vaccination protocol includes vaccination at three months of age followed by a booster one month later and every six months thereafter.[409]

Zoonotic Potential

Human disease is rare and occurs following bites from infected mosquitoes. EEE and WEE both cause an acute infection of the CNS ranging from mild meningoencephalitis to lethal encephalitis or encephalomyelitis. In endemic areas, extensive vaccination of horses has reduced the levels of infection in humans.

Venezuela Equine Encephalomyelitis (VEE)

The causative agent of EEE is a member of the genus Alphavirus (Togaviridae). Birds play a minor role; the main reservoir is rodents. Vectors are *Culex* spp. with preference for rodents. However, in swamp areas some egrets and herons are known to be carriers. The main avian reservoir is the Striated Heron.[114] Human cases are characterized by a general benign course with acute but short fever, headache, myalgia, arthralgia, lymphadenopathy and frequently exanthema, but rarely CNS signs or hemorrhage.

Avian Viral Serositis (AVS)

A toga-like virus is suspected to cause a disseminated serositis in some Psittaciformes.[104] Electron microscopic studies of infected cell cultures revealed viral nucleocapsids (25-31 nm in diameter) accumulating near intracytoplasmatic and plasmatic membranes. Mature enveloped particles are 45 to 54 nm in size.

The host spectrum currently includes several juvenile macaw species, macaw hybrids and a Rose-ringed Parakeet. Experimentally, chickens, mice and rats were susceptible to infections. Interestingly, all the naturally affected birds came from nurseries or were parent-raised on farms where neuropathic gastric dilatation was endemic, and many of the contact birds were known to have died from this disease.

TABLE 32.13 Pathologic Changes Associated with AVS

Liver	Multifocal degeneration (may be vacuolar), hepatocellular necrosis
Lung	Interstitial pneumonia and edema, bronchitis, pleuritis
Proventriculus/ ventriculus	Lymphocytic proventriculitis, multifocal myositis and necrosis, lymphohistiocytic myositis
Serosa	Mesenteritis and serositis (intestinal, hepatic)
Spleen	Heterophilic infiltrates, multifocal lipogranulomas, lymphoid necrosis
Brain	Focal cerebral meningitis, necrotizing encephalitis, nonsuppurative encephalitis
Bursa	Lymphoid necrosis
Heart	Fibrinous epicarditis, lymphohistiocytic epicarditis and myocarditis, degenerative necrosis
Skeletal muscle	Multifocal myositis with necrosis, lymphohistiocytic myositis

Various histologic findings in a group of naturally infected macaws and a Ring-necked Parakeet and experimentally infected chicks with avian serositis virus. Adapted from Gaskin J, JAAV 5:27-34, 1991.[104]

Clinical Signs and Pathology

Affected birds die acutely or lose weight and have distended abdomens containing ascitic fluid (Color 32.18, Figure 32.22). Some birds develop respiratory distress.

At necropsy, the presence of serosal fluid in the abdomen with or without fibrinous clots was the prominent finding. In some cases, the liver was swollen and the lungs edematous (Color 32.16).

Histopathology revealed multifocal degenerative lesions (some vacuolated), necrosis of hepatocytes, interstitial pneumonia and edema, lymphocytic proventriculitis and splenic lymphoid necrosis (Table 32.13).[104] In experimentally infected chicks lymphoid necrosis was common, which may result in immunocompromised birds.

The importance of this virus for parrots and any role this virus may play in neuropathic gastric dilatation require further investigation. Viral particles assumed to belong to the Togaviridae have been described in chicken embryo fibroblasts and also in the epithelial cells of the jejunum and the pancreatic duct in broiler chickens.[100]

Rubivirus, German Measles

Rubivirus (formerly rubellavirus) is classified as a member of the Togaviridae. It is not known to cause disease in any avian species. However, antibodies indicating a carrier state with possible shedding of

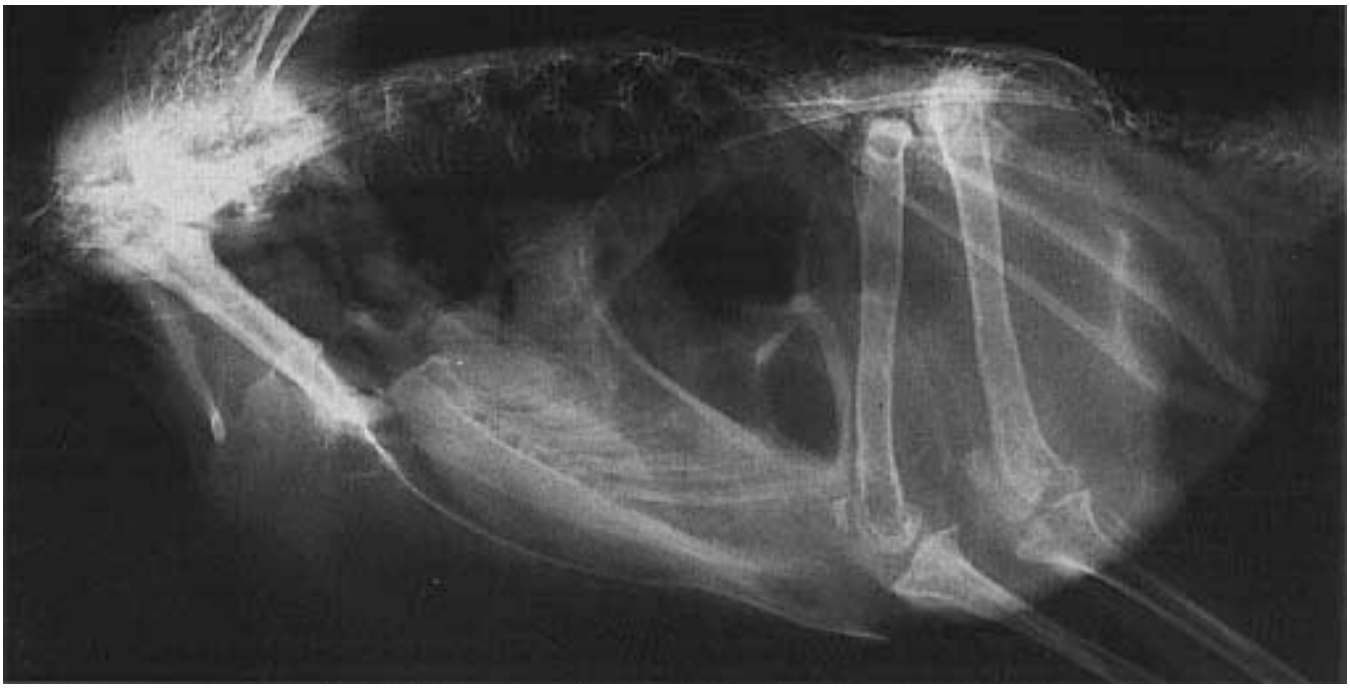

FIG 32.22 Ileus and severe bowel loop distension in a Blue and Gold Macaw with avian viral serositis (see Color 32.18). Note the cranial displacement of the proventriculus and ventriculus.

the virus have been found in urban pigeons (1.2% of population) in Germany.[161] In Munich, antibody titers average 1:16 and the carriers may average 7% of the birds examined.[79] Because rubivirus is a human pathogen, the occurrence of antibodies in free-flying urban pigeons suggests that these birds may be a reservoir for human infections. On the other hand, it has been suggested that pigeons may be infected by virus-shedding humans.[161]

Israel Turkey Meningoencephalitis (ITM)

ITM virus belongs to the flaviviridae. *Aedes aegypti* and *Culex molestus* are the main vectors. The disease was initially described in northern Israel (in season with its vectors), but has now been documented in southern Israel and South Africa. The main host is the domesticated turkey, which under field conditions becomes sick after ten weeks of age. Poults and Japanese Quail are highly susceptible experimentally. The incubation period is five to eight days following experimental infection.

Clinical changes include progressive paresis and paralysis and spastic, uncoordinated movements. Mortality averages 10 to 30%, but can reach 80% in some flocks. Breeders can show a significant drop in egg production. Necropsy findings are unremarkable. Histopathology reveals a meningoencephalitis with perivascular and submeningeal lymphoid infiltration. Clinical and histologic changes are similar to

those described with EEE virus, WEE virus and Newcastle disease virus.

The ITM virus can be detected in the blood and various organs from 24 hours up to 8 days following infection. Blood and parenchymal organs can be used for virus isolation. Virus identification in cell culture can be accomplished by VN. Serologic diagnosis can be made in survivors by using the HI test with goose erythrocytes and an antigen made from infected mouse brains.[182] An attenuated (quail) live vaccine is available and reported to be effective.

Louping Ill Virus Infection

The Louping Ill virus belongs to the Flaviviridae and is serologically related to the Siberian tick encephalitis virus (Russian spring-summer encephalitis) and the Central European tick-borne encephalitis virus. *Ixodes ricinus* ticks are the main vector.[332] The established avian host spectrum includes the Willow Grouse and the subspecies Red Grouse, Rock Ptarmigan, capercaillie, Black Grouse and the Common Pheasant. The first three birds discussed are very susceptible and usually develop CNS signs. The most susceptible birds inhabit moorland and tundra, compared to the less susceptible species that inhabit woodland and forest areas.[332]

St. Louis Encephalitis (SLE), Japanese B-Encephalitis (JBE), Murray Valley Encephalitis (MVE)

The agents belong to the family Flaviviridae. They occur on three different continents and are serologically related. Birds living in the breeding grounds of the vectors (for SLE: *Culex quinquefasciatus, C. pipiens, C. tarsalis;* for JBE: *C. tritaeniorhynchos, C. pipiens, C. gelidus*; for MEV: *C. annulirostis, C. tarsalis, Aedes* spp.) are important reservoirs. There are more than 30 species of susceptible birds that do not become sick. Avian reservoirs include Brown-headed Cowbird, House Sparrow, some egret and heron species, and in Australia, ibises and cormorants.[114] Outbreaks of SLE in humans can be predicted by an increase of seroconversion in sentinel birds and can be prevented or abated by controlling mosquitoes.[182] The human disease is similar to EEE.

Other Arboviruses

Table 32.13a gives a survey on the viral groups, the host spectrum and the main vectors. None of the birds cited in the table develop disease, even if viremic. Migrating birds are responsible for the distribution of the West-Nil virus outside the African endemic area. Because virus or antibodies can be documented in nonmigratory birds in new areas, endemic vectors are at least transitory transmitters. The influence of birds in distributing virus of the Bunyamvera group is limited to the function of transport hosts. Migrating birds carry infected ticks. The Crimean-Congo hemorrhagic fever is transmitted this way.[114,182]

The human disease by Siberian tick encephalitis virus resembles EEE. West-Nil fever is a mild febrile disease in humans and has a promising prognosis. CNS signs occur only rarely, but maculopapular exanthema and lymphadenitis are more common. Crimean-Congo hemorrhagic fever causes clinical signs in humans. The Uukuniemi virus can cause febrile conditions partly with hemorrhage and CNS signs. The California encephalitis group virus (important member: LaCrosse fever) causes clinical conditions similar to VEE. The Tahyna virus shows signs such as fever, headache, vomiting, pharyngitis and more rarely, interstitial pneumonia.

TABLE 32.13a Avian Arboviruses — Zoonotic Potential

Viral Group	Avian Hosts	Important Vectors
Flaviviridae Tick-borne encephalitis; European, Far Eastern subtype	Guillemot; probably other bird species	*Ceratixodes putes, Ixodes* spp.
West-Nil virus	At least 27 avian species, including migratory birds and domestic pigeons	*Aedes* spp., *Culex univittatus*
Bunyaviridae Crimean-Congo hemorrhagic fever	Birds refractory, only transport host for infected ticks	*Hyalomma* spp.
Uukuniemi virus	Passerine migratory birds (5 species)	*Ixodes* spp.
California encephalitis virus	Chicken, Canada Goose	*Aedes triseriatus*
Tahyna fever virus	Chicken, Starling	*Aedes* spp., *Culex modestus*
Reoviridae Kemerovo virus	Passerine migratory birds particularly Redstarts	*Ixodes* spp.

Rhabdoviridae

Birds are not considered natural reservoirs for the rabies virus, but they can nonetheless develop active infections while remaining asymptomatic. Virus isolation has been reported from common buzzards, Goshawks, ducks, a Red Kite and a Barn Owl.[152] Rabies virus infections have been experimentally reproduced in hawks, falcons, ravens, songbirds, pigeons, geese, ducks, chickens and peafowl.

Rabies antibodies have been described in free-ranging populations including Prairie Falcon, Goshawk, Golden Eagle, Short-eared Owl, crow, raven and starling.[126] In one survey, rabies virus titers were detected in six orders of birds representing 22 species. Twenty-three percent of the raptors had titers and eight percent of the non-predatory scavengers including starlings, crows and ravens had rabies antibody titers. These findings suggest that viral exposure occurs through contact with infected prey species.

Infection may occur from bites or from ingestion of infected prey. The virus spreads from the area of trauma via endoneural lymphatic vessels into the gray matter of the CNS. The self-limiting nature of the virus in avian species is believed to be due to a rapid production of antibodies. VN antibodies can be demonstrated within the neural tissue and can neutralize freshly replicated virus released form the neural cells. This explains the limitation of the infection to one area and the inhibition of viral distribution throughout the body.

The natural incubation period in ducks is three weeks to eleven months.[152]

Clinical Disease and Pathology

The clinical course in species naturally and experimentally infected can take 2 to 42 days. A short excitable period with jumping, crying, trying to flee, aggressiveness toward humans and epileptiform convulsions is followed 24 hours later by ataxia, weakness of the limbs, falling on the flanks and, finally, flaccid paresis (including head and neck). Two weeks later somnolence, apathy, compulsive movements and death can occur. Spontaneous recovery has also been reported.[152]

At necropsy, anemia, cachexia and hyperemia of the brain are noted. Histopathology reveals a nonpurulent encephalitis, which is distinct only two weeks after the outbreak of the clinical disease. Negri bodies are not regularly found. There has been no documented case of human rabies from an avian exposure.

Paramyxoviridae

The Paramyxoviridae family consists of two subfamilies:[325a] Paramyxovirinae with the genera Paramyxovirus and Morbillivirus (mammalian only); and Pneumovirinae with the mammalian respiratory syncytial viruses and turkey rhinotracheitis virus.

Members of this family have nonsegmented single-stranded RNA of negative polarity and an enveloped, helical, capsid symmetry. Virions are generally pleomorphic, rounded and 100 to 500 nm in diameter. A filamentous form 100 nm wide and variable in length has been described but may be an artifact. The virion surface is covered with 8 nm projections (so-called "herring bone") nucleocapsids that may be released from disrupted particles. The members of the Paramyxovirus (PMV) genus have neuraminidase, which is absent in the other genus.[9]

Virus replication takes place entirely in the cytoplasm in accordance with the scheme employed by negative-strand RNA viruses. Virus attaches to host cells through the "HN" polypeptide of the virus. Fusion of the virus and host cell membranes takes place (mediated by the "F" protein of the virus) and the nucleocapsid enters the host cell. The "F" and "HN" proteins require cleavage by host-derived enzymes and these procedures control pathogenicity in some strains.

Avian Paramyxovirus

Newcastle disease virus (NDV) is the type strain for avian paramyxoviruses. Numerous, serologically different strains of this virus have been isolated worldwide.[81] Hemagglutination inhibition (HI) tests, neuraminidase inhibition tests, serum neutralization tests and comparison of structural polypeptides have resulted in the identification of nine serotypes (PMV-1 to PMV-9).[4] Strains are designated according to serotype: species or type of birds from which virus was isolated/geographic location of isolation (usually

TABLE 32.14 Avian PMV Prototypes[73]

Virus Strain	Host Spectrum
PMV-1 (Newcastle Disease)	Hundreds of species/27 orders
PMV-1/pigeon/Munich/14/83	Pigeons, doves (see text)
PMV-2/chicken/California/ Yucaipa/56	Passeriformes, turkeys, chickens, Psittaciformes, rails
PMV-3/turkey/Wisconsin/68**	Turkeys
PMV-3/parakeet/Netherlands 75**	Psittaciformes, Passeriformes
PMV-4/duck/Hong Kong/D3/75	Ducks, geese, rails
PMV-5/budgerigar/Japan/ Kunitachi/75	Budgerigar
PMV-6/duck/Hong Kong/18/199/77	Ducks, geese
PMV-7/dove/Tennessee/4/75	Pigeons, doves
PMV-8/goose/Delaware/1953/76	Ducks, geese
PMV-9/duck/New York/22/78	Domestic duck

** Host-related differences shown by monoclonal antibodies

country or state)/reference number or name/year of isolation.[8] Table 32.14 lists the prototypes of various avian PMV serotypes.

Avian PMV, particularly NDV, are important pathogens in domestic poultry and have prompted control measures that have had serious effects on international trade and movement of birds. Environmental and chemical stability, routes of transmission and pathogenesis of infections have been studied only with NDV. Comparisons with other serotypes are subjectively based.

PMV-1

PMV-1 consists of NDV and related strains that are serologically, molecular biologically and pathogenically unique. They are found in Columbiformes and some Psittaciformes. Strain-specific monoclonal antibodies are necessary to distinguish infection caused by these strains of PMV-1, which have been divided into nine distinct groups.[8] Group P contains the pigeon isolates, which are no longer considered to be classic NDV.

Newcastle Disease

NDV is distributed worldwide with the possible exception of the various islands of Oceania. Birds from these islands should be considered immunologically naive with respect to NDV. NDV is serologically uniform and isolates are divided based on their virulence and epizootiologic importance (velogenic, mesogenic or lentogenic). These divisions are applicable only to the domestic chicken. Virulence is host-specific and varies considerably with experimental infections in other species.[46]

The host spectrum includes hundreds of species from at least 27 orders.[195] Susceptibility and the clinical course of disease are highly variable between species and apparently depend on the epitopes and the enzymatic status of the host. Birds of all ages are susceptible to infection. Although overheating may be a triggering factor, no real seasonal peaks have been described. Table 32.15 shows the susceptibility of a variety of orders.[91,148] Some mammals are susceptible to NDV, and humans may develop a severe conjunctivitis.

Transmission

Virus enters the host mainly through the respiratory and gastrointestinal tracts. Embryos can be infected if their shells are contaminated with virus. Vertical transmission can occur, but is rare with velogenic strains because viremic hens usually stop laying. Lentogenic and apathogenic NDV might be egg transmitted via the vitelline membrane. This route of transmission is thought to occur regularly following vaccination with live lentogenic strains (Hitchner B_1). Although virus can be found in respiratory secretions, the main route of viral shedding is the feces.

Mechanical vectors that may spread the virus include wind, insects, equipment and humans. Immune birds can function as carriers and intermittently shed virus. Persistent infections are limited to weeks or months. The most common carriers (reservoirs) include free-ranging waterfowl, Pittidae, Psittaciformes, some Passeriformes and Strigiformes.[21,45,59,90,157,158,183, 249,269,296,354,366,394]

Pathogenesis

NDV has an affinity for erythrocytes allowing the virus to be widely distributed throughout the host's body. Dyspnea may be caused by lung congestion and damage to the respiratory center. Petechiation results from viral adherence and damage to the vascular endothelium. The highly variable virulence of a given strain in a particular host is governed by the amino acid sequences of the "F" and "HN" viral proteins and the type of proteases available in the host for cleavage of the protein precursors.[13] The incubation period varies depending on the host species, previous virus exposure, pathotype of virus and titer of infecting virus.

Clinical Disease and Pathology

Lentogenic, mesogenic and velogenic strains of NDV produce varying clinical disease in chickens. The clinical expression varies widely in other birds, even between two species of the same genus. Several clini-

TABLE 32.15 Newcastle Disease (ND) Susceptibility*

Order	Susceptibility
Struthioniformes (ratite)	Moderate (10,11)
Cariamiformes (seriema)	Low (13) to high (1)
Gruiformes (crane)	Latency (14)
Ralliformes (rail)	Latency (2)
Lariformes (gull, tern)	Low (13)
Sphenisciformes (penguin)	Low (13) to high (12)
Pelecaniformes (pelican)	Low (13)
Columbiformes (pigeon, dove)	Low (5), moderate (4), high (1 - experimental)
Psittaciformes	
Lovebird	Low (13), high (7 - experimental)
Macaw, conure	High (5 or 7 - experimental)
Amazon parrot	High (5 or 6)
Caique	Moderate
Psittaculidae	High (5)
Eclectus Parrot	Moderate
Lory	Refractory
Platycercidae	Latency
Budgerigar	Low (natural), high (6 - experimental)
Cockatoo	High (5)
Cockatiel	Moderate
Strigiformes (owl)	Latency, low (16), high
Falconiformes (falcon)	Low (13), moderate (9)
Accipitriformes (vulture, hawk)	Low (13 or 15), moderate (8)
Saggitariiformes (secretary bird)	Low (13)
Ciconiformes (stork)	Low (13)
Anatiformes	
Geese	Latency (17), moderate (3)
Surface ducks	Latency (20,21)
Bay ducks	Latency
Phasianiformes	
Guineafowl	Moderate (1)
Peafowl	High (1)
Pheasant	High (1 or 2)
Grouse	Latency (15), high (1)
Cuculiformes (cuckoo)	Latency (13)
Upupiformes (hornbill)	Low (16), moderate (10)
Alcediniformes (kingfisher)	Low (15)
Piciformes (toucan)	Low (16)
Passeriformes	
Crow	Latency (17), moderate (12 or 19)
Finch	Latency, low (11 or 17)
Weaver finch	Latency, high (18), low (22)
Others	Latency, low (23), moderate (16)

*The clinical presentations and associated pathology are listed by a number. The number corresponds to the first column of Table 32.16.

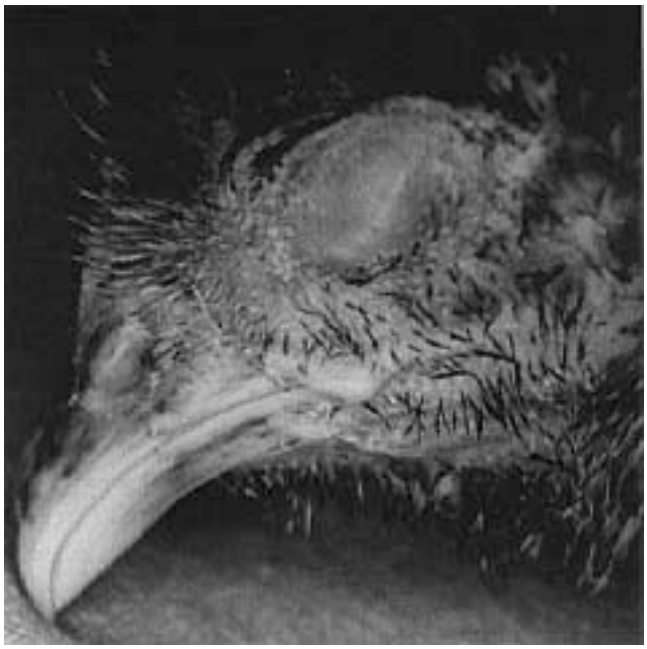

FIG 32.23 The clinical signs associated with Newcastle disease virus vary with the virulence of the virus and the infected host. Acute respiratory infections with clinical changes, including depression and dyspnea, are characteristic.

cal presentations are characteristic, but may vary considerably in their severity. In short, these can be summarized as follows:

- Peracute death; several hours of depression caused by viremia.
- Acute gastrointestinal disease (VVND); voluminous greenish diarrhea accompanied by anorexia, lethargy and cyanosis.
- Acute respiratory disease; upper respiratory exudates, rales and dyspnea.
- Acute gastrointestinal and respiratory disease.
- Chronic central nervous system (CNS) disease characterized by opisthotonos, torticollis, tremors and clonic-tonic paralysis of the limbs.

CNS signs generally occur with the development of humoral antibodies and may occur following an acute or subclinical infection. Virus may not be recovered once CNS signs develop. Partial immunity can alter the clinical progression of disease and pathologic lesions (Figure 32.23).

Affected birds typically have petechia on serosal surfaces and fatty tissues and on the mucosa of the larynx, trachea and proventriculus. Egg follicle hemorrhage may also be noted in protracted cases. Hemorrhagic necrotizing enteritis, mainly within the je-

junum, is common with virulent strains. Lymphatic tissue in association with the hemorrhagic lesions forms "boutons," which are pathognomonic in Phasianiformes. Birds with CNS signs may have no gross lesions, or hyperemia of the brain may occur.

The histopathologic lesions are as variable as the clinical signs. Table 32.16 provides a summary of gross and microscopic changes in a variety of birds. CNS lesions are generally characterized by a nonpurulent encephalitis with vascular and perivascular infiltrates of mononuclear cells. Increased numbers of glial cells and pseudoneuronophagia may occur. Histologic lesions rarely correlate with the severity of clinical signs.

Diagnosis

For the rule-out list, infectious and noninfectious causes of gastrointestinal or respiratory tract disease should be considered. One differentiating factor is that ND is not associated with sinusitis. CNS lesions are typical for ND in a variety of bird species. As a rule, the incubation time is prolonged in these cases, and histopathologic lesions may be difficult to document. Comparable clinical signs may be seen with chlamydiosis (meningitis), salmonellosis (encephalitis purulenta) encephalomalacia, lead toxicity and calcium deficiencies. Histopathologic differentiation is only possible following thorough examination of a variety of affected tissues.

Antemortem diagnosis of NDV can be performed by culturing virus from feces or respiratory discharge (swabs) from affected birds. The number of samples required for a diagnosis depends on the size of the flock, the clinical signs (CNS) and the quarantine situation.

Feces or respiratory swabs should be placed in appropriate transport media, and any sample for virus isolation or serology should be shipped on ice (4°C). Serology results (HI or AGP) generally require two days, while culture results may take from three to five days to several weeks. Postmortem samples for virus isolation should include trachea, lung, spleen, liver and brain shipped in transport media on ice. Fixed tissues from the brain and trachea can be used for histopathology. Cryofrozen sections of the nasal or tracheal mucosa may be processed for staining with fluorescent antibodies (nonspecific reactions can occur). Fluid from the aqueous humor can be collected for HA (detect virus) and HI (antibodies to virus) and can provide the most rapid diagnosis (hours to days), if sufficient antigen is present in the sample.

- ***Direct Virus Demonstration:*** Virus isolation can be achieved using feces, cloacal swabs or discharge from the respiratory tract. Isolation of the virus is required for complete classification. The ability of NDV to adapt to a variety of host systems can make it difficult to demonstrate directly. The fact that latently infected birds have low virus titers and that vaccine strains (even mesogenic ones in imported or migratory birds) may be present, complicate the evaluation of virus isolations.

  Isolates determined to be PMV-1 by HI should be sent to designated laboratories for further differentiation. Specific characterization can be accomplished with monoclonal Abs and by determining virulence for chickens (mean death time of chicken embryos, intracerebral pathogenicity index [Hansen Test], intravenous pathogenicity index, plaque formation test).

- ***Indirect Virus Demonstration:*** The response to antigens by the production of humoral antibodies varies within taxonomic groups and individually. Therefore, indirect virus demonstration by humoral antibodies may be difficult. HI titers can be present by the fourth day post-infection and may vary considerably. Titers may be nonexistent or low (birds of prey, domesticated pigeons, budgerigars), even in birds that have survived the disease. The development of HI antibodies may be delayed, and latent infections can result in the formation of antibodies. The HI titers that develop in Psittaciformes may be low with Amazon parrots and Psittaculidae, having average titers of 1:8 to 1:64, while cockatoos may have titers of 1:320.

Treatment

Hyperimmune serum (2 ml/kg body weight IM) can be used to protect exposed birds but is of no benefit once clinical signs are present. CNS signs occur in the presence of humoral antibodies. Use of B vitamins and anticonvulsants for treating NDV-induced nonpurulent encephalitis is discouraging; in controlled studies, there was no difference in treated or untreated groups. Following improvement (which may take a year), any disturbance or stressful event may cause a bird to have severe convulsions or tremors.[111]

Control

NDV occurs worldwide and many free-ranging birds can function as carriers. Effective vaccination regimes would be helpful in controlling infections in aviaries, breeding farms and zoo collections; however, ND is a notifiable disease in many countries and governmental regulations may control vaccination protocols. Most birds in orders other than Phasiani-

TABLE 32.16 Newcastle Disease Clinical Signs and Pathology

Number-strain	Clinical Signs	Pathology
1-velogenic strains	Systemic disease (peracute-acute) with fever, depression, dull plumage, cyanosis, edema of eyelids and face, severe dyspnea caused by pulmonary edema and catarrhal or fibrinous tracheitis, watery diarrhea. Nervous signs only in survivors after 1-2 weeks. Mortality: 50-90% in 4-8 days.	Gross: muscles conspicuously dark, petechia of serous membranes, edema, tracheitis, cloudy air sacs, enteritis, necrotizing ulcers in Peyer's patches and cecal tonsils (pathognomonic); petechia of mucosa of proventriculus, ventriculus and intestine; leukopenia. Histology: Hyperemia of parenchyma, larynx, ovary, brain and endothelium of blood vessels; hyperemia and necrosis of lymph follicles; tracheitis with epithelial hyperplasia, lymph follicle proliferation or necrosis; with acute death no brain lesions.
1-mesogenic strains	Acute respiratory signs, discharge of mucus, nervous signs (paresis and paralysis of limbs, ataxia, torticollis, myoclonia, tremor) after 2-3 weeks. Mortality: 5-50%.	Gross: dehydration, catarrhal enteritis, airsacculitis, tracheitis, pneumonia, cloudiness of the cornea, petechia of serous membranes and adipose tissue, necrotic foci at the sides of the choanal cleft. Histology: nonpurulent encephalitis with dense cellular infiltration (monocytes, lymphocytes, plasma cells, rarely heterophils) into the walls of the blood vessels (cuffing). CNS lesions are seen in the gray and white matter particularly in the basal parts (thalamus, cerebral peduncle, medulla oblongata); swelling and karyorrhexis of capillary endothelia, hyalinization of the arteriolar walls; frequent degeneration of ganglial cells, but rarely gliosis; neuronophagia within the lumbar spinal cord (posterior gray matter). Proliferation of the tracheal epithelium and slight desquamation. In the lymphatic tissue, edema and necrosis of the reticular cells situated within the lymph-follicles, disappearance of lymphocytes. Pulmonary hyperemia, edema and hemorrhage; edema and cellular exudate in bronchioles and parabronchi.
2-velogenic	Free-ranging pheasants contract the disease rarely; they are unable to stand and refuse to feed; dyspnea (acute tracheitis) may be distinct or totally absent; occasionally hemorrhagic diarrhea.	See number 1.
3	Spontaneous disease rare and without respiratory signs; ataxia and paresis; in geese spontaneous drowning is typical; ducks may develop CNS signs.	Often no lesions, rarely encephalitis.
4-velogenic	CNS signs only; the acute disease is, as a rule, not observed, but if so: emaciation, whitish diarrhea, paresis of one wing, tremor, convulsions of the head muscles, later total paralysis; failure of positioning reflexes; may recover within 1-2 days or death within 5-6 days.	Gross: petechia, hemorrhagic to diphtheritic enteritis. Histology: nonpurulent encephalitis.
5-velogenic or mesogenic	CNS signs such as tremor, enlargement of the pupils, torticollis, reluctance to fly, incoordination of movement, cramps of the toes, convulsive dyspnea, general convulsions and paralysis; bloody feces occasionally; death 4-5 hours following total paralysis. Mortality: up to 100% within 2 weeks.	Gross: hyperemia within the skull's lacunae, hemorrhages in the brain, swollen spleen; hyperemia, petechia or ecchymosis in the intestinal tract (only rarely necrosis); rarely hemorrhagic enteritis or tracheitis, air sacculitis, fibrinous serositis. Histology: only in birds that have been sick for some time: disseminated nonpurulent encephalitis with perivascular cuffing, gliosis in the cerebellum and brain stem, status cribrosus in the medulla of the cerebellum and in the corpus striatum. Degeneration of ganglion cells and pseudoneuronophagia. Hyperemia and perivascular infiltration in the gray matter of the spinal cord. Hemorrhage and necrosis in spleen, liver and intestine.
6-velogenic or mesogenic	CNS signs, see number 5.	Enteral lesions caused by velogenic strains are not distinct.
7-velogenic or mesogenic	Slight ataxia, but high mortality up to 55%.	
8-velogenic or mesogenic	CNS signs 5-7 days post-infection. Starvation due to incoordination (accidents). Birds may recover with supportive care.	See number 5.
9-velogenic or mesogenic	Birds become sick after incubation of 5-13 days and die soon after the onset of CNS signs.	Cause of death is cerebral hemorrhage.

table continued on next page

Number-strain	Clinical signs	Pathology
10-mesogenic	Onset of disease with enteritis followed by sudden ataxia with a body temperature of 41°C, may hold the neck in a corkscrew-like fashion. Spontaneous healing can occur after weeks.	Gross: Petechia, hemorrhagic to diphtheroid enteritis. Histology: Nonpurulent encephalitis.
11-mesogenic	Respiratory signs and watery diarrhea.	Massive hyperemia of the pulmonary vessels with hemorrhage into the interstitium; edema in some parabronchi.
12-velogenic	Peracute death without clinical signs during viremia.	Petechia of serous membranes.
13-velogenic or mesogenic	Totally atypical course of disease, slight apathy, failure of heart and circulation.	Gross: bird in good condition; enteritis, swollen spleen, traumatic skin lesions, rarely tracheitis. Histology: hyaline degeneration of cordal muscle fibers; pulmonary edema and hemorrhage.
14-mesogenic	Anorexia, apathy, diarrhea.	
15-mesogenic	Conjunctivitis, impairment of general condition.	
16-velogenic or mesogenic	Apparently harmless disease (anorexia, torticollis) followed by sudden death. Clinical signs may be completely absent; fecal excretion for months.	Histology: nonpurulent encephalitis.
17-velogenic, mesogenic or lentogenic	As a rule, no clinical disease, but virus is propagated and excreted from the third day onward and totally eliminated by the sixth day; antibodies are present; occasionally signs as with number 11.	No pathologic lesions.
18-velogenic or mesogenic	Acute course of disease, edema of the eyelids with watery to purulent discharge from narrowed lid clefts; photophobia, no CNS signs; cause of death is asphyxia. Mortality: about 40%.	Gross: icterus, catarrhal enteritis, swollen liver and spleen, fibrinous plugs filling syrinx or larynx. Histology: cellular infiltration into iris, edema of cornea, hyperemia of the choroidea, protein and erythrocytes in the aqueous humor.
19-velogenic or mesogenic	Sudden death without prior clinical signs. Mortality: about 20%.	
20-mesogenic	Stable coexistence between mallard and ND virus; virus may be excreted for six months (probably in a few specimens only).	
21-velogenic	Normal latent infection only, but may be 4% mortality in some free-ranging birds.	Pectoral muscles and leg muscles dark. Hemorrhages of serous membranes and fatty tissues.
22-mesogenic	CNS signs following experimental infection.	
23-mesogenic	Mortality up to 20% without prior clinical signs following experimental infection.	

formes must be vaccinated parenterally for an effective antibody response to occur. Inactivated vaccines produced for chickens are useful, provided that there are no governmental regulations that restrict vaccination. Oil-adjuvanted vaccines have been shown to cause abscesses surrounding the injection site in some birds and must be used with caution. Abscesses secondary to subcutaneous infections are easier to treat than those that occur following IM injections.[111]

Live vaccines produced for chickens (and used for other Galliformes) should not be used in other avian orders. The potential infectivity of the vaccine strain of virus in a non-adapted host has not been determined. Vaccines administered to Psittaciformes in the drinking water have been shown to be ineffective.

As a general consideration in an active outbreak, emergency vaccination with Hitchner B_1 and truly apathogenic LaSota strains is possible via ocular or nasal drops (five chicken doses per bird). These strains function as competitive inhibitors, and the local protection induced cannot be determined by an increase in humoral antibodies. In a recent outbreak on a farm with ornamental birds (more than 2000 birds of more than 200 species), this vaccination method successfully protected birds that were not yet clinically sick.[65a]

Dosing with live virus vaccine followed by a booster after three weeks provides three to four months of immunity. Inactivated vaccines provide five to seven months of immunity. A live vaccine followed two to three weeks later by an inactivated vaccine might provide 9 to 12 months of protection. These data are applicable only to gallinaceous birds. Increases in HI titers following vaccination are indicative of a host response and may not correlate with immunity.

Zoonotic Potential

Virulent poultry as well as vaccine strains of NDV can cause severe conjunctivitis in humans. Infected people usually recover with few problems.

PMV-1 Pigeon

A PMV-1 strain that is closely related to NDV but serologically, biochemically and pathogenically unique was first recognized in domesticated pigeons in the late 1970's, probably having arisen in the Middle East.[4,10,196] The virus reached Europe by 1981 and spread all over the world, affecting particularly racing and show pigeons.[40,333]

Monoclonal antibodies have shown PMV-1 pigeon strains recovered in many European countries to be fairly uniform. The host spectrum includes domesticated pigeons, feral doves and the Wood Pigeon. Sensitive (but more or less inadvertently infected) species include Cracidae, Pavoninae, Phasianinae, Common Blackbird, House Sparrow, Barn Swallow, European Kestrel, Common Buzzard, Vinaceous Amazon and Eastern Rosella.[367] The virus is infectious to chickens, particularly immunocompromised individuals.[333,414] Experimentally infected chickens do not become latent carriers.[274] Some infections occur from ingestion of contaminated feces. Feed contaminated with pigeon or dove feces can be a source of infection for other avian species, particularly chickens.[7]

Clinical Disease and Pathology

Affected Columbiformes have nondescript clinical signs including polydipsia, polyuria, anorexia, diarrhea and vomiting. These frequently unrecognized acute signs are followed by clonic-tonic paralysis of the wings (more rarely the hind limbs), head tremors and torticollis. In contrast to ND, flaccid paresis and paralysis may occur, probably from a peripheral neuropathy.[95] Other less frequent signs are unilateral blepharedema, egg deformation, embryo mortality and dystrophic molt. Dyspnea, which is common with ND, does not occur. Mortality is highest in nestlings. Affected older birds may spontaneously recover within three to four weeks after the onset of clinical signs. Gross lesions include hyperemia of the brain and large parenchymatous organs, catarrhal enteritis, swelling of the kidneys and hemorrhage and necrosis of the pancreas.

Histologic lesions are variable. Edema of the meninges and brain and swelling of the vascular endothelium in the meningeal vessels may be noted. Lymphocytic perivascular infiltrates and demyelination of the white matter may occur in the cerebrum, diencephalon, optic lobe, medulla oblongata, intumescentia cervicalis and lumbaris of the spinal cord. Degenerative and inflammatory lesions also occur in the peripheral nerves (plexus brachialis, plexus ischiadicus).[95] Lysis of Purkinje cells in the cerebrum, which was reported initially with PMV-1 pigeon, may have been caused by herpesvirus that was also isolated from affected birds.[277]

Diagnosis

Procedures designed for isolating NDV are effective for PMV-1 pigeon. The HI test can be used to differentiate between NDV and PMV-1 pigeon. Final differentiation is possible only by the use of monoclonal antibodies.

Treatment

LaSota vaccine strains administered via eye or nasal drop are not as efficacious in protecting from infections as expected. The LaSota strains replicate poorly in pigeon tissue so that high vaccine doses are necessary for interference and antibody production (protection only for 8 to 12 weeks).[170] Vaccination with live vaccines may exacerbate latent chlamydia or pigeon herpesvirus infections.[222] Parenteral administration of live Hitchner B_1 vaccine has similar side effects but may provide six months of immunity.

Inactivated vaccines are preferable for pigeons. In an active outbreak, vaccination with an inactivated vaccine will decrease the length of the disease and mitigate the clinical signs.[170] Once CNS signs develop, vaccination is of no value; however, spontaneous recoveries do occur.

Control

For vaccination, homologous, inactivated oil emulsion vaccines are commercially available.[220] Annual boosters are necessary.[220] All birds in a loft, and competitive traveling groups of homing pigeons, should be vaccinated. Squabs from hens vaccinated three months before laying may not have protective antibodies.[220] Squabs can be vaccinated with homologous vaccine by four weeks of age.[222] Inactivated NDV vaccines provide only six months of protection.[166]

Vaccines are best applied subcutaneously in the neck. Intramuscular injections in homing pigeons can cause severe irritation of the pectoral muscles. To prevent fatal hemorrhage from the plexus subcutaneous collaris (see Chapter 44), injections must be given in the caudal third of the neck, near the middle of the dorsal aspect. Oil-emulsion adjuvants produce

superior antibody titers and have fewer side effects than aqueous carbomers.[48,319] An effective oral vaccine has not been developed and requires the isolation of an apathogenic PMV-1 pigeon strain.

PMV-2

PMV-2 strains that occur worldwide display considerable antigenic and structural diversity.[9] Preliminary classification using monoclonal antibodies has identified four groups.[300] Isolates from Psittaciformes, some Passeriformes, one Gadwall as well as several turkey isolates from Israel together with a Mallard and a Coot strain belong to group 1. Group 2 consists of chicken strains from the Arabic Peninsula, and two strains from Passeriformes have been assigned to group 3. In group 4, a variety of strains from Passeriformes has been placed. The type strain PMV-2/Chicken/California/Yucaipa/56 belongs to group 1. The host spectrum includes chickens, turkeys, Passeriformes, Psittaciformes and more rarely, rails and ducks.

PMV-2 strains are endemic in Passeriformes (Ploceidae, Zonotrichiinae, Zosteropidae and Estrildidae), particularly those originating from Senegal. Isolates have been recovered from clinically healthy imported companion and aviary birds (Estrildidae, Viduidae, Ploceidae and Carduelidae). Experimentally, these isolates cause a mild upper respiratory tract disease. PMV-2 infections are more severe in Psittaciformes, particularly in African Grey Parrots, where emaciation, weakness, pneumonia, mucoid tracheitis and mortality are common findings.[64] The Bangor isolate from finches was proposed as a cause of death in a Blue Waxbill. Experimentally the Bangor isolate caused only mild respiratory signs and no pathologic lesions.[263] Further investigations in a variety of bird species are necessary in order to evaluate the virulence of the various strains.

The host spectrum may be much wider than has been shown by direct virus demonstration. Antibodies against PMV-2 have been demonstrated in homing pigeons, healthy Passeriformes (many of them free-ranging) and some birds of prey. Isolates from various finches have not been shown to be pathogenic for chicks.[116,204] Diagnostic methods used for PMV-1 are also applicable to PMV-2.

PMV-3

PMV-3 strains have been isolated from chickens and turkeys in North America, Great Britain, France and Germany. Most isolates from nondomesticated species originated from imported Psittaciformes (lovebirds, cockatiels, budgerigars, macaws, *Psittacula* spp, *Neophema* spp.). Some Passeriformes are also susceptible. Antibodies to PMV-3 have not been documented in feral birds, but a free-ranging avian reservoir probably exists.

Two groups of PMV-3 strains, one consisting mainly of turkey strains and the other of strains isolated from companion birds, can be differentiated using monoclonal antibodies.[19] The virus is serologically related to NDV. PMV-3/Parakeet/Netherlands/449/75 will protect chickens against NDV.[8] Intracerebral pathogenicity indices vary from 0.25 to 0.35[358] up to 1.3.[385]

Clinical Disease and Pathology

The pathogenicity of this virus group varies with the infected species and (probably) virus strain. Conjunctivitis is the initial clinical sign in finches and Weaver Finches (eg, Gouldian Finch, Red-cheeked Blue Waxbill, Canary, White-rumped Canary, Orange-cheeked Waxbill, Black-throated Grassfinch, Double-barred Finch and Avadavat). Yellowish diarrhea, dyspnea and dysphagia occur as the disease progresses. Some affected birds die within a few days, while others recover over a period of weeks.[358] CNS signs are not regularly seen in finches (Black-eared Wheater, Grey-headed Wheater, Red-breasted Flycatcher).[367] Infected Psittaciformes develop CNS signs similar to those with ND. Susceptibility in Psittaciformes is variable. African Grey Parrots may develop ocular lesions (dilated pupils, hemorrhages around the pecten, uveitis and fibrinous exudate into the anterior chamber), unilateral or bilateral paralyses and hemorrhagic nasal discharge.[148]

Latent carriers have been described in Siberian Rubythroat, Long-tailed Grass Finch, Nutmeg-Mannikin and Cutthroat Finch; Japanese Quail and domesticated pigeon.[358,367,385]

Detailed pathologic descriptions are not available. Liver and kidney lesions accompanied by an enteritis with blood in the intestinal lumen are common. Small birds are frequently cachectic, suggesting a chronic disease course or the inability to eat and drink. Histopathologically, hyperemia and a mild proliferation of glial cells in the brain may be seen. The typical nonpurulent encephalitis described with the CNS form of ND is not recognized with PMV-3 infections.

Diagnosis and Control

Salmonella spp., NDV, chlamydia and mycotoxins should be considered in the list of differential diagnoses. The methods for demonstration of the virus are the same as with other PMV groups. Serologically, there are cross reactions with PMV-1. An exact differentiation is possible with monoclonal antibodies. An oil emulsion vaccine was developed in Great Britain to counteract the decrease of egg production in affected turkeys. Another inactivated vaccine produced sufficient immunity in budgerigars and canaries to withstand challenge.[35]

PMV-5

Budgerigars are considered the host of PMV-5. The type strain is called Kunitachi virus[289] and has been since lost. Possibly related strains have been isolated from free-ranging Rainbow Lories and budgerigars from the same area of Australia.[284,285]

Natural and experimental infections in budgerigars are characterized by acute diarrhea, dyspnea, torticollis and death. Affected budgerigars in Australia had severe diarrhea with a 50% mortality rate. Affected Rainbow Lories became depressed, lethargic and had three to four days of diarrhea followed by death. Birds were typically anorexic but drank liberally.

Necropsy findings in budgerigars were limited to hyperemia of the parenchymatous organs. Rainbow Lories had swollen livers and spleens and necrotizing-to-ulcerative or diphtheroid-to-hemorrhagic enteritis, with hemorrhages within the mucosa of the ventriculus and proventriculus as well as edema of the intestinal wall.

Histopathologic lesions included multiple necrotic foci in the liver and kidney with the development of giant cells. In Rainbow Lories, extensive loss of the intestinal epithelium with desquamated necrotic material and erythrocytes in the lumen was common. Mild perivascular infiltration with lymphocytes was common in edematous intestinal walls. The differential diagnosis list should include *Salmonella* spp., NDV, *E. coli* and nutritional deficiencies. PMV-5 *cannot* be isolated via all the same methods as other PMV strains.

PMV-7

PMV-7 has been isolated only from Columbiformes. The type strain was isolated from doves in Tennessee, and another isolate from the Rock Pigeon in Japan. All strains have a heat-stable hemagglutinin, and are considered apathogenic. Whether or not the Japanese and the New World strains are the same has not been determined.[6]

PMV-4, PMV-6, PMV-8 and PMV-9

These groups contain virus strains recovered from clinically healthy waterfowl located in the United States and Asia. PMV-4 is rather uniform and is apathogenic in chickens.[5] The duck strains of PMV-6 may cause a mild respiratory disease and decreased egg production in turkeys.[13] Isolates have been recovered by culture of tracheal and cloacal swabs.[377] Details on PMV-8 and PMV-9 are limited. Carriers of PMV-4 and PMV-6 include Canada Goose, Common Teal, Common Pintail, Mallard, American Black Duck, Ring-necked Duck and Hooded Merganser.[148]

Parainfluenza-2-virus (PI-2-virus)

The PI-2-virus, which belongs to the genus PMV, does not cause clinical disease or decrease in egg production in chickens. The virus can, however, be egg transmitted without influencing the embryonal development. The chicken PI-2-virus is identical to the agent that causes croupous pneumonia in humans. The PI-2-virus is important because it is not easily recognizable as a source of human infections and may be a contaminant in embryonated chicken eggs used for vaccine production.[203,421,422]

Twirling Syndrome

This disease of uncertain etiology has been described in the African Silverbill, Zebra Finch, Gouldian Finch and related species.[27] Clinically, the sudden onset of torticollis and circling is conspicuous, but depression and weight loss are also evident. Clinical signs typically occur within one week of shipment from their place of origin. Some birds will be affected while others from the same shipment remain unaffected. Mortality may reach 20%. Some birds recover completely while others retain a permanent head tilt. Individual companion birds are also known to suffer from this disease. WBC may range between 2,000 and 14,000. Antibiotic therapy does not change the course of the disease. Pathology and histopathology have failed to implicate a specific etiologic agent, but a virus is suspected. PMV should always be considered in Passeriformes with neurologic signs.

Avian Pneumoviruses

The viruses of turkey rhinotracheitis and the swollen head syndrome in chickens are considered to belong to the same group and are classified as avian pneumoviruses. No other hosts have been incriminated as carrying this virus.[14]

Orthomyxovirus

The family Orthomyxoviridae consists of avian influenzavirus (AIV) and all other influenzavirus taxons. Orthomyxoviridae are 80 to 120 nm diameter, segmented RNA viruses with helical symmetry containing glycoproteins that project from the envelope and have hemagglutinating and neuraminidase activity. Influenzavirus can be classified into two groups designated A and C.[141] The specificity is provided by the nucleoprotein and matrix antigens. The nucleoprotein and matrix antigens of the influenza A virus isolated from birds, humans, pigs, horses, mink, seals and whales are closely related. Influenzavirus has a high rate of genetic recombination (particularly with regard to the hemagglutinins), so that "new" sero- and pathotypes (antigenic shift) frequently appear.[86]

Hemagglutinin and neuraminidase antigenic sites may also vary slightly, possibly as expression of mutant selection under the pressure of increasing immunity within a given population (ie, antigenic drift).[283,364] Many avian species, particularly large congregations of migrating birds, may serve as main reservoirs for virus recombination.[22,23,88,154,209,210,221,288,322,387,398]

Influenza C is usually restricted to humans, but there are exceptions.[86] During a human outbreak of influenza (formerly called B) in Hungary, 4.1% of zoo and free-ranging birds examined had antibodies against the same virus type. Infections could be experimentally induced in Common Pheasants and Mallard Ducks.[348]

Avian Influenza A (AIV)

Infections with influenza A virus can cause subclinical to mild respiratory diseases, loss of egg production or generalized acute lethal disease. Acute lethal infection in domesticated chickens is called fowl plague and is a reportable disease in many countries. The recovery of numerous virus strains of identical antigenicity from many avian populations for up to ten years indicates a continuing circulation of those strains.

Influenza A virus is divided into subtypes according to the antigenicity of its hemagglutinin and neuraminidase. Thirteen hemagglutinins and nine neuraminidases have been distinguished to date (H1 to H13 and N1 to N9).[429] The nomenclature proposed by the same committee includes the type (A or C), host of origin (except human), geographic origin, strain number (if any), the year of isolation, and in parenthesis, the antigenic description of the hemagglutinin (H) and neuraminidase (N).

The presence of closely related surface antigens does not correlate with virulence in various avian species;[2] therefore, attempts to classify them according to virulence have been made. However, the interaction among a given virus strain, the host species and environmental factors is poorly understood. AIV with H1, H5 and H7 antigens are considered pathogenic for chickens but there are many exceptions.[2]

A/turkey/Ontario/7732/66/H5N is highly virulent for chickens and turkeys (up to 100% mortality) but is avirulent for ducks. One reason for this difference may be the tissue affinity. Strains staying "locally" in the respiratory or digestive tract usually have a low virulence; those that generalize have a high virulence. Tissue receptors in humans and many mammals differ, and this may be also true in birds. Highly virulent AIV strains possess a hemagglutinin that is readily cleaved and recombined in various host cells. The type of host proteases is important to cleavage and governs the extent of virus replication.[86]

AIV is distributed worldwide and has a large host spectrum that includes domesticated ducks and geese, free-ranging ducks and geese, chickens, turkeys, guineafowl, chukars, quail, pheasants, sandpipers and sanderlings, turnstones, terns, swans, gulls, herons, guillemots, puffins and shearwaters.[3,32,33,34,147,172,374,383] Latent infected carriers also occur. AIV has been isolated from captive birds including Indian Hill Mynahs, various Psittaciformes (Sulphur-crested Cockatoo, African Grey Parrot, budgerigar), Passeriformes, Accipitriformes and Musophagiformes (Lady Ross's Turaco, Purple-crested Turaco, White-crested Turaco, Black-billed Turaco, Guinea Turaco).[86,87,147]

Transmission and Pathogenesis

AIV is distributed around the world by migration of many avian species. Infected birds can shed the virus via respiratory secretions, conjunctiva and feces. Transmission through direct contact and indirect transmission through vectors is possible. There is no information on vertical transmission, although contaminated egg shells can distribute the agent (probable exception is the Helmeted Guineafowl). Clinically normal free-ranging birds such as ducks, geese and Passeriformes (mainly starlings) have been shown to transmit the virus to chickens and turkeys. Clinically affected free-ranging birds have been known to infect domesticated birds. Birds can serve as reservoirs for human and mammalian influenza A infections. Theoretically, humans may also be able to infect their companion birds.

Highly virulent strains of influenza A induce a viremia that is more prolonged than that caused by paramyxovirus. Thrombocytopenia occurs and is followed by a terminal hemorrhagic diathesis. The pathogenesis of less virulent strains in avian species has not been determined.

Clinical Signs and Pathology

For chickens and turkeys refer to Easterday, et al.[86]

A/Tern/South Africa/1961/H5N3 was isolated from common terns and caused an acute to peracute disease in these birds in South Africa. The AIV strain was very closely related to A/chicken/Scotland/1959/H5N3 which, 17 months earlier, had caused a serious epornitic in chickens that was traced to sea birds (Herring Gulls and Kittiwakes). Experimental infections of chickens with the ternvirus caused clinical signs and pathologic lesions similar to fowl plague.[34]

A/pheasant/Washington/1985/H9N9 was isolated from young (two- to eight-week-old) Common Pheasants experiencing a 25 to 35% mortality rate. Adult birds did not show any clinical signs although they were infected and probably excreted the virus over several weeks. Gross pathology included severe air sacculitis, catarrhal tracheitis, purulent rhinitis, fibrinopurulent polyserositis and splenomegaly. Histopathology revealed fibrinous polyserositis with predominant infiltrations of heterophils. Diffuse congestion and interstitial fibrinous secretion were evident in the lungs. The tunica propria of the ventriculus contained multifocal aggregations of lymphocytes.[75] The strain was nonvirulent for chickens and domesticated ducks.

Several flocks of Helmeted Guineafowl in Hungary had decreased egg production (30 and 40%) with normal and reduced hatchability (40 to 50%). Embryonic death following two weeks of incubation was common. Birds died with no clinical signs or following a period of respiratory disease characterized by listlessness and cyanosis. Nervous involvement was observed in the form of incoordination. Some affected birds had no pathologic lesions while others had air sacculitis and petechiation of the serosal and mucosal surfaces of the proventriculus. The virus could not be transmitted experimentally to chickens, ducks, mice or guinea pigs. The virus strains isolated from two flocks were antigenically variable.[402] The strains were closely related to A/quail/Italy/1117/65.[336]

Infections have been documented in breeding flocks of Japanese Quail in Northern Italy. Two different AIV strains have been isolated, with one being A/quail/Italy/1117/65. Environmental factors influence the severity of an outbreak with mortality varying from 15 to 80%. Clinical signs are somnolence, sneezing, nasal discharge, swelling of the sinus infraorbitalis, lacrimation and dyspnea. A few birds are ataxic and have convulsions. At necropsy, a catarrhal-to-fibrinous-to-purulent rhinosinusitis and tracheobronchitis is seen as well as a focal-to-confluent, disseminated, cellular, fibrinous pneumonia. Fibrinous pericarditis, air sacculitis, submiliary pancreatic necrosis, hyperemia and edema of the brain with focal demyelinization may also be seen.[147]

The clinical and pathologic lesions associated with AIV infections in Psittaciformes vary with the virus strain. A/Sittich/Germany/433/70 was isolated from a Sulphur-crested Cockatoo.[147] The majority of viruses isolated from parakeets and parrots have H5- or H7-related hemagglutinins. Affected birds have a two-week course of lethargy and CNS signs (loss of balance, ataxia, torticollis). Mortality rates may reach 30% with virulent strains. At necropsy, hemorrhages in the brain and swelling of the spleen are characteristic. Encephalitis is usually not present.

An AIV related to A/chicken/Brescia/65 was isolated from an African Grey Parrot. The bird was depressed, had dark green feces and died a few days after clinical signs developed. Congestion of the digestive tract was the only gross lesion noted. AIV was also isolated from Yellow-crowned Amazons, Plum-headed Parakeets, Rose-ringed Parakeets, Singing Parrots and Lesser Sulphur-crested Cockatoos.[147]

Experimental infections of budgerigars with A/Budgerigar/Hokkaido/1/77/H4N1 showed that virus replication occurred principally within the nasopharyngeal cavity, trachea, esophagus and lungs. Only birds that were in poor condition developed clinical signs including rough plumage, diarrhea and death. The infected budgerigars did not develop HI antibody titers, which were also poor following booster infection. Generally, budgerigars do not have good humoral antibody responses to many antigens.

Anatiformes are relatively resistent to influenza and are considered a natural reservoir.[299] About 25 to 30% of all free-ranging ducks and geese in the Northern hemisphere carry AIV. The isolated strains have highly variable hemagglutinin and neuraminidase antigens. Chariidriformes (21.4% in Russia) are also considered to be reservoirs.[147] Infected waterfowl may not show clinical signs unless severely stressed by concomitant infections or transportation. Birds shed the virus by the fifth day post-infection and continue to shed for several weeks.

If clinical signs occur, they include depression, anorexia, dyspnea, swelling of the sinus infraorbitalis, lacrimation and diarrhea. Occasionally, CNS signs occur, but because these are a common premortal finding in ducks and geese, these CNS signs are considered nonspecific. The disease lasts about three weeks with mortality rates from 10 to 40%.[147] At necropsy, caseous exudation within the sinus infraorbitalis, fibrinous air sacculitis, polyserositis and tracheitis are common. Microscopically, an interstitial pneumonia may be present.

Replication of AIV in waterfowl takes place in the mucosa of the caudal part of the intestinal tract. Affected birds do not develop humoral antibodies, suggesting that the antigen does not contact cells of the immune system or does not elicit an immunologic reaction (Kösters, unpublished).

AIV with H3 or H11 has been isolated from Musophagiformes (turacos). These strains are pathogenic only for Musophagiformes and experimentally are not transmissible to Gruiformes, Columbiformes, Psittaciformes or Piciformes. Clinically, anorexia, somnolence and severe dyspnea occur. Mortality can reach 20%. The disease takes a course of approximately two weeks and survivors develop HI antibodies. Pathology reveals a heavy bilateral congestion of the lungs as well as hyperemia of the liver and kidneys.[147]

A/carduelis/Hannover/1/72/H1N also designated Co-Ca-Virus (Co=conjunctivitis; Ca=Carduelis-Canary) has been isolated from a Siskin and is experimentally infectious to canaries.[87] Severe conjunctivitis is the principal clinical sign. Death occurs after two to four days. The postmortem examination does not reveal any lesions.

Diagnosis

The differential diagnosis list should include respiratory and gastrointestinal pathogens as well as PMV, *Chlamydia* sp. and *Mycoplasma* spp.

A definite diagnosis depends on the isolation and identification of the strain in question. Fowl plague-like conditions caused by highly virulent strains may be suspected due to the acute to peracute course and the hemorrhages at necropsy. Swabs from the cloaca and the upper respiratory tract are suitable for direct virus demonstration from live birds. Parenchymatous organs (lungs, liver, spleen, brain) provide the best postmortem sample for virus isolation. Samples are to be placed in sterile transport medium containing high levels of antibiotics to inhibit bacterial growth and shipped at no more than 4°C. For storage, -70°C or lyophilization is recommended. The final classification must be made by specialized laboratories (WHO reference laboratories).[429] With high titer infections, virus can be demonstrated in the tissues by IF.

Indirect virus demonstration by serology is hampered by the fact that HI test does not recognize all antibody classes and reacts with nonspecific inhibitors. An ELISA is very sensitive but is no more specific than the ID (only group-specific antigen recognized), which is easier to run.[86,401] Paired samples (acute and convalescent phase) are necessary to document an infection. A four-fold rise in titer is indicative of a recent infection. Sera should be kept frozen (-20°C) and 0.01% sodium azide should be added as a preservative.

Retroviridae

Avian retrovirus is separated into two genera. Avian type C retrovirus group (avian leukosis-related viruses) includes avian sarcoma and leukemia virus (SLV). The type species is avian leukosis virus.[63a] A type C retrovirus that is unrelated to SLV is the causative agent of the lymphoproliferative disease

(LPD) in turkeys.[41,63a,291] The avian reticuloendotheliosis virus is now a species within the genus mammalian type C viruses in the subgenus reticuloendotheliosis viruses.[63a]

Retroviridae are enveloped viruses with knobs on the surface that form the outer part of membrane-associated protein spikes, which connect the capsid membrane and envelope. The helical virion measures 90-120 nm in diameter. The genome consists of a negative-sensed, single-stranded RNA. Retrovirus is further characterized by a reverse transcriptase (revertase) that is necessary for the formation of a DNA provirus during viral replication, which takes place in the cytoplasm. Some retroviruses, particularly the sarcomaviruses, have an incomplete genetic code and need a helper virus (frequently an avian leukosis virus) for the production of infectious viral particles. The helper viruses serve mainly for the development of the envelope, and in such cases the new envelope can contain antigens from the helper virus. Type C retrovirus is assumed to have oncogenic taxons. Defective virus can transform the host cells, but infectious particles are not produced (ie, nonproducer cells). In addition to inducing neoplasms, avian retrovirus can also be immunosuppressive, which is enhanced by concomitant infection with other tumor-inducing viruses or infectious agents. All the immunologic organs can be involved (anemia, bone marrow fibrosis and bursal and thymic atrophy). Immunosuppression is probably due to cessation of B-cell maturation and a block in the development of T-cells, possibly because of interference with the synthesis of interleukin-2.[313]

Avian Sarcoma/Leukosis Virus (SLV)

Avian SLV's share a common group-specific (gs) antigen and can induce neoplasms in chickens and to a lesser extent in other avian species. The group is differentiated into several types or subspecies based on susceptibility of genetically varied chicken fibroblasts, interference patterns with members of the same and different subgroups and viral envelope antigens recognized by VN antibodies.[313]

Subgroup A and B occur as common exogenous viruses (infective viruses released by host cells without damage to the cell). Subgroup A is more commonly encountered. Antibodies to subgroup A and B are common among free-ranging wild fowl and domestic chickens. Subgroup C and D are rare. Subgroup E includes the ubiquitous, endogenous (retroviral genes that are integrated in the genome of gonad cells and can be vertically transmitted to the offspring) leukosis virus. This virus has a low pathogenicity and functions principally as a helper virus for defective avian leukosis virus, allowing the production of group-specific antigens. Subgroup F has been isolated from the Common Pheasant and the Green Pheasant. Subgroup G is assumed to be different from the chicken strains. These strains have been recognized in Lady Amherst's Pheasant, Golden Pheasant and Silver Pheasant. Subgroup H consists of an endogenous virus isolated from a Hungarian Partridge. Subgroup I was isolated as an endogenous virus from Gambel's Quail. Endogenous viruses isolated from the Mongolian Pheasant, Swinhoe Pheasant, Painted Quail and chickens have not been classified.

The host spectrum is dependent on autosomally transmitted susceptibility or resistance of avian cells to receptors of avian retroviral subgroups (susceptibility = dominant, resistance = recessive). Genetic resistance can be selected for or manipulated.[101,313] Subgroups may produce varying types of tumors, and many neoplasms occur in connection with defective viral strains that require a helper virus for replication.[165] Despite high rates of infection (more than 50% in some flocks), few birds (1 to 3%) actually die from a neoplastic disease. The types of neoplasias induced by the avian SL group include fibrosarcoma/mesenchymoma, chondroma, osteochondrosarcoma, osteopetrosis, mesothelioma, endothelioma, hemangioma, undifferentiated stem-cell leukosis, lymphoid leukosis, myeloblastosis/monocyte leukosis, myelocytosis, myelocytomatosis, erythroblastosis (medullary or leukemic), nephroblastoma, renal adenoma/adenocarcinoma, ovarian cystadenoma/adenocarcinoma, thecoma, granulosa cell tumor, seminoma, hepatoma, pancreatic adenoma and carcino-/fibrosarcoma of the intestinal mesentery.[31]

Etiologic confirmation of neoplastic induction has been conducted only for the chicken and turkey. In all other species, the leukotic sarcomatic disease processes are classified according to pathomorphologic and histologic lesions. Virus isolation has been successful only within the order Phasianiformes. Some neoplasms documented in captive-bred companion and aviary birds may prove to be induced by SLV. Because many birds bred in captivity are endangered, more investigations are necessary in order to recognize genetically resistant host groups. The gs antigen of SLV has been described in budgerigars; however, the birds in question were aleukotic.[290]

Lymphoid leukosis is the most common type of retroviral-induced tumor seen in birds. This neoplastic condition has been described in Gruiformes, Sphenisciformes, Columbiformes, Psittaciformes, Strigiformes, Falconiformes, Cinconiiformes, Anatiformes and Passeriformes.[28,55,150,179,420]

Erythroblastosis, myeloblastosis and stem-cell leukosis have been documented in canaries, and erythroblastosis has been diagnosed in a Sulphur-crested Cockatoo. Myeloblastic leukosis has been reported in the Sulphur-crested Cockatoo, budgerigar, Turquoise Parrot and Pacific Parrotlet. Leukemic erythroblastosis has been observed in the Rufous-tailed Weaver and Ultramarine Grosbeak. It is unclear if "erythremic myelosis" in conures (hemorrhagic conure syndrome)[351] should be classified with this group of tumors.

Osteopetrosis has been induced experimentally in guineafowl chicks infected with a virus originating from chickens. Beside the typical bone lesions, the infected birds developed epithelial tumors of the pancreas and the duodenal mucosa.[215]

Transmission

Vertical transmission by gonadal cells (virus in the albumen of the egg) or virus genome (also incomplete) in the haploid egg and semen cells is important. Chicks infected as embryos or very early postnatally remain viremic and do not produce antibodies (immune tolerance). Horizontal infection takes place through contaminated feces and saliva, and antibodies are produced that are not protective. Life-long infections are common.

Decisive age resistance is probably due to the regression of the cloacal bursa. Females are more susceptible to infection than males. Testosterone administration decreases susceptibility and castration of males increases susceptibility. SL affects birds mainly at the time of sexual maturity or later. The incubation period requires months; however, depending on the species involved, virus strain, dose and susceptibility of the host, the incubation period can be short, resulting in an "acute" onset of disease.

Pathogenesis

Depending on the type of oncogenic genes (erythroblastosis, myeloblastosis, myelocytoblastosis), infections with oncogenic strains produce either very small foci of transformed B-lymphocytes (lymphoid strains that have no specific oncogene) in the cloacal bursa or leukocytic precursor cells in other organs, which can disappear or metastasize into a variety of organs (mainly liver, spleen, kidneys) where macroscopic neoplasms are being developed. These tumors are usually malignant and ultimately kill the affected bird.

Clinical Disease and Pathology

A clinical diagnosis depends on identifying visible or palpable tumors. The patient's general condition and ability to fly are frequently undisturbed for a relatively long time. Abdominal enlargement and dyspnea caused by the space-occupying tumors can occur in advanced cases. A massively distended liver may be palpable. Hematology, especially differential smears, are frequently nondiagnostic because avian leukosis rarely results in a leukemic blood picture (ie, tumorous blood cells or their precursors in the peripheral blood). An increase in leukocytes (heterophilia, lymphocytosis and monocytosis) is common. In many instances, the lymphocytes are mature, but in Amazon parrots and chickens, bow-formed pseudopodia may be visible. The AST may be increased if the liver is affected.

SLV causes a variety of non-neoplastic conditions, of which immunosuppressive disorders and suppression of thyroid function are the most important. The latter is considered one cause of stunting in growing chickens.[313] At necropsy, multiple tumors of the liver and spleen, more rarely the kidneys, subcutis, periorbital cavity, heart, lungs, ovary, intestine and cloacal wall are seen. A retained cloacal bursa is suggestive. Affected organs are diffusely swollen with or without a grayish mottled surface and a soft consistency.[244,313] The differentiation of myeloblasts is difficult. One method is based on location: erythrocyte-series myeloblasts develop intravascularly, myeloblasts of the other series develop extravascularly.

Diagnosis

Neoplasms induced by other agents are solitary, while SLV generally causes multiple tumors. In chickens, Marek's disease virus usually affects younger birds and involves nervous tissue, which is rare with SLV-induced tumors (see Chapter 25).

Plasma, serum and neoplastic tissues are best for demonstrating the presence of virus. The virus can also be isolated from oral washings, feces, feather pulp and from the albumen of freshly laid eggs. Samples should be shipped immediately in cooled containers because the virus is heat labile.[244,313] Antemortem diagnosis can be determined using biopsy, endoscopy or differential blood smears. Pathologic

and histopathologic lesions are suggestive. The presence of a retrovirus can indirectly be determined by the demonstration of the reverse transcriptase from neoplastic organs.

Treatment and Control

Treatment is generally ineffective in advanced cases. Experimental application of an androgen analogue "mibolerone" in chicks between the 1st and 49th days of life has been shown to prevent leukosis. The drug is anabolic and had no deleterious effect on egg production.[313] This drug has not been investigated in companion birds. Selection of genetic resistance in the presence of the virus is a useful tool and should be applied wherever possible. The subtype in question should be determined, and the help of a geneticist is necessary. Another hypothetical method includes testing of all breeders for antibodies and antigen in the reproductive cells (female: egg albumen; male: semen), and infected birds should be excluded from breeding. This would allow the production of virus-free flocks; however, this situation may increase the susceptibility of the flock. Vaccines are not available.

Erythremic Myelosis in Conures (Hemorrhagic Conure Syndrome)

This condition has been recognized as an endemic disease in Blue-crowned Conures, Peach-fronted Conures, Orange-fronted Conures and Patagonian Conures. Periodic recurrence of eventually fatal bleeding is characteristic of the disease.[351] During these bleeding episodes, proliferations of erythroblasts are present in the hepatic sinus and in the pancreas. Normal bone marrow is replaced by immature red blood cells suggesting erythroleukosis. A viral etiology (retrovirus) has been suggested, but has not been proven. Calcium deficiencies are believed to trigger the disease.

Clinical Disease, Pathology and Diagnosis

Epistaxis, dyspnea, severe weakness, intermittent polyuria and diarrhea and occasionally ataxia are common. Clinical pathologic changes include packed cell volume of approximately 26%, leukocytosis represented by heterophilia (84%), severe polychromasia and anisocytosis, decrease of the total protein, hypoglycemia and hypocalcemia, elevated creatinine and large numbers of immature erythrocytes in the peripheral blood.

At necropsy, multiple pulmonary hemorrhage, development of pseudocysts in the pectoral muscles and pericarditis are common. Histopathology reveals large numbers of erythroblasts in the sinus of the liver and in the pancreas. Hemorrhages may be noted in the lungs, and hemosiderin has been described in pulmonary macrophages around blood vessels, bronchi and in the air sacs. Hyperplasia of the bone marrow by proliferation of immature erythrocytes can take place.

Clinical pathology changes, bone marrow aspiration and histopathology are the only currently available diagnostic tests. All therapeutic regimes have been unsuccessful. Administration of calcium can prolong a bird's life and may stabilize the patient's condition.

Avian Reticuloendotheliosis Virus (REV)

REV differs from SLV and is related to certain mammalian REV. As with SLV, several subspecies or subgroups that are closely related, but differ in antigenicity and pathogenicity exist. These include reticuloendotheliosis virus (Twiehaus),[84,436] duck infectious anemia virus, spleen necrosis virus, chicken syncytial virus (CSV),[84,436] nonclassified isolates from Muscovy Duck, visceral lymphomatosis of the Common Shelduck[151] and racing pigeon (serologic evidence in 0.1% of examined sera).[161]

Some of the viruses in this group have oncogenic properties and induce tumors principally of lymphoreticular or reticuloendothelial cells. Occasionally, these viruses are associated with other neoplasms such as histiocytic sarcoma, fibrosarcoma or myxosarcoma.[434,435] Non-neoplastic lesions due to degenerative-inflammatory processes are common. As with SLV, defective strains that require helper viruses to replicate do occur.[84,436]

The natural hosts are probably turkeys and waterfowl; however, chickens, ducks, geese and Japanese Quail are also susceptible to natural infection. Experimental infection is possible in pheasants and guineafowl.

Transmission and Pathogenesis

Horizontal transmission occurs among young birds when viremic animals shed the virus via feces or in body fluids. Mosquitos, particularly *Culex annulirostis*, are reported to be capable of transmitting the virus after feeding on a viremic bird. Vertical transmission is possible, but only at a low rate with eggs (albumen) and semen. The virus replicates primarily in the reticular and endothelial cells along the capillary walls. There is no detailed knowledge on the

mechanisms for entering the host cells, but differentiated receptors are indicated by different reactions in various genetic host lines. Following adhesion of the virus there is a proliferation of cells originating from primitive mesenchymal type or the reticulum associated with lymphoid tissue. The type of cells is the same in all susceptible bird species. These proliferating cells can also invade nervous tissues but, in contrast to Marek's disease virus, are not lymphocytes. In contrast to SL, most REV-induced neoplasms occur in young birds, although some chronic cases have been reported. Infections of neonates or young birds that are not immunocompetent result in immunosuppression triggering a rapid proliferation of cells carrying the appropriate oncogene. Infection with REV induces a transient or permanent disturbance of the immune system. The mitogenic stimulation of B- and T-cells is inhibited, as is the activity of the cytotoxic T-lymphocytes (the portion of the immune system directed against neoplastic cells). Suppressor T-lymphocytes are activated, which inhibits the normal proliferation of lymphocytes.[84]

Diseases Caused by the Twiehaus-type Strains

Twiehaus-type strains are transmissible to chickens, Japanese Quail, ducks, pheasants and guineafowl.

- ***Turkeys:*** A case in a free-ranging turkey has been reported.[238] Incubation period in turkeys is 8 to 11 weeks. Morbidity can reach 10 to 33%, but the mortality of clinically ill birds is high (30 to 60%). Turkeys suffer from diarrhea and occasionally from lameness. Some animals die without prior clinical signs. The highly distended liver is palpable. Clinical chemistry shows an increase in serum transferrin and globulin levels, but a decrease in albumin. Hematologic changes are evident only shortly before death.[436]

  At necropsy the liver is several times larger than normal or it may show multiple small tumors that may also be present in the spleen, kidneys, gonads, thymus, cloacal bursa and bone marrow.

  Histopathology shows infiltration of lymphoreticular cells (vesicular nucleus with mainly two nucleoli, light blue cytoplasm following HE staining and numerous mitoses) that replace a high amount of the parenchymal tissue. These cellular infiltrates are also present in peribronchial and pulmonary interstitial tissue as well as in the mucosa, submucosa, tunica muscularis and serosa of the intestine. The villi may be club-shaped. Focal infiltrates may occur in the kidneys and peripheral nerves.

- ***Differential Diagnosis:*** The rule-out list includes SL and LPD. In addition to microbiologic methods for viral demonstration and identification, SL can be suggested histopathologically by the appearance of uniform cells in tumorous tissues. RE and LPD are difficult to differentiate. Splenomegaly (pale pink, mottled surface) and minor swelling of the liver are characteristic for LPD. In many cases of LPD, the thymus is enlarged, although the cloacal bursa is normal. RE usually induces neoplasia in the digestive tract, which is less common with LPD, in which more severe lesions occur in the pancreas. In both diseases, pleomorphic cells (lymphocytes, lymphoblasts, RES cells and plasma cell) are common; however, in LPD, less mitosis is present in the more mature cells.[181]

- ***Japanese Quail:*** It is assumed that strains from these birds belong to the Twiehaus-type because of their high neoplastic potential. Because the REV are serologically related, cross-reactions between subgroups are to be expected.[57,356] In contrast to outbreaks in other birds, the disease appears shortly after sexual maturity (six weeks in Japanese Quail) and lasts for several months. Mortality can reach 100% in birds with depression, anorexia and dyspnea.[57]

  The most striking and consistent lesions are thickenings and nodular foci along the digestive tract (crop, proventriculus, ventriculus and intestine, including the ceca), liver, spleen, lung, heart, pancreas, kidney, ovary, testes, mesentery, thyroid gland, skin and ischiatic nerve. Histopathologic examination reveals the same type of cells as described in turkeys.

- ***Pheasants:*** An etiologic agent related to the REV Twiehaus-type strains has been isolated from pheasants (Pheasant-REV-Hungary-1) (Ph-REV-H-1).[83] The disease occurred in approximately six-month-old pheasants that displayed compact nodules in the skin of the head and on the oral mucosa. The infraorbital sinuses were filled with inspissated material, which caused bulging of the cheeks and the anterior aspect of the eye sockets. The surface of the nodules was occasionally necrotic and covered with pseudomembranous deposits reminiscent of fowl pox. Small grayish nodules in many other organs (ingluveal wall, spleen, liver, kidney, lung, air sacs and skeletal muscles) were evident at necropsy. Histopathology revealed extensive infiltration of neoplastic lymphoblast cells into the corium of the skin or the oral mucosa. Hemorrhage and inflammatory cells were infrequently recognizable in the neoplastic tissue. The presence of a few PSA-positive cells suggests

Russel bodies consistent with plasma cells. No Bollinger bodies were demonstrable in the epithelial cells of the affected cutaneous regions.[83]

- ***Ducks:*** The disease has been observed mainly in Australian free-ranging and domestic ducks. The incubation period is estimated at five to nine weeks. The final classification of the virus is still pending. Clinically, depression and ruffled plumage are noted prior to death. At necropsy, the liver and spleen are soft and enlarged. The surface and cross-sections display multiple, yellow-white foci. Tumors in heart and skeletal muscles are present as well as in the duodenum, pancreas, ventriculus and proventriculus. Histopathology reveals the same type of cells as described for turkeys in the form of perivascular foci in the liver, spleen, lungs, kidneys, brain, spinal cord and the sciatic plexus.

- ***Domesticated Goose:*** The virus is related to the Twiehaus-type strains and is designated REV-Hungary-2.[82] The disease starts at 17 weeks of age and the mortality rate increases to 40% by the 22nd week of life. Affected birds are listless, emaciated, have ruffled plumage and are frequently lame. The spleen and liver are usually enlarged and mottled with irregular yellow-white areas throughout the organs. Other organs show predominantly nodular foci (pancreas, intestine and occasionally heart, kidney and lung). Histopathology reveals primarily lymphoblast-type cells in the organs affected by visible tumors, but the adrenal and thyroid glands, bone marrow, gonads, thymus and cloacal bursa may also be involved. The nervous system is unaffected. Occasionally, amyloid deposits are seen in the walls of the capillaries in the liver and spleen.[82]

Duck Infectious Anemia Virus (DIA)

DIA can be transmitted by *Plasmodium lophurae*, one of the agents of avian malaria. Its main host is the Crested Fireback, but it can also parasitize chickens and ducks. The virus remains present even if the *Plasmodium* is experimentally passaged through canaries, turkeys or mosquitoes. In ducks, the virus can be found in peripheral blood cells and in the plasma. The disease is extremely rare and non-neoplastic.[248]

Anemia is severe and frequently followed by death, even if the plasmodium infection has been treated successfully. The virus can be neutralized by antiserum.

Spleen Necrosis Virus (SNV)

Transmission of SNV takes place by direct contact. The incubation period is seven to ten days. Clinically affected birds have a short course of depression, anorexia and anemia, followed by exitus. Anemia may be diagnosed shortly before death. At necropsy, the birds display conspicuous hemorrhages and necrotic lesions of the spleen. Histopathologically, a proliferation of reticuloendothelial cells in the liver, spleen and kidneys is evident.

Unclassified Isolates

Muscovy Ducks

About 10% of six-month-old Muscovy Ducks (700 birds) died within a 13-week period. Nucleic acid hybridization experiments indicated the presence of REV.[252] After one year without any new cases, a second outbreak occurred at the beginning of the next laying period. Undifferentiated blast cells, assumed to be of lymphoid origin, were prominent in peripheral blood smears of affected birds. These cells were cytochrome-oxidase negative and contained coarse and fine granules of PAS-positive material.

At necropsy, tumors were seen in the thymus (40%), liver, spleen, lung, kidney, pancreas and intestines. Histologic examination showed virtually all organs to be diffusely infiltrated by cells of a fairly uniform appearance with intensely basophilic cytoplasm (can be indented) and nuclei with distinct nucleoli. Numerous mitotic figures were evident. Electron microscopy revealed neoplastic cells consistent with undifferentiated lymphoblasts.[252]

Diagnosis (All REV)

The lack of characteristic lesions, variability of lesions and similarity of lesions caused by different etiologies make diagnosis difficult. Direct and indirect methods of viral demonstration are necessary. Heparinized blood, plasma, leukocytes or homogenates from tumorous tissues are suitable for virus isolation. Cell-free material should be stored at minus 60°C. Cellular material can be stabilized by being treated with 7.5 to 10% dimethylsulfoxide followed by storage in liquid nitrogen. REV normally does not cause CPE, necessitating IF or ELISA to demonstrate the presence of intracellular antigen in cell culture. Monoclonal antibodies have been used to classify antigenic relationships between the groups. ELISA, IF or ID can be used for demonstrating antibodies.

Picornaviridae

Picornaviridae are the second smallest RNA virus known, with a diameter of 20-40 nm. They are nonenveloped, have a cubic morphology with 32 capsomeres and single-stranded RNA. Five genera (Enterovirus, Hepatovirus, Rhinovirus, Aphthovirus and Cardiovirus) can be distinguished.[276a] Of the five genera only Enterovirus has been shown to cause problems in birds. Infections may be asymptomatic or can be characterized by gastrointestinal involvement; CNS signs and hepatopathy may or may not occur.

Information is available elsewhere on turkey viral hepatitis and infectious nephritis.[388,184]

Avian Encephalomyelitis (AE)

The classification of AE is still uncertain. The four virus-specific proteins are larger than those usually associated with Picornaviridae.[52] The AE virus is distributed worldwide. The main host is the chicken, but natural infections have been documented in pheasants, Japanese Quail, waterfowl and turkeys. Antibodies following natural infection (without clinical disease) were found in partridges, probably Rock Partridge and Red-legged Partridge, as well as pheasants and turkeys.[42,395] Egg transmission plays the main role in epornitics. Horizontal transmission distributes the virus within the flock inducing latent carriers. Flocks infected during the breeding season will produce two to four infected clutches.

Pathogenesis

Age resistance occurs by six weeks. Only young birds without maternal antibodies or those that are not immunocompetent develop CNS signs, probably because these circumstances allow the virus to reach the brain. Virus in the intestinal tract does not induce clinical signs in nonproducing birds. Infected layers will have a decrease in egg production (five to ten percent). Humoral antibodies induce immunity. Vertical transmission in chickens results in life-long CNS signs (such as incoordination and visual defects) together with good egg production. These birds have no detectable antibodies (Kösters J, unpublished).

Clinical Disease and Pathology

Descriptions are available only for the chicken.[52] Survivors can develop ocular lesions including enlargement of the eyeball, marked opacity of the lens, seemingly fixed pupils and total blindness. Blindness may also occur in Black Grouse and capercaillie raised with AE-vaccinated chickens. In domesticated turkeys, 1% of the poults may show CNS signs including tremors, ataxia and incoordination. About 30% of the sick turkeys may die.[144] It is unknown if free-ranging turkeys in the United States have contracted the disease. Spontaneous recovery from CNS signs has been observed, especially in non-chickens.

Differential Diagnosis and Diagnosis

Encephalomalacia (vitamin E and selenium deficiencies) is the main rule-out. Diagnostic therapy might be indicated. Intoxications, particularly those with a heavy metal (lead) must be considered. In pheasants, infections with Togaviridae are possible in the appropriate season.

Histologic changes are strongly suggestive. Nonpurulent encephalitis, degeneration of the large motoric nerve cells within the cervical and lumbar medullary marrow, central chromolysis and degeneration of Purkinje cells, focal proliferation of microglia (particularly in the cerebellum) and perivascular mononuclear cell infiltrates in the proventriculus, pancreas and heart are characteristic. Perivascular infiltrates consist mainly of lymphocytes, and proliferation of lymph follicles may also be noted.[144] Virus can also be demonstrated indirectly by serologic means (IF).

For confirming the immunity of breeding flocks, an egg neutralization test with an egg-adapted virus strain can be performed. In eggs that are free of antibodies, a characteristic dystrophy of the skeletal muscles is seen. Serologic examinations are possible with ID and ELISA.

Control

Several types of vaccine are available. Inactivated vaccine injected IM is suitable for birds without humoral antibodies that are ready for breeding and under conditions where the spread of the virus is to be prevented. Live vaccines given orally may also be suitable, but the vaccine should not contain egg-adapted strains, because these have lost the ability to infect via the intestinal tract. Live, adapted, field strains given by wing web can cause clinical signs, and therefore are not recommended for fancy chicken breeds or non-gallinaceous birds.

Duck Virus Hepatitis (DH)

Three types of DH infection are distinguished.

Type I has a worldwide distribution and causes high mortality (up to 100%) in domesticated *Anas platyrhynchos* ducklings, mainly during the first week of life. A distinct age resistance (three to six weeks) is seen in which younger birds are protected by maternal antibodies. In Europe, where chlamydial infections are endemic in ducks, the typical course of the disease can be altered. Infection with *Chlamydia psittaci* concurrently with DH virus can overcome the immunity to DH virus in ducklings older than four weeks. In these birds, hepatopathy as well as duck fatty kidney syndrome and focal pancreatic necrosis have been described.[92] Clinical signs include peracute onset of depression followed by CNS signs (nonspecific) and death. Postmortem findings include hepatomegaly, splenomegaly and petechial hemorrhages on most parenchymatous organs.

Mallard ducklings are susceptible to the virus, but generally remain asymptomatic.[129] The same is true for domesticated *Anser anser* goslings. Experimental infection in turkeys and quails induces low mortality. High mortality occurs in experimentally infected pheasants, geese and guineafowl.[180] The virus has been isolated occasionally from several duck species maintained in zoos, although it is questionable whether or not this virus was the cause of death. The Brown Rat may serve as a vector. Two variant strains have been isolated; their relationship to Type I has not been established.[441]

Type II has been isolated only in East Anglia, United Kingdom. In contrast to Types I and III, it is an astrovirus (antigenically different from astrovirus isolated from chickens and turkeys) that has been associated with 10-50% mortality in ducklings, depending on their age. All the recorded outbreaks have initially involved ducks kept in open enclosures, so that all free-ranging birds and gulls are suspected to be vectors.[441]

Type III has been isolated only in the United States. The virus is not related to Type I. Diseases are generally less severe than those caused by type I with mortality rates rarely exceeding 30%. *Anas platyrhynchos* ducklings appear to be the only susceptible species.[441]

Control

Viral-specific convalescent serum can be used in newly hatched ducklings. A vaccine is available for Type I that can be used in breeder stock to ensure high titers of maternal antibodies. A live avirulent vaccine can also be used in ducklings in the face of an outbreak.[441] Recovered ducklings are considered immune.

Viral Enteritis in Cockatoos

Free-ranging Sulphur-crested Cockatoo and galah (Rose-breasted Cockatoo) chicks (seven to nine weeks old) developed profuse diarrhea and wasting and died shortly after being captured. The incidence of this disease (1,000 to 2,000 birds) is considered to be 10-20% annually in which galahs represented the higher percentage of affected birds. Clinical signs included yellow-green and mucoid feces beginning two to seven days after capture. Affected birds were anorexic, depressed, lost weight and became dehydrated following the onset of diarrhea. All affected birds eventually died or were euthanatized after one to four weeks of clinical disease. The birds failed to respond to treatment with various antibiotics and electrolytes.[272]

At necropsy, the duodenum and the upper jejunum were dilated by yellow-green mucoid fluid and gas, and the walls were distinctly thickened. The birds were dehydrated, and the liver, kidneys, thymus and cloacal bursa were hypoplastic.

Histopathologically, the villi of the duodenum and the upper jejunum were short, occasionally with some fusions. The crypts of Lieberkühn were markedly elongated. Proliferation of the epithelial cells in the crypts resulted in a thickened layer of enterocytes. Mild-to-moderate infiltrates of macrophages and lymphocytes were present in the lamina propria. Hyperplasia of cortical cells in the adrenal gland was seen in some birds.[72]

Particles with the morphologic features of an enterovirus were detected in 18 out of 31 birds by electron microscopy. Because no virus could be isolated in embryonated chicken eggs, as is frequently the case with entero-like virus, the etiologic importance of the particles could not be determined.

TABLE 32.17 Reference Data on Common Avian Viruses

Virus	Incubation	Environmental Stability	Disinfectants	Control
Adenovirus	Natural infection 24-48 hours, slow spread in flock	Stablilty varies with isolate, resistant to many disinfectants, resistant to chloroform, 60-70°C, pH 3, pH 9	Formalin, aldehydes, iodophors (requires 1 hour of contact)	No vaccine, vertical transmission, continuous infectivity cycle
EEE & WEE virus	1-7 days	Stable when refrigerated	0.2% formalin, 3% phenol	Horse vaccine for pheasants
Enterovirus	1-7 days transovarial, 11 days with horizontal transmission	Extremely stable, resistant to chloroform, pH 3, 56-62°C for hours	1% formaldehyde, 2% caustic soda, 2% calcium hypochlorite (3 hours), 5% phenol, undiluted clorox	AE vaccine, several types, see text
Herpesvirus - PDV	Natural outbreak, 3-7 days, experimental, 48 hours	Unstable, cell associated or mucus coated virus more stable, 56°C for 1-5 minutes	Most disinfectants probably effective	Killed vaccine
Herpesvirus - AT	Experimental, 3-4 days			ILT vaccine protects chickens from AT, efficacy of ILT vaccine in Amazon parrots is unknown
Budgerigarherpes	Unknown	Unknown		Interrupt breeding to increase Ab titers
Herpesvirus - DVE	3-4 days			Live attenuated vaccine, protect ponds from free-ranging waterfowl
Herpesvirus - ILT	6-15 days			Chicken vaccine, but not for pheasants
Herpesvirus - PHV	Experimental, 7 days Natural outbreaks, 5-10 days	56°C for 30 minutes		Experimental vaccines decrease clinical signs
Herpesvirus - FHV/OHV	Experimental, 3-10 days depending on virus and host			No vaccine, avoid mixing infected and non-infected birds, artificial incubation and hand-rearing
Influenza	Few hours to 3 days, varies with virulence, route of exposure and avian species	Unstable	Most disinfectents	Ultraviolet radiation, temperature increases
MSD pheasants Adenovirus Group II	6 days with oral infection			Oral vaccination of chicks (4-6 wks), chicks with THE or avirulent MSD
Newcastle disease virus	Experimental, 3-7 days, 25 days in some	Daylight, up to 4 weeks room temperature, 56°C sensitive	Lysol, cresol, phenol, 2% formalin, oxygen, cleaving compound, resistant to most disinfectants	
Orbivirus	Experimental, 4-8 days	Extremely stable	pH 3, resistant to lipolytics	
Papillomavirus	Unknown, probably prolonged	Stable, ether, temperature extremes	See text	
Polyomavirus	Unknown, suspected to be days to weeks	Stable, 56°C for 2 hours	Chlorine dioxide, phenolic disinfectants, Clorox	Experimental vaccine protects macaws from BFD virus
Parvovirus	5-15 days, varies with age and antibody titer	Stable, resistant to organic solvents, pH 3, 56°C for 3 hours, Na hypochlorite, H_2O_2 (1%)	Resistant to many disinfectants	Vaccinate breeder geese six weeks before egg laying (IM vaccine)
PBFD virus	Experimental (min 2-4 weeks), maximum unknown, may be months to years	Probably very stable, CAV stable to 60°C for 1 hour	Unknown	Experimental killed vaccine effective
Poxvirus	Varies (virus strain and host species) generally 1-2 weeks, canaries 4 days (10-12 days for hybrids)	Stable in soil for one year	Steam, 1% KOH, 2% NaOH, 5% phenol	Homologous or heterologous vaccines (see text)
Reovirus	Psittacine infected IM shed virus 2 days PI, geese 3-6 days, experimental, 3-9 days post-infection	Stable, pH 3, H_2O_2, 60°C for 8-10 hours	70% ethanol, 0.59% iodine, aldehydes/alcohols (2 hours)	Experimental inactivated vaccine may be effective
Retrovirus	Unknown	Unstable, stable pH 5 to pH 9, moderate ultraviolet radiation stability	Lipid solvents (detergents), thermolabile, freeze-thawing destroys	

Diseases with Infectious Characteristics but Uncertain Etiology

There are many clinical conditions that suggest a viral infection, and new ones are certain to be recognized with the advent of better diagnostic methods. Few of these conditions have been described sufficiently to be considered as reproducible pathologic processes. The so-called twirling syndrome[27] in the African Silverbill, Zebra Finch, Gouldian Finch and closely related species manifests signs that indicate the possibility of a paramyxovirus as the etiologic agent. The most important disease described in Psittaciformes of uncertain etiology but suspected to be a virus is the neuropathic gastric dilatation or proventricular dilatation (see Chapter 19).

Neuropathic Gastric Dilatation (NGD)

This disease has been observed since 1977.[132] It is suggested that the problem has been imported with macaws from Bolivia. The various *Ara* spp. are considered most susceptible but the disease has been described in many other Psittaciformes including *Aratinga* spp., Nanday Conure and other conures, *Amazona* spp., *Pionus* spp., Hawk-headed Parrot, Grey-cheeked Parakeet, African Grey Parrot, Senegal Parrot and other *Poicephalus* spp., Eclectus Parrot, *Coracopsis* spp., *Alisterus* spp., *Cacatuninae* spp. and cockatiel.[115] A disease with clinical and histologic lesions similar to those described with Psittaciformes has also been confirmed in free-ranging Canada Geese.[70]

Since its first description in South America, the disease has spread to North America and European countries (United Kingdom, Germany, Switzerland, The Netherlands). Several possible viral agents have been described by electron microscopy, but none has been confirmed as the etiologic agent. Approximately 100 nm-sized particles were described in the neuronal perikaryon of the spinal cord.[50] Virus-like particles of 70-80 nm were described in the nuclei of the tubular epithelium of the kidney which were morphologically consistent with an adenovirus.[167] Intranuclear and extranuclear eosinophilic inclusion bodies were described in the neuronal perikaryon of the celiac ganglion and the myenteric plexus, which revealed electron microscopically virus-like particles both inside and outside those inclusions. The morphology of those particles is consistent with paramyxovirus.[253]

Pathogenesis

The pathogenesis can be reconstructed only by means of the lesions. Generally, this is a disease of young birds (nestlings to juveniles),[390] but adults may also develop clinical signs. The destruction of the intramural ganglia of the proventriculus, ventriculus and to a lesser extent the descending loop of the duodenum explains the loss of peristalsis followed by obstruction of the proventriculus, atrophy of the ventricular wall and insufficiently digested food. The obstruction of the proventriculus can cause vomiting (see Color 8). The involvement of autonomic ganglia of the heart, brain, particularly the cerebellum and medulla oblongata, and the spinal cord may cause acute death with 100% mortality in affected birds. It has been suggested that the neurologic lesions may be caused by an autoimmune reaction.[132]

Destruction of the intramural ganglia of the organs mentioned is considered pathognomonic for the disease, and allows morphologic differentiation from other conditions in the region, even those with the loss of peristalsis. Secondary infections may complicate the diagnosis. Because the etiologic agent has not been confirmed, it is impossible to define an "incubation period." Epizootiologic evidence suggest that clinical changes may take from four to twenty-four months to develop.

Clinical Disease and Pathology

NGD is a chronic disease that may be associated with an acute onset of clinical signs. Clinical signs vary with the host and the severity of the condition, but generally include depression, progressive weight loss, vomiting or the passing of undigested food in the droppings (Figure 32.24) (see Color 8). Some birds have an excellent appetite yet continue to lose weight. Anorexia may occur shortly before death. Polydipsia and polyuria may occur as well as neurologic signs such as leg weakness, incoordination and lameness. Diarrhea may occur late in the disease process and is usually the result of secondary bacterial or fungal enteritis. The obstruction of the pro-ventriculus can lead to pressure atrophy of the mucosa, sometimes followed by ulceration and even rupture (Colors 32.14, 32.19). Cachexia may induce cardiovascular failure due to energy deficiencies.[153,167,253]

The hemogram reveals a two- to three-fold increase in leukocytes (heterophils, monocytes and basophilic granulocytes). The negative caloric balance results in hypoglycemia and anemia.[153] An elevation in creatine phosphokinase (CPK) levels has been suggested as a diagnostic tool;[191] however, CPK concentrations are not believed to increase from damage to smooth muscles, and atrophy of striated muscle usually does not cause increased CPK activities.

Necropsy findings include emaciation, cachexia and a distended, frequently impacted proventriculus, ventriculus or crop (Color 32.14). Erosions and ulcerations with or without hemorrhage can be observed on the proventricular mucosa, occasionally even causing ruptures. The muscular layer of the hypotrophic ventriculus appears whitish in color.

Histopathologically, the proventriculus, ventriculus and the descending loop of the duodenum exhibit varying degrees of loss of nervous cells in the myenteric plexus (Auerbach) and substitution by infiltrates of lymphocytes, monocytes and sometimes plasma cells. Similar lesions are present in the minimally developed submucosal plexus (Meissner) and the celiac ganglion; however, not all ganglia are affected, and some are only partially involved. The ventriculus shows multifocal lymphocytic leiomyositis with degeneration of the smooth muscle cells and lymphocytic infiltration of the intrinsic nerves of the tunica muscularis. In some cases, extrinsic nerves are involved as well. A nonpurulent myocarditis with mononuclear infiltration of the ganglia occurs occasionally. Independent of clinical signs, lymphocytic encephalitis with perivascular cuffing can be detected in the cerebellum and medulla oblongata, but rarely in the cerebrum. Gliosis and pseudoneuronophagia have been described in the brain stem. Occasionally asymmetric lymphocytic poliomyelitis or leukomalacia are observed in the lumbar spinal cord. Intranuclear (with halo) and intracytoplasmic inclusion bodies have been described in nerve cells.[153,167,253]

Diagnosis

In the experience of the author, about 10% of dead birds with signs indicative of NGD are not suffering from that disease (see Chapter 19). Any cause of intestinal blockage can cause similar-appearing clinical changes and gross necropsy findings. Neoplasms, scars or larvae migrans have also been found as the cause of impeded passage either in the ventriculus or the jejunum. Clinical signs in combination with contrast radiographs that indicate a dilatated proventriculus and slowed gastric emptying time provide only a suggestive diagnosis. In some early cases, hypermotility of the gastrointestinal tract may be noted.[167] Antemortem diagnosis requires histopathologic examination of biopsies of the ventriculus, which is difficult to sample. The absence of histologic lesions with suggestive clinical signs can indicate that the proventricular dilatation is of another etiology, or that the biopsy sample was collected from unaffected tissue.

Treatment and Control

Apart from hygienic considerations, symptomatic treatment can be attempted consisting of removal of stagnant ingesta, feeding soft or liquid feed and control of secondary infections. Supportive care has been efficacious in keeping birds alive for more than one year. In breeding flocks, affected birds should be removed as soon as possible. Birds that are in contact with patients that have confirmed infections should be placed in quarantine for at least six months together with cockatiel fledglings or breeding pairs as sentinels. New additions to the aviary should be quarantined for at least six months; however, this quarantine period may be insufficient to detect latently infected birds. Numerous cases have occurred in birds from stable flocks with no access to birds outside the collection (with the exception of free-ranging birds) for many months to years. These findings may cast a doubt on the infectious etiology.

Nephroenteritis of the Domestic Goose

This disease has been described in Hungary and was differentiated from goose hepatitis and goose myocarditis.[360,407] Although the agent has not been isolated to date, it is possible to reproduce the disease with filtrated material from the kidneys and intestine of sick goslings. The agent does not serologically react with duck plague virus. The incubation period following experimental infection with organ homogenates of ill birds is 6 to 18 days. Contact birds need six weeks and sometimes even more before clinical signs develop.[359]

Clinical Disease and Pathology

Affected goslings seem to develop normally. The watery feces observed at the onset of the disease is frequently overlooked. Lethargy occurs only a few hours prior to death. Eight to ten hours before death, the feces become malodorous, fibrinous or bloody. In natural outbreaks, the peak of the mortality (up to 100%, but dependant on age) is reached at between 18 to 21 days of age. In contrast to the other diseases mentioned, mortality in contact birds can be ob-

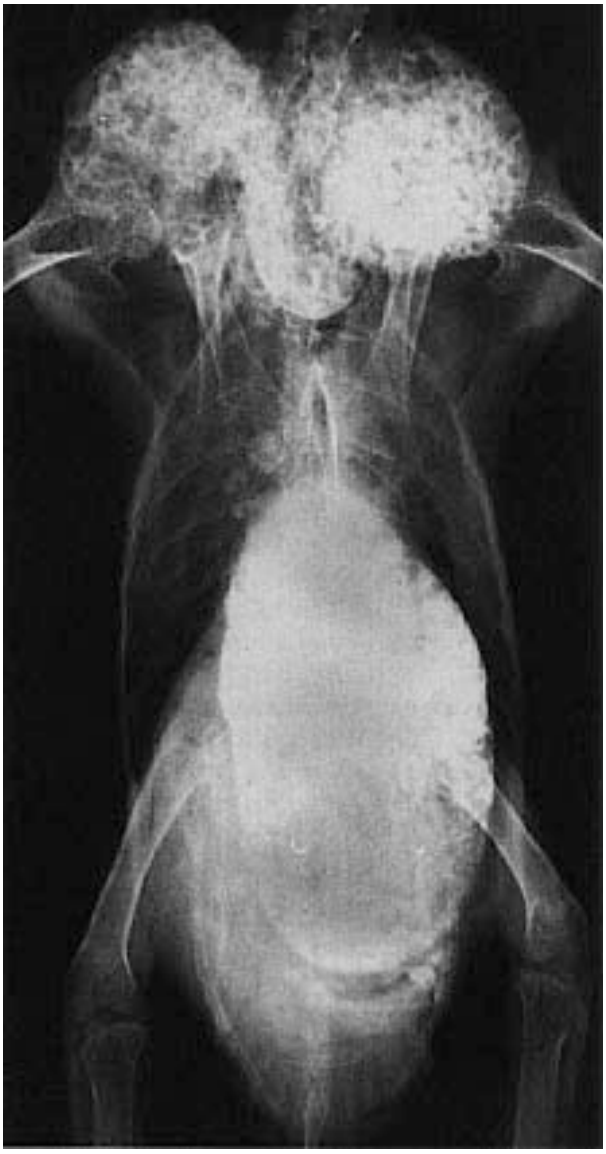

FIG 32.24 A Severe Macaw hen was presented for an acute onset of severe depression and reluctance to move. The bird had been part of a closed breeding aviary for over eight years and had recently fledged a clutch of chicks. The bird was severely emaciated (above). Survey radiographs indicated a large ventral abdominal soft tissue mass. Radiographs (right and below) taken three hours after administration of barium indicated dilatation of the proventriculus and a slowed gastric-emptying time. The histologic diagnosis was neuropathic gastric dilatation.

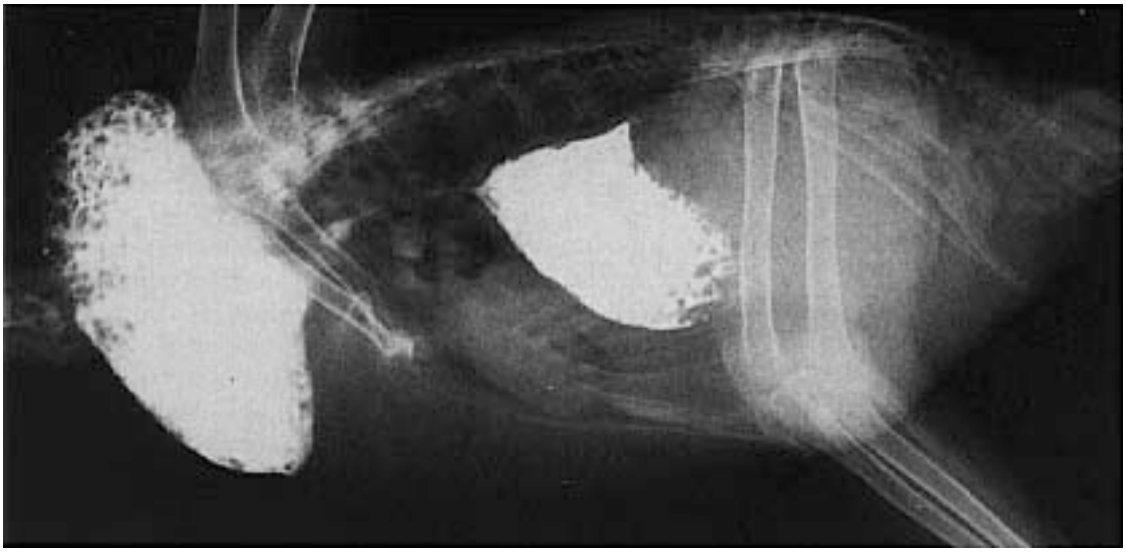

TABLE 32.18 Viruses with Specific Treatments

Virus	Therapy
Avipoxvirus	See text
Herpesvirus	Herpesviruses that code for their own DNA polymerase are sensitive to acyclovir; Baypamun* IM 3 injections within 2 days, 1 ml/kg
PDV	Both Baypamun* and acyclovir can be tried
ILT	None reported
DEV	None reported
AT	Not attempted
PHV	Try Baypamun,* treat secondary trichomoniasis
FHV	Try Baypamun;* acyclovir has renal toxicity; pay special care to birds that consume little water

Therapy for other virus infections consists of supportive care and antimicrobials to control secondary infections.
*Available only in Europe.

served beyond the sixth week of age. At necropsy, a massive mucoid-hemorrhagic, fibrinoid necrotizing enteritis as well as hemorrhagic nephritis is typical. The intestinal mucosa displays irregularly distributed confluent necrotic areas. The kidneys are enlarged, dark red in color and have multiple gray-greasy foci. Edema of the mesentery is considered to be typical as well as edema of the subcutis. Petechia and ecchymosis may be seen in the subcutis and the skeletal musculature. The spleen is moderate to massively enlarged. The consistency of the liver is friable. A hemorrhagic change of the cloacal bursa and the thymus is considered characteristic for the disease. In goslings older than six weeks, the kidney is more severely affected than the intestine. Visceral gout is seen in these birds frequently as a sign of the renal tubular damage.[359,360,407] Uricemia is considered to be a major cause of death.

Histopathology shows serous-to-hemorrhagic interstitial "nephritis." Cellular reactions are rarely seen, because the birds die before the migration of inflammatory cells into the damaged tissue. The tubular epithelium is exfoliated, causing detritus casts in the lumina. The intestinal lesions consist of loss of epithelial cells and the structure of the villi. The result is necrotizing-to-pseudomembranous hemorrhagic enteritis. Lymphocytic cells can be seen in increased numbers in the submucosa. Hyperemia and edema can also be observed in other parenchymatous organs. Details on the daily course of an experimental infection have been reported.[407] Parvoviral hepatitis and reoviral myocarditis should be ruled out. Because of the intestinal lesions duck plague must be considered. The age of the goslings, clinical signs and histopathology, including lesions of the cloacal bursa and the thymus, are indicative. Attempts at viral isolation are encouraged and experimental infections with cell-containing material might be necessary.

CHAPTER

33

BACTERIA

Helga Gerlach

Scientific principles of bacteriology are universal; however, in application, bacteria can adapt to their avian hosts, altering the form and pathogenicity of well known bacterial species. Avian bacteriology is further complicated by the fact that bacteria that are as yet taxonomically undescribed can be isolated from a variety of avian species. Some of these bacterial strains have been erroneously classified as taxons (eg, *Pasteurella haemolytica*, *Alcaligenes faecalis*). In general, bacterial adaption to an avian host minimizes cross-species transmission from birds to mammals. Non-host-adapted transmission usually requires large numbers of organisms, repeated exposures, specific susceptibility or immunosuppression. Some host-adapted strains may form biovars that are specific to one avian species (or a few closely related species) as compared to the dominant species.

Example of Bacterial Taxonomy:

Genus	*Salmonella*
Species	*S. typhimurium*
Subspecies	*S. typhimurium* var *copenhagen*
Biovar	Pigeon strains, chicken strains

Bacterial infections may be primary or secondary. This differentiation is important for the evaluation of a disease process. After becoming established, many secondary invaders are able to maintain a disease process independent of other infectious agents or predisposing conditions. Laboratory examinations (biochemical or serologic) are rarely of any help in differentiating primary from secondary invaders. The companion bird clinician must determine the importance of bacterial isolation for a specific bird species and a specific disease process. Analogous conclusions drawn from poultry literature may not be valid, and experimental infections are frequently not possible. Some specific points may guide the clinician in interpreting bacterial culture results (Table 33.1).

TABLE 33.1 Guides to Interpretation of Bacterial Culture Results[27]

- Isolation of an organism in an almost pure culture (approximately 80% of the colonies present) may indicate that the bacteria is a component in the disease process.
- Isolating large numbers of bacteria in almost pure culture from the heart tissue is suggestive of bacteremia, and the isolated agent should be considered part of the disease process.
- Isolating a bacteria that is part of the autochthonous flora may indicate that it is functioning as an opportunistic (secondary) pathogen.
- If the isolated organism has pathogenicity markers, it is probably involved in the disease process. It is not possible to determine if the bacteria is a primary or secondary pathogen.
- Isolating bacteria from parenchyma with pathologic or histopathologic lesions suggests that the agent contributed to the disease process.
- Isolating a bacterium without identifying other microorganisms (virus, chlamydia, other bacteria, fungi, protozoa) suggests that the agent is a primary pathogen. Finding virus or chlamydia suggests that the bacterium may be a secondary pathogen. Isolation of bacteria from a bird with fungi and protozoa suggests that the bacterium is a primary pathogen.
- Obtaining mixed cultures or identifying individuals within a given flock with different bacterial isolates suggests secondary infections are occurring.
- Isolating small to moderate numbers of bacteria from the liver or kidney can be "normal," because birds have hepatic and renal portal circulations and lack lymph nodes that filter blood before it drains into the liver and kidney. Because lymph follicles are distributed throughout these organs, defense responses actually occur within the parenchyma and not externally, as in mammals. These organs should not be expected to be sterile, but should be expected to contain autochthonous flora. The number of organisms isolated at necropsy depends on the time of death and the method of handling the body (eg, storage, preservation).

Because the isolation of "unusual" bacteria can be expected from avian samples, the clinician can enhance results by providing the laboratory with a thorough anamnesis, exact species of the bird in question, and as far as possible, the names of particular bacteria that may be suspected in the case. This latter point is especially important if special media or environmental conditions are needed for bacterial isolation. In addition, with some organisms, special transport media and shipping methods (eg, on ice) may be necessary to preserve the organism.

Blood cultures are considered a definitive diagnostic tool in humans and some mammals. In these species, samples are, as a rule, taken during a period of fever. A febrile period is difficult to determine in a bird and is generally considered of minimal importance. In birds, organs as well as blood are not necessarily sterile, although the number of bacteria is extremely low. Generally, the isolation of small quantities of autochthonous flora is considered normal, and only the isolation of primary pathogens is really helpful. Because whole blood has bacteriostatic and bactericidal properties, blood culture samples must be transferred immediately after collection to attenuant containing nutrients and one of the artificial heparinoids, for instance Na-polyanetholsulfate. Commercially available blood culture flasks are also useful.

Gram-negative Bacteria of Clinical Significance

"Intestinal bacteria" are considered to be those species that can colonize the intestinal tract. As a group, intestinal bacteria can be part of the normal flora or pathogenic organisms that are not routinely found in the GI tract; in some cases, normal flora can become secondary pathogens. When a bacterium leaves the mucosal surface and penetrates the intestinal wall, it then can induce systemic disease, including septicemia and death. The Enterobacteriaceae are considered the most important avian intestinal pathogens, but other groups, such as *Aeromonas*, *Pseudomonas*, *Alcaligenes*, *Bordetella* spp. and related organisms, as well as *Vibrio* and *Campylobacter*, may also colonize the gastrointestinal tract.

Enterobacteriaceae

The members of the Enterobacteriaceae family typically grow well on commonly used media. Enterobacteriaceae are divided into genera based on specific biochemical and serologic characteristics. Many species are further divided into biotypes and serotypes. In these species, complete identification requires differentiation between the O, K and (in motile species) H antigens. Serologic differentiation between the genera is often difficult since group-specific antigens (lipopolysaccharides) can cross-react.

Enterobacteriaceae are able to propagate in the environment if they are in the proper conditions. Enterobacteriaceae are ubiquitous and considered to be part of the autochthonous intestinal flora in many mammals, including humans and some species of birds (Table 33.2).

TABLE 33.2 Birds in which Enterobacteriaceae are not normal

- Psittaciformes (parrots and parakeets)
- Fringillidae (finches)
- Ploceidae (weaver finches)
- Astrildae (waxbills)
- Accipitriformes (hawks, vultures)
- Falconiformes (falcons)
- Strigiformes (owls)
- Gruiformes (cranes)
- Otididae (bustards)
- Sphenisciformes (penguins)
- Ciconiiformes (storks, ibises)
- Tetraoninae (grouse)
- Musophagiformes (turacos)
- Trochiliformes (hummingbirds)

Isolation of Enterobacteriaceae from the respiratory or reproductive tracts is abnormal. This group of bacteria can colonize most avian tissues, where it is frequently considered as a secondary pathogen. In some cases, Enterobacteriaceae can function as primary pathogens. Substantial differences exist in the virulence of the various Enterobacteriaceae and in the host response to infections. The genera *Shigella* and *Edwardsiella* are normally not cultured from birds (the latter rarely from pigeons). The genera *Enterobacter*, *Hafnia*, *Serratia* and *Proteus* are of a low pathogenicity. The isolation of *Enterobacter agglomerans* (a plant pathogen) in avian feces can indicate the consumption of seeds that contain more than 10^6 bacteria/g of food. This bacterium is common in decaying plant matter; foods containing the bacterium in high numbers should be considered toxic. *Serratia marcescens* is increasingly found in large parrots with chronic debilitating diseases. Predisposing factors seem to include previous antibiotic treatment and immunosuppression.

Escherichia (E.)

E. coli is the most commonly encountered member of this genus; in many avian species it is considered to be a more important pathogen than salmonella (see Table 33.6). This genus contains a number of species that may be motile or nonmotile, encapsulated or nonencapsulated. Classification of the strains of *E. coli* that infect birds has been difficult. The serologic and virulence factors used to classify the *E. coli* strains that infect humans and other mammals do not accurately predict which *E. coli* strains will be pathogenic in birds. Although each serovar of *E. coli* includes both virulent and avirulent strains, there seems to be a slightly higher frequency of virulent strains within the serovars 01, 02 and 078. In experimental transmission studies, all lysine decarboxylase-negative *E. coli* strains have been found to be virulent in birds. Unfortunately, many of the lysine decarboxylase-positive strains are also virulent.

Pathogenesis

The pathogenesis of *E. coli* infections in birds is poorly defined. Mammalian strains produce large quantities of exotoxins that cause many of the clinical and pathologic changes associated with infection. Except for the presence of enterotoxins, avian *E. coli* strains appear to produce few exotoxins. These enterotoxins cause diarrhea by inducing hypersecretion of fluids into the intestinal lumen. Endotoxins may cause hypersensitivity angiitis followed by septicemia and death.

Clinical Disease and Pathology

The clinical signs associated with primary or secondary infections are thought to be governed by the portal of entry to the avian host.

Colisepticemia is characterized by an acute onset of lethargy, anorexia, ruffled plumage, diarrhea and polyuria. *E. coli* septicemia usually involves the kidneys, although clinical signs of renal involvement may or may not be present. CNS involvement is rare. Ocular lesions occasionally occur and include exudation of fibrin into the anterior eye chamber or uveitis. Serofibrinous arthritis can occur as a sequela in some infected birds. Fibrinous polyserositis, the severity of which depends on the chronicity of the infection, may be noted at necropsy. Catarrhal enteritis is common but nonspecific. The most consistent histologic lesion is serofibrinous inflammation with plasma cell infiltration in the liver and kidneys (Figure 33.1).

Localized enteritis caused by *E. coli* is a result of enterotoxin production, which induces an increased secretion of fluids. The resulting diarrhea causes a substantial loss of electrolytes and proteins and induces dehydration and cachexia. Some strains of *E. coli* are capable of colonizing and destroying the intestinal epithelium. These strains typically induce a pseudomembranous or ulcerative enteritis. Clinically infected birds die peracutely or develop nonspecific signs associated with enteritis. Infections with these strains are usually diagnosed on postmortem examination.

Coligranulomatosis (Hjaerre's disease) is particularly common in Phasianiformes including chickens, turkeys, peafowl, partridges and capercaillie. Mucoid (eg, encapsulated) *E. coli* strains, mainly of serovars 08, 09 and 016, are the usual etiologic agents. Coligranulomas are thought to occur when other agents damage the intestinal mucosa and allow a secondary infection with specific *E. coli* serovars. It is currently

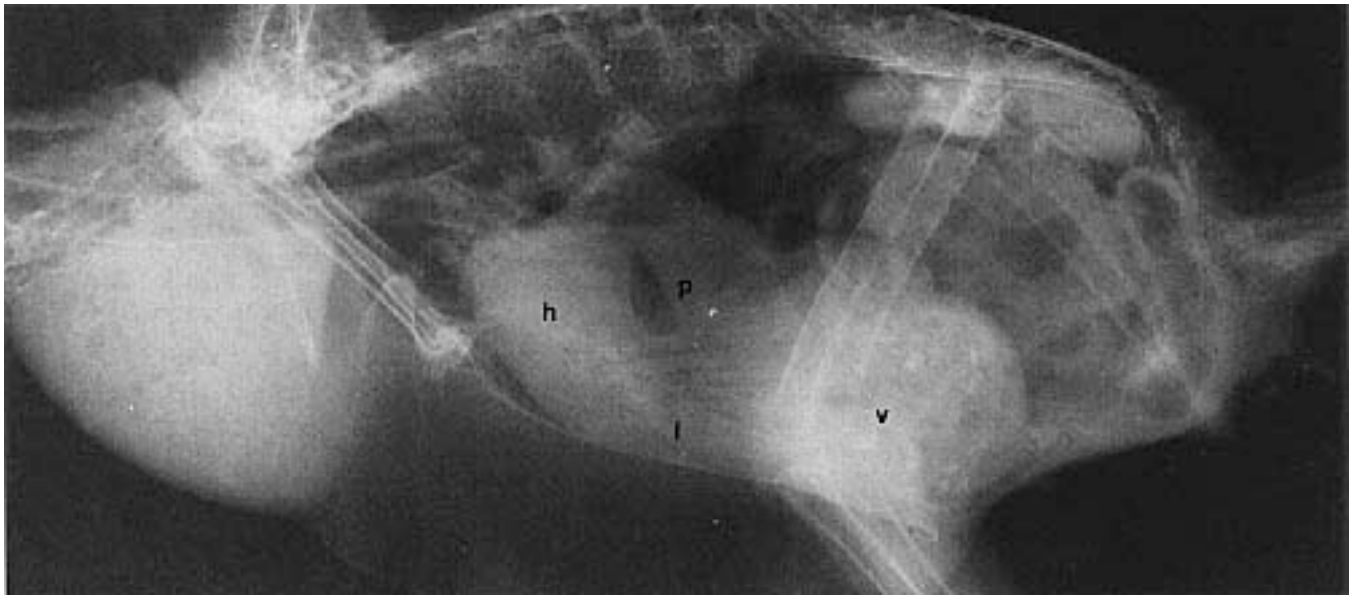

FIG 33.1 A seven-year-old male Amazon parrot was presented for weakness and diarrhea. Abnormal clinical pathology findings included PCV=22, WBC=33,000, SGOT=476. A Gram's stain of the excrement revealed 70% gram-negative rods. Radiographs indicated ileus (gaseous distension of the bowel), a full crop and microhepatia. Dried excrement is visible pericloacally. The dilated bowel loops are displacing the proventriculus (p) cranially and the ventriculus (v), liver (l) and heart (h) ventrally.

thought that galactans found in the *E. coli* capsule stimulate the granulomatous reaction.

Affected birds develop diarrhea, polyuria and chronic weight loss. Granulomatous dermatitis is occasionally noted. Grayish foci of varying sizes in the liver, intestinal subserosa and spleen or kidney are typical findings at necropsy. These granulomas are distinct from those induced by avian tuberculosis because they lack an opening into the intestinal lumen. The center of the foci may be mineralized. Histologic changes are characterized by multinucleated giant cells and a few heterophils around a central necrotic region. Acid-fast staining should be used to rule out mycobacteriosis.

E. coli can cause a primary rhinitis but is generally a sequela to infections elsewhere in the body. Air sac lesions can be severe and may extend to the peritoneum, causing a fibrinous polyserositis. Except for in geese, *E. coli* pneumonia is rare. This is due to the special anatomy of the avian lung. When pneumonia occurs, it is most common in young chicks that have inhaled a high number of virulent *E. coli* with contaminated dust. Affected birds are usually dyspneic and cyanotic. In contrast to mammals, pneumonia is not associated with prominent respiratory sounds.

Hens can develop *E. coli* infections characterized by fibrinous salpingitis or oophoritis originating from organisms that ascend from the cloaca or by imprint metastases from infected air sacs. Infections are usually chronic in nature, with untreated birds eventually dying from salpingoperitonitis. Genital tract infections in males are less common, but when they do occur they usually result in orchitis and permanent sterility.

Secondary colonization of joints and bone marrow can occur following *E. coli* septicemia. These lesions are rare, but when the do occur they are most frequent in nestlings and fledglings. Some of the finch species seem to be particularly susceptible. Bone marrow infections appear to be very painful, and affected birds are usually reluctant to move.

Diagnosis

Polyserositis and granuloma formation are lesions suggestive of *E. coli* infections. Specific diagnosis requires culturing the organism from infected tissues. Serotyping is of academic importance.

Treatment

The ability of a selected drug to penetrate target tissues or granulomas must be considered (see Table 33.7). Oral antibiotics may be effective in treating *E. coli* infections limited to the intestinal mucosa, but parenteral antibiotics are necessary for treating most *E. coli* infections. In addition to antibiotics, therapeutic considerations should also include administration of avian lactobacilli in an effort to lower the intestinal

tract pH and help establish a proper autochthonous flora. Mammalian strains of lactobacillus can be effective in changing the intestinal pH but require the administration of large quantities of product over a three- to four-week period. Lactulose may also be helpful in lowering the intestinal pH. Providing a nutritional diet is important in improving gastrointestinal physiology in malnourished birds.

Salmonella (S.)

The genus *Salmonella* includes approximately 2000 species divided into five subgenera. Subgenus I is the most important in birds. Subgenus III (*S. arizonae*, *Arizona hinshawii*) has occasionally been reported in birds, particularly those that are in contact with reptiles. Most strains are motile and grow on common media. The subgenera are determined by specific biochemical profiles, and species are differentiated serologically (O, K [Vi] and H antigens). Lysotyping is used for further characterization at the research level. Propagation can occur outside the host if the correct ambient temperatures and proper nutrients are available.

Most vertebrates can be infected with some *Salmonella* spp. However, the host susceptibility and development of carrier states vary widely among species. Free-ranging birds can be subclinical carriers and serve as a reservoir for the aviary. In addition to free-ranging birds, rats, flies and other vermin may also serve as vectors of salmonella. Avian species without ceca or with involuted ceca appear to be more susceptible to salmonella infections than birds with fully functioning ceca. Bacteroides and *Spherophorus* spp. are considered autochthonous cecal flora, and these gram-negative anaerobes may function as natural antagonists for *Salmonella* spp. The incidence of various *S.* spp. seems to vary with geographic location and the types of food consumed, particularly the proteinaceous component. Imported birds (and other animals) may serve as reservoirs for nonindigenous *S.* spp. that can cause devastating outbreaks. Some salmonella strains are host-adapted (eg, *S. gallinarum-pullorum* to chickens, *S. typhimurium var. copenhagen* [in two biovars] to either pigeons [malonate-negative] or European finches [malonate-positive]).

Transmission

Salmonella enters the host principally through the oral route. Contaminated dust from feces or feathers may be involved in aerogenic spread in some cases. Egg transmission can occur with fully walled and L-form salmonella. It is most common with adapted strains but is possible with any *S.* sp. Experimental studies indicate that patent infections in embryos occur with fewer than ten bacteria. These infected

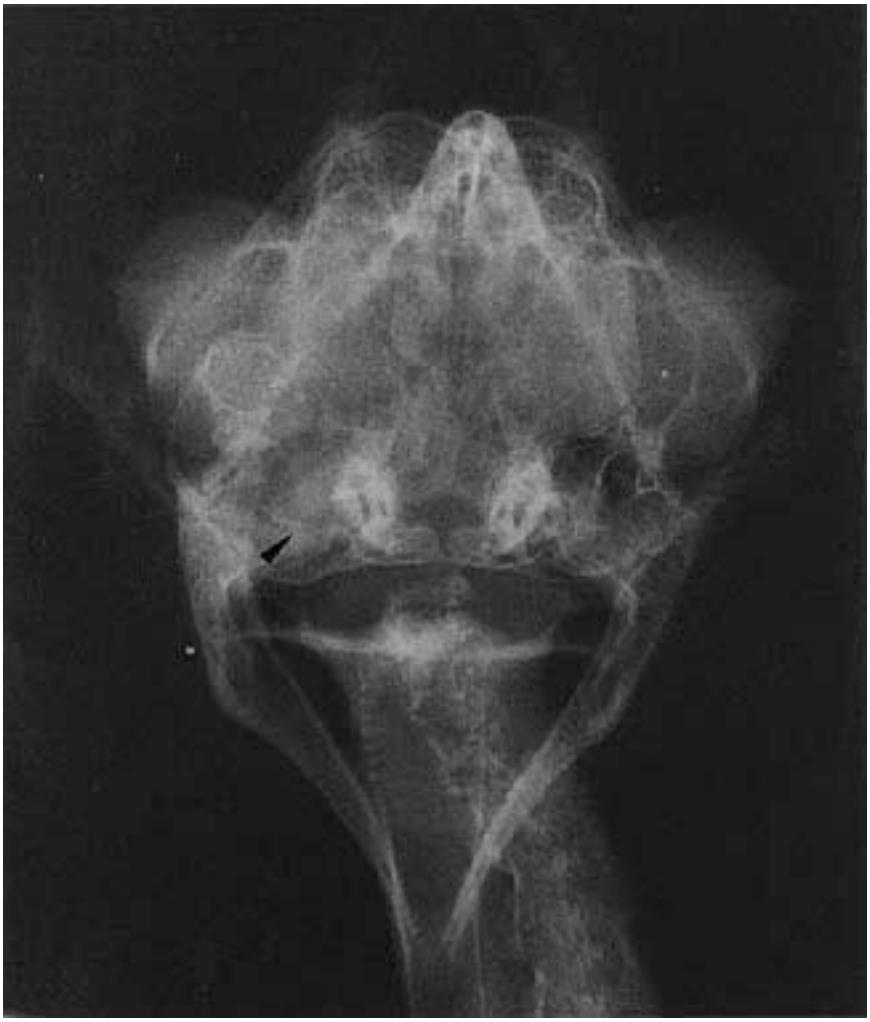

FIG 33.2 An adult Barn Owl from a zoological collection had a three-year history of intermittent depression and anorexia. The bird was presented with severe right-sided head tilt and vertical-to-rotatory nystagmus. The external ear canal was hyperemic, and the tympanic membrane was opaque and edematous. Radiographs indicated a soft tissue density in the right tympanic bullae suggesting an internal ear infection. Auditory evoke potentials indicated lesions in the peripheral and central auditory pathways. *Klebsiella* sp. and *Pseudomonas* sp. were recovered from the infratrochlear area and brainstem at necropsy.

chicks then hatch and spread salmonella by direct contact throughout a nursery. If an embryo has more than ten bacteria, it usually dies before hatching.[47] In freshly hatched chicks, salmonella often serves as the first bacterium to colonize the intestines. This organism becomes host-adapted during the egg incubation period, and the hatched chick can then serve as a subclinical carrier. In some cases, the salmonella infection can eventually induce a septicemia and death. Subclinical carriers allow an infective cycle to occur in the absence of other vectors. Vertical infections may also occur if infected hens feed their young contaminated crop contents.

Pathogenesis

One of the characteristics of the group Enterobacteriaceae is that they all produce endotoxins. Salmonella is no exception, and some cases of food poisoning are linked to this bacterium. Indirect death through endotoxin contamination of food is rare in birds; most avian salmonella problems are associated with direct infections. Interestingly, both virulent and nonvirulent strains of a given *Salmonella* sp. can exist simultaneously in a host. Virulent strains are those that can penetrate an intact intestinal mucosa, and nonvirulent strains are those that require a mucosal lesion to enter a host. Nonvirulent strains often colonize the gut, resulting in asymptomatic infections and intermittent shedding. Once virulent or nonvirulent strains have passed the mucosal barriers, they induce a septicemia that results in an immune response or colonization in tissues and eventual death of the bird. In some cases, *Salmonella* sp. may cause chronic infections that are characterized by intermittent septicemia and clinical signs. Recurrent infections usually result in progressive organ involvement; the CNS and joints are frequently end-stage sites of infection.

TABLE 33.3 Percentage of Psittaciformes Shedding Gram-negative Bacteria and Yeast

	E. coli	Enterobacter	Klebsiella	Pseudomonas	Yeast
Bare-eyed Cockatoo	44	0	0	13	6
Citron-crested Cockatoo	30	0	0	0	0
Major Mitchell's Cockatoo	27	20	0	0	13
Moluccan Cockatoo	81	13	0	0	13
Sulphur-crested Cockatoo	44	0	0	0	11
Triton Cockatoo	84	8	3	0	0
Red-vented Cockatoo	78	0	0	0	0

Hyacinth Macaw	6	0	0	0	11

Incidence (in percent) of the isolation of gram-negative bacteria and yeast from the cloaca of a group of psittacine birds with no observed clinical abnormalities. Gram-positive bacteria were isolated from 91% of the 506 cloacal samples. It is not unusual to find transient populations of gram-negative bacteria in the cloaca of asymptomatic birds. However, the presence of these bacteria in the gastrointestinal tract can cause problems if a bird is stressed. The isolation of gram-negative bacteria from clinically asymptomatic psittacine birds warrants a close examination of management practices. Adapted from Flammer K: Avian Dis 32: 79-83, 1988.

Incubation

Incubation periods vary with the type of salmonella infection. Presumably, these differences are dependent on the strain of infecting salmonella, the route of infection and the condition of the host. In acute diseases, incubation periods are typically three to five days. With egg transmission the incubation period is shorter, generally considered to be two days. Subclinical carriers can have prolonged incubation periods.

Clinical Disease and Pathology

Acute diseases are characterized by nonspecific signs including lethargy, anorexia, polydipsia (sometimes followed by polyuria) and diarrhea. In subacute to chronic cases, CNS signs, arthritis (particularly in pigeons), dyspnea and indications of liver, spleen, kidney or heart damage are common. With high-dose infections, conjunctivitis, iridocyclitis and panophthalmia may occur.

Some individual avian species have unique clinical presentations. Outbreaks in lories (Loriidae) and penguins (particularly Jackass Penguins) are associated with peracute diseases and high flock mortality. African Grey Parrots are also very susceptible, but typically develop a more chronic disease exhibiting phlegmon, granulomatous dermatitis, arthritis and tenovaginitis (Figure 33.3). Respiratory signs with myocardial lesions are common in tangares, quetzals, Red-headed Barbets, terns and House Sparrows. Nonspecific CNS signs are common in

geese and ducks. Some infected ducks will swim with an inverted keel (keel disease) just prior to death. Subacute salmonellosis in many finches (Fringillidae) is characterized by granulomatous ingluvitis that may be confused with candida infections. Granulomatous dermatitis has been reported in several species and is thought to be induced by mosquitoes or other biting insects.

Subgenus III strains are considered less virulent than those of subgenus I; however, the clinical lesions induced by this subgenus are indistinguishable. Ocular lesions appear to be more frequent with subgenus III, and turkeys, ducks, parrots and canaries are particularly susceptible.

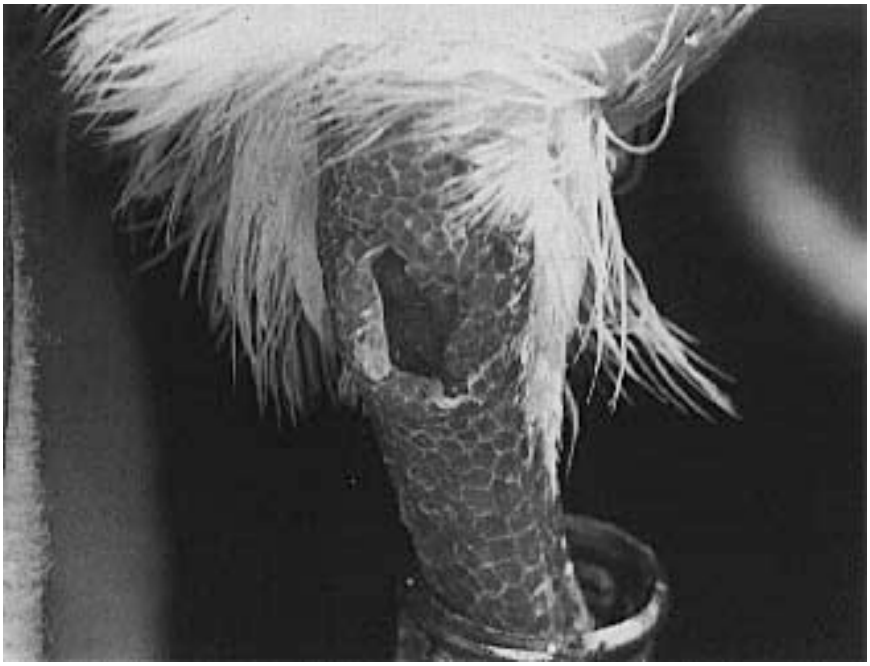

FIG 33.3 A three-month-old pigeon was presented with depression, anorexia, diarrhea and reluctance to move. An open ulcer was present on the bird's hock. *Salmonella* sp. was isolated from the bird's feces and the bird responded to treatment with antibiotics (courtesy of Louise Bauck).

Postmortem lesions include dehydration, degeneration or necrosis of skeletal musculature, gastroenteritis (occasionally with ulcers and granulomas), enlargement of the liver and spleen (with or without disseminated small whitish foci), bile congestion and nephropathy. Chronic infections usually cause pericarditis or epicarditis fibrinosa, granuloma formation in the liver, spleen and kidney, and degeneration or inflammation of the ovary or testis. Fibrin filling the cecal lumen is a common finding.

Histopathologic changes are nonspecific with purulent inflammation in the parenchymal organs. Granulomas are common with chronic infections. Purulent leptomeningitis and exudate formation in the subarachnoidal spaces are usually noted in birds with CNS signs.

Diagnosis

A confirmed diagnosis requires isolation and identification of the *Salmonella* species. Serologic evaluation of a flock can be used only if the precise species is known; however, chronically infected subclinical birds are frequently serologically negative. The same is true for birds infected with L-forms. The development of a serologic response requires penetration of the intestinal mucosa, and most subclinical carriers have infections limited to the intestinal lumen.

Treatment

Whether or not to treat salmonella infections in companion birds is controversial. The author believes that clinically affected birds and companion birds that are identified as carriers should be treated because of public health hazards. Therapy should include appropriate antibiotics (based on sensitivity) and lactobacillus products. In general, the frequently encountered salmonella strains are sensitive to commonly available antibiotics, but some strains from free-ranging birds (particularly from seagulls) demonstrate varying degrees of antimicrobial resistance. CNS signs and chronic infections tend to be refractory to therapy. Flock management of salmonella should concentrate on preventing egg transmission by identifying and removing subclinically infected breeders. Treating birds that have egg-derived infections is extremely difficult. Host-adapted strains of salmonella seem to cycle in periods of approximately three-month intervals. Cycles of egg transmission can best be broken by collecting eggs for future breeding stock four weeks after treating the parent stock. Newly hatched chicks from these birds should be cultured (fecal swabs) at hatching, and infected birds should be treated immediately.

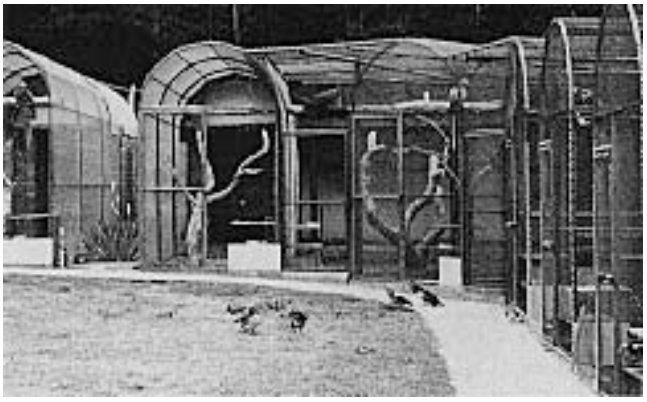

FIG 33.4 Aviary hygiene is important in preventing a bird's exposure to many infectious agents including bacteria. Walk-in type enclosures have several disadvantages when compared to drop-through type enclosures. The birds in walk-in enclosures can fly to the floor where pathogens can accumulate in excrement and food waste. Birds are more likely to come in contact with discharge from flies or rodents that have ready access to organic waste on the floor of the enclosure. Additionally, caretakers can act as mechanical vectors for the transmission of pathogens as they walk from one enclosure into the next.

Treatment of L-forms can be attempted with clindamycin (100 mg/kg body weight) or a combination of erythromycin and ampicillin (both components at the full dose).

Control

Proper hygiene is the best tool for preventing salmonella outbreaks. The effective control of flies, rodents and other vermin is essential (Figure 33.4). Regular cleaning and disinfection of the aviary and nursery, along with proper storage of food, are all important in preventing salmonellosis. Several *Salmonella* spp. vaccines have been evaluated experimentally, but none have proven to be effective.

Companion bird strains of *Salmonella* are not considered important human pathogens in healthy individuals, but can cause problems in infants, geriatric patients or those with immunosuppressive diseases. Humans carrying salmonellosis can infect their companion birds. Such human-to-animal interactions have been shown to occur with African Grey Parrots, Amazon parrots, cockatoos and macaws.

Citrobacter (C.)

The three species of *Citrobacter* (*C. freundii*, *C. amalonaticus* and *C. diversus*) are less commonly encountered than other members of the Enterobacteriaceae. *C. freundii* appears to be the most pathogenic of the group. *C. diversus* is rare in birds. When using serologic assays it is important to know that *C. freundii* antibodies often cross-react with those to *S. typhimurium*.

Citrobacter spp. cause serious secondary infections in weaver finches and waxbills. A rapid bacteremia followed by acute death occurs when the organism penetrates the intestinal mucosa. Ostriches, particularly chicks and young birds, also appear to be very susceptible to *Citrobacter* spp. Infected birds of any species may die without any clinical signs, or they can exhibit a brief period of depression and diarrhea prior to death. Postmortem changes indicate septicemia (petechiation of the heart, musculature and parenchyma). Surviving birds frequently become carriers. *C. amalonaticus* is frequently recovered from the intestinal tract of normal Psittaciformes. Intestinal infections would indicate that a disturbance has occurred in the autochthonous flora. A definitive diagnosis requires culturing the organism from affected tissues. The rule-out list is the same as for *Salmonella* spp. Therapeutic decisions should be based on appropriate culture and sensitivity. Neomycin delivered by gavage is often effective in clearing intestinal infections. In flock outbreaks, the same drug administered in the drinking water may be helpful in controlling infections.

There have been no reported cases of citrobacter infections in humans derived from exposure to infected birds.

Klebsiella (K.)

K. pneumoniae and *K. oxytoca* are frequently recovered from birds in which they can function as primary pathogens, particularly in weaver finches, or they can be involved as opportunists in immunosuppressed or stressed patients. These organisms are nonmotile Enterobacteriaceae, and most members of the genus are encapsulated. The mucoid capsule provides them with substantial protection from environmental extremes and many disinfectants. Heat and drying are the best methods of killing *Klebsiella* spp.

Specific information on the transmission, pathogenesis and incubation period for *Klebsiella* spp. in birds is not available. The *Klebsiella* capsule provides a barrier to protect the organism from cellular immunity. However, the capsule is also highly antigenic and stimulates a protective humoral immune response. *Klebsiella* spp. bacteremia usually results in the colonization of the kidney, causing renal failure. In chronic infections, the lungs may also be involved. In many bird groups (eg, pigeons, weaver finches,

goldfinches and siskins, geese, birds of prey, Amazons and African Grey Parrots), infections are not detected until late in the disease process when respiratory signs occur. Encephalomyelitis is occasionally noted in terminal cases. While systemic klebsiella infections are most common, local infections involving the sinuses, skin, oral cavity and crop may also occur, particularly in Psittaciformes. The diagnosis is made by isolation and identification of the organism. The rule-out list is the same as with salmonella.

Yersinia (Y.)

The genus *Yersinia* currently consists of eleven species.[1] Unlike other Enterobacteriaceae, which are strictly rod-shaped, *Yersinia* spp. form ovoid-to-coccoid rods that replicate in the environment at extremely low temperatures (+4°C) if provided the proper sources of organic nitrogen. Because the organism can grow effectively at low temperatures, infections are particularly common during the winter months.

Y. pseudotuberculosis appears to be the most important avian pathogen. *Y. intermedia*, *Y. frederiksenii* and *Y. kristensenii* are frequently isolated from various avian species, but their pathogenicity remains undetermined.

When grown at 20-28°C, *Y. pseudotuberculosis* is motile; when grown at higher temperatures it is nonmotile. Six serovars have been distinguished. Serovar 1 is most frequently isolated from birds. *Y. pseudotuberculosis* has been recovered in an L-form from free-ranging urban pigeons.

Transmission

Y. pseudotuberculosis is thought to be indigenous to northern and middle Europe. The occurrence of this bacterium in other parts of the world including Canada, the United States, Africa and Australia is thought to have arisen from the movement of European birds and rodents to other suitable geographic locations. An unknown percentage of the free-ranging birds in Europe are considered asymptomatic carriers.

Y. pseudotuberculosis infects a wide range of hosts, including many bird species and various mammals, particularly rodents and including humans. Toucans, toucanets, aracaris, barbets and turacos appear to be extremely susceptible.

Clinical Disease and Pathology

Y. pseudotuberculosis may be associated with peracute, acute or chronic clinical disease. Peracute death without clinical signs is common in infected Piciformes and Musophagidae. Clinical signs associated with acute disease include lethargy, dehydration, diarrhea and dyspnea. Emaciation, wasting and flaccid paresis or paralysis are common with subacute or chronic cases. Birds with a wasting syndrome appear similar to animals infected with tuberculosis. Infected ducks frequently develop tarsal joint swelling. Canaries may be severely dyspneic prior to death.

Gross changes associated with peracute infections include swelling of the liver and spleen and bloody-to-fibrinous exudate into the body cavity. Submiliary-to-miliary, sharply demarcated grayish foci within the liver, lungs, spleen and kidneys are common with the acute course. Chronic infections are characterized by granuloma formation in organs and the skeletal musculature. Ascites and osteomyelitis may or may not be present. Ulcers in the proventriculus, ventriculus and duodenum may occur in infected canaries. Tarsitis chronica deformans with caseous exudate in the joint cavity is frequently seen in ducks.

Coagulation necrosis and thrombophlebitis are the common histologic changes. In acute and chronic cases, inflammatory cells infiltrate the necrotic areas and eventually induce granulomas.

Diagnosis

The histopathologic changes, along with the identification of gram-negative coccoid rods, are suggestive of *Y.* spp. infections. Definitive diagnosis requires isolating the organism from affected tissues. Placing contaminated samples in a cool environment for two weeks may help in recovering *Y.* spp. Isolating avian strains of yersinia appears to be more difficult than isolating mammalian strains. Because there are no demonstrable biochemical or serologic differences, it has been assumed that avian strains are more difficult to grow due to different nutritional requirements. The most consistent isolation results have been obtained by placing fecal or organic material in heart-infusion broth with 5% glucose and storing this material in a refrigerator for two weeks. The material is then inoculated on blood agar plates with 0.2% Tween 80 and 50 ppm tellurite and incubated at 37°C for two days. *Yersinia* causes a reduction of the tellurite, turning the colonies black.[25]

Treatment

Birds with the peracute to acute forms of yersiniosis usually die before therapy can be instigated. Parenteral drug administration is required if therapy has any chance of being successful. Treating chronic cases is difficult because granulomas prevent antibiotics from reaching the yersinia organisms nestled in the center of necrotic debris. Flock outbreaks can be prevented by treating clinically unaffected animals and applying strict sanitary measures.

Control

In non-European countries where *Y. pseudotuberculosis* is not endemic, repeated culture of feces during the quarantine period should be used to prevent infected birds from entering the country. In endemic areas, rodents and free-ranging birds can serve as reservoirs, and flock control depends on preventing these animals from contaminating feed supplies and keeping them out of the aviary. Several experimental vaccines for *Y. pseudotuberculosis* have proven to be ineffective. Feeding infected mice to toucans could serve as a source of infection.

Y. enterocolitica is principally a human pathogen. Gulls, herons, birds of prey, crows, blackbirds and European robins that inhabit areas contaminated with human sewage are frequently infected. Young children of elementary school age are particularly susceptible to infections.

Pseudomonas (Ps.) and *Aeromonas (Ae.)*

These two gram-negative rods are taxonomically unrelated but nevertheless have characteristics that make it best from a clinical perspective to discuss them together. Both of these genera contain numerous species, but only *Ps. aeruginosa* and *Ae. hydrophila* are common avian pathogens. Both bacteria are frequently found in aquatic environments and can propagate in cool water (20°C or lower). Both bacteria will grow on common media and induce β-hemolysis on blood plates. These hemolysins are potent toxins and are capable of damaging many cells in addition to erythrocytes. *Ps. aeruginosa* produces a blue-green diffusible pigment and has a sweetish odor. *Ae. hydrophila* causes the typical bad smell of the proteinolytic organisms and may be confused with *E. coli* on Endo- or MacConkey plates. These bacterial genera are further divided into several serovars and biovars. There have been insufficient studies to divide the avian species in a similar fashion.

Both of these bacteria infect many mammals, including humans, as well as most of the birds that have been tested. Free-ranging waterfowl appear to be particularly susceptible, but any free-ranging avian species that contacts contaminated food or water is probably susceptible. Of the commonly maintained zoo birds, penguins are very susceptible.

Pathogenesis

Some strains of *Pseudomonas* and *Aeromonas* produce a number of extracellular toxins, including hemolysins, elastase, protease and lecithinase, that cause cellular damage resulting in edema, hemorrhage and tissue necrosis. Avian strains of *Ae. hydrophila* that are acetoin-producing (Voges-Proskauer-positive) are considered to be highly toxic.[6] Both species are principally secondary invaders. However, the toxins secreted by these organisms can be life-threatening once colonization of the host occurs. *Ps. aeruginosa* is resistant to many commonly used antibiotics and can cause secondary superinfections in patients being treated for other bacterial infections.

Clinical Disease and Pathology

Virulent strains of these bacteria can cause a septicemia that induces diarrhea, dehydration and dyspnea followed by acute death. Infected skin lesions are edematous or necrotizing. Localized infections may occur in the upper respiratory tract, causing rhinitis, sinusitis and laryngitis. Hemorrhages and coalescent necrosis in the liver, spleen and kidney are the most common postmortem findings (see Figure 33.2). Catarrhal to hemorrhagic enteritis with edema and fibrinous inflammation of the serosal membranes may also be noted. Histologic changes associated with infections include severe inflammatory reactions involving the venous and arterial walls. Bacteria are often identifiable within the lumina. The formation of thrombi, hemorrhage and necrosis of the infected vessels are the results.

Diagnosis and Control

The causative agent should be isolated and identified. Aviary outbreaks of pseudomonas are most common when organic material contaminates the water supply, allowing a proliferation of the organisms in the drinking water (Table 33.3). Routine cleaning of food and water containers, along with any external water pipes, is an important control measure. Incubator contamination can be prevented by periodically cleaning the water reservoir. Waterfowl are particularly susceptible to infections when water temperatures are above 20°C, allowing rapid proliferation of

Ae. hydrophila. Removing waterfowl from ponds during these periods is a good control measure.

Alcaligenes (Ac.) and *Bordetella (Bo.)*

The genera *Alcaligenes* and *Bordetella* are taxonomically related. Both genera are widely spread in the environment. Alcaligenes is found mainly in aquatic environments. *Ac. faecalis*, *Bo. avium* and *Bo. bronchiseptica* infect a wide variety of birds in many orders. Psittaciformes and turkeys as well as many finches seem to be particularly susceptible to these bacteria.

There are no details on the pathogenicity of these genera in birds. Alcaligenes and bordetella are opportunistic pathogens that potentiate viral and other bacterial infections. *Bordetella avium*, a more recently recognized member of the genus, seems to preferentially bind to the ciliated epithelial cells of the upper respiratory tract.

In turkeys, combined infections of *Bo. avium* and the turkey rhinotracheitis virus cause the clinical and pathologic signs of rhinotracheitis. In other avian species, clinical signs are uncommon and, if present at all, are nonspecific. At necropsy, tracheitis, bronchopneumonia and air sacculitis are common findings with subacute to chronic courses of bordetella, whereas alcaligenes infections are characterized by coalescent liver necrosis in addition to respiratory disease.

Diagnosis

A confirmatory diagnosis requires isolation and identification of the causative agent. Serologic flock diagnosis by means of the slide agglutination test or antibody titration by the Gruber-Widal method is possible although no commercial antigens are available.

Campylobacter (C.)

Campylobacter spp. from birds have been classified as: *C. jejuni*, the most frequent, and probably also the most pathogenic; *C. coli*, which is considered to be apathogenic, but is frequently confused with *C. jejuni*; and *C. laridis*, which is isolated from gulls, whose pathogenicity is still not definitely known.[36]

C. jejuni has incorrectly been labeled as *Vibrio* (usually *V. metschnikovii*). This error has serious consequences because *Vibrio cholerae*, serotype 01 and noncholera *Vibrio* can be recovered from healthy birds.

C. jejuni may appear in different forms including a short comma, s-shaped, long spiral or coccoid form. The latter is usually an indication of degeneration. Colony formation takes 72 to 96 hours at 37-42°C in a microaerobic environment. Blood agar or selective media are best for isolation. *C. jejuni* is relatively unstable in the environment (surviving less than one week).

There are at least 50 serovars of *C. jejuni*.[42] While the possibility of birds serving as a source of infection for mammals and vice versa has been discussed, this transmission potential has been insufficiently studied.

The host spectrum is large, and includes chickens, turkeys, pheasants, crows, gulls, ducks, geese, pigeons, shorebirds, Pekin Nightingale, Nandu and the Great Bustard. *C. jejuni* has recently been reported in passerine birds, particularly in tropical finches (Estrildidae) and, to a lesser degree, in canaries.[20] Details of occurrence and pathogenicity in many avian species have been reported.[51] Psittaciformes are susceptible, but few documented infections have been reported.

Pathogenesis

C. jejuni can be isolated from the intestinal tract of clinically affected and asymptomatic birds. Experimental infections generally cause hepatitis. Factors that determine if an infected bird becomes clinically affected have not been established. Clinical disease is common in birds with parasitic infections (coccidia and nematodes), and these agents have been suggested as predisposing factors.

Clinical Disease and Pathology

Clinical signs are generally associated with subacute to chronic hepatitis and include lethargy, anorexia, diarrhea (frequently with yellowish stained feces) and emaciation. Transmission takes several weeks through the flock, but spontaneous recovery and relapses do occur. High mortality has been noted in finches, especially among fledglings.[20] Sudden death as a result of liver rupture is possible. Heterophilia and thrombocytophilia are the most consistent changes in the CBC.

At necropsy the liver is enlarged, pale or greenish in color and is congested, with or without hemorrhage. Perivascular infiltrates make the lobules appear more prominent. Coalescing necrotic hepatitis is a

common histologic finding. Catarrhal enteritis (also hemorrhagic enteritis in pheasants, turkeys, Tengmalm's Owl and coot) has been described. In gulls, erosion of the ventriculus has been reported.

Diagnosis

Diagnosis requires isolation of *C. jejuni* from affected tissues. Phase-contrast microscopy of bile to demonstrate suggestive organisms may provide a tentative diagnosis. Fecal samples can be used for culture in live birds. A transport medium is necessary to ensure survival of the organism.

Treatment and Control

There are discrepancies between the antibiograms and clinical recovery. Erythromycin or tetracyclines, dehydro- or streptomycin (never in Psittaciformes) or furane derivatives (not in waterfowl) can be tried. Diseases frequently recur despite therapy. Thorough cleaning and disinfecting of the aviary may help prevent reinfection. Dogs can be a reservoir for human infections, but it is not known if they can transmit the organisms to birds. Dogs should not be allowed direct access to birds.

Vibrio (V.)

The genus *Vibrio* comprises numerous species that are not easy to differentiate. *V. cholerae* is of utmost importance as a zoonotic organism. In birds, especially in gulls, *V. cholerae* (serovar 01) is demonstrable in the intestinal tract, although no clinical or pathologic signs have been described. Numerous other *V.* spp. are collectively designated NAG (= non-agglutinable), because they do not agglutinate with human cholera antiserum. NAG strains can be isolated from the feces of many bird species, particularly waterfowl (vibrio is generally found in aquatic habitats).[4] NAG vibrios have not been documented as a cause of clinical disease in any avian species. Because some NAG strains can cause a mild intestinal disease in humans, an analysis of avian strains in the vicinity of human cases might be advisable.

Spirochaetaceae

Borrelia (*Bor.*) *anserina* (syn. *Spirochaeta gallinarum*) is a gram-negative, helical motile organism that stains with Giemsa. A granular form of the organism may occur in ticks and the blood of the birds that have recovered from a disease. The host spectrum includes geese and ducks, turkeys, chickens, pheasants, grouse, partridges, pigeons, crows, magpies, House Sparrows, starlings and African Grey Parrots.

Transmission

The main vectors for transmission are ticks, in which the organism can be passed transovarially and survive for over a year. Mosquitoes and other biting insects play a minor role in transmission. Transmission from bird to bird by excreta is of minor importance epizootiologically.

Pathogenesis

Young chicks (one to three weeks of age) are particularly susceptible. Adults may also be infected. *Bor.* is in the peripheral blood from the fourth to the ninth day post-infection and remains in the blood approximately seven days. The organism can then be found in parenchymal organs for another 30 days. Death may occur from embolism due to agglutinating borrelias. A strain-specific immunity develops in survivors. Incubation periods are four to eight days depending on the species of ticks.

Clinical Disease and Pathology

Acute cases are characterized by a high fever (bacteria generally cause a low body temperature), anorexia, depression (droopy, cyanotic heads), yellowish diarrhea, lethargy, ataxia and paralysis. Morbidity is high, and mortality may range from 10 to 100% depending upon the susceptibility of the host. Spontaneous recovery may occur around the sixth day post-infection. Chronic disease is characterized by anemia, paralysis and dyspnea.

The albumin fraction in the serum decreases to 37% and an increase of the aspartate aminotransferase is accompanied by a decrease of the alkaline phosphatase, the total lipids and the cholesterol.

At necropsy, a mottled, severely enlarged liver is characteristic except in pheasants. In these birds the spleen may be small or normal in size.[58] The liver shows hemorrhages and necrotic foci. Mucoid hemorrhagic enteritis, serofibrinous pericarditis and swollen kidneys may also be seen. Histology displays multiple necrotic foci without inflammatory reactions. *Bor.* can be demonstrated by argentation.

Diagnosis

Blood smears stained with Giemsa or examined by darkfield microscopy are useful for diagnosis. Culturing *Bor.* sp. is very difficult. Antibodies (agglutination, fluorescence techniques, immunodiffusion) can be demonstrated from the 4th to the 30th day post-infection.

- ***Treponema (T.) spp.:*** *Treponema* spp. are helical motile organisms that are much smaller than *Spirochaeta* spp. An unclassified *Treponema* sp. (0.5 μm wide with 13 to 15 flagella)[12] is the cause of a watery, intermittent typhlitis in chickens. The organism is antigenically related to but distinct from *T. hyodysenteriae*. Chickens are the only defined host and lose weight in response to a malabsorption syndrome.[12,22] Histopathology shows an increased number of goblet cells in the cecal mucosa, focal epithelial desquamation and many *Treponema* organisms in the small fissures of the epithelium. The incubation period is one to seven weeks dependent on the infective dose. Culture is possible on spectinomycin blood agar in an anaerobic atmosphere. Fluorescent antibodies designed for *T. hyodysenteriae* can be used to demonstrate the organisms in affected tissue.

- ***Spirochaetaceae Undifferentiated:*** A non-classified spirochete from choanal and tracheal mucus of a cockatiel has been described. The organisms were 0.3 to 0.4 X 10 to 15 μm in size and occurred in large numbers on the mucosa. Two other cockatiels have been found to harbor similar organisms in the respiratory passage. Histopathology showed a mild inflammatory reaction in the nasal sinus, but not in the trachea. In the lower parts of the respiratory tract, the organisms could not be demonstrated using argentation. The significance of these findings is unknown. Interference with the ciliary activity of the respiratory mucosa is conceivable.[65]

  Spirochetes were demonstrated in a pharyngeal swab of a cockatiel that was depressed and sneezing. The bird had spent ten minutes with another cockatiel that was showing similar clinical signs ten days before being presented for evaluation.

Pasteurella (P.)

The family of Pasteurellaceae currently includes the genera *Pasteurella*, *Actinobacillus* and *Haemophilus*.[49] All three genera can be pathogens in birds.

Pasteurella characteristically exhibit bipolar staining in tissue smears or from first culture passages when fixed in methanol and stained with methylene blue. There are presently eleven species within this genus, but others will undoubtedly be added. *P. multocida*, which causes fowl cholera, and *P. gallinarum* are two of the most commonly encountered species. The latter is usually considered a secondary pathogen. Some of the *Pasteurella* organisms isolated from waterfowl, pigeons and Psittaciformes have not been taxonomically classified. Some isolates designated *P. haemolytica* (gram-negative, polymorphic rods) are improperly classified and do not belong in this genus. The characteristics of these strains resemble those of the genus *Actinobacillus*. Reports on isolation of *P. pneumotropica* from birds are questionable. This species appears to be host-specific and is found in rats or other rodents. Similarly, *P. ureae* is believed to be host-specific for humans.

Pasteurella has been associated with disease in Phasianiformes, Anatiformes, Psittaciformes, Columbiformes and Passeriformes. There is variance in species susceptibility. The clinical presentations and pathomorphologic changes are similar to those described for yersiniosis. Propagation outside the host can occur but requires very specific conditions of temperature, relative humidity and pH. Such conditions may occur in large bodies of water, and in these situations *Pasteurella* spp. can survive for long periods. Epornitics are most common in the northern hemisphere from November to December. Outbreaks in tropical climates peak with seasonal highs in ambient temperature and humidity.

- ***P. multocida:*** The etiologic agent of fowl cholera, the species is divided into strains based on 16 serologically distinct endotoxins and 4 capsular polysaccharides. Serotypes 1 and 3 and capsule types A and D are most commonly isolated from birds. Three subspecies, *P. multocida (m.) multocida*, *P. m. gallinarum* and *P. m. septica*, have been distinguished based on differences in virulence. The latter is considered to be the most virulent.

- ***P. pneumotropica*** is indigenous in rodents and occasionally causes disease in aviary birds and pigeons. Infected birds develop pneumonia and may exhibit dyspnea shortly before death. Detailed information on the pathogenesis and clinical progression of *P. pneumotropica* in companion birds has not been reported.

- ***P. gallinarum*** appears to have a similar host spectrum as *P. multocida*; however, *P. gallinarum* is thought to be much less pathogenic. If the organism is able to colonize the respiratory mucosa, it can induce conjunctivitis and respiratory signs including coryza, rales and dyspnea. *P. gallinarum* has been isolated from the choanae and nostrils of Psittaciformes with concomitant *Aspergillus* spp. infections in the lungs and air sacs. Aspergillosis is one of the triggering factors that allows this secondary pathogen to overcome host defenses. Postmortem findings associated with *P. gallinarum* include catarrhal to

FIG 33.5 The hallmark sign of bacterial septicemia is depression. Birds that are bitten or scratched by cats frequently develop *P. multocida* bacteremia. Affected birds may appear normal immediately after the injury occurs, and become rapidly depressed and die 12 to 24 hours later. Any carnivore-related injury in a bird is a critical emergency.

fibrinous inflammation of the upper respiratory tract, pneumonia and air sacculitis.

Transmission

Pasteurella infections in birds principally occur in the respiratory tract. Asymptomatic carriers harbor the bacteria in the nasal cavities, sinuses and choanae. Transmission can occur through direct contact with contaminated aerosols or through mechanical vectors such as blood-sucking mites. Infected rodents and free-ranging birds are considered important reservoirs. *Pasteurella* is shed almost exclusively from the upper respiratory tract. Shedding in the feces is rare, and egg transmission has not been documented. *P. multocida* is a common inhabitant of the oral cavity of some carnivores, particularly cats, and septicemic infections can occur through bite wounds. Cats should always be considered to be carriers of *P. multocida*, and any bird that has been mouthed by a cat should be treated with antibiotics immediately (Figure 33.5).[40]

Pathogenesis

Virulent strains of *P. multocida* cause an acute septicemia and death. Less virulent strains result in bacteriemia and colonization of the lungs, liver, kidneys, spleen and heart. Weakly virulent strains generally cause a chronic respiratory disease. The endotoxins produced by *Pasteurella* damage blood vessels, causing edema, hemorrhage and coagulation necrosis, particularly in the liver. Diseases by less virulent strains usually occur in stressed or immunocompromised hosts.

Clinical Disease and Pathology

Acute forms are characterized by cyanosis, dyspnea and diarrhea followed by death. Excess mucus may be present around the nostrils or beak. Birds that survive acute disease often develop respiratory rales, sinusitis, conjunctivitis or swelling of the sinus infraorbitalis. Arthritis and CNS signs have been reported in some chronic cases. Granulomatous dermatitis has been noted in raptors, owls and pigeons.

Postmortem findings with acute disease may be absent or limited to petechiae or ecchymoses of the parenchymal organs. Prolonged cases are characterized by exudative serositis (mainly white, in contrast to yellow with *E. coli*) and the formation of necrotic foci in infected organs. Catarrhal to fibrinous rhinitis, necrotic pneumonia, sinusitis, blepharoconjunctivitis and tracheitis are common with chronic courses. Following bacteremia, *Pasteurella* may colonize numerous tissues, resulting in arthritis, osteomyelitis, otitis media and granulomatous dermatitis. Granulomas may also be noted in the liver and spleen. Some strains will colonize the air cells of the cranial bones causing fibrinous exudate. In waterfowl, a diphtheroid enteritis may be observed. Histologic changes are nonspecific.

Diagnosis

The isolation of the causative agent is necessary. The occurrence of *Pasteurella* spp. in a flock can be determined through serology using immunodiffusion or indirect hemagglutination tests. Unfortunately, commercial antigens for these tests are not available. Serotyping and differentiation of the subspecies require specialized testing.

Treatment

Septicemic birds rarely survive, even when treated intensively. Parenteral administration of broad-spectrum, long-acting sulfonamides can be tried. The combined use of antibiotics and hyperimmune serum has proven to be beneficial. Treating birds with chronic forms is very difficult because of the irreversible damage that occurs to parenchymal organs.

Control

Preventing rodents and free-ranging birds from entering the aviary is important in preventing infec-

tions. Vaccines for *P. multocida* are commercially available, but their effectiveness is poor. Failures associated with the vaccine occur because of the numerous different serotypes and the fact that endotoxins are more immunogenic than the bacterial capsule. The production of vaccines from strains that persist in an aviary may provide successful long-term control.

Actinobacillus (At.)

The genus *Actinobacillus* consists of a group of organisms provisionally differentiated into more than 20 biovars, some of which have a rather high host specificity. The taxonomic reclassification of the Pasteurellaceae is intertwined with the genus *Actinobacillus*. Because of these classification revisions, even the actinobacilli that are pathogenic in birds have not been named. The situation has been complicated in recent years because many new strains have been isolated from Psittaciformes, Columbiformes, Anatiformes and Fringillidae. One biovar has been referenced in the literature as *P. haemolytica* syn. *At. salpingitidis*. However, this classification is not valid. The knowledge of the biology and pathogenicity of the members of the genus is limited.

Actinobacilli are polymorphic rods that may exhibit bipolar staining similar to Pasteurellae. Most strains grow only on blood agar plates or media containing serum. Some strains, particularly of *At. salpingitidis*, hemolyze avian and bovine erythrocytes or produce exotoxins that are capable of causing arteritis. Some strains are considered to be primary pathogens, but the majority of this genus is comprised of opportunistic organisms. There are no simple laboratory tests for differentiation between primary and secondary invaders.

There is little information on routes of transmission. It has been proven that egg transmission of some strains occurs in chickens and geese. Incubation periods in the avian host are not known.

Clinical Disease and Pathology

Many infected birds die acutely. Birds with a more chronic course typically develop joint lesions. Species-specific strains that infect geese morphologically resemble *P. influenzae*. This organism has been referenced as a cause of chronic disease in the gosling,[26] characterized by emaciation, failure to thrive, poor feed conversion and arthritis. Egg transmission may cause reduced hatchability. Asymptomatic infections are thought to occur in adult breeders, with clinical signs developing in goslings each season. At necropsy, liver necrosis, salpingitis, peritonitis, endocarditis valvularis and fibrinous arthritis are typical lesions. In young geese, polyserositis and arthritis are prominent.

Diagnosis and Treatment

Isolation and identification of the causative agent is necessary for diagnosis.

E. coli and other bacteria, particularly anatipestifer infections in waterfowl, have to be considered as causative agents for the salpingitis, peritonitis and polyserositis.

Tetracyclines and chloramphenicol are indicated for initial therapy. Sensitivities for many strains are difficult to interpret because of oversized inhibition zones. In young geese, antibiotics must be given during the first week of life or lesions become too extensive to be reversed.

Haemophilus (H.)

The haemophilus strains that infect companion birds have not been properly classified. Chickens are considered to be the only definitive host of *H. paragallinarum*, which is the agent of coryza contagiosa gallinarum. Experimentally, Columbiformes and Anatiformes are resistant to infection. Several *Haemophilus* spp., including *H. avium* and *H. paravium*, can be isolated from birds with coryza; however, their involvement in the disease process is questionable. They probably serve as secondary invaders that sustain upper and sometimes lower respiratory tract disease.[11,35]

Pathogenesis

Details on the pathogenesis of *Haemophilus* spp. strains that infect Psittaciformes and Columbiformes are scarce. *H. paragallinarum* is known to produce a number of cellular toxins, including neuraminidase, nitratase and catalase. Birds do not appear to develop an immune response following infection, and relapses are common.

Clinical Disease and Pathology

Haemophilus infections generally cause a rhinitis that results in a serous-to-mucoid or even fibrinous exudate. Conjunctivitis and sinusitis may also occur. The most common postmortem finding is catarrhal-to-fibrinous rhinitis. Bronchopneumonia and air sacculitis are frequently described but are usually the result of concomitant infections (virus, other bacte-

ria, *Candida* spp.). For those lesions supposedly caused by *Haemophilus* spp. apart from *H. paragallinarum* see Table 33.4.[32,35] Histopathology reveals uncharacteristic lesions.

TABLE 33.4 Clinical Disease Caused by Haemophilus in Avian Species

Blue Crane	Pneumonia (together with staphylococci) and necrosis of liver tissue
Pigeon	Rhinitis
African Grey Parrot	Pneumonia, air sacculitis
Plum-headed Parakeet	Sinusitis, swelling of the liver together with E. coli or related organisms
Eastern Rosella	Sinusitis, swelling of the liver together with E. coli or related organisms
Budgerigar	Rhinitis (possibly together with Pasteurella or E. coli)
Muscovy Duck	Rhinitis, sinusitis
Andean Goose	Rhinitis, hemorrhage, jejunitis
Turkey	Sinusitis, air sacculitis
Golden Pheasant	Sinusitis, diphtheroid surface lining of the beak cavity
Siamese Fireback	Necrosis of the lung tissue.

Other Gram-negative Rods

New Duck Disease (Duck Septicemia)

The etiologic agent of duck septicemia has been suspected to be *Pfeifferella, Pasteurella* or *Moraxella anatipestifer*. The causative organism has recently been placed in the genus *Cytophaga*, which is a semiaerobic, nonmotile rod.[49] The genus contains at least 19 serovars; serovars 1-3 are most common in Europe; serovars 1, 2 and 5 are most common in the United States; serovar 3 is frequently isolated in Australia. This organism is known to infect ducks and geese, free-ranging waterfowl, turkeys, pheasants and Psittaciformes. There is no information on its virulence or ability to survive in the environment.

Experimental disease does not occur following oral administration, and the respiratory tract is thought to be the primary portal of entrance to the host. Egg transmission resulting in high morbidity and mortality of ducklings is a substantial factor for the flock.

The pathogenicity of cytophaga is undetermined. Undoubtedly, there are strain differences in virulence, and the condition of the host must also play a role. The incubation period in ducks ranges from three to ten days.

Clinical Disease and Pathology

Infected ducklings (two weeks of age) usually die peracutely. Mortality rates in this age group can reach 75% of exposed young. Acute disease develops in older birds and is characterized by sinusitis, conjunctivitis, coughing and diarrhea, followed in two days by tremors, ataxia and convulsions. Survivors are stunted and fail to grow. Fibrinopurulent polyserositis is the characteristic postmortem finding. Other changes include lung congestion, hepatomegaly, splenomegaly, pericarditis and perihepatitis. Cytophaga-induced spondylitis with compression of the spinal cord was reported in turkeys.[10] Diffuse fibrinous meningitis with lymphocytic infiltration around the meningeal blood vessels was a characteristic histologic lesion. There was exudate formation within the ventricles as well as proliferation of microglia in the subpial and periventricular system.

Diagnosis

The occurrence of polyserositis is highly suggestive of an infection. Isolation and identification of the causative agent is necessary in all other cases. An ELISA can be used to survey a flock for serologic response.

Tularemia

Tularemia is caused by *Francisella tularensis*, a motile, short rod, 0.2 X 0.3-0.7 μm in size. Isolates are reported occasionally, mainly from birds that inhabit the northern and subarctic regions of the northern hemisphere, such as the Common Pheasant, Waxwing, Ural Owl, Rough-legged Hawk and Common Raven. Rodents are considered to be the primary reservoir. Nothing is known about the clinical signs. The pathology resembles that of *Pasteurella* or *Yersinia* infections. *Francisella* previously has been classified with these two genera. The organism is considered to be a zoonotic agent.

Acinetobacter calcoaceticus (An.)

This organism forms either cocci (fresh culture) or rods. It grows on commonly used media, even on some selective media for Enterobacteriaceae. The host spectrum is wide, and many avian orders can harbor the organism in the respiratory or intestinal tracts. Egg transmission is possible in many avian species. No reports conclusively describe consistently

occurring lesions in any avian species. Therefore, it is assumed that the organism has a low pathogenicity, and infections indicate a compromised host.

Gram-positive Bacteria of Clinical Significance

Staphylococcus (S.)

Staphylococcus infections can induce sporadic or enzootic disease in many avian species. Clinical manifestations may include acute septicemia or subacute-to-chronic arthritis, osteomyelitis and osteitis. Less common clinical problems include vesicular dermatitis or omphalitis. Staphylococci, particularly *S. aureus*, can function as primary pathogens or may complicate other infections as secondary invaders.

Isolation of the staphylococci is relatively simple using common media and growth conditions. Taxonomy literature[50] currently lists 21 *Staphylococcus* spp., 14 of which can be found in birds and are given here in order of decreasing frequency. *S. xylosis* is considered almost apathogenic. *S. sciuri* and *S. lentus* (the latter a former biovar of *S. sciuri*) have some pathogenicity markers. *S. aureus* includes more virulent strains than any other species. These four *Staphylococcus* species are further divided into several biovars. Because some of these biovars are recovered only in a limited number of closely related bird species, they may represent bacterial organisms that have adapted to specific hosts. Other less commonly isolated species include *S. intermedius*, *S. hyicus*, *S. cohnii*, *S. saprophyticus*, *S. haemolyticus*, *S. warneri*, *S. hominis*, *S. epidermidis*, *S. gallinarum* and *S. capitis*. *S. epidermis* was frequently cited in earlier literature but, using current diagnostic tools, is today rarely found in birds. The isolation of these less common species frequently depends on the internal or external environment of the patient, and limited information is available concerning their pathogenicity.

Staphylococci have several pathogenicity markers including production of the clumping factor, hemolysins, DNase, phosphatase, protein A and leukocidine. The presence of the clumping factor seems to correlate closely with pathogenicity in avian patients. Other pathogenicity markers have not been studied sufficiently to determine their importance in birds. Staphylococcus protein A, which is found in the bacterial cell wall, is capable of binding to the Fc-fragment of immunoglobulin, thereby inhibiting phagocytosis of the organism. The correlation between protein A production and the virulence of avian *Staphylococcus* strains is poorly documented.

Members of the genus *Staphylococcus* (apart from *S. aureus*) are commonly recovered from many avian species and are considered part of the autochthonous flora. When present in diseased tissue, they are generally considered to be secondary invaders. Because *S. aureus* includes the most virulent strains, the following discussion applies mainly to this species.

S. aureus

Avian strains of virulent *S. aureus* are relatively species-specific and rarely induce disease in mammals. The organism is found in abundant quantities in air and dust. Isolation of the organism can frequently be accomplished from the skin and the mucosa of the respiratory or digestive tract of clinically normal birds (Figure 33.6). *S. aureus*, like other *Staphylococcus* species, is relatively stable in the environment and can remain infectious for long peri-

FIG 33.6 A five-year-old Amazon parrot was presented with an acute onset of picking at the feet and legs, which caused hyperemia and scab formation. This syndrome, called Amazon foot necrosis, has been reported in *Amazona* spp., and *Staphylococcus* spp. are frequently isolated from the lesions. However, staphylococci are part of the autochthonous flora and are probably not the primary cause of this problem. This affected Amazon parrot belonged to a client who smoked, and when the owner started washing her hands after smoking (presumably to remove nicotine sulfate, a potent toxin), the foot and leg lesions resolved. The client eventually stopped smoking and the bird had no further episodes of Amazon foot necrosis.

ods of time outside the host. Given proper conditions, the organism can propagate in an external environment. Like many bacteria, *Staphylococcus* can also develop resistance to disinfectants following continuous exposure, and frequent changing of disinfectants is required to prevent the development of resistant strains.

Techniques for differentiating between avian and mammalian strains of *S. aureus* remain unsatisfactory. Evaluating the type of lesions caused by experimental subcutaneous infection of *S. aureus* in birds may prove valuable in differentiating between avian and mammalian strains.

Pathogenesis

The importance of *Staphylococcus* infections in birds is clinically underestimated. Individual strains may cause clinical problems in one bird while being considered normal autochthonous flora in another. Lipoteichoic acid, a major component of the staphylococcal wall, is instrumental in the specific capacity of this organism to bind to host cell receptors, particularly in the respiratory system. Such binding is a precondition for colonization and subsequent infection. However, avirulent strains can also bind to the same receptors and may compete for receptor sites, preventing colonization of virulent strains. This process is called "bacterial interference." Suitable strains of *Staphylococcus* have been used as prophylactic tools, especially in poults. Some of these apathogenic strains also produce bacteriocin, which can inhibit the growth of a variety of bacteria.

Although endogenous infections can be primary, they are frequently secondary to respiratory tract colonization and progress to septicemia. If an infected bird survives the acute septicemic stage of the disease, it will typically develop localized changes. Focal lesions occur as a result of thrombi formation in the arterioles and capillaries, which leads to ischemic necrosis. Clinically, these necrotic areas are frequently localized at the tips of the extremities and in the skin. In addition, infarction can also cause necrotic lesions in internal organs, particularly the liver and kidneys, which are more difficult to discern clinically. The central nervous system (CNS) is another site prone to *Staphylococcus*-induced lesions. Postsepticemic development of arthritis, tenovaginitis, osteitis and osteomyelitis followed by chronic skeletal changes are considered together as one disease process (Figure 33.7). These problems usually occur after a four- to seven-day period of septicemia.

Exogenous infections usually result in localized skin disease, although subsequent septicemia can occur in some cases. Birds, unlike mammals, are generally resistant to wound infection. To become established, exogenous bacteria typically require epithelium damaged by other infectious agents (particularly clostridia or poxvirus), immunosuppression (including immunosuppressive viruses such as retroviruses or reovirus), environmental stressors or prolonged application of an antibiotic.

Localized problems associated with *Staphylococcus* spp. can also result from a delayed hypersensitivity reaction. This type of response is considered to be one of the major factors in treating staphylococcus-related bumblefoot.

Clinical Disease and Pathology

Staphylococcus can induce a wide range of clinical and pathologic lesions, including high embryonic mortality, yolk sac or umbilical inflammation, septicemia, arthritis-synovitis, osteomyelitis, vesicular dermatitis, gangrenous dermatitis and bumblefoot.

Endogenous infections usually cause internal lesions, while exogenous infections frequently result in dermatitis and bumblefoot. Staphylococcal lesions in the umbilical region are typically either dry and brownish or smudgy, reddish and edematous. Clinical problems are most common in newly hatched chicks (up to ten days of age), in which the yolk sac in the body cavity is not absorbed normally, with possible decomposition of its contents.

Staphylococcus septicemia may be characterized by nonspecific clinical signs including lethargy, anorexia, a kyphotic posture, ruffled plumage and sudden death. The acute occurrence of necrosis to the distal digits or adnexa of the head and neck is suggestive of a thrombi-inducing infection, which can be a sequela to staphylococcus septicemia. During the initial phases of the ischemic process, the involved digits may be swollen, congested and painful, and many affected birds exhibit lameness. The acute onset of tremors, opisthotonos and torticollis can often be linked to staphylococcus-induced necrosis in the CNS. Gross lesions associated with staphylococcus septicemia include petechiae and ecchymoses of internal organs. Chronic infections may result in endocarditis valvularis. Histologic changes vary with the clinical course of disease but typically consist of a heterophilic and granulomatous response.

Arthritis-synovitis, characterized by the formation of serofibrinous or fibrinous inflammation of the

FIG 33.7 *Staphylococcus* spp. can cause osteomyelitis either secondary to septicemia or following an injury that allows colonization of the bone. Chronic osteomyelitis, as demonstrated in this radiograph, typically requires surgery to remove necrotic tissue and long-term antibiotic therapy, preferably with clindamycin because of its high affinity to bone and bone marrow.

synovial membranes of tendon sheaths and articular bursae, is frequently noted with staphylococcal infections in gallinaceous species. Any joint may be involved but there appears to be a predilection for colonization of the tarsal and metatarsal joints. Following antibiotic therapy, staphylococcus may be present in its unstable L-form, which is difficult to treat.

In immature birds with active growth plates, *Staphylococcus* frequently localizes in the epiphyseal area with secondary invasion of the bone marrow, resulting in osteomyelitis. Endogenous osteomyelitis is considered to be impossible after consolidation of the growth plate.[46] Infection of the growth plates often leads to chronic skeletal abnormalities. Infections are frequently localized to the proximal epiphyses of the femur, tibiotarsus, tarsometatarsus and fifth to seventh thoracic vertebrae. Vertebral injury may lead to clinical changes described as "kinky back" (Figure 33.8). Swelling and colliquation associated with the infection cause deformation of the vertebral spongiosa, which may lead to narrowing of the vertebral foramina and compression of the spinal cord.

Staphylococcus-induced vesicular dermatitis is characterized by the formation of vesicles containing yellowish exudate that form brownish to blackish crusts following rupture. Concomitant infection with poxvirus (or other immunosuppressive agents) may be involved in the disease process. Histologic evaluation of biopsy samples is required to confirm an underlying poxvirus.

Staphylococcus-induced gangrenous dermatitis is initially recognized by the occurrence of subcutaneous edema and hemorrhage followed by inflammation of the skin. Affected skin is typically blackish and smudgy and feather loss is common. *Clostridium perfringens* or another *Clostridium* sp. is a common secondary invader. Both *Staphylococcus* and *Clostridium* require a triggering factor (often damaged epithelium) to enter the tissue. Gangrenous dermatitis is rare in most bird species.

Advanced bumblefoot is a necrotizing abscess on the plantar surface of the foot. Depending on the location and chronicity of the abscess, infection may or may not extend to neighboring joints, tendon sheaths and bones. The condition is frequently described in raptors but may occur in other avian species. The precise pathogenesis of bumblefoot is undetermined (see Chapter 16). Although staphylococci are frequently isolated from these lesions, they are by no means the only bacteria that can be recovered from diseased tissue. Systemic infections that result in other le-

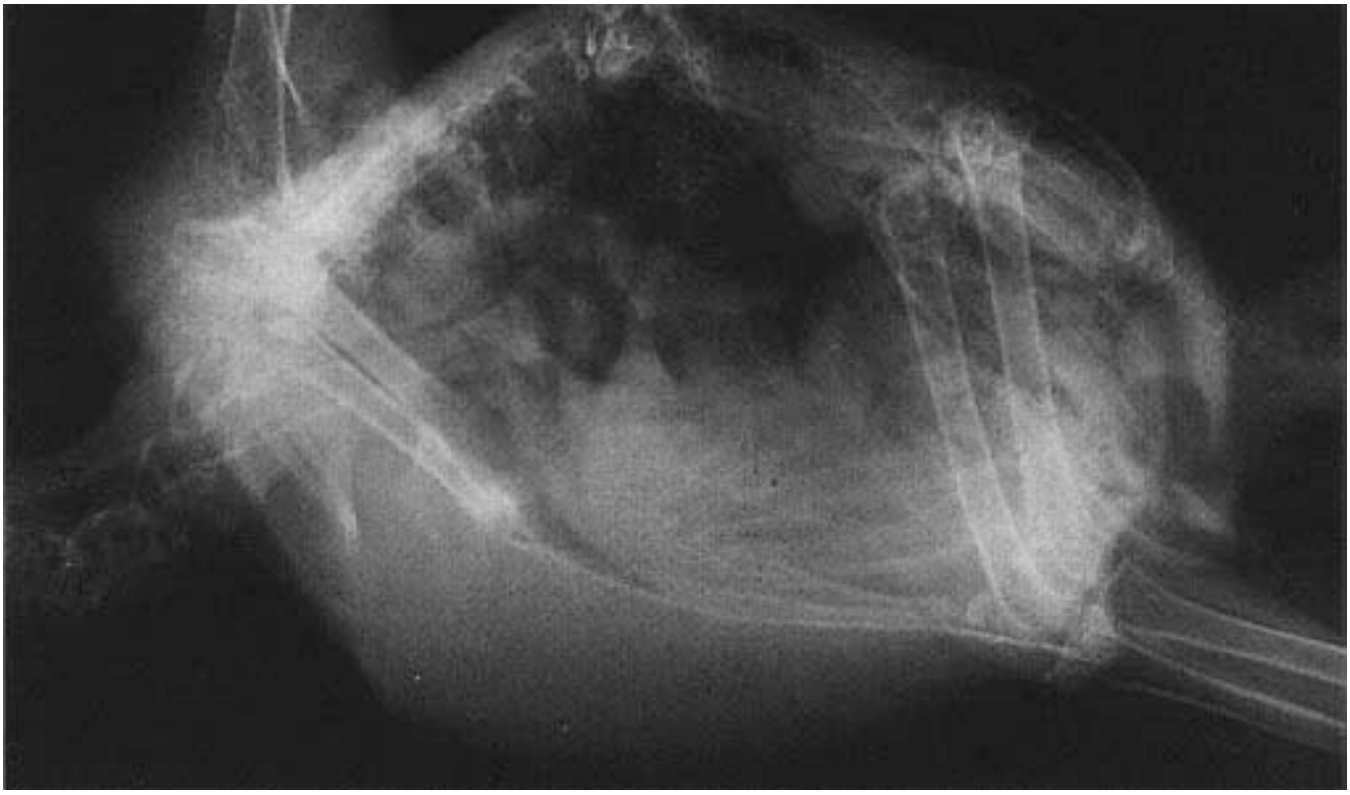

FIG 33.8 An eight-week-old African Grey Parrot was presented for an inability to stand or ambulate properly. On physical examination, the bird was BAR, in excellent weight (325 grams) and had a palpable spinal deformity. Radiographs indicated scoliosis. Bacterial infections including *Staphylococcus* spp. can cause spinal deformities. In this bird, the WBC was normal and the etiology of the problem was undetermined. Congenital abnormalities appear to be particularly common in African Grey Parrots and may have been the cause of this scoliosis.

sions or death can occur secondary to bumblefoot caused by virulent strains of *S. aureus*.

Diagnosis

Staphylococcal colonies, like *Micrococcus* spp., have opaque pigments (from white to yellow). Clumping factor-positive strains are likely to be virulent, and require an aggressive therapy based on antibiotic sensitivities.

Serologic diagnostic techniques using agglutinins, antihemolysins or antitoxins are of little value in diagnosing staphylococcosis. Cross-agglutinins, particularly against *Salmonella gallinarum-pullorum*, frequently result in false-positive reactions.

Streptococcus (Sc.) and *Enterococcus (Ec.)*

Streptococci and enterococci consist of numerous species that readily grow on most commonly used media. Differentiation between the species is based upon morphologic, biochemical and serologic characteristics. These organisms are ubiquitous (mainly in dust and air), and some strains can survive for long periods in the environment. They are sensitive to most commonly used disinfectants.

Sc. and *Ec.* are considered part of the autochthonous flora of the skin and the mucosal surfaces of the digestive, respiratory and reproductive tracts. *Sc.* and *Ec.* transition from normal flora to disease-inducing agents depends on the functional state of host defense systems. Predisposing factors to disease include immunosuppression, concomitant infections and exposure to a variety of toxins and pathogenicity factors that may be produced by some strains of *Sc.* and *Ec.*

The ß-hemolyzing, pyogenic streptococci, frequently found in mammals, are rare in birds. In comparison, α-hemolyzing streptococci are quite common. It has been suggested that most of the latter species should be included into the newly established genus *Enterococcus*.[45,54] Enterococci are less fastidious than streptococci, and many will grow on selective media used for isolating Enterobacteriaceae. Numerous species

of streptococci and enterococci have been isolated from birds.[15,16,17,29]

References to the pathogenicity of several *Sc.* spp. vary. Variance in the observed behavior of these opportunistic organisms may be a result of the effects induced by concomitant viral or chlamydial infections, the lack of experimental infections and confusion in taxonomy or nomenclature. Irrespective of predisposing factors, many *Sc.* and *Ec.* strains produce compounds that facilitate an infection (M-protein, capsules) or produce extracellular substances that inhibit the host defense system (hemolysin S, streptolysin S, hyaluronic acid, streptokinase, DNase, NADase and esterases) or inhibit other competing bacteria (bacteriocins).

Vertical transmission (including L-forms) can be a cause of early embryonic death and post-hatching developmental problems (Figure 33.9). Infections in hatchlings are usually associated with omphalogenic postnatal septicemia.

FIG 33.9 Bacterial infections (*Streptococcus*, *Staphylococcus*, *Enterococcus* and *Salmonella* spp.) of the egg can cause embryonal death, post-hatching developmental problems and yolk sacculitis.

Pathogenesis

The rarely occurring *Sc.* spp. group C can cause a septicemia followed by an embolic-thrombotic systemic disease and death, usually in adult birds. Following infection, hematogenic and intrahepatic spreading results in colonization in almost all organs if the host survives (probably agent- and host-specific). In experimental infections, a persistent bacteremia has been described, the duration of which can range from weeks to months. In addition to the pathogenicity factors already mentioned, *Sc.* group C may also produce reagins that govern the host reactions. Genetic and environmental factors as well as concurrent viral infections or immunosuppressions may predispose mainly adult birds to this rare infection.

Little information is available on the pathogenesis of *Sc. pneumoniae* or *Sc. pleomorphus* lesions in birds. *Sc. bovis* has been described as a pathogen in pigeons[17] and ducks;[52] however, the pathogenesis of these infections is unclear.

Enterococci outside of the digestive tract can cause necrotizing inflammatory lesions in infected organs. However, the pathogenicity of *Ec.* spp. is generally low. Experimental infections indicate that disease induction requires predisposing immunosuppressive factors. As a rule, natural infections occur by the oral route and are most common in postnatal and growing birds.

Ec. faecalis can induce an acute septicemic or a subacute-chronic disease. The acute form predominates in young birds, and survivors often develop endocarditis. Details on pathogenesis are known only in gallinaceous species. *Sc. faecalis* is thought to play a central role in the malabsorption syndrome described in chickens.

Egg transmission of *Ec. faecalis* (also as an L-form) is associated with an acute post-hatching septicemia. The subclinically infected yolk sac is thought to be the source of disease in the hatchling. *Ec. faecalis* is not considered autochthonous flora of canaries and may cause a primary respiratory disease in this species.[18] Subacute-to-chronic tracheitis with dyspnea and rales are considered natural components of the disease. *Ec. cecorum* has not been associated with disease in experimental infections.[14] *Ec. columbae* is mainly found in pigeons and constitutes a component of the autochthonous intestinal flora.

Clinical Disease

The clinical diseases caused by pyogenic streptococci and other streptococci and enterococci are relatively similar. Clinical presentation can be peracute to chronic, with birds surviving six to eight weeks in the chronic form. Omphalitis in recent hatchlings is typical with egg transmission or infections obtained from the hatchery.

An Amazon parrot with a slight nasal discharge was found to have a *Sc.* group G infection that was causing chronic respiratory disease in the children of the house. Presumably, the bird was infected by the children.

Septicemia may lead to a peracute apoplectiform death or severe depression followed by death in two to three days. Other signs such as diarrhea, dyspnea, paresis, conjunctivitis and sinusitis (Japanese Quail) may develop.

Chronic disease is typified by inflammation of joints, tendon sheaths and adnexa of the head. Fibrinous joint lesions, with or without abscess formation, can occur several months after the initial infection. Birds that survive systemic infections may develop cardiac valve insufficiency secondary to endocarditis. This condition is difficult to diagnose and often presents as chronic dyspnea.

Sc. pyogenes has been associated with bacteremia in the Humboldt Penguin, White Pelican, and several Psittaciformes, Anatiformes and Phasianiformes. It has not been clearly defined whether the bacteremia in these cases was a result of true group A streptococci, or whether the inciting strain was *Sc. pyogenes animalis* (classified in group C). Group C *Streptococcus* has been associated with pneumonia secondary to bacteremia in a variety of avian species. In the ostrich, *Sc.* group C cases are characterized by akinesia, anorexia and dysphagia. This organism together with *Corynebacterium pyogenes* can induce diphtheroid lesions in the mucosa of the beak cavity and the crop that can result in similar clinical signs.[32]

Sc. bovis infections in pigeons have been associated with clinical changes ranging from peracute death to chronic lameness (myositis) and arthritis.

Ec. group D is frequently implicated as a cause of pneumonia in various bird species, particularly Passeriformes, and primarily infects young birds. In canaries, *Ec. faecalis* can cause a tracheitis and chronic respiratory disease that manifests clinically as changes in the voice (more "sparrow-like") or complete voice loss. Tracheal mites (*Sternostoma tracheacolum*) can cause similar clinical signs in this species. Epidemiologically, the infection spreads slowly through the whole flock. Some affected birds develop dyspnea and die, while others may temporarily recover. Relapses are common in recovered birds.

Pathology

Gross lesions in birds that die acutely with bacteremia include subepicardial and myocardial hemorrhages and serofibrinous polyserositis. The subcutaneous tissues, serosal membranes and pericardium may be congested, and the spleen is frequently hyperplastic. Lung congestion, pneumonia or petechiation of the laryngeal and tracheal mucosa may be noted in some species. The liver may be slightly swollen and exhibit a greenish discoloration. Catarrhal enteritis, skeletal muscle hemorrhages and swollen kidneys may also be observed. Muscle necrosis and purulent myositis are frequently described in pigeons with *Sc. bovis* infections.

Pathologic changes in chronic cases are characterized by arthritis with a light, mucoid exudate and the formation of coagulated or dried exudates in the body cavity. Cauliflower-like or granulomatous atrioventricular inflammation may develop, particularly on the left cardiac valve. Pyogenic streptococci may cause chronic peritonitis, salpingitis and oophoritis.

Histologically, focal necrosis is common in the liver. This lesion is thought to be caused by bacterial endotoxins or the formation of thrombi in the bile ducts. Heterophilic infiltrates are most common in acute lesions. Granuloma formation (without a capsule and consisting of epithelioid cells and multinucleated giant cells), particularly in the spleen and heart, is more common in chronic cases. Purulent meningitis has been described in some cases. Endocarditis and cardiac infarct may occur secondary to embolic-thrombotic incidents. Localized lymph follicles may be described as hyperplastic.

Diagnosis

In acute cases, samples for culture taken from the liver, heart and brain are most diagnostic. Isolation from the brain indicates that the strain recovered is actively involved in the disease process. A triggering factor might have been necessary to enable the organism to cause septicemia. Special media are necessary for culturing L-forms.

FIG 33.10 White streaking is evident in the pectoral musculature of an Amazon parrot that was being treated with IM enrofloxacin.

Treatment and Control

Aggressive treatment with parenterally administered antibiotics is the recommended therapy. Pyogenic streptococci are generally sensitive to penicillins, erythromycin, tylosin, spectinomycin, clindamycin and pleuromutilin. Enterococci have varying antimicrobial sensitivities. Chronic joint and tendon sheath infections are difficult to resolve and may require a combination of surgery, joint lavage and prolonged antibiotic therapy. Joint lavage appears to be more successful in birds than in mammals because iatrogenic secondary infections are less likely. Streptococci in synovial membranes are frequently in their L- or protoplastic form. Treatment in these cases consists of ampicillin and erythromycin or enrofloxacin (Figure 33.10).

Mycobacterium (M.)

Colony morphology of pathogenic mycobacterium may be smooth or rough and change through successive *in vitro* subcultures. Most strains are nonphotochromogenic and may become yellow with age. Some strains are scotochromogenic and have bright yellow pigments.

All bird species that have been experimentally exposed have been found to be susceptible to *M. avium*. Lesions are typified by large numbers of bacteria in infected tissues. This is in contrast to *M. tuberculosis*, which is typically found in relatively small numbers in infected tissue. *M. avium* is highly resistant to environmental extremes and can survive in the cage or aviary environment for periods ranging from months to years. Shedding from an infected host occurs primarily in the feces and urine, causing contamination of the soil or water supplies within the aviary. Mycobacterium has been found to remain infectious in soil for up to seven years. For disinfection, only compounds tested against mycobacterium are recommended.

- ***M. avium and M. intracellulare:*** DNA cleavage techniques (restriction fragment length polymorphism and pulsed-field gel electrophoresis) have shown that *M. avium* consists of three clusters on the subspecies level as follows:[62]

M. avium subsp. avium: This subspecies is ubiquitous in the environment and is the agent most commonly associated with avian mycobacteriosis. The organism also has a widely documented mammalian host range including cattle, sheep, goats, pigs, cats, kangaroos and humans. In humans, adults typically develop respiratory infections, children usually develop submandibular adenopathies, and disseminated infections are common in patients with immunosuppressive diseases (eg, AIDS). Strains experimentally caused paratuberculosis in cattle and tuberculosis in fowl (Table 33.5).

M. avium subsp. paratuberculosis: This subspecies of *M. avium* requires mycobactin for *in vitro* culture and has not been isolated from the environment. This subspecies is considered to cause paratuberculosis in ruminants and has been implicated as a cause of Crohn's disease in humans.

M. avium subsp. silvaticum: Like *M. avium subsp. paratuberculosis*, these strains also require mycobactin for primary cultivation and have not been recovered from the environment. Most strains have been

isolated from Wood Pigeons and free-ranging ruminants. The agent causes paratuberculosis in mammals and mycobacteriosis as well as paratuberculosis in birds.

M. intracellulare is designated as a distinct species and is considered less pathogenic to birds than *M. avium* (whether justified or not). Morphologic, biochemical and serologic differentiation between *M. avium* and *M. intracellulare* are relatively difficult. These two species are routinely grouped together into the *M. avium-intracellulare* (MAI) complex. MAI complex strains are serologically distinct and have been divided into serovars.[64] *M. avium* is divided into serovars 1 to 11; *M. intracellulare* into three subspecies (subspecies 1: serovar 12 to 17, 19 to 28; subspecies 2: serovar 7; subspecies 3: serovar 18). Serovar 1 is most prevalent and pathogenic in the United States, while serovar 2 is most common in Europe. To date, serovar 3 has mainly been isolated in Europe.

TABLE 33.5 Zoonotic Potential of Bacteria From Companion Birds

Bacteria	Zoonotic Potential
Actinobacillus	None reported
Alcaligenes	None reported
Bordetella	None reported
Campylobacter	Undetermined, possible *C. laridis* – diarrhea in children
Clostridium	Negligible
E. coli	Possible Prevention – good hygiene
Erysipelothrix	Persistent dermatitis Avoid contact with infected birds
Haemophilus	None reported
Listeria	Conjunctivitis when infected from birds
Klebsiella	Theoretically possible None reported Humans – Friedländers pneumonia
Megabacterium	Avian-specific
Mycobacterium	Possible Immunosuppressed humans
Pasteurella	Rare human cases
Pseudomonas	Possible Prevention – good hygiene
Salmonella	Negligible (see text)
Staphylococcus aureus	Negligible Avian-adapted strains
Streptococcus/ Enterococcus	Negligible Birds may be infected by humans
Francisella tularensis	Possible/unlikely from birds
Vibrio	Mild enteritis
Yersinia pseudotuberculosis	High potential Transmission documented Humans – difficult to treat

Serovar 8 has been isolated worldwide and is probably the most frequent serovar reported. Birds living in aquatic environments are particularly susceptible to infections, which can be subclinical. Recently, serovars 25 and 27 have been isolated from sick birds. In addition, *M. avium* strains have been recovered that do not belong to serovars 1 to 28. These newly isolated strains vary serologically, have a broad host spectrum and are considered as virulent as serovar 2.[38]

Transmission

Avian mycobacteriosis primarily involves the alimentary tract. Transmission occurs mainly through contaminated feces, although aerogenic routes of transmission are possible. Arthropods can serve as mechanical vectors of *M. intracellulare* and *M. avium subsp. avium*. Egg transmission can occur but is epornitically unimportant because *M. avium* bacteremia causes an immediate cessation of egg production. Mycobacteria may persist in contaminated soil, litter and, less frequently, feed. Birds of prey can be secondarily infected while consuming infected quarry. The incidence of mycobacteriosis in free-ranging birds is estimated to be less than 1%.[59]

Pathogenesis

The main portal of entrance in birds is the intestinal tract, which typically results in a visceral infection. Initial colonization occurs in the intestinal wall. Subclinical bacteremia occurs early with subsequent spread to the liver through the portal circulation during the infectious process (relatively low numbers of organisms in the blood). The lack of lymph nodes allows unabated hematogenous spread within the host. The lungs can be secondarily infected during bacteremia. Avian mycobacteria are removed from the endothelium of the vessels by reticuloendothelial cells, mainly in the liver, spleen and bone marrow. Locally, avian mycobacteria induce cellular reactions governed by the cell-mediated immune system. In contrast to this typical *M. avium* infection, Columbiformes, Anseriformes and some weaver finches of the genus *Textor* develop lesions only within the lungs (Figure 33.11). An acute bacteremia is frequently observed in cranes (Gruiformes), the Hermit Ibis, Columbiformes and some Passeriformes. Tubercles that form at the site of infection in the intestinal wall commonly remain open to the intestinal lumen. This allows for constant shedding of *M. avium* into the feces (open infection). In birds, three different types of lesions can be recognized although the pathogenesis has not been clarified: 1) classical form with tubercules in many organs; 2) paratuberculous form with typical lesions in the intestinal tract (prone to

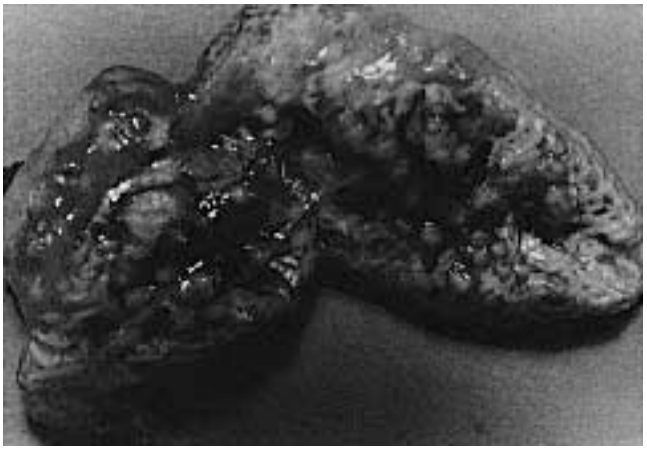

FIG 33.11 In Psittaciformes, mycobacteriotic lesions are generally not limited to the intestinal tract. In Columbiformes and some other species, atypical granulomas may form in the lungs. *Mycobacterium avium* was recovered from the lungs of this pigeon that was presented for severe emaciation and severe dyspnea. Radiographs indicated soft tissue masses in the lungs. Abnormal clinical pathology lesions included WBC=54,000 and PCV=19.

develop this form of myobacteriosis are *Amazona, Pionus, Brotogeris, Psittacula* species and the Horned Parakeet); 3) non-tuberculous form, which may be difficult to recognize at necropsy (many Psittaciformes).

Clinical Disease

In some bird species the clinical course is atypical, and acid-fast rods have been detected more or less accidentally. This is particularly the case with small Passeriformes, especially the Hooded Siskin.[19] Clinical signs associated with mycobacteriosis are highly variable. Adult birds usually develop a chronic wasting disease associated with a good appetite, recurrent diarrhea, polyuria, anemia and dull plumage. Immature individuals frequently develop subclinical conditions. Intermittent switching lameness may occur as a result of painful lesions in the bone marrow. Arthritis, mainly of the carpometacarpal and the elbow joints or tubercle formation of the muscles of the thigh or shank can be seen occasionally. These clinical changes are particularly common in Falconiformes and Accipitriformes. Skin over the affected joint is often thickened and ulcerated. Tubercle formation in the skin is rare, but when it is present, pinpoint to pigeon egg-sized nodules filled with yellow fibrinous material may be noted. Granulomas may be seen within the conjunctival sac, at the angle of the beak, around the external auditory canal and in the oropharynx. Mycobacteriosis should be suspected when tumor-like lesions recur after surgery. Greater Rhea frequently develop granulomas in the upper pharynx. In the Goshawk, loss of balance, convulsions and necrosis of the base of the tongue have been observed.[43] Clinical signs associated with colonization of the lung are rare. However, the peafowl may develop respiratory sounds caused by granuloma formation within the trachea.

Pathology

The pathology associated with *M. avium* infections varies widely, probably based on the species of bird infected and the serovar of the bacterium. Specific relationships between avian hosts and individual serovars have not been defined. The presence of miliary to greater-than-pea-sized nodules in the wall of the intestinal tract and in the liver, spleen and bone marrow are characteristic of *M. avium* infections. These typical lesions have been described in Falconiformes, Accipitriformes, Strigiformes, Phasianiformes, Charadriiformes, Ciconiiformes, Cuculiformes, Piciformes and Ralliformes. Granuloma formation can occur in any organ but is generally localized to the intestinal tract and reticuloendothelial organs. The nodules are frequently necrotic in the center and in chronic cases may be calcified. In contrast, Columbiformes, Anatiformes, Passeriformes and most of the Psittaciformes do not form typical granulomas. Acid-fast rods are found distributed throughout the parenchyma of infected organs. An infected liver or spleen may be only swollen or may show necrotic foci or even general induration. In pigeons, liver lesions may resemble *Trichomonas* abscesses. In pelicans, greasy tumor-like swellings like those seen in leukosis may be observed. The lungs, particularly of geese, weaver finches (genera *Queleopsis*, *Quelea* and *Euplectes*) and some *Amazona* spp., develop necrotizing or ulcerating lesions. Paratuberculous lesions are characterized by the occurrence of clubbed villa containing acid-fast rods in the intestinal mucosa. Lesions may also occur in glands of Lieberkühn, with characteristic proliferation of their epithelial cells.

Histopathologic identification of foci of single or confluent epithelioid cells in affected organs is suggestive of an *M. avium* infection. Parenchymal lesions generally consist of epithelioid cells or multinucleated giant cells (mostly the foreign body type, only rarely the Langhans type) and occasionally contain lymphocytes and plasma cells. Acid-fast rods in varying quantities can be demonstrated in the affected epithelioid or multinucleated giant cells. Acid-fast rods may also be noted in tissues in the absence of cellular reactions. Some infected birds will have cell-free acid-fast rods in the proventriculus or jejunal villi without an inflammatory response. It has been

postulated that the acid-fast rods may actually be contained within lymphatic vessels in the villi. *M. avium* infections frequently induce depletion of lymphocytes in the spleen (particularly the white pulp) and a proliferation of macrophage or reticular cell types in the same tissue. Depletion of the splenic lymphocytes and lymph follicles may induce an immunosuppression.

Diagnosis

The demonstration of acid-fast rods in tissues or on cytologic preparations is suggestive of mycobacteriosis. False-negative staining can occur by not obtaining an adequate sample. The demonstration of acid-fast rods in the feces has been suggested as a useful diagnostic tool in subclinical birds. Mucus present in the feces can interfere with test results, and samples should be processed with one of the sputum solvents used in human medicine before staining. The most consistent results can be obtained by centrifuging the feces and then spreading the surface of the pellet on a slide for staining. This test is relatively insensitive and requires the presence of approximately 10^4 bacteria/g of feces to be positive. The clinician must differentiate between pathogenic and nonpathogenic strains of mycobacteria, both of which may be present in the feces. In general, nonpathogenic strains are wider and are not granular. Demonstrating acid-fast organisms in the stool is not diagnostic for a mycobacterial-induced disease.

Culture is required to make a distinct diagnosis. Some strains of *M. avium-intracellulare* require mycobactin and will not grow on egg medium. *M. avium* subsp. *paratuberculosis* and subsp. *silvaticum* can be separated by responses to six parameters: subsp. *paratuberculosis* has a mycobactin requirement, grows on egg medium, tolerates cycloserine (50 μg/ml), is stimulated by pyruvate but not by pH 5.5, and has no alkaline phosphatase. The subsp. *silvaticum* has the opposite characteristics.[62]

Unfortunately, most of the mycobacterial strains from Psittaciformes have not been cultured. The future availability of species-specific antibodies will help in delineating infections. Endoscopy (with biopsies) can be used for diagnosis in cases of advanced classical tuberculosis. Radiographs may indicate granulomas in respiratory tissues in some cases. Biopsy is required to differentiate between mycobacterial and fungal granulomas, which radiographically appear similar.

Several indirect tests have been discussed for diagnosing *Mycobacterium*. The tuberculin test (allergenic test) and the slide agglutination test (serologic test) have both been used in birds with some success. The tuberculin test is frequently associated with false-negative results, particularly in early and late stages of the disease and is no longer recommended. The slide agglutination test requires fresh plasma or serum and is evaluated against a bank of antigens for the different serovars; there are cross-reactions between the different serovars. Unfortunately, only serovar 2 antigen is commercially available. To estimate the probability of an acute disease process, serotitration (using the Gruber-Widal scheme) is possible. Only titers greater than 1:64 are considered positive. Psittaciformes may exhibit a cyclic reduction in titer and mycobacterial excretion, which may lead to an incorrect suspicion that natural healing or a successful therapy has occurred. An ELISA system has been tested to distinguish between *M. avium* serovars but has been hampered by a high degree of cross-reactivity.

Treatment and Control

Several treatment modalities have been discussed for birds with *M. avium* infections. However, treating infected birds is not recommended because:

- All *M. avium* isolates that have been tested are totally resistant to the antituberculous drugs routinely used in humans. Recent information revealed that ethambutol, while ineffective, does change the cellular wall of *M. avium* in a manner that allows other tuberculostatics to enter the organism.[21] However, successful therapy is then dependent on pharmacokinetic conditions and requires a combination of drugs to be available at the same time, at the correct concentration and at the correct anatomic location. The pharmacokinetic data necessary to ensure that these parameters are met are not available for a single avian species.
- *M. avium* infections are considered to be "open," allowing infected birds to continuously shed large numbers of organisms into the environment.
- There is potential danger to man, and there is no appropriate method of treatment for infected humans.

Birds that are definitively diagnosed (biopsy of affected tissue with histopathology and culture) with *M. avium* or *M. intracellulare* infection should be euthanatized. Contact birds should be removed from the contaminated area, quarantined for two years and tested every six to 12 weeks to determine if they

are reacting. Birds that remain negative (also not shedding the agent with the feces) and are in good physical condition following the quarantine procedure can be considered free of the disease. There are currently no absolute means of control. The chances of introducing *M. avium*-positive birds to the flock can be reduced by performing serologic or repeated fecal examinations of all new additions during the quarantine period.

The transmission of *M. avium* to humans is possible. However, transmission is probably dependent on inherent resistance, the immune status of the person in question, the frequency of exposure and the number of bacteria per exposure.

- ***M. tuberculosis:*** *M. tuberculosis* lesions in Psittaciformes are possible but are extremely rare. When present, they are generally characterized by the formation of benign localized granulomas of the dermis, frequently around the cere or nares as well as the retroorbital tissue.[63] Birds affected are usually pets with very close human contact and, as such, serve as sentinels for patent tuberculosis in the owners. The affected dermis looks granulomatous and may even ulcerate. The swelling of the retrobulbar tissue causes a protrusion of the eye (exophthalmos). Diagnosis can be made by histology or culture of biopsies. Infected birds should be euthanatized.
- ***M. bovis:*** *M. bovis* was associated with a generalized infection in an Amazon parrot. This animal developed a nontubercular lesion similar to those seen in Psittaciformes infected with *M. avium intracellulare*. The strain in question was sensitive to all common tuberculostatic drugs.

Erysipelothrix (E.)

Erysipelothrix rhusiopathiae can induce an acute-to-subacute septicemic disease. Infections are most commonly discussed in ducks and geese but can occasionally occur in other avian species including Psittaciformes.[55,32] The eleven serotypes of *E. rhusiopathiae* are ubiquitous in the environment and can propagate outside the host. Survivability in moist soil and in the water of shallow lakes and ponds, even salt and seawater, is particularly high. Infections in birds occur most frequently in the late fall, winter and early spring (northern hemisphere). Rodents, pigs and raw fish have all been implicated as reservoirs for the bacterium.

Pathogenesis

E. rhusiopathiae infections are most common in waterfowl and fish-eating birds during cold weather when food is scarce and energy requirements are high. Concomitant infections and inadequate hygiene seem to be precipitating factors of natural diseases. Most affected birds die during the bacteremic phase of an infection. Those birds that survive the acute disease frequently have secondary dermatitis and arthritis caused by hypersensitivity reactions.

Clinical Disease and Pathology

E. rhusiopathiae usually causes peracute death. If clinical signs occur, they may include lethargy, weakness, anorexia and hyperemia or bruising of the featherless, nonpigmented skin. Greenish discolored droppings, dyspnea and nasal discharge have been reported in some cases. In the Marabou Stork, infections have been characterized by inflammation and necrosis of the cutaneous adnexa of the neck.

Petechiae in the subcutis, musculature and intestinal mucosa are common gross lesions in diseased birds. The liver and spleen are friable and discolored (red to black). Histologically, these organs are degenerated and necrotic. Chronic *E. rhusiopathiae* cases are rare but have been reported in geese and turkeys. Clinical changes associated with this form of disease include thickened, leather-like skin, serofibrinous arthritis or valvular endocarditis. Histologic changes in these tissues include thrombi and degeneration of vascular walls.

Diagnosis

Diagnosis is confirmed by isolating *E. rhusiopathiae*. The best samples for isolation (if the tissues are fresh) are liver or spleen. In severely autolytic cases, bone marrow samples may be the most diagnostic. As in most bacterial diseases, cell-mediated immunity is more important in resolving infections than the development of humoral antibodies. Thus, serologic methods of diagnosis are of little value.

E. rhusiopathiae adjuvanted bacterins have been used to control flock outbreaks; however, vaccination may sensitize the birds and potentiate chronic disease. Flock control can best be implemented through sound aviary hygiene and rodent control.

Listeria (L.)

Listeria monocytogenes causes β-hemolysis on blood agar. The motility of listeria is dependent on the ambient temperature to which it is exposed. *Listeria*

spp. may infect a number of avian species, including Psittaciformes.[32] Canaries appear to be more susceptible to infections than other birds.

L. monocytogenes is a ubiquitous organism that is frequently found in areas. The bacteria is environmentally stable and can propagate outside the host.[56]

Pathogenesis

The role of *L. monocytogenes* as a primary pathogen is controversial; however, there is no question that ingested bacteria can lead to a latent or abortive infection. Acute disease is characterized by bacteremia progressing to death within one to two days. The subacute and chronic forms of the disease involve reactions of the cell-mediated immune system. Intracellular bacteria like *L. monocytogenes* typically induce cell-mediated immunity.

FIG 33.12 Encephalitis caused by several bacterial pathogens including *E. coli, Listeria, Salmonella, Staphylococcus* and *Klebsiella* spp. can cause neurologic signs characterized by torticollis, tremor, ataxia, depression, paresis or paralysis.

Clinical Disease and Pathology

Clinical disease is usually associated with sporadic deaths in a collection. Epornitics can develop in canaries and related birds that are maintained in dense populations. Chronic infections can induce lesions in the heart, liver and, rarely, the brain. If clinical signs are noted, they are generally associated with CNS signs and include blindness, torticollis, tremor, stupor and paresis or paralysis (Figure 33.12).[41] Subacute-to-chronic cases usually cause a severe monocytosis (10 to 12 times normal).

The presence of serofibrinous pericarditis and myocardial necrosis is considered suggestive of *Listeria*. There are usually no gross lesions evident in the brain. There may be no lesions in birds that die acutely, or there can be a few petechiae present.

Histologically, infections are characterized by degenerative lesions, without a cellular response, in the heart and liver. Brain tissue is usually normal, even in cases in which CNS signs are present and the organism can be recovered from the cerebrum.

Diagnosis

A confirmed diagnosis requires the isolation of *L. monocytogenes* from affected tissues. Appropriate transport media are necessary for proper shipment of samples. Listeria isolates must be speciated, because *L. ivanovii*, *L. innocua* and *L. seeligeri* are commonly recovered from birds.[8] There is little information on the pathogenicity of these *Listeria* spp. although *L. innocua* is considered apathogenic.[37] Latent infections limit the diagnostic value of serologic tests (slide agglutination).

Clostridium (Cl.)

The genus *Clostridium* includes a group of ubiquitous bacteria that are considered to be autochthonous flora in raptors and in birds with well developed ceca, including Phasianiformes (gallinaceous birds) and Anseriformes. In birds in which the cecum is small or absent, clostridium is rarely isolated from the intestinal tract and when it is, it is often considered to be transitory.

Pathogenesis

Clostridium spp. produce more potent toxins than any other bacterial genus. The pathogenesis of *Cl.* spp. toxin-induced damage in a bird remains poorly understood except for *Cl. botulinum*. This *Cl.* sp. principally causes an alimentary intoxication. The ability of clostridia to colonize the intestines appears to depend on reduced gastrointestinal motility. Peristaltic abnormalities can occur as a result of enteritis, low levels of dietary fiber, administration of some

medications, or during some viral infections (particularly reovirus). Experimental reproduction of disease by using a culture alone is usually not possible, and clostridial organisms are considered to be opportunistic pathogens. Following colonization, pathogenic clostridia produce exotoxins, which then induce clinical lesions or death.

It is best to discuss clostridial infections by grouping them under clinical signs because a clostridial species can cause differing clinical signs, and various clostridial species can cause similar-appearing diseases.

Necrotic or Ulcerative Enteritis

Clostridia-induced enteritis can occur in many avian species. Flock outbreaks are most commonly associated with Phasianiformes, especially those within the subfamilies Tetraoninae (grouse) and Odontophorinae (New World quail) or captive and free-ranging lorikeets.[44] Ulcerative gastritis, not enteritis, is the most common form of clostridial infection reported in the ostrich.[60] Clostridial enteritis in game birds (Tetraoninae) is usually associated with *Cl. perfringens* type A. On rare occasions, types B, C or D may be the etiologic agent. *Cl. perfringens* type E is vary rare in Phasianiformes. Ulcerative enteritis in the Bobwhite Quail is usually caused by *Cl. colinum* (species *incertae sedis*). This organism is also thought to cause necrotic enteritis in the other Odontophorinae, grouse, chicken, turkey and domesticated pigeon (Köhler, personal communication).

Necrotic enteritis usually occurs in young birds after the second post-hatching week. Adult birds are more resistant. In the acute form of the disease, clinical changes include diarrhea (with or without blood) and polydipsia, followed by death within a few hours. Birds with chronic lesions exhibit retarded growth and weight loss before dying.

Pathologic changes include diffuse or focal hyperemia of the mucosa, which develops into necrotic areas or ulcers. These lesions are most common in the upper jejunum. Lesions start as pinpoint foci and progress to include a necrotic center with a wall and a reddish halo. Ulcers may coalesce and perforate the intestinal wall. Swelling and necrosis of a grayish liver, spleen and kidney are common.

Identification of characteristic lesions and isolation of the organism are confirmatory. If *Cl. perfringens* is the etiologic agent, a diagnosis can be achieved by demonstrating toxins in the serum, intestinal contents and liver homogenates (sterilized by filtration). The differential diagnosis includes salmonellosis, enterotoxic *E. coli* and drug overdoses. Newcastle disease virus can induce ulcers called "boutons" that resemble those induced by *Clostridium*.

Gangrenous Dermatitis

Gangrenous dermatitis can be caused by *Cl. perfringens* type A, *Cl. septicum*, or *Cl. novyi*. These organisms can directly colonize damaged skin. Microscopic epithelial lesions caused by abrasions, avipoxvirus or staphylococci can become secondarily infected with *Clostridium* spp. The patient's immune status may also play a role in the overall pathogenesis.

The sudden occurrence of regional feather loss with a blue-red or almost black skin discoloration is a characteristic lesion. Affected skin may also be edematous and painful as a result of gas accumulation in the tissue. Sick animals typically develop toxemia and die within 24 hours. With screamers (genus *Chauna*), their corneous-lined bony wing spurs can cause prick-like skin injuries predisposing them to clostridial diseases.

The occurrence of emphysema, edema and hemorrhages (with or without necrosis) in the subcutis, skeletal musculature and myocardium are characteristic necropsy findings. A confirmed diagnosis requires isolation of *Cl.* spp. from affected tissues. *Aeromonas hydrophila*, staphylococci and avipoxvirus can induce pathologic changes similar to those caused by *Cl.* spp. Rapid production and systemic release of toxins usually prevents successful therapy.

Botulism (syn. Limberneck)

Cl. botulinum neurotoxins are typically ingested in contaminated foods. Rarely, clinical disease may result from primary colonization of the alimentary tract. *Cl. botulinum* has been found to produce six thermolabile exotoxins (designated A to F). Types A and C are predominantly involved in inducing pathologic changes (occasionally also type E). High concentrations of clostridium toxins are common in decaying meat and vegetation. Fly larvae (maggots) that feed on decaying material are resistant to the toxins but can serve as a source of intoxication for those species that eat maggots. With a few logical exceptions, most birds are probably susceptible to *Cl. botulinum* toxins. Free-ranging waterfowl are particularly susceptible, and enzootic intoxications are common following periods of drought or flooding. Vultures seem to be resistant to the toxins (by a still

unknown mechanism), and some raptors (that eat carrion) have a reduced susceptibility.

Foods contaminated with *Cl. botulinum* toxins have no particular change in taste or smell and are thus difficult to detect. Toxins enter the body through the intestinal wall, move to the ends of the autonomic and somatic efferent nerves and then ascend into the spinal cord. Once in the spinal cord, toxins selectively and irreversibly bind to the neuromuscular junctions and block the production of acetylcholine. Death is due to respiratory paralysis. Toxins also damage vascular endothelium, resulting in edema and petechiation.

Flaccid paralysis of the skeletal musculature (including the tongue) is the characteristic clinical change. Bulbar paralysis, feather loss and diarrhea may be noted in some birds. Birds with substantial clinical signs usually die, although a few can spontaneously recover. Recovery is more likely with type A rather than type C toxin. Petechial hemorrhage of the cerebellum and focal necrosis and hemorrhage of the central lobe of the cerebrum are indicative of *Cl. botulinum*, but there are no pathognomonic lesions.

Confirming a diagnosis requires using mouse animal models to demonstrate the presence of toxins in serum, filtered liver or kidney from an affected animal. Feed or water (sewage, mud) extracts from a pond also provide diagnostic samples. *Cl. botulinum* toxins are heat-sensitive and degrade at room temperature. Materials to be tested should be preserved by deep-freezing (-20°C).

Intoxication with some algae, eg, red tide (see Chapter 46), may cause clinical signs similar to those caused by *Cl. botulinum*. Affected birds usually have access to muddy, drying bodies of water. *Aeromonas hydrophila* can cause the acute death of large numbers of waterfowl that consume contaminated water. A rapid death, typically in the summer, is characteristic, but some infected birds can develop signs that mimic those of *Cl.* sp. toxin ingestion. *A. hydrophila* and *Cl. botulinum* may both cause epornitics of acute death in connection with contaminated water.

Flock problems can be prevented by reducing contact with decaying foods, removing cadavers, providing toxin-free feed (especially for insect eaters) and regulating the water level and temperature in waterfowl collections (see Chapter 46). A commercial type C antitoxin is available for mink and has proven to be effective in birds. One-half of the dose recommended for mink should be used in birds.

Tetanus

A few cases of *Cl. tetani* intoxication in birds have been reported in older literature. There have been no cases of tetanus reported in birds using more confirmatory diagnostic tests. Generally, birds are considered to be highly resistant to *Cl. tetani*; cases reported in older literature may have been incorrectly diagnosed.

Other Gram-positive Rods

Bacillus spp., *Corynebacterium* spp., *Streptomyces* spp. and *Lactobacillus* spp. are commonly recovered from avian-derived samples. Because these organisms are frequently isolated from clinically normal birds, they are considered to be components of the autochthonous flora. Megabacterium is considered to be a pathogenic organism, although little information is currently available on its involvement in avian disease. *Bacillus* spp. isolated from birds are difficult to differentiate, and most have not been described taxonomically. *Bacillus anthracis* has not been associated with clinical disease in birds, presumably because their high body temperature inhibits the production of the pathogenic toxins. Vultures, and to a lesser extent raptors, are known to be mechanical vectors.

None of the *Corynebacterium* (*Co.*) spp. that have been isolated from birds have been found to be pathogenic. Ostriches have been reported to have concomitant *Co. pyogenes* and *Sc.* group C infections.[32] Antibodies to *Corynebacterium* spp. and *Mycobacterium avium-intracellulare* can cross-react, making differentiation between these organisms difficult.

Streptomyces spp. can occasionally be isolated from the avian respiratory system. The pathogenicity of the organism is questionable. Some reports describe nocardia in birds. These cases were described based on bacterial morphology and not on analysis of wall components, which is necessary to confirm nocardia in infected tissues.

Lactobacillus spp. can be identified on the mucosa of the intestinal, respiratory and reproductive tracts of many avian species. In birds that do not possess Enterobacteriaceae as a normal component of the gut flora, lactobacillus seems to play an important role in inhibiting colonization of Enterobacteriaceae (although probably not in many species of grouse). Supplementing with lactobacillus has been discussed as a method of inducing a natural competitive inhibition

TABLE 33.6 Survey of Clinically Important Bacteria

Bacteria	Characteristics	Incubation	Transmission	Disinfectants/Stability
Alcaligenes/ Bordetella	Motile 0.3-0.5 x 1-2 μm	Turkeys – 5-7 days Others – unknown	Alc. ingestion Shed in feces Egg transmission Bord. respiratory tract, feces Egg transmission	Resistant to drying Environmentally stable (Particularly low temps)
Campylobacter	Gram-negative Motile rod 0.2-0.5 x 1.5-5 μm	5 to 15 days	Ingestion Feces	Survives 1 week out of host Most disinfectants effective
Clostridium	Gram-negative Anaerobic Spore-forming rod	Experimental – hrs to 3 days Natural – unknown	Ingestion Wound infection	Resistant in environment Spores – survive years Most disinfectants ineffective Autoclaving/flaming effective
Erysipelothrix	Gram-positive Nonmotile rods 0.2-0.4 x 1-2.5 μm	Turkeys, ducks – 1.8 days Other birds – unknown	Ingestion Egg transmission (stork)	Most disinfectants effective
E. coli	Gram-negative 0.5 x 3 μm Motile or nonmotile rod	Experimental – 24 to 48 hrs	Ingestion – mainly Aerogenic – dust Egg transmission (normal & L-forms)	Most disinfectants effective
Haemophilus	Gram-negative 0.3-0.6 x 1-3 μm Coccoid-to-pleomorphic rods	*H. paragallinarum* 1-5 days	Respiratory tract Asymptomatic carriers	Survives a few days Most disinfectants effective
Listeria	Gram-positive 0.4 x 0.5-2 μm Motile rod	Unknown	Ingestion Common in aquatic environments Reptiles, amphibians, snails natural reservoirs	Most disinfectants effective
Mycobacterium	Gram-positive Acid-fast Granulated short-to-long rods	Weeks to years Exposure and immune system dictate	Feces, urine Aerogenic possible (rare) Arthropods-mechanical vectors	Persists in contaminated soil or litter for years
Pasteurella	Gram-negative Nonmotile Ovoid-to-coccoid rod	Vary with species Cat bite – 6-48 hrs	Upper respiratory tract Fecal shedding rare See text	Not stable to stable depending on conditions Most disinfectants effective
Pseudomonas Aeromonas	Gram-negative 1-3 x 0.3-0.6 μm	Specifics unknown Pseud — few hrs Aero — 1-3 days	Ingestion Proliferates in H_20 Secondary in open wounds	Pseudo: resistant to most disinfectants – steam, boiling H_20 effective Aero: most disinfectants effective
Salmonella	Gram-negative 0.5 x 3 μm Motile, rarely nonmotile rod	Varies with type Acute 3-5 days Egg — 2 days	Ingestion Egg transmission Normal and L-forms	Dried feces stable – 8 months to 2 years Water stable – 3 weeks Most disinfectants effective >60°C kills most strains
Staphylococcus	Gram-positive 0.8 x 1.0 μm Nonmotile Spherical coccoid	Unknown Few hrs to few months Latent infections	Vertical, horizontal Normal & L-forms Chronic carriers	Environmentally stable Most disinfectants ineffective
Streptococcus Enterococcus	Gram-positive <2 μm Coccoid-to-ovoid pairs or chains	Mammals – days to weeks Birds – unknown	Horizontal, vertical Shed in feces Aerogenic Percutaneous (skin lesion)	Probably no growth in environment Sc spp – short-lived Ec spp – long-lived
Yersinia	0.4 - 0.8 x 0.8 - 1 μm Motile or nonmotile Ovoid-to-coccoid rods	Days to 2-3 weeks	Ingestion Carrier birds & rodents Direct contact Fecal contaminated food or water	Most disinfectants effective

TABLE 33.7 Bacterial Control and Therapeutics

Bacteria	Treatment/Control
Actinobacillus	Tetracyclines/chloramphenicol See text
Aeromonas	Most antibiotics See text
Alcaligenes/Bordetella	Antibiotic resistance common Rx based on sensitivities
Borrelia	Tylosin/Spectinomycin Control ticks Strain-specific vaccines
Campylobacter	Erythromycin/tetracyclines Streptomycin, non-psittacines Furane derivatives in non-waterfowl (See text)
Clostridium perfringens	Clindamycin/spiramycin Laxatives – Remove unabsorbed toxins Wound irrigation Control – Vaccination (toxoid) Zinc bacitracin (200 ppm) (Bobwhite Quail in food) Prevent skin wounds
Clostridium botulinum	Toxoid vaccine, antitoxin Laxatives – remove unabsorbed toxins Guanidine – (15 to 30 mg/kg) May bind neurotoxin Prevent food contamination Activated charcoal See text
Cytophaga	Parenteral antibiotics Treat soon after hatching Bacterins provide sero-specific protection
Escherichia coli	Rx based on sensitivity See text
Erysipelothrix	Parenteral penicillin/doxycycline Surgically remove affected skin Hyperimmune serum See text
Haemophilus	Most antibiotics Sulfonamides – drug of choice Sinusitis – surgical drainage Flushing Topical vitamin A Asymptomatic carriers Detect by culturing sinuses Polyvalent vaccine – poor efficacy
Klebsiella	Resistant to many antibiotics Rx based on sensitivity Enrofloxacin initially
Listeria	Tetracyclines CNS signs – poor prognosis Hygiene critical
Megabacterium	No effective therapy Resistant to all tested antibiotics Control – unknown Acidifying water with HCl
Mycobacterium	Not recommended See text
Pasteurella	Parenteral antibiotics See text Control – Prevent rodents/free-ranging birds Vaccines – poor efficacy
Pseudomonas	Resistant to many antibiotics Rx based on sensitivity Enrofloxacin initially Systemic infections usually fatal See text
Salmonella	See text
Staphyloccocus	Resistant to many antibiotics Semisynthetic penicillins pending sensitivity Bumblefoot – Debride, antibiotics Heparin – prevents fibrin
Streptococcus Enterococcus	Parenteral antibiotics See text Control – hygiene Stimulates minimal immune response
Yersinia	See text

Treatment of all bacterial infections should be based on specific antibiotic sensitivity. Supportive care in the form of fluids and enteral feeding is frequently necessary. Correcting predisposing factors that cause immunosuppression in the host or allow exposure to an organism are critical control methods. Preventing exposure to rodents, insects and free-ranging birds can reduce bacterial exposure. Hygiene is always important, particularly in neonates, to prevent reinfection.

of gram-negative and other pathogenic bacteria. However, there are strong indications that many groups of birds have specific lactobacilli that can effectively colonize the gut. Strains derived from soured milk do not colonize the avian gut and must be given daily for two to four weeks in order to lower the gastrointestinal tract pH. This drop in pH will favor the colonization of autochthonous microorganisms. Inhibitory expulsion itself takes from four to six weeks, provided no serious triggering factors interfere.[23]

Isolation of megabacteria is difficult, and biochemical descriptions that would allow appropriate taxonomic classification have not been performed. This organism has a unique morphology and is a large (1 x 90 μm) gram-positive rod.[13] Successful culture requires the use of Merck's MRS medium; however, not all megabacterial strains have been found to grow on this medium. The colonies are rough and measure 3 to 4 millimeters in diameter with a dented margin. Development requires 48 hours in a moist chamber. Subcultures are progressively more difficult and the organism may stop growing in successive passages.[28]

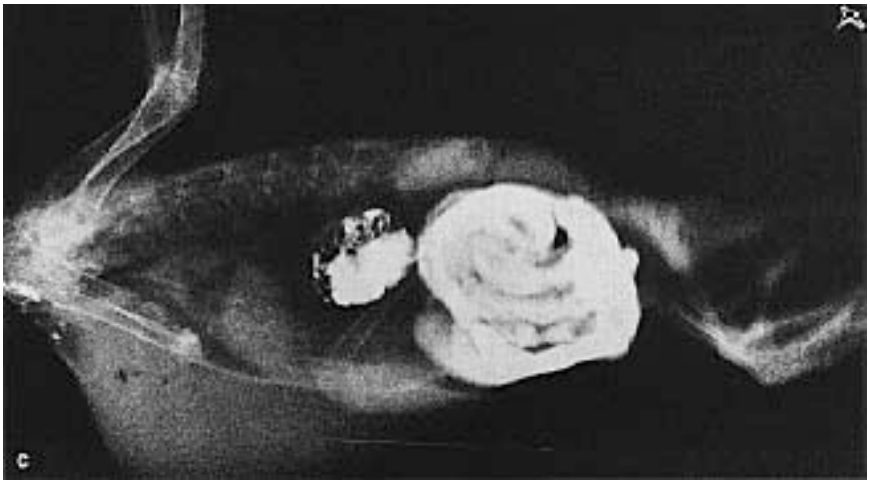

FIG 33.13 A group of budgerigars was presented for occasional melena and chronic weight loss over a prolonged period. Large (1 x 90 μm) gram-positive rods (suggestive of megabacteria) could be detected in the feces. Radiographs in various affected birds indicated **a,b)** proventricular dilatation and **c,d)** filling defects and ulceration in the proventriculus. At necropsy, the filling defects were found to be globules of mucin that had a propensity to accumulate at the isthmus. It should be noted that the presence of a dilated proventriculus is not diagnostic for neuropathic gastric dilatation (courtesy of Nina Ungerechts).

TABLE 33.8 Differential Diagnoses of Bacterial Infections

Arthritis or Synovitis
- Staphyloccoccus
- *Actinobacillus* sp.
- *E. coli*
- *E. rhusopathiae* (ducks and goose)
- *Mycobacterium avium*
- *Mycoplasma* spp.
- *Pasteurella multocida*
- *Salmonella* spp.

CNS Signs
- Listeriosis
- Chlamydiosis
- *E. coli*
- *Klebsiella pneumoniae*
- *Listeria monocytogenes*
- *Salmonella* spp.

Dermatitis
- *Pseudomonas/Aeromonas* spp.
- *Clostridium* spp.
- *Staphylococcus* spp.

Enteritis
- *E. coli*
- *Aeromonas* sp.
- Most enteric organisms
- *Pseudomonas* spp.
- *Salmonella* spp.
- *E. rhusiopathiae*
- Chlamydiosis
- *Listeria* sp.
- *Pasteurella* spp.

Hepatitis
- Most bacteria that cause septicemia
- Campylobacter
- *Pasteurella* spp.
- Chlamydiosis
- *Salmonella* spp.

Pseudomonas enteritis
- *Clostridium* spp.

Respiratory Disease
- Alicalgenes
- Enterobacteriaceae
- *Pasteurella* spp.
- Cytophaga (duck septicemia)
- *Pasteurella* spp.
- Haemophilus
- Chlamydiosis (eg, psittacines, Columbiformes)
- *Salmonella* spp.

Septicemia
- *E. coli*
- Many bacteria
- *Listeria* spp.
- *E. rhusiopathiae*
- *Pasteurella* spp.
- *Salmonella* spp.
- *Yersinia pseudotuberculosis*
- Pseudomonas/Aeromonas
- Most Enterobacteriacae
- Staphylococcus (mimics numerous other infectious agents)
- Streptococcus/Enterococcus
- Borrelliosis (high tick areas)

Morphologically similar strains of megabacterium that were considered normal components of the budgerigar proventricular flora have been described.[53]

Some researchers believe that megabacterium is the causative agent of progressive weight loss ("going light syndrome") in budgerigars. The name "going light syndrome" should provisionally be replaced by megabacteriosis, because weight loss is a clinical sign of a variety of chronic diseases. Experimental infections with pure cultures of megabacterium induce disease only in English standard budgerigars and not in the normal breed.[28] These findings suggest that birds vary in susceptibility to the organism, and other factors are involved in the pathogenesis. Spontaneous recovery was common in experimental cases. The host spectrum includes canaries[34] and related finches, cockatiels, lovebirds, chickens and young (3-week-old) ostriches (Hüchzermeier, unpublished).

Clinically infected birds develop chronic emaciation over a 12- to 18-month period that may or may not involve intermittent periods of recovery. Severely affected birds may pass digested blood in the feces. Contrast radiography typically indicates a sandglass-like retraction between the proventriculus and ventriculus (Figure 33.13). This finding is considered highly suggestive of megabacteriosis.[31] Megabacterium is shed in the feces and can be detected by gram-stained samples from severely sick birds.

At necropsy, a proventriculitis or proventricular ulcer with or without hemorrhages can be observed. Lesions are most common in the pars intermedia gastris. The organisms lie densely together in the necrotic tissue foci. There is usually little inflammatory cellular reaction associated with the organism, which can be seen readily at low magnification from proventricular scrapings. Impression smears from the liver and spleen may be useful in detecting the bacteria, which can be encapsulated in the tissues. There is no treatment because of resistance to all antibiotics commonly used.

CHAPTER

34

CHLAMYDIA

Helga Gerlach

The genus *Chlamydia* currently consists of two antigenically related species, *C. trachomatis* and *C. pneumoniae*,[22] which are restricted to humans, and *C. psittaci*, which has a wide host spectrum among birds (most Psittaciformes and at least 130 non-Psittaciformes), mammals (horse, cattle, sheep, roebuck, domesticated cat, guinea pig, dog) and humans.[4] *C. psittaci* can be highly contagious and induces a disease called psittacosis in parrots and ornithosis (by legal definition) in all other animals and man. Because the same agent is involved, the use of the term chlamydiosis to describe infections caused by this organism should be encouraged. Chlamydiosis is a reportable disease in many countries.

C. psittaci is an obligate intracellular bacterial parasite that contains DNA and RNA and has a rudimentary cellular wall that does not contain muraic acid or peptidoglycan.[43] This organism is capable of autonomic synthesis of species-specific enzymes, but depends on the host cell for energy (by means of adenosine triphosphate and nicotinamide adenosine diphosphate) and probably some amino acids, particularly tryptophan.[57] These requirements prevent chlamydia from growing on cell-free media.[19,23,27]

Chlamydia Replication Cycle

Figure 34.1 illustrates steps in the replication cycle of the chlamydial organism.

Step 1. The first step in replication is the attachment to and penetration of a target cell (mainly columnar epithelial cells of mucous membranes and mononuclear macrophages) by the infectious-toxic but nonpropagating elementary bodies (approximately 0.3 μm). The process is comparable to receptor-mediated endocytosis.[57] The chlamydia is enveloped in an endocytoplasmic vesicle where it remains throughout the replication cycle. By remaining in an endosome, the chlamydia is protected from host-derived lysozymes. The development of a phagolysosome (which would destroy the engulfed organism) is inhibited by chlamydial-derived proteins.[24]

Step 2. The second phase of replication is the transition of the metabolically inert elementary body into the large (0.5 to 1.5 μm), fragile, low density, metabolically active reticulate body. This phase of the replication cycle probably begins with the reduction of the disulfide bond that cross links the outer membrane proteins. The developing reticulate bodies possess several surface projections that are assumed to protrude through the endosomatic membrane to enable the uptake of nutrients from the host cytoplasm.[57] In other respects, the reticulate bodies resemble bacterial L-forms (which have defective cell walls), because they can persist in spite of circulating antibodies and therapeutics designed to inhibit cellular wall formation.

Step 3. The growth and binary fission of the reticulate bodies result in the production of many progeny and micro-colonies containing from 100 to 500 chlamydial organisms per cell. Multiple micro-colonies, also called "inclusions" (Levinthal-Cole-Lillie = LCL bodies) can occur in an infected cell. By the end of the replication cycle, enzymes produced by the intracellular parasite may induce lysis of the host cell (48 hours after the initial infection). These enzymes are susceptible to antibiotics. Endotoxicosis may occur in the host cell when lysosomes are destroyed and endosomatic enzymes are released into the cytoplasm.

Step 4. Maturation of the noninfectious reticulate bodies into infectious elementary bodies involves the restoration of the surface membrane and its associated toxicity. Chlamydia-specific lipopolysaccharide is brought to the host cell surface concomitantly with the growth of chlamydial organisms.[46] This glycolipid is assumed to reduce the fluidity of the plasma membrane, thereby protecting the chlamydial-infected cells from cytotoxic T-cells.[57]

Step 5. Newly formed elementary bodies are released, not always by lysis of the host cell.

Serovars

C. psittaci strains vary considerably in terms of virulence and antigenicity. In addition, five serovars have been distinguished among the avian strains by using monoclonal antibodies: psittacine, pigeon I, duck, turkey and pigeon II.[54]

Whether or not the parrot serovar and turkey serovar are really of particular importance as zoonotic agents[2] is a matter of controversy. It has been found that the different serovars do not only occcur in the named avian species but also in a variety of other host species. Virulent strains replicate more rapidly and enjoy a wider host spectrum. Chlamydia has a genus-specific lipoglycoprotein with an acid polysaccharide as the antigenic determinant (thermostable at 100°C for 30 minutes). Several proteinaceous antigens, including the major outer membrane protein, can show subspecies or even strain-specific variability.[23] Antibodies generated against most of the antigens are not correlated with protective immunity.[23]

Pathogenicity

The pathogenicity of chlamydia cannot be fully explained by the direct damage to the host cells. The most important virulence factor is a toxin, which occurs with various degrees of intensity in the different strains and is closely bound to the outer membrane of the elementary bodies. During chlamydial growth in a particular avian host, metabolic and structural changes occur that can alter its pathogenicity and antigenicity. The degree of change is governed by the number of passages in a particular species. The surface of the elementary bodies that are formed during the replication cycle contains heterologous "new" antigens, which are assumed to be host-specific.[1] Interspecies transfer (eg, in quarantine stations, breeding farms, multispecies aviaries, pet shops) of chlamydia can change the physicochemical properties and, therefore, the antigenic composition, the toxic components and, in terms of virulence, the host spectrum of the agent.[27] However, the newly acquired characteristics are not truly stable.

The outcome of an infection is dependent on the ratio of elementary bodies to macrophages. Lethal lytic reactions occur in phagocytes infected with high

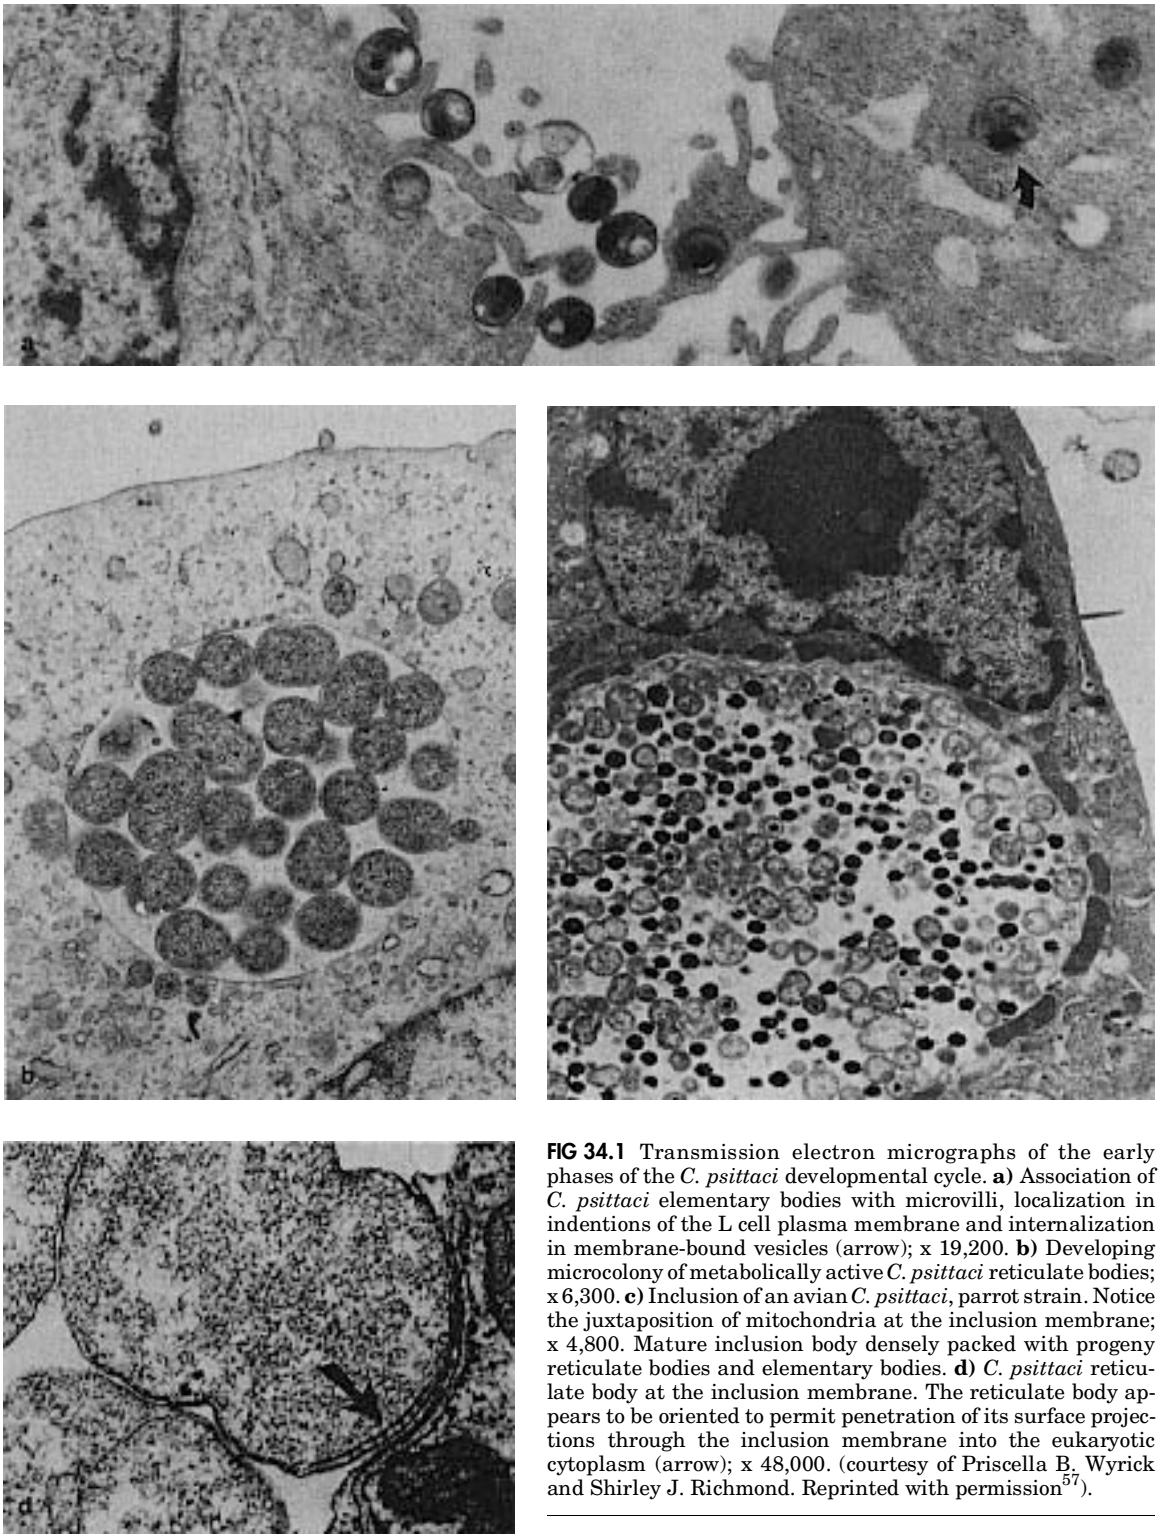

FIG 34.1 Transmission electron micrographs of the early phases of the *C. psittaci* developmental cycle. **a)** Association of *C. psittaci* elementary bodies with microvilli, localization in indentions of the L cell plasma membrane and internalization in membrane-bound vesicles (arrow); x 19,200. **b)** Developing microcolony of metabolically active *C. psittaci* reticulate bodies; x 6,300. **c)** Inclusion of an avian *C. psittaci*, parrot strain. Notice the juxtaposition of mitochondria at the inclusion membrane; x 4,800. Mature inclusion body densely packed with progeny reticulate bodies and elementary bodies. **d)** *C. psittaci* reticulate body at the inclusion membrane. Wyrick and Shirley J. Richmond. Reprinted with permission[57]).

numbers of virulent chlamydial particles. Low doses of a virulent strain are rapidly inactivated by mononuclear and polymorphonuclear phagocytes. If the macrophage is damaged, the chances of the chlamydial organism to survive are reduced. Low doses of a nonvirulent strain do not stimulate an appropriate lytic reaction, resulting in macrophages that are converted into long-lived epithelioid cells that remain chronically infected (see Chapter 5). The life span of these epithelioid cells should govern the duration of antibiotic treatment. However, nothing is known about the longevity of these transformed cells in birds.[19] It is a high probability that infected macrophages transfer their "inclusions" during mitosis in the bone marrow onto the progeny cells.[57] Life-long carriers may be the result. Incomplete autosterilization and phagocytosis into "new" macrophages favor the selection of strains with low virulence for the species in question. These chronic infections favor shedding of large numbers of chlamydia that might be highly virulent for other avian species.[19]

Stability of Chlamydia

The infectious elementary bodies, which can be stained as described by Giemsa, Gimenez, Stamp, Macchiavello or Castaneda, can survive outside the host (protected by proteinaceous material) and inside host cells for several weeks (see Color 10). Bacterial-induced destruction of tissues and the presence of feces rapidly inactivate the organism. "Free" elementary bodies are relatively unstable and can be inactivated in the environment within days. Chlamydia is particularly sensitive to heat and one percent formalin if the temperature is above 20°C. Quaternary ammonium compounds and lipid solvents are poor choices for inactivating chlamydia. Infectivity has been shown to be destroyed within minutes by benzalkonium chloride.[23] In Europe, Orbivet™ and hydrogen peroxide have been shown to be effective against chlamydia.

C. psittaci is endemic worldwide, where it is distributed liberally among free-ranging birds. As a rule, the organism is well adapted to avian hosts and causes few, if any, clinical signs or pathologic lesions. Clinical disease is precipitated mainly by human-induced conditions and procedures. Systematic testing using modern laboratory methods (various versions of the ELISA) has not been performed on free-ranging birds to determine the incidence or prevalence of infections. However, surveys of imported and domestically bred Psittaciformes as well as free-ranging and captive raptors and owls from Germany indicate that between 30 and 70% of the birds tested are infected.[12,13]

Transmission

Elementary bodies present in feather dust and dried feces are primarily dispersed through air circulation. Ingestion of elementary bodies results in infection of the intestinal epithelial cells. Vertical transmission through the egg has been documented in domesticated ducks,[32,47] Black-headed Gulls[32] and budgerigars,[44] and has been suggested in turkeys. Chlamydia can usually be detected in the feces ten days prior to the onset of clinical signs. High numbers of chlamydia can be found regularly or intermittently in the feces (up to 10^5 infectious units per gram of feces), urine, lacrimal fluid, nasal discharge, mucous from the oral and pharyngeal cavities and "crop milk" (pigeons) of infected birds. Insufficient information is available to establish the periods during which birds with clinical disease or carriers can transmit the organism.

Cockatiels are frequent carriers of chlamydia and can shed the agent in the feces for more than one year following an active infection. Infected ducks have been shown to shed chlamydia in the feces for 100 days, and harbor the organism on the nasal mucosa for 170 days. It has been suggested that birds may become subclinical carriers and cease shedding within 30 to 50 days of the initial infection; however, this theory cannot be substantiated using improved methods of chlamydial detection.[13] In any case, carriers may begin to shed the organism following a stressful event. Assumed spontaneous self-elimination of infections within a flock during a four- to five-month period cannot be confirmed. Transmission by hemophagous insects or mites is possible.

Some species like dogs, cats, horses, swine and man develop infections that do not seem to be transmissible to other members of the same species. In contrast, infected birds, cattle, sheep and goats readily transmit chlamydia to other members of the same species. A newly imported Amazon parrot with chlamydiosis was thought to have infected a cat that was restricted to the house (Harrison GJ, unpublished).

Pathogenesis

There are considerable differences between the susceptibility of various host species to chlamydia. The same strain can cause disease in different avian species, which can be distinguished by the number and

type of affected tissues and replication rate as determined by the period necessary for elementary bodies to appear. Similar differences are described with varying chlamydial strains in the same host species.[33] Young birds are generally more susceptible to infections than adults. Macaws and Amazon parrots appear to be more susceptible than Psittaciformes from South Asia, Australia and related islands (eg, cockatoos, lories, King Parrots). The African parrots are even less susceptible than the Asian Psittaciformes. These are generalizations with many exceptions, and the condition of a host is probably more important than any species-specific susceptibility (Figure 34.2). *C. psittaci* can cause a totally asymptomatic infection in mature hosts or acute, systemic, often fatal illness in young birds or with nonhost-adapted chlamydial strains. The precondition for such an adaptation is a latent infection of some time period. The virulence and toxicity of host-adapted strains can be most dramatic when they infect a different species.[19,28]

The virulence, antigenicity and biologic properties of chlamydial strains vary. The surface of the elementary bodies contains hepatotoxic and nephrotoxic components that disappear once the organism enters the host cell. The toxins are once again a factor following replication and release of progeny elementary bodies from the host cell. These toxins present on the elementary bodies induce the production of antibodies that neutralize the toxins and destroy infectivity. These toxins have not been isolated and characterized, but they are believed to be related to the few proteinaceous-specific membrane antigens of the intact elementary body. These proteins have low antigenicity.[28]

The outcome of an infection is determined by the mononuclear macrophages. If an elementary body is phagocytized and is not coated with opsonins, the organism can survive and replicate within the macrophage.[31] Lymphokines secreted by activated lymphocytes inhibit the replication of chlamydia found in phagosomes. In order to maintain inhibitory concentrations, the lymphokines must be continuously secreted. During persistent infection, chlamydia remain within a membrane-bound compartment and release infectious progeny and antigens via exocytosis. It is therefore difficult for the host to remove the microorganisms from an infected cell.[5] In addition, exocytosed antigens released from the cells may not be processed in a way that can be recognized by class I-restricted cytotoxic T-lymphocytes. This allows infection, and probably reinfection, to occur and be maintained in the presence of high levels of humoral antibodies.[57]

These interactions of the host immune system and the intracellular parasite cause the varied incubation times, clinical signs and pathology noted with chlamydial infections.[33] When virulent strains of chlamydia are inhaled, primary propagation occurs within the epithelial cells of the lung and air sacs. Direct spread of the organism from the air sacs to adjacent serosal membranes can lead to polyserositis, including pericarditis.[38]

If chlamydia organisms are ingested, they are believed to initially replicate mainly within the intestinal tract. Given the high number of birds with antibodies to chlamydia, most primary infections must occur without the development of obvious clinical signs. Birds may be fully susceptible following survival of a clinical disease. The amount of antitoxic antibodies seems too low to induce some immunity. It is uncertain if a latent infection prevents another chlamydial strain from entering the host.

FIG 34.2 A five-year-old African Grey Parrot was presented with a 12-day history of progressive upper respiratory disease, polyuria (biliverdinuria), diarrhea and anorexia. On presentation, the bird had a severe rhinitis, conjunctivitis, severe dyspnea and emaciation (275 g). Clinical pathology findings included WBC=35,000, AST=1800, CPK=550 and LDH=1400. Chlamydia antigen was detected in the feces and on a pharyngeal swab by antigen-capture ELISA. The client had an upper respiratory disease and flu-like symptoms. The bird improved the day after receiving an IV injection of Vibravenös and was switched to oral doxycycline. African Grey Parrots are generally considered resistant to chlamydiosis, but as indicated by this case, under some conditions they can become sick.

Incubation Period

Incubation periods for chlamydia are difficult to determine because of differences in strain virulence, varying clinical responses of a wide avian host range and the lifelong infections that can occur in some hosts. The minimum incubation period for naturally infected Psittaciformes is 42 days.[42] An incubation period of seven years was suggested for budgerigars.[48,51]

Clinical Disease and Pathology

The clinical progression of infections varies with the virulence of the infecting strain and the host species. Asymptomatic infections are characteristic in adult birds exposed to moderate numbers of a moderately virulent strain of chlamydia. These infected birds may shed the organism for several months while remaining asymptomatic. Extreme environmental changes or concurrent infections may activate persistent infections, resulting in the occurrence of clinical disease. Epizooitologically, outbreaks in offspring from asymptomatically infected parents and young birds to which they are exposed are common.

Clinical Signs

Young birds exposed to high doses of a virulent strain develop acute systemic infections frequently resulting in death. Clinical signs can include rough plumage, low body temperature, tremor, lethargy, conjunctivitis, dyspnea, rales, coryza (pigeons) and sinusitis (budgerigars). Emaciation, dehydration, yellowish-to-greenish droppings (suggesting liver involvement), or grayish, watery droppings may also be noted (see Color 8). Death ensues within 8 to 14 days. Spontaneous recovery is rare. Survivors may have poorly formed feathers. Table 34.1 lists the typical clinical pathology changes associated with a symptomatic chlamydial infection.

Subacute or protracted diseases are typical for all avian species with a reduced susceptibility or for those infected with a moderately virulent strain. Progressive emaciation, greenish diarrhea, occasional conjunctivitis and high levels of urates in the droppings are common. Clinical signs may be subtle and overlooked. Psittaciformes occasionally develop CNS signs, including paroxysmal or continuous clonic-tonic convulsions, tremors and opisthotonos. Untreated birds die within a few weeks. In the cockatiel and the Houbara Bustard, incapacitating flaccid paresis and paralysis have been described.

TABLE 34.1 Clinical Pathology Findings Associated with Chlamydiosis[41]

Parameter	Change
WBC	Elevated (2 to 3 times normal)
Hct	Decreased (20 to 30%)
Heterophils	Normal
Lymphocytes	Decreased to normal
Monocytes	Normal
Eosinophils	Normal
Basophils	Normal
SGOT	Elevated (> 3 times normal)
CPK	Elevated (> 2 times normal)
LDH	Elevated (> 2 times normal)
AST	Elevated (> 3 times normal)
Total protein	Slight increase
Uric acid	Normal
Bile acids	Elevated (> 2 times normal)

A distinct, sometimes recurrent, keratoconjunctivitis with no other, or only subtle, signs has been described for small Australian parakeets (especially in the genus *Neophema*), pigeons, ducks, and European finches (Figure 34.3). Diseases in *Neophema* spp. are frequently refractory to therapy. Conjunctivitis and nasal discharge are characteristic of chlamydiosis in domestic pigeons. Mortality rates of the ophthalmic form are about 10%, but can reach 100% if untreated.[19,27] Conjunctivitis may be the predominant clinical sign in infected domestic ducks and geese. Mortality, particularly in ducklings, can range between 10 to 80%.[52]

Chlamydiosis in ratites can cause clinical and pathologic lesions of a rather nonspecific type. High mortality has been reported in ostrich chicks infected with *C. psittaci*.[23,45] The chronic course is clinically inconspicuous, although anemia is common and LDH and AST levels may be increased five to ten times. Birds with persistent infections may not be recognized until they infect other animals or their caretakers. The documentation of infections in nestlings from an apparently healthy breeding pair is also suggestive of latently infected adults.

Gross Lesions

Gross lesions can vary as widely as the clinical disease. Acute lesions are characterized by hepatomegaly, fibrinous peritonitis, air sacculitis, perihepatitis, pericarditis, bronchopneumonia, enteritis and nephrosis. Miliary necrosis of parenchymal organs is common, probably due to the effects of chlamydial toxins. Splenomegaly is frequently discussed

FIG 34.3 A two-year-old cockatiel was presented for severe epiphora and conjunctivitis of two days' duration. A conjunctival scraping revealed a mixed population of gram-positive cocci and a few gram-negative rods. Gimenez staining was negative for chlamydia. The patient responded to treatment with tetracycline ophthalmic solution. Chlamydia is frequently implicated in conjunctivitis in cockatiels.

as a common finding in chlamydiosis (Figure 34.4). However, fibrinous air sacculitis is more indicative of chlamydiosis in Psittaciformes and pigeons (see Figure 12.52).

Splenomegaly may not occur with chlamydiosis at all. In sexually active males, chlamydial-induced orchitis or epididymitis results in permanent infertility. Oophoritis is rare.

Subacute to chronic lesions are characterized by anemia caused by a panmyelopathy in the bone marrow and tissue deficiencies of heterophils and macrophages.[19,27] The pathogenesis of the panmyelopathy is undetermined. Chronic cases are characterized by proliferation of connective tissue (up to cirrhosis) in the liver and kidney. Pancreatic necrosis has been described particularly in budgerigars and pigeons.

Histopathology

Histopathologic findings are mostly nonspecific except for the presence of LCL bodies, which are pathognomonic. LCL bodies can occur in many organs but are especially common in serosal membranes. Typical of more acute disease is the intrasinusoidal proliferation of Kupffer's star cells (pearl string-like appearance) in the liver. Proliferation of monocytes and activation of the RES may occur in parenchymal organs, particularly the spleen, liver and kidney. Epithelioid cell granulomas in the liver and pneumonia with proliferations of epithelial cells in the air capillaries are common with chronic cases. Swollen epithelial cells may be vacuolated, and immigration of lymphocytes into the damaged tissue can be seen. CNS lesions consist of nonpurulent meningitis. Secondary bacterial, fungal or viral infections may alter lesions and confuse chlamydial changes.[19,20,27]

Differential Diagnosis

The clinical and pathologic presentation of chlamydiosis is so variable that it can normally be ruled out only with laboratory investigations. The more common rule-outs include infections with herpesvirus, paramyxovirus, influenza A virus and Enterobacteriaceae, particularly salmonellosis. The CNS signs should be differentiated from Newcastle disease and salmonellosis, and the conjunctivitis in ducklings and goslings from influenza A infections and mycoplasmosis.

Diagnosis of Chlamydiosis

Diagnostic Methods

Cytology

Conjunctival smears of birds with conjunctivitis can be stained for LCL bodies (see Color 10). As a rule, smears contain heterophils, some lymphocytes, some plasma cells and occasionally macrophage-like cells containing intracytoplasmic LCL bodies. Preparations containing numerous cells provide the greatest likelihood of a positive diagnosis. Since LCL bodies are difficult to detect, a positive test is confirmatory while a negative smear does not rule out chlamydiosis. Immunofluorescent methods using commercially available conjugates[a] are more sensitive. Every veterinary hospital should be able to perform cytologic evaluation of imprint slides including postmortem samples of the liver, spleen and air sacs (see Chapter 10). Other diagnostic methods require a specialized laboratory.

Culture

Culture of chlamydia is routinely performed in McCoy cell line, Buffalo Green Monkey cells or chicken embryo fibroblasts.[16] Cell culture is sensitive and able to detect small numbers of chlamydia within two to three passages. For isolation, parenchymal organs (liver, spleen, lungs, kidneys,) and feces should be shipped in transport medium (glucose 74.6 g/l,

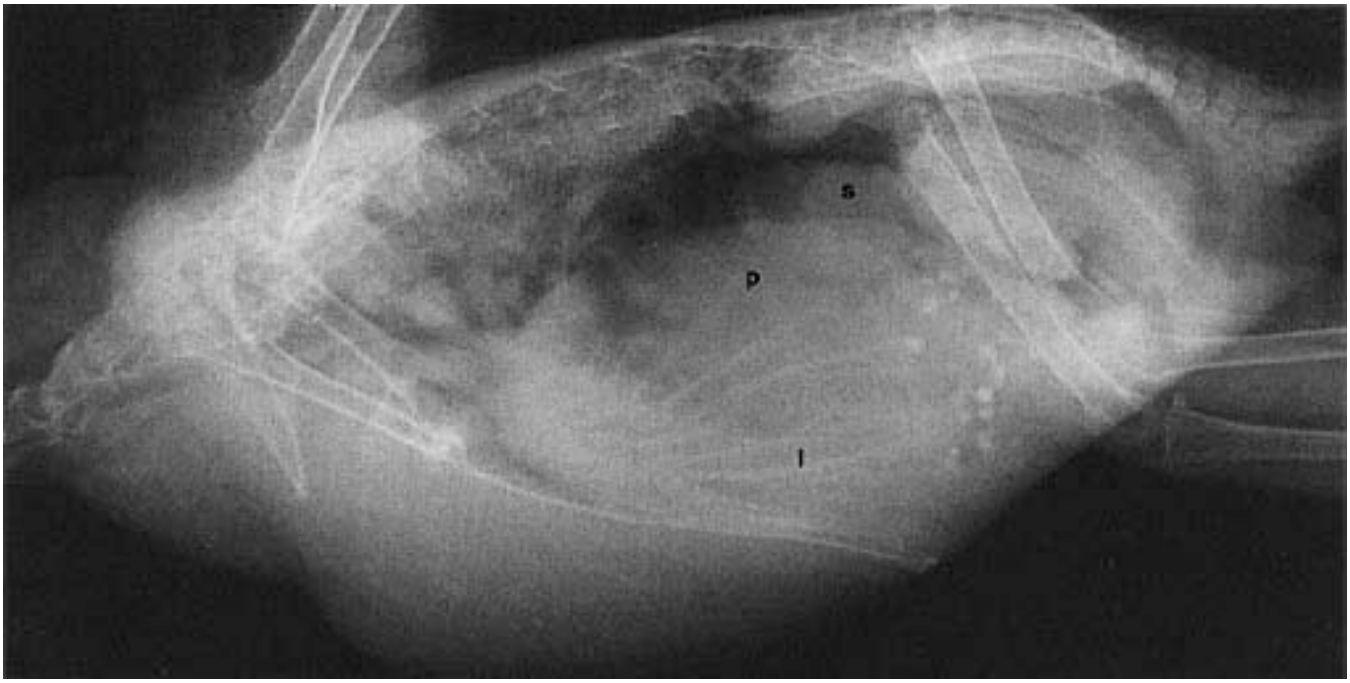

FIG 34.4 A mature Amazon parrot was presented with biliverdinuria, diarrhea, dyspnea and anorexia of four days' duration. The bird had been obtained from a "bird farm" about six weeks earlier. Radiographic findings included hepatomegaly (l) and splenomegaly (s). The enlarged liver is displacing the proventriculus (p) and the spleen dorsally. The bird responded to oral doxycycline and improved 12-16 hours after the initial dose.

K_2HPO_4 1.237 g/l, L glutamic acid 0.721 g/l, 10% fetal calf serum, vancomycin and streptomycin 100 μg/ml, gentamicin and nystatin 50 μg/ml).[50] Sucrose albumin phosphate solution (pH 7.2) cooled to 4°C is an effective storage and transport medium for feces. Fecal samples and tissue samples contaminated with feces are cleaned by labor-intensive centrifugation. The first passage takes up to six days, the second and third passages require three days each, so that three passages require approximately two weeks. Culture is the only way to directly demonstrate *Chlamydia psittaci*.

Antigen Detection Systems

Highly sensitive and specific ELISA test systems are available for detecting chlamydial antigen or anti-chlamydial antibodies (Table 34.2). An antigen test kit developed for human *C. trachomatis* has been used successfully for *Chlamydia psittaci*, which has the same group-specific antigens. Comparisons between this test kit and cell culture indicated that false-negative results occurred with ELISA when insufficient numbers of chlamydial particles (less than 2.5 ng[3,53] [600 elementary bodies]) were present in the sample. False-negative cell culture results occurred when chlamydial organisms were no longer viable.[14,15,34]

Culture results were poorest with fecal samples that were desiccated, subjected to bacterial deterioration or contaminated with litter or other "foreign" materials. The sensitivity was 84.2 % for ELISA and 80% for cell culture when a cloacal swab shipped in transport medium was used for testing instead of feces.[13] In evaluating 7,000 cloacal swabs for the diagnosis of chlamydiosis, it was determined that the antigen ELISA is sensitive, quick to perform (results in four hours) and can be made noninfectious for laboratory staff by heating at 100°C for 15 minutes. Cloacal

CLINICAL APPLICATIONS

- Interspecies transfer of chlamydia (in quarantine stations, breeding farms, multispecies aviaries, pet shops) can change the physicochemical properties, antigenic composition, toxic components and the host spectrum of the organism.
- Surveys indicate that between 30 and 70% of the birds tested have anti-chlamydial antibodies. Clinical disease is precipitated mainly by human-induced conditions and procedures.
- Chlamydia can usually be detected in the feces ten days prior to the onset of clinical signs.
- Carriers may begin to shed the organism following a stressful event.
- Antibody production with an active infection may be poor, and birds that survive infection are fully susceptible to disease.

swabs, not fecal samples, should be used for testing. The former does not require a centrifugation step and probably contains a higher concentration of chlamydial organisms (possibly in cloacal mucosa cells).[12]

Extremely high concentrations of avian *Staphylococcus aureus* (more than 10^8,[51] or more than 1.5 x 10^9/ml suspension[3]) can cause false-positive ELISA results.[53] *Actinobacillus salpingitidis*, which is rarely found in feces,[3] and *Acinetobacter calcoaceticum*[53] can also cause false-positive results. *Staphyloccus hyicus*, a non-avian staphylococcus, has also been implicated in false-positive reactions.[53] False-negative results with the antigen ELISA may occur because of the irregularity of antigen shedding in latently or persistently infected birds.[11,34,51] Administration of several antibiotics including chloramphenicol, tylosin, erythromycin and tetracyclines can also interfere with the detection of chlamydia in cell culture.

Comparison of Antigen Capture Tests

The reproducibility of some latex agglutination tests has been poor.[3] The latex agglutination test Clearview Chlamydia (CC)[b] used for the diagnosis of *Chlamydia trachomatis* by means of cervical epithelial cells can be easily performed in the veterinary hospital.[3] The CC test was found to be more sensitive (detected 130 elementary bodies/ml) than the IDEA[c] test (required 600 elementary bodies/ml of sample). However, the CC test is unsuitable for use with homogenized organs, fecal material or samples purified by centrifugation. When cloacal samples were collected and transported in tubes provided by the manufacturer, CC and IDEA agreed in 84.6% of the samples. Samples positive only with CC could not be confirmed positive by other methods (one exception). The CC test is more likely to have false positives as a result of bacterial contamination than is the IDEA test. Moderate to high numbers of a mixed bacterial flora, high numbers of *Staphylococcus aureus, Pasteurella multocida*, and *Sarcina* sp. can cause false-positive CC results.[3]

The Chlamydiazyme[d] test kit was compared with the IDEA for detection of chlamydial antigen.[39] Chlamydiazyme was found to be less sensitive, but was more likely to have false positives from nonspecific cross reactions (decreased specificity). These findings were confirmed by other testing, and the Chlamydiazyme test system was estimated to detect 312.5 pg (= 4,800 particles). False-positive results occurred with *A. calcoaceticus, S. aureus* and *S. hyicus, Legionella pneumophilus, Bartonella bacilliformis, Corynebacterium pyogenes, Pasteurella multocida* and *Enterococcus faecalis*.

The Surecell[e] ELISA test kit produced by Kodak is easy to use and can be performed in any hospital. Unfortunately, it, like other antigen detection tests that use antibodies, is plagued with false-positive results, probably due to cross-reacting bacteria. A recent study indicated that this test had a specificity of 80% and a sensitivity of 100% (compared to culture). Cross reactions were not found to occur with a variety of bacteria.[37] The minimum quantity of chlamydial material that the producer claims can be detected is 70 per gram. In some cases, birds may have chlamydiosis and are shedding insufficient numbers of organisms to be detected by an antigen capture system. The development and use of *C. psittaci*-specific DNA probes may prove to be the best method to detect birds that are actively shedding the organism.

TABLE 34.2 Antigen Detection Systems for Chlamydia

Diagnostic Test	Number of Elementary Bodies Detected	False positives (specificity)	False negatives (sensitivity)
IDEA[c]	600	+	+
Culture		None	
Clearview Chlamydia[b]	130	+++	+
Chlamydiazyme[d]	4800	+++	+
SureCell[e]	70	+	+

Specificity: Some bacteria will cross-react in antigen detection kits for chlamydia, creating false positives. ++ = some bacteria; +++ = many bacteria.
Sensitivity: The sensitivity of any chlamydia antigen test is affected by the number of elementary bodies present. + = high sensitivity; ++ = lower sensitivity.
Antigen detection systems are used to document shedding in clinically affected birds.

Antibody Tests

Detection of anti-chlamydial antibodies using complement fixation (CF) was proven to be unsuitable because birds produce mainly non-CF antibodies following a chlamydial infection.[26,49] The C1 of guinea pig complement, which is a critical component of the CF test, is incompatible with the serum of many avian species. A test that functions independent of the species in question was necessary for serologic diagnosis of chlamydiosis in the class Aves. An inhibitory ELISA (= BELISA) that recognizes four times more infected birds than CF has been developed.

The relationship between CF and BELISA indicates that high anti-chlamydial antibody titers detected by

CF and BELISA are indicative of a positive reaction; low titers are diagnostic only with BELISA.[34] Ten months following an experimental chlamydial infection, CF antibodies decrease considerably, while BELISA shows a continuous increase. This finding suggests that the composition of the antibodies detected varies[49] and that only those antibodies detected by BELISA are stimulated by the permanent intracellular presence of chlamydia.

A comparison of antigen excretion and antibody status showed that flocks with clinically affected birds had higher antibody titers and excreted chlamydia at a higher rate than non-clinically affected flocks. A small number of birds with an extinction just beneath the cutoff and no demonstrable antibodies gave the reasons for a final correction of the cutoff value. BELISA is suitable for identifying infected birds, whether they excrete the agent or not.[12] A commercially available test kit using the principles of BELISA has been developed (*C. psittaci*-AK-EIA).[f] The antigen and antibody ELISA tests have been compared with cell culture and CF for the detection of chlamydia in thousands of field cases.[8,10,12,13,34] False-negative results may occur with this test kit in fresh infections (no antibody production as yet), following treatment (inhibition of antibody production and no shedding of the agent), pre-test handling of the samples and cross reactions with bacteria.

The high sensitivity of BELISA has shown that *C. psittaci* antibodies are more widely distributed than previously thought. Sustained detection of antibodies by BELISA suggests that chlamydia may cause a life-long persistent infection, which is difficult to eliminate with treatment.[7]

Treatment of Chlamydiosis

Therapeutic Agents

Many countries have instigated governmental regulations for treatment and control of chlamydiosis to prevent zoonotic infections. The following therapeutic considerations address only the scientific aspects of treating chlamydiosis, and the reader should be aware of local laws governing therapy. Several antibiotics have *in vitro* activity against chlamydia, but only the tetracyclines and enrofloxacin have been used successfully *in vivo*, the latter only in limited trials.[40]

The tetracyclines alter the replication of chlamydia by inhibiting the synthesis of enzymes, the growth and fission of the reticulate bodies and possibly the reorganization of the elementary bodies. Antimicrobial-induced damage that occurs to the reticulate and elementary bodies may be temporary, with the organism resuming normal replication within 5.5 days of ceasing therapy. The host defense mechanisms must be intact to remove damaged chlamydial elements before they can recover and begin replicating.[17] Providing the immune system with the time necessary to remove these damaged reticulate and elementary bodies is one reason for long-term anti-chlamydia therapy.

Tetracyclines are effective only against actively metabolizing microorganisms, ie, during growth or fission. This drug is not effective in treating latently or persistently infected birds in which the chlamydia is located inertly in macrophages. The hypothesis that chlamydia is eliminated by the natural replacement of infected host cells (if treatment is continued for such prolonged periods) has not been confirmed using currently available diagnostic techniques.

Strains of chlamydia that are resistant to tetracyclines are still rather rare (one strain from ducks > 75 μg tetracycline),[35] but strains with reduced sensitivity continue to be recognized.[18] It has been shown that there is no direct correlation between the blood level of tetracyclines and therapeutic efficacy. Thus, the suggested blood level of >1 μg/ml cannot be assumed to equate with successful treatment. In some situations, subtherapeutic blood levels (<1 μg/ml) may be successful[58] while in other cases, full therapeutic levels do not resolve an infection.[28] These clinical experiences have been supported by laboratory testing.

The *in vitro* MIC for 12 *C. psittaci* strains ranged from 0.01 to 0.08 μg/ml, and 0.2 μg/ml completely inhibited the production of elementary bodies of 62 strains in cell culture. Varying dosages of antibiotics in owls resulted in almost equal plasma concentrations but different time periods of shedding the agent following the discontinuation of the treatment (high dosages shedding 4.5 months, low dosages 9.5 months until the end of the trial).[11] Some chlamydial strains can develop resistance to tetracycline if exposed to sub-therapeutic levels for prolonged periods of time.

In acutely sick birds chlamydial organisms undergoing rapid metabolism, and treatment with tetracyclines leads to immediate cessation of shedding and

a clinical recovery in accordance with the severity of the parenchymatous lesions. In these birds, elimination of *Chlamydia psittaci* is possible; however, under practical conditions, not likely. Nevertheless, treatment reduces the infectious pressure in the environment and, therefore, minimizes the risk of infection for humans and other animals. Birds with severe lesions may die, even if the agent is completely inactivated.

Chlortetracycline

Chlortetracycline (CTC) for oral application can be administered in soft mixed feed (cooked grain with or without egg [yolk, albumen]), in commercial parrot pellets or on dehulled seeds covered with CTC. The latter is recommended (500 ppm) for budgerigars and small finches. Food containing 5,000 ppm of CTC is normally provided, although there are many avian species, particularly among the Psittaciformes, that reach effective blood levels with CTC concentrations of 2,000 to 2,500 ppm. Birds will generally consume more food when it contains a lower concentration of CTC. Birds that have been shown to do well with food containing lower concentrations of CTC are listed in Table 34.3.

Chlortetracycline is renally excreted and should be used cautiously in patients with kidney damage (see Chapter 17). Birds dislike eating medicated feed or pellets, and therapeutic blood levels are reached only within ten days. Because infected birds will continue to shed, the delayed induction of proper blood levels poses an additional risk for caretakers and for other birds. No other food components can be fed during the treatment period.

Oxytetracycline

Intramuscular injections of oxytetracycline (OTC) at a dosage level of 100 mg/kg have been suggested. The birds listed in Table 34.3 should be given 75 mg/kg. Oxytetracycline (LA 200) produces a long-lasting blood level at a dose of 75-100 mg/kg body weight. Injections induce effective blood levels within hours, and the shedding of *Chlamydia psittaci* will stop 24 hours post-injection. This treatment regime also allows a bird to remain on its normal diet while being treated (see Chapter 18). OTC has the same side effects as CTC. In addition, severe muscle necrosis may occur at the site of injection.

Doxycycline

Doxycycline is a preparation that has been developed for intravenous administration in humans. The solvents are different in doxycycline products manufactured in the United States and Europe. Intravenous preparations available in the United States cause severe local necrosis of the muscles when given intramuscularly. European preparations may be safely given intramuscularly and induce blood levels of 1 μg/ml that last approximately seven days when administered at a dose of 75 to 100 mg/kg body weight. The quantity of drug to be injected is rather large, and several injection sites should be used.

TABLE 34.3 Birds That Respond to Lower Food Concentrations of CTC[27,41]

Large macaws	Eastern Rosella
Genus *Agapornis*	Pale-headed Rosella
Grey-cheeked Parakeet	Red-fronted Parakeet
Canary-winged Parakeet	Turquoise Parakeet
Red-winged Parrot	Scarlet-crested Parrot
Mulga Parrot	Bourke's Parrot
Western Rosella	Cockatiel

During long-term treatment, which is still legally stipulated in many countries, the drug is increasingly eliminated from the blood so that injection intervals decrease. Some countries have regulations controlling the injection intervals, although these should vary according to the species. Doxycycline is excreted mainly extrarenally (feces, bile), and the metabolites are microbiologically almost inert. This treatment reduces the destruction of autogenous intestinal flora seen with other tetracyclines. A doxycycline-medicated food was found to provide >1 μg/ml plasma concentration in a group of psittacine birds (Table 34.4).

TABLE 34.4 Doxycycline-medicated Food Diet*[41]

29% canned cooked kidney beans
29% canned whole corn
29% cooked white rice
13% dry oatmeal cereal (by weight)
1000 mg doxycycline hyclate (from capsules) per kg of feed

* Adapted from Flammer K, et al. Proc Assoc Avian Vet, 1991, pp 1-5. Medicated diets have been found to maintain acceptable plasma doxycycline concentrations in Goffin's Cockatoos, African Grey Parrots, Blue-fronted Amazon Parrots and Orange-winged Amazon Parrots.

An antimicrobial that can be added to the drinking water and effectively treat chlamydia in Psittaciformes remains elusive, but enrofloxacin has shown some potential. Birds in the USA with severe, acute chlamydiosis can be initially treated with an IV injection of Vibramycin, followed by oral doxycycline when the bird is stabilized (generally in 24 hours).

A micronized suspension of doxycycline has shown moderate promise in the treatment of chlamydia. In one study involving pigeons, IM administration of

micronized doxycycline (100 mg/kg body weight) three times at weekly intervals maintained a plasma level about 1 μg/ml for 43 days. (More research is planned to increase the doxycycline concentration from today's 66 mg/ml to 132 mg/ml and a prolonged plasma level accordingly.) There was no clinical evidence of pain or histologic lesions suggestive of necrosis associated with the injection site. Exercise would cause a sharp rise in the plasma doxycycline concentrations.[6]

Apart from specific treatment with tetracyclines, symptomatic therapy in acutely sick birds is frequently necessary. Birds should be kept isolated in warm rooms, and intravenous fluids, hepatoprotective therapy and paramunity inducers should be administered according to the clinical signs. Chicks should be fed frequently with small amounts of a liquid formula.

Enrofloxacin

Enrofloxacin inhibits the *in vitro* growth of *C. psittaci*, but only a few avian strains have been tested. The MIC of enrofloxacin for *C. psittaci* was found to be 0.125 mg/l; the minimum bactericidal concentration is much higher: 50 to 75 mg/l. Concentrations between 0.5 and 1.0 mg/l evoked irreversible damage to the majority of the chlamydia particles.[40]

Preliminary results indicate that treatment with enrofloxacin-medicated food for three weeks was effective in eliminating chlamydia from parakeets. Seven groups of experimentally infected budgerigars and other psittaciforme birds (Alexander Ring-necked Parakeet, Senegal Parrot, Canary-winged Parakeet) were effectively treated for 14 days with medicated food containing 500 ppm (budgerigars=250 ppm) enrofloxacin. From seven days after the beginning of treatment until four to five weeks after the end of treatment, no chlamydia could be isolated. Complete elimination of chlamydia from a quarantined group of 196 Senegal Parrots was reached only after substituting their normal mixed food with medicated corn containing 1000 ppm enrofloxacin.[40] A minimum blood level of 0.5 mg/l for enrofloxacin for at least 14 days was considered necessary to control chlamydiosis.[36,40]

Control

Persistent, probably life-long, infections require new ideas on control. Legal regulations should be reformulated and concentrate on clinically sick and seropositive birds. Seronegative birds should not be treated. During treatment and in clinically healthy but infected flocks, regular cleaning and disinfecting programs will minimize the chlamydial contamination in the environment and reduce the occurrence of reinfection or transmission. Birds that recover from chlamydiosis are fully susceptible to future infections. Ideally, breeding birds would be seronegative for chlamydia but, given the prevalence of the organism as detected by antibody titers in the companion bird population, it seems unlikely that a seronegative population could be established. Free-ranging birds that may transmit chlamydia should not have access to aviary birds.

Vaccination programs for the control of chlamydiosis remain elusive because chlamydia effectively inhibit the host defense system (see pathogenesis). Subunit vaccines designed to inhibit or block the host membrane receptors could damage normal epithelial cells.[53] Although the group-specific antigen is common to almost all chlamydial strains, it does not elicit a protective response. The antigenic variability among the avian strains is large, so that polyvalent vaccines might be necessary.[7] Because cell-mediated immunity plays an important role in the host defense to chlamydia, vaccines may sensitize the host and initiate excessive host reactions and disease.

Zoonotic Potential

C. psittaci strains from Psittaciformes, domesticated ducks (in Europe) and turkeys (in USA) appear to cause the most severe disease in humans. It appears that the host animal in which chlamydial passage occurs prior to the human infection influences the pathogenicity of the agent for humans. The only reported case of human chlamydiosis from free-ranging birds involved the Northern Fulmar on the Faroe Islands.[19] Pigeon strains of chlamydia are considered less virulent for humans.

Human infections are characterized by flu-like clinical signs including a high fever, severe headaches, chills, shortness of breath and general debilitation. If untreated, atypical pneumonia or CNS signs mainly caused by meningitis can develop, in addition to liver and kidney lesions due to the presence of toxicity.[52]

In rare cases, neuritis with severe pain is described. Chronic manifestations can be arteritis, cardiovascular insufficiencies and thrombophlebitis including insufficiency of the venal valves. Treatment with doxycycline is recommended for three weeks. A four-fold increase in titer should not be expected to occur in humans being treated with tetracyclines, and diag-

nosis requires culture or detection of antigen in sputum (antigen ELISA). As in birds, the CF test is not sensitive enough for accurate diagnosis in humans. Serologic determinations with the antibody ELISA have shown that humans can also be carriers following treatment, and recrudescence is possible when strong stressors activate the agent.

Chlamydiosis is a reportable disease in the United States because of its potential as a zoonotic agent. Current regulations dictate closing a business or aviary, a forced quarantine period and treatment of all exposed birds with chlortetracycline-medicated foods. These recommendations do not effectively address the problems associated with treating or controlling chlamydiosis and should be evaluated and modified accordingly.

CHAPTER

35

MYCOSES

Louise Bauck

Fungal infections are frequently associated with morbidity and mortality in companion birds. Like bacterial- and viral-induced diseases, the clinical features of a fungal infection may be influenced by stress factors and the age and condition of the patient. Candidiasis is frequently associated with gastrointestinal problems in neonates. Aspergillosis continues to be an important respiratory disease in psittacine species, zoo species and raptors. Improved preventive techniques and therapeutic regimes have enhanced the practitioner's ability to deal with common fungal pathogens.

However, many clinical reports detail the effects of less commonly diagnosed fungal pathogens about which relatively little is known. Current interest in avian pathology has resulted in the identification of disease conditions that were unrecognized in the past. Several of the avian fungal agents have zoonotic implications that must be addressed in the management of the patient.

Reducing stress, maintaining a healthy environment, carefully limiting the use of antibiotics and reducing exposure to fungal organisms are important in preventing these diseases.

Common Fungal Diseases

Candidiasis

Candida albicans is an opportunistic yeast that can cause a variety of problems associated with the avian digestive tract (see Color 19). This agent is frequently implicated in cases of ingluvitis (commonly referred to as "sour crop").[16] The clinician should be reminded that this terminology is a summation of a clinical sign and not a diagnosis. *Candida* sp. can apparently be a primary cause of crop-related infections or can be a secondary pathogen that takes advantage of an already damaged esophageal mucosa or of a slowed crop-emptying time.

Transmission and Predisposing Factors

Candida albicans is a common environmental organism and may be a normal inhabitant of the avian digestive tract. The loss of normal bacterial flora (eg, through the use of antibiotics) can cause an increase in the number of candida organisms. Immature animals are thought to develop spontaneous primary candidiasis possibly because of an immature immune system or incompletely developed gastrointestinal (GI) defenses. Neonatal cockatiels are thought to be especially prone to primary candidiasis.[45]

Pathogenesis and Incubation

Reduced competition with normal gut flora or a break or weakness in the mucous membranes may precipitate colonization and budding by this opportunistic yeast. The magnitude and outcome of the infection may depend on the age of the bird and status of the immune system. Chronic or systemic infections may result in septate hyphae and reproductive chlamydospores that can be demonstrated by histologic examination. *Candida* sp. infections are characterized by necrosis with minimal inflammation.[5] The exact incubation period is unknown, but birds being treated with antibiotics frequently show increased numbers of yeast several days after initiating antibiotic therapy.

Systemic candidiasis is rare but has been reported in companion birds. In these cases, yeast may be present in the blood, bone marrow and parenchymous organs.[17] Severe stress or immunosuppression may be necessary to potentiate systemic infections.

Clinical Disease and Pathology

In most young birds, the crop is the principal site of a candida infection. In many cases, the crop may be the only portion of the digestive tract affected. However, several reports also indicate that in some young birds, the proventriculus or ventriculus can be the primary site of yeast replication in the absence of crop lesions.[7,17,20] The characteristic *Candida* lesion is a catarrhal-to-mucoid exudate consisting of raised, white mucosal plaques and whitish-to-clear mucus that may or may not be associated with a foul odor. Chronic cases may develop a "turkish towel" appearance produced by multiple tag-like plaques of mucosa and inflammatory cells (Figure 35.1) (see Color 19).[52]

Clinical signs associated with candida-induced ingluvitis in neonates include regurgitation or vomiting, increased crop-emptying time, depression, anorexia and occasional crop impactions.[42] In older birds, the crop may be distended with mucus, and crop emptying may be hindered by necrotic mucosal debris. Candida lesions in the oral cavity are recognized by the appearance of white plaques covered by a tenacious mucus.[31,34] Candida has been associated with impacted food, beak abnormalities and tongue necrosis in a variety of adult birds. Yeast infections in ratites have been associated with extensive necrosis of the upper beak.[34]

Although less frequent, candida infections may also be found outside of the GI tract. Yeast infections affecting the cloaca and vent of turkeys and geese have been reported.[4,28] Skin lesions, particularly on the head and neck, have been described in companion birds and pigeons.[39,52] Primary candida infections have also been associated with foot lesions in waterfowl.[12,36] Respiratory infections caused by candida occasionally have been reported in psittacine

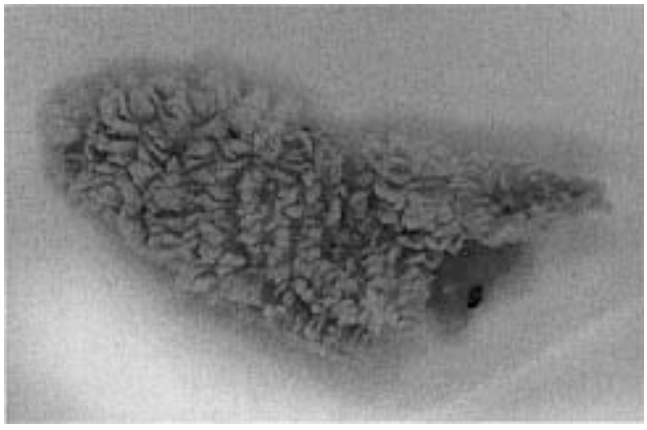

FIG 35.1 Characteristic "turkish towel" appearance of the crop mucosa in a young budgerigar with severe candidiasis.

birds.[19,20] Birds being treated with prolonged antibiotic therapy for upper respiratory tract infections may develop secondary candida infections. Systemic candidiasis in a flock of canaries was associated with central nervous system signs in addition to those routinely noted with gastrointestinal infections.[35] Pericardial lesions attributed to *Candida* spp. were reported in a Sun Conure.[48] Lameness was the principal clinical sign in a Blue-fronted Amazon with candidiasis.[17]

Diagnosis and Differential Diagnosis

A subjective diagnosis of gastrointestinal candidiasis is often suggested by the history and clinical signs. A Gram's stain of material collected from the site of suspected infection is helpful in confirming a diagnosis (see Color 8). Identifying yeast with a Gram's stain suggests only that the organism is present. Histologic evaluation of biopsy samples is necessary to confirm that the yeast are causing pathologic changes. However, identifying large numbers of budding organisms is suggestive of a prolific population of yeast. Negative cytologic results do not rule out candidiasis, because deep mucosal scrapings are necessary to achieve adequate samples in some cases.[34]

Gram's stains usually provide adequate visualization of yeast but dry smears can also be stained with Diff-Quik[a] and new methylene blue. Lactophenol cotton blue is recommended for wet mounts.[5] The yeast organism, which is often budding, is small (3 to 6 μm diameter), and has been compared to the size of an avian red blood cell nucleus.[27] Hyphal forms are considered more diagnostic of a primary yeast infection but are less commonly found in a live patient (see Color 10).

Because candida is frequently a secondary pathogen, the clinician should attempt to determine the predisposing factors that lead to a candida infection. Oral and upper gastrointestinal candidiasis may show signs similar to those of trichomoniasis, hypovitaminosis A, avian poxviruses, bacterial infections, psittacine beak and feather disease, neonatal gastrointestinal viruses, ingested foreign bodies and toxicities. Culturing the organism may be helpful, especially in cases involving beak abnormalities or systemic problems. Sabouraud's[b] or cornmeal agar are the recommended culture media.[5]

Treatment

Effective candida therapy must include the resolution of predisposing factors such as environmental or nutritional stress, poor hygiene and unnecessary antibiotic therapy. Nystatin is the most frequently used medication for initially treating upper gastrointestinal candidiasis in the avian patient, although some of the azole antifungals are undoubtedly more effective. Nystatin has few side effects and is not absorbed from the gastrointestinal tract following oral administration. It is readily accepted by most birds and can be mixed with a neonate's feeding formula (Table 35.1). Ocular candidiasis is usually responsive to amphotericin B ointment or amphotericin B injected subconjunctivally.

TABLE 35.1 Some Antifungal Agents Used in Companion Species

Amphotericin B[c] (injectable)	1.5 mg/kg IV TID x 3 days 1.0 mg/ml saline intratracheal BID 1 mg/ml saline nebulized for 15 min BID
Flucytosine[d] (capsules)	250 mg/kg PO BID x 21 days
Ketoconazole[e] suspension (tablets)	10-30 mg/kg BID x 21 days
Itraconazole[f] (beads in capsules)	5-10 mg/kg BID in food for 7-21 days
Fluconazole[g] (tablets)	5 mg/kg SID for 7 days
Nystatin[h] (suspension)	100,000 units (1 ml) per 400 gram bird PO BID x 7 days

Ketoconazole is recommended for severe or refractory candidiasis. Although more costly and difficult to administer, it is a very effective systemic antifungal with a high therapeutic index.[5,32,46] Side effects may include vomiting and elevation of liver enzymes.[17] Ketoconazole is normally mixed with a slightly acidic liquid (eg, orange juice, pineapple juice) to facilitate its dilution. Candida prefers an alkaline environment and this acidification of the GI tract will have therapeutic value.

Strains of *Candida* spp. resistant to ketoconazole have been reported, and fluconazole has been suggested as a treatment of choice for these strains.[33] Little information is available on the use of this drug in birds; however, reported side effects have been minimal. Itraconazole has also been used to treat candidiasis,[15,20,23] but may offer no real advantage over other azoles. Miconazole has been reported to be effective in treating yeast infections, but few reports exist on its use in companion birds.[54] Azole antifungals may cause depression, anorexia, vomiting and hepatic toxicity.[38]

Aspergillosis

Aspergillosis is a disease of economic importance in the poultry industry (brooder pneumonia), and is a frequent cause of respiratory disease in companion, aviary and free-ranging birds. *Aspergillus fumigatus* is the most common etiologic agent, followed in frequency by *A. flavus* and *A. niger*. Aspergillosis may be chronic and insidious, or it may cause peracute death. Established aspergillosis infections are clinically challenging to resolve.

Transmission and Predisposing Factors

Penguins, birds of paradise, pheasants, waterfowl (especially diving birds and shorebirds), Goshawks and Gyrfalcons are believed to be especially susceptible to *Aspergillus* spp.[15,37,45] Among companion birds, a high prevalence of aspergillosis has been reported in African Grey Parrots, Blue-fronted Amazon Parrots and mynah birds.[30,45] Aspergillosis is occasionally described in pigeon flocks with one report listing a prevalence of 2.4%.[37]

Gallinaceous birds (particularly quail) often become infected as chicks following inhalation of spores from contaminated brooders.[16] Hand-raised psittacine birds could be infected in a similar manner. Older gallinaceous birds, and presumably aviary birds as well, can be exposed when maintained on moist contaminated bedding. Moldy straw is a particularly common source of numerous fungal pathogens including *Aspergillus* spp. Waterfowl may be infected by feeding on moldy corn or wheat straw.[29] Zoo birds that are contaminated with oil, or birds maintained in damp, poorly ventilated areas are frequently infected.

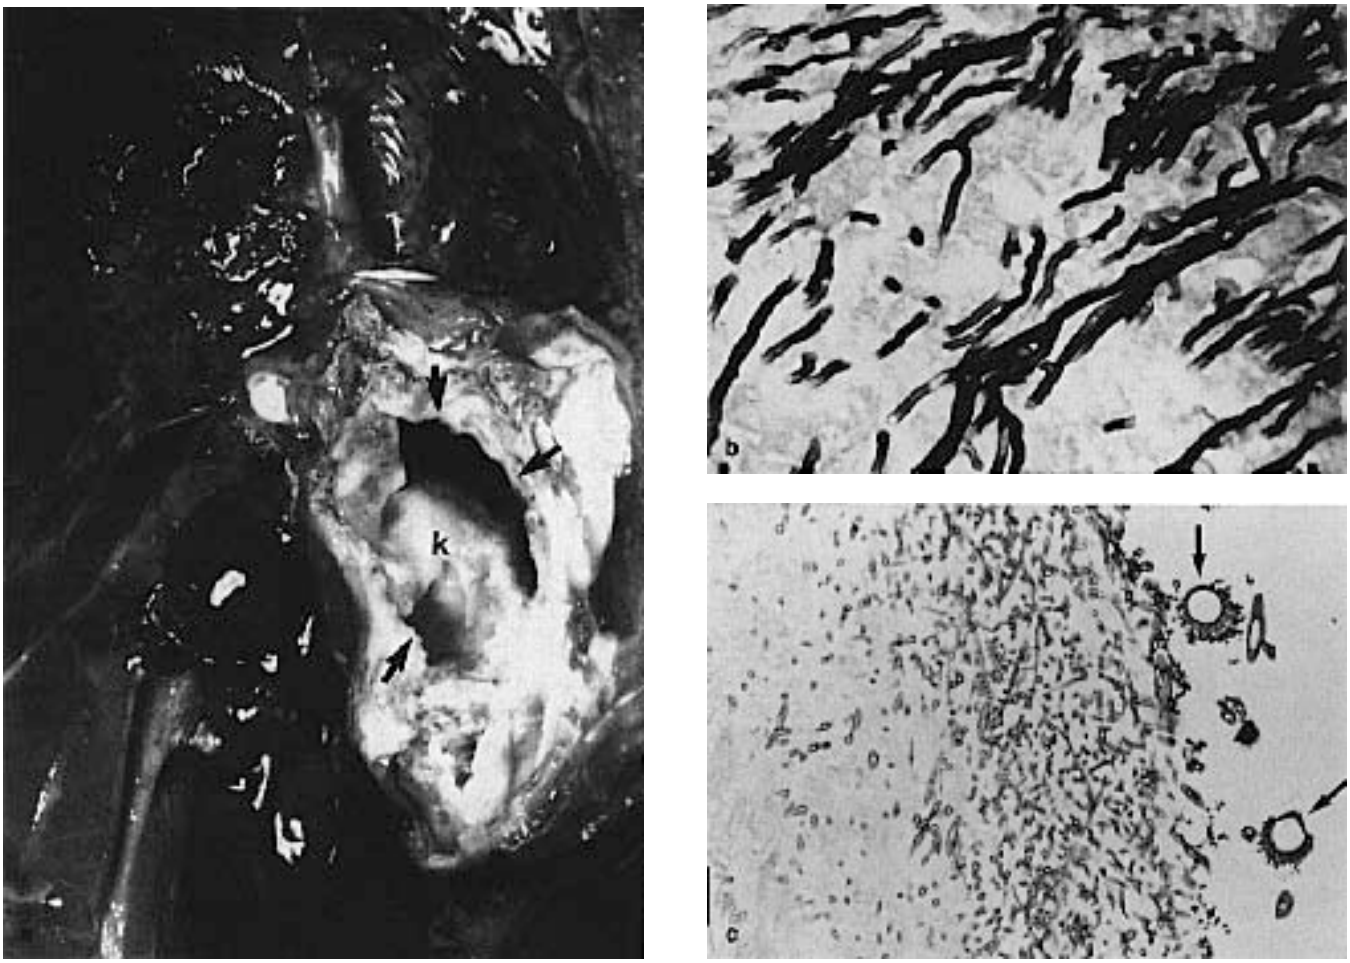

FIG 35.2 A mature Black Palm Cockatoo had a history of progessive rear limb ataxia and weight loss. The bird was presented for necropsy. **a)** Gross findings included a proliferative, white, fuzzy mass that was covering a thickened left abdominal air sac. When the ventral border of the mass was removed, the cranial and middle lobes of the left kidney were also found to be involved. **b)** An impression smear from the interior of the mass stained with new methylene blue revealed numerous branching septate hyphae suggestive of *Aspergillus* spp. **c)** Histopathology indicated thickened air sacs with fungal hyphae and fruiting bodies, which are characteristic of *Aspergillus* spp. growth in an oxygen-rich environment (courtesy of Kenneth Latimer, reprinted with permission[18]).

Pathogenesis and Incubation

Aspergillus is ubiquitous, and infections should always be considered to occur secondarily to an immunosuppressive event. It has been suggested that healthy birds exposed to high concentrations of spores are generally resistant to infections, while immunocompromised hosts exposed to small concentrations of spores are frequently infected. Factors that influence the susceptibility of a bird to aspergillosis include shipping, overcrowding, malnutrition, poor ventilation, very young or old age, antibiotic therapy (particularly tetracyclines), corticosteroid administration, respiratory irritants (eg, disinfectant fumes, cigarette smoke, ammonia) or concomitant disease.[5,16,24]

The type of disease induced by aspergillosis is thought to be dependent on the source and number of spores contacted and the general condition of the bird.[6] Healthy birds can generally withstand exposure to a high concentration of spores.

Aspergillosis infections are generally divided into local and systemic diseases. Lesions frequently originate in one system or area (eg, lower respiratory tract) and later advance into adjacent organs and systems as the disease progresses (Figure 35.2). Acute cases occur when spores germinate in a particularly vital area or when multiple lesions germinate at once.

A single air sac lesion may have a protracted course while a single lesion in the trachea or syrinx may quickly prove fatal (see Color 22). The syrinx or tracheal bifurcation is thought to be a common location for aspergillosis colonization because air turbulence patterns may cause the spores to drop out of the air stream at this point in the respiratory system.[49] Alternatively, the narrowing in the respiratory tract at this point may predispose it to blockage with necrotic debris.

There is a small area of stratified squamous epithelium in the syringeal area of some birds that can be modified by hypovitaminosis A. Tissue hypertrophy and hyperkeratosis may occur, allowing colonization by inhaled aspergillosis spores (Figure 35.3). Nasal aspergillosis also occurs in the avian patient.[25,55] Cutaneous, skeletal and gastrointestinal forms have been reported in rare instances.[11,24,26] An ocular form has been described in gallinaceous birds.[6,16] The incubation period associated with aspergillosis varies with the type of exposure. Experimentally infected ostrich chicks died two to eight days following exposure to spores (see Color 22). Air sac infections in mature birds may progress for weeks, or can induce granulomas that are present for months.

FIG 35.3 A ten-year-old Amazon parrot was presented with a three-week history of progressive dyspnea that had advanced to the point of post-exercise collapse. The bird was anesthetized with isoflurane, and an air sac tube was placed in the abdominal air sac. Tracheoscopy revealed a large proliferative white mass in the syrinx. The bird was breathing through a hole in the center of the mass the size of a 20 ga needle. Attempts to remove the mass were unsuccessful. At necropsy, the bird was normal except for the aspergilloma in the syrinx. The air sacs were clear. The bird was on an all-seed diet, which may have resulted in squamous metaplasia in the syrinx and precipated an infection.

Clinical Disease and Pathology

Clinical signs associated with aspergillus infections of the respiratory tract may include dyspnea, depression and emaciation (Table 35.2).[10] Open-mouthed breathing, pronounced excursions of the keel, tail "bobs" and respiratory distress after exercise are typical. Biliverdinuria is common. Wheezing, squeaking or stertor and a voice change are also sometimes present. Posterior paresis and lameness were the presenting signs in a Black Palm Cockatoo with *Aspergillus* spp. air sacculitis that spread to the kidney and pelvic nerve roots.[18] Signs related to the target organ(s) are seen in the less common forms of aspergillosis. Aspergillosis may be associated with ascites caused by peritonitis or cardiopulmonary im-

pairment, usually secondary to aspergillosis-induced thrombi in the pulmonary vessels.

TABLE 35.2 Clinical Findings in Companion Birds with Aspergillosis*

Emaciation	64%
Respiratory distress	26%
Neuromuscular disease	18%
Abnormal droppings	11%
Regurgitation	9%
Vocalization changes	7%
Poor appetite	7%
Nasal discharge	4%
Gout	4%
Hemoptysis	2%

* Adapted from McMillan MC, et al.[30]

In systemic cases in gallinaceous chicks, lesions are typically found in lungs, air sacs, heart muscle, liver and abdominal viscera.[13] Grossly, lesions in all areas are similar. A cream- to yellow-colored granuloma or plaque is present with or without gray or white "cotton-wool" mycelial masses (see Color 22).

Destruction of adjacent tissue, including bone or beak, may be substantial (Figure 35.4). Nasal aspergillosis typically presents as a dry, granulomatous, destructive swelling within one nostril. Histopathological examination of granulomas generally shows a necrotic foci surrounded by macrophages, heterophils and giant cells, sometimes within a connective tissue capsule (Table 35.3). Tracheal or syringeal aspergillosis lesions usually occur as plugs of creamy white necrotic debris at or near the tracheal bifurcation. Ocular aspergillosis in chicks may be recognized as a white exudate within the conjunctival sac.[6]

TABLE 35.3 Histopathologic Findings in Birds with Aspergillosis

Granulomatous pneumonia	66%
Fungal air sacculitis	53%
Bronchopneumonia	37%
Tracheobronchial mycetomas	20%
Acute necrosis with thrombosis	17%
Concurrent infection	40%

* Adapted from McMillan MC, et al.[30]

Diagnosis and Differential Diagnosis

History, signalment, physical examination findings and hematologic findings (heterophilia and anemia) may be suggestive of an aspergillosis infection. Fungal culture, hematology, serology, cytology, radiology and endoscopy or exploratory surgery are among the methods used to diagnose infections (Table 35.4). It should be noted that culture of *Aspergillus* spp. in the absence of lesions is not diagnostic, because the organism is ubiquitous in the environment. Radiographic findings can be negative or may show hyperinflation (enlargement) of the abdominal air sacs, focal densities in lungs or air sacs, reduced coelomic cavity details, loss of definition of air sac walls and asymmetrical opacity of abdominal air sacs (Figure 35.5).[30] Cytology of air sac washes or endoscopic-guided biopsy are useful in diagnosing lower respiratory infections.

FIG 35.4 A mature African Grey Parrot was presented with an advanced case of nasal aspergillosis. The nostril and operculum had been damaged by pressure necrosis. The extent of damage to the germinative epithelium is demonstrated by a severe defect in the beak. This photograph was taken several weeks after debridement and treatment of the infected tissues with miconazole (courtesy of Louise Bauck).

For definitive antemortem diagnosis, cytologic samples from granulomas with associated mycelial areas (wet mounts with lactophenol cotton blue, new meth-

TABLE 35.4 Typical Clinical Pathology Changes with Aspergillosis

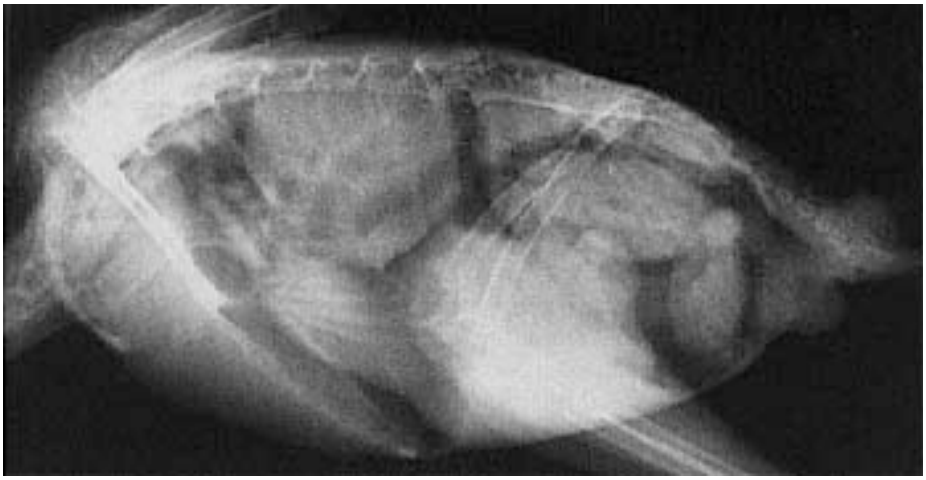

FIG 35.5 A mature Double Yellow-headed Amazon Parrot was presented with a history of severe dyspnea. Radiographs indicated a large soft tissue mass that was localized to the right lung and cranial thoracic air sac. A slightly oblique, rather than ventrodorsal, radiograph was made to better visualize the thoracic mass. An aspergilloma was diagnosed at necropsy (courtesy of Marjorie McMillan).

ylene blue and culture on Sabouraud dextrose agar or blood agar) may be diagnostic. The presence of branching septate hyphae, sometimes with spores and sporulating areas, is highly suggestive (see Figure 35.2b). Culture may distinguish *Aspergillus* spp. from other fungal organisms such as *Penicillium* spp. and *Mucor* spp. If access to a suggestive lesion is not available, then serology may be helpful. Although not widely available, aspergillosis titers using ELISA systems show promise in diagnosing infections.[3,57] Latex agglutination and complement fixation methods have also been described. Several of these tests are available on a commercial basis for gallinaceous birds, and an ELISA test is available in the United States for detecting anti-aspergillus antibodies.[22]

The differential diagnosis for a mature bird with weight loss and severe heterophilia might include chlamydiosis and mycobacteriosis. Neoplastic disease may sometimes cause weight loss and heterophilia. Severe dyspnea can also be caused by increased abdominal pressure (eg, mass, ascites, hepatomegaly), pneumonia and inhaled foreign bodies. Eye lesions, as described in gallinaceous birds, may be caused by hypovitaminosis A.

Treatment

Treatment of aspergillosis often depends on the location and extent of the lesion. Resolving advanced cases of aspergillosis is difficult, especially in anatomic areas where surgical removal of affected tissues is not possible. Correction of underlying stress factors is a mandatory component of successful therapy. Surgical debridement of plaques and granulomas should be employed when feasible.[5,29,44] Flushing lesions with amphotericin B or chlorhexidine solutions may be helpful, although caution should be exercised in certain anatomic areas. A severe granulomatous sinusitis occurred in an African Grey Parrot following the accidental use of amphotericin B suspension rather than a solution as a nasal flush.[55]

Intratracheal administration of amphotericin B has been used in treating tracheal and pulmonary asper-

gillosis. The medication is given via the glottis during inspiration and the patient is positioned to distribute the drug to the affected anatomic area.[40,44] Nebulization with antifungals may be helpful in early cases of upper respiratory aspergillosis.[5,48] Topical treatments with amphotericin B or other antifungal creams may be of value in external lesions in combination with systemic therapy (see Figure 35.4).[5,25] Systemic therapy is difficult because amphotericin B must normally be administered intravenously TID for three days. Intraosseous administration should be possible, but has not been documented. Amphotericin B is potentially nephrotoxic.

Flucytosine is also frequently used to treat aspergillosis, especially in combination with amphotericin B (Table 35.5). The advantage to this drug is that it can be administered orally; however, bone marrow toxicity has been reported in some cases. Monitoring for hematologic changes suggestive of bone marrow damage is recommended when this drug is used.

Some of the azole antifungals have good efficacy against aspergillosis in mammals and may be administered orally. Ketoconazole has been used to successfully treat aspergillosis in some avian species. This drug preparation has an advantage over other antifungals in having a wide therapeutic index.[2,26,42,44,47,53]

Current information suggests that itraconazole may have greater efficacy against *Aspergillus* spp. than amphotericin B or any other azole antifungal.[15,20,53,54] Itraconazole is thought to be less toxic than amphotericin B, but its safety in most companion bird species has not been established. Itraconazole has been used in waterfowl, shorebirds, poultry and penguins without serious side effects.[15,54] Anorexia, vomiting and depression have been reported in an African Grey Parrot being treated with itraconazole.[38] Monitoring for anorexia and depression is recommended. Enilconazole also has good efficacy against *Aspergillus* sp., although not as great as itraconazole.[54] Miconazole and parconazole may be less efficacious than other azoles in treating aspergillosis.

TABLE 35.5 Suggested Concurrent Therapy for Advanced Aspergillosis

Amphotericin B – IV and/or IT or in the affected air sac – BID for 5 days
Ketoconazole – orally – TID for 10 days
Flucytosine – orally – TID for 20 to 30 days
Kapracydin A – orally – TID for 5 days

Immunization therapy has been suggested to be of value in stimulating host response to *Aspergillus* spp. although information on the success of this treatment is still limited. Levamisole therapy has been suggested as an immunostimulant, but its efficacy is unknown.[5]

Control

Prevention of aspergillosis in general is dependent on the reduction of predisposing stress factors. Limiting exposure may be accomplished by reducing contact with organic bedding or nesting material that may be contaminated with mold or spores. Careful cleansing and disinfection of hatching equipment is essential. Feed for companion and aviary birds should always be free of fungal growth in order to limit exposure to fungal pathogens and mycotoxins (see Chapter 37). Vaccination with an autogenous mycotin may be effective in reducing aspergillosis in susceptible species such as captive penguins and waterfowl.[57]

Cryptococcosis

Cryptococcus neoformans is an imperfect, saprophytic yeast that has been reported as a cause of disease in psittacine birds and pigeons.[9,14,43] The transmission and pathogenesis in birds is largely unknown, but it is isolated frequently from the droppings of pigeons. In gallinaceous birds, cryptococcosis has been described as a necrotic granulomatous disease of the intestines, liver, lungs and spleen. In companion birds, a diagnosis of cryptococcosis is usually made at postmortem.

Antemortem diagnosis of cryptococcosis may be challenging. An impression smear of any accessible gelatinous material may reveal the characteristic encapsulated yeast-like organism. A latex agglutination antibody titer may be elevated in an exposed or infected bird.[41]

Central nervous system signs in birds with gelatinous masses should be considered suspicious. A Moluccan Cockatoo with disseminated cryptococcosis was presented for diarrhea and blindness; gelatinous material was present in the long bones, respiratory spaces and abdominal cavity.[14] In another case of cryptococcosis, a Green-winged Macaw was presented for diarrhea and paralysis.[9]

Dyspnea, weight loss and anemia are frequent clinical signs, and heterophilia may or may not be present.[43] The clinician should exercise caution when being exposed to clinical material that may contain *C. neoformans* spores.

The prognosis for disseminated cryptococcosis is poor. Amphotericin B and ketoconazole have been suggested as possible therapies.[43] In humans, amphotericin B, flucytosine and rifampin are sometimes effective. Cryptococcosis is a potentially serious zoonosis and may occur when humans inhale dust from the dried droppings of pigeons, starlings or other avian species.[9,56] Other transmission routes may also be possible. Respiratory signs, encephalitis or meningitis may occur; the outcome is frequently fatal. Treating cryptococcus cases should be carefully considered given the zoonotic potential for this organism.

Histoplasmosis

Histoplasmosis is similar to cryptococcosis in many ways but is less commonly reported in birds. *Histoplasma capsulatum* is an infectious but not contagious disease of the reticuloendothelial system. *Histoplasma* spp. grow readily in soil and appear as a white-to-brown mold with two types of spores.[6] The organism has been associated with or found in the feces of chickens, blackbirds, pigeons and gulls.[41] This fungus could potentially proliferate in enclosed aviaries with dirt floors. Surveys of aviary soil are needed to determine the incidence of this organism. The transmission and incubation periods are unknown, but in experimental situations, the organism can be recovered from the liver and spleen 7 to 45 days after intravenous inoculation.

Diagnosis of histoplasmosis is based on culture of the organism (mycelial phase may sometimes be recovered on Sabouraud's agar) and histopathology (periodic acid-Schiff, Bauer's and Gridley stains).[6]

Histoplasma sp. has zoonotic potential and may cause pneumonitis that progresses to a disseminated disease of the reticuloendothelial system.

Uncommon Fungal Diseases

Dermatophytosis, mucormycosis, trichosporosis, rhinosporidiosis and penicilliosis have all been documented in avian species. Dermatophyte infections are of some interest to the avian practitioner because of their role in skin and feather abnormalities. While frequently implicated, fungal infections of the skin in psittacine birds have rarely been documented.

Trichophyton gallinae is the principal dermatophyte of gallinaceous species, and is associated with a white crust on the comb and wattles ("fowl favus") (see Color 8). *Trichophyton* sp. has been documented as a cause of dermatologic problems in the duck, pigeon and canary.[5,41,52] Diagnosis of fungal skin infections is usually made with cytologic evaluation of wet mounts or Gram's-stained smears, culture (canine and feline dermatophyte media for in-hospital use may not be suitable) and biopsy (histopathology). Topical treatment with antifungal creams is recommended, with attention to any underlying stress factors. *Trichophyton gallinae* is a zoonotic disease and has been described as a pruritic, scaly lesion of the scalp.[51]

Mucormycosis is a term that includes a variety of fungal pathogens. In birds, disease caused by *Rhizopus* and *Mucor* spp. have been reported. Granulomas of the gut and ventriculus were found in a group of canaries that were being fed sprouted seed; concurrent antibiotic treatment may have been a predisposing factor.[39,53] Infections caused by members of the phycomycetales (zygomycota) can sometimes mimic aspergillosis (eg, tracheal obstruction, mycelial granulomas).

Systemic trichosporosis was reported in a Green-winged Macaw that was presented for weight loss and polyuria. Granulomatous inflammation involving the liver, myocardium and lung was associated with *Trichosporon beigelii*.[50] *Penicillium griseofulvum* is another rare fungal isolate that caused a systemic infection in a group of captive toucanets.[1] Septate, branched mycelia were found in the lungs, air sacs and liver. Conidiophores and conidial chains were present in the air sacs. Nocardiosis (*Nocardia asteroides*) involving the lungs and air sacs of two Pesquet Parrots has been reported.[5]

Rhinosporidiosis seems to be found most frequently in birds living in aquatic habitats. It has been documented in ducks and geese but not in Psittaciformes or Passeriformes. It also occurs in man and the dog, and in most species it can take the form of an erythematous nasal polyp.[10]

A mycetoma caused by *Curvularia geniculata* was reported in a Grand Eclectus Parrot. Mycetomas in man are eruptions of the extremities that usually involve granuloma formation by one of a number of obscure fungal pathogens.

CHAPTER

36

PARASITES

Ellis C. Greiner
Branson W. Ritchie

Avian parasites range from single-celled protozoans that develop either intracellularly or extracellularly to multicellular helminths and arthropods. The effects of an infection can vary from benign to acute deaths. Parasitic life cycles may be direct or complex indirect cycles requiring various arthropod or animal hosts. Some species of parasites can infect nearly every organ system, although individual genera will inhabit specific organs or tissues. For example, mature tapeworms (Cestoda) and spiny-headed worms (Acanthocephala) are restricted to the small intestines. Mature flukes (Trematoda) occur in the intestines, liver, kidney, air sacs, oviducts, blood vessels and on the surface of the eyes. Adult roundworms (Nematoda) parasitize the crop, proventriculus, ventriculus, intestines, ceca, body cavities, brain, surface and periorbital tissues of the eyes, heart and subcutaneous tissues. Mites (Acarina) live in and on the skin, feather shafts and follicles, choanal slit, nasal passages, trachea and air sacs. Immature and mature biting lice and ticks remain on the integument. Single-celled organisms with discrete nuclei (Protozoa) may be found in the lumen of the intestinal tract, extracellularly in the blood or within cells of many tissues.

It should be stressed that identifying a parasite (or parasite egg) does not imply clinical disease. Many parasites coexist with their avian hosts without causing pathologic changes. Long-term symbiotic parasite-host relationships are usually characterized by benign infections compared with parasites that have been recently introduced to a new host. The fact that companion and aviary birds from widely varying geographic regions are combined creates an opportunity for exposure of a naive host to parasitic organisms that may cause few problems in their natural host. Parasites that are apathogenic in endemic avifauna can cause chronic disease or rapid death in unnatural hosts.

With companion and aviary bird species, parasitic infections are most common in birds that are recently imported or that have access to the ground. Some parasites are host-specific, while others can infect a wide range of avian species. Free-ranging birds should be restricted from an aviary to prevent them from serving as sources for parasites. Parasitic problems are best managed by designing facilities that restrict a bird's access to infectious stages of a parasite and by practicing sound hygiene. Birds maintained indoors or in suspended welded wire enclosures are unlikely to have parasites that have an indirect transmission cycle. In contrast, parasitic infections are common in countries where birds are maintained in walk-in type aviaries with access to the ground.

Treatment for parasitic infections should include appropriate anthelmintics (when available) and management changes that will prevent reinfection (Table 36.1). Relatively apathogenic parasites may cause severe clinical disease in birds that are immunosuppressed or stressed or have concomitant infections.

TABLE 36.1 Suggested Parasite Treatments

Parasites	Therapy
Haemoproteus	Not recommended in asymptomatic birds
Leucocytozoon	Pyrimethamine, Clopidol (0.0215 to 0.025%) in food as preventative
Plasmodium	Chloroquine phosphate, Primaquine
Giardia	Metronidazole
Histomonas	Ipronidazole, Dimetrodazole
Atoxoplasma	See text
Cryptosporidium	No effective therapy
Sarcocystis	Pyrimethamine, Trimethoprim, Sulfadiazine
Cestodes	Praziquantel
Ascarids	Pyrantel pamoate, Piperazine
Oxyspirura	Ivermectin
Capillaria	Mebendazole, Fenbendazole, Ivermectin (resistant strains occur)
Syngamus	Ivermectin, Physical removal
Knemidokoptes	Topical ivermectin
Sternostoma	Ivermectin, Physical removal
Gapeworms	Thiabendazole, Mebendazole
Trichomonads	Dimetronidazole, Metronidazole
Coccidia	Metronidazole

Life cycles for most avian parasites are poorly understood. Much of the currently available information is based on comparative data from similar taxa in other hosts. Diagnostic stages of most avian parasites have not been matched to the adults of the same species and thus characterization is usually limited to order or superfamily. Avian parasitology will be enhanced by cooperation among aviculturists, avian veterinarians and parasitologists.

Diagnosis of Parasites

Parasitic infections in birds may be diagnosed through examining samples from living birds or through necropsy of affected individuals or representatives of flocks.

It is important to determine which parasites are present because: 1) related parasite/host systems may cause clinical signs similar to the ones being observed, providing the clinician with information on potential life cycles; 2) determining which groups of parasite(s) are present will ensure the selection of appropriate antiparasitic agents; and 3) determining a potential source of infection would help in designing a preventive program for individual birds and the flock.

TABLE 36.2 Common Parasites in Companion Birds

African Grey Parrots	Tapeworms (common), blood parasites* (occasional)
Australian Parakeets	Proventricular worms (common), nematodes (frequent)
Budgerigars	*Trichomonas* (common), *Giardia* (common)
Canaries	Air sac mites
Cockatiels	Ascarids* (common), *Giardia* (frequent)
Cockatoos	Tapeworms (common), *Haemoproteus*,* microfilaria,* liver flukes*
Finches	Air sac mites, tapeworms (common), *Trichomonas**
Lorikeets	Coccidia, roundworms* (frequent)
Macaws	*Capillaria* (frequent, imports), ascarids* (common)
Toucans	*Giardia* (common), coccidia (frequent)

* Relatively uncommon in captive-bred birds in the United States

Diagnosis in the Living Bird

Depending on the parasite, appropriate antemortem diagnostic samples could include feces, blood, tissue

GREINER'S TENETS FOR FECAL EXAMINATION[44]

1. Examine an adequate quantity (1 to 2 grams) of fresh feces. Some nematode eggs will larvate if allowed to age, producing atypical eggs or larvae that are difficult to identify. Some parasitic forms (trophozoites of *Giardia* for example) are fragile and will perish if the sample is not examined immediately.
2. Collect feces per cloaca or from nonabsorbent cage lining such as waxed paper or aluminum foil. Using nonabsorbent material to collect feces provides a moist sample of greater volume when compared to scraping a sample off newsprint or paper toweling. Samples collected from corn cob, wood shavings or cat litter should not be considered diagnostic.
3. Conduct the test that specifically demonstrates the parasite that is most likely to be causing the clinical changes. Fluke eggs cannot be demonstrated by flotation. Trophozoites of *Giardia* and *Trichomonas* will be destroyed if placed into saturated salt or sugar flotation solutions. *Giardia* trophozoites die in tap water and are best identified by using warm saline or lactated Ringer's solution as a diluent.
4. Examine each prepared sample completely and systematically. The low power objective (10x) should be used for scanning. The high dry objective can be used to magnify and examine a particular structure. Scan the coverslip beginning at one corner and traversing the length of the coverslip, then move the slide to the next field of view and reverse the field of movement. Repeating this procedure until the entire coverslip has been viewed will provide a systematic examination of the total preparation and reduce the likelihood of missing a parasite. Examine the entire slide and do not stop when eggs of one kind have been identified. Some helminths produce very few eggs that may not be detected unless the entire slide is examined.
5. Standardize procedures so that results are repeatable and comparable. If a diagnostic technique is not standardized, the results are of limited value. Egg counts are of little value because there is no direct correlation between the number of eggs per gram of feces and the number of adult parasites present. Comparing egg counts between treated and untreated birds may provide some information on the effect of an anthelmintic.

biopsies or integument for the detection of intact parasites, eggs or intermediate life forms. Specific diagnostic procedures are dictated by the size and species of bird, clinical signs and the types of parasites that might be contributing to the problems.

Egg characteristics that should be evaluated include shape, size (determined by using a calibrated ocular micrometer), color (colorless, yellowish to brown), texture (smooth, pitted, mammillated), single operculum, bipolar plugs, stage of development (single cell, morula or larvae) and type of larva present in the egg (nematode larva, hexacanth larva, miracidium or acanthor).

The diagnostic stage of most avian helminths is an egg that is detected in the feces by either flotation or sedimentation. The flotation method will remove extraneous debris and concentrate the eggs of nematodes, cestodes and acanthocephala and the cysts and oocysts of protozoa. The most generally used flotation medium is saturated sodium nitrate (568 g sodium nitrate/ 1000 ml water). Sheather's sugar solution (500 g table sugar, 320 ml water and 6.5 g phenol crystals) is most commonly used to detect coccidian oocysts. Saturated zinc sulfate (336 g zinc sulfate/ 1000 ml water) is best for concentrating cysts of *Giardia* and may be better for detecting spiruroid eggs than sodium nitrate.

Flotation can be performed by mixing feces in a volume of flotation medium and passing the mixture through a piece of double-layer gauze or cheesecloth placed on top of a vertical tube. The tube should be filled until a slight positive meniscus is formed. A coverslip is placed on top of the tube and allowed to stand for ten minutes. As an alternative technique, the feces can be placed on a gauze pad on top of a 15 ml centrifuge tube and washed with lactated Ringer's solution. The collected fluid is then centrifuged at 1200 to 1500 rpm for ten minutes and the sediment is mixed in the appropriate flotation medium. The coverslip from either method is then examined microscopically.

TABLE 36.3 Best Tests for Detecting Avian Parasites

Parasite	Test
Hexamita, Giardia, Trichomonas	Fresh direct mount with warm LRS (not H_2O)
Coccidia oocyst	Flotation - Sheather's sugar
Giardia, spiruroid eggs	Flotation - Zinc sulfate
Nematodes, cestodes, acanthocephala	Flotation - Sodium nitrate
Flukes	Sedimentation
Plasmodium, Haemoproteus, Leucocytozoon, Atoxoplasma, Trypanosoma, microfilaria	Blood smear - Wright's stain (see Color 9)
Microfilaria, *Trypanosoma*	PCV tube, inspect at blood plasma interface using microscope

Fecal sedimentation is used primarily for the detection of fluke eggs that do not float in commonly used media. Feces is mixed in a liquid soap-in-water solution (0.1 to 1%) and allowed to stand for five minutes without centrifugation. The supernatant is gently removed and the tube is refilled with soapy water and allowed to stand for another five minutes. This procedure removes particulate material and concentrates the fluke eggs. It can also be used in place of flotation to detect eggs and cysts but is more time-consuming and may not be as sensitive as a flotation method.

A direct smear is best for detecting motile protozoan trophozoites (*Giardia*, *Trichomonas* or *Hexamita*). Samples are not diagnostic if they are more than 15 minutes old. Feces or tissue swabs are mixed with LRS or normal saline (0.85% sodium chloride), not tap water. The proper density of the preparation is achieved when newsprint can be easily read through the preparation. The microscope light should be adjusted to provide maximum contrast. The morphology of the parasites may be confirmed by fixing feces in polyvinyl alcohol and staining a slide preparation with trichrome.

Blood films are used to detect avian hematozoa, including microfilariae of filarial worms. Commonly identified blood parasites include intracellular stages of *Plasmodium*, *Haemoproteus*, *Leucocytozoon* and "*Atoxoplasma*," and extracellular stages of *Trypanosoma* and microfilariae from various filarial worms. Blood smears may be made on microscope slides or on coverslips. Coverslips have the advantage of being in view when mounted on slides and the sample is protected from being wiped off the slide. Giemsa or Wright's/Giemsa staining procedures provide the best results and long lasting stain quality (see Chapter 9). Alternatively, blood may be collected in a hematocrit tube and centrifuged, and the plasma/cell interface examined.

Arthropods collected for identification should be fixed and stored in 70% ethanol. Larvae of myiasis-causing flies should be killed by placing them briefly in boiling water and then transferring them to 70% ethanol. Mites, ticks, fleas and lice can be placed directly into 70% alcohol. Arthropods may be removed from the skin or feathers with forceps, or those living under crusting skin can be collected by scraping the encrusted area with a dull scalpel and allowing the crusts to fall into a petri dish containing 70% ethanol. A dissecting microscope can be used to demonstrate the mites. Arthropods present in the choanal slit can be collected with a moistened cotton-tipped swab.

Feather mites can be collected by placing the affected feather in 70% ethanol. Quill mites (ones living in the shaft of the feather) may be detected by microscopically examining the transparent portion of plucked primary feathers or coverts. These parasites can be recovered by slitting the shaft lengthwise and placing it in alcohol. Lice can be located by running a finger through the feathers. Bird fleas can be manually removed. However the mouth parts of some fleas, such as *Echidnophaga*, may remain attached to the bird (see Color 8). Hippoboscid flies are flattened, move rapidly under the feathers and are difficult to catch (Figure 36.1). The use of a pyrethrin-based flea spray, designed for puppies and kittens, is a safe and easy way to collect topical parasites from birds. A minimal dose (one drop under each wing of a cockatiel) is effective.

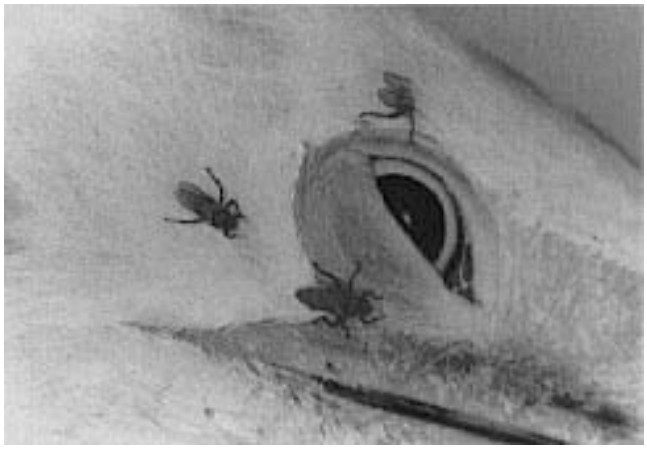

FIG 36.1 Many of the biting and chewing flies that live in and on the feathers of birds (such as this hippoboscidae) are flattened and move quickly, making it difficult to collect them for identification.

Diagnostic Stages Found in Birds

The following information is a review of the few references on the partial or generic identification of parasitic life stages passed by birds. Figures 36.2 to 36.4 illustrate fluke eggs that were detected from sedimentation. Helminth eggs that were recovered by flotation are shown in Figures 36.5 to 36.8. Figures 36.9 to 36.21 are nematodes eggs. Figure 36.22 is the egg of an acanthocephalan and Figure 36.23 is a mite egg. Most mite eggs are large (100 μm) and often contain a larva with jointed legs. Note all mite eggs seen in fecals do not indicate acariasis as some are normal grain mites being consumed in the bird's food. Figures 36.24 to 36.27 are coccidian oocysts that have been sporulated. They would appear with a granular spherical mass in the center of the oocyst when passed in the feces, and must be sporulated to determine the genus.

Diagnosis in Dead Birds

Any bird that dies should be necropsied and tissues should be collected for histopathology. If parasites are identified, they should be collected for classification. Gross and histologic lesions should be correlated with any recovered parasite to determine if the

FIG 36.2 *Orchipedum* egg from Sandhill Crane, 77 x 45 μm, with prominent operculum.

FIG 36.3 Strigeid egg from Bald Eagle, 95 x 60 μm, with obvious operculum.

FIG 36.4 Dicrocoelid egg from macaw, 33 x 22 μm, with inapparent operculum and typical dark brown coloration.

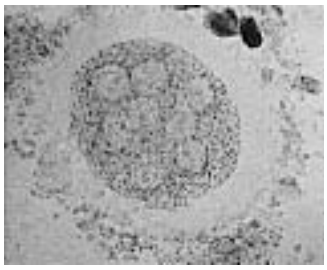

FIG 36.5 *Raillietina* tapeworm egg packet from an African Grey Parrot, clear halo, 223 x 193 μm, several eggs each with oncosphere bound in a gelatinous mass.

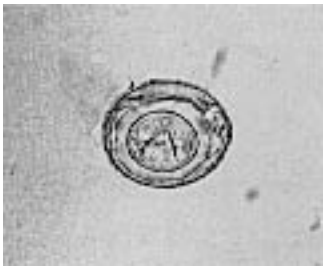

FIG 36.6 Tapeworm egg from peafowl, 50 x 38 μm, note 2 of 3 pairs of oncosphere hooks in focus.

FIG 36.7 Tapeworm egg from cockatiel, 74 x 68 μm, outer membrane intact and most hooks on oncosphere in focus.

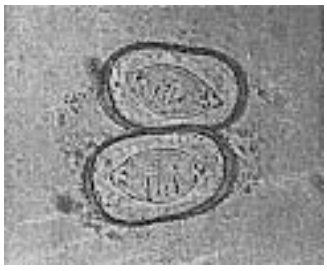

FIG 36.8 Tapeworm egg (possibly *Pulluterina* sp.) from unidentified parrot, 62 x 26 μm, four of six hooks on oncosphere in focus and rectangular shell with distinctive shape of oncosphere.

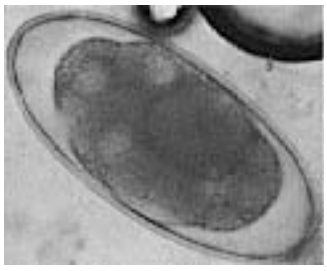

FIG 36.9 *Deletrocephalus* egg from rhea, 169 x 77 μm, very large.

FIG 36.10 *Codiostomum* egg from ostrich, 60 x 35 μm.

FIG 36.11 *Trichostrongylus* egg from wild turkey, 67 x 37 μm.

FIG 36.12 *Syngamus* egg from Barred Owl, 54 x 33 μm, note shape and polar plugs.

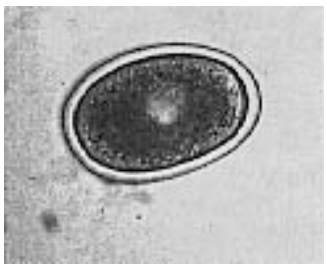

FIG 36.13 *Ascaridia* egg from macaw, 77 x 52 μm, smooth, thick, ellipsoid shell.

FIG 36.14 *Porrocaecum* egg from Bald Eagle, 66 x 55 μm, rough-walled, subspherical shape.

FIG 36.15 *Contracaecum* egg from pelican, 65 x 50 μm, smooth egg wall and subspherical.

FIG 36.16 *Habronema*-like egg from macaw, 57 x 22 μm, elongate, larvated.

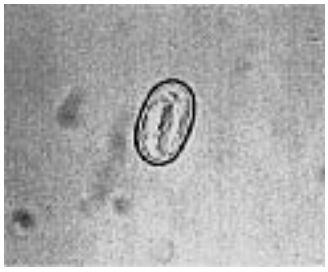

FIG 36.17 Spiruroid egg from cockatiel, 35 x 22 μm, thick-walled, symmetrical and larvated.

FIG 36.18 *Capillaria* egg from Bald Eagle, 62 x 29 μm, bipolar plugs and pitted wall.

FIG 36.19 *Capillaria* egg from Barred Owl, 59 x 29 μm.

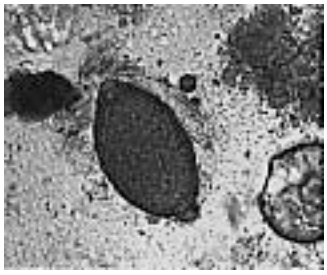

FIG 36.20 *Capillaria* egg from Great Horned Owl, 64 x 36 μm.

FIG 36.21 *Capillaria* egg from pigeon, 52 x 31 μm.

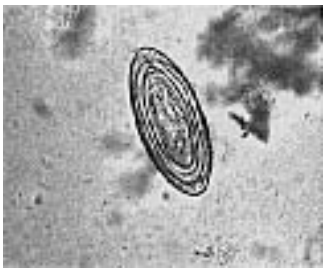

FIG 36.22 *Centrorhynchus* egg (an acanthocephalan), 58 x 23 μm, laminated-appearing egg with central larva (acanthor).

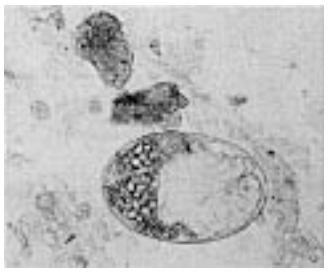

FIG 36.23 Mite egg from peafowl, 157 x 134 μm.

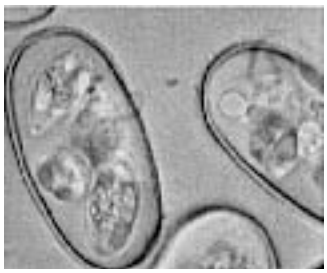

FIG 36.24 *Eimeria* oocyst from Blue-fronted Amazon, 47 x 25 μm, note the 4 sporocysts each with two sporozoites.

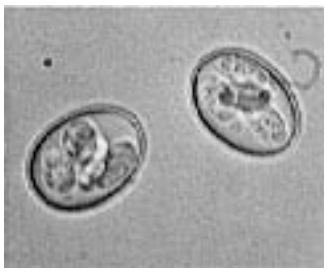

FIG 36.25 *Eimeria forresteri* oocyst from Toco Toucan, 23 x 18 μm, same sporocysts arrangement as Figure 36.24.

FIG 36.26 *Isospora* oocyst from House Sparrow, 25 x 25 μm, note 2 sporocysts each with four sporozoites.

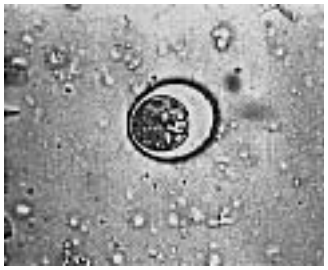

FIG 36.27 *Caryospora* oocyst from Red-shouldered Hawk, 36 x 31 μm, note single sporocyst and eight sporozoites.

organism is contributing to a specific set of clinical changes (Figure 36.28).

It is always a good policy to contact the parasitologist and request special submission instructions. Parasites for classification should be collected from each affected organ, placed in separate containers and fixed as discussed below. The host species, host identification number, location of parasite in the host and date collected should be written in soft pencil on a good quality white paper and included in the vial with the specimens. Other useful information includes whether the bird was imported or captive-raised, its duration in captivity and the number of birds affected.

The complete gastrointestinal tract should be opened lengthwise, section by section. In small birds, each section of bowel may be opened in a series of petri dishes containing water. In large birds, the bowel contents should be washed through #40 and #100 standard sieves. The mucosa should be scraped to free attached helminths, and the residue on the sieve should be back-flushed into a dish and evaluated for the presence of parasites. Detection and recovery of helminths can also be accomplished by placing the gut contents into one-liter flasks and allowing a sediment to form. This procedure is repeated until the water remains clear. Parenchymous organs should be sequentially sliced and evaluated for the presence of helminths. The body cavities, air sacs and orbits of the eyes should be examined grossly for worms. Skin over swellings on the feet or legs should be excised, and the area should be examined for the presence of adult filarial worms. All recoverable parasites should be collected to maximize the information that can be ascertained from the infection.

Nematodes should be placed briefly in full-strength glacial acetic acid or hot 70% ethanol. This process should kill and fix the nematodes in a straight, uncoiled manner. They should then be transferred into glycerin alcohol (9.0 parts 70% ethanol and 1.0 part glycerin) for storage.

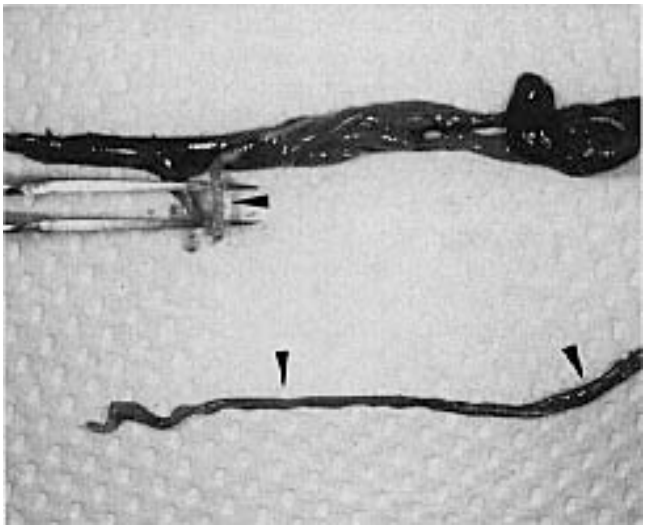

FIG 36.28 An adult African Grey Parrot was presented with a two-week history of progressive diarrhea. The bird was emaciated and dehydrated and had dried excrement around the vent. The bird did not respond to supportive care and died several hours after presentation. Tapeworms (arrows) were identified in the intestinal tract. Note the dark (hemorrhagic) bowel loops.

Cestodes should be relaxed in tap water in a refrigerator for two to four hours and then fixed in AFA (8.5 parts 70% ethanol, 1.0 part full strength formalin and 0.5 part glacial acetic acid). The parasites collected should have an intact scolex (holdfast), which is important in tapeworm identification.

Trematodes should be relaxed by placing them in tap water in the refrigerator for 30 to 60 minutes. Thin-bodied flukes should be placed into AFA. Thick-bodied flukes should be gently held in place between two glass microscope slides while AFA is instilled between the slides. After a few minutes, the top slide is removed.

Acanthocephalans should be gently removed from the gut wall to prevent rupture of the parasite, which will destroy the hydraulic system that extends the proboscis (making identification of the parasite nearly impossible). Acanthocephalans may lose their torpor and detach from the gut wall when the host dies. They may then resemble a yellowish to whitish, short, wrinkled tapeworm. Placing the parasite into tap water overnight in a refrigerator may cause the proboscis to extend, at which point the parasite is fixed in AFA.

A fecal examination should be performed at necropsy so that eggs detected by fecal flotation or sedimentation can be compared to the eggs in the adult worms.

Clinically Significant Parasites

Protozoa

The single-celled parasites include the malarial parasites (*Plasmodium* spp.) and their relatives (*Haemoproteus* spp. and *Leucocytozoon* spp.), the coccidians (*Eimeria*, *Isospora*, *Sarcocystis* and *Toxoplasma*), the microsporidians (*Encephalitozoon*) and flagellates in the gastrointestinal tract (*Giardia*, *Trichomonas* and *Hexamita*) and the peripheral circulation (*Trypanosoma*) (Table 36.5).

Gastrointestinal Flagellates

Protozoans with flagella that reside in the gastrointestinal tract of psittacine birds include *Trichomonas gallinae, Hexamita* and *Giardia* spp.

- ***Trichomonas:*** Trichomonads do not require an intermediate host or vector and are transmitted through direct contact or through ingestion of contaminated water or food. Infected adults can transmit the parasite to their chicks during feeding activities. Parental feeding of young is an effective method of parasite transmission. There is no resistant cyst form, and only the motile trophozoite has been described. This extracellular parasite measures 8 to 14 μm in length (may vary in different host species), has four free anterior flagella and possesses an undulating membrane that creates a wave-like appearance along the cell surface. It moves in a jerky manner and the body diameter remains constant as it moves.

Depending on the species, infections may be localized in the mouth, oropharynx, esophagus, crop and trachea, or the pulmonary and hepatic tissues can be invaded. Pathogenic strains cause inflammation and white plaques on the gastrointestinal mucosa or necrosis with an accumulation of cheesy material that might occlude the esophagus and trachea. Overcrowding and poor hygiene may potentiate infections in individual birds as well as increasing the incidence of disease in a flock. Infections in young birds are generally associated with poor growth and high mortality. In adult birds, infections are usually characterized by emaciation, dyspnea or vomiting. A pathogenic strain caused the death of all ages of naive pigeons four to 18 days after infection. Blue-fronted Amazon Parrots, cockatiels and budgerigars are

known to be susceptible.[40,54,79,104] Trichomoniasis is particularly common in pigeons and raptors (frounce) (see Chapter 8). Pathogenic and nonpathogenic strains of *T. gallinae* have been described in pigeons; thus, not all infections may be a threat to the host. Feeding pigeons to captive raptors (especially species that do not normally eat pigeons such as eagles and large hawks) may result in the transmission of *Trichomonas*. Advanced cases with large necrotic masses are difficult to treat and generally have a poor prognosis (see Chapter 19).

- ***Giardia:*** The *Giardia* sp. recovered from budgerigars appears to be morphologically distinct from those found in other animals and has been identified as *G. psittaci*.[31] Most reports of giardiasis in psittacine birds involve budgerigars, cockatiels, lovebirds and Grey-cheeked Parakeets. Rarely, infections may be detected in Amazon parrots, conures, cockatoos, macaws, toucans, Galliformes and Anseriformes.[15,38,97] *Giardia* has not been reported in finches or canaries.

Giardia sp. is commonly found in the feces of asymptomatic adult budgerigars and cockatiels, suggesting an asymptomatic carrier state (see Color 8). In a group of 77 parakeets from several sources, 66% of the birds were found to be shedding *Giardia*.[84] In another study, 70% of cockatiels, 55% of budgerigars, 25% of lovebirds, 5% of Grey-cheeked Parakeets and less than 5% of other psittacine birds were found to be shedding giardia. Asymptomatic birds may intermittently shed the parasite.[84]

Psittacine birds with giardiasis may be asymptomatic, or the birds may exhibit signs of loose, malodorous stools, mucoid diarrhea, debilitation, gram-negative enteritis, anorexia, depression, recurrent yeast infections, eosinophilia and hypoproteinemia. Dry skin and feather picking, particularly in the carpal-metacarpal, flank, axilla and lower leg areas, has been described as a clinical sign of giardiasis in budgerigars and cockatiels (see Chapter 24). Giardiasis can cause poor growth and high mortality in budgerigar and cockatiel neonates. Mortality rates of 20 to 50% have been described in some infected budgerigar flocks.[84]

In mammals, *Giardia* is frequently considered an opportunistic pathogen that requires an immunocompromised host. The role that the immune system plays in preventing a bird from developing giardiasis has not been determined. However, many clinically affected psittacine birds are fed marginal diets, are maintained in overcrowded, hygienically unsound conditions or are heavily inbred. Birds that recover from an infection are susceptible to re-infection indicating that a long-lasting protective immune response does not occur with infection.

Giardia spp. have a motile trophozoite and a cyst stage that can be identified in the feces or from mucosal scrapings collected at necropsy (Figure 36.29). Direct transmission occurs following the ingestion of food contaminated with feces from infected birds. The environmentally stable cysts can serve as a source of infection to other hosts. *Giardia* trophozoites are not stable outside of the host.

Cytologic preparations must be examined within ten minutes of collection or trophozoites may not be recognized. False-negative results are common if the feces is over ten minutes old when it is examined. Trophozoites are flat and move in a smooth rolling manner. If a fecal sample cannot be examined immediately, it should be fixed in polyvinyl alcohol for trichrome staining.

Multiple, fresh, direct fecal smears stained with carbol fuchsin (one minute) or iodine may help in detecting trophozoites (see Color 8). Flotation techniques with zinc sulfate may improve the accuracy of a

FIG 36.29 Electronmicroscopic view of giardia attached to the mucosal lining of the intestine (courtesy of Kenneth Latimer).

diagnosis. Trophozoites can range from 10 to 20 μm in length and 5 to 15 μm in width, depending on the host or type of fixation. The trophozoites have eight paired flagella (including an anterior and trailing posterior pair), two nuclei and a sucking disc that occupies most of the rounded end. The trophozoites attach to the surface of the villi in the small intestine. The sucking disc may be seen if the light is adjusted to maximize contrast. Cysts are believed to be intermittently shed in the feces, and multiple samples must be examined before considering that a bird is uninfected. The cysts measure 10-14 μm x 8-10 μm and contain four nuclei and fibrillar structures. ELISA tests have been developed to detect *Giardia* spp. in humans, but their efficacy for use in birds has not been evaluated.

Keeping the aviary as clean and dry as possible will reduce the viability and number of cysts available for transmission. Relapses are common after treatment either from endogenous parasites that are not destroyed or from reinfection from exposure to environmental reservoirs. Contaminated water supplies have been discussed as a method of repeated exposure of mammals to *Giardia* and may serve as a source of infection in birds. *Giardia* cysts survive the standard chlorination of water. *Giardia* appear to be limited in host range, and species isolated from birds have not been found to be infectious in mammals.

- ***Hexamita:*** *Hexamita* sp. has been detected in emaciated Splendid Grass Parakeets and cockatiels and can cause loose stool and weight loss.[51] This genus has a trophozoite with eight flagella and two nuclei as does *Giardia*, but it lacks the sucking disc and is often truncated in appearance. Cysts are probably the infectious form. Generally, *Hexamita* is smaller than *Giardia*, swims in a smooth linear fashion and may be associated with chronic diarrhea. *Hexamita* has been described as a cause of disease in lories. Demonstration of the parasite is common in asymptomatic pigeon feces and does not appear to cause a problem unless the birds are maintained in poor condition.

- ***Histomonas:*** Histomoniasis is common in gallinaceous birds. The induced disease is called blackhead and is caused by a flagellated protozoan parasite (*Histomonas meleagridis*) (see Color 20). In some birds, this parasite is considered a major pathogen while in other birds it is considered an incidental finding. When lesions occur, they generally include hepatomegaly (with necrosis) and ascites. Histomonads have also been described in the liver of several non-gallinaceous birds.

Most infections occur following the ingestion of infected embryonated eggs of the cecal worm *Heterakis gallinarum*. The histomonas are released from the larvae and invade the wall of the cecum where they may cause ulceration or small nodules. Parasites in the liver can cause severe hepatocellular necrosis.[30]

Coccidia

Coccidian parasites include a variety of life styles and means of transmission. Oocysts of most genera are passed unsporulated. They are typically less than 45 μm in length, contain a granular-appearing spherical body (sporoblast) and may be round, ellipsoid or ovoid. There may be a thinning of the wall (the micropyle), and if the micropyle is present, it may have a cap. The wall may be smooth, mammillated or pitted and colorless to dark brown.

Coccidia are common in mynahs, toucans, pigeons, canaries, finches and lories (Figures 36.24, 36.27). By comparison, infections are rare in captive Amazon parrots. Infections in mynahs and toucans rarely cause clinical changes unless the birds are maintained in crowded, unsanitary conditions. Clinical disease is occasionally seen in canaries and finches. Coccidiosis is a major cause of enteritis in Columbiformes and Galliformes.

- ***Eimeria and Isospora:*** Two species of *Eimeria* and one of *Isospora* have been described in psittacines (see Figure 36.24). *Eimeria dunsingi* oocysts are ovoid, lack a micropyle and are 26-39 x 22-28 μm. *E. haematodi* has broad ovoid oocysts with a large micropyle and measures 25-40 x 21- 35 μm.[108] *Isospora psittaculae* are round to broadly elliptical and measure 29-33 x 24-29 μm (see Figure 36.26). Sporulated oocysts of *Eimeria* are subdivided into four sporocysts each with two sporozoites, whereas with *Isospora*, the oocysts have two sporocysts each with four sporozoites. *Eimeria* and *Isospora* have direct life cycles. *Isospora canaria* completes its life cycle in the intestines. *E. dunsingi* has been discussed as being pathogenic, but support for this claim is lacking. In general, some cases of coccidiosis are associated with severe clinical disease, while other birds will pass numerous oocysts in the feces and remain asymptomatic.

Isospora is most common in Passeriformes, Psittaciformes and Piciformes, and Eimeria is most common in Galliformes and Columbiformes. Infected birds may be asymptomatic or develop clinical signs of melena, depression, diarrhea, anorexia and death. Direct transmission occurs through ingestion of fecal-contaminated food or water.

- ***Atoxoplasma:*** *Atoxoplasma* spp. may cause disease in canaries and other Passeriformes. Adults are generally asymptomatic carriers that shed oocysts in the feces. Prevalence can be high in young birds during fledging. The *Atoxoplasma* sp. found in House Sparrows was not found to be infectious to canaries, indicating a degree of host specificity.[16,17]

Mortality can approach 80% in juvenile birds between two and nine months of age.[28] Clinical signs are nonspecific including depression, anorexia and diarrhea. Birds less than a year of age are most likely to develop clinical changes.[36,85] Clinical signs may occur in birds that are or are not shedding oocysts in the feces. An enlarged liver and dilated bowel loops can occasionally be observed through the transparent skin (see Color 20). With severe infections, zoite forms of the parasite may be demonstrated in lymphocytes using Romanowsky staining methods (see Color 9).[36]

Atoxoplasma serini has an asexual reproductive cycle in the mononuclear cells, and spreads through the blood to parenchymal organs where it infects reticuloendothelial and intestinal epithelial cells. *Atoxoplasma* spp. may be diagnosed by finding 20.1 x 19.2 μm oocysts in the feces or by demonstrating reddish intracytoplasmic inclusion bodies in mononuclear cells (Giemsa stain). Staining a buffy coat may improve the diagnostic sensitivity of blood smears. Transmission is direct through ingestion of contaminated feces. Canaries have been found to shed for eight months following infection.[36] Infected birds can intermittently shed large numbers of oocysts. Coccidial oocysts are environmentally stable and are not killed by most disinfectants.[85]

In a group of infected canaries, atoxoplasmosis could be identified in impression smears of the heart, liver and pancreas using Giemsa stain. Atoxoplasmosis was the cause of death in two young Bali Mynahs. Oocysts were identified in the feces from young and adult birds in the affected group. Gross lesions in the mynahs included pinpoint white foci in the liver, splenomegaly, a swollen pale nodular pancreas and pericardial effusion (see Color 20).[85]

No effective therapy for atoxoplasmosis has been described, but primaquine has been suggested to suppress the tissue form of the parasite, and sulfachlor-pyrazine may decrease oocyst shedding. *Atoxoplasma* infections may persist for over four months, while *Isospora* infections are usually resolved within several weeks.[36]

- ***Cryptosporidium:*** *Cryptosporidium* are spheroid-to-ovoid protozoa that infect and may cause disease in the mucosal epithelial cells lining the gastrointestinal, respiratory and urinary tracts of birds.[3,42,67] *Cryptosporidium* develop intracellularly at an extracytoplasmic location on the apical surface of epithelial cells. This is in contrast to other coccidia, which replicate in the cytoplasm.[70] *Cryptosporidium* oocysts are the smallest of any coccidia, usually measure 4 to 8 μm in diameter and contain four naked sporozoites.

Cryptosporidiosis has been documented in Galliformes, Anseriformes, Psittaciformes, ostriches, canaries and finches (Table 36.4). Limited data suggest that cryptosporidial infections may be transmitted among closely related species, which should be considered when managing this coccidia in a collection. In the respiratory tract, *Cryptosporidium* may inhibit normal function of the mucociliary elevator, and have been associated with depression, anorexia, rhinitis, conjunctivitis, sinusitis, tracheitis, air sacculitis, coughing, sneezing and dyspnea in gallinaceous birds, ducks, geese and budgerigars. At necropsy, there may be an excessive amount of mucus in the respiratory tree.[42]

Psittaciformes		x	
Finches			x

In the GI tract, *Cryptosporidium* may infect the salivary glands, intestines, colon, cloaca and cloacal bursa, resulting in enteritis (diarrhea) in gallinaceous birds, Amazon parrots, budgerigars, macaws, cockatiels, lovebirds and cockatoos.[10,29,42] Postmortem findings with gastrointestinal cryptosporidiosis may include dilated intestines containing yellowish fluid and blunting fusion and atrophy of intestinal villi.[10] Cryptosporidiosis caused cuboidal metaplasia of glandular epithelium in the proventriculus in a finch that died following an acute onset of diarrhea.[13] Proventricular lesions have also been described in in-

fected canaries.[107] Cryptosporidial renal disease has been described in gallinaceous birds and finches. The kidneys of both birds were enlarged and pale.[42,68]

In some cases *Cryptosporidium* is considered a primary pathogen; however, in most situations it is considered to cause severe infections only in immunocompromised hosts. Suggestive of the opportunistic nature of *Cryptosporidium* was the detection of the parasite in four cockatoos with PBFD virus. In three birds, the parasite remained localized to the epithelium of the cloacal bursa. In the other bird, *Cryptosporidium* was present throughout the large intestines, small intestines and bursa (see Figure 32.16).[65]

Cryptosporidium sp. was identified by Sheather's flotation in 14 of 165 (8.5%) adult ostriches in a quarantine station. The number of parasites varied from a few to several million per gram of feces. There were no clinical signs in any of the birds in which *Cryptosporidium* was identified. *Cryptosporidium* recovered from the ostriches was not infectious to two-day-old chickens inoculated orally. None of the birds in this study had clinical signs of infection, but the possibility exists that *Cryptosporidium* could cause problems in young or immunocompromised birds.[39]

This coccidian parasite can be transmitted through the ingestion or inhalation of sporulated oocysts. The life cycle is direct. *Cryptosporidium* undergoes endogenous sporulation resulting in autoinfection in the parasitized host. As few as 100 oocysts can induce severe enteritis and diarrhea in experimentally infected Bobwhite Quail in the company of reovirus.[50]

Cryptosporidium spp. are sporulated when shed in the feces so the frequent cleaning regimes that are used to control other coccidia are ineffective in preventing exposure to cryptosporidial oocysts. *Cryptosporidium* is resistant to many disinfectants. Formal saline (10%), ammonia (5%) and heating to 65°C for 30 minutes have been suggested as effective control measures for *Cryptosporidium*.[105]

The small size of the organism (4 to 6 μm) and low shedding rate make diagnosis of infection difficult. Diagnosis can be improved by centrifuging diluted feces in a high-concentration salt solution or using Sheather's flotation. Fecal smears stained with Giemsa, carbofuschin or PA Schift stains may be used to demonstrate oocysts. With modified acid-fast stain, *Cryptosporidium* stains pink against a blue background. *Cryptosporidium* oocysts were identified in the feces of budgerigars, parrots and macaws using Auramine 0.[66]

Cryptosporidium spp. that infect birds are different from the species that infect mammals and there is no known zoonotic potential.

- ***Toxoplasma:*** *Toxoplasma* is a coccidian parasite with an indirect life cycle. Toxoplasmosis, causing fatal infections in most species, has been documented in the Red Lory, Swainson's Lorikeet, Regent Parrot, Superb Parrot and Crimson Rosella.[52,57] *Toxoplasma gondii* is considered a ubiquitous organism with a broad host range, and probably could infect any mammalian or avian host. Oocysts produced and passed in the feces of infected cats would be the only source of infection to psittacine birds. Infections may cause congestion and consolidation of the lungs, hepatomegaly, vasculitis and necrotic foci in the lungs, liver and heart.[57]
- ***Sarcocystis:*** Sarcocystis is a coccidian parasite that undergoes sexual multiplication in the intestine of a definitive host. *Sarcocystis falcatula* appears to be restricted to North America and has been associated with acute deaths in a variety of psittacine species. The pathogenicity of sarcocystosis in psittacine birds appears to depend on the species of bird and the infective dose of the parasite.[18] Severe life-threatening infections are most common in Old World Psittaciformes although neonates of New World species may also die following infection. Adult New World Psittaciformes appear to be relatively resistant (Table 36.5). The susceptibility of Old World Psittaciformes and resistance of New World Psittaciformes may reflect a lack of immunity in the former because the definitive host (and presumably the parasite) are not found in the Old World. Infections appear to be more common in the winter months and males appear to be more susceptible than females. There is no apparent age resistance and a bird over 33 years of age died in one outbreak.[23,24,56,82]

TABLE 36.5 Psittacines Confirmed Susceptible to Sarcocystis

African Grey Parrot	Military Macaw
Amazon parrots	Pesquet's Parrot
Blue and Gold Macaw	Port Lincoln Parrot
Budgerigar	Princess Parrot
Cockatiel	Red-capped Parrot
Cockatoo	Red Shining Parrot
Conures (Halfmoon, Patagonian)	Thick-billed Parrot
Eclectus Parrot	White-crowned Pionus
Great-billed Parrot	Tori Parakeet
Green Rosella	
Lories (Red)	

TABLE 36.6 Blood Parasites

Blood Parasite	Location	Some Susceptible Species	Intermediate Host	Clinical Changes
Haemoproteus	Gametocyte in erythrocytes, schizonts in endothelial cells	Anseriformes, Passeriformes, raptors, cockatoos, Columbiformes	Culicoides, louse flies	Rare; anemia (severe infections), reduced stamina in pigeons
Microfilaria	Adults in air sacs, fascial planes, tendon sheaths, pericardial sac	Psittaciformes, raptors	Culicoides, black flies, some lice, mosquitoes	Generally apathogenic, adults (tendinitis in Amazons), Pericarditis in cockatoos, Asphyxiation from occluded capillaries
Trypanosomes	Extracellular in blood	Passeriformes (esp. canaries), Galliformes, Anseriformes, Columbiformes, some Psittaciformes	Louse flies, mosquitoes, black flies	Minimal pathogenicity
Leucocytozoon	Gametocytes in leukocytes or red blood cells	Anseriformes, Galliformes, Passeriformes, Psittaciformes	Black flies, *Culicoides*	Anemia, dyspnea, death (with some species)
Plasmodium	Gametocytes, trophozoites, schizonts in erythrocytes or its precursors	canaries, penguins, Galliformes, Anseriformes, Columbiformes, Psittaciformes		Anemia, dyspnea, weakness, anorexia, death
		Passeriformes (carriers)	Mosquitoes	Asymptomatic, vomiting, anorexia, depression
Atoxoplasma	Sporozoites in lymphocytes and monocytes; schizonts, oocysts, gametocytes in internal organs	Passeriformes	None	Depression, hepatomegaly, diarrhea
Babesia	Erythrocytes		Ticks	Non-pathogenic

Infections are usually peracute; birds may appear normal and healthy one day and be dead the next. Experimentally infected cockatoos were found to die 10 to 14 days after oral inoculation. If clinical signs occur prior to death, they are characterized by severe dyspnea, yellow-pigmented urates and lethargy. Infected birds have been found to have high LDH and AST enzyme activities.[23,24]

Pulmonary edema with hemorrhage is the most consistent sign in birds that die acutely (see Color 22). Splenomegaly and hepatomegaly also are common (see Color 14). Histopathologic findings include diffuse interstitial and exudative pneumonia, reticuloendothelial cell hyperplasia and schizonts or merozoites in the capillary endothelium. The lung is the tissue of choice for diagnosis where schizonts may be noted.[24,58] Rarely, schizonts may be identified in the brain of birds with CNS signs.[56,59] Generally, psittacine birds die before sarcocysts develop in the muscles.

The two-host replication cycle of *S. falcatula* involves sexual reproduction and sporogony in the intestines of the definitive host (opossum) with passage of infectious sporulated oocysts or sporocysts in the feces. Following ingestion of the sporocysts, asexual reproduction with schizogony and sarcocyst formation occur in the intermediate host (psittacine birds).[101] The ingested sporozoites invade intestinal mucosa followed by infection of numerous tissues and schizogony in the reticuloendothelial cells, particularly in the lungs. Asexual reproduction then occurs in the walls of arterioles (first cycle) and capillary and venule walls (second cycle). These replication cycles can cause occlusion of the affected vessels resulting in the fatal lesions characteristic of infections in Old World Psittaciformes.

In a normal infectivity cycle, the intermediate host survives schizogony in the vascular endothelium and mature cysts containing bradyzoites are subsequently formed in striated (skeletal or cardiac) muscles. In Old World Psittaciformes, infections usually cause fatal vascular changes before cysts are formed. Schizogony in the vascular endothelium of experimentally infected budgerigars was found to cause death by occlusion of the vessels secondary to endothelial hypertrophy, schizont formation and endophlebitis.

In adult New World Psittaciformes, the merozoites produced through asexual reproduction are trans-

ported via the circulatory system to striated muscles where they undergo further reproduction in sarcocysts (270 x 37 μm). Old World psittacines that survive schizogony in the endothelium of the lungs have been found to develop cysts ten weeks post-infection.[18] *Sarcocystis* also infects Passeriformes and Columbiformes, where cockroaches and flies can serve as transport hosts.

Psittacine birds in outdoor facilities throughout the range of the opossum are at risk. Infected opossums can shed sporocysts in the feces for 100 days. Cockroaches can serve as transport hosts by eating infected opossum feces and being consumed by susceptible birds.[24,56,100] Prevention requires fencing to prevent access of opossums to the aviary. Flightless chickens have been suggested as a method of controlling cockroaches within a compound (see Chapter 2).

Sarcocystis was responsible for the deaths of 37 Old World Psittaciformes in a zoologic collection over a 15-month period. Lories, cockatoos, Pesquet's Parrot, Port Lincoln Parrot, lorikeets, Princess Parrot and rosellas were included in the affected group. About half of the birds developed clinical signs prior to death, while the other birds died with no premonitory signs. When clinical signs occurred, they included anorexia, diarrhea, weakness, tachypnea, ataxia, posterior paresis, head tilt and dyspnea prior to death. Some birds had clinical signs that lasted several hours while others had clinical signs that progressed over a 52-day period. Characteristic necropsy findings included pulmonary hemorrhage, spleno-megaly and hepatomegaly.[56]

In a zoologic collection, five Eclectus Parrots and four Hispaniolan Amazon Parrots were diagnosed with sarcocystosis over a six-month period. Four of the Eclectus and two of the Amazon parrots died. Elevations in CPK, AST and LDH enzyme activities were noted in all the affected birds. Clinical signs included weakness, dyspnea and blood in the oral cavity. Affected birds died one to 36 hours after presentation. Radiographic findings indicated an increased lung field density, hepatomegaly, splenomegaly and renomegaly. Some birds that were only slightly lethargic and had no other clinical signs survived following treatment with 0.5 mg/kg pyrimethanamine PO BID and 30 mg/kg trimethoprim-sulfadiazine IM BID for 30 days. The surviving birds responded to therapy with improved attitude, appetite and decreased serum enzyme activity. Muscle biopsies after treatment revealed multifocal myositis and sarcocysts, indicating that the birds had survived the schizogony phase of the infection allowing muscle cysts to form.[81]

Encephalitozoon sp. is a microsporidian parasite with a broad host range that includes mammals and birds. This parasite has complex spores measuring 1.5 x 1.0 μm and containing a coiled polar filament. The latter will be seen only with the aid of electron microscopy. Lovebirds of the genus *Agapornis* are frequently infected,[93] but an Amazon parrot with a microsporidian infection has also been reported.[69,90] The spores were documented in kidney tubules, lung, liver and the lamina propria of the small intestine.[69,89]

Few birds have been reported with this parasite and all cases were detected at necropsy. One report gave the details of a die-off of 140 lovebirds in Great Britain in which the birds were moved to a different facility, stopped eating and lost condition.

An infected Amazon parrot developed progressive anorexia, weight loss, respiratory disease and diarrhea over a one-month period. Postmortem findings included pale, swollen kidneys and an enlarged, mottled liver. Kidney tubular epithelial cells were filled with tiny spores, as were epithelial cells in the liver and small intestine. Histologic changes were characterized by multifocal nephritis, hepatitis and enteritis.

Hemoparasites

Haemosporidian parasites have been detected in parrots being imported into England and Japan.[78,86,88] *Haemoproteus* was commonly seen in imported Psittaciformes[12,96] and *Haemoproteus* and *Leucocytozoon* were detected in free-ranging birds in southeast Asia.[71] It is unknown what role, if any, that flies indigenous to North America could play in transmitting the species of *Haemoproteus* or *Leucocytozoon* that occur in birds from other geographic regions. The sexual phase and a form of asexual reproduction occur in biting flies, resulting in the production of sporozoites that localize in the salivary glands and are inoculated into the avian host. Asexual reproduction also occurs in an infected bird.

- ***Haemoproteus:*** Under normal circumstances, species of *Haemoproteus* are considered nonpathogenic and a few species of *Leucocytozoon* and *Plasmodium* are considered pathogenic. If clinical signs occur, they are associated with anemia, splenomegaly, hepatomegaly and pulmonary edema. The lymphoid-macrophage system becomes hyperplastic. High parasitemias of apathogenic *Haemoproteus* and *Leucocytozoon* can cause clinical problems if a bird is stressed or immunosuppressed. Racing pigeons in-

fected with *H. columbae* are frequently discussed as performing poorly in comparison to uninfected birds.

Haemoproteus spp. are the most commonly occurring avian blood parasite; they use *Culicoides* (biting midges or punkies) or louse flies as vectors. In some studies, up to 50% of recently imported cockatoos were found to be positive. In contrast, only 5% of long-term captive cockatoos were found to have *Haemoproteus*.[25] In a survey of 81 African Grey Parrots, 5.7 % had *Haemoproteus*.[96] Most infected birds are subclinical but severe infections in stressed birds may lead to life-threatening anemia. Infections may be potentiated by concurrent disease or stress.

H. handai gametocytes completely encircle the red blood cell nucleus.[12] Initial parasite development occurs in endothelial or skeletal muscle cells followed by the production of pigmented gametocytes in RBCs (see Color 9). Some European dieoffs of psittacine birds that were attributed to *Leucocytozoon* were probably caused by *Haemoproteus*. In Roseate Parakeets infected with sporozoites of *H. handai*, large schizonts developed in the skeletal muscles.[73] In another study with *H. meleagridis* in turkeys, it was demonstrated that development of large schizonts occurred following inoculation of sporozoites.[5]

- ***Leucocytozoon:*** *Leucocytozoon* spp. use Simuliidae (black flies) as vectors. Initial development occurs in the liver and spleen followed by the development of unpigmented gametocytes in white blood cells or RBCs, depending upon the species (see Color 9). Infected host cells are distorted beyond recognition. Although there have been occasional reports of *Leucocytozoon* on blood films taken from psittacine birds, much of the emphasis on this genus in the European literature is based on finding megaloschizonts in muscles of birds that have presumably died as a result of the infection.[41,103] No one has reported blood stages that are more definitive for generic identification, although the birds may have died prior to the development of gametocytes. These deaths probably resulted due to infections of *Haemoproteus*, not *Leucocytozoon*.

Leucocytozoon has a seasonal incidence in the wild with parasitemia being highest in the spring. Following infection, high numbers of the parasite may be detected in the blood within four to nine days. The parasite produces an anti-erythrocytic factor, which causes intravascular hemolysis and anemia, the principal clinical sign. *Leucocytozoon* is highly pathogenic in young Anseriformes and Galliformes.[45] Fatal infections have been described in budgerigars. Hepatomegaly, splenomegaly, pulmonary congestion and pericardial effusion are the most characteristic gross findings. Pyrimethamine has been suggested for treatment.

- ***Plasmodium:*** *Plasmodium* spp. use mosquitoes as vectors. Initial parasite development occurs in the avian reticuloendothelial system followed by the development of pigmented schizonts and gametocytes in the erythrocytes (RBCs) (see Color 9). Schizogony occurs in the erythrocytes, which means that blood-to-blood transfer, without an intermediate host, can result in an infection.

Plasmodium spp. have been described in a number of companion and aviary birds. Species of *Plasmodium* are most likely to occur in an avicultural setting because it has the widest host range of all the haemosporidian parasites. Apathogenic strains of *Plasmodium* may cause asymptomatic infections in cockatoos and passerine birds. Some Passeriformes serve as asymptomatic carriers. Some strains of *Plasmodium* are highly pathogenic in canaries, penguins, Galliformes, Anseriformes, Columbiformes and falcons. Clinical signs are most common in recently infected birds and are characterized by anorexia, depression, vomiting and dyspnea for a few hours or days prior to death. In penguins, depression, anemia, vomiting, seizures and high levels of mortality may be noted.[34] Nonpathogenic strains of *Plasmodium* have also been described in many of these same avian orders.

Six species of *Plasmodium* and one of *Haemoproteus* have been reported from Psittacidae.[11] *P. relictum* is a large species that is round as both gametocytes and schizonts (8 to 24 merozoites) and displaces the RBC nucleus toward the pole. *P. nucleophilum* is a small form with elongate, amoeboid gametocytes, which along with small schizonts (4 to 8 merozoites), tightly adhere to the RBC nucleus. *P. vaughani* is another small species with amoeboid gametocytes; the merozoites (4 to 8 per schizont) of schizonts appear to lack cytoplasm, and neither stage clings to the RBC nucleus. *P. dissanaike* has larger elongate gametocytes that fill the lateral cytoplasm of the RBC and its small schizonts (4 to 12 merozoites) may adhere to the RBC nucleus. *P. circumflexum* has large halteridial gametocytes that usually wrap around the ends of the host cell nucleus and fill most of the RBC cytoplasm. Its schizonts are larger than the RBC nucleus and contain 6 to 30 merozoites, which are arranged in a halter around the RBC nucleus. *P. polare* has variable gametocytes, but they often are

halteridial or at least the length of the RBC. The schizonts are usually in a polar position and are irregular, round or fan-shaped with 8 to 14 merozoites.

- ***Trypanosoma:*** *Trypanosoma johnbakeri* is an extracellular, flagellated blood parasite that is transmitted by a biting midge and has been demonstrated in Roseate Parakeets, but has not been associated with clinical signs.[74] In one study, trypanosomes were identified in 14% of imported Hyacinth Macaws, and 20% of imported Green-winged Macaws examined.[25]

Helminths

Flatworms

Flatworms include digenetic flukes and tapeworms. Flukes found in psittacine birds may reside in the liver (*Platynosomum*, *Lyperosomum, Dicrocoelium* and *Brachylecithum*) or in the blood vasculature (a schistosome believed to be *Gigantobilharzia*). Tapeworms live in the small intestine (*Triuterina, Biporouterina, Cotugnia* and *Raillietina*).

- ***Flukes:*** Flukes living in the bile ducts are members of the family Dicrocoelidae. All of the cases reported in North America have probably occurred in imported birds (Old World species) that were infected by endemic species in their country of origin. Birds may be infected by eating an arthropod, which serves as a second intermediate host. Liver flukes have rarely been demonstrated in New World Psittaciformes, even though there are a number of genera that occur in North American avifauna. Clinical changes associated with liver fluke infections include hepatomegaly, depression, anorexia, mild anemia, weight loss, diarrhea, hepatic necrosis, elevated liver enzymes and death.[61,64,92] There is a single case reported of a schistosome in a Nanday Conure that died after showing weight loss, anorexia and blood-tinged diarrhea.[48] Histologic evidence of colitis and cloacitis was present along with an epithelial hyperplasia of the lower gut.

  Hepatic trematodiasis has been reported in cockatoos. Numerous trematode eggs were seen on direct smears of the feces. Necropsy findings were primarily limited to the liver and were characterized by hepatomegaly, increased firmness, numerous streaks, brown and yellow mottling and fibrosis. In some birds, trematodes were found in dilated bile ducts. Histologic lesions were characterized by hepatic fibrosis and bile duct hyperplasia. Clinical improvement following treatment with fenbendazole and praziquantel was minimal; however, the number of eggs per gram of feces did decrease dramatically following therapy.[92] Biliary cholestasis and cystic dilatation have also been described in birds with trematodiasis.[77] Schistomiasis can cause heavy motility in free-ranging Anseriformes.[111,112]

- ***Tapeworms:*** Tapeworms infecting psittacine birds[27,72] can be asymptomatic or the parasite may steal nutrients from the host causing a bird to appear unthrifty and have diarrhea (see Figure 36.28). Infections are most common in finches, African Grey Parrots (15 to 20% of imported birds), cockatoos (10 to 20% of imported birds) and Eclectus Parrots.[22,95] Infections occasionally occur in South American Psittaciformes. Eosinophilia has been discussed as a clinical change associated with tapeworm infections. However, there has been no direct relationship demonstrated between parasitism and eosinophilia in birds. In general, infections are nonpathogenic although large numbers of worms can cause impaction. With severe infections, birds may die following a period of weight loss and diarrhea.

  Tapeworms require intermediate hosts, and infections are uncommon in birds that do not have access to the ground. Either proglottids or whole worms may be noted in the feces. Eggs of *Triuterina* and *Biporouterina* are single whereas those of *Raillietina* and *Cotugnia* are passed in clusters encased in a mucilaginous material. Focusing through the individual rounded eggs to see the hooks on the hexacanth larva may be necessary to demonstrate that these are tapeworm eggs. Infections may not be detected during routine fecal exams unless a proglottid present in the feces has ruptured. The eggs contain six hooks on oncosphere and hexacanth larvae.

Roundworms

Roundworms (nematodes) are more diversified than flatworms and live in the small intestine (*Ascaridia, Ascarops* and *Capillaria*), proventriculus and ventriculus (*Microtetrameres, Procyrnea* and *Ascarops*),[33,37] the surface of the eye (*Thelazia, Oxyspirura, Ceratospira* and *Annulospira*) and in subcutaneous regions, body cavity and air sacs (*Eulimdana, Pelecitus, Cardiofilaria* and *Cyathospira*).

- ***Ascarids:*** Ascarids are the most common parasite found in birds that are maintained in enclosures with access to ground. Infections are particularly common in budgerigars and cockatiels. Species that infect psittacine birds include *Ascaridia columbae* (shared with pigeons), *A. galli* (shared with gallinaceous birds)[87] and *A. platycerci*,[76] which is restricted thus

far to Psittaciformes. While there are other species described, their validity is questionable.[53,75,76]

The direct life cycle requires a two- to three-week period for embryonated larva to form within the egg, which is viable for extended periods in moist warm environments. The eggs are resistant to disinfectants but can be controlled with steam or flaming. The ingested larvae infect the intestinal mucosa. Mild infections can cause malabsorption, weight loss, anorexia, growth abnormalities and diarrhea. Heavier parasite loads may cause intussusception, bowel occlusion or death (Figure 36.30).

Providing a dry clean environment will decrease the possibility that eggs will survive to embryonate. Piperazine, pyrantel pamoate and fenbendazole may be effective in resolving infections.

Cerebrospinal nematodiasis caused by larvae from *Baylisascaris procyonis* (raccoon ascarids) has been reported in gallinaceous birds, cockatiels, ratites and several Passeriformes.[4,80] Infective eggs are ingested by the bird; the larvae are digested free from their eggs, where they penetrate the intestinal wall and begin migrating through the tissues. They do not mature and continue to migrate in a form of visceral larval migrans. When they enter the central nervous system, the larvae induce considerable damage leading to ataxia, torticollis, depression and death.[4]

In a group of mixed macaws, seven of ten potentially exposed birds developed ataxia, torticollis and depression after being placed in contact with raccoons. *B. procyonis* larvae were identified in the cerebrospinal tissue of 6 of the birds. The earliest clinical signs developed 35 days after potential exposure to the raccoons. Other birds developed clinical signs over a nine-month period. Some birds developed lesions 7.5 months after being removed from any exposure to the parasite.[22] An ostrich and two emus developed progressive ataxia (two to three weeks) and eventually died. Necropsy findings included multifocal encephalomalacia of the brain stem and cerebellum caused by *Baylisascaris* larvae. Infective eggs were recovered from the ground of the ostrich pen.[62,63]

Because no diagnostic stages of the parasite are released to the environment, and no commercially available serological diagnostic kit is available, this parasite is normally diagnosed histologically at necropsy. The best means of control is to prevent access of free-ranging raccoons to aviaries, and thus prevent contamination of the environment by these thick-walled and long-lived eggs.

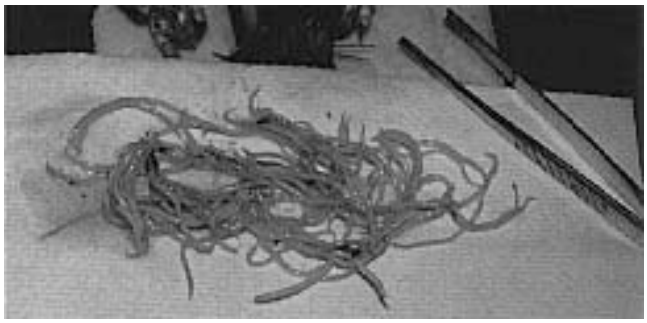

FIG 36.30 A two-year-old Severe Macaw was presented with vomiting, diarrhea and chronic weight loss, even though the bird had a voracious appetite. The bird had lost most of its pectoral muscle mass (weight 230 g), and had a distended abdomen. Radiographs indicated enlarged bowel loops, diffusely filled with linear soft tissue densities. A fecal exam revealed thousands of ascarid eggs. The bird did not respond to supportive care. This bird was maintained in a mixed species outdoor exhibit with access to the ground. Intestinal nematodes are rare in companion birds maintained indoors and in aviary birds maintained in suspended enclosures.

Ascarids in the genus *Heterakis* can infect the ceca of gallinaceous birds, Anseriformes and other birds. Nodular lesions consisting of fibrotic and granuloma-

tous tissue may develop in the submucosa of the ceca, particularly in pheasants (see Color 14). The life cycle is direct following ingestion of embryonated ova. In some species (quail), infections are subclinical, while other affected birds can die from complications associated with the mucosal and submucosal lesions.

- ***Capillaria:*** Species of *Capillaria* are tiny thread-like nematodes that may infect the gastrointestinal tract of most species of companion and aviary birds.[22,109] Infections appear to be most common in macaws, budgerigars, canaries, pigeons and gallinaceous birds. Severe infections can cause diarrhea (which may contain blood), weight loss, anorexia, vomiting and anemia.[22] Little has been published on these worms as to the species present or their true influence on these birds; the clinical effects are not severe. Species of this genus in other birds are profound pathogens when they reside in the upper digestive tract, particularly in gallinaceous birds. The life cycle of *Capillaria* is direct.

  Embryonation requires approximately two weeks, and eggs can remain infectious in the environment for several months. The adults can burrow into the mucosa of the esophagus, crop or intestinal tract causing depression, dysphagia, regurgitation, diarrhea, melena and weight loss. *Capillaria* that infect the crop, esophagus and oral cavity burrow into the mucosa, creating tracts that may fill with blood, producing hyperemic streaks. Frank hemorrhage may occur in the upper intestinal tract in heavily parasitized animals. Diphtheritic lesions may occur in the mouth, pharynx, esophagus and crop of some infected species.

  Scrapings of suspect lesions or fecal flotation can be used to detect the characteristic bipolar eggs (see Figure 36.18). Magnification may be necessary to see the adults.

- ***Spiruroidea:*** The superfamily Spiruroidea represents the most diversified group of nematodes in birds. Little on the biology and pathology of these nematodes is known, but the life cycle probably involves an insect intermediate host. *Ascarops* sp. has been recovered from the intestines of a Greater Sulphur-crested Cockatoo and *A. psittaculai* was described in a Rose-ringed Parakeet.[102,110] *Procyrnea kea* was described from the New Zealand Kea where it lives under the koilin of the ventriculus.[20] *Microtetratmeres nestoris* was found in the proventriculus of the North Island Kaka where it caused hyperplasia and metaplasia of the duct epithelium, glandular atrophy and limited necrosis and hemorrhage.[21]

  Four genera of eyeworms (*Thelazia* and *Ceratospira*) have been reported (see Color 26).[2,19,66,106] The intermediate host is considered to be the fly. Eyelid spasms and mild conjunctival hyperemia were evident in a Senegal Parrot with *Thelazia* even though only three adults were recovered. The worms were removed after they were incapacitated with 0.125% demecarium bromide.[19] In contrast, no pathology was associated with numerous *Ceratospira* infecting a Moluccan Cockatoo. *Thelazia digitata* has been recovered from the eye of several macaws.[2] *Annulospira* has been removed from the eye orbits of a Rose-ringed Parakeet.[60]

  Oxyspirura sp. is common in the eye of cockatoos where it resides beneath the nictitating membrane or in the conjunctival sac. Severe infections may cause conjunctivitis, chemosis and scratching at the eye. The eyelids may close due to the accumulation of caseous debris. The parasite has an indirect life cycle that involves an arthropod (cockroach) intermediate host. Ivermectin can be used to kill the worms, which are then removed by flushing.

  Streptocara spp. are pathogenic spiruroids that burrow into the mucosa of the esophagus, crop, proventriculus and ventriculus, principally in Anseriformes. Crustaceans serve as an intermediate host. In severe infections, diaphoretic esophagitis or gastritis associated with ulceration and frank hemorrhage may occur.

  Spiroptera incerta and *Dispharynx nasuta* have been reported in association with thickening of the proventricular mucosa in a number of Psittaciformes (see Color 19). The adult worms burrow into the proventriculus causing ulcers, inflammation and nodule formation. The proliferative mucosa may prevent the passage of ingesta resulting in chronic vomiting and weight loss (Figure 36.31).

  A large-mouthed worm (*Cyathostoma cacatua*) related to gapeworms has been reported from the air sacs of a Sulphur-crested Cockatoo.[14] Lungs from infected birds were consolidated, had extensive necrosis and caseation and contained bacteria and many parasite eggs.

- ***Syngamus:*** *Syngamus trachea* (gapeworm) has been diagnosed in many species of companion and aviary birds. Infections are rare in companion birds but are common in Galliformes and Anseriformes (Figure 36.32). The red Y-shaped adult parasite can be visu-

alized on the mucosa of the trachea and primary bronchi. Adult birds are generally resistant and most infections occur in young birds. Coughing, open-mouthed breathing, dried blood at the beak commissure, dyspnea and head shaking are common. With severe infections, death can occur secondary to tracheal ulceration, anemia and asphyxiation. The eggs of the parasite can be detected in the feces. The life cycle is direct but earthworms can serve as a transport host. Thiabendazole has been recommended for treatment. Ivermectin can be used to kill the parasites and they can be mechanically removed by repeated transtracheal washes.

- ***Filariidea:*** The filariid nematodes have indirect life cycles and are transmitted to birds by blood-feeding diptera. A recent key to the genera of adult filarial worms has been published.[7] The diagnostic stage of these worms is the microfilaria and in most cases, the microfilariae have not been matched to the adults. The adults live in the body cavity, chambers of the eyes, heart or air sacs (Figure 36.33). Species of *Pelecitus*, *Chandlerella*, *Cardiofilaria* and *Eulimdana* occur in psittacine birds. Adult *Pelecitus* reside in subcutaneous tissues causing masses, typically on the legs and feet.[1,47] A taxonomic revision of the genus *Pelecitus* has been made.[8] Other filariae have been documented in psitticines, but nothing has been discussed about known or potential pathogenesis.[9,26]

Microfilariae were at one time considered common in the peripheral blood of Passeriformes and Psittaciformes with the incidence in imported cockatoos being particularly high (up to 45%). By comparison, only six percent of imported non-cockatoo psittacine birds were found to have microfilariae in one study.[25] Many cockatoos with microfilariae are also found to be infected with *Haemoproteus*. Microfilariae are easiest to detect by examining the buffy coat on a hematocrit tube. Microfilariae exhibit periodicity and several blood tests may be necessary to demonstrate the parasites.

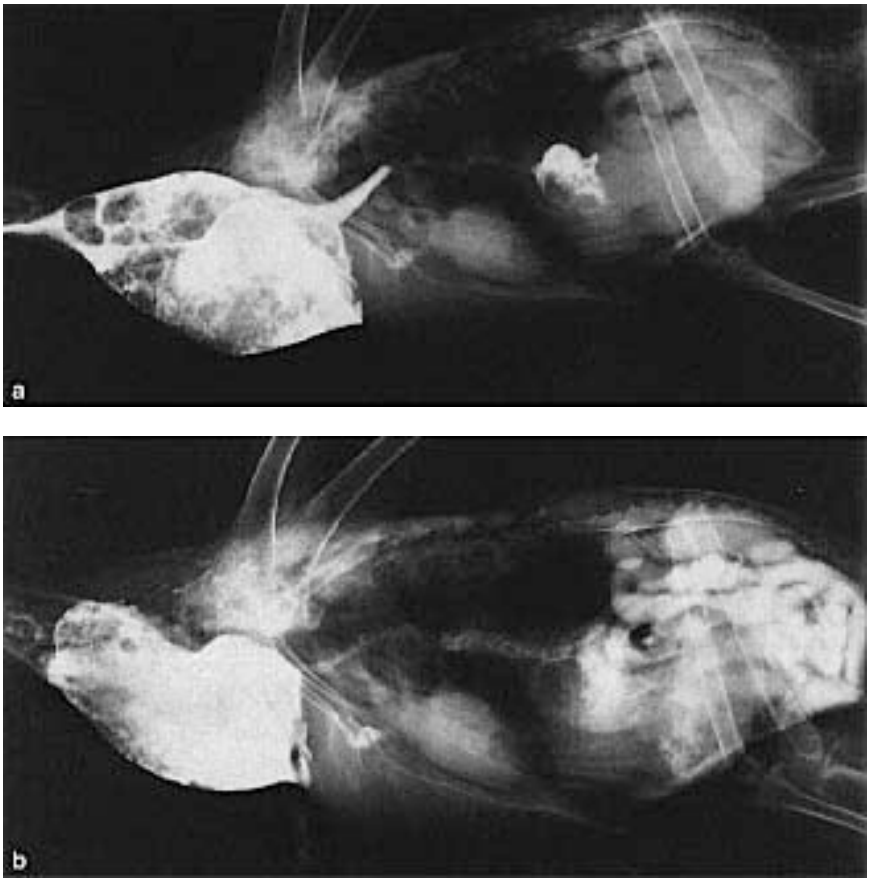

FIG 36.31 A mature Umbrella Cockatoo was presented with a history of progressive weight loss of one month's duration. The bird had been vomiting for a week before presentation. Survey radiographs indicated a thickened proventriculus. Contrast medium was instilled into the crop and indicated a thickened proventricular mucosa and slowed gastric emptying time: **a)** at 20 minutes; **b)** at six hours. Note the small heart (suggestive of severe dehydration) and microhepatia. The client chose euthanasia. At necropsy, the proventricular mucosa was ulcerated and inflamed and had numerous nodules. *Spiroptera* eggs were identified in proventricular washings.

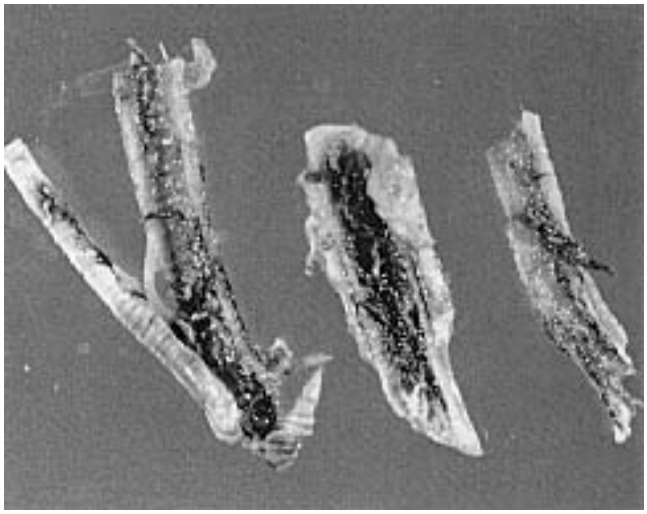

FIG 36.32 *Syngamus* spp. are seen in the trachea of a duck. Note the hemorrhage and accumulation of necrotic debris associated with the parasites (courtesy of Robert Schmidt).

FIG 36.33 Uncharacterized filariid nematodes (open arrow) were found in the air sacs of a free-ranging Barn Owl that died from a gunshot wound. The air sacs were clear and appeared to be unaffected by the parasites. A loop of bowel (arrow) is also evident.

The adults primarily inhabit the air sacs but may also occur in the joints, subcutaneous tissue and pericardial sac. In most situations, the adults and microfilariae are considered apathogenic; however, filarial worms in the joints and subcutaneous tissues can cause severe problems and should be removed (Figure 36.34).

Adult filarial worms filling the pericardial sac of a Red-vented Cockatoo caused death.[22] An Umbrella Cockatoo with a one-week history of anorexia, ataxia, diarrhea and increased vocalization was found at necropsy to have microfilariae in the small vessels of the brain, lungs, kidneys, spleen, heart and liver. Adult filariae were identified in the vena cava.[55] Adult filariae were found in the heart of a recently imported Ducorp's Cockatoo with PBFD (see Color 14).

Arthropods

Hematophagous diptera including mosquitoes, black flies and biting midges can feed on psittacine birds and transmit blood parasites. Direct effects of these parasites may include anemia, which is particularly common in neonates during the rainy season in South Florida (see Color 24).

Biting lice known to occur on psittacines include *Neopsittaconirmus*, *Psittaconirmus*, *Eomenopon* and *Pacifimenopon*. Lice may cause pruritus and poor feather condition. The parasites can be observed directly, or the nits (eggs) can be seen attached to the feathers (see Figure 48.21). Most species are host specific and die quickly when they leave a host. Dusting with pyrethrin can control infections. Because many of the parrots and their relatives have not been examined for lice, there are probably many more species that have not been characterized.[90,91]

- ***Mites and Fleas:*** Numerous mites have been detected on and in psittacine birds. The scaly leg and face mite, *Knemidokoptes pilae*, is the most fre-

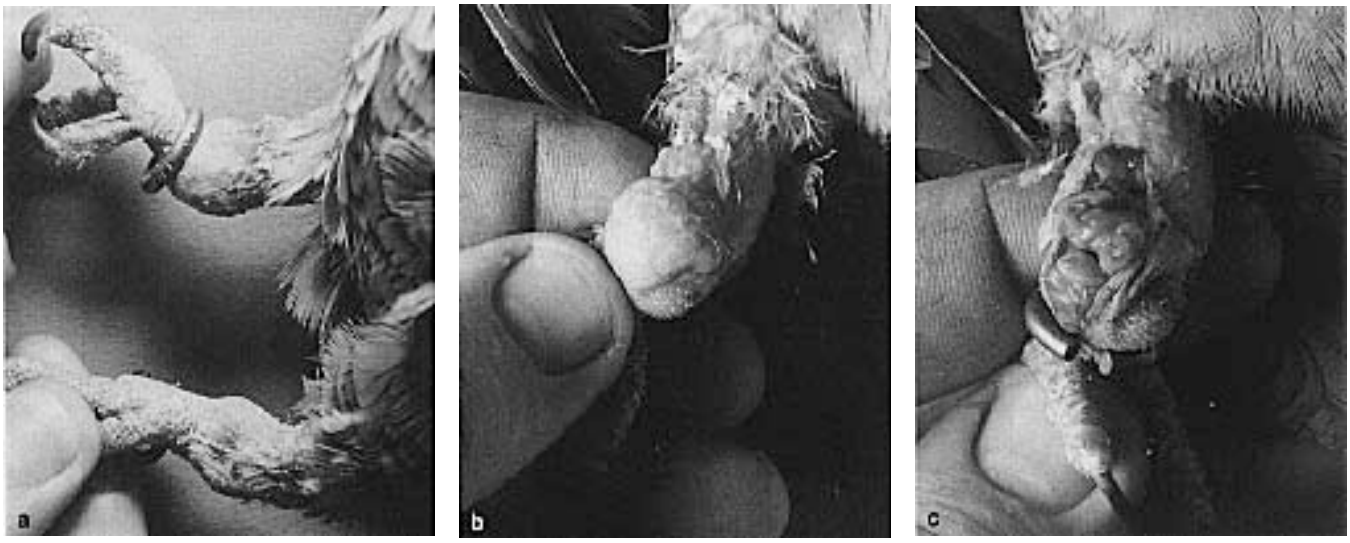

FIG 36.34 **a)** A Tucamon Amazon Parrot was presented with a history of bilateral, flocculent swellings of the metatarsal area. **b)** There were no clinical indications of discomfort or dysfunction associated with the masses. A fine-needle aspirate of the swelling revealed microfilaria. **c)** The masses were incised and numerous adult filariid worms (*Pelecitus* sp.) were removed.

quently diagnosed and causes prominent and disfiguring lesions (see Color 24).[98,113] Infections are most common in budgerigars, but they may also occur in other Psittaciformes and Passeriformes. Typically, there is a proliferation of tissue on the beak. Lesions may also occur on the feet, legs and cloaca in some birds (see Color 24). Tunnels in the proliferative tissue create a characteristic honey-combed appearance. The mites can be detected by examining skin scrapings. Using an operating microscope, the adult females can be observed in the tunnels. Histologically there will be shallow burrows in which the adults will be stationed near the entrance.

Young birds are commonly affected, but adults may be infected in some situations. A genetic predisposition to develop *Knemidokoptes* infections has been suggested because only a few birds in a group may be infected. A selective immunosuppression may also be a predisposing factor, but has not been documented. In canaries, *Knemidokoptes* infections on the feet and legs may cause large proliferative masses frequently referred to as "tassel-foot" (see Color 24). *Knemidokoptes* and giardiasis are most commonly seen in inbred birds suggesting a genetic immunosuppression. Epidermoptid mites may cause hyperkeratosis, hypouricemia and feather loss. Infections are most common around the head and neck and appear to be severely pruritic.

A species of *Knemidokoptes* mite that is morphologically distinct from *K. pilae* and *K. laeris* was recovered from several groups of Red-fronted Parakeets with feather loss. The featherless skin was hyperemic and feather loss was prominent on the head and neck. The mites were identified by microscopic examination of material collected from the thickened calamus. Mites were identified in adult and immature birds but only the adults developed clinical signs.[99] Treatment consisted of two drops of a 1:20 dilution of 1% moxydectin topically on the neck.

Sternostoma tracheacolum can infect the trachea of canaries, finches (especially Lady Gouldians), parakeets and cockatiels. The larva, nymph and adult forms of the parasite can be found in the respiratory tract of affected birds, suggesting that the entire life cycle occurs in the infected host. Clinical signs include dyspnea, coughing and sneezing. Nasal discharge and open-mouthed breathing may also be

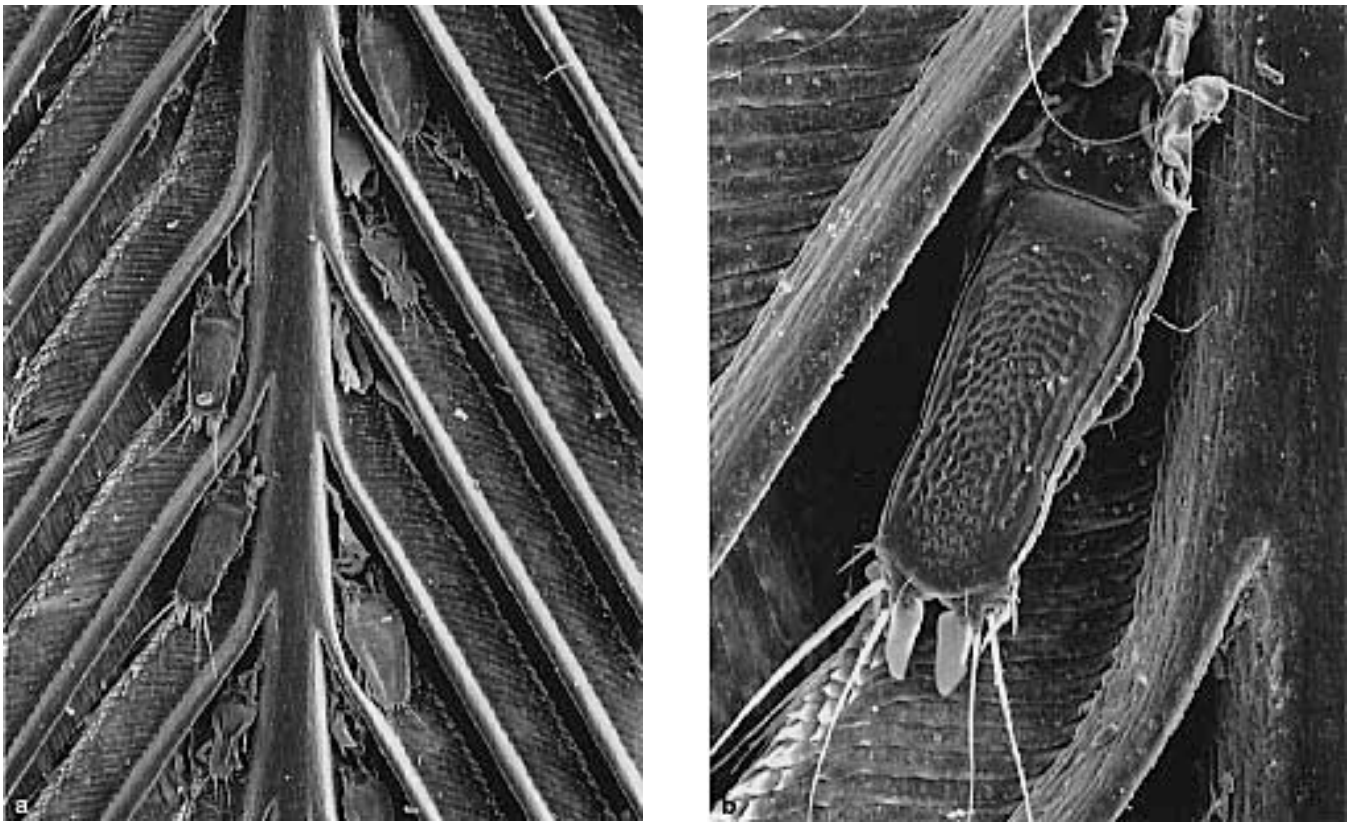

FIG 36.35 *Aralichus elongatus* mites on the ventral surface of the feathers of a White-capped Parrot. **a)** Males, females and exuvia. Note the structure of the rachis, barbules and barbs. **b)** Male (courtesy of W. T. Atyeo).

noted. Infections can be mild to severe with resulting death by asphyxiation. These small black mites can be identified by transillumination of the trachea, or the eggs can be identified in the feces or following a transtracheal wash. Young birds may be infected when being fed by infected parents. The incubation period in Gouldian Finches is three weeks but may be months in other species. Mite-free Society Finches can be used to cross-foster Gouldian Finches to produce mite-free flocks.[35]

Numerous feather mites have been described in birds (Figures 36.35 and 36.36). Six species have been described in African Psittaciformes and three to four species have been described in Australian Psittaciformes. Fifteen species of feather mites have been described in New World Psittaciformes. Feather mites have highly specific microhabitats, infecting specific portions of the feathers. In general, feather mites are apathogenic in their host-adapted species, but can cause clinical problems in non-host adapted species, or with heavy infestations when the mites move from the feathers to the skin.

As an example of the highly specialized nature of feather mites, two species that frequently infect budgerigars were studied. *Prolichns* spp. were found to live on the exposed surfaces of the wing and tail feathers, while *Dubininia* spp. lived on the small body feathers.[6]

Myialges (*Metamicrolichus nudus*) were demonstrated in a Grey-cheeked Parakeet with sinusitis, weight loss, pruritic dermatitis and feather loss of the head. The skin was hyperkeratotic (several millimeters thick), and the parasite was demonstrated in pits within the stratum corneum and feather cavity. The females of this parasite generally attach to the exoskeleton of lice or hippoboscid flies for oviposition. The source of infection in this bird was undetermined.[49]

Myialges was diagnosed by finding eggs in a skin scraping taken from an Amazon parrot with a one-week history of scratching around the eyes. The skin around the lores was dry and flaky and the head, cere and lore area appeared to be pruritic. Ivermectin was effective in controlling the infection.[94]

FIG 36.36 *Rhytidelasma gaud* from an *Aratinga* sp.; **a)** Nymphs. **b)** Cast skins (exuvia). Note the barbicels of the feather (courtesy of W.T. Atyeo).

Nonhost-specific fleas are occasionally noted in companion and aviary birds. If they cause clinical problems (eg, pruritus, anemia, poor feather condition) they can be controlled with a light dusting of pyrethrin powder. The mite protectors sold in most pet supply stores have no effect on common external avian parasites and may cause liver disease. The use of these products is discouraged.

Other mites that have been associated with occasional skin or feather disease in birds include: *Dermanyssus* spp. (red mites), *Ornithonyssus* spp. (fowl mites), *K. laevis* (depluming mite), epidermoptoid mites and quill mites (*Syringophilus* spp., *Dermotoglyphus* spp., *Pterolichus* spp. and *Analges* spp.). *Dermanyssus* feed on blood and may cause anemia, pruritus and poor growth in young birds. They infect the bird only at night and spend the daytime in crevices within the aviary. Under magnification, they can be recognized as rapidly moving dark brown spots. Free-ranging birds can serve as a source of infestation and should not be allowed to nest or roost in the aviary. *Ornithonyssus* can cause problems similar to those seen with *Dermanyssus*. This parasite completes its life cycle on the bird. Dusting with pyrethrin should be effective for controlling the mites. Quill mites may cause damage to developing feathers. The mites can be demonstrated by examining the pulp material within a developing feather.

CHAPTER

37

TOXINS

Genevieve Dumonceaux
Greg J. Harrison

Birds are curious pets and frequently investigate unusual textures, containers and locations throughout the home. Many of the items that birds may encounter during these quests can be dangerous. Contact with or consumption of certain plants, cleaners, pesticides and household disinfectants may cause acute or chronic intoxication. Even some types of foods provided to birds can be toxic.

Most compounds considered toxic to mammals should also be considered toxic to birds. Table 37.1 offers a guide for treatment of intoxication from some common household products. Based on their size and physiology, birds are more prone than mammals to intoxication by some compounds, such as volatile chemicals and fumes. Psittaciformes have a propensity to chew on almost anything. All avian clients should "bird-proof" their homes to provide a safe and enjoyable environment for their companion birds.

Birds should be supervised at all times when out of their enclosures. It has been suggested that the consumption of foreign bodies (eg, metal, wood, jewelry), over-consumption of grit and coprophagy may all be mediated by malnutrition (Gerlach H, unpublished). Therefore, birds on a formulated diet would be expected to chew less on plants, perches and toys than birds on a seed-based diet.

TABLE 37.1 Normal Household Compounds That May be Toxic to Birds

Agent	Toxic Components	Clinical Effects	Therapy
Bleaches, pool chemicals	Chlorine	Photophobia, epiphora, coughing, sneezing, hyperventilation, GI irritation or ulceration	Dilution with water or milk orally. Irrigate skin with cool water. GI protectant, demulcent
Cleaning agents, accumulated excrement	Ammonia	Respiratory tract irritation, immune suppression	Fresh air, antibiotics, supportive care
Combustion exhaust (autos, furnaces)	Carbon monoxide	Somnolence, depression, cyanosis, death	Fresh air, oxygen, warmth, support
Denture cleaners	Sodium perborate	Direct irritation, salivation, lacrimation, vomiting, sometimes CNS depression	Irrigate with water, GI protectant, demulcent
Deodorants	Aluminum chloride, aluminum chlorhydrate	Oral irritation and necrosis, hemorrhagic gastroenteritis, incoordination and nephrosis	Careful lavage of crop and proventriculus
Detergents (anionic)	Sulfonated or phosphorylated forms, alkaline product	Dermal irritation, vomiting, diarrhea, GI distension, usually not fatal	Lavage with water
Detergents (cationic)	Quaternary ammonium with alkyl or anyl substituent groups	Vomiting, depression, collapse, coma, may cause corrosive esophageal damage	Oral milk or activated charcoal. Soap for surface areas. Treat seizures and shock as needed
Drain cleaners	Sodium hydroxide, sodium hypochlorite	Caustic to skin and mucous membranes, irritation, inflammation, edema, necrosis, burns in mouth, tongue, pharynx	Flush affected areas with water or milk. Do not use emetics or lavage. Treat for shock and pain
Fireworks	Nitrates, chlorates, mercury, antimony, copper, strontium, barium, phosphorus	Abdominal pain, vomiting, bloody feces, rapid shallow respiration, chlorates may cause methemoglobinemia	Crop or gastric lavage. Use methylene blue or ascorbic acid for methemoglobinemia. Treat for specific metal(s) ingested
Furniture polish	Petroleum, hydrocarbons, mineral spirits	Early CNS depression, disorientation, necrosis, mucosal irritation, aspiration or hydrocarbon pneumonia, hepatorenal damage	Prevent aspiration pneumonia. Avoid gastric lavage or proceed with caution. Monitor and treat for pneumonia
Gasoline, crude oil	Petroleum and petroleum distillates	GI irritation, skin and feather damage, aspiration pneumonia	Wash feathers and skin with mild soap and water. Vegetable or mineral oil gavage. Antibiotics and supportive care
Matches	Potassium chloride	Gastroenteritis, vomiting, chlorates may induce methemoglobinemia with cyanosis and hemolysis	Treat symptomatically. Use methylene blue or ascorbic acid for methemoglobinemia
Paint/varnish removers	Benzene, methanol, toluene, acetone	Dermal irritation, depression, narcosis, pneumonia, hepatorenal damage	See “furniture polish.” Rinse contact areas thoroughly with warm water
Pencils	Graphite	GI irritation	Demulcent
Perfumes	Volatile oils	Local irritation of skin and mucous membranes, pneumonitis, hepatorenal damage with albuminuria, hematuria, glycosuria, excitement, ataxia, coma	If ingested, gastric or crop lavage with weak bicarbonate solution. Prevent aspiration. Demulcents. Provide plenty of ventilation
Pine oil disinfectants	Pine oil 5-10%, phenols 2-6%	Gastritis, vomiting, diarrhea, followed by CNS depression, occasional mild seizures, phenols may induce nephrosis	If ingested, gastric lavage with caution to prevent aspiration. Mineral oil. Monitor pulmonary and renal function. Provide fresh air if strong fumes are present
Overheated non-stick cookware, drip pans, heat lamps, irons, ironing board covers	Polytetrafluoroethylene	Sudden death, dyspnea, depression, pulmonary hemorrhage	Fresh air or oxygen, fluids, steroids for pulmonary edema, antibiotics, supportive care
Poor grade peanuts, peanut waste, moldy grains, corn and corn screenings, moldy cheeses, meats	Mycotoxins: aflatoxin, ochratoxin, trichothecenes	Gastrointestinal irritation, dermal irritation, oral necrosis, secondary infections due to immunosuppression	Clean feed, antibiotics for secondary infections. Treatment as indicated for clinical syndromes

table continued on next page

Agent	Toxic Components	Clinical Effects	Therapy
Rodenticides	Anticoagulants	Weakness, dyspnea, hemorrhage, petechiation, anemia	Vitamin K_1 (2.5-5 mg/kg) IM or PO q 24 hr. Minimize stress. Warfarin, treat for 10-14 days. Chlorophacinone, treat for 21-28 days. Brodifacoum, treat for 28-30 days
Rodenticides	Cholecalciferol	Causes hypercalcemia and renal failure, vomiting, diarrhea, depression, anorexia, polyuria, polydipsia	Activated charcoal, fluid therapy. If hypercalcemic, saline diuresis, prednisolone PO 2 mg/kg q 12 hr, furosemide 2-5 mg/kg q 8-12 hr, salmon calcitonin SC 4-6 IU/kg q 2-3 hr until calcium stable (mammalian protocol)
Rubbing alcohol	Ethyl alcohol	Impaired motor coordination, cutaneous hyperemia, vomiting, progress to peripheral vascular collapse, hypothermia	Gastric or crop lavage. Monitor temperature, cardiac and pulmonary function
Shampoo	Laurel sulfates and triethanolamine dodecyl sulfate	Ocular irritation, stimulation of mucous production, ingestion causes diarrhea	Activated charcoal or kaolin orally
Salt, crackers, chips, prepared foods, salt water, sea sand (as grit)	Sodium chloride	Gastrointestinal irritation, dehydration, depression, weakness, PU/PD, death	Rehydration, offer small amounts of water frequently. SC, IV or IO fluids, supportive care
Styptic pencil	Potassium aluminum sulfate	Corrosive due to release of sulfuric acid during hydrolysis of the salt, oral necrosis from chewing on pencils	Oral neutralizer such as magnesium oxide or hydroxide. Do not give bicarbonate orally for acid poisonings

Many of the therapeutic recommendations for the above products have been taken from small animal sources.[8,8a,36a,46a]

TABLE 37.2 Some Commonly Encountered Toxins and their Potential Effects in Birds[19]

Alcohol	Depression, regurgitation
Aminoglycosides	Renal tubular necrosis
Arsenic	Pruritus, polyuria, dyspnea, death
Atropine	Gastrointestinal stasis
Brodifacoum	Death
Cephaloridine	Blindness
Chloramphenicol	Death
Chlorine	Epiphora, upper respiratory signs, tachypnea
Chocolate	Vomiting, diarrhea, death
Cigarette smoke	Dermatitis, sinusitis, pneumonitis
Copper	Anemia, weakness, death
Coumarin	Fatal hemorrhage
Cythioate	Death
Diazinon	Death
Dihydrostreptomycin	Paralysis, death
Dimetridazole	Incoordination, ataxia, seizures, death
Fenbendazole	Depression, ataxia, mydriasis
Formaldehyde	Epiphora, upper respiratory signs, death
Gentamicin	Apnea, renal tubular necrosis, death
Ivermectin (propylene glycol formulation)	Weakness, death
Lead arsenate	Depression, CNS signs, death
Levamisole	Depression, vomiting, ataxia, mydriasis, paralysis, death (hepatotoxicity)
Lincomycin	Death
Medroxyprogesterone	Lethargy, obesity, polydipsia, fatty liver
Mercury	Depression, hematuria, death
Metronidazole	Death in finches
Niclosamide	Death
Nicotine	Depression, dyspnea, coma, death
Nitrates	Anorexia, vomiting, diarrhea, ataxia, convulsions, death
Nitrofurazone	Ataxia, convulsions, death
Nitrothiazole	Death
Polymyxin B	Lethargy, ataxia, vomiting, death
Polytetrafluoroethylene gas	Dyspnea, seizures, death
Praziquantel	Depression, death
Procaine penicillin	Paralysis, death
Rotenone	Vomiting, ataxia, convulsions, death
Selenium sulfide	Death
Sodium chloride	Depression, PU/PD, ataxia, convulsions, death
Ticarcillin	Hepatotoxicity
Vitamin D_3	Calcification of kidneys and other organs
Zinc	Depression, vomiting, ataxia, death

FIG 37.1 Psittacine birds may be exposed to numerous toxins because of their chewing behaviors. In this case, a conure was presented with lead poisoning secondary to the consumption of lead-containing solder used to hold his feeding dish. The case was further complicated by gastrointestinal impaction secondary to the ingestion of pieces of the plastic dish and malnutrition caused by a diet of wild bird seeds. Clinicians should carefully evaluate the environment in birds with clinical signs consistent with toxicity.

Birds are generally more susceptible to inhaled toxins than mammals because of their rapid metabolic rate, small size, highly efficient respiratory system and low body fat content. In comparison, many compounds that cause intoxication following ingestion by mammals are relatively nontoxic in companion birds; however, birds should be restricted from access to compounds known to be toxic in mammals (Figure 37.1).

Products that produce fumes, fogs or mists are not recommended for use in areas where birds are present. Good ventilation should be maintained to prevent the accumulation of harmful gases and fumes. Some toxins may be absorbed directly through the skin causing systemic intoxication, while others cause localized reactions (eg, nicotine dermatitis). Systemic intoxication could occur from birds perching on wood or branches treated with preservatives or pesticides.

A bird's response to a toxin may vary depending on the age, size, health status and plane of nutrition of the patient, as well as on the route, duration and quantity of toxin exposure. A malnourished bird is more likely to develop clinical problems from a toxin exposure than is a bird on an adequate diet. A bird suffering from chronic malnutrition is more likely to develop pansystemic diseases following exposure to toxic agents. Table 37.2 lists some compounds that have been associated with toxicity in birds and their principal clinical changes.

Free-ranging birds, particularly Anseriformes, are commonly poisoned through chronic exposure to a contaminated, abused environment. Toxin-contaminated water, air and food supplies can affect birds through direct contact or through poisoning of components in the food chain. Often the intoxication is subtle, and poisons accumulate over time (eg, lead in waterfowl, organochlorines in birds of prey).

Birds of prey and fish-eating birds are particularly susceptible to contaminants in the food chain because of biologic magnification. It is of interest that the health of free-ranging birds is frequently ignored as a sensitive indicator of human-induced damage to our environment.

In addition to human-related toxins, food and water supplies encountered by free-ranging birds may also be contaminated by biologic organisms that produce their own toxins, including molds (mycotoxins), bacteria (endotoxins) and certain blue-green algae (hepatotoxins).

When submitting samples for toxicologic analysis, it is best to call the laboratory for information on proper sample preparation and shipment. Most laboratories request frozen samples (except whole blood), preferably individually wrapped to prevent cross-contamination. Samples submitted for heavy metal analysis should not be wrapped in foils or contact any metal during shipment. Complete request forms, including the specific analyses to be run and the species involved, improve the speed and accuracy of the results.

Further information on products and chemicals as well as assistance with poisonings is available from the National Animal Poison Control Center, University of Illinois, College of Veterinary Medicine, Urbana, IL 61801, 1-800-548-2423 (credit cards only, $30 per case) or 1-900-680-0000 ($20 for the first 5 minutes, plus $2.95 for each additional minute [$20 minimum]). This center's experience is limited when dealing with companion birds and they often refer calls to experienced practitioners.

A useful conversion in toxicology analysis is 1 ppm = 100 μg/dl.

Ingested Toxins

Lead (Pb)

Lead intoxication is one of the most commonly reported and clinically recognized poisonings of companion and free-ranging birds. Lead is inconspicuously included in numerous products found around the home and the precise cause of lead intoxication is frequently undetermined. Table 37.3 offers some examples of possible household sources of lead. The common lead weights used to balance wheels may be an underestimated source of contamination within a bird's environment. Once ingested, the lead is degraded by acids in the stomach and absorbed into the bloodstream. Raptors can be exposed to lead by ingesting carcasses containing lead shot. Unless paints state that they are "lead free" they may still have toxic levels of lead in the drying agent rather than in the base. Lead exposure may also occur through the inhalation of fumes from lead-containing gasoline (Figure 37.2).

Lead deposited in muscle tissue of birds is generally considered to pose minimal health risks; however, lead shot implanted subcutaneously and intramuscularly in pigeons resulted in decreased levels of delta-aminolevulinic acid dehydratase (ALAD) enzyme activity, indicating the absorption of lead into the bloodstream.[51]

TABLE 37.3 Potential Sources of Lead

- Weights (curtains, penguin bird toys, fishing and diving, sailing and boating accessories, wheel balances)
- Bells with lead clappers
- Batteries
- Solder
- Lead pellets from shotgun shells
- Air rifle pellets
- Lead-based paints (varnishes, lacquers)
- Lead-free paints with leaded drying agents
- Hardware cloth
- Galvanized wire (lead and zinc)
- Champagne and wine bottle foils (some)
- Base of light bulbs
- Linoleum
- Contaminated bone meal and dolomite products
- Leaded gasoline fumes
- Glazed ceramics (especially imported products)
- Costume jewelry
- Contaminated cuttlefish bone
- Plaster
- Stained glass (decorative glass) – lead seam
- Seeds for planting (coated with lead arsenate)
- Some lubricants (lead naphthalate)

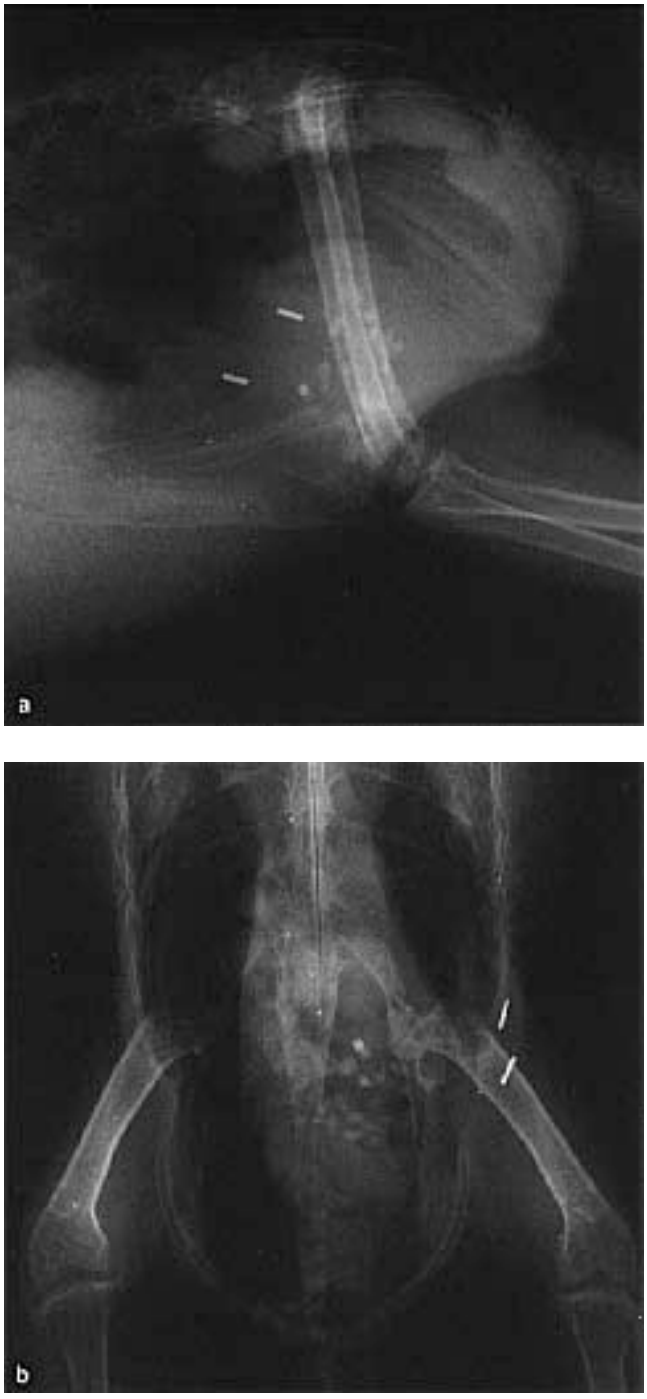

FIG 37.2 A mature cockatoo was presented with a history of an acute onset of depression, regurgitation and diarrhea. **a)** It is a common but inappropriate practice to obtain only a lateral radiograph when attempting to detect heavy metals in the gastrointestinal tract. **b)** In this case, two metal-density objects that appeared to be in the proventriculus and ventriculus were found to be hemostatic clips that had been used in a previous laparotomy incision.

Lead poisoning and death occurred in an African Grey Parrot that was sprayed with an automobile lubricant[a] to prevent feather picking. The product contained 4.5% lead naphthenate and had previously been used to treat a lovebird that died with a similar clinical progression. Radiographic and clinical pathology data were unremarkable. The bird's only clinical signs were diarrhea, anorexia and depression.[65] Blood lead levels in the bird were 3.9 μmol/l (78 μg/dl) suggesting lead intoxication. Neither the product label nor information sheet divulged that it contained such a high level of lead.

A simple lead testing kit[b] is available for the detection of lead in environmental samples. A swab supplied with the kit is moistened with a supplied reagent and rubbed against an item to be tested (eg, wire, paint). The tip of the swab turns red if lead is present in the sample. This rapid, in-home test is less reliable than tests performed by commercial laboratories.

Clinical Signs

Clinically, lead toxicosis may occur as an acute or a chronic problem. Chronic intoxications are most common in Anseriformes and other free-ranging birds. The chronicity of these problems probably occurs because the animals are not evaluated until critically ill from prolonged intoxication. The most commonly reported effect in free-ranging birds is a decrease in population densities. Because companion birds are carefully observed on a daily basis, the non-specific signs of acute lead toxicosis are frequently recognized and birds are presented for medical evaluation.

The presence and severity of clinical signs depends on the amount of lead ingested, the surface area of the particles and the length of time the lead is in the gastrointestinal tract.[19,36] The type and amount of abrasive material in the ventriculus alters the speed of lead digestion and may affect the type of clinical presentation.[36]

Once in the bloodstream, lead causes pansystemic damage, particularly to the gastrointestinal, nervous, renal and hematopoietic systems. Clinical signs of lead intoxication in psittacine birds may include lethargy, depression, anorexia, weakness (wing droop, leg paresis), regurgitation, polyuria, diarrhea, emaciation, ataxia, head tilt, blindness, circling, paresis, paralysis, head tremors, convulsions and death.[19,35,36] Some birds may die with no clinical signs and in others, the only noted abnormalities may be weakness and chronic weight loss.[65] Hemoglobinuria has been reported as a clinical sign of lead poisoning in Amazon and African Grey Parrots, but it may not occur in all cases.[72] This finding is thought to be secondary to intravascular hemolysis and is frequently misinterpreted as bloody diarrhea.[36] Lead poisoning in waterfowl, cranes and pigeons may cause ileus of the crop, esophagus, proventriculus and ventriculus.[6] In waterfowl and poultry, lead poisoning can cause clinical signs similar to those that occur with botulism. Response to chelation therapy (lead or zinc) or antitoxin (botulism) is suggestive of a diagnosis (see Chapters 28, 33, 46).

Pathology

In some cases, hematologic parameters may provide an indication of lead intoxication. A hypochromic, regenerative anemia occurs in some affected birds.[36] Basophilic stippling and cytoplasmic vacuolization of red blood cells reported in mammalian lead poisoning cases are not recognized in avian patients.

Elevations of LDH, AST and CPK have been reported. Increased LDH and AST are primarily related to liver damage in birds. High CPK activities may be a result of lead-induced neuronal damage.[14]

The functional capacity of the renal system should be carefully evaluated in birds suspected of having lead poisoning. Most commonly used chelating agents have potentially nephrotoxic side effects, and therapy for heavy metal intoxication should be instituted with caution in birds with impaired renal function. There are no reports detailing serious nephrotoxic side effects from the use of chelation therapy in companion birds; however, swans that did not recover from lead poisoning with chelation therapy had markedly elevated uric acid levels, visceral gout and renal nephrosis.[6]

Gross necropsy findings in lead-poisoned swans include weight loss and green liver tissue. Histologic lesions are most severe in birds that survive for several weeks. In these birds, necrohemorrhagic enteritis secondary to *Clostridium perfringens* is common. Other findings include fibrinoid vascular necrosis, renal nephrosis and multifocal myocardial degeneration.[6]

Radiography

The identification of metallic densities in the gastrointestinal tract of birds with clinical signs of heavy metal intoxication is suggestive. However, the absence of metal densities in the presence of clinical signs does not rule out heavy metal intoxication (Fig-

FIG 37.3 A two-year-old female Rose-breasted Cockatoo was presented with dyspnea and weight loss (257 g). Abnormal clinical pathology findings included WBC=48,000 (toxic heterophils), LDH=2791, AST=1562, bile acids=291. The bird was negative for chlamydia by ELISA antigen testing of the excrement. Zinc levels were 370 μg/dl. Radiographs indicated severe hepatomegaly and an auxiliary mass that was determined by cytology to be a lipoma. One week after initiating therapy with CaEDTA, clinicopathologic findings included AST=901, LDH=1500 and bile acids=613.

ure 37.3). In one study involving swans, 25% of lead poisoned birds did not have lead pellets that could be identified by radiographs.[6,19] Some intoxications can occur from absorption of lead that is in a nonradiodense form (eg, paint chips or gas fumes), or a bird can develop clinical signs following the mobilization of lead stored in the bones months after an initial ingestion has occurred.

Metal particles usually are visualized in the ventriculus but may be seen anywhere along the gastrointestinal tract. In chronic cases involving free-ranging birds, eroded pellets have been radiographically documented at necropsy.[19] In some cases, the source of lead may be eliminated from the gastrointestinal tract before clinical signs are recognized.

Toxicologic Analysis

Several blood tests are available to confirm lead intoxication. They require a small volume of blood, but results require from four days to several weeks. Whole, unclotted blood is the sample of choice for determining lead concentrations because 90% of circulating lead is in red blood cells. Lithium heparin is a suitable anticoagulant. EDTA should not be used because this anticoagulant may interfere with testing.[31] Diagnostic blood levels may vary widely between species.

Whole blood lead levels greater than 20 μg/dl (0.2 ppm; 1.25 μmol/dl) are suggestive, and levels greater than 40 to 60 μg/dl (0.4 to 0.6 ppm; 2.5 μmol/dl) are diagnostic of lead intoxication in psittacine birds when accompanied by appropriate clinical signs (Table 37.4).[19,30] Some birds may have clinical signs and respond to therapy with levels as low as 10 μg/dl. Blood from a normal bird of the same species can be submitted along with that of the ill patient to allow more accurate interpretations of the laboratory results. Higher levels of blood lead have been reported in many avian species with no clinical signs of intoxication.[30]

In cockatiels experimentally exposed to lead, peak blood concentrations ranged from 44 to 129 μg/dl.[36] In a study involving zinc toxicosis, the cockatiels in the experimental group had a mean blood lead level of 5 μg/dl.[21] In adult Cuban Whistling Tree Ducks, the blood lead level of one affected bird was 163 μg/dl; compared with the normal value of its mate of 32 μg/dl. An affected Eastern Turkey Vulture in that same report had a blood lead level of 320 μg/dl.[22] In Mallards and Bald Eagles, values have been reported as high as 500 μg/dl.[36] A Blue and Gold Macaw with

TABLE 37.4 Suggested Normal Blood Lead Levels

Swan	6 μg/dl
Mallard	5 – 39 μg/dl
Canada Goose	10 – 37 μg/dl
Pigeon	17 – 81 μg/dl
Cockatiel	5 μg/dl
Most Psittaciformes	<20 μg/dl

lead and zinc poisoning (exposure to galvanized wire) had a reported blood lead level of 50 μg/dl and a blood zinc level of 1500 μg/dl.[40]

With the wide range of lead values reported in blood, this criterion alone may not be sufficient to diagnose clinical lead poisoning.[31] Other reports disagree.[36] With a strong suspicion of lead intoxication, therapy should be initiated while awaiting laboratory results. A rapid response to therapy lends evidence to a diagnosis of lead (or other similar heavy metal) poisoning.[36]

The inhibition ALAD activity has been used as a reliable and sensitive indicator of exposure to lead in ducks.[6,19,36] It also has been recommended as a diagnostic tool in other avian species. In cockatiels, ALAD activities less than 86 units were considered indicative of lead poisoning.[36] In two studies in ducks, lead concentrations of 0.5 ppm in the brain and 200 ppm in the blood were found to correlate with a 75% decrease in ALAD activity in the blood.[7]

Detecting ALAD activity may be of value only in birds with low levels of lead exposure because enzyme activities failed to decrease in humans and pigeons with high exposures to lead.[31] In swans, ALAD activities could not be used as a prognostic indicator for recovery. Additionally, in swans, as the blood levels increased, the ALAD activity was also found to increase rather than decrease.[6] ALAD activity returned to normal in many birds that were treated but subsequently died.[6]

Lead interferes with ALAD activity, which reduces heme synthase activity and causes an increase in protoporphyrin IX concentrations in the blood. Free erythrocytic protoporphyrin (FEPP) and zinc protoporphyrin (ZPP) levels are considered accurate methods of detecting lead intoxication in birds.[31] FEPP levels were found to be suggestive of acute toxicity, while ZPP levels were of more value in documenting chronic lead poisoning. Total protoporphyrin levels were not considered an effective prognostic indicator of recovery.

Blood protoporphyrin levels that exceed 40 ppm are common following lead ingestion. CNS signs occur with levels of 500 ppm. Protophyrin levels drop rapidly following chelation therapy. Instrumentation used to measure protoporphyrin levels in humans must be altered by removing the filters to compensate for the low levels of zinc protoporphyrin that occur in avian erythrocytes.[31,55] Diagnostic results may be obtained with one or two microhematocrit tubes of whole blood.[36]

Treatment

Supportive care for heavy metal poisoning may include chelation therapy (both oral and IM), intravenous lactated Ringer's, 5% dextrose solution, multicomplex B vitamins, iron dextran, antibiotics, assisted alimentation and prophylactic treatment for aspergillosis (waterfowl).[6]

The prognosis for lead intoxication is guarded if chronic exposure has occurred or if the bird has severe CNS signs. In other cases, the response to therapy is dramatic, with most patients responding to chelation therapy within six hours of administration. Many hematuric birds can die in this same time period. Gastrointestinal stasis and impaction of the proventriculus is a complicating factor in waterfowl.[6]

Chelation therapy is designed to remove lead circulating in the bloodstream. Calcium disodium ethylene diamine tetracetate (CaEDTA) or calcium disodium versenate are commonly used chelation agents. The calcium form of EDTA should be used to reduce the chances of drug-induced hypocalcemia.[27]

The recommended dosage of CaEDTA is 10-40 mg/kg twice daily intramuscularly. CaEDTA is poorly absorbed from the gastrointestinal tract and must be used parenterally to remove circulating lead in critically ill patients.[36] Chelation therapy should be used for the least amount of time that is necessary to resolve the intoxication. In general, therapy should not persist for over ten days without a break in drug administration; however, some clinicians have used CaEDTA until there is no radiographic evidence of lead in the gastrointestinal tract (up to 30 days) with no clinically apparent side effects.[28,36,40] CaEDTA may be administered orally at twice the injectable dose two to three times daily in asymptomatic birds to prevent lead from being absorbed.[72] CaEDTA must be used carefully as it may cause gastrointestinal and renal toxicosis.[25,36] If evidence of chelation toxicosis is seen (eg, polydipsia, polyuria, proteinuria, hematuria), CaEDTA should be discontinued for a period of five to seven days. Therapy can then resume if the patient is stable.

D-penicillamine (PA) is an effective lead chelator that can be used orally (55 mg/kg twice daily). It has been suggested that PA may increase the gastrointestinal absorption of lead;[30] however, more recent reports suggest that PA is a superior chelating agent to CaEDTA and does not increase absorption.[35] Combining CaEDTA and PA for several days until a bird is asymptomatic followed by the use of PA for three to

TABLE 37.5 Chelating Agents for Heavy Metal Toxicities

CaEDTA	Beryllium, copper, cerium, iron, zinc, lead
BAL (dimercaprol)	Arsenic, gold, mercury, copper, iron, nickel, thorium, zinc, lead
D-Penicillamine	Copper, mercury, lead, zinc

six weeks may prove to be the best therapeutic regime for lead poisoning. Birds should be monitored for clinical signs of copper depletion including lethargy, anemia and weight loss.

Dimercaprol (British Anti-Lewisite - BAL) is the best agent for removing lead from the CNS; however, this agent is rarely used because of its low therapeutic index and the positive response of most birds to PA or CaEDTA. The recommended treatment regime is 2.5 mg/kg IM every four hours for two days, then twice daily for up to ten days or until clinical signs resolve (Table 37.5).[27]

Lead-induced seizures can be controlled with diazepam at 0.5-1 mg/kg intramuscularly two to three times daily as needed.[36] The primary therapy for any heavy metal intoxication is to remove the source of the toxin from the body. Both surgical and nonsurgical approaches may be useful, depending on the circumstances of an individual case.

Emollient cathartics (mineral oil or peanut butter) can be administered to aid in the passage of small particles of heavy metal out of the gastrointestinal tract. Other substances that have been used to aid in the passage of heavy metal particles include barium sulfate, psyllium and corn oil. The comparative effectiveness of these agents has not been determined. The use of sodium sulfate (Glauber's salts) has also been recommended for the removal of lead.[16] Additionally, this agent can be mixed with activated charcoal and used following the ingestion of unknown toxins for its cathartic and absorptive effects. Sulfate will bind free lead in the gastrointestinal tract forming an insoluble lead sulfate that cannot be absorbed (mode of action similar to oral Ca EDTA and PA). Treated birds will generally develop diarrhea, and patients must be carefully monitored to prevent dehydration and severe electrolyte imbalances.[16] The sodium sulfate is given as a slurry for up to two doses (in large birds) or until lead is gone from the gut. Aluminum sulfate is very irritating to the kidneys and is not recommended. Magnesium sulfate is not recommended as the released magnesium is depressing.[16]

An experimental chelating agent, dimercapto succinic acid (DMSA) has been found to improve survival from lead poisoning by 35 to 50% when used in conjunction with CaEDTA in swans.[6,35] This drug is experimental and requires a special FDA permit. The experimental dose is 25 to 35 mg/kg BID orally for five days per week for three to five weeks.

The administration of three to five appropriately sized pieces of grit may help in the removal of metal particles from the ventriculus by reducing their size[27] and facilitating passage, particularly when used in conjunction with psyllium (hemicellulose).[40]

Activated charcoal is recommended to bind small lead particles in the gastrointestinal tract and make them unavailable for absorption. The small animal dose for activated charcoal is 2 to 8 g/kg body weight.[46] This should be gavaged as a slurry with water according to manufacturer's instructions. Activated charcoal will be inactivated if administered with mineral oil. Activated charcoal may be administered one to two hours before administration of a cathartic. This allows sufficient time for free heavy metals to be bound to the charcoal before the system is purged.

Endoscopic removal of heavy metal particles using appropriate forceps[30] or gastric lavage can be attempted in stable patients that are of sufficient size to tolerate this procedure.[6] This technique is particularly effective when metal fragments in the ventriculus are too large to pass through the lower gastrointestinal tract in a reasonable period of time. Lead particles were removed from the gastrointestinal tract of swans by fasting eight to twelve hours followed by the insertion of a 110 cm tube into the ventriculus. The birds were tilted head down at a 45° angle and warm water was pumped into the ventriculus using a gastric lavage syringe.[c] The contents were filtered through a towel to evaluate the number of particles removed. Radiographs of the head, neck and abdomen were used post-lavage to determine the presence and location of any remaining lead particles.[6] Occasionally, a proventriculotomy may be necessary if other attempts to remove metal particles fail (see Chapter 41).[56,72]

Zinc (Zn)

Zinc is another frequently encountered heavy metal that causes toxicity when ingested by birds. Zinc toxicosis should be included in the differential list when heavy metal intoxication is suspected. Galvanized wire and the clips used to construct enclosures are common sources of zinc. The clinical syndrome

described in birds that ingest zinc from a wire enclosure is frequently referred to as "new wire disease."[40] The brighter and shinier the wire, the higher the zinc level.[21] The occurrence of "new wire disease" can be reduced (but not eliminated) by scrubbing the wire with a brush and mild acidic solution (vinegar).[50] Galvanized wire may also contain lead.[40] Some galvanized coatings contain 99.9% zinc while others are 98% zinc and 1% lead. The white rust associated with the galvanized coating is also toxic.[21] Galvanized containers and dishes are other sources of zinc contamination.[27] Pennies minted in the USA since 1982 contain from 96% to 98% zinc that is coated with copper.[1,29,30,40] Monopoly™ game pieces are made of 98% zinc.[1]

A duck from a zoological collection developed an acute onset of weakness and depression and died during examination. On necropsy, the ventriculus contained five tightly stacked, well eroded pennies. Some were minted after 1982. Pennies thrown into the duck's pond by park visitors were the source of intoxication.

Common signs reported in zinc-intoxicated birds include polyuria, polydipsia, gastrointestinal problems, weight loss, weakness, anemia, cyanosis, hyperglycemia and seizures.[28,30,50,68] Systemic effects are related to hypoproteinemia-induced damage in the kidneys, gastrointestinal system and pancreas.[52] There are two cases of zinc depressing fertility, one in a male Mallard[15] and one in a female Black Bustard.[30]

Cockatiels fed the zinc coating from galvanized wire, or white rust from the same wire, developed clinical signs that included lethargy, weight loss, greenish diarrhea, ataxia, recumbency and death. This was the most common presentation in acute cases. A more chronic clinical course was characterized by intermittent lethargy, dysphagia and depression. Gross necropsy findings were limited to ileus. Histopathologic changes included focal mononuclear degeneration in the liver, kidney and pancreas.[21]

Serum concentrations of zinc can be used to confirm a diagnosis. Samples must be properly collected and stored to avoid extraneous contamination. Only glass or all-plastic syringes and tubes should be used for samples intended for zinc analysis. Rubber stoppers on serum tubes and the grommets on most plastic syringes can be a source of zinc contamination.[37] Serum tubes with royal blue-colored stoppers are free of zinc and are best for sample handling. A serum sample collected from a clinically normal bird of the same species and handled identically will assist with interpreting results. In general, blood zinc levels of greater than 200 μg/dl (2 ppm) are considered diagnostic for zinc toxicosis.[40] In a group of normal cockatiels, the mean blood zinc level was found to be 163 μg/dl (1.63 ppm). The pancreas proved to be the best tissue for postmortem zinc level determination. Before exposure, the mean pancreatic zinc levels were 26.11 μg/g dry weight. The level in zinc-intoxicated birds ranged from 312.4 μg/g to 2418 μg/g.

Calcium EDTA is recommended as an effective chelating agent.[27,30,40,52] D-penicillamine is also useful. Radiographically and clinically, zinc toxicosis cannot be differentiated from lead intoxication. Fortunately, the therapy is the same for poisonings caused by either of these heavy metals. The primary treatment involves removal of the foreign body. If a bird has ingested galvanized wire, this zinc-coated ferrous metal can be removed using a powerful neodymium-ferro-barium alloy magnet attached to a small diameter catheter with a removable, flexible steel grid wire (see Figure 19.13).[32]

Fluoroscopy-guided removal is ideal; however, particles can also be removed by repeatedly passing the apparatus into the ventriculus until no further metal particles are removed. The success of the removal process can be determined with radiographs (Figure 37.4).[32] Often, zinc foreign bodies can be removed with bulk cathartics (sodium sulfate), activated charcoal or mineral oil as described for lead. Gastroscopic removal using blunt-jawed forceps has been described.[32,40] Surgical removal may be necessary if the object cannot be removed with other methods. It may be necessary to monitor packed cell volumes periodically if the bird is anemic.

Copper (Cu)

Factors that have been shown to affect the toxicity of copper in mammals include dietary zinc and molybdenum concentrations.[46] There are wide differences in how various animal species maintain copper hemostasis in the body, and birds appear to tolerate higher levels of copper than many mammals. Some reports have suggested that water contaminated with antifouling paints can be a source of copper intoxication in waterfowl.[39] Other sources of copper include copper wire, chronic over-supplementation in the diet, pennies minted before 1982 or any copper-coated objects small enough to be ingested. In a warm climate, copper sulfate used to control algae on a

FIG 37.4 An adult Amazon parrot as presented with an acute onset of depression and regurgitation three days after a lead sinker was placed in the bird's enclosure as a toy. The metal in the crop, esophagus and proventriculus was removed either by endoscopy or gastric lavage. The bird was given oral D-penicillamine and a bulk laxative (psyllium). Response to therapy was excellent.

pond accumulated over time and caused the intoxication and death of swans.

Clinical abnormalities associated with copper intoxication have rarely been reported in birds. There have been reports of Mute Swans tolerating liver copper residues of up to 1000 mg/kg.[13] A Mute Swan with inanition, anemia and generalized weakness showed signs of toxicity with liver copper levels in excess of 3000 mg/kg and over 50 mg/kg copper in the kidneys.[13] Evidence of intravascular hemolysis (which is described in mammals) has not been documented in waterfowl.[13,39] Postmortem findings following copper intoxication include anemia and coal-black discoloration of the liver (see Color 20).[39]

D-penicillamine increases the renal excretion of copper and is the chelating agent of choice for copper toxicosis in mammals. In mammals, a dose of 52 mg/kg/day for six days has been recommended.[46] High-quality nutritional support is necessary to prevent chelation and removal of other vital minerals. Supportive care with fluids, warmth and minimal stress may aid in recovery. In severely anemic birds, blood transfusions may be necessary. In advanced cases the prognosis is poor.

Mercury (Hg)

Mercury poisoning is becoming an environmental concern as levels in water continue to rise. Fish accumulate mercury, which is then further concentrated in fish-eating birds. An Amazon parrot that consumed the back of a mirror died following a period of profuse hematuria.[34] BAL (and presumably DMSA) and D-penicillamine chelate mercury.

Arsenic (Ar)

Polyuria, polydipsia, feather picking, pruritus, weight loss, dyspnea (air sacculitis), egg binding, poor feathering and death occurred in a group of aviary birds, presumably secondary to the consumption of arsenic-contaminated mineral block. Necropsy findings included cystic ovaries and adrenal gland enlargement. Clinical changes started when a new group of mineral blocks was used in the aviary. These blocks were found to contain 0.5% arsenic, and all clinical problems in the birds resolved when the mineral blocks were removed.[67]

Oil

Crude oil is extremely toxic, and quantities of 0.3 μl placed on the outside of eggs caused death in 50% of embryos; the embryos that survived had malformations of the eye, brain and beak. Generalized edema, hepatic necrosis, cardiomegaly and splenomegaly were noted also.[45]

FIG 37.5 The pelletized fertilizers found on the surface of the soil in many house plants are more of a threat to companion birds than the houseplant itself. These encapsulated products contain high levels of nitrates that can be rapidly fatal (courtesy of Genevieve Dumonceaux).

Selenium

A dog shampoo containing selenium sulfide caused the death of a budgerigar.[19]

Nitrates

Nitrates are common components of fertilizers and may cause polydipsia, dyspnea, cyanosis and death following ingestion. The pelletized form of nitrate-containing fertilizers are particularly hazardous because they resemble seeds and may be readily consumed by birds (Figure 37.5).[19]

Plants

Clients are frequently concerned when a bird consumes a houseplant; however, plant intoxications are rare (Table 37.6). Free-flying companion birds frequently encounter and consume a variety of plants found in the home, few of which are at all toxic, some of which are thought to be toxic and some of which are of unknown toxicity. Determining the amount of plant ingested is always difficult, because birds seem to enjoy shredding leaves more than ingesting them. There have been few documented cases of plant poisonings in birds, and their rapid gastrointestinal transit time is thought to play a role in the low incidence of intoxication.

The ability of parrots to consume plants and fruits that are deleterious to other animals may have allowed these birds to reach their current widespread distribution in the wild.[42] It has been proposed that parrots can consume toxic plants because they carefully remove the outer covering, which frequently contains the highest concentration of toxins. Alternatively, it has been suggested that the consumption of clay by free-ranging birds may serve to absorb some toxic materials and prevent them from passing through the gastrointestinal mucosa. However, many birds consume potentially toxic plants and only macaws have been observed consuming clay. It is more likely that the ingested plant material is eliminated before dangerous levels of the toxic component can be systemically absorbed.[12] The Cedar Waxwing and the House Finch can safely consume fruit from the pepper tree (*Capsicum annuum*) that is toxic to mammals.[43]

In one study, yew, oleander, Virginia creeper, black locust, clematis and avocado[59] were described as toxic to budgerigars when administered by gavage. Many other plants that were tested had no harmful effects under the same testing conditions. In another study, oleander, lily of the valley, rhododendron, poinsettia and philodendron were not found to be major health hazards for budgerigars.[12]

In a similar study involving canaries, oleander, lupine, foxglove, yew leaves and diffenbachia were considered to be highly toxic. Nine other plants that have traditionally been considered toxic (parsley, hoya [wax plant], rhododendron, black locust, wis-

C = clinical report; E = experimental

The state of an animal's health should be expected to have an impact on its response to ingested plants. The experimental doses used to demonstrate that some of these plants were toxic are not likely to occur in natural settings.

teria, clematis, cherry, pyracintha [fire thorn] and privet) caused no, or only transient, clinical problems. Most canaries that died did so within minutes to hours following the ingestion of the plants.[2]

Split-leaf philodendrons have been used in some aviaries in Florida for years with no signs of toxicity. However, in one case, two Amazon parrots that destroyed a large split-leaf philodendron had a two-hour course of lethargy and vomiting followed by complete, unsupported recovery.

Cherries, plums and peaches (*Prunus* spp.) have pits containing seeds that produce cyanogenic glycosides; however, there are no reports of cyanide poisoning in birds following the ingestion of these fruits. It has been suggested that cyanide poisoning may be more common in ruminants because of a rapid enzymatic degradation of the glycoside to free cyanide. Alternately, detoxification may be more effective in simple-stomached animals.[12]

Avocados (*Persea* spp.) have recently been suggested as toxic for companion birds. At one time it was believed that only the pit was a danger; however, some studies suggest that all parts of the avocado, including the fruit, are toxic to birds.[5,18] The toxin in the avocado has not been described.[5] There are several varieties of avocados commercially available (eg, Guatemalan, Mexican, Nabal and Fuerte), which appear to differ in their toxic capacity. In one study involving rabbits, the Guatemalan and Nabal varieties caused death from pulmonary congestion within 24 hours after ingestion.[5] The Mexican variety was nontoxic.[5]

Signs of avocado toxicity (Guatemalan and Fuerte varieties) in budgerigars and canaries include cessation of perching, anorexia, fluffed feathers, increased respiratory rate, outstretched wings and death. At necropsy, intoxicated birds are in good overall condition, and the crop and ventriculus may be full of ingesta, indicating the acute nature of the toxicity. Subcutaneous edema of the pectoral region has been reported in some affected birds, and others will have pectoral muscles that bulge slightly above the sternum with mild pale streaks running parallel to the muscle fibers. Histologic lesions have been limited to generalized congestion, especially in the lungs.[18]

To the authors' knowledge, a specific treatment regimen for avocado intoxication in birds has not been established. Based on clinical signs and postmortem findings, activated charcoal and general supportive measures such as oxygen, warmth and perhaps a mild diuretic may be indicated. Birds have been reported to die as soon as 9 to 15 hours after consuming avocado. Some birds died within 10 to 15 minutes after developing signs of respiratory distress without prior clinical signs.[18]

FIG 37.6 Crown Vetch ingestion has been associated with tremors, opisthotonos, seizures and death in budgerigars, cockatiels and lovebirds (courtesy of Michael Lutz).

Budgerigars, cockatiels and lovebirds developed tremors, opisthotonus and seizures twelve hours after consuming crown vetch (Figure 37.6). Eighty percent of the birds with clinical signs died despite treatment. Deaths in the flocks reached 10% until the plant was removed, and no further losses were reported.[33] The inciting toxin was not confirmed, but may be a cyanide.

Oak toxicosis (coast live oak - *Quercus agrifola*) was confirmed in a cassowary that consumed the leaves. Clinical changes included anorexia, ataxia, diarrhea, severe polydipsia and death. Necropsy revealed diffuse serosal hyperemia, ulcers and hemorrhage in the small intestine. Liver tissue and gastric contents tested for tannins showed levels of 178 and 340 ppm respectively, which supported the diagnosis of oak toxicosis.[23]

Rape seed has been suggested as a hepatotoxin; however, canary breeders routinely feed soaked rape seed to breeding canaries and their offspring without a problem. Parsley has been shown to cause photosensitization and skin lesions in ostriches and experimentally in ducks.[44]

Mycotoxins

Mycotoxins are chemical metabolites produced by various species of fungi that grow on grains and foodstuffs. Each fungus has its own light, temperature and moisture requirements.[74] Some of these fungi grow on crops in the field during periods of high moisture content (*Fusarium* spp.). Others grow on foods during storage, when moisture contents are relatively low (*Aspergillus* spp.). Aflatoxin production can be decreased by storing food in a low-oxygen, high-CO_2 environment. In areas of the southern United States, where the preferred conditions for aflatoxin production are common (25-30°C, humidity 85%), refrigeration of food is often necessary to prevent aflatoxin production.

The conditions that induce a fungus to produce toxins may be different than those needed for fungal growth; therefore, the fungus can grow without toxin production. Likewise, the toxin can be present after the fungus has stopped reproducing. Clinically, this means that the presence of a fungus on a foodstuff does not necessarily indicate that a toxin is present, nor does its absence mean that food or grain is free of mycotoxins.

The amount of toxin present can vary within any given batch of grain or feed. Depending on the storage methods and size of the stored sample, one area may have no detectable mycotoxin, while another may have a very large concentration (known as a "hot spot"). Attempts to determine if mycotoxins are present using ultraviolet light are of little value, because both false-positive and false-negative results are common.

Toxins can enter an avian host through surface-to-skin contact. The effects of mycotoxin exposure can vary based on the type of toxin and on the species, nutritional state and physiologic status of the patient. A stressed bird or one on a poor diet is more likely to be poisoned by a lower dose of mycotoxin than is a healthy, well-fed bird. Ducklings have been shown to be much more sensitive to aflatoxin than chicks, indicating species variance in sensitivity.[41]

There are no specific antidotes for mycotoxicoses. It is easier to prevent exposure to mycotoxins than to attempt treatment following their ingestion. All foods and seeds available to birds should be clean and fresh. Foods that are dusty, damaged by insects or have molds present should not be offered to birds. Particular caution should be exercised with poor quality corn and peanuts, as these are common sources of toxin-producing molds. Some high-quality formulated diets are certified free of mycotoxins. Treatment involves providing clean food free of molds, supportive care, broad-spectrum antibiotics and specific therapies for clinical signs.

There are four main mycotoxins of concern to birds: aflatoxin B_1, ochratoxin A, deoxynivalenol (vomitoxin) and the trichothecenes, especially T_2 toxin. These are all potent mycotoxins that affect different body organs or systems. The molds producing these toxins can grow on various foods, including grains, peanuts and peanut products, breads, meats, cheeses and cereal grains. Whole kernel peanuts of apparently good quality can harbor high concentrations of aflatoxins.[74] Brazil nuts are banned in Austria because a mycotoxin-free nut was not available (Hochleithner M, unpublished). Diagnosis is based on clinical signs, postmortem and histopathologic findings, and detecting high quantities of the toxin in the gastrointestinal contents or the food. However, it is difficult to establish a diagnosis of mycotoxicosis in birds. Clinical and histologic changes usually mimic other diseases or may be due to secondary infections. Often, by the time signs are apparent, the toxin-contaminated food source has already been consumed and is not available for evaluation.

Aflatoxin B_1 is a known hepatotoxin. It is produced by *Aspergillus* spp. and may cause depression, poor growth, anorexia and other signs related to liver disease. Postmortem changes include an enlarged, pale liver (probably the result of fatty infiltration), an enlarged spleen, an enlarged pancreas, atrophy of the cloacal bursa and less-than-normal body fat deposits (see Color 20).[61]

Aflatoxins inhibit protein and nucleic acid synthesis. Microscopic examination shows hepatic cell degeneration and bile duct hyperplasia. The kidneys may have swollen proximal convoluted tubules.[41] Anticoagulant activity is altered, and a bird with a prolonged whole blood clotting time and prothrombin time may be suffering from aflatoxicosis. Gastrointestinal hemorrhage is also common. Immunosuppression through a reduction in alpha and beta

globulins has also been linked to aflatoxin exposure. Serum electrophoresis to detect this IgG pattern may be useful in diagnosing aflatoxicosis.

The trichothecenes, including T_2 toxin, are produced by *Fusarium* spp., which commonly grow on crops in the field. This toxin has corrosive effects on the mucous membranes of the oropharynx, and occasionally the gastrointestinal tract, causing necrotic lesions of the hard palate and other oral areas. Lesions can appear within 48 hours of ingestion.[58] Trichothecene intoxication in Sandhill Cranes caused signs including flaccid paralysis of the wing and neck, depression and flying with the head and neck perpendicular (in those birds that could fly). These birds were exposed to waste peanuts that contained high levels of trichothecenes.[71] Peanut farmers are encouraged to plow ground containing waste peanuts to prevent their consumption by free-ranging birds, particularly Sandhill Cranes.

FIG 37.7 Birds should not be allowed to consume high-salt foods, chocolate in any form or alcoholic beverages (courtesy of Genevieve Dumonceaux).

Trichothecene T_2 toxin may also cause contact dermatitis (from contaminated litter), poor growth and feathering, constrictive lesions of the digits (dry gangrene) and occasionally neurologic disorders.[71,73] In one study, a high incidence of T_2 toxin was reported in grains heavily damaged by insects.[4]

Histopathology of affected birds may reveal congestion and hyperemia of the gastrointestinal tract, hemorrhagic myositis, hepatic and renal swelling and congestion.[71] In chronic cases, evidence of secondary infections may be noted.

Ochratoxin is produced by species of *Aspergillus* and *Penicillium* fungi. The toxin has an immunosuppressive effect and has been associated with air sacculitis, nephrotoxicity, CNS signs, hepatotoxicity and bone marrow suppression. It has been shown to cause depression of the immunoglobulin-containing cells in the lymphoid organs.[9] Clinical changes are commonly related to secondary infections that take advantage of a depressed immune system.

Ethylene Glycol

Free-ranging birds may consume ethylene glycol. In gallinaceous birds, consumption of antifreeze has been associated with lethargy, ataxia and polyuria. Characteristic calcium oxalate crystals form in the kidneys.[28]

Harmful Foods

Clients frequently share favorite foods with their companion birds; however, some of these treats can be life-threatening through a single or chronic exposure. Chocolate is contraindicated as a treat for any pet, including birds. Consumption of small quantities of chocolate can result in hyperactivity, vomiting, diarrhea, cardiac arrhythmias, seizures, dark-colored feces and death. The progression of these effects can be rapid when large concentrations of the active ingredients (theophylline and caffeine) are ingested. A rule of thumb for chocolate toxicity is that the less sugar that is present, the more of the toxic active ingredients there are in the product. It is best to avoid feeding any type of chocolate to birds (Figure 37.7). Treatment for chocolate toxicosis includes the administration of gastrointestinal protectants and cathartics.

Excessive consumption of sodium chloride can cause polydipsia, polyuria, depression, neurologic excite-

ment, tremors, opisthotonos, ataxia and death. Necropsy changes are generally limited to cerebral edema and hemorrhage.[28]

Consumption of alcoholic beverages can lead to severe ataxia and death. Additionally, birds may become intoxicated if compounds containing high levels of ethanol (STA) are used to clean open wounds.

Iatrogenic Intoxications

Properly administered medications can be life-saving; however, many drugs have a low therapeutic index, and the safest of drugs may be toxic in excess quantities. Pre-existing systemic disease, nutritional status, state of hydration, drug interactions, carrier agents and species-specific idiosyncracies of a particular therapeutic agent should all be considered before initiating drug therapy (see Chapter 18). The most common cause of iatrogenic drug toxicosis is a failure to base the dose on an accurate weight. A dosing table[d] that can be used to quickly and accurately determine drug dosages is commercially available.

There are only a few therapeutic agents approved for use in birds; however, many drugs approved for other species can be beneficial in the treatment of sick and injured avian patients. Administering drugs at the proper dose, at an appropriate time interval, through a recommended route of administration and with consideration for patient-specific contraindications will minimize the potential for iatrogenic intoxications.

Some drugs given parenterally at the appropriate dosage (especially IM) can cause various degrees of local tissue damage (see Figure 17.4). Many of these reactions can be attributed to the carrier in the formulation. Injectable products that contain propylene glycol (PG) or oil as a carrier may cause an abscess or toxic reaction. Oral consumption of propylene glycol has not been reported to cause acute signs of toxicity, but the long-term effects of PG used as a food preservative have not been studied in birds. In cats, ingestion of PG can cause anemia. Ethoxyquin is another food preservative that may have unreported toxic side effects. This compound was originally used as a herbicide, and there have been some discussions that it may cause reproductive abnormalities in dogs.

Anthelmintics

Ivermectin in a PG base may cause toxic reactions when administered IM to budgerigars. Oral or topical administration is safer and equally efficacious. Ivermectin that is diluted in PG and allowed to stand should be mixed thoroughly before administration. Oral administration of a product that was not shaken caused seizures in several canaries and budgerigars. High-dose steroids reversed the clinical signs in these cases. Ivermectin persists in the environment and is excreted unchanged in the urine. Low concentrations that accumulate in water are extremely toxic to crustaceans, and whales may be particularly sensitive to this drug.

Dimetridazole was shown to have a low therapeutic index when added to the drinking water of cockatiel chicks. In nestlings (one to eight days old), the recommended concentration of 0.1% dimetridazole in the drinking water caused signs of toxicity including weakness, depressed growth rates, tremors and death. Older nestlings (over eight days old) showed no signs of toxicity at 0.1% concentrations.

At 0.5% dimetridazole, older birds developed signs of ataxia, weakness, inactivity, tremors, extensor rigidity of the legs and necks, and death. Consistent necropsy findings included multiple hemorrhages, pale livers and enlarged, pale kidneys. Treatment of adult cockatiels at the recommended dose appears to be safe. Dimetridazole should not be used in the drinking water during the breeding season when males may consume excess quantities of the drug and feed it to nestlings, causing toxicosis and death.[60]

Vetisulid and some other sulfa-containing antibiotics have been reported to cause hypersensitivity reactions leading to a hemorrhagic syndrome in gallinaceous birds.[17] They may also interfere with renal tubular excretion and are contraindicated in dehydrated or uricemic patients.[10] These antimicrobial agents should be limited in use to sensitive bacteria and the treatment of coccidiosis.[17]

Levamisole hydrochloride (oral) and levamisole phosphate (injectable) have been used to treat intestinal parasites in birds. Side effects associated with these agents in Psittaciformes and Galliformes include regurgitation, ataxia, recumbency, catatonia, dyspnea and death. Effects are immediate, and sur-

viving birds are clinically normal within one hour after administration. The dosage range used to study toxic effects in birds was 22-100 mg/kg. A dose rate of 22 mg/kg was considered effective for some parasites and was well tolerated by many genera of aviary birds.[54] Regurgitation is the most common side effect associated with oral levamisole administration, and food and water should be withheld for several hours prior to dosing.

The parasiticides praziquantel and fenbendazole have been reported to cause problems in finches and pigeons ranging from feather malformations to vomiting and death.

Antibiotics

Aminoglycosides have a narrow therapeutic index and are nephrotoxic. Gentamicin causes severe renal tubular necrosis and is the most frequently discussed member of the group. Systemic, topical and ophthalmic canine products can cause nephritis and are generally contraindicated in all companion birds. Amikacin is a safer alternative when an aminoglycoside is indicated. Renal function should be monitored during treatment. Administration of aminoglycosides into the leg is generally avoided due to the renal portal system of birds. It is speculated that drug administration in the leg muscles may cause excessive renal concentrations of the aminoglycoside, increasing the potential for nephrotoxicosis. If an intoxication is suspected, the antibiotic should be discontinued and diuresis with physiologic saline should be initiated immediately.

Tetracyclines, cephalosporins (especially cephaloridine) and amphotericin B[48] may also cause nephrotoxicosis in patients with impaired renal function.

Procaine penicillins have been associated with some toxic reactions in birds (see Chapter 18). A South American Black-collared Hawk experienced vomiting and acute collapse following an intramuscular injection;[48] however, this class of antibiotics is still considered effective and indicated in many bacterial infections. Vomiting may be noted following the IM or oral administration of doxycycline.

The popularity of enrofloxacin has been increasing in avian medicine because of its broad spectrum of activity and its good tissue penetration. Abnormalities in articular cartilage have been reported in squabs dosed at 800 ppm. Only one chick was affected at a dose of 200 ppm. Enrofloxacin was not shown to cause clinically recognizable joint abnormalities in a group of psittacine birds from a large aviary.[3,26]

Chloramphenicol, penicillin, tetracycline, oxytetracycline and sulfa drugs may cause deformities in embyos and should not be used in hens near or during the breeding season.[45]

Antifungals

Antifungal agents can have serious side effects, particularly with prolonged use. Amphotericin B has been associated with acidosis, azotemia, vomiting, seizures, hypokalemia, hepatic dysfunction, anemia, anaphylaxis and nephrotoxicosis.[48] Flucytosine may cause bone marrow depression, anemia, thrombocytopenia and leukopenia. Decreased renal function may precipitate gastrointestinal signs and elevate liver enzymes.[48] Amphotericin B used as a sinus flush caused a severe granulomatous reaction in an African Grey Parrot resulting in death.[66] The toxic side effects of these drugs should be considered when treating a bird for a fungal infection, and these agents should be used only when specifically indicated.

Hypervitaminosis

Increased awareness of the nutritional needs of birds and the availability of formulated diets and numerous dietary supplements have created problems associated with the consumption of toxic levels of some nutrients. Of particular concern are vitamins A, D_3 (cholecalciferol) and calcium. Many formulated diets contain excess quantities of these nutrients, and further supplementation of these diets with vitamin and mineral products can result in life-threatening toxicities.

Hypervitaminosis A can cause osteodystrophy characterized by thickening of the proliferative-maturation zone, metaphyseal sclerosis, hyperosteoidosis and decreased numbers of osteoclasts. Parathyroid gland hyperplasia can also occur (see Color 14).[63] Hypervitaminosis D_3 can cause mineralization of parenchymal organs including the liver, kidneys, stomach, intestines, heart and blood vessels.[64] High levels of vitamin D_3 cause an increase in serum calcium levels, which may affect cardiac conduction and smooth muscle contractions.[8] Renal calcification in macaws and African Grey Parrots suggests that they may be particularly sensitive to hypervitaminosis D and excess calcium consumption.[64] Excessive calcium

can lead to skeletal abnormalities, especially in developing chicks (see Chapter 3).

A thorough dietary history must be included in the general history of any patient presented for evaluation. Vitamin injections are often used in debilitated birds. If the patient has been on a formulated diet or over-supplemented previously, parenteral administration of a multivitamin preparation may cause or exacerbate a vitamin intoxication problem.

The formulation of the injectable supplement used is important. Injacom 100 is the injectable vitamin supplement recommended for use in birds. It is water-soluble and contains 100,000 IU vitamin A and 10,000 IU vitamin D_3 per milliliter. Regular Injacom is an oil-based product containing five times as much vitamin A and 7.5 times as much Vitamin D_3, which increases the potential for toxicosis when administered to birds.

Airborne Toxins

The avian respiratory system is more efficient than that of mammals. The disadvantage to this efficient system is that it readily extracts harmful gases and particles from inhaled air, increasing a bird's sensitivity to inspired toxins. Administering 100% oxygen to birds for more than 12 hours was found to be fatal with death occuring in four to eight days; exposed birds appeared stressed and uncomfortable as early as three days post-exposure.[62]

Polytetrafluoroethylene Gas

Polytetrafluoroethylene (PTFE) gas, released when various non-stick surfaces such as Teflon® overheat or burn, is a common respiratory toxin in birds. Potential sources of PTFE gas exposure include non-stick cookware, drip pans, irons, ironing board covers, the heating elements of some reverse-cycle heat pumps and heat lamps. As these surfaces are heated to above 530°F (280°C), they undergo pyrolysis and PTFE is degraded releasing irritant particles and acidic gases.[69,70]

The lungs are the target organ for PTFE poisoning in birds. Clinical signs are usually limited to sudden death, but depending on the degree of exposure may include somnolence, dyspnea, wheezing, incoordination, weakness, respiratory distress and terminal convulsions.[69,70] Death usually occurs too rapidly for treatment to be initiated.

Hemorrhage and congestion of the lungs are the usual postmortem findings (see Color 22).[69,70] These lesions are thought to be caused by exposure of the respiratory epithelium to inhaled acidic gases.[70] Occasionally, PTFE particles may be recognized histologically in some lung sections.

With minimal exposure, birds may respond to immediate transfer to fresh air, coupled with the administration of intratracheal and systemic steroids, broad-spectrum antibiotics, fluids and a warm environment to prevent shock, pulmonary edema and bronchopneumonia.

Tobacco Products

Birds should never be allowed to consume tobacco products. Ingestion of small quantities of nicotine can cause hyperexcitability, vomiting, diarrhea, seizures and rapid death. Treatment is supportive and symptomatic.

Passive inhalation of cigarette, cigar and pipe smoke can cause chronic ocular, dermatologic and respiratory disease in companion birds (see Chapter 22). Birds that live in homes with smokers will often present with clinical signs including coughing, sneezing, sinusitis and conjunctivitis due to continuous irritation of the respiratory system. The clinical signs may resolve without treatment if no secondary infectious agents are involved, the clients stop smoking or the bird is placed in a location where there is no smoke. Secondary bacterial invasion of the damaged respiratory epithelium is common and requires therapy; however, therapy for these infections will be of little value if the bird is continuously exposed to smoke.

In order to keep pet birds healthy, they should be maintained in well-ventilated, smoke-free environments (Ritchie, BW unpublished). Exposure to secondary smoke from marijuana can cause severe depression and regurgitation and should be strictly avoided.

Nicotine sulfate has been shown to cause severe skeletal malformation, reduced body weight, torticollis, edema, muscular dystrophy and malformation of the beak, heart and kidneys.[45] Pododermatitis has been observed in some birds handled by people who smoke routinely. Repeated exposure to the nicotine

FIG 37.8 An adult Amazon parrot was presented with a ten-day history of progressive picking at the feet with scab formation. The bird was fed a formulated diet supplemented with some fresh vegetables. The feet were hyperemic and the feathers were dull and appeared tattered, particularly at the ends. The bird had mild epiphora and a serous nasal discharge. Both adult clients were heavy smokers. The bird's ocular, respiratory and foot problems resolved when the clients stopped smoking in the house and washed their hands before handling the bird.

residues on the hands of smokers is thought to cause this local irritation (Figure 37.8). Macaws may suffer a similar dermatitis on the bare cheek patches following repeated contact with a smoker's hands. Many birds with severe feather picking problems will resume normal preening behavior when removed from exposure to cigarette smoke (Ritchie, BW unpublished).

Disinfectants

Disinfecting agents used to clean enclosures and food dishes should be used cautiously in aviaries and where companion birds are housed. Hatchlings and nestlings are especially prone to respiratory problems associated with chronic exposure to disinfectants or their fumes. A standard drain opener that contains sodium hypochlorite produced fumes that killed a Goffin's Cockatoo, African Grey Parrot and a cockatiel within minutes after a Clorox solution was also poured into the sink.

Irritation and dermatitis may occur following contact with many concentrated cleaning solutions (phenols, chlorhexidine and chlorine). All enclosures, nest boxes or aviary tools that are placed in disinfectants should be thoroughly rinsed with clean water before they are in contact with a bird.[11]

Direct contact between the bird and cleaning solutions should be avoided. If contact occurs, the area should be rinsed copiously with sterile saline. Application of antibiotic creams and bandaging may be necessary in some cases. When ingestion of cleaning products or disinfectants occurs, the manufacturer's recommendations for therapy should be followed. If recommendations are not available, then birds ingesting non-caustic materials should be treated with a mild laxative to speed passage of the solution out of the body. Gentle gavaging or flushing is indicated if a corrosive material has been ingested to prevent perforation of the esophagus or crop.[11] Corrosive materials require immediate dilution with water. Eyes or skin areas exposed to corrosives must be rinsed with clean water for at least twenty minutes. Systemic poisoning must be treated symptomatically, as there are no antidotes for disinfectant intoxications.

Ammonia and bleach are frequently used in household cleaning, and fumes from these products are commonly encountered by companion birds. Ammonia can be absorbed into the circulation by inhalation. In some species, increased blood ammonia concentrations have been shown to reduce lymphocyte function and alter their mitogenic activity resulting in a decreased cellular and humoral immune response. One study showed that blood ammonia concentration in excess of 1 mg/dl was an indication of toxicity. Even subtoxic concentrations (<1 mg/dl) in birds can predispose them to infectious diseases (see Figure 5.3).[24]

Ammonia and chlorine vapors can also irritate the epithelial linings of the eyes, conjunctiva, nares and respiratory tract. The resulting inflammation and damage can predispose these surfaces to secondary bacterial and fungal infections. Severe inflammation from exposure to strong concentrations of ammonia may impair respiration. Treatment consists of oxygen therapy, steroids to reduce inflammation and broad-spectrum antibiotics to combat secondary bacterial infections.

Miscellaneous Aerosols

Common household aerosol products such as perfumes, deodorants and cleaning agents may cause respiratory problems in birds. These problems arise from direct irritation of the respiratory tract by the fluorocarbons and particulates in these aerosols. The most common effect is inflammation and edema of the respiratory tract leading to dyspnea. In severe cases, death may occur shortly after a large or direct exposure. It is the authors' recommendation that aerosol sprays not be used in areas where companion birds may be directly exposed, and definitely not

sprayed directly on the bird. Formaldehyde fumes have been associated with epiphora, dyspnea and death in canaries (see Figure 5.3).[19] An ozone generator caused the deaths of some birds in a pet shop. A cockatoo that was in the same room where a suede protector was used developed dyspnea within two hours, and died five hours after being exposed to the fumes from this product.

Leaks in natural gas lines may cause subtle respiratory signs in birds, even when no odors are detected by the clients. With more serious leaks, sudden death can occur. When birds are presented with respiratory problems or weakness of unknown etiology, careful questioning concerning the home environment may help determine if a leaking gas line could be a contributing factor. Kerosene fumes may also be toxic to birds, and combustible space heaters should not be used in homes containing companion birds.

Carbon monoxide (CO) is an odorless, colorless, tasteless gas produced by combustion engines and some furnaces. Birds maintained in poorly ventilated, heated areas, or transported in poorly ventilated vehicles (especially in car trunks) are at high risk of CO poisoning. Carbon monoxide competes with oxygen for hemoglobin binding sites in the blood. The affinity of hemoglobin for CO is about 250 times greater than its affinity for oxygen in mammals. Binding of CO to hemoglobin decreases the ability of oxygen to dissociate from hemoglobin, resulting in hypoxia. Carbon monoxide poisoning can occur when birds are placed in a confined area where the gas cannot escape.

Birds suffering from CO poisoning may die acutely and have bright red, apparently well oxygenated blood and pink- or red-colored tissues. Other signs of CO poisoning include depression, somnolence and dyspnea.

If CO poisoning is suspected, fresh air should be provided immediately, and emergency care should include the administration of 90 to 95% oxygen in a cool, dark, stress-free environment. Oxygen toxicosis can occur if a bird is exposed to O_2 levels of 90% to 100% for prolonged periods.[62]

Pulmonary silicosis caused chronic dyspnea and death in a Blue and Gold Macaw. The bird was exposed to the silicone through peat moss used as nesting material. In humans, a silicone/sulfur ratio of over 0.3 is considered indicative of silicosis. The ratio in this Blue and Gold Macaw was 9.07.[49]

Grossly, this bird's lungs appeared necrotic, and unencapsulated pyogranulomatous nodules that contained deposits of pale, amphophilic, refractory crystalline material that displayed birefringence when exposed to polarized light were seen histologically. Similar toxicities have been described in a rhea, ostrich, turaco, swan, owl, crane, duck, kiwi and Ring-neck Pheasant.[49]

Insecticides

Exposure to high concentrations of pesticides can lead to nonspecific signs of poisoning including gastrointestinal problems, tremors, weakness, dyspnea, seizures or sudden death. Chronic low-grade exposure to pesticides may induce more subtle clinical signs that are more difficult to attribute to a toxin exposure. These exposures may cause immunosuppression and increased susceptibility to disease, decreased reproductive activity or generalized unthriftiness (Figure 37.9).

The most commonly used household insecticides contain pyrethrins, carbamates and organophosphates. While pyrethrins and carbamates are occasionally used as pesticides in association with birds, these agents are nonetheless toxic, especially following inhalation or contact with high concentrations. Pesticides may be absorbed through the skin following secondary contact with treated surfaces. Additionally, many insecticides contain carriers that can be irritating to the skin and respiratory tract mucosa.[11] Ingestion of foods contaminated with common agriculture pesticides could be a source of intoxication in birds. All grain products, fruits and vegetables that are not certified organic have levels of pesticides that have been determined to be acceptable ("safe" is a relative term) for human consumption. The effects of constant exposure of birds to these toxins has not been determined.

If absolutely necessary, dusting powders containing pyrethrins or carbamates (eg, 5% Sevin) can be used with some margin of safety on birds.[11] These compounds are not absorbed through the skin and are more likely to penetrate the feathers than sprays; however, excessive preening (ingestion) or inhalation of the dusts can lead to systemic intoxication that is dose-related.

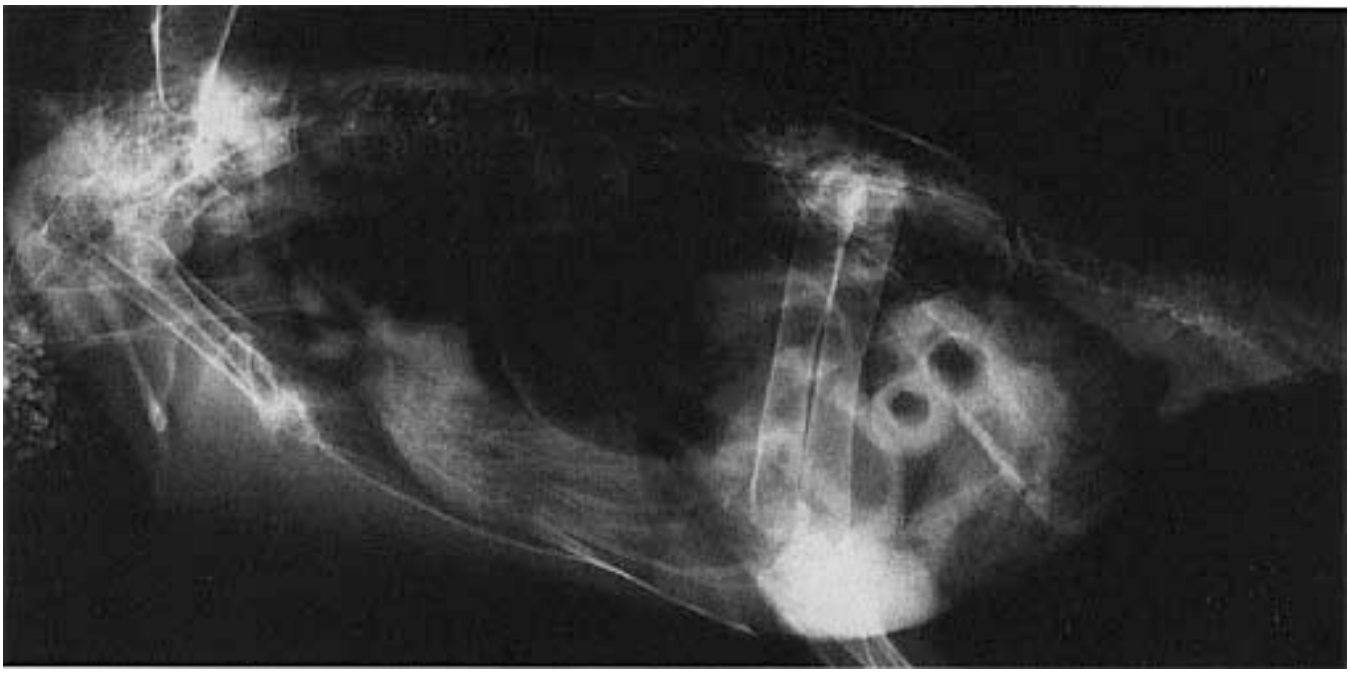

FIG 37.9 A Scarlet Macaw that was housed ten feet from a cyclic (every 30 minutes) pyrethrin mister was presented for regurgitation and severe weight loss (590 g). Radiographs indicated ileus, microcardia and microhepatia. Note the gastric distension of an empty cranial gastrointestinal tract and a full crop. The bird did not respond to supportive care. A perforating proventricular ulcer and liver cirrhosis were demonstrated at necropsy (see Color 19).

Clients can minimize a bird's exposure to insecticides by providing clean water and residue-free foods. If fresh fruits and vegetables are provided, they should be thoroughly rinsed in clean water to remove any insecticides used by the grower. Care must be exercised when pesticides and other volatile chemicals are used in and near a bird's area. Any materials used for perches should be thoroughly scrubbed and rinsed before being placed into the bird's enclosure.

Most potential contaminants are difficult to detect, and it is best to err on the side of caution. The effects of modern petro-chemicals on companion birds can only be postulated using the statistics that suggest their impact on the declining migratory bird populations in North and South America.

Organochlorines

The use of some organochlorines (DDT and DDE) have been banned in the United States and other countries, yet reports of poisoning in native species persist.[47] Migratory birds may be exposed in other countries that still use DDT produced in the United States. Poisoned birds may develop signs of convulsions, blindness (pupils may or may not respond to light), ataxia, anemia and hypoproteinemia. Gas chromatography can be used to determine tissue concentrations of these compounds.[47]

Organophosphates

Clinical signs of organophosphate toxicity are caused by inhibition of acetylcholinesterase. Organophosphate poisoning in raptors appears clinically different than is typically described for mammals. Raptors are frequently contaminated by consuming poisoned starlings or grackles.[47] Clinical signs include ataxia, spastic nictitans, a detached attitude, inability to fly and occasionally convulsions. If present, convulsions are characterized by rigid paralysis, tightly clinched talons, rapid respiration, alivation, twitching of muscles and anascaria.

Scoliosis, lordosis (shortening or contortion of the axial skeleton) and severe edema were described in embryos exposed to parathion. Diazinon caused incomplete ossification and stunting. Carbaryl, methomyl and permethrin were considered relatively nontoxic to embryos.[45]

Dichlorvos (DDVP, Vapona) is a commonly used organophosphate that is impregnated in insect repellant strips. It is best for birds not to be exposed to any inhaled toxins; however, if a dichlorvos insecticide

must be used, it should be placed in a well ventilated room of appropriate size. Direct oral exposure should be avoided. Smaller species (eg, canaries, finches) are more sensitive to the pesticide vapors than budgerigars and larger psittacine birds.[11] In addition, higher ambient temperatures increase the risk of intoxication.[11] Other sources of avian exposure to organophosphates include flea collars, contaminated fruit limbs and frequently treated baseboards. There have been reports of birds being poisoned by consuming food that was stored in containers in which dichlorvos strips had been placed to control insects. A mite protector (para-chlormetazymol) placed in a container of finch seeds was thought to have caused the death of a finch. Seven of 15 canaries and finches died when moth balls were enclosed in a container that held their seed mix.[23] The toxic ingredients in these products are naphthalene and para-dichlorobenzene, respectively.

Pyrethrins have perhaps the lowest degree of toxicity in birds and warm-blooded mammals. They are often combined with the synergist piperonal butoxide to enhance insecticidal activity.[11]

General Considerations

Birds suffering insecticide intoxication can manifest symptoms similar to those observed in mammals including sudden anorexia, incoordination, weakness, ataxia, muscle tremors, diarrhea, convulsions, respiratory difficulty and bradycardia.[23,34,53] Sudden death is usually due to respiratory failure from a single high-dose exposure.[38] Other less obvious signs of exposure include reductions in hatchability and egg production. These clinical changes are more common in breeding populations chronically exposed to pesticides.[38] While taking a history, clients should always be questioned about their use of insecticides in and around (outside open windows) the home.

A tentative diagnosis of insecticide poisoning is usually possible with a history of recent exposure and appropriate clinical signs. Whole blood acetylcholinesterase activity can be used to confirm a diagnosis of organophosphate intoxication. This test is frequently available in human pediatric laboratories. A sample from an unexposed bird should be included to serve as a control. In quail dusted with carbaryl, plasma cholinesterase activities were depressed up to 27% within six hours.[20]

There are usually no gross postmortem changes associated with insecticide poisoning, although in some cases lung edema and hemorrhage may occur. A definitive postmortem diagnosis can be made by tissue analysis of the liver, kidneys, body fat and gastrointestinal contents for insecticide residues. Brain cholinesterase activity can be used to determine if the bird's death was due to an organophosphate intoxication; clinical analysis of tissues may not always be reliable due to the rapid metabolism of these insecticides.[38] Any tissues to be analyzed for insecticide residues or acetylcholinesterase activity should be submitted frozen in separate containers.

Treatment for organophosphate toxicosis includes supportive care (supplemental heat, fluids and diazepam to control seizures). Atropine is indicated for cholinergic signs (0.2 to 0.5 mg/kg one-fourth dose IV or IM every three to four hours).[47,53] Pralidoxime hydrochloride (2-PAM) is antidotal for organophosphate intoxications. 2-PAM was administered to King Pigeons with good results at 10 mg/kg IM.[53] The recommended range for mammals is 10 to 100 mg/kg. Steroids may be beneficial for the treatment of pulmonary edema or shock. For maximum effectiveness, antidotal therapy must be initiated within 24 hours of exposure. Organophosphates irreversibly bind to acetylcholinesterase. The more binding that is allowed to occur, the less effective the antidote will be.

Carbamates

Carbamates' mode of action, induced clinical signs and methods of diagnosis and treatment are the same as for organophosphates, although 2-PAM is contraindicated. Over 2,000,000 bird deaths are estimated to occur annually in the United States as a result of the granular carbamate, carbofuran.[47]

Rodenticides

Most rodenticides are of the anticoagulant variety. The first-generation products (warfarin) are less toxic and require longer periods of exposure than the newer generation products (brodifacoum). Clinical signs of toxicity include depression, anorexia, petechiation, epistaxis and subcutaneous hemorrhage. The antidote is vitamin K_1. Some rodenticides contain cholecalciferol or bromethalin and are potentially more difficult to treat than the anticoagulant types. Rodenticide poisoning has been reported in quail and aviary birds when the poison is carried into the bird's food or water by contaminated rodents. Secondary poisonings of raptors from consumption of poisoned rodents (brodifacoum - Talon) have also been reported.[19]
