Acknowledgements

Enormous cooperation and support from many individuals are required for a project of this magnitude. It has truly been an honor to coordinate the efforts of so many dedicated authors, and we appreciate their giving of their personal time in participating in this undertaking.

We especially want to thank Dr. Lesley E. Sealing, who was extremely committed to the tedious and long-term effort of developing the medical illustrations, including the anatomy overlay of the cockatoo.

We are indebted to the international authors, particularly Helga Gerlach and Sjeng Lumeij, for their immense contribution to the book (some of these authors had to write in a "foreign" language — all scrutinized the world's literature and brought a fresh perspective to this work); additionally, John Olsen, Kenneth Latimer and Avery Bennett contributed beyond their initial commitment.

Deep appreciation is extended to those whose lives and schedules were disrupted by the time commitment of the editors: the research team, staff and students at the University of Georgia, including Cheryl Greenacre, Ken Latimer, Frank Niagro, Phil Lukert, Denise Pesti and Michelle Weatherly; the staff and clients of The Bird Hospital and Harrison's Bird Diets; and the staff, board of directors and members of the Association of Avian Veterinarians.

The outstanding color reproductions of hematology cells from Lucas and Jamroz' originals were produced by Alex Webber from the Educational Resource Center at the University of Georgia. Joey C. Rodgers and Stacy Koffman from the Education Resource Center produced the exceptional quality black and white prints. Color endophotographs were made possible through the support of Karl Storz Veterinary Endoscopy - America. The color separation skills provided by Color Trend, Inc. were responsible for the quality of the color prints.

We are grateful for other colleagues who were willing to share portions of their previous works through this medium: Karen Hicks, John Wade, Murray Fowler, Alice Blue-McClendon, Peter Stettenheim, Irene Pepperburg, Charles Munn and Ken Fletcher; and for the radiographs, illustrations and photographs from Stephen A. Smith, Bonnie J. Smith, Maria-Elisabeth Krautwald-Junghanns, Murray Fowler, Brett Hopkins, Busch Gardens Tampa, Jane Turrell, Apalachee River Aviary, R. Korbel, Robert Schmidt and Ellman International Manufacturing, Inc.

In addition to the authors, the editors would like to thank Martin Orr, Robert Clipsham, Nina Ungerechts, J. Richmond, Priscilla B. Wyrick, W.T, Atyeo, Michael Lutz, K. Göbel, Exotic Animal Medical Products, Mark Spreyer, D. Brückner, Curt Vogel, S.W. Jack, David Ley, Richard Cambre, Louis Filippich, Cheryl Greenacre, R.J. Montali, Michael Murray, L. Karpinski, Jean Paré, K.C. Barnett, S. West, Dan Wolf, Isabel Taylor, W.S. Steffens, Jean Sanders, Bob Dahlhausen, Carol Partington, Elizabeth Watson, Ramiro Isaza, John Randolph, and Avian Research Associates for providing photographs used in this book. Others who contributed to the graphic aspects include Lauri Maniccia, Lynda Hare and Tom Elfers.

We appreciate the comments of colleagues who received early manuscripts: Jim Stunkard, Christopher Murphy, James Harvey Johnson, Don Harris, Louise Bauck, James Harris, Michael Murray, and for technical support from Vicki McConnell, Carrie Reynolds, Donna Hurd Smith, Mamie Watson, Randi Gilbert, Chris Migliore, Shirley and Bob Harlan.

For extra and continued support, without which this book would not have been possible, we thank Terry Clyne, Helga Gerlach and Marion Litonski, Dana O'Donoghue, Harrison's Bird Diets, and Irving Cowan for his support of avian health.

And finally, our deepest thanks to the staff of Wingers Publishing for transforming our concepts into reality.

Foreword

Avian medicine has been an integral part of veterinary medicine for a long time, but still relatively few veterinarians include members of the avian species among their patients. This is rapidly changing as companion birds become increasingly popular. The economic and emotional value of these pets is significant. Veterinarians who have adequate education and talent to provide services for companion and aviary birds have a competitive advantage in private practices.

Avian Medicine: Principles and Application fills a critical need for a reference and medical text capable of raising the standard of veterinary care for birds. It can be predicted that users of this text will become more competent, provide improved service to their patients and clients and, realizing their limitations, understand when to refer cases to colleagues with more expertise. The scope of this work is comparable to that of other reference texts that have been available for many years for most of the other animal species with which veterinarians practice their art and science. For companion avian practitioners, the book documents the scientific basis for veterinary practice that benefits these animals. *Avian Medicine: Principles and Application* also marks a stage in the maturity and acceptance of avian species as patients for veterinary practitioners.

Veterinarians and other scientists interested in the avian species will recognize the considerable efforts that the editors and authors have made. *Avian Medicine: Principles and Application* is rooted in fact and made relevant to practice by the experience of the contributors. These experiences, when combined with scientific facts derived from dispersed literature sources as a foundation, plus the excellent illustrations, come together in a way that makes *Avian Medicine: Principles and Application* a powerful tool for education.

Education in avian medicine is expanding in some of our veterinary colleges. Some colleges have strong, internationally recognized programs in poultry and/or companion avian medicine. These programs are likely to provide centers of excellence for all veterinary students interested in birds. This book will be a resource to stimulate and enhance that student interest.

Avian medicine has a great future. New standards based on comprehensive scientific information are available. In the past, much empirical or clinical experience information was held by relatively few practitioners. Their experiences, while shared through traditional continuing education programs and some publications, were not widely accepted as having a strong scientific foundation. This book provides critical linkage between scientific data and clinical experience. Time will prove the acceptance and usefulness of the efforts of the editors and authors. I commend them for their contribution to veterinary medicine and appreciate having this opportunity to provide a few introductory thoughts.

Oscar J. Fletcher, Dean
College of Veterinary Medicine
North Carolina State University
Raleigh, North Carolina

Preface

With the increased need for competent avian practitioners and the formation of avian specialty programs worldwide, clinicians as well as academicians will be required to have a more comprehensive understanding of applied anatomy, physiology, internal medicine, pharmacology, disease management and preventive medicine.

Avian Medicine: Principles and Application has evolved to reflect this change and provides its readers with a definitive reference text that blends the science of health with the art of clinical medicine.

This book was designed to provide relevant information for every reader: it introduces the beginner to avian medicine; it provides a learning opportunity for the veterinary student; it stimulates the seasoned practitioner to expand and deepen his diagnostic and therapeutic skills; and it heightens the awareness of the avicultural community to state-of-the-art medical care.

By applying the information presented in this book, the competent avian practitioner will be able to effectively provide the highest quality care for his patients and guide the companion bird client or aviculturist in implementing an effective preventive health program.

Beginning practitioners can learn basic evaluation, support and surgical techniques while developing an expanded understanding of advanced procedures that can be performed by specialists in avian medicine and surgery.

Most of the principles in this book have been detailed with respect to psittacine birds. In general, these principles can be applied to the care of other avian species. For example, information presented in the endocrinology, theriogenology, cardiology and flock management sections of the book may be applicable to ratites, pheasants or waterfowl.

With the restriction of bird imports, it is now necessary for aviculturists to produce all companion birds in the United States. The success of this endeavor will depend on continued exchange of knowledge between the aviculturist and the veterinarian. It is hoped that this book will emphasize the importance of this liaison, even if in a consulting capacity.

According to philosopher Emmet Fox, "The mere acquisition of fresh knowledge received intellectually makes no change in the soul." Likewise, scanning the book for drug doses will not improve the quality of one's avian practice. A commitment to studying and applying the principles set forth in this book will.

Readers may be encouraged to approach this book, especially some of the comprehensive "core" chapters, from a new perspective. For example, study groups may be developed to systematically examine the individual chapters and discuss their application to the care of birds.

No matter how the book is approached — from group study, individual investigation or as reference for a clinical case, the challenge to the reader is to improve the health of birds by fully applying the information provided in this text.

Advancement in the field of avian medicine will require all interested individuals and allied industries to provide the means necessary to advance our understanding of birds through sound, well designed, clinically relevant research. It was the intention of the authors and editors of this book to stimulate its readers to become actively involved in the advancement of avian medicine.

Although the amount of information concerning the care of companion and aviary birds is increasing at incredible speeds, there are times when one has to concede that, with regard to avian medicine we don't even know what we still don't know. This paradox can only be resolved by constantly investigating the unknown, and applying newly derived information to the resolution of identified problems.

Prologue

Avian Conservation: The Veterinarian's Role

Robert Groskin

What is the role of the avian practitioner in avian conservation? How can a conservation philosophy be integrated into veterinary practices? What are the current issues in avian conservation science?

A conservationist is an individual who advocates for the planned preservation of natural resources. The roots of conservation can be found with early man, who lived at a time when there was ample food and land. A hunter's success was believed to be based not on his skill, but on his ability to show ample respect for his prey, whereupon his prey would present itself to him. In return, the hunter would perform a ceremony, releasing the animal's spirit. In this way the animal could return to replenish the herds of antelope or schools of fish. Joseph Campbell characterizes this concept as the beginning of religion.[3] Perhaps it was also the beginning of conservation.

Early Native Americans correctly saw no difference between man and animals. They believed that all beings were brothers and sisters. All creatures had knowledge to impart. Man, being the youngest creature, had the most to learn. The Plains Indians considered the two-legged creatures (eg, man, birds, bears) to be healers, and these creatures needed to work together to correct the imbalances of nature.[4] By demonstrating humility and respect toward their brothers, man believed the other animals would share their knowledge.[4] The three concepts of 1) oneness with nature, 2) humility and respect for nature and 3) a desire to care for and protect one's brother or sister have become fundamental ideas of contemporary conservation philosophy and stewardship.

"In the end we will conserve only what we love, we will love only what we understand, we will understand only what we are taught."

Baba Dioum, Senegal

Modern conservation philosophy is expressed in many of the ideas of Aldo Leopold, forester, writer and conservationist. He recognized man's increasing isolation from nature and his need to relate in some way to nature and to life on earth, from both an evolutionary and ecological perspective (defining to some extent the human-animal bond).[12,14] Leopold had a strong love and respect for the forest, and as a landowner maintaining his property, he had to choose which trees needed to be felled. To him, the best definition of a conservationist was "written not with a pen, but with an axe. It is a matter of what a man thinks about while chopping, or while deciding what to chop. A conservationist is one who is humbly aware that with each stroke he is writing his signature on the face of his land. Signatures of course differ, whether written with axe or pen, and this is as it should be."[14]

As avian practitioners, what do we think about when we are treating our patients? Are we aware of the connection between ourselves and our patients? When we treat our avian patients, do we see them as brothers and sisters? Do we demonstrate humility and respect for them such that we in our role as healers may learn from them? Do we see our role as stewards extending beyond the examination table? How can we help ourselves, each other and our clients develop an ethic "to correct the imbalances in nature" that we have created?

Man and Birds

Humans have related to birds primarily as consumers, using birds for recreation, as food and as religious symbols.

Historical Affinity

In Medieval times, falcons were symbols of authority and were used for recreation and hunting. In the 18th and 19th centuries as European cities grew, wealthy landowners wanted their estates to resemble more "natural" settings. They collected live birds, especially waterfowl, and established private mini-zoological gardens.

Colonialism exposed wealthy Europeans to birds from other continents, and large outdoor aviaries were built for non-indigenous species. Commercialization of trade in live birds for indoor and outdoor exhibits and bird products (eg, skins, feathers, eggs) grew during this period. In the mid-19th century, curators were hired to manage some of the largest collections of bird skins. Their studies heralded the emergence of ornithology as a separate biological science.[11]

Ornithology attracted considerable attention among the scientists of that time. Some of the basic questions that were asked in the early 1800's dealt with the distinction between varieties and species, what determined the distribution of the various species, and what was the relationship between extinct and living species. The discussion of these topics set the framework for much of Darwin's hallmark thesis, "The Origin of Species."[9]

The consumption of birds purely for collection still exists today, but on a much more limited basis. As avian veterinarians, one of our primary responsibilities is to educate our clients about the responsibility of individual companion bird stewards and to discourage the "collection" mentality.

The ornithological community is currently debating the need for collecting and killing birds for scientific study.[7] Some ornithologists have captured new species to study them in the laboratory and later released the birds back into the wild.[8]

Modern Relationships

The common thread for recreational use of birds today, which includes hunting, falconry, watching and photographing activities, feeding, pet ownership, rehabilitation and aviculture, is the individual's desire to contact nature. People seek to contact their roots and appreciate the oneness of life around them. Conservation reflects a "state of harmony of man and the world he lives in."[14] It provides an understanding of man's past and present roles on earth, which guides the future roles. The recreational uses of birds can enhance conservation when they increase that understanding. Recreational uses of birds have the greatest value when they do not impact on free-ranging bird populations.

Bird watching, photographing and feeding have minimal effects on bird populations and benefit both humans and birds.

Approximately 34% of Americans either photograph birds or watch birds. Bird watchers have been re-

sponsible for the collection of large databases concerning bird populations, habitats, breeding sites and numbers, migratory patterns and other biologically related statistics.[20] As a result of their amateur wildlife research, bird watchers provide invaluable scientific information and simultaneously enhance their own appreciation for the integrity of our entire ecology.

A 1989 survey of non-hunting recreational activities revealed that 46% of Americans feed birds either in parks or at backyard feeders.[9] This activity helps children develop an appreciation for wildlife and a conservation ethic. Seasonal group bird counts and surveys provide demographic data regarding wintering species.[20]

Rehabilitation

Because of their interest in birds, avian veterinarians are often called upon to treat injured native birds. Assisting injured wildlife offers an opportunity for the veterinarian to expand the public's understanding of avian conservation. Many native birds are protected by federal and state laws and permits are required for veterinary care and even short-term possession of these species. Developing a relationship with a qualified rehabilitator could be helpful to both the rehabilitator and the veterinarian. The care of certain native species, ie, endangered or threatened species, should be undertaken only by veterinarians experienced in the care of these birds and with suitable facilities. Wildlife rehabilitation centers are always in need of volunteers. Clients who have demonstrated a strong interest in wildlife should be encouraged to volunteer at these facilities.

Hunting

Hunting as a recreational use of birds consists of two categories: hunting free-ranging wildlife and hunting stocked species. In terms of conservation ethics, hunting stocked wildlife is similar to the consumptive use of birds for food. Contemporary hunting of free-ranging birds initially was useful as a conservation management tool. Bag limits today, however, function to preserve the species, not to help reduce excess populations. Hunting has conservation value when the hunter appreciates both his prey and the environment of the animal. With the use of high-tech equipment, the hunter has become more isolated from his prey; consequently, the experience provides less conservation value. Some hunting groups (eg, Ducks Unlimited) are actively engaged in habitat preservation.

Falconry is one of the oldest recreational uses of birds. Falconers have been successful in breeding and reintroducing falcons. Of the 566 raptors bred in captivity in the United States in 1988, 25% were used for reintroduction programs, 50% for falconry and 25% were returned to captive-breeding programs.[6]

Aviculture

Aviculturists support avian conservation by using birds already in captivity for their breeding programs to decrease the need for importation. The chicks they produce for the companion bird market will further reduce the pressure on wild populations. In addition, the knowledge they gain from captive breeding efforts is used by field biologists to more effectively evaluate and manage native populations. Avian veterinarians can bridge the gap between aviculturists, biologists and conservationists by encouraging the sharing of knowledge and experience.

The success of the Peregrine Falcon, California Condor and Whooping Crane breeding programs is due, in part, to the commitment of aviculturists to conducting in-depth studies of a single species. This focus saves time and money and prevents the dilution of energies that often occurs with aviculture programs that involve a variety of different species.

Some areas of the United States seem to be better suited for the breeding of some species. The concept of focusing avicultural efforts on bird species that breed well in a certain geographic region needs to be carefully considered.

Companion Birds

The recreational use of birds as pets has had a profound and permanent effect on the population of many free-ranging bird species.[6] From a conservation perspective avian veterinarians should encourage clients to continue to buy domestically raised or ranched birds, thereby supporting captive breeding and sustained harvesting, and thus relieving pressures on native populations.

In addition, clients should be educated about the physical and emotional needs of their companion birds, thereby ensuring the health and welfare of the birds and increasing the involvement of the owners with their bird. The goal is to change the nature of the relationship from one of consumptive ownership to a companionship/stewardship relationship.

Conservation Biology

Conservation is a science as well as a philosophy. Avian populations, especially psittacines, have experienced recent dramatic declines. Of the nearly 330 Psittacidae species that are seriously threatened or at risk of extinction, most are a result of habitat loss and the pet trade.[6] Considerable efforts are being made by conservation biologists to halt these losses. Figure 1 summarizes the current approaches to parrot conservation.[14] Many of these methods are equally valuable to other species.

One of the key approaches to conservation of neotropical parrots involves aviculture. Working with the aviculturist, veterinarians can help provide healthy birds for the pet trade. The advances in avian theriogenology, neonatology and pediatrics discussed in this text are not only useful for the pet trade but are essential for the success of species survival plans (SSP) for endangered species, sustained harvesting of parrots and reserve management. Some species exist today only in captivity. Maintaining a viable genetic pool of these birds is essential.

There are many questions regarding captive breeding. Are the progeny of these birds releasable in their native habitat or non-native habitats? Are there genetic changes that result from captive breeding that might affect the ability of captive-bred birds to survive in the wild? What are the risks of introducing diseases to native populations or altering the ecology of the habitat with the introduction of captive-bred birds?

Domestication of Companion Bird Species

With the exception of budgerigars, cockatiels, canaries, pigeons and lovebirds, the psittacine birds we see in practice today are a blend between free-ranging and domestic. As a consequence of domestication, there are behavioral and anatomic changes which become evident within the first few generations. The behavioral changes include three major characteristics: docility, curiosity and a disrespect of species barriers.[15] All three of these characteristics are considered neotenic, ie, youthful, traits.

In an avicultural setting, individuals displaying neotenic behavioral characteristics would most likely be favored by the aviculturist.

What effects does domestication have on resistance to disease? Younger animals tend to have an increased susceptibility to disease. Will domestication and the favoring of neotenic traits also lead to an increase in disease? Are more diseases being found in companion birds than in their free-ranging counterparts because companion birds are more easily studied, or is the effect of captivity and domestication increasing susceptibility or exposure to disease?

Infection is difficult to assess in free-ranging birds. The relationship between parasite and host is carefully balanced in nature. What effect will domestication have on this relationship? Will, for example, subclinical parasites such as *Haemoproteus* sp. become more significant diseases with increased domestication?

Are the reproductive problems associated with cockatiels a result of their domestication? Why are there so few flocks of budgerigars and cockatiels found in non-native habitats? Escape from homes is very common, yet flocks of these birds are established only in limited areas. Have these domesticated birds lost much of their ability to survive?

Research on White-naped Crane eggs has shown that the microclimate surrounding these large eggs is actually a substantial thermal gradient. Incubated eggs do not have any temperature gradient. Is this microclimate essential for successful hatching of

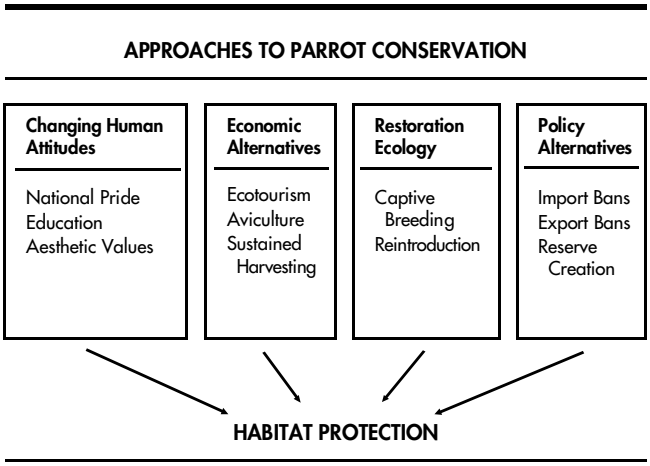

FIG 1 A general scheme of approaches to conserving neotropical parrots (courtesy of Bessinger SR, Snyder N (eds): New World Parrots in Crisis. Washington DC, Smithsonian Institute Press, pp xiii, 1992).

FIG 2 Preservation of native habitat is a major challenge in the conservation of bird species.

large eggs? Does this thermal gradient have a specific function? How is the phylogeny of incubator-hatched birds being affected?[17]

Over a century ago, Darwin and Wallace proposed conflicting views about the origin and function of prominent male secondary sexual features and their effects on the female's choice of a mate. Research and debate on this subject is still very intense today.[18,19] How are genetics, resistance to disease and reproductive strength of avian species being altered when birds are artificially paired? How large a flock is needed to allow mate selection and adequately protect the genetic pool? Is valuable genetic stock being removed by hybridization of easily bred species? Should this practice be discouraged in order to preserve as much of the gene pool as possible?

Aviculturists who intend to provide birds for reintroduction programs will need to establish specific flocks for this purpose that are separate from birds intended for pet trade purposes. These birds must be maintained and managed differently from companion birds to minimize the effects of domestication. Individuals who have committed themselves to such an endeavor face difficult economic and scientific obstacles. As avian veterinarians, we need to acknowledge, encourage and support these valiant efforts.

Harvesting

Avian veterinarians will need to play a significant role in the sustained harvest, or ranching, of birds. Ranching differs from captive breeding in that the breeder flock is not removed from its native habitat. The number of offspring "harvested" is based on the local site biological data.

Parrots appear to have considerable potential as a sustainable harvest. They can be harvested as nestlings (low reproductive value) and require minimal captivity time before reaching the market. Both large and small landowners can participate, and there is considerable potential to increase harvests through existing management techniques.

Because habitat protection is an integral part of successful ranching, this method of conservation has the

potential to protect not only the species being ranched but the entire ecology.

Some of the problems associated with harvesting include the social and political structures needed to allow for the lawful export of the harvest, protection of the birds from poaching and over-exploitation, fluctuations in demand for birds, ensuring that importation of these birds does not increase the level of young taken from the wild and the need to develop adequate data upon which to base harvesting levels.

Avian veterinarians may play an important role in the prevention of disease on the ranch and during the collecting and shipping stages. The use of herpesvirus and poxvirus vaccines and DNA probes to detect birds subclinically infected with PBFD virus or polyomavirus are examples of contributions avian veterinarians can make to enhance sustained harvesting.

Captive Breeding and Reintroduction

When faced with imminent extinction, captive breeding with the goal of reintroduction remains the only alternative for preservation of a species. The conservation community is not in full agreement about captive breeding of endangered and threatened species because of the many scientific, economic and political considerations involved.

However, before a captive breeding program for a species can be established, several questions need to be asked. What is the appropriate time to start a program? How many founding members are needed to ensure an adequate gene pool? Where will this program be based and is the institution willing to provide sufficient economic and administrative commitment to sustain such a program for the period of time needed for reintroduction? If not based in a public institution, does sufficient cooperation and accountability exist among private breeders to ensure a successful breeding program? How has the issue of ownership of progeny been resolved?

Although many technologies exist to aid these programs, the species that require captive breeding assistance often have a poor level of reproductive success in captivity. As mentioned above, genetic changes in captive breeding may develop within the first few generations, necessitating reintroduction as soon as possible to ensure the maintenance of wild-type breeding stock.

The potential for introducing diseases common in captive populations into native populations as a result of releasing birds is a significant consideration. To prevent losses, the flock must be divided into viable groups, managers must be attentive to husbandry and sanitation and movements must be restricted between populations. Avian veterinarians will be important members of the management teams.

With a decrease in available habitat, all the factors for disease transmission among free-ranging birds (eg, nutrition, increased proximity, stress) become more significant. Conservation biologists are concerned that these aspects not be neglected.[18] The role of the avian veterinarian will become more important in helping to assess disease in free-ranging avian populations.

Psittacines have the potential for reintroduction once appropriate criteria have been met. Factors that contributed to the decline of the native population must be modified sufficiently in order for the newly released birds to survive. Habitat protection, predator control, harvest of free-ranging birds and reduction of human activity, both recreational and commercial, must also be considered. Until we have a greater understanding of how these and other factors affect populations, release of captive-bred psittacine birds may not be an effective conservation method.

Under some circumstances it may be preferable to establish new populations in previously non-native but suitable habitats. The impact of these introductions needs to be thoroughly evaluated to minimize any risks to the native species and habitat.

Treaties and Legislation

Trade in neotropical parrots has played a significant role in the decline of these species, affecting perhaps as many as 17% of the endangered neotropical parrots. Trade and habitat destruction affects an additional 36% of these species.[5] Attempts to control this trade include legislation designed to decrease or eliminate the import and export of these species. The Convention on International Trade in Endangered Species (CITES) is the most important international treaty affecting avian conservation. The 1992 CITES meeting in Japan focused on the issue of bird trade. New procedures enacted at that meeting allow the Standing Committee of CITES to immediately halt trade in an Appendix II species (species for which careful management is required to ensure that trade

remains sustainable) or to stop trade altogether from a treaty member of CITES. These changes have the potential to significantly improve the situation for these endangered and threatened species.

Until 1992, all United States legislation effecting trade in wild-caught birds was at the state level. In 1984, New York State was the first state to enact legislation banning the importation and sale of wild-caught birds. This ground-breaking law sought to establish importation restrictions that would be enforceable, not result in an increased rate of smuggling or diseased birds and allow for the growth of the avicultural industry. One of the major impacts of this type of legislation was to increase the public's awareness of avian conservation.

Wild Bird Conservation Act

Ultimately the conservation community, aviculturists and the pet industry realized it was in the interest of all parties' to ensure the continued survival of wild bird species. After several years of discussions and negotiations, the Wild Bird Conservation Act of 1992 was enacted. This is the most significant legislation affecting the importation into the United States of wild-caught birds. Avian veterinarians contributed to the passage of this act. Provisions of this act require certification of foreign breeding facilities by the U.S. Fish and Wildlife Service. Input by avian veterinarians will continue to be needed in this area. One important goal of these types of legislation is to help ensure protection for wildlife in foreign countries equal to the protection we provide for our own wildlife.

No single act will have as much influence on the avian practitioner as the Wild Bird Conservation Act. What will be the effect of domestic breeding on the population of companion birds? What will be the effect on diseases of pet birds as a result of their increasing domestication? How will the pet bird differ from the wild bird? With a shrinking habitat and increasing human population, almost all species are feeling the presence of humans, both directly and indirectly. By watching carefully the effects of domestication on "wild" species of birds, we might be able to anticipate and prevent those changes in other species we want to keep "wild." The avian veterinarian is observing in practice what ecologists in the field have only been able to theorize. These observations can be of extreme importance to the conservation of many species.

In summary, conservation is both a science and a philosophy. Only when avian veterinarians have defined their own conservation ethic, can they help companion bird clients and aviculturists better understand their roles in conservation biology. Avian veterinarians can work together with conservationists, aviculturists and biologists to continue to improve the welfare of all birds.

SECTION ONE

THE COMPANION BIRD

I

CHAPTER

1

THE AVIAN PATIENT

Ross A. Perry

Veterinary medical decisions are often made by comparing the similarities and differences that occur between individual patients and an established animal model. This comparison concept is functional because of the relative similarity between a collie and a poodle, or a Persian and a Siamese, or a holstein and an angus. Any respective difference in anatomy or physiology or in an animal's response to a drug or infectious agent is easy to qualify when compared to a generic species model.

Not so, with the avian patient. In a single day, an avian practitioner may be presented with patients that belong to five different orders. Each of these orders is unique, having evolved specific anatomic, physiologic and behavioral characteristics that allow effective competition in a specific ecological niche. Which of the numerous avian genera will serve as an appropriate comparative model (ie, generic bird patient)?

The avian clinician can be most effective by disposing of the philosophical handicap of basing medical decisions on a generic companion bird. Instead, the veterinarian must look for the natural differences that exist in patients from such diverse geographic locations as a rain forest and an African savannah.

There is not a wealth of scientifically derived information available, particularly with respect to variances in avian dietary adaptations, behavioral characteristics and response to drug preparations and infectious agents. The clinician must compensate by applying a broad medical checks-and-balances system based on the use of numerous diagnostic and therapeutic tools. Medical management decisions for a particular genera within an order must be based on the interpretation of several changes that indicate that an abnormality is truly an abnormality. For now avian veterinarians will continue to be required to diagnose and treat many medical problems subjectively until results from avian research efforts begin to satisfy the demand for information.

In developing a health plan, clients and veterinarians must strive to view the world from the bird's perspective, and, in so doing, caretakers will have greater empathy for the emotional as well as the medical needs of the bird. If the complete needs of a bird are not met (nutritional, environmental and psychologic), disease will inevitably follow. The veterinarian must prescribe health, not drugs. By being familiar with the behavioral attributes and species-specific medical problems that may occur, a veterinarian is more likely to recognize early signs of disease in an individual bird of a given species.

Selection of Companion Birds

Birds are remarkable life forms with individual behavioral and personality characteristics. These characteristics are the result of a complex and often changing interaction of environmental influences that include food availability, seasonal weather conditions and flock dynamics. From a companion bird's perspective, flock dynamics involve the interaction of family members with each other and with the bird.

In providing exceptional care and management advice, the veterinarian can become a model for responsible companion bird ownership. Unfortunately, many individuals obtain a bird for the wrong reasons (Table 1.1), instead of for the purpose of adding an intelligent, sensitive being to the family.

TABLE 1.1 Misguided Reasons for Choosing Birds as Pets

- Entertainment
- Amusement
- Admiration
- Material acquisitions
- Self-admiration ("He says my name!")
- Toys for adults
- Toys for the children
- Didn't want to see it suffer in the pet shop.

Some clients rarely handle their birds, even if they do not bite. To highly social birds, this forced isolation must be a fate worse than death. Most clients are very appreciative of some supervised training from their veterinarian on how to handle their bird, but may be reluctant to ask for guidance (see Chapter 4).

Bird Attributes

Individual clients are likely to differ as to which attributes of companion birds are desirable and which are undesirable. Before choosing a companion bird, a client may want to give careful consideration to the following questions:

- Is it possible to tame and touch this bird?
- How big does its enclosure need to be?
- How much exercise does it need? Can it take care of all of its exercise needs within the enclosure?
- Does this species bond to one person and resent others, or is it likely to allow and enjoy companionship from several people?
- What are its dietary requirements and what is involved in daily maintenance?
- Are its eating habits and droppings messy?
- What is its expected life-span? 3-5 years? 5-10 years? Over 20 years?
- Does this species have a tendency to pick its feathers?
- How susceptible is this species to disease?
- Does this bird have singing ability?
- What is the potential of this species for screeching, screaming or chewing?
- Is this species known for its talking (mimicking) ability? (Table 1.2)
- Does this individual fulfill expectations for physical beauty in a bird?
- Will this bird be a source of disease for family?
- How expensive is the bird to buy and maintain?
- How much time does the bird require?

TABLE 1.2 Species With Potential Mimicking Ability

- African Grey Parrots - male, individual variability
- Mynah bird
- Double Yellow-headed Amazon
- Yellow-naped Amazon
- Blue-fronted Amazon
- Macaws - genus Ara
- Eclectus Parrot
- Budgerigar

By learning more about the characteristics of individual species, the client is able to make a more informed decision. Avian veterinarians and aviculturists should also strive to match the correct personality of a bird with the personality of an owner. For example, Table 1.3 presents a brief reference guide to some well known characteristics of popular companion bird species. Bird clients who understand

the "uniqueness" of avian species are usually happy with their birds' qualities (Figure 1.1).

Wild-trapped and Imported Birds

It is the belief of the author and editors that to be effective messengers for conservation and responsible stewardship, every avian veterinarian and aviculturist must strive to understand the damage induced by the harvesting of wild-caught birds, and to take every perceivable opportunity to stop these activities. If companion birds are to be relinquished to flightlessness, they should be individuals that were produced in captivity as companion birds and have never understood flight. Additionally, the trappers, brokers, dealers and consumers that trade (illegally, in most instances) in rare and endangered animal life (frequently under the guise of avian conservation) should be viewed by the community with great disdain. Protecting dwindling habitat should be the focus of individuals truly concerned with avian conservation.

Additionaly, the international movement of wild-caught birds undoubtedly results in the spread of infectious agents that could have far-reaching and devastating effects on indigenous avifauna. Wild-caught birds that escape into suitable habitats can establish viable populations that irreversibly alter the habitat of native species (eg, European Starlings, Common House Sparrows). Captive breeding programs can more than sufficiently supply consumers with the bird species that make the best companions.

Captive-bred, Hand-raised Birds

Captive-bred, properly hand-raised birds make better pets than their wild-trapped conspecifics; however, malnutrition, candidiasis, stunting and various leg, toe, nail and beak deformities can occur in captive-raised birds. This is especially true if the birds are cared for by novices or in large breeding aviaries where caretakers lose sight of the needs of the individual neonate. Bonding and breeding behavior in captive-bred and hand-raised birds (eg, masturbation, bizarre courting and behavioral rituals, excessive feather plucking and self-mutilation) can occur in improperly socialized birds as they reach sexual maturity. Male birds rubbing their backside and leaving "water" on their owner's hand is a common and notable example. Some clients will not accept that the bird is masturbating and needs behavioral modification support (see Chapter 4).

Some species such as Rose-breasted Cockatoos, large macaws, conures, Monk Parakeets and Sulphur-

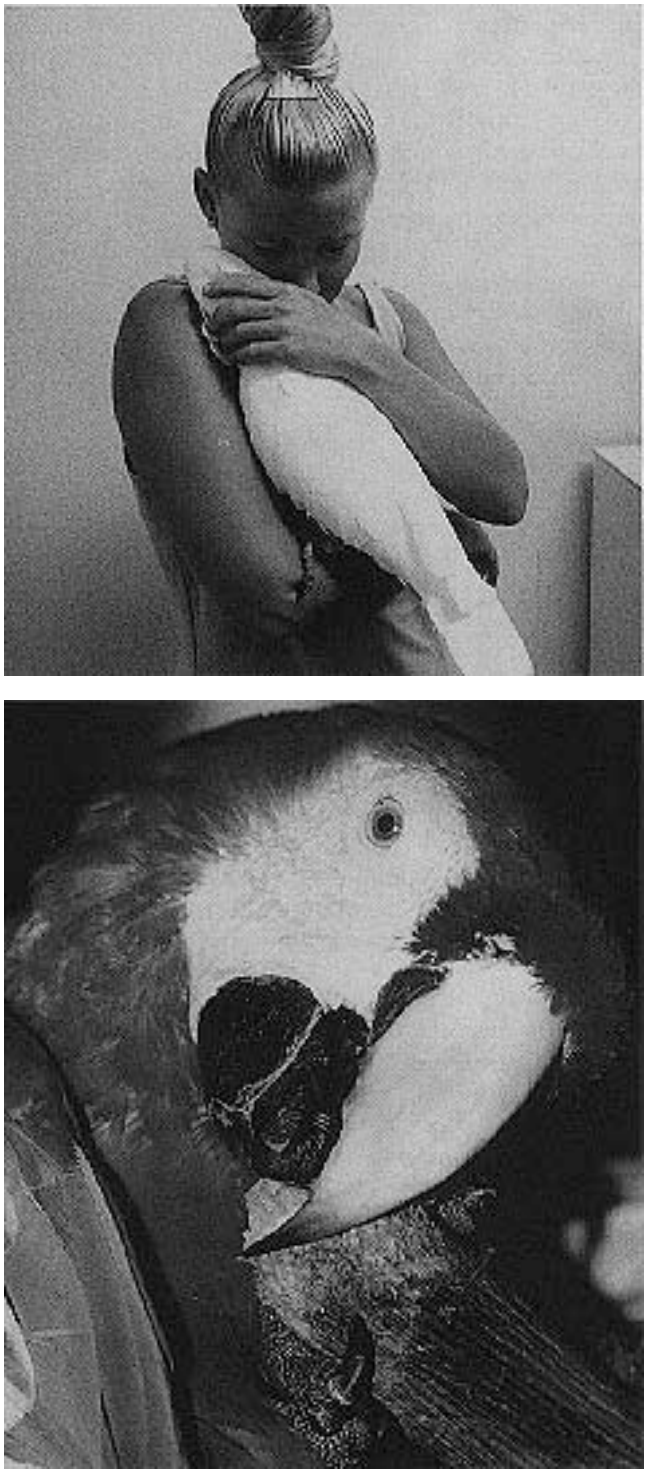

FIG 1.1 Important behavioral characteristics to consider when selecting companion birds are their tolerance for handling, their tendency toward destructive behavior and their likelihood to scream. In general, hand-raised Umbrella Cockatoos tend to seek affection from multiple family members and are relatively quiet. Larger macaws are beautifully colored and playful, but they can be quite loud, tend to be destructive and usually develop a relationship with an individual family member.

TABLE 1.3 Profiles of Common Companion Birds (Some characteristics are rated on a scale from 1 to 10, with 10 being the highest value.)

African Grey Parrots (Africa)
Excellent talkers - individual variability (9)
Extremely intelligent - high-strung
Prolific breeders once initiated
Require attention (10)
Relatively playful (8)
Tend to form individual bonds

Amazon parrots (Mexico to South America)
Few enjoy "petting"
Excellent talkers (9) species-dependent
Extroverted personalities
Aggressive during breeding season
Tend to form individual bonds
Require attention (9)

Budgerigars (Australia)
Gregarious - easily tamed (10)
Good talkers but require work (7)
Quiet and nondestructive
Wild-type are most disease-resistant
Relatively gentle (7)

Canaries (Australia and Africa)
Color mutations are genetically weak
Breed prolifically in captivity
Males are vocal singers
Tidy and easy to care for
Do not like to be handled

Cockatiels (Australia)
Excellent companion birds (10)
Easily tamed and gentle (9)
Quiet and nondestructive (8)
Good whistlers - limited talkers
Mutations - weak

Cockatoos (Australia, New Zealand, South Pacific Islands)
Require attention (10)
Scream if neglected
Crave physical contact (10)
Hand-raised Umbrella Cockatoos are extremely gentle (9)
Intelligent, easily house-trained
Produce abundant powder (10)
Can be noisy; destructive; must be socialized
Mate aggression is common, particularly in Sulphur-crested group

Conures (Mexico to South America)
Species variability
Smaller species are gregarious and playful (9)
Enjoy and seek attention (9)
Noisy and destructive (7)
Generally poor talkers

Eclectus Parrots (Australia and South Pacific Islands)
Generally lethargic and unplayful
Dimorphic (males=green, females=red)
Males are more gentle than females
Tend to form individual pair bonds

Finches (Australia and Africa)
Melodious songs
Short-lived

Lories, lorikeets (Australia, South Pacific Islands)
Colorful, playful, active
Noisy and limited talking ability
High-carbohydrate liquid diet; messy
Frequently bathe

Lovebirds (Africa)
Relatively nondestructive, quiet
Hand-raised birds are calm
Parent-raised birds are difficult to tame

Macaws (Mexico to South America)
Extremely intelligent
Require attention (10)
Can be destructive
Require large living space
Tend to be noisy (10)
Aggressive during the breeding season
Blue and Gold most family-oriented
Hyacinth - least noisy and most mellow

Mynahs (India)
Prefer not to be handled
Good talkers (7)
Loose, messy droppings
Nondestructive

Pionus parrots (Mexico to South America)
Small and quiet
May hyperventilate when disturbed
Highly stressed
High altitude species cannot tolerate heat and humidity

Toucans (South America)
Quiet and antic
Prefer some live food (rodents)
Highly territorial
Messy, loose droppings

crested Cockatoos are particularly prone to excessive bonding and self-mutilation secondary to separation anxiety. Other species may become suddenly aggressive toward a family member. Excessively bonded Bare-eyed Cockatoos (Little Corellas) can become quite "spiteful." These pets are less appropriate in families where the bird will remain alone for long periods. The "mini" macaws, smaller Amazon parrots, Pionus parrots, *Poicephalus* species and Umbrella Cockatoos are less likely to develop these traits. These problems can be prevented in most birds by an effective socialization program when the bird is young. Repeated generations of captive birds become increasingly docile and more adaptive to captivity.

Taming Companion Birds

Young, hand-raised Psittaciformes adapt readily to new surroundings and handling procedures. They should be exposed early in life to novel situations (eg, car travel, hospital visits, multiple visitors in the household, other household pets) so that they are well adjusted to these events. Older birds, especially wild-caught adults, are usually very difficult to tame. Patience, self-discipline, a sense of ritual, food bribery and reward are necessary to tame some adult birds (see Chapter 4). Even then, they are rarely trustworthy and may bite without provocation.

Genetic Factors

The physical and psychological characteristics of a bird are influenced by genetic factors interacting with aspects of management and disease. Some attributes are common to most individuals within a species. Others are peculiar to particular strains of birds that have been selectively bred over many generations in captivity.

Determining the physical and behavioral attributes of related birds, especially the parents and siblings, can be of value in selecting a companion bird. It should be noted that large Psittaciformes have the capacity to live as long as humans, and adding a large psittacine bird to the family should be undertaken as a life-long commitment. Knowing the genetic background and characteristics of the relatives of a bird is particularly critical when choosing a pair of breeding birds.

Color Mutations

Color mutations are highly valued by many aviculturists. The specific genetics involved in establishing these color mutations are discussed in a number of avicultural publications. It should be noted that mutations in color are generally the result of continued inbreeding. In selecting for particular color mutations (eg, lutino cockatiels), scant priority is placed on other important attributes, so that decreased disease resistance, disorders, reduced longevity and birth defects often result. In Australia, clinical impressions suggest that there is a higher incidence of PBFD virus in the color mutations of Peach-faced Lovebirds than in wild-type green lovebirds.

Conformation and Size

Conformation of birds is influenced by genetic factors. This is most apparent when comparing the different breeds of canaries and budgerigars. Currently, show budgerigars are approximately twice the mass of their free-ranging conspecifics. Attempts to produce larger birds has also led to numerous undesirable characteristics including feathering that impairs flight, interferes with normal ambulation, accumulates excrement pericloacally and protrudes across and sometimes into the cornea.

Longevity

Longevity, the potential maximum duration of life for a species, has little relevance to exhibition or show bird breeders (who discard imperfect nestlings and older breeding birds) but should be of critical importance to the companion bird client. Some highly bred strains of birds may have life expectancies one-third to one-tenth the duration of "wild-type" or less highly inbred individuals of the same species. For example, it is believed that inbreeding has contributed to the reduction in the life expectancy of cockatiels from a record of 32 years to the present-day average of four to six years. When seeking a healthy companion bird that has the greatest potential of reaching its full life expectancy, clients should avoid highly inbred birds in favor of the wild-type characteristics.

Currently, the available information on the population dynamics of free-ranging birds and those maintained as pets is sparse. It is doubtful that the longevity for many companion bird species is known because of a lack of scientifically derived diets and less-than-ideal management parameters; however, some general working guidelines with respect to longevity are listed in Table 1.4. An increase in longevity data will require that aviculturists and avian veterinarians keep and compile information from accurate and long-term records.

TABLE 1.4 Suggested Longevity of Selected Companion Species

Bird	Maximum	Average
Gouldian Finch	unknown	4
Zebra Finch	17	5
Canary	20	8
Mynah	8	3
Toucan	unknown	4
Budgerigar	18	6
Agapornis sp.	12	4
Neophema	10	5
Cockatiel	32	5
Rainbow Lorikeet	15	3
Rosella	15	3
Eclectus Parrot	20	8
Galah	20	5
Bare-eyed Cockatoo	40	15
Sulphur-crested Cockatoo	40	15
African Grey Parrot	50	15
Pionus parrot	15	5
Amazon parrot	80	15
Macaw	50	15
Conure	25	10
Grey-cheeked Parakeet	15	8
Superb Parrot	36	6
Domestic pigeon	26	15

Selected Species Recommendations

The Grey-cheeked Parakeet, Dusky and Maroon-bellied Conures and Monk Parakeets are reputed to be relatively resistant to common diseases and are longer-lived than most cockatiels, budgerigars and lovebirds. Grey-cheeked Parakeets have been described as quiet but playful; the conures are not as quiet, yet they can be tame and affectionate; and the Monk Parakeet is considered docile, quiet and relatively nondestructive (chewing). Other bird species that are considered relatively quiet include the Ring-necked Parakeet, Pionus species, Hawk-headed Parrot, Caique, Dusky-crowned Conure, Senegal Parrot, Jardines Parrot, Cape Parrot, Meyer's Parrot, Red-bellied Parrot and Brown-headed Parrot.

An individual wishing to obtain a companion bird should be patient. Developing a relationship with an aviculturist or pet retailer and checking several references are well worth the effort. Some unscrupulous

pet retailers (particularly traveling dealers) will use dyes and bleaches to make common inexpensive birds look like less-common, more-expensive birds in the same genus. This is a frequent practice with Amazon parrots that enter the United States from Mexico and some South American countries. The consumer should be wary of strange and exotic color mutations.

Choosing a Healthy Bird

Parameters that may increase the likelihood of adding a healthy, mentally stable companion bird to the family are:

- Obtaining the bird from a reputable breeder who specializes in the particular species or genus of bird that is desired and has a closed flock.
- Obtaining the bird from a reputable source who works in close liaison with an avian veterinarian.
- Obtaining a young, recently fledged, parent- or hand-raised bird.
- Obtaining a well adapted companion bird from an individual who is no longer able to provide for the pet (due to age, moving, finances).
- Obtaining a bird that has normal-appearing feathers and droppings, a good appetite, appears to be bright, alert and responsive to its environment, and has not been exposed to birds from other sources.

Parameters that increase the likelihood of adding a diseased, unhappy bird to the family are:

- Obtaining a wild-trapped bird.
- Obtaining a recently imported bird.
- Obtaining a bird suspected of being smuggled.
- Obtaining a bird with an asymmetrical beak, excessively scaly legs, twisted digits, missing toes, a blocked nostril, slight swelling around the eyes, deformed eyelids, stained feathers above the nostrils, stained feathers around the vent, tail bobbing, fluffed appearance, soiled vent, poor feather quality, diarrhea, yellow urates, increased urine production, pectoral muscle atrophy, abdominal distention, fault lines and depigmented feathers (eg, black or yellow where normally green plumage occurs).

Identifying an overtly ill bird in a retail outlet should caution the consumer to purchase a bird from another source. Birds that are unusually inexpensive for the species may have a sordid past that can include specific diseases or exposure to pathogens that may cause problems when the birds are introduced to a home or aviary. Wild-caught birds, particularly those that are likely to be illegal imports (smuggled), should always be avoided.

Health Checks

A veterinarian is well advised to seek legal advice in developing a form to be used as a certificate of examination. The term "health certificate" should be avoided because it is impossible to certify "health." It is possible only to certify that no abnormalities were detected using a particular battery of tests. The expectations of a dealer or client regarding a veterinary examination may be quite different, and requirements and liabilities are likely to vary among countries and states.

Clients should always be offered state-of-the-art diagnostic, medical and surgical services that are available on a national level. It is then the client's choice to determine what level of care they desire for their pet. It is important to note in a patient's medical record what services were offered to a client and which of those services were chosen, in order to prevent accusations of negligence. A state-of-the-art health examination for birds can include a physical examination, CBC, biochemistries, radiographs, endoscopy, Gram's stain of the feces and rostral choanal slit, *Chlamydia* sp. screening and (where available) DNA probing for psittacine beak and feather disease (PBFD) virus and polyomavirus. Because the results of a single diagnostic test are not absolute, the practitioner must combine the values reported by the laboratory with his assessment of a bird's overall condition, diet and environment.

When all the data on a patient is collected and evaluated, the practitioner can state only that in his opinion, there were no detectable abnormalities at the time of testing. Table 1.5 lists some disease conditions that are frequently diagnosed in popular companion bird species.

Transporting the Bird

Clinicians will need to evaluate a bird's excrement for the day or two before an examination; therefore, a bird's enclosure should not be cleaned for the two days before it is taken to the veterinarian. If the bird's enclosure is too large to move (in most situations it should be), then clean butcher's wrap or any non-absorbent paper should be placed on the bottom of the bird's enclosure for 12 to 24 hours before an

TABLE 1.5 Common Diseases in Companion Birds by Species*

African Grey and Timneh Grey Parrots
- Feather picking
- Rhinoliths (bacterial, fungal, secondary to malnutrition)
- Oral abscesses
- Hypocalcemia syndrome
- Hypovitaminosis A
- Resistant bacterial infections - *Klebsiella, Pseudomonas, E. coli, Staphylococcus*
- Aspergillosis
- Neoplasms (apparent higher incidence than other species)
- Tapeworm infestation (imported birds)
- Blood parasites (occasionally imported birds)
- Reovirus
- PBFD virus
- Hematuria syndrome in infants
- Non-regenerative anemia (neonates)
- Neuropathic gastric dilatation

Amazon parrots
- Bumblefoot
- Hematuria with metal poisoning (Zn, Hg, Pb)
- Egg-binding
- Chronic sinusitis, pharyngitis, tracheitis
- Hypovitaminosis A
- Chlamydiosis - rhinitis, sinusitis, enteritis
- Polyomavirus
- Malcolored feathers (hepatopathy or malnutrition)
- Oral abscesses
- Lymphocytosis
- Poxvirus infection (primarily imports)
- Mutilation syndromes
- Cloacal papillomatosis
- Epilepsy in Red-lored Amazons (idiopathic)
- Neoplasia (especially liver adenocarcinomas)
- Herpesvirus-induced tracheitis
- Coagulopathies

Budgerigars
- Neoplasm (lipoma, testes, ovary, liver, kidney)
- Goiter
- Hypothyroidism (not documented)
- Polyomavirus
- Unilateral leg paralysis - renal or gonadal neoplasia
- *Knemidokoptes* sp. mites infections
- Feather mites and lice in Australian budgies
- Retained feather sheaths
- Overgrowth of beak and nails (malnutrition or hepatopathy)
- Egg-binding
- Pododermatitis
- Gout
- Trichomoniasis
- Obesity
- Diabetes mellitus
- Hyperglycemia secondary to neoplasms
- French Moult (acute PBFD or polyomavirus)
- Polyfolliculosis
- Chlamydiosis (usually chronic low grade)
- Giardiasis
- Megabacteria
- Mycoplasmosis
- Salpingitis
- Ovarian cysts
- Stroke (older budgerigars)
- Coccidiosis
- Splay leg in juveniles
- Cere abscesses
- Hepatopathy
- Pancreatic insufficiency

Canaries
- Feather cysts
- Obesity - lipoma
- Alopecia syndrome
- Straw feather syndrome
- *Knemidokoptes* sp. mite infection
- Air sac and tracheal mites
- Canary pox
- Dry gangrene of extremities
- Myeloproliferative disease
- Egg binding, egg-related peritonitis
- Dyspnea (acute, inhaled seeds)
- Yolk emboli
- Lymphocytosis
- Eosinophilia with inflammation
- Cataracts
- *Plasmodium* sp. and toxoplasmosis

Cockatiels
- Giardiasis (in USA)
- Ascaridiasis in Australia
- Mycoplasmosis
- Spirochetosis
- Obesity
- Idiopathic neurologic dysfunctions
- Diabetes mellitus
- Egg-binding and egg-related peritonitis
- Dyspnea (acute, inhaled seed)
- Yolk emboli
- Eosinophilia with inflammation
- Upper respiratory sinusitis, conjunctivitis
- Paralysis of lower eyelid, weak eye blink
- Mouth and tongue paralysis (esp. neonates)
- Yellow feathers in lutinos (hepatopathies)
- Pancreatitis
- Liver failure - fatty liver, cirrhosis, neoplasia

Cockatoos
- Self-mutilation (feathers, skin)
- Psychotic behavior
- Idiopathic liver cirrhosis
- Tapeworm infestation (wild-caught)
- Blood parasites (recently imported)
- Proliferative foot lesions (herpesvirus)
- Pododermatitis
- Cere hypertrophy and occluded nares
- Oral abscesses
- Trematode infestation (imported birds)
- Obesity
- Lipomas (Rose-breasted and Sulphur-crested)
- Cloacal prolapse (idiopathic)
- Microhepatia

Corella, Short-billed and Long-billed
- Acute and chronic PBFD virus
- Malnutrition
- Upper respiratory tract infections
- Bumblefoot and leg calluses
- Anti-social behavior
- Jealousy and aggression (breeding season)

Gang Gang Cockatoos
- Malnutrition
- Metabolic bone disease (juveniles)
- Feather picking, barbering and self-mutilation
- PBFD virus

Major Mitchell's Cockatoos
- PBFD virus
- Aspergillosis
- Sinusitis
- Metabolic bone disease in juveniles
- Pododermatitis and leg calluses
- Feather picking and barbering

Rosellas
- PBFD virus
- Feather picking
- Aggression toward people and other birds
- Flightiness
- Pododermatitis (often severe)
- Motile protozoa (fatal intestinal disease)

Conures
- Black splotches in feathers (malnutrition, hepatopathy)
- Pacheco's disease virus carriers (probably no more so than other South American species)
- Polyomavirus
- Bleeding syndrome (erythemic myelosis)
- Screaming
- Feather picking (severe)
- Cannibalism
- PBFD virus
- Megabacteria
- Heat stress
- Neuropathic gastric dilatation

Eclectus Parrots
- Lead poisoning, biliverdinuria
- Female aggressiveness
- Annular toe deformities
- Feather picking
- Cataracts
- PBFD virus
- Polyomavirus
- Hypovitaminosis A

Finches
- Air sac mites - Gouldians
- Tapeworms
- Trichomoniasis
- Bacterial infections (particularly susceptible)
- Egg binding
- Lymphocytosis
- Foreign body constrictive toe necrosis
- Dry gangrene of extremities

Frogmouths, Tawny (Australian captive)
- *Erysipelas*
- Subcutaneous white worms
- Nutritional deficiencies (vitamin B complex-responsive neurologic signs)
- Fatal pandemic convulsive syndrome
- Obesity

Grey-cheeked Parakeets (*Brotogeris* sp.)
- Sarcoptiform mange (*Metamicrolichus nudus*)
- Chronic active hepatitis (*E. coli*)
- Normally high AST values
- Mycobacteriosis
- Chlamydiosis
- Feather picking refractory to therapy
- Resistance to disease and stress
- Screaming
- Nail trimming lameness

TABLE 1.5 Common Diseases in Companion Birds by Species *(continued)*

Kakariki
- *Knemidokoptes* sp. (new species in feathers)
- PBFD virus

Kookaburra
- Obesity and fatty liver syndrome (excess fat)
- Vitamin B complex-responsive neurologic disorders
- Gapeworm

King Parrots (Australia)
- Acute PBFD virus (juveniles)
- Chlamydiosis

Lorikeets
- Hepatopathy
- PBFD virus
- Fungal infections
- Coccidiosis
- Ascaridiasis
- Cestodes
- Bacterial infections
- Injuries
- Necrotic enteritis (possibly clostridial)

Lovebirds (*Agapornis* spp.)
- Aggression
- Cannibalism
- PBFD virus
- Polyfolliculitis
- Megabacteria
- Heat stress
- Lovebird pox
- Epilepsy (idiopathic)
- Viral infections
- Obstetrical problems (egg binding)
- Bilateral clenched foot syndrome
- Capillariasis
- Self-mutilation "stress dermatitis" axillae, patagium and base of tail

Macaws
- Avian viral serositis
- Neuropathic gastric dilatation
- Sensitive to doxycycline, trimethoprim, gas anesthetics
- Behavioral problems
- Capillaria and ascarid infestation (imported birds)
- Feather cysts in Blue and Golds
- Oral and cloacal papillomatosis
- Feather picking and mutilation
- Herpesvirus feet lesions
- Sunken eye sinusitis
- Annular toe deformities in young macaws
- Pancreatic dysfunctions
- Cataracts
- Polycythemia in Blue and Golds
- Sensitive to vitamin D_3
- Uric acid gout in young Blue and Golds
- Upper respiratory tract infection and sneezing
- Malcolored feathers (turn black in Blue and Golds and miniature macaws)
- Polyomavirus
- Microhepatia
- Coagulopathies

Magpies, Australian
- Soft pliable beaks and bones in juveniles (parathyroid gland dysfunction)
- Spiruroid throat worms
- Scaly leg mite (*Knemidokoptes*-like)

Mynahs
- Hepatopathies
- Iron storage disease
- Cirrhosis of liver
- Chronic active hepatitis
- Combination hepatopathy
- Heart disease
- Eye diseases (corneal scratches, keratitis, chronic keratoconjunctivitis)
- Epilepsy (idiopathic)

Pionus Parrots
- Obesity
- Malnutrition
- Respiratory infections
- Poxvirus infection

Toucans
- Hepatopathies
- Bacterial infections
- Giardiasis
- Coccidiosis
- Beak injuries
- Diabetes mellitus (Toco Toucans)
- Iron storage disease

*This list is a guide to the most commonly reported clinical problems. All species discussed are susceptible to malnutrition, bacterial infections, fungal infections and toxicities. All Psittaciformes are susceptible to *Chlamydia* sp. to varying degrees. Unless a species has a particular propensity or a characteristic presentation, these problems are not mentioned.

Diseases mentioned may be common in some localities or bird populations, whereas the same diseases are rarely encountered in other localities or populations.

appointment. The paper should then be brought with the bird to the veterinarian.

A clean, padded cardboard box or carrying crate with adequate ventilation is suitable for most short periods of transportation. The bird should be maintained at an ambient temperature of 70° to 80°F and should never be left unattended. Containers that have been previously used to transport birds must be cleaned and sterilized before reuse (see Figure 2.17). Carrying containers constructed of wood should be used only once, because they are impossible to disinfect. Most birds travel quite well in dark, cool enclosures and do not require, nor should they be given, tranquilizers (see Chapter 7).

For safety, the bird should remain in some type of secure enclosure in the veterinarian's waiting room. A bird that flies in the reception area is subject to substantial injuries.

The Home Environment

Quarantine

If a client already has companion birds, any new additions to the household should be isolated (quarantined) for six to eight weeks. The purpose of the quarantine period is to allow sufficient time for newly acquired birds to exhibit clinical signs of disease and to prevent transmission of disease to other birds. During this quarantine period, the bird should be examined by a veterinarian and any identified problems should be corrected. It should be noted that many avian infectious diseases involve a carrier state (eg, PBFD virus, polyomavirus, Pacheco's disease virus) and that quarantine alone is insufficient to ensure that one of these diseases is not introduced to a home. As diagnostic tests become available to detect

subclinically infected birds, they should be integrated into the post-purchase examination procedure (see Chapter 6).

Enclosures

Enclosures for birds come in numerous shapes, sizes, styles and materials. Many are designed primarily to appeal aesthetically to the client but fail dismally to address the needs of the bird. The materials or designs of some enclosures may actually create a health hazard for a bird (Table 1.6).

TABLE 1.6 Inappropriate Enclosure Designs

- Bubble-shaped (domed plastic, usually with peat substrate)
- Small rectangular or cuboidal shape
- Short or tall cylindrical shapes of small diameter (< 2 meters)
- Bamboo construction
- Highly convoluted enclosures (ornately designed)
- Multiple crevices and hard to clean areas
- Enclosures that prevent full extension of the wings
- Stacked perches that result in fouling of the lower perch
- Perches placed so the bird fouls its water or food container
- Galvanization (lead/zinc poisoning)
- Metal water containers soldered at the seams (lead poisoning)
- Copper fittings (copper poisoning)
- Internal hooks (trauma), sharp objects or sharp edges
- Fine, easily chewable mesh construction
- Little room to hop (preferably to fly) between two perches
- Overcrowded with toys and food containers (obesity)
- Difficult to clean or service
- Unpolished welds/brass "beads" (foreign body ingestion)
- Difficult access to the bird (small door)
- Insecure door latches.

Enclosures for companion birds should be as spacious as possible, with emphasis on length more than depth or height (Figure 1.2). The minimum size would allow a bird to spread its wings without touching the sides of the enclosure. The enclosure should be clean and easy to service and should be constructed of a durable, nontoxic material. Enclosures should be used to house the bird when no one is home and at night; therefore, the enclosure should be secure and free of potential traps. Gaps between sections of the enclosure can entrap toes, beaks or wing tips and should be minimal in a well designed enclosure (Figure 1.3). Newspaper, paper towels or paper bags appear to be the best substances for the bottom of the enclosure. They are inexpensive, easy to clean and do not promote the growth of pathogens as do wood chips or ground corncob. Cedar, redwood and pressure-treated wood chips should not be used for substrate or nesting material in birds. The design of the enclosure should minimize the likelihood and possibility of a bird having access to its own or other birds' droppings.

Position of Enclosure

A bird's enclosure should be positioned so that at least some of the perches allow the bird to be at or above eye level of standing family members. Birds are generally more secure at this level than lower and are less likely to develop dominant or aggressive tendencies than if they are placed at higher levels. The enclosure should be positioned so that it partially receives direct sunlight on a daily basis and offers a shaded area. Because a bird's normal hormonal cycles are influenced by photoperiod, it is best for the enclosure to be placed near natural lighting. The need to avoid drafts is exaggerated. Covering birds is discouraged because fresh air is more important than being exposed to home lights. A bird is best kept in the dark for sleeping.

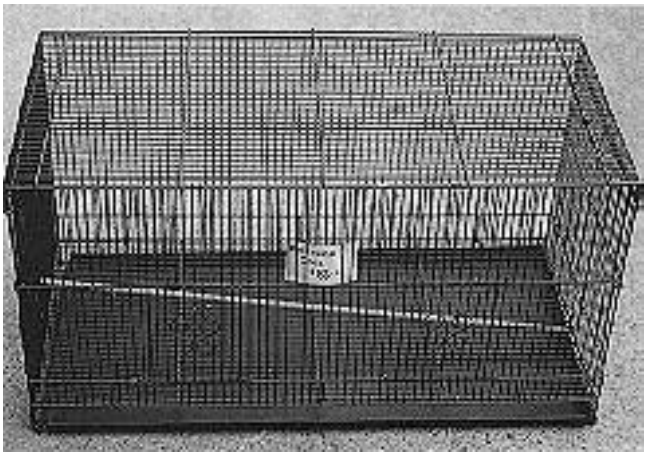

FIG 1.2 Enclosures that are long and provide some room for exercise are preferable to enclosures that are extended in height. The extra height of the enclosure creates no advantage for the bird. Doweling-type perches should be replaced with clean, nontoxic hardwood perches of variable size (courtesy of Ross Perry).

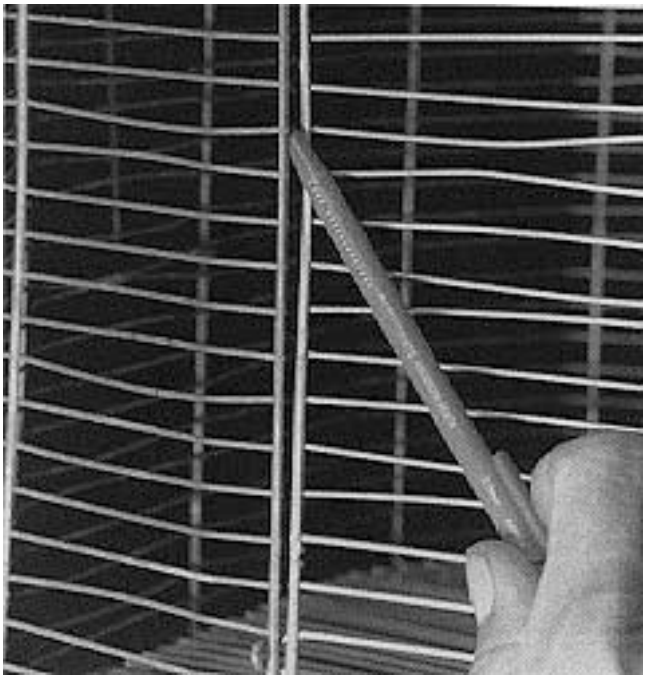

FIG 1.3 Enclosures with gaps (particularly those that have a "spring" action) should be avoided. These areas of the enclosure can entrap toes, beaks or wings and result in fractures, concussions or death. Note the damage to the enclosure bars, indicating that this wire was not of sufficient strength for the Amazon parrot it housed.

It is ideal for a companion bird to have a large outdoor enclosure in which it can be placed on a regular basis for exercise and exposure to fresh air and sunlight. An outdoor enclosure for a companion bird should be protected from extremes in weather as well as from predators and rodents. The enclosure should be securely placed on its fittings to prevent movement, and food and water supplies should be protected from contamination by free-ranging birds.

Perches

Perches should be made from selected branches of clean, nontoxic hardwood trees and shrubs that have never been sprayed with pesticides or chemicals and are free from mold and wood rot. Variably sized perches should be provided; those with small diameters allow the toes to almost touch when wrapped around the perch and those with large diameters cause the feet to be flattened. The branches should be irregular in cross section, as opposed to cylindrical, to decrease the pressure placed on any one point of the foot and reduce the potential for bumblefoot. Bumblefoot is believed to be induced primarily by malnutrition but may be aggravated by inappropriate or fouled perches. Providing chew toys may prevent some birds from destroying a perch as quickly. Perches should be replaced frequently, especially if fouled by feces. Perches should not be positioned above each other or above the food and water containers (Figure 1.4). The use of concrete perches in combination with wood perches is becoming increasingly popular and appears to be safe as long as the diet is balanced and natural perching is also available. Sandpaper perches should never be used in a bird's enclosure. They have no effect on nail length and may predispose a bird to foot problems.

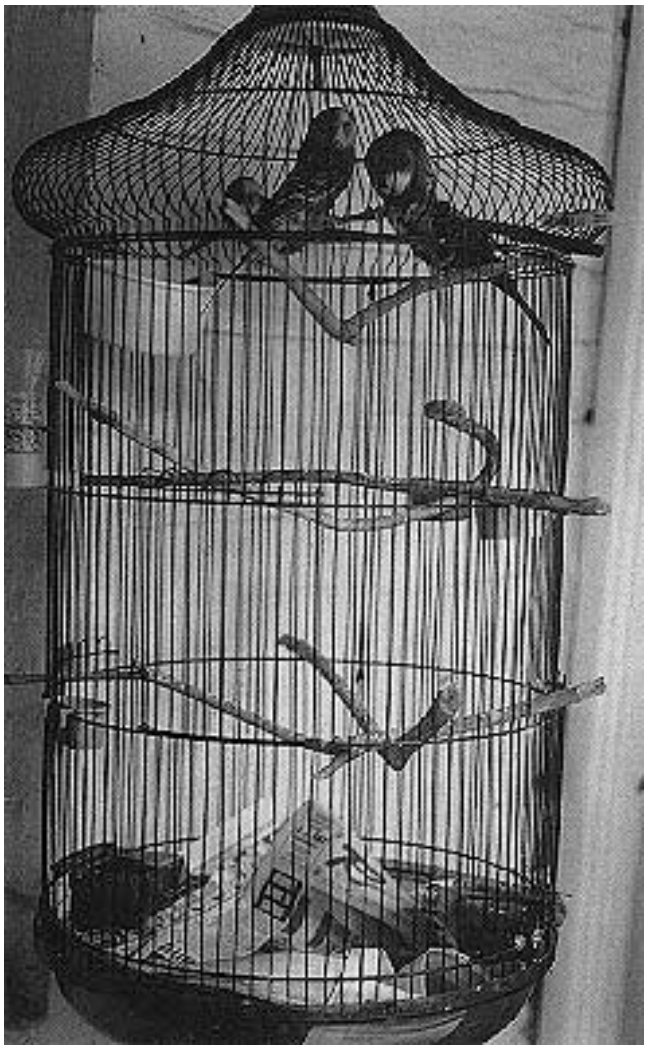

FIG 1.4 Perches should not be positioned over each other or over the food and water containers. Note the excrement contaminating the lowest perches and the water containers. Additionally, this enclosure does not have a grate, allowing birds access to their own excrement (courtesy of Ross Perry).

Accessories

Overcrowding the enclosure with toys and food containers can be detrimental. Some birds will use and

seem to enjoy a swing but it should be placed so that it does not obscure a flight or jumping path. If there is insufficient room for both proper perching and a swing, the swing should be removed. Food and water containers should be placed in the enclosure to encourage and maximize activity in a healthy bird; the water container should be placed high at one end of the enclosure, and the food container low at the other end of the enclosure. If a bird is ill, food and water containers should be easily accessed with a minimal expenditure of energy.

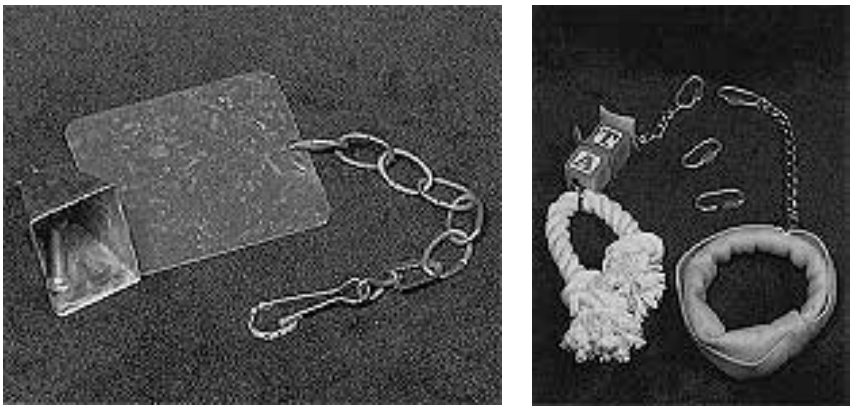

FIG 1.5 Unsafe toys have snap-type clasps, open chain links and easily consumable toxic components. Toys that are safe for a bird under supervision have screw-type clasps and closed chain links. Toys with long ropes or chains should not be left in the enclosure of an unsupervised bird.

Toys

Any toys available to a bird must be free of toxic metals, hooks, sharp objects or small, easily consumed components. Various gadgetry can be placed in a psittacine's enclosure to stimulate activity and satisfy its natural tendency to chew. It is best to have a collection of different toys that are changed on a daily basis to keep a bird from becoming bored with any one type of toy. There is no quality control for the avian toy market, and the client must be acutely aware of potentially dangerous toys. Toys designed for small birds should not be used with larger birds. In general, there is not one multiple-part toy that is 100% safe. There are some common toy components that are more dangerous than others. These include snap-type clasps, open chain lengths and bell clappers that can be removed and swallowed. Safer toys have a screw-type clasp with closed chain links (Figure 1.5). Most toys with a thin rope or substantial length of sheet chain should be provided to a bird only while it is under direct supervision. If left in an enclosure, a bird can become easily entangled in these toys and die from asphyxiation (Figure 1.6). The most suitable toys for unsupervised birds include natural foods such as grass runners (eg, kikuyu, buffalo grass), various seed pods (eg, melaleuca, hakea, eucalyptus, callistemon and especially banksia for larger cockatoos), liquid amber, pine cones, vegetables, apple cores, clumps or tufts of grass freshly sprayed with water and short lengths of soft wood with bark attached (especially if live beetle larvae or borers are present). Any natural plant materials provided to birds must not have been sprayed with pesticides, chemicals or fertilizers. Fresh-cut branches from unsprayed fruit trees or vines with the bark intact are favorite treats for birds.

Mirrors

Many smaller birds housed alone are offered mirrors. Some mirrors contain mercury, which is toxic if consumed. Some properly made and designed glass and plastic mirrors are suitable for small birds but can be readily demolished and consumed by large Psittaciformes. Polished stainless steel mirrors are more suitable for large birds. Sexual regurgitation of food onto the mirror is common. If regurgitated debris is allowed to accumulate on or near the mirror, the debris may become a source for exposure to fungus or mycotoxins. Windows and large mirrors in rooms

FIG 1.6 Some publications discuss the use of leg chains to restrain companion birds. Chains can cause lacerations, fractures, concussions or death and should never be used with companion birds (courtesy of Ross Perry).

where birds are allowed to exercise should be covered to prevent inexperienced or startled birds from flying into these fixed objects causing severe head and neck trauma.

Hygiene and Sanitation

With a companion bird, it is better to be fanatical with cleanliness rather than to rely on disinfectants to prevent disease transmission in a dirty, contaminated environment. Good hygiene involves the frequent cleaning of a bird's enclosure and is far more important in the prevention of disease than the use of disinfectants. Organic debris (food, excrement, feathers) must be physically removed before a disinfectant will be effective. Water and food containers should be physically scrubbed or placed in the dishwasher on a daily basis to prevent the accumulation of slime and algae.

Multiple layers of butcher's paper, recycled computer paper or newsprint can be used in the bottom of the enclosure. The soiled layer should be removed each day and the entire enclosure should be thoroughly cleaned and dried in sunlight on a weekly basis. Clients should be advised to avoid the inhalation of mold spores and dried, aerosolized particles of excrement.

There has been some discussion of an increased risk of lung disease in clients that are exposed to companion birds. The primary problems that have been reported are in association with the keeping of pigeons in loft-type enclosures where fecal and food debris are allowed to accumulate. One report that discussed an increased risk of lung cancer in association with the keeping of companion birds did not address the type of birds or adjust for exposure to cigarette smoke. However, clients that maintain any type of pet in the home should keep the pet's living space clean and should ensure a fresh supply of air at all times. The addition of electrostatic-type air filters to a central air system can also reduce the amount of animal-related debris that is circulating in the air. Clients should always be encouraged to inform their physicians that they have companion birds. This information may be of value in diagnosing and treating some zoonotic diseases.

When disinfectants are necessary, chlorine or glutaraldehyde preparations are effective for most avian pathogens (see Chapter 2). Many disinfectants emit toxic fumes and should be used only with adequate ventilation and never near a bird. Disinfectants should be thoroughly rinsed from an enclosure to prevent the bird from contacting residual compounds.

Home Hazards

Birds that are allowed unrestricted access to the home can encounter numerous physical dangers or toxins (see Chapter 37).

Mixed Aviaries

Many species of birds are highly territorial or aggressive toward other species of birds and would not be suitable for a mixed aviary. Others may be compatible except during the breeding season. The dietary preferences of some birds change during the breeding season such that they may predate eggs and nestlings from other birds. Some birds may appear quite compatible during the day but become active and possibly predatory at night.

The birds in established mixed flights develop a pecking order or hierarchy that is likely to be upset by the introduction of another bird, even if it is of a compatible species. This introductory period causes a substantial "stress" in the flock and may precipitate subclinical disease problems. It is best to plan well in advance the number and species of birds intended for a mixed aviary and to introduce all the birds to the facility at the same time. Almost certainly there will be a need for multiple feeding and drinking stations, each of which can be easily cleaned and accessed by the aviculturist. At least some of these feeding stations should be situated within smaller "trap-type enclosures" constructed within the large flights. The trap door is normally secured in an open position, but can be used to safely catch a particular bird with minimal disturbance of the other birds. Mixed flight aviaries should be provided with a variety of sight barriers and retreat areas for those individuals low in the pecking order. Each bird needs to have an area in which it can rest and feel secure.

Feeding and Watering Techniques

Healthy birds should always have a supply of clean, fresh, uncontaminated water. There is frequent discussion concerning the use of chlorhexidine in the water to reduce bacterial growth; however, in addition to reducing bacteria in water, this agent also alters the normal microbial population of the gastrointestinal tract (see Chapter 5). The routine addition of any disinfectant to a bird's water should be discouraged. Water that has been "sitting" in plastic or copper pipes can accumulate toxic levels of some chemicals, and pipes should be flushed for several minutes before collecting drinking water. During the

summer months, some city municipalities add disinfectants and algae inhibitors to the water that can be toxic to birds and fish.

Many companion birds will readily adapt to a water bottle, which is easier to clean and keep free of contaminating food and excrement than a water bowl. The use of water bottles is encouraged in birds that will use them and not destroy them (see Figure 2.9). In general, medication should not be added to drinking water; this is particularly true when water bottles are used. If a medication settles out of solution, it will settle to the bottom of the bottle, which could result in a bird consuming toxic levels of a medication (see Chapter 17).

Birds should be provided fresh food in clean bowls on a daily basis. A combination of formulated diets (70%) supplemented with some fresh fruits and vegetables (30%) appears to keep a bird in the best health (see Chapter 31). Some companion bird clients allow their pets to eat at the dinner table, by serving the bird from its own plate or by allowing the bird to roam the table and sample whatever it chooses from the plates of family members. Other clients may hold food in their lips and allow a companion bird to nibble at the food. This practice should be discouraged. High levels of salt and ingestion of some foods (chocolate, avocado) can be toxic (see Chapter 37).

Grit

Whether or not to provide soluble shell grit and insoluble coarse sand grit to a bird is controversial. This practice is viewed with disfavor in the United States, especially if given free choice, which may lead to over-consumption and obstructive gastritis. In Australia, grit is frequently offered to companion birds with few ill effects; however, birds fed formulated diets are unlikely to need either insoluble or soluble grit. As a compromise, a cockatiel-sized bird can be offered five grains of grit biannually; a cockatoo-sized bird can be offered a half-teaspoon of grit biannually. Cuttlefish bone may be provided as a supplemental source of calcium; however, with the widespread availability of formulated diets, these agents are no longer required to provide supplemental calcium. Additionally, cuttlefish bone may accumulate high levels of toxins (particularly heavy metals), and with the severe and continued degradation and pollution of the environment, this product may pose a health hazard to birds (see Chapter 37).

Seed bells that have been fashioned with wood glue should not be offered to birds. Additionally, these products may contain a wire loop or hook that is a potential health hazard. Mite protectors are not effective for birds, and the constant exposure to the aerosolized toxins in these products may be a health hazard. Effective therapy is available for the occasional bird that develops a mite infection (see Chapter 36). In nature, birds will sometimes be observed feeding from sun-bleached, uncooked bones. Charcoal may be consumed by a bird when it is offered; however, it has been shown that charcoal can cause a vitamin B deficiency and it should not be offered on a regular basis.

Preventive Care

Wing Clipping

Advantages and disadvantages exist for each of several methods for clipping the wings. The clinician should determine the client's expectations of the appearance and the reduced flight capacity of the bird prior to performing a wing clip. The client should authorize the trimming or removal of any feather that will alter the appearance or function of the bird, particularly with respect to show or racing birds. It is important to identify and avoid any pin feathers (blood feathers, blood quills), as a developing feather that is cut below the pulp cap will bleed profusely.

The goal of clipping the wings is to prevent the bird from developing rapid and sustained flight and *not* to make a bird incapable of flight (Figures 1.7, 1.8). A bird that is unable to gain any lift with the wings becomes a free-falling object if it jumps from a high location. Excessive wing trims can result in fractures of the legs, wings or lacerations of the keel (see Color 8).

A bird will require additional trimming eight to twelve weeks after the start of a molt cycle. Wing clipping has been loosely associated with feather picking and self-mutilation in species that are prone to this behavior (Gang Gang Cockatoos, Major Mitchell's Cockatoos, Moluccan Cockatoos, Rose-breasted Cockatoos or rosellas); however, the role that feather clipping plays is unsubstantiated. In smaller athletic birds, both wings may require clipping to reduce flight capacity.

Nail Clipping

Healthy birds usually have strong, sharp nails that can be uncomfortable to the client when the bird is perching on the arm or shoulder. A short length (usually about 2 mm) of the nail can be removed by trimming or grinding without causing pain or bleed-

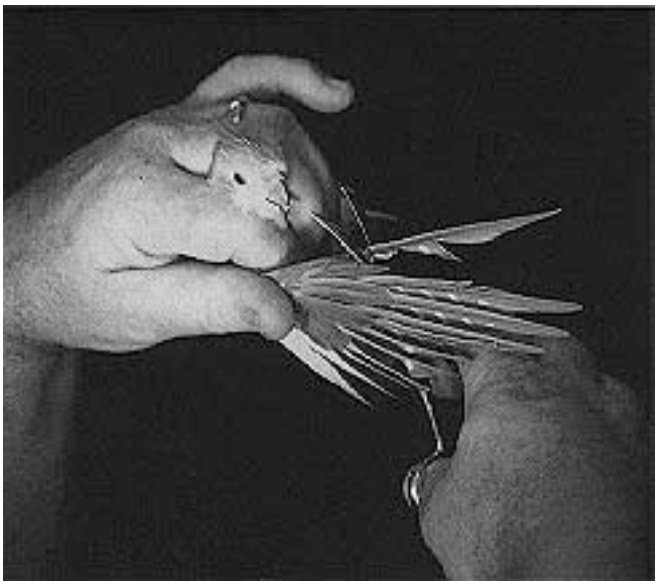

FIG 1.7 During the wing trimming process, the wing is held at the shoulder with the humerus in a fixed, extended position. Each individual feather is depressed with the scissors and cut below the covert, being sure to miss any pinfeather shafts to avoid bleeding. An aesthetically pleasing wing trim can be performed by pushing a feather to be cut ventrally and then clipping the quill at a level under the wing covert feathers.

ing (Figure 1.9). Sandpaper perches are contraindicated for birds and are not an alternative to nail trimming. Short-blade podiatric nail clippers can be used to trim the tip of the nail with minimal risk of accidentally cutting adjacent toes.

Alternatively, a motor driven hobby grinder (preferably with a rheostat foot switch) with a cone-shaped stone may be used for filing and shaping nails and beaks (Figure 1.10). When using a grinder, it is easy to slowly reduce the length of the nail or beak and to stop at a point just before bleeding might occur. Any bleeding that does occur is best controlled with a bipolar radiosurgical unit (beak), silver nitrate stick (nails) or Monsel's solution (both). It is best not to use a silver nitrate stick around the beak. The silver nitrate deposited at the wound site can remain active and cause caustic burns to the tongue or oral mucosa. The dust created by grinding the nails and beak is a health hazard and should be exhausted. The grinding stone and nail clippers should be sterilized between birds.

Bathing

Many birds enjoy a bath or shower and should be given the opportunity to determine the degree and duration of exposure to moisture. Frequent misting encourages normal grooming activity, which is critical to proper feather maintenance. After bathing, birds should have access to a warm, draft-free area to preen and dry. Some birds like a shallow container in which to bathe, while others prefer a fine spray (clean misting bottle). Some smaller birds prefer to bathe in a wet clump of grass or wet salad greens. Some like to fly onto and off the client's shoulder or head while the client is having a shower.

Very few birds like to be physically placed in bath water and washed. The few indications for manually bathing a bird include the removal of oils, greases, waxes, paints, dirt and dried medications. Unless a material contaminating the plumage is toxic, it can be removed a little at a time with repeated baths of short duration. This prevents the bird's exposure to excessive quantities of soaps and detergents (see

FIG 1.8 In larger birds, clipping the secondaries and all but the most distal two or three primaries generally results in a bird that has some flight capabilities that allow it to float to the ground in a spiral fashion. In smaller athletic birds, both wings may require clipping to reduce flight capacity.

Chapter 15). It may take months for birds that have been washed in soaps and detergents to regain the normal color and water resistance of their plumage.

Medications or food particles that have dried and become encrusted on the feathers around the mouth are removed by pre-moistening the material, then gently washing with a cloth a few minutes later.

Identification Methods

Leg Band Removal

Open leg bands should always be removed from companion birds. Some closed leg bands aid in the identification of a bird and may suggest that the bird was captive-bred; however, they can constitute a health hazard. Potential band-induced problems include entrapment of the leg in the enclosure accessories or the accumulation of a constrictive ring of keratin (usually associated with malnutrition or *Knemidokoptes* mites) between the band and the leg that can lead to impaired circulation and necrosis (Figure 1.11). Flat bands that are often too wide to comfortably ride on the tarsal bone can lead to traumatic exosteal bone formation. Any details on the leg band should be recorded in the bird's record prior to removal. The client's consent should always be obtained before the band is removed. A highly prized breeding bird could be rendered almost valueless if its leg band is removed and no other form of identification (such as a microchip) is available. A band that is removed should be given to the client.

Bands are easiest to remove before they begin to constrict the tissues. It is generally recommended to anesthetize a bird with isoflurane to ensure that a band is safely removed. This prevents the bird from suddenly moving during the band removal process, which can result in lacerations or fractures of the leg depending on the type of removal device used. In removing any band, it is important that forces be applied to the band itself; pressure must not be applied from any direction to the leg.

Small closed bands made of plastic or aluminum can be easily transected with Heath-type stitch removing scissors (Figure 1.12). Two diagonally opposing cuts

FIG 1.9 Nail trimming is most easily achieved using a motor driven hobby tool.

FIG 1.10 Beak trimming can best be accomplished using a motor driven hobby tool. Resting a finger on the beak or head can facilitate control when trimming the upper beak. The lower beak can be most easily trimmed by placing the tip of the upper beak inside the lower beak.

are made and the band falls off in two halves. Large split bands are easiest to remove by using two pairs of locking pliers to apply opposing force at the site of the opening. Attempting to cut large, open import bands can result in collapse of the band against the leg, resulting in bruising, lacerations or fractures (Figure 1.13). Additionally, the force placed on the band becomes uncontrolled at the point where the cutters fully penetrate the band, and undue stress is placed on the leg.

Bands that are associated with constrictive accumulations of keratin (in-grown bands) can best be removed by using a variable speed hobby tool and a fine tip cutting bit. The bird should be anesthetized and the leg should be held by the individual using the hobby tool to prevent slipping of the tool or leg, which can result in severe laceration (Figure 1.14). The constrictive rings of accumulated keratin should be removed by moistening them with skin softeners or aloe vera gel and gently peeling them away. A bandage or light splint may be necessary to support the bone if it has been weakened by the constricting material.

Closed bands are applied to developing neonates to indicate that the bird is captive-bred; however, this is not reliable identification because closed bands may also be placed on free-ranging neonates in the nest, or chicks of free-ranging species can be close-banded after their eggs were stolen from the nest and carried illegally to other countries. Closed leg bands can be of different colors and may have imprinted on them a variety of coded information. They are designed to be worn permanently by the bird but can create problems in some situations.

Tags

Numerous shapes and sizes of tags have been applied with varying degrees of success to the wings, the patagial membrane or backs of birds. This method of identification is used by field biologists in the study of free-ranging birds and is rarely encountered with companion birds.

Tattoos

Specific information placed in the skin of a bird by tattoo rarely remains legible. In practice, tattoos are

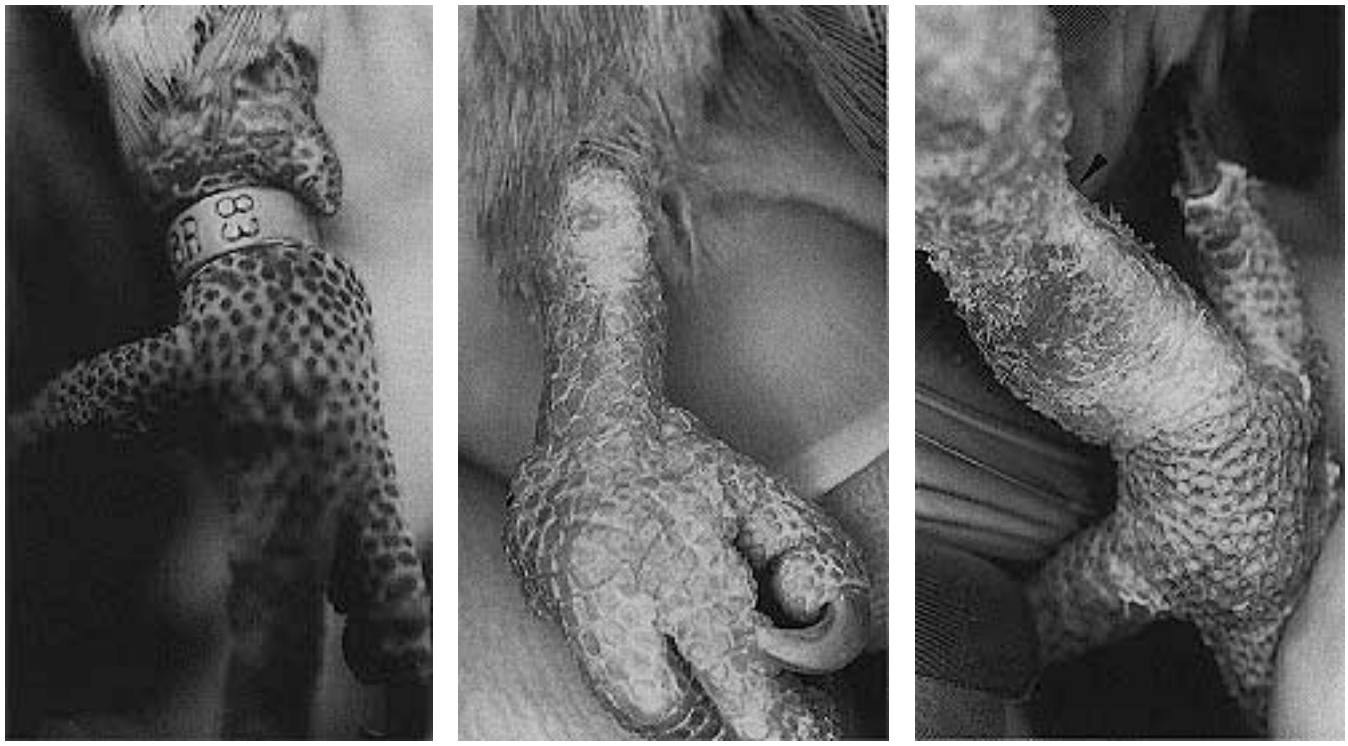

FIG 1.11 Closed bands that are too small can cause constrictive lesions or can lead to the accumulation of keratin debris under the band, which results in constriction. The leg of an Amazon parrot after removal of a band shows the constriction of the soft tissue (arrow), and bruising and swelling of the distal limb (open arrow).

generally restricted to indicating the gender of a bird following endoscopic evaluation of the gonads. By convention, tattoo ink injected into the left patagial membrane indicates a female and in the right patagial membrane indicates a male (see Color 8). The tattoo ink used should be sterilized to prevent the ink from serving as a nidus for bacterial granulomas.

Microchips

Microchips are small electronic devices that are injected into the musculature (usually, the pectoral muscle of birds) to provide permanent identification. A radiograph can establish the presence and location of a chip (Figure 1.15). The microchips are coded and the code can be read by use of an appropriate reader (see Figure 2.1). Microchips are of particular use for establishing proof of ownership of

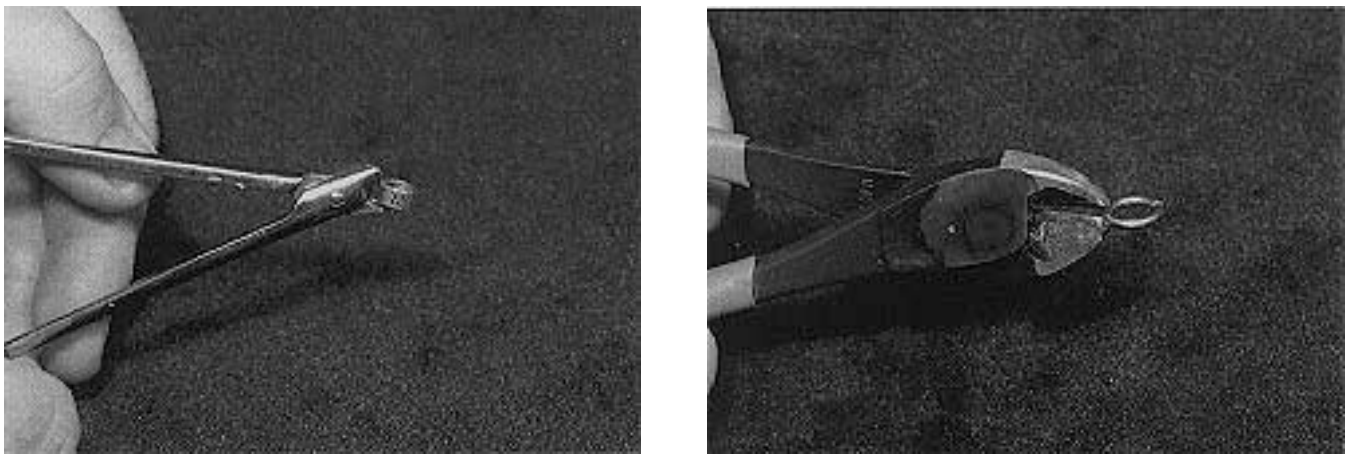

FIG 1.12 Stitch removal scissors and flush cutting or diagonal cutters can be used to remove small aluminum or steel bands, respectively.

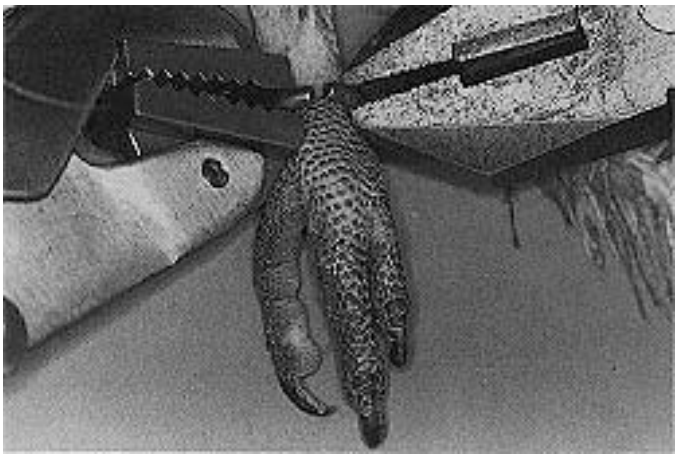

FIG 1.13 The easiest and safest way to remove open steel bands is to use two pairs of locking pliers to control the opposing force of the band's opening. Attempting to use large bolt cutters to remove these bands can cause lacerations or fractures. Note that gaining sufficient purchase on the band with the cutters places opposing force on the leg (arrow).

birds that are likely to be stolen. The use of microchips is hindered only by their cost and the restricted availability of readers. Unfortunately, there is no industry standard, and a single reader model cannot identify all available microchips. Microchips can be injected into the pectoral muscle of most birds without sedation or anesthesia, although given the option, the author prefers to perform the procedure in an anesthetized bird. The public awareness of the implantation of microchips into endangered birds or other populations that are susceptible to illicit trapping may act as a deterrent to illegal collection and movement of these birds.

DNA Fingerprinting

DNA fingerprinting offers a technique for accurately identifying an individual bird and, with proper samples, identifying the bird's immediate relatives. Storage banks for DNA collected from Psittaciformes are currently available in some countries. Collecting and storing the information is relatively inexpensive, but the manipulation or evaluation of the data is relatively expensive.

DNA fingerprinting may be of particular value in studying free-ranging birds for government officials involved in the monitoring of local and international bird trade or for establishing genetic information on birds in large aviaries or zoologic collections. In sev-

FIG 1.14 A hobby tool with a fine cutting bit is best for removing closed bands that are constricting tissue. The patient should be anesthetized for the removal process and fluids should be constantly flushed over the band to prevent it from heating during the cutting process.

eral legal cases, DNA fingerprinting was used to evaluate the lineage of birds. In one case in Europe, this technology was used to prove that a group of birds had been illegally imported, resulting in the proper criminal prosecution of a smuggler. In another case, DNA finger printing was used to disprove that

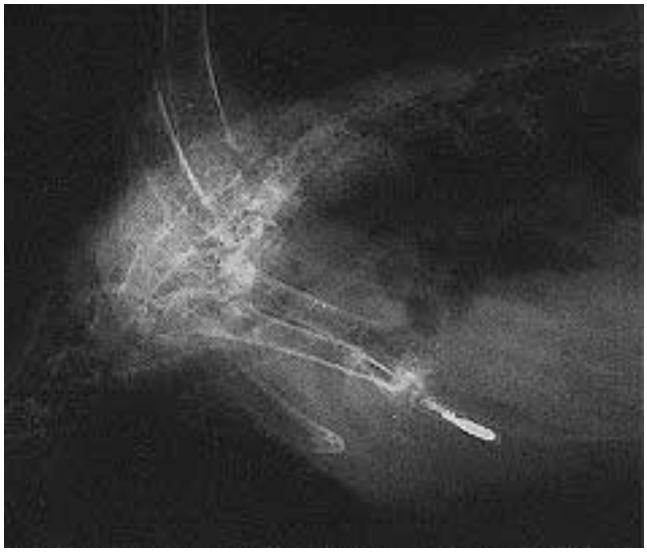

FIG 1.15 Radiographic appearance of a microchip implanted in the pectoral muscle of a companion bird.

a pair of supposedly proven breeding birds had not been the parents of a neonate.

CHAPTER

2

THE AVIAN FLOCK

Susan L. Clubb
Keven Flammer

Changing attitudes and regulatory pressures are transforming the companion bird industry. Birds for pets and aviculture are being increasingly supplied by domestic breeding programs, and the importation of wild-caught birds is no longer necessary or acceptable for most species. As aviculture advances, veterinarians must play a major role in maintaining the health and increasing the productivity of individual pairs and flocks. The quality of avian medicine available for individual birds has advanced tremendously in recent years. The successful growth of aviculture will require simultaneous advances in the knowledge and application of preventive medicine from the veterinary community.

Avicultural medicine differs from clinical care of individual companion birds in several very important ways. In general, the health of the flock is of primary concern, and establishing a diagnosis or preventing exposure of the flock to an infectious agent is usually more important than providing supportive care for the individual ill bird.

The economics of the companion bird industry are also changing. As production increases, sale prices for individual captive-bred birds decline. The commercial producer, as is the case with any livestock producer, often operates on a slim margin of profit, which can be profoundly affected by disease or management problems. Understanding the economics of the companion bird industry is vital for a successful avicultural practice.

Flock Preventive Medicine

The Veterinarian / Aviculturist Relationship

To be of service to the aviculturist, a veterinarian must understand some of the principles of aviculture as well as the principles of medicine and disease. A knowledgeable avian veterinarian will serve as part of a well coordinated aviary team. Table 2.1 lists routine veterinary services that are beneficial to aviculturists.

Veterinary/client confidentiality is of utmost importance for the avicultural client. Inappropriate discussions concerning disease problems in an avicultural facility can permanently and irreparably damage a facility's reputation. The clinical staff must be counseled in strict professional behavior to ensure that they also maintain client/doctor confidentiality.

TABLE 2.1 Veterinary Services of Benefit to Aviculture

- Perform new bird examinations
- Perform resident bird examinations
- Assist in establishing and maintaining records
- Establish a preventive medicine program
- Offer husbandry advice
- Provide emergency care for aviary birds
- Take appropriate action in the face of disease outbreaks
- Evaluate reproductive failure
- Assist with incubation and pediatric problems

Commercial Breeder vs. Hobbyist

The primary goal for the commercial breeder is to produce young companion birds at a profit. Rare or endangered species, species that inherently make poor pets, species that reproduce poorly in captivity or species that have extraordinary housing requirements are not advisable for the commercial breeder. The true economic advantages and disadvantages of a particular-sized facility should be carefully evaluated. Increases in housing density may be economical but can also contribute to the incidence and severity of disease outbreaks, necessitating a detailed monitoring system to prevent health hazards. The commercial breeder should select species that are easy to produce in captivity, that adapt well to the environment in which they will be kept and are popular, acceptable companion birds.

Hobbyists may specialize in a species, or group of species, in order to produce birds for exhibition, for the pure pleasure of aviculture or for the more altruistic goal of establishing or preserving a species in captivity. Hobbyists typically sell offspring to recover the costs of maintaining their collection or to allow them the freedom of devoting more time to aviculture. Profit is not typically the primary motive of a hobbyist breeder. Many aviculturists may start as hobbyists and turn that hobby into a profitable business as they gain expertise and appropriate species of birds.

Flock Monitoring Team

The veterinarian should work closely with the aviculturist to establish an effective preventive medicine program. Quarantine procedures, parasite control techniques, pest control, identification systems, first aid procedures and subclinical disease testing (chlamydia, PBFD virus, polyomavirus) should be discussed. A healthy, pre-existing aviculturist/veterinarian relationship ensures fast action if a disease outbreak occurs.

Aviculturists must be viewed as the veterinarian's eyes and ears. They see and evaluate their birds daily and must be willing to discuss even the slightest changes in behavior, appetite, stance or excrement output with the attending veterinarian. The aviculturist must respect the veterinarian's medical judgement and strictly implement any and all suggestions. If the advice of the veterinarian is not sought after and respected, a new veterinarian should be engaged.

Aviary Visits

Veterinarians and their staff should be aware of potential biosecurity hazards to avoid being mechanical vectors for disease transmission between individual patients or avicultural facilities. The veterinarian should visit only one avicultural facility a day, preferably in the morning prior to entering the hospital. If this is not feasible, it is best to have each facility maintain coveralls, scrubs and shoes that can be worn while evaluating that facility. These clothes then remain at the facility for laundering.

When it is necessary to handle a bird in the aviary, it is important to remove the bird from its enclosure with a minimal amount of disturbance. This can be achieved by having all necessary equipment and supplies readily available, with the least number of people involved and minimal noise. The number of assis-

tants and visitors that a veterinarian uses while making any aviary call should be minimized.

Selling Birds

Offering a liberal warranty may be used as a method to sell birds. However, long-term guarantees given on the health or life of birds, especially unweaned neonates, can be complicated. Pre-sale testing for selected infectious diseases such as polyomavirus, PBFD virus or chlamydiosis, may help assure the buyer of good health. The best guarantee of good health would logically stem from a stable flock of known health history and good husbandry practices. Pet retailers and breeders often require a veterinary examination within a certain period of time in order to activate a guarantee.

A suggested guarantee may last for 14 to 30 days post-purchase as long as the buyer has the bird examined within seven days. An immediate refund should be considered if the buyer's veterinarian determines that a bird has a health problem. The veterinarian must practice good judgement in recommending return, and not reject birds for frivolous or unsubstantiated reasons.

The New Bird

Acquisition

Initially, most aviculturists have little concept of which species they will ultimately be breeding. They often acquire, and later sell, many pairs or individual birds before determining which species are best for their aviary. Proper selection of a species for breeding will increase reproductive success, be personally satisfying and will provide better financial return. Choosing species that can easily adapt to the climatic conditions of a region will usually increase breeding success. For example, species that inhabit dry, high altitude environments may be unduly stressed and more susceptible to disease when housed in outdoor aviaries in a warm humid climate; likewise, species from lowland tropical forests may not thrive in dry desert areas.

Ideally, the aviculturist should attempt to envision what he or she would ultimately like to accomplish before establishing an aviary collection.

Sources of birds for captive breeding include imported wild-caught birds, captive-bred juvenile birds and surplus birds, either wild-caught or captive-bred, from other aviculturists or pet owners.

In the past, aviculturists have relied principally upon wild-caught birds for the majority of their breeding stock. A program was established in 1992 for phasing out the importation of wild-caught birds; the availability of these birds is limited to aviculturists who are willing to participate in cooperative breeding programs. As importation ceases, so too does the exposure of immunologically naive birds to previously unencountered pathogens. This provides the veterinary preventive research community with the time necessary to control some of the diseases that have already been introduced to the aviary through previous importation programs.

The purchase of captive-bred birds for breeding stock is a logical alternative for many species. Many psittacine and passerine species have adapted well to captivity and breed prolifically in properly designed aviaries. The psittacine species that have proven to be difficult to breed in captivity will require further work. In some cases, hand-fed neonates are not thought to produce well in captivity, while in other cases these birds reach sexual maturity at a much younger age than expected and readily reproduce.

Although the purchase of culled breeders from another aviculturist should be viewed with suspicion, moving a pair of healthy, unproductive birds to a new environment frequently initiates breeding activity.

Care must be taken to avoid the purchase of smuggled birds. Bargain-priced birds should always be viewed suspiciously. The addition of illegally imported (smuggled) birds to a collection has both unacceptable disease and legal risk.

The buyer should attempt to obtain as much information as possible about the seller and the bird before

CLINICAL APPLICATIONS

- Veterinary/client confidentiality is of utmost importance for the avicultural client.
- A healthy, pre-existing aviculturist/veterinarian relationship ensures fast action if a disease outbreak occurs.
- The level of husbandry advice provided by the veterinarian must be adjusted to compensate for the experience of the aviculturist.
- If a bird leaves a facility for any reason and is exposed to any other birds, it should be considered contaminated and must be placed in quarantine before return to the aviary.
- An aviary must meet the physical and psychological needs of the birds. Healthy, happy birds breed. Healthy, unhappy birds may not breed.

purchase. The first question to ask the potential seller would be, "Why is this bird or pair being sold?"

The aviculturist should determine the original source of the bird. If the bird was wild-caught, it is wise to determine the country of origin and the importer. If the bird has changed owners several times, it is best to determine why. For captive-bred birds, it is advisable to determine where the bird was produced, when it was hatched and if the bird was parent-raised or hand-fed. If the bird is represented as captive-bred but is not closed banded, it is useful to know why. Determining the genealogical history of the bird, determining if any previous health problems have occurred and evaluating as much information as possible about the flock of origin can guide the aviculturist in making a wise choice in adding birds. A copy of all medical and reproductive records should be requested. If a proven pair is being sold, are the birds identified and are breeder's records available? Knowing when and how the gender was determined in a bird may help identify reasons for reproductive failure. Male cockatoos are frequently available for sale after they have killed their mate. If a seller is unwilling to freely provide any requested information, the buyer should be concerned about the validity of any claims that are made concerning a pair of birds.

Evaluating a Prospective Purchase

The addition of new birds to an established aviary increases the potential for introducing an infectious disease. Additionally, new birds that are misrepresented (inaccurately sexed or sold, due to previous reproductive failure) represent a loss to the aviculturist by occupying space and requiring care that could be used for productive pairs. Examination of a breeding bird being considered for addition to the aviary should be more than a health exam. The bird's gender and the visual health of the reproductive tract should be confirmed by laparoscopy. Diagnostic testing should be based on the client's needs, species of birds, source of the birds and any questionable abnormalities detected on physical examination.

Quarantine

A routine quarantine program for new birds is vital to protect an established avicultural collection from the introduction of infectious diseases. The type of examinations performed, length of the quarantine period and preventive techniques vary according to the resources of the aviculturist, the species and source of the birds being added and the type of collection. If a bird leaves a facility for any reason and is exposed to any other birds, it should be considered contaminated and must be placed in quarantine before being returned to its normal enclosure. Neonates that leave the nursery and come into contact with other birds should not re-enter the nursery.

Quarantine Facilities

Facilities used for quarantine will vary among aviculturists. In many instances there is no opportunity for strict segregation of new arrivals, and in these cases it is prudent not to add new birds to a facility. Ideally, birds in quarantine should be housed separately from the remainder of the collection for a minimum of sixty days. Birds in quarantine should be attended by an individual who has no contact with the established collection, who takes care of established birds prior to servicing the quarantine facility or who showers and changes clothes after servicing the birds in quarantine. Quarantining birds off the aviary property (eg, a neighbor's home) is a practical means of providing an effective quarantine period.

Birds placed in separate rooms within a home provide a minimum amount of separation between new and established residents. Birds that are maintained in any enclosure (home or building) with the same air space should not be considered to be in quarantine. The bowls and all handling equipment used for birds in quarantine should not come in contact with the remainder of the birds in a collection.

New Bird Examination

Birds should be examined at the beginning of quarantine to establish any pre-existing problems and again at the end of quarantine to detect any clinical changes that may have occurred (see Chapter 8).

It is critical for the aviculturist to understand that quarantine is only a "safety valve" in the prevention of infectious disease and does not ensure that a new bird is not an asymptomatic carrier of parasitic, bacterial or viral pathogens.

The new bird exam and quarantine testing program should be tailored to the needs and resources of the aviculturist and the species of bird. Suggested screening techniques would include a thorough physical examination, Gram's stain of feces and evaluation of a blood smear. Complete blood count, blood chemistry profile and cultures are useful to detect birds that require more extensive evaluation. By performing a complete CBC, biochemical profile and radiographs on each new bird in a facility, the veterinarian is able to establish a "normal value" for

a particular test in a particular bird. In essence, this testing allows the veterinarian to establish a "point-in-time" medical fingerprint for the individual bird. Specific diagnostic screening tests that should be considered include ELISA tests for chlamydia and DNA probes for polyomavirus and psittacine beak and feather disease virus (see Chapter 32). Direct and flotation examination of feces for internal parasites should also be considered in birds that were recently imported or that are in flights with access to the ground (see Chapter 36). Any thin birds, especially species susceptible to neuropathic gastric dilatation (formerly proventricular dilatation syndrome) should be examined radiographically. Some diseases that are characterized by an asymptomatic carrier state (Pacheco's disease virus, giardiasis) are easily missed with routine testing.

Identification

Each new bird should be permanently identified during its initial physical examination. Implantable transponders provide the least alterable identification with minimal risk to the bird.[a-c] The transponder number should be included in the medical, genealogical and breeding records to provide positive identification of the bird throughout its lifetime (Figure 2.1). Closed bands can be used as an adjunct to or replacement for transponders but are not ideal. Properly fitting closed bands are an indication (not proof) that a bird was bred in captivity.

Closed bands are currently required for export of captive-bred birds of CITES-listed species. Unfortunately, the numbers often wear off closed bands and large birds may collapse them, resulting in leg or foot injuries. In addition, bands can catch on loose enclosure wires. These disadvantages should not dissuade the serious aviculturist from closed banding nor should they encourage the veterinarian to remove those bands.

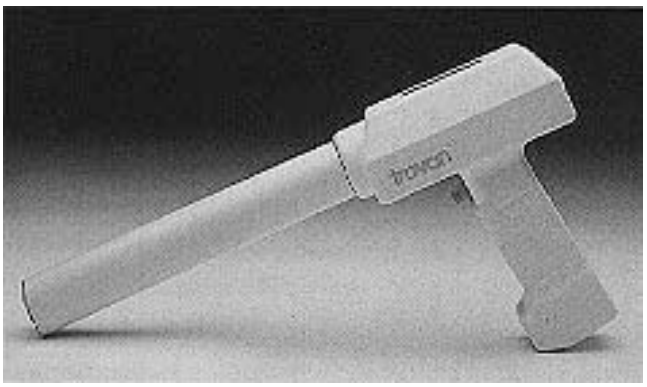

FIG 2.1 Electronic transponders provide the most permanent, least alterable and safest method for identifying a breeding bird.

FIG 2.2 A closed band on a bird may or may not indicate that the bird was domestically bred. Slightly oversized closed bands can be placed on the leg of most birds. Alternatively, a bird that was captive produced in another country and imported into the United States could have a closed band and an open import band. Such was the case in this macaw.

Open bands are the least desirable but are none the less an effective means of identification. The rolled steel bands used for identifying birds in USDA quarantine stations have sufficient tensile strength to preclude complete closure, increasing the risk of entanglement when compared to closed bands (Figure 2.2). An alternative to removal of these bands is to close them as tightly as possible, thereby reducing the risk of the gap slipping over enclosure wire. The numbers are typically more durable on steel open bands than on breeders' closed bands, which are usually made of aluminum. Metal bands must be removed from the legs of birds exposed to sub-freezing temperatures, as they contribute to frostbite. The importance of individual identification was graphically demonstrated in the aftermath of Hurricane Andrew's assault on South Florida in August 1992. Many birds escaped when their enclosures were damaged and could not be identified by the aviculturist to facilitate recovery.

The veterinarian can help the aviculturist establish a record system that is best for a particular facility, assist in developing and implementing effective identification systems and evaluate production records. Records that include all available medical information should be established at the time the bird enters the aviary.

Trends indicate an increasing interest in the establishment of stud books and cooperative breeding programs involving private aviculturists. The more information that is available for a particular bird, the

more valuable that bird is to captive reproductive programs.

Acclimation

Birds should be acclimated to their new surroundings as soon as they arrive. Birds may refuse food for several days (small birds) or up to a week (larger species), especially if the bird was a previous pet. New birds should be weighed upon arrival and observed closely for weight loss. Gavage feeding should be used only if the weight loss is dramatic (15% of initial weight) in order to avoid unnecessary stress. A bird that is reluctant to eat can be maintained on the diet to which it is accustomed and slowly changed to the diet used by the aviculturist. Changes in the quality of water may cause temporary intestinal upset. A species that will be housed outdoors must be slowly acclimated to its new climatic conditions. Tropical birds can tolerate northern temperate climates if acclimated for several months before being exposed to winter temperatures. Exposure to direct sunlight can cause burns on the unfeathered portions of the face. Eye rings, facial patches in macaws and exposed skin in feather-plucked birds will eventually "tan" and show color changes indicative of melanization or deposition of other protective pigmentation. Biting insects may cause dermatologic reactions that can become quite severe in a new arrival (see Color 24). Housing of affected birds indoors until the severity of such reactions subsides may be helpful. The possibility of birds becoming sensitized (allergic) to pollens or resins of plants has been suggested.

Preventive Husbandry Practices

The level of husbandry advice provided by the veterinarian must be adjusted to compensate for the experience of the aviculturist. Successful aviculturists frequently have vast experience in animal husbandry and carefully evaluate the behavior and condition of their birds on a daily basis. They often understand intuitively when problems are occurring that require veterinary assistance to identify, correct and prevent. If a veterinarian expects client compliance, recommended therapeutic programs must be designed to address the daily problems faced by the breeder and require minimum input of time, labor and resources. Minimal disruption of the collection may be the most important factor in maintaining a stable, healthy collection of breeding birds.

A routine preventive medicine program should be designed around a detailed health history for the collection. Fecal samples should be evaluated on an annual basis and can be grouped (no more than three to five pairs/sample) to facilitate testing for paraites in a large aviary. Infected groups can then be screened on an individual basis and treated as needed.

Annual prophylactic treatment for chlamydiosis is often advocated even in the absence of a diagnosis of chlamydiosis. This may be beneficial in birds housed outdoors and exposed to free-ranging birds, especially pigeons. In most cases, the indiscriminate use of antibiotics is not recommended. Exposing birds in a flock to unnecessary or sub-therapeutic levels of antibiotics will create "super" strains of bacteria that are resistant to a particular antimicrobial agent. If birds are medicated, treatment should be delayed until the non-breeding season (the fall for most species). Egg production will typically decrease during treatment, and chicks that hatch from eggs laid during treatment may have developmental abnormalities.

Commercially available oil emulsion adjuvant vaccines for Pacheco's virus disease, pox and salmonella can be beneficial in populations at risk. These vaccines were developed for use in wild-caught imported birds to prevent catastrophic disease outbreaks. In an avicultural collection, the benefits of vaccination must be weighed against the potential for granulomatous reactions to oil emulsion adjuvants.

Feeding Aviary Birds

Proper nutrition is vital to avicultural success. Diets should be complete and balanced for optimal health and reproduction. The goals in formulating diets for captive breeding birds include meeting the known or perceived nutritional requirements, maintaining good food hygiene, providing psychological enrichment by offering variety, and having a diet that is easy to prepare and minimizes labor, waste and expense. In general, breeding birds should receive a formulated diet, a variety of fresh fruits and vegetables and some seeds and nuts. In-the-shell peanuts should be avoided because of their potential for exposing a bird to aflatoxins. Establishing a species in captivity requires an understanding of the feeding habits of free-ranging conspecifics. Knowing what free-ranging birds consume will define dietary preferences, may suggest nutritional requirements and will help provide psychological stimulation that could enhance breeding success.

In captivity, birds are usually offered the same diet year-round. In contrast, free-ranging Psittaciformes must forage for food. In their quest for food, birds

typically ingest a varied diet that might include fruits, flowers, buds, pollen, seeds, grains, roots and some insects. Many of these foods will be seasonally available as dictated by the wet and dry seasons, which often control the reproductive cycles. The seasonal provision of extra soft foods prior to the onset of the breeding season may stimulate reproduction.

Birds that are housed outdoors are exposed to natural sunlight and should not require supplemental Vitamin D_3. Macaws are especially susceptible to Vitamin D toxicity, which could be potentiated by unnecessary supplementation.

Facility Design

An aviary should be designed to be easy to maintain while providing safety, security and sanitary conditions for its inhabitants. It must also meet the psychological needs of the birds. Healthy, happy birds breed. Healthy, unhappy birds may not breed. A part of making a bird feel secure is to provide it with a defendable space (its enclosure), which is rarely, if ever, violated. Additional factors in providing a secure environment include having visual barriers to separate the nesting areas of secretive birds, and keeping louder, more boisterous birds (eg, macaws) widely separated from quieter, more timid birds (eg, African Grey Parrots). Indoor/outdoor facilities provide the most natural conditions for the birds, but may be unsatisfactory in urban areas. In these situations, properly designed indoor facilities can be used to successfully raise birds.

- ***Indoor Facilities:*** Indoor housing has several advantages over outdoor facilities including improved pest control, the ability to manipulate lighting, temperature and humidity, and protection from inclement weather and theft. Routine care is not affected by seasonal changes, rainfall and weather conditions. Disturbance by nocturnal predators or other wildlife and the exposure to infectious agents through contact with free-ranging birds is eliminated.

Indoor aviaries also have disadvantages. They are generally more crowded than outdoor aviaries, the increased proximity of birds to each other potentiates the spread of infectious agents, and the lack of seasonal cycling of light and other unknown climatic factors may alter or prevent normal breeding behavior. The per-unit cost of building and maintaining indoor units is generally higher than an all-outdoor facility. Indoor areas require more frequent cleaning to prevent the accumulation of feces, food wastes and dust, all of which reduce the air quality and increase the likelihood of a disease outbreak. The potential hazard that dust poses for human health should also be considered. Full spectrum light must be used to facilitate Vitamin D synthesis, which is necessary to maintain the general health of a bird. The concept of full spectrum light is confusing. In general, if a light source is not sufficient to induce "tanning," then it should not be considered full spectrum from a biologic perspective.

The most important considerations when planning an indoor aviary are to avoid overcrowding and to ensure ease of cleaning and frequent air exchange. Walls and floors should be designed to allow pressure

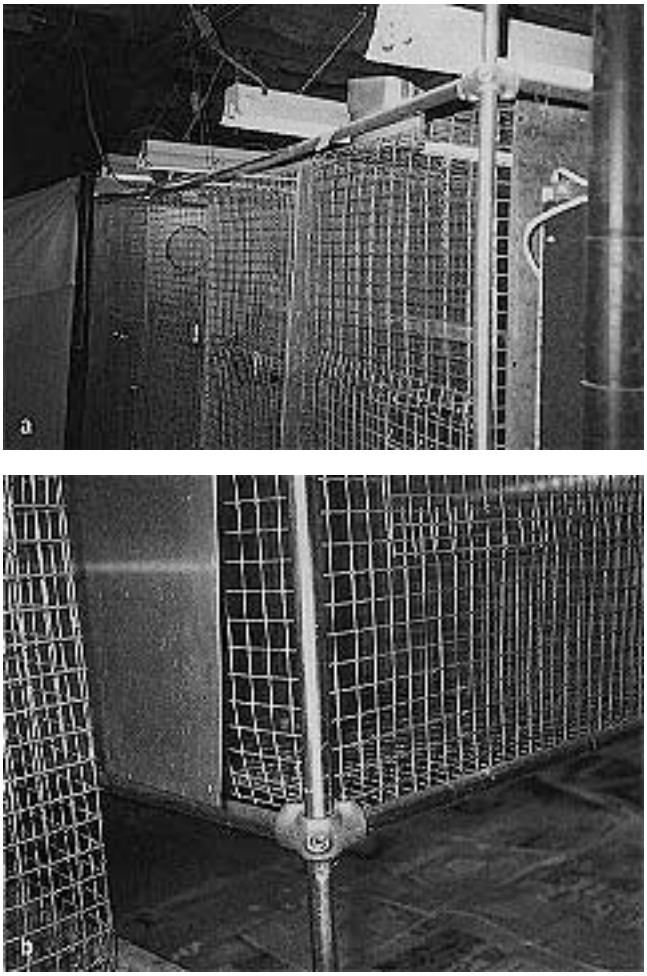

FIG 2.3 Birds can be successfully bred in indoor aviaries. However, these facilities are more labor-intensive and increase the likelihood of disease outbreaks. Indoor facilities should be easy to clean, provide adequate fresh air and must have a source of full spectrum light. This facility provides adequate light for each pair of birds but is impossible to clean with the exposed beam ceilings and open light fixtures. Newspaper is used to remove the bulk of droppings followed by rinsing of the concrete floors. The three-way hex-nut connectors are an easy way of putting conduits together to make the frame for enclosures.

cleaning, and floor drains should be of sufficient size to prevent blockage by debris or feed (especially seed that sprouts in drains). Floor drains should be covered to prevent pests, especially rats, from entering the facility. The facility should be designed to minimize any disturbance of the birds during cleaning activities (Figures 2.3).

The use of ventilation fans and air filters is necessary to ensure adequate air quality, to reduce stress and minimize the spread of infectious agents. The air in an indoor facility should be completely changed or filtered every two minutes. Tropical species may need additional humidity during dry winters.

- ***Outdoor Facilities:*** Site selection and preparation is the first step in outdoor aviary planning and construction. Considerations include location of aviaries in relation to support buildings, flow of traffic through the aviaries, source of water and electric power, the effects of noise on neighbors and potential disturbances from people, free-ranging animals and traffic. Drainage may be critical if aviaries are built in low-lying areas. The degree of protection from inclement weather should be evaluated. Natural or artificial windbreaks may be necessary in some parts of the country. The primary direction of wind and rain should be considered in the design of roofs in order to maximize protection of nest boxes and food bowls from rain (Figure 2.4). Privacy may be provided by the use of vegetation or fences or by placement of birds as far as possible from roads or houses. The need for shade will vary among species. Desert species may prefer a more sunny, open aviary while forest species may feel more secure in wooded or secluded aviaries.

FIG 2.4 Outdoor facilities with a covered area to keep the food bowls and nest box dry can be used to breed birds in appropriate climates. The enclosure can be constructed over concrete pads with a drainage ditch to one side for ease of cleaning.

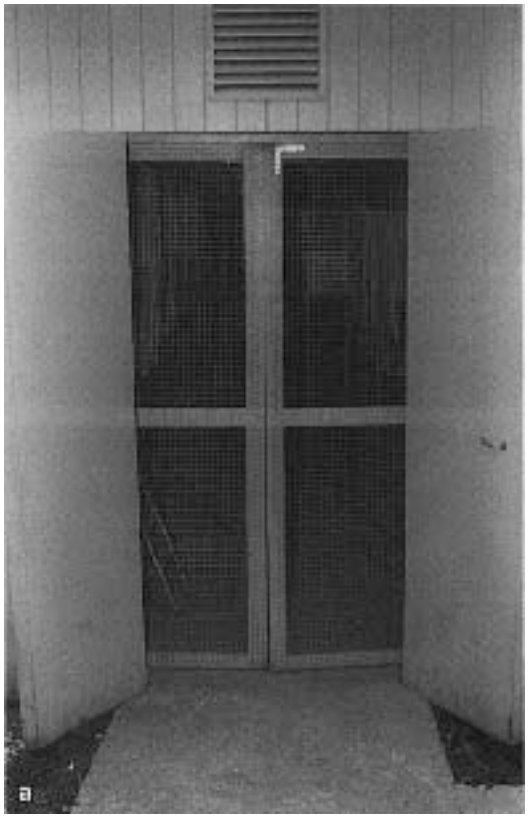
Outdoor aviaries should be designed to reduce the entrance of predators. Raccoons, opossums, foxes, rats and free-ranging cats and dogs may directly injure birds, frighten them into causing self-inflicted injuries or introduce infectious agents. Electric fences are helpful in excluding free-ranging predators from aviaries. Well behaved, properly trained dogs can be used in an attempt to exclude predators. Poorly trained, noisy or excitable dogs may affect production by disturbing or frightening the birds. A fenced "kill zone" that is patrolled by dogs should reduce the entrance of pests and predators into the aviary grounds.

Outdoor aviaries are common in the southern United States, and offer natural conditions and constant exposure to fresh air and sunlight. The per-unit cost of this type of facility is usually lower than an indoor facility. Exposure to natural, seasonal variations in weather may stimulate reproduction.

Disadvantages to an outdoor breeding facility include the inability to control inclement weather, increased difficulty in pest control, the potential of noise irritation to neighbors and increased risk of theft. Some birds may be bothered by biting insects or aerosolized allergens.

- ***Combination Indoor and Outdoor Facilities:*** Heated indoor facilities that are attached to outdoor flights are ideal for breeding birds in areas where the birds cannot remain outdoors year round. One facility that might be used as a model was designed to hold up to 24 pairs of birds and was completely constructed for less than $25,000 (Figure 2.5). A concrete slab was poured for the base of the indoor building. The concrete floor was sealed with a waterproofing agent to make cleaning easier and more effective. The slab was constructed with a 15-20% slope to one end. Two, covered four- to six-inch drainage pipes that drain water outside the perimeter fence were placed in each end of the building, and an easily removable sink was installed in one end. The sides of the building were made of concrete block with holes to the outside placed at the desired height (bottom of the bird's cage floor) and at numerous horizontal intervals (the number would depend on the width of the interior and exterior enclosures).

The ceiling was made of exterior grade plywood, and the walls and ceiling were sealed with an industrial-grade epoxy paint that can withstand pressure cleaning. A strip of florescent lighting was positioned down the center of the building. A central heating unit was installed in the attic of the building with four evenly



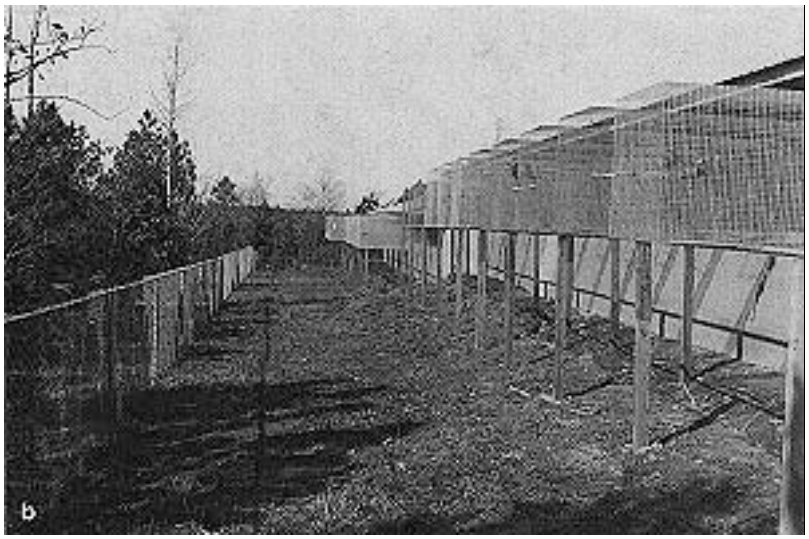


FIG 2.5 Indoor/outdoor facilities are ideal for breeding birds in climates where supplemental heat is needed in the winter. The lighted indoor facility is made of concrete blocks on a concrete slab for ease of cleaning. Wire doors on either end allow flow-through ventilation when opened. The outdoor flights are connected to the indoor flights through a hole in the concrete block. Note the height of the enclosures, which provides extra physiological security for the birds, and the perimeter fence with a "kill zone" to discourage unwanted intruders (eg, raccoon, opossums, rats, snakes) (courtesy of Apalachee River Aviary).

spaced registers and a centrally located return. Insulation was placed in the attic to reduce heat loss in the winter and keep the buildings cooler in the summer. The lights were placed on a timer and are adjusted seasonally to correlate with the natural changes in photoperiod.

The interior enclosures are suspended from beams in the attic. Alternatively, individual enclosures may be placed on pipe racks attached to the concrete floor; however, these are more difficult to clean. The thermostat for the heating system is placed at a level even with the enclosure perches and maintained at 50°F in the winter. By placing the thermostat at this position, a bird's living space is heated to the desired temperature while the area below the outdoor entrance hole (bottom of the enclosure floor) remains unheated.

Enclosures

The two primary styles of enclosures used in breeding aviaries are suspended wire enclosures and flights. A suspended enclosure is separated from the ground and is not entered by aviary personnel. Suspended enclosures are easy to construct, clean, modify or move, and are relatively inexpensive and secure. Birds have reduced exposure to their feces and accumulated food, simplifying disease and parasite control. These enclosures should be placed so that the perches are above eye level of aviary personnel to contribute to the security and contentment of the birds housed within (Figure 2.6).

Enclosures should be spaced far enough apart to prevent any physical contact between birds in adjacent housing. In general, the larger the size of the enclosure, the better (Table 2.2). Obese birds rarely breed, and larger enclosures provide for improved exercise. Suspended wire enclosures may not be advisable for toucans or some aggressive species that need ample room to escape from attacking mates.

Most enclosures for Psittaciformes are constructed from appropriate gauge welded wire (10 ga for larger macaws, 14 to 16 ga for cockatoos and Amazon parrots). Wire that is galvanized after welding is superior in strength to wire that is galvanized before welding. The galvanized coating that is used on welded wire does contain heavy metals. This wire should be thoroughly scrubbed with acetic acid using a wire brush and rinsed immediately to remove loose galvanizing material. "Weathering" the wire (ie, the practice of leaving rolls of wire in the open for six months to a year before use) does not reliably remove heavy metals (see Chapter 37).

FIG 2.6 Suspended enclosures provide an advantage over walk-in flights in being easier to clean and less expensive to construct and in reducing the birds' access to contaminated food or droppings. Enclosures should be placed as high as possible to increase the inhabitants' feeling of security. Note that the African Grey Parrots in this picture are completely unconcerned about the photographer. The perches in this bird's enclosure are about seven feet above ground level (courtesy of Apalachee River Aviary).

Flight enclosures extend to the floor or ground. Large flights are aesthetically pleasing to people and provide more space for exercise and normal behavior. However, these enclosures are difficult to clean and to maintain pest- or parasite-free. Additionally, aviary personnel walking from one enclosure to the next can serve as mechanical vectors for the transmission of infectious agents.

Enclosures should be designed with access locations that allow the capture of birds with minimal chasing. Escape proofing is suggested and may be accomplished by safety aisles or suspended safety netting. In outdoor facilities without safety aisles or netting, a portable safety cage or drape can be suspended over the door, surrounding the handler in order to reduce the chance of escape.

Containers to hold the food bowls should be designed to reduce dumping, to prevent or reduce perching on the bowls and to keep the food dry. Food bowls should be positioned away from perches to reduce excrement contamination of the food and water containers (Figure 2.7) Alcove-type feeding troughs are ideal for preventing food and water bowls from being turned over. Alcove servicing also prevents escapes because an enclosure door is not opened to gain access to the food and water containers. These alcoves can be designed to slide onto the floor or to fit under the floor of the enclosure. In either case, the access to the food bowls should be covered by a hinged, locking flap that provides two to three inches of coverage on each side of the alcove opening (Figure 2.8). Some aviculturists are finding that the use of bottles serves as an effective method of maintaining a constant supply of clean, fresh water at all times (Figure 2.9). However, birds in a dry climate that are incubating eggs must have access to a bowl of water in which to bathe to help control egg humidity.

TABLE 2.2 Suggested Minimum Sizes for Suspended Enclosures and for Nest Boxes

	Enclosure	Nest Box
Large macaws	6'x6'x12'	48"x16"x16"
Large cockatoos, medium macaws, obese Amazons	4'x4'x8'	36"x12"x12"
Amazons, African Grey Parrots	2'x2'x6'	24"x12"x12"
Pionus, mini-macaws	2'x3'x8'	24"x12"x12"
Conures, caiques	2'x2'x6'	18"x12"x12"
Small conures, cockatiels	2'x2'x3'	16"x10"x10"
Lovebirds, parrotlets, budgerigars	2'x2'x2'	8"x8"x24"

* Enclosure and box dimensions are height x width x depth

Perches must be secure and non-movable in order to provide an optimal site for successful copulation.

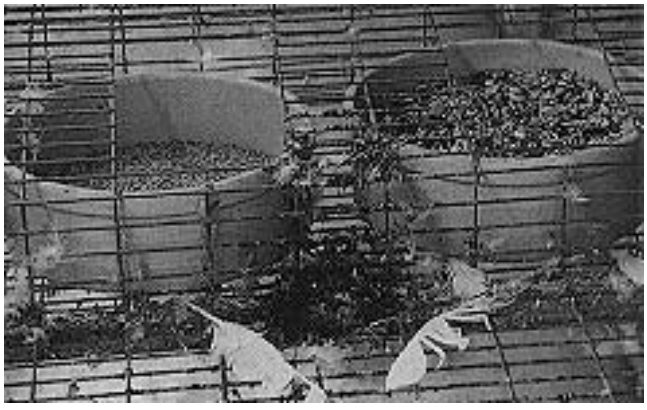

FIG 2.7 Food and water containers should be positioned away from perches or nest box openings to reduce excrement contamination. In this case, the feeding alcove was placed directly under the nest box, resulting in continuous excrement contamination of the food and water. Note also that these unproductive breeding birds were on an all-seed diet. The incidence of recurrent enteritis in the breeding adults and gram-negative bacterial septicemia in the neonates was high in this breeding facility.

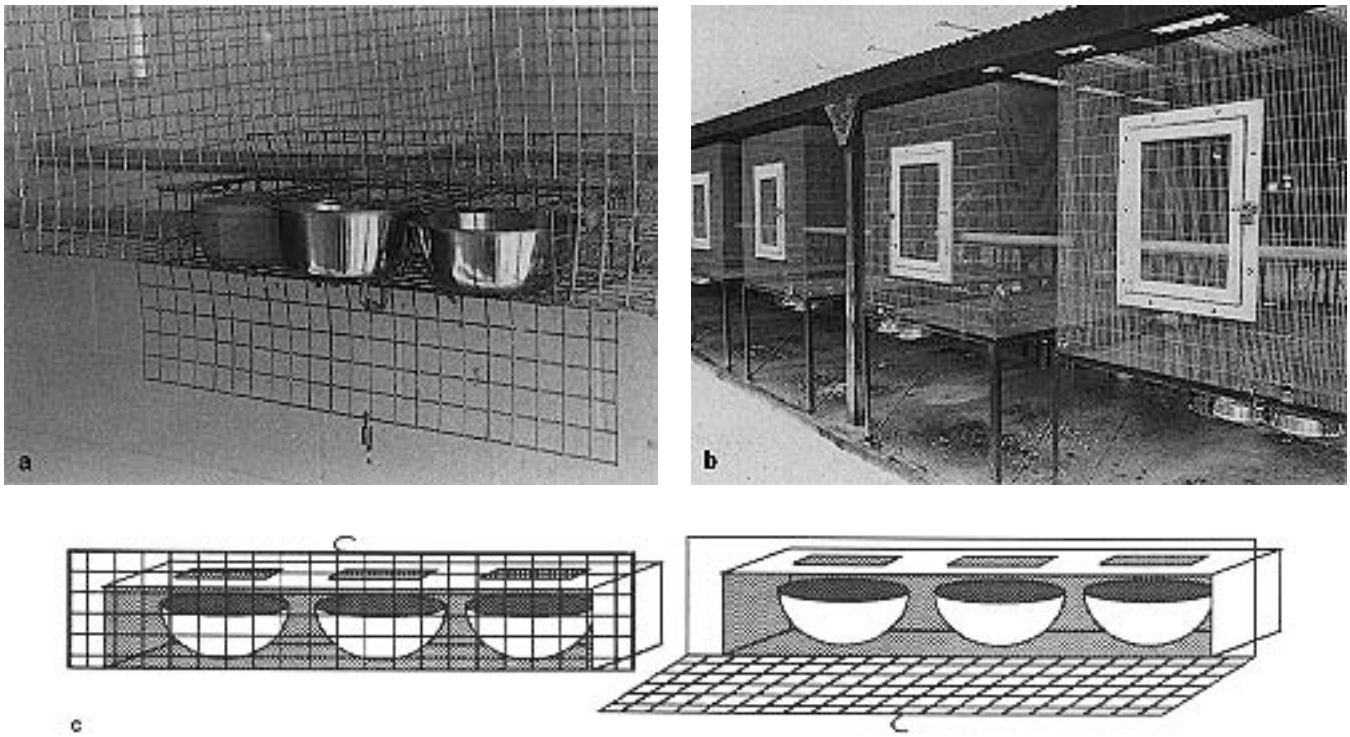

FIG 2.8 Alcove-type feeding trays can be placed **a)** on the bottom of the enclosure (courtesy of Apalachee River Aviary) or **b)** under the enclosure. This type of feeding tray allows easy access to the food and water containers without opening a door to the enclosure that could allow an inhabitant to escape. Note that both of these alcove designs are lockable and have a flap that sufficiently covers the opening to the alcove. Note also the use of stainless steel or hard plastic food and water containers. **c)** Diagrammatic illustration of an alcove-type feeder.

Wood perches that vary in diameter and surface texture provide the most natural standing surface. For larger psittacine birds, these perches should be made of manzanita, Australian pine or oak to prevent their rapid destruction. Excessively large or flat perches may cause pressure lesions on the ventral surfaces of the hocks. More permanent perches can be constructed of PVC, steel pipe or some synthetic materials. These should be used only in combination with some type of natural wood perch. Having wooden perches in an enclosure provides psychological stimulation (chewing) and will help maintain beak health. Some foot and leg problems may be associated with continuous perching on hard surfaces, especially in cold climates where chilling of the feet or frostbite may occur.

Nest Boxes

Nest boxes should be placed in or on the enclosure in such a way as to allow easy and frequent examination. Placing nest boxes on the same end as the feeding and watering station allows simultaneous feeding and nest box examination (Figure 2.10). Shy birds are more likely to use a nest box that is secluded from high traffic areas. Nest boxes must be waterproofed or placed so they do not get wet during heavy rains. The nest boxes should also be shielded from direct sunlight, which may cause overheating of the occupants. Some aviculturists believe that certain species such as Amazon parrots require visual isolation around the nest box, while other species such as cockatoos are less affected by visual contact with conspecifics. These differences may arise from flock-

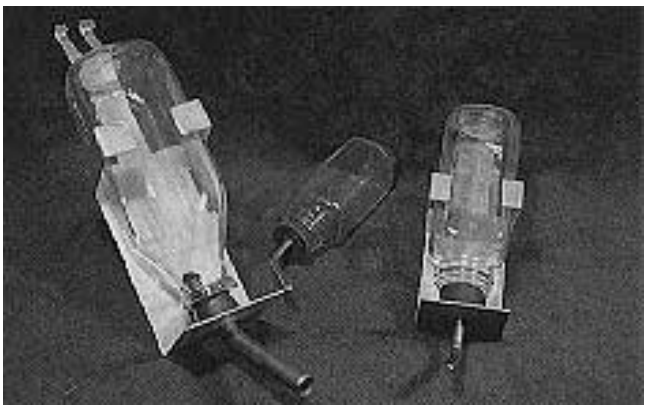

FIG 2.9 Many aviculturists are finding that bottles are an effective way to ensure a clean, fresh supply of water. Both a bowl and a bottle should be used during the transition phase to bottles. Changes in feeding or watering techniques are best performed after, not before or during the breeding season.

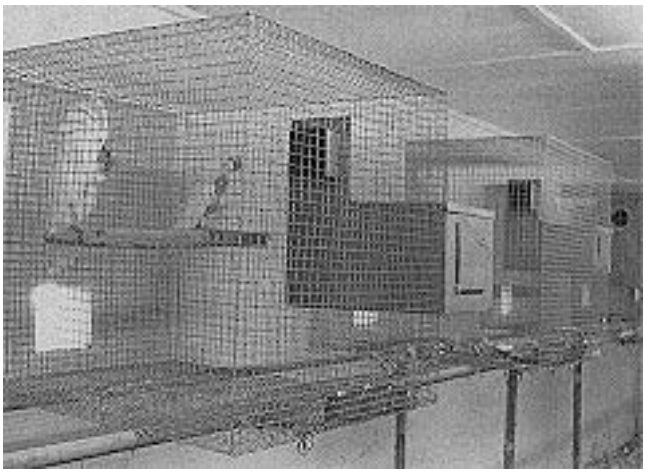

FIG 2.10 Nest boxes can be made of wood or metal depending on the degree of destructive behavior exhibited by a particular pair. Nest boxes should be positioned so that they are easy to inspect and stay dry and cool (courtesy of Apalachee River Aviary).

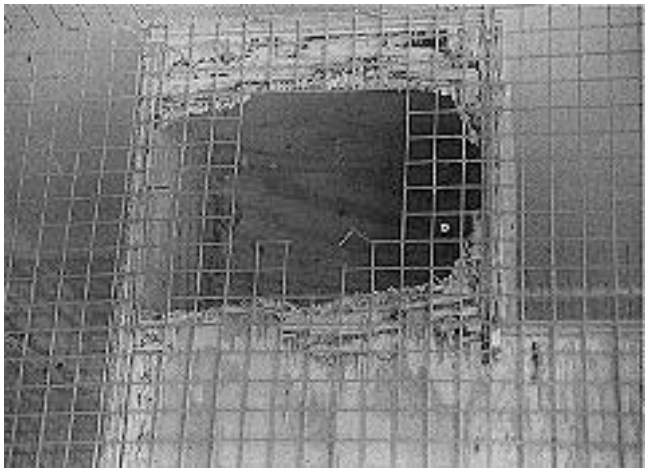

FIG 2.11 Attempts to protect wooden nest boxes by covering them with wire can result in ragged metal edges that can cause severe lacerations, broken bones or death. In extremely destructive birds, metal nest boxes that are protected from extremes in temperature are superior to wooden or plastic boxes. This wooden nest box from a pair of prolific Umbrella Cockatoos was replaced with a metal box with no change in productivity (courtesy of Apalachee River Aviary).

ing behavior and the existence or lack of communal nesting behavior in a particular species.

Nest boxes may be constructed of many materials, with plywood being the most common. Pressure-treated plywood contains numerous toxins and should not be used to construct nest boxes. Lining the nest box with wire will decrease chewing damage; however, chewed wires can produce dangerous projections that can cause injuries to the chicks or adults (Figure 2.11). Plastic or metal barrels are more permanent than wooden boxes and can be disinfected; however, they are more susceptible to extreme temperature fluctuations. Nesting materials can contribute to disease problems. The use of potting soil, corn cob bedding, eucalyptus leaves or hay may contribute to fungal growth. There is a high incidence of cancer in laboratory rodents that are maintained on pine or cedar shavings. Assuming that long-term exposure to these nesting materials could have adverse effects on companion birds, it is best to use large hardwood or aspen chips in the nest box (Figure 2.12).

FIG 2.12 Large hardwood or aspen chips are best for use in Psittaciforme nest boxes (courtesy of Apalachee River Aviary).

Health Maintenance Program

The health maintenance program should be designed to address problems common in a species as well as endemic problems for a particular aviary. For example, Old World Psittaciformes housed in outdoor aviaries in southern coastal states must be protected from opossums to prevent an inevitable outbreak of sarcocystosis (see Chapter 36). Mosquito populations are high in the same geographic regions, and susceptible species of birds should be protected from poxvirus by vaccination.

Physical examinations and aviary repairs should be planned for the non-breeding season, typically in the fall.

Good hygiene is vital to good health; however, the level of hygiene must be balanced with the level of disturbance that it creates. Enclosure designs should be easy to clean with minimal labor, cost and disturbances (which, in the aviary, can reduce the chances of successful reproduction in shy birds). Frequent disinfection of enclosures is not necessary if birds are healthy, organic debris is not allowed to build up in the enclosure and the food and water bowls are changed daily.

FIG 2.13 Food hygiene is critical to prevent the spread of food-borne pathogens. All open food containers should be stored in sealable containers to prevent infestation by flies, roaches or rodents. Unopened food containers should be stored in a dry, cool environment (courtesy of Apalachee River Aviary).

FIG 2.14 Fresh frozen vegetables should be stored in the freezer until opened for use. In addition, the dry, powdered formula used for neonates should also be stored in the freezer in a sealed container (courtesy of Apalachee River Aviary).

Exceptional food hygiene is vital to prevent the spread of food-borne pathogens or the spoilage of moist foods within an enclosure. Opened food cartons should be stored in sealable containers to prevent infestation by insects or rodents (Figure 2.13). Food stuffs have been frequently blamed for flock outbreaks of bacterial enteritis. In reality, formulated foods designed for companion birds are usually of excellent quality, and bacterial contamination is more likely to occur from improper food handling (allowing food to get wet or be infested by rats or insects) than from milling-related contamination. By comparison, foods designed for gallinaceous birds (eg, chick starter, chicken scratch) frequently have large numbers of gram-negative pathogens and should not be used in association with companion birds. Hygiene is especially important when dealing with soft or fresh foods in which spoilage is rapid (Figure 2.14). Bean sprouts are considered highly nutritious and are thought to stimulate breeding by many aviculturists. However, sprouts can be a source of bacterial or fungal pathogens, and they should be avoided or rinsed thoroughly with dilute hypochlorite, chlorhexidine or peroxide solutions prior to feeding. Fruits or vegetables that remain on the floor of an enclosure can be a source of bacterial and fungal pathogens and should be removed daily, especially in warm climates. The use of a commercial coleslaw machine to grind and blend vegetables allows for easy removal of uneaten food by simply washing the remaining food bits out of the enclosure.

Birds should have potable, fresh water provided in a clean bowl daily. Vitamins should not be added to the drinking water; they oxidize rapidly and provide a growth media for bacteria and fungus. Water should be collected directly from a tap that is run for 30-45 seconds before filling a container. *Pseudomonas* sp. can frequently be cultured from garden hoses and from PVC pipe systems. Automatic watering systems reduce labor, ensure that birds have a clean fresh supply of water at all times and prevent food or fecal contamination of the water supply. Water should be flushed through the lines daily as part of the maintenance routine. Weekly flushing of water lines with hypochlorite or iodophores is necessary to keep the lines free of bacteria and algae. Automatic watering systems should be checked daily to ensure that they are working properly. Mortality levels could be high if a watering system fails and it is not detected immediately.

The use of foot baths is frequently discussed as vital in the management of infectious diseases. Realistically, they are probably of minimal value as long as aviary personnel are not entering flight enclosures.

More attention should be focused on the cleanliness of objects that come in direct contact with the birds, such as clothing, nets and hands. The veterinarian must take precautions when going from one premise to another to avoid transmission of pathogens on contaminated foot wear. Having a pair of rubber boots that remain on each premise is the best way to prevent disease transmission. Any equipment that comes in contact with a bird should be disinfected, rinsed and thoroughly dried before it is used again. Nets and equipment that are not disinfected between birds can serve as fomites.

Air conditioners and ventilation systems may serve as foci for bacterial or fungal growth in an indoor facility. They can also harbor aerosolized viral particles. In a finch breeding facility, recurrent bacterial infections were traced to an air conditioner filter that supported the growth of *Aeromonas* sp. In another facility, *Aspergillus* sp. was believed to have been harbored and disseminated through an air conditioner filter that was not changed frequently.

Food and water bowls should be made of stainless steel, hard plastic or crockery and should be washed daily. Bowls can be washed in soap and water and returned to the same enclosure. If cleaned as a group, the bowls should be disinfected (with Clorox) before reuse (Table 2.3). For ease of washing, a series of tubs can be set up as follows: detergent and hot water, rinse, immersion for at least 30 minutes in a properly diluted disinfectant solution (Clorox), a second rinse and air drying on a rack. A commercial dishwasher is a viable alternative to hand-washing techniques as long as organic debris can be adequately removed (Figure 2.15).

FIG 2.15 Food and water bowls used in the aviary should be cleaned and allowed to dry daily. Use of a commercial dish-washer is an excellent way to maintain bowl hygiene in larger facilities.

The dark, damp interior of a nest box can provide an ideal environment for the proliferation of or dissemination of pathogens. Nest boxes should, at a minimum, be thoroughly cleaned on an annual basis, and nest material should be changed after each clutch if chicks were allowed to hatch in the nest. Nest boxes constructed of wood or other porous material should be destroyed if the inhabitants develop a viral or bacterial infection. Embryos may die in the shell or septicemic chicks may occur if an egg becomes moist in the nest box, allowing bacterial agents to pass through the shell pores.

- ***Disinfectants:*** All aviary facilities should be clean and sanitary. Organic debris must be removed from a surface before disinfecting. Disinfectants should

TABLE 2.3 Commonly Used Disinfectants in an Aviary

	Sodium Hypochlorite (Clorox bleach)	Quaternary Ammonium (Roccal)	Phenol (One-Stroke)	Chlorhexidine (Nolvasan)
Bacteria	Most	Most	Most	Not *Pseudomonas* sp.
Mycobacterium	Ineffective	Ineffective	Effective	Ineffective
Chlamydia	–	Recommended	–	–
Candida	–	–	Effective	Less effective
If organic debris present	Ineffective	Ineffective	Less effective	Less effective

All disinfectants are toxic and should be used in a conservative fashion for the specific purpose of preventing exposure to infectious agents. There is no such thing as a safe disinfectant. If it is safe, it does not kill any microbial agents. The least toxic agent that will effectively meet the disinfecting needs should be chosen. In most cases, a 5% dilution of sodium hypochlorite is the safest and most efficacious with the least potential for leaving toxic residues. Materials should always be cleaned before they are disinfected, because few disinfectants are effective in the presence of organic debris. Only household chlorine bleach should be used. Granulated chlorine products release toxic levels of chlorine gas. Birds should not come in direct contact with disinfectants, and it is best if they are not exposed to disinfectant fumes as well. Either decreasing the pH or increasing the temperature will increase the efficacy of Clorox. As a general disinfectant, bleach is mixed at a rate of 200 mls/4 liters of water.

always be used according to the manufacturer's recommendations. Stronger solutions are not more effective and may be toxic. The constant use of powerful disinfectants in the absence of a disease threat is not beneficial, and continuous contact with these chemicals can be detrimental to the birds and aviary personnel. Chlorine bleach should be used only in well ventilated areas, and a 5% solution is effective for most uses.

Pest Control

- ***Insects:*** Insects and rodents are potential vectors for disease and parasites. They also may irritate and disturb the breeding birds. Cockroaches that eat contaminated opossum feces can transmit *Sarcocystis falcatula* by defecating in a bird's food or by being eaten by a bird. Control of roaches, especially in outdoor facilities in southern coastal climates, is challenging, if not impossible. Insecticides alone are usually not effective and are potentially dangerous to the birds. Biological control of roaches is preferable to insecticides. Clean, sealed facilities reduce hiding places for roaches. Insectivorous animals (gecko lizards or chickens) can be used to consume the insects. The use of flightless silky chickens is recommended to prevent the chickens from roosting on the aviary enclosures.

  Ants can transmit some parasites such as the proventricular worm *Dispharynx*. Ants may reduce food consumption by swarming food bowls or may build nests in the nest boxes. Control procedures should include baiting of nests and trails, keeping facilities clean and avoiding foods with high sugar and fat content, which attract ants. The incidence of mites and lice is low in captive psittacine birds but they may be introduced into an aviary by free-ranging birds. The red mite (*Dermanysis gallinae*) can be troublesome in some avicultural situations. This mite is nocturnal and hides in crevices in the aviary and nest boxes during the day. These mites are blood feeders and can kill chicks by exsanguination. For the control of mites inhabiting nest boxes, five percent carbaryl powder has been used successfully without apparent harm to chicks or adults. Mosquitos can also be a problem for chicks in the nest box.

- ***Rodents:*** Rats may enter an aviary at night and spread infectious agents, disturb nesting birds or actually kill some smaller species. In a survey on one breeding farm in South Florida, 50% of resident rats were found to be carrying *Salmonella* sp. In Southern coastal areas, rat populations seem to rise in the fall. Biological control methods start with constructing a facility that discourages nesting in or around the aviary. For example, in outdoor aviaries, concrete slabs are frequently used to provide additional cleanliness under suspended cages; however, rats almost invariably tunnel and nest under these slabs. Enclosures suspended on poles can be fitted with rat guards, or the poles can be greased to prevent climbing. Sheet metal guards can be wrapped around trees to prevent nesting. Bait boxes should be used as needed and with caution. Snap traps baited with small quantities of ground meat are particularly effective.

- ***Snakes:*** Snakes will occasionally enter enclosures and consume small birds, but will rarely attack larger Psittaciformes. If an aviculturist is breeding small birds (canaries, finches, budgerigars, lovebirds) outdoors, the enclosure should be constructed with small wire or screen to prevent entry of snakes.

Evaluating and Treating Flock Problems

Emergency Care

An experienced aviculturist is usually the first individual involved in providing emergency care to a sick or injured bird. The client should be well schooled in providing first aid and recognizing signs of illness that require veterinary intervention. The veterinarian should assist the aviculturist in preparing a first aid kit, in being prepared to provide post-examination nursing care and in having the necessary supplies to safely and effectively transport a sick bird (Table 2.4) (Figure 2.16). The experienced aviculturist should know how to administer stabilizing therapy (SQ fluids, tube-feeding, hemostasis) that can be used if the veterinarian cannot immediately attend to an ill bird. Helping the aviculturist handle emergency problems will encourage the involvement of a veterinarian in the management of the collection (Figure 2.17).

The aviculturist should visually evaluate each bird every day during routine feeding procedures. In addition to the health, behavior and attitude of the bird,

TABLE 2.4 Avicultural First Aid Considerations

- Quiet, isolated area with appropriate enclosure
- Enclosure that will provide heat, humidity and preferably oxygen
- Balanced electrolyte solutions
- Feeding tubes and syringes
- Syringes and needles
- Emergency medications (to be prescribed by the veterinarian)
- Bandage materials - non-stick elastic bandage material, adhesive tape, non-stick wound pads, antibiotic ointment, hydrogen peroxide or iodine solutions
- Scissors and forceps
- Coagulants for bleeding nails
- Disinfected container for transporting sick or injured birds

the aviculturist should also evaluate the enclosure for signs of bleeding and feather loss that may indicate a traumatic episode. Fresh excrement should be evaluated for color, consistency and amount of feces, urine and urates (see Chapter 8).

Managing Disease Outbreaks

Rapid action early in a disease outbreak can prevent catastrophic losses. Isolation and appropriate therapy is warranted with an individual sick bird. In an avicultural setting, maintaining flock health must be the priority, and containing an infectious agent, determining its source and implementing control procedures are mandatory. The more complete the medical examination (blood work, cultures, radiographs, endoscopy), the more likely the veterinarian is to be able to identify the problem and to make specific recommendations to prevent further illness in the flock. Sick birds should be immediately removed from the collection and a thorough diagnostic evaluation performed. If the bird dies, a complete necropsy

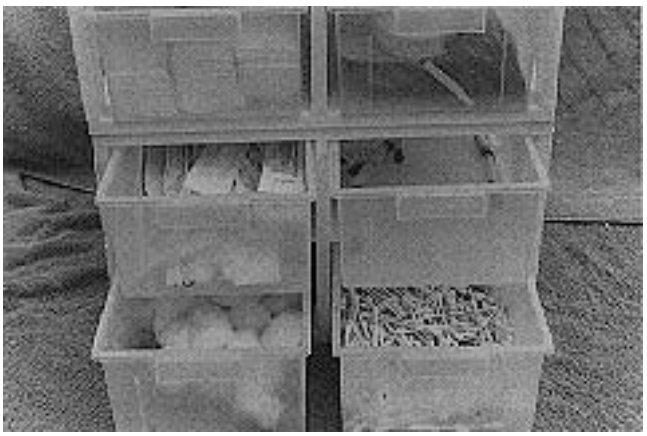

FIG 2.16 The advanced avicultural client should have a readily available supply of routinely used culturing, blood collection and selected medical supplies (courtesy of Apalachee River Aviary).

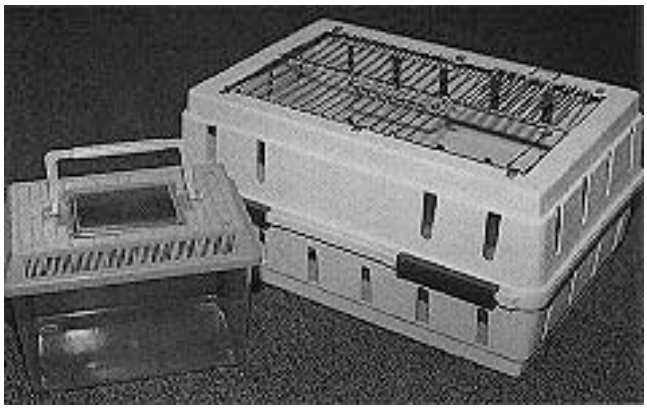

FIG 2.17 An attending veterinarian should help the avicultural client maintain first aid supplies including clean, disinfected containers for safe transport of sick or injured birds to the hospital (courtesy of Cathy Johnson-Delaney).

with collection of representative tissues from all organ systems is critical. The speed with which histopathology results can be obtained is also critical. Many state diagnostic laboratories have free or relatively inexpensive fees for histopathology services. However, the period of time that elapses before these results can be obtained may allow an infectious agent to spread through a collection. When histopathology results are needed quickly, it is best to advise the aviculturist to spend the extra money and send samples to a private laboratory. Following an infectious disease outbreak, all materials that cannot be properly cleaned (eg, perches, wooden nest boxes) should be removed and destroyed. The remainder of the facility should be steam-cleaned several times. In any given medical situation, repairing management flaws and using biological control measures are superior to drug therapy.

An easily and completely cleanable isolation area for new and sick birds should be available, and protocols should be established for managing this area. Storage for medical supplies and equipment should be discussed.

Evaluating Reproductive Failures

Resident Bird Examination

Annual examinations of all birds in a collection can be used to detect flock problems, establish and confirm the accuracy of identification systems and collect data that may lead to the removal of unproductive individuals. The efficacy of husbandry practices and the plane of nutrition can be determined by assessing the physical condition of the birds.

The causes of reproductive failure may be multifactorial and illusive (Table 2.5). The veterinarian working in unison with the aviculturist may be able to determine correctable physical, hormonal, nutritional, behavioral and psychological causes of reproductive failure.

A review of the potential health problems identified during the previous breeding season and appropriate testing of nonproductive birds can provide information that is critical to identifying the source of a problem (see Chapter 29). Estimating the age of a bird may be helpful in understanding reproductive failure.

TABLE 2.5 Evaluation of Reproduction Failure

- Obtain detailed histories
- Review health and production records
- Perform complete physical examination including cloacal mucosa
- Perform diagnostic tests as dictated by the findings
- Use laparoscopy to verify gender and visually evaluate the reproductive system and other organ systems
- Evaluate husbandry practices
  - Is diet appropriate, balanced and accepted?
  - Are enclosures appropriate in design and size?
  - Are nest boxes secure, dry, clean, free of pests and placed properly in the enclosure?
  - Are secure perches available for copulation?
  - Is the pair protected from environmental extremes?
  - Are aviary disturbances (visitors, pests) minimized?
- Evaluate behavior
  - Is one bird in a pair or in a colony exhibiting excessive aggression?
  - Does the pair exhibit a strong pair bond?
  - Has the pair been observed copulating?
  - Does the pair show any interest in or inspect the nest box?
  - Do the birds exhibit signs of stress, fear or unrest in the present location?
  - Do birds quarrel with, or display to, birds in adjacent enclosures?

Culling

Culling is a vital technique to improve the quality of captive breeding stock. Decisions to remove a bird from a breeding program can be emotionally difficult, especially when dealing with tame birds that are considered pets and with species that are endangered. In reality, maintaining breeding birds that are not vigorous, that fail to adapt to captivity or that are of poor genetic lineage is a detriment to the future of aviculture and to the species. While no birds should be considered disposable, in the breeding situation the aviculturist must be aware of the necessity of selective breeding to the overall success of an aviary.

The purchase of culled breeding stock, especially birds represented as proven breeders, carries with it a degree of risk. Birds are often culled because they failed to breed, and the novice aviculturist frequently adds someone else's problems to his collection. Birds purchased as part of an entire collection that is being dissolved may be less risky.

Dealing with birds that are to be removed from a collection can challenge the ethics of the veterinarian. Euthanasia of valuable birds due to poor reproductive success or due to poorly understood medical problems (such as cloacal papillomatosis) is unacceptable to many people. Resale of these birds without full disclosure of their problems is equally unacceptable and can strain the client/veterinarian relationship. It is never advisable for the same veterinarian to represent both the buyer and the seller in a bird transaction.

Incubation and Pediatrics

Veterinarians should be involved in evaluation of incubation failures and management of the psittacine nursery. Successful incubation entails extensive experience, and subtle problems in egg handling, especially prior to or in early incubation, can result in developmental abnormalities that may not be expressed until hatching (Figure 2.18). A definitive cause of embryonic mortality is often illusive. Ideally, all fertile eggs that fail to hatch should be examined in an attempt to detect patterns of mortality, which

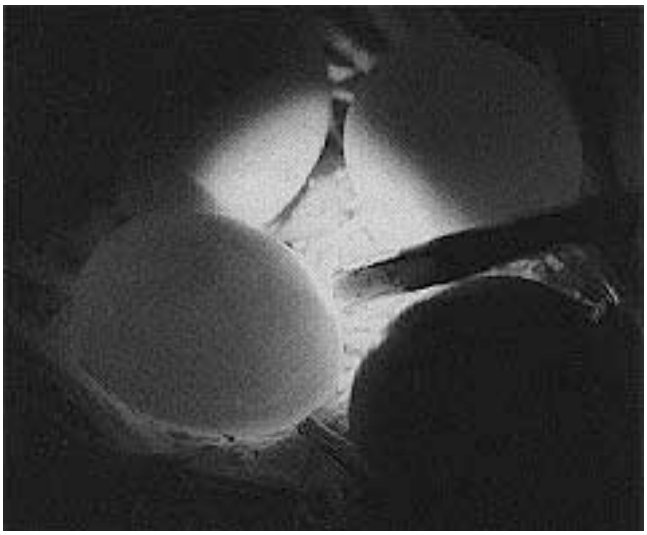

FIG 2.18 The avicultural veterinarian should have a thorough understanding of the incubation process and how to determine the cause of embryonic or early chick mortality. Every embryo that fails to hatch should be necropsied and submitted for histopathology to help identify management or disease problems in the flock. A fertile six-day-old Red-bellied Parrot egg is being candled in the nest (courtesy of Isabel Taylor).

may be helpful in identifying problems associated with incubation (see Chapter 29).

A veterinarian who is experienced in nursery management can provide advice and management recommendations that could prevent the occurrence of clinical disease related to husbandry or nutritional problems of neonates (see Chapter 30).

CHAPTER

3

NUTRITION

Randal N. Brue

The feeding of companion birds has become a true art form with as many theories and practices suggested as there are those feeding birds. This feeding "art" has evolved out of necessity brought about by a lack of valid scientific information on the nutritional needs of these birds. Most current nutritional beliefs stem from years of "trial and error" feeding practices that are perceived as successful for the individual. A number of these practices have gradually been passed on, modified and eventually accepted as status quo by aviculturists. Their endorsement has come through the realization of certain improvements over previous feeding standards (such as the addition of fruits and vegetables to an all-seed diet), with the conclusion being that this small degree of improvement represents an end. These feeding practices may be deeply instilled in the bird enthusiasts' anthropomorphic views (ie, "humanizing" the pet and perceiving all of its needs through the eyes of the owner). There is often a belief that nothing can be too good for the bird, and it is provided with an incredible variety of often not-so-nutritious foods. Theory in companion bird nutrition has also been inundated with self-proclaimed experts, trying to achieve personal gain or recognition through their emphatic and frequently unsupported recommendations of certain feeding programs.

As aviculture has advanced over the past decade through the efforts of truly dedicated aviculturists, sound feeding practices that are based on the eating habits of long-lived birds or on sustained reproductive successes have begun to emerge. Although most of this information is still anecdotal, there appear to be valid principles to support many of these practices. Some of these dietary theories are based on what a particular species of bird is perceived to eat in the wild. Placing too much emphasis on this rationale can be deleterious. There is only a moderate understanding of what free-ranging birds eat, partly because their diets vary widely with the seasons. The majority of companion and aviary birds are considered opportunistic omnivores; that is, they will eat a large number of the foods that are available to them at any specific time. In most cases, this includes a wide array of vegetative material and a variety of animal products, as well as the consumption of soil and mineral deposits. Even a relatively accurate analysis of 90% of a bird's intake may not be truly reflective of the total nutrient profile of the diet,

because items consumed in trace amounts are difficult to quantitate and can have a significant impact on the bird's overall nutritional status. Additionally, most free-ranging birds do not live to their full genetic potential. This is due not only to predation and disease exposure, but also to the frequency of malnutrition caused by seasonally insufficient supplies of nutrient-adequate foods.

Nutritional Research Potential

The science of feeding companion birds has lagged behind that of most other pet species, due largely to historic perception that the diets available were not nutrient-deficient. The lack of financial incentives for either university or industry to employ nutritionists to study these species, and the expense and difficulty of studying nutrient requirements in a variety of species and metabolic conditions have further delayed avian nutritional research.

It has been only in the last decade that nominal research has begun on the nutritional needs of companion bird species, and it will take several decades to establish a partially accurate picture. Fortunately, however, general nutritional principles apply to nearly all vertebrates, with a few notable exceptions. Additionally, the most studied living species from a nutritional standpoint has been the domestic chicken. Although they are obviously not identical to each other in all ways, the domestic chicken does share similar physiologic parameters with popular companion Psittaciformes and Passeriformes. The greatest difference among these species is the fact that Galliformes are precocial (the neonate is mobile and generally self-sufficient at only a few hours of age). In addition, domestic poultry have been genetically selected and modified over the course of several hundred generations of domestication to thrive on commercially produced diets. Nonetheless, domestic poultry provide a starting point for the study of companion bird nutrition. It is at this point that the anecdotal nutritional information that pervades aviculture becomes of great significance. Subtle differences among the species have become obvious, as several species on a dietary regime will perform adequately, while another species on the same diet will do poorly. These observations suggest that species-specific nutritional requirements exist, but because many species of a genus or family perform similarly on a certain diet, it can be assumed that the variations in nutritional requirements are minor.

Poultry Adaptations

Current nutrient recommendations for companion birds are derived from an extrapolation of the nutritional requirements for commercial poultry, the application of general nutritional principles that are fairly constant among all vertebrates, an evaluation of ornithological information (eating habits in free-ranging birds, the role of ecological niches, any known anatomic or physiologic differences) and information that has been generated through the years of trial and error feeding, which has resulted in certain species-specific or family-specific feeding practices. The culmination of this multifaceted approach has resulted in a general estimation of the nutrient needs for companion birds that can be shown to be successful in growth studies and long-term feeding trials. It does not, however, determine the specific requirement of an individual nutrient or necessarily produce a diet that is totally optimized. It also fails to elucidate any species-specific problems, but rather attempts to compensate for them.

To optimize health, longevity and production of companion bird species, a great deal of nutritional research will be required. It is doubtful that the nutritional needs of either the Psittaciformes or Passeriformes, not to mention of a specific individual species, will ever be fully known. Even today, after almost a century of research in chickens and rats, the entire nutritional picture has not been completely elucidated for these species. There are substantial data on the nutrient requirements for the growing animal, but there are still many questions as to the requirements for optimal reproduction, optimal health and maximal longevity. The latter tends to be of little concern in any commercial species, but does have eminent importance for companion animals. The knowledge base of canine and feline pet nutrition is well over 50 years ahead of its companion bird counterpart. Although research in this area involves only two species and is strongly supported by universities and hundreds of competitive manufacturers, the science of canine and feline nutrition is still rather limited and is rapidly evolving.

Role of Nutrition in Bird Health

Nutrition itself is a critical link between the management practices provided for a bird and the bird's good health. Figure 3.1 illustrates a simple building block approach to the final goal of bird health. The foundation of the entire pyramid is the genetic background of the individual, which is largely responsible for the

FIG 3.1 Factors contributing to bird health.

nutrient needs. It can also predispose the individual to health problems and may even have implications for management techniques. Pet owners, nutritionists and veterinarians seldom have any impact on genetic background because it is predetermined at conception. The breeder, however, can impact this area through selection of breeding stock. Regrettably (especially in larger birds), the genetically poorer individual is frequently kept for breeding. These individuals may be physically, emotionally or behaviorally abnormal and are abandoned as companion birds and relegated to breeding. This is a counterproductive process, because the breeder may unknowingly be selecting for undesirable traits. The selection of certain unusual traits or the practice of heavy breeding within a very small gene pool will ultimately accentuate both desirable and undesirable characteristics represented in the original genotype. This has created considerable problems in budgerigars, cockatiels, canaries and finches.

Without good, sound management techniques (see Chapter 2), an otherwise genetically strong and nutritionally sound bird will not maintain its good health. Finally, a properly balanced diet and a professionally administered health care program must be provided to ensure the long-term health of a bird.

Just as providing complete, thorough veterinary care is impossible without proper training, so is the formulation of a properly balanced, complete diet. The formulation, development and production of a diet is surprisingly complex due to the large number of nutrient interactions, the differing bioavailabilities of nutrients from different ingredients and the difficulty of procuring and administering micronutrients into the diet. A well formulated, properly balanced diet represents a precise combination of over 40 nutrients, sometimes provided by just as many different ingredients.

Water

Although not a nutrient per se, water is essential to the body for cooling and for the maintenance of intracellular and extracellular fluids. It is the medium in which digestion and absorption take place, nutrients are transported to cells and metabolic waste products are removed.

The quality of water provided to companion birds should be of utmost concern to both the client and the veterinarian. Water and "soft foods" (foods containing high moisture content over 20%) are frequently implicated in exposures to high concentrations of bacteria. An open water container that becomes contaminated with fecal material or food will promote rapid bacterial proliferation. In water containing added vitamins, there can be a 100-fold increase in the bacterial count in 24 hours. Changing the water and rinsing the container will obviously decrease the bacterial load, but an active biofilm remains on the container walls unless it is disinfected or washed thoroughly. Contamination in the water container, in addition to the aqueous medium and compatible environmental temperatures, provide all the requirements for microorganisms to thrive. Likewise, high-moisture foods such as egg foods, nestling foods, cooked foods, sprouts, fruits and vegetables provide excellent growth media for microorganisms. At warm environmental temperatures, these types of foods can become contaminated in as little as four hours.

Water intake will be greatly influenced by the type of diet provided. Most birds can derive the majority of their water requirement from foodstuffs when the diet consists primarily of fruits, vegetables or moist foods. Processed diets tend to increase the bird's water intake over that typical for a seed diet because they generally are dry, lower in fat and tend to have overall higher nutrient levels. Slightly moister feces are often observed in birds on a formulated diet.

Nutrient Interrelationships

There exists a vast array of interrelationships between the different nutrients. Ideally, these must all be evaluated to protect against nutrient imbalances and interferences, and to ensure that the proper amounts of nutrients are being both consumed and absorbed by the bird. One of the most frequent misinterpretations is to judge the nutrient adequacy of a diet strictly on the total amount of a nutrient in the food. It is critical to go beyond this quantitative approach and evaluate both the quality of the nutrient and the animal's actual intake of the nutrient. By evaluating the intake level and the quality (bioavailability), the total body uptake can be determined. A simplistic example of nutrient intake miscalculation is the baby bird being hand-fed recommended volumes of a well balanced, high-nutrient diet that is prepared excessively dilute. In this situation, the nutrient uptake is insufficient to support growth.

The Effective Energy Content of Food

It is important that the individual nutrient levels be balanced with respect to the energy content of the food, because the food intake by the animal is largely dependent on the total caloric density of that food. In the case of very low caloric density foods, the gastrointestinal tract capacity can become a limiting factor for adequate caloric intake. Conversely, if the dietary caloric density is extremely high, the appropriate feedback systems that regulate satiety may not have time to respond before the caloric needs are exceeded, resulting in overconsumption.

Energy content of the diet, or specifically fat content, also has an influence on the rate of food passage through the system. As the fat content of a diet increases, the rate of passage is slowed. This not only has an effect on the bird by prolonging satiety, but also improves digestibility of most nutrients in the food by increasing the length of exposure to digestive enzymes and the time for absorption. This improved absorption, however, is generally not very dramatic. An example of this relationship is given in Table 3.1. This shows how some moderate increases in dietary protein and rather small increases in dietary calcium are required to balance the daily intake levels between a low and a very high fat diet. Although there is a substantial difference in the metabolizable energy values of these two diets, the daily intake of protein and calcium is identical with respect to the energy content of the diet. Consumption of 30 grams and 22.5 grams of diets A and B, respectively, both provide 90.5 kilocalories to the bird. This example illustrates how some seemingly dramatic differences in nutrient levels can actually give very similar results in the animal.

TABLE 3.1 The Effect of Dietary Energy Level on Intake and Proper Nutrient Density

	Diet A Approx. 4% Fat	Diet B Approx. 22% Fat
Energy Content, kcal/kg	3,015	4,020
Intake, grams	30.0	22.5
Energy Intake, kcal	90.5	90.5

Mineral Interrelationships

There are a vast number of different mineral interrelationships, with every mineral affected by at least one other. The most critical in companion bird nutrition, and in most species, is the relation between calcium and phosphorous. For proper growth, bone maintenance and health, a ratio of calcium to available phosphorous should be 1.5:1 to 2:1. In these proportions, both minerals are most effectively absorbed in the gastrointestinal tract as well as metabolized within the body. The widest tolerable range of calcium to phosphorous ratio should be considered to be 0.8:1 to a maximum of 3.0:1 (3.3:1 produces rickets and leg abnormalities) Additionally, excess levels of calcium can precipitate deficiencies of magnesium, iron, iodine, zinc and manganese if these are only marginally supplied.

Vitamin Interrelationships

The most obvious example of vitamin interrelationship is the effect of the absorption of fat-soluble vitamins, in which an excess of one would decrease the absorption of the others due to competition for binding sites in the intestinal mucosa. For this reason, it is necessary that all the fat-soluble vitamins be balanced with respect to one another to assure proper absorption of them all.

There is also an interrelationship in the metabolism of folic acid and choline (and the amino acid, me-

thionine) as they relate to the metabolism of single carbon units (ie, methyl groups). This metabolic role is also dependent on vitamin B_{12} as part of the enzyme system.

Vitamin and Mineral Interactions

Although there are many cases of interactions between vitamins and minerals, certainly the most significant metabolically is the relationship of calcium, phosphorus and vitamin D_3. It is obligatory for adequate vitamin D_3 to be available for the proper absorption of both of these minerals to take place. Inadequate vitamin D_3 levels in the body can cause calcium deficiency symptoms in an otherwise calcium-adequate diet. Conversely, excess levels of dietary vitamin D_3 can produce hypercalcification even in a diet normally considered to be marginally sufficient in calcium.

The other critical vitamin/mineral interaction is that between vitamin E and selenium, in which their biologic functions are essentially the same, but occur in different parts of the cell (lipid-based and aqueous, respectively). Even though they act in different parts of the cellular structure, a generous supply of one tends to spare a marginal supply of the other by quickly scavenging the additional free radicals that are produced (because of the lack of one nutrient) as they migrate throughout the cell structure, coming into contact with both the aqueous and lipid phases of the cell.

Another example of a mineral and vitamin interrelationship is the increased absorption of iron in the presence of ascorbic acid.

Amino Acid/Vitamin Interactions

In addition to several of the vitamins' direct roles in enzyme systems that are involved in protein synthesis and metabolism, there are also interactions between amino acids and vitamins that may have an effect on the absolute requirements of each other.

The most notable interrelationship between a vitamin and an amino acid is the relationship of niacin and tryptophan. In fact, a significant portion of the niacin requirement can be spared by an excess of tryptophan in the diet over what is required for necessary protein biosynthesis. This bioconversion is most efficient when levels of both niacin and tryptophan are low in the diet. The ultimate efficiency of this conversion is determined by the liver enzyme, picolinic acid carboxylase, which catalyzes the breakdown of the immediate precursor of niacin. This enzyme activity is species-dependent, affecting the animal's potential use of tryptophan to satisfy the niacin requirement. Additionally, several of the reactions in the bioconversion require riboflavin and pyridoxine-dependent enzyme systems. Protein, energy and hormonal status also play roles in this series of reactions.

Choline is an example of a vitamin that can directly spare the requirement of an amino acid, namely methionine. This occurs through its ability to act as a methyl donor in a fashion similar to methionine, thereby limiting the specific role that methionine would serve if an otherwise insufficient level of methyl donors existed.

Nutrient Antagonists (Anti-nutritional Factors)

There are a number of nutrient antagonists that can be present in foodstuffs. Many of these are natural compounds within the food, some of which can be tolerated in limited amounts. Others can be treated commercially to minimize their impact on the animal. Some compounds, most notably mycotoxins (the toxic metabolic byproducts of molds) can be produced when field or storage conditions are less than ideal.

Enzyme Inhibitors

Enzyme inhibitors are present in a large variety of foods, and most can be largely inactivated by thorough cooking. The largest group of enzyme inhibitors are the protease inhibitors, which inhibit the digestive enzymes trypsin and chymotrypsin and others. Fortunately, these inhibitors are thermosensitive and readily inactivated by cooking. Ingestion of a diet high in active inhibitors results in poor protein digestion and pancreatic hypertrophy, stimulated by the direct inactivation of digestive enzymes or the effect of limited bioavailability of methionine (decreasing the synthesis of digestive enzymes).[35] Protease inhibitors are present to some degree in all plants, with significant levels found in all of the legumes (mature beans), barley, beets, buckwheat, corn, lettuce, oats, peas, peanuts, potatoes, rice, rye, sweet potatoes, turnips and wheat. Potatoes are extremely high, with a large percentage (15%) of protein comprised of inhibitors.

Tannins, found in a variety of plant sources, can bind protein, inhibit digestive enzymes and reduce the bioavailability of iron and vitamin B_{12}. At high levels, they can cause liver and epithelium damage. These

polyphenolic compounds found in most plants are associated with an astringent taste and cause the normal browning on fruits and vegetables when they are cut or bruised. Tannins are found at high levels in acorns, carrots, rape seed, milo, grape seeds, tea, coffee, chocolate, bananas, grapes and raisins, lettuce, spinach, rhubarb and onions.

Some of the other enzyme inhibitors include amylase inhibitor in beans, wheat, rye and sorghum; plasmin inhibitor (inhibiting blood clotting) in some beans; kallikrein inhibitor in potato (decreases antibody formation); and cholinesterase inhibitors in asparagus, broccoli, carrots, cabbage, celery, radishes, pumpkin, raspberries, oranges, peppers, strawberries, tomatoes, turnips, apples, eggplant and especially potatoes.

Mineral Antagonists

Oxalate (oxalic acid) is an organic acid that efficiently binds calcium and other trace minerals, making them unavailable to the animal. The highest levels of oxalate is found in tea, spinach and rhubarb, with lower levels found in peas, beets and beet greens, lettuce, turnips, carrots and berries. Potentially toxic levels are found in the leaves of rhubarb and the common house plant, diffenbachia. High levels of oxalates can cause vomiting, diarrhea, poor blood clotting and convulsions. Lower levels can result in decreased growth, poor bone mineralization and kidney stones.

Phytate or phytic acid is a complex of phosphoric acid and sugar, and is very effective at chelating minerals such as zinc, iron and calcium, resulting in an unavailable complex. Phytates are most commonly found in nuts, legumes, cereal grains (germ and bran) and, in lesser quantities, in green beans, carrots, broccoli, potatoes, sweet potatoes and berries.

Vitamin Antagonists

Thiaminase is a naturally occurring enzyme that destroys thiamine. Thiaminase is most often associated with raw fish, but it can also be found in a number of fruits and vegetables such as beets, brussel sprouts, red cabbage and berries, some organ meats and as a product of certain microorganisms that can inhabit the gastrointestinal tract.

A compound found in flax seed (and therefore linseed meal) acts as an antagonist to pyridoxine (vitamin B_6). This compound apparently is an amino acid-type compound that forms an unavailable complex with pyridoxine.

Natural Plant Toxins

Although not nutrient antagonists as such, lectins or phytohemagglutinins can cause kidney, liver and heart damage, destruction of gastrointestinal epithelium, red blood cell agglutination and cell mitosis interference. These compounds occur in legumes, especially the castor bean and black bean, and in lower levels in other plant seeds.

When saponins are consumed in high amounts, diarrhea and vomiting can occur. They are found in soybeans, alfalfa, spinach, asparagus, broccoli, potatoes, apples and eggplant.

There are several foods that have goitrogenic properties that could cause symptoms mistaken for iodine deficiency, or that could exacerbate a marginally iodine-deficient diet. Goitrogens are contained in soybean, peanuts, pine nuts and the entire brassica family (turnips, rutabaga, broccoli, brussel sprouts, cabbage, cauliflower, kale, kolrabbi and mustard). They are also found to a lesser degree in carrots, peaches, pears, radishes, strawberries and millet. Low-protein diets increase the effects of goitrogens (anti-thyroid effects).

Other natural toxins or nutrient antagonists present in foods include gossypol, cyanogenic glycosides, photosensitizers and a variety of alkaloids and phenolic compounds. The significance of these compounds in most species is questionable. Many have shown beneficial effects in the body when provided at low amounts, but at higher amounts they may be toxic or carcinogenic. Low exposure to these items should never be considered to be dangerous, but the inclusion of any of them at high amounts in the diet, particularly in the raw form, should be avoided.

Mycotoxins

Mycotoxins are compounds that are produced under certain conditions as metabolic by-products of molds. There have been nearly 100 mycotoxins identified since their initial recognition in the 1960's. They possess varying degrees of toxicity, some of which are carcinogenic. Mycotoxins are not associated with all molds, nor are they always produced by mycotoxin-producing species. The difficulty with mycotoxins is that they are totally undetectable by sight, smell and taste. Any product that is known to be moldy should not be fed due to the possibility of mycotoxins, as well as nutrient degradation and decreased palatability. Toxins, sources and pathology are shown in Table 3.2.

TABLE 3.2 Sources of Exposure and Pathology Related to Mycotoxin Ingestion

Mycotoxins	Common Feed Sources	Agent	Pathology
Aflatoxins	Corn, peanuts, cottonseed	Aspergillus flavus A. parasiticus	Liver damage Hepatomegaly Immunosuppression Kidney damage
Ochratoxin	Corn, barley, oats, wheat	A. ochraceus Penicilliumviridicatum	Kidney and liver damage Hemorrhaging
Zearalenone	Corn, wheat	Fusarium roseum F. graminearum	Production of estrogen-like compounds
Trichothecenes (T_2 toxin)	Corn, wheat, barley, oats, forages	F. tricinctum F. roseum F. graminearum	Oral inflammation and lesions Neural disturbances Immunosuppression Hemorrhaging
Vomatoxin (2-deoxynivalenol)	Corn, sorghum, wheat	F. roseum F. graminearum	Gastrointestinal inflammation Vomiting
Ergot	Rye, barley, wheat, oats	Claviceps purpurea	Tissue death Kidney and liver damage

Mycotoxins can have a broad range of effects on the body ranging from a toxic dose with mortality in two to three days to chronic exposure of moderate levels where decreased disease resistance is encountered along with lesions in the liver, kidneys, nervous system, reproductive system and integument. Carcinogenic, mutagenic or teratogenic effects may also be exhibited. The type of effect and response is related to the exposure level and duration.

Mycotoxins are some of the most carcinogenic compounds known, with chronic exposure of levels in parts-per-billion causing cellular transformation. Species differ considerably as to their susceptibility, with ducklings being among the most susceptible. The LD_{50} ranges from 0.5 mg/kg (duckling) to 60 mg/kg (mouse).[13]

Aflatoxin levels in food must be controlled by good harvesting, handling and storage procedures. Peanuts and corn are considered to be the human population's largest source of aflatoxin. The United States Food and Drug Administration does not allow any peanuts to be used in human food products with levels greater than 20 parts per billion of aflatoxin. This is also the level used by the livestock industry as the safe, allowable level in grain products. Certain crops, depending on the climatic conditions during the growing season and at harvest (peanuts, hay, corn, wheat), may be considered the most common sources of aflatoxin.

Mycotoxin contamination usually occurs when fungus is able to penetrate a seed hull or protective coating and reach the kernel. Because molds are ubiquitous, spores will always be present on untreated crops. Plant damage such as drought, stress and insect damage will increase the incidence of mold penetration into the seed and the possibility of mycotoxin production. After inoculation, warm and humid conditions help promote the mold growth and toxin development. Unfortunately, mycotoxins are very stable to heat and typical processing methods.

Some of the mycotoxins (trichothecene or T_2 toxin) are among the most potent protein synthesis inhibitors known. It has also been found that T_2 toxin reduces the plasma level of vitamin E by affecting micelle formation in the gastrointestinal tract.[11] Similarly, aflatoxin increases the dietary requirement for vitamin D_3 and lowers the vitamin A stores in the liver. In addition, many of the mycotoxins, particularly aflatoxin, the trichothecenes (T_2 toxin) and ochratoxin, have metabolic effects in the body that impair the defense mechanisms.[32,33]

Methods for Determining Nutrient Requirements

Growth Requirements

There are a number of approaches for determining the requirement of a specific nutrient in a bird. The simplest and probably most effective way is to examine the nutrient's influence on growth. Diets that are identical in all aspects, except the experimental nutrient, are provided to groups of experimental birds. By feeding specific diets (each of which contains an incrementally larger level of the test nutrient), growth and other parameters are measured. The point at which no further statistically significant increase in growth is observed would be considered to be the requirement of that particular nutrient in that particular diet, under those specific experimental conditions. If this result is consistently reproducible, it can be considered valid. This method is relatively accurate, and a single study can be performed rather quickly. This experimental design is most often used to evaluate nutrient requirements for growth, but it

may also be used to evaluate a nutrient's influence on egg production, antibody production and bone strength.

Because growth is the period in which most nutrients are required at their highest levels, this type of study can establish the upper end of the suggested nutrient range. The use of these levels for adults would certainly provide a level far greater than the true metabolic need but, in most cases, these would still be within the safe range. The determination of the requirements for adults is very difficult, complex and in many cases impractical. Additionally, the differing requirements for each separate strain within a species is often different. Because of this, the accepted practice in humans has been to establish a minimum daily allowance, which is designed to meet or exceed the estimated requirement of 97.5% of the entire population, or approximately two standard deviations above the mean. This approach compensates for the great degree of biological variability within the entire species, as well as bioavailability in foods, variability of absorption efficiency, health status, environmental conditions and genetic background. *(Editor's note: The correlation of growth rate and health has not been established for companion birds.)*

Evaluating Nutrient Status

The nutrient status of an individual is most easily accessed by carefully evaluating the adequacy of the diet provided. Considering the current feeding practices of many bird owners, it is likely that basic deficiencies can be discovered with very little effort. If simple dietary evaluation is not possible, or seems inconclusive, further testing is possible (however, somewhat difficult and inconclusive). The only practical method for further testing is through serum or plasma samples. These samples are ideally taken after a fast to reduce the presence of nutrients that were recently absorbed from a meal. Additionally, the circulating levels of many nutrients are tightly controlled, and, therefore, only show levels outside the normal range when body stores are severely depleted or exceeded. The matter is further complicated by the lack of reliable normal ranges (or in some cases, no information at all) and the high cost of certain nutrient assays. Many laboratories, however, are equipped to run plasma retinal or carotene levels (for vitamin A), plasma alkaline phosphatase (an indicator of vitamin D status), prothrombin time or clotting time (indicator of vitamin K status), serum calcium, phosphorous, electrolytes, trace minerals (although they may inaccurately reflect status) and parameters for the evaluation of lipids and proteins.

Estimation of Nutrient Requirements

There is a severe need to set dietary guidelines to serve as a reference point that can be used as a standard for testing. Safe guidelines are needed to help aviculturists and companion bird owners who choose to feed a widely varied diet, to guide the commercial food manufacturers in producing diets that can assure longevity and good health, and to help veterinarians assess a patient's diet and educate the client in proper feeding methods. Because of the extreme difficulty in accurately determining the requirement of all nutrients, even for a single species, documented studies and specific requirements will not be available for decades, if ever. It is therefore necessary to derive these nutrient recommendations from other species that are better understood. Extrapolation from known species, if done wisely, can provide a reasonable starting point from which to base diets and efficacy studies. With subsequent evaluation of this derived nutrient profile and long-term monitoring to assess overall nutrient status, recommendations or allowances can be generated for a particular genus, species or strain that may be unique with regard to dietary requirement, digestive efficiency or other physiologic differences. This methodology does not look at "minimums" but rather at nutrient levels that would attempt to optimize all experimental parameters by providing more generous nutrient allowances. Table 3.3 lists the possible minimum requirements (an extrapolation from poultry species) and the dietary recommendations for companion bird species.[7]

Nutrient Needs During Different Life Stages

Embryonic

An egg produced by a hen fed a nutrient-adequate diet is normally a rich source of the essential amino acids, energy, linoleic acid and all of the required vitamins and minerals for normal cell division, growth and maturation. If a hen is fed a nutrient-deficient diet that will allow production, embryo development may progress, but will be abnormally affected. This most often is observed as early embryonic death, usually with the formation of a blood ring after approximately three days of development (vitamin A deficiency), losses immediately prior to hatch due to an embryo with insufficient strength to complete the hatching process (riboflavin, biotin, folic acid and vitamin B_{12} deficiencies) or embryonic malformation (zinc and manganese deficiencies).

TABLE 3.3 Recommended Nutrient Allowances for Companion Bird Diets[7,29]

These allowances can be used as general dietary guidelines for most psittacines and the commonly kept passerines. Species differences do occur, but have not been listed due to insufficient research. The anticipated minimum requirement (as extrapolated from other species) is included for comparison. These values do not compensate for nutrient bioavailability, genetic variability and other conditions.

Nutrient	Anticipated Minimum Requirement	Recommended Allowance for Maintenance[1]
Protein, %	10.00	12.00*
Fat, %	–	4.00*
Energy, kcal/kg	–	3000.00
VITAMINS		
Vitamin A, IU/kg	2500.00	5000.00*
Vitamin D_3, IU/kg	500.00	1000.00*
Vitamin E, IU/kg	15.00	20.00*
Vitamin K, ppm	0.80	1.00
Thiamine, ppm	2.00	5.00
Riboflavin, ppm	4.00	10.00
Niacin, ppm	40.00	75.00
Pyridoxine, ppm	4.00	10.00
Pantothenic acid, ppm	12.00	15.00
Biotin, ppm	0.15	0.20
Folic acid, ppm	1.00	2.00
Vitamin B_{12}, ppb	5.00	10.00
Choline, ppm	750.00	1000.00*
Vitamin C	No requirements demonstrated*	
MINERALS		
Calcium, %	0.30	0.50*
Phosphorus (available), %	0.15	0.25*
Phosphorus (total) approx., %	0.30	0.40*
Sodium, %	0.10	0.15
Chlorine, %	0.10	0.15
Potassium, %	0.30	0.40
Magnesium, ppm	500.00	600.00
Manganese, ppm	60.00	75.00
Iron, ppm	60.00	80.00
Zinc, ppm	40.00	50.00
Copper, ppm	6.00	8.00
Iodine, ppm	0.30	0.30
Selenium, ppm	0.10	0.10
AMINO ACIDS		
Lysine, %	0.45	0.60
Methionine, %	0.20	0.25
Tryptophan, %	0.10	0.12
Arginine, %	0.50	0.60
Threonine, %	0.35	0.40
Other essential amino acids are sufficient in common diets.		

1. The recommended allowances will support normal maintenance of companion birds and have been demonstrated to be adequate during long-term feeding. These levels, however, may not be sufficient for optimized health under varying conditions and will not be adequate for breeding and growth, which may require higher levels of certain nutrients.
* Increased levels are suggested for growth/breeding diets due primarily to high requirements for adequate chick growth as opposed to increased demands for low-level breeding.

Growth

Shortly before hatch, the embryo absorbs the remaining portion of the yolk sac into its abdominal cavity. At hatch, the absorbed yolk sac serves as a temporary energy reservoir. This may be adequate to supply the chick with nutrients for the first one to three days, depending on the species. As the chick's digestive system becomes fully functional, the period of rapid growth begins. Due to the high metabolic rate and the rapid division and growth of cells, the amino acid, energy, linoleic acid, vitamin and mineral requirements are at the highest point of the animal's normal life. Furthermore, if brooding temperatures are not sufficient, there is a further increase in the energy demand to maintain adequate body temperature. The requirement for amino acids are further increased during the period of feather development. These feathers, which are comprised of more than 90% protein (on a dry matter basis), can approach up to 10% of the total body weight in the young bird.

Under normal situations, the absolute nutrient requirements decrease throughout the growth phase, since the level of growth proportional to body weight declines with age. If optimal nutrient levels are not present at an earlier growth phase, but are present in excess of requirement towards the end of the growing cycle, the bird will display compensatory growth (compensating for an earlier lack of normal growth). Compensatory growth is characterized by both the flattening and extension of the normal growth curve, with the end result of a chick that reaches normal adult weight, but requires a longer time to do so. This is often observed when a baby is fed a nutritionally marginal diet (see Chapter 30). As the chick advances through the growth period, at some point the once marginal diet becomes adequate and eventually may even provide a generous proportion of nutrients relative to the requirement at that time. The compensatory growth phase is generally marked by a temporary increase in feed efficiency and rate of gain when compared to normal chicks of the same age.

Maintenance

Requirements for the maintenance of an adult bird are the lowest for the entire life cycle. The bird's greatest need at this time is to provide adequate energy to maintain body temperature, metabolic functions and the appropriate activity level. Protein requirement is minimized, because the primary need is for the replacement of dead cells or of amino acids used in various metabolic systems (ie, enzymes). Similarly, the need for vitamins and minerals is to replace those that were lost through metabolic proc-

esses. In nearly all cases, these needs are considerably lower than for the growth period (or any other stage of production) due to the lower rate of cell formation and overall metabolic rate. Any increase in activity level, ambient temperature outside of the thermoneutral zone, molting and the exposure to any type of stress will alter the minimum nutrient levels required for maintenance.

Breeding

The increased requirements by the hen for breeding can be divided into two general categories: those required for egg production and those required for maximum hatchability of the embryo. On a dry matter basis, the egg (without the shell) consists of approximately 45% fat and 50% protein. Additionally, the shell, which comprises approximately 10% of the total egg weight, is approximately 94% calcium carbonate (38% calcium). These three constituents represent the largest increase in nutrient needs in order for the hen to produce eggs. Because birds generally eat to meet their energy demands, increasing the energy content of the diet is not generally necessary. The diet does, however, require higher levels of protein, particularly of the sulfur amino acids (eg, methionine) and lysine. Calcium levels in the diet should be increased to minimize the decalcification of the bone and to prevent the formation of soft egg shells. Other nutrients that improve egg production (in poultry) when present at levels higher than the minimum maintenance requirement are vitamins A, B_{12}, riboflavin and zinc. Vitamin D_3 levels slightly over the requirement will tend to improve egg shell characteristics, with larger amounts having no additional benefits.[19] To maximize hatchability of the embryo, increased levels of vitamin E, riboflavin, pantothenic acid, biotin, folic acid, pyridoxine, zinc, iron, copper and manganese are required over what is adequate for egg production.

Much of the reason for dramatically increasing the nutritional plane of a breeding bird's diet is to provide adequate dietary components for the chick to be fed. Psittacine and passerine birds are relatively low egg producers and their increased demand for nutrients required for egg production is transient. With adequate body stores through proper daily feeding, a diet designed specifically for egg production is not necessary (such as a diet that will meet the immediate need for calcium during the days of production). Instead, a moderately high plane of nutrition that will optimize body stores, allow ready repletion of depleted stores and provide adequate nutrition for chick growth is probably the simplest and safest means of dietary management. This will allow for adequate chick growth and satisfactory levels of all nutrients for egg production. Calcium can be quickly repleted without the risk of over-supplementing by providing an "egg production" diet during the breeding season. Feeding for optimal chick growth not only decreases the duration in the nest of parent-raised chicks, but also promotes rapid recycling of the hen (repletion of body stores and physiologic preparation for returning to nest).

Geriatric Nutrition

To date, there has been no research on the nutritional needs of geriatric psittacine birds. This is due largely to the relative scarcity of geriatric birds in aviculture or as companion animals. Because of the historically poor diets offered to these birds and their subsequent shortened life-span, the mean population age of companion birds is low with respect to the potential. As the husbandry and veterinary care of these species continue to improve, proper geriatric nutrition will become a concern. Based primarily on geriatric research (in humans, rats, dogs and cats), it can be assumed that the geriatric bird should be provided with a highly digestible diet that maintains proper weight while providing slightly reduced levels of proteins, phosphorous and sodium, and levels of other vitamins and minerals similar to those received earlier in life. Slight increases in vitamins A, E, B_{12}, thiamine, pyridoxine, zinc, linoleic acid and lysine may be helpful to overcome some of the metabolic and digestive changes accompanying old age.

Stress

Companion and aviary birds are possibly subjected to more stresses than any other animals maintained in captivity. Stresses are both psychological and physical. Whether the bird is imported from the wild or is one of the most "domesticated" species, captivity alters its innate behaviors. The caretaker is often viewed as a threat, and the natural social interactions (flocking, mate selection) are inhibited. Crowding, handling, exposure to unusual pathogens, unsanitary conditions and malnutrition may all be considered stress factors. Stresses tend to be cumulative, and a single stress often has very little clinical effect on the bird. However, when one or more additional stress is applied, the bird may be weakened to the point of clinical illness or death. Stress in young birds results in a decrease in weight gain and, if left uncorrected, weight loss and morbidity may occur.

The body's response to stress is the "flight or fight" syndrome, and the immediate response is to mobilize

and produce glucose for the increased energy need. After carbohydrate stores are depleted (within approximately 24 hours), protein and fat stores are broken down, with the breakdown of skeletal muscle supplying amino acids for gluconeogenesis. The changes in metabolism also affect the normal metabolism or levels of vitamin A, C, calcium, zinc, iron, copper and magnesium. Attempts to restore these nutrients through special dietary modifications are probably futile. Instead, adequate diets should be provided to ensure the normal presence of sufficient body stores, which will also allow for satisfactory repletion of stress-depleted stores.[44]

Disease

There has been very little research done on the specific effects of diseases on the requirement and metabolism of each nutrient, and how these might affect the total requirement of individual birds. As the body enters the disease state, it rapidly begins to conserve nutrients in order to maintain needed functions. The most critical nutrient for the body to maintain during illness is water (see Chapter 15).

Secondly, the necessary energy supplies to the body must be maintained. Because of the increased metabolic rate during illness, there is a higher energy need. In humans, it has been found that the basal energy requirement will be exceeded by 50-120%, depending on the severity of the stress response. Although much of this energy demand still falls within the normal maintenance requirement, it is critical to maintain or exceed the typical energy intake, which can be provided via carbohydrates, fats or protein.

Dietary protein is the third most critical component to be provided to the debilitated patient. With the increased metabolic rate, there is a subsequent increase in body protein turnover, much of which is recycled by the body and not lost. Because this degradation and resynthesis is not completely efficient, an increase in metabolic rate results in an increased amino acid requirement. There is also increased demand for amino acids because of the need for additional immune components and tissue repair. Without adequate amino acid intake, labile protein stores (plasma, liver, muscle) are degraded for the process of gluconeogenesis. There may also be a decreased efficiency in the utilization of proteins, thereby further increasing the needs and importance of an adequate protein diet. The exceptions to increasing the protein in the diet are during the acute phase of liver or renal disease.

TABLE 3.4 Changes in Need for Nutrients During Periods of Debilitation

Vitamin C	The debilitated animal may not be able to adequately synthesize enough vitamin C, especially in the case of hepatic damage. Increased vitamin C in other species exposed to a number of different types of stresses has shown to improve production and health criteria.
Vitamin D	In diseases affecting the liver and kidneys, the enzymes required to produce the metabolically active form of vitamin D_3 will be impaired. In these situations, or in the case of a marginally deficient animal, it may be beneficial to provide vitamin D_3 therapy.
Vitamin K	For animals that have undergone extensive antibiotic therapy and are being maintained on an unsupplemented or marginally supplemented diet, it may be necessary to provide vitamin K because of its decreased synthesis by normal intestinal flora.
Vitamin B complex	In the case of an anorectic animal, it may be beneficial to supply additional B vitamins, especially thiamine. Other water-soluble vitamins such as riboflavin, pyridoxine and folic acid are particularly important in protein and energy metabolism; therefore, these vitamins have increased importance in the disease state.
Zinc	In a nutritionally compromised animal, zinc will improve healing and is an important component in protein synthesis; therefore, zinc is necessary for the maintenance of the immune system and phagocytic activity.

There is a lack of consistent studies in the literature indicating increased vitamin or mineral requirements in the debilitated animal. Supplying nutrients at recommended levels is probably sufficient in most cases; an increase in certain vitamins and minerals may be prudent, however (Table 3.4).

Current Nutritional Knowledge

Protein Needs

There have been few scientific studies conducted to investigate the nutritional needs of companion and aviary birds. Most of the beliefs on nutrition stem from observations in clinical and avicultural settings. Two of the best scientifically conducted studies that have been published investigated the total protein requirement and lysine requirement of the growing cockatiel. Chicks performed best and reached the

weaning stage earliest on a 20% crude protein diet. Those fed a 10% or 15% crude protein diet grew considerably slower, with stunting and slightly increased mortality occurring in the group fed 10% protein. On 5% crude protein diets, chicks were severely stunted, with subsequent mortality. Those fed a 25% crude protein diet performed similarly to the 20% group, but developed behavioral problems marked by meal refusal and increased aggressiveness. Those provided with a 35% protein diet displayed slight growth depression and further increased signs of aggression.[21,40,41]

Lysine Needs

The requirements for lysine were estimated by providing purified diets that were equal in all respects except lysine levels. In two experimental trials, diets supplying 0.1, 0.4, 1.0 or 2.0% lysine and 0.2, 0.4, 0.6, 0.8 or 1.2% lysine were provided. Cockatiel chicks showed the best growth responses when given diets in the range of 0.8 to 1.2% lysine. At lower levels, growth was proportionately depressed, displaying a typical nutrient-to-growth-response curve. The two lowest levels of dietary lysine resulted in little growth and high mortality. Performance on the 2% lysine diet was slightly poorer than the 1% diet, most likely due to the creation of a marginal amino acid imbalance at the higher level. Unlike poultry species, which exhibit feather depigmentation (the formation of feathers lacking melanin pigment) during a lysine deficiency, all cockatiels, even those on the most severely deficient diet, had normal feather pigmentation. This suggests a metabolic difference between poultry and altricial birds (at least the cockatiel).[38,39]

Energy

Energy requirements have been estimated in a variety of companion bird species. The approximate daily metabolizable energy (ME) needs for budgerigars appear to be between 12 and 16 kilocalories (kcal) per day in a normal maintenance situation.[7,17,47] Canaries require approximately 12 kcal/day[7,24] if maintained at 70°F. A 350 g Amazon parrot would require an intake of 100 kcal/day, and a 1000 g macaw would require 220 kcal/day. Temperatures above or below 70°F would result in lower or higher needs, respectively.[9]

Current Beliefs on Nutrient Requirements

Based on avicultural and clinical observations, there have been a number of hypotheses developed regarding species-specific differences in nutrient requirements. These have not been scientifically tested, but many have been substantiated by repeated reports in a variety of situations. It is difficult, however, to distinguish between the actual increased requirement of a nutrient in a specific species and species-specific differences in the manifestation of clinical deficiency signs. That is, on a marginal diet, one species may not display overt deficiency signs, while another on the same diet (same nutrient intake) could possible show distinct clinical changes. In a clinical situation, the overall adequacy of the diet should be evaluated before additional supplementation is suggested for the species (Table 3.5).

Vitamin Differences

It has been suggested that several species may have increased needs for vitamin A over most other commonly kept species. Those most frequently seen to respond to "higher" levels are Eclectus Parrots, conures[20] and certain Amazon parrots, most notably the Blue-fronted Amazon. The increased need for vitamin A in Amazon species is often linked to increased immunity against viral disease (poxvirus). This could well be an example of the variation in needs to maximize specific metabolic functions. Generally, the amount of a nutrient required to maximize a production parameter (such as growth or egg production) is often not sufficient to maximize immune response or other parameters. Limited research on vitamin A requirements indicates a need of 7,000 IU/kg feed in budgerigars. Clinically, a level equivalent to 5000 to 10,000 IU per kg in the diet has proven successful in preventing deficiency symptoms.[15]

Certain neonatal macaw species, especially the Blue and Gold Macaw and Hyacinth Macaw, seem more prone to the development of hypervitaminosis D_3 than other psittacine chicks. When a cross section of large psittacine babies was fed a moderately high level of vitamin D_3 (2500 International Chick Units [ICU]/kg *dry mix*; 1.0% Ca), Blue and Gold Macaws were the only species to develop mild signs of hypervitaminosis D_3, characterized by enlarged kidneys and mild, early calcification of the renal tubules.[5] Similar findings have been reported on a hand-feeding diet containing between 1000 and 4000 ICU/kg (the range due to the variable addition of vitamin supplementation), which resulted in crop stasis, increased serum uric acid levels and the presence of articular gout and regurgitation after feeding. Radiographically, the kidneys were found to be enlarged, with areas of calcification in the kidneys and proventriculus. Subsequent necropsy showed widespread soft tissue calcinosis.[46] In both reports, other species fed similarly on the same diets were not affected.

TABLE 3.5 Potential Toxic Effects of Nutrients

VITAMIN A
(20-100 times required)[43]
- Weight loss
- Decreased food intake
- Swelling/crusting eyelids
- Inflammation of mouth
- Inflammation of nares
- Decreased bone strength
- Dermatitis
- Hepatopathy
- Hemorrhaging

VITAMIN D
(4-10 times required)
- Increased calcium absorption
- Increased bone resorption
- Hypercalcemia
- Decreased PTH
- Mineralization of soft tissues
- Nephrocalcinosis
- Polyuria

VITAMIN E
(100 times required)
- Decreased growth
- Anemia
- Increased prothrombin time
- Decreased bone mineralization
- Decreased liver storage of vitamin A

VITAMIN K (Menadione)
(1000 times required)
- High mortality
- Anemia
- Hyperbilirubinemia
- Toxicity unlikely
- Thiamine (rapidly excreted by kidneys)
- Riboflavin (rapidy excreted by kidneys)
- Pantothenic acid
- Folic acid
- Cyanocobalamin
- Vitamin C

NIACIN
(10 times required)
- Flushing - vasodilation
- Pruritus
- Gastroenteritis

PYRIDOXINE
(50 times required)
- Decreased egg production
- Infertility

CHOLINE CHLORIDE
(2 times required)
- Increased mortality
- Decreased use of vitamin B_6

CALCIUM
(2.5% of diet)[45,48]
- Nephrosis
- Visceral gout
- Renal gout
- Hypercalcemia
- Hypophosphotemia
- Decreased food intake

MAGNESIUM
(20 times required)
- Decreased growth
- Decreased egg production
- Decreased egg quality

MANGANESE
(20-50 times required)
- Iron deficiencies

SELENIUM
(50 times required)
- Decreased weight gain
- Weight loss

(100 times required)
- Decreased egg weight
- Decreased hatchability
- Dermatitis

(Severe excesses)
- Blind staggers
- Pulmonary congestion/edema
- Liver cirrhosis

COPPER
(50 times required)
- Decreased growth
- Hepatopathy
- Accumulates in liver
- Death

ZINC
(10-20 times required)
- Gastroenteritis
- Decreased food intake
- Anemia
- Decreased bone mineralization
- Depression

See text for toxic effects associated with excesses of phosphorus, potassium, sodium, chloride, iron and iodine.

High levels of vitamin D_3 frequently result in the occurrence of gout.[18]

It has also been suggested that conures have a higher requirement for vitamin K, due to the bleeding disorder often seen in this species. This theory may not be valid because incidence of the syndrome has not been reported on a nutritionally adequate diet. This bleeding syndrome has also been alleviated by calcium supplementation and a generally improved diet, empirically verifying the importance of calcium status for blood clotting and suggesting that the syndrome is not dependent on vitamin K alone.[37]

Minerals

Cockatiels have been noted to be particularly sensitive to high calcium or high calcium and vitamin D_3 levels in the diet. Adult diets containing over 1% calcium, particularly when accompanied by generous levels of vitamin D_3 (over 2000 ICU/kg dry diet) have been found to be excessive in long-term feeding studies.[2] Normal egg production criteria have been satisfied at dietary calcium levels as low as 0.3 and 0.35%.[6,41]

Research in adult poultry has indicated that normal bone mineralization, plasma calcium and alkaline phosphatase levels can be maintained at below 0.05% calcium in the diet.[28,42] This is supported by a similar observation in cockatiels,[41] and is consistent with dietary levels of unsupplemented seeds, which have sustained birds for decades, although poorly. Levels for optimal health would seem to be considerably higher.

Energy

Large macaws, particularly the Hyacinth, appear to perform better on a higher fat diet than other species. This does not seem surprising considering the predominance of oil-based foods in the native diet of some of these species. An increase of approximately 25% fats over that adequate for other species has been found to be necessary to support maximum growth.[8]

A number of species are more prone to obesity than others. This can be a result of lower metabolic needs (ie, more energy efficient), better energy absorption, lower energy expenditures (ie, more sedentary in nature) or poor satiety biofeedback to the hypothalamus (overeating). Rose-breasted Cockatoos (galahs) and budgerigars are very prone to obesity and are probably examples of birds with slightly lower energy requirements. Amazon parrots frequently become obese due to their sedentary behaviors. In all birds, the likelihood of becoming overweight is increased as the bird ages and its metabolic rate decreases. Reducing the caloric density of the diet or limiting intake (by reducing food quantity or feeding duration) and

encouraging additional activities are essential in these cases.

Differences in Nutrient Metabolism and Requirements Based on Evolutionary Diversion

There is no generic companion bird with respect to nutritional requirements. It is highly likely that there will be distinct species' differences verified as the base of nutritional knowledge of companion birds increases. Based on the ecological diversity in which species have evolved, differences can be expected. For instance, budgerigars, cockatiels and a number of the grass parakeets and finches range into the vast, arid interior of Australia. These birds are expected to have developed biological adaptations allowing them to conserve both nutrients and water for existence in this sparse habitat. The sensitivity of cockatiels to calcium and vitamin D_3 levels that apparently have no negative impacts on other psittacines may be an example of such an adaptation. In the wild, these birds exist on a diet composed primarily of seeds,[50] which tend to be only a moderate source of many nutrients. Conversely, psittacines of the neotropics tend to consume a wide variety of foodstuffs, including an abundance of fresh vegetative matter, providing a less seasonally dependent, higher plane of nutrition. Birds in this environment have not had the need to develop any nutrient-conserving mechanisms, and may, therefore, have somewhat higher needs.

Nutritional Labeling of Commercial Products

Commercial labeling is frequently misunderstood, particularly with respect to the guaranteed analysis. All pet foods are required by law to list levels of crude protein, crude fat, crude fiber and moisture. These are not precise numbers, but rather guarantees of either the minimum or maximum amounts contained in the product. Protein and fat are listed as minimums, because they are of specific nutritional value and are among the most expensive components of food. The food should not contain less than the guaranteed level, but may contain any amount in excess of this minimum. In a processed food, these levels are generally close to the guarantee because of the significant added cost in oversupplying these nutrients.

The protein guarantee is analytically quantitative, being determined from the amount of nitrogen in the product (usually calculated as % crude protein = % nitrogen x 6.25). It provides no estimation of protein quality (ie, the product's amino acid profile). Indeed, non-protein nitrogenous sources will be reflected in the crude protein value.

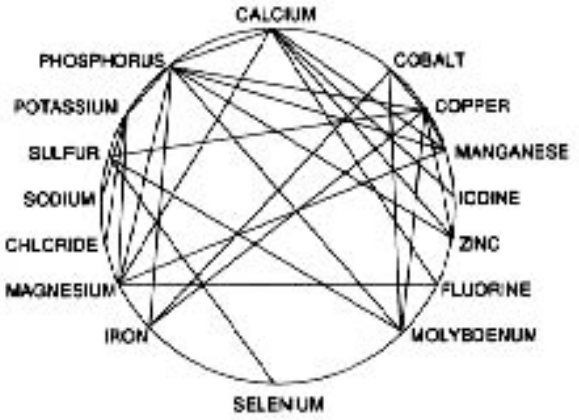

FIG 3.2 A well formulated, properly balanced diet represents a precise combination of over 40 nutrients, sometimes provided by just as many different ingredients.

Fiber and moisture are required to be listed as maximum amounts in the product, because both are traditionally considered of little nutritional importance and can, at higher levels, create quality problems. Manufacturers will often list the highest possible value that might occur in order to avoid violations, unless of course there is a negative consumer impression associated with the high value, in which case the manufacturer will guarantee a value with a narrower margin of safety.

Other nutrient guarantees are optional, except when the product specifically states that it is supplemented with certain nutrients (or category of nutrients), in which case those nutrients must be guaranteed. This law exists to ensure that all nutrient supplements are adequately labeled and the consumer is protected and informed about the product that they are buying. In the case of products that claim "vitamin-enriched" or other similar statements, those nutrients must be guaranteed so that a knowledgeable consumer can differentiate among the class of products (eg, diet, supplement, concentrate). In general, regulatory officials discourage the guaranteeing of vitamins, minerals and amino acids due the difficulty of ensuring compliance. Unless a product expiration date is listed on the package, the guarantees are stated for the life of the product. Due to normal loss of vitamin potency, a product that is not sold quickly may eventually fall

below the levels guaranteed. These nutrients often are expensive to analyze; therefore, regulatory officials are limited in the extent to which they can verify product compliance.

Complete nutrient listings may encourage the purchase of a product with unnecessarily high nutrient levels. Because of the typical philosophy that "more is better," number comparison between products will often result in the decision to purchase the product with the highest level. This may be particularly dangerous, especially in light of the relative lack of information regarding companion bird diets. Because of the lack of reference values, incorrect decisions can be expected to be the norm and should not be encouraged by listing numbers that may be relatively "meaningless."

Ingredient Statement

Companies are required to list the ingredients contained in the food in their order of dominance, (eg, in order from highest to lowest concentrations). This order is very difficult to police and is essentially left to the manufacturer to, in good faith, provide accurate information to the consumer. While still maintaining accuracy in labeling, manufacturers may opt for labeling techniques that become vague or "hide" ingredients that have poor consumer perception. Instead of listing each ingredient by its full, approved term, "collective" terms can be used to group similar products together under an umbrella term. Therefore, the collective term "grain products," can be used to describe the product's total content of cereal grains (corn, wheat, oats, barley), regardless of its form (whole, ground, heat processed). Likewise, the term "animal protein products" can be used to reflect a wide variety of ingredients such as meat meal, blood meal, dried milk, hydrolyzed feathers or fish residue. If the manufacturer chooses this method of terminology, all major ingredients must be listed in the collective manner. This gives manufacturers the opportunity to make major changes within general ingredient categories in order to take advantage of least-cost formulation.

Multiple ingredients serving the same functional purpose are sometimes used so that each ingredient can be listed in a lower position on the ingredient statement. For example, corn syrup, honey, sugar, dextrose or fructose could all be used as sources for natural sweeteners and could be combined in a product to make an individual ingredient appear very low on the ingredient listing, while maintaining a very high level of the functional compound (ie, sugars). This type of ingredient selection can make the product, through the labeling, more consumer-appealing.

TABLE 3.6 Control of Product Oxidation

1. **Environmental control** - Lowering the product temperature to decrease the rate of oxidation (refrigerating), or modifying the atmosphere to remove the available oxygen (packing in nitrogen), minimizes the amount of oxidation.
2. **Rapid product use** - Oxidation is minimized by using the product as quickly as possible after the ingredients are mixed and processed. This is particularly critical with a complete, processed food that does not contain antioxidants, because the presence of trace minerals acts as a catalyst for the oxidation process.
3. **The use of antioxidants** - Either natural or chemical antioxidants can be used. Natural antioxidants such as vitamin E (and other tocopherols) and vitamin C tend to have a limited antioxidant life and do not give the product the length of protection that is possible with chemical antioxidants. Chemical antioxidants (ethoxyquin, BHT, BHA) provide the longest period of protection. There are no scientific studies detailing the effects of any preservatives on the long-term health of companion birds.

   Chemical antioxidants are assumed to be safer than the carcinogenic compounds that are known to be produced through oxidative rancidity.

Antioxidants

Some form of protection against product oxidation is essential to maintain nutritional adequacy of the product, to ensure a high level of palatability and to prevent the formation of oxidative by-products, some of which are carcinogenic. Oxidation of formulated diets can be minimized through a number of techniques (Table 3.6).

Grit

Grit is not required in the normal, healthy psittacine or passerine bird. Grit, defined as a granular, dense, insoluble mineral material (generally granite or quartz) is required in birds that consume whole, intact seeds. Examples of birds that require grit are pigeons, doves, free-ranging gallinaceous species and Struthioniformes. These species naturally eat whole grains as a varying portion of their diet. Because of the inert nature of the fibrous coating of many seeds (particularly corn, peas), digestive enzymes are relatively ineffective against them. Grit in the ventriculus acts to grind the whole seeds, thereby providing a substrate on which the digestive enzymes can act. Psittacine and passerine birds normally remove this fibrous hull, allowing the ingested portion to be easily acted upon by the digestive enzymes. It is likely, however, that in the case of a bird with a pancreatic

dysfunction or other problems involving the physical digestion of food, grit could provide a benefit by enhancing the surface area for digestive enzymes to act. There have been numerous examples of birds not having grit for 15 to 20 years and still not showing any signs of decreased performance or poor digestion. Amazon parrots that did not receive grit for over five years still maintained high digestibility of ingested sunflower seeds, showing the unimportance of grit in the healthy bird.[1] There have been numerous reports of birds, especially with health problems and depraved appetites, consuming copious quantities of grit and developing crop or gastrointestinal impactions. Considering the small chance of benefit and the potential risk, ad libitum feeding of grit should be avoided.

Food Selection

Psittacines, in particular, have individual preferences for foods based on previous experience (or habit), food placement (position in the cage), particle size, fat content, texture, shape, color and taste. These preferences can be strong, and most clients encourage them by providing what the bird is most likely to readily eat. Some owners even interpret these avid habits as an "addiction" to a certain food (often sunflower seeds or peanuts) because the bird refuses to eat anything else by its own volition. This type of limited feeding pattern can result in severe nutrient deficiencies if the selected food is not nutrient-complete and balanced. This is especially likely if the poor eating habits are left unchecked for an extended length of time. It must be emphasized that these preferences are individualized, especially in the larger psittacines, with some individuals having very distinct preferences. This can be illustrated by the choice of food based on color. Some individuals have no color preferences whatsoever, while others have distinct biases for certain colors (eg, red, yellow, brown).[3] Birds must be trained to eat new foods. This is best accomplished by providing limited portions, or meals, to encourage consumption of everything offered, as opposed to a virtual ad libitum feeding program where the bird can reach satiety by eating only one or two of its favorite ingredients. Providing a large variety of foods immediately pre- and post-weaning is a very effective way to develop good eating habits that will tend to persist throughout life. This will result in a healthier, less finicky companion bird.

Essential Nutrients and Their Biological Functions

Essential nutrients are those that are required to properly drive biochemical reactions within the body. These nutrients may be required as a specific energy source, as structural components or as factors and cofactors in specific biochemical reactions or processes (Table 3.7).

Energy

The total amount of energy, or the gross energy contained within the feed, is broken into several fragments as it is metabolized in the body. During the process of digestion, potential energy sources are lost through the feces, urine and urates. What remains is the metabolizable energy (ME), or what is available for the body's metabolic processes. A portion of the ME is lost as heat (the heat increment). The remaining energy (net energy value of the food) is available for maintenance of the bird. Any energy that remains after satisfying the basic maintenance requirements is available for production activities such as growth of body mass and feathers, deposition of fat, production of eggs and for exercise.

The bird derives energy from proteins, fats and carbohydrates in the diet. Of these, protein is the least efficient source of energy, because the body must deaminate the amino acid, excrete the nitrogen as uric acid and then use the remaining carbon skeleton for glucose or fat synthesis. The average gross energy of protein is 5.65 kilocalories/gram. After the losses through deamination and subsequent metabolic reactions, protein yields a net of 4.1 kcal/g.

Carbohydrates are the most important energy source for the body because they are the only energy form that the brain can use. Of the carbohydrate family, energy is derived from starches (digestible polysaccharides), disaccharides (sucrose, maltose) and the simple sugars or monosaccharides (glucose, fructose, mannose, galactose). Lactose, the disaccharide contained in milk, is a very poor energy source for avian species because of an inefficient supply of lactase in birds to hydrolyze lactose into its components of glucose and galactose. Carbohydrates are efficiently metabolized with an ME value of 4 kcal/g.

TABLE 3.7 Relative Nutrient Content of Commonly Used Food Sources[4,30]

NUTRIENT	EXCELLENT (Over 20 times requirement)	GOOD (Over 2 times requirement)	ADEQUATE (1/2 - 2 times requirement)
VITAMINS			
Vitamin A	Fish liver oil Liver Alfalfa meal Carrots Sweet potato Greens (spinach, parsley, kale, dandelion, turnip greens) Red peppers	Dried milk Cheese Egg	Fish meal Corn Peanuts
Vitamin D_3	Fish liver oil Liver (depending on levels fed) Fish oil	Eggs (especially yolk)	Dried milk
Vitamin E	Safflower oil Sunflower oil	All vegetable oils Alfalfa meal Sunflower seeds Safflower seeds Soybeans Wheat germ meal Corn gluten meal and germ	Cereal grains Dried milk Fish products
Vitamin K		Parsley Cabbage Brussel sprouts Spinach Cauliflower	Lettuce Broccoli Carrots Liver Turnip greens Milk Eggs Fish meal
Thiamine	Dried brewer's yeast	Wheat germ meal Rice bran Sunflower seeds Soybeans Wheat middlings Corn germ (and by-products) Peas and beans Dried whey Wheat Oats Peanuts Millet Carrots	Soybean meal Eggs Alfalfa meal Dried milk Fish meal Liver Most whole grains Potatoes
Riboflavin		Brewer's yeast Dried whey Dried milk Wheat germ Liver Eggs Fish and fish by-products Alfalfa meal	Millet Peas Beans Wheat Corn
Pyridoxine (B_6)		Brewer's yeast Eggs Whey Liver Alfalfa meal Black strap molasses Peanuts Sunflower and safflower Peas Soy products Alfalfa meal Wheat germ Fish by-products	Flax Millet Milo Buckwheat Wheat Other whole grains
Niacin		Yeast products Sunflower seeds Meat & fish by-products	Peanuts Corn by-products Wheat germ Alfalfa meal Wheat Barley Corn
Pantothenic Acid	Royal jelly	Yeast products Eggs Whey and dried milk Liver Alfalfa meal Peanuts Sunflower and safflower seeds Wheat germ meal	Peas Millet Wheat Oats Corn Other whole grains
Folic Acid		Yeast products Alfalfa Soybeans Wheat germ Liver	Beans Wheat Oats Peanuts Other whole grains Beets Spinach
Biotin		Safflower Liver Eggs Molasses Dried milk and whey Soybean products Alfalfa meal Milo Oats Peas Peanuts Corn gluten meal	Barley Beans Flax Wheat
B_{12}	Fish and meat by-products	Eggs Dried milk Yeast products	
Choline		Fish and meat by-products Yeast products Rape seed Dried whey Wheat germ Sunflower and safflower seeds Soybean products Peanuts	Alfalfa meal Most whole grains Beans Peas Eggs

TABLE 3.7 Relative Nutrient Content of Commonly Used Food Sources (cont.)[4,30]

NUTRIENT	EXCELLENT (Over 20 times requirement		GOOD (Over 2 times requirement)		ADEQUATE (1/2 - 2 times requirement)	
MINERALS						
Calcium	Calcium carbonate (incl. cuttle-bone, egg shell)	Bone meal Dicalcium phosphate	Fish and meat meals Kelp	Alfalfa meal Whey	Dried milk Cheese	Oil-type seeds Most nuts
Phosphorous	Dicalcium phosphate	Bone meal	Fish and meat meals Brewer's yeast Dried whey Wheat germ meal	Peanuts Pumpkin seeds Most oil seeds Nuts	Corn gluten meal Cereal grains	Egg
Magnesium					Kelp Bone meal Sunflower, safflower and other oilseeds	Nuts Alfalfa meal Brewer's yeast Wheat germ meal
Sodium	Salt	Bone meal	Dried whey and milk	Dried parsley Fish meal	Dried leafy vegetables Dried carrots	Alfalfa meal Eggs
Chlorine	Salt		Molasses Meat and fish products Dairy products	Alfalfa meal Dried parsley Carrot	Egg Green leafy vegetables	Broccoli Cereal grains
Potassium			Dried peppers Whey Dried carrot Alfalfa meal Molasses Soybean products Dried apricots	Bananas Brewer's yeast Oil seed products Legumes Oil seeds Wheat germ meal	Nuts Dried fruits and vegetables	Oil-type seeds Cereal grains
Manganese			Dicalcium phosphate	Calcium carbonate Wheat germ meal	Hemp seed Wheat products Soy products	Oat products Nuts
Iron	Bone meal		Dried parsley Fish and meat meals Calcium carbonate Corn gluten meal	Alfalfa meal Dried whey Soybean meal Brewer's yeast	Most cereal grains (especially millet, barley, oats, canary grass seed)	Oil-type seeds Nuts Dried carrots
Copper			Dried whey Molasses Brewer's yeast	Oil seeds Corn gluten meal Nuts	Fish and meat products Peas	Alfalfa meal Cereal grains
Zinc			Fish and meat meals Wheat germ meal	Wheat middlings Bone meal	Oil-seed products Soybean meal Nuts	Wheat Oats Corn gluten meal
Iodine	Dried whey		Fish and meat meals	Molasses	Egg Cheese	Brewer's yeast
Selenium	Fish meal		Brewer's yeast Corn gluten meal Wheat middlings Oil seeds Alfalfa meal	Wheat germ meal Rice Dried parsley and spinach Oats	Cheese Egg Soybean meal	Cereal grains (depending on soil)
AMINO ACIDS						
Lysine			Fish and meat meals Soybean meal Dried parsley and spinach	Brewer's yeast Wheat germ meal Peas Dried whey	Oil-type seeds (especially sunflower and safflower) Corn gluten meal Alfalfa meal	Nuts Oats Canary grass seed Barley Buckwheat Millet
Methionine			Corn gluten meal Fish and meat meals Brewer's yeast Soybean meal	Canary grass seed Sunflower Wheat germ meal Dried whey	Oil seeds Millet Peas Alfalfa meal	Nuts Wheat, oats, barley & other cereal grains

Carbohydrates also form the fiber fraction of the diet, broadly classified as undigestible carbohydrate. This fraction consists mainly of cellulose, which is essentially undigested because of the bird's lack of the enzyme cellulase. Also included are the hemicelluloses and lignin, all of which are poorly digested. These fibrous agents generally minimize the absorptive space in the gastrointestinal tract. The hemicellulose, psyllium, is an exception, as it acts to increase absorption. The required dietary fiber intake of varying species of companion breeds is undetermined.

Dietary fat is not only an important source of energy but it is the primary storage form of energy in the body. The ME in fat is concentrated with a value of 9 kcal/g, 2.25 times greater than that of either carbohydrates or protein. Fat is also easily absorbed into the body via the gastrointestinal tract, with its digestibility being dependent on the fatty acid composition.

Essential Fatty Acids

Animals and birds have no requirement for fat per se, but they do have a requirement for the individual fatty acids that make up fat. Fatty acids are characterized based on their length (ie, the number of carbon atoms contained in the chain), the degree of saturation (the number of double bonds in the chain, commonly referred to as saturated, unsaturated or polyunsaturated) and the location of the initial double bond.

The primary essential fatty acid for animals and birds is linoleic acid. This compound cannot be synthesized in the body so it must be provided through the diet. Arachidonic acid is sometimes considered to be an essential fatty acid; however, it can be synthesized from linoleic acid.

The predominant fatty acid compounds in bird tissues are oleic acid, palmitic acid and linoleic acid. Body fat composition will be somewhat influenced by dietary fatty acid content because of the absorption and subsequent deposition of some intact fatty acids. Common vegetable oils are generally high in linoleic acid (eg, corn oil, soybean oil, peanut oil = 50%; sunflower oil = 60%; safflower oil = 75%). Tropical oils, such as coconut oil, contain substantial amounts of medium chain fatty acids, and are therefore poorer sources of linoleic acid.

Absorption of these fatty acids varies depending on the type, the form (free or as part of a triglyceride), the ratio of unsaturated to saturated fatty acids in the diet, other dietary constituents and the intestinal microflora. Generally, oleic and linoleic acids are the most efficiently absorbed by the bird. This occurs because of the ease with which these fatty acids form mixed micelles with the bile salts, thereby improving their digestion by pancreatic lipase. In this manner, they will also enhance the absorption of other less efficiently absorbed fatty acids when they are present together.

The essential fatty acids are used as structural components in the cell with particular importance in the cell membranes. They are also precursors of prostaglandins.

Based on the general requirements for most other species, it can be safely predicted that the linoleic acid requirement for companion and aviary birds is 1.0 to 1.5% of the diet. In seed-based diets, this would rarely fall short, but in a processed, low-fat diet there could be a marginal deficiency.

Amino Acids and Protein

Amino acids are the building blocks of the protein chain. The type of protein synthesized depends on the complex genetic process of transcription and translation between the DNA and RNA of the body. A specific protein is created by the shaping of the polypeptide chain into its unique three-dimensional structure based on interactions between the individual amino acids of the chain.

The protein chain can contain up to 22 different amino acids. Of these, ten cannot be manufactured by the body, so they must be routinely provided by the diet (essential amino acids). They are lysine, arginine, histidine (basic amino acids), methionine (sulfur-containing), tryptophan (heterocyclic), threonine, leucine, isoleucine, valine (aliphatic) and phenylalanine (aromatic). Three other amino acids (cystine, hydroxylysine and tyrosine) are formed through modification of an essential amino acid (methionine, lysine and phenylalanine, respectively). These are not considered essential per se, but they may affect the total amount of the essential amino acid required, depending on their level in the diet. There are nine additional amino acids that are nutritionally nonessential because they are manufactured from other compounds in the body.

The quality of a protein is determined by two primary factors. The first is the balance of amino acids within

that protein. To be optimally utilized, the protein should have an amino acid profile similar to that of the animal's body. If this occurs, each individual amino acid will be present in approximately the right proportion that the body needs with no major excesses or deficiencies of any one amino acid. This profile is achieved only in a few foods, most notably in eggs and in milk. It seems obvious that these two protein sources would fit the profile of the body, because they provide the only source of food during early periods of rapid growth.

Very few ingredients have an amino acid profile that approaches ideal; therefore, it is preferable to choose individual ingredients for the diet that complement each others' amino acid profile. With proper selection, the ingredients work together in a synergistic manner to enhance the overall performance of the mixed diet. By dividing the percentage of a specific amino acid in the protein of an ingredient by the percentage of that amino acid in an ideal protein, an evaluation of the degree of amino acid adequacy can be determined. Doing this to all the essential amino acids for an ingredient will determine the limiting amino acid, or that essential amino acid that is present in the lowest proportion of ideal. This amino acid will have to be supplemented by either adding an ingredient that is particularly high in this amino acid or by supplying the specific amino acid in a purified form. Similarly, this kind of evaluation can be performed on the entire diet to determine the adequacy of the amino acid profile. These values would be reflected in the amino acid requirement of the animal at its particular stage of life.

The second criteria that affects protein quality is the availability of the amino acids within the foodstuff. Certain ingredients have structural characteristics or contain chemical compounds that will decrease the bioavailability of an amino acid. A typical example of this would be the interaction between lysine and dietary simple sugars resulting in a chemical complex that makes lysine unavailable to the animal. Another example would be the trypsin and chymotrypsin inhibitors in unprocessed soybeans that prevent normal proteolytic activity of these digestive enzymes, thereby decreasing digestibility. The specific structure of an amino acid chain can also render a protein undigestible. This occurs due to secondary and tertiary structural characteristics preventing the enzymatic hydrolysis of the amino acid chain in the body. An example of this is the extremely poor digestibility of keratin and the other fibrous proteins.

After a protein source is consumed, it is initially processed by the combination of pepsin and hydrochloric acid secreted by the glandular stomach (proventriculus). The resultant polypeptide chains are then further degraded by a series of enzymes from the pancreas (trypsin, chymotrypsin, carboxypeptidases), aminopeptidases and finally dipeptidases. The individual amino acids that result from this series of enzymatic hydrolyses are then absorbed in the small intestine, predominantly in the jejunum, although all sections of the small intestine are involved in absorption.

Vitamins

The vitamins are chemically unique but share similar metabolic roles and modes of action and are therefore grouped together.

Generally, vitamins are defined as natural food components that are present in minute quantities, are organic in nature and are essential for normal metabolism and health. They will cause specific, characteristic deficiency symptoms when they are severely limited in the diet. Metabolism will generally be affected to a degree proportional to the level of the deficiency; therefore, in the case of mild deficiency, the symptoms are usually vague and nonspecific, such as poor performance or compromised health. Vitamins are generally not synthesized by the body in amounts sufficient to meet the physiologic requirement.

Vitamins are now subcategorized into two general groups based on their solubility characteristics. The fat-soluble vitamins are comprised of vitamins A, D, E and K. The water-soluble vitamins include thiamine (vitamin B_1), riboflavin (vitamin B_2), niacin, pyridoxine (vitamin B_6), pantothenic acid, biotin (vitamin H), folic acid (vitamin M), vitamin B_{12} (cyanocobalamin), choline and ascorbic acid (vitamin C). Other vitamin compounds that are generally not considered to be required by higher animals include lipoic acid (occurs widely in natural foodstuffs), inositol (synthesized by higher animals and widely distributed in most foodstuffs), and para-aminobenzoic acid (required by microorganism for the synthesis of folic acid).

Vitamin A

Vitamin A occurs in several forms: retinol (alcohol), retinal (aldehyde) and retinoic acid, all having different metabolic activity. Plants do not contain active vitamin A, but instead contain vitamin precursors.

These exist in the form of carotenoid plant pigments, with the carotenes being the most important of the pro-vitamin A compounds. In the avian species studied, beta carotene is the most active of the carotenoid compounds, yielding the equivalent of 1667 international units (IU) of vitamin A activity per milligram. The sum of the vitamin A content (expressed in retinol equivalents or IU) and the contribution from carotene represents the total vitamin A activity of the food.

The most well understood function of vitamin A is its role in vision, but the most impactful action of vitamin A in avian medicine is its effect on the growth and differentiation of epithelial tissues, with deficiencies resulting in keratinization of the tissue. It is in this function that vitamin A is obligatory for normal disease resistance because it is required for the maintenance of adequate mucous membranes and for the normal functioning of secretory tissues (eg, the adrenal glands for the production of corticosteroids).

Vitamin A is also required for normal mucopolysaccharide formation and apparently affects the stability of cell membranes and of the subcellular membranes (such as the mitochondria and lysosomes). A major metabolic function of vitamin A may be the maintenance of the structural integrity and the normal permeability of the cell membrane. Vitamin A also functions in the proper growth of bones and in the maintenance of normal reproduction.[34]

It is generally accepted that vitamin A improves the immune function of the body; however, its mode of action has not been totally elucidated. Vitamin A apparently acts by the increased production and differentiation of immune related cells, while the carotenoids possibly improve the activity of lymphocytes. Obviously, this function is also significantly influenced by the importance of vitamin A in maintaining healthy mucosal membranes.

The liver will typically contain over 90% of the total body stores of vitamin A with the preferential storage form being retinyl palmitate. Additional supplies are also contained in the kidneys, lungs, adrenals and blood. As vitamin A is required by the body, it is mobilized from the liver by the hydrolysis of the retinyl esters to free retinol by the enzyme retinyl ester hydrolase.

Vitamin A is usually considered safe up to approximately ten times the requirement in monogastrics (including poultry). Experimentally, vitamin A toxicities have been achieved by feeding over 100 times the daily requirement for extended periods of time. Probably an excess of 1000 times requirement would be necessary to induce an acute intoxication. Carotenoids in the diet do not contribute to potential vitamin A toxicity, because they are not converted to retinol unless there is a metabolic need for vitamin A. At excessive levels, they may result in a temporary yellow pigmentation of the skin and fat.

Vitamin D

There are two predominant forms of vitamin D: ergocalciferol (vitamin D_2), a plant derivative, and cholecalciferol (vitamin D_3), produced exclusively in the bird's body. In all of the birds studied, vitamin D_3 is considered to be 30 to 40 times more potent then vitamin D_2 as a source of vitamin D activity. Therefore, plant sources of vitamin D are essentially disregarded when providing vitamin D to birds. Vitamin D_3 levels are quantified in International Chick Units (ICU) as a way to differentiate it from vitamin D_2 or total vitamin D. Unlike most other vitamins, the active form of vitamin D_3 can be synthesized in the body by the conversion of 7-dehydrocholesterol in the skin and sebaceous secretions by irradiating with ultraviolet rays. Early studies in poultry showed that sufficient Vitamin D_3 could be formed to prevent rickets in growing chickens and maximize growth with 11 to 45 minutes of sunshine (not filtered by glass) each day.[22]

The cholecalciferol formed in the skin is then transported by the blood to the liver, where it is hydroxylated by a liver microsomal enzyme (to a lesser extent, the reaction may also occur in avian kidneys). This new compound is then transported to the kidney, where it is again hydroxylated to the metabolically active form. When the renal levels of calcium and phosphorus are normal and parathyroid hormone (PTH) is being secreted, an inactive form is produced. Unlike other vitamins, the active metabolite actually acts as a hormone in the body being transported to the intestines, bones and other target organs where it exerts its role in the metabolism of calcium and phosphorus (see Chapter 23).

The most important physiologic role of vitamin D is the homeostasis of calcium and phosphorus levels in the body. There is also evidence that the active form has additional roles, eg, induction of cell differentiation and immune system regulation.[12,36]

The active metabolite also acts in the body in a manner similar to a steroid hormone, acting on a specific receptor protein in the target organ. The

vitamin D receptor is located in the nucleus of the intestinal mucosal epithelial cells.

Hypervitaminosis D_3

In a prolonged feeding study with cockatiels on a diet containing 1.0% Ca, 0.5% P and 4000 ICU vitamin D_3 (18% crude protein and 3150 kcal/kg), high egg production for approximately one year was followed by a rapid decline in reproductive performance, concurrent with the onset of polyuria in all birds. Most had signs of anorexia and lethargy, with some exhibiting signs of diarrhea or lameness. Radiographs indicated the presence of nephrocalcinosis. These signs were exacerbated with the onset of subsequent reproduction. Several females were lost, with necropsies showing extensive soft tissue mineralization, especially of the kidneys. The onset of reproduction and subsequent increasing hormonal activity (presence of prolactin) and related increases in calcium uptake in females were found to enhance the problem. Males were affected to a much lesser extent, with all clinical signs disappearing after the birds were removed from the experimental diet.[2]

Vitamin E

Vitamin E is a compound of plant origin with eight active forms derived from four tocopherols and four tocotrienols. The compound of the greatest biologic importance in the avian species is alpha-tocopherol. Vitamin E is essentially a biologic antioxidant that functions at the intercellular and intracellular level by preventing the oxidation of saturated lipid compounds in the cell, thereby maintaining membrane integrity.

Free radicals, the highly reactive breakdown products from reactions such as the oxidation of polyunsaturated fatty acids to fatty hydroperoxides, can be extremely damaging to the cell. Free radicals occur in the body through normal oxidative metabolism, cytochrome activity and from stimulated phagocytes. These free radicals can then attack the polyunsaturated fatty acids of membranes, creating additional radicals, producing a chain reaction that can continue until all of the polyunsaturated fatty acids in the membrane are oxidized. Vitamin E acts to scavenge these radicals, thereby preventing the initiation as well as interrupting propagation of peroxidation.

Working in conjunction with vitamin E are several metalloenzymes, which block the initiation of peroxidation in the aqueous phase of the cell. These enzymes incorporate manganese, zinc, copper, iron and selenium as active components. Glutathione peroxidase (GSHp) is probably the most important of these metalloenzymes because of its integral relationship with vitamin E. This selenium-containing enzyme is very active in the destruction of peroxides before they cause membrane damage. Because of their similar activity, selenium and vitamin E tend to have a sparing effect on each other. Exudative diathesis, the condition observed in poultry, generally appears only when both selenium and vitamin E are limited in the diet. Additionally, sulfur-containing amino acids can exhibit a similar sparing effect on vitamin E because they are precursors of GSHp.

Vitamin E has been suggested to be active in several other metabolic systems: 1) cellular respiration; 2) normal phosphorylation reactions (eg, ATP metabolism); 3) cofactor in the synthesis of ascorbic acid; and 4) sulfur amino acid metabolism.[43] There is also considerable evidence in poultry that levels higher than those required for optimum growth can increase immunity, as evidenced by decreased mortality after challenge of treated birds by *E. coli*.[27] This protective effect occurs by increasing phagocytosis and antibody production as well as stimulating the activity of macrophages and lymphocytes.

Vitamin E is absorbed through passive diffusion and is dependent upon normal lipid digestion requiring proper micelle formation and the presence of bile salts and pancreatic juices. Any malabsorption syndrome will decrease uptake. Vitamin E is absorbed predominantly as a free alcohol in the small intestine. Vitamin E enters the portal circulation in association with chylomicra, but is readily transferred to plasma lipoproteins for transportation to the liver. Initial storage occurs in the liver, being released primarily in the high density lipoproteins, and to a lesser degree, the low density lipoproteins and very low density lipoproteins. Liver and plasma stores of vitamin E are the most readily accessible to the body in times of need. Vitamin E stores of the body tend to be relatively stable and may not be effective in preventing a vitamin E deficiency from occurring. It appears that lipolysis of fatty stores may be required for vitamin E to be released.

Vitamin E is abundant in plant materials (particularly those high in oil) and in plant leaves. In cereal grains, vitamin E is concentrated in the germ. Alfalfa leaves are a particularly high source of vitamin E.

Vitamin K

Vitamin K actually represents a large number of related compounds that possess widely varying de-

grees of anti-hemorrhagic characteristics, all being forms of the compound naphthoquinone. Vitamin K comes from three sources: 1) green plants (phyloquinones - K_1 series), 2) bacteria (menaquinones - K_2 series) and 3) synthetic forms (menadione - K_3). The microbial synthesis of vitamin K_2 is significant in most species. It is generally difficult to produce a vitamin K deficiency without the use of germ-free animals, the use of antibiotics to kill intestinal flora or the prevention of coprophagy (the ingestion of excreta).

Natural vitamin K compounds require the presence of dietary fats and bile salts for proper absorption from the gastrointestinal tract; therefore, altered micelle formation (eg, decreased pancreatic and biliary function) will impair the normal absorption of vitamin K. Menadione salts are fairly water-soluble so they are less reliant on micelle incorporation. Absorption of the K_2 and K_3 forms occurs by passive diffusion throughout the intestines and also in the colon, while K_1 is absorbed via an active transport process in the proximal small intestine. Vitamin K then enters the portal circulation and, in association with a chylomicron, is transported to the liver. Generally, vitamin K is stored only briefly in the liver before it is released into the body and transported to all tissues via lipoproteins. It is believed that menadione is well absorbed but poorly retained, while phylloquinone is rather poorly absorbed but retained much longer in the body. Vitamin K absorption has been observed to range from 10 to 70%, depending on the form of vitamin.

A number of plasma clotting factors (eg, prothrombin) are dependent on vitamin K for their synthesis. This occurs by activating inactive protein precursors that occur through the action of an enzyme; this is found predominantly in the liver, but also in lung, spleen, kidney, bone and skin. The bone also contains a vitamin K-dependent protein (osteocalcin), which acts in the regulation of calcium phosphate incorporation into bone.

Thiamine (Vitamin B_1)

Thiamine is fairly common in food sources, but generally at only low concentrations. In plants, thiamine exists as the free vitamin, while in animal tissue it is present in its phosphorylated form, thiamine pyrophosphate. Several compounds in nature possess anti-thiamine activity, many of which exhibit competitive inhibition with thiamine based on their structural similarities. An example of this is amprolium, which inhibits thiamine absorption from the intestine and prevents thiamine phosphorylation.[26] Another well known compound is thiaminase, a thiamine-splitting enzyme contained in some raw fish and produced by certain types of bacteria. Other thiamine antagonists include caffeic acids, chlorogenic acid and tannic acid, (often found in deeply pigmented fruits and vegetables such as blueberries or beets as well as coffee and tea). These compounds react with thiamine to prevent its absorption. Sulfites, a frequently used food preservative, can also destroy thiamine under certain conditions.

Thiamine is readily available from natural sources when normal amounts of gastric hydrochloric acid are present. Thiamine is absorbed both by an active transport system and at high luminal concentrations, by passive diffusion. After absorption, thiamine is transported via the portal vein to the liver, predominantly bound to serum albumin. Thiamine is not stored for any length of time in the body. It is excreted primarily through the urine and in lesser amounts through the feces. About 80% of thiamine in the body is present as thiamine pyrophosphate. The remaining fraction exists as the triphosphate, monophosphate and free forms.

Riboflavin (Vitamin B_2)

In foods, riboflavin is generally bound to proteins in the form of flavin mononucleotide (FMN) or flavin adenine dinucleotide (FAD). Riboflavin contained in plant materials is generally less available than from animal sources because of decreased digestibility of the flavin complexes in plants.

In the gastrointestinal tract, the phosphorylated forms of riboflavin are hydrolyzed. The free riboflavin enters the mucosal cells via an active transport system in the proximal small intestine. In the intestinal mucosa, riboflavin is rapidly phosphorylated, producing FMN. Both free riboflavin and FMN then enter the portal circulation, predominantly bound to plasma albumin (and to a lesser degree to globulins and fibrinogen). These compounds are then transported to the liver and other tissues, where riboflavin enters the cell in the free form.

Very little riboflavin is stored in the body; the highest concentrations are found in the liver, kidney and heart. Unlike other tissues, the egg contains predominantly free riboflavin. Laying chickens have been found to have specific riboflavin-binding proteins in the plasma. These are produced in the liver under the influence of estrogen and are believed to be involved in the transovarian passage of free riboflavin.

Riboflavin as part of the coenzymes FMN or FAD (flavoproteins) act in a large number of enzyme complexes that are responsible for essential reactions in the utilization of carbohydrates, fats and proteins. The flavoprotein enzyme complexes often contain a metal ion (eg, iron, molybdenum, copper) and function to help regulate cellular metabolism, the metabolism of carbohydrates, the breakdown of amino acids, the formation of uric acid, the formation of ascorbic acid, fatty acid biosynthesis and degradation, oxidation of various substrates in drug metabolism and other functions.

Riboflavin toxicity is very unlikely due to the fact that it is rapidly excreted, and when fed at high levels, the transport system across the gastrointestinal mucosa becomes saturated, thereby limiting the amount absorbed.

Niacin

Niacin exists in two major forms, nicotinic acid and nicotinamide. Niacin is widely distributed in foods, but that found in plants has low bioavailability. It is also not uniformly distributed within the feedstuff so milling often removes the fraction with the highest content. Therefore, in diet formulation, the natural content of niacin in plant materials is generally ignored. Bioavailability in animal products tends to be very high. Niacin can also be synthesized from the essential amino acid tryptophan; however, the amino acid's preferential use is for protein synthesis, so only tryptophan in excess of the animal's needs will be available for bioconversion to niacin.

Plants generally contain protein-bound nicotinic acid while animal sources are present as NAD and NADP. These forms are digested by the body, releasing nicotinamide that is then absorbed by diffusion. The greatest concentrations of niacin compounds are in the liver, but no true storage occurs.

The coenzymes NAD and NADP are important components in carbohydrate, fat and protein metabolism, being especially important in the energy-yielding reactions of the body. These functions are critical to the generation of energy for the body as well as for normal tissue integrity, especially of the skin, alimentary tract and the nervous system.

Pyridoxine (Vitamin B_6)

Vitamin B_6 refers to the group of three compounds: pyridoxal, pyridoxamine and pyridoxal phosphate. Pyridoxal is the form predominantly found in plants, the other two are found mainly in animal tissues. Large amounts of vitamin B_6 in foods are bound to proteins or complexes, some of which have very low bioavailability. After digestion to free the vitamin from these protein complexes, vitamin B_6 is absorbed by passive diffusion throughout the entire small intestine and is transported to the liver. The various forms are then converted and phosphorylated to the predominate tissue form, pyridoxal phosphate, which requires both niacin (as NADP) and riboflavin (as FMN) for the enzyme systems. Pyridoxal phosphate and lesser amounts of pyridoxal are found in the circulation associated with plasma albumin and erythrocyte hemoglobin. Minimal amounts of the vitamin are stored in the body, primarily as pyridoxal phosphate and secondarily as pyridoxamine phosphate. Storage occurs predominately in the liver, brain, kidney, spleen and muscle.

The metabolically active form of vitamin B_6, pyridoxal phosphate, is involved in a number of enzyme systems as a coenzyme. It is required in essentially all major areas of amino acid utilization, the synthesis of niacin from tryptophan and in the formation of antibodies. It is required in the decarboxylation of glutamic acid to form gamma-aminobutyric acid (GABA), the lack of which has been shown to cause seizures. A deficiency of pyridoxine creates a deficiency of many other important metabolites and hormones such as serotonin and histamine. Evidence also suggests that it may play a role as a modulator of steroid hormone receptors.

Pantothenic Acid

Pantothenic acid is a structural component of coenzyme A (CoA). Pantothenic acid is present in feeds in both the bound form (predominantly CoA) and free forms. During the digestive process, the free form is liberated prior to absorption. Pantothenic acid is then absorbed via a saturable transport system and at high levels, simple diffusion also occurs. The free form is then carried via the plasma to the rest of the body. Tissues convert pantothenic acid to coenzyme A (predominantly), with the greatest concentrations found in the liver, adrenals, kidneys and brain. The majority of the pantothenic acid in the blood is found as CoA in the erythrocytes. CoA is one of the most critical coenzymes in tissue metabolism, forming the compound acetyl CoA. Acetyl CoA acts as the entry point into the citric acid cycle for carbohydrate metabolism, a point of entry for amino acid degradation and as an essential component in fatty acid biosynthesis and degradation, the synthesis of triglycerides and phospholipids, as well as in the formation of

compounds such as acetylcholine, mucopolysaccharides, cholesterol, steroid hormones and many more.

Biotin

Biotin is widely distributed in foods but generally at low concentrations. A relatively large portion of naturally occurring biotin is present in a protein-bound form with varying degrees of biological availability. There is evidence that suggests that the synthesis of biotin by intestinal microflora is important in an animal. Microbial-derived biotin would be manufactured and absorbed in the large intestine.

Intestinal proteases help free the bound biotin prior to absorption. Free biotin is then absorbed, apparently both by facilitated and simple transport systems. It is carried to the tissue through the plasma, possibly in conjunction with a biotin-binding protein (identified in both yolk and plasma of laying chickens). The largest concentrations of biotin in the body are found in the liver; however, this storage site seems to be poorly mobilized during times of biotin deprivation.

Biotin is an active part of four different carboxylase enzymes in the body, and is responsible for the fixation of carbon dioxide (carboxylation). These enzymes have important functions in the metabolism of energy, glucose, lipids and some of the amino acids.

Folic Acid (Folacin)

Folic acid is the compound pteroylmonoglutamic acid. Additionally, there is a large group of modified folic acid compounds, referred to collectively as folates. At one time, PABA was believed to be essential in the diets of vertebrates, but it has since been determined that if the requirement for folic acid is met, PABA provides no additional benefit.

Folates are generally widely distributed in foods and are present as the polyglutamic derivatives of folic acid. These are converted by hydrolysis to free folic acid and absorbed by both an active transport system and passive diffusion in the duodenum and jejunum. The absorption process is only moderately efficient (<50%).

Folic acid's primary metabolic role is in the transfer of single-carbon moieties in a wide variety of reactions. This function is particularly important in amino acid metabolism, in the bioconversion of amino acids and in the biosynthesis of nucleotides.

Because of folic acid's requirement in the synthesis of three of the four nucleic acids, a deficiency results in impaired cellular division and an alteration of protein synthesis. This is particularly noticeable in the young growing animal. Additionally, due to impaired cell mitosis in a deficient bird, females do not physiologically prepare for breeding, as noted by a lack of oviduct hypertrophy in the presence of estrogen. Further, there is an effect on normal red blood cell maturation, resulting in the characteristic macrocytic anemia. Similarly, deficiencies result in immune system impairment due to the effects on cell replication and protein synthesis. Folic acid is involved in the formation of uric acid, so there is an increased requirement when high-protein diets are provided. Folic acid is required for the production of white blood cells and a severe deficiency can reduce immunologic response through decreased WBCs or reticuloendothelial cells.

In some species, a deficiency of zinc has been found to impair the utilization of dietary sources of folic acid. A zinc deficiency decreases the absorption of folic acid because of impaired activity of the mucosal enzyme that creates an absorbable form of folic acid. Enzyme inhibitors are present in a number of foods such as cabbage, oranges, beans and peas (in the seed coat) and brewer's yeast. These inhibitors are generally destroyed by processing since they are heat-labile. Sulfa drugs (eg, sulfanilamide) may increase the requirement of folic acid since they will compete with structurally similar PABA in the bacterial synthesis of folic acid.

Vitamin C and iron may improve the bioavailability of folates in food.

Vitamin B_{12}

Vitamin B_{12} or cyanocobalamin is a product of bacterial biosynthesis and therefore must be obtained by consuming a bacterial source or animal tissues that accumulate the vitamin. The only exceptions are a few plants, such as peas, beans, spirulina and kelp, that may be able to synthesize minute amounts of this vitamin, although this accumulation is likely due to their close symbiotic association with bacteria.

Naturally occurring vitamin B_{12} occurs in the coenzyme form bound to protein. This complex is broken, primarily through the normal action of pepsin and trypsin. Free vitamin B_{12} is absorbed by the intestinal tract via an efficient active transport system involving a vitamin B_{12} specific-binding protein. At very high levels, simple diffusion occurs throughout the small intestine.

Most of the vitamin B_{12} in the body is found in the liver with secondary stores in the muscle. Lesser

amounts (but high concentrations) are contained in the pituitary gland, kidney, heart, spleen and brain. Vitamin B_{12} is stored efficiently, with a long biological half-life (approximately one year in humans).

Vitamin B_{12} is a critical component of a large number of metabolic pathways. It interacts with several other nutrients such as folic acid, pantothenic acid, choline and methionine. Similar to folic acid, most of the metabolic reactions of vitamin B_{12} involve single carbon units and are very important in the synthesis of nucleic acids and protein as well as carbohydrates and fats.

Like folic acid deficiencies, vitamin B_{12} deficiencies result in an impairment of protein synthesis causing failure or delay of normal cell division. This affects growth rate and feed intake, may result in nervous disorders and poor feathering, perosis, anemia, ventricular erosion and fat accumulation in the heart, liver and kidneys. Deficiency of vitamin B_{12} can also create a folic acid deficiency.

Some research indicates that vitamin B_{12} absorption is decreased in the presence of protein, iron or vitamin B_6 deficiencies or by dietary tannic acids.[23]

Choline

Natural sources of choline are widely distributed and occur primarily in the form of phosphatidylcholine (lecithin). It is also present as free choline, acetylcholine and in other phospholipids, such as sphingomyelin.

Phosphatidylcholine is readily hydrolyzed in the intestinal lumen and is absorbed by the mucosa via both active transport and passive diffusion, depending on luminal concentrations. Of the free choline that is ingested, up to two-thirds may be metabolized by intestinal microorganisms. The remainder is absorbed intact. Choline is found in all tissues as a part of the membrane phospholipids, with the greatest concentrations in organs such as the brain, liver and kidney (as phosphatidylcholine and sphingomyelins).

Choline can be synthesized in the body but in the avian species tested to date, it cannot be synthesized at high enough levels to meet the needs of the young bird. It appears that with age, the synthetic abilities improve, thereby meeting most of the body's needs. This is especially true when choline-sparing compounds such as methionine, betaine and myo-inositol are present in the diet. Dietary sulfates can also have a sparing effect on choline by helping to spare methionine.

Choline has four general metabolic functions: 1) As a component of phospholipids, choline is an essential part of the cell membrane and is required for maintaining cell integrity; 2) Choline is required for maturation of the cartilage matrix of bone; 3) Choline is involved in fat metabolism of the liver by promoting fatty acid transport and utilization, and is therefore necessary to prevent hepatic lipidosis in the normal bird; 4) Choline is acetylated to form the neurotransmitter acetylcholine.

Because of their interrelated functions, the requirement for choline is dependent upon the levels of folic acid and vitamin B_{12} available to the animal. Excess protein increases the choline requirement, as do diets high in fat. Dietary levels of choline chloride (the normal supplemental form) should not exceed twice the requirement.

Vitamin C (Ascorbic Acid)

Vitamin C has not been demonstrated to be a required nutrient for any of the avian species, except for a few highly evolved, largely frugivorous species (Willow Ptarmigan and Red-vented Bulbul).[10] Vitamin C is easily manufactured in birds with the enzyme L-gulonolactone oxidase. This enzyme works on a substrate generated from glucose producing an intermediate that is then converted to L-ascorbic acid. This process occurs in the liver in most passerine species, and in the kidneys of psittacines and other older phylogenetic orders of birds. Biosynthesis of ascorbic acid can be inhibited by deficiencies of vitamin A, E and biotin.

Vitamin C occurs in the forms of ascorbic acid and dehydroascorbic acid, with both forms having similar biological activity. Vitamin C is found in the highest concentration in fruits, vegetables (but not seeds) and organ meats (particularly the liver and kidney).

Dietary sources of vitamin C are absorbed by passive diffusion in those species that do not have a specific dietary requirement. Absorption appears to be relatively high when fed at normal levels. Decreased absorption occurs as the physiologic dose is exceeded. The highest concentrations of vitamin C are found in the pituitary and the adrenal glands followed by the liver, spleen, brain and pancreas. Vitamin C also tends to accumulate around healing wound sites. The metabolic functions of vitamin C are related to its ability to act in oxidation and reduction reactions. Its best understood role is in the synthesis of collagen, where it is involved in the hydroxylation of procollagen residues. Collagen, the major component of skin

and connective tissue and also the single most abundant protein in the body, is critical for proper cell structure and integrity. In species requiring vitamin C in their diet, the breakdown of this function produces the classic deficiency symptoms (scurvy, capillary fragility, gum and bone alterations and poor healing).

Vitamin C is also an excellent antioxidant, acting to neutralize free radicals that are produced in the body. Ascorbic acid can also regenerate vitamin E (the active lipid antioxidant).

Based on their scientific orders, evolutionary status and limited testing, psittacine and passerine birds appear to have no requirement for vitamin C. In other species with no specific requirement (eg, domestic poultry), there have been documented benefits of providing a dietary source of vitamin C to birds at certain stages of life or under certain conditions. Stressful conditions that have been shown to improve with supplemental vitamin C are: 1) dietary deficiencies of energy, protein, vitamin E, selenium or iron; 2) high production or high growth rates (the newly hatched chick has a slower rate of ascorbic acid synthesis); 3) management stresses, eg, handling, insecure environment, transportation, crowding; 4) extreme temperature variations from normal; 5) health stresses: fever and infection reduce blood ascorbic acid and diseases with liver involvement decrease synthesis while increasing overall requirement for ascorbic acid.[25] Supplemental ascorbic acid has been shown to increase total sperm production in turkeys[14] and improve broiler fertility and hatchability, due to decreased early embryonic mortality.[31]

Considering the normal stresses that companion and aviary birds experience, it seems reasonable that a supplemental source of vitamin C may be of some benefit during certain situations. This may be even more important considering that many birds lack proper diet and health care. Fresh food sources should be considered as the most important way to supplement the diet because of the vitamin's general instability in manufactured products.

Minerals

Minerals are essentially classified in one of two groups: macro minerals and trace or micro minerals. The macro minerals can be classified based on their use in the body. Calcium and phosphorus act primarily in the body's skeletal structure, while sodium, potassium and chlorine (along with phosphates and bicarbonates) function to maintain homeostasis in the body (acid/base balance and proper osmotic pressures). The required trace minerals are magnesium, manganese, zinc, iron, copper, iodine, selenium and, in certain situations, cobalt and molybdenum. These trace elements have their primary function as parts of enzymes, hormones or as enzyme activators. Additionally, in purified diets, there have been beneficial effects achieved by the addition of some of the other trace elements such as fluoride, nickel, silicone, tin, vanadium and chromium. These benefits have usually been seen only in sterile conditions with extreme environmental controls. At this time, they should not be considered as dietary essentials because of a lack of conclusive evidence regarding their essentiality and the poor understanding of their metabolic function.

As the normal digestion process breaks food into its components, the minerals are liberated, and the cationic elements are converted to chloride salts in the presence of gastric hydrochloric acid. Once in the intestinal tract, they are able to easily dissociate and be absorbed. There is also considerable complexing with other minerals or chelating agents. An example of this is the calcium and phosphorus precipitate that is formed by excess levels of these minerals while in the alkaline conditions of the small intestine. This complex can then adsorb manganese or zinc, causing excretion of the trace mineral, and subsequently, an increased requirement.

Mineral (particularly trace mineral) concentrations of foodstuffs are largely dependent on the original mineral source. Concentrations in plant products are dictated by the soil mineral content, while those of animal products are dependent on the diet consumed.

Calcium

Calcium is the predominant mineral in the body (approximately 1.5% of body weight) with primarily skeletal system containment. Calcium is also contained in the body fluids, where it plays an essential role in blood coagulation and membrane permeability, and maintains normal excitability of the heart, muscles and nerves. Several enzyme systems are also activated by calcium. Ionic calcium (Ca++) is the physiologically active form. Low Ca++ concentrations result in a decrease in electrical resistance and an increase in membrane permeability (to sodium and potassium) of nerve tissue, which causes hyperexcitability of neural and muscle tissue and can result in spontaneous fiber discharge.

Calcium absorption occurs predominantly in the upper small intestine by an active transport system involving a calcium-binding protein. This is regulated by the active metabolite of vitamin D_3 in response to low plasma calcium levels. A lesser amount of absorption also occurs in the lower small intestines through passive diffusion. High-protein diets and acidification of the intestines aid calcium absorption. Compounds such as phytate (in cereal grains), oxalates (in spinach, rhubarb and related vegetation) and phosphates will decrease absorption of calcium due to the formation of complexes. Similarly, high intestinal concentrations of free fatty acids (from very high-fat diets or because of impairment in fat digestion) will result in the formation of insoluble calcium soaps. Once absorbed, calcium is carried by the plasma as ionized calcium, protein-bound calcium and a small amount of chelated calcium (chelated with citrate and phosphate). Regulation of calcium metabolism involves parathyroid hormone, calcitonin and vitamin D_3 (see Chapter 23).

The calcium content of dried, fat-free bone is approximately one-third of the total weight, predominantly present in the form of calcium phosphate, with lesser amounts of calcium carbonate. In egg shells, calcium carbonate is the structural compound. For maintenance of proper bone tissue, the calcium to available phosphorus ratio should be approximately 2 to 1. A range of 0.5:1 to 2.5:1 can be tolerated. The further this ratio deviates from the ideal level, the more critical proper vitamin D_3 levels become. Vitamin D_3 is essential to regulate absorption and metabolism of calcium and phosphorus, especially when dietary levels are unbalanced. During growth of most species, ratios of approximately 1:1 are required to support adequate growth, 1.5:1 to maintain normal serum calcium and phosphate and alkaline phosphatase values, and 2:1 to achieve maximum bone density. High egg-producing hens (poultry) may be provided with dietary ratios in excess of 10:1 in order to support daily shell production. This must not be confused with the significantly lower needs of a hen (most companion birds) that produces a periodic clutch of eggs. This ratio is based on the amount of phosphorus available to the bird, not the total phosphorus content of the diet. As much as 70% of the phosphorus in certain ingredients can be present in a form that is unavailable to the bird. Therefore, an estimation of the diet's available phosphorus is essential in order to balance these two minerals.

Levels of over 1.0% calcium in the diet have been observed to decrease the utilization of proteins, fats, vitamins, phosphorous, magnesium, iron, iodine, zinc and manganese. Where there are marginal intakes of one or more of these nutrients, increased calcium intake can induce a deficiency state.

Phosphorus

In addition to being an important bone constituent, phosphorus is also a component of proteins, carbohydrates and lipid complexes that perform vital functions in the body. Phosphorus has a wider range of biological functions than probably any other element.

Phosphorus is widely distributed in nature, occurring as phosphates, orthophosphoric acid salts and organophosphates. Absorption of phosphorus in the orthophosphate form takes place primarily in the duodenum, with efficiency of adsorption being dependent on the metabolic requirement and affected by a number of factors such as its source, calcium:phosphorus ratio, intestinal pH and dietary levels of vitamin D, potassium, magnesium, manganese, iron and fat. Once absorbed, it is readily incorporated into bone and other tissues, with bone acting as the metabolic reservoir. Like calcium, circulating levels are regulated by parathyroid hormone and calcitonin, with plasma levels being inversely related to plasma calcium levels. Excretion of excess amounts of phosphorus takes place primarily through the kidneys.

In plant sources, phosphorus is often complexed with phytin, making it unavailable to all monogastric animals because of their lack of the enzyme phytase. When the diet consists predominantly of high-phytin foods, phytase-producing microorganisms may colonize the gastrointestinal tract and provide a modest improvement in the phosphorus availability. This is low, however, because the amount of phytate hydrolysis is limited by the rapid transit time through the avian gut, with poor absorption of the liberated phosphorus due to hydrolysis occurring primarily in the distal portion of the tract. As a general rule, phosphorus from animal products or inorganic supplements is almost completely available, while that from plant sources is generally considered to be approximately 30% available. These typical values can be used to generate an estimation of the available phosphorus in the diet.

When kept within the range of acceptable calcium:phosphorus ratios, moderately higher phosphorus does not create a significant problem. Amounts of phosphorus outside these acceptable ratios, however, will cause decreased performance and will interfere with the absorption of calcium from the gastrointes-

tinal tract. Additionally, high serum phosphorus levels can induce nutritional secondary hyperparathyroidism by suppressing serum calcium, resulting in stimulation of the parathyroid. In some species, increased excretion results in the development of urolithiasis. It is estimated that the level of available phosphorus, when balanced with calcium and vitamin D, can be supplied at approximately two times the requirement without adverse effects. Amounts greater than this level have resulted in increased mortality in a number of species.

Magnesium

Most of the body's magnesium is present in the bone, complexed with calcium and phosphorus. In the body fluids, the majority of magnesium is found in the blood cells, whereas calcium is predominantly associated with the plasma. Magnesium (like potassium) is found at the highest concentrations in soft tissue cells (intercellularly) such as liver, striated muscle, kidney and brain. In these tissues, magnesium serves as an activator for many of the enzymes involved in phosphate transfer and metabolism.

Magnesium is absorbed in a manner similar to calcium and phosphorus, with the efficiency of absorption dependent on the concentration in the gastrointestinal tract. With low levels, absorption tends to be very efficient, with decreasing efficiency as levels become higher. Most of this mineral appears to be absorbed in the small intestine. Levels of calcium and phosphorus in a diet affect the magnesium requirement, with high levels of either of the former tending to increase the requirement of the latter.

Magnesium generally functions in enzyme systems by catalyzing the reaction through the formation of a metal-enzyme complex, where the magnesium ion is loosely associated with the enzyme.

Potassium

Potassium is widely distributed in most foods, making deficiencies unlikely in adult animals. Unlike sodium, potassium is located primarily intracellularly, and is found at the highest levels in muscle, erythrocytes, brain and liver. Potassium is the primary intracellular cation, affecting acid-base balance and osmotic pressure. It is also involved in protein biosynthesis, cellular uptake of amino acids and as a cofactor in a number of enzyme systems. In the extracellular fluids, potassium reduces muscle contractility and induces relaxation, therefore having the opposite effect of calcium.

Potassium is absorbed predominately in the upper small intestine by passive diffusion, although absorption occurs to a lesser extent throughout the entire intestinal tract. Excess potassium is excreted through the kidneys under the influence of sodium and aldosterone levels. Severe stress can create hypokalemia because of an increase in renal potassium excretion caused by elevated plasma proteins. This hypokalemia can be extended during the adaptation to the stress as potassium stores are replenished in the muscle and liver.

The minimum requirement of potassium is influenced by the dietary levels of sodium, total chlorides, the energy content of the food and possibly the protein content.

Potassium toxicity is not likely due to the capacity of the unimpaired kidney to excrete large concentrations of the mineral. Excesses of three times the required amount have presented no problems in avian species.

Sodium

Sodium is the primary cation of the extracellular fluid, and is predominantly responsible for the regulation of the body's acid-base equilibrium by associating with either chloride or bicarbonate. Sodium is critical in the maintenance of the proper osmotic pressure in the body, protecting against excessive fluid losses. It is also involved in the transmission of nerve impulses, the permeability of cells and acts to inhibit mitochondrial enzyme systems that are otherwise activated by the intercellular ions, potassium (K+) or magnesium (Mg++).

Sodium salts are readily and efficiently absorbed by the body (primarily in the ileum), and can be efficiently conserved when the dietary supply is limited. Excess sodium, on the other hand, can be efficiently excreted through the kidneys by an increase in water consumption. Sodium retention is regulated by the adrenal hormone, aldosterone, which maintains proper plasma sodium levels and regulates sodium excretion.

Depending on the species, bone will contain between 25 and 50% of the total body sodium, which is bound to the inorganic matrix of the bone. The rest of the sodium is predominantly found in the extracellular fluid of the body, with highest concentrations in plasma, nervous tissue and muscle tissue. Nearly all the species investigated show a sodium plasma content of 3.3 to 3.4 g/l. Total body sodium content is similar in all animals, ranging from 0.11 to 0.13%.

The body has a specific mechanism for concentrating sodium in the extracellular fluid while concentrating potassium in the intracellular fluid. This high concentration gradient is maintained by the sodium-potassium/ATPase pump system. This system transports Na+ out of the cell, while transporting K+ in. This is an energy-requiring process that uses intracellular ATP as an energy source. Intracellular sodium activates the enzyme system, which uses Mg++ as a cofactor.

In the presence of chronic renal disease, especially when the animal is in acidosis, sodium levels are depleted because of poor tubular resorption and the use of sodium for the buffering of acids. Both renal disease and diarrhea may cause sodium depletion. This will often be followed by a rapid loss in weight due to dehydration.

Moderate increases in dietary sodium are relatively nontoxic providing adequate (low sodium) water is provided for renal excretion. Levels of five to ten times the requirement can be provided before there is a decrease in growth and loss of appetite in a young bird. At all stages of life, there will be a considerable increase in water intake resulting in looser droppings. Higher levels of sodium intake result in poor feathering, polydipsia, polyuria, nervousness, edema, dehydration and mortality.

Chlorine

Chlorine, metabolically active as the chloride ion, is closely associated to sodium in foods, in the body and in metabolic processes, and both will be excreted under the same conditions. Chloride is also essential in maintaining the body's acid-base balance, osmotic pressure and water balance. It is a component of the hydrochloric acid that is produced by the body as a primary gastric secretion. In the body, chloride is concentrated in spinal fluid and blood.

It is critical to evaluate the overall dietary sodium, chlorine and potassium levels together. In the diet there must be a balance of the total sodium and potassium content with the total chloride and sulfate content in order to maintain the proper acid-base balance in the blood. This becomes particularly important with the addition of relatively high levels of dietary supplements that are complexed with one of these ions (such as high levels of choline chloride or lysine hydrochloride), especially when the chloride or sulfate form increases the acidity of the diet.

Toxicity of chloride alone is seldom a problem, but excess dietary chloride (in conjunction with unbalanced cations) can result in cartilage anomalies in chicks. Correction of the acid-base balance alleviates this symptom.

Essential Trace Minerals

Iron

The functions of iron in the body are almost entirely related to the cellular respiration processes. In the body, iron exists as heme iron (which is chelated with a porphyrin group) and non-heme iron (which is found bound to proteins). Iron is present in the body at approximately 50 to 100 parts per million.

Iron is unique in that body reserves are conserved and recycled very efficiently with negligible excretion. The primary method of iron depletion is through bleeding. Any iron found in the feces is generally a result of unabsorbed iron from the diet. Because the body has no normal pathway for the excretion of excess iron, intestinal absorption is carefully controlled to prevent accumulation. Under normal situations, the absorption of iron from the gastrointestinal tract is poor, however, if the body becomes marginally deficient, the absorption is improved until the situation is corrected.

Normally, heme iron (from animal sources) is considered to be approximately 20-25% available to the animal, while nonheme, vegetative sources are usually less than 5% available. Additionally, the nonheme iron present in most foods is in the ferric form (Fe^{+++}), which is poorly absorbed. This can be present either as the free ferric ion or loosely associated with an organic compound. In order for proper absorption to take place, ferric iron must be reduced to the ferrous state (Fe^{++}). In the ferrous form, iron becomes more soluble and therefore absorption is improved. This can be accomplished by any reducing compound in the food, with ascorbic acid being one of the more efficient agents. Proteins also enhance absorption, probably by forming soluble amino acids chelated with the iron. Additionally, absorption may be improved by dietary organic acids (eg, citrate, lactate), fructose and vitamin E, as well as by diets low in phosphorus. Normal gastric secretion is necessary to solubilize iron and increase its availability. Total iron absorption from a variety of mixed diets has been observed to range from 2 to 20% across a number of species. The deficient state can increase these efficiencies by over three-fold.

In the normal, healthy animal there should be no toxicity symptoms from moderate excesses of dietary

iron because of the efficient controls the body has over iron absorption and metabolism. Excess iron can reduce performance, however, by creating interactions with a number of nutrients. Examples of this would be reducing phosphorous absorption through the formation of an insoluble iron phosphate compound or the adsorption of vitamins or other trace minerals, preventing absorption into the body. Chronically high iron intake can result in elevated blood levels, increased tissue concentrations (especially of the liver and spleen) and the eventual development of hemosiderosis and possibly hemochromatosis (skin pigment changes). Liver damage and sometimes pancreatic fibrosis occur in this condition, which in other species is most often due to a genetic anomaly (extremely efficient absorption). Iron storage diseases have been predominantly seen in mynahs and toucans, possibly being caused by a combination of genetic and dietary factors.[16,49]

Copper

The copper content in the bodies of most species is approximately two parts per million. The largest concentrations are in the liver. Copper is a component of several proteins, enzymes and certain natural pigments. It is required for hemoglobin synthesis, proper collagen (bone), elastin and keratin formation and maintenance of the nervous system.

Copper is well distributed in normal feedstuffs, so the likelihood of a copper deficiency on a mixed, practical diet is not great. Availability can be affected by the chemical form as well as the copper status of the animal, with more efficient absorption occurring when the animal is deficient or when the dietary concentration is low.

Zinc

Zinc is critical to the animal for growth, reproduction and normal longevity because of its involvement in tissue repair and wound healing. It functions in a number of reactions in protein and carbohydrate metabolism, cell division and mucopolysaccharide formation. It also functions in the mobilization of vitamin A from the liver. Zinc is required in a large variety of enzymes, either as an enzyme activator or as a component of certain metalloenzymes.

Zinc is widely distributed in foodstuffs, but generally is not present in adequate supply to fill the needs of the young or producing animal. In plant sources, phytate can actively bind with inherent zinc, producing varying degrees of zinc availability. Some high-phytate ingredients, such as wheat bran or buckwheat, may also bind zinc from other dietary sources. Additionally, zinc requirements are increased with added calcium in the diet.

Manganese

Manganese is present in most plant sources at moderate to poor levels. Compounding the problem of marginal levels is its relatively poor availability. The formation of chelates appears necessary for the proper absorption of manganese, which occurs throughout the intestinal tract. Bile salts are important in the absorption, excretion and reabsorption of this mineral. Recycling appears to occur several times before the mineral is finally excreted in the feces. In addition to the constantly recycling pool in the intestines, the primary storage sites for manganese are bone, kidney and liver. High concentrations are also seen in the pituitary and pineal glands. At the cellular level, the mitochondrion is the principal site for manganese uptake. With high dietary intakes, the skin and feathers will accumulate large quantities of this element.

Manganese has several functions in the body. It is essential for normal bone structure, being required for the formation of the organic bone matrix through involvement in the synthesis of chondroitin sulfate (at two separate points in its synthesis).

Iodine

Iodine's sole metabolic function is for the biosynthesis of the thyroid hormones. Thyroid hormone functions to control the rate of energy metabolism in cells. In this way it influences growth and tissue differentiation or maturation, with resultant effects on other endocrine glands, neuromuscular function, skin and tissue development and nutrient metabolism.

Iodine is easily absorbed from the gastrointestinal tract in the reduced iodide state. Iodide is transported by loose attachments to plasma proteins. A large portion of the ingested iodide is excreted by the kidney, while the remaining amounts are taken up primarily by the thyroid gland. Small amounts can also be found in the salivary glands, stomach and other locations. The iodide uptake by the thyroid is stimulated by thyroid stimulating hormone (TSH) produced by the pituitary (see Chapter 23).

Moderate increases in dietary iodine do not present a problem because of the efficient excretion process in the body. Prolonged intake of high dietary levels of iodine causes reduced iodine uptake by the thyroid with antithyroidal or goitrogenic effects. Levels of

about 1000 times requirement are required before effects on growth, egg production or hatchability are seen in poultry.

Selenium

To a greater degree than other trace minerals, selenium content in foods is largely dependent upon the soil selenium content in which they were grown. Fortunately, some of the most productive agricultural states (for livestock foods) are in regions with adequate-to-high selenium soils (namely, the Great Plain states).

Because the consumption of "accumulator" plants by grazing animals caused blind staggers and death within a few days, this mineral was originally considered to be only toxic. Its essentiality was not recognized until 1957, when it was accidentally found to prevent liver necrosis in rats and exudative diathesis in chicks when studies were being conducted to determine minimum toxic intake levels.

The absorption of selenium is dependent upon its chemical form. The bioavailability of selenium in most plant products ranges from 60 to 90%, while in animal products it is less than 25%. Of the different chemical forms of selenium, selenite has the highest availability followed by selenomethionine, selenide and lastly, elemental selenium. The efficiency of absorption is also dependent upon the levels in the diet, with absorption higher during a deficiency situation. Once absorbed, selenium is carried in association with plasma proteins and transported to all tissues. Although selenium is distributed throughout the body, it is found in the highest concentration in the kidneys, pancreas, pituitary and liver. Other then the enzymatic form, there are no stores of selenium, making the selenium pool quite labile.

Selenium's metabolically active form is as a component of glutathione peroxidase. This enzyme is located in the aqueous phase of the cell and is responsible for oxidizing reduced glutathione, allowing it to act as a biological antioxidant. Reduced glutathione serves to protect membrane lipids and other cellular constituents by preventing oxidative damage by neutralizing any hydrogen peroxide and fatty acid hydroperoxides that are formed in the body.

Vitamin E and selenium are interdependent, each having the ability to spare the other. Selenium is important to the vitamin E status by preserving pancreatic integrity, maintaining normal fat digestion, micelle formation and vitamin E absorption. Selenium, as a part of glutathione peroxidase, destroys peroxides and prevents them from attacking the polyunsaturated fatty acids in cell membranes. This reduces the amount of vitamin E that is required to maintain the integrity of these membranes. Finally, selenium helps retain vitamin E in the blood plasma.

Conversely, vitamin E spares selenium by helping to prevent selenium loss from the body through its own antioxidant properties. By limiting the chain reaction destruction of membrane lipids, vitamin E minimizes the production of hydroperoxides, which would later require glutathione peroxidase to neutralize.

It is through these methods of sparing one another that selenium and vitamin E work together in the prevention of exudative diathesis. This disease is characterized by generalized edema (first appearing on the breast, wing and neck) due to abnormal capillary permeability, resulting in the leaking and accumulation of fluid. This is accompanied by decreased growth, leg weakness and mortality. Exudative diathesis has not been shown to occur except when both vitamin E and selenium are deficient.

The protection of lipid membranes from exposure to free radicals is not only important for the cell membrane, but also for the membranes of the mitochondria and microsomes. Because these act to both fuel and protect the cell, it is necessary for adequate vitamin E and selenium to be present for the cell to maintain its defense mechanisms.

CHAPTER

4

Perspective on Parrot Behavior

Greg J. Harrison

Veterinarians who treat companion birds must be knowledgeable about not only avian medicine and husbandry, but also behavior. Every year many birds are euthanatized, sent to zoos or breeding facilities, released, abused or ignored because a client is not able to tolerate or change a bird's abnormal behavior.[1,7] Fortunately, most companion birds are loving, valued family members that are well adjusted to a captive environment. In order to understand the difference between a well adapted bird and one with behavioral problems, dozens of variables must be analyzed, including species, age, past history, health, diet, environment and the client's lifestyle.

Parrots appear to have a complex communication system. Vocalizations were found to be distinct among pairs of Puerto Rican Amazon Parrots and in parrots within Peru's Manu Biosphere Reserve. Differing vocalizations were used to signal danger, food or to greet another bird.[15,31]

To understand the behavior of companion birds, it is necessary to remember that many captive-bred birds are only one generation removed from the wild and thus retain many of the characteristics of their free-ranging conspecifics. This, coupled with their relatively high level of intelligence, can make them challenging pets.

Some species of free-ranging parrots have been noted to spend all waking hours flying, eating, preening and vocalizing with their mates. For such intensely social birds, life in an enclosure with no companionship must be the ultimate "psychological torture."[15] It has been suggested that large birds, especially macaws, should never be kept as a single bird unless the client can meet their extensive needs for social interaction.

Behavior in the Wild

From Hatching to Weaning

Even before hatching, communication appears to occur between parent and embryo. Some parents segregate infertile eggs, sometimes discarding them from the nest. Incubation studies have shown that hatching may be synchronized and that pipping sounds may actually encourage the hatching of other chicks.

The newly hatched chick is primarily concerned with staying warm and eating. The parent bird will use its beak to stimulate a feeding response by gently stroking the soft caudolateral part of the chick's beak. Some chicks (eg, Lady Gouldian Finches) have brightly colored spots in the roof of the mouth that are thought to strengthen the parents' feeding instincts. The neonate gapes (opens the mouth fully), and the parent positions its beak so that not a morsel of food is lost during transfer. In harmony with the neonate, a pumping rhythm is established as the parent regurgitates food into the chick's oral cavity. Clutch mates often pump on each other.

It has been shown that parents tend to feed the strongest beggar first. If food is in short supply, this pumping activity tends to weaken smaller chicks, ensuring the survival of stronger clutchmates. It has been estimated that as many as 80% of a clutch of neonates from free-ranging parents may not survive past the first few days or weeks of life. In nesting macaws, it was found that out of 20 nests, 7 failed completely, and only 15 to 25 young were raised from 100 pairs of nesting birds.[15]

As the neonate matures, the sound of the parent at the nest opening will stimulate begging sounds, first hissing and later crying. When the eyes open, the visual areas of the brain begin to map who the bird is and what it accepts as normal. This process is closely associated with the pin feather development. If the bird is in a nest and experiences only its natural parents, it "imprints" as that type of bird. It is usually quite robust and carefree about life up to that point, but once it has imprinted, strange objects may cause it to freeze in alarm.

As the chick approaches weaning, strange sights cause cries of fear and often panic behavior (eg, fluttering, thrashing, flipping backwards). Macaw neonates are particularly prone to flip onto their backs when disturbed. The parents start to ignore the chicks begging to be fed, and an urge to exercise the wings starts to override the desire to be fed. Wing exercise results in a loss of weight and toning of muscles in preparation for sustained flight. The trim lines of the adult replace the bulgy abdomen of the infant, and the neonate starts to fly.

Once the bird leaves the nest (fledges), it becomes versed in the flock experience. Weaning is nearly complete as the parents feed larger, more natural sizes of food, often presenting them to the mouth rather than placing them in the pharyngeal area. In some cases, food for the neonate is placed on the nest or perch to stimulate food gathering behavior. The chick will model its eating habits after those of the parents.

In one field observation of a trio of Black Cockatoos, the parents would fly from branch to branch tearing open pine cones one after the other, ignoring the constant cries of the fully sized and adeptly flying youngster. After 30 minutes of begging and crying, the neonate finally ingested the edible parts of several pine cones unassisted. In some species, this stage of weaning is complete within weeks, while with others, it may take up to a year.

Flock Socialization

As juvenile parrots mature in a flock, they become socialized. If the leader moves, the flock moves. Free-ranging macaws have been observed congregating in large numbers in the trees around a clay lick and waiting for the first bold pair to move onto the ground. The birds then squabble to secure an ideal position on the ground, while an alert bird stays in the tree tops as a lookout. At the slightest hint of danger, the sentry "gives an exceedingly loud alarm squawk, where upon all the parrots take off".[15] Young parrots also learn to submit to the leader. If they try to share the leader's food or perch they are bitten and chased away.

The White-fronted Amazon Parrot was studied over a period of two years to map the normal social behavior patterns termed playing.[13,29] Those behaviors deemed strictly "play" included play solicitation (moving into the other bird with head and body lowered), play biting or play fighting (slowly and gently biting the tarsi and toes of each other, and foot clawing — opening and closing the raised foot directed at the opposing bird.

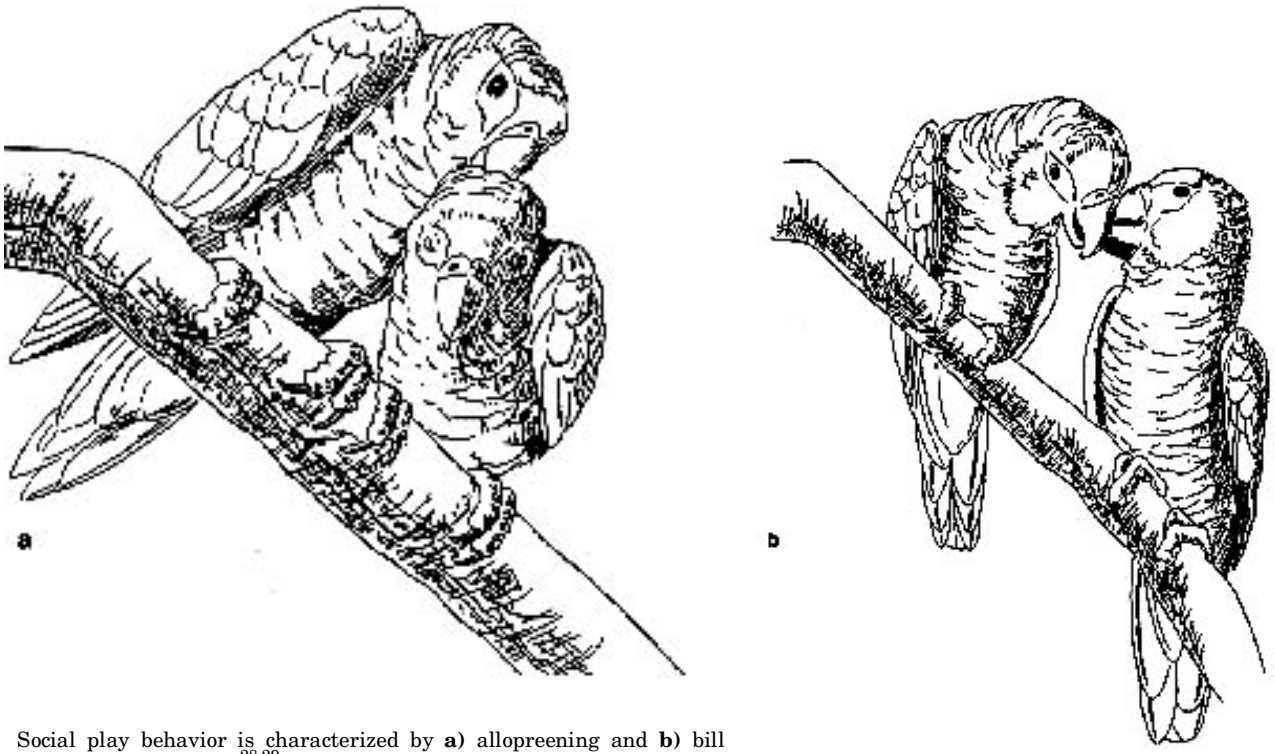

FIG 4.1 Social play behavior is characterized by **a)** allopreening and **b)** bill nibbling (modified from Skeate[28,29]).

Other play behaviors were associated with pair bonding and included allopreening (grooming one another's feathers), bill nibbling or gently locking bills while flicking tongues together, and pseudo-copulation (Figure 4.1). Other play behaviors were considered agonistic and included foot lifting, attack sliding and neck stretching. True aggressive behavior consisted of rapid jabs of the beak, usually directed at the head.

Courtship and Breeding

Courtship activities initially involve allopreening (see Color 8). In Amazon parrots, lovebirds and the genus *Melopsittacus* the preening is confined to the head and neck region, while in *Aratinga*, *Brotogeris*, *Ara* and *Cacatua* the area preened includes the head, wings and tail.[13,15] Solicitation is performed by lowering the head towards the mate and assuming a ruffled appearance (Figure 4.2). As a pair bond is formed, the two birds begin traveling together and sleeping side by side. Males feeding females helps to develop this bond, but is not considered a sexually motivated activity because it occurs year round in some Amazon parrots, conures, lovebirds and Grey-cheeked Parakeets.

An older juvenile male (eg, Amazon parrots) may court submissive males until he is old enough to court an adult female in breeding condition. After several years of practice, the juvenile develops the courage to challenge a dominant male. As breeding season approaches, the dominant males establish their own territory on the perching sites and chase other birds away. The males begin eating less and the females, more. The female is often fed by the male.

Posturing for copulation begins with the female fanning her tail, leaning forward and making various vocal sounds. Mounting attempts by the male occasionally end in rolling and what appears to be fighting until finally the female allows the male to complete copulation for several days in a row. Amazon parrot and macaw males stand to the side of the soliciting female, placing one foot on her back (Figure 4.2). In cockatiels, lovebirds, conures, lories and *Brotogeris*, the male stands with both feet on the female's back.

The pair chooses a nest site and becomes increasingly protective of the territory. Some birds (eg, Amazon parrots, macaws, Sun Conures and occasionally cockatiels) will fly at and attack intruders. In the case of most Amazon parrots, no other female is

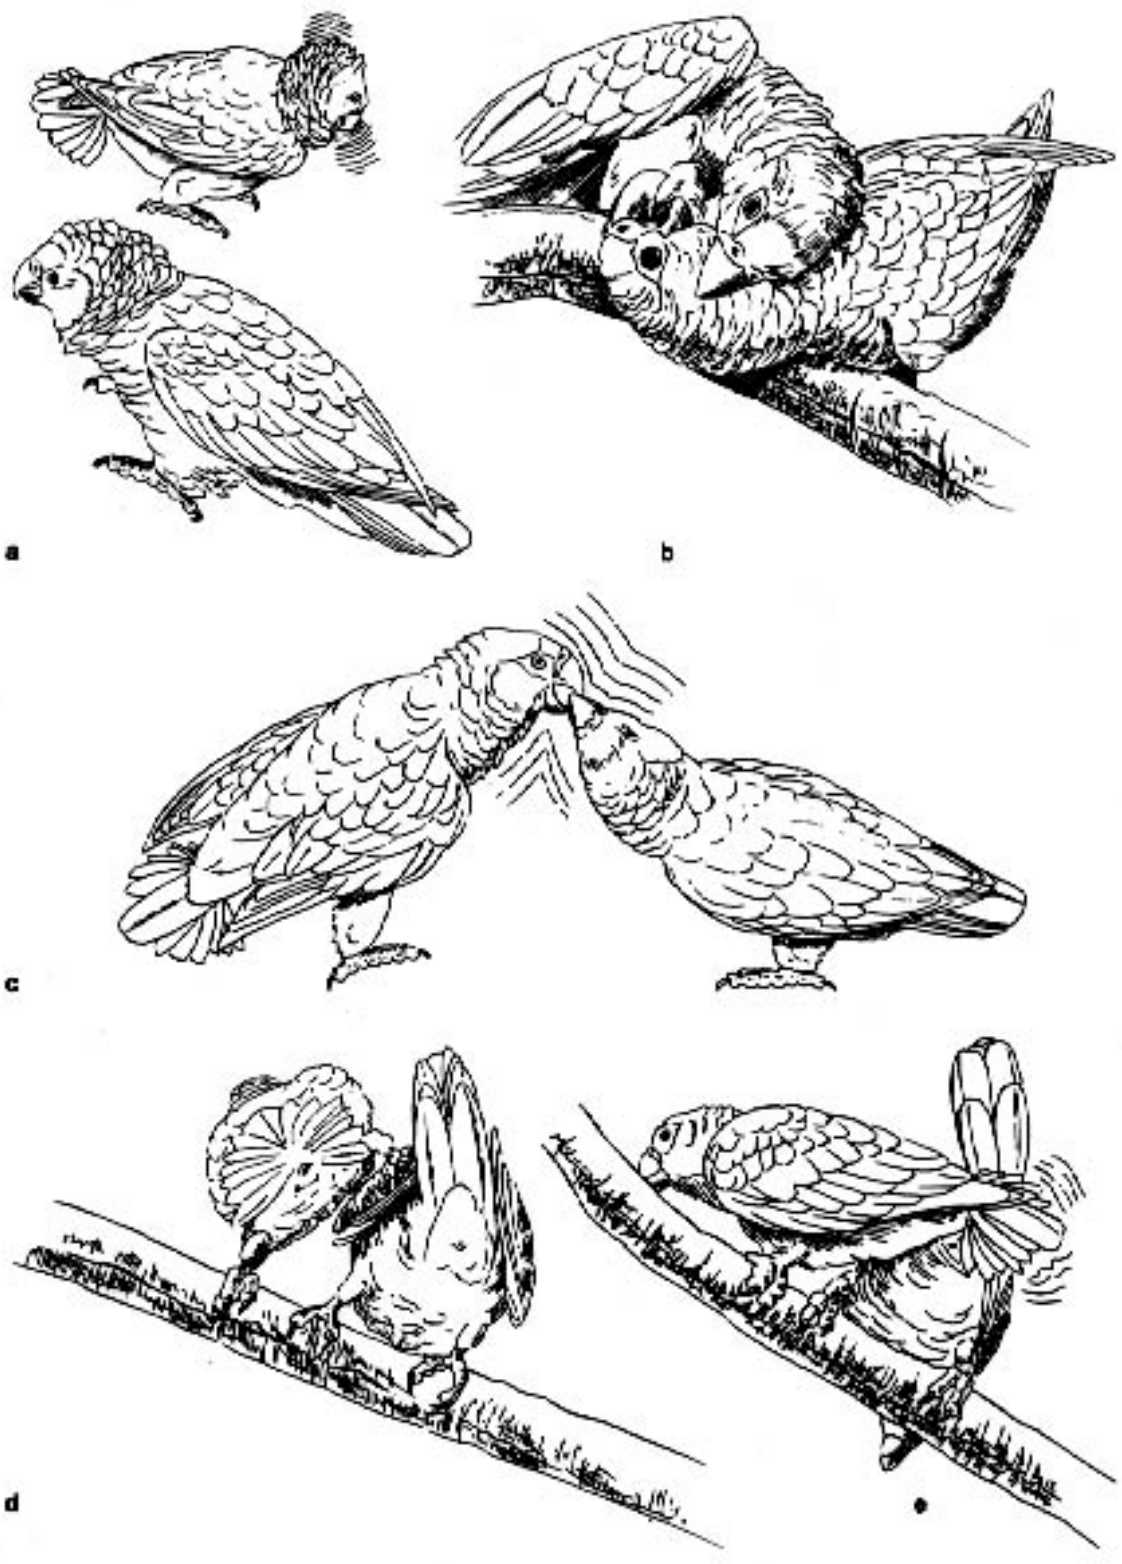

FIG 4.2 **a)** Sexual solicitation is characterized by lowering the head toward the mate and assuming a ruffled appearance. **b,c)** Allopreening and the male feeding the female are indications of a successful pair bond. **d,e)** During copulation, Amazon parrot and macaw males stand to the side of a soliciting female and place one foot on her back (modified from Skeate[28,29]).

allowed in the area, while in some species of cockatoos (eg, Moluccans), conures and macaws other females may approach the nest area.[31] Other species such as Monk Parakeets and Queen of Bavaria Conures are communal nesters, with several pairs assisting in nest building. In the case of macaws, conures and cockatiels, both genders incubate the eggs, whereas male Amazon parrots seldom go in the nest.

Many aviculturists believe that the sounds of one pair of birds courting and mating act as a stimulus to cascade breeding activity among a group of aviary birds. Some cockatoos seem inhibited by the visual presence of other birds, while limited visual interaction and opportunities for simulated combat are considered stimulating to others (Amazon parrots).

Some birds become obsessed with driving competitive birds out of their territory and breeding does not occur. This competitive behavior has also been noted in free-ranging birds when the number of birds in a flock exceeds the carrying capacity for an area. The Puerto Rican Amazon Parrot has lost so much habitat that the breeding birds must heavily compete for nest sites. This competition has been shown to prevent a pair from breeding. In addition, life-threatening physical injuries may occur from any territorial defense interactions.[32]

In the case of large macaws, the flock creates a buffer zone with the non-breeding birds on the fringes of the territory to warn against intruders. Several pairs of birds are involved in what appears to scientific observers as preparation of the nesting area, and only one out of several pairs breeds at any one time. Estimates of only one-third of a macaw flock breeding during any one season have been made. Thus, the number of birds in a macaw flock may be important to breeding success, and removing adult birds from an established breeding group may be extremely disruptive to other pairs within the flock (aviary).[15]

During incubation, some birds exhibit an aggressive walk, which is interpreted as an intraspecific threat display. Amazon parrots, pionus, conures, lories and Hawk-headed Parrots have been observed performing this parade-like walk.

It is commonly believed that some birds such as Amazon parrots mate for life, but this theory does not always prove correct. Free-ranging male Amazon parrots have been noted to challenge a nesting male, drive it away and then breed with the female.[32]

In a group of breeding cockatiels, one male was found to incubate eggs, while a second male would guard the nest and help feed the young. Both males would take turns breeding the female with one male preening the hen while the other male was involved in copulatory activity.

Companion Bird Behavior

Birds have been shown to be capable of discrimination, tool use, numerical competency and problem solving involving simple labeling and intermodal associations. They have further been shown to be able to transfer learned information and thus are considered to have abstract thought. An excellent insight into avian intelligence and learning ability is presented by an African Grey Parrot that has been shown to comprehend certain number-related concepts at a fairly advanced level.[18,19]

One companion bird was observed to cache food in the folds of its enclosure cover. A Blue and Gold Macaw learned to smack a stick of wood on the table, imitating the owner in an effort to discourage the house cat from coming near its enclosure.[12] A Boat-tailed Grackle, after repeated unsuccessful attempts to kill a frog with its beak, was video-taped using a stick to impale and kill the frog. Free-ranging birds have been filmed using sticks to remove bugs from dead trees.

Hand-raising

Birds raised by human foster parents will imprint as people, not birds. As they mature, their natural instincts to choose a mate may cause objectionable behaviors (eg, feather picking, screaming) (Figure 4.3). An imprinted bird will spend all of its time attempting to drive unwanted individuals, other pets or objects out of its territory, while trying to find one chosen person with whom to mate.

Molding a companion bird's behavior should begin when it is a neonate. It should be raised in an area where there is lots of activity and opportunity for new experiences. It should be handled and fed by different people using a variety of feeding methods. Chicks that are exposed to different situations are more stable as adults. Chicks raised "en masse" in boxes

FIG 4.3 A diagnosis of psychological feather picking should be reserved for cases in which no other medical cause for the abnormality can be identified. Psychological feather picking is particularly common in African Grey Parrots but can occur in any species.

without a variety of socializing experiences will be less tolerant and more fearful of new situations as adults. These birds rarely enjoy handling or close contact with people.

Weaning is an important part of early training, and it is crucial that human foster parents understand that begging and whining are a natural part of the weaning process. Some birds, especially Umbrella Cockatoos and lories often go through a prolonged crying time as they approach weaning. Overindulgent clients can inadvertently teach the chicks that screaming, begging and throwing food will get the results they are seeking (eg, food or attention).

The weaning area should be free of perches, toys and other distractions so that the new food will be the entertainment. A flat plate covered with the formulated diet and several kinds of soft vegetables and fruit can be placed on the bottom of the enclosure. When the bird begins to reject hand-feeding, the midday feeding should be eliminated. As it begins eating more on its own, the other feedings can be gradually decreased in volume, with the evening feeding being the last to be eliminated.

When a healthy baby is refusing food but begging constantly, it is often overly client-dependent (eg, "spoiled"). In these cases, it may be necessary to have an experienced aviculturist complete the weaning process, because the chick will not beg so intensely from a stranger. Varying the type of feeding utensil (eg, spoon, syringe), adding small chunks of whole food to the formula, or gradually moving the utensil from the bird to the feeding dish may help. It is a common practice by some aviculturists to offer foods from the hand or mouth; however, it should be noted that as a bird becomes older it is capable of seriously injuring the lips or face of the feeder.

Preventing Behavioral Abnormalities

Successful weaning is only the beginning of molding the behavior of a companion bird. In order for the bird to recognize that it is a bird, not a human, it must understand its boundaries. Clear, consistent communication through words and actions will make the bird feel secure and realize that it is the follower, not the leader.

Herd and flock animals are guided by natural desires to lead or to follow. If a bird is allowed to lead, it will determine who can and cannot enter its territory. It may choose the person it perceives as the leader in the household, especially if that person is a good communicator of boundaries. It will also demand that certain foods or items be present in its territory. As it matures sexually, the demands increase and it becomes more and more frustrated, if allowed to lead.

Training

Model-Rival Training

Free-ranging parrots use other members of the flock as models for behavior. This natural learning process can be used by clients in a model-rival training program to teach birds what is and is not acceptable behavior.[12] This program involves the use of one per-

son as the trainer, while a second person acts as the bird's rival, and models both good and bad behavior.

For example, the goal of a training session for the African Grey Parrot, Alex, was to review and improve his pronunciation of the label "five." To accomplish this goal, two trainers, **A** and **B**, were used in a model-rival training program. The dialogue included:

- **A** (acting as trainer): "Bruce, what's this?"
- **B** (acting as model/rival): "Five wood."
- **A**: "That's right, five wood. Here you are.. five wood." **A** hands five wooden popsicle sticks to **B**, who begins to break one of the popsicle sticks apart in a manner similar to that of Alex.
- Alex: "I wood."
- **B** (now acting as trainer, quickly replaces broken stick and presents them to Alex): "Better."
- Alex: "No!"
- (**B** turns from Alex to establish visual contact with **A**.)
- **A**: "What's this?" (presents sticks)
- Alex (now acting as model/rival): "I wood."
- **B**: "Better." (Turns, then resumes eye contact): "How many?"
- **A**: "FIVE wood." (Takes wooden sticks.) "Five wood." (Now acts as trainer, directs gaze to Alex and presents sticks to him.) "How many wood?"
- Alex: "Fife wood."
- **A**: "OK, Alex, close enough. Fivvvvve wood. Here's five wood." (**A** places one stick in the bird's beak and the others within his reach.)[19]

Goals and Reinforcers

A list of goals for desirable behavioral attributes for a companion bird might include: be loving and gentle, be quiet, be clean, be willing to consume a balanced diet, come when called, stay where placed, allow wings and feet to be handled, get on a perch, be controllable and be house trained. Once the behavioral goals for a bird have been established, they can be taught by using positive reinforcers.

A primary positive reinforcer is any item or action that will stimulate a behavior to recur. Trainers have traditionally used highly desirable food items, praise or affection as primary reinforcers, but it has been suggested that the use of object rewards increases the speed of learning.[19] The bird is allowed to play with a variety of items until it chooses a favorite. That object is then used as a reward for that day's lessons. Using the same reward every day causes boredom and slows learning. In talking lessons, it is best to use the item being taught as the reward. For example, to teach the word "strawberry," a strawberry should be the reward.

The intensity and amount of interaction with the reinforcer, or the most desirable item of the day should be varied. The first positive response should elicit a large positive reinforcement, and each succeeding response would be a little less dramatic and much less time-consuming.

After choosing a highly desired item as a primary reinforcer, it is a good idea to also choose a secondary reinforcer. These are items or events that, through repetition, have become associated with the primary reinforcer. The advantage is that they can be interchanged with each other. For example, a sound such as a kiss, a bell, a whistle, or a clicker, can be given as a secondary reinforcer. Each time the primary reinforcer is offered, the bird develops a Pavlovian response to the secondary reinforcer. This is important because it is not always easy or appropriate to offer the primary reinforcer. The bird may be doing a series of actions and rather than stop to offer a primary reinforcer, the sound can be offered and the bird knows the desired action has occurred and is likely to repeat the performance.

Negative Reinforcement

A negative reinforcer is something that a bird is willing to work to avoid and can be used to diminish or extinguish unwanted behavior. Negative reinforcement should be used only as a last resort after the bird has successfully completed as much of the positive training program as it is able; it is the trainer's responsibility to make certain the tasks given the bird were not too difficult. Frequently, clients try negative reinforcement first, and the bird learns that negative actions get attention. Intelligent birds consider the negative reinforcers as a form of entertainment. Especially violent negative reinforcement may destroy the bird's will to learn and cause it to reach a permanent learning plateau. Birds that are frightened may behave, but they would not be expected to seek interactions with the client or enjoy learning.

As with positive reinforcement, negative reinforcement must be given at the exact time the negative event occurs. Immediately placing the bird in a small "timeout" enclosure on the ground is an effective negative reinforcement. Neither the traveling enclosure nor the regular enclosure should be used as a negative reinforcing area. A sturdy cardboard box works well. Other possible negative reinforcers include spraying the bird with water, leaving the room and scolding.

Verbal negative reinforcers should be presented fairly, using commanding, not violent, tones. Identifying certain shapes or colors the bird dislikes may be useful. Merely showing a disliked item from a nonthreatening distance at the moment a negative action is beginning may be a deterrent. Perhaps the use of a remote or voice-activated shocking perch would be effective for feather picking and screaming.

Initiating Training

When training a chick, a commitment of at least 15 minutes, three times a week, for three to six months is a minimum. Training sessions should be uninterrupted, and begin and end at the same time each day. They should be held in an unfamiliar place, away from the bird's play or living area. Training of juvenile birds should begin with simple, one-word commands given over and over to elicit a chosen response. The command must be the same each time, and the bird's response must be the same each time in order for the bird to receive reinforcement. Commands should be issued in a command tone that is sharp, louder than a normal talking voice and delivered with authority.

During the early part of training, the minimal effort on the bird's part must be rewarded, and every time the desired action is repeated it is reinforced. Timing of reinforcement is critically important. The reinforcing event must occur at the exact second that the positive action has been completed. This makes it easy for the bird to understand what is being reinforced and increases the possibility of a repeat performance.

After the desired behavior is established it is recommended to attempt two performances to get reinforcement, then three, four and so on until ten behaviors in a row are performed for one reinforcement. At that point, the reinforcement should be changed from a predictable schedule (ten behaviors = one reinforcer) to a random schedule. Thus, a reinforcer may require 10 behaviors one time and two the next. It takes a while to establish random scheduling, but once established it will produce the strongest performance.

Teaching Commands

In order to be good companions, birds should respond to a minimum of six or seven commands such as "come," "up," "stay," "wing," "foot," "hood" and "go potty."

Training should begin while the neonate is still being hand-fed and the pin feathers are just beginning to open. In order to teach the bird to come, a desired item should be presented to it while giving the command, "come." Beginning with a feeding utensil first thing in the morning often works well, especially if no food has been left in the enclosure overnight. The "stay" command should be taught second, while placing a hand in front of the bird in a stop-sign fashion.

With the bird already on a perch, the "stay" command should be given. While the trainer's hand remains in a stop-sign fashion, a second perch is presented to the bird. The "up" command is given and the bird is encouraged to step up onto the perch.

The "wing" command is accomplished by gently taking each wing from the folded to the open position. Repetition and reinforcement may be needed for ten to twelve weeks. By the time of the emergence of the first pin feathers, the bird should be able to lift its wing on command. Once fledging age is reached, the primary feather tips may be easily clipped one portion at a time by using the commands "stay" and "wing."

Likewise, "stay" and "foot" commands are taught for nail trimming. Over a period of weeks, the bird learns to present its foot and allow the nails to be filed.

For ease of mouth examination, "stay," and "tongue" commands are used. The bird can be taught to allow its tongue to be held for up to ten seconds.

By covering the head with a hood, most birds can be easily handled for nail and wing clips and even minor surgery. This has been shown to be an effective way of calming pionus parrots, cockatiels, conures, cockatoos, some Amazon parrots and macaws. A doll bonnet can be modified by stitching a length of cloth to the brim and inserting a draw string in the bottom edge, making a sort of bee keeper's bonnet. Towels and plastic trash liners have also been used successfully. The hood should be slowly introduced during play time, making sure it does not frighten the bird. Gradually, over several play sessions, the hood can be placed on the bird's head. Hooding time can be extended to accommodate long periods of time such as those that occur with travel. Hooding prior to anticipated times of stress (eg, visits to the veterinarian) is a good way to prevent fear reactions.

House Training

Many birds have a natural inclination to keep the nest clean. They will defecate over the edge or in an area away from the nest. Companion birds usually defecate when they are aroused first thing in the

morning. Other common times are when first picked up and every few minutes thereafter on a fairly predictable schedule. With some patience, ingenuity and reinforcement, most birds can be house trained. Each time the bird is picked up, it should be held over the "toilet" area and the "go potty" command should be given. Signs of impending defecation such as legs apart, squatting and leaning back are cues for moving the bird to the "toilet" and issuing the command. Some larger psittacine birds can be trained in a week, but smaller species make less obvious preparation for defecation and are somewhat more difficult. Nervous birds can be expected to go more often and should be presented with the opportunity to do so.

Diet Changes

The first step in changing a bird's behavior is a thorough physical examination to detect any subclinical disorders. It is difficult to change behavior in a bird that is ill. Included should be a blood panel for liver function and CBC, Gram's stain, possibly radiographs and cultures. If the bird is on a seed diet, the injection of vitamins, minerals and oral lactulose should precede diet change by three weeks.

For many large birds, offering a highly palatable diet alone for 24 hours is sufficient. If they refuse to eat, mixing the new diet in the old seed diet or adding a treat such as popcorn, fruit juice, cheese or other sweet or fatty items may help. Table food may also be mixed with the new diet for several days, and then gradually decreased. Frequently, the biggest obstacle in correcting an improper diet is the client. Most birds will switch to the new diet within five days if they are placed in a different environment separate from the client.

Many birds are so accustomed to seeds and the familiar surroundings in their enclosure, that adding anything new is stressful. A bird may sit on the opposite side of its enclosure for weeks after a piece of carrot or a new toy has been added. For these birds, a diet change is often more successful if food is not the only change made. The bird is placed in a box, aquarium, bath tub or travel enclosure with no bowls, toys or perches. The food is sprinkled on the floor of its new enclosure, and after several hours of walking on the food, the fear is gone. The natural picking curiosity returns and the food is eaten. Placing food over a mirror on the floor may also help. Use of a bird already on the diet as a model is often rewarding.[10]

A number of formulated diets are available today based on nutritional requirements of various companion bird species. Some are more readily accepted than others. As a general rule the extruded diets are more palatable than pelleted diets. Several studies have shown that birds tend to choose a diet most like the diet available in nature.[4,17,22,25] Subtle shades of black, brown, yellow and green (naturally occurring colors of food) have been shown to be most acceptable. The use of dyed grains has been found to decrease the acceptance of food in several studies.[11,17]

Birds are able to taste, which is supported by the presence of taste receptors. Preference testing experiments that showed responses to sweet, bitter, acid and salt solutions.[3,6,9,30] Sugar or fat can be added to a diet to facilitate its acceptance; however, the continued use of 10% sugar and 15% fat by weight in a formulated diet has been shown to be detrimental. Birds have been shown to avoid foods treated with pesticides if given a choice.[2,11,23,24]

Behavioral Modification

Although it is ideal to train birds when they are young, adult birds with behavioral problems can also be trained. The quickest route to an obedient bird is to let the bird know it must depend on you for leadership.

A hand-held perch and portable stand perches of several heights (all shorter than the handler's shoulders) are required for the training sessions. Plastic jugs or buckets can be cut to scabbard the arm, keeping the bird off the arm and shoulder and also preventing biting, while a hand cover may be cut from a sheet of dark plastic or a garbage can liner. A hood should also be available.

The bird's favorite color may be discovered by using children's beads or other toys that are similar in size and shape but of different colors. The color the bird chooses to play with is considered a favorite and should be used on perches, clothes and reinforcers. The training routine and the commands used must remain consistent. The same stands, perches and reinforcers should be used at each session, and the trainer should even wear the same uniform (eg, a favorite hat or shirt in the bird's favorite color) (Figure 4.4).

FIG 4.4 To be the most effective, training sessions should occur at the same time each day and there should be consistency with respect to the routine. In this case, an adult Blue and Gold Macaw is being taught to step onto a perch and to allow itself to be stroked. The bird appears to prefer blue colors and the perch and clothing of the trainer reflect this preference. A perch is presented and the command is given to "step up." A blue plastic bag is used to facilitate contact with the bird as the initial step to acclimate the bird to being stroked.

Only one person should be the trainer for at least the first three to four weeks, but a tape recorder, video camera or coach may help monitor communication between the trainer and the bird. Methods for training problem birds are similar to those for neonates. Simple, one-word commands in a relatively strong, authoritative voice should be given only once and only when in training. The trainer must be ready to demonstrate appropriate behaviors and must have positive reinforcers chosen and ready to be delivered. To be effective, behavior correction sessions must occur four times each week for a minimum of 15 minutes for each session. Practice sessions should take place in the training area only and should be uninterrupted.

Specific Behavioral Problems

Companion birds are frequently presented to the avian practitioner with behavioral problems. Birds exhibit a variety of negative behaviors including biting, screaming, feather picking, favoring one person and an unwillingness to go in or come out of an enclosure. Training steps that can be used to correct many of these problems are listed in Table 4.1. Many of these problems can be prevented by encouraging the client to carefully select a companion bird based on specific attributes (see Chapter 1).

Biting

A good way to overcome negative behavior is to avoid it. A biting bird should receive no affection (eg, pet-

TABLE 4.1 Steps to Behavior Modification

Stage 1	During the first week of training, the bird should learn to stay on command. To do this, it needs to identify the word, "stay" with some negative visual signal (eg, holding the hand up with the flat palm facing the bird, or holding a large black object in front of the bird). If the bird tries to move or bite, the visual signal is offered with the word "stay". If the bird responds (a response in this case is lack of movement), it should be verbally praised. When the "stay" command is mastered and the bird has successfully responded ten times in a row, the training can move to Stage 2.
Stage 2	The bird is ready to be picked up with a perch on command. First issue the "stay" directive, even as the hand-held perch is being presented (without the "up" command). Hesitate to see if the bird steps up on its own. If so, present the negative visual signal but do not repeat "stay." Then give the "up" command. If the bird does not step up, gently slide the perch closer into the bird's abdomen to force it to step up on the perch. Reinforce (verbally praise) the bird for stepping up. Repeat the process, going from the hand-held perch to a stand perch using the same commands, "stay" (with the stop sign) and "up" for moving to the perch (at the discretion of the trainer, not the bird). The bird can then be trained to "stay" on the perch stand, for increasing periods of time.
Stage 3	Using a feather or a stick, the wing is slightly opened away from the bird's body, while the command, "wing" is given. The bird is praised, and the steps are repeated. The same series of exercises can be performed to enable the bird to lift a foot on the "foot" command. Eventually, the bird will respond comfortably so the wings and nails can be trimmed without restraint.
Stage 4	When "stay," "up," "wing" and "foot" are performed successfully, the bird is ready to receive a hood. A large soft article of an acceptable color (towel, piece of opaque plastic, etc) is gently draped over the bird's body while the command "hood" is given. The article is left on for only a few seconds at first, gradually increasing the time of each phase as the material is maneuvered up over the head. The size is gradually decreased so a small "hood" is actually placed over the head, obscuring the bird's vision. The hood is then removed at intervals. Stages 1 through 3 should be repeated with the hood over the bird's head. Over time, the trainer should be able to touch and walk around with the hooded bird on the hand-held perch, and even trim the wings or nails and transfer the bird to a new person without incident. Additional challenges should be added from time to time to keep the bird interested and the bird/trainer relationship strong.

FIG 4.5 Some cases of psychological feather picking can progress to the point of self-mutilation.

ting, holding) for one to two months. If the bird is biting out of fear the trainer must first gain its confidence. If it is biting because it is "spoiled" or needs to show dominance, it must first be trained to respect the client. If the bird runs up the perch and bites the trainer's hand, a section of PVC pipe placed over a portion of the perch so it will spin if stepped on, can be used as an effective barrier.

Screaming

Screaming is a serious behavioral problem, especially in cockatoos and macaws. The time of day and circumstances associated with screaming should be charted for several weeks in order to arrange training or play sessions for the time just before the screaming behavior usually begins. If that is impossible, the bird may be hooded or taken to a dark time-out location prior to screaming periods. The remainder of the training is routine, with special emphasis placed on the trainer leaving the room for increasing periods of time during the stay command. If the bird screams during training, the trainer should leave the room, and if it continues, the bird should be hooded or placed in a time-out location until it stops. Yelling back at a bird is never useful, as it will quickly learn that screaming is a good way to get attention. The trainer should always wear ear protection when working with a screaming bird.

Feather Picking

Feather picking may be caused by pathologic and psychologic conditions, and the first step in solving the problem is a thorough physical examination. Once medical causes of feather picking have been ruled-out, psychologic causes should be explored. The two most common primary causes of feather picking in the author's experience are frustrated mating instincts and lack of proper training (Figure 4.5).

Sexual frustration is common in birds, especially in cockatoos and many domestically bred birds. Programmed in the wild to be constantly with a mate, a bird becomes distraught when its "person mate" is gone much of the day. It may also become jealous of other family members or maladjusted following a change in environment (eg, change of enclosure location, a new dog or child). Even the client's emotional state can affect the bird's behavior.

Training is the first step in solving psychological feather picking, with correction of any dietary deficiencies being a critical part of the therapy. Birds that feather pick often consume pin feathers as if they are attracted to the taste of blood. A craving for the minerals, protein and fat of mature feathers may even be the cause for this pica. Birds given a balanced diet tend to feather pick less and spend less time chewing plants and perches. Many birds pick when first left alone, so early training in anticipation of the problem may be an effective preventive. Once feather picking is established, training may decrease the severity of the feather picking but will rarely stop the habit (see Chapter 24).

Favoring One Person

A bird that fiercely favors one person should be given the basic training, and when the training is finished, several other people should become involved in giving the commands and continuing the training interactions. Sexual stimulation such as stroking, playing with favorite toys and hiding in dark places should be avoided (Figure 4.6). When other people are present, the bird should be kept away from areas it wants to defend, such as shoulders and its enclosure. Sexually induced regurgitation, masturbatory behavior and pulling ears and jewelry can be corrected using preventive measures, basic training and finally, negative reinforcement.

Going In and Out of Enclosure

A bird that refuses to leave its enclosure should be fed just outside the enclosure door. The food should be left out for 15 minutes and then removed. Once the bird is accepting food in a bowl placed on the outside of the enclosure, it should be made to eat a portion of each day's meals from a spoon. With a perch stand placed near the enclosure door, the bird should be taught the "come" command while the trainer holds the food for several minutes. If this is repeated several times a day, the bird will gradually learn to perch outside the enclosure and can then be moved to other eating areas away from the enclosure.

FIG 4.6 Masturbatory activity is common in imprinted adult birds that accept a client, enclosure furniture or toys as a mate.

A bird that refuses to go back into its enclosure may be trained in the same manner by placing food in the enclosure for 15 minutes. If the bird enters within that time period, it is allowed to eat for a few minutes before the food is removed and the door is closed.

A bird that has psychogenic polydipsia may respond to a similar behavioral modification program. Consumption of water is restricted to two ten-minute periods a day. These birds should be examined for possible disease.

Support Groups

Veterinarians, bird trainers, behaviorists and bird clubs have begun to offer group support for prevention and correction of bird behavior problems. Some resources for behavior modification are: Chris Davis, PO Box 1067, Sierra Madre CA 91025; 818-355-2267; Eddie Callahan, 5770 Lake Worth Road, Lake Worth FL 33463; 407-964-2121; Parrot Responsive, PO Box 66 Dept. RHH, Riverside IL 60546; 708-442-8081; Parrot People, PO Box 1650, Bellaire TX 77402-1650; 713-447-6622.

CHAPTER

5

DEFENSE MECHANISMS OF THE AVIAN HOST

Helga Gerlach

The defense mechanisms of avian species are generally comparable to those of mammals despite fundamental differences in the structure of the system. Detailed information is available only for the chicken, which serves as the model for studying the development of bursa- and thymus-derived lymphocytes. Conclusions concerning the immune system of other avian species from information derived from the chicken may or may not be valid. Initial comparisons among the immune systems of chickens, ducks and geese indicate substantial similarities. The strength and functionality of the defense system is genetically determined, and in free-ranging birds is based on natural selection. Likewise, birds from arid or arctic environments are not exposed to the same pathogens as birds from temperate or tropical areas, and consequently have developed adaptations to a different group of pathogens. Birds indigenous to one environment that are moved to a different environment may have no immediate protection against the new group of microorganisms they would encouter. Many captive birds have been inbred for color mutations. This inbreeding may weaken the immune system and cause these birds to be more susceptible to disease than their free-ranging relatives (Figure 5.1).

The purpose of the defense system is not only to protect the individual against invasive organisms, but also to eliminate abnormal body cells. These include cells with minor structural or antigenic deviations, such as old cells, virus-infected cells and transformed (cancer) cells. The defense system also functions in the recognition of foreign cells, as is observed in graft rejection phenomena. For this system to function properly, it is mandatory that the body be able to distinguish between normal body cells (self antigens) and those antigens that are unlike self (foreign antigens). If the body becomes intolerant of its own cells, then an autoimmune disease occurs.

The defense system consists of several integrated components: nonspecific defense, and specific defense, which includes the humoral immune system, cell-mediated immune system and tolerance.

FIG 5.1 In general, inbreeding only to obtain specific color mutations can be expected to weaken a bird's immune system compared to its wild-type relatives. Cockatiels with color mutations have a reduced life-span and increased infectious disease problems. Few color mutation cockatiels approach the 15- to 20-year longevity that their wild-type relatives enjoy. For the health of the individual animal, inbreeding should be discouraged.

Each component of the defense system is intricately connected to the other components through the interaction of cells and hormone-like mediators or secretions. These mediators are responsible for activating or suppressing other components of the system, keeping the defenses in proper balance. It is essential for the avian clinician to have an understanding of the importance and interaction of the important components of the defense system.

Nonspecific Defense

Epithelial Surfaces

The primary barriers that any animal has in preventing pathogen access to the body are the skin and the mucosal linings of the intestinal, respiratory, urinary and reproductive tracts. In the normal host, this is achieved by establishing environments that are suitable exclusively for the best-adapted microorganisms with a low pathogenicity or none at all, which effectively inhibit colonization by other, less well adapted and frequently more pathogenic organisms. This is achieved by adhesion of bacteria to the epithelial cell, eg, by pili or fimbria, by production of bacteriocins and by tolerance of environmental conditions (Figure 5.2). The skin serves, among other things, as a physical barrier to potentially invasive microorganisms.

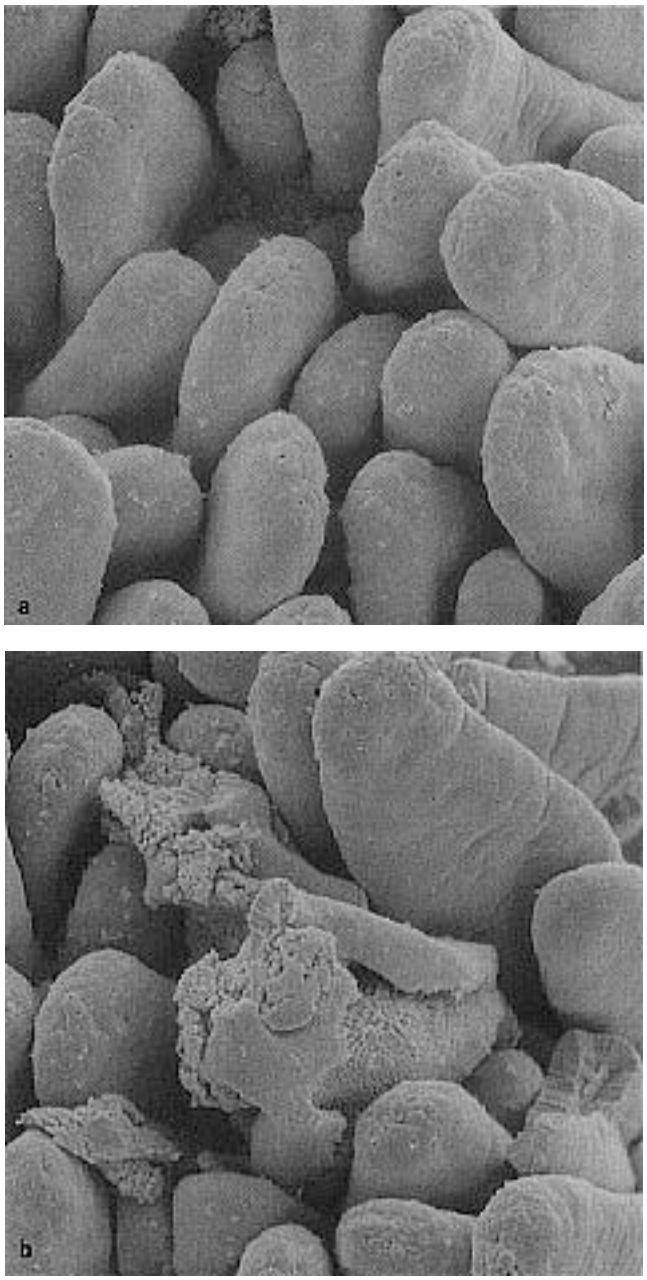

FIG 5.2 **a)** The normal mucosal surface of the intestinal tract is covered with local immune factors (IgA) and autochthonous bacterial flora to provide a barrier that prevents microbes from gaining access to the host. **b)** If the mucosal barrier is damaged by exposure to toxins, malnutrition or primary pathogens, secondary pathogens may colonize the gastrointestinal tract or enter the body and cause systemic disease (courtesy of WS Steffens).

The native flora of the skin is specified and regulated by factors such as desquamation, desiccation and a relatively low pH.[10] Changes in local environmental factors can damage the flora and allow invasion by other microorganisms.

Autochthonous Flora

The normal or autochthonous flora of the intestinal tract is developed in the newly-hatched chick during the first three to four weeks of life. This flora is species-specific, and its composition is governed by the prevailing physical and chemical conditions in the lumen. The acquired flora takes up the available space, occupies receptors and acts competitively against invaders by various mechanisms such as inhibitory metabolic products, bacteriocins and production of a low pH environment. A practical example of the protective nature of resident bacteria in the gastrointestinal tract is the inhibition and expulsion of Enterobacteriaceae by lactobacilli. This inhibition is particularly important in birds in which Enterobacteriaceae are not considered to be normal components of the intestinal flora. The natural development of the immune system also depends on continuous antigenic stimulation by the autochthonous flora. Mucosa-associated lymphatic tissue forms the so-called lymphoepithelial system, which appears to function by capturing and processing antigens from the mucosal surface.

The mucosa of the respiratory, urinary and reproductive tracts of birds is similarly colonized by specific flora whose compositions are relatively unknown; however, thus far it has been shown that none of these mucosal surfaces normally contain Enterobacteriaceae. The mucosal surfaces contain goblet cells that secrete a tenacious mucus. The mucus serves to cover cellular receptors for bacteria or viruses. This mucus also contains lysozyme (which has antibacterial and antiviral activities) and immunoglobulin (Ig) A. In addition, the respiratory mucosa to the level of the secondary bronchi is equipped with cilia that transports foreign material collected from material suspended in the inspired air back out of the system (Figure 5.3).

Myeloid System

The cellular (myeloid) system provides the next line of defense against any pathogens or foreign materials that succeed in penetrating the epithelial or mucosal barriers. This system consists of three cell types that all originate from the bone marrow: polymorphonuclear granulocytes (the most important of which is the heterophil), thrombocytes and mononuclear cells, which differentiate into macrophages.

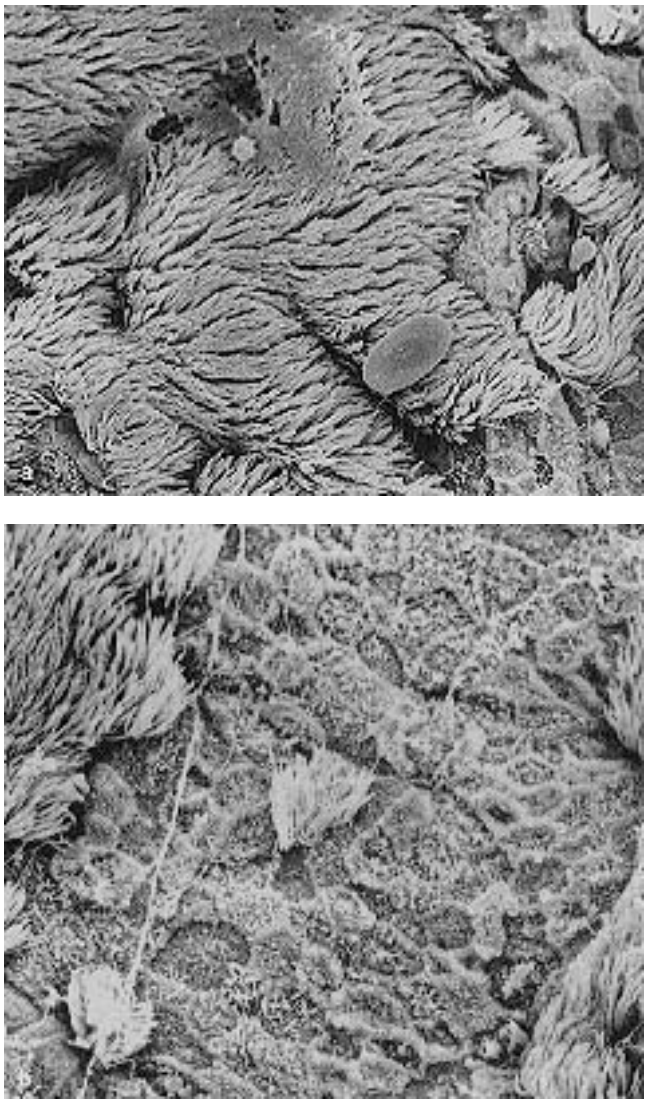

FIG 5.3 **a)** The normal tracheal mucosa is covered with a mucociliary blanket that serves to remove foreign material that enters the trachea and also serves as a barrier that prevents microbes from entering the circulation. **b)** When the mucociliary blanket is damaged, the patient becomes increasingly susceptible to infectious agents. In this case, the mucociliary blanket has been destroyed by indiscriminate exposure to disinfectant fumes (courtesy of Jean Sanders).

Leukocytes

Generally speaking, the nucleus of the avian heterophil is multi-lobulated when it leaves the bone marrow. Therefore, the left shift seen in mammals is difficult to ascertain. Heterophils are rather short-lived (a few hours or days), and their granules are packed with a variety of enzymes (peroxidases, proteases, hydrolases) and lactoferrin. Lactoferrin serves to bind free iron, which is a required growth factor for many bacteria. The main function of heterophils is to phagocytize and destroy "foreign" mate-

rial or damaged cells without having to process them as antigens for presentation to the immune system. The ability of heterophils to ingest some pathogens depends on their being coated with opsonins. Several blood proteins, including fibronectin, antibodies or C3b complexes derived from the complement cascade (in the case of the alternate pathway, this may occur independently of antibodies) can function as opsonins.[15] A depletion of fibronectins, induced by trauma or large numbers of bacteria can block the phagocytic cells and suppresses the nonspecific cellular defense system.

The second way in which heterophils eliminate bacteria is by producing OCl^-, hydroxyl radicals ($OH^\bullet$), and singlet oxygen. OCl^- causes oxidation of bacterial capsular proteins, and the latter two substances are highly unstable and react with lipids to form toxic, bactericidal hydroperoxides. These reactions are called the "respiratory burst."[15] Animals genetically deficient in superoxide dismutase or myeloperoxidase lack this defense mechanism and frequently suffer from recurrent bacterial infections. Heterophils have only limited energy resources that cannot be replenished. They are consistently reproduced and serve merely as the first line of internal defense. When a pathogen is able to resist these defense systems, the macrophage system, with prolonged diversified functions, assumes the responsibility for protecting the host.

The information on avian eosinophils is still rather poor. Responses by eosinophils are at least partly species-specific. In contrast to mammals, birds are not generally thought to respond to parasitic invasion with an increase of eosinophils. The fact that avian eosinophils are difficult to distinguish from heterophils may explain some of the literature reports suggesting parasite-induced eosinophilia. It appears that avian eosinophils participate in hypersensitivity reactions. The degree of involvement is thought to be dependent on the species, inciting antigen and age of the individual.[9]

Avian basophils are morphologically and functionally identical to tissue mast cells. Their granules contain vasoactive amines and proteins, prostaglandins and activators for the coagulating cascade, as well as anticoagulants such as heparin. These cells function to accelerate inflammation at the site of antigen deposition.

Thrombocytes

Unlike mammalian platelets, avian thrombocytes are capable of phagocytosis. It is currently undetermined if the phagocytic process is the same as that used by heterophils.

Macrophages

All macrophages are derived from the bone marrow and enter the peripheral blood as monocytes. The morphologies of the macrophages vary according to their location and functional state (Table 5.1).

TABLE 5.1 Macrophage Morphology by Location

Morphology	Location
Monocyte	Peripheral blood
Histiocyte	Various tissues
Kupffer's stellate cell	Liver sinus
Multinucleated giant cell	Granulomatous tissue
Langhans' giant cell	Tuberculous granuloma
Epithelioid cell	Macrophages with intraplasmatic inclusion
Microglial cells	Brain

Cells corresponding to the alveolar macrophages of mammals have not been demonstrated in the avian lung. However, as a compensatory mechanism the entire epithelial surface in the parabronchi, atria and part of the infundibulum is capable of taking up particulate matter and transporting it into phagosomes, which are subsequently processed by interstitial macrophages. This defense system may partially explain the relatively high resistance of the avian lung to infectious agents[6] (see Chapter 22).

Macrophages have a long life-span unless they are destroyed by the material they ingest. They are equipped with lysosomes containing various substances that can be set free according to their respective functions. These substances are involved in phagocytosis, promoting fever (much rarer in birds than in mammals), inducing inflammation, processing antigens to stimulate an immune response and tissue healing. Phagocytosis is the fundamental process of macrophages. These cells possess receptors for complement factor (C) 3 and antibodies. Foreign particles that are opsonized (covered) with either of these substances can then bind to specific receptors on macrophages and be ingested. Functional macrophages isolate ingested material within a specialized intracytoplasmic compartment called a phagosome. These cells secrete a protein called interleukin 1 (IL-1), which seems to function in mobilizing hetero-

phils, altering host metabolism and inducing inflammation. Macrophages are activated by τ-interferon released by T-lymphocytes. Activation causes macrophages to increase in size, mobility and metabolic activity. The phagosomes enlarge and produce increased amounts of hydrolytic enzymes. As a consequence, more IL-1 is secreted, causing intracellular microorganisms engulfed by phagosomes to be destroyed more easily. Some microorganisms are able to survive inside the macrophage.

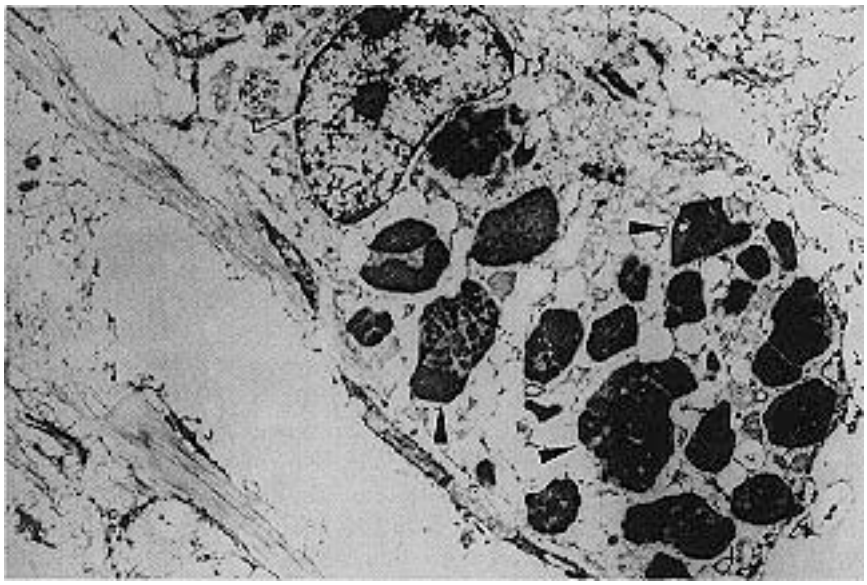

FIG 5.4 The macrophage engulfs and processes foreign material that enters a bird. The macrophage then activates the immune response by stimulating the propagation of B-cells and T-cells. If a pathogen persists in the macrophage, then a bird's immune system will not be stimulated to destroy the invading pathogen. Such is the case with PBFD virus. The PBFD virus present within the intracytoplasmic inclusion bodies (arrows) in this macrophage is able to persist rather than stimulate an immune response. Nucleus = open arrow.

Macrophages are active factors in the inflammatory process. They are chemotactically attracted to the site of microbial invasion where they help to eliminate the intruder. In addition, they secrete factors such as complement factors C2, C3, C4 and C5, enzymes such as lysozyme, elastase and collagenase and plasminogen activators. Cyclic AMP, prostaglandins and leukotrienes are also released. Macrophages also activate fibroblasts and stimulate wound healing. The ability of a host to survive an infection is usually dependent on the functional capacity of the macrophages (Figure 5.4) An increase of monocytes in the peripheral blood can therefore indicate that the host successfully resisted microorganisms.

Not all foreign material is totally ingested or destroyed in macrophages. Some antigen molecules remain on the cell surface for long periods of time. The surface of this macrophage subpopulation expresses special antigens (class II histocompatibility antigens: cell membrane antigens on macrophages, B-cells and activated T-cells) that regulate the interaction between the antigen-presenting macrophage and the antigen-recognizing cells (lymphocytes). If an antigen evades the macrophages and reaches the antigen-sensitive cells, then the host either will manifest a poor immune response or will be tolerant of the antigen.

Macrophage-like cells (called dendritic cells) are characterized by long, filamentous cytoplasmic processes and are distributed throughout the spleen and lymph follicles in the parenchymal organs. The dendritic cells have poor phagocytic activity, but they have surface receptors for complement, antibodies and class II histocompatibility antigens. They can absorb antibody into their cytoplasmic filaments in such a way that antigens can be trapped. Antigens that are bound to dendritic cells are very powerful immunostimulants that may play a major role in anamnestic response to antigens.

Immune Modulators

Several immune modulators, including adjuvants and paramunity inducers, function principally at the macrophage level. Adjuvants function in various ways to enhance the immune response to antigens. Many of them, such as aluminum hydroxide or some oils, function only to inhibit the resorption of antigens, causing a prolonged local antigenicity. Adjuvants are usually insoluble and provoke local inflammatory reactions (granulomas). The tissue inflammation (severe inflammation is an undesirable adverse response) increases the number of antibody-producing cells in the affected tissues. These cells then contribute a significant portion of the total antibody produced. Some adjuvants cause increased phagocytosis activity; in particular, Freund's adjuvant can activate the alternative complement pathway, leading to undesirable results. Some adjuvants enhance the "trapping" of lymphocytes in the spleen, ie, lymphocytes are rendered incapable of escaping from the spleen, causing an accumulation of lymphocytes and stimulation of the immune response. The

lymphocytes are released from the spleen approximately seven days later.

Paramunity inducers, especially those consisting of inactivated components from various poxviridae, can stimulate phagocytosis by macrophages and granulocytes, natural killer (NK) cells and, depending on the strain of poxvirus used, the production of τ-interferon and the prostaglandins E and A. Complement and interleukins can also be activated. The activation of NK cells seems to be an important factor in the nonspecific defense mechanism, especially against virus infections and virus-induced tumor cells. NK cells destroy target cells by cytotoxicity.[5] They seem to play a distinct role in "genetic" resistance to virus-induced neoplasms. Very recent results show that the avian NK cells are independent of the thymus but have CD3 and CD8 antigens at their surfaces.

Antibiotics, especially some tetracycline preparations, inhibit the immune system to varying degrees. An indirect effect is a transient increase in the serum corticosterone level, which depresses macrophage activity. Direct effects include interference with protein synthesis, phagocytosis and antigen processing. Because of their potential side effects, antibiotics should be used only when absolutely necessary, particularly when treating secondary bacterial infections associated with viral diseases. Antibiotics should not be used prophylactically, but only when specifically indicated.

Specific Defense

Nonspecific defense mechanisms function to destroy foreign material the moment it touches or enters the host. Specific defenses have a prophylactic quality in defending the host against ubiquitous microorganisms and recurrent infections. The specific defense mechanism relies mainly on antigen-sensitive cells, B- and T-lymphocytes, to recognize each antigenic epitope (antigenic determinant) and to produce organism-specific antibodies (humoral immune system), or to provoke cell-mediated reactions (cellular immune system). Depending on whether the host has been exposed to the particular antigen before or if it is an initial encounter, specific defense responses to an antigen may be delayed for two to three or even five to ten days, respectively.

Antigens are the trigger for stimulating the specific defense response. For a substance to be immunogenic, it must be a structurally stable macromolecule and foreign to a host, and it must possess surface structures (epitopes) against which the immune response will be focused. The specific site on an antigen that reacts with antibodies is called an epitope and only comprises a few molecules (10 to 12 amino acids in proteins). Several epitopes may exist in each antigen molecule (approximately one epitope per 5,000 daltons). With such a defined antigenic site, the main portion of foreign macromolecule is nonantigenic, and the immune response of the host is dependent on recognizing defined epitopes as not "self." Individual hosts respond differently to the same epitopes. The type of reaction is mainly controlled by immune response genes, which code for regulatory proteins located on the surface of cells of the immune system. Epitopes may also stimulate a varying response depending on the manner in which the antigen is presented to the lymphocytes. Individual epitopes may induce antibody production, cell-mediated reactions, tolerance or immunosuppression. The immune response that follows natural infection is thus a mixture of responses (ie, polyclonal). Since epitopes are specifically defined and occupy rather small areas on an antigen, an antibody produced against one antigenic site may react with an epitope on another totally unrelated antigen. This cross-reaction between totally different antigens can create diagnostic problems in some serologic tests. It has been experimentally suggested that approximately ten million epitopes exist that can stimulate an immune response.

In addition to macromolecules, small molecules (called haptens) that are linked to a carrier may also provoke an immune response. Haptens of particular interest to the clinician are small, metabolized molecules of drugs, which may bind to serum (or other) proteins. These molecules are recognized as foreign and often induce hypersensitivity responses. Classical examples of hapten-induced reactions in mammals are reactions to penicillins and cephalosporins. Hypersensitivity responses appear to be less common in birds but have been linked to some antimicrobial sulfonamides. Responses to hapten-carrier molecules indicate that production of antibodies to epitopes of the haptens is possibly independent of the carrier molecule itself. Nevertheless, cell-mediated response may be initiated against the hapten-carrier as such, and is therefore called "carrier-specific." The latter

point is of practical importance, since binding of haptens to carriers is a common occurrence *in vivo*.

Humoral System

Immunoglobulins

The primary function of the humoral immune system is the production of antibodies directed mainly against extracellular phases of antigens. Antibodies are immunoglobulins, with the major part of the molecule containing ligands for membrane receptors, complement activation and isotype-specific (antigenically unique) structures. Immunoglobins can be differentiated into isotypes (IgM, IgG, IgA and, in mammals, also IgD and IgE). No subclasses of any of the isotypes has currently been demonstrated in birds. In ducks and some geese, the predominant immunoglobulin is called IgN, a 5.7 S protein molecule that does not fix complement (which occurs in some fishes, turtles, marsupials and rabbits). Although the other avian isotypes are not the same as those in mammals, they do share the same functions and are termed similarly.[1] However, there are some biochemical differences between mammalian and avian immunoglobulin. Avian immunoglobulins aggregate in a 8% NaCl solution. This is in contrast to mammalian immunoglobulin, which will aggregate in a 0.8% NaCl solution. Although chicken complement is fixed by immune complexes, it is not affected by complement from the guinea pig. This means that the routine complement fixation test cannot be carried out in many avian species.

- ***IgG:*** (synonym IgY because of its structural and weight difference from mammalian IgG) is the most common antibody in the serum, and due to its small size (7 S), it can penetrate into tissue spaces and across body surfaces. IgG can opsonize, agglutinate and precipitate antigen.

- ***IgM:*** is the major isotype produced following the initial contact with an antigen. Because of its size (19 S), IgM is normally confined to the peripheral bloodstream and is more active than IgG in opsonization, agglutination, virus neutralization and complement activation.

- ***IgA:*** exists in both monomeric and polymeric forms and when coupled with a secretory component, is excreted onto the mucosal surfaces of the respiratory, genitourinary and digestive tracts. In the chicken, IgA also occurs in the bloodstream and in pigeons, this immunoglobulin is found in high concentrations in the crop milk.[7] IgA does not activate the complement cascade, nor can it act as an opsonin. It can agglutinate particulate antigens and neutralize viruses. Its major task is to prevent antigens from adhering to the mucosal surfaces of the body.

FIG 5.5 Neonatal birds depend on IgG absorbed with the yolk to protect them from environmental pathogens until they become immunocompetent. In some cases, improper hatching will prevent the egg-yolk from being absorbed and it must be surgically removed. Neonates that do not properly absorb the yolk sac are considered to be immunologically naive and are more susceptible to infectious disease.

Antibody Production

Although antibody production is the main feature of the humoral defense system, the concentrations of IgM and IgG in the serum are generally not indicators of immunity. As a rule, birds with high antibody titers against a certain infection are better protected than those with a low titer. However, there are many exceptions to this generality, particularly with respect to antibodies directed against bacteria. In many instances, an effective response requires the interaction of antibodies and components of the cell-mediated immune system. The fate of the antibody-antigen complex is either phagocytosis (binding to macrophages on the Fc fragment of the antibody) or lysis with the aid of the complement cascade. In the case of phagocytosis, the immunoglobulins can be recycled by virtue of the noncovalent complex bonds.

The humoral immune system requires time to respond to a pathogen and the respective lymphocytes responsible for humoral immunity do not migrate

into the secondary lymphatic organs (where they mature) until around the time of hatching. The newborn chick is, therefore, ill prepared to respond to all environmental antigens. For compensation, the newly hatched chicks receive maternally derived antibodies (IgG) transmitted via the yolk (Figure 5.5). The type and quantity of antibodies that the chick receives depend on the immunologic status of the hen. Vaccination (plus a booster) of the breeder hens with the appropriate antigens is carried out four to six weeks prior to the beginning of egg production in order to ensure significant levels of IgG in the yolk. The antibodies are absorbed from the yolk by the third day of life, and their purpose is to help protect the chick before it achieves immunological maturity around 20 to 25 days of age. The half-life of the maternally transmitted antibodies is four to six days. Neonates from hens vaccinated against PBFD virus were found to have HI antibody titers that decreased 20 to 45 days post-hatching, suggesting maternal antibodies may have a longer half-life in psittacine chicks.[16]

Maternal antibodies may present an obstacle to early vaccination programs by neutralizing the vaccinal antigen and, at the same time, depleting the chick's natural protection. Early vaccination successfully inhibits the production of immunoglobulins.[15] It is also known that IgM and IgA secreted by the oviduct diffuse from the albumen into the amniotic fluid where they are swallowed by the embryo, thus coating the surface of the intestine with a protective covering of these immunoglobulins.

Lymphocyte Activity

The cellular basis of humoral immunity is the B-lymphocyte, which is the antigen-sensitive cell. Precursor cells colonize and develop in the cloacal bursa during embryonic life. In chickens, the bursal microenvironment is established from the fourth day of incubation onward as a special outgrowth of the cloacal epithelium. The bursa is thought to attract lymphoid precursor cells through the secretion of bursin (and maybe other mediators from the bursal epithelial cells). The first antigen that is localized on B-lymphocytes is the histocompatibility complex class II antigen, followed by cells with surface IgM. Unlike in mammals, no pre-B-cells with intracytoplasmic μ-chains have been described in chickens.[12] Between the 14th and 16th days of incubation, the first IgG- and IgA-carrying B-cells can be demonstrated within the bursa (Figure 5.6).

Around hatching time, the mature B-lymphocytes migrate in large numbers from the bursa into the secondary lymphatic organs (spleen, cecal tonsils, Peyer's patches, Meckel's diverticulum, lymph follicles in the various organs, paraocular and paranasal lymphatic tissue) where they start to function. Here the Harderian gland is particularly important, and parts of the cloacal bursa, which act as a secondary lymphatic organ. There are some indications for the existence of extrabursal sites of B-cell differentiation (suggested to be gut-associated lymph tissue, Harderian gland, and bone marrow). Around hatching, the Harderian gland has already accumulated actively secreting plasma cells within the interstitial space prior to antigen exposure. By this point in

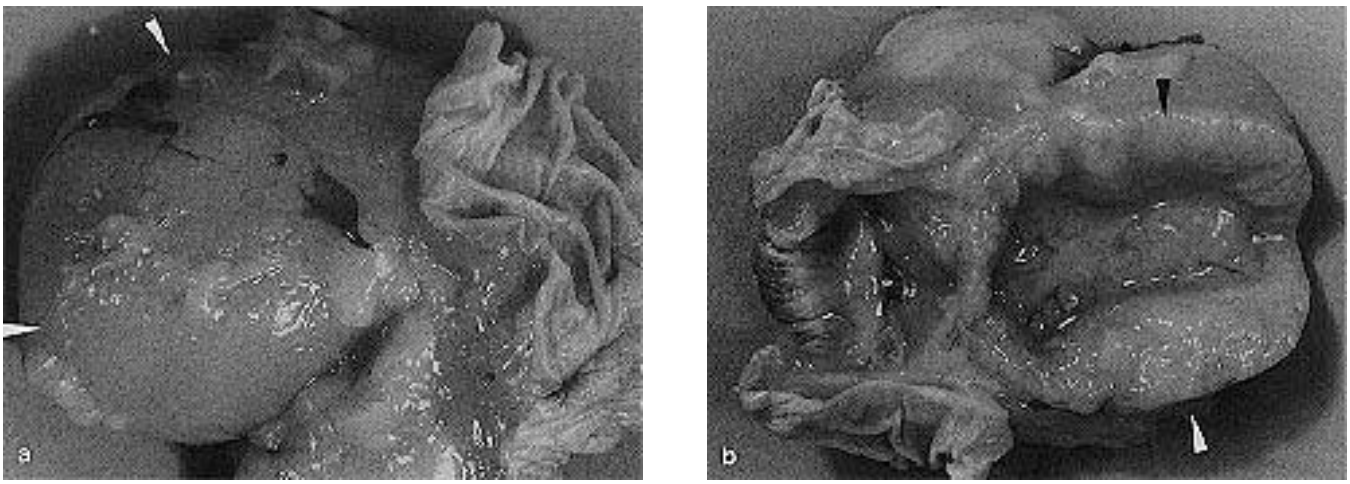

FIG 5.6 **a)** The cloacal bursa is the site of B-lymphocyte differentiation and growth (arrows). The bursa is large in neonates (as in this five-week-old Umbrella Cockatoo) and decreases in size as the bird matures. **b)** The hollow bursa is located in the dorsal wall of the cloaca to which it connects (arrows). The bursa functions as an immunologic organ by taking up particulate matter from the cloaca and stimulating an immune response to the organisms that pass through the cloaca.

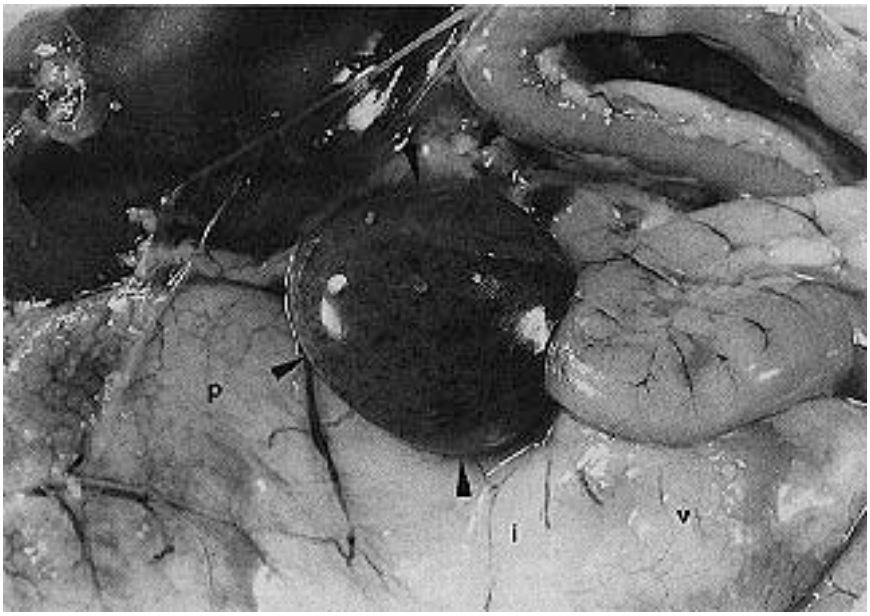

FIG 5.7 Splenomegaly (arrows) is a common finding in birds. The proventriculus (p), isthmus (i) and ventriculus (v) are also noted.

development, neither hormonal treatment nor surgical bursectomy can suppress the infiltration of these plasma cells.

It has also been suggested that mediator-secreting cells migrate from the bursa into the germinal centers of the spleen and the cecal tonsils (probably also into other secondary lymphatic tissues that are capable of forming germinal centers) to monitor the microenvironment (Figure 5.7). It is also assumed that ellipsoid and ellipsoid-associated cells are derived from the mediator-secreting cells. Further studies, particularly of the spleen, have shown that the penicilliform capillaries possess stomata that allow particulate antigen (probably soluble antigen as well) to enter the ellipsoid cells, which are surrounded by ellipsoid-associated cells and dendritic cells. The latter bind the antigen to their surfaces and migrate to the appropriate T- or B-cell-dependent regions of the periarteriolar sheath. In birds, the cloacal bursa is colonized by developing B-lymphocytes until four to six weeks of age. Subsequently, those lymphocyte clones spread to populate the peripheral lymphatic organs. These lymphocyte cells are capable of restoring humoral immunity in the long term, but only as long as the various kinds of "reticular" cells representing the ellipsoid and ellipsoid-associated cells are intact.

The binding of antigen to the membrane of a B-cell stimulates proliferation of the cellular clones and ends in the differentiation of two functional cell populations: plasma cells and memory cells. The proliferation of B-cells is rigorously controlled and occurs only if certain additional factors are present: 1) The antigen has to be presented fixed to the surface of certain cells, mainly macrophages (which secrete IL-1 and possess class II histocompatibility antigens); 2) T-helper cells must also respond to the same antigen and secrete soluble mediators.

The T-helper cells bind to the same macrophage (but not necessarily to the same epitope) as the B-cell. However, the T-cell binds not only with the antigen, but in combination with a class II histocompatibility antigen. The T-cell then secretes two proteins: the B-cell growth factor (IL-4) and IL-2. IL-2 binds to the IL-2 receptors (produced under the influence of IL-1) on the B-cell, where it stimulates DNA synthesis and division. The B-cell differentiation factor (IL-5) secreted by T-helper cells regulates the switch of isotypes. This cascade results in two cell subpopulations: plasma cells and structurally unchanged memory cells, although the latter have switched their isotypes, mainly to IgG.

Plasma cells differentiate from B-cells to form a series of intermediates until they attain their typical morphology (eccentric wheel-like nucleus and copious cytoplasm). The specificity of the immunoglobulin is the same as in the B-parent cell. Plasma cells can produce up to 2,000 Ig molecules per second, and these antibodies are normally secreted by reverse pinocytosis. Plasma cells survive for only three to six days due to gradual catabolism of the immunoglobulins.

In order to maintain high serum immunoglobulin levels, it is necessary to expose a bird to a second dose of antigen to achieve a so-called booster effect. The memory cells, which survive for many months or even years (perhaps not strictly as individuals, but as clones), are stimulated by the proper antigen, inducing the production of more antigen-sensitive cells. The resulting immunoglobulin production is both faster and more vigorous than the initial response. The booster effect, the duration of antigenic exposure, the half-life of the serum antibodies and the expected age of an individual or flock dictate the

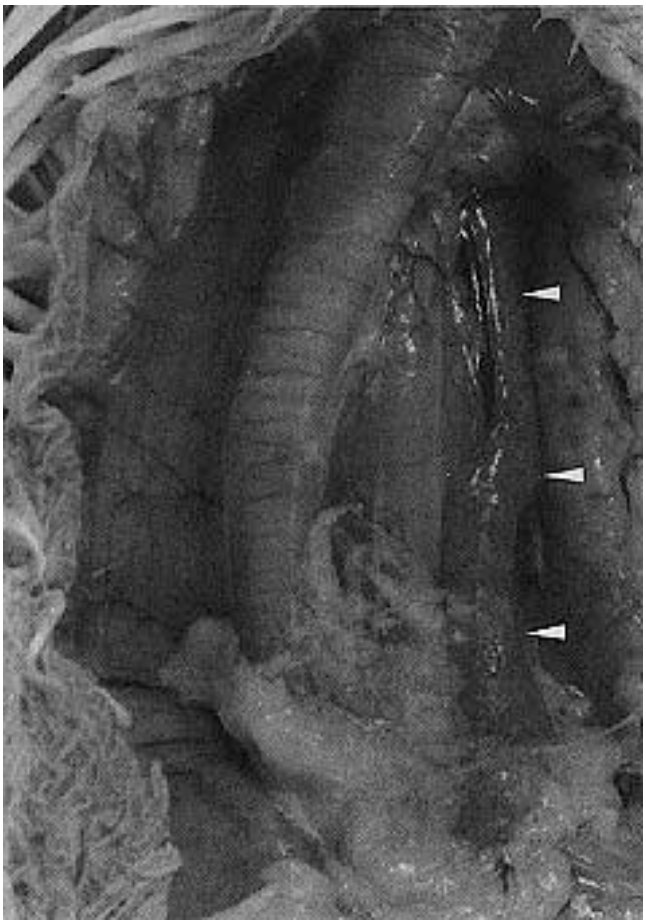

FIG 5.8 The thymus is the site of differentiation and development of T-lymphocytes. In neonates, the thymus is present bilaterally with seven lobes each at the lateral sides of the neck (arrows).

intervals of vaccination and revaccination that are necessary to achieve a desired level of individual and flock immunity.

Function of the Cell-mediated System

The cell-mediated system is essential for protection against viruses, virus-infected cells, intracellular bacteria, foreign tissue grafts, parasites, fungi and some tumor cells. Thymus-derived lymphocytes (T-cells) also mediate the inflammatory response known as delayed hypersensitivity. T-cells form the basis of the cell-mediated system, but in contrast to the uniform B-cells, T-cells form many subgroups including:

- effector cells, which produce lymphokines provoking cytotoxicity
- helper cells, which produce lymphokines
- suppressor cells, which inhibit the responses of other B- or T-cells.

During development, avian T-lymphocytes differentiate and mature in the microenvironment of the thymus (Figure 5.8). At least part of the microenvironment may be provided by nurse cells. The thymus also functions as a gland in secreting several mediators that participate in the T-lymphocyte maturation process.

T-cell subpopulations are characterized by the expression of surface molecules, designated CD1 to CD11, and by the T-cell antigen receptor TRC.[2]

CD4 and CD8 molecules are associative recognition structures for the major histocompatibility complex (MHC) class II and class I molecules, respectively. Antigens have to be presented in association with these MHC molecules for them to be recognized by T-cells. All T-cells express the CD3 molecule, which is noncovalently associated with the T-cell receptor and which represents a signal-transducing structure.

As in a B-cell response, three mutually interacting cells are necessary for a cell-mediated immune reaction to occur: the antigen-presenting macrophage, the effector cell (carrying the CD8 antigen) and the CD4 helper cell. The epitope must be closely linked to the class I histocompatibility antigen in order for the effector cell to be able to recognize the antigen. Once an antigen is recognized, the helper cell secretes IL-2, causing T-cell proliferation and leading to the production of both effector and memory cells. The effector cells, somewhat larger than the parent cell and with an activated metabolism, are capable of performing various functions. They can secrete several lymphokines, or they can cause direct toxic reactions on contact with foreign or modified cells.

In addition to the cells listed above, vascular endothelial cells, keratinocytes, and cutaneous Langerhans cells have also been found to be capable of presenting antigen. They can take up antigen and synthesize IL-1 under the influence of interferon, and express the class II histocompatibility antigen. Langerhans cells play an especially important role in the development of skin allergies, delayed hypersensitivity reactions, and allergic contact dermatitis.

Lymphokines produced by effector cells can be divided into several groups:

- regulatory factors, such as IL-2, IL-3, τ-interferon, IL-4, IL-5.

- inflammatory mediators that increase vascular permeability.
- macrophage activity modulators, such as migration inhibitory factor, leukocyte inhibitory factor, and macrophage fusion factor for inducing giant cell formation.
- cytotoxic factors, such as lymphotoxins, tumor necrosis factor, perforins,
- fibroblast stimulation factor.

Immune Tolerance

Tolerance is defined as a host's failure to respond to produce reactions against a specific antigen. The most important example of tolerance is the absence of antibodies against normal body components. Tolerance to self-antigens is established during embryonal life. The mechanism is not quite clear, but it may depend on the immature condition of the antigen-sensitive cells at the time of their first encounter with antigens. The same matured cell type is later fully responsive to antigens that it encounters for the first time. An embryo may develop tolerance to viruses or some bacteria that are egg-transmitted.

Tolerance in adults can be facilitated by administering either high doses of antigens (particularly polysaccharides) or very low doses of antigen, by giving antigen in the absence of antigen-presenting cells or by applying antigen that is free of aggregations.

The development of tolerance also implies a rigorous control mechanism to maintain balance between the various components of the defense system in order to avoid depressed immune reactivity (ie, increased susceptibility to infection and spontaneous tumors) or excessive immune reactivity (which results in autoantibodies, amyloidosis, lymphoid tumors and allergies). Immune response regulation is a complex mechanism.[8,13] Principally it can be divided into:

- genetic control by immune response genes located at the major histocompatibility complex B (which means that reactivity to antigens can be subject to genetic selection by a breeder),
- activity of T-suppressor cells bearing the CD8 antigen,
- control of B- or T-cell metabolism by insulin and/or prostaglandins and by adjusting the ratio of cyclic adenosine monophosphate and guanosine monophosphate,
- regulation by the amount and structure of the antigen,
- regulation by antibody or antigen-antibody complexes via a feedback mechanism.

Disturbance of the Defense System

Both the nonspecific and the specific defense systems can be impaired at almost any site. Depending on whether a stimulatory or suppressing portion of the system is damaged, impairment can result in either deficiency or exaggeration of the system. In addition to the aforementioned immunosuppression caused by antibiotics, certain mycotoxins and many tumors, particularly the virus-induced tumors, can decrease the efficiency of the defense system.[15] A variety of viruses (Newcastle disease virus, several herpesviruses, adenovirus and reovirus) are known to inhibit the immune system. This inhibition is often at the level of the T-cells, resulting in a bird that is prone to secondary infections. Other viruses, such as PBFD virus and polyomavirus that frequently cause degeneration or necrosis in lymphatic organs are almost certainly also immunosuppressive.

Genetic defects of the immune system in birds are infrequently reported, possibly because of insufficient information concerning the immune system of birds. In chickens, hypo- or dysgammaglobulinemia have been described; in obese strain chickens, the first step in the cascade of events appears to be a dysfunction of immune regulation.

Autoimmunity

Autoimmune antibodies are directed against self-antigens. At a very low level they can be considered as normal, but in higher concentrations they may cause disease. Autoimmune diseases have rarely been reported in birds. This may be a result of our inability to recognize autoimmune disease rather than a resistance to autoimmune problems. The obese strain chickens produce antibodies against thyroid cells, thus causing hypofunction and thyroiditis.

Hypersensitivity

An excessive immunologic reaction can cause a type of inflammation called hypersensitivity. Four differ-

ent types of hypersensitivity reactions have been described in mammals. Type I, the mechanism of which is not fully clear, occurs rarely in birds, because birds do not have IgE, which is essential for the reaction in mammals. Nevertheless, birds have large numbers of mast cells in their lymphatic tissues, particularly in the thymus. The latter does not always become completely involuted in avian species.

Type I = immediate hypersensitivity. IgE isotypes can attach to mast cells (= basophils) by their Fc fragment. If antigen is fixed to such a cell-bound antibody, the basophil releases vasoactive substances (including histamine), which causes a local inflammation within minutes.

Type II = cytotoxic hypersensitivity. The destruction of cells can be carried out either by antibodies activating complement or by cytotoxic cells. Heterophils, macrophages and some lymphocytes have receptors for Fc immunoglobulin fragments and may, therefore, lyse target cells that are coated with immune complexes. Both forms of lysis release many biologically active products from the doomed cells, causing inflammation as is also seen in graft rejection.

Type III = immune complex hypersensitivity. Immune complexes are able to activate complement, even in tissues. The C5a component, which leads to vasoactive anaphylatoxins, is also a potent heterophil attractor. As these heterophils try to digest the immune complexes, they release proteolytic enzymes, thus causing tissue damage. This triggers a vicious circle: heterophil-activated plasmin activates the complement system, which causes aggregation of thrombocytes and the release of more vasoactive factors, while mast cell degranulation may be caused by anaphylatoxin. The end result is inflammation and tissue destruction. The Arthus phenomenon and immunogenic glomerulonephritis are common examples.

Type IV = delayed hypersensitivity. This reaction is caused by cell-mediated immune responses occurring at least 24 hours after antigen contact with sensitized T-cells. The local inflammatory response is caused by vasoactive lymphokines and substances released by mast cells. This type of reaction is caused by various bacterial antigens and virus-infected cells.

Immune Complex Reactions

Chronic lesions caused by immune complexes can occur in the form of amyloidosis. In ducks, geese and swans, reactive amyloidosis is quite frequently associated with chronic suppurative disease processes. Although amyloids differ in their composition, the amyloid proteins share the common feature of having polypeptide chains arranged in ß-pleated sheets. This uniquely stable molecular configuration renders the fibers virtually insoluble and almost completely resistant to proteolysis. As a consequence, amyloid is deposited in tissues and cannot be eliminated, resulting in a loss of parenchymal cells and tissue destruction.

Avian defense mechanisms are rather complex, and many of the intricacies of the systems have not been defined for poultry, much less for pet or aviary birds. Understanding the avian immune system is further complicated because of the involvement of hormonal and nutritional factors. Since antibodies and several of the mediators are proteins, deficiencies in essential amino acids may cause immunosuppression. Some of the vitamins, in particular vitamins A and C, influence both the epithelial nonspecific defense and the interaction between the humoral and nonspecific systems.[12] Of the trace elements, zinc is essential for one of the mediators in the thymus. Therefore, a well-balanced diet free of immunosuppressive mycotoxins is essential for birds that are to be capable of adapting satisfactorily to their environment with its multitude of infectious agents.

CHAPTER

6

FUTURE PREVENTIVE MEDICINE

Branson W. Ritchie

Traditional methods of detecting infectious disease agents have relied on recovering the inciting organisms from tissue samples, excretions or secretions, or indirect demonstration that an organism has been present in the body through the detection of a host immune response (principally antibody production).

All of these detection systems have inherent problems. Techniques that detect the presence of an organism (eg, electron microscopy, antigen ELISA, antigen immunodiffusion assays and histopathology) are either non-specific, relatively insensitive or both.

Many microbes cannot be propagated *in vitro* and are present in low numbers in secretions or excretions, making their antemortem detection difficult. *In vitro* propagation may require weeks, reducing the clinical value of the information obtained.

Documenting an infection through the host's production of antibodies requires a functional immune system. Additionally, paired serum samples collected two weeks apart must be tested to demonstrate a four-fold increase in antibody titer. The accurate detection of an infection, based on an acute and convalescent serum sample, is effective for documenting active infections, but the information is obtained too late to influence disease management. Determination of antibody titers may also be ineffective in detecting subclinical carriers, latently infected animals or slow infections.

Nucleic acid amplification and detection technologies will continue to improve and will compensate for many of the problems associated with other diagnostic techniques. Every clinician should have a rudimentary understanding of the methodologies, applications and problems associated with these test systems. Nucleic acid probe technology is currently being used to detect microorganisms, determine gender and detect genetic abnormalities.

Overview of DNA and RNA

The ability to selectively amplify and detect nucleic acid from pathogens is based on the fact that unique sequences of DNA or RNA are present in all living organisms. As a review, DNA is a polymer made of four units (bases): adenine (A), guanine (G), cytosine (C) and thymidine (T). RNA is a polymer made of four bases: adenine, guanine, cytosine and uracil (U). In the cell, the replication of DNA or RNA is catalyzed by specific enzymes (polymerases). Specifically derived heat-stable polymerases can be used *in vitro* to reproduce nucleic acid.

DNA generally exists in a double-stranded form (some viruses have single-stranded DNA or RNA). When double-stranded DNA is heated, the individual strands will separate (melt) from each other. When the strands are allowed to cool, the individual strands will rebind (reanneal) to their complementary strand of DNA, so that adenine from one strand binds to thymidine on the other strand, and cytosine on one strand binds to guanine on the other strand (Table 6.1).

If two single strands of DNA (for example, a synthetically produced DNA probe and a target sequence of pathogen DNA) bind together, the process is called hybridization (Figure 6.1). This hybridization process is the basis of using pathogen-specific DNA sequences (probes) to detect the presence of an organism's nucleic acid in samples collected from a host.

TABLE 6.1 Complimentary Binding of DNA and RNA Bases

For DNA	For RNA
A is complementary (binds to) **T**	**A** is complementary (binds to) **U**
C is complementary (binds to) **G**	**C** is complementary (binds to) **G**

If two strands of single-stranded DNA with the complimentary sequences;
Single strand 1 = 3′ **TACGGACCTTACG** 5′
Single strand 2 = 5′ **ATGCCTGGAATGC** 3′
are mixed together under the correct conditions they will bind together (hybridize) to form a double-stranded molecule.
Double stranded = 3′ **TACGGACCTTACG** 5′
5′ **ATGCCTGGAATGC** 3′
If two strands of single-stranded DNA that do not have complimentary sequences;
Single strand 1 = 3′ *TAC***GGACCTTA***CG* 5′
Single strand 2 = 5′ *ATG***TTAAGGCG***GC* 3′
they will not bind together (hybridize) and will remain as two single stranded molecules
Single strand 1 = 3′*TAC***GGACCT***TACG* 5′
Single strand 2 = 5′ *ATG***TTAAGG***ATGC* 3′

FIG 6.1 DNA hybridization process.

DNA Probe Technology

Use of DNA Probes

The ideal diagnostic test would provide maximum sensitivity (no false negatives), specificity (no false positives) and rapid results. Advances in the understanding of molecular biology have lead to the development of techniques that allow for the amplification (increasing quantities) and detection of organism-specific nucleic acid sequences. These test systems are based on the use of organism-specific DNA probes, and this new generation of tests most completely meets the requirements of an ideal method of detecting and identifying an organism (Figure 6.2).

The sensitivity and specificity of nucleic acid probe technology, the speed of obtaining results and the fact that the process can be used to detect organisms that will not replicate *in vitro*, may ultimately lead to nucleic acid probes replacing culture techniques as the gold standard in detecting pathogens.

With some microorganisms, DNA probes may be useful in detecting active as well as subclinical infections. The identification of subclinically infected animals requires that the reservoir site for the infectious agent be identified, and that samples be collected from the appropriate site at the correct stage of the infection. Depending on the organism and the host, these reservoir sites may be blood cells, hepatocytes, enterocytes, neurons or possibly any cell within the body. Samples that might be effective in detecting subclinical carriers could then include whole blood, liver biopsies or excrement (Figure 6.3).

Given the correct conditions, synthesized DNA probes will bind to specific, complementary target DNA (in a diagnostic test this is pathogen DNA), and the hybridization that occurs can be detected by using a number of visual indicator systems (eg, color change systems, radiographic sensitive systems).

An oligonucleotide DNA probe is a short sequence of nucleotide bases that is designed to detect a complementary strand of nucleic acid in a diagnostic sample

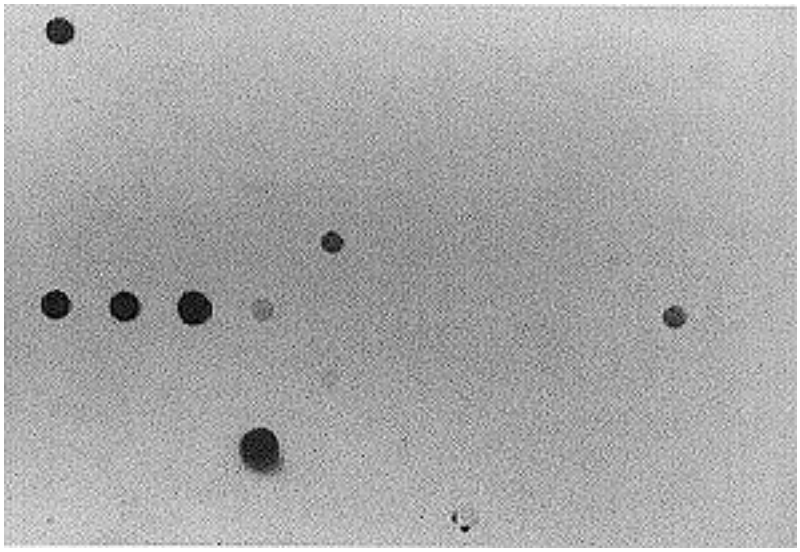

FIG 6.2 The 96-well format is used to test for the presence of PBFD virus nucleic acid in birds' white blood cells using viral-specific DNA probes. Each black dot represents a positive test (courtesy of Avian Research Associates).

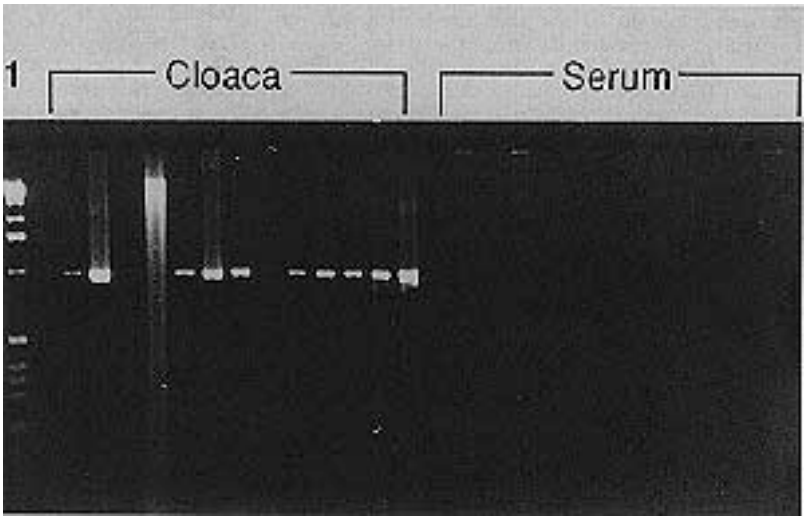

FIG 6.3 For a DNA probe to be effective in detecting a subclinical infection in a bird, it is necessary to know where the pathogen is located in the body so that the correct sample can be collected and tested. In this case, viral-specific DNA probes were used to compare cloacal swabs and serum for detecting the presence of polyomavirus. Lane 1 is a control. The white bands present in the cloacal swab samples indicate the presence of polyomavirus nucleic acid. The absence of bands in the serum samples indicates that polyomavirus nucleic acid could not be detected in the serum of birds that were shedding polyomavirus.

(eg, tissue, sputum, blood, feces). For a DNA probe to be specific, it must be developed from a known genomic sequence of the organism in question. A probe designed from unknown sequence can create errors in interpretation.

For example, if a specific portion of the polyomavirus genome had bases arranged in the order:

5′...GGTACGTA**ACTTAAGGCCAATTCG**GCCTCGG...3′,

a DNA probe with the sequence

3′ - **TGAATTCCGGTTAAGC** - 5′

would be complementary to this sequence and would bind (hybridize) when the two nucleic acid strands were incubated in the proper conditions. This probe could be used to detect the presence of this specific polyomavirus genome sequence in infected liver tissue, saliva, urine or in a contaminated environment (if the nucleic acid from the virus were present in the sample).

Once a probe has bound to a target DNA molecule, the probe must be able to be detected. This detection can be accomplished by incorporating labels (eg, P^{32}, S^{35}, I^{125}, alkaline phosphatase, digoxigenin, horseradish peroxidase) into the probe. Most commercial probes use alkaline phosphatase, digoxigenin, or horseradish peroxidase to avoid the management problems associated with radioactive isotopes.

For example, if a labelled DNA probe with the sequence

5′ - **AATTCCGG** -3′ Dig
(a digoxigenin labelled probe for mycobacteria)

was mixed into a processed sample containing the mycobacterial nucleic acid sequence

.... 3′ - GACGTA**TTAAGGCC**TAGCAT.... 5′

then the probe would bind (hybridize) to the target sequence. Bound digoxigenin (on the probe) could then be detected by means of a routine series of reaction steps.

If on the other hand, the DNA probe was mixed into a processed sample that contained *E. coli* genome with the sequence

5′ ... AGTAGCCTTAGGAC... 3′

and no mycobacterial nucleic acid sequence (target) then the probe with attached digoxigenin would not bind and would be washed away.

These examples illustrate that the key to a DNA probe detection system is to identify a pathogen-specific nucleic acid sequence and to synthesize nucleic

acid probes to bind specifically to this sequence. The specific nature of the probe prevents cross-reactions with other pathogens, imparts specificity and reduces false-negative results.

Specificity of Nucleic Acid Probes

Nucleic acid probes can be designed to be so specific that they can differentiate between two related organisms that are antigenically similar (induce production of similar antibodies) but have differences in nucleic acid sequence that alter the pathogenicity of the organism. As a hypothetical example, two adenoviruses that are antigenically similar could occur in a bird population. Because they are antigenically similar, these adenoviruses would be difficult to differentiate using an antibody-based diagnostic test. Clinical evidence suggests that in some cases, these adenoviruses are highly pathogenic with high levels of mortality, while in other cases, infected birds develop an immune response and remain subclinical.

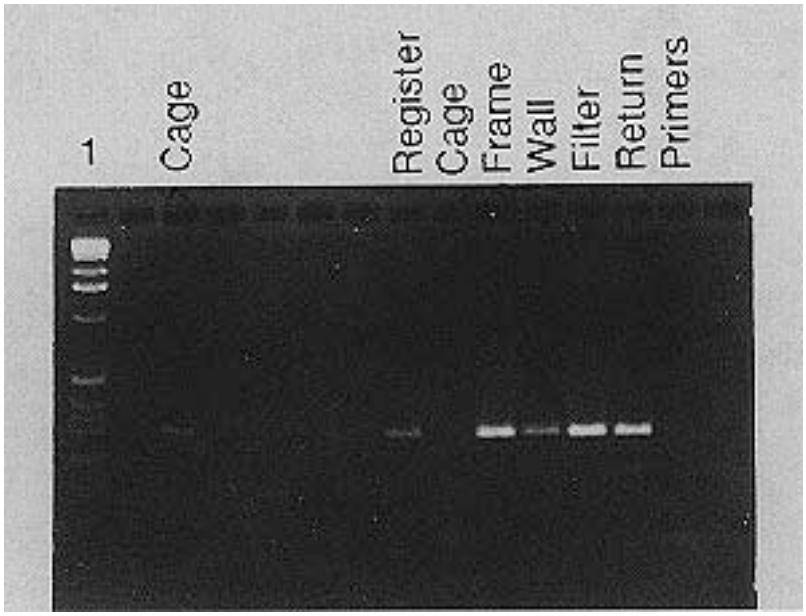

FIG 6.4 Pathogen-specific DNA probes can be used to determine if an area is contaminated with nucleic acid from an organism. Lane 1 is a control. The white bands indicate environmental samples that contain PBFD virus nucleic acid. In this case, the home of a client that had a bird with PBFD virus was screened for environmental contamination by the virus. Before cleaning, the enclosure was positive for PBFD virus nucleic acid (lane 3). After cleaning, the enclosure was negative for PBFD virus nucleic acid (lane 9); however, the registers, returns and filter associated with the heating system, as well as the wall and a picture frame in the room where the bird was housed were positive for PBFD virus nucleic acid.

By determining the DNA sequence of virus recovered from different birds, it might be discovered that the virus that causes high mortality has a different nucleic acid sequence than the virus that induces a subclinical infection. This difference might be:

5′ ...ATTG**CCATGGAAT**CCGATT... 3′
for the pathogenic strain and

5′ ...ATTG**TTAGGCTAG**CCGATT...3′
for the nonpathogenic strain.

A DNA probe with the sequence

3′- **AATCCGATC** -5′

could then be used to specifically detect the nonpathogenic strain. A probe with the sequence

3′- **GGTACCTTA** -5′

could be used to detect the pathogenic strain.

From a diagnostic perspective, probes are extremely valuable because they can be developed for pathogens so that they are genera-, species- or strain-specific, depending on which portion of a nucleic acid sequence they are designed to detect. For example, a probe could be developed that would detect any *E. coli* or only an *E. coli* that had a unique biochemical function. In the following example three strains of *E. coli* exist: one is highly virulent, one is considered normal flora in an animal and one is considered an environmental contaminant. The three strains have the nucleic acid sequences:

5′.... GCTATGCTT**AGGCCTTA**....3′ virulent strain

5′.... GCTATGCTT**GCCGATAA**....3′ normal strain

5′.... GCTATGCTT**GATCGGTA**.... 3′ environmental strain.

An oligonucleotide probe with the sequence

3′ CGATACGAA 5′

would detect all three of the *E. coli* organisms because it is designed to be complementary (and will hybridize) to a conserved sequence that is common to all three strains of *E. coli*. A probe with the sequence

3′ **CTAGCCA** 5′

would detect only the strain of *E. coli* considered an environmental contaminant because this sequence is unique to that strain of bacteria (Figure 6.4).

Once a probe has been developed, it can be used to detect nucleic acid that is extracted from a sample and attached to a membrane, or it can be used to detect pathogen-specific nucleic acid in a section of paraffin-embedded, formalin-fixed tissue that has been processed for histopathologic evaluation (*in situ* hybridization).

In situ hybridization using pathogen-specific nucleic acid probes is particularly effective when a pathogen is present in relatively small numbers or produces a lesion that histologically resembles that induced by other pathogens. For example, the intranuclear inclusion bodies caused by polyomavirus can appear morphologically similar to the intranuclear inclusion bodies caused by PBFD virus or adenovirus (see Color 32). *In situ* hybridization using viral-specific DNA probes can quickly and correctly determine which of these viruses induced the identified inclusion bodies. When compared to antibody staining techniques for the identification of pathogens in tissues, nucleic acid probes are more specific and more sensitive than other pathogen detection techniques. They also detect organisms that may have been antigenically altered during processing.

In addition to confirming the presence of a pathogen in tissue, *in situ* hybridization can also be used to detect the type of cell infected and whether the pathogen's nucleic acid is present in the cytoplasm or nucleus of the host cell. This last finding is of particular importance in understanding the replication scheme of many viruses, which can be critical for understanding how infections can be treated or prevented.

Sensitivity of Nucleic Acid Probes

In infected tissues where high numbers of the organism are present, the use of DNA probes to detect the presence of an organism's nucleic acid is fairly straight forward. In contrast, detection of a pathogen in excretions or secretions where numbers of the organism may be small requires further processing. To increase the likelihood of finding an organism in a diagnostic specimen (increased sensitivity), a sample to be tested is often subjected to a group of reactions that will amplify (increase) the number of pathogen DNA molecules in the sample, thus improving the ability of the probe to detect the organism.

The most commonly employed technique for amplifying target nucleic acid is the polymerase chain reaction (PCR) (Table 6.2). Theoretically, when used in combination with pathogen-specific nucleic acid primers, PCR can use one copy of a nucleic acid sequence to produce 1,000,000 copies. The most important component of this process is the pathogen-specific oligonucleotide primers. It is these oligonucleotide primers that allow the process to preferentially increase the number of pathogen nucleic acid molecules without increasing the number of all other contaminating nucleic acid molecules that would be present in a sample.

TABLE 6.2 PCR Amplification of Nucleic Acid

PCR amplification involves three phases:
1) separating (denaturing) ds DNA to create ss DNA
2) binding (annealing) pathogen-specific primers to the ss DNA target (pathogen) nucleic acid
3) synthesizing new strands of target (pathogen) nucleic acid

For example, a fecal sample collected for polyomavirus testing might contain 10 polyomavirus particles, 300 *E. coli*, 10,000 *Staphylococcus* spp., 150 host-derived WBCs (nucleated and containing DNA), 50 host-derived RBCs (also nucleated in birds and containing DNA) and 300 *Candida* spp. It would not be possible to detect only ten copies of the target (polyomavirus) DNA. By using primers designed specifically for the polyomavirus nucleic acid, the amount of target sequence (portion of polyomavirus DNA to be detected) can be increased from 10 copies to 10,000,000 copies, while the contaminating DNA from the *E. coli*, staphylococcus, WBCs, RBCs and candida remain the same and become dilutionally unimportant. The 10,000,000 synthesized copies constitute a quantity that can be easily detected.

A PCR cycle involves heating the target DNA (from the pathogen in a sample) to cause ds DNA to become ss DNA, thus exposing the target sequence on the pathogen's DNA to the oligonucleotide primers, where they can anneal to prime the generation of new sequence. The temperature of the reaction is then adjusted so that an enzyme (DNA polymerase) will synthesize a new strand of nucleic acid starting from one end (3') of the primer. At a specified time (determined for each pathogen-specific set of primers), the reaction is heated to stop the DNA polymerase and separate the created ds DNA into new target ss DNA.

This process is cyclic and is usually performed 40 times. The synthesized strands of ss DNA serve as new templates for the reaction, and each cycle results in an exponential increase in molecules (ie, one molecule makes two, two molecules make four, four molecules make eight).

From a simplified perspective, the two most critical components for the amplification and detection of nucleic acid from an organism are the pathogen-specific nucleic acid primers used to increase the sensitivity of the test (increases the likelihood of detecting only a few of the organisms) and the pathogen-spe-

cific nucleic acid probes used to ensure the specificity of the test (ensures the amplified sequence is that of the target organism).

Sample Collection

Minimal contamination of a diagnostic sample can be a problem with the amplification step that is used to increase the sensitivity of the test. A knowledgeable clinician can minimize contamination by practicing sound techniques in collecting any samples for DNA probe testing. The same degree of care must be exercised when collecting samples for bacterial culture. For example, if a clinician were testing a bird to determine the presence of PBFD virus in the blood, and the blood sample was collected from a toenail, a positive result may indicate the presence of PBFD virus either in the blood or on the bird's toenail. Washing the bird's nail before collection would not be expected to reduce the potential for contaminating the sample. A blood sample properly collected into a sterile syringe by venipuncture would be less likely to result in a contaminated sample.

Vaccines

Conventional Vaccines

Modified live, killed or subunit vaccines are currently available for use in protecting animals from various infectious diseases. The function of a modified live vaccine is to produce an infection (thus inciting an immune response) without producing disease. Modified live vaccines have inherent risks including possible reversion to a virulent form or an attenuation that alters the antigenicity of the vaccine strain to such a degree that it is not protective against a field strain of a virus. Modified live vaccines may be virulent in animals that are immunosuppressed, may be immunosuppressive themselves, may cause a low level of morbidity that affects reproduction and must be handled with care to prevent inactivation.

Killed vaccines are produced by growing a pathogen *in vitro* and then inactivating it to prevent replication in the vaccinate. These vaccines require exposing the vaccinate to a large dose of antigen and frequently require the addition of harsh adjuvants that can cause unacceptable tissue reactions in the vaccinate.

Subunit Vaccines

To develop a subunit vaccine, the protein from a pathogen that induces a protective immunologic response in the host must be identified. The nucleic acid sequence (gene) that codes for this protein is then inserted (cloned) into a plasmid of an *E. coli* or other organism, which then produces the desired protein. The immunologic protein is then purified away from the producing organism and can be used as a vaccine. Subunit vaccines allow proteins that would protect an animal against different serotypes to be included in the same mixture.

Subunit vaccines represent only the portion of the viral protein that is responsible for eliciting an immune response and are completely safe because the vaccinate is not exposed to the nucleic acid of the pathogen (prevents replication of the organsim in the vaccinate). This prevents potential problems associated with the conversion of attenuated vaccine strains of a virus into a virulent strain. It also eliminates the possibility that a vaccinate may be exposed to a virus that has not been killed.

Several subunit proteins from the same organism can be combined in a vaccine to increase the immunologic response (as is seen with a natural infection) without the risk of inducing disease. In the development of subunit vaccines, it may be advantageous to combine several proteins from the same pathogen in order to stimulate both virus-neutralizing and T-cell immune responses. Subunit vaccines also create the possibility for incorporating several proteins from numerous pathogens into one vaccine.

Other Vaccines

Many pathogenic bacteria have been found to have capsular polysaccharides that function as virulence factors and elicit immune responses. For some human pathogens, these capsular polysaccharides have been purified and conjugated to proteins, which elicit immunologic responses and protect the host from the target bacterium. An better understanding of the interaction between bacteria and the host immune system may lead to methods to prevent rather than treat bacterial infections. A similar increase in the knowledge concerning the host immunologic response to parasites will be necessary before parasitic infections can be prevented through vaccination.

Adjuvants

The oil-emulsion adjuvants that are commonly used in mammalian vaccines have been shown to cause severe muscle necrosis in some species of birds (see Figure 32.8). One method of preventing these reactions is to use solid-matrix-antibody-antigen complexes in place of adjuvants. These complexes have been shown to be particularly effective in augmenting the immunologic response induced with subunit vaccines, and are being investigated for use in birds.

Liposomes have shown promise as carriers for immunogenic proteins that can be used for vaccination or immunotherapy. Injected liposomes are rapidly consumed by mononuclear phagocytes, particularly circulating macrophages.[5] In theory, any antigens present in these phagocytized liposomes would be processed and stimulate an immune response.

Antimicrobial Therapy

Conventional antimicrobial therapy depends on using chemotherapeutic agents that selectively interfere with metabolic processes that are unique to bacteria, parasites or fungi, while having little or no effect on the metabolism of the host cell. While this is generally effective for bacteria, parasites and fungi, it is ineffective for most viruses and tumor cells, which use the host cell metabolic pathways for energy production and replication. Antiviral agents are generally designed to prevent uncoating of a virus particle, and thus stop a virus from replicating.

Liposomes have been shown to be effective in transporting agents with immunologic activity against antigen-expressing tumors into the affected cells. For treating cancer, this type of immunotherapy would be far superior to chemotherapeutic methods currently used, because immunotherapy could be targeted specifically for the cancer-producing cells with no effects on normal cells within the affected host. Liposomes can also carry chemical compounds, such as muramyl-tripeptide-phosphatidylethanolamine, which increase macrophage activity.[4]

Monoclonal antibodies have been used as a therapeutic agent for some types of cancers with antigen presenting capabilities. By binding cytotoxic agents to the monoclonal antibodies, high concentrations of therapeutic agents are delivered directly to the affected cells to which the antibodies bind.[1]

Antisense RNA Therapy

In the process of replicating DNA, the cell produces a complementary copy of the DNA in the form of a messenger RNA. This mRNA is then used as a copy to make new DNA molecules. In the 1960's, a concept was developed of inhibiting the replication of DNA by introducing a nucleic acid sequence that would bind to the mRNA and prevent its use as a template for replication. This was termed antisense RNA therapy.

When fully implemented, antisense RNA therapy will revolutionize the way that neoplastic and viral diseases are treated. By binding specifically to mRNA, the antisense RNA would inhibit the replication of cancer cells or viruses, while having no adverse affect on unaffected host cells. Thus, antisense RNA would represent a safe, cell-specific therapy.

As a simplified example, the replication of a DNA virus may involve the initial nucleic acid sequence

5′ ATGCGGCCTTACCATGACAT....3′

The mRNA template for this sequence (in RNA, uracil is found in place of thymidine) would be

3′ **UACGCCGGAA**UGGUACUGUA...*5′*

If the antisense RNA sequence

5′ - **ATGCGGCCTT** - 3′

was introduced to the infected cell, it could bind to the mRNA sequence and prevent it from serving as a template for viral replication.

To be clinically applicable in the treatment of viral and neoplastic diseases, antisense RNA technology must advance to the point where therapeutic nucleic acid sequences can be introduced to the body in such a way that they enter an affected cell, and subsequently interfere with replication of a virus or neoplastic cell. The use of antisense RNA therapy is likely to evolve into a useful therapeutic regimen over the coming decade.

SECTION TWO

PATIENT EVALUATION

II

CHAPTER

7

PRACTICE DYNAMICS

Cathy Johnson-Delaney

For veterinarians with a strong interest in treating companion birds, the advantages of incorporating avian medicine into the small animal practice are numerous. With only minimal equipment additions and some intense continuing education with the desire to learn, the practitioner can increase patient diversity and practice volume and be introduced to the challenge of avian diagnostics and therapeutics.

Membership in the Association of Avian Veterinarians (AAV) and participation in conferences with carefully planned avian programs are necessary to keep abreast of the rapidly expanding information on the diseases and treatment of companion birds. The *Journal of the Association of Avian Veterinarians* and other journals and textbooks as well as popular bird magazines are essential reading for serious practitioners (Figure 7.1).

Within the extensive network of the AAV, there are many experienced members who are willing to share information and advice. Veterinarians with limited experience in treating birds should be realistic about their expertise and be ready to refer complicated cases that require advanced diagnostic, surgical or therapeutic techniques. A veterinarian may advertise a special interest in birds, but use of the word "specialist" is reserved for only those who are board certified in avian practice.

Attending aviculture seminars, visiting established avian practices and teaching bird handling skills to staff and colleagues are other good ways for beginning avian veterinarians to increase competence. Avian veterinarians in one city improved the care available to local avian patients by providing a training program and procedure manual for emergency clinicians in the area.[17]

FIG 7.1 Membership in the Association of Avian Veterinarians is suggested for any veterinarian planning to work with birds. Reading the information published in the Journal and the Proceedings of the Annual Conferences is essential to stay abreast of rapidly evolving information (courtesy of Cathy Johnson-Delaney).

Getting Started

There are many effective ways to attract avian clients, including adding birds to the logo on signs, stationery and business cards, placing avian magazines and client information in reception and exam areas, and decorating the clinic in an avian motif. Display of the AAV membership plaque, certificates presented by bird clubs and other organizations and newspaper clippings or articles help demonstrate a clinic's commitment to companion bird medicine (Figure 7.2).

Client education displays should include publications available from the AAV, diet manufacturers and other practitioners, as well as specific information sheets on such topics as diet, disease, husbandry, grooming and training. Some clinics find that establishing a library is well received by clients. Videotapes for in-clinic viewing can be made available and may include commercial tapes addressing avian management or training, as well as short demonstrations of wing and nail trimming, handling, restraint and treatment techniques. Videotaped "Nature" or "National Geographic" episodes dealing with birds or conservation are instructive, entertaining and create an opportunity for the avian veterinarian to discuss the importance of habitat preservation and sound avian stewardship.

The sale of formulated diets, nutritional supplements and avian care accessories (hemostatic agents, grooming aids, carriers), helps to demonstrate the clinic's dedication to the total well-being of companion birds. Alternatively, local pet retailers may be informed of a veterinarian's recommendations for diets and other avian products, and clients may be referred to those shops whose policies and products meet with established standards (Figure 7.3).

Advertising in the yellow pages or other local business listings and supplying pet supply retailers with business cards and client education materials are also effective practice builders. Training sessions for pet store employees and clients create an opportunity for the veterinary staff to address specific questions and to stress the importance of preventive health programs. Establishing a post-purchase examination program that is paid for by the pet supplier will reinforce the reputation of a dealer for selling healthy birds and provide the veterinarian with an increased client base. Most pet shops and breeders appreciate veterinary surveillance of not only their birds, but also of their facility design (eg, quarantine and traffic flow), diets and use of disinfectants.

Avian veterinarians should establish a program for visiting aviaries or multiple-bird households to perform preventive health screenings and aviary management evaluation (see Chapter 2). Problems associated with diet or husbandry can be more easily determined in the birds' home environment than from descriptions provided during office visits. Fees for aviary management consultations, multiple-bird examinations and large-volume laboratory work should accurately reflect the time involved in collecting and interpreting samples, yet not be cost-prohibitive to the client.

Avian veterinarians also benefit from membership in local avian, exotic animal and wildlife organizations. Participating in the activities of bird clubs (meetings, newsletters, bird fairs) and volunteering to speak at school career days, civic groups and scout meetings are other excellent ways to achieve visibility and credibility with companion bird clients.

Many practitioners provide instructional sessions to acquaint new bird clients with their pets. One successful program is called "parrot kindergarten."[16]

FIG 7.2 Providing an avian library, decorating in an avian motif and providing client information handouts and displaying professional awards or scientific publications (right) are all effective methods of keeping clients informed and communicating a hospital's interest in avian care (courtesy of Cathy Johnson-Delaney).

Sessions are conducted by a veterinarian, an aviculturist and a bird trainer to provide experienced insight into avian health care, management and psychological stimulation.

It is important for the beginning practitioner to become acquainted with local people who can serve as additional sources of information for individuals who keep birds. These people may include experienced aviculturists who are willing to share knowledge, "foster parents" who will temporarily take unwanted birds, zoo aviary keepers, experienced ornithologists, librarians and the curators of natural history museums.

Finally, it is easiest to build a referral practice by assuring local veterinarians that their clients' birds will be seen, but that their other pets will not. It is a good idea to send the referring veterinarian a "Thank you for the referral" card and a written synopsis of the diagnostic and treatment plan. It is especially important to maintain good communication with the referring veterinarian if a client lives in another area and the referring veterinarian will need to evaluate the effect of therapy or to provide further medications. Treatment and follow-up visits should be done locally whenever possible.

Staff Responsibilities

Staff members play a major role in the success of any practice. They should be familiar with the clinic's general recommendations on diets, husbandry and preventive health care. Developing an office manual that includes job descriptions, client instructions, hospital protocol and general data on various species of birds will serve as a reference text for the entire staff. Veterinary assistants should be expected to keep the hospital clean, maintain a patient's food and water supply, fill prescriptions and perform routine procedures such as restraining, medicating and grooming birds. All staff members should be encouraged to have their own companion birds in order to better relate to the clients and their birds. It is critical that staff members' and clinic birds be screened for infectious diseases to prevent them from serving as a source of infection for clients' birds. Assistants should also be encouraged to attend continuing education seminars.

FIG 7.3 Some veterinarians maintain a select group of avian diets and safe toys while others refer clients to pet supply retailers that meet established standards. Videotapes can be used in the reception area to teach clients how to better care for their pets. Client information brochures are available in the waiting room and in the examination room (courtesy of Cathy Johnson-Delaney).

Communicating with the Client

When a client calls for an appointment, the receptionist must instruct the client on the proper way to transport the bird to the clinic so that an evaluation of enclosure management and diet can be made. The water dish should be emptied before transport, but enclosure substrates should not be changed so that droppings from the past several days can be evaluated. The client should also be instructed to collect several fresh fecal samples at home by placing plastic wrap under the perch. The samples should be folded in the plastic and refrigerated until transport to the clinic. A paper towel placed over the enclosure substrate will help identify fresh droppings produced during the trip to the hospital. The client should also bring previous medical records, samples of the normal diet and samples of any abnormal discharges.

If the bird is showing signs of illness, the client should be instructed to warm the enclosure interior to 85-90°F and to cover it in such a way that this temperature may be maintained on the way to the hospital. Loose layers of plastic wrap under the regular enclosure cover may be helpful. If the ambient temperature is less than 60-75°F, it is recommended that the car be pre-warmed as well. Likewise, if ambient temperature exceeds 90°F, care must be taken to prevent hyperthermia.

A bird brought into the hospital on its owner's arm is an accident waiting to happen (Figure 7.4). Therefore, it should be hospital policy that all animals be maintained in an enclosure while in the reception area. If it is not possible to bring a bird's enclosure, a small animal carrier can be modified with the addition of a perch.

It is helpful for the staff to introduce themselves to new clients and to tell them what to expect during the office visit. The receptionist should give instructions for filling out the information forms. The technician should weigh the bird, discuss husbandry with clients and assist with restraint during the examination. At many clinics, a client can make an appointment with the veterinary technician for routine grooming procedures such as wing clips, weight monitoring and beak and nail trims.

An initial hospital visit will require extra time for filling out paperwork and providing a client with instructions concerning proper husbandry. Detailed information about the diet and home environment are crucial in evaluating the avian patient, as malnutrition and improper management are common causes of medical problems. The technician should take a Polaroid snapshot of the client and bird for the bird's medical record. The client should be provided a folder-type health record with a pocket to maintain receipts and examination certificates. This folder will serve as a reminder that birds need the same kind of routine preventive medical care as other pets.

For most psittacine birds, semi-annual examinations are recommended with emphasis on detecting subclinical problems (see Chapter 8). Many practices give the new client a "New Bird Kit" on the initial visit. This kit can include the health examination folder, client education materials, a hemostatic agent, a telephone sticker with the phone numbers of the clinic and recommended emergency clinic, samples of recommended avian foods and subscription information to bird magazines. Many clinics have customized bags with the clinic name, address, phone number and logo, as well as a space provided for the

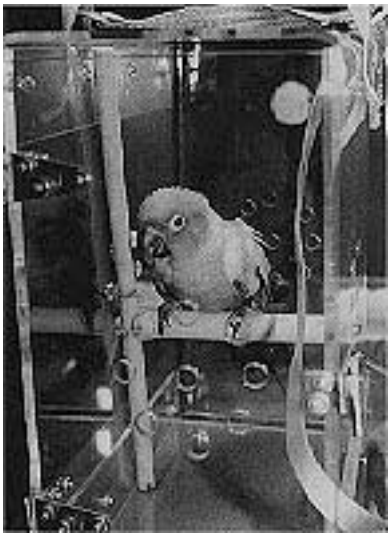

FIG 7.4 To prevent serious injuries to avian patients, the hospital policy should be that all birds are maintained in an enclosure while in the hospital. Additionally, birds being transported from one area of the hospital to another should be placed back in an enclosure to prevent accidental releases and injuries (right) (courtesy of Cathy Johnson-Delaney).

bird's name. This helps emphasize the clinic's commitment to personalized attention for each patient.

Record Keeping

The medical record system used in most small animal clinics can be modified for avian patients. A problem-oriented checklist works well for avian cases. A copy of the initial history and examination form should be included in the folder sent home with the client. A certificate of veterinary examination is usually necessary when performing post-purchase examinations for aviaries or pet shops. Two copies should be made so that one remains in the clinic records and the other goes with the client.

The computerized record systems used in many small animal practices can be easily adapted for avian patients, including modifying reminder forms to list avian procedures. Diagnostic software packages for the avian patient are under development.

Another proven way to maintain a positive client relationship is by communicating with them through the use of "Welcome to the practice" cards, sympathy cards and clinic evaluation forms.

From the initial examination and identification of potential problems with diet and husbandry to daily assessment of a hospitalized bird's condition, communication with the client is essential. If a bird must be hospitalized, the client should be given a written estimate of the medical plan and costs, and a hospital consent form should be signed. The higher cost of avian services as compared to those for dogs and cats reflects the increased amount of time avian patients require, as well as the increased training and expertise required by the veterinary staff.

Hospitalization Protocol

Clients apprehensive about hospitalizing their birds may feel more at ease if they are introduced to the staff members who will be caring for the bird and shown where their bird will be housed. To avoid disturbing other patients, a videotape of the facility may be used. Sometimes it is enough to explain how the enclosure is set up and what enrichments are provided such as heat, light, music and visibility of humans. Visitation policies may vary on a case-by-case basis. A patient that is highly bonded to its family and becomes depressed when separated (beyond its illness) may greatly benefit from regular visitation. The client may also be able to entice a reluctant patient to eat. On the other hand, if the bird has a contagious disease or is recovering from a serious injury or surgical procedure, the excitement and activity associated with a visit may be contraindicated. In any case, clients should be encouraged to call during specified times to receive updates on the condition of their pets.

Before a bird is discharged from the hospital, the technician should instruct the client on how to administer medications and provide the recommended care, including provisions for keeping the bird warm on the way home. It is usually advisable that written home care instructions, the hospital bill and the recheck appointment be discussed prior to reuniting the bird and the client to prevent the client from being distracted by the pet.

A phone call the day after discharge allows the veterinarian to evaluate the patient's condition and gives the client an opportunity to ask questions. A client evaluation form mailed several days following a visit may help reveal the client's perspective of the clinic's strengths and weaknesses. The survey should be short and include multiple choice questions and space for written comments regarding clinic facilities, staff, telephone courtesies, pricing and medical treatment. A return envelope will encourage client participation.

Travel Considerations

Occasionally clients will request health certificates in order to transport birds between states or countries. Most airlines are now refusing to transport wild-caught birds, and many domestic carriers are refusing to ship companion birds on the grounds that it is difficult to differentiate between domestically raised and imported birds. Airlines that will ship companion birds within the United States will specify the type of carrier they will accept and the conditions of release from liability that must be authorized. According to aircraft manufacturers and airline engineers, temperature ranges in the cargo bins, which are designated for carriage of animals, vary from 40°F to approximately 70°F, depending upon the aircraft type used by the transporting airline. Newer-generation jets (eg, 757s) generally have warmer temperatures in the cargo bins and therefore are more comfortable for animals.

Carrier specifications for international shipment are set by the International Air Transport Association, and many airlines use these standards for domestic flights as well. It is advisable to be familiar with these carrier specifications and to contact the state veterinarian regarding what is considered a properly completed health certificate for a companion bird. Use of the term "health certificate" should be discouraged because it is impossible to determine from a physical examination if a bird is healthy. A complete evaluation requires extensive laboratory work and radiology, and even then it may be impossible to determine if the bird is latently infected with an infectious agent. Use of a "Certificate of Veterinary Inspection" to accompany the state regulatory form may be appropriate. An evaluation does not guarantee that a bird will remain healthy following transportation.

If a client plans to take a bird traveling by car, it is recommended that the bird first be given a full examination to detect subtle problems that might manifest during the stress of traveling. When possible, it is advantageous to place the bird in a familiar enclosure for travel. An adequate food supply should be carried, as not all diets are available in all areas. Clients should also consider weather, potential hazards (eg, animals, children) in homes or campgrounds where they will be staying, policies of hotels and motels, and if the disruption in daily routine will adversely affect the bird. For some birds, it is less stressful to be left at home or boarded. A brochure entitled "Traveling with Your Pet" is available from the ASPCA Education Dept., 441 East 92nd St., New York, NY 10128.

Birds that are boarded at a veterinary clinic must be kept isolated (different air space with different caretakers) from ill birds as well as from other boarding birds from different households. Clinics with limited space may board birds from a single household at one time. Establishing a bird-sitting service using clinic staff or outside individuals works well and decreases the risk of exposing birds to infectious agents. If bird-sitters visit more than one household a day, they must take precautions to prevent disease transfer between homes.

Accommodating the Avian Patient

In order to transform a traditional small animal clinic into an "avian friendly" clinic, a number of modifications should be considered. A separate avian waiting room would be ideal, but if that is not possible, an area that is not in direct contact with dogs, cats and children should be designated for bulky bird enclosures and carriers.

Furnishings for the avian practice should be comfortable, durable, washable and easily disinfected. Reception and exam room chairs should be of varnished, metallic or plastic finishes. The removable canvas backs and seats of director's-style chairs can be easily washed and disinfected and come in many colors and fabric designs.

Safety Considerations

The areas of the hospital where birds will be handled outside of their enclosures should be bird-proofed, and appropriate nets for catching birds should be available. Ceiling fans are not recommended for avian hospitals. Wall fans, radiators, baseboard heaters, light fixtures and other electrical equipment must be shielded from direct contact. Open windows should be securely screened and be covered with blinds or draperies. Open shelves, bottles and jars may be viewed as perches by free-flying, frightened birds. Waste baskets should be placed in cabinets or

have fitted lids, cold sterile instrument trays should be covered, and counter tops should be kept clean.

Equipment in the exam room, including a gram scale, an auxiliary light source, a magnifying head loop, speculums, towels or restraint cloths, oxygen, heating pad, lamp and diagnostic and first-aid equipment should all be within easy reach. Furniture should be minimal, including chairs for the clients, sufficient table surfaces for enclosure security and a stool for the practitioner. Areas with minimal furniture are more secure and easier to keep clean.

Housing

Appropriate enclosures for avian patients must also be considered. A separate avian housing area that can be maintained at 80-85°F is preferable, but not essential. Birds may be housed in aquariums with screened covers, intensive care units or converted small animal enclosures. Aquariums are relatively inexpensive and easy to clean and disinfect. Screen-covered tops provide good ventilation, while the aquariums themselves hold heat and reduce hospital contamination from discarded food and droppings. They also offer complete visibility and easy access to the patient. Heating pads placed under or along one side of the aquarium can raise the interior ambient temperature to 85-90°F. Surgical drapes or clean towels can be used to cover portions of the aquarium to retain additional heat and allow the bird a more private convalescent area. A five-gallon aquarium works well for small birds, a ten-gallon size for medium-sized birds and a twenty-gallon size for larger birds.

Commercial and custom-designed aquariums heated with warm water make excellent housing units for sick birds. Some hospitals use avian isolation units, complete with separate heat and ventilation.

Existing small animal kennels can be converted by installing a removable perch and lining the enclosure with brown wrapping paper or butcher paper. Newspaper print may stain the feathers of white birds. Heating pads or clamp-lamps provide supplemental heat, and towels, plastic wrap, acrylic or plexiglass sheets can be placed over the front of the enclosure to retain heat (Figure 7.5). Enclosure doors should be removed, scrubbed and soaked in disinfectant after each bird. Spraying a light coat of Pam cooking oil or silicone on the bars will facilitate the removal of excrement.

Avian enclosures should be easily viewed from across the room or through a window to minimize the need to approach the enclosure to evaluate a patient. The staff member who feeds, cleans and interacts with the bird should not be the same person who provides "threatening" medical treatment. The bird is less likely to be defensive around a non-threatening person, and a more accurate assessment of changes in its daily condition can be made.

Preventing the Spread of Disease

Many avian pathogens can be spread through aerosol and feather particulates, and an efficient ventilation system of laminar flow design will minimize hospital contamination. As fresh air enters one side of the room, it passes across the examination area and is pulled outside by exhaust fans with vents placed approximately two feet above floor level in the opposite wall from the fresh air vent. Air filtration systems (purifiers) designed to decrease particulates and pathogens to the 0.1-1.0 micron range are recommended for use in the reception, examination, treatment and housing areas. The maintenance requirements and volume of air exchanged vary with each system. These units reduce aerosolized hair, dander, feathers, dust and contagions that would otherwise accumulate in the environment. In initially designing a hospital, areas with separate air flow systems should be incorporated to allow for the separation of patients that require routine care from those that may have infectious diseases. Hospital suites for housing sick birds should be divided into small, easily cleaned areas that also have separate air flow systems.

FIG 7.5 A small animal hospital enclosure can be easily modified to house avian patients. Plastic curtain rod holders are glued to the sides of the enclosure to hold removable perches. Hard plastic containers are used for food and water, and the bottom of the enclosure is covered with butcher wrap (newspaper ink may stain some feathers) (courtesy of Cathy Johnson-Delaney).

All equipment used on avian patients should be thoroughly disinfected between patients. It should be stressed that all disinfectants are toxic and must be handled with care to prevent problems in hospital premises or patients. No disinfectant can work effectively in the presence of organic material (see Chapter 2). Food and water dishes, feeding devices, perches and other enclosure accessories should be free of food and excrement prior to being soaked for 30 minutes in a phenol or quaternary ammonia disinfectant. Disinfected items should then be put through an automatic dishwasher (hot water cycle), rinsed thoroughly and dried before re-use. Disinfected supplies should be stored in closed cabinets or containers away from areas where they may be exposed to aerosols and particulates from ill patients. Quaternary ammonia solutions (quats) are satisfactory for use as table washes or in cold sterilization trays, and can be used to clean enclosures and soak capture nets, dishes, perches and grooming tools. Because these solutions may be nephrotoxic to birds, equipment must be thoroughly rinsed after being soaked in quaternary ammonia compounds. Quats are the disinfectants of choice against chlamydia and have a wide range of effectiveness against many other pathogenic bacteria and viruses. A phenol-type disinfectant is recommended by the United States Department of Agriculture (USDA) for use in quarantine stations and other avian facilities. It has activity against the Newcastle disease virus and many other pathogens. Phenols may be used for cleaning enclosures and other equipment, but because they are irritating to skin, rubber gloves should be worn, and enclosures and instruments must be thoroughly rinsed prior to direct contact with birds.

Chlorhexidine has the advantage of being gentle to tissues and equipment and is effective against viruses and candida, but it is not effective against chlamydia and many other pathogenic bacteria. It can be used in some cases in the drinking water or as a wound or sinus irrigation solution or in liquid diets and hand-feeding formulas. Other types of disinfectants useful in the avian practice are isopropyl alcohol for cleaning surfaces and instruments; iodophores such as povidone iodine solutions (hand soaps, scrubs and wound irrigations) and chlorine bleach for cleaning non-metal surfaces, equipment and utensils. Good ventilation is important when using any disinfectant, and surfaces must be thoroughly rinsed and dried before coming in contact with birds.

Floors in the avian hospital should be vacuumed frequently to prevent the accumulation of feathers, dander and foodstuffs. Because vacuum cleaners, electric brooms and small portable cleaners tend to scatter viruses into the air, it is advisable to spray the bags prior to, during and after use with a disinfectant. In vacuums that do not use bags, the intake pieces, brush attachment and collection chambers must be disinfected thoroughly after each use. The exteriors of such appliances, as well as the exhaust vents, need to be kept clean and disinfected as well.

The order in which hospitalized avian patients should be maintained follows the same pattern as that for working with other animals: clean, feed and treat beginning with the healthiest and ending with the most highly contagious and critically ill. Any bird within the hospital that is sick for an unconfirmed reason should be considered highly contagious until proven otherwise. When working with a patient with a highly infectious disease, it is advisable for the attendant to wear a mask and hospital gown that can be changed. Attendants should also use a disinfectant spray on their clothing and hair between birds. Hospital counters, shelves and tables should be wiped down with disinfectants after each use.

Equipment

The specialized equipment needed to practice avian medicine is minimal. Many small animal practices already have isoflurane anesthesia (mandatory for avian practice), ophthalmic-sized surgical instruments and suture materials, an endoscope, a radiosurgery unit and radiographic equipment. Additional equipment acquisitions should include a high quality gram scale (Figures 7.6, 7.7), avian mouth speculums, gavage needles and a radiographic positioner. Bandaging and splinting supplies, protective collars and dental acrylics for orthopedics and beak repair are also necessary.

Other equipment required for an avian practice includes heavy ceramic bowls and a variety of perches that can be easily cleaned and disinfected (Figure 7.8). It is important that hospital perches be made of non-porous material such as heavy plastic or epoxy/resin composites. Perches of porous material (eg, wood) should be disposed of after use. Household fixtures (eg, towel racks, curtain rods, shower rods) and PVC pipe are good choices for perches (Figure 7.9).

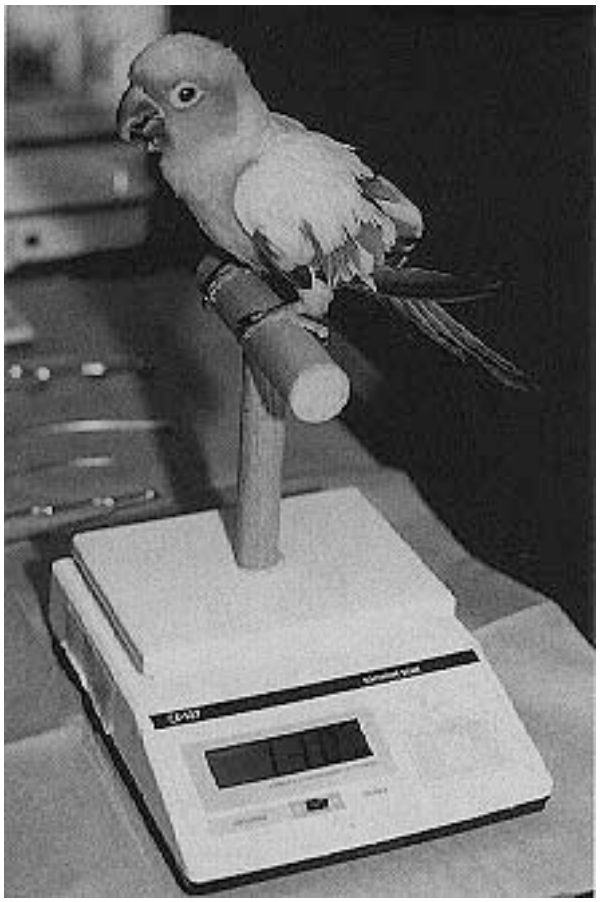

FIG 7.6 An accurate gram scale is mandatory in the avian hospital (top left). Scales can be fitted with perches, or light-weight containers can be used to facilitate weighing (bottom left). Digital units that have an automatic tare feature are easiest and fastest to use (above) (courtesy of Cathy Johnson-Delaney).

Diagnostic Equipment

Equipment necessary for basic in-house avian diagnostic tests includes a binocular microscope with oil immersion capability (1000x), hematocrit centrifuge, refractometer, hemacytometer, bacteriologic incubator, alcohol lamp or Bunsen burner, and basic laboratory supplies such as staining kits, coverslips, slides, hematocrit tubes, serum separators and culturettes (Figure 7.10).

Several serum chemistry testing systems are commercially available. Dry chemistry analyzers are fast, easy to operate and require very small sample sizes. Those currently used in avian practices are the Kodak DT60 Analyzer,[a] the VetTest 8008,[b] the Reflotron[c] and the Seralyzer.[d] Both the Kodak and the VetTest units can run a typical avian profile including AST, uric acid, glucose, calcium, total protein and albumin. The Kodak DT60 has the largest test menu and includes a full electrolyte panel. The VetTest includes software that provides some normal avian values and diagnostic information (Figure 7.11). Both machines have proven to be reliable, easy to operate and have demonstrated consistent results when used in avian practice.

"Wet chemistry" analyzers such as the Gemstar II Chemistry System[e] and the Analyst[f] also run tests applicable to avian patients but require larger sample sizes than do the dry chemistry analyzers. These machines have been shown to be reliable and provide good quality results in some clinics; however, the sample size needed may be prohibitive with some avian patients. The major advantage to the wet

chemistry systems is the significantly lower cost per test. Hematology, cytology and microbiology equipment, techniques and supplies are covered in depth in Chapters 9, 10 and 11.

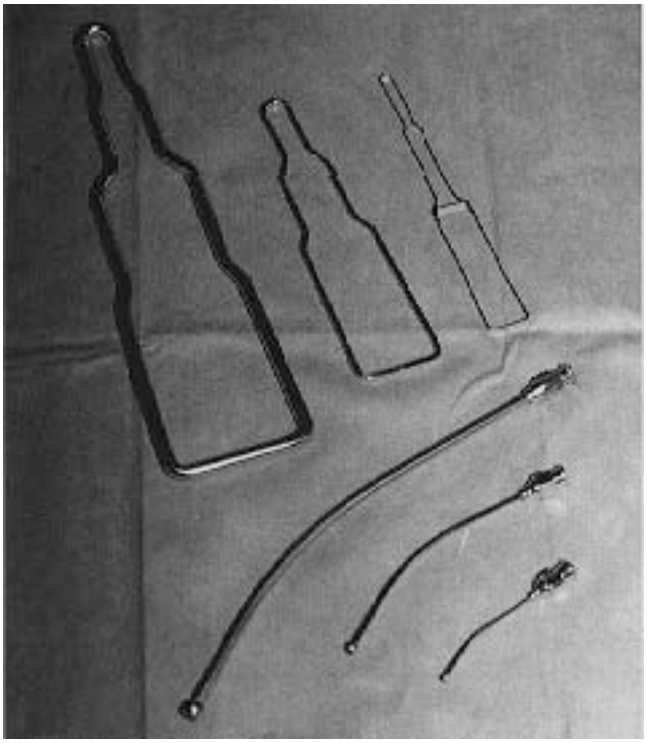

FIG 7.7 Mouth speculums and feeding tubes (either stainless steel or red-rubber type) are essential pieces of equipment in the avian practice (courtesy Cathy Johnson-Delaney).

FIG 7.8 Food and water containers used in the hospital should be durable, noncorrosive and easy to disinfect. Stainless steel, hard plastic and crockery bowls work best.

Although many clinics perform in-house diagnostic tests, most find it necessary to use the services of consultants from time to time. Board certified radiologists and histopathologists who have had experience diagnosing avian cases are especially helpful. Commercial clinical pathology laboratories that specialize in avian and exotic patients are indispensable for isolation and identification of avian pathogens that require specialization beyond the capacity of most veterinary hospitals.

Submitting Samples to an Outside Laboratory

The decision regarding which tests to perform in-house and which to send to other laboratories depends on several factors: speed of desired results, effect of results on therapeutic decisions, staff ability to perform tests accurately and frequently enough for proficiency, the amount of staff time needed to perform a test, equipment sensitivity and suitability for sample volume, cost of equipment, staff training, consultation and trouble shooting. While it is frequently convenient to have results of tests available during the patient's visit or on weekends and holidays, the results have to be accurate and reliable, as well as cost-effective.

Considerations for choosing an outside laboratory include experience in avian diagnostics, types of services and tests available, sensitivity and specificity of the tests offered, policies regarding laboratory supplies and transport media, mailers, billing and invoice policies, direct fees for tests, turnaround time for results being reported and method of reporting (telephone, fax, computer, mail). A laboratory that is reporting sensitive data by fax should require that the clinician sign a release form stating that the fax

FIG 7.9 PVC pipe can be used to construct low perches that are used for extremely ill birds. This material is easy to clean and disinfect but should not be used for long-term perching (greater than two weeks) to prevent foot and leg problems. The perch can be wrapped with a layer of self-adherent bandage material to improve traction. The bandage material is changed between patients (courtesy Cathy Johnson-Delaney).

is secure to receive confidential information. There are potential legal ramifications of laboratories reporting sensitive information regarding infectious diseases by phone, and high quality laboratories will provide this information only by mail or to a secure fax machine. It is important to become acquainted with laboratory submission and shipment protocol and methods of reporting results. Submitted samples should always be clearly identified and accompanied by a written report indicating the tests requested, a brief history of clinical signs, differential or tentative diagnosis and any medications being used. It is advisable to keep appropriate transport media and shipping containers in the hospital. Sources of dry ice, liquid nitrogen or cold packs should be identified before these products are required. Ideally, all samples submitted should meet the following criteria:

1. Baseline samples should be taken prior to administration of medication. Correct sample collection techniques should be used (free-flowing blood not nail clip for blood work).
2. Samples should be collected aseptically from anatomic sites likely to contain pathogens.
3. Samples should be taken during the acute phase of the disease rather than the chronic stage.
4. A relevant synopsis of the disease process or flock outbreak should be included.
5. Any pertinent background information and differential diagnoses should be provided.

Samples submitted for bacteriology, virology, chlamydia isolation or necropsy require special consideration. Direct communication with the laboratory prior to shipment is advisable. If the laboratory does not provide pick-up service, other couriers may be used. Shipments should be planned to arrive early in the day during the week.

Most samples for bacteriologic screening should be kept moist in an appropriate transport medium, refrigerated but not frozen and sent immediately with cold packs. Chlamydia isolation may be more successful if tissues are frozen and shipped with dry ice, rather than refrigerated immediately and then shipped on regular ice. Fecal samples or cloacal swabs in specific chlamydia transport medium may be submitted for antemortem diagnosis. Refrigerants must be sealed in leak-proof plastic bags, and dry ice should be packed to allow for the carbon dioxide to escape after sublimation, without contaminating the samples. Refrigerants should constitute about 50 percent of the weight of the contents of the package. Styrofoam-lined boxes with sturdy cardboard, wood or plastic exteriors are preferred for shipping refrigerated specimens. To comply with legal and medical responsibilities, specimens should be packed with sufficient material to absorb any leaking fluid as well as to protect the specimen from damage.

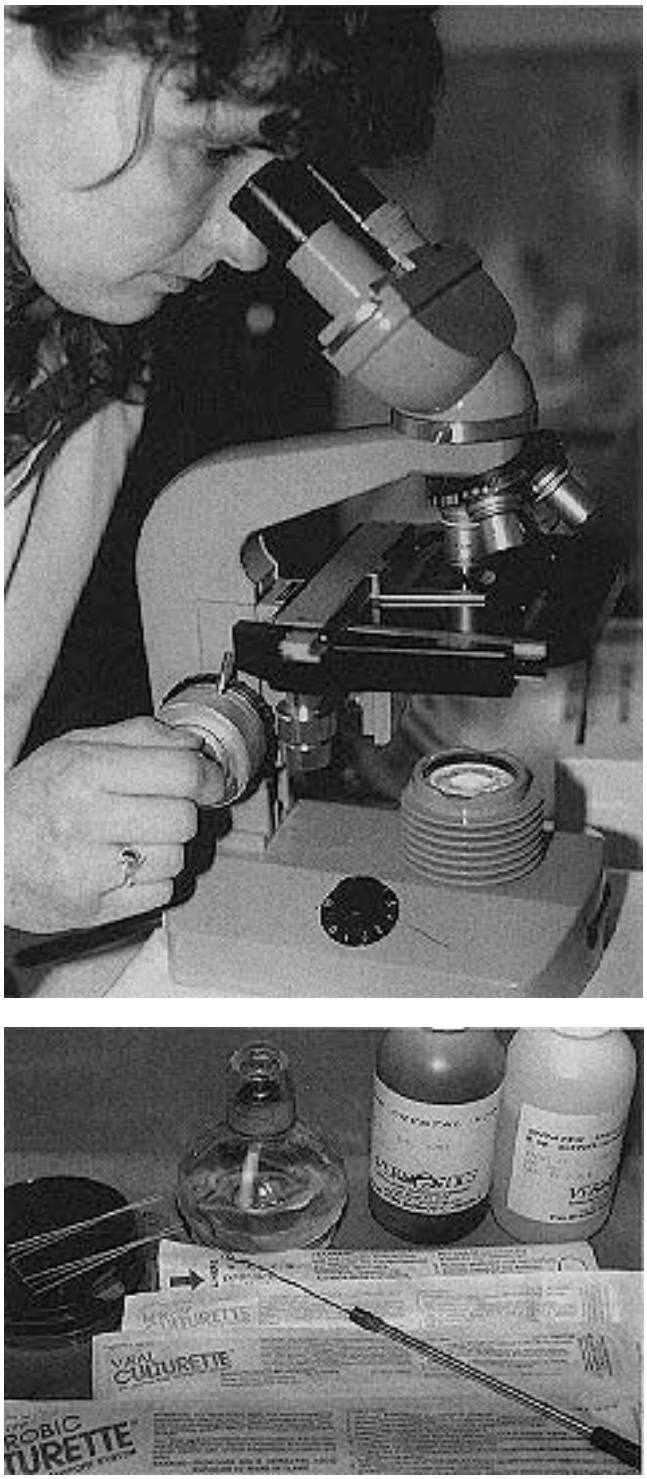

FIG 7.10 A binocular microscope and standard supplies for collecting culture samples should be available in the avian practice (courtesy of Cathy Johnson-Delaney).

Pharmaceuticals

Very few pharmaceuticals are specifically licensed for use in avian species, but the Federal Drug Administration (FDA) has exercised discretion in enforcing extra-label drug use in companion animals to avoid the adverse impact on animal health that could result if the human drugs were unavailable for veterinary use. Avian practitioners should be aware that the promotion, distribution and use of human drugs in animals results in violation of the Federal Food, Drug and Cosmetic Act when:

1. A drug labeled for human use accompanied by labeling which prescribes, recommends, or suggests a use for animals, for which the product is not generally recognized as safe and effective, is an unsafe new drug under section 512(a) and is adulterated under section 501(a)(5) of the Act.
2. The use or intended use of a human drug in animals by a veterinarian causes such drug to be considered a misbranded drug under section 502(f)(1) of the Act.
3. A drug labeled for human use that is promoted, distributed or otherwise intended for animal use is misbranded under section 502(f)(1) of the Act if its labeling fails to bear adequate directions for animal use.
4. The use of a human drug in food-producing animals may cause adulteration of the food. If the residue is a human drug, the food is adulterated under section 402(a)(2)(A) of the Act.

Regulatory action has not ordinarily been considered concerning the distribution of human drugs for use in companion or non-food-producing animals provided all of the following conditions exist:

1. Intended animal use of the human drug is not established by labeling, advertising, promotional activity or in any other overt manner.
2. There is no approved veterinary drug version of the human drug available.
3. The human drug does not represent a significant risk to the animal when prescribed, dispensed or administered by a veterinarian.

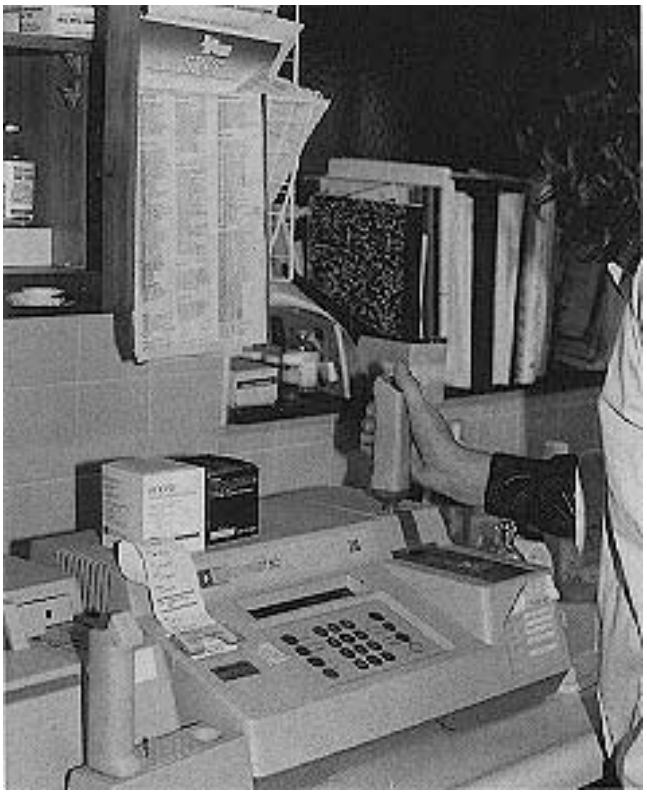

FIG 7.11 Several types of "dry" and "wet" serum chemistries machines have been shown to be effective in the avian practice. These machines have the advantage of providing rapid, inexpensive test results (courtesy of Cathy Johnson-Delaney).

Environmental Responsibility

In addition to medical care for individual pets, avian practitioners also have a responsibility to the global avian population because of their importance in the environment. Many of the species maintained as pets are threatened or endangered in the wild because of habitat destruction and capture for the pet trade. Most leading professional, avicultural and conservation-oriented organizations are actively promoting domestically raised, not wild-caught, birds for pets. Throughout the world there are increased legislative efforts to stop or at least control importation of wild-caught birds. The avian practitioner should promote the purchase of domestically raised birds and keep clients informed of conservation efforts.

Occasionally, the avian practitioner must try to determine the origin of a bird for medical purposes. Imported birds that have passed through USDA quarantine stations are banded with a stainless steel band with a code of three letters followed by three numbers. The quarantine system is designed strictly to prevent diseases of importance to the poultry industry from entering the United States. Quarantine procedures for imported birds include a 30-day stay in an approved quarantine facility, screening for Newcastle disease, and a 30-day treatment with

chlortetracycline for chlamydiosis. Random screening for *Salmonella enteritidis* phage type 4 is being conducted by the USDA to prevent this human pathogen from entering the United States. Quarantine procedures are being reviewed by the USDA, but major changes in the system will require time. Information concerning the importation and quarantine process, USDA regulations, ports of entry and health certificates for shipment of birds out of the country are available from state veterinary offices or regional APHIS/REAC offices. Other regulatory agencies in the United States involved in bird trade are the US Department of the Interior, The Convention on International Trade in Endangered Species (CITES) and the US Department of Treasury — Customs Service, which watches for smuggled birds. The Fish and Wildlife Service is charged with restricting imports and exports of many species of birds which may require special permits if listed in CITES. Information about transporting listed species may be obtained through the US Fish and Wildlife Service, PO Box 3507, Arlington, VA 22203-3507; 703-358-2093.

Avian veterinarians should be able to assist clients in purchasing healthy birds by recommending reputable breeders. Clients should be advised that a tame, domestically raised bird may initially cost more but will be a better-adjusted, healthier pet and require less medical care and behavioral training than a wild-caught, imported, less-expensive bird of the same species. Clients should be wary of "bargain" birds from the flea market, classified advertisements or garage sales. If a bird is diagnosed with exotic Newcastle disease (VVND) virus and definite proof of proper importation cannot be produced, the bird along with any birds that have been in direct contact may be confiscated, tested and euthanatized. Many states also require proof of hatching or legal importation before issuing a license to an aviary or breeding facility. The avian veterinarian should record a bird's band number, tattoo number, microchip number, or any pertinent physical information in the medical record. If the band is removed, the client should keep a copy of this record along with the removed band.

CHAPTER

8

MAKING DISTINCTIONS IN THE PHYSICAL EXAMINATION

Greg J. Harrison
Branson W. Ritchie

The purpose of the relationship between an avian veterinarian and the client is to ensure a long, comfortable, disease-free life for the companion bird. Clinicians must thoughtfully combine information from the anamnesis, physical examination and minimum database to advise clients on how to prevent medical problems in a companion bird.

In the practice of avian medicine there is a decisive difference between the diagnosis and treatment of obvious problems and the ability to detect, identify and correct subtle abnormalities. By carefully and systematically evaluating the patient and its environment, subtle abnormalities become increasingly obvious. Avian species attempt to hide signs of disease as a survival adaptation. Individuals that appear sick or injured are easy prey for predators and may also be segregated or attacked by the flock. Birds are less capable of successfully hiding signs of disease from clinicians that have become skilled and acute in their observations.

An incomplete understanding of the physical, nutritional, physiologic and psychologic needs of birds frequently leads to long-term, inadequate care. It is these predisposing factors that must be corrected in order to restore and maintain the health of an avian patient. Because of management faults, finding "normal" birds during a physical examination is, unfortunately, rare.

Establishing these predisposing factors requires identifying a common pathogenesis for the abnormalities noted on physical examination. It is when the interconnection between the clinical signs of disease is determined that the true cause of a problem can be clearly defined and corrected. Feather abnormalities and a respiratory disease may have a common etiology that includes a systemic fungal infection, poor nutrition, inadequate exposure to sunlight or frequent exposure to cigarette smoke.

Clients should be instructed to evaluate the movement, body posture, head position, behavior, appetite, attitude, ocular clarity and excrement output of their birds on a daily basis. This will help identify abnormalities before a disease process progresses to an irreversible point. Advanced stages of disease that a client may recognize include drowsiness, increases or decreases in food or water consumption, changes

in the color or consistency of feces, urine or urates, coarse, ruffled or moist feathers, picking or scratching, or changes in body posture, wing position or talking and singing abilities. Clients that are taught to observe a bird's fecal output (not food consumption) can be instructed to seek immediate medical assistance when changes are noted.

To help identify management and disease-related problems early, it is advisable to perform a complete physical examination on a new patient twice in the first year, and annually thereafter. The initial evaluation periods will provide the clinician with an opportunity to identify and correct problems before they can cause irreparable organ damage. A well designed preventive medicine program will improve the quality of a companion bird's life, save the client money and help maintain a positive attitude in the clinical staff.

Anamnesis

Clinically evaluating an avian patient involves combining information collected from the history, physical examination and minimum database. A thorough history frequently provides obscure clues that may identify risk factors important in diagnosing and resolving a patient's problems. Early identification and correction of subtle abnormalities caused by environmental stresses (eg, exposure to cigarette smoke, kerosene heaters, chemical fumes, disinfectants), management flaws (poor hygiene) or nutritional inadequacies (eg, all-seed diet, excess vitamin supplementation) are clinically more rewarding than attempting to stabilize a chronically compromised patient with an acute, life-threatening metabolic crisis (Figure 8.1).

Developing the Anamnesis

When and where was the bird obtained? Birds obtained from traveling dealers are frequently exposed to infectious diseases and may be illegal imports that have not been through a USDA quarantine system. Many high-quality pet retailers are specializing in domestically raised hand-fed chicks, which generally have fewer medical problems and make much better companions than their wild-caught conspecifics (see Chapter 30).

Specific Questions for Developing the Anamnesis

- What is the duration of observed problems?
- Are there other pets?
- What exposure does the bird have to other birds?
- Are other pets ill?
- Are family members ill?
- Has the bird had other medical problems?
- Has the bird received any medications?
- When was the bird first introduced to the home?
- Where was the bird obtained?
- Did the bird come with a health guarantee?
- Where is the bird kept in the home?
- What substrate is used in the enclosure?
- Is the home heater electric or gas?
- What temperature is the home?
- What houseplants does the bird have access to?
- Is the bird frequently exposed to fresh air and sunlight?
- Is the photoperiod natural and regulated, or random and irregular?
- Are exterminators used?
- Is the bird exposed to cigarette smoke?
- What potential aerosols is the bird exposed to (household chemicals, disinfectants, hair sprays)?
- What disinfectants are used in the enclosure and how often?
- Have any changes recently occurred in the home (new enclosure, different diet, painted house, changed carpet, moved to a new location, new pet or strange people in the house, moved bird to a new location in the house)?
- What types of foods are offered?
- What types of foods are consumed?
- What feeding schedule is used?
- Are any dietary supplements used?
- Is the appetite increased or decreased?
- Have the droppings changed in color, frequency, consistency or quantity?
- Has the water intake changed?
- Any coughing, sneezing, diarrhea or vomiting?
- Have noted changes remained the same or progressed?

How long has the bird been in the household? Recently obtained birds (within the last year) are more likely to be suffering from problems associated with infectious disease or stress, while long-term pets are more likely to have problems with malnutrition or chronic systemic diseases.

Have any new birds recently been added to the household or aviary? New birds can invariably be a source for previously unencountered pathogens. A bird obtained from a breeder whose flock is closed to new birds and is constantly being monitored for subclinical problems (eg, PBFD virus, polyomavirus and

FIG 8.1 The quality of the beak, nails, feathers and skin will provide valuable information about the condition of an avian patient. In this Canary-winged Parakeet, the abnormal white-colored feathers, abundance of pin feathers, overgrown nails and hyperkeratotic rhamphotheca were caused by an inadequate diet and a lack of exposure to sunlight.

chlamydia), is less likely to have an infectious disease than a bird obtained from a source that mixes birds from different locations (eg, substandard pet retailers, brokers, bird shows, quarantine stations). The recent addition of birds that are frequent carriers of infectious diseases should also be noted. Contact with free-ranging birds can also expose companion birds to some infectious agents.

Has there been a change in food or water consumption? Subtle increases or decreases in food or water consumption can be signs of disease. It is important to distinguish between the food offered to a bird and the food consumed by a bird. An adequate diet may be offered, but an inadequate diet may be consumed. A bird on a seed-based diet (even with supplements) may develop progressive malnutrition that will become increasingly evident over several months to years depending on the bird's age. Young birds are more susceptible to malnutrition and will develop acute signs of disease, while mature birds are more likely to suffer from chronic malnutrition. Many domestically raised neonates are being weaned onto good quality, formulated diets and a variety of nutritional foodstuffs. Unfortunately, many of these birds will be switched by the new owners to a seed-based diet, which induces obvious clinical signs of malnutrition over several years.

Are other pets or family members ill? If other pets or family members are ill, the clinician should consider a common etiologic agent (infectious disease or exposure to an environmental toxin). A client should always be advised to seek medical attention if any family members are ill. It should be noted that companion birds may learn to mimic the sneeze or cough of a family member, which should not be interpreted as an abnormality.

Is the bird restricted to an indoor environment? Frequent exposure to fresh air and sunlight is important for a bird's overall health. Medical problems are more common in birds that are restricted to indoor environments. Drafts have no effect on healthy birds that are acclimated to normal temperature fluctuations.

Is the bird exposed to toxic compounds, particularly aerosols? Determining if the indoor environment is contaminated with toxins can help with an immediate diagnosis and guide suggested changes to prevent future problems. Birds have an efficient respiratory system, and brief exposures to toxins can be life-threatening. Commonly encountered, but infrequently discussed, toxins that could have a dramatic effect on the health of a bird include cigarette smoke, fumes from disinfectants (eg, Clorox, ammonia, Lysol), furniture polish, floor wax, paint, hair spray, dry cleaning fluid and carpet and furniture cleaners (see Chapter 37).

Have any medications already been administered? Discussion of a bird's previous medical problems, and how they were diagnosed and treated, may provide important information to the clinician. With referral cases, all available records should be carefully reviewed. Some breeders and pet retailers recommend the use of over-the-counter (OTC) medications (usually tetracyclines or erythromycin) for the treatment of sick birds. These OTC preparations usually have little or no therapeutic value and further complicate the disease picture by weakening the immune system and encouraging the proliferation of secondary bacterial or fungal pathogens. Knowing which antibiotics have been administered will influence the interpretation of results obtained from cytology, culture and sensitivity.

Have there been changes in a bird's behavior? Changes in behavior that should be noted include excessive sleeping, resting in a fluffed condition and a decrease in talking, singing or playing. Scratching and excessive preening may indicate a local or systemic abnormality. Personality changes, including increased aggression, screaming, intolerance of strangers or biting the enclosure or toys also may indicate problems.

What is the bird's reproductive status? Seeking seclusion (eg, hiding under furniture, in drawers,

behind book cases, under papers) tearing up paper, a crouched copulatory stance and masturbatory actions with certain family members, toys, mirrors, other animals or inanimate objects are suggestive of breeding behavior. Reproductively active Amazon parrots may fan the wings and lean forward with the iris dilating and contracting, while making a low "purring" type sound. Reproductively active cockatoos, especially Umbrella Cockatoos, may pant rapidly while being stroked. Some birds, especially the larger macaws, may incubate balls or other round objects and will defend stuffed toys as if they were chicks. Single cockatiel hens can lay 20 to 40 eggs a year for several years then gradually reduce, and finally stop egg laying. These birds may continue to go through the behavioral motions of egg laying and develop egg-related peritonitis (eg, depression, anorexia, swollen abdomen) weeks to months after ceasing oviposition.

Physical Examination

The physical examination can be viewed as a three-part process: observing a bird's response to its environment, examining the bird's environment and systematically examining the patient.

A mental picture of a free-ranging bird (slick, solidly colored feathers; clear, dry skin; bright inquisitive attitude) should serve as a comparative model for evaluating the condition of avian patients (Color 8.1). By carefully performing the same thorough physical examination on each patient, the practitioner can develop an image for the average and a perspective of what should be considered clinically normal. The quest of the physical examination should be to proclaim that a patient is clinically normal, a condition that rarely exists (Color 8.2).

Evaluating the Bird in its Environment

Birds that are stressed will frequently alter their behavior in an attempt to hide signs of disease. This is particularly true while a patient is in the examination room, and it is a challenge for the clinician to distinguish between stress-related behavior, normal behavior and a disease process. A bird that the client describes as listless at home may appear bright, alert and responsive when subjected to the stress of the hospital environment. To overcome this problem, the examination room should be free of extraneous noises and interruptions, and a bird should be acclimated to the examination room for five to ten minutes before beginning the evaluation process.

The general appearance, attitude, posture and activity level of the bird should be determined while it remains securely within its enclosure. Birds being observed at a distance are more likely to feel unthreatened and exhibit changes associated with lethargy and depression (Color 8.7). In an aviary setting, birds can best be initially viewed from a distance with the aid of binoculars.

Observational clues that a patient is seriously ill include ruffling of feathers, partially closed eyes, frequent blinking, tucking the head under a wing, labored breathing, sitting on the bottom of the enclosure, a hunched stance, straining to empty the cloaca, cloacal winking and loss of balance (Color 8.15). Birds that are stressed may shiver, causing a rapid movement of the body feathers. A bird that is depressed and lethargic will respond poorly to external stimuli when disturbed and then return to a calm, detached state (Color 8.6).

Abnormalities in body function may include lameness, wing droop, standing on one leg, shifting weight from one leg to another, resting on the sternum or standing on the metatarsus rather than the foot. A bird's wings should be held tightly to the body with the carpi symmetrical. A bird that is hot or excited may hold the wings out from the body, yet still in a symmetrical position. One drooping wing is an indication of an abnormality (eg, fracture, arthritis, tendon or ligament damage, nerve damage, bruising, mass) (see Figure 28.8).

Normal respiratory effort in the bird should not be noticeable, and the mouth should remain closed. Open-mouthed breathing is an indication of severe dyspnea. Resting respiratory rates vary from 6 to over 30 cycles per minute, depending on the size of the bird (Table 8.1). Small birds have higher respiratory rates; large birds have lower respiratory rates. Some avian species (notably Amazon parrots and *Pionus* spp.) may pant when stressed. This normal physiologic response should not be misinterpreted as disease-induced dyspnea.

Respiratory disease is common in birds, and subtle signs are best detected while the bird is in its enclosure. Excessive chest movement, excessive tail motion when breathing (tail-bobbing), open-mouthed

TABLE 8.1 Normal Heart and Respiratory Rates of Birds (per min)*

Weight	Heart Rate (Rest)	Heart Rate (Restraint)	Resp. Rate (Rest)	Resp. Rate (Restraint)
25 g	274	400-600	60-70	80-120
100 g	206	500-600	40-52	60-80
200 g	178	300-500	35-50	55-65
300 g	163	250-400	30-45	50-60
400 g	154	200-350	25-30	40-60
500 g	147	160-300	20-30	30-50
1000 g	127	150-350	15-20	25-40
1500 g	117	120-200	20-32	25-30
2000 g	110	110-175	19-28	20-30
5000 g	91	105-160	18-25	20-30
10 kg	79	100-150	17-25	20-30
100 kg	49	90-120	15-20	15-30
150 kg	45	60-80	6-10	15-35

*The resting or flying heart rate of any sized bird can be estimated with the formulas: Resting HR in beats/sec = 12 x (4 x Wg)$^{-0.209}$. Flying HR beats/sec = 25 x (1 x Wg)$^{-0.157}$. Multiply results of either by 60 for beats per minute. From King AS, McLelland J: Form and Function in Birds Vol. 2. London, Academic Press, 1981 (see Chapter 27).

breathing, neck stretching, yawning, extending the wings away from the body, and forward movement of the head (bobbing) on inspiration or expiration are all indications of respiratory system compromise. Dyspnea associated with the upper respiratory tract or lungs is frequently accompanied by open-mouthed breathing. Lung and lower respiratory tract problems are usually associated with a rhythmic jerking of the tail (tail-bob). Respiratory problems associated with excessive fluid production may cause gurgling sounds that are audible on inspiration and expiration.

Dyspnea induced by protracted respiratory disease is usually associated with other clinical signs including weight loss, depression, ocular or nasal discharge, sneezing or wheezing. Acute dyspnea in an apparently healthy bird usually results from exposure to aerosolized toxins, dislocation and movement of tracheal plaques (from malnutrition or infectious agents) or aspiration of foreign bodies (particularly seed husks or enclosure substrates).

Gender Determination and Aging

During the physical examination, feather color, patterns and markings can be used in some species to differentiate between various hybrid varieties. Male cockatiels in general have a dark-yellow crown and a dark-orange cheek patch. They may whistle a melody or sing. Females tend to have a light-yellow crown with a blotchy orange cheek patch. They chirp, bite more often and seldom talk or sing melodies. A wild-type immature cockatiel has a gray body, white primary horizontal bars on the underside of the wings, a light-yellow head and orange cheek patches (Color 8.12). Except in pied and pearl mutations, males over one year of age lose these horizontal bars, while females do not. In pieds, some or all of the gray feathers are white. Pearls will have a splotched, repeated pattern of interspaced grey and white feathers. This pearl pattern is retained in the adult female and lost in the adult male. A lutino is characterized by the replacement of gray feathers with white feathers that contain various shades of yellow. Hepatitis, chlamydiosis or heredity should be considered in cockatiels that are dark yellow (Color 8.8). A young pied has stripes in the central tail feathers, which are retained in the mature female but replaced with solid-colored central tail feathers in the mature male. Heavier pieds are difficult to sex by feather color.

With continued inbreeding to create color mutations, it has become increasingly difficult to accurately determine gender based on feather color. This is particularly true with albino (colorless with pink eyes) and cinnamon cockatiels. In these birds, endoscopic or genetic testing for gender is required.

Immature male and female wild-type budgerigars are green and appear similar. The male tends to have a "halo" or lighter colored ring around the nares. As the male matures, the cere turns from light pink to blue. Sexually maturing females develop a brown cere. Males tend to be brighter colored, bite less and sing and talk more than females. The color varieties are more difficult to visually sex. For example, with some line-bred budgerigars, as many as 50% of the birds with light blue ceres can be hens. Behavior can indicate gender in some species. For example, male finches tend to sing and perform a mating ritual dance when stimulated by a receptive hen.

Important genetic information can be obtained by determining the phenotype of a bird. For example, a blue budgerigar (or any color other than wild-type green) would clinically be expected to have a substantially reduced life expectancy (six years versus >15 years). Wild-type cockatiels have the potential to live over 20 years, but most color mutations usually die before they are ten years old. Table 8.2 lists some physical changes observed in long-term captive macaws.

Examining the Bird's Environment

If the bird is transported to the hospital in its regular enclosure (which the client should have been instructed not to clean before the bird's appointment),

TABLE 8.2 Effects of Aging in Macaws

- Muscle wasting > 40 years old
- Joint stiffness suggestive of arthritis
- Loss of skin tone and elasticity
- Neurologic disease
- Decreased feather production > 40 years old
- Twisting deformities of the carpi > 40 years old
- Pigment spots, polyps, wart-like blemishes, cysts, wrinkling facial skin
- Thinning of the skin on the face and feet > 40 years old
- Cataracts > 35 years

From Clubb SL, Karpinski L: Aging in macaws. J Assoc Avian Vet 7(1):31-33, 1993.

the clinician can examine the enclosure and determine what types of foods are offered and which of these foods are actually consumed. Fruits, vegetables and other moist foods can spoil rapidly, promoting the growth of bacteria (particularly *Pseudomonas* spp. and *E. coli*) and fungi. A cuttlebone should be examined for beak marks to determine if it is being consumed by the bird.

Excrement that is allowed to accumulate in the bottom of the enclosure, and perches that are dirty or positioned over the food or water containers are hygienically undesirable (see Chapter 1).

Birds should always have a supply of clean, fresh water with no additives. Vitamins added to the water oxidize quickly (become inactive) and provide an excellent growth media for bacteria and fungi (see Chapter 3).

Excrement

Examining the color, texture, consistency and volume of the feces, urates and urine will provide information about a bird's appetite, behavioral patterns and gastrointestinal, renal and hepatic functions (Color 8.34 to 8.58). Droppings should be visually evaluated by the client on a daily basis. The amount and character of feces is a more accurate reflection of a bird's condition than the owner's impression of the body weight and food consumed.

The frequency of defecation and the volume of excrement varies with the species of bird. In general, smaller birds with more rapid metabolic rates will defecate more frequently than larger birds with a slower metabolic rate. A normal budgerigar may produce from 25 to 50 stools per day, while a Blue and Gold Macaw may defecate 8 to 15 times a day (Color 8.39). A reduced quantity of excrement can be an indication of decreased food intake, a decreased gastrointestinal transit time or a blockage (Color 8.42). Dry, scant droppings may indicate dysphagia or food and water deprivation. Birds may have scant droppings for a few days if a change in diet has caused them to consume less food (eg, medicated diets).

The normal excrement should consist of a fecal component, urates and liquid urine (Color 8.34). Normal feces may be green, light- to dark-brown and be slightly loose-to-firm in consistency. Normal urates should be white and the urine should be clear. The physical characteristics of feces can be influenced by the species and age of the bird, the time of day, type of diet consumed, quantity of food and water available, reproductive status, medication administered, renal disease, liver disease and the presence of parasitic, bacterial, chlamydial, fungal or viral pathogens.

It is common for a bird in the exam room to have a stress-induced polyuria or diarrhea. Over-consumption of fruits, vegetables or a recent change in the diet can alter the color and consistency of the feces. Birds that consume heavily pigmented foods (eg, blackberries, blueberries, sweet potatoes, raspberries, beets, some highly colored crackers) can produce oddly colored feces. The reddish-to-black discoloration that is common with the consumption of blackberries and raspberries should not be confused with melena (Color 8.44).

Dark-colored feces (not caused by fruit consumption) is indicative of melena. This is a common finding in budgerigars on an all-seed diet, but may be abnormal considering that the melena stops when birds are placed on a formulated diet. Blood in the excrement can originate from the GI tract, oviduct, kidneys, testicles or cloaca. Frank blood in the excrement may be associated with coagulopathies, liver disease, cloacal pathology, pre- or post-oviposition, malnutrition or enteritis (Color 8.49). Bright-green, loose feces and yellow, green or brown urates may indicate hemolysis or hepatitis and are common with malnutritional, toxic, chlamydial, bacterial or viral hepatitis (Color 8.36). Clay-colored feces are indicative of maldigestion or malabsorption (Color 8.35).

Birds consuming some formulated diets or large quantities of fruits and vegetables will produce a loose voluminous feces and more urine than birds on a principally seed diet. Monkey biscuit and some other formulated diets cause the production of brown feces, while parrots consuming seeds generally have green feces. Neonates fed most standard formulas have soft, semiformed voluminous feces, as do hens

in the pre- and post-ovulatory period (Color 8.53). Voluminous droppings may also indicate malabsorption (eg, gastrointestinal disease, pancreatitis, peritonitis or parasites), diabetes or renal tumors (Color 8.52). For some birds, especially house-trained birds, a voluminous feces is a normal morning dropping.

Normal feces are smooth, and some high-fiber formulated diets will cause them to cling together in a tight, gelled cylinder. A granular or rough stool can indicate abnormal digestion. The presence of undigested food in the feces is not normal and must be differentiated from food that has fallen into the feces. Excreting poorly digested food can be an indication of maldigestion, malabsorption or hypermotility caused by parasites, pancreatitis, proventriculitis, ventriculitis or intestinal disease (Color 8.57).

Diarrhea is rare in companion birds. Loose, watery feces are normal in lorikeets and birds that consume liquid or nectar diets. The normal feces of Anseriformes also contain a high water content. In psittacine birds, most cases of diarrhea reported by clients are actually polyuria in which the feces are dispersed in an increased volume of urine. Finding bubbles (gas) in the feces is common in birds with true diarrhea (Color 8.51). Diarrhea can occur with various parasitic, fungal, chlamydial, viral and bacterial infections, systemic diseases and following the administration of some medications.

Direct examination of the feces should include a Gram's stain (to detect fungi, bacteria and inflammatory cells), fecal flotation (for helminths), direct wet mount examination for protozoa and determination of pH. The normal pH of the cloaca is 6.5 to 7. A basic pH (>7.5) favors the growth of yeast and Enterobacteriaceae.

Urine and Urates

The kidneys excrete a pasty white-to-yellow urate (produced in the liver) and a sparse, clear, colorless watery urine that can be separated from the urates for analysis. The stress of being transported to the clinic will cause most birds to be polyuric when they are examined by the attending clinician. The presence of hematuria in any form is abnormal. Blood that is in the urine may originate from the GI tract, oviduct, kidneys, testicles or cloaca (Color 8.48).

Yellow-green urates are indicative of hemolysis or liver disease (Color 8.41). Idiopathic, reddish-brown urates have been described in some hand-fed babies that seem to be otherwise healthy with normal growth patterns (Color 8.36). This phenomenon is more common in birds that are receiving an animal protein-based diet, and some cases will resolve when a neonate is switched to a plant protein-based formula.

Urine for detailed analysis should be collected from an impervious surface as soon as possible after it is excreted (see Chapter 11). The avian urinalysis should include cytology and determination of the pH, glucose, sediment, color and specific gravity. Glucose should be completely absorbed and is not normally detected in the urine. The presence of ketones is abnormal and may suggest diabetes mellitus. The presence of casts is an indication of renal disease. Uric acid crystals can be dissolved by adding several drops of sodium hydroxide to a urine smear. This will facilitate the identification of casts, bacteria and cellular debris.

Urine may be excreted without urates when birds are nervous, polydipsic or consuming fruits and vegetables with a high-water content. Polyuria may be noted in birds that are egg laying, feeding chicks or holding their droppings overnight. It is also common in hand-fed babies and birds that are excited or housed in hot environments (Color 8.53). Pathologic causes of polyuria include diabetes, renal disease, wasting disease, certain medications (eg, aminoglycosides, steroids, medroxyprogesterone) and exposure to various toxins (Color 8.37).

Vomiting vs Regurgitation

Detecting foamy, sticky, partially digested food on the walls or floor of the enclosure or attached to the feathers or the bird's head and face is suggestive of regurgitation or vomiting. The distinction between regurgitation and vomiting is not as easily made in birds as in mammals. The expulsion of ingesta from the crop is considered regurgitation. The pH of material regurgitated from the crop is generally neutral to slightly alkaline. The normal pH of the crop is 7 to 7.5. Regurgitation can occur as part of the normal mating activity. If regurgitation is part of courtship activities, the patient will be of normal weight and will have no other clinical signs of disease.

Vomiting is considered the expulsion of ingesta from the proventriculus (see Chapter 19). Vomitus is usually acidic, may be bile-tinged and generally contains partially digested food (Color 8.58). An acute onset of vomiting caused by a pathologic process is often accompanied by depression, severe dehydration and shock.

Regurgitation, and in some cases vomiting, is common in hand-fed babies, if the formula is excessively

thin, if gastrointestinal disease is present, if they are fed excessive amounts of food or if they are being weaned.

Odors

Varying species of birds, and individuals within the same species, can omit distinct odors that originate from the food consumed, the feces and urine, the uropygial gland oil, the breath, the skin or the feathers.

Normal fresh excrement from companion birds is basically odorless. Birds that consume animal protein (eg, raptors) usually have a distinct odoriferous stool. Foul breath is rare in birds and, when present, indicates an abnormality that might include candidiasis, oral or upper gastrointestinal tract ulcerations, oral or upper GI abscesses or gastroenteritis (Color 8.22). Unpleasant skin and feather odors are usually associated with necrotic tissue secondary to cysts, abscesses or neoplasias. Pasty droppings that adhere to the vent and produce a metallic, offensive odor are frequently noted in cockatoos. These birds generally have abnormally acidic (pH 4 to 6) feces of unknown etiology. Birds consuming high animal fat diets (eg, ribs, chicken marrow bones, fried foods) may have a rancid oil odor that can persist for several weeks after a diet change.

Gram's Stain

Gram's stains of samples from the feces, cloaca, choanal slit and crop can be used to evaluate a bird's overall health by estimating microbial populations (Figure 8.2). In contrast to cultures, which limit the growth of some organisms, cytologic evaluation of a sample will provide information about the type and relative number of each microbial organism present, including difficult-to-culture anaerobic or fastidious organisms. Fresh feces appear to be the most useful sample to evaluate.

In general, the digestive tract of grain- and fruit-eating Psittaciformes contains a gram-positive bacterial flora with a few yeast (Color 8.59). A normal fecal Gram's stain should contain 100 to 200 bacteria per high-power field with 60 to 80% gram-positive rods and 20 to 40% gram-positive cocci. A few yeast or gram-negative bacteria per high-power field could be considered normal but should alert the clinician to carefully evaluate the patient for subtle abnormalities. The normal microbial flora of birds maintained indoors may be slightly different than the flora of birds residing in a flight outdoors.

Gram-negative bacteria are common in the oral cavity and in feces of clinically normal carnivorous or insectivorous Passeriformes, raptors, Galliformes and Anseriformes. The feces of canaries and finches normally have a reduced population of bacteria and often show various types of yeast one-fourth to one-half the size of candida.

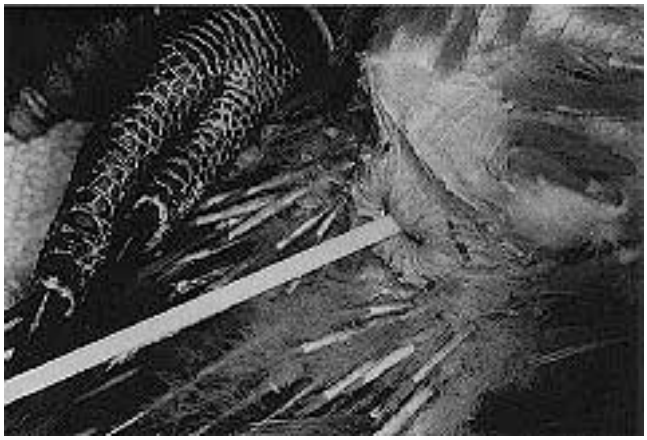

FIG 8.2 If fecal Gram's stain results are abnormal, samples collected directly from the cloaca can be cultured for the presence of abnormal bacteria or yeast. It is best to moisten a swab with sterile transport media or LRS before inserting it into the cloaca to prevent the dry swab from causing excessive tissue damage.

In most psittacine birds, an absence or decrease in the number of bacteria, the detection of WBCs, a shift from a gram-positive to a gram-negative bacterial population or the presence of a high number of yeast (> 5/HPF) in samples from the choana, cloaca or feces may indicate a primary microbial infection or that immunosuppression with colonization by secondary pathogens has occurred (Table 8.3) (Color 8.61). Occasionally, gram-negative bacteria and yeast can be transiently present in the choana or cloaca of clinically normal birds. Some formulated diets and most breads contain brewer's yeast, which can be passed in the feces and morphologically resembles *Candida* spp. In general, yeast of clinical concern will be budding, while brewer's yeast will not (Color 8.63).

The avian clinician must interpret the results of a fecal Gram's stain with respect to the patient's environment, diet, general condition and clinical signs.

TABLE 8.3 Abnormal Fecal Gram's Stain Findings

- Low bacterial count
- Reduced numbers and percentage of G + cocci
- Reduced numbers and increased percentage of G+ rods
- Increased numbers and percentage of G - rods
- Increased numbers and percentage of budding yeast

Making Distinctions in the Physical Examination

Color 8.1
Normal Hyacinth Macaw. Note the normal yellow color of the skin around the eye and lower beak. This coloration should not be misinterpreted as hyperbilirubinemia (courtesy of Apalachee River Aviary).

Color 8.2
Normal Blue and Gold Macaw exhibiting a defensive behavior (wings extended) in response to being approached. Note the sharp, distinct coloration of the feathers, the bright alert eyes, dry nostrils, smooth black beak and blemish-free facial skin. The nares of Blue and Gold Macaws are clearly visible, while those of other macaws can be covered with feathers.

Color 8.3
Birds will be at their peak of condition and health when provided a formulated diet supplemented with fresh fruits and vegetables and frequent exposure to fresh air and sunlight. Close observation of this Green-winged Macaw shows black discoloration of the blue remiges on the left wing, frequently seen with nutrient oversupplementation and microhepatia.

Color 8.4
A resting Major Mitchell's Cockatoo. Normal sleeping behavior must be differentiated from lethargy or depression (Color 8.6). Note that the feathers of this clinically normal bird are clean, have a reflective quality and are evenly colored.

Color 8.5
Companion grooming behavior indicative of an effective pair-bond in normal Military Macaws. Note the smooth, evenly colored feathers, bright eyes and clean, dry perinasal area. The blushing noted on the hen's cheek area is common when birds are stressed or excited and should not be misinterpreted as pathology.

Color 8.6
Birds frequently sleep with their beaks tucked into the shoulder area. A bird that exhibits this behavior in a stressful situation (eg, examination room) would be considered severely depressed. Note the partially closed eyelids in this Yellow-naped Amazon Parrot.

Color 8.7
Birds should always be observed from a distance to detect any subtle behavioral abnormalities. This Crested Cardinal would start singing and hop from limb to limb when approached; however, when viewed from a distance, the bird appeared depressed, and the feathers were held away from the body ("fluffed up"), suggesting difficulties in maintaining normal body temperature.

Making Distinctions in the Physical Examination

Color 8.8
Yellow discoloration of the feathers in lutino cockatiels is frequently associated with active hepatitis.

Color 8.9
Loss of the papillae and hyperkeratosis of the plantar surface of the feet are common in malnourished birds. Hypovitaminosis A is frequently implicated. If unresolved, these lesions can become infected (eg, bumblefoot), causing crippling or life-threatening changes.

Color 8.10
Normal (left) and abnormal Yellow-naped Amazon Parrots. The bird on the right was fed an all-seed diet, was overweight and had elevated liver enzymes. Note the thin, discolored feathers and the rotund nature of the proventer (breast) region in the abnormal bird. This bird's overall health improved when it was changed to a formulated diet supplemented with limited fresh fruits and vegetables and was given frequent exposure to sunlight.

Color 8.11
Stick-tight flea on the lore region of a cockatiel.

Color 8.12
Distinct yellow crossbars on the ventral surface of the flight feathers in a female lutino cockatiel.

Color 8.13
A near comatose Severe Macaw with neuropathic gastric dilatation. Note the glazed, sunken eye (dehydration) and partially closed eyelids. This bird would exhibit intermittent periods of vocalization and wing-flapping, and would then slip back into a comatose state.

Color 8.14
a) Bacterial otitis externa in a Mitred Conure. Note the hyperemia and swelling of the tissues associated with the auditory meatus. **b)** Normal auditory meatus for comparison.

Color 8.15
Severely depressed Gouldian Finch. Note the yellowish discoloration of the urates (suggestive of liver disease) and the absence of feces. Because of their rapid metabolism, small birds can die within a few hours if they do not consume adequate levels of energy-rich foods.

Identifying an organism in a sample does not mean it is associated with a disease process. Different strains of a particular bacteria may appear morphologically similar, but may vary widely in pathogenicity. Distinguishing between pathogenic and nonpathogenic strains of the same genera of bacteria or fungi requires detailed biochemical analysis.

Properly interpreting a Gram's stain requires that the clinician determine if the organism detected is pathologically colonizing a mucosal surface. A clinically normal bird with an abnormal Gram's stain should be observed for changes that could indicate a problem. The management practices associated with the bird should be carefully evaluated to identify problems that could increase a bird's exposure to pathogenic bacteria or that could be weakening the immune system. A shift from an abnormal to a normal Gram's stain over a three- to six-week period is common in birds that are changed from an all-seed to a formulated diet.

An improperly evaluated Gram's stain can result in unnecessary antibiotic therapy that is detrimental to an individual bird or to an aviary as a whole. Damage to the normal flora caused by the indiscriminate use of antibiotics or contact with disinfectants precipitates the colonization of opportunistic pathogens.

Examination of the Patient

Once a bird's enclosure has been evaluated for clues that may indicate abnormalities and the bird has been carefully observed in its environment, it is time to perform a hands-on physical examination. The initial consideration in performing a physical examination is in handling the patient in a safe and efficient manner. Even the simplest procedure can become life-threatening if improperly performed. A client should be informed that handling a critically ill bird can destabilize the patient to a point where it can no longer compensate.

The examination room used for birds should be secluded, sealable, easily cleaned, contain minimal furniture, have dimmable lights and should not have ceiling fans or uncovered windows. With smaller, easily stressed species (eg, finches, canaries), performing the physical examination in a dimly lighted room will help calm the patient.

Any equipment or supplies that may be needed should be prepared before a bird is removed from its enclosure. This will expedite the physical examination and decrease restraint-induced stress. The clinician should wear ear protectors to prevent hearing loss when handling large screaming psittacine birds. The use of a magnifying loop, operating microscope or slit lamp will help in discerning subtle changes associated with the skin, feathers, head, cloaca, oral cavity, eye and limbs (Figure 8.3). The ear canal of birds can be examined using a small otoscope cone. An otoscope may also be useful in evaluating the oral cavity, cloacal mucosa and pharyngeal area. The physical examination process should be performed quickly and efficiently. With practice, a thorough examination can be performed on a critically ill patient in less than three minutes.

The physical examination should involve the clinician's use of vision, sound, smell and touch to identify the areas of the body that are unusual. It is a clinical judgement to determine if something is normal for the individual patient yet abnormal for the species as a whole. While a physical examination can be performed using different regional or anatomic approaches, the key to detecting subtle abnormalities is to consistently use the same approach (using a physical examination form may be helpful).

Initial restraint of flighted birds can be accomplished with a net. A small bird can easily be removed from its enclosure by turning out the lights and gently removing the bird from its perch. A paper or cloth towel can be used for removing larger patients from their enclosures. Paper towels are best for handling birds because they can be discarded after use. If cloth towels are used, they should be laundered and autoclaved between each bird to prevent nosocomial infections.

With practice, the most refractory psittacine birds can be easily restrained using a towel. Gloves should never be used to restrain psittacine or passerine birds. Tame birds may associate the shape of the glove with discomfort and may equate the hand with danger. Removing the top or bottom of an enclosure may be easier than attempting to remove the bird through the enclosure door. The towel can be used to position the bird so that it is facing the side of the enclosure in order to have free access to the back of its head. The best time to grab the bird is when it bites the side of the enclosure.

Small birds can be restrained with one hand by placing the bird's head between the second and third fingers (Figure 8.4). Larger birds can be initially removed from the enclosure with a towel or net and

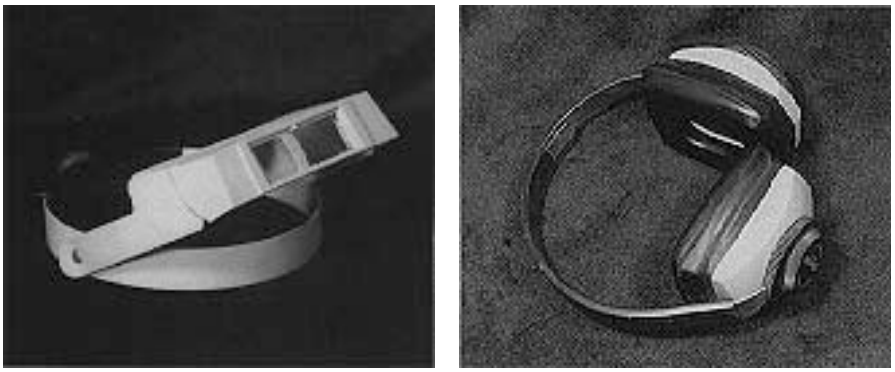

FIG 8.3 Magnifying loops and high quality lighting will facilitate the detection of subtle abnormalities in avian patients. Ear protectors should always be available in the examination room and treatment area to prevent the hearing loss that can occur from repeated exposure to screaming patients.

then restrained by placing the thumb and index finger on either side of the mandibles. A bird must be able to move the sternum in order to breathe, and excessive force on the chest can result in asphyxiation. The bird should be held upright or parallel to the floor. Holding a sick bird upside down can compromise respiratory effort.

The towel used to initially remove a bird from its enclosure can remain around the bird at a level even with the upper eyelid and just below the nares. This gives the bird something to chew on, as well as reduces its vision to help keep it calm. A large bird can be cradled on its back between the clinician's body and arm. The lower forearm can be used to press the wings gently against the body (Figure 8.5). Using this method of restraint, both hands are free to palpate body surfaces and to manipulate the feet and wings, improving the access of all body surfaces for examination. For some clinicians, a complete physical examination requires that the patient be anesthetized with isoflurane, especially large and aggresive birds.

The Dermis and its Unique Adaptations

The feather condition of a bird is an excellent indication of its overall health. The feathers and skin should be evenly colored, sleek, clean and dry (Color 8.4). A bird normally has feathered areas (pterylae) and non-feathered areas (apteria) of the body. Normal anatomic areas that may be featherless in some species include the eye ring, top of the head, mid-proventer and axillary regions. Genetically induced baldness has been described in cockatiels. Some incubating hens will develop a featherless area on the abdomen called a brood patch. Most other areas of baldness should be considered abnormal.

The normal feather brilliance or "sheen" is derived from a combination of physical color, structural reflection of light (structural color), the presence or absence of powder from the powder down feathers (if present) and oil from the preen gland (if present). A bird loses its sheen if abnormalities occur in any of the factors that contribute to the reflectivity of the feathers (Color 8.13). Affected feathers appear dull and dirty (see Chapter 24).

The primary flight feathers have clean, uniformly smooth edges, and the color pattern changes slowly and evenly from one portion of the feather to another.

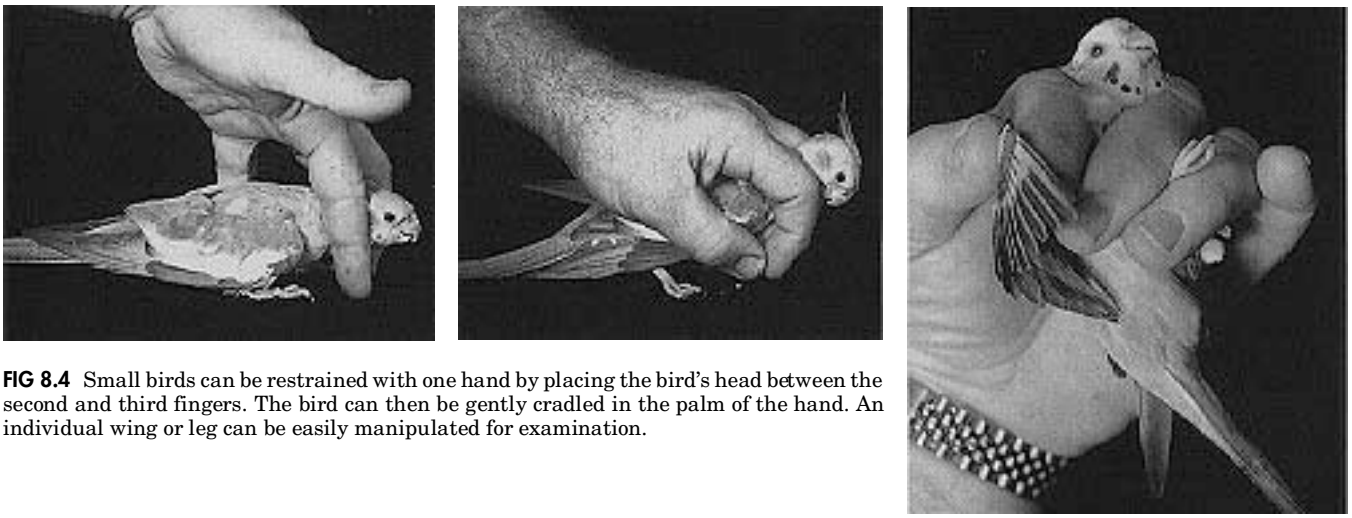

FIG 8.4 Small birds can be restrained with one hand by placing the bird's head between the second and third fingers. The bird can then be gently cradled in the palm of the hand. An individual wing or leg can be easily manipulated for examination.

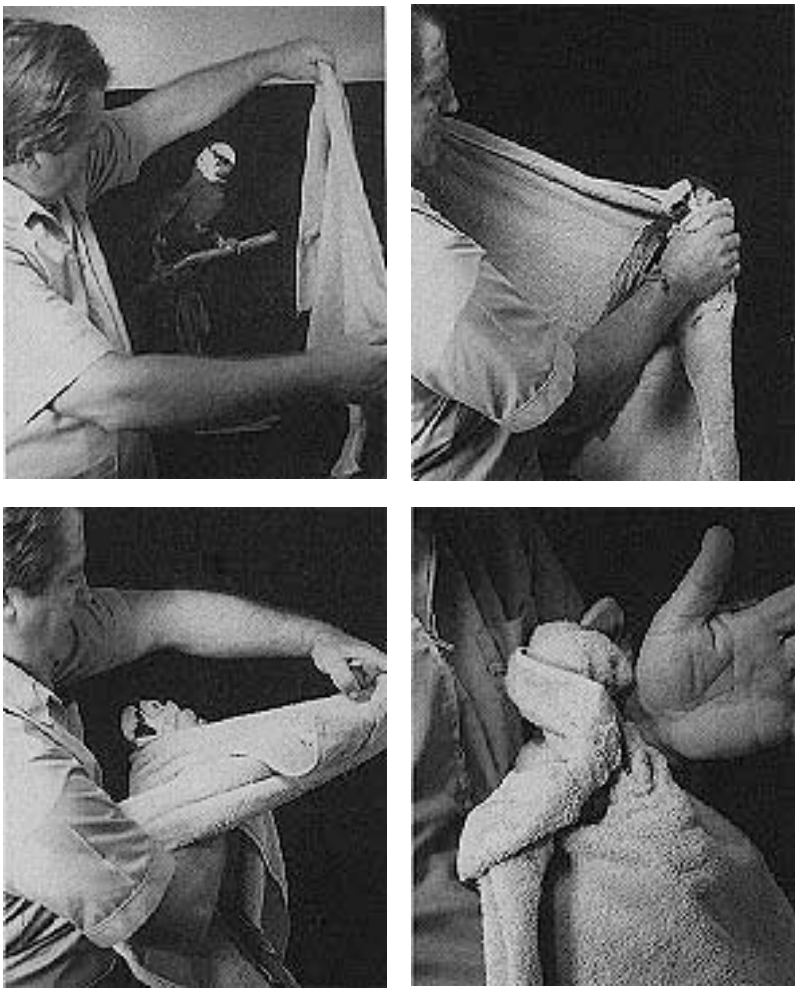

FIG 8.5 A large bird can be restrained using a towel to gain access to the head, which is then gently held between the thumb and first finger. The towel can be wrapped around the bird's body to provide additional restraint. The bird can be cradled in a sitting position between the clinician's body and arm, leaving both hands free to palpate body surfaces and to manipulate the feet and wings during examination.

A disparity in any of these lines should be noted. The feather shaft (rachis) is smooth and gradually changes from thin at the tip to thick at the base (calamus). Feathers are usually darker toward the tip and lighter toward the base. The contour feathers that cover the body should blend with each other, giving the bird a smooth, compact appearance (Color 8.10). Feathers should be complete and intact throughout their length and width. Bent, malformed, broken or frayed feather edges are indications of a problem (see Color 24).

Malnutrition in general may cause these kinds of feather problems. Such birds appear sparsely feathered, not because the feathers are reduced in number but because the feathers that are present are abnormal.

The skin over most of a bird's body is thin, soft, dry and relatively translucent (Figure 8.6). Small portions of discarded feather sheaths are normally found on the skin and should not be confused with dry, flaky skin. Uric acid deposits may be noted under the skin in cases of gout. Examination of subcutaneous tissues can be enhanced by wetting the overlying feathers with warm water or alcohol (Figure 8.7).

Balding, thinning, swelling, peeling or ulcerations of the skin or scales of the feet and legs are indications of abnormalities. The skin and feathers of birds consuming an all-seed diet are rarely normal. Changing a bird from a seed-based to a formulated diet, supplemented with fresh fruits and vegetables, will generally cause a dramatic difference in the skin and feather condition. The improvement in the feather quality will be most noticeable with the first molt following the diet change.

Feathers should be evaluated on a region by region basis. When a bird is relaxed, the feathers lie flat and follow the natural contour of the body. Feathers that are out of place may indicate abnormalities. Body swellings may push feathers away from the body, and feathers from a damaged follicle may twist or grow in an abnormal direction (see Color 24). Localized feather abnormalities should alert the clinician to carefully evaluate certain areas of the body. Wet, sticky or stained feathers around the nares are indications of rhinitis. Generalized feather abnormalities indicate systemic abnormalities that should be evaluated.

One of the many functions of feathers is to retain body heat. If chilled, a bird increases its insulation capacity by increasing the distance between the feathers and the skin (fluffing up), therefore creating an air space between each feather. Some fluffing can be considered normal in birds that are restricted to an indoor environment. A bird that is diseased may be "fluffed" because it is chilled or because it is consuming insufficient energy to maintain a proper metabolic rate and compensate for normal heat loss. Birds may also fluff their feathers when they are

FIG 8.6 The skin over most of a bird's body is thin, soft, dry and relatively translucent. The fact that avian skin is translucent allows direct visualization of many subcutaneous structures including vessels, the crop, tendons, ligaments, body musculature, bone and, in small birds, abdominal structures.

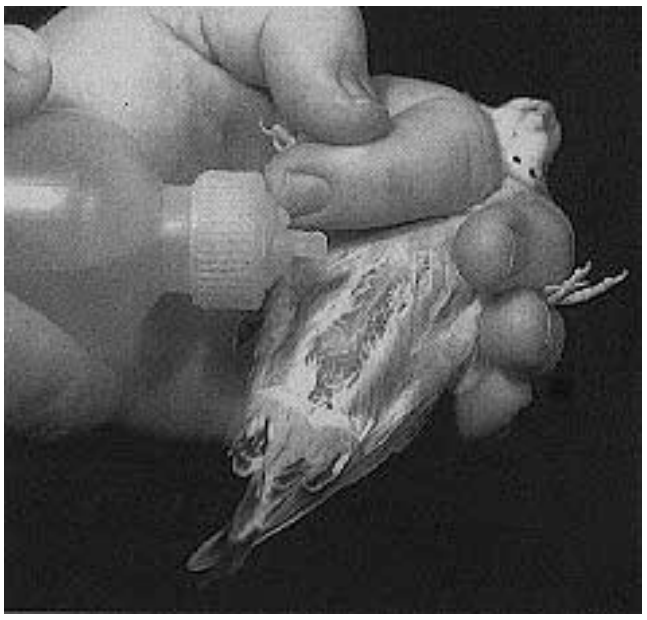

FIG 8.7 Examination of subcutaneous tissues can be enhanced by wetting the overlying feathers with warm water or alcohol. Ethanol should be cautiously applied to open wounds because the systemic uptake of this product can cause intoxication.

content or when they wish to be preened or as a part of the mating ritual. A bird that is fluffing due to illness will show other signs of disease (Color 8.15).

Feather problems should be divided into those that occur before, during or after development. Lesions occurring before development are caused by damage in the follicle, and the feathers do not emerge properly, if at all. These problems are often characterized by discharges from or enlargement of the feather follicles (see Color 24). Damage that occurs to a feather during development is characterized by an abnormal feather structure or color that is evident as the sheath is removed from the differentiated feather. Dark lines located transversely across several feathers (stress lines) indicate that an adrenocortical surge occurred while the affected feather was developing. Post-developmental feather problems are characterized by an abnormal rachis, barb or barbules but a normal follicle and calamus.

The molting process varies with the individual bird. Some birds (eg, canaries, raptors, pheasants) molt seasonally (typically after breeding season) while other birds molt continuously (budgerigars and cockatoos). The normal molt should be orderly and uneventful with an old feather being forced out by a newly developing feather (see Chapter 24). Birds should lose the feather sheath from the differentiated portion of a feather within days. Retention of the feather sheath is not normal, and may indicate malnutrition, pansystemic disease or an infectious agent. Birds will normally preen the head , neck and facial feathers of a companion.

Damaged pin feathers cut or broken off at the surface may be black and mistaken for mites. These damaged feathers may cause pruritus and excessive preening. Head feathers may appear abnormal in canaries that are malnourished, especially in reproductively active hens. The skin of the neck is frequently hyperkeratotic in these cases (Color 8.24). The powder down feathers of the prolateral region should be examined for the presence of powder formation or feather deformities. Moist lacerations or ulcerations may be noted in the axillary region in some birds with dermatitis (see Color 24).

Birds that are fed a marginal diet, that are not exposed to fresh air and sunlight and that are not allowed to bathe regularly have feathers that appear worn and tattered. The feathers that are replaced may have retained sheaths that give the bird the appearance of having an excessive number of pin feathers. The beak, skin and nails in these birds will frequently contain accumulations of keratinized epithelium (see Figure 8.1). Birds that are provided an inadequate diet may enter a molt cycle when their nutritional requirements are satisfied. Following a

diet change, these birds may go through a period when they seem to scratch and preen excessively.

Head

The head should be symmetrical with respect to the eyes, periorbital areas, cere, beak and nostrils. The eyes of a normal bird are clear, bright and centered in the socket (see Color 26). The blink response can be evaluated by lightly touching the canthus. Normal eyelid margins should be symmetrical and smooth. Scabs, scars or active pustules on the lid margins may be indicative of poxvirus (particularly in Amazon parrots) (see Color 26).

Periophthalmic swelling, epiphora or conjunctivitis all indicate ocular or sinus abnormalities. Conjunctivitis is most common in cockatiels, lovebirds and Amazon parrots. In cockatiels and lovebirds, bacterial, mycoplasmal, chlamydial or viral conjunctivitis may damage the lids resulting in dry eye (see Color 26). Malnutrition, primary or secondary to giardiasis, may also cause conjunctival damage. A common problem in cockatiels is partial lid paralysis, with ectropion and conjunctivitis (see Chapter 41).

Cere

The color of the cere varies with the species. An immature budgerigar will have a flesh-colored cere that normally turns dark blue (male) or stays light blue or pink (female) as the bird matures. Some browning of the cere is normal in reproductively active budgerigar hens. An abnormal accumulation of keratinized tissue on the cere (brown hypertrophy of the cere) can occur in some budgerigars with endocrine abnormalities (see Color 24). Estrogen-producing tumors may cause a male budgerigar's cere to change from blue to brown. Hyperkeratotic swelling and hypertrophy of the cere that causes occlusion of the nares may be noted in some Umbrella and Moluccan Cockatoos. A crusty cere and beak may be indicative of *Knemidokoptes* spp. mites (see Color 24).

Nares

The nares and operculum (keratinized plate inside the nostril) should be smooth, relatively dry, symmetrical and evenly sized and colored. In some species (ducks), the nares are located within the beak, while in other species (Psittaciformes) the nares are at the margin of the beak and edge of the facial skin (Figure 8.8). The feather configuration around the nares varies among species. Cockatoos have dense feathers that completely surround the nares. By comparison, Amazon parrots have sparse bristle-type feathers around the nares. In cockatiels, Amazon parrots and lories, the nares are round, while in cockatoos the opening forms a slit. Any degree of moisture around the nares should be considered abnormal.

Nasal discharges may be unilateral or bilateral and may appear clinically as dirty, malpositioned or moist feathers around the nares. Mild cases of rhinitis may be accompanied by severe cases of air sacculitis, sinusitis and caseous accumulations in the nares or sinuses. Periorbital swelling usually indicates a sinus infection. Signs of previous respiratory disorders may include grooves in the beak or loss of feathers associated with the nares (see Chapter 22).

The operculum should be well defined in the nasal cavity. The abnormal accumulation of desquamated cells adjacent to the operculum can create a mass that can become secondarily infected with bacteria or fungus, resulting in a unilateral rhinitis accompanied by severe tissue necrosis (see Chapters 22 and 41).

Pathology in the sinus or nasal cavities may alter the normal flow of air, causing the skin over the infraorbital sinus to move in and out as a bird breathes. This abnormality may be subtle and the bird may otherwise appear normal. Mild blockages that are not corrected can progress and cause severe sinusitis and conjunctivitis (cockatiels) or atrophic rhinitis (African Grey Parrots) with structural damage to the rhinal cavity and surrounding bony structures (sunken sinus syndrome in macaws) (see Color 22). In some species, transillumination of the sinus areas may help identify pockets of debris.

The feathers on the head should be smooth and uniform. The ear canals can be evaluated for discharge or the abnormal accumulation of desquamated hyperkeratotic skin by parting the feathers on the side of the head (Figure 8.9). The glistening, translucent ear drum can be visualized and will move slightly with respiration (see Color 13). Ear problems are infrequently seen in birds (Color 8.14). Those that do occur are generally caused by granulomas or neoplasms, and early detection and surgical correction are necessary to insure a favorable prognosis. The ear canal may be hyperemic in birds with sinusitis.

The beak color and shape varies dramatically among species; however, the surface of the beak should be smooth, shiny and uniform regardless of the species. The occlusal surface of the upper and lower beak should meet at midline and be even throughout the margins. The beak of a psittacine bird should grow

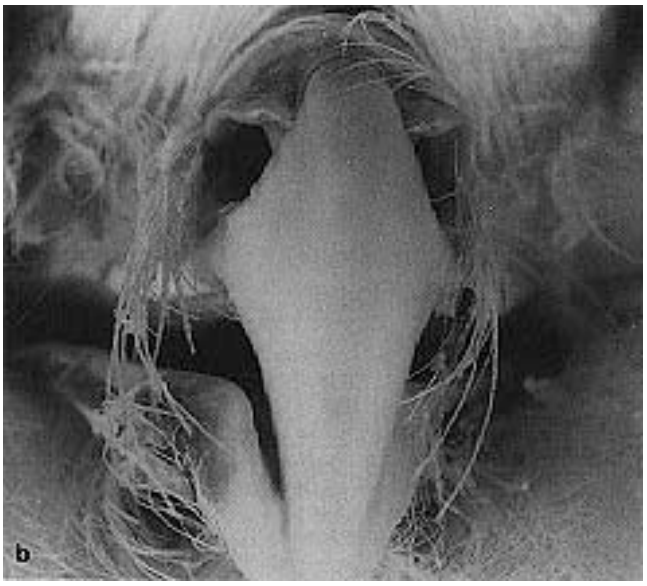

FIG 8.8 The location of the nares, and the feather configuration around the nares, will vary among species. In Amazon parrots, the nares are surrounded by bristle feathers and are located at the edge of the skin margin and the beak. In some species, like this owl, and in Anseriformes, the nares are located in the beak and may not be surrounded by feathers. Any degree of discharge from the nares should be considered abnormal. Serous discharges are usually associated with respiratory irritants while mucopurulent discharges are most commonly associated with infectious agents.

about 0.25 inches per month, yet maintain a consistent length. In free-ranging birds, the beak is maintained in good condition through exposure to moisture followed by drying from exposure to sunlight. As the bird eats and chews on woody plants, the dry outer edge of the beak is removed, which maintains its proper shape and length.

Dry, flaky layers on the beak and skin around the cere are abnormal and may signal poor management or systemic disease (Figure 8.10). Birds that frequently bathe, are fed formulated diets and have regular exposure to fresh air and sunlight have fewer beak problems than birds that are fed a seed diet and restricted to an indoor environment. Grooves in the beak originating from the area of the nostril may indicate a previous or ongoing sinus infection (see Chapter 22). Physical damage (bite wounds) to the epithelial growth centers of the beak can cause similar lesions. Proliferative growths associated with the beak are common with *Knemidokoptes* sp. infections (see Color 24).

Oral Cavity

Evaluation of the oral cavity can be augmented using a speculum or gauze strips to open the mouth (Figure 8.11). A detailed examination of the oral or pharyngeal mucosa may require isoflurane anesthesia.

The oral cavity should be relatively smooth, glisten-

Making Distinctions in the Physical Examination

Color 8.16
Normal choanal area in a Sun Conure. Note the smooth, even color of the oral mucosa and the well defined choanal papillae (arrows).

Color 8.17
White-to-yellow, proliferative, diphtheritic mass on the sublingual mucosa of a pheasant. These lesions can be caused by poxvirus, bacteria, trichomonas, candida or hypovitaminosis A.

Color 8.18
Severe, diphtheritic inflammation of the buccal and pharyngeal mucosa in an Umbrella Cockatoo that was DNA probe-positive for PBFD virus. Cytologic evaluation of samples collected from the lesions revealed high numbers of gram-negative bacteria and yeast.

Color 8.19
Blunting of the choanal papillae and accumulation of mucopurulent discharge in the palatine area of a conure with hypovitaminosis A and bacterial sinusitis and tracheitis.

Color 8.20
a) Swollen, edematous, ulcerated masses associated with the buccal and pharyngeal salivary glands secondary to hypovitaminosis A. The largest mass occluded the glottis and caused asphyxiation. **b)** normal tongue (t), laryngeal mound (l) and trachea (tr).

Color 8.21
Proliferative, white-to-brown, cheesy masses on the pharyngeal mucosa of a Red-tailed Hawk. Trichomoniasis was diagnosed cytologically.

Color 8.22
a) Ulcerative lesion on the palate of a bird with choanal atresia. In addition to the deformity in the choana, this bird did not have an infundibular cleft and **b)** the lacrimal ducts were not patent (courtesy Cheryl Greenacre).

Color 8.23
An adult Green-winged Macaw was presented with a severe upper respiratory tract disease two weeks after being purchased from a traveling bird dealer. In addition to rhinitis, the bird also had diarrhea and mild tremors. A tenacious, mucopurulent discharge was noted in the pharyngeal area bulging from the choanal slit (arrow). The bird did not respond to supportive care. Histology indicated pneumonia, enteritis and lymphocytic perivascular cuffing in the brain.

Making Distinctions in the Physical Examination

Color 8.24
a,b) Hyperkeratosis and feather loss in a malnourished canary. The bird's feathers, skin and overall health improved when it was changed from an all-seed to a formulated diet.

Color 8.25
Bruising, ulceration and necrosis of the cranial edge of the sternum secondary to a traumatic injury. Because the bird's wings had been improperly trimmed, the bird landed hard on its sternum on a concrete floor during attempts to fly. The trimmed flight feathers were removed to enable them to regrow. After feather regrowth, surgical debridement of the wound and removal of the necrotic portion of the sternum were necessary to correct the lesion.

Color 8.26
Chronic ulcerative dermatitis on the back of a lovebird. Note the dry, hyperkeratotic skin at the periphery of the open, bleeding lesions.

Color 8.27
Severe obesity in a Screech Owl that was fed obese rodents and provided no room for exercise. Note that the keel is not visible, and accumulated fat is bulging into the thoracic inlet area.

Color 8.28
Tattoo ink is frequently injected into the propatagium to indicate the gender of a bird following endoscopic evaluation of the gonads. Traditionally, tattoo ink is injected into the right propatagium of males and the left propatagium of females.

Color 8.29
Defect in the comb, wattle and beak secondary to debeaking and a *Trichophyton* sp. (*favus*) infection. A correctly healed bird's beak (left) is shown for comparison (courtesy R. Korbel).

Color 8.30
Proliferative mass on the head of a canary characteristic of the dry form of poxvirus. Note the ulcerations and scab formation (courtesy of Patricia Macwhirter).

Color 8.31
A mature Amazon parrot hen was presented with a two-day history of depression and blood-tinged feces. Veterinary assistance was requested when frank hemorrhage was noted in the feces. The cloacal wall was edematous and prolapsed secondary to tenesmus caused by hemorrhagic enteritis.

Color 8.32
a) Caudocranial view of the left pelvic limb of a duckling, demonstrating medial luxation of the Achilles tendon. The trochlear groove (arrow) is visible through the skin. **b)** Normal (left) hock joint and soft tissue damage (right) associated with medial luxation of the Achilles tendon (courtesy of John H. Olsen).

Color 8.33
Proliferative, ulcerative lesion (bumblefoot) on the plantar foot surface of a swan (courtesy of John H. Olsen).

FIG 8.9 The feathers on the head should be smooth and uniform. The ear canals can be evaluated for discharge or for abnormal accumulation of desquamated hyperkeratotic skin by parting the feathers on the side of the head.

ing and evenly colored (white to black depending on the species) (see Color 13). Some birds (particularly Passeriformes) may have brightly colored spots in the mouth that play a role in brooding activities. The tongue has a dry sheen while the choanal slit and pharyngeal and laryngeal mucosa are slightly moist (see Color 13). Choanal papilla are well formed in some species (Amazon parrots and macaws) and less distinct or absent in other species (Color 8.16). Excessive moisture in the mouth may indicate inflammation in the oral cavity, choanal slit, sinuses or pharyngeal and laryngeal areas.

Accumulations of debris or food, abnormal coloration, erosions or ulcerations, sticky white mucus or perichoanal, pharyngeal or sublingual swellings are abnormal. White plaques that are easily removed and blunting or swelling of the choanal papillae are common with hypovitaminosis A (Color 8.20). Shallow yellow or white plaques that are attached and difficult to remove are common with pox or bacterial ulcerations (Color 8.17). White or brown cheesy lesions are suggestive of candidiasis or trichomoniasis (Color 8.21). Accumulations of desquamated hyperkeratotic epithelium, recognized clinically as small white bumps on the dorsal surface of the tongue base are common in cockatiels. Birds with these lesions are frequently infected with *Candida* sp.

FIG 8.10 Layers of dry, flaky hyperkeratotic epidermis on the beak and around the cere are abnormal and may be a sign of malnutrition, lack of exposure to moisture and sunlight or of systemic disease (particularly hepatopathies).

A decreased jaw tone may indicate a systemic weakness. Vitamin E or selenium deficiency and giardia have been suggested as causes of this problem in cockatiels. These birds may not be able to crack seeds and frequently have poor tongue control resulting in food accumulation in the oral cavity.

Respiratory Tract

For examination purposes, it is easiest to divide the respiratory system into the upper respiratory tract (sinuses and trachea), lungs and lower respiratory tract (thoracic and abdominal air sacs). A bird that is in severe respiratory distress may require oxygen before it can tolerate the stress of a physical examination.

The respiratory rate should be determined before and during the hands-on physical examination (see Table 8.1). If the bird is calm and does not struggle during the physical examination, the respiratory rate will generally remain constant. In these birds, the respiratory rate should be increased by gently holding the feet and moving the hand in a downward motion. This will stimulate wing flapping and should increase the respiratory rate. In a normal bird, the respiratory rate should return to its pre-exercise rate within two minutes of ceasing the exercise. A sustained tachypnea can indicate respiratory disease, cardiovascular disease or a mass that is blocking air flow in and out of the caudal air sacs.

Auscultation

A pediatric stethoscope is ideal for auscultating the avian lungs, heart and air sacs (Figure 8.12). Some sounds can be detected by placing the bird's body

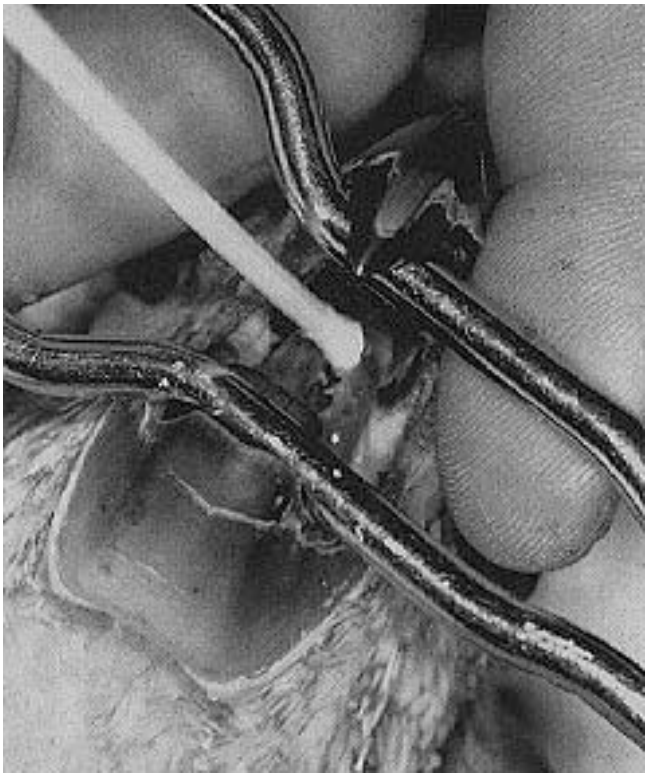

FIG 8.11 If a speculum is used for the oral examination, it should be firm enough to keep the mouth open but pliable enough not to damage the corneum of the beak. This is particularly true with young birds.

directly to the ear. The heart rate will vary from 45 to 600 beats per minute depending on the species and level of excitement (see Table 8.1).

Hearing a slight rush of air is normal. The sounds associated with inspiration are noted first and are typically louder and shorter in duration than those associated with expiration. The avian lungs move minimally during respiration, and detection of the respiratory clicks that are common with fluid increases in mammalian lungs is rare in birds. Detected cracks, pops, wheezes or whistling sounds are indications of severe respiratory tract abnormalities. Most abnormal respiratory sounds in birds are associated with rhinoliths, infraorbital sinusitis, tracheal stenosis or air sac disease. There may be a decrease in inspiratory sounds if a lung or air sac is consolidated. Sharp clicking sounds are occasionally noted in an apparently healthy bird that is being restrained. These sounds are thought to be caused by a subluxating joint.

Body Examination and Palpation

The submandibular and neck areas should be palpated, with particular attention to the esophagus and

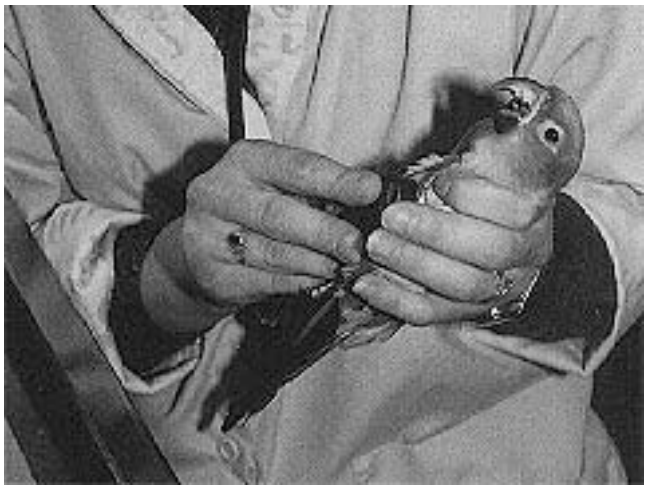

FIG 8.12 A pediatric stethoscope is ideal for auscultating the avian lungs, heart and air sacs. The stethoscope is first placed on the dorsal midline of the back at the level of the scapula, then moved slowly caudally and to the left and right to listen for respiratory sounds in both lungs and the thoracic and abdominal air sacs (courtesy of Cathy Johnson-Delaney).

crop. The esophagus as it extends down the right side of the neck can be palpated for swellings. Large food items (eg, grapes, vegetable chunks) may be swallowed intact and can be palpated as soft fluctuating masses. The crop is normally the largest palpable structure in the thoracic inlet. In Psittaciformes, the majority of the pendulous sac of the crop lies on or to the right of midline (see Anatomy Overlay). If distended with food, the crop can be quite large, and care should be exercised when handling the bird (particularly a neonate) to prevent regurgitation, which may lead to aspiration pneumonia. If empty, the crop and esophagus can be palpated. The crop should feel thin and striated longitudinally (see Colors 13, 19). In adult pigeons, the crop mucosa will be thickened for several weeks after a clutch hatches; this normal physiologic change should not be confused with pathology. Peristalsis of the crop is easy to observe (one to three per minute), particularly in neonates.

The crop and esophagus can be visually examined by wetting the feathers around the thoracic inlet and placing a small, high-powered light (eg, endoscope light) on one side of the crop. Using this transillumination technique, the relative thickness of the crop mucosa and its vascularity can be determined (see Color 19). If empty, expanding the crop with air and holding it in place by digital pressure on the esophagus allows improved transillumination. Thickening or increased vascularization of the crop or esophagus are indications of inflammation.

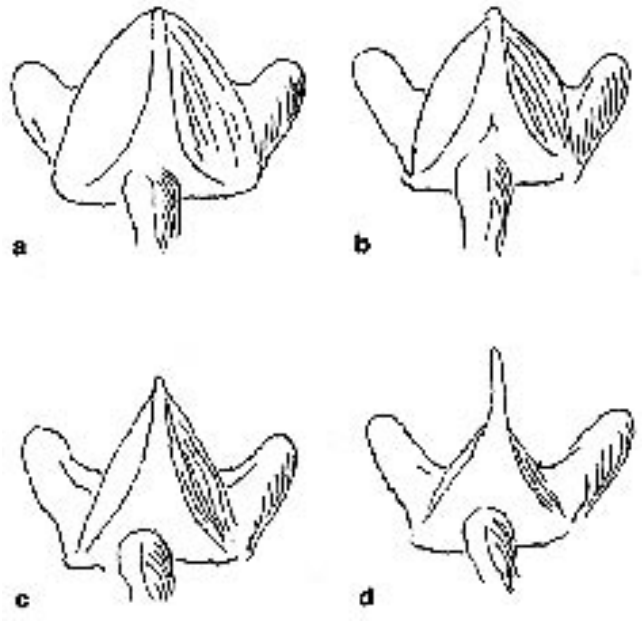

FIG 8.13 The patient's general condition can be subjectively evaluated by palpating the pectoral muscles to determine the ratio of muscle mass to sternum. **a)** A normal adult bird should have solid, well formed, rounded pectoral muscles with a slight dip on either side of the sternum. **b,c)** The sternum becomes prominent as a bird's muscles atrophy with weight loss. **d)** A bird that has lost a substantial amount of weight has a reduced muscle mass and prominent sternum.

The patient's general condition can be subjectively evaluated by palpating the pectoral muscles to determine the ratio of muscle mass to sternum (Figure 8.13). If a slight depression is not palpable, the bird is probably overweight. The sternum should be straight, and deviations suggest malnutrition during development or a previous traumatic injury.

A bird's weight in grams should be determined with each visit. A scale that has been fitted with a perch can be used for tame birds (Figure 8.14). Most digital gram scales have a tare feature that allows a bird to be weighed in different containers. The actual weight should be compared to the estimated condition of the bird based on palpating the pectoral musculature. This will provide a clinical perspective of the ideal weight of a particular bird (see Table 30.5). For example, the weight range of Umbrella Cockatoos is 450 to 750 grams. Finding an individual bird that weighs 500 grams but is severely emaciated would indicate that this bird is abnormal even though it falls within a normal weight range. Some hens may have a thirty percent seasonal fluctuation in body weight (usually heaviest in the spring); however, these birds should never be emaciated or have clinical signs of disease.

The feathers over the sternum and abdomen should be moistened with alcohol to visually determine the amount of subcutaneous fat deposits. The abdomen should be slightly concave or flat. A convex bulging of the abdominal wall is indicative of a space-occupying mass (eg, egg, neoplasm, ascites, enlarged organ).

Abdominal organs are difficult to palpate in birds, particularly in small species; however, the ability to palpate unusual structures in the abdomen can provide important information. Normally, the abdomen should be flat, tight and slightly concave in the center. With liver enlargement, ascites, proventricular or ventricular distension or displacement, egg development, egg-related peritonitis or mass formation, the abdomen may appear distended, doughy and convex. The right liver lobe extends farther caudally than the left and can be detected most easily if enlarged (see Color 20). Gentle palpation under the caudal edge of the sternum should not be painful, and if a bird responds to this procedure it could indicate hepatitis. Palpation on a bird with a swollen abdomen should be performed gently. If fluid is present in the peritoneal space and an air sac is ruptured by excessive digital pressure, fluid can rush into the lungs causing asphyxiation. Extra-abdominal wall swellings caused by hernias or lipomas may be visualized and palpated.

In a well muscled, low-body-fat canary or finch the abdominal musculature is almost transparent, and portions of the gastrointestinal tract and liver (especially with hepatomegaly) can be visualized.

Cloacal Area

A pericloacal accumulation of excrement may indicate enteritis or polyuria or can be associated with cloacal dysfunction (Figure 8.15). If the dried excrement and associated feathers have formed a solid mass that is partially or totally preventing defecation, a bird may produce a voluminous, malodorous stool when the dried excrement is removed. The pericloacal feathers of a bird with chronic biliverdinuria are often stained greenish or greenish-yellow (see Color 20).

Inspection of the cloacal mucosa can be accomplished using a moistened cotton-tipped applicator. The applicator is gently inserted into the cloaca and slowly withdrawn while pushing the tip to one side. As the applicator is withdrawn, the cloacal mucosa will protrude through the vent. Alternatively, the cloaca may be examined by bending the bird's tail over its back

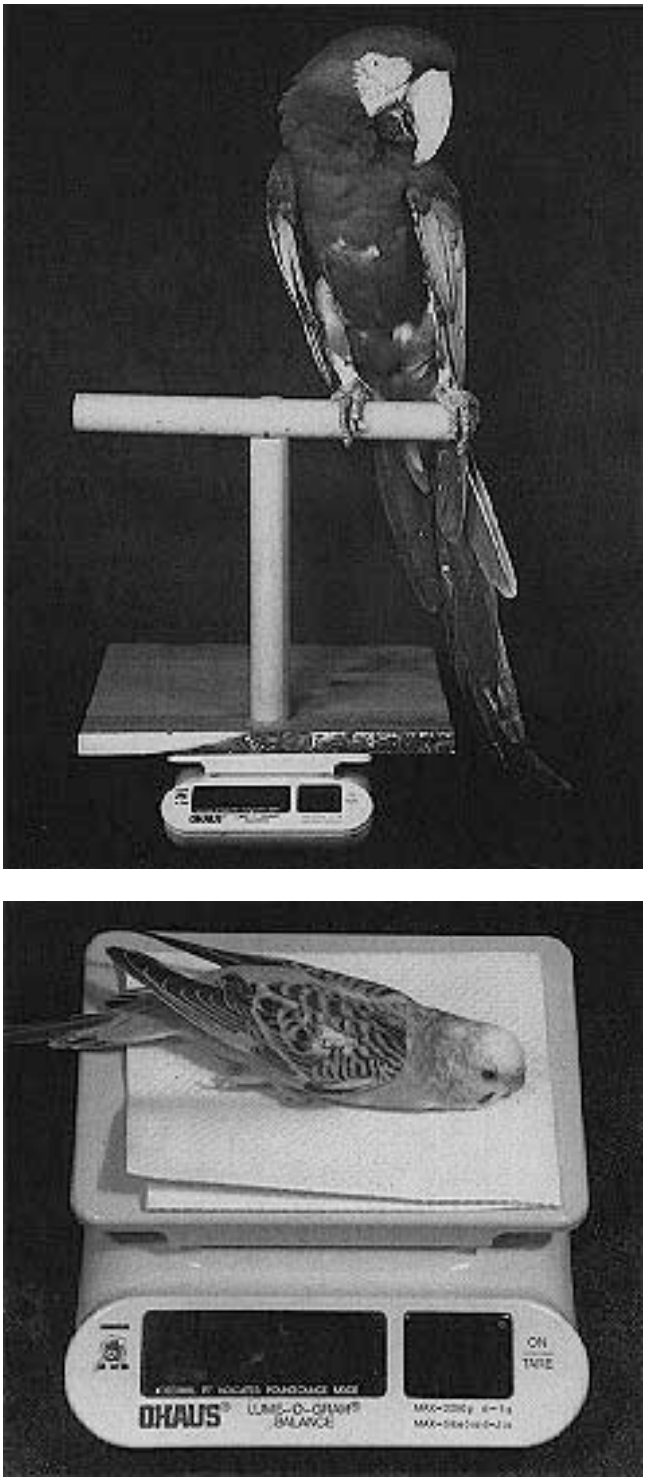

FIG 8.14 A bird's weight in grams should be determined with each visit. A scale that has been fitted with a perch can be used for tame birds. Small birds can be temporarily disoriented by moving them in several rapid, large circles. This procedure will provide the necessary time to obtain their weight using a digital scale.

and gently pinching the sides of the cloaca to expose the mucosa (Figure 8.16).

The cloacal mucosa should be carefully checked for papillomatous growths. Five percent acetic acid (apple cider vinegar) will cause papillomatous tissue to turn white and can facilitate visualization of subtle lesions. In most species, tissue should not protrude from the cloaca. The cloaca may be distended and partially everted if the bird has a developing egg, cloacal mass (eg, papilloma, fecalith), tenesmus or is constipated. Protruding tissue can be colon, uterus, ureter or cloacal wall (Color 8.31). The cloaca normally everts in reproductively active Vasa Parrots.

The openings of the urinary, gastrointestinal and genital tracts can be examined using an otoscope cone, vaginal speculum, human nasal speculum or endoscope. This procedure induces some level of discomfort and is best performed in an anesthetized bird. In sexually mature hens, the cervix may be observed in the left lateral wall of the urodeum (see Anatomy Overlay).

The uropygial gland, located dorsal to the cloaca at the end of the pygostyle, is well developed in some species (canaries) and absent in other species (Amazon parrots). If present, the gland should be smooth, evenly colored and contain a small amount of yellow, creamy material (see Figure 24.7). A change in the surface structure of the gland, a loss of feathers or a discolored discharge should all be considered abnormal. Infections and neoplasia are the two most common causes of abnormalities. Malnourished birds may have excessively dry, brittle feathers and skin that can spontaneously rupture, particularly in the postventer region (see Figure 24.20).

The internal temperature of a bird can vary from 107 to 112°F and temperatures often elevate rapidly during periods of stress. The temperature of a bird is not routinely determined during the physical examination because the procedure provides little valuable information and danger is associated with forcibly passing a thermometer through the cloacal wall. Tympanic thermometers are being clinically evaluated.

Wings, Legs and Feet

The bones and some of the musculature of the wing can be directly visualized for signs of bruising, swelling or fractures by wetting the surface of appendages with alcohol. Green discoloration (bruising) of subcutaneous tissues usually represents the breakdown of extravascular hemoglobin. In general, it takes about

FIG 8.15 The pericloacal area of a normal bird is clean and dry and has minimal feather discoloration. A combination of feces and urates may adhere to the cloacal rim and the surrounding feathers. This pericloacal accumulation of excrement may indicate enteritis or polyuria or can be associated with cloacal dysfunction.

two days after a traumatic event for this green color to appear, providing the clinician with an indication of the chronicity of an injury.

Hemorrhagic, necrotic dystrophic feather shafts are an indication of damage to the developing feather that can be caused by a number of infectious or metabolic problems (see Color 24). Mites may be observed moving on the underside of the wing or the nits may be attached to the feather vanes (see Color 48). Increased translucency, color alterations or structural changes in the flight feathers can be an indication of malnutrition or mismanagement. The ventral surface of the wing and prolateral region are common locations for feather picking in cockatiels, African Grey Parrots, cockatoos, Grey-cheeked Parakeets and Quaker Parrots (see Color 24). The presence of splintered or damaged feather shafts may indicate that a bird is preening excessively or feather picking (see Chapter 24).

Ulnar vein turgidity and skin consistency on the neck, abdomen and dorsal surface of the digits can be used to evaluate the hydration status of the bird. Flat veins that do not immediately refill when depressed

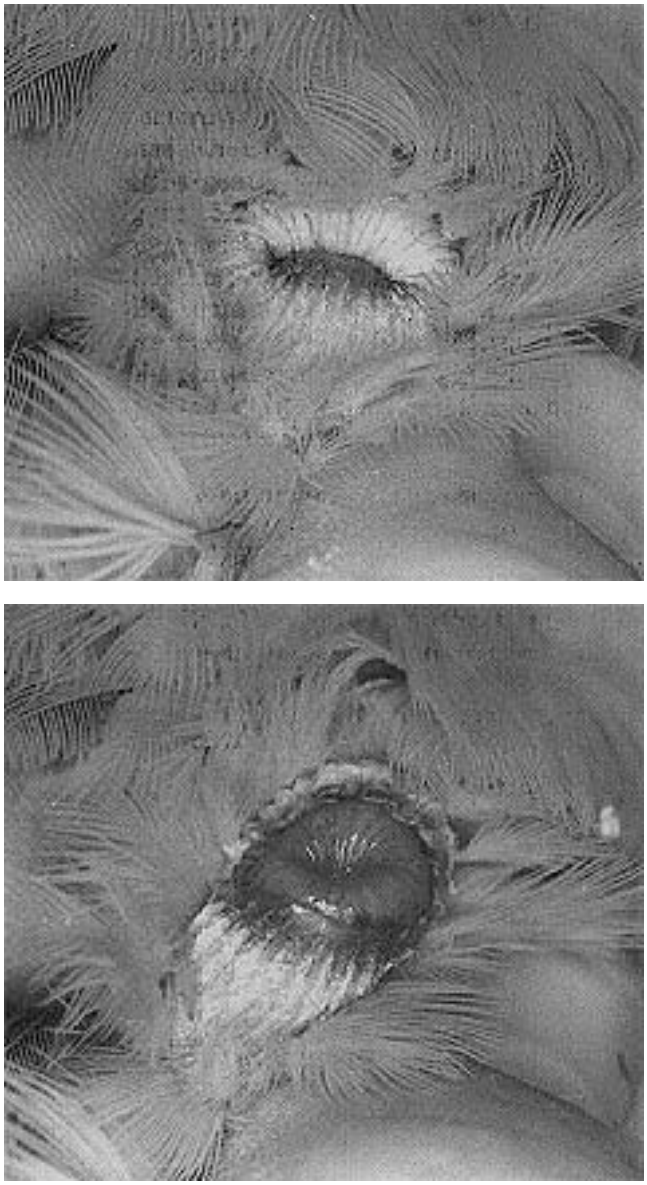

FIG 8.16 Inspection of the cloacal mucosa can be accomplished by bending the bird's tail over its back and gently pinching the sides of the cloaca to expose the mucosa. The cloacal mucosa in a normal bird is pink, evenly colored, slightly moist and smooth.

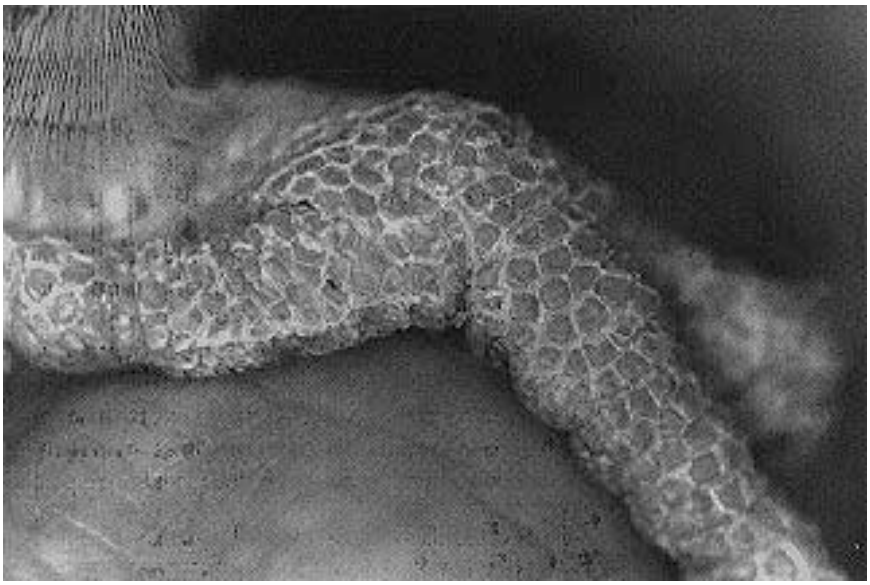
may indicate hypoproteinemia, anemia, dehydration or shock.

The feet and legs should be uniform in texture and color. The feet should have prominent scale patterns on both the dorsal and plantar surfaces (Figure 8.17). Changes that result in smoothing of the plantar foot surface can instigate chronic and severe foot and leg problems (Color 8.9). Common etiologies of foot abnormalities include hypovitaminosis A, a lack of sunlight, contact with nicotine sulfate (from the hands of cigarette smokers) and improper perches (eg, size,



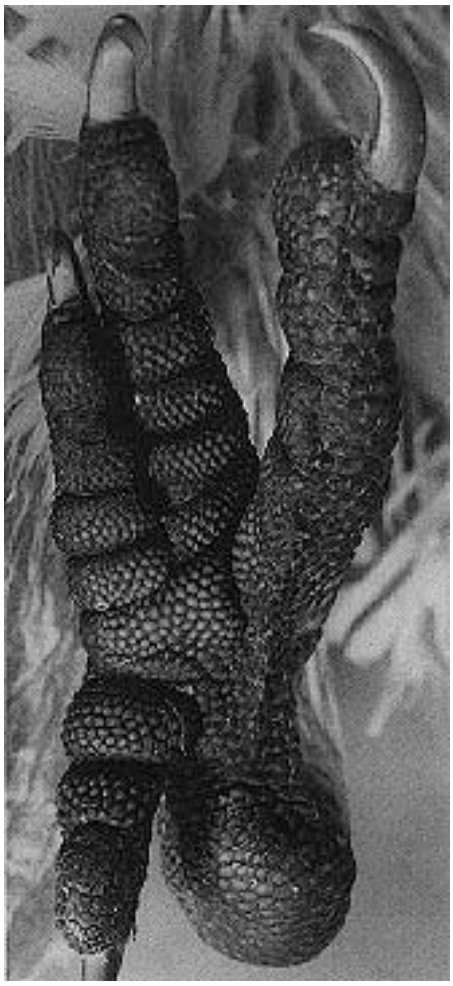


FIG 8.17 The feet and legs should be uniform in texture and color. The feet should have prominent scale patterns on both the dorsal and plantar surfaces. Flaking, balding, cracking, hemorrhage and peeling of the skin on the feet are all signs of abnormalities.

texture or firmness). Any ulcerative lesion or swelling of the feet should be addressed immediately. Ulcerative lesions can rapidly become infected (bumblefoot) and can be life-threatening if infectious agents invade associated tendon sheaths and bones (Color 8.33). Bacteremia is common in many birds with ulcerative lesions on the feet. The accumulation of exfoliated, dried hyperkeratotic scales is common in malnourished Passeriformes (see Chapter 24). Proliferative lesions on the feet of canaries (tasselfoot) are common with knemidokoptes infections (see Color 24).

The length of a bird's nails should be evaluated and the client should be instructed to carefully monitor the nail growth at home. Overgrown nails are common in birds with hepatopathies and can result in trauma to the fat pads (inducing bumblefoot) or entanglement in enclosures or toys. Hemorrhage in unpigmented nails is an indication of trauma or liver disease.

A weak grip can indicate systemic weakness or specific neuromuscular disease of the feet or legs (see Chapter 28). Leg paresis, ataxia and muscle atrophy may occur in birds with abdominal tumors. This lameness is typically the result of tumors that place pressure on the ischiatic nerve. Unilateral lameness is most common, but bilateral lameness may also occur. Bilateral lameness can also be a direct result of primary neural lesions (eg, aspergillosis, Marek's disease virus, lymphoid leukosis, spinal injuries, vitamin E or selenium deficiencies and B vitamin deficiencies).

Once the physical exam is completed, the minimum database can be collected. The decision of which test to perform is based on the condition of the patient. For the most accurate results, blood samples for CBC and biochemistries should be drawn when a bird is not stressed. Leaving a bird in a dark clinic overnight so that blood may be drawn the first thing in the morning may be the best solution (Table 8.4).

TABLE 8.4 Suggested Ideal Examination Database for Medium and Large Psittacines

▪ Physical examination	▪ Radiographs
▪ Body weight	▪ Fecal Gram's stain
▪ CBC	▪ Chlamydia testing
▪ Biochemistries - TP, Glucose, CA, AST, LDH, CPK, UA, Bile Acids	▪ DNA probe testing for PBFD virus, polyomavirus

Making Distinctions in the Physical Examination

Color 8.34
Normal excrement from a conure. Note the green fecal component, white urate component and clear, liquid urine component, typical of a bird on a formulated diet with limited fruits and vegetables.

Color 8.35
Clay-colored, voluminous feces in an Amazon parrot with maldigestion/malabsorption syndrome.

Color 8.36
Yellow discoloration of the urates is suggestive of hepatitis. The consumption of some yellow-pigmented vegetables and administration of parenteral B vitamins can cause a similar discoloration of the urates. In this case, biliverdinuria was present secondary to Pacheco's disease virus-induced hepatocellular necrosis. The volume of urates and lack of feces are indicative of anorectic disorders.

Color 8.37
Polyurates and polyuria in a bird with pancreatic or bile-related renal disease.

Color 8.38
Biliverdinuria and liquid diarrhea in an African Grey Parrot with chlamydiosis.

Color 8.39
Variation in the color, quantity and consistency of the excrement passed by a normal Amazon parrot in a six-hour period. These illustrate the effects of stress on the nature of the excrement.

Color 8.40
Variance in the color, form and consistency of excrement from a normal King Pigeon.

Color 8.41
Biliverdinuria and polyuria in a cockatoo with bacterial septicemia and hepatitis.

Color 8.42
A five-square-inch area of the bottom of an Amazon parrot's enclosure. The enclosure substrate had been changed 24 hours earlier. The grouping of the excrement indicates that the bird had remained in the same location. A scant quantity of feces is present in the oldest droppings, but the more recent droppings (consisting exclusively of urates) suggest that the bird has been anorectic for at least 24 hours.

Color 8.43
A mature Yellow-collared Macaw was presented as an emergency for an acute onset of bloody diarrhea. The bird was bright, alert and responsive. The suspected "hemorrhage" was caused by red dyes on the underside of the newsprint "bleeding" through.

Color 8.44
A cockatiel was presented for emergency evaluation of what the client described as bloody diarrhea. The bird was bright, alert and responsive. The bird had consumed a substantial quantity of fresh blackberries approximately two hours before presentation, and the abnormal color of the excrement was caused by pigments in the blackberries.

Color 8.45
Frank hemorrhage in an Amazon parrot hen with on ovarian adenocarcinoma, hepatitis and bacterial enteritis.

Color 8.46
Bluish discoloration of the excrement secondary to blueberry ingestion.

Color 8.47
Discoloration of the feces and polyuria in a Blue and Gold Macaw that consumed several large slices of sweet potato.

Color 8.48
A four-year-old Yellow-naped Amazon Parrot was presented for anorexia, depression and straining to defecate. A fecal occult blood test was positive. A Gram's stain of the feces and results of a glucose test and clotting time were normal. Hematology indicated a decreased WBC with a mild left shift. Radiographs indicated metallic densities in the ventriculus, and the bird responded to treatment with CaEDTA.

Color 8.49
Severe hematochezia in a mynah bird with bacterial enteritis. Abnormal clinicopathologic findings included TP=3.2, PCV=12.

Color 8.50
A 23-year-old obese Amazon parrot was presented with a one-day history of passing unclotted blood. Radiographs indicated a soft tissue density that originated near the cranial division of the kidney and extended ventrally into the abdomen. Polyostotic hyperostosis was also evident. The bird did not respond to supportive care. Histopathology indicated severe fatty liver degeneration, bacterial septicemia and ovarian cysts.

Color 8.51
Air bubbles are frequently present in the feces of birds with diarrhea.

Color 8.52
"Slug-like" excrement in a caique with pancreatic exocrine insufficiency.

Color 8.53
Polyuria in a Blue and Gold Macaw chick being fed a standard monkey biscuit-based formula. Polyuria is common in birds fed diets containing a high moisture content.

Color 8.54
Polyuria and discolored excrement in a bird with mucoid enteritis.

Color 8.55
Diarrhea, biliverdinuria and polyuria in an Amazon parrot with Pacheco's disease virus-induced hepatitis.

Color 8.56
Normal excrement in a stressed Umbrella Cockatoo hen. The excrement was one of several with greenish discoloration of the urates caused by bile pigments passing in the urine due to increased heart rate and kidney overload.

Color 8.57
Undigested seeds that are a component of the feces (right) must be differentiated from seeds that have fallen onto the feces. This cockatiel had neuropathic gastric dilatation.

Color 8.58
Vomitus from a Severe Macaw with neuropathic gastric dilatation. Note the frothy nature of the material and the chunks of undigested seeds. The pH of the material was 2.6, confirming that it had originated from the proventriculus.

Making Distinctions in the Physical Examination

Color 8.59
Gram's stain of samples collected from the **a)** crop and **b)** feces of a normal Umbrella Cockatoo. Note that the bacterial population consists primarily of gram-positive rods and cocci; no gram-negative bacteria or yeast are present. The red material represents normal undigested dietary components.

Color 8.60
Gram-positive and gram-negative bacteria and epithelial cells collected from the choanal slit of a clinically asymptomatic Amazon parrot. Although the choanal slit is normally free of gram-negative bacteria, transitory gram-negative rods in the pharynx are common. A repeat Gram's stain should be performed several days after potential sources of gram-negative bacteria have been removed from the diet.

Color 8.61
Gram's stain of the **a)** crop and **b)** feces of an Amazon parrot with depression, vomiting and diarrhea. Note the predominance of gram-negative rods suggestive of a bacterial enteritis. If a Gram's stain is improperly performed, gram-positive rods can appear as though they are gram-negative. To avoid the misinterpretation of an improperly stained sample, it is important to scan the entire slide and make certain that both gram-positive and gram-negative organisms can be identified. A Gram's stain checking system (Gram Q-Chek, Fisher Scientific) is available for quality control of the stains and procedure.

Color 8.62
Wright's stain of feces from a budgerigar with severe weight loss. Note the large rod-shaped organisms suggestive of megabacteria. Nucleated RBC's are also present.

Color 8.63
a) Gram's stain of feces from a clinically normal Blue and Gold Macaw chick. The blue-staining masses are characteristic of yeast. Note that the yeast are not budding. This bird was being fed a diet containing brewer's yeast. These nonpathogenic yeast are frequently passed in the feces and should not be misinterpreted as a fungal enteritis. **b)** Gram's stain of the crop in a Moluccan Cockatoo chick presented for regurgitation and weight loss. Note the budding yeast suggestive of an active *Candida* sp. infection. Detecting an abnormally high number of yeast in the crop or feces is an indication that a bird is immunosuppressed. **c)** Yeast should stain gram-positive. Finding gram-negative staining yeast is an indication that the staining process was improperly performed. Non-viable yeast that have been killed with antifungal therapy will appear as clear halos against the stained background.

Color 8.64
a) Carbofuschin or **b)** iodine stains can be used to detect *Giardia* sp. trophozoites in the feces (courtesy of Bob Dahlhausen).

Color 8.65
Gram-negative bacterial rods (magnified) from a conure with hemorrhagic enteritis.

Color 8.66
Sperm from a budgerigar detected during a routine Gram's stain evaluation of the excrement.

Color 8.67
Urate crystals are frequently found during microscopic examination of the feces.

Color 8.68
Stain precipitates and strands of cotton from a swab will appear as large, amorphous, gram-positive masses.

CHAPTER

9

HEMATOLOGY

Terry W. Campbell

Evaluation of the avian hemogram involves counting the various blood cells per microliter of blood as well as cytologic evaluation of the cells. The techniques involved in the evaluation of the avian hemogram are easily performed by in-house veterinary laboratory personnel. Because avian blood does not store well (eg, during transport), hematologic results obtained soon after collection are preferred over those performed several hours later.[6,18,34]

Blood volume in birds depends on the species and varies from 5 ml/100g in the Ring-necked Pheasant to 16.3 to 20.3 ml/100g in the racing pigeon. In general, birds are better able to tolerate severe blood loss than mammals, which is due to their greater capacity for extravascular fluid mobilization. However, there is a marked variation among avian species in response to blood loss, which may be a reflection of differences in blood volume or extravascular fluid depots. In healthy Mallard Ducks and racing pigeons, a blood volume equivalent of up to three percent of the body weight can be collected. In Passeriformes, pheasants and Psittaciformes, up to one percent of the body weight can be collected with few ill effects (0.9 ml from a 90 g cockatiel).

Blood can be collected from a variety of sites in avian patients. The choice of a blood collection site is influenced by the species of bird, preference of the collector, physical condition of the patient and volume of blood needed. For best results, venous blood should be collected for hematologic studies. Blood collected from capillaries (eg, blood from clipped nails) often results in abnormal cell distributions and contains cellular artifacts such as macrophages and material not normally found in peripheral blood (Figure 9.1). Blood to be used for hematology should be collected into a collection tube containing EDTA (ethylenediaminetetraacetic acid) as the anticoagulant. Other anticoagulants, such as heparin, interfere with cell staining and create excessive cell clumping, resulting in erroneous cell counts and evaluations (Color 9.3)[6,18,34]

Processing the Avian Hematologic Sample

Blood Collection

Jugular venipuncture is a procedure that can be used for collecting blood from most avian species.[6,18,34,38,71] It is the method of choice for small birds that do not have other blood vessels large enough for venipuncture. The right jugular vein is usually chosen over the left for blood collection because in many birds it is the larger of the two. To collect blood from the jugular vein, the bird is properly restrained with the head and neck extended (Figure 9.2). Extending the neck encourages the highly movable jugular vein to fall into the jugular furrow. In many species, there is a featherless tract of skin (apterium) overlying the jugular vein; therefore, lightly wetting the feathers with alcohol in this area will aid in the visualization of the vein. Blood is collected into a syringe, and the size of needle is governed by the size of the vein. Complications of jugular venipuncture include difficulty in proper restraint of the bird or stabilization of the vein and hematoma formation. Improper attention to technique and hemostasis can cause a large hematoma to form during or following jugular venipuncture. However, jugular venipuncture becomes a skill perfected with practice, and complications are infrequent in skilled hands.

Venipuncture of the ulnar or wing vein is a common method for obtaining blood from medium to large birds. A needle is inserted into the vein, which is found crossing the ventral surface of the humero-radioulnar joint (elbow) (Figure 9.3). Blood is either aspirated into a syringe or allowed to drip from the needle hub into a microcollection device. Collecting blood in this manner reduces but does not eliminate hematoma formation. A variety of these devices is available.[a-c] These collecting tubes contain EDTA for hematology studies, are plain (with or without a serum separator) or contain heparin (lithium heparin is the preferred form) for blood chemistry studies. Hematoma formation, which can be severe, is common when the ulnar vein is used for blood collection. A needle with an extension tube, such as a butterfly catheter,[d] aids in stabilization during sample collection to minimize tearing of the vein.

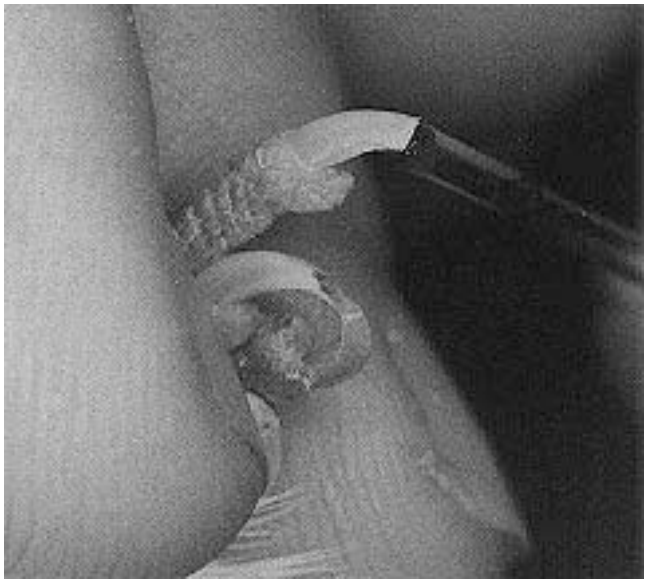

FIG 9.1 Blood for hematologic evaluation should be collected from a free-flowing venous source. Blood collected from a toenail clip may yield abnormal cell distributions and cellular artifacts.

Venipuncture of the medial metatarsal (caudal tibial) vein, which lies on the medial side of the tibiotarsus at the tibiotarsal-tarsometatarsal joint, is another common method for blood collection in medium to large birds (Figure 9.4).[6,18] The primary advantages of this method over other methods of blood collection is that the surrounding leg muscles protect the medial metatarsal vein from hematoma formation and, in some species, the leg is more easily restrained than the wing.

Blood can be collected from the occipital venous sinus of birds. This technique should be reserved for birds used in research or for blood collection prior to euthanasia,[6,78] because of the potential for injuring the brainstem. When properly executed, however, this method can be safely used for collecting repeated blood samples from birds. The bird must be completely restrained. The head is held firmly in a flexed position in a straight line with the cervical vertebrae. The occipital venous sinus is just below the skin in the space between the base of the skull and the first cervical vertebra. To collect blood from this sinus, an evacuated tube with needle and holder is required. The needle is passed through the skin at a 30 to 40° angle to the cervical vertebrae on the dorsal midline just above the sinus. Following penetration through the skin, the evacuated tube is advanced in the holder, allowing penetration of the tube stopper by the needle within the holder. The needle is advanced slightly downward to penetrate the venous sinus.

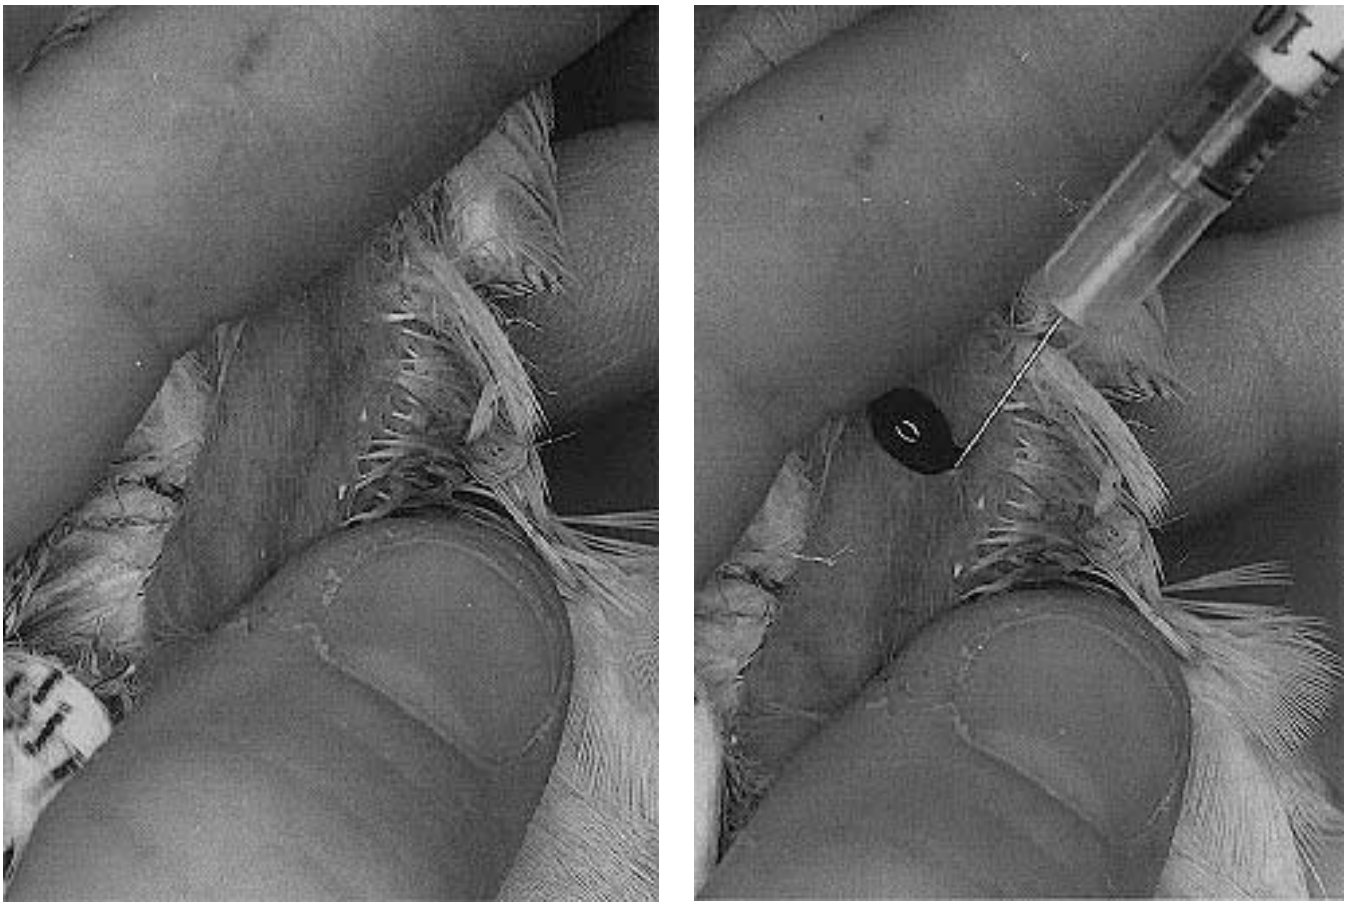

FIG 9.2 The right jugular vein (left) is the preferred site for blood collection in most species of birds. The vessel is easy to visualize and is larger than the left jugular vein. The neck and head are held in extension, and the mid-cervical area is lifted slightly to improve the angle for venipuncture. The vessel is occluded at the thoracic inlet (right) to facilitate distention and blood collection. Note the featherless tract (apterium) overlying the right lateral neck and jugular furrow. The vessel can be entered from either a cranial or caudal direction.

When this occurs, blood will rapidly fill the evacuated tube. Cardiac punctures should be used only for blood collection prior to euthanasia.[1,45,77]

Laboratory Techniques

After the blood is collected, a blood film is made. The film can be made either from blood containing no anticoagulant (especially if blood parasites are suspected) or blood containing EDTA. EDTA will cause hemolysis of erythrocytes in some birds including Corvidae, currasows, Crowned Cranes, hornbills and Brush Turkeys. Prolonged exposure to EDTA may result in increased disruption of cells in the blood film in some species (Color 9.3). Therefore, when using an anticoagulant, a blood film should be made immediately following blood collection. Heparin should be avoided whenever possible for hematologic studies. Heparinized blood contains artifacts such as clumping of cells (especially leukocytes in counting chambers) and frequently results in staining artifacts (Color 9.3).[6,34] When preparing a blood film, the standard two-slide wedge technique used in mammalian hematology usually works well with avian blood.[6,12,67] It is advisable to use precleaned, bevel-edged microscope slides to minimize cell damage during preparation of blood films. Peripheral blood films can also be made using a two-coverglass technique. A drop of blood is placed in the center of one coverglass;[16,17] a second coverglass is placed on top of the first, and the two are pulled apart as the blood begins to spread between the two surfaces. A similar technique using a microscope slide and a rectangular coverglass (24 mm x 50 mm) can be used to prepare a film on a microscope slide rather than on coverglasses, making the sample easier to stain.[6,18] Using the two-coverglass or microscope slide-coverglass methods should be considered if the standard two-slide wedge technique creates excessive smudging of the cells. Most veterinarians and technicians accus-

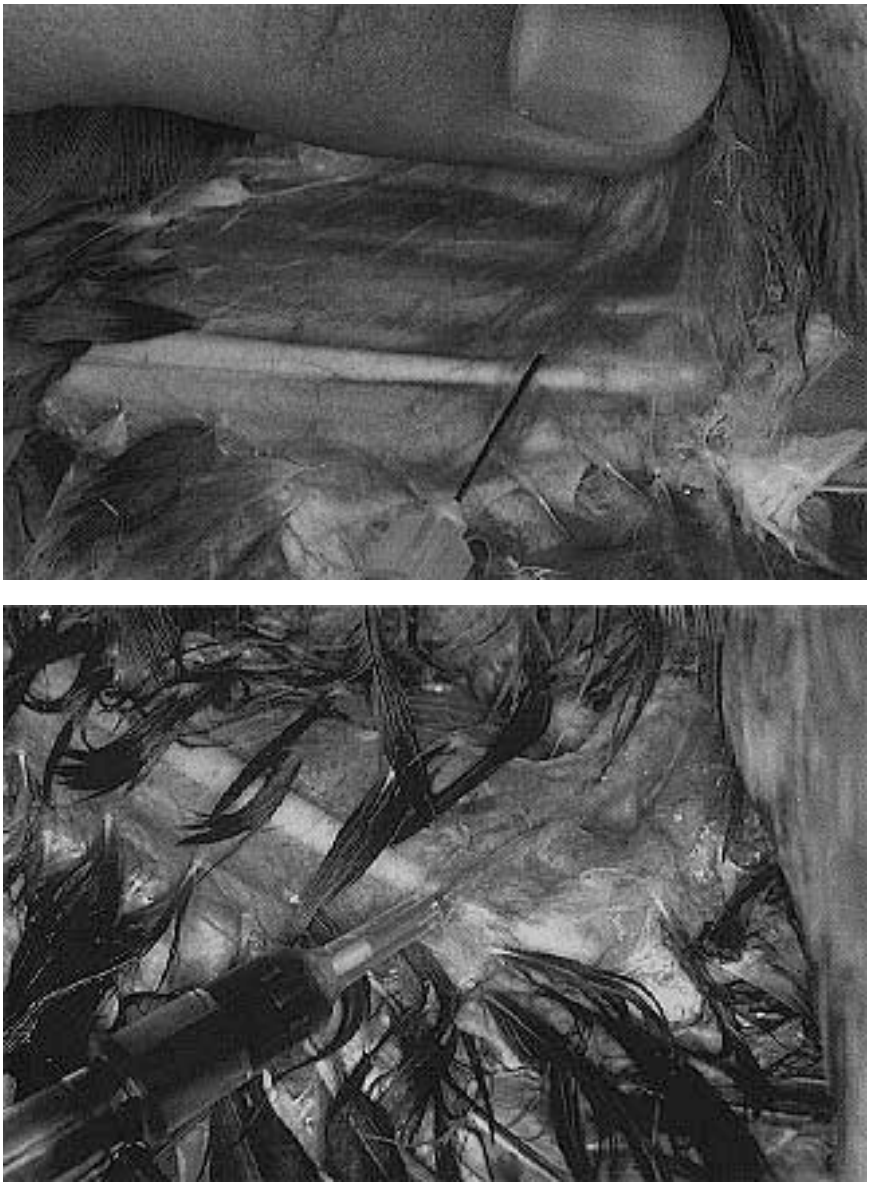

FIG 9.3 The cutaneous ulnar vein should be considered an inferior site to the right jugular vein for blood collection. The vessel (top) is easy to access on the ventral surface of the wing, but hematoma formation is common. Note that the bevel of the needle is up and the brachial vein is being occluded with the thumb. A small gauge needle (bottom) is used to minimize hematoma formation and is threaded into the vessel to decrease "wobble" and endothelial damage from the needle tip.

tomed to performing the two-slide wedge technique with mammalian blood have little difficulty in using the same technique to prepare proper avian blood films.

A variety of hematologic stains can be used to evaluate the air-dried blood film. Romanowsky stains, such as Wright's, Giemsa, Wright-Giemsa, Wright-Leishman or May-Grunwald and their combination, are preferred[6,18,34] (see Chapter 10). Wright's stain has been the standard in veterinary hematology, and all cell descriptions and illustrations used in this text are based upon that stain. These descriptions also apply to a great extent to the other commonly used quick stains, which essentially are modifications of the classic Wright's stain procedure.[e,f] The use of an automatic slide stainer[g] simplifies the staining procedure and provides a means for consistency and high quality staining by removing variations that occur with hand-staining procedures.

After making a blood film, the remainder of the blood sample is used to obtain a packed cell volume (PCV), hemoglobin concentration and cell count. The PCV is obtained by centrifuging a microhematocrit tube full of blood at 12,000 G for five minutes. The hemoglobin concentration is measured spectrophotometrically by using the manual or automated cyanmethemoglobin method after centrifugation removal of free red cell nuclei and membrane debris.

The red blood cell (RBC) count is obtained either by automated or manual methods. The automated cell counters[h] provide a quick, reliable method for obtaining a RBC count in birds. The two manual methods that can be used are the erythrocyte Unopette system[i] (standard method in mammalian hematology) or Natt and Herrick's method. The latter method requires the preparation of a methyl violet 2B diluent.[55] A 1:200 dilution of the blood is made using this solution and a diluting pipette. After mixing, the diluted blood is discharged into a Neubauer-ruled hemacytometer and the cells are allowed to settle to the surface for five minutes before enumeration. The red blood cells are counted using the four corner squares and one central square of the central large primary square of the hemacytometer. The number of red cells counted is multiplied by 10,000 to obtain the RBC count per microliter of blood. Appropriate secondary squares are counted on each grid and the counts are averaged.

FIG 9.4 The medial metatarsal vein can be used to collect smaller quantities of blood from medium- to large-sized birds. This vessel is supported by the soft tissues of the leg and in comparison to other blood collection sites, hematoma formation is rare (courtesy of Kathy Quesenberry).

The mean corpuscular values can be calculated using the PCV, hemoglobin and RBC count values. The mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC) are useful in the characterization of the erythrocytes, especially in the evaluation of anemia.

$$\text{MCV} = \frac{\text{PCV} \times 10}{\text{RBC count}}$$

$$\text{MCH (pg)} = \frac{\text{Hemoglobin} \times 10}{\text{RBC}}$$

$$\text{MCHC} = \frac{\text{Hemoglobin} \times 100}{\text{PCV}}$$

A reticulocyte count can be useful in the evaluation of the red cell regenerative response. The erythrocytes are stained with a vital stain, such as new methylene blue stain, and the reticulocytes are identified as red blood cells that contain distinct rings of aggregated reticulum encircling the cell nucleus (Color 9.1).[6,34] Other erythrocytes may contain varying amounts of reticulum, but those with the distinct ring of aggregated reticulum surrounding the cell nucleus appear to be cells that have recently entered the peripheral circulation, and thus reflect the current regenerative response.

The white blood cell (WBC, leukocyte) count of birds is obtained using manual techniques because the presence of nucleated erythrocytes and thrombocytes interfere with the counting of white blood cells using electronic cell counters. The current methods of choice for obtaining a total leukocyte count in birds are the indirect method using the eosinophil Unopette brand 5877 system or the direct leukocyte count using Natt and Herrick's method.[6,13,18,55] Estimation of leukocyte numbers from a blood film should be reserved for those occasions when a quantitative count is unavailable or when there is suspicion of error in a value obtained from the other methods.

The indirect eosinophil Unopette brand method involves the filling of the 25 μl pipette with blood, mixing the blood with the phloxine B diluent in the vial provided in the system and charging the hemacytometer chamber for cell counting. The blood-phloxine mixture should not be allowed to stand in the Unopette vial for longer than five minutes or erythrocytes may also be stained. The charged hemacytometer should stand undisturbed for at least five minutes to allow the cells to settle to the surface of the counting grid. It is advisable to keep the charged hemacytometer in a humid chamber to prevent dehydration of the sample if the chamber is going to sit for longer than five minutes. The granulocytes that stain distinctly red (heterophils and eosinophils) are counted in both sides of the hemacytometer (representing 18 large squares). Therefore, a total absolute heterophil and eosinophil count is obtained. A WBC count is obtained by determining a leukocyte differential from the peripheral blood film and using the formulas in Table 9.1.

A total thrombocyte count can be obtained using the Natt and Herrick's method; however, thrombocytes tend to clump, making an accurate count difficult to achieve. A subjective opinion as to the number of thrombocytes present can be made from the peripheral blood film. An average of one to two thrombocytes are present in monolayer oil immersion (100 x) fields in blood films of normal birds. Numbers less than this suggest a thrombocytopenia and those greater suggest a thrombocytosis. An estimate of the thrombocyte count can be made from the peripheral blood film by obtaining the average number of thrombocytes in five monolayer oil immersion fields. This

represents the average number of thrombocytes per 1000 erythrocytes in most species of birds.

A more accurate method would be to count the number of thrombocytes per 1000 erythrocytes in the blood film. The number of thrombocytes per 1000 erythrocytes is multiplied by the erythrocyte count and divided by 1000 to obtain an estimated thrombocyte count per µl of blood. If the actual erythrocyte count is not known, then 3,500,000 can be used to represent the average number of erythrocytes per µl of blood in most species of birds having an average PCV of 45%. If the PCV is below 40 or above 50, the estimated thrombocyte count (est T) can be corrected using the following formula:

$$\text{Corrected est T} = \frac{\text{est T X observed PCV}}{\text{normal PCV (averages 45\%)}}$$

Cell Identification

Erythrocyte Morphology

The normal mature avian erythrocyte is oval with a centrally positioned oval nucleus. The cytoplasm is abundant and stains a uniform orange-pink, resembling the cytoplasm of mammalian erythrocytes (Color 9.1). The nucleus of the mature erythrocyte is condensed and stains dark purple. The nuclear chromatin is uniformly clumped. The red cell nuclei vary with age, becoming more condensed and darker staining as the cells age.

Variations from the typical mature erythrocyte are occasionally seen in the peripheral blood of birds. Avian erythrocytes frequently demonstrate diffuse polychromasia. Polychromatic erythrocytes demonstrate cytoplasmic basophilia and have nuclei that are less condensed compared to mature erythrocytes (Color 9.1). Immature round erythrocytes (eg, rubricytes) may also be found in the peripheral blood of birds. These developmental stages have been described in this chapter with the discussion of the evaluation of hematopoietic tissue. Occasionally, round erythrocytes with oval nuclei may be found, especially in anemic birds. This is suggestive of an asynchronous maturation of the cell nucleus and the cytoplasm, probably owing to accelerated erythropoiesis. Anucleated, oval erythrocytes (erythroplastids) are rare findings in peripheral blood films of birds (Color 9.2). The shape of the red blood cell may appear irregular, or smudging may occur as a result of artifacts created by the preparation of the film. The most common artifact found in peripheral blood films of birds is the rupturing of cells during preparation of the film (Color 9.3). The majority of these cells appear to be erythrocytes. The free red cell nuclei appear as amorphous, pink-to-purple material on the film. Other abnormal findings include variations in the location of the cell nucleus within the cell and nuclei having indentations, constrictions or protrusions (Color 9.3). Perinuclear rings are usually artifacts of staining (eg, a form of cellular crenation). Cytoplasmic basophilic stippling is also indicative of abnormal erythrocyte morphology. Hypochromasia is indicated by pale-staining cytoplasm, cytoplasmic vacuoles and round, pyknotic nuclei (Color 9.2). Agglutination of erythrocytes in the blood film is a rare, abnormal finding.

TABLE 9.1 Formulas for Determining WBC counts

The total heterophil and eosinophil count T(h+e) is obtained by using the formula given for the eosinophil Unopette brand system:

$$T(h+e)/mm^3 = \text{cells counted} \times 10 \times 32 / 18$$

The total leukocyte count (TWBC) is obtained using the leukocyte differential and the following formula:

$$TWBC/mm^3 = (T(h+e) / \%\ \text{heterophils + eosinophils}) \times 100$$

The TWBC can be calculated using the formula:

$$TWBC/mm^3 = \frac{\text{number of cells counted} \times 10 \times 32 \times 100}{(\%\ \text{heterophils + eosinophils}) \times 18}$$

This formula can be simplified by using the formula:

$$TWBC/mm^3 = \frac{\text{number of cells counted} \times 1.111 \times 16 \times 100}{\%\ \text{heterophils + eosinophils}}$$

or

$$TWBC/mm^3 = \frac{\text{number of cells counted} \times 1778}{\%\ \text{heterophils + eosinophils}}$$

The Natt and Herrick's method is a direct method for obtaining a TWBC and utilizes the same dilution and charged hemacytometer used to obtain a RBC count. The dark-staining leukocytes are counted in the nine large squares of the hemacytometer chamber. The TWBC is obtained using the following formula:

$$\text{TWBC count}/mm^3 = \frac{(\text{total leukocytes in 9 squares}) \times 10 \times 200}{9}$$

or simplified to:

$$TWBC/mm^3 = (\text{total leukocytes in 9 squares} + 10\%) \times 200$$

Hematology

Illustrations for Colors 9.1 to 9.10 are computer-generated reproductions of blood cells originally printed in Lucas AJ, Jamroz C: Atlas of Avian Hematology, USDA Monograph 25, Washington DC, 1961.

Color 9.1
Normal erythropoiesis (Wright's-Leishman stain unless otherwise noted).

a) Rubriblast with prominent nucleolus, finely granular chromatin pattern and dark-blue cytoplasm.

b) Prorubricyte with moderately granular chromatin pattern and dark-blue cytoplasm. A nucleolus is not present.

c-g) Various stages of developing polychromatophilic erythrocytes. As maturation progresses, the nuclear chromatin pattern condenses, the cytoplasm becomes less basophilic and the nuclear and cell shapes transform from round to elliptical. The presence of these cells in the blood indicates polychromasia or erythrocyte regeneration.

h,i) Appearance of polychromatophilic erythrocytes as reticulocytes following new methylene blue staining. Ribosomes are stained and aggregate as particulate material around the nucleus.

j,k) Mature erythrocytes contain abundant hemoglobin, which imparts an orange color to the cytoplasm. As erythrocytes continue to mature or age, the cell and nuclear shapes become more elongate, and the chromatin pattern is extremely condensed.

l) Early polychromatophilic erythrocyte in mitosis. These cells are observed most commonly in bone marrow smears but are rare in peripheral blood.

Color 9.2
Common erythrocyte abnormalities in the stained blood smear.

a-c) Poikilocytes are misshapen erythrocytes. These cells may assume a variety of shapes including a unipolar-to-bipolar, spindle appearance. Cytoplasmic constrictions also may be present.

d) A macrocyte is an enlarged erythrocyte with voluminous cytoplasm and a condensed, displaced nucleus. These cells may be observed with certain forms of anemia.

e,f) Microcytes are small erythrocytes with a minimum of cytoplasm. These cells are associated with lack of iron or iron deficiency anemia.

g) Anucleated erythrocytes are observed infrequently. These cells also are called erythroplastids.

Color 9.3
Common erythrocyte artifacts resulting from improper collection or preparation of blood smears.

a) Smudge cell resulting from traumatic disruption of a blood cell, usually an erythrocyte.

b) Diffuse, non-refractile, cytoplasmic vacuolation suggesting cytoplasmic edema from loss of membrane integrity. These changes often result from cellular damage during blood smear preparation.

c) Refractile artifact caused by water or air trapped between the cell membrane and mounting medium or immersion oil. This artifact is commonly mistaken for a hemoparasite.

d) Staining artifact seen most commonly in smears from blood collected in heparin and subjected to Romanowsky staining (Wright's or Giemsa staining).

e) Intact erythrocyte nucleus following cellular disruption.

Color 9.4
Normal thrombocytopoiesis.

a) Thromboblast containing an indistinct nucleolus, finely granular chromatin pattern and basophilic cytoplasm.

b,c) Immature thrombocytes containing round nuclei, a moderately granular chromatin pattern and moderately blue cytoplasm.

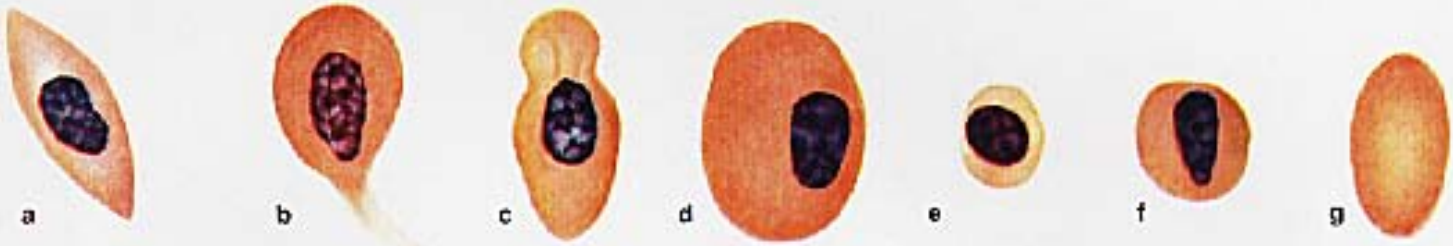
d) Late immature thrombocyte. As maturation progresses, the cellular and nuclear profiles become more elliptical. Cytoplasmic vacuolation and granules may appear.

e-g) Mature thrombocytes are elliptical with a round-to-oval nucleus, condensed chromatin pattern and light-blue vacuolated cytoplasm. One to three cytoplasmic granules may be present, but granules may vary from absent to abundant.

h,i) Shrunken, degenerating thrombocytes with pointed cytoplasmic projections or a condensed nucleus. These cells are observed more frequently in old blood specimens.

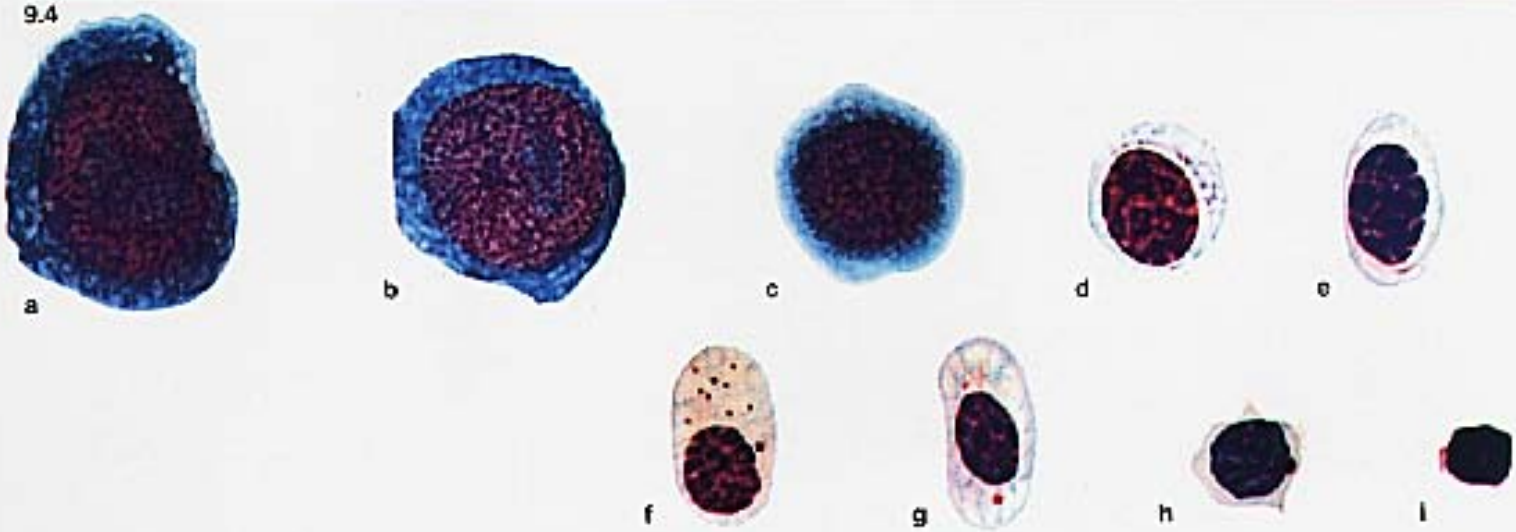
9.1

9.2

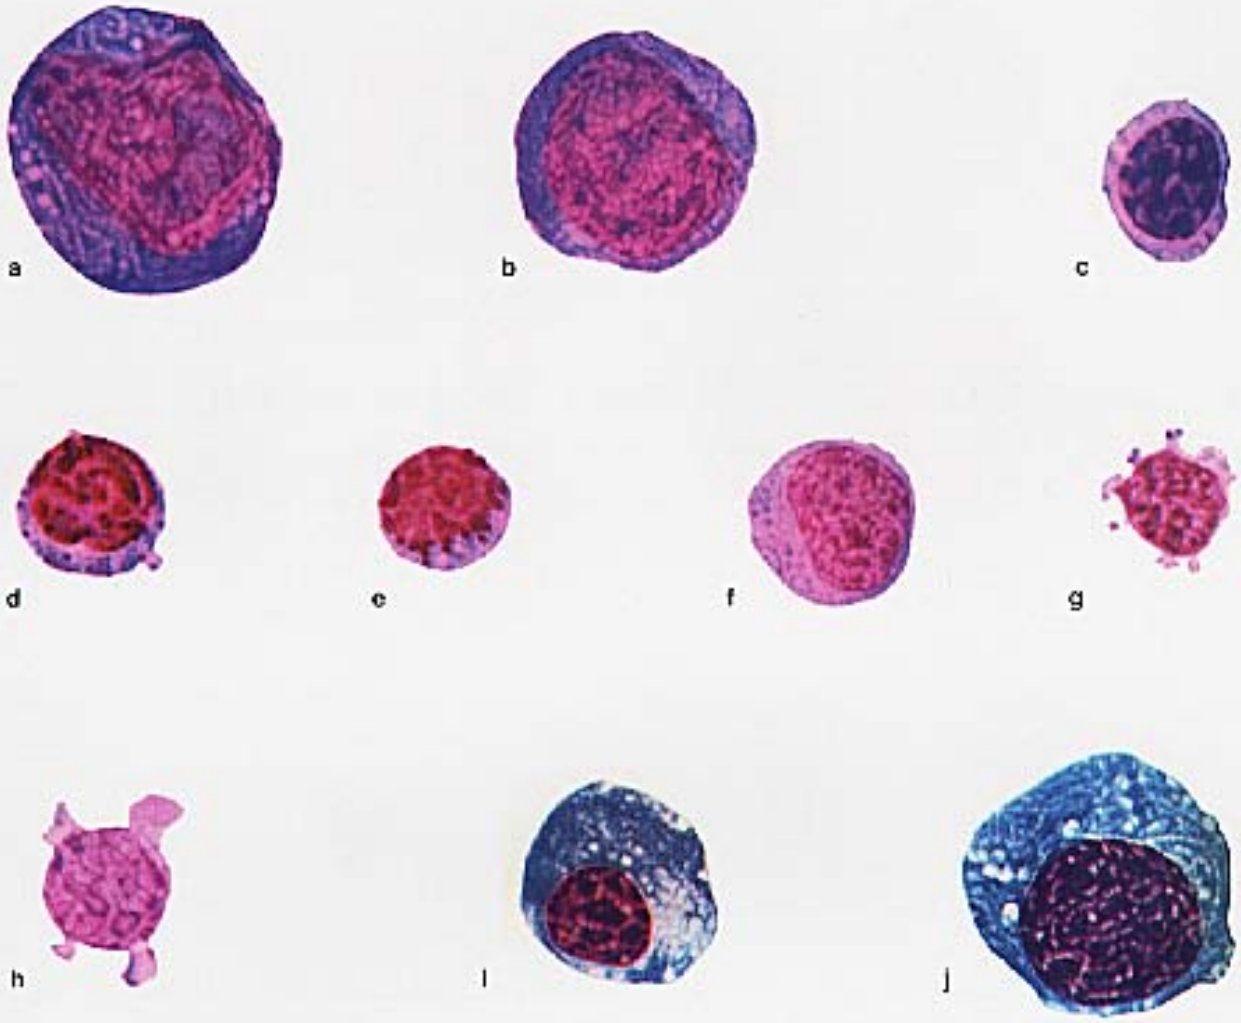


9.3

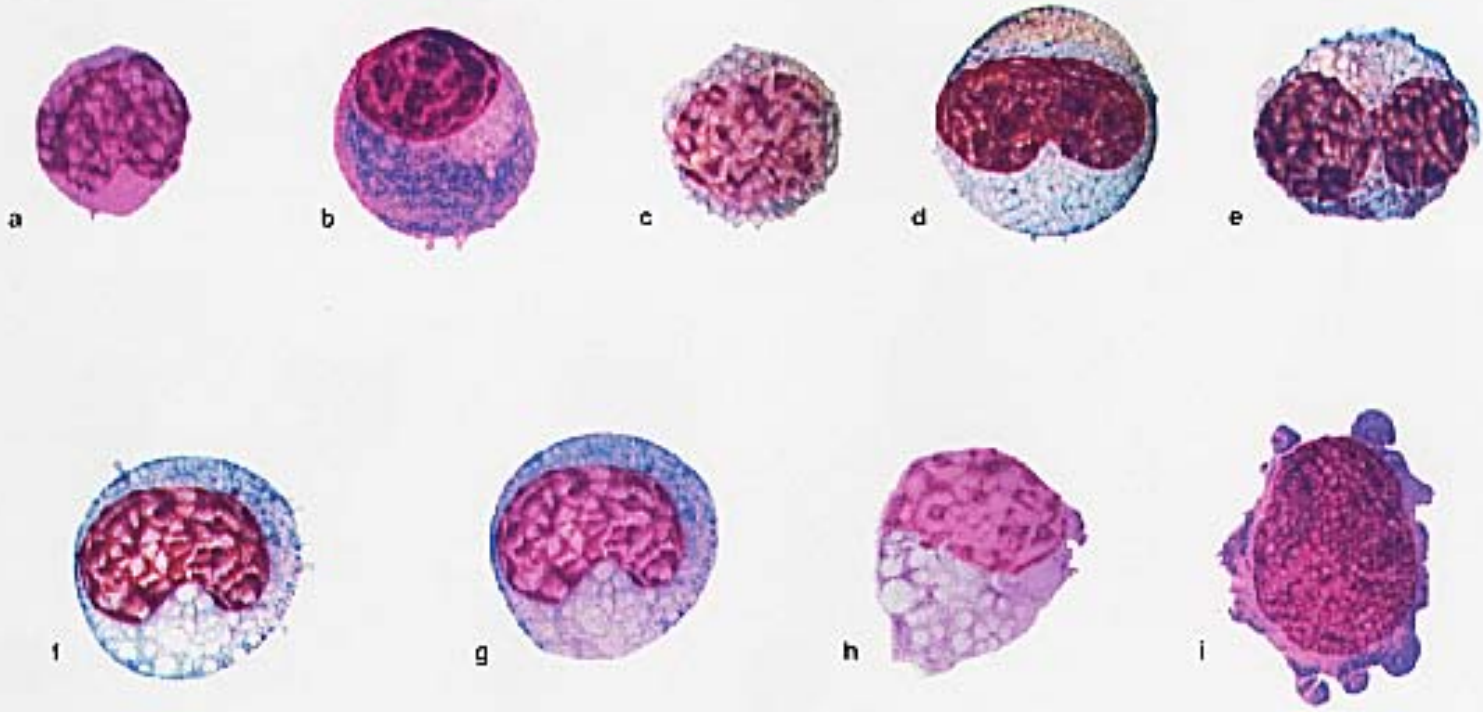
9.4



9.5



9.6



Hematology

Color 9.5
Normal lymphopoiesis.

a,b) Lymphoblasts with a round to slightly irregular nucleus, fine chromatin pattern, multiple nucleoli and basophilic cytoplasm. These cells may be found within the bone marrow in health, but suggest neoplasia when observed within the peripheral blood.

c) Small lymphocyte with a scant rim of basophilic cytoplasm. These cells are often confused with thrombocytes by an inexperienced microscopist.

d) Typical small lymphocyte with an eccentric nucleus and scant basophilic cytoplasm.

e) Small lymphocyte with cytoplasmic azurophilic granules. In mammals, these cells are "killer" lymphocytes.

f) Large lymphocytes are observed infrequently in the blood. Usually, monocytes are misidentified as large lymphocytes.

g,h) Degenerating lymphocytes with cytoplasmic blebs or broad pseudopodia. These cells are seen most frequently in old blood specimens.

i) Plasma cells are the ultimate expression of a B-lymphocyte. These cells are round-to-rectangular with an eccentric nucleus, condensed chromatin pattern, abundant royal-blue cytoplasm and a pale golgi zone. Plasma cells are observed frequently in cytologic preparations, but are rare in blood smears.

j) An immunocyte is an antigenically stimulated lymphocyte. These large cells contain a round-to-scalloped nucleus, condensed chromatin pattern and dark-blue cytoplasm. Scattered immunocytes may be observed in the blood smear following antigenic stimulation from immunization or disease.

Color 9.6
Monocyte development.

a-c) Monocytes with oval to slightly indented nuclei, a variable nuclear-to-cytoplasmic ratio and gray cytoplasm. These cells often are misidentified as lymphocytes.

d,e) Mature monocytes with an indented to bilobed nucleus, abundant gray cytoplasm and occasional pseudopodia.

f,g) Monocytes with cytoplasmic vacuolation or increased dust-like eosinophilic cytoplasmic granules. Cytoplasmic vacuolation usually occurs if the blood specimen is allowed to stand before making blood smears. The eosinophilic granules are lysosomes.

h,i) Two degenerating monocytes are present. The first monocyte has nuclear edema and cytoplasmic vacuolation. The second monocyte has broad pseudopodia or cytoplasmic blebs. These cells are observed most frequently within old blood specimens.

Leukocyte Morphology

The granulocytic leukocytes of birds are heterophils, eosinophils and basophils.[6,18,34,36,44] The heterophil is a round cell with distinct eosinophilic cytoplasmic granules (Color 9.9). These granules are oval to spindle-shaped and often contain a distinct refractile body in the center of the granule. The mature heterophil nucleus is lobed, usually containing fewer lobes than mammalian neutrophils (Color 9.8). The nuclear chromatin contains heavy chromatin clumping. The cytoplasm of normal mature heterophils is colorless and nonvacuolated (Color 9.8).

Avian eosinophils are round granulocytes and contain distinct round-to-oval cytoplasmic granules that lack the central refractile body seen in heterophil granules (Color 9.9). The cytoplasmic granules of eosinophils typically stain brighter or differently from heterophil granules in the same blood film. The intense eosinophilic appearance of eosinophil granules is most likely related to the high concentration of arginine.[19] The cytoplasm of avian eosinophils stains clear blue. The eosinophil nucleus is lobed and generally stains darker than the nuclei of heterophils (Color 9.9). There is variation in the morphologic appearance of the eosinophils of several avian species.[34,41]

The normal basophil is slightly smaller than the heterophil and has a colorless cytoplasm that contains strongly basophilic granules (Color 9.10). These granules often dissolve or coalesce in alcohol-based stains, such as the Romanowsky stains. Avian basophils have round-to-oval, non-lobed nuclei that are often hidden by cytoplasmic granules (Color 9.10).

The mononuclear leukocytes found in the peripheral blood of birds are lymphocytes and monocytes (Color 9.5, 9.6). The mature avian lymphocytes are round cells that frequently "mold" around adjacent cells in the blood film. These cells have high nucleus to cytoplasm (N:C) ratios. The nucleus is usually centrally positioned and round with a scant amount of homogeneous blue cytoplasm appearing as a small band surrounding the nucleus (Color 9.5). Avian lymphocytes often vary in size, and the larger lymphocytes that have pale-staining nuclei may be confused with monocytes. The nuclear chromatin of mature lymphocytes is densely clumped. Occasionally, the cytoplasm of small mature lymphocytes may contain irregular projections.

Monocytes are the largest leukocytes found in the peripheral blood films (Color 9.6). They vary in shape from round to ameboid. Monocytes have an abundant amount of cytoplasm compared to lymphocytes. The cytoplasm generally stains darker than the cytoplasm of normal lymphocytes. The cytoplasm of monocytes has a finely granular, blue-gray appearance and often contains vacuoles. Often two distinct cytoplasmic zones can be seen in monocytes: a light-staining area adjacent to the nucleus and a darker staining area on the periphery. The cytoplasm of monocytes may occasionally contain fine, dust-like eosinophilic granules. The nucleus of monocytes generally contains less nuclear chromatin clumping as compared to mature lymphocytes. The shape of the monocyte nucleus is variable, ranging from round to bilobed.

TABLE 9.2 Characteristics of Blood Cells Using Wright's Stain

Erythrocytes	Dark purple nucleus; orange-pink cytoplasm
Heterophils	Violet, lobed nucleus; colorless cytoplasm, orange-red, rod-shaped granules in most species
Eosinophils	Violet, lobed nucleus; blue cytoplasm; red-orange, round granules in most species
Basophils	Purple, non-lobed nucleus; dark purple cytoplasm granules
Monocytes	Purple nucleus; abundant, finely granular, blue-grey cytoplasm
Lymphocytes	Dark purple, non-lobed nucleus; pale blue, homogeneous cytoplasm
Thrombocytes	Dark purple nucleus; colorless cytoplasm; red granules

On occasion, abnormal-appearing leukocytes are found in the peripheral blood films of birds (Color 9.5). Immature heterophils are abnormal findings in avian blood films, and their appearance has been described in the evaluation of avian hematopoietic tissue at the end of this chapter. The immature stages most commonly found are heterophil myelocytes and metamyelocytes. In general, immature heterophils have increased cytoplasmic basophilia, nonsegmented nuclei and immature cytoplasmic granules compared to mature heterophils (Color 9.5). Usually when immature heterophils are found on a blood film, mature heterophils can also be found.

Mature heterophils appear to show toxic changes in a manner similar to the toxic changes identified in mammalian neutrophils.[6,12,67] Signs of toxicity include increased cytoplasmic basophilia, vacuolation, abnormal granules, degranulation, and degeneration of the nucleus (Color 9.18). The degree of toxicity is reported subjectively on a scale of +1 to +4, where the lower rating reflects slight change and the higher indicates severe change. A +1 toxic heterophil shows increased cytoplasmic basophilia (Color 9.8). An

overall assessment of the staining of the blood film must be made to assure the hematologist that the film is not overly stained blue, giving the impression that the heterophils have increased basophilia. A +2 toxic heterophil has increased cytoplasmic basophilia, vacuolation and partial degranulation (Color 9.11). A +3 toxicity shows a deeper cytoplasmic basophilia, vacuolation and abnormal granulation (Color 9.8).

Abnormal granulation is indicated by the presence of granules that vary in appearance from the typical rod-shaped eosinophilic granules (eg, large, pale, round eosinophilic granules and small, deeply basophilic granules). A +4 toxic heterophil resembles a +3 toxic heterophil except the cell nucleus has undergone karyorrhexis or karyolysis. The number of toxic heterophils present is an indication of severity and suggestive of duration of an inflammatory response. A slight number (25% or less) of toxic heterophils may be present in the early stages of disorders responsible for their occurrence. As the disorder becomes increasingly severe, the number of toxic heterophils will increase. A marked number (greater than 25%) of toxic heterophils is common in birds showing this heterophil abnormality. It is common for birds with toxic heterophil changes to have all of their heterophils affected on the blood film. Clinically, these birds will be severely compromised.

Cytologic indications for reactivity in lymphocytes include increased cell size, increased cytoplasmic basophilia, the presence of azurophilic cytoplasmic granules and smooth nuclear chromatin (Color 9.12). Blast-transformed lymphocytes have a deeply basophilic cytoplasm and smooth nuclear chromatin (Color 9.5). Blast-transformed lymphocytes may also have nucleoli and distinct Golgi. Occasionally, plasma cells can be found in the peripheral blood of birds. These are relatively large lymphocytes with eccentric, mature-appearing nuclei; abundant, deeply basophilic cytoplasm; and prominent Golgi adjacent to the nucleus. Lymphocytes containing azurophilic granules (large purple cytoplasmic granules) are considered abnormal in birds. Lymphocytes having scalloped cytoplasmic margins are found occasionally in avian blood films; however, large numbers of these cells are considered abnormal.[5,62] Immature lymphocytes in the peripheral blood films are also considered to be abnormal (Color 9.5).

An occasional monocyte having a few cytoplasmic vacuoles is normal, but the presence of large numbers of highly vacuolated monocytes is abnormal.

Cells that contain large granules that fill the cytoplasm are frequently found in blood films of birds. Often these granules fail to stain or may stain blue.[6,34,41] These cells are common in blood films of some species of birds (eg, cockatoos) and suggest either staining artifact or represent variation owing to different cytochemical properties of these cells compared to other avian species. The differential for the type of cell involved includes eosinophils, basophils and rarely, Mott cell variant of plasma cells.

Careful examination of the blood film most often reveals normal staining basophils and no evidence of lymphoid reactivity (which may support the possibility of Mott cells being present), but there are no eosinophils present that stain normally. Based on these characteristics, the majority of these cells have been identified as eosinophils.[6, 34, 41]

Thrombocyte Morphology

Birds have nucleated cells (thrombocytes) rather than cytoplasmic fragments as platelets that participate in blood coagulation. Thrombocytes are derived from a distinct line of cells found in hematopoietic tissue. Mature thrombocytes are small oval cells that appear more rounded than the erythrocytes (Color 9.4). The nucleus is pyknotic and the cytoplasm is colorless in mature cells. The cytoplasm may contain one or more red granules and small vacuoles or clear spaces (Color 9.4). Thrombocytes, like mammalian platelets, tend to clump in blood films. Thrombocytes are differentiated from small, mature lymphocytes by having a colorless, nonhomogeneous cytoplasm; small, round, red cytoplasmic granules; and a smaller N:C ratio. Small mature lymphocytes have high N:C ratios with a scant amount of blue, homogenous cytoplasm (Color 9.5).

Abnormal thrombocyte cytology includes the presence of reactive and immature thrombocytes. Reactive thrombocytes are usually found in aggregates, have a diffusely eosinophilic cytoplasm (suggesting release of chemicals from the granules) and irregular cytoplasmic margins. Reactive thrombocytes tend to be more spindle-shaped than nonreactive thrombocytes (Color 9.4).

Immature stages of thrombocytes are occasionally found in the blood film of birds (Color 9.4). The mid-immature and late-immature thrombocytes are most often seen when immature cells are present.

Interpretation of the Avian Hemogram

Interpretation of the Erythron

The normal PCV of birds ranges between 35 and 55 percent. A PCV less than 35 percent is indicative of anemia, and a PCV greater than 55 percent is suggestive of dehydration or polycythemia. An increase in red cell polychromasia is indicative of red blood cell regeneration (Color 9.17). In normal birds, the number of polychromatic erythrocytes (or reticulocytes) found in the peripheral blood film ranges between one and five percent of the erythrocytes. An anemic bird with a five percent or less degree of polychromasia (or reticulocytosis) is responding poorly to the anemia or there has not been enough time for the bird to demonstrate a significant response. An anemic bird showing a ten percent or greater degree of polychromasia is exhibiting a significant regenerative response. The presence of immature erythrocytes (eg, rubricytes) in the peripheral blood along with an increase in polychromasia is indicative of a marked regenerative response.

Some common causes of anemia in birds are discussed in Table 9.3.

Hypochromasia can be associated with certain nutritional deficiencies in birds, especially iron deficiency. Hypochromasia has also been seen in lead toxicosis.[34,42] Lead toxicosis may also create a dichotomous population of erythrocytes in the blood film of a nonanemic bird. In such cases, small senescent, mature erythrocytes with pyknotic nuclei and young erythrocytes (eg, rubricytes) are present in the blood film without the appearance of normal, mature erythrocytes. This condition resembles the inappropriate release of nucleated erythrocytes in the blood of nonanemic dogs suffering from lead poisoning. Basophilic stippling in the cytoplasm of erythrocytes is a rare finding with lead poisoning in birds.[42] Basophilic stippling may be associated with erythrocyte regeneration and hypochromic anemia.

Polycythemia is rarely reported in birds.[74] Increases in the PCV (relative polycythemia) are usually associated with dehydration in birds; however, absolute polycythemia can also occur. The conditions often associated with absolute polycythemia in mammals are expected to be the causes of this condition in birds as well.

TABLE 9.3 Causes of Anemia in Birds[2,10,11,20,24,32,33,39,48,49,61,63,84]

Blood-loss Anemia
(Appears regenerative except in the peracute stage)

1. Traumatic injury
2. Parasitism (ticks, *Dermanyssus* mites, coccidia)
3. Primary coagulopathy (rarely reported in birds)
4. Toxicity resulting in a coagulopathy (aflatoxicosis and coumarin poisoning)
5. Organic disease (ulcerated neoplasm, gastrointestinal ulcers, organ rupture)

Hemolytic Anemia (Regenerative)

1. Red blood cell parasites (*Plasmodium, Aegyptianella* and, rarely, *Haemoproteus* and *Leucocytozoon*)
2. Bacterial septicemia (salmonellosis and spirochetosis)
3. Toxicity (mustards and petroleum products)
4. Immune-mediated (rarely reported in birds)

Depression Anemia (Nonregenerative)

1. Chronic diseases (tuberculosis, chlamydiosis, aspergillosis, neoplasia)
2. Hypothyroidism
3. Toxicity (lead poisoning and aflatoxicosis)
4. Nutritional deficiencies (iron and folic acid deficiencies)
5. Leukemia (lymphoid leukemia and erythroblastosis)

Interpretation of the Leukogram

There is wide variation in the normal leukograms among birds of the same species. Therefore, values of diagnostic importance must differ greatly from normal reference intervals, which are generally much broader than those obtained from domestic mammals. Preparing normal reference values on healthy individual birds is the best method for evaluating blood parameters of a bird during illness. When these specific values have not been determined, the avian clinician must rely on reference intervals obtained from several birds that are presumed to be healthy. It is best to use values obtained in the laboratory that routinely performs the clinician's avian profiles. Published values obtained from other laboratories can be used as a guide, but may differ from the avian clinician's routine laboratory.

In general, total leukocyte counts greater than 10,000/μl are considered suggestive of leukocytosis in tame, adult psittacine birds. The total leukocyte

count in the blood of normal psittacine birds not accustomed to handling may be high (greater than 10,000/μl) owing to a physiologic leukocytosis. The general causes of a leukocytosis include infection (general or localized), trauma, toxicities, hemorrhage into a body cavity, rapidly growing neoplasms and leukemias. The leukocyte differential aids in the assessment of the leukocytosis. Because a leukocytosis is often caused by inflammation, a heterophilia is usually present.

Although avian heterophils lack the myeloperoxidase and alkaline phosphatase of mammalian neutrophils, studies of their ultrastructure, cytochemistry and function suggest they perform a similar function in the inflammatory response.[14,35,46,52,60] The magnitude of the heterophilia usually indicates the magnitude or severity of the initiating inflammatory process. Although avian heterophils do not produce hydrogen peroxide during phagocytosis, they do contain lysosomal enzymes and have a bactericidal function.[23,50,59,60,75,76] A leukocytosis and heterophilia can be associated with infectious agents (eg, bacteria, fungi, chlamydia and parasites) and noninfectious etiologies (eg, traumatic injury and toxicities). A slight to moderate leukocytosis, heterophilia and lymphopenia can result from either an exogenous or endogenous excess of glucocorticosteroids (stress response).[3,15,31,56,69,83] Species that normally have high numbers of circulating lymphocytes may develop a leukopenia and lymphopenia in the initial stress response, but up to 12 hours later show a leukocytosis and heterophilia.[15] Birds that normally have higher numbers of circulating heterophils than lymphocytes often show a less dramatic change in the leukogram initially. A marked leukocytosis and heterophilia are often associated with chlamydiosis, avian tuberculosis and aspergillosis.

Immature heterophils occur rarely in the peripheral blood of most species of birds. When present, they generally represent an overwhelming peripheral demand for heterophils and a depletion of the mature storage pool in the hematopoietic tissues.[73] The presence of immature heterophils in the peripheral blood usually indicates a severe inflammatory response, especially in association with a leukopenia (degenerative left shift) (Color 9.18). A marked number of immature heterophils may be associated with a granulocytic leukemia, a rare condition in birds.

The presence of toxic heterophils is also uncommon in the peripheral blood of birds. When present, they suggest the presence of a septicemia or toxemia (especially associated with bacterial toxins affecting the microenvironment of the hematopoietic tissue). The greater the degree of toxicity, the more severe the condition. The presence of a marked number of +4 toxic heterophils indicates a poor prognosis for survival in birds (Color 9.18).

The general causes of leukopenias in birds are depletion of peripheral leukocytes and depression or degeneration of leukopoiesis. Leukopenias associated with heteropenias can be associated with certain viral diseases (eg, Pacheco's disease virus) and overwhelming bacterial infections.[58,64] A leukopenia and heteropenia associated with immature heterophils is suggestive of exhaustion of the mature heterophil storage pool owing to excessive peripheral demand for heterophils. A depression of the hematopoietic tissue is indicated by a leukopenia, heteropenia and few, if any, immature heterophils. A degenerative response is indicated by the presence of a leukopenia, heteropenia, immature heterophils and toxic heterophils. This degenerative response can be differentiated from depletion only by the presence of toxic heterophils or by following the decreasing leukocyte count with serial leukograms. Leukopenias associated with lymphopenias have been reported in early response to corticosteroids in some species of birds.[5,15] A lymphopenia also may be expected with certain viral diseases; however, viral causes have not been well documented in birds.

A lymphocytosis may be expected with antigenic stimulation associated with certain infections. The presence of many reactive lymphocytes is also suggestive of antigenic stimulation. An occasional reactive lymphocyte may be found in the blood film of normal birds. A marked lymphocytosis with or without the presence of immature lymphocytes can occur with lymphocytic leukemia. A marked lymphocytosis, with the majority of cells appearing as small mature lymphocytes with scalloped cytoplasmic margins, is suggestive of lymphoid neoplasia.[5,6,62]

A monocytosis can be found with certain diseases that produce chemotactic agents for monocytes. These conditions include avian chlamydiosis, mycotic and bacterial granulomas and massive tissue necrosis.[32] It should be emphasized that although these disorders can create a peripheral monocytosis, it may not always occur. A monocytosis can also occur in birds on a zinc-deficient diet.[82]

The function of the avian eosinophil is unclear.[54] Although this avian granulocyte was given the name

eosinophil, there is evidence that its function may differ from the mammalian eosinophil. Thus, conditions responsible for inducing avian eosinophilias most likely differ from those causing mammalian eosinophilias. Eosinophilias associated with gastrointestinal nematode infections have occasionally been reported; however, it has been difficult to induce this condition experimentally using parasite antigens.[47] Studies suggest that avian eosinophils may participate in delayed (Type IV) hypersensitivity reactions.[51] Idiopathic eosinophilias occur sporadically in birds, and more research is needed to clarify the meaning of this condition.

As with avian eosinophils, the exact function of basophils in birds is unknown. Avian basophils are similar to mammalian basophils in their ability to produce, store and release histamine.[9] Basophils appear to participate in the initial phase of the acute inflammatory response in birds, but this is not always reflected as a basophilia in the leukogram.[8,54] Because basophils appear to play a role in early inflammation and possibly hypersensitivity reactions in birds, a peripheral blood basophilia may suggest the presence of these conditions.

Interpretation of Thrombocyte Changes

Avian thrombocytes play a primary role in hemostasis in a manner similar to mammalian platelets. They may also have a phagocytic function and participate in removing foreign material from the blood.[19,30] A normal thrombocyte count ranging between 20,000 and 30,000/µl of blood or 10 to 15/ 1000 erythrocytes can be used as a general reference for most birds.[6,19] Thrombocytopenias are usually indicative of excessive peripheral demand for thrombocytes, although a depression in thrombopoiesis should be considered. Thrombocytopenias are often seen with severe septicemias, where a combination of excessive peripheral demand for thrombocytes and depression of thrombocyte production may occur. A thrombocytosis may reflect a rebound response following hemorrhage or recovery from other conditions associated with excessive utilization of thrombocytes. Often a regenerative response can be detected by the presence of immature thrombocytes in the peripheral blood film.

Identification of Common Blood Parasites

For a complete review of avian parasites see Chapter 36.

The diagnosis of *Haemoproteus* is made by the detecting characteristic intraerythrocytic gametocytes in peripheral blood films. Only the gametocyte stage of this organism appears in the peripheral blood, whereas schizogony occurs in the tissues (eg, lung, spleen and liver).[70] The mature gametocyte contains yellow-to-brown, refractile pigment granules (Color 9.21). The typical mature gametocyte occupies greater than 50 percent of the red cell cytoplasm, partially encircles the host cell nucleus forming the classic "halter-shape" and causes little displacement of the red cell nucleus. It is rare for more than one mature gametocyte to occur in a cell. Macrogametocytes stain blue with Romanowsky stains and have pigment granules dispersed throughout the cytoplasm of the parasite. The smaller microgametocytes stain pale blue to pink with pigment granules appearing in spherical aggregates. If blood containing *Haemoproteus* organisms is allowed to stand at room temperature for a few hours prior to preparing a blood film, gametes may be released from the cells and found in the extracellular spaces of the blood film. The macrogametes appear as spheres that resemble the macrogametocytes within the red cell cytoplasm. The microgametes appear as small spindle-shaped structures. When gametes are found, it should be considered as an artifact of blood film preparation because these structures normally leave the host red cell following ingestion by the intermediate insect host (hippoboscid flies).

Leucocytozoon is easily identified from blood films because it grossly distorts the host cell (usually immature erythrocytes) that it parasitizes. Like *Haemoproteus*, only the gametocyte stage of *Leucocytozoon* occurs in the peripheral blood of birds (Color 9.22).[70] The large, round-to-elongated gametocytes cause the host cell to enlarge and appear to have two nuclei: the host cell nucleus pushed to the margin of the cell and the parasite nucleus, a pale-pink nucleus within the parasite. The parasitized cell usually has tapered ends with the remnants of the cell membrane trailing away from the cell. The macrogametocyte stains dark blue with a condensed nucleus and occasional cytoplasmic vacuoles. The microgametocyte stains light blue with a diffuse, pale-pink nucleus. Gametocytes of *Leucocytozoon* lack the refractile pigment granules found in *Haemoproteus*.

The intraerythrocytic gametocytes of *Plasmodium* spp. are often confused with those of *Haemoproteus* spp. because they also contain refractile pigment granules. However, *Plasmodium* gametocytes usually occupy less than 50 percent of the host cell

cytoplasm, and those of some species alter the position of the red cell nucleus (Color 9.26). Two key features that aid in the detection of *Plasmodium* are the presence of schizogony in the peripheral blood and gametocytes or schizonts in blood cells other than erythrocytes.[70] Schizonts appear as round-to-oval intracytoplasmic inclusions that contain dark-staining merozoites. The number of merozoites produced depends upon the species of *Plasmodium*. As with *Haemoproteus*, *Plasmodium* macrogametocytes stain darker than the microgametocytes. Both *Plasmodium* and *Haemoproteus* infections may reveal small, ring-like forms (trophozoites) in the cytoplasm of infected erythrocytes. In rare cases, only these forms may be seen, and it is impossible to identify the parasite involved. In such situations, resampling a week or more later will often reveal the developed forms having the characteristics described for either *Plasmodium* or *Haemoproteus*. Mosquitos (*Culex* and *Aedes* spp.) are the intermediate hosts for *Plasmodium*.

Microfilaria are frequently found in the peripheral blood of a variety of birds.

Atoxoplasma sp. is identified by its characteristic sporozoite within the cytoplasm of mononuclear leukocytes, especially lymphocytes (Color 9.27).[40] The sporozoites appear as pale-staining, round-to-oval intracytoplasmic inclusions that compress the host cell nucleus and create a characteristic crescent shape to the nucleus. This organism can be found in the per-ipheral blood films or imprints of tissues such as the lung, liver and spleen.

Aegyptianella can occur within the cytoplasm in one of three forms: 1) anaplasma-like initial bodies appearing as small (less than one micrometer in diameter), round, basophilic inclusions; 2) intermediate stages resembling *Babesia* and measuring between one and two micrometers in diameter; and 3) large, round-to-elliptical forms measuring between two and four micrometers in length.[70] *Aegyptianella* spp. are considered to be pathogenic to many species of birds (primarily Passeriformes) but may be difficult to detect because the parasitemia stage of the disease is often very short and easily missed.

Evaluation of the Hematopoietic Tissue

Hematopoiesis occurs primarily in the bone marrow of post-hatch birds; however, hematopoietic activity may also be found in various internal organs (eg, liver and possibly spleen).[4,19] A bone marrow sample should be obtained for cytologic evaluation in avian patients with persistent nonregenerative anemia, thrombocytopenia, panleukopenia and heteropenia. Bone marrow evaluation is also indicated for suspected cases of leukemia or if unexplained abnormal cells are found in the peripheral blood. An evaluation of the hemogram should accompany any bone marrow evaluation to properly assess hematopoiesis.

Bone Marrow Collection

In general, the proximal tibiotarsus just below the femoral-tibiotarsal joint (knee) is the preferred site for bone marrow collection in most birds.[6,79] After surgical preparation of the skin either on the cranial or medial aspect of the proximal tibiotarsus, a small stab incision through the skin is made using a scalpel blade. A bone marrow aspiration biopsy needle is pushed through the thin cortex and into the marrow space using clockwise-counterclockwise rotational movements. Once the needle has entered the marrow space, the stylet is removed from the needle and a syringe is attached to gently aspirate a small amount of marrow into the needle lumen. Excessive pressure during aspiration should be avoided to prevent peripheral blood contamination of the sample. Following aspiration, the needle is removed from the bone and the syringe is detached from the needle. The syringe is filled with air and reattached to the needle hub. Using the air in the syringe, the marrow within the needle lumen is forced onto a microscope slide. A second slide is placed across the first on top of the marrow sample. As the two slides are pulled horizontally apart, two marrow films are made for cytologic examination.

Marrow can also be obtained from the sternum (keel) of some birds with the biopsy needle inserted into the widest part of the sternal ridge.

Bone marrow biopsy needles commonly used include pediatric Jamshidi bone marrow biopsy-aspiration

Hematology

Color 9.7
Early myeloblast with a fine chromatin pattern, nucleolar ring and dark-blue cytoplasm. The myeloblast is the progenitor cell for the heterophil (Color 9.8), eosinophil (Color 9.9) and basophil (Color 9.10).

Color 9.8
Heterophil development.

a) Myeloblast with fine chromatin pattern, nucleolus and light-blue cytoplasm.

b) Promyelocyte with oval nucleus, pale-blue cytoplasm and round to slightly irregular metachromatic cytoplasmic granules.

c) Heterophil myelocyte with an oval nucleus and a mixture of metachromatic granules and scattered round-to-rod-shaped eosinophilic granules.

d) Heterophilic metamyelocyte with a slightly indented nucleus.

e) Heterophilic band with U-shaped nucleus.

f,g) Mature, segmented heterophils with numerous needle-shaped granules. The granules may obscure nuclear detail, making assessment of lobulation difficult.

h) Heterophil with mild toxic changes including cellular swelling, partial degranulation and a basophilic cast to the cytoplasm.

i,j) Toxic heterophils with progressive granule dissolution leaving the round granule core intact. The cell is slightly swollen and has basophilic cytoplasm. This cell may occasionally be confused with an eosinophil, except for retention of a few needle-shaped granules. Stain-induced heterophil degranulation is not associated with cytoplasmic basophilia.

k) Heterophil with non-staining cytoplasmic granules. This may be an artifact resulting from exposure of the blood smear to formalin vapor during transport or mailing.

l) Disrupted heterophil showing typical needle-shaped granules. These smudge cells are ignored during the leukocyte differential count.

m) Smudged heterophil with dissolution of the outer granule matrix leaving intact round central cores. Granule dissolution may cause an eosinophil-like appearance; however, smudge cells are ignored during the leukocyte differential count.

Color 9.9
Eosinophil development.

a) Late myeloblast with condensing chromatin pattern and light-blue cytoplasm.

b) Eosinophilic myelocyte with an oval nucleus and scattered, variably sized, round, secondary granules.

c) Eosinophilic myelocyte with a slightly indented nucleus and round, red-orange granules.

d) Eosinophilic band with U-shaped nucleus and round, red-orange granules.

e) Segmented eosinophil with a lobulated nucleus and abundant secondary (specific) granules.

f) Disrupted or smudged eosinophil. These cells are ignored during the leukocyte differential count.

Color 9.10
Basophil development.

a,b) Basophilic myelocytes with round nuclei and round, variably sized, metachromatic granules.

c,d) Basophils with round, intensely stained, metachromatic granules. Basophil granules have high affinity for Romanowsky stain, often resulting in poor staining of the cell nucleus. In addition, cytoplasmic granules may obscure nuclear detail.

e) Basophil degranulation may occur with disease or as an artifact of blood smear staining.

f) Disrupted basophil (smudge cell). These cells are ignored during the leukocyte differential count.

Hematology

All photographs on this page were provided courtesy of Terry W. Campbell.

Color 9.11
An adult female Red-tailed Hawk was presented with clinical signs of lethargy, a marked reduction of the pectoral muscle mass and diarrhea. A diagnosis of salmonellosis was made based upon necropsy and bacterial culture two days later. The hemogram revealed: PCV = 28%, RBC = 1,950,000/ mm^3, WBC = 31,876/ mm^3, heterophils = 28,050/ mm^3, lymphocytes = 1,594, monocytes = 638/ mm^3 and eosinophils = 1,594/ mm^3. A toxic heterophil (2+ toxicity) and two eosinophils are shown. Wright's stain.

Color 9.12
A Blue-fronted Amazon Parrot was presented with multifocal, depigmented, nonraised lesions involving the skin on the feet. Serum chemistries and erythrocyte parameters were within normal limits. The leukogram revealed the following: WBC = 7,543/ mm^3, heterophils = 1,886/ mm^3, lymphocytes = -4,601/ mm^3, monocytes = 830/ mm^3 and eosinophils = 226/ mm^3. Typical reactivity of lymphocytes demonstrated by Wright's stain.

Color 9.13
A critically ill Green-cheeked Amazon Parrot was presented for evaluation. The bird was extremely weak and unable to perch. Severe uveitis was present in both eyes. The bird was housed in a room where varnish was being applied to furniture. Important hematologic findings included: PCV = 40%, total protein = 5.0 gm/dl, WBC = 16,140/ mm^3, heterophils = 13,880/ mm^3 (10% of the heterophils were myelocytes and 20% were metamyelocytes), lymphocytes = 807/ mm^3, monocytes = 1,453/ mm^3 and thrombocytopenia. A heterophilic myelocyte is demonstrated by Wright's stain.

Color 9.14
A juvenile Red-tailed Hawk was presented with marked reduction of the pectoral muscle mass. Radiographic evaluation revealed a fracture of the left coracoid bone. The hematologic findings included: PCV = 37%, Hb = 11.5 g/dl, RBC = 2,250,000/ mm^3, 4% polychromasia, total protein = 2.6 g/dl, WBC = 32,932/ mm^3, heterophils = 25,687/ mm^3, lymphocytes = 1,976/ mm^3, monocytes = 988/ mm^3, eosinophils = 3,952/ mm^3 and basophils = 392/ mm^3. A heterophil, eosinophil, basophil and *Haemoproteus* gametocyte (0.7% of the erythrocytes contained these gametocytes) are demonstrated by Wright's stain.

Color 9.15
A Blue and Gold Macaw was examined 93 hours following severe blood loss that resulted from a traumatic injury to the foot. The hemogram revealed: PCV = 21%, RBC = 1,660,000/ mm^3, Hb = 5.8 g/dl, WBC = 19,457/ mm^3, heterophils = 12,255/ mm^3, lymphocytes = 6,615/ mm^3, monocytes = 97/ mm^3 and basophils = 389/ mm^3. Twenty-two percent of the erythrocytes exhibited polychromasia, and an occasional immature erythrocyte was noted. Polychromasia and a round, immature erythrocyte (early polychromatic rubricyte) are demonstrated by Wright's stain.

Color 9.16
The hemogram from a Harris Hawk that died three days later from an acute pneumonia revealed a moderate anemia, leukocytosis, heterophilia and left shift. Marked anisocytosis and polychromasia are illustrated as well as a binucleate erythrocyte (which were frequently seen in the blood film). A heterophil, eosinophil, two lymphocytes, a thrombocyte and an immature erythrocyte (basophilic rubricyte) can also be seen by Wright's stain.

Color 9.17
A juvenile Bar-headed Goose was presented for weakness and weight loss. Six other geese in the group appeared normal. The hemogram revealed: PCV = 28%, Hb = 9.0 g/dl, RBC = 1,950,000/ mm^3, 11% polychromasia, WBC = 39,556/ mm^3, heterophils = 31,645/ mm^3, lymphocytes = 5,645/ mm^3, monocytes = 1,187/ mm^3 and basophils = 791/ mm^3. Blood lead levels were normal. The erythrocyte morphology revealed polychromasia, hypochromasia and stippled basophilia. Wright's stain.

Color 9.18
A juvenile Red-tailed Hawk was presented with open fractures of the left radius and ulna and poxvirus lesions along the margins of the beak and on the feet. The bird was extremely depressed and died within 24 hours of presentation. The hemogram showed: PCV = 35%, Hb = 11 g/dl, RBC = 3,020,000/ mm^3, WBC = 42,240/ mm^3, monocytes = 3,802/ mm^3, eosinophils = 1,267/ mm^3 and basophils = 422/ mm^3. The majority of the heterophils appeared extremely toxic (4+). Wright's stain.

Color 9.19
An adult African Grey Parrot was presented with a history of an intermittent seizure disorder and was successfully treated for hypocalcemia. The hemogram revealed: PCV = 49%, RBC = 2,940,000/ mm^3, WBC = 15,740/ mm^3, heterophils = 6,453/ mm^3, lymphocytes = 8,814/ mm^3, monocytes = 315/ mm^3 and eosinophils = 157/ mm^3. Eosinophils with large, blue cytoplasmic granules are demonstrated by Wright's stain.

Color 9.20
An adult Red-tailed Hawk was presented with multiple gunshot wounds and open fractures involving the right radius and ulna. The hemogram revealed: PCV = 16%, Hb = 5.3 g/dl, RBC = 1,300,000/ mm^3, WBC = 15,740/ mm^3, heterophils = 6,453/ mm^3, lymphocytes = 8,814/ mm^3 and monocytes = 472/ mm^3. The reticulocyte count was 20% and there were many immature erythrocytes present. A mid-polychromatic rubricyte is demonstrated by Wright's stain.

Color 9.21.
Haemoproteus sp. gametocytes in a blood film stained with Wright's stain from a Great Horned Owl.

Color 9.22
Haemoproteus and *Leukocytozoon* spp. gametocytes in a blood film stained with Wright's stain from a Great Horned Owl.

Color 9.23
Haemoproteus sp. microgametes in a blood film stained with Wright's stain from a Screech Owl.

Color 9.24
Plasmodium sp. gametocytes and schizonts in the cytoplasm of erythrocytes from a Skua stained with Wright's stain.

Color 9.25

needles[j] and disposable Jamshidi Illinois-Sternal/Iliac aspiration needles. Disposable spinal needles can be used to sample small birds because they contain a stylet to facilitate passage of the needle through the cortex without occlusion of the needle lumen with bone.

Erythropoiesis

The terminology describing the different stages of erythrocytic development varies in the literature.[6,19,34,44] In general, there are six recognizable stages involved in red cell development. The earliest recognizable stage is the rubriblast (proerythroblast) (Color 9.1). This cell has large, prominent nucleoli or nucleolar rings. The round nucleus is centrally positioned within the cell. The coarsely granular chromatin is atypical for most blast-type cells. The abundant cytoplasm stains deeply basophilic and contains fine, clear spaces (mitochondrial spaces). Rubriblasts have high N:C ratios, typical of immature cells.

The second stage in erythrocyte development is the prorubricyte (basophilic erythroblast). This cell resembles the rubriblast, but the nucleoli are either absent or indistinct, and the cytoplasm lacks the mitochondrial spaces of the rubriblast (Color 9.1).

The next three stages are the rubricyte stages. These are round-to-slightly oval cells that are smaller than rubriblasts and prorubricytes. Rubricytes are divided into three groups based upon their appearance in the cytologic sample. In order of increasing maturation they are the basophilic rubricyte (early polychromatic erythroblast), early polychromatic rubricyte (late polychromatic erythroblast) and late polychromatic rubricyte (orthochromic erythroblast). The basophilic rubricyte has a high N:C ratio, homogeneous basophilic cytoplasm and round nucleus with distinct chromatin clumping.

The early polychromatic rubricyte appears smaller than the basophilic rubricyte and is the first stage of red cell development in which hemoglobinization of the cytoplasm can be detected with Wright's stain. The hemoglobin gives the cytoplasm a gray, slightly eosinophilic appearance. The nucleus appears smaller with increased density, and the cytoplasm is more abundant when compared to the previous stage of development. The late polychromatic rubricyte is a round-to-slightly oval cell with an eosinophilic gray-to-weakly eosinophilic cytoplasm (Color 9.1). This cell appears to have increased cytoplasmic volume when compared to the previous stage, and the nucleus may appear oval with irregularly clumped chromatin. The penultimate stage of erythrocyte development is the polychromatic erythrocyte, which resembles the oval, mature erythrocyte except for the cytoplasmic basophilia and nuclear chromatin that appear less condensed than the pyknotic nucleus of the mature cell (Color 9.1).

Granulopoiesis

Avian granulopoiesis appears to follow developmental stages similar to those described for mammalian granulocytes.[6,34,44] These stages are the myeloblast (granuloblast), progranulocyte (promyelocyte), myelocyte, metamyelocyte and mature granulocyte.

Myeloblasts are large, round cells with a narrow rim of cytoplasm that appears less basophilic than that of rubriblasts.[44] In general, the nucleus is round with a delicate reticular chromatin pattern and distinct nucleoli. No cytoplasmic granules are present. The myeloblast stage is common to all the granulocytes (Color 9.7).

The next stage toward maturation is the progranulocyte. These are large cells with cytoplasmic granules and light blue cytoplasm. The granules are variable in appearance. An attempt has been made to differentiate progranulocytes into their respective granulocytic cell lines based upon the appearance of the cytoplasmic granules.[44] Heterophil progranulocytes contain orange spheres (primary granules) or rings and dark magenta granules or rings. The ring forms are thought to be characteristic of the heterophil cell line. Eosinophil progranulocytes lack the dark magenta granules and rings and contain only brightly staining orange spheres (primary granules). Basophil progranulocytes have magenta granules that appear smaller than those of heterophil progranulocytes and have fewer ring forms. The nucleus of progranulocytes is typically eccentric in its cellular position, has a delicate reticular chromatin pattern and often has indistinct margins.

The myelocytes are smaller than the progranulocytes and contain the specific granules (secondary granules) for each cell line. Heterophil myelocytes are round cells with light blue cytoplasm containing primary granules, magenta granules and rings and the definitive rod-shaped heterophil granules. The definitive granules occupy less than 50 percent of the cytoplasmic volume. Eosinophil myelocytes contain primary and secondary granules. The specific or secondary granules occupy less than 50 percent of the

cytoplasmic volume. The basophil myelocyte has magenta granules and mature basophil granules (secondary granules) that occupy less than 50 percent of the cytoplasmic volume. The nucleus of myelocytes is round and has coarsely granular chromatin.

Metamyelocytes resemble myelocytes, except the cell nucleus is slightly indented and may have distinct chromatin clumping. Heterophil metamyelocytes have definitive, rod-shaped granules that occupy greater than 50 percent of the cytoplasmic volume. The primary granules and magenta spheres and rings may be present, but fewer in number than the previous stage. The definitive granules of the eosinophil and basophil series also occupy greater than 50 percent of the cytoplasmic volume in their respective metamyelocyte stages. The basophil myelocyte nucleus remains round.

The granulocytic cell series will occasionally reveal a band cell stage similar to that described in mammalian granulocytes. However, the cell nucleus is often hidden by the cytoplasmic granules (especially in heterophils), making it difficult to differentiate the band cell from mature cells. Mature avian basophil nuclei do not segment.

Thrombocytopoiesis

The developmental stages involved in thrombopoiesis are the thromboblast, early-immature thrombocyte, mid-immature thrombocyte, late-immature thrombocyte and mature thrombocyte (Color 9.4).[6,44] As the cell develops toward maturity, the cell size decreases, the N:C ratio decreases, the nucleus becomes increasingly pyknotic and cytoplasm becomes less basophilic.

Thromboblasts are large, round-to-ameboid-shaped cells with a narrow rim of deeply basophilic cytoplasm surrounding the round nucleus. The nuclear chromatin often appears punctate, making nucleoli difficult to detect. The cytoplasm may contain small clear spaces.

The early-immature thrombocyte is smaller than the thromboblast. It has a round-to-oval nucleus and smaller N:C ratio than the previous cell. The cytoplasm is basophilic with small, clear spaces or vacuoles. The nuclear chromatin is irregularly clumped and nucleoli are absent. The mid-immature thrombocyte appears slightly elongated or irregular with a pale blue, vacuolated cytoplasm. Specific red cytoplasmic granules may be seen at this stage. The nucleus usually has marked chromatin clumping. The late-immature thrombocyte is an oval cell that has the appearance of the elongate, mature thrombocyte, except the cytoplasm is a pale blue and the nuclear chromatin is less condensed.

Lymphopoiesis

Lymphocyte development may be seen occasionally when evaluating hematopoietic tissue (Color 9.5). Three distinctive stages can be identified for lymphocyte development: lymphoblasts, prolymphocytes and mature lymphocytes. Lymphoblasts are large, round lymphocytes with high N:C ratios. The nucleus has smooth chromatin, in comparison to the mature cell, and contains distinct nucleoli. The cytoplasm of lymphoblasts stains deeply basophilic.

Prolymphocytes resemble lymphoblasts but are slightly smaller, lack nucleoli and have a less basophilic cytoplasm. In normal lymphoid tissue, lymphoblasts and prolymphocytes represent less than ten percent of the lymphoid cells. Thus, the majority of the cells should be mature lymphocytes with the heavy nuclear chromatin clumping, high N:C ratio and scant amount of blue, homogeneous cytoplasm.

Other Bone Marrow Cells

Other cells frequently encountered in bone marrow samples include osteoclasts, osteoblasts, monocytes, plasma cells and mitotic figures. Osteoclasts are large, multinucleated cells that are ameboid in shape. The abundant cytoplasm is weakly basophilic and often contains vacuoles and small red granules of various shapes. The nuclei are round-to-oval and usually contain distinct nucleoli. Osteoblasts are large cells that vary in shape. The oval-to-round nucleus is eccentrically positioned in the cell. The abundant, foamy, basophilic cytoplasm contains a prominent clear space (Golgi) that is located a distance from the nucleus.

CHAPTER

10

CYTOLOGY

Terry W. Campbell

Cytology is designed to be a rapid, inexpensive "in-house" diagnostic procedure, and the use of cytodiagnosis should be easily within the realm of any veterinary clinician. The basic cytodiagnosis of inflammation, tissue hyperplasia, malignant neoplasia and normal cellularity are easily differentiated from each other (see Figures 10.10, 10.11). One who is well versed in mammalian cytodiagnosis should have little trouble in the interpretation of avian samples. The goal is to achieve a quick presumptive or definitive diagnosis during the patient's initial visit to the veterinary clinic in an effort to provide an immediate and specific treatment plan. Cytology can then be used to monitor the success of therapy by evaluating changes in microbial and cell populations within or on the host. Cytology should be considered as a part of the minimum database in birds with discharges, masses or swellings. Cytologic evaluation of tissue imprints and fluids collected during a postmortem examination can be used to develop a presumptive diagnosis that can guide disease management decisions within the flock until a definitive diagnosis is provided by culture, DNA probe or histopathology. Cytological samples are of greatest value if they are collected fresh and immediately processed for evaluation. To obtain a cytologic sample and send it to an outside laboratory defeats the purpose and usefulness of cytology. By cytologically examining antemortem and postmortem samples, the clinician can compare the information that is derived from cytology, radiographs, CBC, serum chemistries and histopathology. This will serve to improve understanding of the pathogenesis and cellular effects of a disease process.

Sample Collection

A variety of sample collection methods can be used to obtain samples for cytologic examination.[4] The method of choice depends upon the location and nature of the material being sampled. Cytologic sample collection methods can be divided into two broad categories: aspiration and contact smears.

Sample Collection by Aspiration

Fine-needle aspiration biopsy is a simple, inexpensive procedure for obtaining material for cytologic examination (Figure 10.1). Using an alcohol swab, the skin overlying the biopsy site is cleansed and allowed to dry. Excessive application of alcohol should be avoided. A hypodermic needle (eg, 22 ga, one-inch needle) attached to a syringe (12 ml or larger) is inserted into the tissue to be sampled. A full vacuum is applied to the syringe using the syringe plunger. The needle is moved at different angles in the tissue without releasing the vacuum. It is important to release the vacuum before withdrawing the needle from the tissue, because the aim of the procedure is to obtain a small amount of sample in the lumen of the needle only, not in the syringe itself. Once the needle has been withdrawn from the tissue, it is detached from the syringe and the syringe is filled with air. The needle is reattached to the syringe, and with the point of the needle lying against the slide surface, the air within the syringe is used to force the sample onto a glass microscope slide. A second glass microscope slide placed on top of the first allows the sample to spread between the two glass surfaces when the slides are pulled horizontally apart. Two specimens for cytologic examination are thus created. This technique is often referred to as the "squash preparation technique" because the sample is compressed between the two slide surfaces.

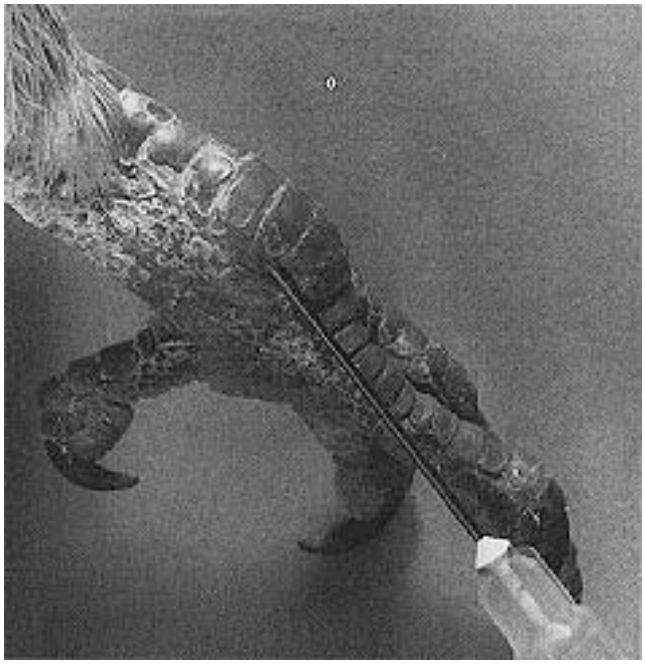

FIG 10.1 A mature pigeon hen was presented for lameness, an unwillingness to fly and depression. The hen had been incubating eggs, and it was uncertain how long she had been clinically symptomatic. Several joints were swollen and firm. The elbow and ankle joints were severely affected. The masses in areas where the skin was thin appeared grossly as small, white-to-yellow nodules. Cytologic examination of a fine-needle aspirate from the mass revealed numerous crystalline structures suggestive of urate crystals. Articular gout is common in birds that become dehydrated or that have primary or secondary renal disease.

Abdominocentesis is an aspiration biopsy procedure used to collect cytologic samples from birds with abdominal fluid accumulation. The abdominal space is small in normal birds and contains little fluid. Because the abdominal air sacs occupy a large portion of the abdomen, it is difficult to enter the peritoneal cavity of normal birds. However, as peritoneal fluids accumulate, the air sacs are compressed laterally, increasing the size of the peritoneal cavity and making it easier to sample. Abdominocentesis begins with a surgical preparation of the site along the ventral midline just distal to the point of the keel. The needle (21 to 25 ga, one-inch) is attached to a syringe and is directed through the body wall at the midline, pointing toward the right side of the abdomen to avoid the ventriculus, which lies to the left of the midline (Figure 10.2). The abdominal fluid is aspirated into the syringe and prepared for cytologic examination, either by making a direct smear as one would prepare a blood film or by using a concentration method.

The goal of abdominocentesis is to collect fluid from the abdominal cavity for diagnostic purposes. If the abdomen is distended with a soft-shelled egg, ovarian cyst, dislocated bowel loops or an abdominal mass, the fluid may not be collected during abdominocentesis. The material that is collected (eg, gut contents, egg yolk, cells from a mass) should be evaluated with respect to its potential source. Interestingly, some avian species (macaws) will produce *small* quantities of fluid in response to egg-related peritonitis, while others (cockatiels) will produce voluminous fluids.

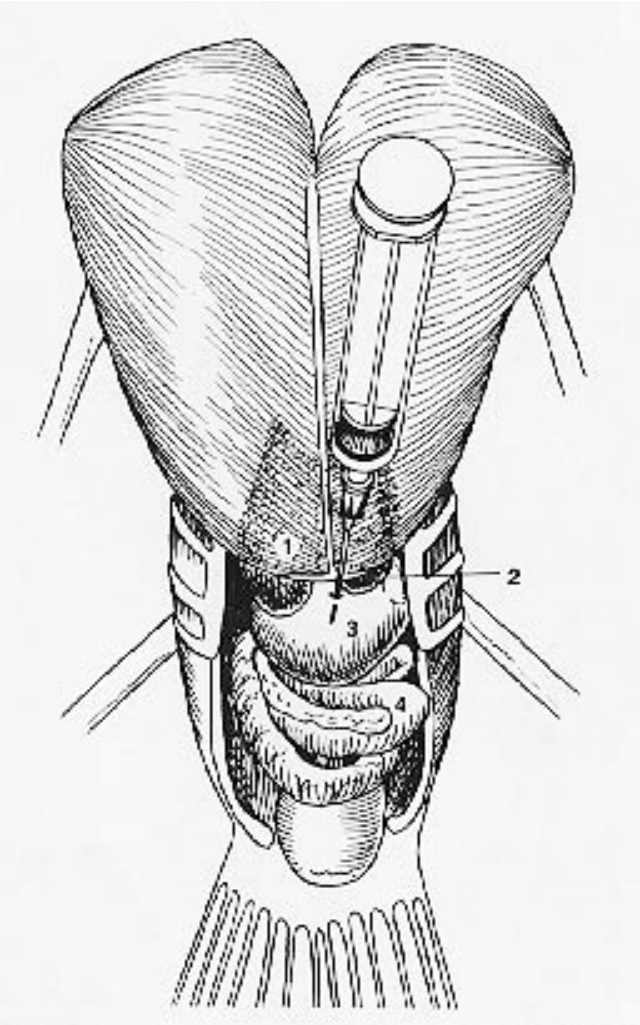

FIG 10.2 For abdominocentesis, the needle is attached to a syringe and is directed through the body wall at the midline, pointing toward the right side of the abdomen. 1) Caudal edge of sternum 2) liver 3) ventriculus and 4) intestines.

Fluid samples having low cellularity require a concentration procedure for easier examination of the cells. A variety of techniques can be used to concentrate cells on microscope slides. A simple method is to marginate the cells on a smear made by the conventional wedge technique used for making blood films. A drop of the fluid sample is placed on a microscope slide and spread slowly using a spreader slide. Just prior to reaching the end of the smear, the spreader slide is quickly backed slightly into the advancing smear, just before lifting it from the surface of the slide containing the smear. This should produce a slide with the marginated cells concentrated at the end of the film.

Cells can be concentrated by centrifugation in a manner similar to that used in mammalian urinalysis procedures. The fluid is placed in a plastic test tube and centrifuged at 600 G (gravity) for ten minutes. Unlike urine sediments, cytologic sediments from poorly cellular fluids do not have a visible button or pellet at the bottom of a spun tube. Therefore, the concentrated cells are usually obtained by aspirating the fluid at the bottom of the tube into a pipette or syringe. The sample is then placed onto a microscope slide and a smear is made in the manner described for concentrating cells in a smear. Special cytocentrifuge equipment[a] is available for concentrating cells on microscope slides while absorbing the fluid onto filter paper. This equipment is expensive and not practical for the average veterinary laboratory.

Because centrifugation distorts the appearance of the cells, a cell concentration method that utilizes gravity provides a concentrated sample with normal appearing cells. A simple, inexpensive sedimentation device can be made for use in the veterinary laboratory. This device consists of a base to support the slide and a clamping mechanism to hold the fluid column onto the microscope slide (Figure 10.3). The column that holds the fluid is made from a one millimeter tuberculin syringe barrel with the tip removed. The base of the syringe barrel allows for the syringe to be held in place by a clamp (usually made of wood). A piece of filter paper (eg, Whatman #2) is cut to the dimensions of the microscope slide and a standard 2 mm paper hole punch is used to create a hole in the center of the filter paper. The filter paper is placed on top of the slide, and the base of the tuberculin syringe barrel is placed on top of the filter paper with the opening of the syringe superimposed over the hole in

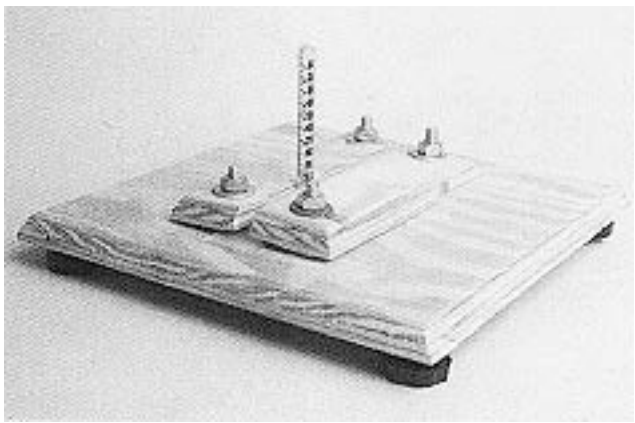

FIG 10.3 Centrifugation can distort the appearance of cells that are intended for cytologic evaluation. A simple device that uses gravity to concentrate cells provides cytologic samples of better quality than centrifugation (courtesy of Terry Campbell).

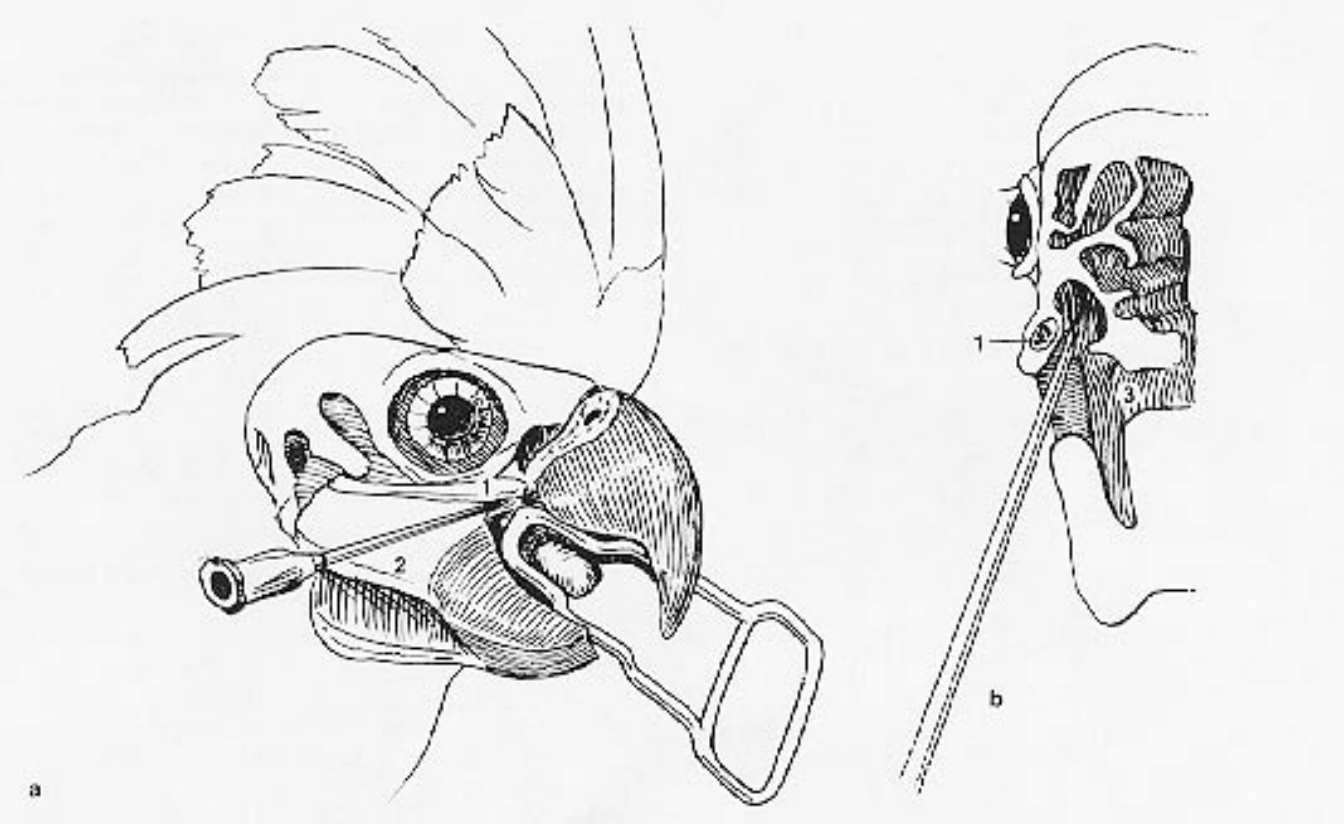

FIG 10.4 Aspiration of the infraorbital diverticulum of the infraorbital sinus in psittacine birds can be performed by **a)** passing a needle through the fleshy skin at the commissure of the mouth and directing it toward a point midway between the eye and external nares, **b)** keeping parallel with the side of the head and passing under the zygomatic arch. 1) Zygomatic arch 2) mandible 3) oral cavity.

the filter paper. The clamp is used to secure the column to the slide. A small amount of fluid (eg, 0.2 to 0.5 ml) is placed into the syringe column. When allowed to stand undisturbed, the fluid is drawn by gravity and absorbed into the filter paper. The cells in the fluid fall onto the surface of the slide where they adhere. Once the fluid has drained from the column, the apparatus is disassembled and the slide is allowed to air dry. After staining, the cells can be found concentrated in the two millimeter circle created by the filter paper and column.

Cytologic evaluation of the ingluvies (crop) can be performed from samples obtained by aspiration. This is indicated in birds showing clinical signs of regurgitation, vomiting, delayed emptying of the crop or other crop disorders. A crop aspirate is obtained by inserting a sterile plastic, metal or rubber feeding tube through the mouth and esophagus into the ingluvies (see Figure 15.6). The tube should pass freely and not be forced into the crop. Passage of the tube is facilitated by extending the head and neck to straighten the esophagus. The crop content is gently aspirated into the tube using a syringe attached to the free end. Excessive vacuum should be avoided to prevent damage to the crop mucosa. In cases where material cannot be aspirated for examination, a wash sample can be obtained by infusing a small amount of sterile isotonic saline into the crop and aspirating the fluid back into the tube and syringe.

Aspiration of the infraorbital sinus of birds suffering from sinusitis can provide diagnostic material for culture and cytologic examination. One technique of sinus aspiration in psittacine birds samples the large sinus between the eye and the external nares (Figure 10.4). With the head and body properly restrained, a needle (eg, 22 ga one-inch) is passed through the fleshy skin at the commissure of the mouth. The needle is directed toward a point midway between the eye and external nares, keeping parallel with the side of the head. The needle passes under the zygomatic bone, which lies between the lower corner of the rhinotheca (upper beak) and the ear. Often the passage of the needle is improved by keeping the bird's mouth open with an oral speculum. Once the

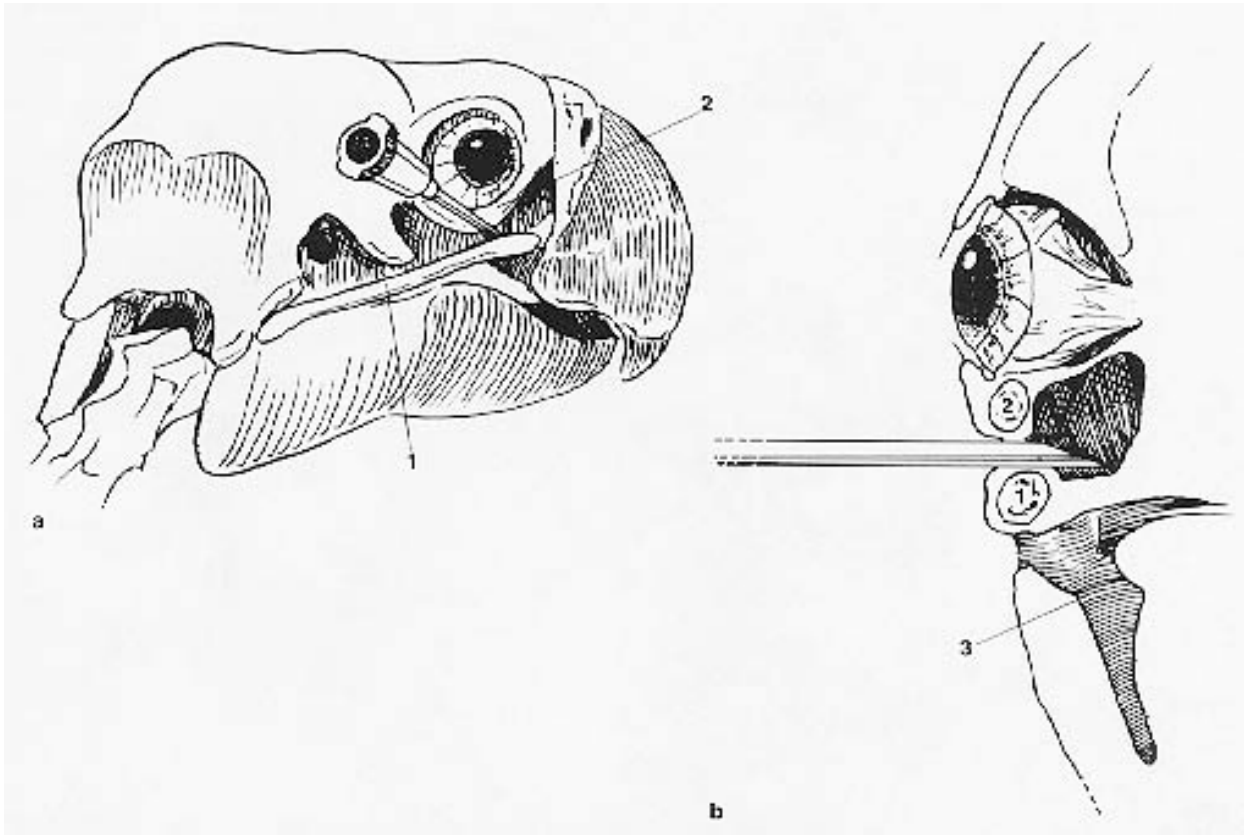

FIG 10.5 The infraorbital diverticulum immediately beneath the eye can be approached by passing a needle **a)** over the zygomatic arch, with **b)** the needle directed rostrally. This procedure requires some practice and complete restraint to prevent damage to the globe. 1) Zygomatic arch 2) suborbital arch of prefrontal and temporal bone 3) oral cavity.

needle has entered the sinus, the sinus contents can be aspirated. A caudally misdirected needle could result in penetration of the ocular orbit; however, more commonly, a misdirected needle results in penetration of the surrounding muscles, causing peripheral blood contamination of the sample. It is important to note that in some species (eg, some passerine birds), the sinuses may not communicate with each other as they do in psittacine birds. Therefore, a bilateral sinusitis may require bilateral aspirations. *(Ed note: If a routine sinus flush does not produce an adequate sample, the anesthetized bird may be held with the head parallel to the floor and the affected sinus down. The sinus is flushed from underneath with the needle directed up; see Chapter 22).*

A second site of sinus aspiration is the small sinus immediately below the eye. This sinus usually yields a smaller sample volume than the previously described sinus. This sinus can be entered directly by inserting the aspiration needle at a perpendicular angle through the skin just below the eye (Figure 10.5). It can also be approached from a rostral direction by entering through the commissure of the mouth, directing the needle under the zygomatic bone and ending in the sinus cavity below the eye (Figure 10.6).

Collection of synovial fluid by arthrocentesis is another example of sample collection by aspiration. After the skin over the joint has been prepared as for surgery, a needle (22 ga or smaller) attached to a syringe is used to aspirate a small amount of fluid by direct penetration of the joint space. The cytologic sample is prepared by making direct smears using the "squash preparation technique."

Wash samples are aspiration techniques in which a small amount of sterile isotonic saline is infused into an area and immediately re-aspirated in an effort to collect a cytologic sample from locations that may be difficult to sample or that provide a poorly cellular field. Tracheal washes are commonly performed in birds suspected of having respiratory disease of the trachea, syrinx and bronchi. Depending on the patient, this procedure can be performed with or with-

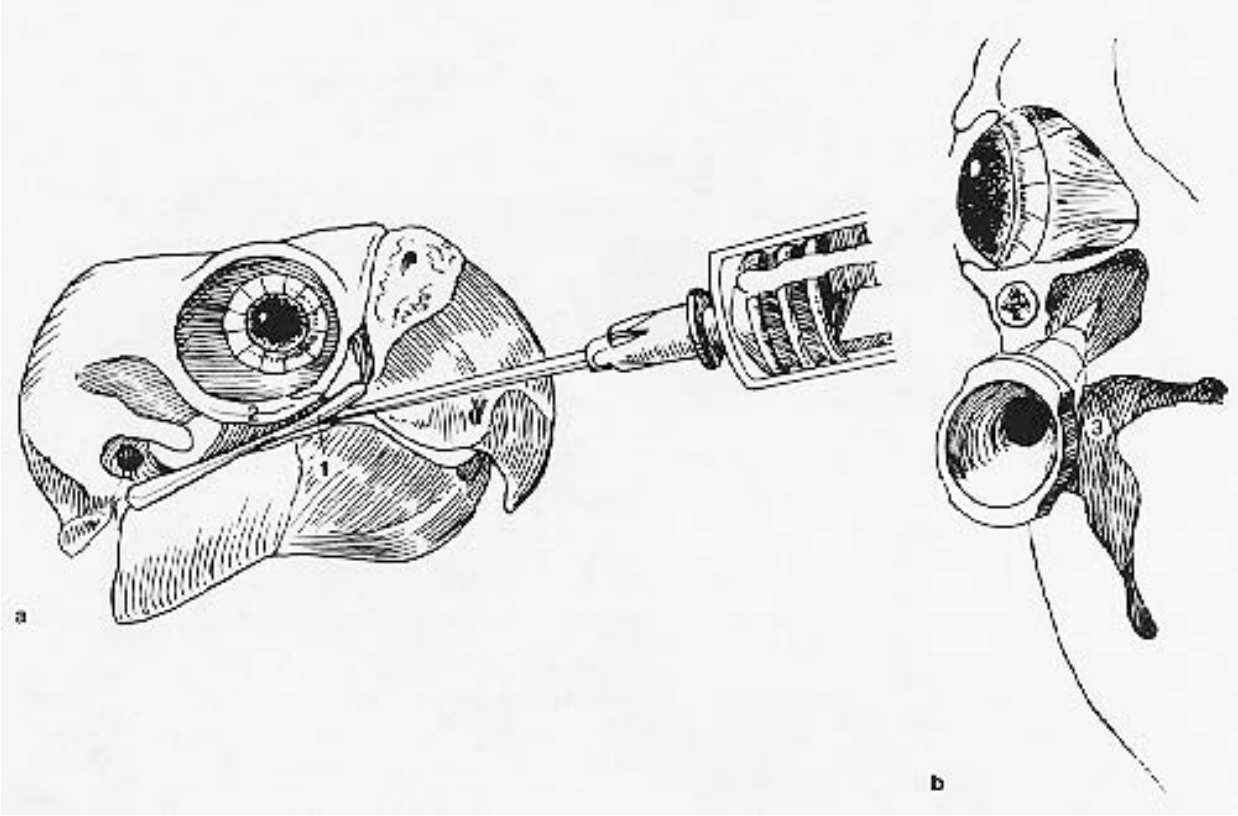

FIG 10.6 Aspiration of the suborbital diverticulum of the infraorbital sinus can be accomplished by **a)** entering through the commissure of the mouth, directing the needle under the zygomatic bone and **b)** ending in the sinus cavity below the eye. 1) Zygomatic arch 2) suborbital arch 3) oral cavity.

out general anesthesia. A soft, smooth-tipped, sterile plastic or rubber tube or catheter small enough to pass through the trachea is inserted through the open glottis taking care not to contaminate the tip in the oral cavity. The tube is passed to the level of the thoracic inlet near the syrinx. An oral speculum should be used in birds (eg, large psittacine birds) capable of biting off the tube. The animal is held parallel to the floor, and sterile saline (0.5 to 2 ml/kg body weight) is quickly infused into the trachea and immediately re-aspirated to complete the wash sample. Similar wash techniques can be used to collect cytologic samples from the air sacs, ingluvies and infraorbital sinus.

Contact Smears

Cytologic samples can also be obtained by direct contact between the tissue being sampled and the microscope slide. Often referred to as contact smears, these samples are used to evaluate postmortem tissues or antemortem tissue biopsies. Imprints of solid tissues should be made from freshly cut surfaces that have been blotted with a clean paper towel to remove the excess fluid and blood. It is best to lay the slide against the tissue surface using the weight of the slide to make the imprint. If the tissue is brought to the slide, too much force is used and the resulting specimen is too thick for evaluation.

Contact smears made from tissues that exfoliate poorly (eg, connective tissue) may require traumatic exfoliation to improve the cellularity. One method of improving cellular exfoliation is to scrape the tissue to be sampled with a scalpel blade and to make the contact smear from either the scraped surface or the material remaining on the scalpel blade. Using a drop of oil on the scalpel blade may improve the ability to detect mites but will interfere with staining for cytologic evaluation. Imprints should be made from biopsy of internal organs (eg, liver, spleen and kidney) using the impression technique.

Scrapings are commonly performed to collect cells from the palpebral conjunctiva, cornea, oral cavity or tissues that normally yield poorly cellular samples. A metal or plastic spatula is used to gently scrape these

tissues, and the exfoliated cells are transferred to a microscope slide.

Cytologic samples can also be obtained using a sterile swab.[b] Once the sample has been collected, the swab is gently rolled across the surface of a clean microscope slide, using light pressure in order to avoid cell damage. The swab should be rolled in one direction only and not rolled back and forth across the smear to prevent the creation of an excessively thick smear. Cytologic samples of internal tissues can be obtained using endoscopic equipment. Samples can be obtained either from the tip of the endoscope or by using brushes or biopsy forceps. The sample is applied directly to a microscope slide.

Evaluation of the Cytologic Sample

Tables 10.1 to 10.3 describe the use of stains most commonly available for cytology.

Classification of Cells and Cellular Responses

The cells observed in the cytologic sample can be classified as either hemic, epithelial, mesenchymal or nervous tissue cells.[13] Hemic cells are those cells found in the blood and the hematopoietic tissues (see Chapter 9). It is extremely important to recognize

TABLE 10.2 Results of Cytologic Staining

	STAIN USE	RESULTS
Acid-fast stain	Mycobacterium	red
	Other bacteria	blue
	Leukocytes	blue
	Cellular debris	blue
Giemsa stain	Cell nuclei	reddish purple
	Chlamydial elementary bodies	purple
	Chlamydial initial bodies	blue
	Mycoplasma	pink or purple
Gram's stain	Gram-positive bacteria	violet
	Gram-negative bacteria	red
	Eukaryatic cells (except yeast)	red
	Yeast	deep violet
Modified Gimenez stain	Chlamydial elementary bodies	red
	Chlamydial initial bodies	blue
	Heterophil granules	red
	Eosinophil granules	red
	Mycoplasma	like chlamydia
New methylene blue stain	Granulocytes	purple nuclei, pale blue cytoplasm
	Erythrocytes	purple nuclei, distinct cytoplasmic border, cytoplasm greenish blue
	Heterophil granules	not stained
	Eosinophil granules	not stained
	Fibrin	not stained
Stamp stain	Chlamydia, rickettsia	bright red
	Cocci tissue, other organisms	green
Sudan III stain	Fat globules	red-orange
	Cell nuclei	blue
	Cell cytoplasm	green
Wright's stain	Blood cells(see hematology)	

TABLE 10.1 Cytologic Stains Commonly Used in Avian Practice

1. Romanowsky stains (Wright's and Wright-Giemsa)
These stains are commonly used for peripheral blood films and routine cytology. They require air-dried smears. Commercially prepared quick stains are available to simplify the staining procedure. These stains can be used to prepare a permanently stained slide.

2. New Methylene Blue stain
This is a routine cytologic stain used as a wet preparation on dried smears. It does not provide a permanent stain. It is useful in the demonstration of fibrin, lipid droplets, fungal hyphae and other structures that stain poorly with alcohol-based stains.

3. Acid-fast stain
This specific stain is used to demonstrate acid-fast positive organisms, such as Mycobacterium sp. Acid-fast positive organisms stain red, whereas other bacteria stain blue. This stain is not used to evaluate cells.

4. Gram's stain
This is a microbiologic stain used primarily for the classification of bacteria grown on culture media. Gram-positive organisms stain deep violet, whereas gram-negative organisms stain red. Because of the nature of material on most cytologic preparations, it is difficult to achieve uniformity of staining on the smear. This stain is not used to evaluate cells.

5. Macchiavello's stain
This stain is used to identify chlamydia and mycoplasma inclusions. Chlamydia elementary bodies (0.2 - 0.3 μ) stain red, whereas the initial bodies (0.9-1.0 μ) stain blue. Mycoplasma colonies resemble chlamydia. Other particles in some smears may stain red and make the interpretation of the smear difficult. This stain is not used to evaluate cells.

6. Gimenez stain
This stain is used to identify chlamydia inclusions which stain red against a blue-green cellular background. There is less interference with non-chlamydia particles staining red with this stain as compared to Macchiavello's stain. This stain is not used to evaluate cells.

7. Stamp stain
This stain is used to detect chlamydia and rickettsia, which appear as small, bright red, "cocci" intracytoplasmic inclusions.

8. Giemsa stain
This stain is used to identify chlamydia and mycoplasma.

hemic cells because these cells can be either important features of the cellular response or common contaminants of the cytologic sample.

Epithelial cells typically exfoliate easily and are found in clusters or sheets.[13] Epithelial cells vary in shape depending upon their origin. They can be oval, cuboidal, columnar or polygonal (eg, squamous epithelial cells). Epithelial cells typically have an abundant cytoplasm, small round-to-oval nuclei and distinct cytoplasmic margins. Cells from secretory epithelium may contain cytoplasmic granules or vacuoles.

Mesenchymal cells tend to exfoliate poorly and normally occur as single cells. These cells vary in shape and usually have indistinct cytoplasmic margins. The fibroblast is the most frequently encountered cell of this group. Fibroblasts are typically spindle-shaped with small nuclei that usually follow the shape of the cell. The cytoplasm has indistinct margins. Fibroblasts usually exfoliate as single cells rather than in sheets or clusters.

Nervous tissue cells are rare in cytologic specimens.[13] They may be seen as deeply basophilic, stellate cells with cytoplasmic projections.

During the cytologic examination, an assessment of the cells is made by identifying the majority of the cell types, the morphology of the cells and character of the noncellular background. The goal of cytology is to identify the cellular message and classify the cell response into one of the basic cytodiagnostic groups. These groups include inflammation, tissue hyperplasia or benign neoplasia, malignant neoplasia and normal cellularity.[14]

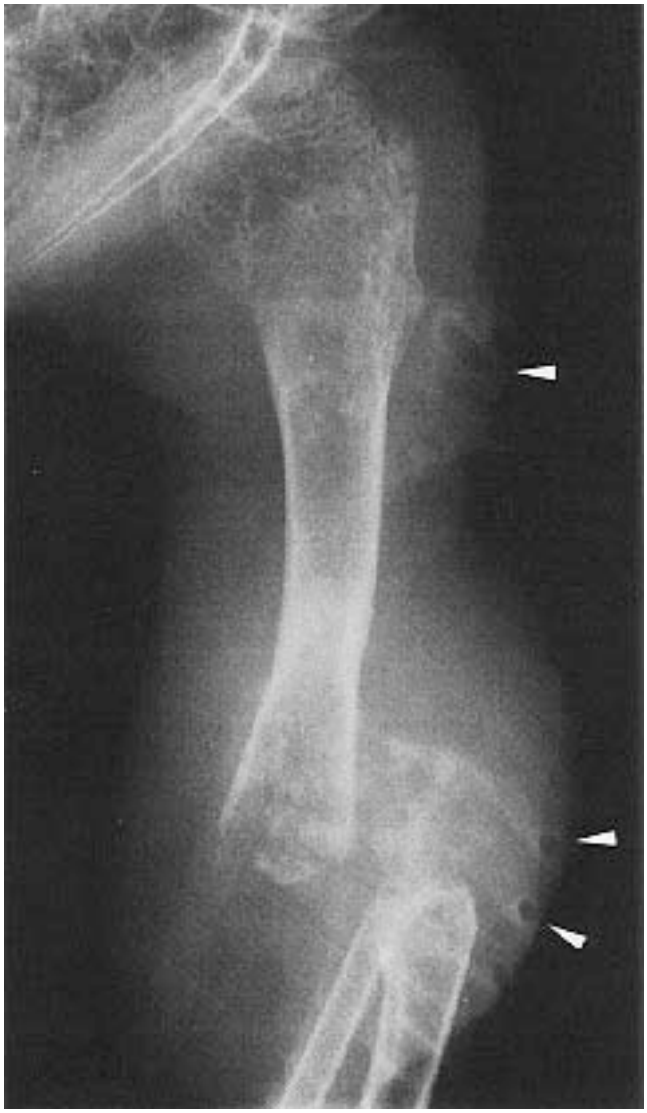

FIG 10.7 Cytology is an effective technique for differentiating between masses caused by infectious agents and those caused by neoplasia. In this goose, several fine-needle aspirates from a soft tissue mass associated with a humeral fracture revealed numerous degenerating heterophils and macrophages containing phagocytized bacteria suggestive of osteomyelitis. There were no pleomorphic cells, abnormal nuclei or mitotic figures suggestive of a neoplasm. Because neoplastic cells were not demonstrated, the client chose surgical removal of the humerus, which was uneventful. The presence of feather follicles (arrows) visible on the displaced antebrachium should not be confused with intralesional gas production.

Inflammation

A cytodiagnosis of inflammation is made when an increased number of inflammatory cells is detected in the cytologic sample. The inflammatory cells of birds are heterophils, lymphocytes, plasma cells and macrophages (Figure 10.7). Peripheral blood heterophils and lymphocytes have been described in the hematology chapter. It should be emphasized that heterophils found in tissues and fluids other than peripheral blood may not appear the same as those found in hemic tissue. Heterophils found in inflammatory lesions often degranulate and may resemble mammalian neutrophils. Depending upon the microenvironment, they may appear degenerate. Plasma cells are large, oval lymphocytes with an abundant, deeply basophilic cytoplasm; an eccentric, mature nucleus; and a prominent perinuclear halo (Golgi). Macrophages are large cells with an abundant cytoplasm that may contain small granules, vacuoles or foreign material. Macrophages and their nuclei vary in shape and can coalesce into multinucleated giant cells.

Eosinophils may be included in the list of inflammatory cells; however, eosinophilic inflammation is either extremely rare in birds or difficult to detect based on routine cytologic methods. Heterophils and eosinophils may be difficult to differentiate in cytologic samples using the standard Romanowsky stains. Eosinophils of domestic fowl stain peroxidase-positive and heterophils stain peroxidase-negative with the benzidine or p-phenylenediamine methods.[9,11] A suspected eosinophilic inflammatory response may be confirmed by peroxidase staining; however, one must keep in mind that cytochemical staining may vary among avian species. Avian eosinophils may not behave in the same manner as mammalian eosinophils.[2,7,8,10] Because these cells were given the same name, there is an implied similar function, but the function of avian eosinophils is currently unknown.[11]

The inflammatory response is classified as either heterophilic, mixed-cell or macrophagic inflammation based upon the types of inflammatory cells present.

Heterophilic inflammation is represented by a predominance of heterophils (greater than 70 percent of the inflammatory cells) in the cellular response. Heterophilic inflammation indicates an acute inflammatory response in birds.[11] It is important to examine the heterophils closely for signs of degeneration or phagocytized material.

Degenerate heterophils indicate a toxic microenvironment, usually caused by microbial toxins. Degenerative changes in heterophils include increased cytoplasmic basophilia, vacuolation, degranulation and nuclear karyolysis. If bacterial phagocytosis can be demonstrated, the cytodiagnosis of septic heterophilic inflammation can be made. If only extracellular bacteria are found, it cannot be determined that there is a bacterial etiology since the extracellular bacteria may represent either normal flora (depending upon the location of the inflammation) or contaminants of the sample.

Because macrophages migrate quickly (within a few hours of onset) into inflammatory lesions, mixed-cell inflammation is the most commonly found inflammatory response in birds.[11] Mixed-cell inflammation is represented by the presence of heterophils and mononuclear leukocytes (eg, macrophages, plasma cells and lymphocytes). Heterophils represent at least 50 percent of the inflammatory cells in mixed-cell inflammatory responses. Mixed-cell inflammation usually represents an established, active inflammation. The heterophils in this type of inflammation are usually nondegenerate, suggesting a microenvironment free of microbial toxins even though there may be a bacterial etiology.

Macrophagic inflammation is indicated by the predominance of macrophages (greater than 50 percent) in the inflammatory response. This type of inflammation does not necessarily imply chronicity, but may be suggestive of a number of etiologies (eg, intracellular pathogens). Macrophagic inflammation is common to certain avian diseases. These include avian tuberculosis, chlamydiosis, foreign body reaction, mycotic infections and cutaneous xanthomatosis. Multinucleated giant cell formation is often associated with macrophagic inflammation. Giant cells can appear within hours of the onset of some inflammatory responses and, unlike in mammals, their presence does not imply chronic inflammation.[1,5,12]

Tissue Hyperplasia or Benign Neoplasia

Tissue hyperplasia resulting from cellular injury or chronic stimulation is difficult to differentiate from benign neoplasia based upon cytology. Cells from hyperplastic tissue appear mature and do not exhibit much pleomorphism. They may appear immature by exhibiting increased cytoplasmic basophilia owing to the increased RNA activity within the cell.[14] Proliferating cells may also exhibit an increase in mitotic figures; however, the nuclear features do not show immaturity. Examples of tissue hyperplasia, frequently seen in birds, include the fibrous and epithelial cell proliferation adjacent to chronic inflammatory lesions, thyroid hyperplasia (especially in budgerigars) and squamous hyperplasia secondary to hypovitaminosis A. A common benign neoplasm of birds is the lipoma, especially in budgerigars (see Color 25).

Malignant Neoplasia

Cells obtained from malignant neoplasms show varying degrees of pleomorphism. The severity of the malignancy increases with the greater degree of pleomorphism. The appearance of the cell nucleus can provide important clues to the detection of a malignant neoplasm.[14] Increased nuclear size, which is reflected by an increased nucleus to cytoplasm (N:C) ratio, is suggestive of an abnormal cell. Nuclear anisocytosis (variation in size) and pleomorphism (variable nuclear shapes) are features of malignant cells. Multinucleation can also be a feature of malignancy.

The nuclear chromatin may also be abnormal in malignant cells. Coarse, hyperchromatic chromatin is suggestive of neoplasia. Other nuclear features of malignant cells include abnormal nucleoli (very large or multiple, such as greater than five), irregular nuclear margins, abnormal or increased mitotic figures and abnormal lobation, especially in cells that normally do not have lobed nuclei.

Cytoplasmic features of malignant cells include increased basophilia, abnormal vacuolation or inclusions, decreased volume, variation in cell margins and variability in the staining.[14] Abnormal cytoplasmic inclusions may include satellite nuclei (small nuclear fragments) and phagocytized cells.

Once a decision has been made for the cytodiagnosis of malignant neoplasia, an attempt to classify the neoplasm should be made. The four basic classifications of malignant neoplasms based upon cytologic features include carcinomas, sarcomas, discrete-cell neoplasia and poorly differentiated neoplasia.[14] Carcinomas are malignancies of the epithelial cells; therefore, the abnormal cells in the sample have features of epithelial cells. Adenocarcinomas are frequently seen in birds, especially ovarian adenocarcinomas. Cytologic evidence of adenocarcinomas includes epithelial cells that tend to form giant cells, have cytoplasmic secretary vacuoles and tend to occur in aggregates (eg, balls, rosettes or loose groupings). Sarcomas are malignancies of mesenchymal cells and therefore tend to exfoliate cells poorly. Fibrosarcomas are the most frequently encountered sarcomas of birds (see Color 25). Cells from fibrosarcomas are abnormal-appearing fibroblasts, which are spindle-shaped cells that typically exfoliate as single cells. Abnormal fibroblasts show increased cellular size and N:C ratios, nuclear and cellular pleomorphism and exfoliation when compared with normal fibrous tissue. Other mesenchymal cell neoplasms such as chondromas, chondrosarcomas and osteogenic sarcomas may produce a heavy eosinophilic background material (chondroid or osteoid) that can be seen on the microscope sample.

A common discrete or round cell neoplasm of birds is lymphoid neoplasia (see Color 25). The abnormal lymphocytes found in this type of neoplasm exfoliate extremely well. Cellular features of malignant lymphocytic tissue include a marked increase in the number of lymphoblasts, nuclear and cellular pleomorphism, increase in cytoplasmic basophilia and mitotic figures, and abnormal or multiple nucleoli.

Poorly differentiated neoplasms produce cells having features of malignant neoplasia; however, the cells are difficult to classify as carcinomas or sarcomas. In such cases, a cytodiagnosis of a poorly differentiated neoplasm is made.

Circumstantial evidence for a malignant neoplasm without the demonstration of abnormal cells is seen in older birds (eg, female budgerigars) with a spontaneous hemoperitoneum and no history of trauma. This is suggestive of an ulcerated neoplasm leading to abdominal hemorrhage. Ovarian adenocarcinomas of budgerigars and cockatiels often present in this manner. Evidence for malignancy may also be obtained by the demonstration of ectopic cells in unusual anatomic areas. An example of this would be the presence of a large number of cells other than hepatocytes and hemic cells in a cytologic sample of the liver. This is suggestive of a metastatic lesion, even if the cells do not have features of malignant neoplasia.

Mixed Cellular Response

Occasionally, a mixed-cellular response may be seen, especially in areas of ulcerated neoplasms. A cytologic sample obtained from an ulcerated neoplasm may reveal features of malignant neoplasia as well as inflammation or hemorrhagic effusion.

Cytology of Commonly Sampled Fluids and Tissues

Abdominal Fluids

Birds presented with abdominal distention may have an abnormal accumulation of fluid within the peritoneal cavity that may be detected by palpation or radiology. Cytologic evaluation of this fluid is often the main technique for establishing a presumptive or definitive diagnosis.

Abdominal effusions can be classified based upon cellularity, types of cells present, protein content, specific gravity and gross appearance. Abdominal fluids are classified as transudates, modified transudates, exudates, hemorrhage and malignant effusion.[14] Transudates are odorless, transparent fluids characterized by a low cellularity (total cell counts

usually less than 1000 /mm^3), a specific gravity less than 1.020 and a total protein less than 3.0 g/dl. Transudates are typically colorless or have a straw color resembling diluted serum. Transudative effusions do not clot. These poorly cellular fluids contain primarily macrophages and occasional mesothelial cells. Transudates occur as a result of oncotic pressure changes or other circulatory disturbances. The same causes for abdominal transudative effusions in mammals most likely occur in birds. These include hepatic cirrhosis, cardiac insufficiency and hypoproteinemia.

Modified transudates resemble transudative effusions; however, they have an increased cellularity (total cell counts usually less than 5000 /mm^3 but greater than 1000 /mm^3). The mononuclear leukocytes predominate in this type of effusion with occasional mesothelial cells and rare heterophils. The mesothelial cells usually appear reactive. Reactive mesothelial cells tend to be round or oval with increased cytoplasmic basophilia (Color 10.1). The cell margins often have a scalloped or villus-like appearance. The nuclei have coarse chromatin and prominent nucleoli. Multinucleation, cytoplasmic vacuolation and mitotic activity are often associated with reactive mesothelial cells. Proliferation of mesothelial cells results in the exfoliation of mesothelial cell aggregates that appear as cellular sheets, balls or rosettes (Color 10.2). Care should be taken not to mistake these cells for malignant neoplasia. Modified transudates result from hydrostatic pressure changes or irritation of long-standing transudative effusions. Transudative and modified transudative effusions are commonly found in the abdominal cavity of mynah birds suffering from hemochromatosis.

Exudative effusions are characterized by high cellularity (total cell counts usually greater than 5000 /mm^3), a specific gravity greater than 1.020 and a protein content greater than 3.0 g/dl. The majority of the cells found in exudative effusions are inflammatory cells (Color 10.3). Acute exudative effusions demonstrate primarily a heterophilic inflammatory response; however, macrophages quickly move into the fluid, creating a mixed-cell inflammatory response within a few hours of onset. Lymphocytes and plasma cells are often seen in long-standing exudative effusions. Exudative effusions vary in color and turbidity. They are frequently viscous, have a foul odor and tend to clot. Abdominal lesions often associated with exudative effusions include septic peritonitis, egg-related peritonitis and abdominal malignancies.

Hemorrhagic effusions are identified by the presence of erythrocytic phagocytosis in the fluid sample (Color 10.4). Without demonstration of erythrophagocytosis, one cannot differentiate hemorrhage from peripheral blood contamination of the sample. If thrombocytes are present, the sample was most likely contaminated with peripheral blood during the sampling procedure. Thrombocytes disappear rapidly in hemorrhagic effusions. Proof of erythrophagocytosis is made by the detection of macrophages that have phagocytized erythrocytes (suggestive of recent hemorrhage), or that contain iron pigment or hemosiderin crystals resulting from erythrocyte degradation (implying a duration greater than 48 hours). Iron pigment appears as gray to blue-black pigment in the cytoplasm of macrophages using Wright's stain. Hemosiderin appears as diamond-shaped, golden crystals within the macrophage cytoplasm.

Malignant effusions have features of either exudative or hemorrhagic effusions, but contain cells compatible with malignant neoplasia (Color 10.5, 10.6). Abdominal effusions caused by neoplasms are the result of blockage of blood or lymphatic vessels. Cystadenocarcinomas of the ovary of older female birds are a common cause of malignant effusions. These effusions can resemble hemorrhagic or exudative effusions that contain epithelial cells with features of malignant neoplasia. These cells often form cellular aggregates of balls or rosettes and have cytoplasmic secretory vacuolation.

Urate peritonitis is a rare effusion that can occur in the abdomen of birds when urinary fluids leak into the abdominal cavity. The cytology of the acute lesion is poorly cellular but contains a marked number of sodium and potassium urate crystals. These crystals are the same ones found in the urate portion of the bird's droppings. Urate crystals are spherical (2 to 8 mm) and have a spoke-wheel appearance. They are also birefringent under polarized light. The milky appearance of this type of abdominal effusion resembles that of the urate portion of avian droppings. If the bird survives this condition long enough, inflammatory cells will migrate into the fluid.

Cytology of the Alimentary Tract

The oral cavity, esophagus, ingluvies (crop) and cloaca are often sampled for cytologic examination. Lesions in the oral cavity may have different etiologies but similar gross appearance. Therefore, sampling of oral lesions for cytologic examination is a quick and simple procedure for differentiation of these etiolo-

gies. The differential diagnoses for common oral lesions include septic stomatitis, candidiasis, trichomoniasis and squamous cell hyperplasia. The normal cytology of the oral cavity shows occasional squamous epithelial cells, varying amounts of background debris and extracellular bacteria represented by a variety of morphologic types (Color 10.7). Bacteria associated with the surface of squamous epithelial cells are considered part of the normal flora. *Alysiella filiformis*, a gram-negative bacteria common to the upper alimentary tract of birds, occurs as small coccobacilli in pairs forming ribbon-like chains, and is often associated with squamous epithelial cells[6] (see Color 10.7 for Diff-Quik stain).

Smears made from a bacterial abscess reveal either a heterophilic or mixed-cell inflammation with bacterial phagocytosis (Color 10.8, 10.9). Heterophils may appear degenerate if bacterial toxins are present. Squamous epithelial cells are usually present. An increase in the amount of background debris and bacteria is also common.

Cytologic evidence for candidiasis is the presence of numerous narrowly based budding yeast (Color 10.10). Candida yeast are typically oval and often stain deeply basophilic with the Romanowsky stains. Occasionally they stain poorly, however, and may appear as "ghosts" in the cytologic specimen. *Candida* sp. can be a normal inhabitant of the upper alimentary tract of birds and may average as few as one per high power field (40x). The cytodiagnosis of candidiasis is made when the yeast increase in numbers. Because these organisms can be part of the normal flora of the upper alimentary tract of birds, low numbers of the yeast do not usually elicit an inflammatory response. However, an inflammatory response often occurs when the infection has involved the mucosa indicating the condition has become more serious. The presence of hyphae formation also indicates a potential lethal infection and suggests a systemic involvement by the yeast (Color 10.11, 10.15).

Trichomoniasis is best diagnosed by observing the movement of the piriform flagellate protozoa in a wet mount preparation. However, it is important to recognize these organisms in a stained cytologic sample if wet mount preparations are not part of the cytologic routine or trichomoniasis is not suspected. Trichomonads appear as basophilic, piriform cells with flagella on Wright's stained smears (Color 10.12, 10.13). These cells vary in staining intensity from poorly stained to deeply basophilic. The cell nucleus usually stains more eosinophilic than most cell nuclei. An eosinophilic axostyle can often be seen as a straight line running from the nucleus to the opposite pole of the cell. Eosinophilic flagella at the nuclear end and an undulating membrane on one side of the cell are usually present. Because trichomonas protozoa are not considered part of the normal flora and fauna of the alimentary tract of birds, an inflammatory response is usually found associated with trichomoniasis lesions. Much debris and extracellular bacteria are usually present. The gross appearance of trichomoniasis can vary from ulcerations to the accumulation of large amounts of necrotic debris, depending on the host (species)-parasite relationship.

The gross appearance of lesions caused by squamous hyperplasia and metaplasia from hypovitaminosis A can resemble lesions caused by bacteria, yeast and protozoa; however, the cytology has a very different appearance. Normally, squamous epithelial cells exfoliate as single cells or small groups following gentle scraping of the oral cavity. However, lesions resulting from squamous cell hyperplasia produce smears containing large numbers of cornified squamous epithelial cells that exfoliate in large sheets or aggregates. In the early stages of this condition, there is little background debris. Therefore, the cytology resembles that of the vaginal cytology of a dog in estrus. It is equally important in the diagnosis of squamous cell hyperplasia to note what is not present in the cytologic specimen. One does not see inflammatory cells (at least in acute lesions), yeast or protozoa. Squamous hyperplasia often occurs in the tissue surrounding the choanal slit in the roof of the mouth. As this lesion becomes increasingly chronic, secondary bacterial infections often occur, creating a septic inflammatory response associated with the squamous cell hyperplasia on the cytologic sample.

Cytologic evaluation of the esophagus and ingluvies (Color 10.14) is indicated in birds with clinical signs of regurgitation, vomiting, delayed crop emptying or other suspected esophageal and crop disorders. The normal cytology reveals occasional squamous epithelial cells and a variable amount of background debris and extracellular bacteria (represented by a variety of morphologic types). A rare yeast is accepted as normal. It should be emphasized that some foods (eg, monkey biscuits) fed to birds may contain yeast as a source of supplemental B vitamins. In these birds, there may be a high number of nonbudding yeast in a cytologic sample (see Color 8). In addition, the crop will have a normal pH and no other cytologic abnormalities. A sample of the food can be stained to confirm the source of the nonbudding yeast.

The same lesions and cytodiagnoses described for the oral cavity also apply to the normal cytologies of the esophagus and crop. Another cytologic indication of a disorder involving the esophagus and crop is the presence of many bacteria represented by one morphologic type (as compared to the normal variety of types), even though there is no apparent inflammatory response (Color 10.15). This condition is typical of a peracute ingluvitis, and the disorder is often referred to as "sour crop." It is indicative of a peracute bacterial infection, and an inflammatory response has either not been established or the response has been overwhelmed and the degenerate heterophils cannot be recognized in the background debris. The pH is often greater than 7, whereas normal crop pH is 6.5 to 7. Capillaria ova may be detected in cytologic samples from the esophagus or crop of some birds with capillariasis. These ova are double operculated and may not stain (see Chapter 36).

Examination of the cloacal cytology is indicated whenever a disorder of the lower intestinal tract, reproductive tract, urinary tract or cloaca is suspected. The normal cytology of the cloaca reveals a few epithelial cells (noncornified squamous or columnar), extracellular bacteria (variety of morphologic types), background debris and urate crystals. Abnormal findings would include the presence of inflammatory cells, large numbers of yeast and a uniform population of bacteria. Because the cloaca is a common opening to the intestinal tract, urinary tract and reproductive tract, cells found in cloacal samples may have originated from any of these systems or the cloacal tissue. Therefore, if inflammatory cells are found, for example, one cannot determine which system is involved based upon cytologic findings alone.

The use of a speculum and a swab or tube may allow collection of cytologic samples at the cloacal opening of the intestinal tract, urinary tract or reproductive tract. Uterine samples may be obtained through the cervix, especially in hens that have recently laid eggs. Abnormal post-parturient hens (usually showing uterine inflammation) may require flushing of the uterus with lactated Ringer's solution until the inflammatory cells disappear from the wash fluid. Cytology of the lower intestinal tract is usually poorly cellular with occasional epithelial cells, background debris and a variety of extracellular bacteria. Special stains may be required for the detection of pathogens, such as *Mycobacterium* and *Giardia* spp (see Table 10.1).

The normal fluid excreted from the urinary tract of birds is a poorly cellular, cream-colored, thick, mucoid semisolid (see Color 8). The cytology reveals a marked amount of sodium and potassium urate crystals. Abnormal urinary fluid is watery and may contain cellular elements such as inflammatory cells and cellular casts.

Cytology of the Respiratory Tract

The normal cytology of the nasal and infraorbital sinuses of birds reveals occasional noncornified squamous epithelial cells and low numbers of extracellular bacteria with little background debris. The normal cytology of tracheal wash samples consists of a few ciliated respiratory epithelial cells and goblet cells (Color 10.16, 10.17). An occasional squamous epithelial cell may be found. These cells may represent cellular contamination from the oral cavity if the end of the tube is not passed directly into the glottis or they may originate from the syrinx, which contains bistratified squamous epithelium in some birds. Ciliated respiratory epithelial cells are columnar or prismatic in shape and have an eccentric nucleus at the small pole of the cell. Eosinophilic cilia are located at the opposite, larger pole of the cell. Goblet cells are columnar cells with eccentric nuclei. They lack cilia but contain eosinophilic cytoplasmic granules and vacuoles.

Cytologic evidence for periorbital sinusitis is provided by the presence of inflammatory cells in the aspirate. Lesions with a bacterial etiology are indicated by a septic, heterophilic or mixed-cell inflammation. Mycotic lesions often reveal either a mixed-cell or macrophagic inflammation with the presence of fungal elements, such as yeast, hyphae or spores. Sinus infections associated with chlamydia often reveal a mixed-cell or macrophagic inflammation (Color 10.18). Chlamydial inclusions appear as small, blue-to-purple spherules, often in dense clusters, within the cytoplasm of macrophages when stained with Wright's stain. Chlamydial stains, such as Gimenez or Macchiavello's stains, may be used to aid in the detection of chlamydia (see Color 10.33). The chlamydial inclusions appear red, and the host cells appear blue-green with Gimenez stain. The chlam-ydial elementary bodies stain red, and the larger initial bodies stain blue with Macchiavello's stain (see Color 10.34).

A septic tracheobronchitis is identified from a tracheal wash sample by the presence of inflammatory cells showing bacterial phagocytosis. An endoscope is

excellent for collecting cytologic samples from the trachea of psittacine birds the size of an Amazon parrot or larger. In severe cases, the ciliated respiratory epithelial cells appear degenerate. Degenerate respiratory epithelial cells show loss of cilia, cytoplasmic vacuolation and karyolysis. Degeneration and fragmentation of the ciliated respiratory epithelial cells in association with a macrophagic and lymphocytic inflammation are suggestive of a viral etiology. Inflammation of the trachea and bronchi usually results in an increase in goblet cells and mucin formation, which causes an increased thickness to the noncellular background.

Mycotic lesions involving the trachea, syrinx and bronchi may reveal fungal elements on the tracheal wash samples. Aspergillosis is a common fungal pathogen of the avian respiratory tract. Aspergillosis is characterized by thick, septate hyphae that branch at 45° angles (Color 10.19, 10.20). Occasionally conidiophores can be seen. Other fungal lesions, such as phycomycosis, may reveal nonseptate, branching hyphae (Figure 10.8). Mycotic lesions usually reveal a mixed-cell or macrophagic inflammation. Aspiration of foreign material also results in a macrophagic inflammation. A mixed-cell inflammation generally occurs when secondary bacterial pathogens become involved.

The cytologic evaluation of the lower respiratory tract (lungs and air sacs) is made from either biopsy samples, endoscopy impressions or imprints from necropsy specimens. Imprints of avian lung tissue have an alveolar-like appearance microscopically. The walls of these alveolar-like structures may reveal abnormal cytologic findings of inflammatory cells and etiologic agents such as yeast or fungi (Color 10.19, 10.20). Lung tissue is highly vascularized and imprints usually contain a marked number of erythrocytes.

Normal air sac samples are poorly cellular with the presence of a few noncornified epithelial cells. Bacterial infections show the typical septic inflammatory patterns. Chlamydial and mycotic lesions demonstrate mixed-cell or macrophagic inflammation with the presence of chlamydial inclusions or fungal elements, respectively.

Neoplastic lesions of the respiratory tract of birds are rare; however, they can occur. Cytologic evidence for malignant neoplasia is the presence of cells showing features of malignant cells. A secondary inflammatory response is often associated with malignant lesions.

FIG 10.8 A mature Blue and Gold Macaw hen was presented for progressive dyspnea and weight loss of two weeks' duration. Radiographs indicated a diffuse soft tissue density in the right caudal thoracic air sac (arrows). Endoscopy indicated a white thickening of the air sac. Impression smears of endoscopically guided biopsies revealed branching fungal hyphae characteristic of aspergillosis. Abnormal clinical pathology findings were limited to marked leukocytosis (WBC=35,000). An agar gel diffusion test was considered positive for *Aspergillus* sp. antibodies.

Cytology of the Skin

Bacterial infections involving the skin are usually associated with a heterophilic or mixed-cell inflammation. Cytology of skin samples typically contains squamous epithelial cells, debris and extracellular bacteria. Therefore, bacterial phagocytosis must be demonstrated to detect a septic inflammatory lesion.

Foreign bodies typically create a macrophagic inflammatory response with multinucleated giant cell formation. If a secondary bacterial infection has been established, lesions caused by foreign bodies may show a mixed-cell inflammatory response.

Cutaneous xanthomatosis is a unique condition of birds caused by an excessive accumulation of lipids in the skin (see Color 25). A macrophagic inflammatory response with multinucleated giant cells and cholesterol crystals is observed on the cytologic specimen (Color 10.21, 10.22). Cholesterol crystals appear as angular, translucent crystals that vary in size and shape. They often appear stacked upon each other. Skin affected with xanthomatosis is thickened, yellow and friable. It is often found in areas where previous hemorrhage (eg, feather cysts and skin trauma) or pressure from underlying tumors (eg, lipomas) has occurred (see Color 25).

Subcutaneous lipomas produce a cytologic specimen that appears "greasy" on the unstained slide. The cytology reveals numerous lipocytes, which vary in size (Color 10.23). Avian lipocytes often have large cytoplasmic vacuoles in association with clusters of small vacuoles. The vacuoles tend to be round. The cell nucleus appears pyknotic and pushed to one edge of the cell, often appearing as if pushed beyond the cell margin. The background material in slides from lipomas resembles the cytoplasm of the lipocytes and contains numerous fat droplets. These clear, round, fat droplets usually partially dissolve in the alcohol-based stains (eg, Wright's stain) but are easily seen in the water-soluble stains such as new methylene blue. Special fat stains such as Sudan IV can be used to demonstrate the fat droplets.

The cytology of feather cysts varies, depending upon the chronicity of the lesion (see Color 24). Early stages of feather cyst development reveal a marked number of red blood cells in the sample. Often erythrophagocytosis can be found. As the lesion becomes more chronic and caseous exudation develops, the cytology resembles that of mixed-cell inflammation with a marked amount of background debris and occasional multinucleated giant cell formation. Feather fragments may also be found.

Cutaneous and subcutaneous malignant neoplasms are rare in birds, but can be detected on cytologic examination. Lymphoid neoplasia produces a highly cellular sample of immature lymphocytes (Color 10.24). These lymphoblasts and prolymphocytes are large, round cells that exfoliate as single cells. They have large nuclei with fine chromatin and multiple or large prominent nucleoli. The cytoplasm stains basophilic. Bizarre-appearing lymphocytes and mitotic figures may also be present. The background of lymphoid tissue, such as lymphoid neoplasms, typically contains small, irregular, blue cytoplasmic fragments. Finding these fragments may be helpful in the cytologic identification of lymphoid tissue.

Cutaneous melanosarcomas have also been found in birds. Poorly differentiated melanosarcomas reveal mesenchymal cells that contain few cytoplasmic melanin granules. The gross appearance of the involved skin shows dark pigmentation. The malignant cells usually exfoliate as single cells, and the background may contain melanin granules from ruptured cells. The round melanin granules vary from black to dark brown to golden in color.

Avian poxvirus lesions reveal clusters of squamous epithelial cells that contain large cytoplasmic vacuoles (Color 10.25). The large cytoplasmic vacuoles found in the affected squamous cell push the cell nucleus to the cell margin. These vacuoles represent the ballooning degeneration of the squamous epithelium typical of pox lesions. These cytoplasmic vacuoles often contain small, pale eosinophilic inclusions with oil immersion examination of Wright's stained smears. A secondary septic inflammatory response is often associated with ulcerated pox lesions.

Cytology of the Cornea and Conjunctiva

Normal conjunctival scrapings provide poorly cellular samples with little background material. The cells normally found are epithelial cells that may contain intracytoplasmic pigment granules. The normal cytology of the cornea is also poorly cellular and consists of occasional noncornified squamous epithelial cells. Inflammatory lesions involving the cornea and conjunctiva reveal inflammatory cells and increased numbers of exfoliated epithelial cells. The epithelial cells often demonstrate degenerative changes, such as cytoplasmic vacuolation, karyolysis or karyorrhexis. Chronic inflammatory lesions may show an increase in the number of epithelial cells that contain pigment granules. Chronic lesions may also reveal the presence of cornified squamous epithelial cells that are not normally found in the conjunctiva or cornea (Figure 10.9).

Cytology of Synovial Fluid

The amount of fluid in synovial joints of most birds is normally too small for sampling; however, an abnormal accumulation of joint fluid may provide enough sample for evaluation. Normal synovial fluid is poorly cellular. The cells are mononuclear cells, representing either synovial lining cells or mononuclear leukocytes. The background of normal synovial fluid

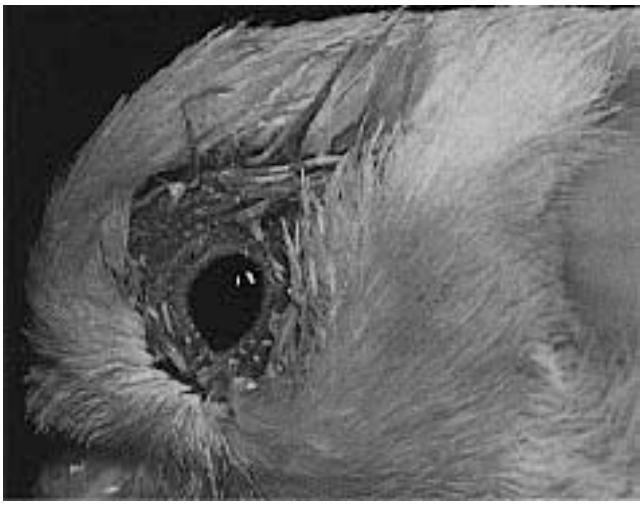

FIG 10.9 An adult canary was presented with bilateral epiphora and mild conjunctivitis. Cytologic evaluation of conjunctiva scrapings may have been helpful in determining an etiology for this bird's problems. This bird responded to treatment with tylosin (courtesy of Michael Murray).

cytology consists of a heavy, granular, eosinophilic substance representing the mucin in the fluid.

An increase in the inflammatory cells and change in the color, clarity, and viscosity of the fluid is indicative of inflammatory joint lesions (see Figure 12.77). There may be a decrease in the granular eosinophilic background material, suggesting a decrease in mucin content. Erosion of the articular cartilage may result in the presence of multinucleated osteoclasts in the synovial fluid. Spindle-shaped fibroblasts suggest erosion into the fibrous layer of the articular capsule. Septic joint lesions may demonstrate bacterial phagocytosis by leukocytes (primarily heterophils). An increase in the number of inflammatory cells, especially heterophils, is also seen with traumatic arthritis. The presence of erythrocytes and erythrophagocytosis is supportive of a cytodiagnosis of hemarthrosis.

Articular gout produces a cream-to-yellow-colored deposit in affected joints (see Color 21). The cytology of this material reveals numerous, needle-shaped crystals (monosodium urate) (Color 10.26). These crystals are birefringent under polarized light. They occasionally stain eosinophilic with Wright's stain. Inflammatory cells are often present and the mucin content is often reduced, as reflected in the reduction in the amount of eosinophilic granular background.

Cytology of Internal Organs

The liver, kidney and spleen are occasionally sampled by biopsy to achieve an antemortem diagnosis in birds. Cytologic evaluation should also be performed whenever lesions involving these organs are found on postmortem examinations.

Birds typically do not have lymph nodes as found in mammals. Avian lymphoid tissue appears as lymphoid aggregates in the walls of the intestines, internal organs (especially the spleen and liver) and skin. The cloacal bursa of young birds is a sac-like lymphoid nodule found in the dorsal wall of the proctodeum of the cloaca (see Figure 5.6). The cytology of normal lymphoid tissue shows a predominance of small mature lymphocytes (greater than 90 percent of the lymphoid cells) (Color 10.27). The larger prolymphocytes, lymphoblasts and plasma cells normally occur in low numbers. Reactive lymphoid tissue demonstrates an increase in the number of immature lymphocytes (prolymphocytes and lymphoblast) and plasma cells (Color 10.28). Reactivity of the lymphoid tissue is suggestive of antigenic stimulation of the immune system. Lymphoid hyperplasia causes an increase in the lymphoid tissue mass; however, the cytology appears normal with the exception of a slight increase in the number of prolymphocytes. Lymphoid neoplasia produces a marked increase in the number of immature lymphocytes, especially lymphoblasts, in the cytologic specimen. The neoplastic cells may show varying degrees of cellular features of malignant neoplasia. There is usually an increase in the number of mitotic figures in samples obtained from lymphoid neoplasia.

Cytologic samples of the liver are usually highly cellular with a predominance of hepatocytes, erythrocytes and free nuclei. Depending upon the location of sampling, there may be numerous lymphocytes present. Hepatocytes are large epithelial cells that occur in sheets or clusters or as single cells. Normal hepatic cytology reveals uniform-appearing hepatocytes. These cells have an abundant, basophilic, finely granular cytoplasm and a round-to-oval, slightly eccentric nucleus. Binucleation is occasionally seen. Hepatocytes are easily ruptured during slide preparation; therefore, the background of hepatic tissue resembles that of the hepatocyte cytoplasm, and many free nuclei are commonly seen. Normal hematopoiesis is occasionally found because the liver is a common location for ectopic hematopoiesis. Also, macrophages containing iron pigment (hemosiderin) are occasionally seen.

Inflammatory lesions of the liver reveal numerous mature heterophils and an increase in the number of macrophages and plasma cells (Color 10.29). It is important not to confuse normal ectopic granulopoiesis with heterophilic inflammation. If developing stages of the heterophils can be found, the cytology is representative of granulocytopoiesis (see Chapter 9). If the heterophils are mature cells, however, then the cytology indicates inflammation. The hepatocytes may demonstrate degenerative changes in the presence of hepatic inflammation.

Avian tuberculosis produces a macrophagic inflammatory response in the liver (see Color 20). The cytology reveals numerous macrophages and multinucleated giant cells. When stained with Romanowsky stain, the background of the smear contains numerous large bacterial rods that do not stain. Likewise, macrophages may contain numerous bacterial rods that do not stain (Color 10.30). Because mycobacterium have a waxy cell wall, they do not stain with routine cytology stains. Therefore, an acid-fast stain is required to demonstrate the tubercle bacilli, which stain red (Color 10.31). However, the presence of a macrophagic inflammation with multinucleated giant cells and "ghost-like" bacterial rods provides a presumptive diagnosis for tuberculosis.

Avian chlamydiosis often results in a mixed-cell or macrophagic inflammation in the spleen or liver with a marked increase in the number of plasma cells (Color 10.28). Small, blue-to-purple, intracytoplasmic inclusions suggestive of chlamydial elementary and initial bodies may be seen in macrophages (Color 10.32). Confirmation of chlamydial inclusions is aided by special stains (eg, Gimenez or Macchiavello's).

Hepatic lipidosis produces cytologic specimens that appear "greasy" on gross examination. The stained smears reveal enlarged hepatocytes that contain round, cytoplasmic vacuoles (Color 10.35). The background material also contains these round vacuoles suggestive of lipid material.

Primary neoplasm of the liver reveals hepatocytes showing features of malignant neoplasia. Affected cells are usually pleomorphic with deep, cytoplasmic basophilia and immature-appearing nuclei (eg, smooth nuclear chromatin and multiple or large prominent nucleoli). Ectopic cells that show features of malignant neoplasia may also be found and are indicative of a metastatic lesion in the liver.

Occasionally, parasites may be found on splenic hepatic imprints (Color 10.36). Those commonly seen are schizogony of *Haemoproteus* and *Leukocytozoon*, sporozoites of *Atoxoplasma* and microfilaria.

Normally, cytology of the spleen shows a marked number of erythrocytes and lymphocytes, reflecting the cytology of a lymphoid tissue. Macrophages are also present and occasionally contain iron pigment from erythrophagocytosis of senescent red cells. Excessive splenic iron pigment is seen in birds with hemolytic anemia owing to increased red cell degradation by the spleen (Color 10.37). Chlamydial infections often cause a marked increase in the number of splenic plasma cells. Macrophages often demonstrate intracytoplasmic chlamydial inclusions. Developmental stages of blood parasites may also be found in splenic samples (see Color 9). Systemic bacterial or fungal infections may result in an increase in the number of inflammatory cells, especially mature heterophils, in the spleen. Often, the etiologic agent can be found either within the leukocytes or in the noncellular background.

The normal kidney produces a highly cellular sample that contains numerous epithelial cells with an abundant, slightly basophilic cytoplasm and slightly eccentric, round-to-oval nuclei. Numerous erythrocytes and free cell nuclei are usually present. Urate crystals are also common. Abnormal cytology includes an increase in the number of inflammatory cells or the presence of cells having features of neoplasia. Epithelial cells from renal adenomas show increased cytoplasmic basophilia, slight pleomorphism and occasional mitotic figures. Renal adenocarcinomas produce epithelial cells having features of malignant neoplasia. Nephroblastomas (embryonal nephroma) produce poorly differentiated epithelial and mesenchymal cells. The cuboidal epithelial cells are associated with spindle-shaped cells of the fibrous stroma, and the background may contain a heavy, eosinophilic substance. This background material is suggestive of a cellular attempt to produce a matrix (eg, chondroid or osteoid).

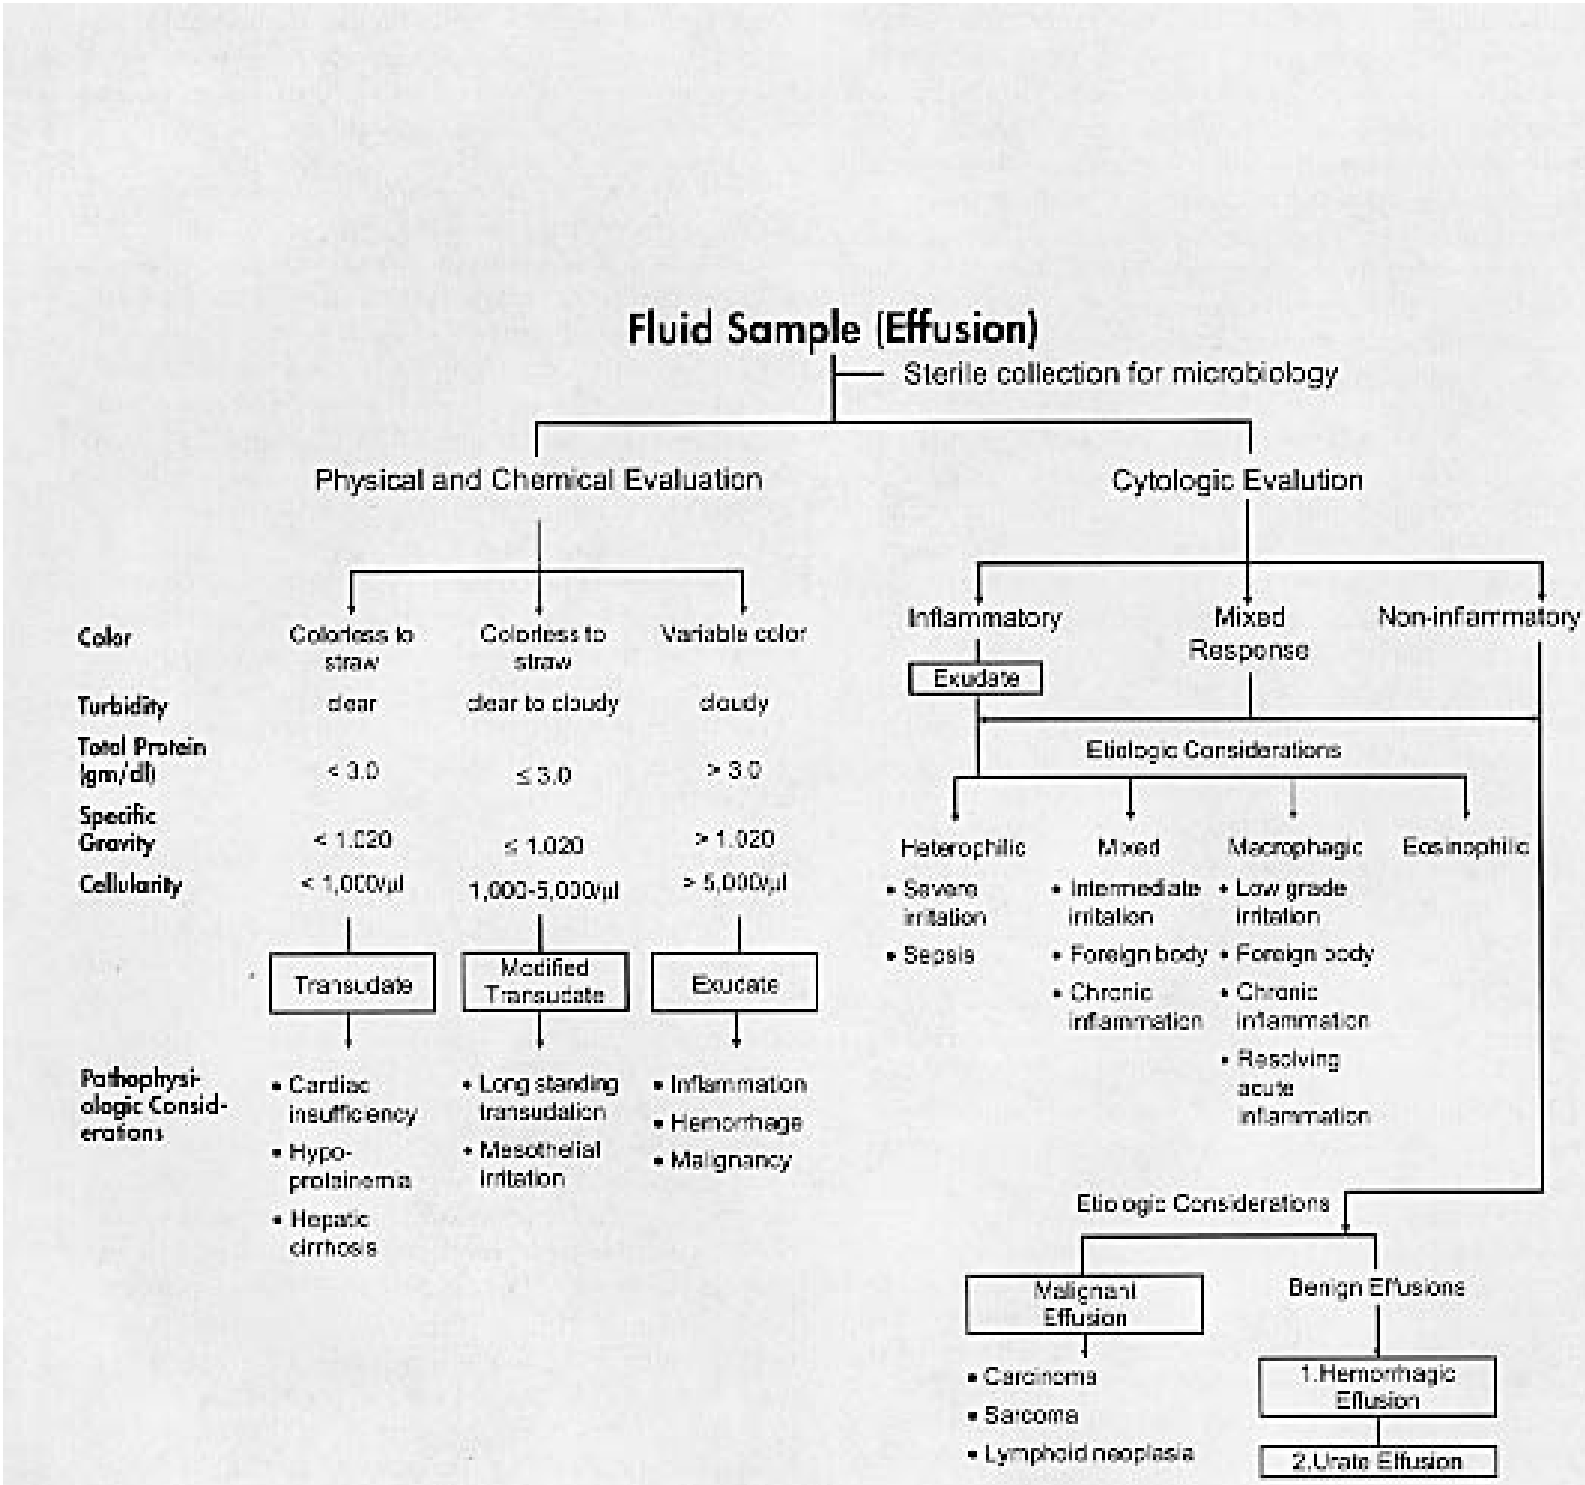

FIG 10.10 Flow chart for characterization of fluids

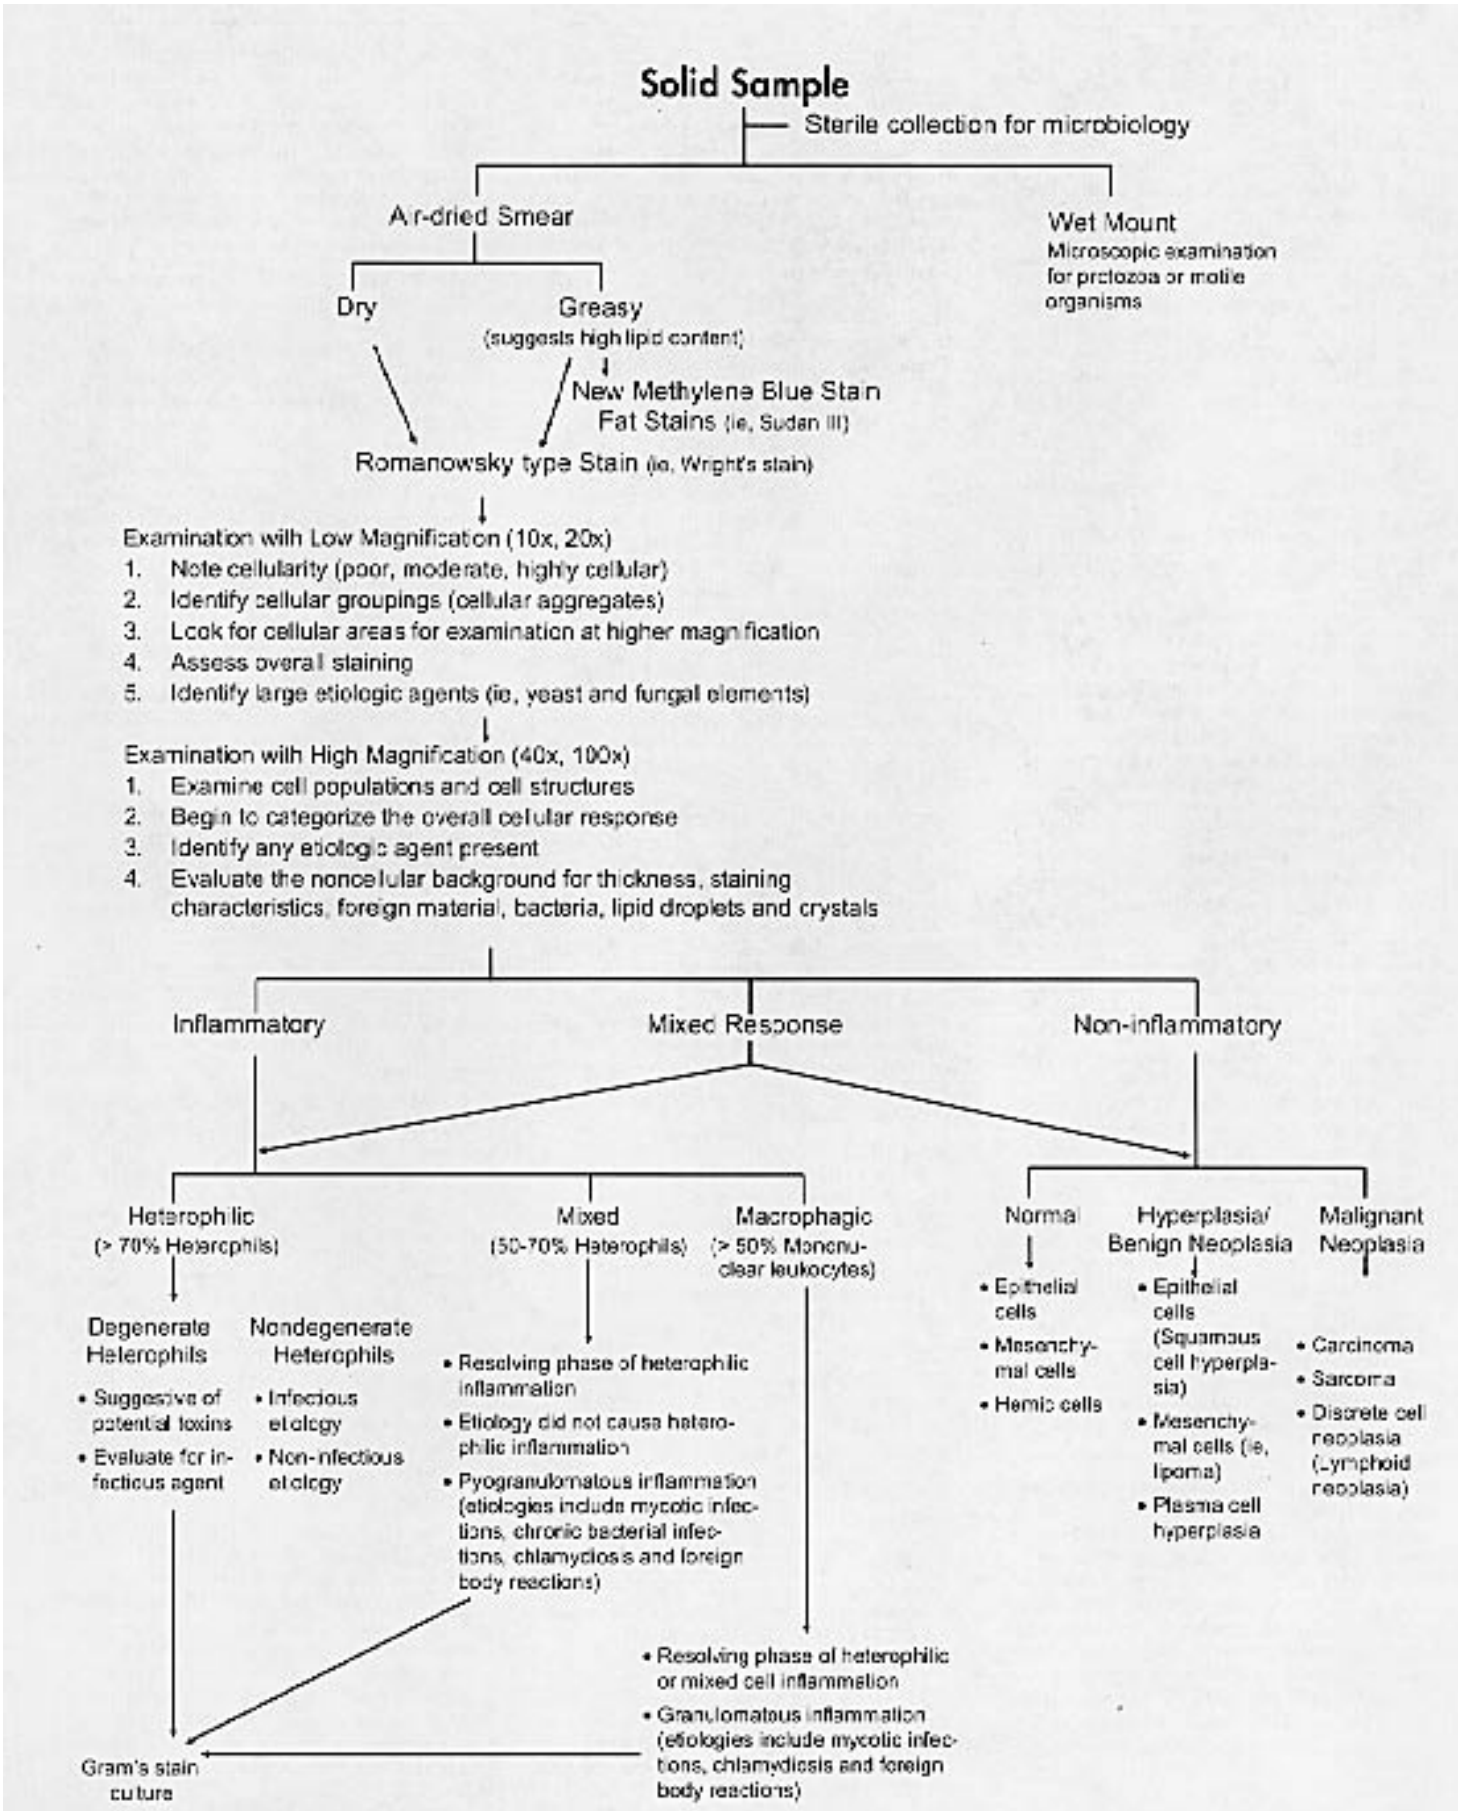

FIG 10.11 Cytologic evaluation of tissue samples

Unless indicated otherwise, cytology photographs are provided courtesy of Terry W. Campbell.

Color 10.1
An adult mynah bird was presented with a marked dyspnea at rest and abdominal enlargement. Abdominal palpation suggested fluid within the abdomen. An abdominocentesis was performed. The fluid was pale yellow and slightly cloudy. The specific gravity was 1.025. Fluid was prepared by a cytospin preparation and the smear was stained with Diff-Quik stain. Cytology was compatible with a modified transudate. Illustrated are a reactive mesothelial cell and erythrocytes.

Color 10.2
Shown are a cluster of reactive mesothelial cells, macrophages, erythrocytes and one heterophil from the mynah bird described in Color 10.1.

Color 10.3
An adult female budgerigar was presented with fluid distension of the abdomen. An abdominocentesis was performed, and a direct smear was made of the fluid and stained with Diff-Quik stain. The fluid appeared thick, red, slightly greasy and contained flocculent material. The photograph demonstrates numerous foaming macrophages, erythrocytes and blue amorphous material in the non-cellular background. A mixed cell or macrophagic inflammation associated with amorphous material is often seen with egg-related peritonitis.

Color 10.4
A six-year-old, 37 g female budgerigar was presented with a complaint of abdominal enlargement and dyspnea. There was no history of egg laying. An abdominocentesis was performed, the fluid was prepared with a cytospin preparation and the smear was stained with Diff-Quik stain. The fluid sample was pale orange and slightly cloudy. The specific gravity was 1.032. The macrophage shown demonstrates erythrophagocytosis, indicative of a hemoperitoneum.

Color 10.5
A second area of the preparation from the budgerigar in Color 10.4 shows numerous erythrocytes and a large epithelial cell with basophilic cytoplasm, a large nucleus with smooth chromatin and a large nucleolus. Note the numerous epithelial cells with features of malignant neoplasia. Necropsy revealed an ovarian cystadenocarcinoma.

Color 10.6
A ten-year-old female cockatiel was presented with a complaint of a large abdomen and dyspnea. The physical examination indicated ascites. An abdominocentesis was performed and a direct smear of the fluid was made and stained with Diff-Quik stain. The fluid was dark yellow and cloudy. The specific gravity was 1.036. Shown is a highly cellular sample with aggregates of pleomorphic cells with abundant vacuolated or basophilic cytoplasm. Necropsy revealed an ovarian cystadenocarcinoma.

Color 10.7
An adult female African Grey Parrot weighing 480 g was presented for a pre-purchase examination. A small area of depigmentation was found in the oral cavity adjacent to the choanal slit. A scraping of the depigmented area was made. The smear was stained with Diff-Quik stain. The smear was characterized by low cellularity with an occasional squamous epithelial cell and a variety of extracellular bacteria. The large, ribbon-like bacteria associated with the squamous cells is *Alysiella filiformis*. These cytologic findings are considered normal for the oral cavity.

Color 10.8
A hand-raised crow was presented with a two-day history of anorexia. The physical examination revealed caseous material in the oral cavity. A scraping of the material in the oral cavity was made, and the smear was stained with Wright's stain. Numerous nondegenerate heterophils are seen, indicating a heterophilic inflammation.

Color 10.9
An adult Red-tailed Hawk was presented with a healed, malaligned fracture of the right radius and ulna. Examination of the oral cavity revealed multiple, raised, white foci just caudal to the choanal slit. A scraping of the lesion was made, and the smear was stained with Wright's stain. The smear shows a marked number of extracellular bacteria and degenerate heterophils, suggesting a severe septic inflammation.

Color 10.10
A hand-fed, three-week-old, 68 g cockatiel was presented with delayed emptying of the ingluvies during the past 36 hours. An aspirate of the ingluvies was stained with Diff-Quik stain. Cytology revealed numerous, narrowly based, budding yeast and a marked amount of background debris indicative of candidiasis.

Color 10.11
A three-week-old Eclectus Parrot was presented with weight loss and delayed emptying of the crop. A crop aspirate was taken and a smear was stained with Wright's stain. Narrowly based budding yeast and hyphae formation are seen, indicative of severe candidiasis.

Color 10.12
A 723 g adult Barred Owl was presented in an emaciated, weak condition. Physical examination revealed multiple ulcerations in the oral cavity. A scraping of the oral lesions was made, and the smear was stained with Diff-Quik stain. The smear shows numerous pale and dark-staining piriform flagellate protozoa with eosinophilic nuclei and flagella (arrow). There is a moderate amount of background debris, free nuclei and bacteria. A few erythrocytes are present. The cytology is indicative of trichomoniasis.

Color 10.13
An adult male budgerigar was presented with chronic regurgitation and weight loss. The bird was thin, and regurgitated material was present on the feathers of the head and face. A crop aspirate was performed, and the dried smear was stained with Wright's stain. A typical oil immersion field shows numerous piriform flagellate protozoa with eosinophilic nuclei, flagella, undulating membrane and axostyle (arrow). Leukocytes are also present. The cytology indicates severe trichomoniasis.

Color 10.14
A six-week-old Military Macaw chick was presented with a history of inadequate growth. A routine blood profile revealed no abnormalities. A crop aspirate was performed and a typical oil immersion field of this cytologic preparation is shown. The sample was poorly cellular and contained a slight to moderate amount of background debris. Bacteria represented by a variety of morphologic types were seen in the background. The cytology is considered normal for the ingluvies.

Color 10.15
A four-week-old, hand-raised cockatiel was presented with frequent regurgitation of a fluid with a fermented odor. A crop aspirate was performed for cytologic examination and a smear was stained with Wright's stain. The smear demonstrates a typical oil immersion field showing a uniform population of bacterial rods and yeasts beginning to form hyphae. No inflammatory cells are seen. A cytodiagnosis of peracute septic ingluvitis and candidiasis was made, and the bird was successfully treated with antibiotics and a systemic antifungal medication.

Color 10.16
Ciliated respiratory epithelial cells (arrow) in a lung imprint stained with Wright's stain from an African Grey Parrot.

Color 10.17
Goblet cells in a tracheal wash sample stained with Diff-Quik stain from a Night Hawk.

Color 10.18
An adult, 28 g, male Scarlet-chested Parakeet was presented with a history of sinus infection. A sinus aspirate was performed and the smear was stained with Diff-Quik stain. Shown is a mixed cell inflammation with degenerate heterophils. The heavy eosinophilic background suggests high protein content, most likely representing inflammatory proteins associated with a sinusitis. Although no etiologic agent can be seen, a bacterial or chlamydial etiology is suspected.

Color 10.19
A Blue-fronted Amazon Parrot was found dead. The only pathology noted on gross necropsy was a tan discoloration on the caudolateral margin of the left lung representing one-fourth of the lung mass. An imprint of the lesion was made, and the smear was stained with Wright's stain. High dry magnification was used to demonstrate a mixed cell inflammation and septate branching hyphae. A cytodiagnosis of aspergillosis was made.

Color 10.20
An adult, 520 g African Grey Parrot on an all-seed diet was presented because it no longer growled, a typical behavior when approached. A tracheal wash sample was collected, and a smear was prepared by a cytospin preparation and stained with Diff-Quik stain. A highly cellular sample containing numerous erythrocytes is illustrated. There are multinucleated giant cells and septate fungal hyphae, indicative of a mycotic infection involving the respiratory tract.

Color 10.21
An adult, 1342 g Green-winged Macaw was presented with a complaint of feather loss on the distal end of the right wing. A feather cyst had been removed from this area three months earlier. Physical examination revealed thickened, yellow, friable skin on the dorsal aspect of the right metacarpus. A contact smear of the excisional biopsy of the abnormal skin was obtained and stained with Diff-Quik stain. Multinucleated giant cells and macrophages (arrow) on a heavy granular background are demonstrated.

Color 10.22
Multinucleated giant cells and cholesterol crystals (arrow) from the bird described in Color 10.21. These findings are compatible with xanthomatosis, which typically reveals a macrophagic inflammation with multinucleated giant cell formation.

Color 10.23
The physical examination of a 30 g, adult, male budgerigar (fed an all-seed diet) revealed a large, firm, subcutaneous mass overlying the keel. A fine-needle aspiration biopsy of the mass was made, and a smear was stained with Diff-Quik stain. Typical avian lipocytes (arrow) are shown. The cytology is compatible with a lipoma.

Color 10.24
A 23-year-old, 320 g Spectacled Amazon Parrot was presented with a marked swelling around the right eye and feather loss on the head. A fine-needle aspiration biopsy of the mass on the head was performed, and the smear was stained with Diff-Quik stain. The highly cellular sample shown contains numerous lymphocytes. The majority of the lymphocytes are large, immature and frequently show mytotic activity. These findings are indicative of lymphoid neoplasia.

Color 10.25
An adult, 112 g Ring Dove was presented in a morbid condition and died soon after the physical examination. The bird was housed in an outdoor aviary, and was presented for marked depression and multiple, raised, irregular cutaneous lesions on the head, legs and feet. A fine-needle aspiration biopsy of a raised lesion near the right eye was made, and the smear was stained with Diff-Quik stain. Shown are epithelial cells with large cytoplasmic vacuoles (arrow) typical of avian poxvirus lesions.

Color 10.26
An adult, 160 g Nanday Conure was presented with a swollen left tibiotarsal and tarsometatarsal joint and left leg lameness. Arthrocentesis of the affected joint was performed and the smear was stained with Diff-Quik stain. The sample contains numerous free nuclei, possibly from ruptured erythrocytes, and needle-like crystals. The cytology is compatible with articular gout.

Color 10.27
An imprint of a normal spleen from a King Penguin that was euthanatized because of a severe skeletal deformity. Note the predominance of small-to-medium, mature lymphocytes, one lymphoblast and two plasma cells.

Color 10.28
A splenic imprint from the Yellow-naped Amazon Parrot described in Color 10.32-10.34 shows a marked increase in plasma cells, indicative of reactive lymphoid tissue.

Color 10.29
A four-year-old male budgerigar was presented for bilateral leg paralysis. Whole body radiographs revealed a large mass in the area of the kidneys, and a presumptive diagnosis of renal neoplasia was made. At the owner's request, the bird was euthanatized. Necropsy revealed a large, locally invasive mass that appeared to involve both kidneys. A histologic diagnosis of nephroblastoma was made. Necropsy also revealed a slight discoloration of the liver, which appeared pale. The imprint of the liver shown here reveals normal-appearing hep-atocytes and erythrocytes. There is also an increased number of mature heterophils present, suggesting a mild heterophilic inflammation and hepatitis. Histology confirmed the hepatitis; however, no etiology could be determined.

Color 10.30
An adult, female, 370 g Blue-fronted Amazon Parrot was presented for necropsy. The bird had shown no previous signs of illness. Necropsy revealed multiple, raised lesions throughout the liver parenchyma. The lesions were varied in size and tended to be round. No other gross lesions were seen. A contact smear of the liver was made, and the smear was stained with Diff-Quik stain. Shown is a typical oil immersion field demonstrating numerous macrophages and bacterial rods in the background that did not stain.

Color 10.31
Acid-fast-positive reaction (arrow) of the bacteria in the Blue-fronted Amazon Parrot described in Color 10.30, supportive of a diagnosis of avian tuberculosis.

Color 10.32
An adult, 270 g Yellow-naped Amazon Parrot was presented in critical condition with a history of anorexia, weight loss, frequent regurgitation and loose droppings with green urates. Whole body radiographs revealed hepatomegaly and splenomegaly. The blood profile indicated marked leukocytosis, toxic heterophilia and marked elevations in serum AST. The bird died within one hour of presentation. Necropsy revealed a marked reduction of the pectoral muscle mass, sinusitis, cloudy air sacs, hep-atomegaly and splenomegaly. An imprint of the enlarged spleen was made, and the smear was stained with Diff-Quik stain. A marked number of plasma cells was noted in the splenic imprint (see Color 10.28). Also shown is a macrophage that contains small, intracytoplasmic inclusions suggestive of chlamydia.

Color 10.33
Chlamydial inclusions stained with Gimenez stain.

Color 10.34
Chlamydial inclusions stained with Macchiavello's stain.

Color 10.35
An obese, five-year-old, 125 g female cockatiel was presented for marked lethargy and dyspnea. Whole body radiographs revealed hepatomegaly. The blood profile revealed a lipemic serum sample with a normal CBC and chemistry profile. A biopsy of the liver was performed and the smear was stained with Diff-Quik stain. Shown is the typical appearance of the hepatocyte, which was enlarged and contained numerous vacuoles. The background contained round, fat droplets. The cytology is compatible with hepatic lipidosis.

Color 10.36
A severely debilitated, adult, male American Kestrel was presented with an open fracture of the right proximal humerus. The peripheral blood smear revealed a marked number of *Haemoproteus* gametocytes. The bird died 24 hours after presentation and an imprint of the spleen was made and stained with Diff-Quik stain. Round *Haemoproteus* schizonts (arrow) were found throughout the splenic imprint as shown here. There is also a large amount of dark-blue iron pigment present.

Color 10.37
An adult African Grey Parrot housed in a pet store was presented with a history of lethargy and anorexia. A blood profile revealed a moderate degenerative anemia (PCV=21%). The bird died within six hours of presentation. Gross necropsy revealed a slightly enlarged spleen. A splenic imprint was made and stained with Diff-Quik stain. Illustrated is a typical oil immersion field of the splenic imprint showing a marked amount of dark-blue iron pigment. The large amount of iron pigment was also seen histologically. This finding is suggestive of a hemolytic anemia; however, the etiology could not be found.

Color 10.38
Impression smear from the spleen of a mynah bird. Wright's stain was used to demonstrate *Atoxoplasma* sp. in macrophages. Note that the organism is causing indentation of the nucleus of the infected macrophages (courtesy of Carol Partington).

TABLE 10.3 Staining Procedures

Acid-Fast Stain
1. Air-dry then gently heat fix
2. Cover with carbol fuchsin
3. Steam over water bath (3 to 5 min.)
4. Rinse with tap water
5. Decolorize with acid alcohol until most red color is removed
6. Rinse twice in tap water
7. Cover with methylene blue stain (1 min.)
8. Gently rinse with tap water (air dry)

Gram's Stain
1. Air dry and gently heat fix slide
2. Cover with crystal violet (1 min.)
3. Gently rinse in tap water
4. Cover with Gram's iodine (1 min.)
5. Gently rinse in tap water
6. Decolorize with 95% ethyl alcohol (15 to 30 sec.)
7. Gently rinse in tap water
8. Cover with safranin (1 min.)
9. Gently rinse in tap water (air dry)

Macchiavello's Stain
1. Air dry then heat fix
2. Cover with basic fuchsin (5 min.)
3. Quickly rinse in tap water
4. Dip in citric acid one to ten times (1 to 3 sec.)
5. Rinse in tap water
6. Cover with methylene blue (20 to 30 sec.)
7. Rinse in tap water (air dry)

Modified Gimenez Stain
1. Air dry then heat fix
2. Cover with carbol fuchsin (1 to 2 min.)
3. Rinse in tap water
4. Cover with malachite green (6 to 9 sec.)
5. Rinse in tap water
6. Recover with malachite green (6 to 9 sec.)
7. Rinse with tap water (air dry)

Sudan III Stain
1. Apply stain to wet or dry smear
2. Apply coverslip

New Methylene Blue Stain
1. Completely air dry or use as a wet mount
2. Apply small drop of stain
3. Add coverslip

Stamp Stain
1. Air dry smear then heat fix
2. Cover for 10 min. with carbolated fuchsin as used for Gram's stain diluted 1:4 with water
3. Rinse with tap water
4. Differentiate in 0.5% H_2SO_4 until the preparation looks gray; time according to thickness of the smear
5. Counterstain with 5% malachite green or methylene blue (15 sec.)
6. Rinse with tap water (air dry)

Wright's Stain
1. Air dry slide
2. Flood with Wright's stain (stand 1 to 3 min.)
3. Add equal amount of Wright's buffer
4. Gently mix by blowing until a metallic green sheen is formed
5. Allow to stand twice as long as step two (2 to 6 min.)
6. Rinse with tap water (air dry)

Diff-Quik Stain
1. Air dry slide
2. Dip in fixative five times (1 sec. each)
3. Dip in solution one to five times (1 sec. each)
4. Dip in solution two to five times (1 sec. each)
5. Rinse in distilled water (air dry)

Giemsa Stain
1. Air dry slide
2. Fix in methyl or ethyl alcohol (2 to 7 min.)
3. Air dry
4. Immerse in Giemsa stain (15 to 40 min.)
5. Rinse in tap water (air dry)

CHAPTER

11

BIOCHEMISTRIES

Manfred Hochleithner

Managing abnormalities in birds requires an understanding of how disease processes change the biochemical functions of the body. Because the clinical signs of illness in birds are frequently subtle, clinical chemistries are necessary to evaluate cellular changes. Properly evaluating a biochemical profile requires knowledge of the diagnostic sensitivities and specificities of tests, correct intervals for a specific test in a given species and a list of diseases that can induce the observed changes.

Adding clinical pathology data to the anamnesis and physical examination findings is important for diagnosing most organopathies. There is a need for further documentation of the clinical and pathologic changes induced by specific diseases of all avian organ systems. Many functional disorders can be diagnosed in birds for which an exact pathomorphologic or pathophysiologic explanation has yet to be reported. Many disease reports based on postmortem findings frequently lack clinicopathologic data that would be of value to the clinician.

With many diseases, a clinician will be able to demonstrate disruption of functional integrity of an organ by means of associated clinicopathologic changes. Supportive therapy, aimed at reestablishing homeostasis, is often lifesaving and enables the body to restore normal organ function. Sometimes a cause for the organ dysfunction can be found for which a specific treatment can be given. Only when distinct diseases can be diagnosed clinically will it be possible to rationally evaluate the effects of a specific therapy.

Laboratory Considerations

Nearly all routine hematologic and biochemical investigations can be performed with blood placed in lithium heparin, the anticoagulant of choice when dealing with most avian blood samples. The ability to use one single sample for numerous different tests limits unnecessary blood wastage, which can be an important consideration when dealing with small birds. The amount of blood needed to perform a specific diagnostic test depends on the equipment and technical capacity of the laboratory. When dealing with small birds, the use of micromethods is a necessity.

A blood smear should be made immediately after the blood is collected. A hematocrit-capillary tube is filled and the amount of blood needed for a total white cell count is collected in a diluting pipette. Immediately thereafter, the sample is centrifuged to separate the plasma. Any delay in separation may cause artificial changes of several plasma chemical variables. For example, if whole pigeon or chicken blood is stored at room temperature, a rapid decline (10% in 10 minutes, 30% in 30 minutes, up to 65% in two hours) in plasma potassium concentration occurs due to a shift of potassium ions from the plasma into the red blood cells.[47]

Many reference values for avian blood chemistries are based on values determined using serum instead of plasma, or plasma from blood samples that were not centrifuged immediately. When serum is prepared for blood chemistry, it is inevitable that the blood has to stand for a certain period to allow coagulation, which can cause changes in the sample. Some authors believe that plasma is superior to serum for blood chemistry in birds.[47]

Analytic Goals

Clinical laboratory data is used by the veterinarian to answer specific questions about a patient's metabolic state. The analytic sensitivity of the test, precision with which the test is performed and the way the sample is handled during collection and processing will affect the validity of the test.

The questions that laboratory results can answer generally fall into one of five categories:

1. Is an unapparent disease present? (screening)
2. Is a particular disease process occurring? (pathophysiology)
3. Is a tentative diagnosis correct? (confirmation)
4. What is the severity of a disease process? (prognosis)
5. Has therapy favorably altered the disease process? (monitoring)

Any disease should be considered an evolving process and not a fixed condition. Diagnostic considerations include the cause (etiology), the destructive and reparative processes involved (pathogenesis), the abnormalities observed (diagnostic criteria) and the probable outcome (prognosis). With the complexity of these considerations, rarely does a single test provide a definitive understanding of the clinically apparent disease process, not to mention any subclinical changes that occur at a cellular level.

Accuracy and Precision

The two most important concepts for evaluating the analytic performance and thus the validity of any test are: 1) analytic accuracy, which is the agreement between the best estimate of a quantity and its "true" value; and 2) analytic precision, which is the agreement between replicates. Different results from the same sample may be produced by different analyzers. Likewise, repeat analysis of the same sample by the same analyzer may provide different results. This is true for all laboratory equipment including inexpensive dry chemistry units and high quality computerized analyzers.

Other considerations in interpreting test results include analytic sensitivity (the ability of an analytic method to detect small quantities of the measured component) and analytic specificity (the ability of an analytic method to determine solely the component it is designed to measure).[7,39,41,68]

Human clinical pathology laboratories have found that day-to-day variabilities in an individual patient make it difficult to accurately predict certain biochemical levels. For example, calcium is measured with an average precision of 2.0%, but the day-to-day variation in humans and mammals is around 0.9%. This means that normal analytic variations in the test can be interpreted as abnormal. Creatinine kinase, on the other hand, is usually measured with a

precision of 9.0%, which is much better than its day-to-day variation, at least in humans, of 13.0%.

In birds, some blood chemistry variables may show a circadian rhythm (ie, plasma corticosterone) or a circannual rhythm (ie, plasma thyroxine).[38a,49a] Because of these inherent problems in determining specific serum chemistry values it is important to have a basic knowledge of the technical and statistical methods used in establishing the value of these tests. Developing this working knowledge is further complicated in avian medicine due to a lack of knowledge concerning the day-to-day variations that occur in different biochemical parameters in different avian species.

To be of optimum use, clinical chemistry data must be evaluated based on the values in healthy individuals, the precision of quantitative measurements and the clinical chemistry changes characteristically expected in various pathologic states.

Reference Values – Reference Intervals

Values for any set population of living organisms will have a range that have high, median and low values. For this reason, "normal" is a state of the individual and is not a term that can be easily extrapolated from any given individual as a comparison to others. *The terminus technicus* is to compare the values of an individual to the reference intervals established to define normal limits for a healthy population.[24,65]

Reference ranges established for a population of animals are statistically reduced to reference intervals to allow discrimination between health and disease. Reference intervals of plasma chemical variables are highly dependent on the materials and methods used in the determination, and can vary among different laboratories. At best, reference intervals can be defined for a set population of birds on a given diet, maintained in a given geographic location at a given time of year.

In mammalian medicine, reference intervals are of statistical significance because of the substantial studies that have been performed to evaluate the biochemical changes that occur in various states of disease. Until reference intervals are established for birds free from subclinical infections (particularly viral diseases) and maintained on adequate diets for long periods, it will be impossible to define precise reference intervals on a population basis. Many normal values published in the literature have been collected by diagnostic laboratories, which generally receive samples from abnormal birds.

In addition to varying among populations, reference intervals may also vary among laboratories because of variation in test methods. A laboratory must be able to provide a reference interval established in that laboratory for the species and variables concerned, or the results from the laboratory will be of little value.

In interpreting clinicopathologic data, it should be noted that:

1. There are subtle changes that exist between health and disease. The concept of normality rarely exists.
2. Not all values from healthy individuals will fall within a normal reference interval (usually encompasses 95% of healthy individuals).
3. Some values from abnormal individuals will fall within the reference interval.

Reference intervals are established statistically to produce a 95% confidence interval. Because many biological data do not have a Gaussian distribution, it is often incorrect to define the reference range as the mean plus or minus two standard deviations. In most cases non-parametric statistics must be used to establish reference intervals for clinicopathologic tests because the data are not normally distributed.

If data is normally distributed, 5% of the healthy population with values that are higher or lower than the defined 95% intervals are considered abnormal. With this test evaluation system, it is accepted that there are 2.5% (one out of 40) of the normal population that fall above or below the normal range even though they are clinically healthy.

Further, reference values established for a species may not be normal for an individual. The individual may regularly have a test value that is in the lower part of the normal range. If such a bird developed pathology, the test parameter could stay within the normal range for the species, even though it is elevated for the individual. Consequently, reference values established for an individual bird are more sen-

sitive in detecting subtle abnormalities than comparing test results to reference intervals for a population. These idiosyncrasies in interpreting data confirm the importance of using laboratory tests as only one part of the patient evaluation process (in conjunction with physical examination, clinical changes, radiography) and not as diagnostic panacea.

Units of Measurement, SI Units

To be meaningful, a measurement must be expressed with both a number and a unit. The unit identifies the dimension (eg, mass, volume, concentration) of a measured property. The number indicates how many units are contained within a given sample size. Traditionally, measurements in clinical laboratories are expressed in metric units.

An International System of Units, the so-called SI Unit System (Systeme International d'Unites) was adopted in the 1970's to standardize measurements.

Standardization created a change in the numerical values of many frequently used tests. The mol, for example, indicates the amount of a substance in terms of molecules. The concentration of all substances is now expressed in terms of liters. For biochemical substances, the molar concentration per liter, which is expressed in sub-multiples (millimoles per liter - mmol/l or micromoles per liter - μmol/l) is the preferred standard of measurement.

The advantages of an accepted, worldwide standardized system are obvious. Unfortunately, the standardized system is not always used to report data. Many refereed journals continue to use the conventional rather than SI units. All publications before 1975 used the conventional units, and even in countries that are committed to SI units there are laboratory instruments still in use that produce results in conventional units. Most enzyme activities are still expressed in terms of international units per liter (IU/l or U/l) because the SI unit, the catal, has not been widely adopted. It is often necessary to convert values expressed in conventional units to SI units. Conversion tables are provided in the Appendix.

Types of Testing

Enzymology

Each cell within an organ has a specific function and contains enzymes designed to perform those functions. In some situations, enzymes are unique to specific cells within an organ, and in other cases, enzymes are found in numerous cells from various organs. When the integrity of a cell is disrupted, enzymes escape into the surrounding fluid compartment, where their activities can be measured as an index of cellular integrity.

An enzyme that is released into the serum/plasma must be easy to assay in order to be of diagnostic value. In addition, the assay must be economically feasible and indicate pathologic changes in a specific organ, or a defined small group of organs. The enzyme must also be stable in the serum/plasma for a sufficient time to permit its detection.

It is important to realize that cells must be damaged before they release enzymes into the serum/plasma. Therefore, enzymatic-based tests are a measure of cell damage, and not necessarily a measure of organ function. Anoxia causes the cell membrane to lose its integrity so that soluble enzymes from the cytosol can leak into the serum/plasma.

With liver disease, it is common to have normal histology with marked biochemical changes.This loss of integrity may be observed histologically as a swelling of the cell. Anoxic red blood cells, for example, leak cytosolic LDH into serum/plasma, causing an increase of LDH activity in a sample. Combining the values obtained for several enzymatic assays will increase the diagnostic value of the biochemical evaluation of a patient.

Enzyme activities in tissue or serum/plasma are usually in such low concentrations that it is not practical to quantitate the enzyme directly. Therefore, enzymes are measured indirectly based on their *in vitro* activity under controlled or specific conditions at which their activity is proportional to enzyme concentration. There are a multitude of methods used by different laboratories for detecting enzyme activities, and the reference intervals will vary among these laboratories despite all results being expressed in U/l. Test

values will vary depending on the substrate, buffer and incubation temperature used by the laboratory.

Metabolites

Metabolites can be measured to provide information about the functional capacity of the organs that are involved in a particular metabolic pathway. Tests are usually designed to provide measurements of endpoint metabolites. Commonly measured metabolites include: plasma ammonia, enzymes, bile acids, bilirubin, calcium, cholesterol, creatinine, glucose, inorganic phosphate, iron, total protein, urea, uric acid and triglycerides.

Electrolytes

Electrolytes may be positively charged (cations) or negatively charged (anions). Balances of these electrolytes are essential for all living matter, and commonly measured electrolytes include potassium, chloride and sodium. Trace elements including magnesium may also be determined. The major electrolytes occur primarily as free ions. The trace elements exist primarily in combination with proteins.

Hormones

It has been suggested that hormone concentrations may be good indicators of disease in humans or mammals, but their analytic accuracy and precision are difficult to evaluate in birds.[50,62,37] Hormones are usually detected using a radio-immunoassay (RIA) or an ELISA, both of which require an antigen/antibody reaction. Nonspecific cross-reactions that occur when tests designed for mammalian hormones are used for bird plasma can lead to questionable results.

Assay Methods

Historically, wet chemistry systems have been used for evaluation of blood parameters. Wet chemistry means that liquid reagents act with a certain volume of sample under strictly defined constant conditions (eg, temperature, pH, time) and produce a change of color that is proportional to the concentration of substances or the activity of enzymes. As the indicator dye changes color, the reaction is read spectrophotometrically. Because the reagents can be prepared in the laboratory, the cost for frequently used tests is inexpensive on a per test basis. The minimum sample size often depends on whether reagents are added by hand (older systems that may require 100 to 200 µl/parameter) or automatically (Autoanalyzer Two only requires 20 µl/parameter).

With dry chemistry systems,[30,35,42] test reagents are dried in layers and are dissolved by the fluid in a sample. Incubation steps, reaction time and factors for calculation of the results are all contained within the reagent strip or slide. The technician need only apply the sample and wait for the result. Like a wet chemistry test, the reaction causes a change in color that is measured photometrically by light reflectance. Specific strips or slides are needed for each test, and these are available only from the manufacturer. When compared to wet chemistry tests, dry chemistry assays are more expensive.

Indices

Biochemical tests that can be used to evaluate avian patients will be discussed in alphabetical order within three specific groups: enzymes (see Table 11.2), metabolites (see Table 11.3) and electrolytes.

The discussion of each test will include:

- ***Sample:*** Recommendations for the best sample to collect for testing are listed in Table 11.1. Specific concerns with respect to sample handling are discussed with all indices.
- ***Method:*** An overview of the common assay techniques designed to show why results will vary between different laboratories.
- ***Physiology:*** The physiologic role of the parameter in the bird.
- ***Diagnostic Value:*** The validity of a parameter in suggesting or confirming the presence of disease.
- ***Physiologic Influence:*** The influence of physiologic conditions on a test assay.
- ***Pathologic Changes:*** The effect that pathologic changes have on test values with reference to special literature.

Reference intervals for different avian species using various testing methods are provided in the Appendix.

TABLE 11.1 Recommended Samples for Biochemical Tests[41]

Tissue Enzymes	Sample
ALT	Hemolysis-free plasma or serum
AP	Heparinized plasma or serum
AST	Heparinized plasma or serum
CPK	Serum is preferred. Citrate and fluoride inhibit CK activity.
GGT	EDTA plasma or serum (see text)
GLDH	Heparinized plasma or serum
LDH	Hemolysis-free plasma or serum
Metabolites	**Sample**
Plasma Ammonia	EDTA (see text)
Amylase	Heparinized plasma or serum
Bile Acids	Heparinized plasma or serum
Bilirubin	Heparinized plasma or serum
Calcium	Heparinized plasma or serum (see text)
Cholesterol	Heparinized plasma or serum
Creatinine	Heparinized plasma or serum
Glucose	Heparinized plasma or serum (see text)
Iron	Heparinized plasma or serum
TIBC	Heparinized plasma or serum
Lipase	Heparinized plasma or serum
TP	Heparinized plasma or serum
Triglycerides	Heparinized plasma or EDTA plasma
Urea	Heparinized plasma or serum
Uric Acid	Heparinized plasma or serum
Electrolytes	**Sample**
Chloride	Heparinized plasma or serum
Potassium	Heparinized plasma or serum
Sodium	Heparinized plasma or serum

TABLE 11.2 Causes of Tissue Enzyme Increased Activities[41]

Enzyme	Activity	Causes of Increases
ALT	Present in most tissues 1.6 times higher in RBCs than plasma	Cell damage (nonspecific)
AST	Liver, heart, skeletal muscle, brain, kidney	Mainly liver or muscle disease Vitamin E/Se deficiencies
AP	Mainly duodenum and kidney Low activity in liver	Increased cellular activity (not damage) Higher in juveniles Egg-laying
CK	Skeletal muscle, heart muscle, brain	Mainly muscle damage IM injections Neuropathies Vitamin E/Se deficiencies Lead toxicity
GGT	Biliary and renal tubular epithelium	Hepatocellular damage Some renal diseases
GLDH	Mitochondrial enzyme found in most tissues Liver, kidney, brain	Hepatocellular necrosis
LDH	Skeletal muscle, cardiac muscle, liver, bone, kidney, RBCs	Hemolysis Hepatic necrosis Muscle damage

Enzymes

Alanine Aminotransferase ALT (GPT)

- ***Method:*** It is not possible to monitor transaminase (ALT and aspartate aminotransferase AST) reactions directly; however, continuous monitoring assays can be performed by coupling the transaminase reactions to specific dehydrogenase reactions. Because of the value of AST and ALT activities in diagnosing disease, standardization of reference methods for these two enzymes have been given priority by national and international groups. These groups have chosen a coupled-reaction with malate or lactate dehydrogenase as the indicator enzymes. These methods differ with respect to substrate concentration, nature of buffer and assay temperature.[68]

- ***Physiology:*** Alanine aminotransferase and AST belong to a group of enzymes that catalyze interconversion of amino acids and oxoacids by the transfer of amino groups. While there are numerous enzymes involved in the conversion cascade, AST and ALT are the two enzymes of greatest clinical importance.

- ***Diagnostic Value:*** Alanine aminotransferase activity occurs in many different tissues. Specific diagnostic value of these enzymes in birds is poor. In many cases, patients with severe liver damage have had normal ALT activities, reflecting a low level of enzyme activity in liver cells from certain species. Alanine aminotransferase activities often increase due to damage in many different tissues. In some avian species, normal ALT activities are below the sensitivity of many analyzers.[35,36]

- ***Pathologic Changes:*** Elevated activities are difficult to interpret, and this enzyme has limited usefulness in birds because it can be increased by pathologic changes in almost all tissues. Activity in erythrocytes is 1.6 times higher than in plasma, and hemolysis will cause elevated activities.[50]

- ***Physiologic Influence:*** Age-dependent elevation (increased activity with aging) of enzyme activity has been described in birds.[25] In raptors, seasonal variation in ALT activities has been reported. These changes were independent of reproductive activity.[22]

Alkaline Phosphatase - AP

- ***Method:*** Numerous methods of determining AP activity are currently used. The variety of methods in

use make it difficult to compare AP activities between laboratories or reference literature.

- ***Physiology:*** Alkaline phosphatase operates at an alkaline pH and is possibly involved in energy transfer for exchange of ions across the cell membrane. Alkaline phosphatase activity has been found to occur predominantly in the duodenum and kidney. Low AP activities were reported in the liver with no activity in other organs of pigeons.[50,51] Similar findings have been described in chickens[8] and turkeys.[9] Most enzyme assays are used to document damage to cells resulting in enzyme release. In contrast, plasma AP activity is induced by increased cellular activity (increased synthesis) rather than cell damage.

- ***Diagnostic Value:*** Alkaline phosphatase activities may be elevated due to irritation of the cells in different tissues. Increased activities have no specific importance.

- ***Physiologic Influence:*** Juvenile birds have significantly higher AP activities from bone growth and development than adults.[15,16,17,32] In hens, activities are elevated prior to egg laying.[28] Seasonal variations in activities have been described.[4]

- ***Pathologic Changes:*** Elevations are most common with liver disease even though the level of activity in this organ is low. Hyperparathyroidism-induced stimulation of osteoplastic activity may also cause increased AP activity. Enteritis has been described as a cause of higher AP activities but activity of this isoenzyme is labile and difficult to measure.[36] Aflatoxin B_1 intoxication with massive liver destruction in pigeons, cockatiels, Red-tailed Hawks and Great Horned Owls was not found to significantly increase AP activity.[13] Low AP activities have been linked to dietary zinc deficiencies.

Aspartate Aminotransferase - AST (GOT)

- ***Method:*** See ALT.

- ***Physiology:*** See ALT.

- ***Diagnostic Value:*** High AST activity has been described in liver, skeletal muscle, heart, brain and kidney cells. The distribution of AST in avian tissues varies among the species.[43,25,50] Elevated activities are usually indicative of liver or muscle damage. Aspartate aminotransferase activity provides the best information when combined with other more specific tests.[49,36] Creatinine kinase activity can be used to exclude muscle damage as a cause of increased AST activity.

- ***Physiologic Influence:*** Aspartate aminotransferase values are age-dependent to varying degrees among different species.[25,15,16,17] The cause of this age-dependent increase in activity has not been defined. Gender differences have not been described.[4,32]

- ***Pathologic Changes:*** In general, AST activities in birds greater than 230 U/l are considered abnormal. Abnormal activities have been linked to vitamin E, selenium or methionine deficiencies,[25] liver damage (particularly psittacosis or Pacheco's disease virus),[23,61,63] pesticide and carbon tetrachloride intoxication[43] and muscle damage. Intramuscular injections of irritating substances may cause elevation of CK with no increases in AST activity. In other patients, both the CK and AST activities will increase post-injection.

Creatinine Kinase - CK (CPK)

- ***Method:*** Numerous colorimetric, fluorimetric and coupled enzyme assays have been developed to detect CK activity.[68]

- ***Physiology:*** Creatinine kinase functions in skeletal muscle, heart muscle and brain tissue. In muscle, this enzyme makes ATP available for contraction by the phosphorylation of ADP from creatinine phosphate. There are three isoenzymatic forms of CK that can be separated by electrophoresis. In mammals, quantization of isoenzymes can be used to determine the tissue source of the enzyme.[39,68] There have been no reported attempts to separate tissue-specific creatinine kinases in birds.

- ***Diagnostic Value:*** Elevations in activities are mostly seen because of muscle cell damage. This enzyme has value in distinguishing muscle from liver cell damage. However, the clinician should consider that muscle and liver cell damage can occur simultaneously from the same or different pathologic processes.

- ***Physiologic Influence:*** In mammals, CK activity is subject to a number of physiologic variations (eg, muscle mass of an individual, gender, age, physical activity).[39,68] Physiologic changes of CK are well known and are also described in avian species. CK activity in healthy turkeys is extremely sensitive to physical stress and exercise[50] Neither gender[32] nor age[15,16,17] has been shown to significantly affect CK activity.

- ***Pathologic Changes:*** Increase in CK activity has been linked to muscle cell necrosis, convulsions, intramuscular injections (depending on the volume and degree of irritation), vitamin E and selenium defi-

ciencies, neuropathies, lead toxicity and occasionally chlamydiosis.[36,43]

Gamma Glutamyl Transferase - GGT

- ***Sample:*** EDTA plasma or serum can be used to determine GGT activity. Heparin will interfere with the test reactants causing turbidity; citrate, oxalate and fluoride may artificially depress activity.[68]

- ***Method:*** Reagent kits for GGT determination use different substrates that have different sensitivities. Results are totally dependent on the assay used.[68]

- ***Physiology:*** Peptidases constitute a broad group of enzymes of varied specificity, and some individual enzymes catalyze the transfer of amino acids from one peptide to another amino acid or peptide. Gamma glutamyl transferase cleaves the gamma-glutamyl group from peptides and moves them to an appropriate accepter. This is primarily a brush border enzyme with greatest activity in the biliary and renal tubular epithelium. Serum activity is from biliary origin.

- ***Diagnostic Value:*** Little is known about the significance of plasma GGT activity for the diagnosis of hepatobiliary disease in birds. In racing pigeons GGT has been found to be a specific indicator for liver disease. One investigator reported measurable activities in the kidney and brain of pigeons, and the kidney and duodenum of budgerigars.[50] Another investigator[13] concluded that GGT is not a sensitive test for the detection of liver disease in different avian species. Enzyme activity in normal birds typically falls below the sensitivity range of most analyzers.

- ***Pathologic Changes:*** Elevations in GGT activity have been described in association with liver disease, but not on a regular basis.[36] The highest levels of activity have been reported in the kidneys. However, elevations do not always occur with renal disease, probably because the enzyme is excreted in the urine.

Glutamate Dehydrogenase - GLDH

- ***Method:*** Methods for the determination of GLDH can be based upon both forward and reverse reactions, and results are dependent on the temperature of the reaction.[68]

- ***Physiology:*** Glutamate dehydrogenase is a mitochondrial enzyme found in numerous tissues.

- ***Diagnostic Value:*** Significant amounts of this enzyme have been found in the liver, kidney and brain of chickens, ducks, turkeys and racing pigeons.[50,51] In budgerigars, the highest enzyme activity has been reported in the kidney.[50] Significant elevations have been observed in birds with liver disease, but few reference intervals are available for avian species.[36]

- ***Physiologic Influence:*** Glutamate dehydrogenase is present in normal serum only in trace amounts. No physiologic variations have been described for this enzyme.

- ***Pathologic Changes:*** Activity in plasma or serum is increased in all conditions in which hepatocellular damage is present. As an exclusive mitochondrial isoenzyme, GLDH is released from cells that are necrotic or markedly injured. Therefore, activities are lower in inflammatory processes that do not result in cellular necrosis.

- ***Reference Intervals:*** Hyacinth Macaw - 0 to 1 U/1 (method, temperature not described)[54]; Psittacines - < 2 U/1 (German Society of Clinical Chemistry, 25°C).[36]

Lactate Dehydrogenase - LDH

- ***Sample:*** Heparinized plasma or serum are satisfactory if hemolysis is not present. Serum must be separated from the clot immediately to prevent LDH contamination of the sample caused by damaged erythrocytes. Plasma containing other anticoagulants, especially oxalate, should not be used.

- ***Method:*** Numerous LDH assays have been introduced over the last 25 years. Procedures use the forward (lactate to pyruvate) or the reverse (pyruvate to lactate) reactions in almost equal numbers. Methods using the forward reaction are more expensive and less precise, but have fewer problems with substrate inhibition of the test.

- ***Physiology:*** Lactate dehydrogenase functions in glycolysis. Erythrocytes contain high activities of LDH, and *in vitro* hemolysis will result in falsely elevated values. There are five LDH isoenzymes, each of which occurs in a wide variety of tissues, in particular skeletal muscle, cardiac muscle, liver, kidney, bone and red blood cells. Electrophoretic separation of the isoenzymes can help establish the source of increased activity, but is seldom used in veterinary laboratories.

- ***Diagnostic Value:*** Although this enzyme is not specific for any organ, elevations are most common with hepatic disease in psittacines. Lactate dehydrogenase activities are thought to rise and fall more quickly than AST activities in birds with liver disease.[61] These differences may provide information on the chronicity of liver disease.

- ***Physiologic Influence:*** Seasonal variations[43] and gender differences[32] in LDH activities have been described. The highest physiologic activities have been reported in canary finches.[64]
- ***Pathologic Changes:*** Elevated enzyme activity can be observed due to liver and muscle damage.

Nutrients and Metabolites

Plasma Ammonia

- ***Sample:*** EDTA is the anticoagulant of choice. Lithium heparin can be contaminated with ammonium heparin, which will lead to falsely elevated values. Samples must be analyzed immediately because ammonia is released through the catabolism of various substances (eg, urea).[11] Ammonia levels in serum are significantly but variably higher than corresponding plasma values.[68]
- ***Method:*** There are several techniques for the determination of ammonia. In private practice, the dry chemistry method used by the Kodak Ektachem System can be used. This assay measures creatinine and ammonia in two different steps.
- ***Physiology:*** Blood ammonia is principally absorbed from the intestines, although some is derived from protein catabolism, particularly in the skeletal muscles. Normally, ammonia absorbed from the bowel is converted into uric acid and urea in the liver, and blood concentrations of ammonia are maintained at a low level.
- ***Diagnostic Value:*** Little data is available on the use of ammonia concentrations as a diagnostic test in birds.
- ***Pathologic Changes:*** High blood ammonia concentrations may indicate reduced liver function or ammonia poisoning. Ammonia toxicity usually occurs from buildup of ammonia gases in poultry houses and has rarely been reported in companion birds. Atmospheric ammonia can contaminate a blood sample that is left open in room air.
- ***Reference Values:*** Budgerigar - 7-141 μmol/1 (Kodak Ektachem, 25°C).[32]

Amylase

- ***Method:*** Some 20 methods have been described for assaying amylase activity. These tests are based on nine different principles, and various substrates and reference intervals are dependent on the detection method used. With dry chemistry units, the amylase

TABLE 11.3 Causes of Increases in Metabolic Tests[41]

Metabolite	Comments	Causes of Increases
Ammonia	Absorbed from intestines Released through catabolism	Old sample Decreased liver function Ammonia poisoning
Amylase	Derived from pancreas, liver, small intestine	Pancreatitis Enteritis
Bile acids	Indicator of liver function and enterohepatic circulation	Reduced liver function
Biliverdin	Major bile pigment	Liver disease
Calcium		Hyperproteinemia (dehydration) Ovulating hens Osteolytic bone Hypervitaminosis D
Cholesterol	Precursor of steroid hormone Precursor of bile acids Component of cell membranes	Lipemia (high fat diet) Fatty liver degeneration Males > females Liver disease Hypothyroidism Bile duct obstruction Starvation
Creatinine	Derived from catabolism of creatine	Low sensitivity Severe renal disease Decreased filtration rate Egg-related peritonitis Septicemia Nephrotoxic drugs Renal neoplasias
Glucose	Energy source	May be higher in neonates Variation in age, time of day, stress Diabetes
Phosphorus	Diagnostic value poor	Renal disease Secondary hyperparathyroidism Hypoparathyroidism Hemolysis
Iron	Unknown	Pre-ovulatory period
TIBC		Iron deficiency
Lipase	Produced in pancreas	Possibly with pancreatitis
TP		Advancing age Pre-ovulatory period Immune stimulation Dehydration Chronic infections
Triglycerides		Egg-related peritonitis Hyperadrenocorticism? Exercise
Urea		Low urine flow Dehydration Bilateral ureteral obstruction
Uric acid	Synthesized mainly by the liver Excreted by the renal tubules	Postprandial Renal disease Ovulation Decreased glomerular filtration Tissue damage Starvation Hepatocellular disease

activity of approximately 30% of avian samples will exceed the upper range limit of the test. Samples that exceed the test limit must be diluted and reanalyzed.

- ***Physiology:*** Amylase occurs in plasma as a number of isoenzymes that are principally derived from the pancreas, liver and small intestine. In birds, the isoenzymes have not been separated, making it impossible to determine which specific tissues are responsible for increased plasma amylase activity.

- ***Diagnostic Value:*** Little information is available on amylase activity in birds. In some cases it has been found to be useful in the diagnosis of neuropathic gastric dilatation.[36]

- ***Pathologic Changes:*** Increased enzymatic activity can be seen with acute pancreatitis. In these cases enzyme activity may exceed three times the upper limit of the reference interval. Activities less than twice the upper limit of the reference interval are sometimes seen in macaws with severe enteritis in the absence of pancreatic lesions. In most cases of neuropathic gastric dilatation, amylase activity is normal or only slightly elevated.[36]

- ***Reference Values:*** Budgerigars (187-582 U/1); African Grey Parrots (211-519 U/1); Amazon parrots (106-524 U/1); macaws (276-594 U/1) (Kodak Ektachem, Amylopectin, 25°C).[33]

Bile Acids

- ***Method:*** Several assays have been used to quantitate either total or individual bile acids. The most frequently used assays are gas liquid chromatography, high performance liquid chromatography, enzymatic assays and immunoassays (RIA, ELISA). Among these, RIA and enzymatic methods are mainly used by commercial laboratories. RIA-derived values are not comparable to those detected using other methods. Nonspecific cross reactions occur when human anti-bile acid antibodies are used to detect bile acids in bird plasma; therefore, enzymatic methods seem to be the assay of choice for use in birds.

- ***Physiology:*** The liver synthesizes the primary bile acids (cholic acid and chenodeoxycholic acid). It then excretes these acids as sodium salts into the bile. With the ingestion of food, bile is carried via the bile duct into the small intestine where the bile acids act principally as emulsifying agents in fat digestion and absorption. Most bile acids that enter the gastrointestinal tract are reabsorbed in the distal small and large intestines where they return, via the portal circulation, to the liver. They are then extracted from the blood and recycled. Only a small percentage of the total pool of bile acids is lost in the feces each day. A small quantity of the total bile acids reabsorbed from the gastrointestinal tract is not removed from the blood by the liver and reaches the general circulation. It is this fraction of unextracted bile acids that is measured. The quantity of bile acids in the plasma normally increases following the ingestion of food.

- ***Diagnostic Value:*** If liver function is impaired, bile acids are not properly reabsorbed from the blood, and consequently the proportion of excreted bile acids reaching the peripheral circulation increases. Circulating bile acids can therefore be used as a sensitive indicator of liver function, and of the integrity of the circulation through the liver, biliary tract and intestines. It has been suggested that chronic liver disease that results in cirrhosis may decrease the production of bile acids with a subsequent decrease in the plasma. This may be particularly true in a postprandial sample. Further investigations are needed to determine if decreased bile acid concentrations are a reasonable indicator of a loss of functional liver mass. Low bile acid concentrations are common in birds with microhepatia (as detected radiographically), poor feather formation and an overgrown, malformed beak.

- ***Physiologic Influence:*** A significant postprandial increase of bile acids has been documented in racing pigeons and the Mallard Duck. Healthy birds with a gall bladder may not have significantly different postprandial bile acid concentrations when compared to species that do not have a gall bladder.[55]

- ***Pathologic Changes:*** Elevations in bile acids have been shown to correlate with liver disease in pigeons,[55] chickens[10] and African Grey Parrots.[50] With further research, bile acid assays may prove to be one of the best tests for liver function in birds.[38] Bile acids are stable in plasma for prolonged periods, allowing shipment of specimens to distant laboratories for analysis.

- ***Reference Intervals:*** African Grey Parrots (18-71); Amazon parrots (19-144); cockatoos (23-70); macaws (25-71).

Bilirubin

- ***Method:*** Most methods for measuring bilirubin are based on the diazo reaction, in which diazotized sulfanilic acid reacts with bilirubin to produce two azodipyrroles. These products are reddish purple at neutral pH, and blue at low or high pH.

- ***Physiology:*** In birds, the major bile pigment is biliverdin. The enzyme biliverdin reductase is absent, and biliverdin is not converted into bilirubin.[44,45]

- ***Diagnostic Value:*** Low concentrations of bilirubin were detected in the sera of healthy ducks. Concentrations increased following infection with duck hepatitis virus.[1] The diagnostic value of bilirubin appears to vary among species. It has no value in chickens that cannot form bilirubin, but may be of value in other species.

- ***Pathologic Changes:*** Bilirubin cannot normally be detected in plasma of normal psittacines. With severe hepatic disease (eg, chlamydiosis or Pacheco's disease virus) bilirubin concentrations up to 44.5 μmol/l have been reported. A slight yellow coloration (icterus) could be seen in the facial skin of two macaws with bilirubin concentrations exceeding 40 μmol/l.

Calcium

- ***Sample:*** Heparinized plasma or serum can be used. Some calcium-binding anticoagulants, like EDTA, citrate and oxalate (fluoride oxalate is used for determining glucose levels in mammals) will cause falsely low values. For the determination of ionized calcium levels, whole blood, heparinized plasma or serum can be used, but the pH of the specimen must be the same as that of the patient's blood at the time of sampling. This is most readily achieved by collecting and processing the specimen quickly and anaerobically.

- ***Method:*** Total calcium concentrations include the sum of biologically active ionized calcium, protein bound calcium (which is bound mainly to albumin) and calcium chelated with anions, like phosphate or citrate. Bound calcium is biologically inactive and can be decreased (thus decreasing the measurement of total calcium) without causing any clinical effects. Of the many methods described to measure total calcium, atomic adsorption spectrophotometry and spectrophotometry of calcium-dye complexes are most often used. Ionized calcium levels have been shown to be clinically valuable; however, this is not a commonly available assay.

- ***Physiology:*** As a major constituent of bone, calcium plays a vital role in the structure of the body. It also has important physiologic functions involving the transmission of nerve impulses, the permeability and excitability of all membranes, the activation of enzyme systems (eg, blood clotting), calcification of egg shells and contraction of the uterus during oviposition.

- ***Diagnostic Value:*** Total calcium should always be interpreted along with albumin concentrations. Hypoalbuminemia will reduce the quantity of bound calcium and result in a decreased total calcium concentration without reducing biologically active calcium (ionized fraction).[31,36,53] The hyperproteinemia that occurs with dehydration may result in an increased total calcium concentration.

- ***Physiologic Influence:*** Ovulating hens have significantly higher calcium levels than non-reproductively active females. Female budgerigars were found to have significantly higher calcium concentrations than males. Young birds generally have lower calcium concentrations than adults.[32,27]

- ***Pathologic Changes:*** Decreased calcium concentrations are common in seizuring African Grey Parrots. This hypocalcemia syndrome has been described as a unique form of hypoparathyroidism in which calcium is not properly released from bone.[31,33,36] Glucocorticoid therapy will decrease total calcium concentrations. Increased calcium concentrations have been reported with dietary excesses of Vitamin D, osteolytic bone tumors and dehydration. Even in cases of severe dietary calcium deficiency, parahormone will normally mobilize bone to maintain calcium blood concentrations within physiologic limits.

Cholesterol

- ***Method:*** Cholesterol consists of both free cholesterol and cholesterol esters, which are measured together as total cholesterol. Either enzymatic or chemical methods can be used for quantification. Enzymatic procedures have virtually replaced chemical methods in the clinical laboratory. The initial reaction steps are common to all enzymatic procedures. These include the hydrolysis of cholesterol esters to form free cholesterol, which is measured after a subsequent oxidation step utilizing O_2 to produce H_2O_2.

- ***Physiology:*** Cholesterol is a major lipid that is a precursor of all the steroid hormones and bile acids as well as a component of the plasma membrane of cells. It is obtained from the animal protein sources in the diet as well as being synthesized by the liver.

- ***Diagnostic Value:*** Elevated and decreased cholesterol concentrations may occur from a number of physiologic influences and different diseases; however, the diagnostic value of this test in birds appears to be poor. Very high cholesterol concentrations usually accompany lipemia, especially in Amazon parrots, macaws and Rose-breasted Cockatoos with fatty liver degeneration.

- ***Physiologic Influence:*** Cholesterol concentrations will vary with a bird's diet. Carnivorous birds have higher concentrations, whereas fruit- or grain-eating birds have lower concentrations.[43] Male budgerigars were found to have significantly higher cholesterol concentrations than females.[32]

- ***Pathologic Changes:*** Elevations can occur because of hypothyroidism, liver disease, bile duct obstruction, starvation or high fat diets.[2,25,73,36] High cholesterol concentrations have been reported in budgerigars with xanthomatosis.[36] Decreased cholesterol levels have been associated with some cases of liver disease, aflatoxicosis,[73] reduced fat in the diet, *Escherichia coli* endotoxemia and spirochetosis.[25]

Creatinine

- ***Method:*** Most currently used assays are based on the Jaffe reaction.[68] This reaction occurs between creatinine and the picrate ion formed in an alkaline medium.

- ***Physiology:*** Blood creatinine is derived mainly from the catabolism of creatine found in muscle tissue. Phosphocreatine is used to store energy in muscle, and its catabolism to creatinine occurs at a steady rate. Excretion of creatinine is solely via the kidneys. It is freely filtered and reabsorbed in the tubules.[25] In birds, creatine is excreted in urine before it has been converted to creatinine.[6] The urinary excretion of creatine may be one reason that creatinine levels do not provide an accurate assessment of avian renal function.

- ***Diagnostic Value:*** There is a slim margin between the physiologic and pathologic levels of creatinine. For many analyzers, physiologic values are below the detectable range. This test parameter is very insensitive and is a relatively poor diagnostic test in birds.

- ***Physiologic Influence:*** Normally, creatinine production is relatively constant and is minimally affected by catabolism of dietary or tissue proteins. Theoretically, the pool of creatine from which creatinine is liberated depends on the total muscle mass. However, in all avian species that have been investigated, the reference interval for creatinine has been between 0.1-0.4 mg/dl, with no significant differences between species.

- ***Pathologic Changes:*** Severe kidney damage can lead to increased creatinine levels, especially if the filtration rate is decreased. Elevations have also been described in connection with egg-related peritonitis, septicemia (eg, chlamydiosis), renal trauma and nephrotoxic drugs.[43]

Glucose

- ***Sample:*** Heparinized plasma or serum can be used. For reliable glucose determination in avian blood, it is not necessary to prevent glycolysis as long as the blood is not stored for more than two hours.[57] This is contrary to the situation in mammals in which sodium fluoride is often used to ensure accurate glucose determinations. This is because avian erythrocytes consume very little, if any, glucose, and depend primarily on fatty acid metabolism for energy.

- ***Method:*** Glucose levels may be determined using enzymatic (eg, hexokinase) or colorimetric (eg, toluidine) techniques. There is a reasonable agreement in the values among the most commonly used methods.[68] Simple colorimetric tests in the form of a dip stick have been used with some success in birds. Lipemia or hemolysis of the sample can interfere with photometric methods of measurement, giving falsely elevated values.[11] This is less likely to occur with kinetic assays that evaluate a change in optical density over time and are therefore self-blanking.

- ***Physiology:*** Glucose is continuously required as an energy source by all the body cells and must be maintained at adequate levels in plasma. Glucose levels are maintained principally through the conversion of liver glycogen, with some being derived from non-carbohydrate sources (hepatic gluconeogenesis). In periods of starvation, glucose is increasingly derived from the breakdown of fats and proteins, primarily from muscle tissue, through gluconeogenesis in the liver and the kidneys. All plasma glucose is filtered from the blood through the renal glomeruli and then totally reabsorbed in the tubules.

  Interestingly, 73 hours of starvation in pigeons induces hyperglycemia rather than starvation hypoglycemia.[57] This finding has important consequences for avian anesthesia and gastrointestinal surgery, as presurgical fasting varying from four hours (emptying of the crop) to 24 hours (emptying of the entire gastrointestinal tract) can be advantageous. Prolonged fasting is not recommended in birds that weigh less than 100 grams.

- ***Diagnostic Value:*** Glucose is often a part of a laboratory panel[25,43,73] even though pathologic changes in birds are seldom detected.[36] Glucose should be evaluated in convulsing birds or those with glucosuria.

- ***Physiologic Influence:*** Plasma glucose levels are higher in juvenile than adult budgerigars.[32] Variations also occur due to time of day and amount of environmental stress.[43] Plasma glucose concentrations in fasted birds are subject to a circadian rhythm. A rise in plasma glucose concentration starts during the scotophase, reaching peak values early during the photophase. Subsequently, a gradual increase can be observed with the lowest values at the end of the photophase. Afternoon plasma glucose concentrations in birds that are fed early during the photophase are significantly higher when compared to fasted birds.[57]

- ***Pathologic Changes:*** Increases in plasma glucose levels are due to increased glucose production or release. For example, increases occur after meals, with excitement or stress or because of decreased glucose usage (diabetes mellitus).[2,25,50,73] Diabetes mellitus has been confirmed in budgerigars, cockatiels, Amazon parrots, Scarlet Macaws, Umbrella Cockatoos and a Toco Toucan.[43] Transient elevations in glucose have been reported in cockatiels with egg-related peritonitis.[63] Decreases in plasma glucose levels can be due to hepatic dysfunction (eg, Pacheco's disease virus), impaired glucose production or its excessive utilization (eg, septicemia, neoplasia, aspergillosis).[61,63] In young birds of prey, hypoglycemia can cause convulsions.[36] Starvation of up to four days' duration will not cause hypoglycemia in all birds, but in some (particularly raptor neonates), hypoglycemia can occur after a few days of anorexia.[50] Glucose concentrations can be artificially decreased during storage if the blood sample is contaminated with bacteria.[34]

Phosphorus

- ***Sample:*** Heparinized plasma or serum is suitable. Anticoagulants such as citrate, oxalate or EDTA should not be used because they interfere with the formation of the phosphomolybdate complex. Hemolysis must be avoided, because the phosphate concentration of erythrocytes is higher than that of plasma, and hemoglobin interferes with the colorimetric detection reaction used to determine phosphorus levels.

- ***Method:*** Most assays for inorganic phosphate rely on the formation of a complex of phosphate ion with a molybdate compound.[20]

- ***Physiology:*** Inorganic phosphorus is derived from the diet. It is a major constituent of bone and a vital cellular component, playing important roles in the storage, release and transfer of energy and in acid-base metabolism.

- ***Diagnostic Value:*** Changes in inorganic phosphorus concentration can occur with several diseases, but not on a consistent basis. The diagnostic value is poor.

- ***Physiologic Influence:*** Diets that consist mostly of seeds may lead to increased phosphorus levels. Juvenile budgerigars were found to have higher concentrations than adults.[32] No changes in inorganic phosphorus levels were noted in laying hens.[43]

- ***Pathologic Changes:*** Increased plasma inorganic phosphate levels can be seen in some cases of severe kidney damage [2,36,73] due to vitamin D hypervitaminosis,[2] nutritional secondary hyperparathyroidism[43,73] and hypoparathyroidism.[31,33] False elevations will occur if samples are hemolyzed. Occasionally, decreased plasma inorganic phosphate levels may occur from hypovitaminosis D (calcium level also decreased), malabsorption because of phosphate binding agents in the diet (calcium normal) and long-term glucocorticoid therapy.

Iron

- ***Sample:*** Heparinized plasma or serum can be used. Plasma specimens collected with EDTA, oxalate or citrate are unsatisfactory, because they bind iron. Markedly hemolyzed specimens are nondiagnostic because free hemoglobin will increase the total serum iron levels.

- ***Method:*** For iron level assays, reduced Fe (II) is complexed with a chromogen. This complex has a high light absorbance that is proportional to the iron concentration.[68] Most assays require a large sample size (200 μl).

- ***Physiology:*** Iron is an essential constituent of the heme portion of hemoglobin. As the hemoglobin in aged erythrocytes is broken down, iron is recycled and fresh hemoglobin is synthesized. Iron is transported in the plasma attached to a β-1-globulin known as transferrin.

- ***Diagnostic Value:*** The value of determining iron in different avian species has not been thoroughly investigated. A recent report shows a failure to correlate serum iron levels with liver biopsy and subsequent toxicologic analysis for iron.[75]

- ***Physiologic Influence:*** Prior to egg laying, iron levels will increase two to three times normal in some species.[25] Raptors maintained in captivity have significantly lower values than their free-ranging counterparts.[36] Captive toucans have approximately three

times higher reference values of iron than psittacine birds (see Chapter 47).[74]

- ***Pathologic Changes:*** Severe and chronic loss of blood will increase iron values. Iron deficiency anemia has been described in raptors.[40] Changes in plasma iron levels in mynah birds and toucans with iron storage disease are described in Chapter 47.

Total Iron-Binding Capacity (TIBC)

- ***Method:*** An excess amount of ferric ammonium citrate is added to serum to saturate the transferrin iron-binding sites. The unbound Fe (III) is removed and the iron content of the supernatant is assayed as described for iron.[68]

- ***Physiology:*** Normally, only one-third of the iron-binding sites of transferrin are occupied by Fe (III), creating a reserve of iron-binding sites. The total iron-binding capacity (TIBC) is a measurement of the maximum concentration of iron that serum proteins, principally transferrin, can bind. A urine iron-binding capacity (UIBC) test is also available.[75]

- ***Diagnostic Value:*** Abnormalities in TIBC occur with some disorders of iron metabolism. Very little data from birds is available. This parameter appears to have little importance in diagnosing hemochromatosis, but insufficient research has been performed.[74,75]

- ***Pathologic Changes:*** TIBC may be increased with iron deficiency and decreased in chronic inflammatory disorders.

Lipase

- ***Method:*** There are various methods for determination of lipase activity, and the reference ranges depend on the method used.

- ***Physiology:*** Lipase measured in plasma or serum is produced in the pancreas. This enzyme functions in the digestion of fat in the diet.

- ***Diagnostic Value:*** Lipase and amylase activities were high in a caique with clinical signs of pancreatic exocrine insufficiency when compared to the activities of these enzymes in the mate (Ritchie BW, unpublished). Hemolysis inhibits enzyme activity.

- ***Pathologic Changes:*** Although no reference values are currently available, birds do exhibit high lipase activity in severe cases of acute pancreatitis. For diagnostic purposes, a blood sample from a representative of the same species should be included for comparison.

Total Protein (TP)

- ***Sample:*** When only small amounts of blood can be collected, it may be advantageous to use plasma instead of serum to determine the TP concentration. In pigeons, the concentration of TP in plasma is about 1.5 g/l higher than in serum, because the former contains fibrinogen.[58a]

- ***Method:*** Total protein levels may be determined using a chemical method or a refractometer. The chemical method of choice is the biuret method, which measures the TP in fluids colorimetrically using the formation of a blue peptide (copper complex in alkaline solution). This method is extremely accurate for the protein levels typically found in plasma or serum (1 to 10 g/dl), but is not precise enough to determine the low concentrations of proteins that are found normally in other body fluids. Both wet and dry chemistry methods use this technique, but the results vary with the instrument used.

  Most commercial laboratories use a human standard when determining TP and albumin concentrations, and various studies have shown that there are significant differences between TP concentrations when different standards are used (eg, human, bovine, pigeon, chicken). Because it is impossible to have a species-specific standard for all species presented to the avian practitioner and because there is a high correlation between the results obtained with the various standards, it seems wise to establish reference values for the various species using the human standard.[53]

  The refractometer is widely used by veterinarians to measure change in the refractive index of a solution, which is caused mainly by the proteins in solution and is proportional to the concentration of total solids or protein. Most refractometers are temperature-compensated and already calibrated in scales expressing TP concentration (g/dl) and specific gravity of urine.

  Information on the reliability of the refractometric method to determine TP concentrations in avian blood is conflicting. One study indicated that temperature compensated refractometers provide reliable results when compared to non-temperature-compensated devices.[3] In another study, temperature-compensated and non-compensated refractometers yielded higher values than the biuret method, with the temperature-compensated instrument being consistently higher in readings than the non-temperature-compensated refractometer. In juvenile

Eclectus Parrots,[15] macaws[16] and cockatoos,[17] proteins measured by refractometer were consistently higher than those measured by the biuret method.

Due to its dependence on the transmission of light, it is important that a refractometer be used only for clear, non-turbid and non-lipemic fluids. A moderate degree of hemolysis or icterus should not alter the values.[39] In mammals, hyperglycemia (> 700 mg/dl) affects the accuracy of a refractometer for determining TP.[68] At protein concentrations < 3.5g/dl, refractometric results are likely to be inaccurate.[68] Hemolysis causes the release of hemoglobin and intracellular proteins that will increase the refractometry reading. Because of the higher glucose and lower TP concentrations in birds, correlation of results from the refractometer and the biuret methods may not be possible in some species.[3,15-17,47,48,51,52,53,72] Refractometry should be considered a rapid method for determining an estimate of the body fluid protein. Ideally, total protein concentrations have the most value when considered with the results of plasma protein electrophoresis.

- ***Physiology:*** Most plasma proteins, with the exception of immunoglobulins and protein hormones, are synthesized in the liver. They form the basis of organ and tissue structure, operate as catalysts (enzymes) in biochemical reactions, are regulators (hormones) and are transport and carrier compounds for most of the constituents of plasma. The biological activity of proteins for these various functions is dependent upon their primary and secondary structure.

  In female birds, a considerable increase in plasma TP concentration occurs just prior to egg laying, which can be attributed to an estrogen-induced increase in globulins. The proteins are the yolk precursors (vitellogenin and lipoproteins), which are synthesized in the liver and transported via the plasma to the ovary where they are incorporated in the oocyte.

- ***Diagnostic Value:*** Total protein is often used as an indicator for the health status of a patient. Determination of plasma protein concentrations may be of value in diagnosing gastrointestinal, hepatic or renal diseases. Furthermore, plasma proteins will be abnormal in infectious diseases that cause a stimulation of the immune system. Although determination of plasma proteins seldom leads to a specific diagnosis (eg, in the case of monoclonal gammopathies), it will help the clinician to evaluate the severity and progression of a disease.[49] Changes in protein concentration can occur passively due to dehydration (hyperproteinemia) or over-hydration (hypoproteinemia) or actively due to dysproteinemias.

- ***Physiologic Influence:*** Changes in TP must be interpreted with respect to physiologic influences disassociated with disease. Age and stage of development will influence the concentration of TP in birds. Advancing age has been associated with increases in TP in several species.[15-17,25] Hormones can have either an anabolic or catabolic effect on TP. In general, hormonal effects on TP are minimal. However, testosterone, estrogen and growth hormone were found to increase TP in chickens; thyroxine decreased concentrations.[39] The effects that diet has on the total protein concentrations are subtle and difficult to detect or interpret. Temperature stress (hypothermia or hyperthermia) is associated with nitrogen loss, increased adrenal activity and increased protein turnover, resulting in a decrease in TP. Similar findings are observed following crushing injuries, bone fractures and extensive surgery.[39]

- ***Pathologic Changes (Dysproteinemia):***
  Hypoproteinemia can reflect reduced synthesis caused by chronic hepatopathies, malabsorption caused by chronic enteropathies (enteritis, tumors, parasitism), increased loss caused by proteinuria due to renal disease, blood loss and malignant tumors (rarely seen in birds) or starvation and malnutrition. Hyperproteinemia may be induced by chronic infectious diseases that stimulate production synthesis of gamma globulin. It also has been seen with chronic lymphoproliferative disease that resembles leukosis in chickens[43] and myelosis in budgerigars.[36] As mentioned previously, dehydration should always be ruled out as a cause of hyperproteinemia.

Electrophoresis

- ***Sample:*** Serum is most commonly used for protein electrophoresis in mammals, so fibrinogen is not included in the sample. Hemolysis will affect electrophoresis results, and heparinized plasma is often used to prevent this problem.[50,54,72]

- ***Method:*** Electrophoresis is used to separate different types of plasma proteins, making it possible to determine their relative proportion in a particular sample. At a neutral or alkaline pH, serum or plasma, supported on a specific matrix, is placed in an electrical field, causing the different protein fractions to migrate at varying speeds toward the anode based on their relative charge. Following staining, these fractions appear as bands of varying intensity, which can be scanned by a densitometer to produce an electro

phoretic tracing. The length and height of each peak ithin the pattern indicates the relative amount of a particular protein or group of proteins. This can be translated into percentage readings and, by combining this information with the TP concentration, absolute values for the concentration of each protein, or protein group, can be calculated.

- ***Physiology:*** Most frequently used electrophoresis methods identify five main protein fractions in birds: albumin, α1-, α2-, β- and γ-globulins.[66] A pre-albumin fraction has been described in pigeons and some parrot species.[15,16,17,50,54] The α-globulins are acute phase proteins that typically increase with acute inflammation; β-globulins are composed of complement, hemopexin, ferritin, fibrinogen and lipoproteins.[39] Some immunoglobulins, including IgM and IgA, also migrate in the β-globulin range. The β-globulins are also acute phase proteins. The γ-globulin fraction is mainly composed of immunoglobulins (IgA, IgM, IgE and IgG).[66]

- ***Diagnostic Value:*** In healthy birds the albumin fraction is the largest protein fraction. An inflammatory process will cause a rise in TP because of increased concentrations of α, β or γ globulin fractions. Often albumin concentrations are decreased in these situations. The combined effect of these changes is a decrease in the albumin/globulin (A/G) ratio. Often the TP concentration is within the reference range, while the A/G ratio is decreased. Therefore, the A/G ratio is of greater clinical importance than the TP concentration. Examples of diseases with a decrease in the A/G ratio are egg-related peritonitis, and chronic infectious diseases such as aspergillosis, psittacosis and tuberculosis.

  Serum or plasma protein electrophoresis can be used to monitor response to treatment. When the bird responds favorably, an increase in the albumin concentration and a decrease in the globulin concentration can be observed, which leads to normalization of the A/G ratio. In birds with liver failure, extremely low plasma protein concentrations can occur in combination with a decreased A/G ratio. Gastrointestinal and renal diseases can also lead to severe hypoproteinemia. These changes are caused by a loss of albumin. Elevated TP concentrations with a normal A/G ratio can be expected in dehydrated birds.

- ***Physiologic Influence:*** Physiologic factors that may change the protein concentration and therefore affect protein electrophoresis results include gender, age, dietary protein, temperature stress, state of hydration, hemorrhage and inflammation.[66]

- ***Pathologic Changes:*** Decreases in albumin concentration can occur from decreased synthesis due to chronic liver disease or chronic inflammation, increased albumin loss due to renal disease, parasitism or over-hydration.[72] A decrease in albumin causes edema because of a decrease in oncotic pressure. Increases are seen because of dehydration.

  Increases in α- and β-globulins may be caused by acute nephritis, severe active hepatitis, systemic mycotic diseases (γ-) and the nephrotic syndrome.[72] Increases in γ-globulins occur with acute or chronic inflammation, infection, chronic hepatitis and immune mediated disorders.[72]

Triglycerides

- ***Sample:*** Serum and lipemic specimens should be warmed to 37°C and vigorously mixed prior to analysis.

- ***Method:*** Usually, triglycerides are enzymatically detected by breaking down the triglycerides and measuring the glycerol that is liberated.

- ***Physiology:*** Triglycerides are the major storage form of lipids, and are a major energy source. Each molecule of triglyceride consists of three fatty acid molecules attached to a molecule of glycerol. They are synthesized in the intestinal mucosa and liver from the components of fat digestion and absorption.

- ***Diagnostic Value:*** Triglyceride values have been insufficiently evaluated in birds. Several factors can influence the blood concentration and increases may not be of clinical importance.

- ***Physiologic Influence:*** Triglyceride levels may vary based on climate, hormone influence, diet and gender. Increases may occur during starvation, particularly in obese birds. Estrogen injections have been shown to elevate triglyceride concentrations in some species.[25]

- ***Pathologic Changes:*** Egg-related peritonitis has been associated with high concentrations of triglycerides.[73] High concentrations (2000-5000 mg/dl) were reported in Amazon parrots showing signs of hyperadrenocorticism. Because triglyceride values are determined based on enzymatically released glycerol, these values may be falsely elevated after exercise or following any event that causes increased levels of blood glycerol (eg, catching birds in an aviary).

Urea

- ***Method:*** Both indirect methods (based on preliminary hydrolysis of urea with urease) and direct methods (based on variations in the thiazide reaction) are used for urea determination. This reaction involves the condensation of diacetyl with urea to form the chromogen diazine.[68]

- ***Physiology:*** In the liver, protein breakdown to amino acids releases urea, which is excreted by glomerular filtration in the kidney. Tubular reabsorption can occur and is dependent on the state of hydration. In dehydrated birds, nearly all of the filtered urea is reabsorbed. If properly hydrated, almost all of the filtered urea is excreted.

- ***Diagnostic Value:*** Urea is present in very small amounts in avian plasma, and determining urea levels has generally been considered of little value. However, recent investigations have shown good correlation between increased plasma urea concentrations and renal disease in pigeons.[50] In other avian species, urea may have little value in detecting renal disease but can be used as a sensitive indicator of dehydration.

- ***Physiologic Influence:*** Physiologic conditions are known to change urea concentrations in mammals, but similar effects have not been documented in birds.

- ***Pathologic Changes:*** High urea plasma levels can occur in all conditions that cause low urine flow, such as dehydration or bilateral ureteral obstruction.[50]

Uric Acid

- ***Method:*** Both wet and dry chemistry systems use oxidation of urates by uricase as a detection method. Most uricase methods are extremely specific and only a few structural analogues to uric acid will interfere with the test. In general, the concentrations of these analogues are low in biological fluids.[68]

- ***Physiology:*** In birds, uric acid is the major product of the catabolism of nitrogen. Synthesis occurs mainly in the liver[50] and in the renal tubules.[14] Approximately 90% of blood uric acid is eliminated by secretion into the lumen of the tubules. Only 50% of the healthy avian kidney is actually used for excreting protein waste, providing a large functional reserve.[25]

- ***Diagnostic Value:*** The evaluation of uric acid concentrations in plasma or serum is widely used in birds for the detection of renal disease. Species differences in the ability of the avian kidney to compensate for damage before uric acid levels are elevated reduces the diagnostic value for this test. However, if reference intervals are available, hyperuricemia is a good indicator of renal disease. Normal uric acid concentrations do not guarantee that the kidneys are healthy.

- ***Physiologic Influence:*** Age and diet may influence the concentration of blood uric acid in birds. Juvenile birds have lower concentrations than adults.[15,16,17,32] Hyperuricemia has been documented during ovulatory activity.[43] Grain-eating birds have approximately 50% lower uric acid concentrations than do carnivorous birds.[25] Uric acid levels are higher shortly after food consumption. Gender differences have not been reported.[5]

- ***Pathologic Changes:*** Hyperuricemia can be expected if the glomerular filtration is decreased more than 70 to 80%. Decreased filtration may occur from hypovitaminosis A-induced damage to renal epithelial cells, dehydration, intoxications or from some bacterial and viral (Newcastle disease) infections.[2,5,21,25,36,73] Uric acid levels may also be increased from the release of nucleic acids caused by severe tissue damage or starvation. If a toenail clip is used for blood collection and urates from the droppings contaminate the sample, the uric acid levels may be falsely elevated.[21,43]

  If the blood uric acid concentration exceeds its solubility it will be deposited in different locations in the body. High plasma or serum concentrations of uric acid are a prognostic indicator that gout may occur. Use of nephrotoxic drugs may also lead to hyperuricemia. Hypervitaminosis D_3-induced renal damage is frequently associated with gout and extremely high uric acid levels. This problem is particularly common in macaws. This has been described for aminoglycosides (gentamicin),[2,25,43] and allopurinol in Red-tailed Hawks.[56] Interestingly, in most species, allopurinol is effective in treating, not inducing gout.

  Hypouricemia is much less common in birds than hyperuricemia. Severe hepatocellular disease with reduced synthesis of uric acid has been suggested as one etiology.

Electrolytes

Chloride

- ***Method:*** Different methods are in use, but ion-selective electrode methods are most common.

- ***Physiology:*** Chloride is the major extracellular anion. Sodium and chloride together represent the majority of the osmotically active constituents of plasma.

- ***Diagnostic Value:*** Elevations in chloride concentrations rarely are detected.

- ***Physiologic Influence:*** In budgerigars, no gender or other physiologic variables have been observed.[32]

- ***Pathologic Changes:*** Hyperchloridemia can occur with dehydration.[25,36] The role of chloride in maintaining acid-base balance has not been sufficiently evaluated in birds.

Potassium

- ***Sample:*** Either heparinized plasma or serum is appropriate for detecting potassium. If ion-selective electrode methods are used, whole blood is also an effective sample. Differences in the electrolyte concentrations in serum and plasma must be considered when interpreting results. Potassium levels are usually higher in serum due to the release of potassium from thrombocytes damaged in the coagulation process. Hemolysis will elevate the plasma concentration of potassium (500 to 700%).[39] Potassium concentrations were found to rapidly decline in pigeon and chicken plasma allowed to sit for two hours.[46] For accurate results, plasma should be separated within minutes of collection. Hyperproteinemia and hyperlipemia will result in falsely low potassium levels caused by a decreased aqueous fraction of the total plasma volume.

- ***Method:*** Potassium may be determined by atomic adsorption spectrophotometry, flame emission spectrophotometry or electrochemically with a sodium ion-selective electrode. The last two systems are most commonly used.[30,68]

- ***Physiology:*** Only two percent of the body's potassium is in the extracellular fluid. The other 98% is kept within the cells by "potassium pumps" in the cell membranes.

- ***Diagnostic Value:*** Alternatives in potassium homeostasis have serious consequences. Decreased extracellular potassium is characterized by muscle weakness, paralysis and cardiac effects. Many potassium abnormalities are the result of hemolytic samples.

- ***Physiologic Influence:*** High amounts of potassium in the diet can elevate plasma concentrations.

- ***Pathologic Changes:*** Hyperkalemia can be caused by severe tissue damage, reduced potassium excretion by diseased kidneys,[25,73] adrenal disease[73] or because of redistribution of potassium from the intracellular to the extracellular fluid (acidosis).[25] Dehydration[25,73] and hemolytic anemia[25] can also cause hyperkalemia.

  Hypokalemia may be caused by decreased potassium intake, increased potassium loss due to chronic diarrhea or diuretic therapy (seldom used in birds)[73] and the shift of potassium from the extracellular to the intracellular fluid (alkalosis).[25]

Sodium

- ***Sample:*** Either heparinized plasma or serum is appropriate for sodium assays. With ion-selective electrodes, whole blood may be used. Electrolyte concentrations are different between serum and plasma. Hyperlipemia and hyperproteinemia will cause falsely low potassium levels by a mechanism similar to that described for potassium.

- ***Method:*** Sodium may be determined by atomic adsorption spectrophotometry, flame emission spectrophotometry or electrochemically with a sodium ion-selective electrode. The last two systems are most commonly used.[30,68]

- ***Physiology:*** Sodium is present mainly in the extracellular fluid and is primarily responsible for determining the volume of the extracellular fluid and its osmotic pressure. Intracellular sodium levels are kept low by a relatively impermeable cell membrane and a sodium pump which removes sodium from the cell. The amount of sodium in the body is regulated by the kidney. In addition, many avian species have a specialized nasal gland (salt or supraorbital gland) that is able to secrete large quantities of sodium in response to osmotic changes, thus allowing these birds to drink salt water. When sea birds are kept in fresh water for a period of time the gland shrinks so that when returned to salt water the birds can no longer tolerate high sodium levels.This mechanism of decreasing sodium concentration in the serum and urine of birds is mediated by a pituitary-adrenal response.[66]

- ***Diagnostic Value:*** Abnormal sodium levels that are not caused by technical failures are rarely seen in birds. If they do occur, they are good indicators of a pathologic situation. Salt poisoning, mainly from high salt foods, may occur more frequently in companion birds than is documented.

- ***Physiologic Influence:*** Sodium plasma levels are maintained within narrow limits, despite wide fluctuations in dietary intake.
- ***Pathologic Changes:*** Hypernatremia can occur from increased sodium intake (peanuts, crackers), excessive water loss or decreased water intake.

  Hyponatremia may be due to increased sodium loss as in kidney disease[73] or severe diarrhea.[25,73] It may also be caused by over-hydration as in psychogenic polydipsia or after intravenous fluid therapy with sodium-free or low sodium solutions. The relative over-hydration, which follows a reduction in renal perfusion possibly because of decreased colloid osmotic pressure, may also cause hyponatremia.

Total Carbon Dioxide Content (Bicarbonate)

- ***Method:*** Heparinized plasma or serum can be used. Bicarbonate levels are determined by mixing the sample with a strong acid and measuring the carbon dioxide (CO_2) release. Most of the carbon dioxide produced is derived from bicarbonate, but a small amount is generated from dissolved carbonic and carbamino acids.
- ***Physiology:*** Alterations of bicarbonate and CO_2 dissolved in plasma are characteristic of acid-base balance. For clinical purposes, the total CO_2 content is the same as the bicarbonate content.[11]
- ***Diagnostic Value:*** Bicarbonate levels are useful for establishing whether or not acidosis or alkalosis is present and, if so, how severe it is.
- ***Pathologic Changes:*** Increases are mainly due to metabolic alkalosis and decreases due to metabolic acidosis. Reference intervals for most avian species are not available.
- ***Reference Values for Adult Budgerigars:*** 21 to 26 mmol/l.[32]

Blood Gases - pCO_2, pO_2 and pH

- ***Sample:*** Venous heparinized blood is the most likely specimen that will be collected for blood gas analysis. Determination should be performed as quickly as possible (in house).[68] When measuring blood gases and acid-base status in birds, it is necessary to collect blood samples in pre-cooled syringes and store the samples on ice to stop the metabolism of the erythrocytes. The nucleated avian erythrocytes possess virtually all the enzymes typical of metabolically active cells and consume oxygen seven to ten times faster than mammalian erythrocytes. Even during analysis, which occurs at 37°C, the values are being influenced by temperature.
- ***Method:*** An expensive blood gas instrument is necessary.
- ***Diagnostic Value:*** Clinical significance in companion birds has not been thoroughly investigated.
- ***Pathologic Changes:*** Acidemia (decrease in blood or plasma pH) has been reported in some birds with renal disease.
- ***Reference Values for Budgerigars:***[32] pH (7.334 to 7.489); pCO_2 (30.6 to 43.2 mm Hg) (see Chapter 39).

Other Tests

Delta-Aminolevulinic Acid Dehydratase

- ***Method:*** Plasma or serum can be used to measure delta-aminolevulinic acid dehydratase colorimetrically.
- ***Diagnostic Value:*** Delta-aminolevulinic acid dehydratase can be used to detect lead intoxication, and decreased plasma activity is pathologic.
- ***Pathologic Changes:*** The activity can decrease depending on the dosage of lead and the species up to 50% of the normal value.[18,19,25] Central nervous system changes have been reported if plasma activity is below 86 U/l (see Chapter 37).

Acid Phosphatase

This enzyme consists of a number of isoenzymes in a variety of organs. The activity is much lower than that of alkaline phosphatase. Ovulation has been shown to increase acid phosphatase activities.[25]

Copper

- ***Method:*** Atomic adsorption spectrophotometry after direct dilution is the method of choice for determining serum copper.[68]
- ***Physiology:*** Copper is a component of several major enzymes and plays a vital role in hemapoiesis. It is involved in the absorption and the transfer of iron and hemoglobin synthesis. In the plasma it is mainly bound to ceruloplasmin.
- ***Diagnostic Value:*** Elevation occurs with copper intoxication. In postmortem specimens, copper concentration in the liver provides the best diagnostic sample.[25]
- ***Physiologic Influence:*** Copper levels are generally higher in female mammals under the influence of

estrogens. In birds, the effect of estrogens on copper levels has not been investigated.

- ***Pathologic Changes:*** Copper intoxications will increase the serum level.

Plasma Dye Clearance Test

In many animal species, the hepatic uptake and excretion of different organic dyes injected intravenously has been used for diagnosis of liver disease. Indocyanine green has been successfully used to detect liver disease in three raptor species.[70] The dye was non-irritating if accidentally injected perivascularly and clearance occurred.

In contrast, Bromsulphalein must be injected with care, because perivascular injection causes severe pain. In chickens, the clearance is markedly influenced by age and gender.[6,58] The clinical value of these two tests has been insufficiently studied in birds.

Urinalysis

Urinalysis is indicated if renal disease is suspected. Polyuria is a common clinical presentation in companion birds.[71] It may be caused by excitement, in which the content of the cloaca is shed before the water is reabsorbed; by the intake of large amounts of fluids (fruits, vegetables); by renal disease, neoplasia, diabetes, sepsis, toxins, adrenal disorders or gout; after administration of some medications; and with impending egg laying. In all of these cases, it is relatively easy to separate the urine from the feces via aspirating the liquid deposited on a water-resistant surface. Transient polyuria can be induced by administering water by crop tube. This will usually result in urine production within 30 minutes after administration.[73] In pigeons, urine for analysis has been collected directly from the cloaca using a cannula.[26] Urine samples can be collected from individual ureters of anesthetized parrots using a speculum.

Volume, Color and Consistency[73,25]

Urine evaluation should include a measurement of volume, a record of appearance (color, consistency) and determination of specific gravity. Normal companion birds produce a small quantity of urine, and if it can easily be collected it is generally abnormal (stress or disease). The urine is usually clear in most companion bird species, but in other birds, such as ratites and Anseriformes, it is normally opaque, cloudy or slightly flocculent.

Many factors can influence the color of avian urine. It can change with the ingestion of water-soluble vitamins (especially Vitamin B), the amount of uric acid and feces mixed with the urine, the specific gravity and certain diseases (see Color 8). Macaws often have very dark yellow urine, which is not normal.

The white crystalline portion of the urine in birds is seldom evaluated except for color. Birds that are in a negative nitrogen balance (severe cachexia, catabolic disease) usually have an increased quantity of urates.

- ***Pathologic Changes:*** Lead intoxication in some species may result in chocolate milk-colored urine and urates. This hemoglobinuria is common and normal for some nervous birds. Severe liver disease, like that induced by chlamydia or Pacheco's disease virus, can increase the secretion of biliverdin, which results in yellow-green or mustard-colored urine and urates. Because many other severe clinical diseases cause this color to be present, it is not pathognomonic.

Specific Gravity

- ***Normal:*** The specific gravity varies with the state of hydration and with the individual bird. In the polyuric bird, values from 1.005 to 1.020 are considered normal. A refractometer can be used for this determination. Water deprivation should be used to evaluate the kidney's ability to concentrate low levels, often due to psychogenic polydipsia.
- ***Pathologic Changes:*** Increased loss of water without an increased loss of solute will create a low specific gravity. This situation can be caused by intravenous fluid therapy, hyperthyroidism, liver disease, pituitary neoplasia, progesterone or glucocorticoid therapy. Any disease that causes polyuria and polydipsia can cause a low specific gravity. A reduced ability to concentrate or dilute the glomerular filtrate will lead to an increased specific gravity and severe renal pathology.

Specific Evaluation

Substances filtered by the normal kidney generally have a molecular weight of less than 68,000 (eg, water, uric acid, urea, glucose, electrolytes). Two substances that are on the border of this molecular weight cutoff are hemoglobin and albumin. Most other physiologic proteins have higher molecular weights. Most substances that are filtered by the kidneys are critical to normal bodily functions and are completely reabsorbed (eg, amino acids, glucose, vitamins). The excretion or retention of other substances are regulated according to the body's needs.

Urinary pH and the concentration of some chemical constituents in the urine can be measured using commercial test strips designed for use with human urine. It should be noted that the sensitivity of these tests has been adjusted to detect what would be regarded as abnormal levels of certain substances in human urine. These sensitivities are not necessarily applicable to birds and the fact that a "higher" reading is obtained on an area of the test strip does not necessarily imply an abnormality. For example, alkaline urine can produce falsely elevated protein levels. The color of the urine sample may also affect the results of some test parameters.

- ***Normal pH:*** Most pet birds have a pH between 6.0 to 8.0, which is largely related to the diet. Birds fed large amounts of protein (carnivores) have an acidic urine, while grain-eating birds have more alkaline urine.

- ***Pathologic Changes:*** Companion birds with urine pH lower than 5.0 are considered acidotic.[73] Increased protein catabolism will cause a lower pH. Bacterial metabolism tends to cause an alkaline pH. Companion birds with papillomatosis and other disorders that typically cause tenesmus may have acidic urine. Presumably this is caused by excretion of fluids from the upper intestinal tract.[8] It has been suggested that the cloacal mucosa of a normal companion bird is neutral to slightly alkaline when measured with litmus paper (Harrison GJ, unpublished).

Urinary Protein

- ***Normal:*** Trace amounts of protein can be detected in the urine of 90% of birds tested.[73]

- ***Pathologic Changes:*** Many renal disorders will result in a mild to moderate proteinuria. Non-renal sources of proteinuria include hematuria, hemoglobinuria and hyperproteinemia, which are usually caused by an increase in the production of immunoglobulins. Inaccurate protein levels will be detected if the urine is alkaline or if the strip is soaked in urine (instead of briefly dipped), which leaches out the citrate buffer.

Glucose

- ***Normal:*** Avian urine normally contains no glucose. In healthy pigeons, reference values between 0 and 3.2 mmol/l were established by the hexokinase reaction.[50] Trace glucose readings may be detected in normal avian urine by using dip sticks.[73]

- ***Pathologic Changes:*** The threshold for glucosuria to occur varies with the species.[73] Glucosuria will occur in most birds when the blood glucose level exceeds 600 mg/dl. In diabetes mellitus, birds may have blood glucose concentrations above 800 mg/dl.

Ketones

Ketones should be absent from the urine of birds. Any significant shift in energy production from carbohydrates to fats results in the increased oxidation of fatty acids and the production of intermediate metabolites that accumulate faster than they can be oxidized by the tissues. Catabolic processes such as severe hepatitis in combination with low blood glucose concentrations and diabetes mellitus can cause ketonuria.

Bilirubin

Bilirubin is not normally present in birds. Biliverdin is the major bile pigment, but will not react with the bilirubin portion of a mammalian urine dip stick.

Urinary Urobilinogen

Normal readings are 0.0 to 0.1 in healthy birds. Pathologic changes would be expected in cases of intravascular hemolysis and severe liver disease, but are seldom reported. Falsely high levels of urobilinogen in urine can be due to drugs which appear red in acid urine (eg, Vitamin B_{12}) or if sulphonamides are present.

Blood

Commercial strip tests are available that can distinguish hematuria (ie, an abnormally large number of intact RBCs in the urine) and hemoglobinuria (ie, hemoglobin that is free within the urine and not contained within cells). With hematuria, individual erythrocytes lyse on the test area, giving individual spots of color. If there is free pigment, the color change is uniform throughout.

Normal readings are negative or trace. Blood in the urine may originate from the cloaca or from the urinary, reproductive or gastrointestinal tracts. Hemoglobinuria can be due to intravascular lysis of RBCs (rare) or lysis of RBCs present in the urine.

Urinary Nitrite

This test is included on many commercial test strips and is used to screen for bacteriuria. It is an unreliable test for avian urine.

Urinary Sediment

Examination of the urinary sediment is a valuable part of urinalysis but one that is often omitted. A fresh or refrigerated sample is required. With time,

there is increasing alkalinity causing progressive lysis of blood cells and casts. Usually centrifugation is used to concentrate the sediment to approximately ten percent of its original urinary volume.

White and Red Blood Cells

The number of RBCs and WBCs in the sediment is reported as the number per high power field (HPF). Normal urine contains 0 to 3 RBCs/HPF and 0 to 3 WBCs/HPF.[73] More than 6 white or red blood cells per HPF is a cause for concern. All cells noted within the urine sediment may have origins within the cloaca or the urinary, reproductive or gastrointestinal tracts.

Epithelial Cells

Normal urine contains no epithelial cells. The presence of any epithelial cells (eg, renal tubular cells) should be considered abnormal.[73]

Casts

Casts are cylindrical structures molded into the shape of the renal tubules. Normally no casts are seen in avian urine. Casts are frequently noted in cases of renal disease. Granular casts are most common. Cellular casts (which incorporate cells like RBCs, WBCs or tubular epithelial cells) and hyaline casts (consisting of mucoprotein gel) may also be seen.

Bacteria

In mammals, it is believed that bacteria in excess of 3 x 10^4/ml of urine must be present before they are detectable in urinary sediment.[68] Gram-positive cocci and rods may be noted in the avian urinary sediment if the sample has been contaminated with fecal material.

- ***Pathologic Changes:*** Reports of bacteria that are "too numerous to count" or numerous cocci and rods in reasonably clean urine samples should be viewed with suspicion.[73] Avian urine is sterile leaving the kidneys, and Gram's stains or cultures comparing stool and urine flora may be helpful in documenting bacteria that originate from the urinary tract. Bacteria may multiply en route to the laboratory, which will lead to high counts in the sample.

CHAPTER

12

IMAGING TECHNIQUES

Marjorie C. McMillan

With advancing technology, diagnostic imaging techniques available for avian patients now include ultrasound, fluoroscopy, computed tomography (CT) and nuclear scintigraphy; however, routine radiography remains the most frequently performed imaging modality in birds and frequently is diagnostic without the need for more sophisticated procedures. Information obtained from radiographs will frequently complement results from other testing methods, providing for a more thorough evaluation of a disease process.

Both risk and benefit to the patient should be considered when radiography is used as a screening procedure in an apparently normal companion bird. In general, radiography should be performed only when indicated by historical information, physical examination findings and laboratory data. Indiscriminate radiographic studies create an unnecessary risk to the patient and technical staff.

Radiographic findings should always be correlated with surgical, endoscopic or necropsy findings. These comparisons will refine a clinician's ability to detect subtle radiographic changes, and improve diagnostic capabilities and therapeutic results.

Technical Considerations

The size (mainly thickness), composition (air, soft tissue and bone) and ability to arrest motion are the primary factors that influence radiographic technique. Although the skeleton is easy to visualize, specific soft tissue structures within the coelomic cavity may be difficult to differentiate, especially in smaller birds. Interpretation of the radiographs may be complicated by the blending of soft tissue structures caused by the compact viscera, rudimentary mesenteric attachments and minimal fat. Even in obese birds, contrast of the coelomic cavity is minimally improved, suggesting that, radiographically, the opacity of avian fat is similar to that of soft tissue. In the absence of pathology, the air sacs provide negative contrast throughout the thorax and abdomen that can help in differentiating structures.

Multiple factors influence the quality of a radiographic image. In radiographing the avian patient, the goal is to produce a properly positioned, detailed study with a long scale of contrast, minimal motion and the least exposure of the patient and technical personnel to radiation. In general, the image quality is controlled by:

- the production of the image—influenced by radiographic equipment, technical settings (kVp, mA and time), focal-film distance, part-film distance, focal spot size and collimation;
- the recording of the image—influenced by the type of film, cassette and screen combination; and
- the development of the image—influenced by the darkroom environment and type of processing equipment.

Attention to quality in all aspects of obtaining a radiograph will result in consistent, high quality radiographs with reduced repeat rates, increased efficiency, less patient stress, reduced radiation exposure and economic savings. A quality control program that encompasses all the factors contributing to the radiographic image is beyond the scope of this chapter and appropriate references should be reviewed.[3,5,25]

Radiographic detail depends on sharpness of the image and radiographic contrast. Sharpness, the ability to define an edge, is compromised by motion, uneven film-screen contact and a large focal spot. Radiographic contrast is controlled by subject contrast, scatter, and film contrast and fog. Detail is improved by using a small focal spot, the shortest possible exposure time (usually 0.015 seconds), adequate focus-film distance (40 inches), a collimated beam, single emulsion film and a rare earth, high-detail screen. The contact between the radiographic cassette and the patient should be even, and the area of interest should be as close as possible to the film.

There is increasing discussion of the use of mammography machines for imaging avian patients. While these machines do produce excellent quality images with extremely refined detail, the clinician should be aware that imaging requires exposure to high levels of radiation in comparison to standard radiographs. In general, mammography machines can be considered to deliver low-dose radiation therapy (levels of radiation that cause tissue destruction), and the long-term effect of exposing the body of a bird to this level of radiation is undetermined.

Radiographic Technique

The specific technical factors needed to obtain a high quality radiograph will vary with the type of radiographic equipment, film-screen combinations and various settings used for specific purposes. A technique chart for the various species can be developed.[28] As a general rule, the clinician should choose the lowest kV, a high mA and a short exposure time.[7] Usually, non-bucky techniques applicable for radiography of cats provide reasonable radiographic settings for medium to large psittacine birds.[5]

In circumstances where single emulsion, rare earth, high-detail systems are used, kVp ranging from 60 to 75 at five mAs (300mA, 1/60th of a second) usually provides an appropriate scale of contrast and eliminates motion. In small Passeriformes, such as canaries and finches, reducing the focal-film distance by one-fourth (to 30 inches) and decreasing the mAs by one-half may improve the radiographic image. Decreasing the focal-film distance can result in loss of detail due to magnification; however, with small patients, a shorter focal-film distance does not seem to compromise the radiographic image.

Although the single-emulsion film and single screen, rare earth systems result in greater detail, they do require increased exposure when compared to double emulsion film-cassette combinations. Low-absorption cassette fronts may provide comparable detailed studies with less radiation exposure.[29]

It is important to radiation safety to maintain an adequate distance from the source of radiation by using techniques that do not require personnel to restrain the patient during a radiographic study. If hospital personnel must be present during an exposure, they should wear a lead apron, lead gloves, thyroid shield, protective glasses and a film badge. No portion of a person's body should be in the primary beam, even if covered by lead. With practice, restraining methods can be developed so only the patient is exposed to radiation.

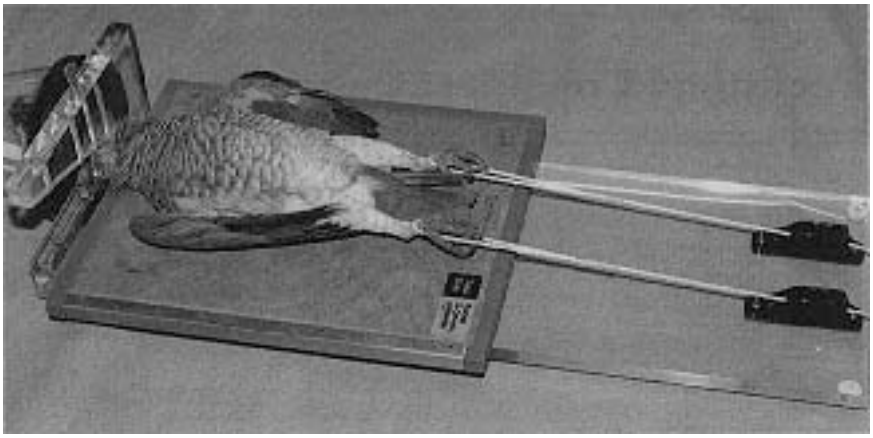

FIG 12.0 A plexiglass restraint board can be used for positioning anesthetized or unanesthetized birds for radiographs. An anesthetized bird is shown in the proper position for a VD radiograph.

Restraint and Positioning

Poor positioning is the most frequently encountered factor that compromises a radiographic study and hampers interpretation of subtle lesions. Some birds can be adequately restrained for routine views with mechanical plexiglass devices and positioning aids such as sandbags, foam blocks, lead gloves, velcro, pipe cleaners and plastic and paper tape.[10,18] Other patients will require isoflurane anesthesia to obtain the most diagnostic radiographs; however, it should be noted that anesthesia or chemical restraint for radiographic examination will decrease normal gastrointestinal motility and as such is generally contraindicated in studies to evaluate the function of this organ system. Anesthesia should be considered mandatory when radiographing strong, powerful birds or patients that are fractious, highly stressed, experiencing significant respiratory distress or those that have an injury that may be exacerbated by struggling. If anesthesia is required, appropriate evaluation of the patient prior to anesthesia is indicated (see Chapter 39). With experience, a complete set of diagnostic, high quality radiographs can be obtained in an anesthetized bird in less than five minutes.

If heavy metal intoxication is suspected in a critically ill bird, a quick radiographic screening for metal densities can be obtained by placing the bird in a bag and taking a DV radiograph. A horizontal beam radiograph can also be taken through the bag to provide a lateral view. This technique is useful only to demonstrate radiographically detectable metal particles (Harrison GJ, unpublished).

The most frequently performed radiographic studies in companion birds are ventrodorsal (VD) and left-to-right lateral (LeRtL) whole body projections. To use a plexiglass restraint board, the neck of the bird just below the angle of the mandible is secured in the stock-like, contoured portion of a restrainer while the body is still wrapped in a towel. For the VD view, the head is restrained and the wings are extended 90 degrees from the body and secured with sandbags, velcro straps or tape. The wings should be restrained close to the body to prevent iatrogenic fractures. The legs are pulled caudally and parallel to the body and secured at the tarsometatarsus with tape or velcro straps (Figure 12.0).

For the LeRtL view, the wing and leg restraints are loosened while the head and body are rotated into right lateral recumbency. The dependent wing is extended 90 degrees to the body and secured. A foam block or other soft material is placed between the wings, and the left wing is extended and restrained slightly caudally to the right. Placing a block of foam between the wings helps to prevent overextension and potential injury. Both legs are extended caudally with slight tension and secured individually at the tarsometatarsus. The dependent leg is positioned slightly cranially. Securing the legs individually helps to reduce rotation of the body, which is common if the legs are fastened together. The beam should be collimated to the patient size to reduce scatter, and radiopaque right or left markers should be appropriately positioned.

In a symmetrically positioned VD view, the spine and sternum will be superimposed, and the scapulae, acetabula and femurs will be parallel (Figure 12.1).

In LeRtL projection, the ribs, coracoid, acetabula and kidneys will be superimposed, if the positioning is accurate (Figure 12.3).

While in the VD position, collimation may be used to obtain radiographs of the pelvis, craniocaudal projection of the legs and mediolateral view of the wings (Figure 12.9, 12.10). The orthogonal view of the wing in the caudocranial projection requires horizontal beam radiography. In the lateral position, views of the pelvis, spine and legs can be achieved (Figure 12.11, 12.12).

Radiography of the skull requires general anesthesia to ensure accurate positioning and to minimize motion. Complete evaluation of the skull requires LeRtL, RtLeL, VD, dorsoventral (DV) and rostrocaudal (RCd, frontal sinus) views (Figure 12.5 to 12.8). In evaluating skull trauma, left and right 75° ventrodorsal oblique views are recommended.[7]

Radiographic Interpretation

If radiographic films are manually processed, an initial assessment of positioning and technique can be made during a "wet" reading; however, final interpretation should be reserved until the film is completely dry. The environment in which interpretation occurs is important. A dimly lighted area with minimal disturbance and an evenly illuminated viewing box at eye level improves viewing conditions. Personal preference determines whether an organ-by-organ approach or concentric circle system is used to evaluate the radiograph. Whichever method is chosen, it is important that the entire radiograph is studied, and that the observer does not just focus on the lesion. Minifying and magnifying lenses may improve interpretation by enhancing detail or magnifying structures, especially in smaller avian patients. It is advantageous to use a standardized form when recording radiographic findings.

Neonatal Radiography

Stress should be minimized when radiographing neonatal birds. The surface of the cassette should be warmed with a towel to avoid placing a young bird on a cold surface. Paper tape should be used for restraint to avoid damage to the numerous blood feathers. In some circumstances, proper positioning may be sacrificed in the best interest of the patient. Pressure must not be placed on a full crop to prevent regurgitation and subsequent aspiration.

The abdomen of neonates appears pendulous because the gastrointestinal tract is dilated, fluid-filled and blends with the other soft tissue organs (see Figure 30.7). This results in a homogenous appearance to the coelomic cavity. The air sacs are relatively indistinguishable. The skeleton is incompletely mineralized and will have a reduced density, and fractures may be difficult to detect (Figure 12.76).

Musculoskeletal System

Radiographic Anatomy

The cranium of birds contains numerous connections to the sinuses, which are reflected radiographically. The osseous scleral ring is clearly visible radiographically, while the interorbital septum that lies between the eyes is barely visible (Figures 12.5,12.6).

The articulation between the clavicle and sternum in birds is membranous rather than bony. The distal ends of the clavicle are fused, forming the furcula (wishbone) (Figures 12.1 to 12.4). The coracoid articulates with the cranial portion of the sternum and the shoulder joint. Only the radial and ulnar carpal bones are present. The distal carpal bones are fused with each other and with the proximal ends of the metacarpal bones. This area is referred to as the carpometacarpus. The digits are traditionally numbered I (alular), II (major) and III (minor). Developed feathers are hollow, and the rachis will have an air density center. Developing feathers contain blood to the level of the pulp cavity and will appear as soft tissue densities (Figure 12.9).

The spine is separated into cervical, thoracic, synsacral (fused thoracic, lumbar, sacral and caudal), free-caudal and fused caudal (pygostyle) sections. The number of cervical vertebrae varies with the species (budgerigars = 11, Amazon parrots = 12). In Galliformes, the last cervical vertebra is fused to the first three thoracic vertebrae. The number of thoracic vertebrae varies from three to ten depending on the species.

Ribs are present on the cervical and thoracic vertebrae. The cervical ribs have short, ventrally oriented spines that are fused to the cervical vertebrae. The thoracic ribs are complete (number varies with the species) and are divided into two portions; the dorsal

portion articulates with the vertebra and the ventral portion articulates with the sternum (Figure 12.1). It should be noted that not all ribs have a sternal portion. The sternal rib is equivalent to the mammalian costal cartilage. Uncinate processes that anchor the caudal edge of several vertebral ribs to the cranial edge of the subsequent rib may be present on some ribs (see Anatomy Overlay).

There are 10 to 23 synsacral vertebrae and 5 to 8 free caudal vertebrae. The ilium and ischium are fused and are also fused to the synsacrum. The pubic bones are long, thin and unfused (except in ratites), presumably as an adaptation for egg laying (Figure 12.1).

No separate tarsal bones occur. The proximal tarsal bones are fused with the tibia; this structure is termed the tibiotarsus. The digital tarsal bones are fused with the metatarsal bones resulting in a tarsometatarsus. In parrots, each digit has one more phalange than the number of the digit. For example, digit III is composed of four phalanges (Figures 12.11, 12.12).

Various portions of the skeletal system may be perfused by air sacs in some avian species. The cervical vertebrae may be perfused by the cervical air sac; the thoracic vertebrae, ribs and humerus may be perfused by the interclavicular air sac; and the synsacrum and femur may be perfused by the abdominal air sacs (see Anatomy Overlay).

Avian long bones are characterized by thin cortices. The ossification of long bones is different in birds than in mammals, which should not be misinterpreted as pathology (see Chapter 42).

Radiographic Evidence of Skeletal Disorders

Categorizing abnormalities aids in reducing the differential diagnoses and allows some judgement as to the aggressiveness and chronicity of a lesion.[15,24]

The species and age of a bird influence the type of musculoskeletal pathology that will be encountered. In companion birds, bone changes associated with metabolic bone disease and pathologic fractures are more common than traumatic injury or infection. Congenital bone abnormalities are uncommon; however, developmental changes associated with poor husbandry and improper nutrition occur frequently. Hypovitaminosis D_3 and calcium and phosphorus imbalances result in changes in the size, shape and length of bones that are characterized by generalized osteopenia and folding fractures secondary to osteomalacia (see Figure 31.10).

Valgus deformity of the tibiotarsi (bow leg), kyphosis, scoliosis, lordosis and sternal compression may occur secondary to osteomalacia (see Figure 33.8). If the spinal or sternal abnormalities are severe, compromise of the thoracic cavity may occur that causes displacement of the heart and respiratory distress. "Splay leg" may be complicated by osteomalacia as well as contracture of tendons and muscles, causing clenching of the feet and rotation at the stifle joint. Hypervitaminosis D_3 can cause diffuse metastatic mineralization within soft tissues, particularly the kidneys (see Figure 21.3).[7]

Skeletal trauma may result in fractures, sprain injuries and concussions (see Chapter 16). Luxations are infrequent and usually involve the digits, stifle or coxofemoral joint, and often occur due to dangling from leg bands, inappropriate toys and unsafe enclosures (Figure 12.78). The important considerations in the radiographic evaluation of fractures include location, articular involvement, bone density, periosteal reaction, soft tissue involvement and whether the fracture is simple or comminuted and open or closed (see Chapter 42).

In companion birds, head trauma most often results in concussion and soft tissue injury. In birds, fractures of the cranium are infrequently discussed, possibly because of the necessity of taking multiple radiographic views to delineate between normally superimposed structures of the head and fracture lines. Detection of non-displaced fractures generally requires a CT scan. Fractures of the jugal arch, pterygoid bone and displacement of the quadrate bone have been reported (Figure 12.37).[18] Penetrating skull injuries occur in big bird-little bird encounters and cat attacks.

Fractures of the cervical spine are infrequent, but may be incorrectly diagnosed due to the normal sigmoid curve in this region. Accurate radiographs of the cervical spine require extension of the head and

CLINICAL APPLICATIONS

A general approach to interpretation of skeletal disorders includes the evaluation of:

- Change in bone density (osteopenia or osteosclerosis)
- Distribution of lesions (diffuse, monostotic or polyostotic)
- Architecture of the bone (cortical changes, disruption in continuity, size and shape, trabecular pattern)
- Periosteal change (smooth or coarse, lamellar or irregular)
- Margination (sharp, well-defined or poorly defined)
- Soft tissue changes

neck without rotation of the skull or body. When vertebral fractures occur, they are often located in the caudal thoracic region or the synsacrum.[7]

Diaphyseal fractures of the extremities are the most common traumatic injury. Acute fractures are characterized by sharp, well-defined margins, absence of periosteal response and concurrent soft tissue swelling (see Figure 16.16). Chronic fractures are characterized by rounding, flaring and indistinct fracture ends, periosteal change and minimal soft tissue involvement or atrophy. Fracture repair depends on the bone involved, location, type of fracture and chronicity. Avian fractures heal in a manner similar to that described for mammals, except the endosteal component is more pronounced.[2] Healing is usually complete within three to eight weeks. Lack of visualization of the fracture lines and smooth, well-defined callus bridging all cortices indicate complete healing (see Figure 42.2).

Osteolysis is the predominant radiographic change with infectious or neoplastic processes, and differentiation between these etiologies will require biopsy (see Figure 25.8). Osteomyelitis and septic arthritis may occur secondary to open fractures, penetrating wounds, iatrogenic contamination, hematogenous sources, extension from air sac disease or pododermatitis. Acute infection may show bone destruction with minimal periosteal reaction. Periosteal change is usually present with chronic infections (see Figure 33.7).

Fungal osteomyelitis may cause pronounced periosteal reaction or increased medullary opacity due to granuloma formation. *Mycobacterium* spp. may also cause medullary granulomas as well as septic arthritis and bone lysis. Infection is most common in the extremities, and vertebral osteomyelitis is rare. Osteomyelitis in the calvarium is usually due to extension from chronic rhinitis, sinusitis or periorbital lesions, and aspergillosis and mycobacteriosis may be involved. When infection occurs in association with fractures, there is often delayed union, and chronicity is characterized by regions of sclerosis and lysis. Fragments of increased density suggest compromised vascular supply and potential sequestra formation.

With acute septic arthritis, joint effusion due to synovitis may be the only radiographic change, and arthrocentesis is necessary for diagnosis (Figure 12.77). Bacteria, mycoplasma, mycobacteria and parasites may be causative agents. As an infection progresses, destruction of articular cartilage results in loss of joint space, and osteolysis and periosteal changes may occur in the epiphysis and metaphysis. Distal joints are most commonly affected, especially when the infection is secondary to septic pododermatitis. Occasionally, luxation of the affected joint may occur. Effusion and diminished joint space may occur also with degenerative joint disease, but they are usually accompanied by chronic changes such as periarticular lipping, sclerosis of subchondral bone and osteophytes (see Figure 42.11).

Primary bone neoplasia such as osteosarcoma is uncommon but has been reported in the proximal humerus, maxilla and wing tips. Bone neoplasia is frequently characterized by osteolysis with minimal periosteal change; however, osteoblastic tumors with marked periosteal reaction do occur. Most tumors involving bone occur secondary to soft tissue neoplasia (see Figure 25.2). These tumors are frequently associated with soft tissue swelling, bone destruction and pathologic fractures, and biopsies are necessary to differentiate between tumors and osteomyelitis. Metastatic bone lesions are rare.

Normal pre-ovulatory hens will have an increased medullary bone density (polyostotic hyperostosis). Prolonged, abnormally elevated estrogen levels cause a diffuse, increased medullary bone density.[14] The bones have a "marble" or mottled appearance, depending on whether bone deposition is uniform or patchy (Figure 12.65). Discrete, nodular regions of bone resembling osteomas occasionally occur on the ribs, vertebrae or pubic bones. Polyostotic hyperostosis has also been reported in hens with oviductal tumors and in cocks with sertoli cell tumors.[21,23]

Hypertrophic osteopathy is rare, but has been reported in association with pericardial effusion.[4] Radiographic lesions were characterized by extensive, fine, brush-like periosteal reaction involving most of the long bones. In other species, hypertrophic osteopathy is associated with pulmonary disease and neoplasia involving the lungs, bladder or liver.

Cardiovascular System

Radiographic Anatomy

In general, the base of the heart is angled craniodorsally and lies at the second rib. The apex is directed in a caudoventral direction and lies between the fifth and sixth ribs (varies with species) (Figure 12.1 to 12.4, 12.15, 12.16). The size and shape of the cardiac

silhouette will vary with the phase of respiration, cardiac cycle and species.

In mammals, various formulas for measuring the cardiac size from radiographs have proved inaccurate, and currently echocardiography is the most reliable method for assessing cardiac size and function. In the VD view of a normal Amazon parrot, the cardiac silhouette as measured across the heart base at the level of the atria is about 50% of the width of the coelomic cavity measured at the fifth thoracic vertebra (Figure 12.1). The lateral margins of a normal heart and liver in psittacine birds create an hourglass shape (Figure 12.1). In macaws, there is normally a ventrally directed kink between the heart and liver in the lateral view (Figure 12.35).

Radiographic Evidence of Cardiac Disease

Primary cardiac disease is rare, although congenital defects are occasionally detected on postmortem examination. Congenital and viral diseases should be considered in juvenile birds with cardiac murmurs, exercise intolerance and cardiomegaly. The latter is usually accompanied by other systemic changes. Secondary cardiac disease is more common. Pericardial effusion is recognized radiographically as a symmetrical, globoid enlargement of the cardiac silhouette and may occur in birds with chlamydiosis, polyomavirus, tuberculosis and neoplasia (Figure 12.63).

With cardiomegaly, heart enlargement is usually asymmetrical. Cardiomegaly may be caused by cardiomyopathy secondary to poxvirus (reported in macaws[12]), myxomatous valvular degeneration, endocarditis (particularly secondary to pododermatitis), hemochromatosis, chronic anemia and compression from extrinsic masses (see Chapter 27). Elongation of the heart shadow, loss of the caudal and cranial waists, loss of indentation at the junction between the heart and liver lobes and an increase in transatrial dimensions indicate an increase in cardiac size.

Microcardia is associated with hypovolemia due to acute volume loss or endotoxic shock (see Figure 21.2). There is retraction of the heart from between the liver lobes, a more angular appearance to the cardiac shape and decreased transatrial size. Whatever the etiology, microcardia suggests a critical state, and appropriate volume replacement should be instituted immediately.

Atherosclerosis with mineralization will result in prominence of the great vessels and may cause an increased density of the caudal lung field. Although seen most often in older birds on high-fat diets, severe vascular changes may occur in young birds. Acute myocardial infarcts, syncope and seizures (perhaps due to hypoxemia) have been described in birds with atherosclerosis in the absence of radiographic lesions.

TABLE 12.1 Radiographic Lesions of the Respiratory System

Differential Diagnosis	Radiographic Interpretation
Parabronchial infiltrates	Blotchy pulmonary pattern
Caseous exudate, hemorrhages or edema	Non-distinguishable parabronchi
Tumor, fungal granuloma or abscess	Abnormal pulmonary pattern (anatomy)
Air sac disease	Fixed full inspiration, barrel shape to cranial body cavity
Bacterial and fungal infection, hypovitaminosis A	Consolidating air sacculitis
Trauma, infraorbital sinus infection	Subcutaneous emphysema
Abscess or granuloma	Pulmonary masses

Respiratory System

Radiographic Anatomy

The radiographic changes associated with respiratory disease are often subtle, and high quality radiographs are necessary to detect these lesions (Table 12.1). The trachea in toucans and mynah birds deviates ventrally at the level of the thoracic inlet (see Figure 47.3). Radiographically, the normal syrinx is difficult to visualize but lies between the second and third thoracic vertebrae in most birds (Figure 12.3). The heart covers much of the lung field in the VD view and only the caudal edge of the lungs can be visualized (Figure 12.35). In normal birds, the borders of the air sacs cannot be distinguished.

Lung parenchyma appears as a honeycombed structure with the majority of the air densities representing an end-on view of parabronchi (Figure 12.35). The bronchioles can be visualized as transverse, indistinct, linear structures on the ventrodorsal radiograph. Air bronchograms and atelectasis, which occur in mammals with pulmonary disease, do not occur in birds because of their unique lung anatomy (a network of inter-connecting tubules with the lungs adhered to the thoracic wall).[12] Bacterial or fungal infections are the most common cause of pathologic abnormalities involving the respiratory tract. Chronic nasal discharge, periorbital swelling and soft tissue masses are indications for radiographs of the nasal cavity and infraorbital sinus.

Radiographic Evidence of Respiratory Disorders

Hypovitaminosis A may cause an accumulation of caseous exudate that appears as a soft tissue opacity within the sinus without bone destruction. Soft tissue swelling with osteolysis of the calvarium is often associated with osteomyelitis due to aspergillosis or mycobacteriosis. Air-filled swellings from distention of the cervicocephalic air sacs may be caused by infection, granulomas or idiopathic obstruction and should be differentiated from subcutaneous emphysema, which is more diffuse.[27]

Changes in tracheal diameter may be caused by intrinsic or extrinsic masses, stricture or stenosis. Intraluminal soft tissue masses or undulating soft tissue plaques may be caused by bacteria, hypovitaminosis A, parasites, fungi, foreign body or neoplasm. A solitary mass in the syrinx may cause severe obstructive, open-mouthed dyspnea with no obvious radiographic changes. Superimposition of the great vessels, ribs and soft tissue over the syrinx compromises interpretation. A subtle increase in soft tissue in this region or fluid accumulation in the distal trachea suggests obstruction. Although contrast tracheography may help delineate some masses, tracheoscopy is less stressful to the patient and more definitive (Figure 12.47).

Soft tissue surrounding the distal trachea is usually apparent. Tracheal strictures secondary to trauma from fight-induced injuries or cuffed endotracheal tubes occasionally occur. Tracheal stenosis and deformity of the tracheal rings are uncommon. Peritracheal masses may occur in the thoracic inlet due to thyroid enlargement secondary to goiter or neoplasm (Figure 12.45). Thyroid masses are usually well defined with smooth margins. *Aspergillus* sp. granuloma encasement of the syrinx often causes a hoarseness in vocalization and slow, progressive respiratory distress (Figure 12.46).

With pulmonary disease, the normal honeycombed pulmonary parenchyma may be enhanced by parabronchial infiltration causing prominent ring shadows obliterated by filling of the parabronchial lumen with fluid or caseous exudate or replaced by neoplastic or granulomatous infiltrates (see Table 12.1). Pneumonia often causes a prominent parabronchial pattern in the hilum and mid-portion of the lungs (Figure 12.47). As pneumonia progresses, the air-filled parabronchial lumen is replaced with caseous exudate, causing a blotchy mottled appearance to the lungs. This change is common at the caudal aspects of the lungs and is best detected on VD radiographs. Pulmonary edema and hemorrhage have a more diffuse appearance (Figure 12.50). Discrete, well defined masses are usually abscesses, granulomas or tumors (Figure 12.49).

The size of the air sacs will vary between inspiration (increased) and expiration (decreased). Additionally, the lung architecture will be more apparent on inspiration. Air sac disease may cause a barrel-shaped appearance to the thorax (Figure 12.51). Consolidated or thickened air sacs are not as compliant as normal air sacs, causing the inspired air to be deposited in a relatively fixed cavity.

Radiographic changes indicative of inflamed air sacs include diffuse thickening, nodular infiltration or consolidation. Fine lines across the air sacs with mild increased opacity indicate thickening and are best detected on the lateral radiograph (Figure 12.52). The loss of visualization of abdominal viscera, blending of the air sacs, blending of the interfaces between air and soft tissue and a hazy heterogeneous appearance to the air sacs are suggestive of consolidation (Figures 12.53, 12.54). Hyperinflation of the air sacs in combination with a radiolucent appearance suggest air trapping due to obstructed flow or abnormal compliance.

Subcutaneous emphysema may result from traumatic rupture of an air sac or as a complication of endoscopy (see Chapter 22). Fractures of the coracoid or ribs may penetrate the air sacs, causing emphysema.

Coelomic Cavity and Gastrointestinal System

Radiographic Anatomy

The crop is present in the right lateral thoracic inlet area on the VD view. It may extend to varying degrees across the midline depending on the presence of ingesta and the species of bird (Figure 12.71, 12.74). The thoracic portion of the esophagus can usually be differentiated on the VD and lateral radiographs. The cervical portion of the esophagus cannot be distinguished without contrast media.

The proventriculus lies dorsal to the liver on the lateral view (Figure 12.35). The left lateral border of the proventriculus may be difficult to distinguish from the left lateral edge of the liver on the VD view. If the liver is of normal size, the proventriculus shadow will lie slightly lateral to the liver on the VD view. If the ventriculus contains radiodense material, it can generally be viewed on both the VD and lateral

radiographs in its normal location, caudal and ventral to the proventriculus.

The position of the intestinal tract is widely variable but it generally occupies the caudal, dorsal abdominal cavity (Figure 12.72). The cloaca may or may not be visualized, depending on its contents. The summation between the liver and proventriculus on the VD view should not be misinterpreted as pathology (Figure 12.35). The duodenal loops lie to the right of the ventriculus in the VD view (Figure 12.72).

Spleen

If detectable on the VD radiograph, the spleen will be noted as a slightly oblong, rounded structure to the right of midline between the proventriculus and ventriculus. On the lateral view, the spleen, if visible, overlaps the caudal end of the proventriculus and may be slightly dorsal to it (Figure 12.35). Suggested normal spleen sizes include: budgerigar = 1 mm, African Grey Parrot or Amazon parrot = 6 mm, Umbrella Cockatoo = 8 mm. The spleen of a pigeon is elongated or bean-shaped. In many other species it is spherical. Splenomegaly may be caused by infectious, neoplastic or metabolic diseases (Figure 12.62), (Table 12.2).

Liver

The liver does not normally extend beyond the sternum on the lateral radiograph (Figure 12.35). In psittacine birds, the liver should not extend laterally past a line drawn from the coracoid to the acetabulum. The size of the hepatic silhouette can best be determined by making measurements of a VD radiograph taken on inspiration. The distance is measured in millimeters from the mid-sternum to the lateral-most aspect of the ribs at the base of the heart. This measurement is referred to as the sternal/rib distance (SR). This distance is divided by one-half and should be equal to the width of the right liver as measured at the base of the heart. The size of the right liver is determined by measuring from the mid-sternum to the edge of the liver at the base of the heart. If the actual measurement of the liver is greater than its anticipated size as determined by the SR value, then the liver is considered enlarged. If the actual measurement of the right liver is less than its anticipated size as determined by the SR value, then the liver is considered to be reduced in size (Harrison GJ, unpublished).

The liver in macaws and cockatoos frequently appears to be reduced in size (Figure 12.58). The importance of this finding remains undetermined; however, many birds with microhepatia are being fed seed diets that may or may not be supplemented with fruits and vegetables. Many affected birds have abnormally low populations of gram-negative bacteria, low bile acids levels and elevated LDH, AST and GGT activities. The CPK may be normal or elevated (Harrison GJ, unpublished). The pesticide residues that are present in most commercially available foods may play a role in the high incidence of hepatopathies in companion birds and should be addressed in birds with microhepatia. In obese pigeons, the liver will appear enlarged, which will resolve when the birds are fasted.

TABLE 12.2 Differential Diagnosis for Hepatomegaly, Splenomegaly and Nephromegaly

Hepatomegaly	Etiologies
Infectious	Chlamydial, viral (eg, Pacheco's disease virus, reovirus, polyomavirus), bacterial, mycobacterial and fungal
Neoplastic	Primary (biliary adenocarcinoma, hepatocellular carcinoma, fibrosarcoma, hemangiosarcoma, hepatoma and lymphoma) and Metastatic (adenocarcinoma, fibrosarcoma and melanoma)
Parasitic	Toxoplasmosis (mynahs), *Sarcocystis* sp., flukes (cockatoos) and *Plasmodium* sp.
Metabolic	Lipidosis, fatty degeneration, hemochromatosis (mynahs and toucans) and gout
Splenomegaly	**Etiologies**
Infectious	Chlamydial, viral, bacterial and mycobacterial
Neoplastic	Lymphoma, hemangiosarcoma, fibrosarcoma and leiomyosarcoma
Metabolic	Lipidosis and hemochromatosis
Nephromegaly	**Etiologies**
Infectious	Bacterial, chlamydial
Neoplastic	Adenocarcinoma, embryonal nephroma
Metabolic	Dehydration, lipidosis, gout
Cystic	Occluded ureters, congenital
Toxic	Heavy metals

(modified from McMillan[13])

The liver is frequently involved in systemic disease, and hepatomegaly is a common radiographic finding. Symmetrical enlargement of the liver lobes is most common and is usually associated with infectious and metabolic processes (Table 12.2). Neoplasms and granulomatous diseases can cause asymmetrical enlargement of the liver.

Radiographic changes associated with liver enlargement are loss of hourglass waist in the VD view, rounding of liver lobe margins, compression of abdominal air sacs, extension of the liver lobes beyond the scapula/coracoid line, cranial displacement of the

heart, dorsal elevation of the proventriculus and caudodorsal displacement of the ventriculus (Figure 12.1, 12.60).[13] A dilated, fluid-filled proventriculus may appear radiographically similar to hepatomegaly, and a careful assessment of the VD view can be used to differentiate between these lesions.

Pancreas

Radiographic changes involving the pancreas are rare, although diminished contrast in the right cranial abdomen due to sanguineous exudate from acute necrotizing pancreatitis has been reported. Pancreatic masses are uncommon; however, space-occupying lesions in the right cranioventral abdomen may involve the pancreas, and large pancreatic cysts do occur.

Gastrointestinal Tract

The specific areas of the gastrointestinal tract are best visualized through barium contrast examination. The presence of gas, change in position and abnormal distention suggest a disease process. Altered gastrointestinal motility causing uniform or segmental dilatation can be due to functional or mechanical ileus.

Birds do not normally have gas in the intestinal tract, and any gas should be considered abnormal. Aerophagia can occur secondary to severe respiratory disease or is frequently seen as an artifact of gas anesthesia (Figure 12.69). Distended, fluid-filled bowel loops should be considered abnormal except in mynah birds and toucans.

Inflammation, infection, foreign bodies, parasites, intussusception, stricture, granuloma and neoplasia may cause intraluminal obstruction and segmental increases in the diameter of the gastrointestinal tract lumen secondary to excess gas and fluid accumulation. Extraluminal masses such as neoplasm, abscesses, eggs and cysts may compress the gastrointestinal tract and cause changes similar to intraluminal obstruction.

Uniform distention of the gastrointestinal tract is most commonly associated with functional ileus due to viral or bacterial infections, toxicity (eg, heavy metals), septicemia, hypoxemia, peritonitis or anesthesia. Distention of the ingluvies, proventriculus or ventriculus may be due to a localized process or obstruction within the intestines. A barium contrast study is indicated for complete evaluation of the intestinal tract.

The cloaca may be distended from a retained soft-shelled egg, papilloma, cloacalith, neoplasm or idiopathic atonic dilatation (Figure 12.70). Atonic distension of the cloaca may occur with spinal trauma and infiltrative neoplasms involving the sacral nerves.

Abdominal masses usually cause a change in the location of the gastrointestinal tract. Hepatomegaly usually causes dorsal displacement of the proventriculus and caudodorsal displacement of the ventriculus. Splenic, testicular, ovarian and renal masses compress the gastrointestinal tract ventrally and either cranially or caudally. Adhesions due to inflammatory or septic peritonitis from ruptured eggs or perforation can also result in displacement of the gastrointestinal tract (Figure 12.67).

Abdominal effusion is associated with liver disease, neoplasia, metabolic disorders, sepsis, inflammation and cardiac failure. Fluid results in a homogeneous appearance to the intestinal peritoneal cavity (IPC) and obscures visualization of specific organs (Figure 12.67). Consolidating air sacculitis can appear radiographically similar to fluid in the IPC in the lateral view, but differentiation is possible in the VD radiograph. If a pathologic process is occurring within the air sacs, specific organs within the intestinal peritoneal cavity will be definable in the VD view. If the fluid is within the IPC, there will still be a homogeneous appearance to the region of the viscera, and the air sacs will be compressed (Figure 12.67). Fluid accumulation in the IPC may compress the liver ventrally and displace the proventriculus and ventriculus cranially.

Urogenital System

The anatomy and physiology of the avian kidneys prevent the radiopacity that is characteristic of mammalian kidneys. The kidneys are attached to the synsacrum, are flattened dorsoventrally and have smoothly rounded cranial and caudal divisions (Figure 12.35).

The kidneys are best visualized in the lateral view. Because the renal silhouettes are superimposed, lateral oblique views may be necessary to distinguish each kidney. The cranial division of the kidney protrudes from the pelvic brim, and the caudal division may also be visualized on the lateral view. The kidneys are generally not visible on the VD view, although the rostral edge of the cranial division can occasionally be seen. If the kidneys are enlarged or

increased in opacity, they may be more readily visualized in the VD position. The length of a normal African Grey Parrot kidney is about 3 cm on the lateral view. In the Umbrella Cockatoo, the suggested normal kidney size is 3 cm x 0.7 cm. The kidneys are normally surrounded by air, and loss of the air shadow indicates renal enlargement, dorsal displacement of abdominal organs or the presence of abdominal fat or fluid (Figure 12.56).

Bilateral symmetrical nephromegaly results in a diminished abdominal air sac space surrounding the kidneys and occurs with infection, metabolic disease, dehydration, post-renal obstruction and lymphoreticular neoplasia. Dehydration may also be associated with increased renal density (see Figure 21.2). A localized enlargement with irregular borders is most commonly associated with a neoplasm, although abscesses may appear radiographically similar (Figure 12.57).

Most renal tumors are locally invasive and usually do not metastasize. A solitary mass with smooth, well defined margins is suggestive of a cyst; however, biopsy is the only definitive way to differentiate cysts, neoplasms and abscesses. Intravenous excretory urography is necessary to confirm renal disease when severe nephromegaly obliterates the air space and creates a positive silhouette sign with other viscera.

Masses involving the spleen, oviduct, testicles, ovary and intestines may occupy space in the caudodorsal abdomen and mimic renal lesions (Figure 12.62). The testes of a reproductively active male are easily distinguishable and should not be misinterpreted as renal enlargement.

Testicular abnormalities causing radiographic signs are uncommon. Occasionally tumors cause testicular enlargement, and functional sertoli cell tumors may cause polyostotic hyperostosis. Orchitis is most easily diagnosed through laparoscopy, and radiographically cannot be distinguished from physiologic hypertrophy.

In a hen, an active ovary resembling a bunch of grapes may be apparent cranial to the kidneys, and an increased soft tissue opacity in the caudodorsal abdomen just ventral to the kidneys represents the oviduct (Figure 12.64). The most common radiographically detectable abnormalities involving the female genital tract are retained eggs, cystic oviduct and egg-related peritonitis.

Mineralized eggs are easily visualized and often located in the terminal oviduct. Multiple eggs may be present, and eggs may be free in the coelomic cavity due to reverse peristalsis or oviductal rupture. Soft-shelled eggs are difficult to differentiate from other abdominal masses, and ultrasound may aid in the diagnosis (Figure 12.66).

Hyperestrogen syndrome is common in budgerigars and is characterized by an enlarged, distended oviduct, medullary hyperostosis, diminished abdominal detail, visceral displacement, abnormal attempts at egg formation and abdominal hernia (Figure 12.65).[14] Egg-related peritonitis can be difficult to discern from other causes of abdominal effusion. Cessation of egg laying, weight loss and abdominal distention in a hen with a history of chronic egg laying are suggestive of egg-related peritonitis. Abdominocentesis and ultrasound can be used to differentiate between causes of abdominal fluid (Figure 12.67).

Contrast Procedures

Administration of contrast agents can be used to enhance visualization of intraluminal abnormalities involving the gastrointestinal tract, respiratory system, cardiovascular system and subarachnoid space, and provides a qualitative assessment of function. Contrast agents used in mammals are considered safe in birds, although limited studies have been performed to assess specific contrast media reactions.[6,14]

The presence of concurrent disease and a patient's age, size and state of hydration should all be considered prior to initiating a contrast study. Severely debilitated and seriously ill birds should be stabilized and any fluid and electrolyte imbalances corrected prior to the study. Contrast studies are often stressful because of the number of radiographs required, and sedation is contraindicated in studies involving the gastrointestinal tract because of its effect on gastrointestinal motility. If anesthesia is used, it will slow the passage of contrast media, which should not be misinterpreted as a pathologically induced decrease in transit time.

Gastrointestinal Positive and Double Contrast Procedures

Gastrointestinal studies are the most frequently performed contrast procedures in birds. They are useful in delineating the position, structure and function of the gastrointestinal tract and associated organs.

Indications for barium follow-through examination are acute or chronic vomiting or diarrhea that is nonresponsive to treatment, abnormal survey radiographic findings suggestive of an obstructive pattern, unexplained organ displacement, loss of abdominal detail suggesting perforation, hemorrhagic diarrhea, history of ingestion of foreign material and chronic unexplained weight loss.[11] Dehydrated birds should be rehydrated before administration of contrast media to prevent the material from forming concretions within the gastrointestinal tract.

Gastrointestinal motility may be altered by pathologic conditions, stress and medications. Any drugs that may alter motility such as tranquilizers, anesthetics and anticholinergics should be discontinued for twenty-four hours prior to the gastrointestinal contrast study. The age, size, diet and condition of the patient will all affect gastrointestinal transit time. Faster transit times occur in small birds on soft diets. Passage is slowed in large seed-eating birds, obese birds, in neonates on soft diets and in anesthetized birds.

Obtaining survey radiographs prior to beginning a procedure will ensure proper technique as well as provide a method of re-evaluating any changes in the radiographic pattern that may influence the study. The best contrast study can be performed when the gastrointestinal tract is empty. Excess fluid in the ingluvies should be removed with a gavage tube prior to the administration of contrast media. The presence of ingesta or fluid interferes with the quality of the study and may obscure lesions. Usually, a four-hour fast is adequate for emptying of the gastrointestinal tract without placing undue stress on smaller avian species. The gastrointestinal tract may be empty at the time of presentation in birds that are regurgitating.

Commercial barium sulfate suspensions provide the best studies. Chemical grade barium is difficult to mix properly and may flocculate. If perforation of the gastrointestinal tract is suspected, an organic iodine is recommended; however, these preparations are hypertonic and can cause dehydration, especially in small patients. Additionally, organic iodines are hydroscopic and are rapidly absorbed from the gastrointestinal tract. Dilution of the contrast medium with intraluminal fluid may compromise the study and interfere with defining the region of perforation. These agents do not coat the mucosa like barium does and are not recommended for routine gastrointestinal examinations.

In juvenile birds, barium should be warmed prior to administration. This is not necessary with adult birds. To administer barium, the head and neck are extended and a soft, flexible feeding tube is passed into the crop (see Figure 15.6). Small species do not require a speculum for passage of the tube; however, larger species need the beak held open either with a speculum or gauze. Measuring the distance from the beak to the crop and marking the tube helps ensure that the tube is within the crop and not accidentally passed into the tracheal lumen. The tube should be palpated within the crop prior to the administration of contrast material.

The dose of barium sulfate varies depending on the species and presence or absence of a crop, and ranges from 0.025-0.05 ml/g body weight, with the lower dose range used in larger species. Lesions in the mucosa are best identified by using a higher dose, and a lower dose can be used if the intention is to simply identify borders of the gastrointestinal tract.

The contrast media should be administered slowly until the crop is comfortably distended. Placing a finger over the distal portion of the cervical esophagus may help prevent reflux of barium sulfate while it is being administered. Placing excessive pressure on the full crop may induce regurgitation. Slow removal of the tube may also help reduce reflux. If any regurgitation occurs, the administration of contrast media should cease in order to reduce the risk of

CLINICAL APPLICATIONS

Radiographic abnormalities that may be defined by gastrointestinal contrast studies include:

- Change in location, size or shape of abdominal organs
- Differentiation between the gastrointestinal tract and other organs
- Altered motility (increased or decreased)
- Increased or decreased luminal diameter
- Mucosal irregularities
- Filling defects
- Changes in wall thickness
- Extravasation of contrast media
- Dilution of contrast with mucus or fluid

pulmonary aspiration (see Chapter 22). Barium has been used for bronchography in non-avian species because it is less irritating than other contrast agents.[25] It is the volume of barium inhaled into the respiratory tract and not the agent itself that may cause problems.

Radiographic sequence may vary depending on the species and condition under investigation; however, in general, radiographs should be taken immediately after administration of contrast media and at 0.5-, 1-, 2-, 4-, 8- and 24-hour intervals (Table 12.3). The temporal sequence may vary if a lesion is identified during the study.

If the crop is the only area of concern, a double contrast ingluviography may be performed in association with a barium follow-through study or as a separate procedure. Double contrast studies allow enhanced visualization of the crop wall for irregularities such as thickening, mucosal defects, masses and the detection of foreign bodies that may be obscured by a single-phase contrast study. The total volume of contrast to be administrated (0.025 ml/g) is determined. Half of the total volume is given as air and the rest as barium. The air should be administered first to prevent air bubbles from forming within the contrast media. Although double contrast cloacography can also be performed, direct visualization with endoscopic equipment or an otoscope is preferable (Figure 12.70).

Contrast Study Findings

Delayed transit time may be caused by functional or mechanical ileus. Mechanical ileus, depending on the level of obstruction and degree of luminal compromise, usually causes segmental dilation of the gastrointestinal tract. Functional ileus usually causes a uniform distention of the gastrointestinal tract (see Figure 32.22). Mechanical obstruction occurs with intraluminal or extraluminal masses, foreign body ingestion, helminthiasis and stricture. Intraluminal masses such as neoplasm, abscess, granuloma, intussusception and papilloma will cause filling defects within the contrast column (see Figure 25.15). Mucosal irregularity and ulceration may aid in differentiating neoplasia from more benign processes, but fungal disease and neoplasia can be difficult to distinguish radiographically, and biopsy is the only definitive method to differentiate these diseases. Extraluminal masses involving the thyroid gland, spleen, gonads, oviduct or kidney may compress the lumen of the gastrointestinal tract and cause altered motility or obstruction.

Functional ileus occurs most frequently with neuropathic gastric dilatation and most often involves the proventriculus and ventriculus, although portions of the intestines may also be involved (see Figure 32.24).[11] Neurotoxins such as lead, inflammatory processes involving the coelomic cavity, severe enteritis and anesthetics may cause functional ileus.

Displacement of the gastrointestinal tract may occur with organomegaly, accumulations of fluid in the intestinal peritoneal cavity, adhesions or hernia. Hepatomegaly causes dorsal elevation of the proventriculus and caudal movement of the ventriculus. Splenic, gonadal and renal lesions may displace the intestines ventrally. Masses originating from the cranial division of the left kidney may push the ventriculus cranially. Adhesions associated with egg-related peritonitis may result in abnormal positioning of portions of the gastrointestinal tract, with a fixed appearance and changes in luminal diameter. Hernias, usually in hens, cause caudoventral displacement of the gastrointestinal tract.

A change in luminal diameter and wall thickness most often occurs with obstruction or functional ileus. Fungal diseases and neoplasia can cause narrowing of the lumen due to mural infiltration. Inflammatory changes can also increase wall thickness and influence motility (see Figure 36.31). Mucosal defects are most pronounced with aggressive diseases such as neoplasia or fungal infections. Spiculation of the contrast column due to a hyperemic mucosa, stringing out of barium from mixing with mucus, diminished bowel distensibility and increased transit times occur with inflammation (see Figure 19.12).

TABLE 12.3 Barium Sulfate Transit Times*

	Stomach	Small Intestines	Large Intestines	Cloaca
African Grey Parrot	10-30	30-60	60-120	120-130
Budgerigar	5-30	30-60	60-120	120-240
Racing pigeon	5-10	10-30	30-120	120-240
Indian Hill mynah	5	10-15	15-30	30-90
Hawk	5-15	15-30	30-90	90-360
Amazon parrot	10-60	60-120	120-150	150-240
Canary	5	10-15	15-30	30-90
Pheasant	10-45	45-120	120-150	150-240

*Time in minutes for barium sulfate administered by crop gavage to reach and fill various portions of the GI tract.

Extravasation of contrast media occurs most often with foreign body perforation, although metal feeding tubes or inflexible catheters can result in iatrogenic perforation of the gastrointestinal tract if improperly used. Mural erosion in association with neoplasm, abscess or granuloma are less frequent causes of perforation (see Figure 25.14). If a perforation is suspected, an organic iodine contrast agent is recommended to prevent contamination of the coelomic cavity with barium.

Repeatability of a lesion on multiple views is important when attempting to identify intraluminal masses. Gas bubbles and ingesta can create artifacts that mimic mucosal defects and can lead to an incorrect diagnosis. Tailoring the study to the individual patient and obtaining additional views during the study will aid in accurate interpretation.

Intravenous Excretory Urography

In birds, the absence of a urethra, bladder, renal pelvis or division between the medulla and cortex, as well as the glomerular filtration rate, tubular resorption and the renal portal system make contrast urography of limited value. The primary indication for intravenous excretory urography is in defining mass lesions associated with the urinary tract or delineating the size and shape of the kidneys if they cannot be adequately visualized on routine radiographs (Figure 12.55).[14] Excretory urography may also have some application for diagnosing functional disorders. Excretory urography should not be attempted in patients with dehydration or debilitation or if renal function is severely compromised.

Sodium diatrizoate (680 mg of iodine/kg), iothalamate sodium (800 mg of iodine/kg) or meglumine diatrizoate (800 mg of iodine/kg) have been used for urography in birds with no observable adverse effects.[6,14] These organic iodines should be warmed prior to administration through the ulnar, jugular or medial metatarsal veins. Radiographs are taken immediately after contrast administration and at one-, two-, five-, ten- and twenty-minute intervals using the same technique developed for the survey radiograph.

Most diagnostic information is obtained within the first five minutes of the study (Figure 12.55). The aorta, heart and pulmonary artery will be visualized within ten seconds; kidneys and ureters in 30 to 60 seconds; and cloaca in three to five minutes after administering the contrast media (Figure 12.55).[7] In the nephrographic phases of the study, there is an immediate, uniform opacification of the kidneys highlighting their size, shape and contour. In the normal kidney, the three divisions are readily discernible. There is no pyelographic phase.

Mass lesions such as renal tumors and cysts cause changes in the size, shape and contour of the kidneys and are distinguishable from gonadal lesions because of the contrast enhancement. Tumors are usually solitary mass lesions with irregular margins and are best visualized in the lateral view. Cysts tend to have smooth, well defined borders. Biopsy is necessary to definitively differentiate between tumors and cysts. Abnormalities of the ureters are rare, but they may be compressed in birds with egg binding and cloacal or abdominal masses.[1] Occasionally, cloacal lesions may be outlined during urography.

Radiographic changes in the excretory urogram are most striking when the renal disease is unilateral because the unaffected kidney is usually hypertrophied. In contrast, obstruction of a ureter may increase the radiodensity of the ipsilateral kidney by delaying the washout from the kidney. If urine containing contrast medium is discharged into a pool of urine containing no contrast media, the opacification will be delayed and reduced. Because a large pool of urine may be retained in a hydroureter and with hydronephrosis, late films should be taken when no contrast media is noted on early radiographs.

If one kidney appears to be non-functioning, it is important to consider the urinary protein concentration, cytologic features of sediment and the size of the contralateral kidney. In acute renal failure, the excretory function is rapidly and severely, but often reversibly, compromised. If the contralateral kidney is hypertrophied, the absence of function on the opposite side is probably chronic in nature (urolithiasis) and may even indicate agenesis of that kidney (see Figure 21.4).

Positive Contrast Rhinosinography

Contrast studies of the nasal cavity and sinuses may aid in evaluation of the upper respiratory tract; however, CT has replaced these procedures in other species (Figure 12.38 to 12.40). A 15 to 20% organic iodine agent can be injected into the sinus, and the same views recommended under skull radiography are taken for evaluation. Reactions to the contrast agent include edema and periorbital swelling. At the end of the procedure, the media can be flushed out of the sinuses with sterile saline to decrease the amount

of local irritation. Space-occupying masses such as neoplasms, abscesses or granulomas may cause an obstruction to the flow of contrast media (Figures 12.42, 12.43). In normal psittacine birds, there should be communication between the infraorbital sinus, nasal cavity, opposite sinus, periorbital region and tympanic region (Figures 12.39, 12.40).[12] In some Passeriformes, the sinuses do not communicate (Figure 12.41).

Positive Contrast Tracheography and Bronchography

Contrast studies of the lower respiratory tract should be considered high risk because patients requiring these procedures are usually experiencing serious respiratory compromise. Tracheoscopy is preferable in patients of sufficient size (300 g). Focal lesions in the terminal trachea or at the tracheobronchial bifurcation that are difficult to visualize on survey radiographs may be defined by contrast tracheography (Figure 12.47).[12]

Patients should be stabilized with oxygen therapy and a tube placed in an abdominal sac to provide oxygen and anesthesia. Birds should be anesthetized for these studies. Contrast media is administered via a tube placed in the trachea. Small aliquots (approximately 0.1 ml) of a non-ionic agent or propyliodone should be given at a time, and radiographs taken to determine tracheal filling. A minimal amount of contrast media will be needed if fluoroscopy can be used to identify a foreign body.

Non-selective Angiography

Cardiac disease requiring definition by contrast studies is rare. Diseases such as cardiomyopathy, some congenital shunts and valvular disease may be defined by angiography in some larger birds; however, ultrasonography is being utilized with greater frequency in other species. Non-selective angiography has been used for defining the normal cardiac silhouette and major vessels. The same agents used for urography can be injected as a single, rapid, intravenous bolus in the jugular or ulnar veins to enhance visualization of the heart and great vessels. A rapid film changer, cinefluoroscopy or videotaping is necessary to record the image.

Myelography

Assessment of back trauma or congenital defects may require myelography. Patients must be anesthetized for this procedure. The bird is placed in lateral recumbency and a 25 ga needle or smaller is carefully inserted into the subarachnoid space. Cerebral spinal fluid will flow into the needle, and several drops can be collected for cytology. A non-ionic contrast media (0.25 ml/kg) is slowly injected into the cerebellar medullary cistern. Routine radiographs of the spine are taken.

Alternative Imaging

Fluoroscopy

A fluoroscope can be connected via an image intensifier to a video camera that can be used to make real-time recordings of organ movement. In birds, fluoroscopy is the best way to monitor the motility of the gastrointestinal tract. Patients can be placed in a darkened box to perform fluoroscopy. This technique may be particularly useful for detecting hernias, neoplasms, proventricular dilatation, hypermotility, ileus and gastric ulceration. In a normal parrot given a bolus of barium sulfate by crop tube, the barium will fill the proventriculus and ventriculus in five to ten minutes. The barium will reach the intestines in 15 minutes. These findings suggest that unrestrained (reduced stress) birds have a faster gastrointestinal motility time than is routinely reported using standard radiographic techniques.[22]

Ultrasound

Ultrasonography is an imaging technique that makes use of high frequency sound waves transmitted by a transducer that is in contact with the skin. The waves are transmitted through the tissues in the abdomen and the echoes are recorded by the receiving transducer unit. The resistance to sound waves depends on the molecular structure of the tissue that is being penetrated. If the sound waves encounter bone, most of the waves are absorbed and not reflected. If the sound waves are transmitted through air, most are reflected and not absorbed. In both of these cases, organs that lie behind these structures will not be detected.

Ultrasound studies in birds are somewhat limited by patient size and conformation and the presence of air sacs; however, in larger avian patients with abdomi-

Radiographic Anatomy and Abnormalities

Radiography is an extremely valuable diagnostic tool in avian patients. Every avian clinician should be comfortable with radiographic techniques and interpretation of radiographic findings. One of the challenges of identifying subtle changes in radiographs of birds is the wide species variability in normal anatomic structures. Radiographs and xeroradiographs of the Orange-winged Amazon Parrot, cockatiel, Bobwhite Quail and Mallard Duck are provided to assist the clinician in developing a more complete understanding of the unique anatomic structures encountered in varying genera of birds. These radiographs were provided by Bonnie J. Smith and Stephen A. Smith and are reprinted with permission from Veterinary Radiology 31:114-124, 1990; 32:87-95, 1991; 31:226-234, 1990; 32:127-134, 1991.

Following the initial radiographs that address normal radiographic anatomy are case presentations demonstrating characteristic radiographic changes associated with pathology in various organ systems. The reader is encouraged to compare the radiographic findings in these cases with the normal radiographs and xeroradiographs presented in the first section. Additionally, radiographs detailing changes associated with specific organ systems can be found in respective sections throughout the book.

FIG 12.33 Mediolateral xeroradiograph of the pelvic limb of a normal Bobwhite Quail (courtesy of Bonnie J. Smith and Stephen A. Smith).

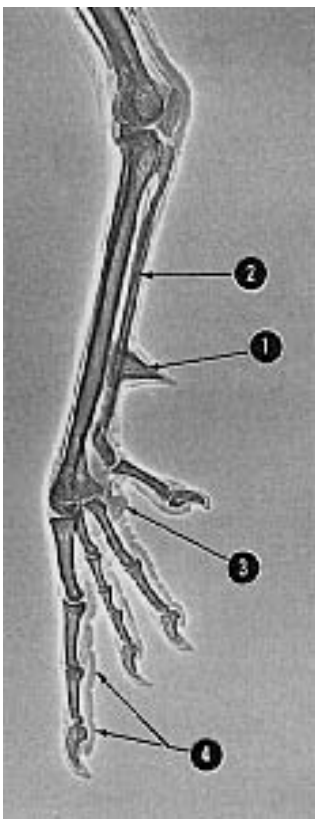

FIG 12.34 Mediolateral xeroradiograph of the pes of a peacock. 1) the calcarial process is the osseous core of the metatarsal spur or calcar. Note the horny sheath covering the process. 2) Note also the mineralization of the digital flexor tendons as well as the 3) well-developed metatarsal and 4) digital pads in this ground-dwelling bird (courtesy of Bonnie J. Smith and Stephen A. Smith).

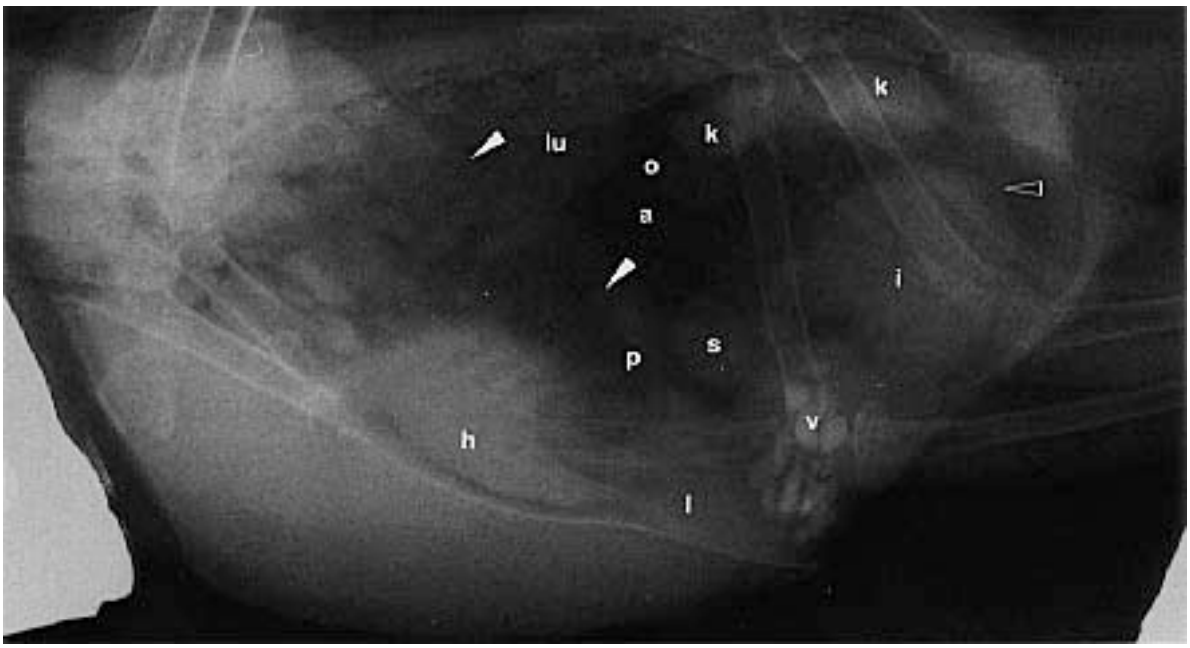

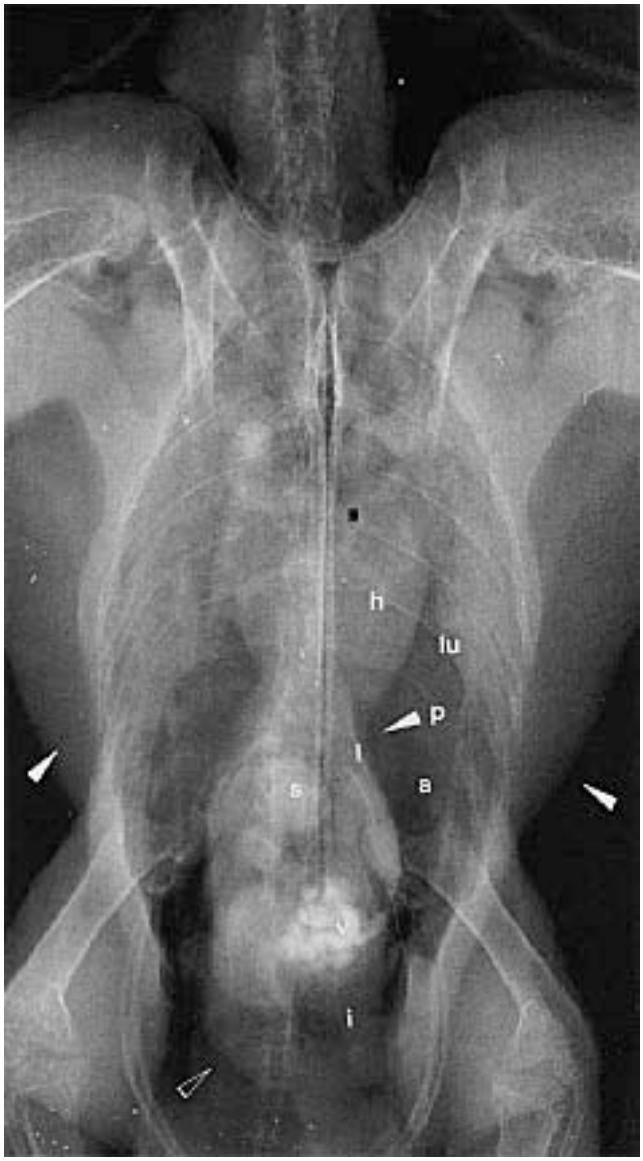

FIG 12.35 Low contrast radiographs of a Hyacinth Macaw demonstrating soft tissue structures: heart (h), spleen (s), liver (l), lung (lu), kidneys (k), proventriculus (p), ventriculus (v), ovary (o), intestines (i), contiguous area of the caudal thoracic and abdominal air sacs (a), body musculature (arrow) and right abdominal air sac (open arrow) (courtesy of Marjorie McMillan).

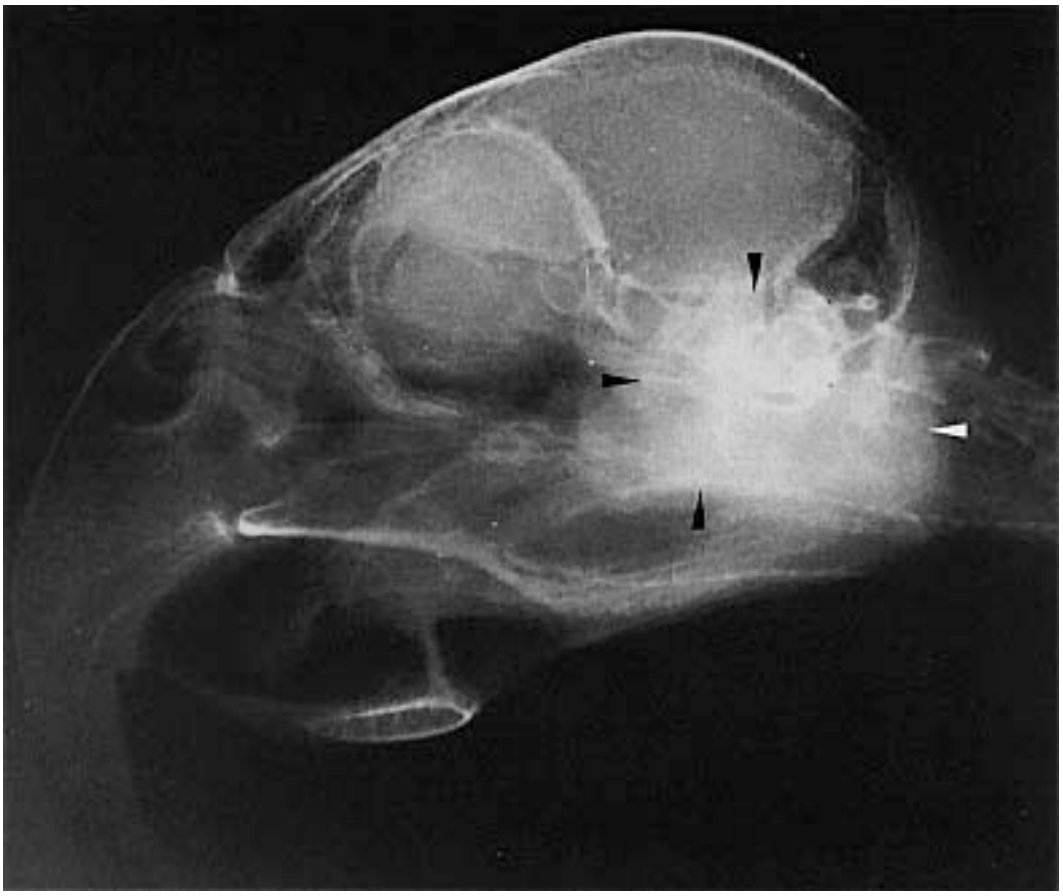

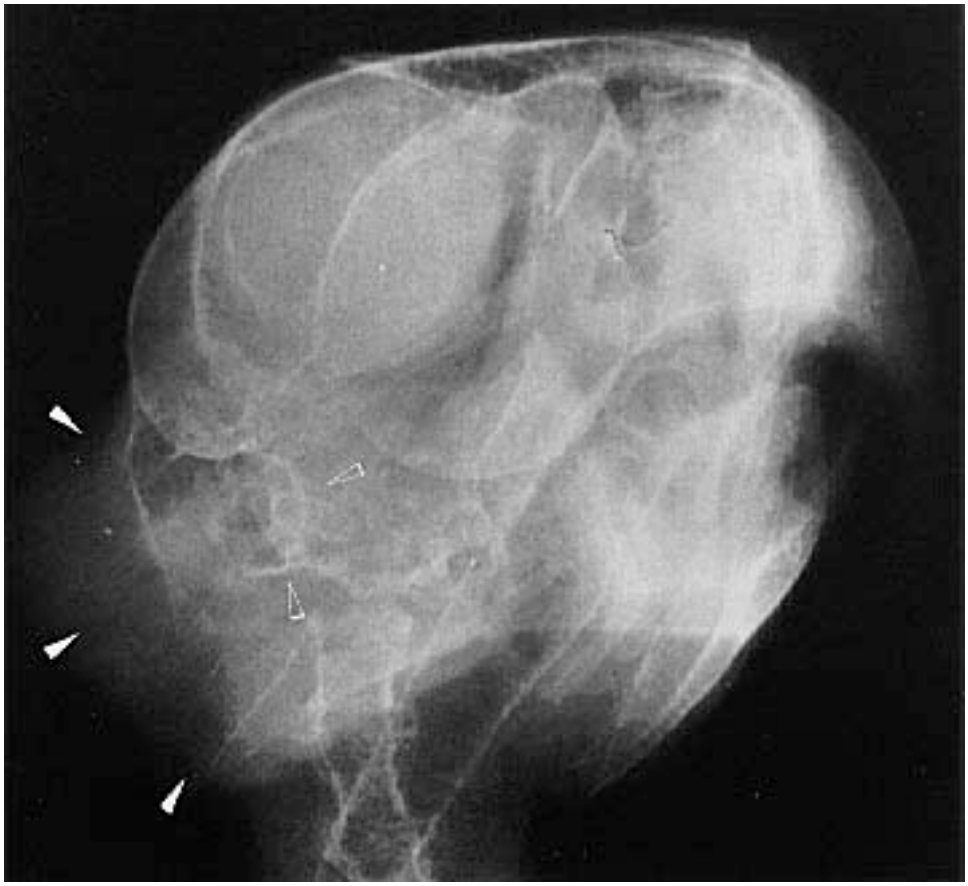

FIG 12.36 A six-year-old Amazon parrot was presented with firm bilateral swelling surrounding the auditory meatus (arrows). The masses were solid and attached. **a)** Surgical biopsy of the mass indicated chronic fibrosing cellulitis. **b)** The mass is easily visualized on an oblique view of the head (arrows). The tympanic area can also be visualized (open arrows). The masses resolved when the bird was changed from an all-seed to a formulated diet.

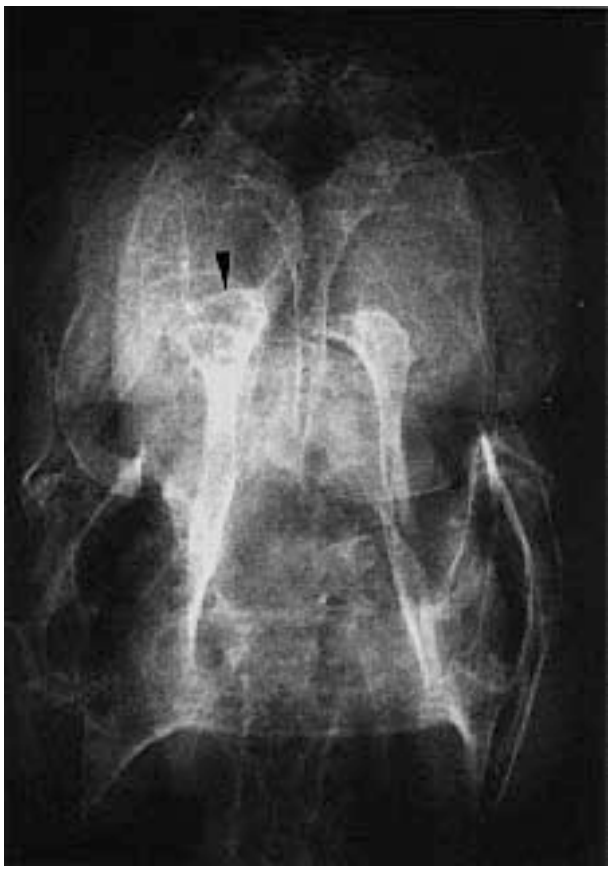

FIG 12.37 Alexandrian Parakeet with lateral deformity of the maxillae. The deformity had been present since hatching. The parents of this bird produced a defective neonate every four to six chicks, suggesting that the problem was genetic in origin. Rostrocaudal radiograph showing dorsal displacement of the right palatine bone (arrow). Ventrodorsal radiograph showing lysis of the right palatine bone (arrow).

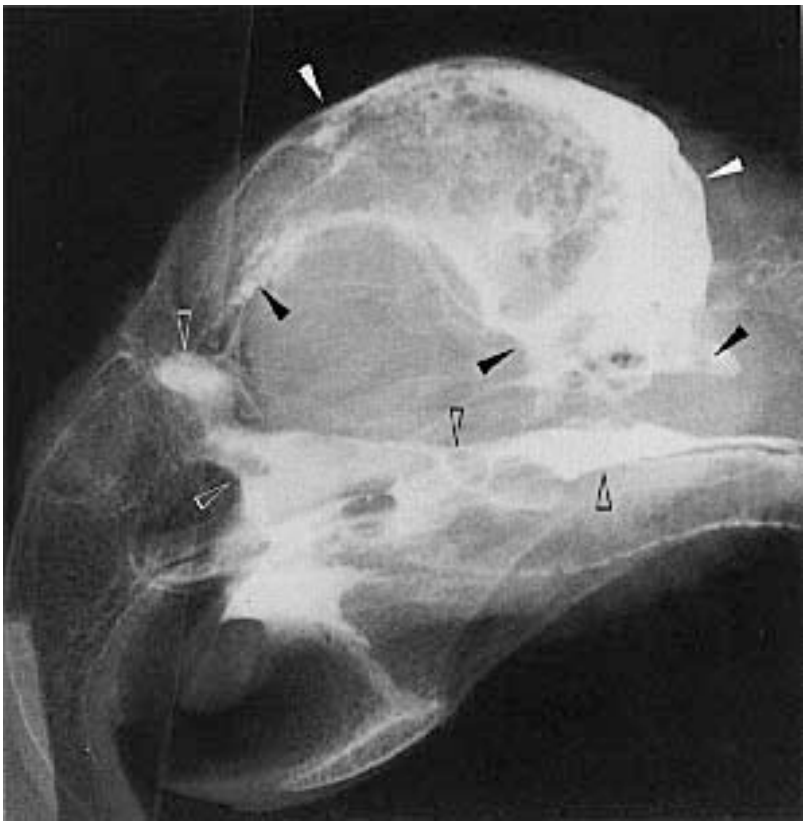

FIG 12.38 Lateral positive contrast air sacculography demonstrating the extent of the cephalic air sac in a mature Blue-fronted Amazon Parrot. The cephalic portion (arrow) of the cervicocephalic air sac connects to the caudal aspect of the infraorbital sinus (open arrow) (courtesy of Marjorie McMillan).

FIG 12.39 Lateral view of a rhinogram performed on a normal Bare-eyed Cockatoo showing the flow of contrast medium from the nasal cavity (open arrows) through the choanae at the level of the palate and into the nasopharynx and oral cavity (open arrow). Other structures include the mandible (m), zygomatic arch (z), ceratobranchial bone of hyoid (c) and tracheal tube (t) (courtesy of Elizabeth Watson).

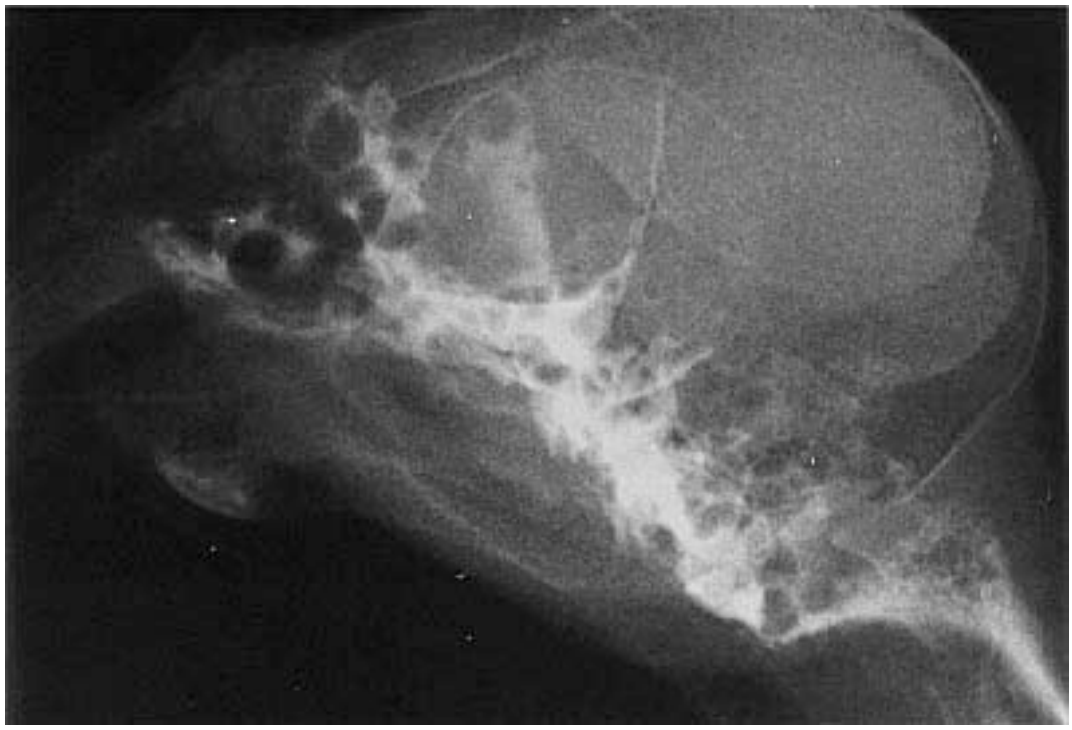

FIG 12.40 Positive contrast sinography in an adult cockatiel showing drainage and interconnections of the infraorbital sinuses (courtesy of Marjorie McMillan).

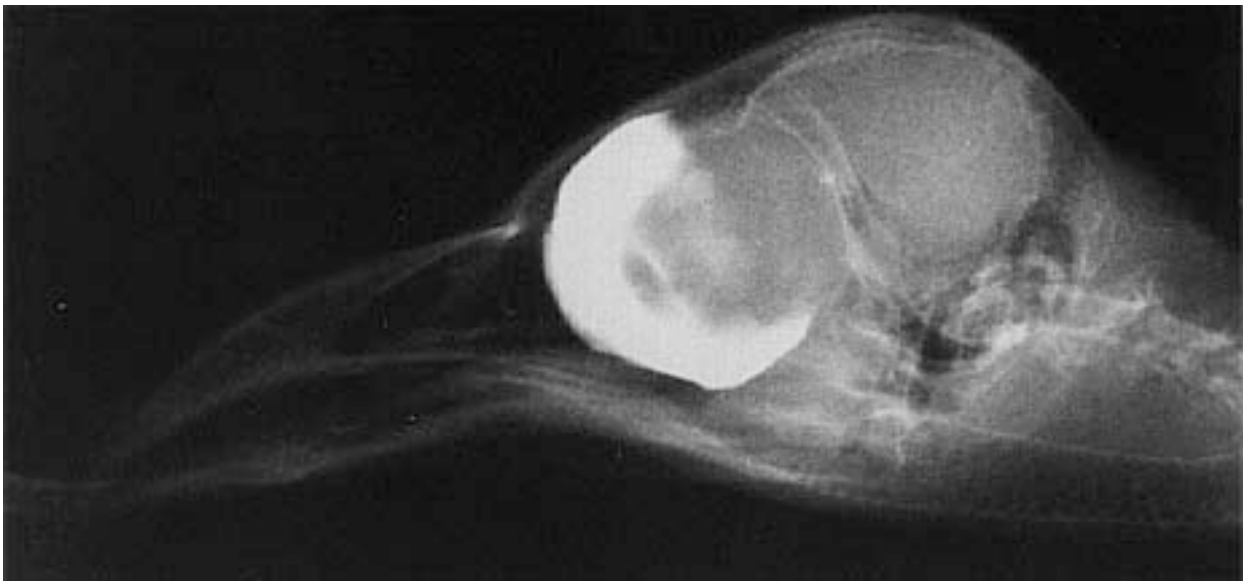

FIG 12.41 Positive contrast sinography in a mynah bird showing minimal drainage of contrast medium in comparison to Psittaciformes. Additionally, there is not communication between the infraorbital sinuses, and contrast medium injected into the right infraorbital sinus remains localized (courtesy of Marjorie McMillan).

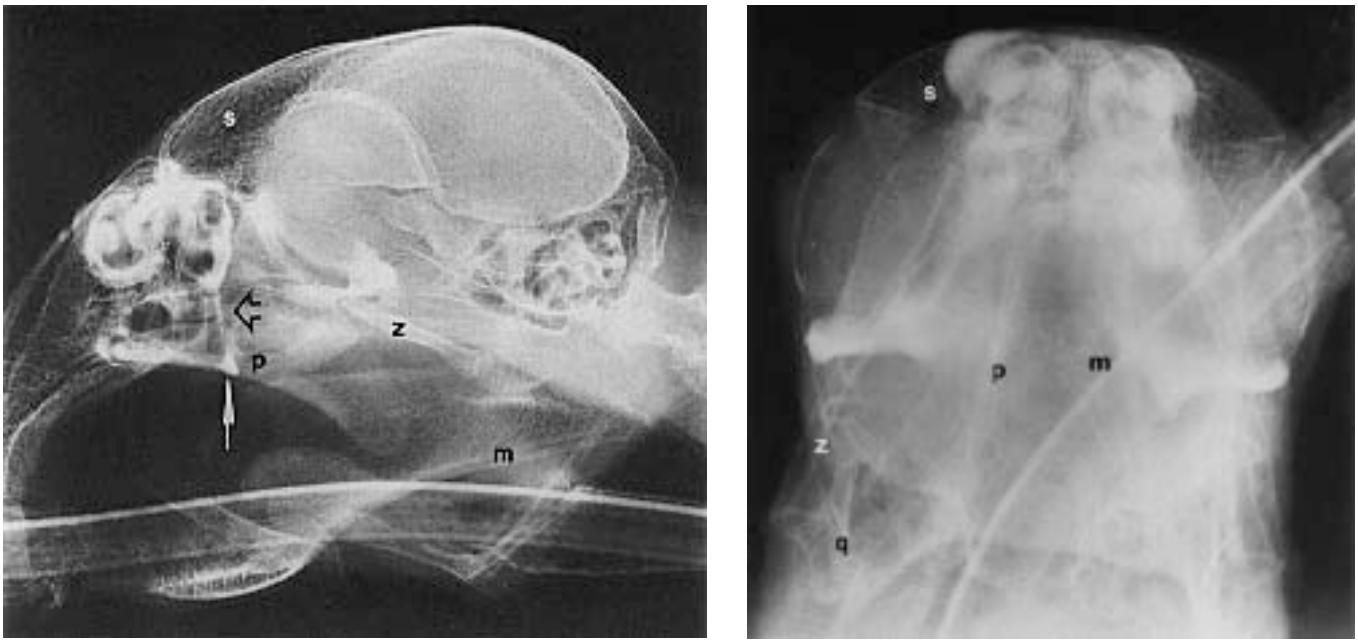

FIG 12.42 A four-month-old African Grey Parrot was presented with a life-long history of persistent serous to mucopurulent nasal discharge. Antibiotic therapy would change the discharge from mucopurulent to serous but would not resolve the problem. On physical examination, it was noted that fluid introduced into the nostrils would not exit through the oral cavity. Lateral view of rhinogram indicating that contrast medium moved ventrally through the nasal cavity (open arrow) and stopped abruptly at the level of the palate (closed arrow). Endoscopy indicated a persistent membrane covering the choana. Rostrocaudal radiograph following infusion of contrast medium into the right nostril showing communication between the infraorbital sinuses. Note that the contrast medium does not properly pass into the oral cavity in this bird. Other structures of interest include the palatine bone (p), zygomatic arch (z), mandible (m), quadrate (q) and the periorbital diverticulum of the infraorbital sinus (s) (courtesy of Elizabeth Watson).

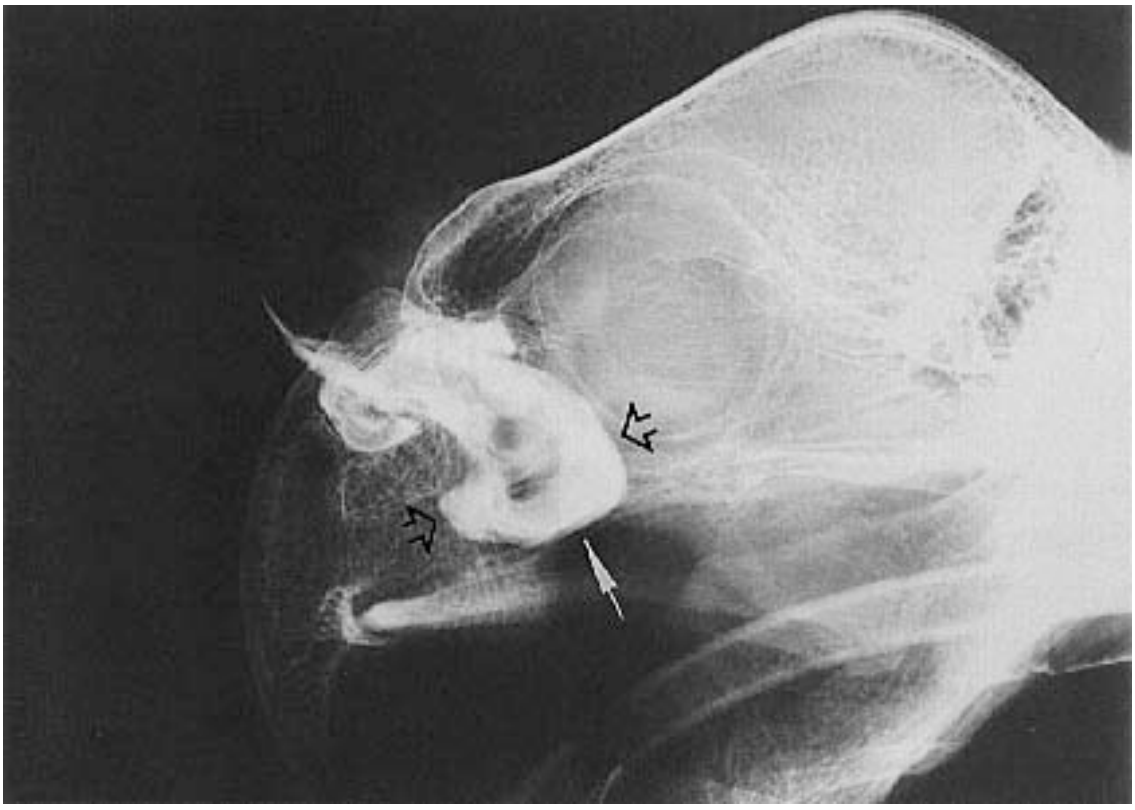

FIG 12.43 A four-year-old Umbrella Cockatoo was presented with a long history of bilateral oculonasal discharge. Fluid flushed into the nostrils failed to enter the oropharynx. A lateral rhinogram indicated that contrast medium moved through the nasal cavity (open arrows) and stopped abruptly at the level of the palatine (closed arrows) (courtesy of Elizabeth Watson).

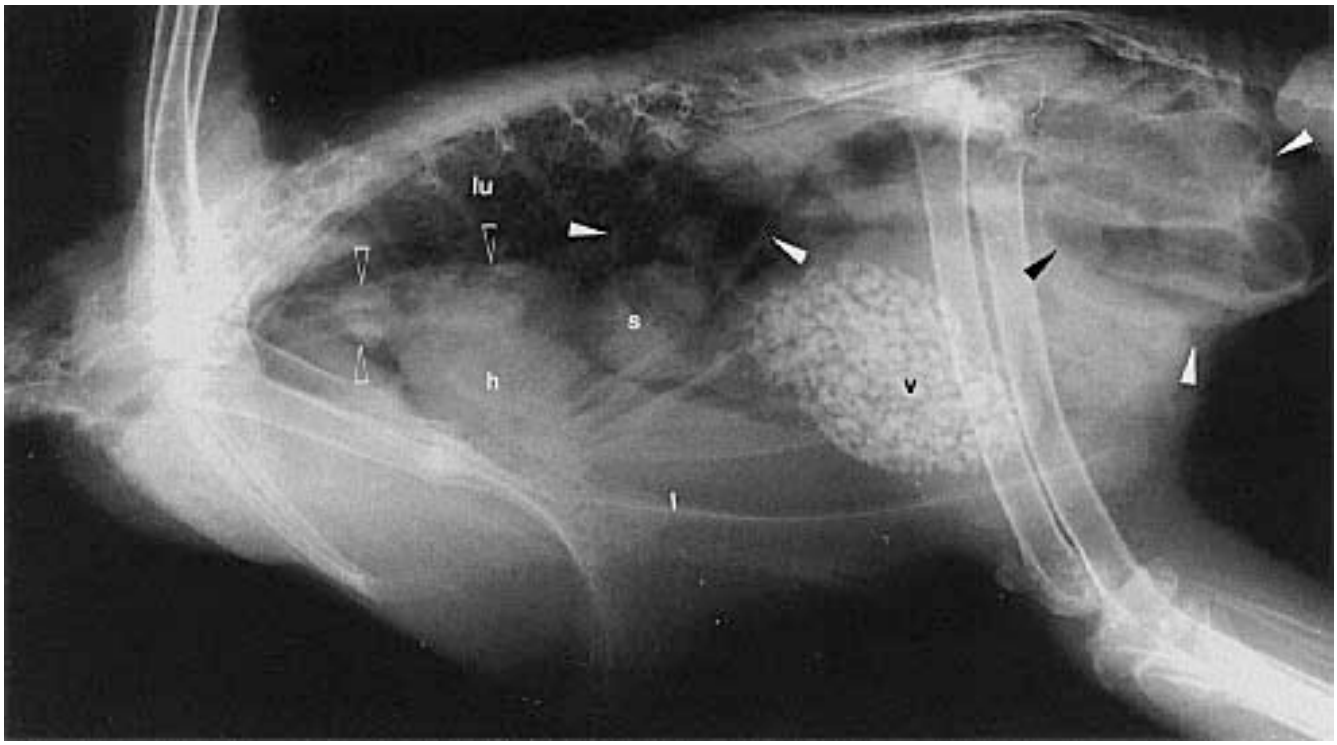

FIG 12.44 An adult male Satyr Tragopan Pheasant was presented with an acute onset of dyspnea and depression. Abnormal clinicopathologic findings include PCV=23, SGOT=490, LDH=671. Radiographs indicate gaseous distension of the gastrointestinal tract (arrows) causing cranial displacement of other abdominal organs. Increased densities were noted in the syringeal area (open arrows), and the spleen (s) was enlarged. The bird did not respond to supportive care. Necropsy findings included pericarditis and granulomatous pneumonia and tracheitis. Heart (h), liver (l), lung (lu), ventriculus containing grit (v).

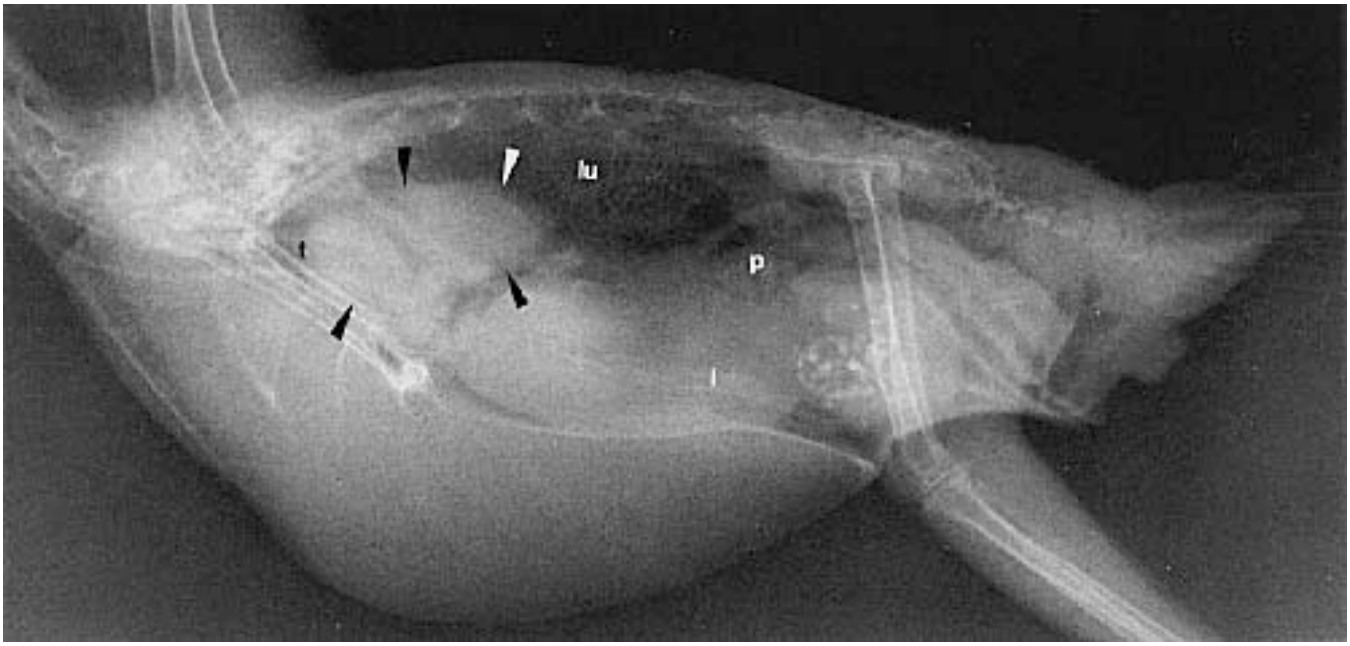

FIG 12.45 A two-year-old male cockatiel was presented for evaluation of a voice change and progressive dyspnea. A lateral radiograph showed a large, lobular, soft-tissue mass surrounding the distal trachea (arrows) that extended into the lung (lu) and displaced the trachea (t) ventrally. The liver (l) is also enlarged and is displacing the gas-filled proventriculus (p) dorsally. The histologic diagnosis was thyroid adenocarcinoma (courtesy of Marjorie McMillan).

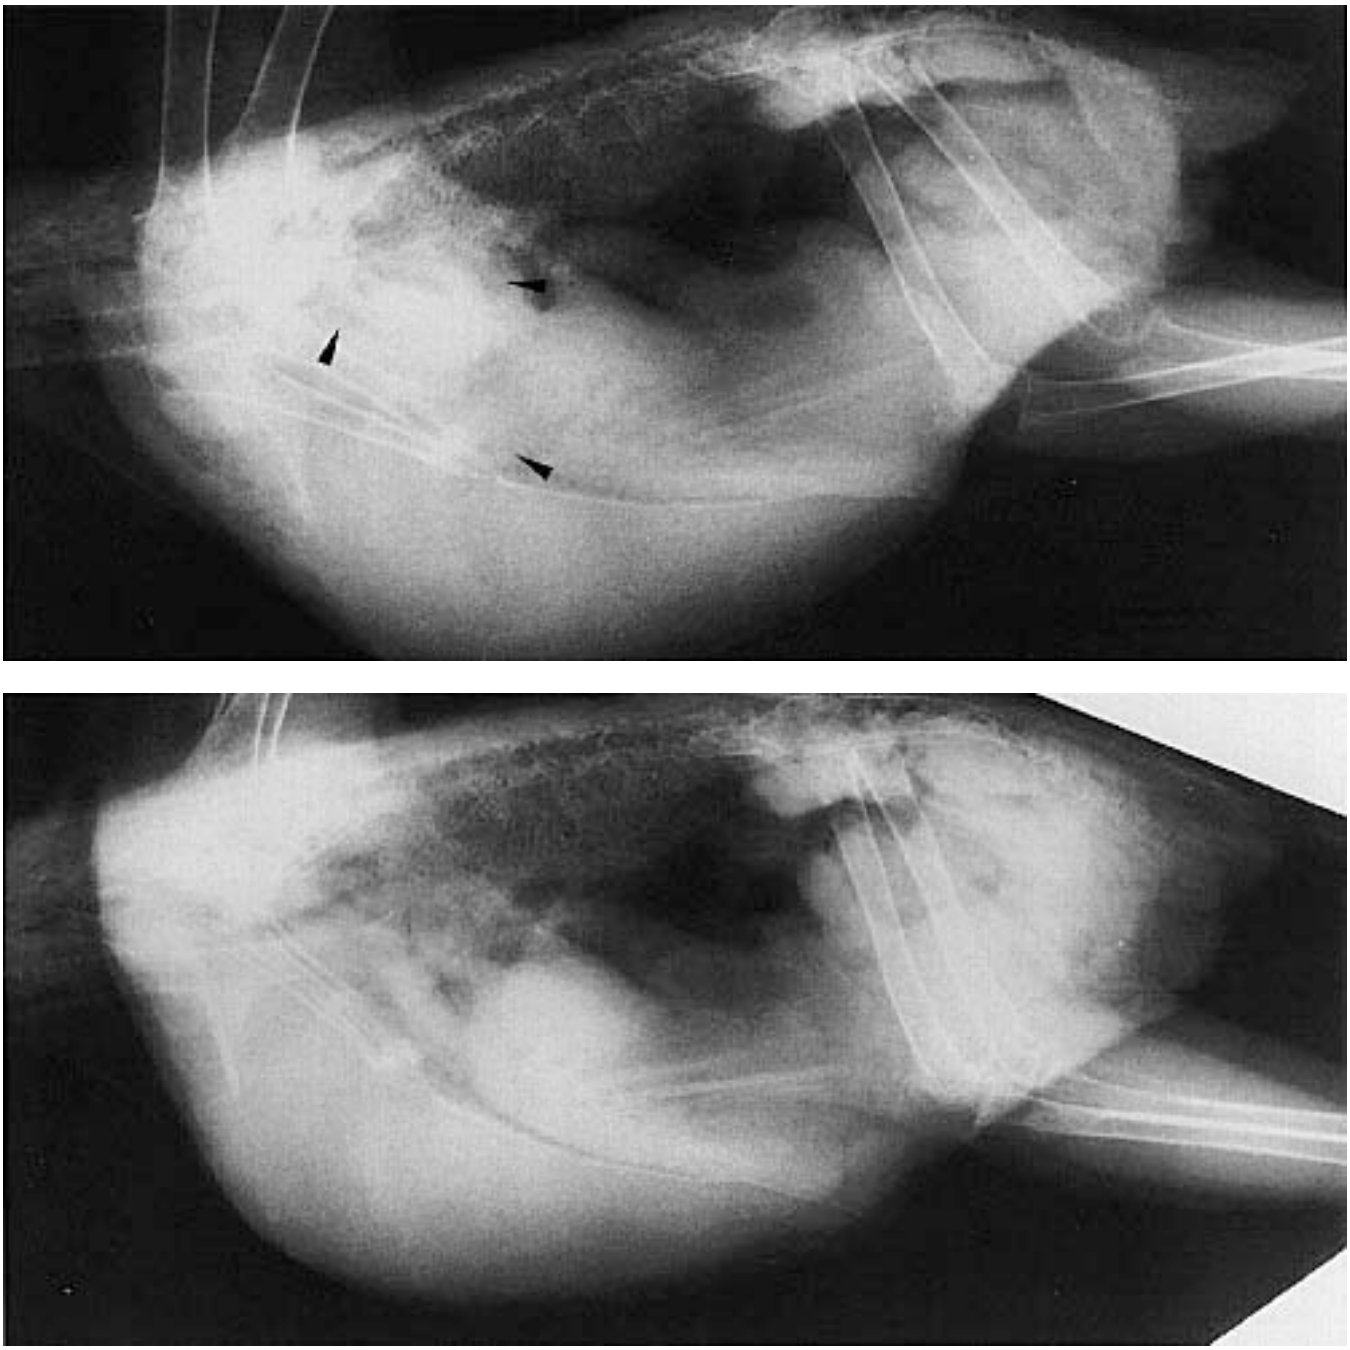

FIG 12.46 A Red-lored Amazon Parrot was presented with coughing and a voice change. Initial radiographs showed a large, soft-tissue mass (arrows) ventral to the trachea and syrinx. Radiograph taken 11 months after treatment with antifungal agents demonstrates resolution of the mass (courtesy of Marjorie McMillan).

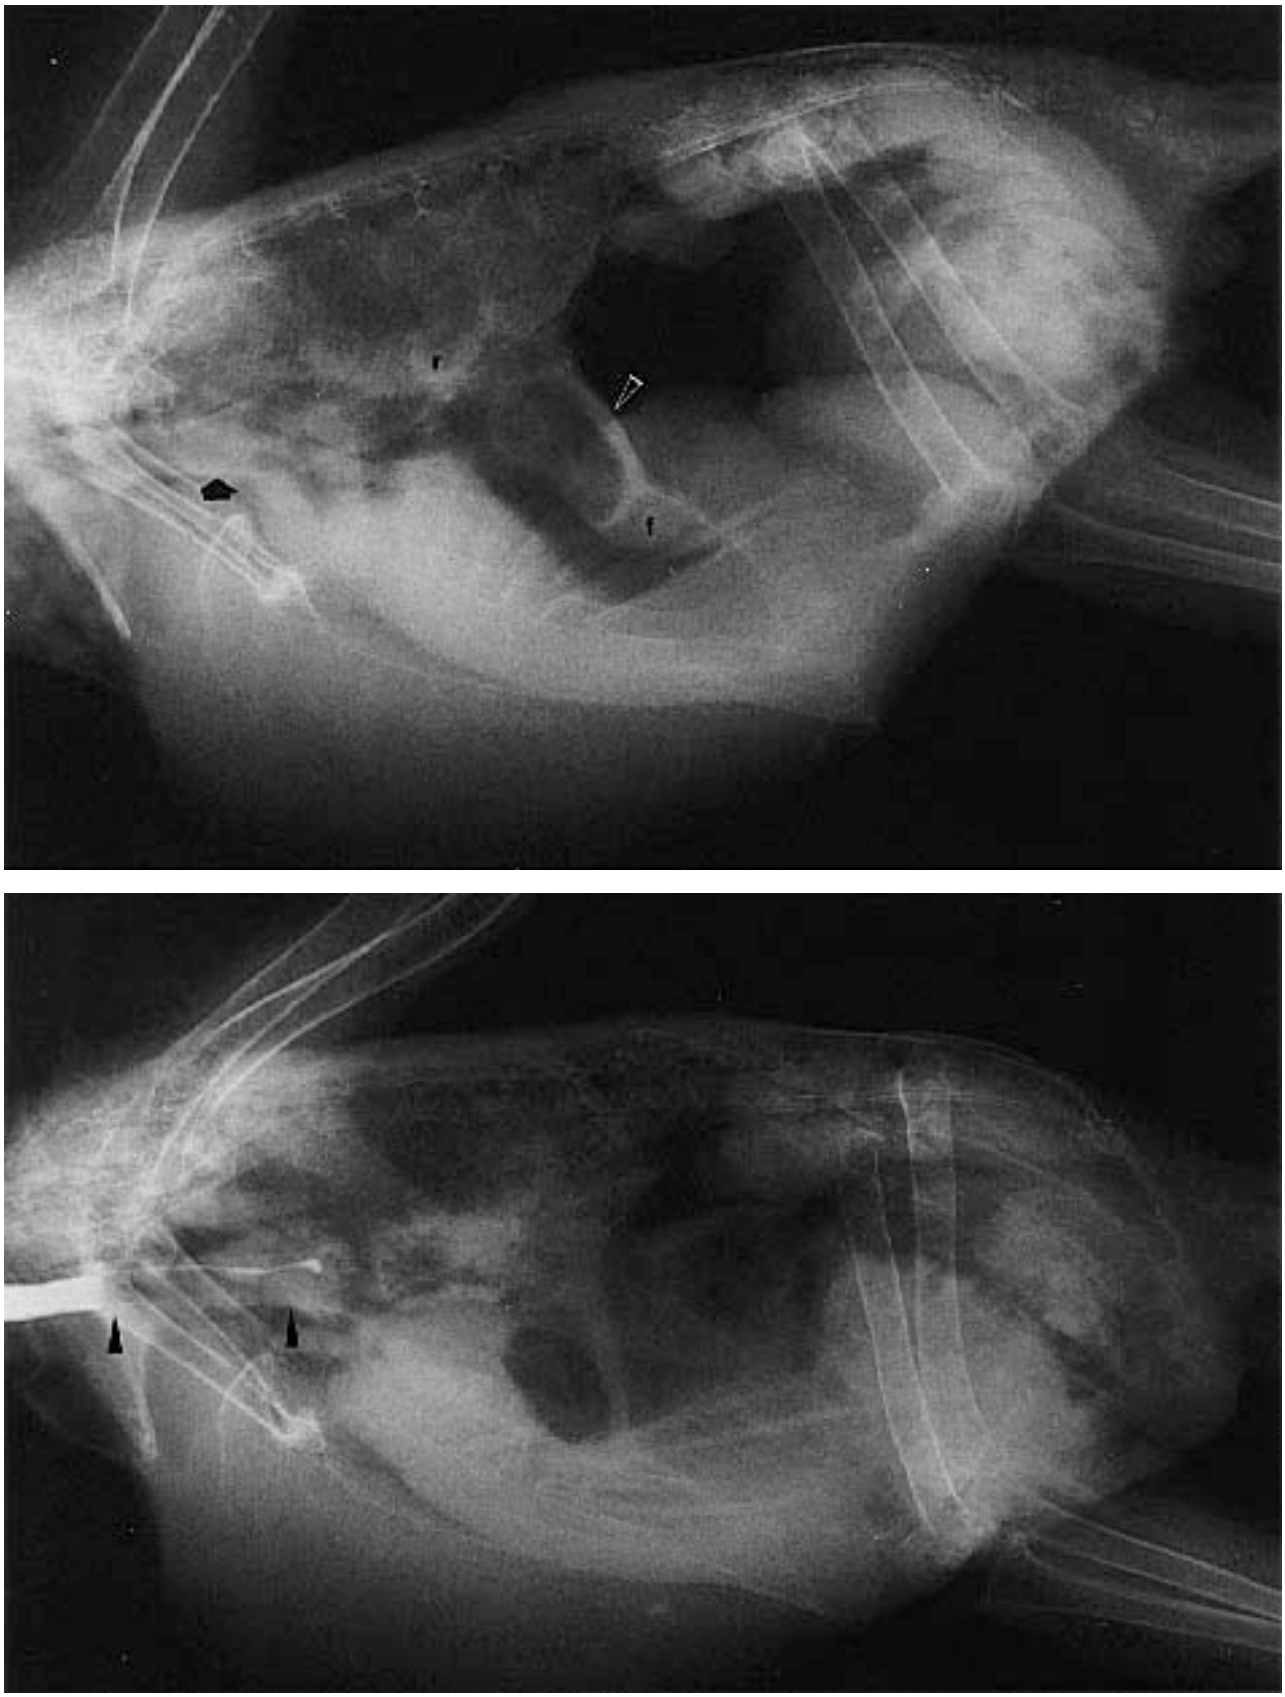

FIG 12.47 **a)** Lateral radiograph of a mature Blue-fronted Amazon with dyspnea. Abnormal findings included increased parabronchial densities (ring shadows -r), hyperinflation of the air sacs and thickening of the contiguous wall of the cranial and caudal thoracic air sacs (open arrow). The ventral separation of the contiguous wall of these air sacs forms a distinguishable fork (f) with the cranial thoracic air sac coursing cranially and the caudal thoracic air sac coursing caudoventrally. An increased soft tissue density in the trachea suggests a mass (arrow). **b)** Positive contrast study of the trachea using an oil-based contrast medium. The medium is passing dorsally across an intratracheal mass (arrows) (courtesy of Marjorie McMillan).

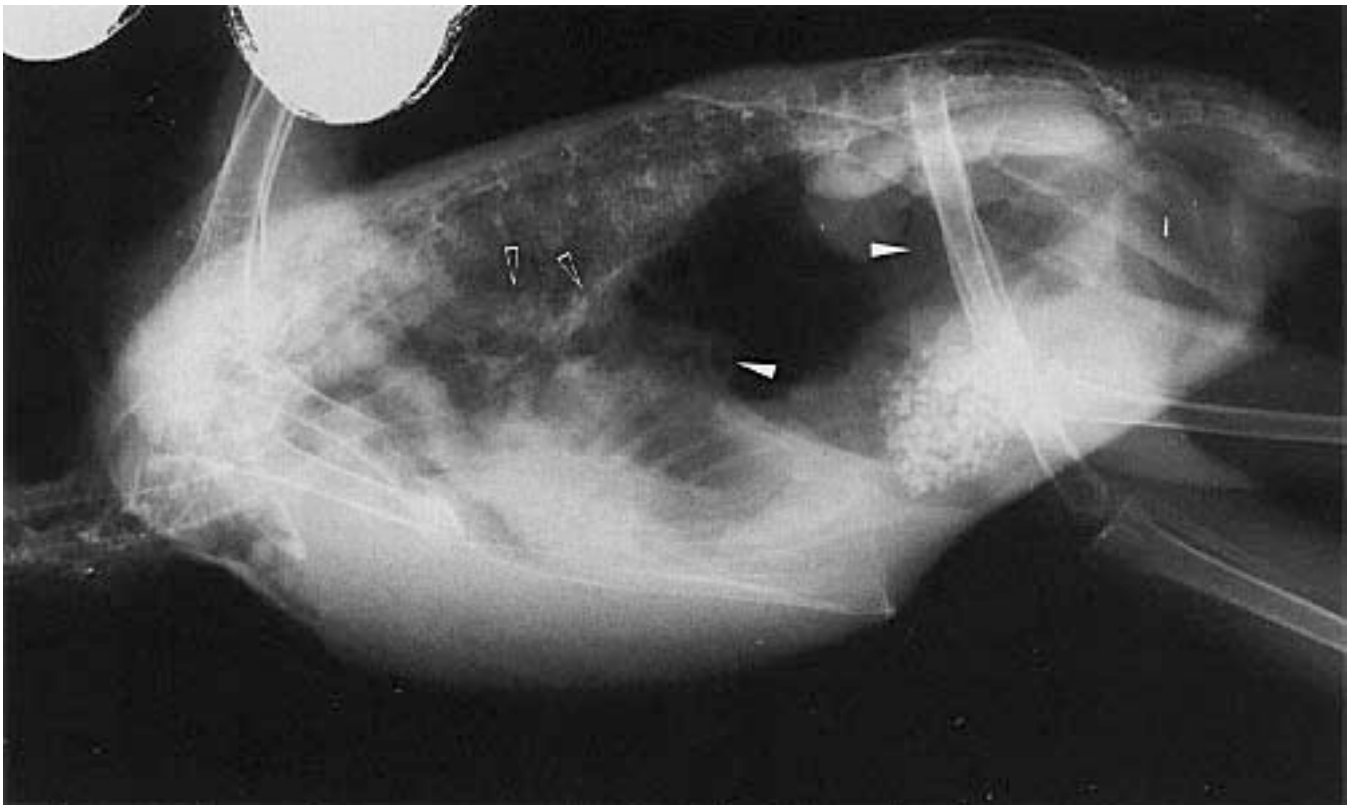

FIG 12.48 An adult Blue-crowned Amazon Parrot was presented with nasal discharge and dyspnea. The increased parabronchial densities (open arrows) in the mid and caudal portions of the lung are suggestive of pneumonia. Several thickened air sac walls are visible (arrows). The intestines (i) are filled with gas secondary to aerophagia caused by severe dyspnea. The right abdominal (ra) and left abdominal (la) air sac areas are clearly visible. The cloacal wall (c) is also evident.

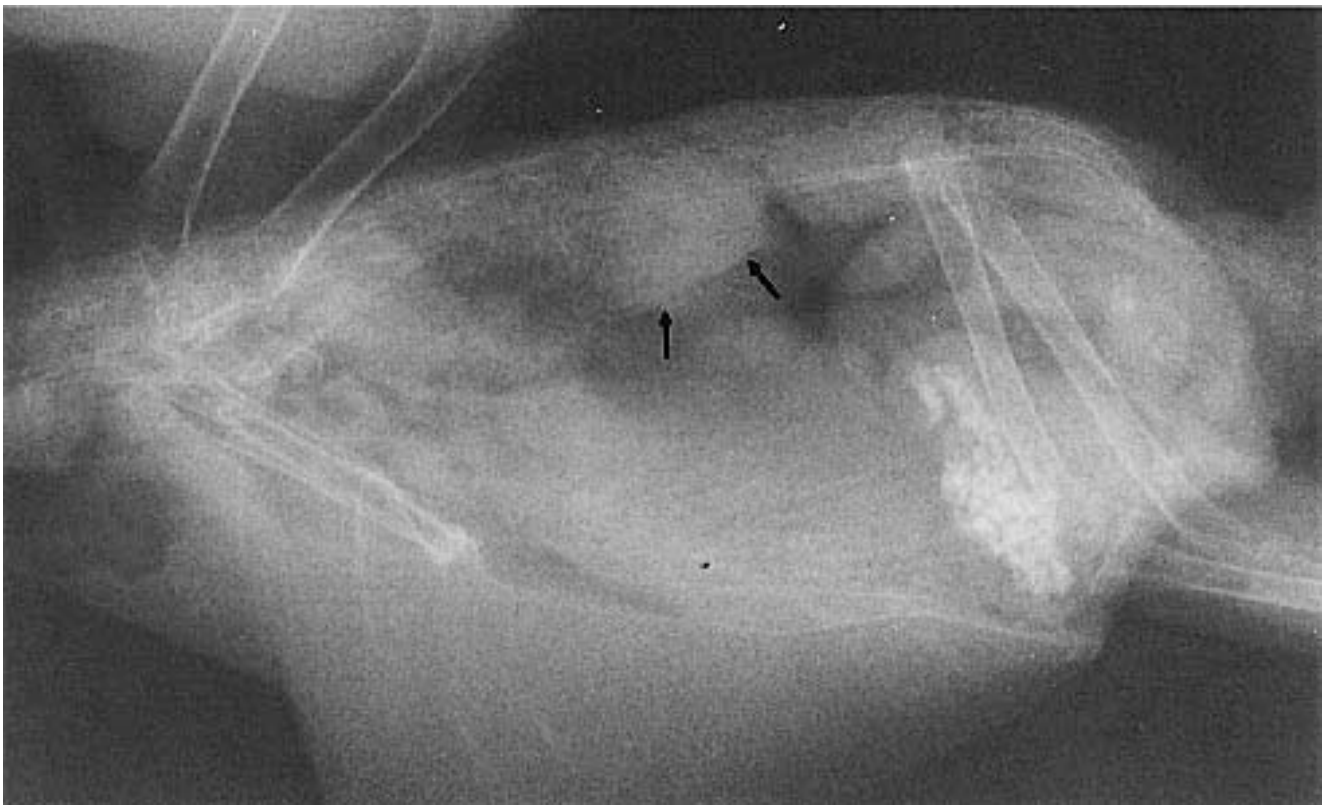

FIG 12.49 A four-year-old lovebird with a round cell carcinoma of the wing and secondary metastasis to the lung (arrows) (courtesy of Marjorie McMillan).

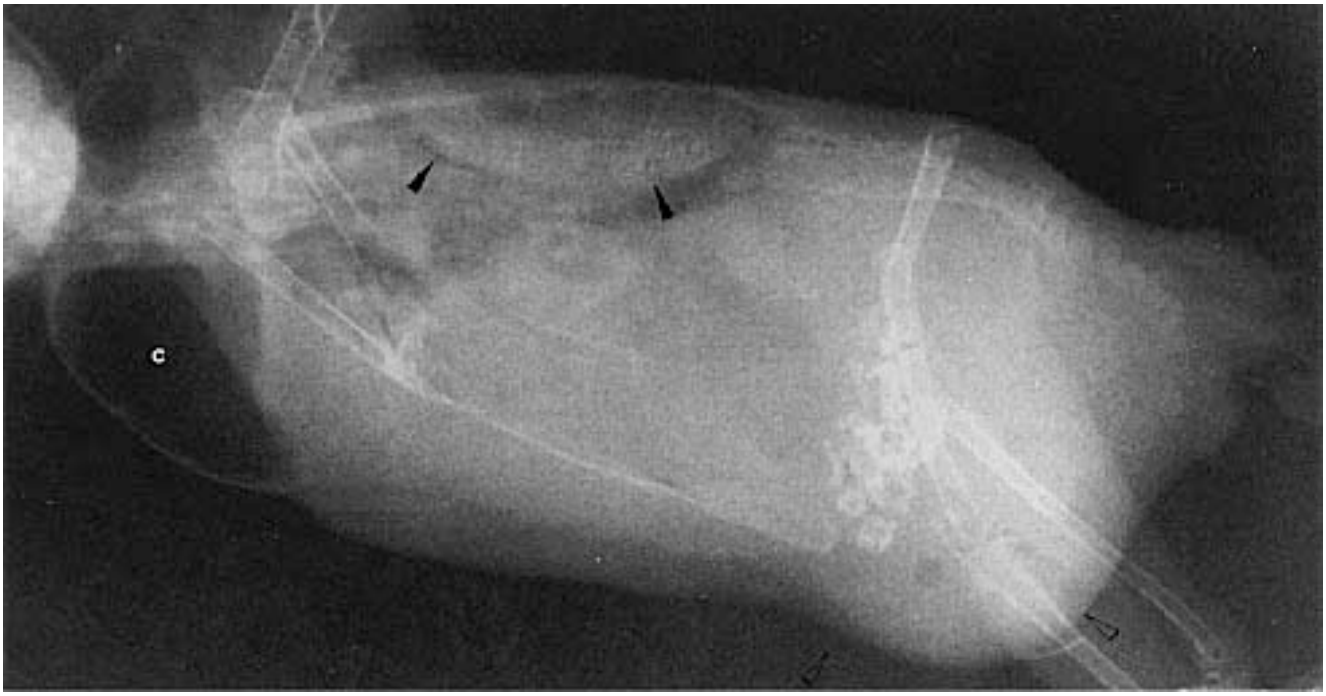

FIG 12.50 A five-year-old male budgerigar was presented for lethargy and dyspnea. Lateral radiographs indicate an air-filled crop (c) secondary to aerophagia. There is a uniform increase in the parabronchial pattern (arrows) and obliteration of the abdominal air sac space due to bulging of the abdominal wall (open arrow). The homogenous appearance of the abdomen is due to a combination of effusion and a mass. The pulmonary pattern is consistent with edema, which responded to diuretic therapy (courtesy of Marjorie McMillan).

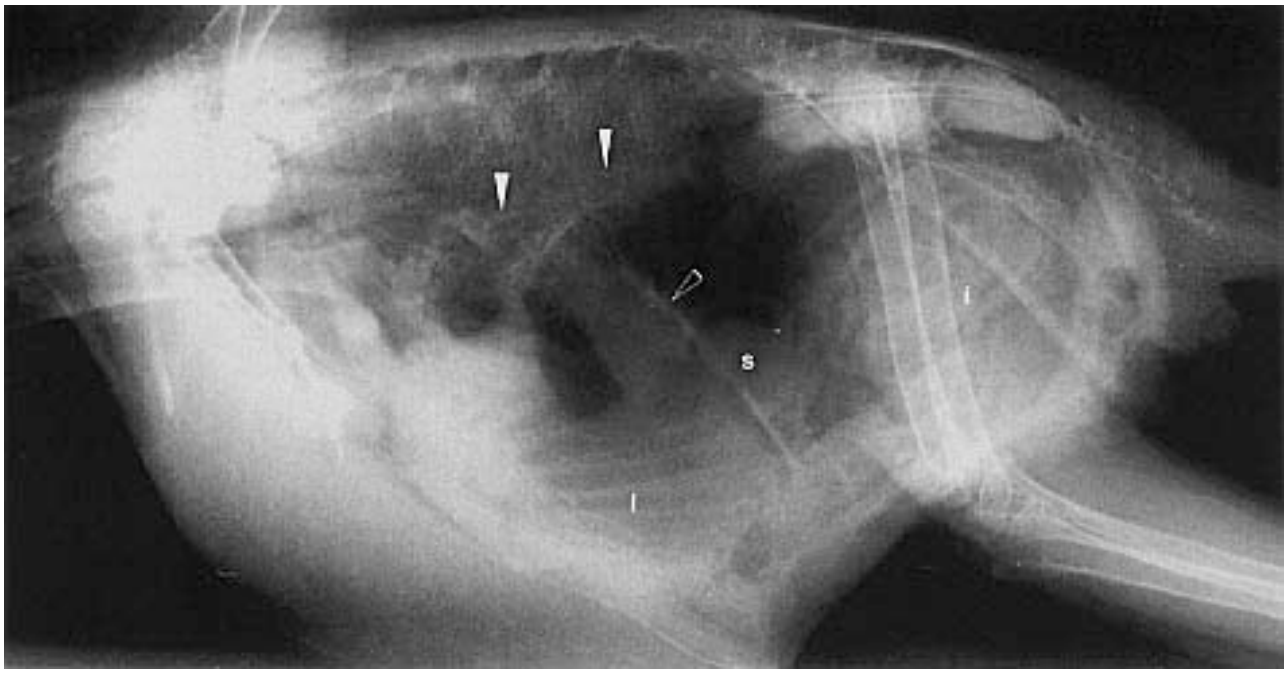

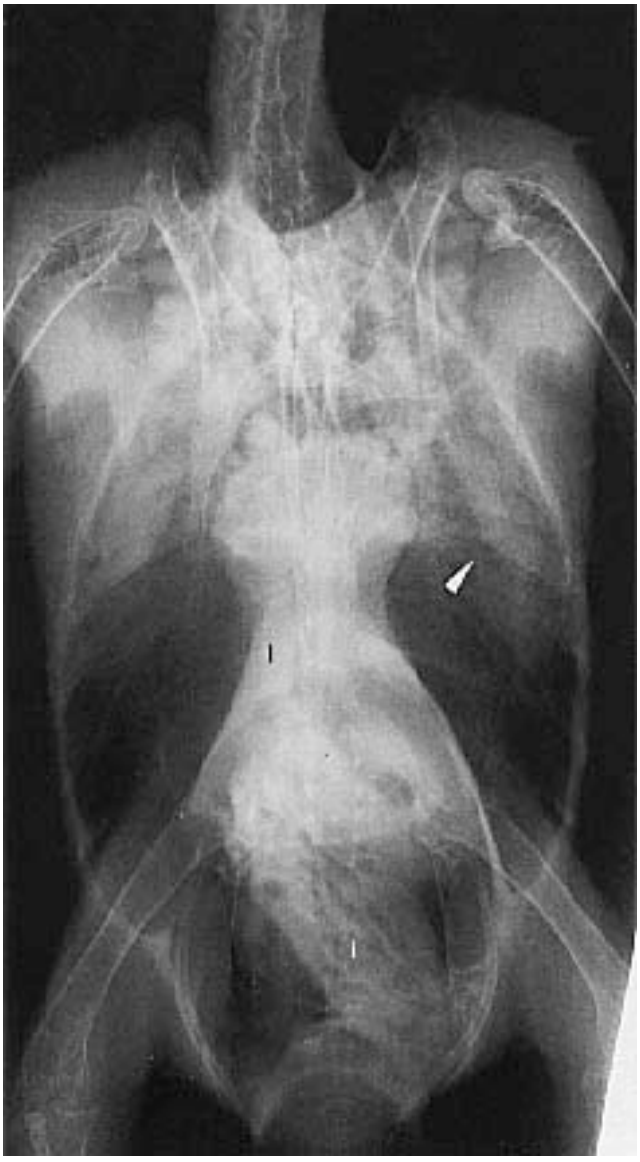

FIG 12.51 A four-month-old Double Yellow-headed Amazon Parrot was presented with a bilateral, purulent nasal discharge and dyspnea. Radiographs indicated parabronchial ring shadows (arrow) consistent with pneumonia. Hyperinflation of the thoracic and abdominal air sacs and thickening of the air sac membranes are characteristic of air sacculitis (open arrows). Note the barrel shape of the body in the VD radiograph indicative of dyspnea. Cultures from the trachea were positive for *Klebsiella* sp., and the bird responded to antibiotics. Liver (l), intestines (i) and spleen (s).

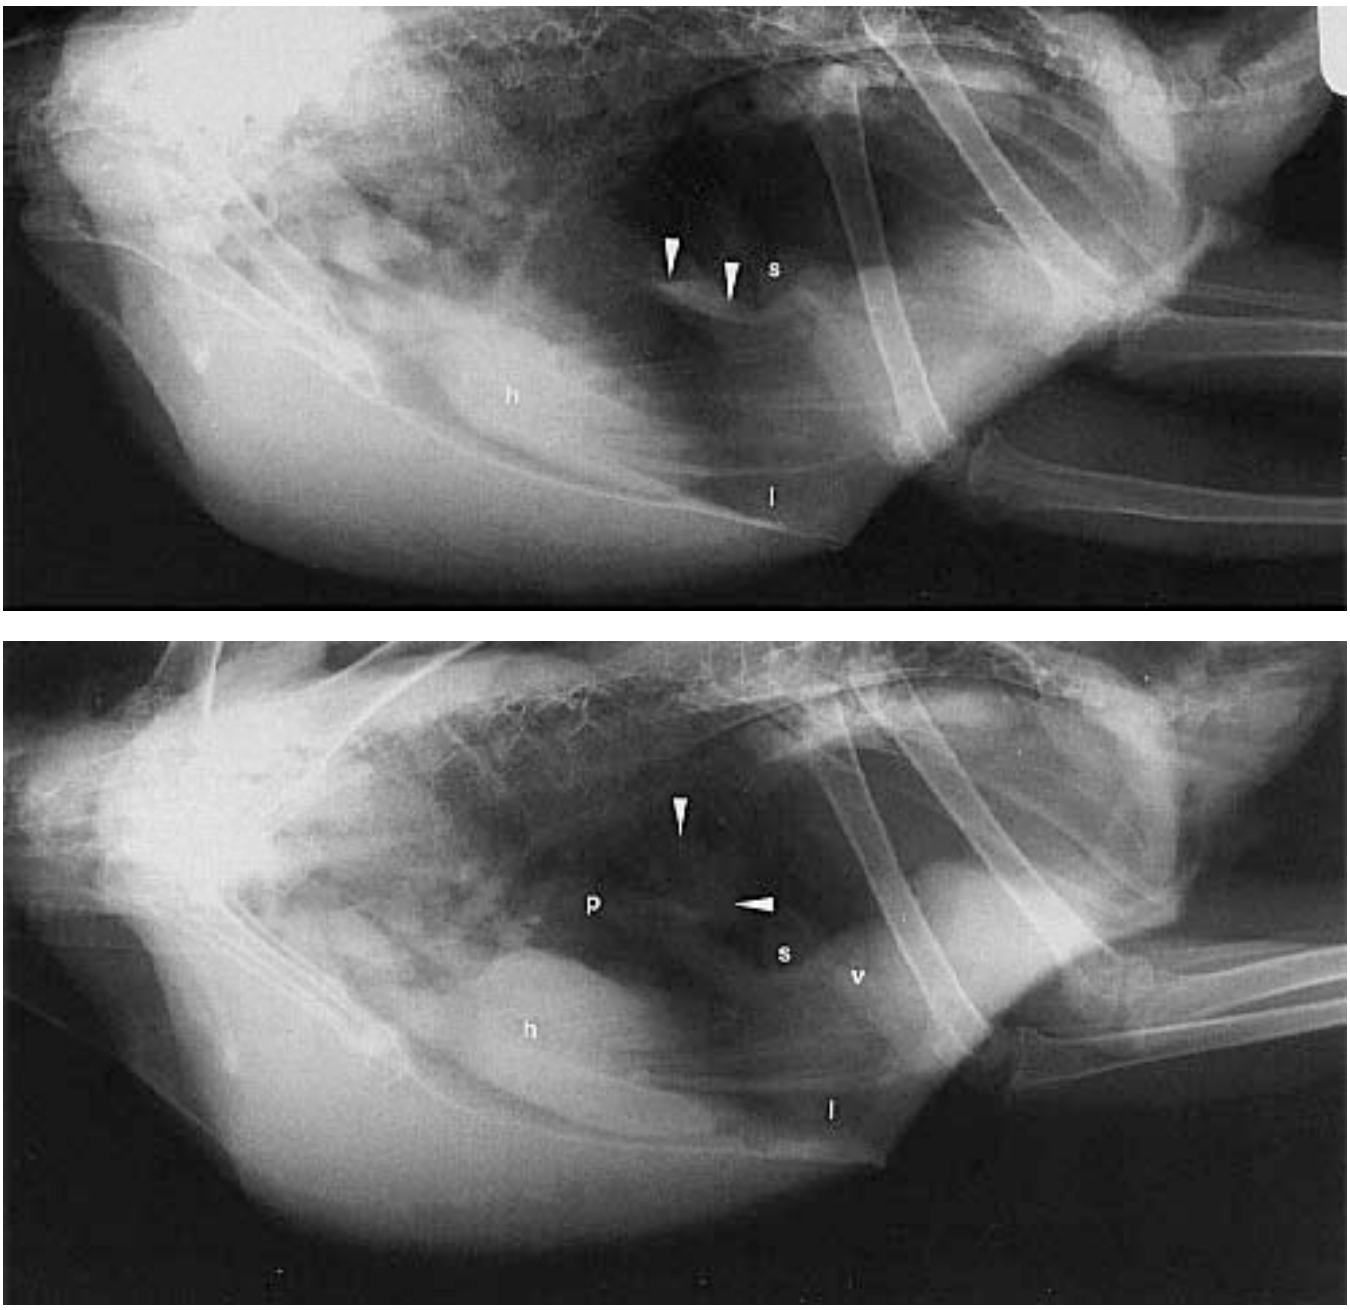

FIG 12.52 A ten-year-old Green-winged Macaw was presented with exercise intolerance. Initial radiographs (top) indicated thickening or edema of the air sacs. Radiographs one month after the initiation of antibiotic therapy indicate a decrease in the soft tissue opacity of the air sacs. However, the presence of residual thickening (arrow) would warrant continuation of therapy. Spleen (s), proventriculus (p), ventriculus (v), heart (h), liver (l) (courtesy of Marjorie McMillan).

FIG 12.53 An African Grey Parrot with a soft tissue opacity in the left cranial and caudal thoracic air sacs (courtesy of Marjorie McMillan).

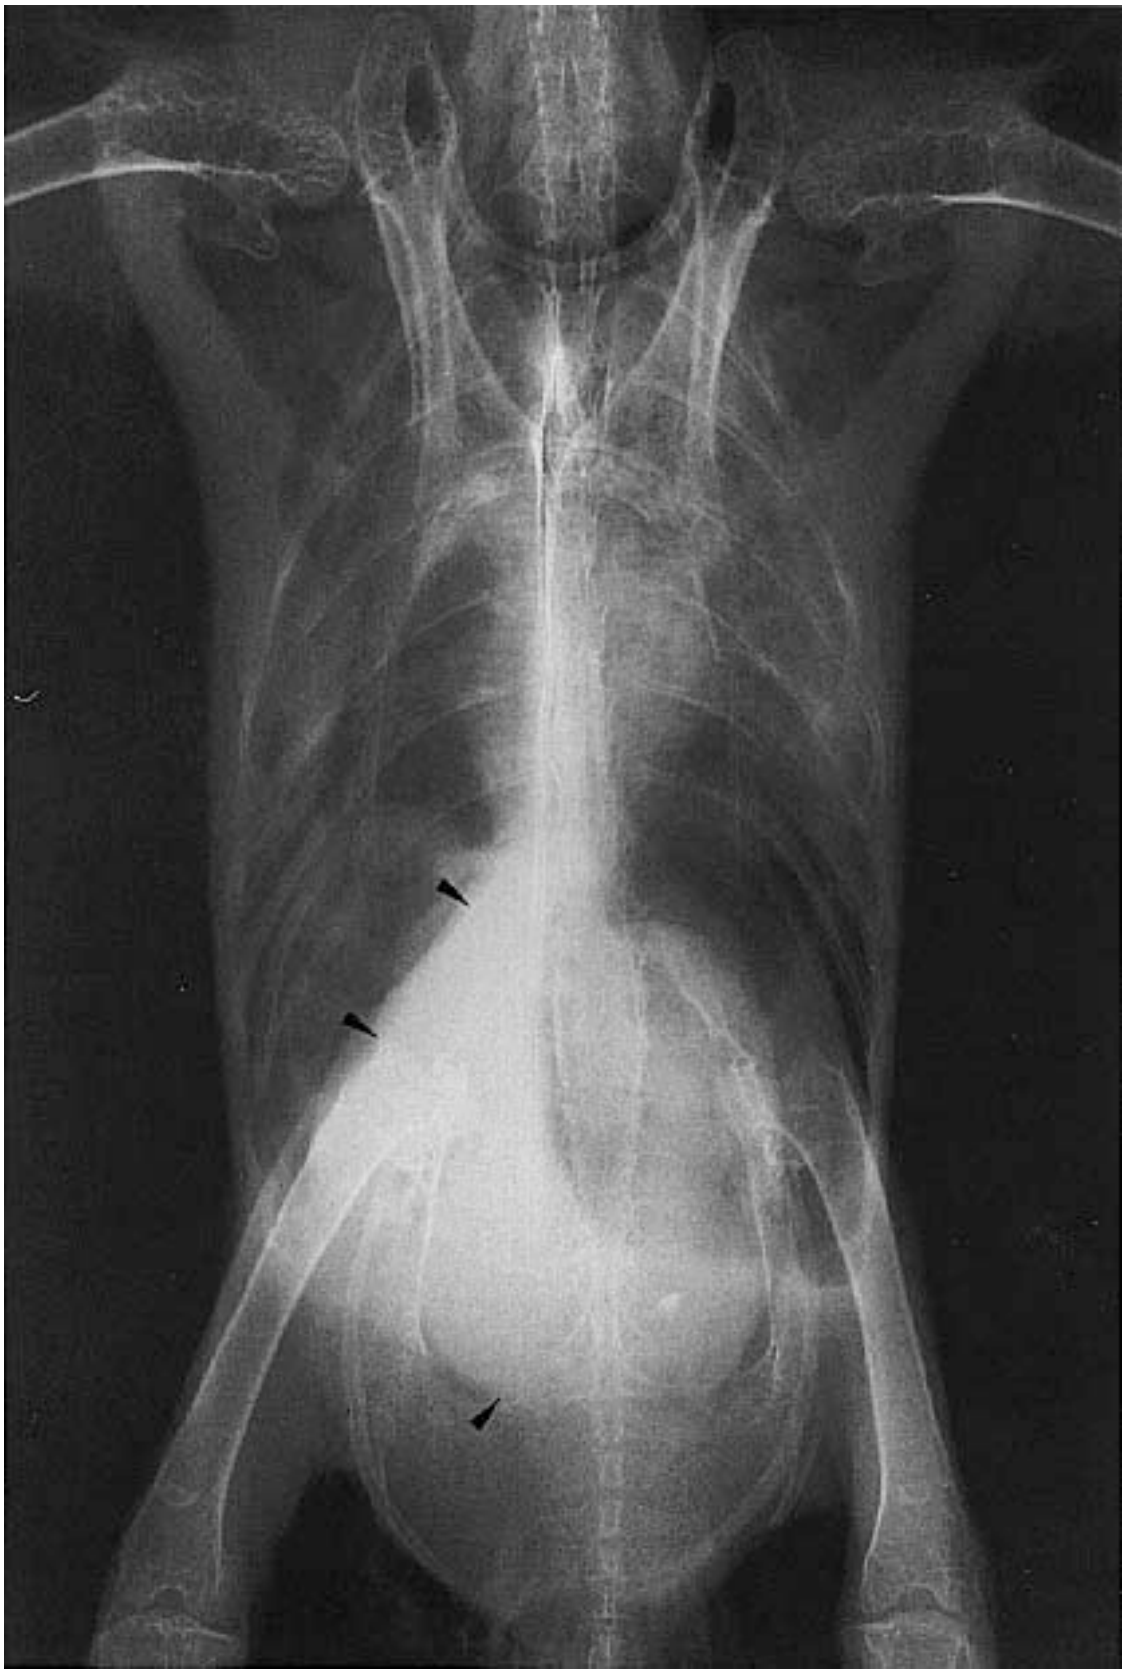

FIG 12.54 A Blue-fronted Amazon Parrot with a soft tissue plaque in the right abdominal air sac (arrows) (courtesy of Marjorie McMillan).

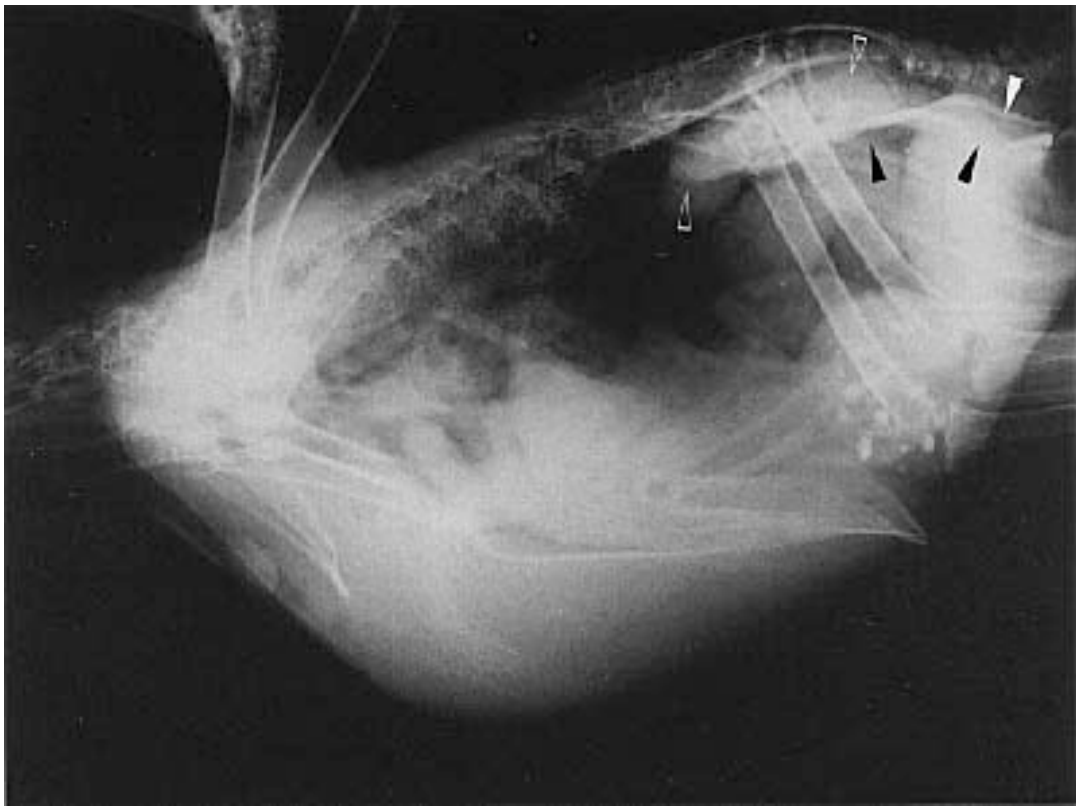

FIG 12.55 Excretory urogram in an African Grey Parrot. The radiographs were taken 30 seconds after the injection of contrast medium. The kidneys (open arrows) and ureters (arrows) are opacified. Note the rim of air that is normally present dorsal to the kidneys (courtesy of ME Krautwald).

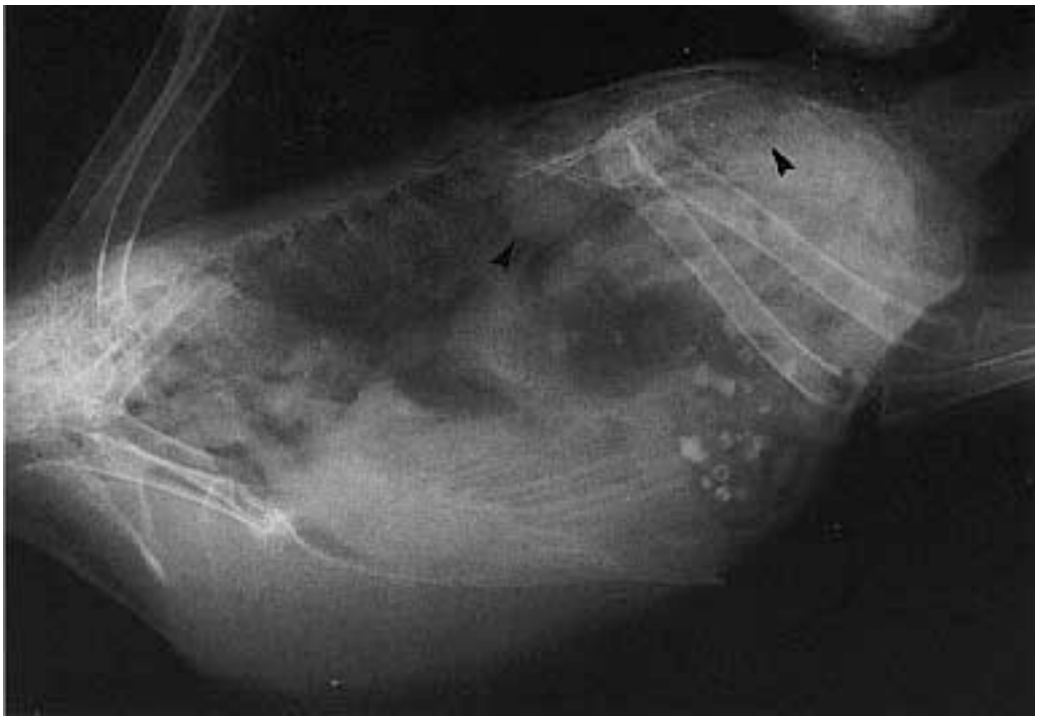

FIG 12.56 A Blue-crowned Amazon Parrot with nephromegaly (arrows). The diminished serosal detail in the coelomic cavity was caused by hemorrhage from the diseased kidney. The pathologic diagnosis was glomerulonephropathy, infarction and arteritis (courtesy of Marjorie McMillan).

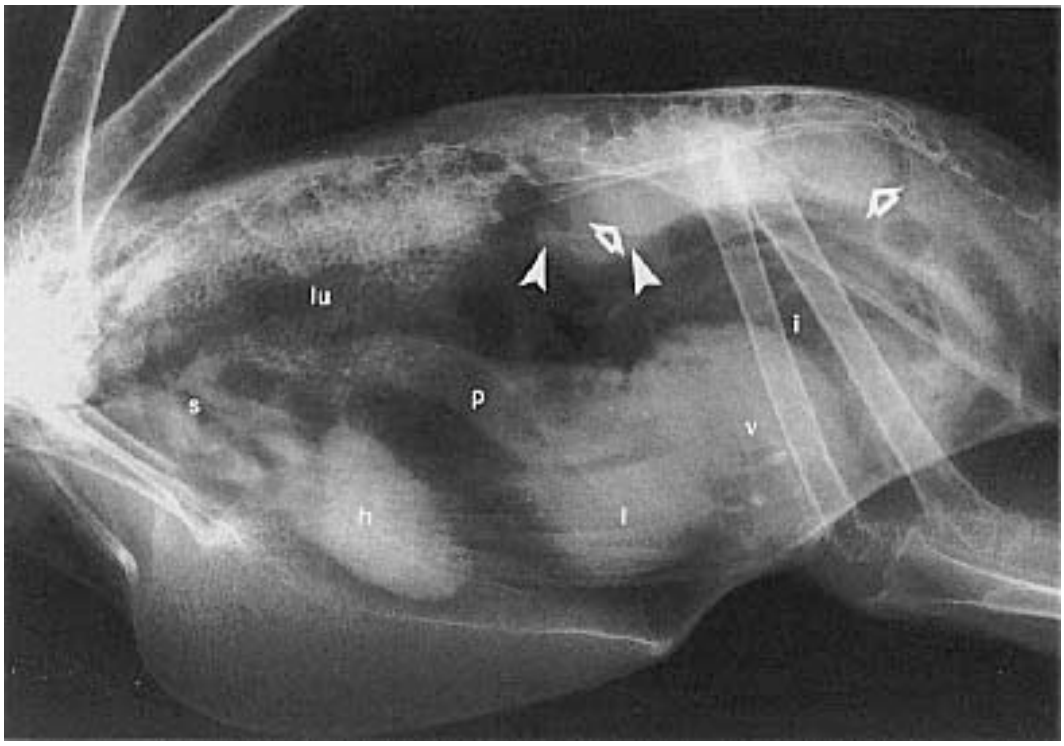

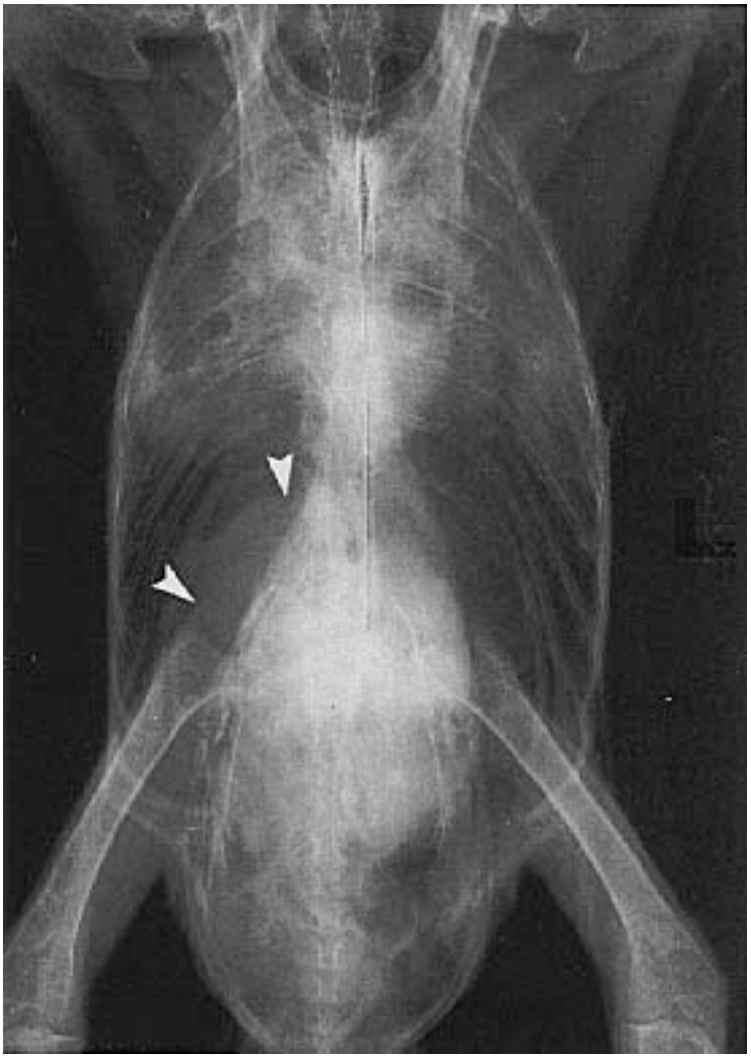

FIG 12.57 Sulphur-crested Cockatoo with nephromegaly (open arrows) and a perirenal granuloma (arrow) caused by aspergillosis. The severe air sac distension is causing the liver (l) to appear reduced in size. Other structures that are easy to identify include the heart (h), syrinx (s), lung (lu), proventriculus (p), ventriculus (v) and intestines (i) (courtesy of Marjorie McMillan).

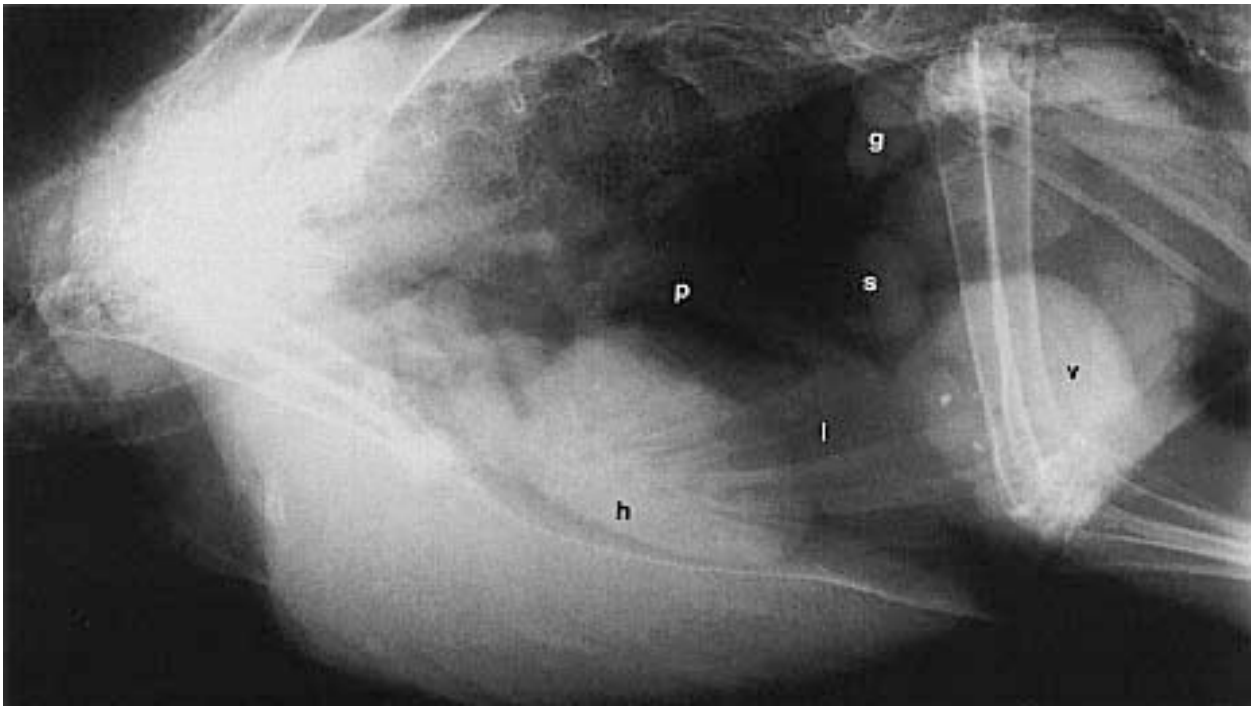

FIG 12.58 A two-year-old Blue and Gold Macaw was presented with anorexia and mild dyspnea. Increased lung sounds were noted by auscultation. Radiographs indicated microhepatia and splenomegaly. It is common for the liver to be smaller than expected in macaws and some larger cockatoos. The importance of a small liver in these birds has not been defined. Heart (h), liver (l), spleen (s), syrinx (s), proventriculus (p), ventriculus (v), gonad (g).

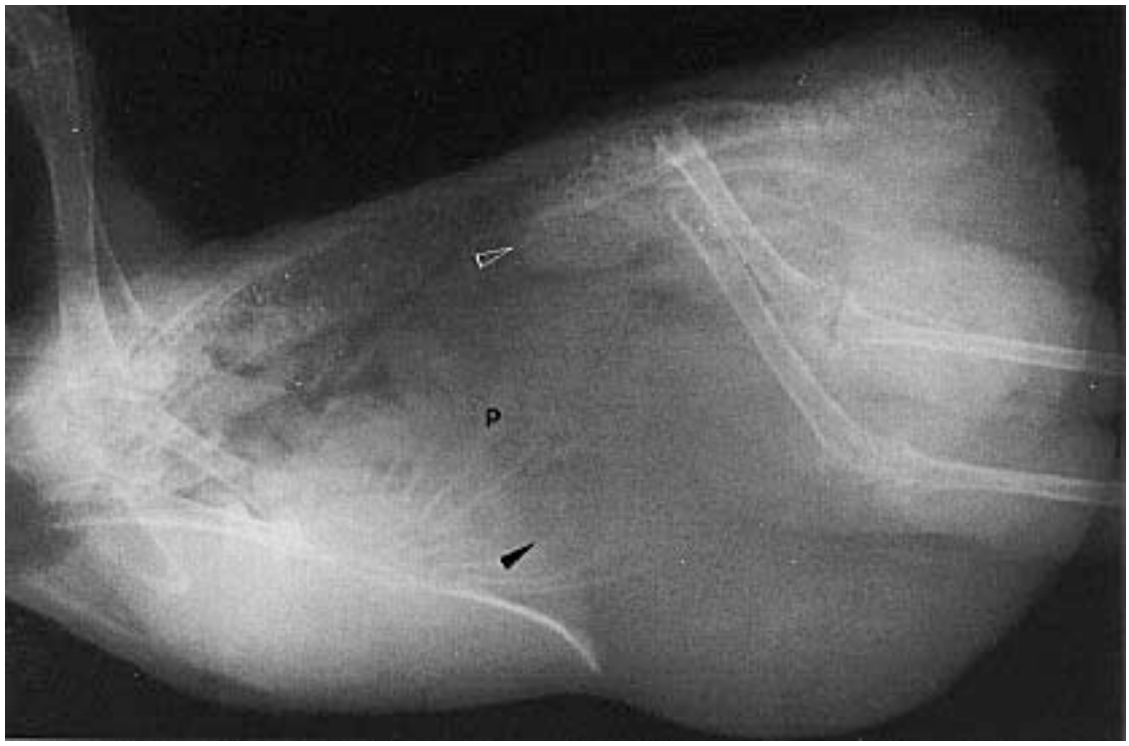

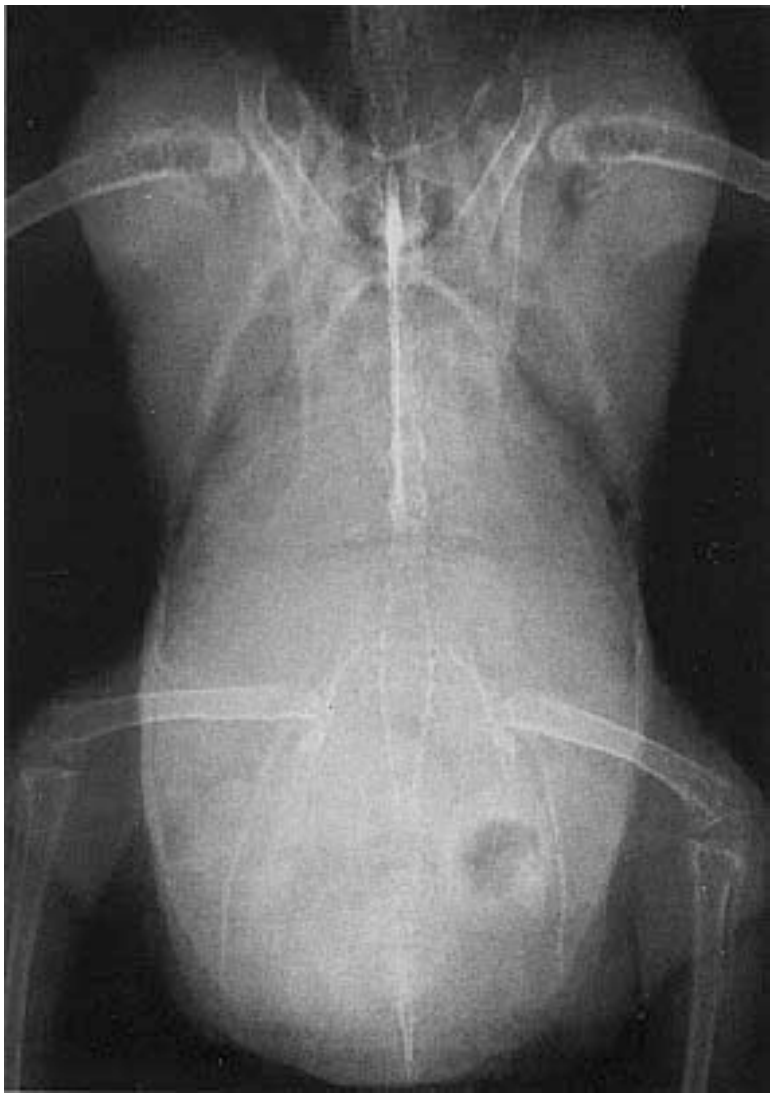

FIG 12.59 An eight-week-old Sulphur-crested Cockatoo with nephromegaly (open arrows) and massive hepatomegaly (arrows) caused by lipidosis. Note that the normal air sac triangle above the proventriculus is obliterated and the proventriculus (partially gas-filled) is being displaced cranially (courtesy of Marjorie McMillan).

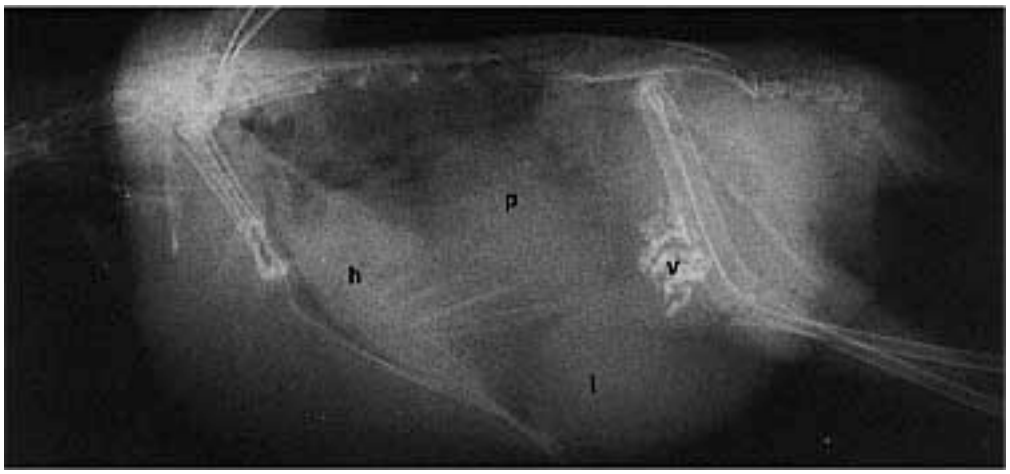

FIG 12.60 An adult male cockatiel was presented with weakness, a distended abdomen and harsh, moist respiratory sounds. Radiographs indicated massive hepatomegaly (l) with cranial displacement of the heart (h), dorsal displacement of the proventriculus (p) and caudodorsal displacement of the ventriculus (v). A mild diffuse parabronchial pattern secondary to edema was also present. Histopathology indicated severe, chronic active hepatitis and cirrhosis (courtesy of Marjorie McMillan).

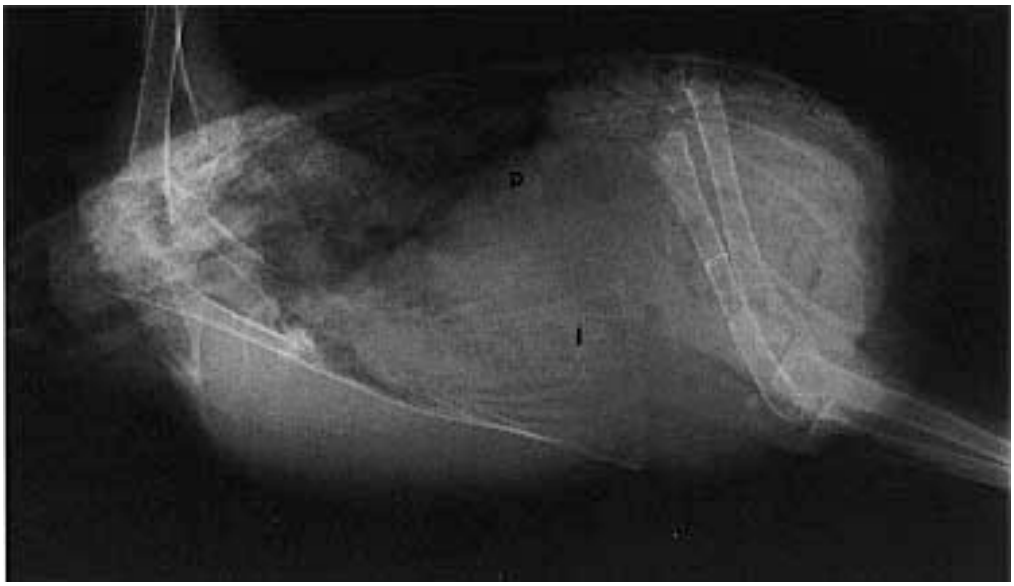

FIG 12.61 A ten-week-old Blue-fronted Amazon Parrot with a palpable abdominal mass was presented for anorexia and lethargy. Abnormal clinicopathologic findings included WBC=20,000 (4% bands), AST=12,420, LDH=8,000. Radiographs indicated hepatomegaly (l) with dorsal displacement of the proventriculus (p). Ultrasound confirmed the liver enlargement. *Chlamydia* sp. was detected in the bird's excrement using an antigen capture ELISA, and the bird responded to therapy with doxycycline.

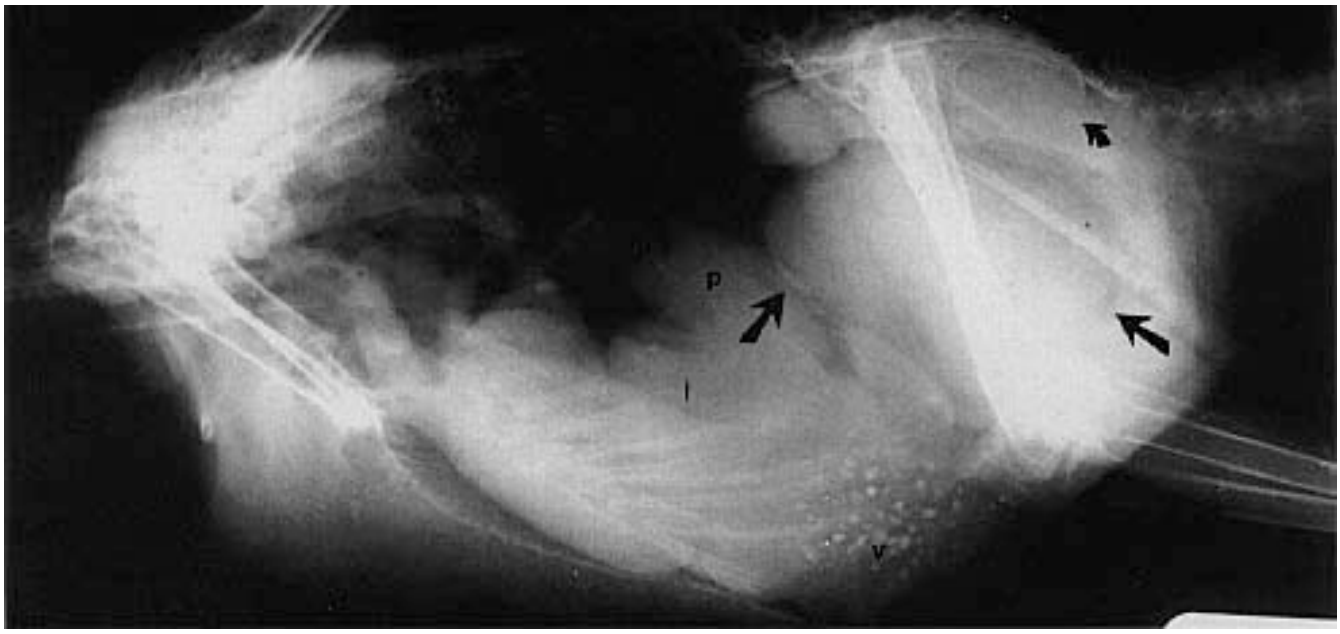

FIG 12.62 A two-year-old Blue and Gold Macaw was presented with lethargy, anorexia and abdominal distension. Radiographs indicated a massive splenomegaly (arrow) and nephromegaly (curved arrow) caused by *Chlamydia* sp. The enlarged spleen is displacing the proventriculus (p) and ventriculus (v) ventrally and the liver (l) cranially (courtesy of Marjorie McMillan, reprinted with permission of Comp Cont Ed 8:1986).

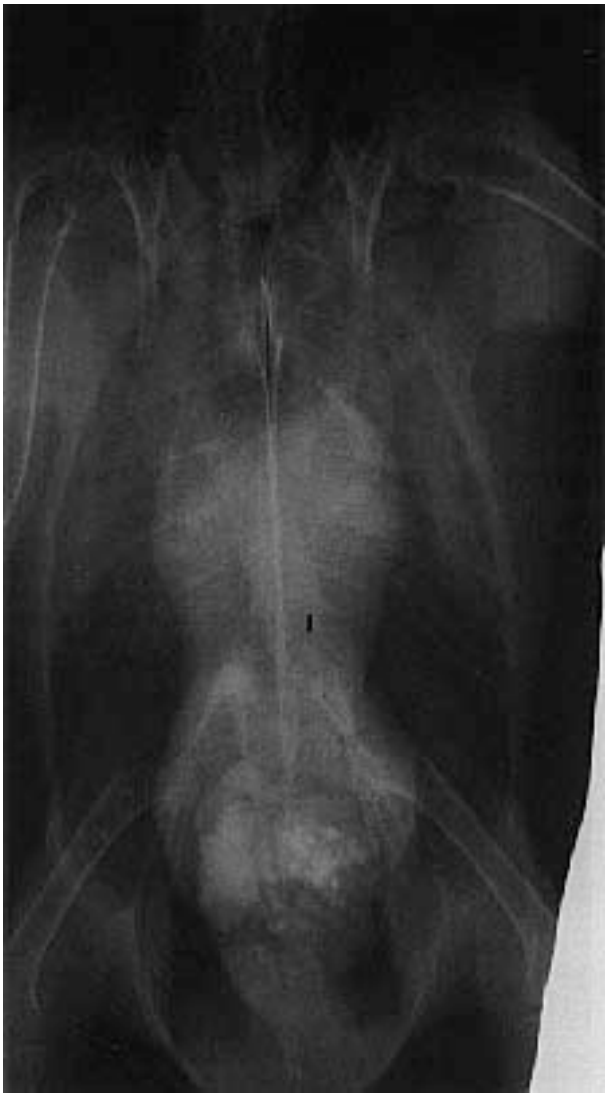

FIG 12.63 A Blue-fronted Amazon Parrot was presented with lethargy and exercise intolerance, intermittent episodes of panting and syncope. VD radiographs indicated a biatrial enlargement and a decrease in the cardiohepatic waist caused by cardiomegaly. Liver (l) (courtesy of Marjorie McMillan).

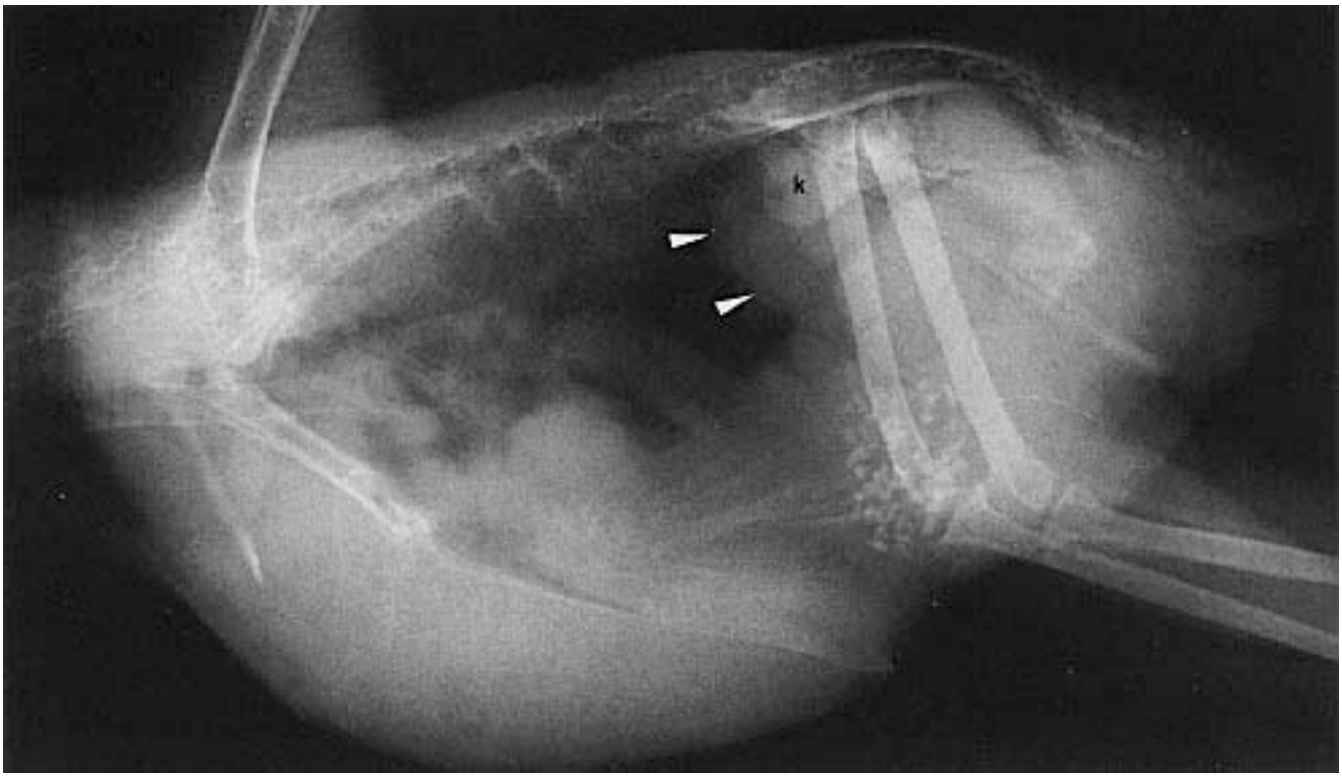

FIG 12.64 Lateral radiograph of a Double Yellow-headed Amazon Parrot with an active ovary (arrow). Note the "grape-like" cluster of follicles cranioventral to the kidneys (k) (courtesy of Marjorie McMillan).

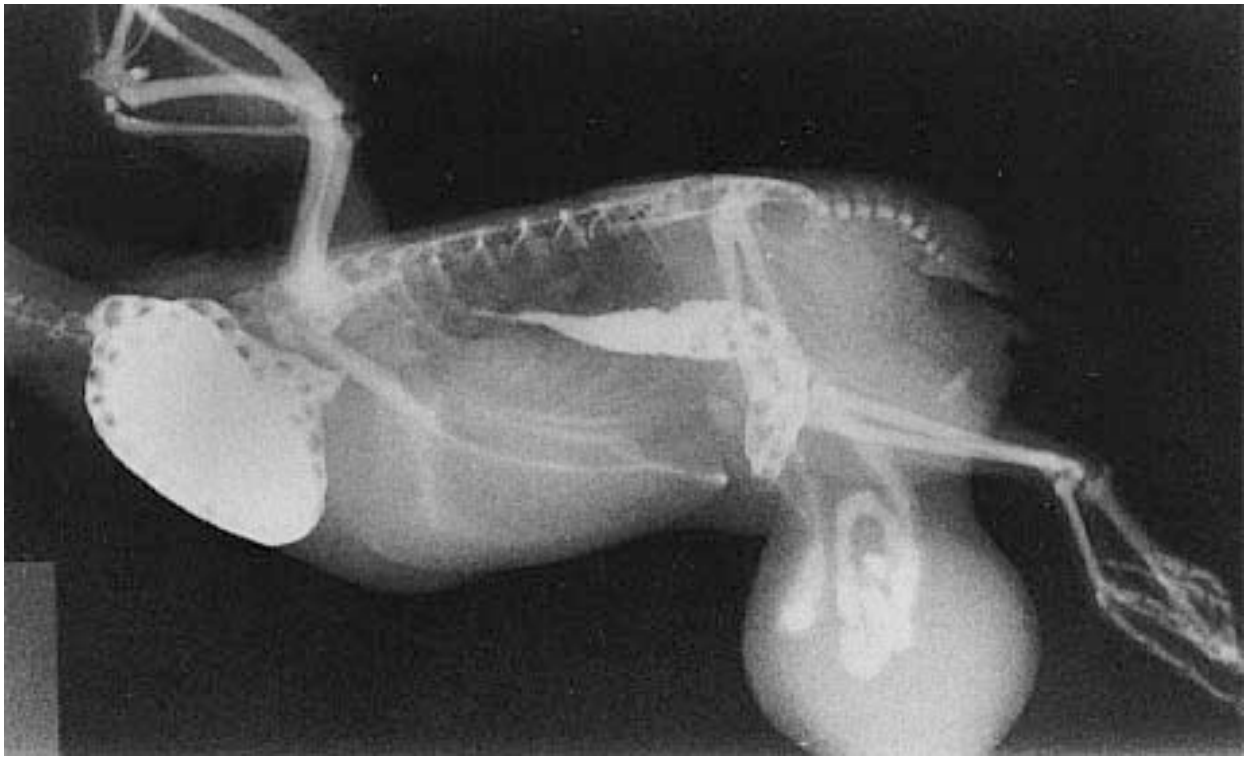

FIG 12.65 A female budgerigar was presented for evaluation of a ventral abdominal mass. A barium contrast study indicated that the mass was herniated intestines. Note also the increased density of the skeleton (polyostotic hyperostosis). Herniation and polyostotic hyperostosis are characteristic of hyperestrogenism (courtesy of Marjorie McMillan).

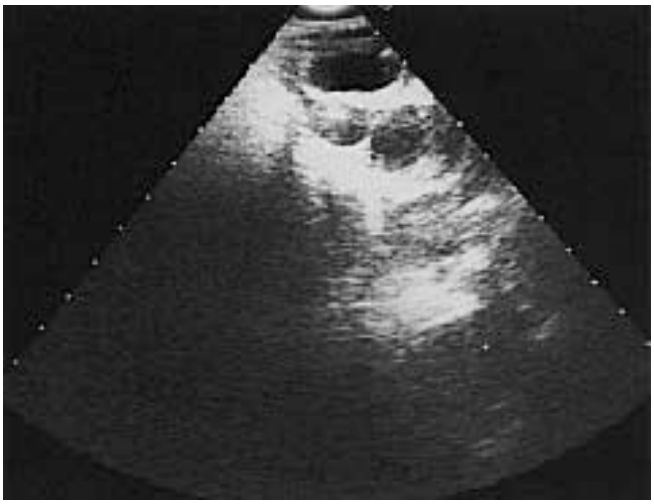

FIG 12.66 Radiographs of an egg-bound cockatiel suggest the presence of one large abnormally shaped egg and one smaller incompletely formed egg. Ultrasound indicated the presence of four eggs (courtesy of Marjorie McMillan).

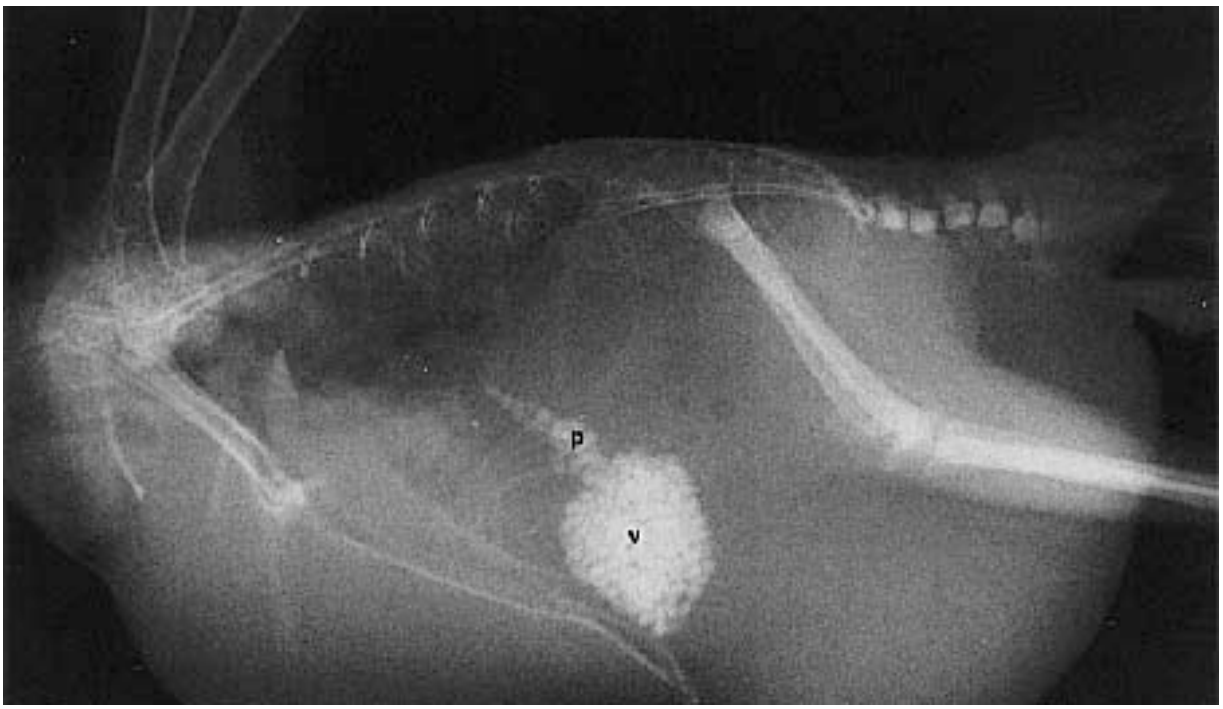

FIG 12.67 A mature cockatiel hen was presented for dyspnea and a swollen abdomen. Radiographs indicated a fluid-filled abdomen with cranial displacement of the ventriculus (v) and proventriculus (p), both of which are impacted with grit. Abdominocentesis was consistent with an exudative effusion, and the diagnosis was egg-related peritonitis. The cranial displacement of the abdominal viscera indicates that the fluid is present in the intestinal peritoneal cavity (courtesy of Marjorie McMillan).

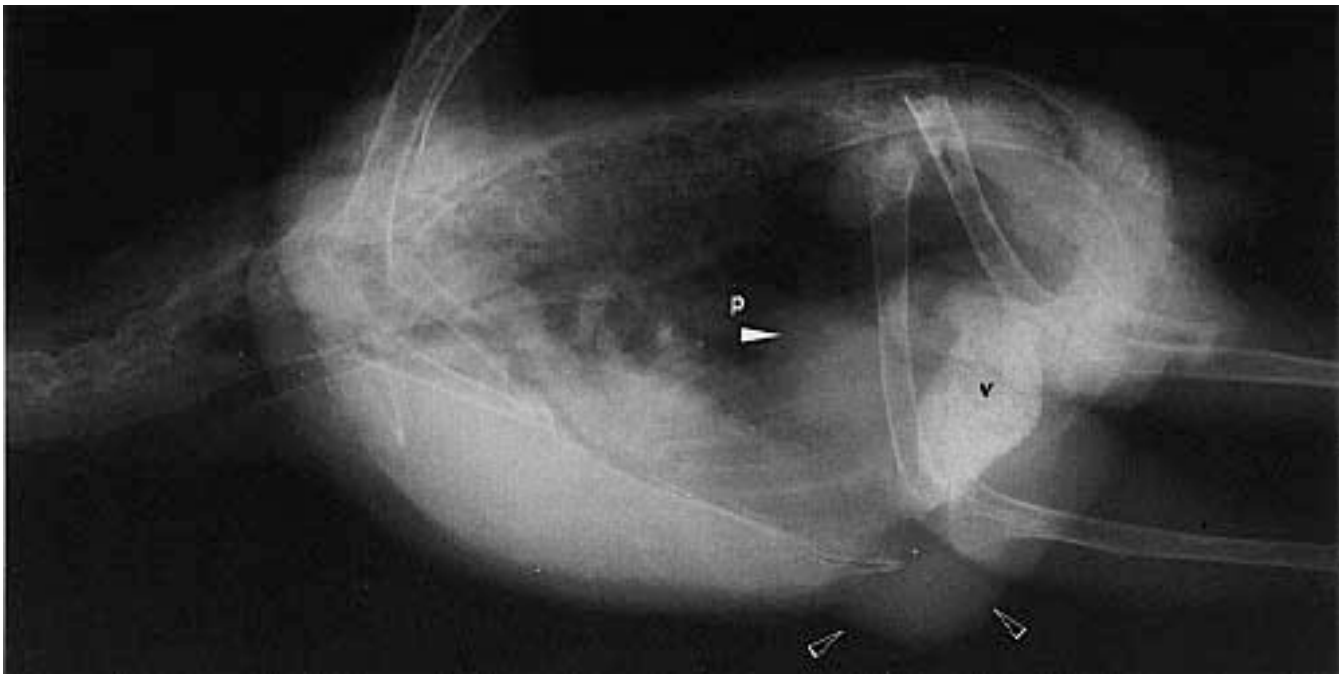

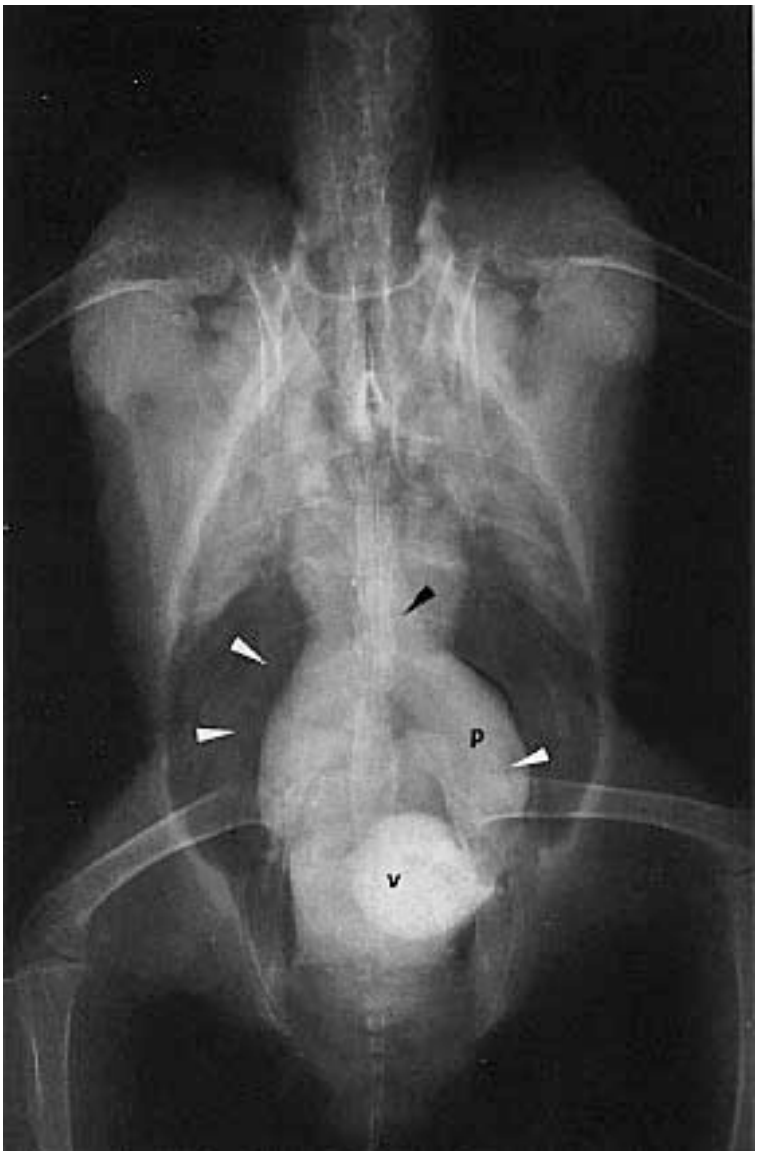

FIG 12.68 A 35-year-old Yellow-headed Amazon Parrot was presented with a firm ventral midline mass. Radiographs indicated rounding of the liver lobes and hepatomegaly (arrows). The mass was visible as a soft tissue opacity at the caudal edge of the sternum (open arrow). An exploratory laparotomy revealed a herniated liver. Proventriculus (p), ventriculus (v) (courtesy of Marjorie McMillan).

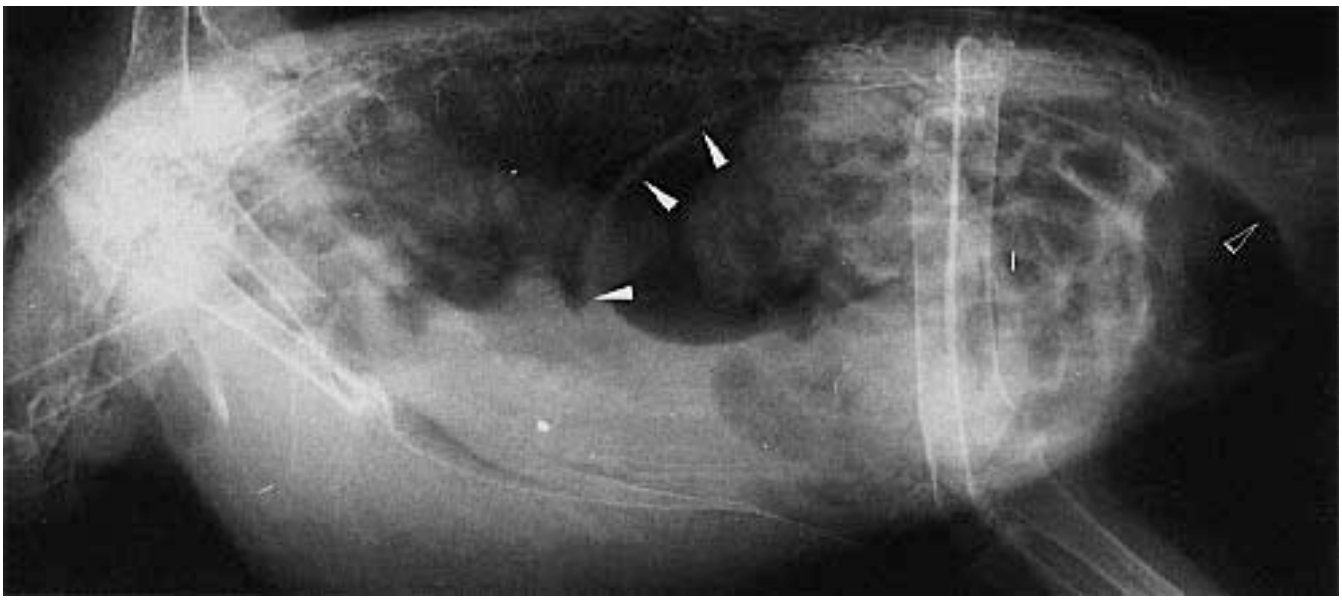

FIG 12.69 A Blue and Gold Macaw was presented with severe dyspnea including a tail bob. The bird was sneezing and had both ocular and nasal discharges. The only abnormal clinicopathologic finding was WBC=18,000. Radiographic changes included gaseous distension of the intestines (i), thickening of the contiguous membrane of the caudal thoracic and abdominal air sac (open arrow). The client was a heavy smoker, and the lesions resolved over a three-month period when the client quit smoking and the bird received daily exposure to fresh air and sunlight.

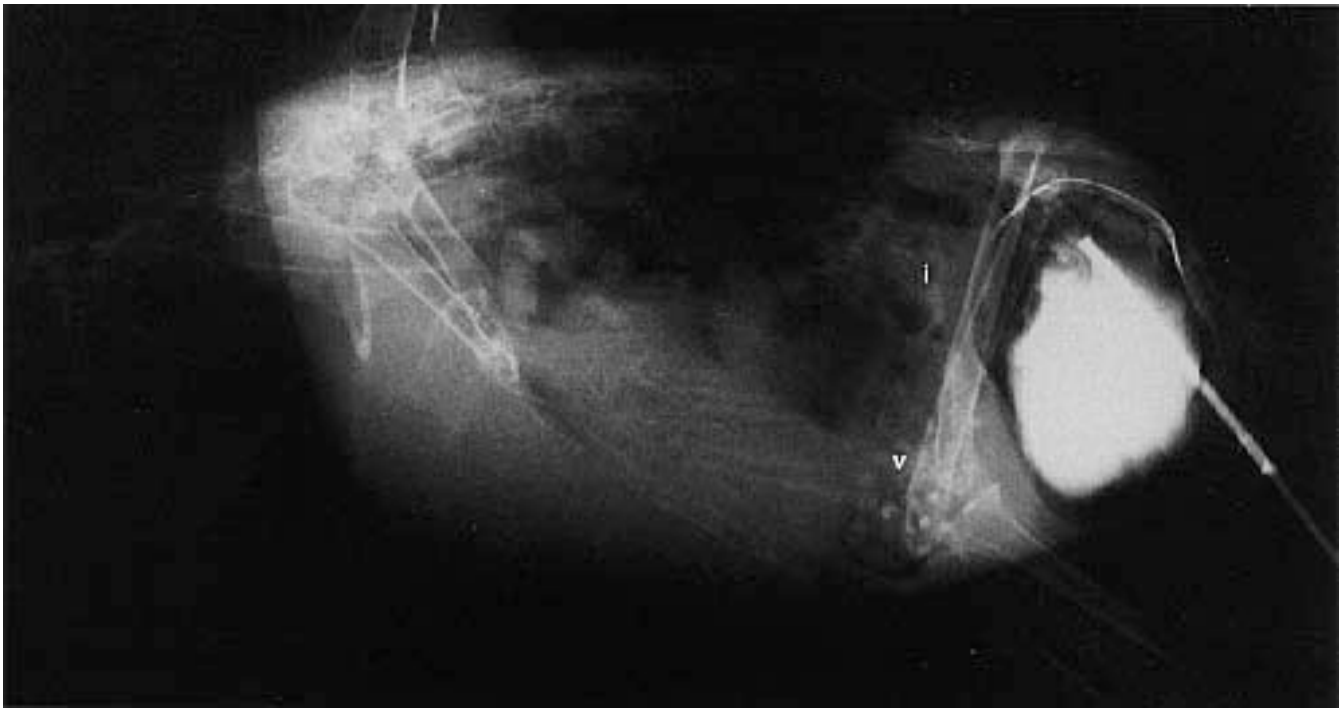

FIG 12.70 Contrast medium was injected into the gaseous distended cloaca of an Amazon parrot with severe dyspnea. Note the cranial displacement of the intestines (i) and ventriculus (v).

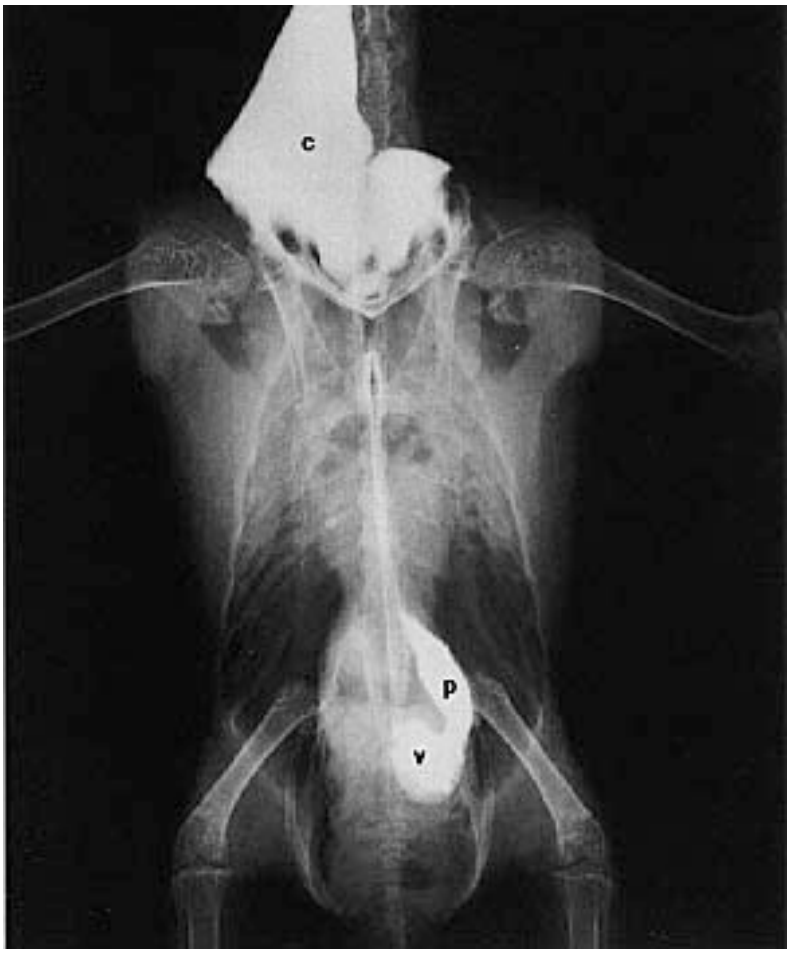

FIG 12.71 Radiographs of an adult African Grey Parrot ten minutes after administering barium sulfate. Crop (c), thoracic esophagus (arrow), proventriculus (p), ventriculus (v) (courtesy of ME Krautwald).

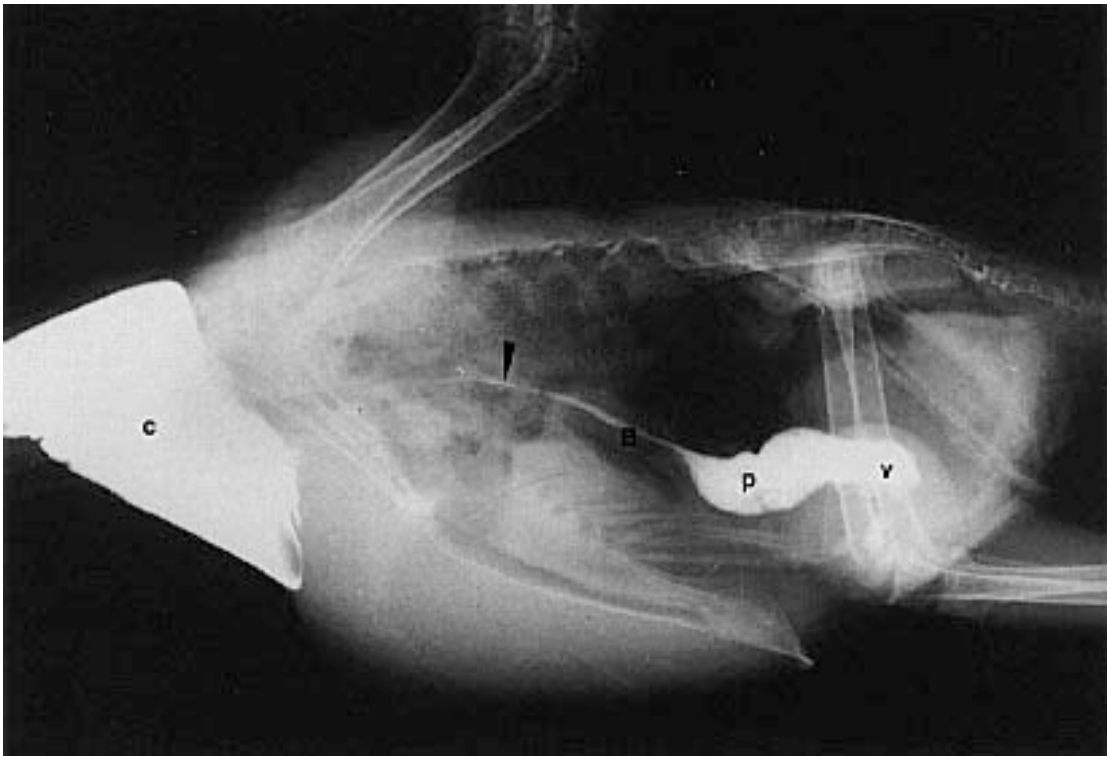

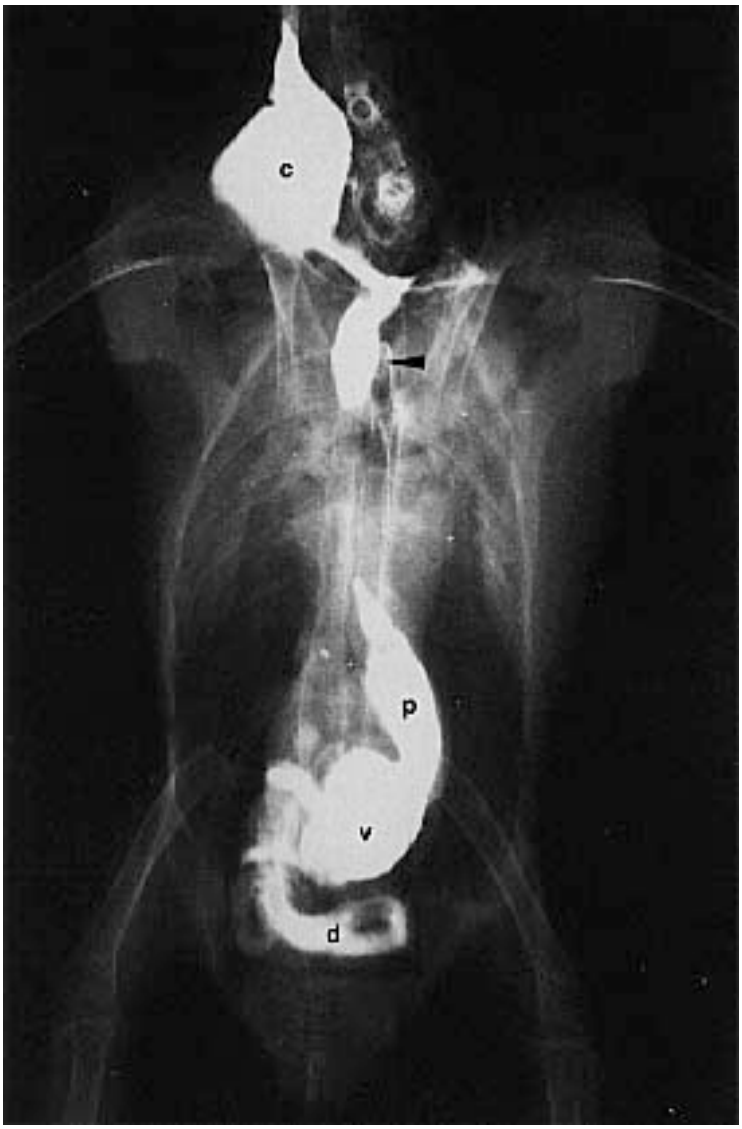

FIG 12.72 An Amazon parrot 20 minutes after barium sulfate administration. Crop (c), thoracic esophagus (arrow), proventriculus with filling defects (p), ventriculus (v), duodenum (d), ilium and jejunum (open arrow).

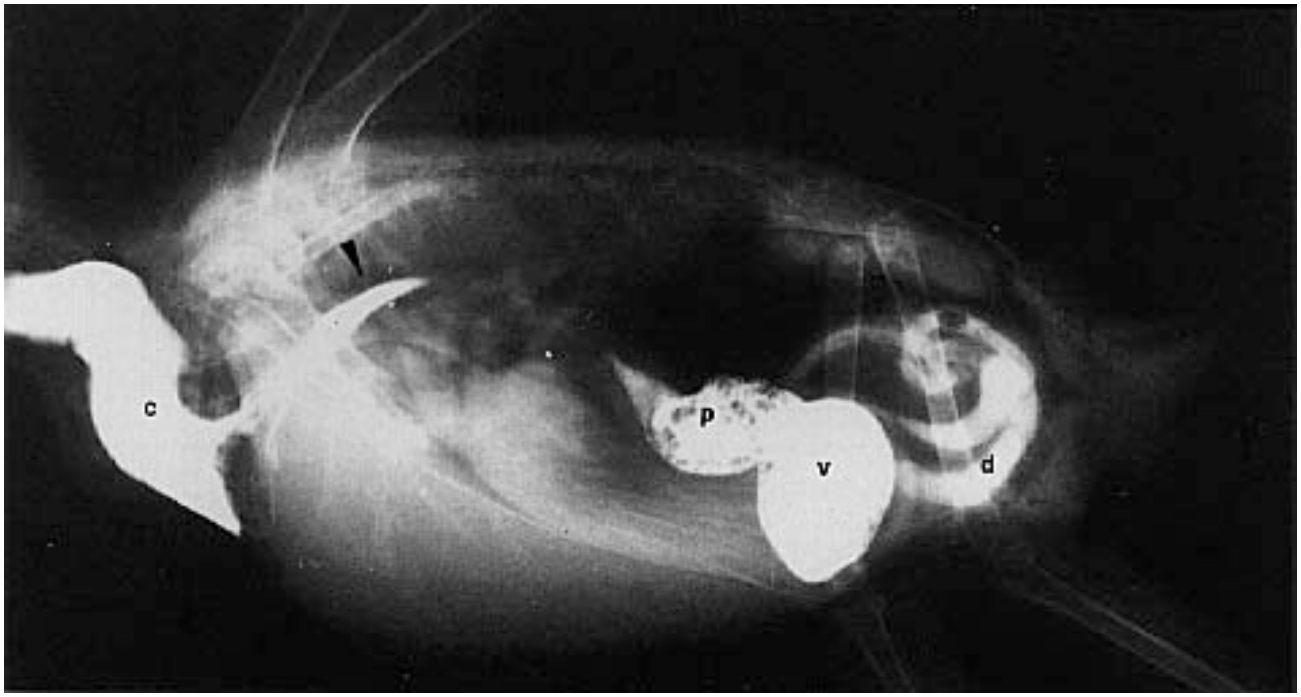

FIG 12.73 Radiographs of an adult African Grey Parrot 60 minutes after administering barium sulfate. Crop (c), thoracic esophagus (arrow), proventriculus (p), ventriculus (v), duodenum (d), intestines (i), colon (open arrow) (courtesy of ME Krautwald).

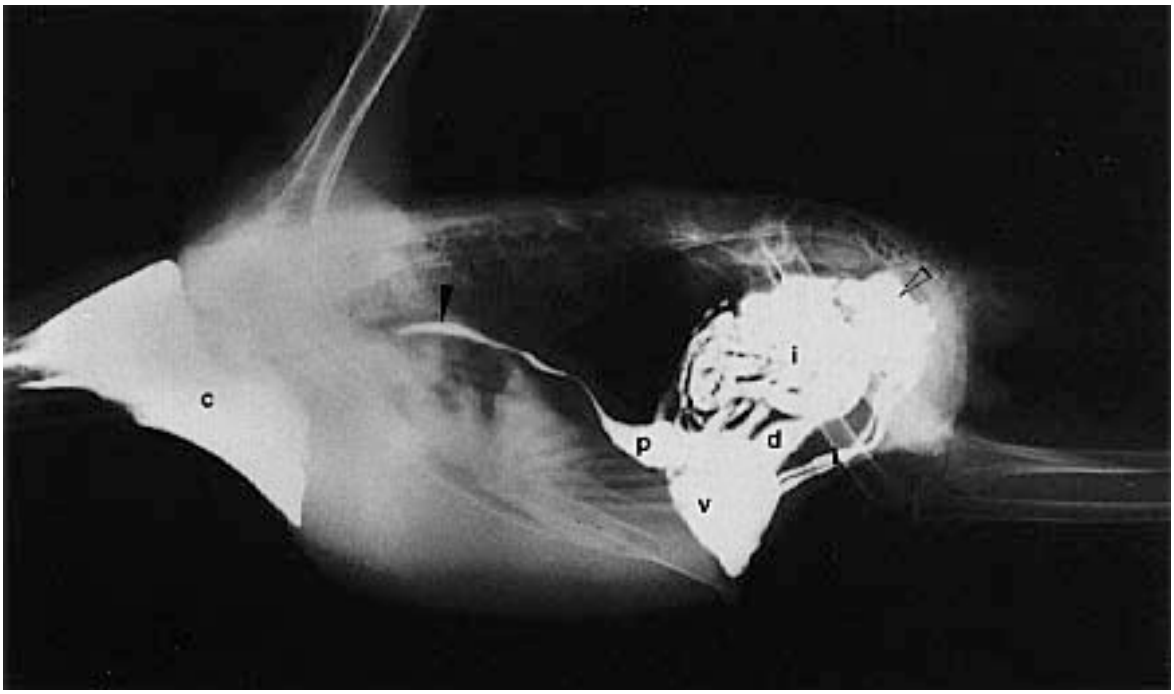

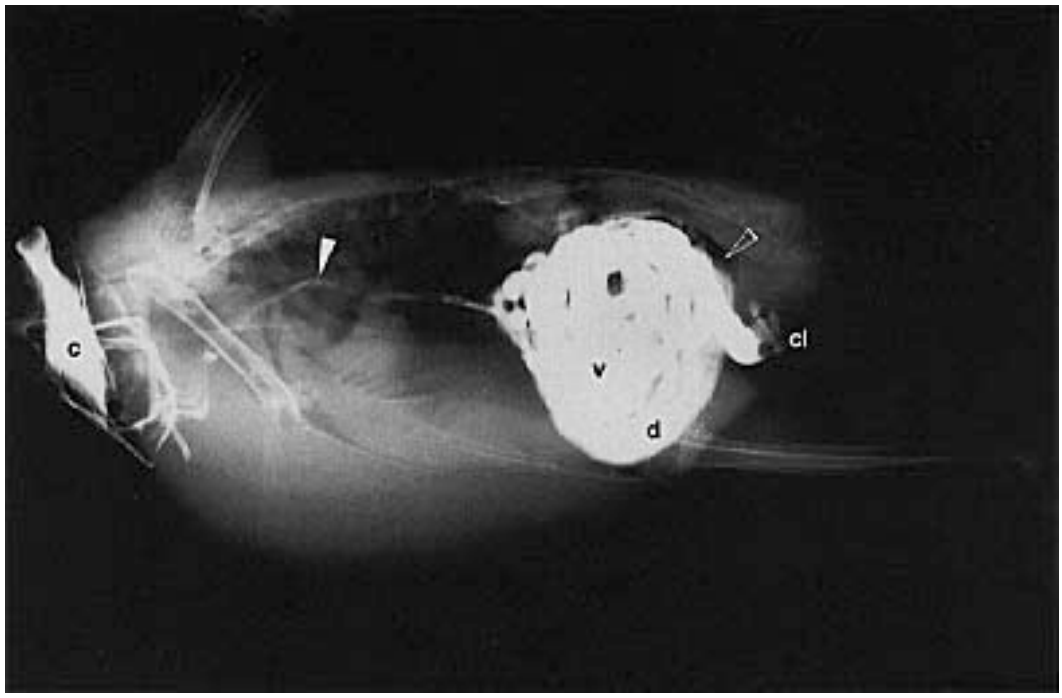

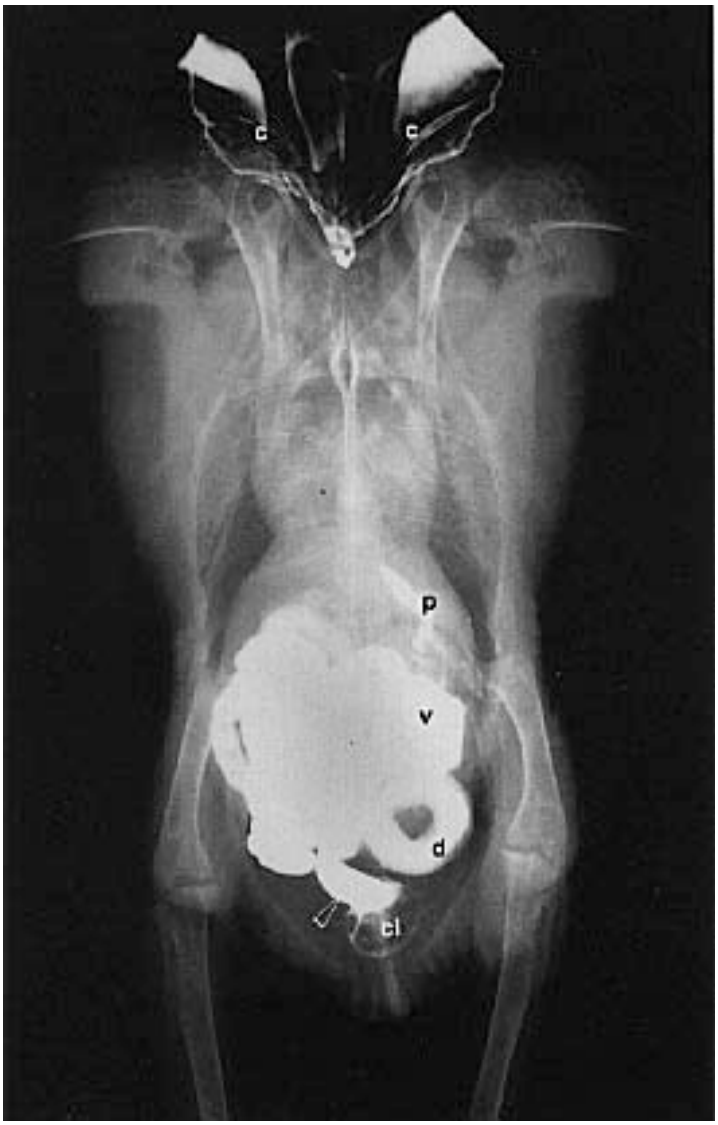

FIG 12.74 Radiographs of an adult pigeon 20 minutes after administration of barium. Note the crop (c) is composed of two lateral compartments. Thoracic esophagus (arrow), proventriculus (p), duodenum (d), colon (open arrow), cloaca (cl) (courtesy of ME Krautwald).

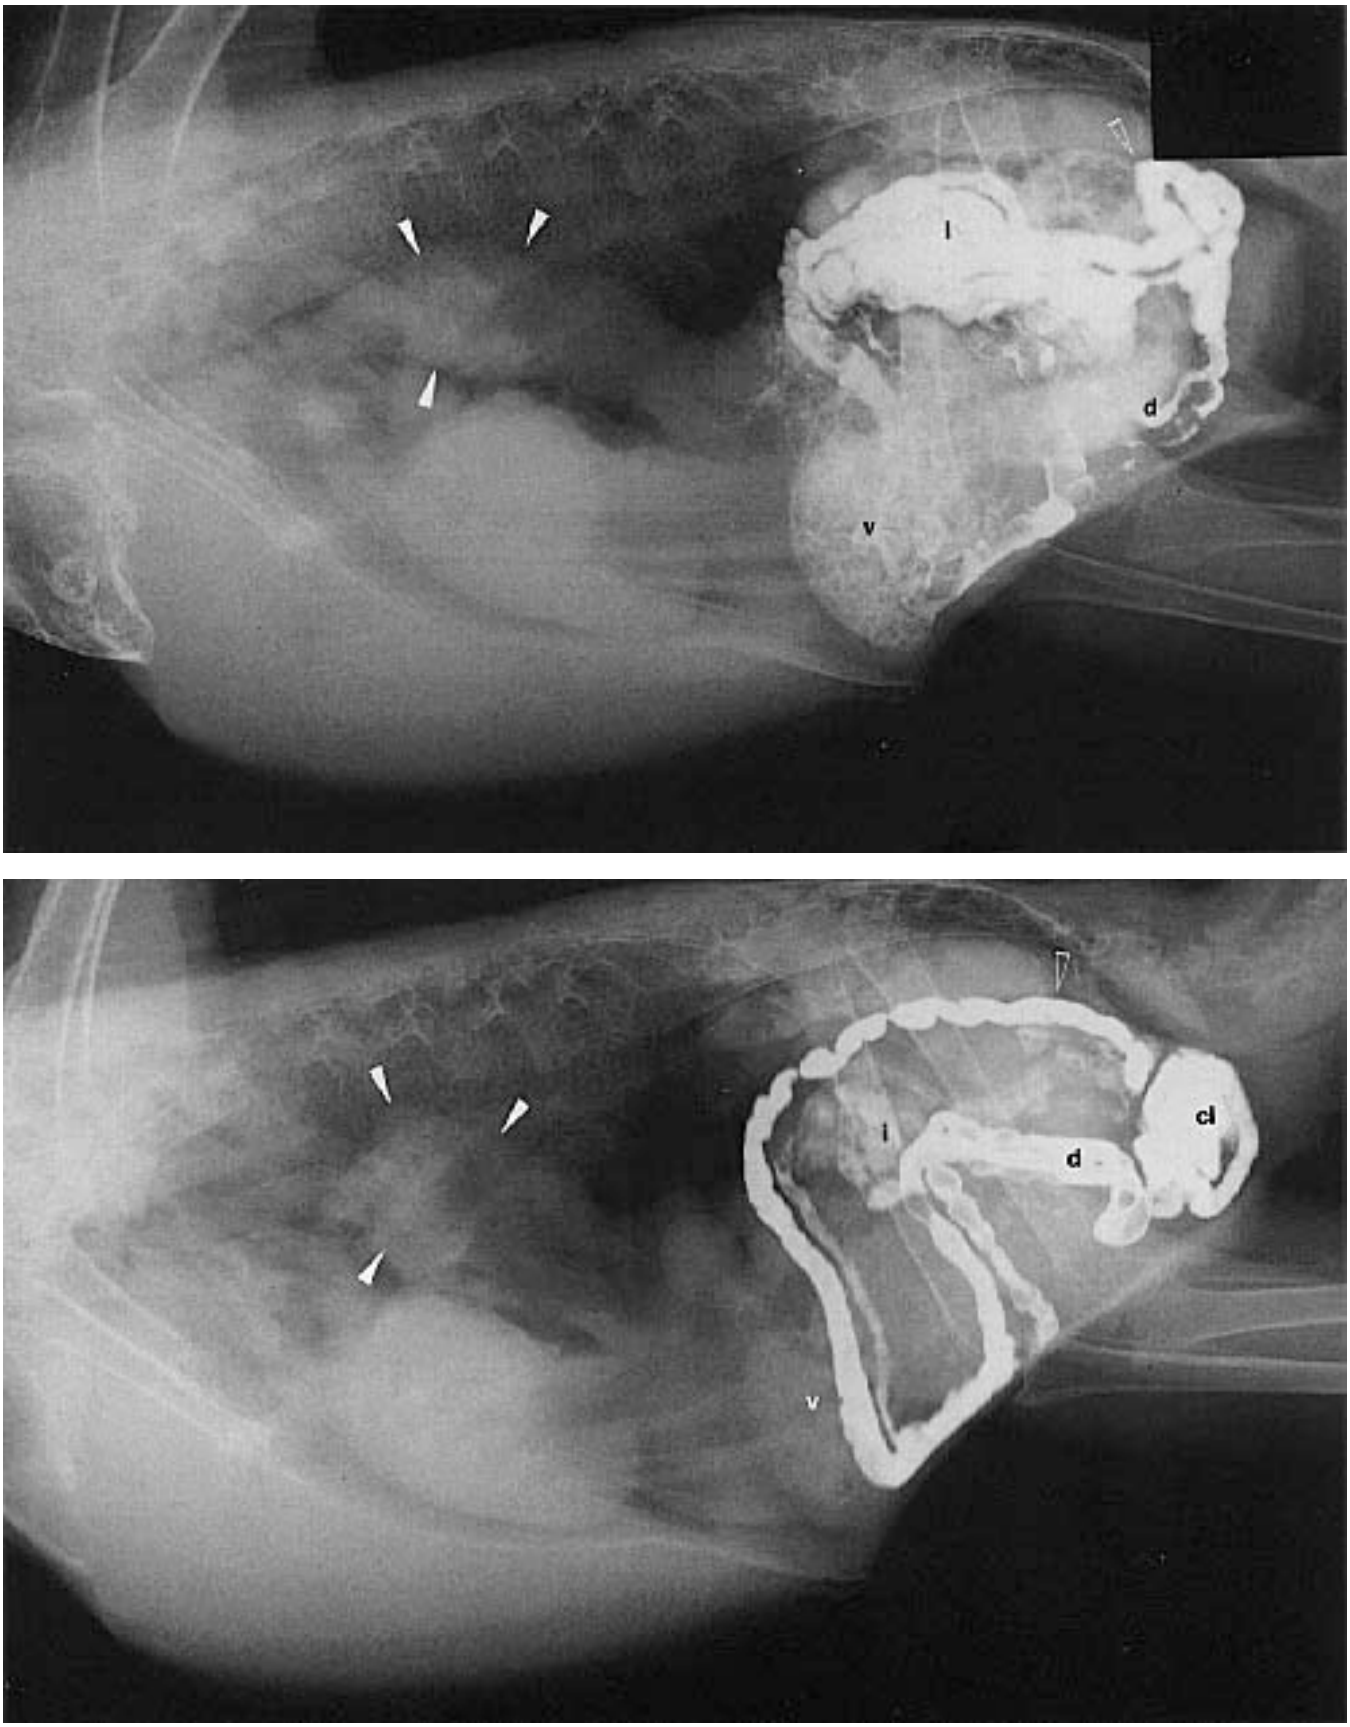

FIG 12.75 An adult Amazon parrot was presented with a history of dyspnea and weight loss. A mass (arrow) was identified in the dorsocranial thorax. Barium contrast radiography indicated that the mass was associated with the thoracic esophagus. Radiograph **a)** was taken 45 minutes and radiograph **b)** was taken 2 hours after barium administration. Contrast medium can be seen in the ventriculus (v), ascending and descending colon (d), jejunum and ileum (i), colon (open arrow) and cloaca (c).

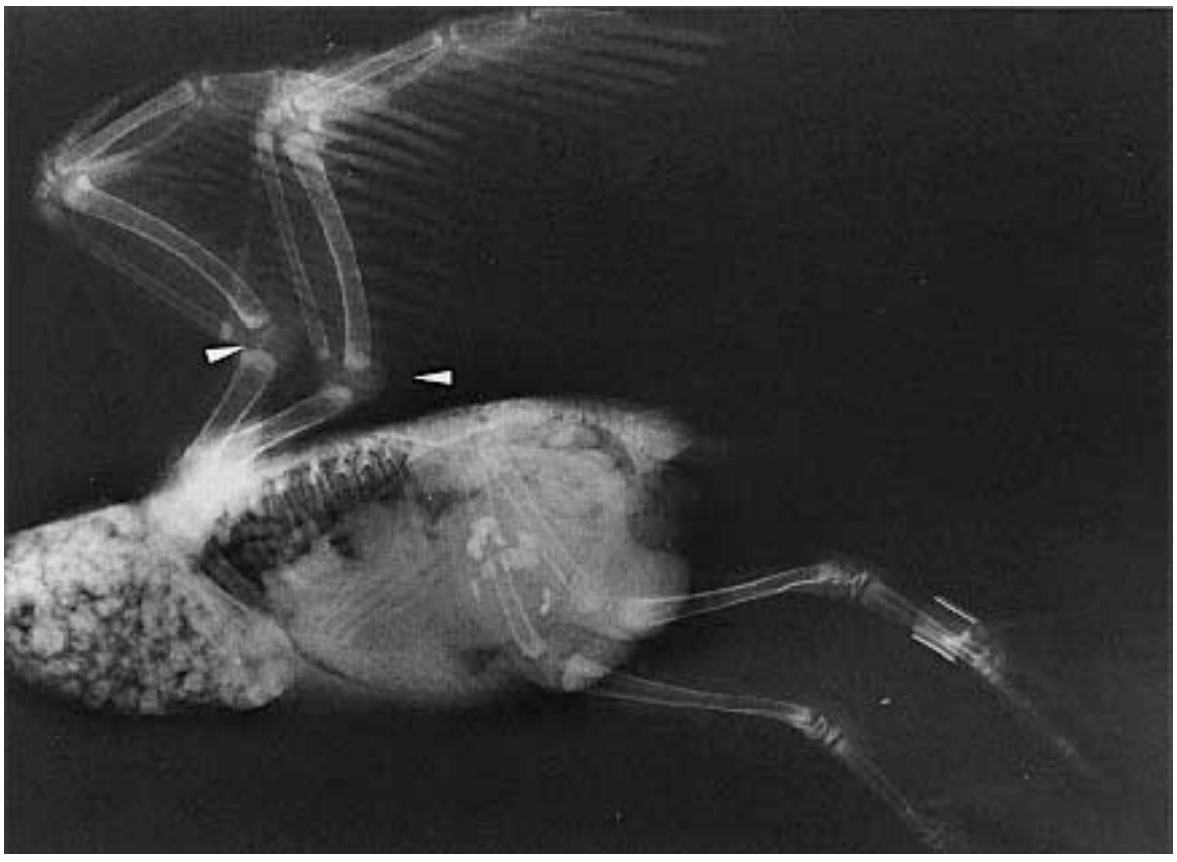
FIG 12.76 Two-week-old pigeon. The gastrointestinal tract of neonates stays distended with food, making the delineation of abdominal structures difficult. Note the large joint spaces characteristic of developing bones in birds (arrows) (courtesy of ME Krautwald).



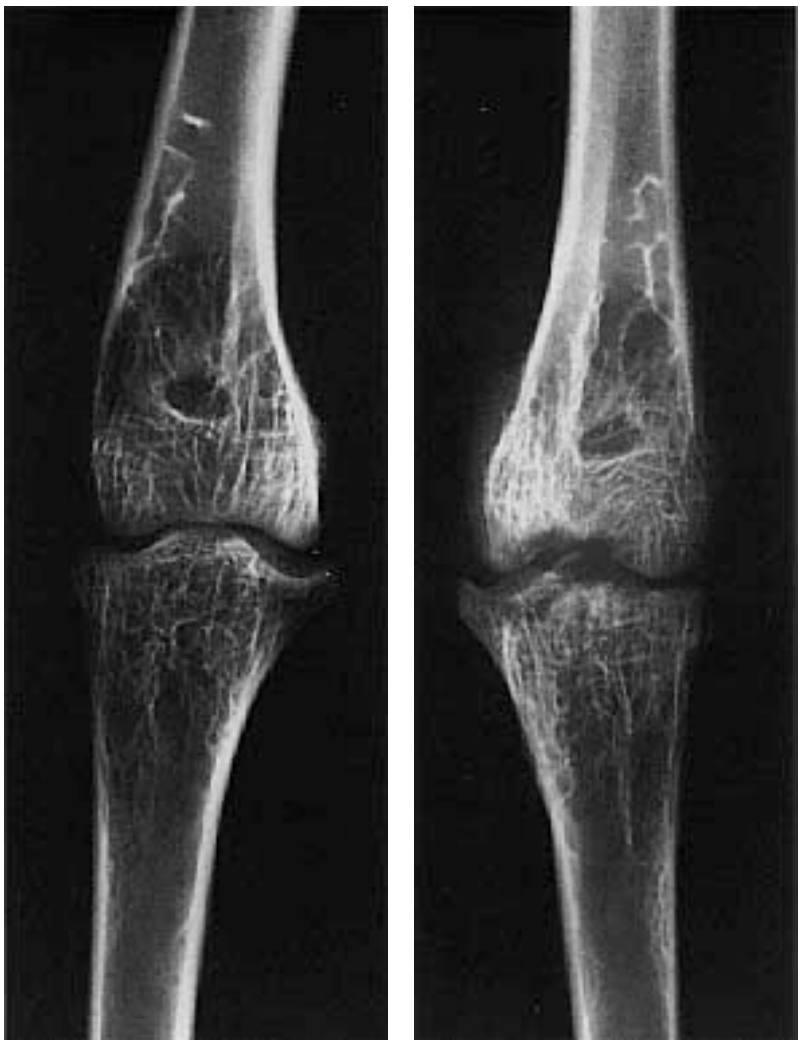


FIG 12.77 An adult swan was presented with intermittent lameness. The tibiotarsal joint was hot, firm and swollen. Radiographs indicated joint enlargement, subchondral bone lysis and erosion of the intercondylar space. These lesions were suggestive of septic arthritis. Radiograph of the normal leg for comparison.

FIG 12.78 A fledgling Golden Eagle was presented with an inability to stand and a decreased range of motion in both pelvic limbs. The bird had been equipped with a radiotransmitter and released from a hack tower several weeks before presentation. The bird was not being monitored and was found hanging upside down from a tree limb with the transmitter entangling the legs. Radiographs indicated necrosis of both femoral heads. EMGs indicated denervation of both pelvic limbs. The bird was euthanatized.

Continued from page 260

nal effusion or organomegaly, ultrasound may be used to characterize lesions (Figure 12.66).[14,19,20] Most studies can be performed without anesthesia. Patients may be held or secured with a plexiglass restraining device. Many birds that are minimally restrained in an upright position are extremely tolerant of the procedure. Feathers may be parted or removed, and a water-soluble, acoustic coupling gel is used to improve the transducer contact with the skin.

A 7.5 MHz end-fire mechanical sector scanner or phased array scanner is best in most birds, but 5.0 MHz and 10 MHz transducers may also be used. Higher frequency scanners provide less tissue penetration but finer resolution and are most useful in smaller species. Linear array transducers can also be used, but because of their shape, they do not conform well to the patient's body.

If the patient is in dorsal recumbency, the transducer is placed just caudal to the sternum and the beam is angled cranially. The liver has a uniform, slightly granular, echogenic pattern and is easily recognized (Figure 12.61). The right and left hepatic veins can be identified as anechoic channels on the dorsomedial aspect of the liver. A uniform, hyperechoic, hepatic parenchyma has been described in birds with fatty liver degeneration and hepatic lymphoma.[16] Discrete hyperechoic masses throughout the liver may represent granulomas, abscesses or neoplasms.

Hepatomegaly should be suspected if the liver can be detected caudal to the sternum. Ultrasound is of little value in detecting acute or chronic hepatitis, and it is difficult to differentiate between cirrhosis and necrosis. Granulomas and neoplasms typically appear as focal hyperechoic walls with an echoic center. Hematomas and subcapsular bleeding will appear hypoechoic.

The liver may be used as a window to visualize the cardiac silhouette. Pericardial effusion and enlargement of cardiac chambers and valvular abnormalities can be detected in larger species. Pulmonary masses such as large granulomas have been defined using ultrasonography. A lateral approach can be used for visualization of the spleen, which is normally hyperechoic in comparison to the liver and is difficult to define unless enlarged.[16]

Ultrasonographic visualization of the kidneys and gonads is not possible due to the presence of the air sacs, although large ovarian follicles can occasionally be defined. Ultrasound can be used to differentiate between soft-shelled eggs and egg-related peritonitis. Poorly mineralized eggs are often oval with a hyperechoic rim surrounding a hypoechoic content. With egg-related peritonitis, there is a heterogeneous hyperechoic appearance to the coelomic cavity (Figure 12.66). Effusion due to other processes is often anechoic or hypoechoic.

The presence of ingesta or gas will obscure portions of the gastrointestinal tract. Differentiation of the proventriculus, ventriculus and cloaca can be enhanced by administering water.

Ultrasound-guided biopsy can be used to collect diagnostic samples from the liver. The patient must be sedated or anesthetized. A variety of needles may be used for the biopsy. In larger species a 22 ga Westcott needle is used to obtain specimens for cytology, histology and culture. Spinal needles and 25 ga hypodermic needles may be used, but may be difficult to localize with the ultrasound beam and often yield only enough material for cytology.

Nuclear Scintigraphy

The potential value of nuclear medicine studies in avian patients remains unexplored. The usefulness of musculoskeletal scintigraphy in other species is well recognized.[9] Three-phase bone scans allow evaluation of the blood supply, soft tissue component and skeleton and are especially useful in occult lesions or abnormalities that are undetectable on survey radiographs. Unexplained abnormalities of the extremities, especially following trauma, would be most suitable for bone scintigraphy. Evaluation of the extent of osteomyelitis, joint disease, vascular compromise, impaired fracture healing and less commonly, bone neoplasia, is enhanced by nuclear medicine studies.

Technetium-99m(^{99m}Tc) is the isotope most frequently used because of its short half-life (six hours) and ideal energy range (140KeV). For bone scanning, the radiopharmaceutical most commonly used is ^{99m}Tc methylene diphosphonate (MDP). A whole body scan of most birds is easily obtained because the entire patient can rest on the head of the gamma camera.

Patients must be kept motionless, so sedation or anesthesia is necessary. One millicurie of radioisotope is administered intravenously, and dynamic images are obtained immediately for the vascular

phase, and within the first 15 minutes for the soft tissue phase. Delayed static images are taken within three to four hours for the bone phase.

Computed Tomography

Computed tomography (CT) is superior to other modalities except magnetic resonance imaging for evaluation of head trauma and abnormalities involving the brain and spinal cord; however, the lack of availability and high cost often prevent the use of computed tomography in birds. Patients must be anesthetized to prevent any motion during the scan. Technical factors are inadequately studied in birds; however, slice section thickness ranging from 2 mm to 5 mm non-overlapping with varying window settings have been described for body scans.[8,17] The value of CT in avian diagnostic radiology remains relatively uninvestigated, but characterization of lesions with CT should prove as valuable as in other species.

CHAPTER

13

ENDOSCOPIC EXAMINATION AND BIOPSY TECHNIQUES

Michael Taylor

The development of a rigid rod-lens system and the perfection of fiberoptic cables in the late 1950's and early 1960's heralded the modern age of endoscopy in human medicine. A unique lens design[9] allowed for improved light transmission in small diameter telescopes. Over the next decade, various rigid endoscopes were introduced into human gynecology, orthopedics and otolaryngology. By the middle 1970's veterinarians were employing these endoscopes in animal species, and the concept of rigid endoscopy was introduced to avian practitioners.[2,27]

A growing interest in aviculture, particularly of psittacine birds, must also be credited with stimulating the field of avian endoscopy. Endoscopic determination of gender (surgical sexing)[22] has become an integral part of the captive management of many avian species. Birds are ideal subjects for endoscopic examination due to the unique design of their respiratory system, which provides extensive pneumatization of the coelom. A variety of diagnostic uses for endoscopy in birds has previously been described;[2,8,19,21] however, the greater benefits of this technology have hardly been explored. New developments in equipment and techniques are certain to increase the value of endoscopy to avian veterinarians.

b) An artist's impression of the VD view of a bird showing anatomic structures of importance when performing endoscopy from various entry sites: When the scope is introduced through entry site 6 (see Figure 13.2), it enters the caudal thoracic air sac. On the VD view it may appear as though the scope goes through the abdominal air sac as well. The abdominal air sac actually forms a backwards C positioned dorsal and ventral to the caudal thoracic air sac (see Anatomy Overlay). In some species, the right and left abdominal air sacs may be more symmetrical than shown.

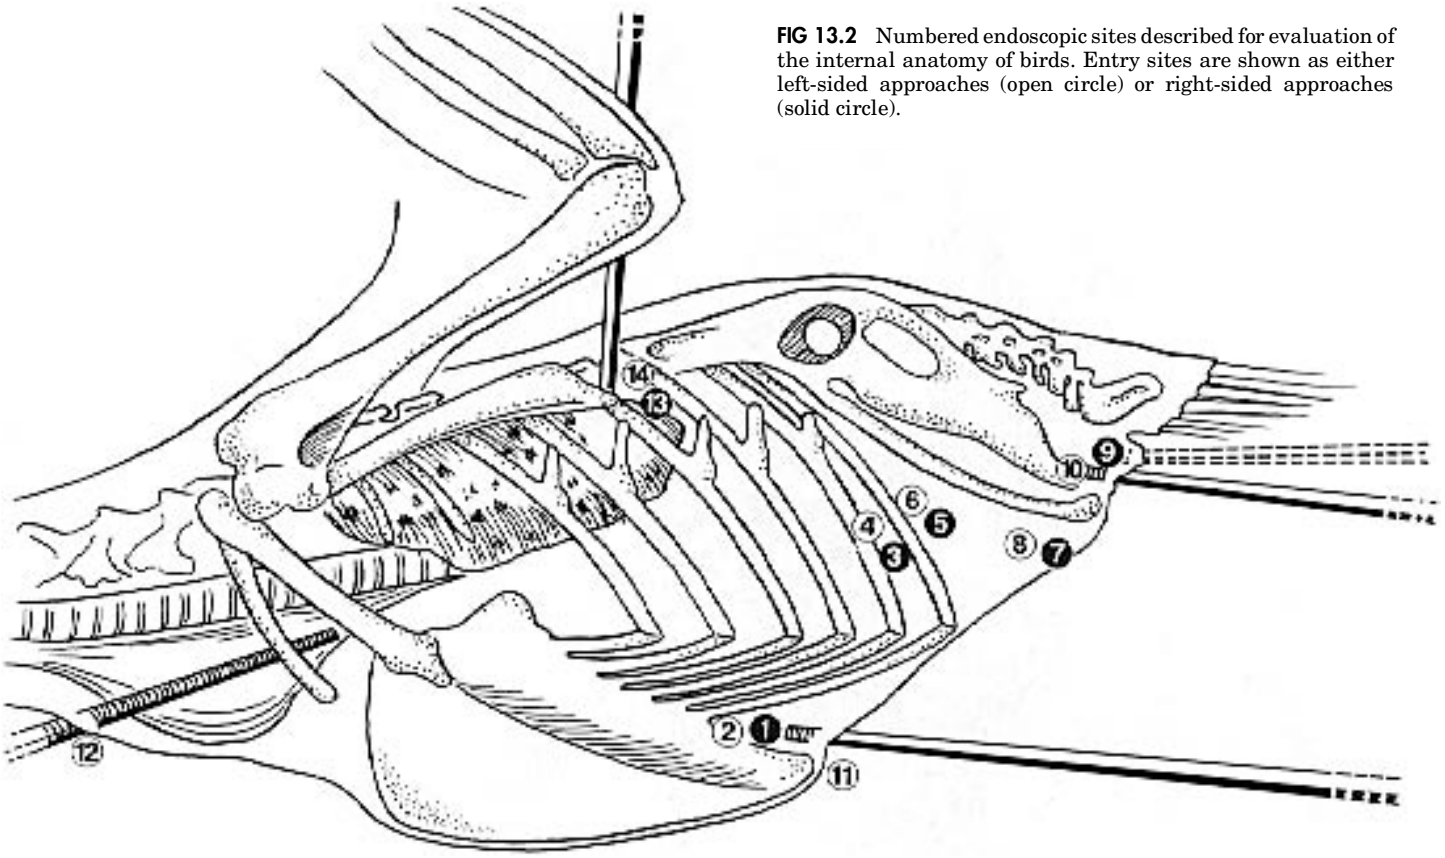

FIG 13.2 Numbered endoscopic sites described for evaluation of the internal anatomy of birds. Entry sites are shown as either left-sided approaches (open circle) or right-sided approaches (solid circle).

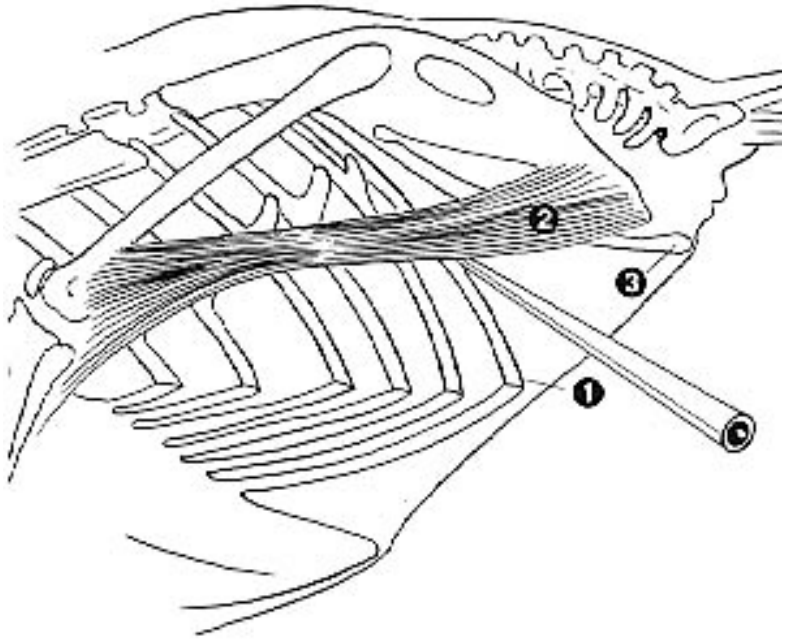

FIG 13.3 Left flank approach for endoscopic evaluation of the bird. The leg is pulled cranially and the entry site is at the junction of the caudal edge of the 1) eighth rib and the 2) flexor cruris medialis muscle. 3) The pubic bone serves as an additional landmark. This approach is listed as entry site 6 in Figure 13.2.

Endoscopic laparotomy can be performed from either the right or left side of a bird, and 14 different approaches have been described. These approaches are depicted in Figure 13.2. Site 4, located between the seventh and eighth ribs, is frequently used for endoscopic evaluation of the gonads; however, an entrance point through the left flank (site 6, Figures 13.2, 13.3) just ventral to the flexor cruris medialis muscle and caudal ventral to its intersection with the vertebral portion of the eighth rib and the pubic bone is a site that provides better visualization of many abdominal structures.

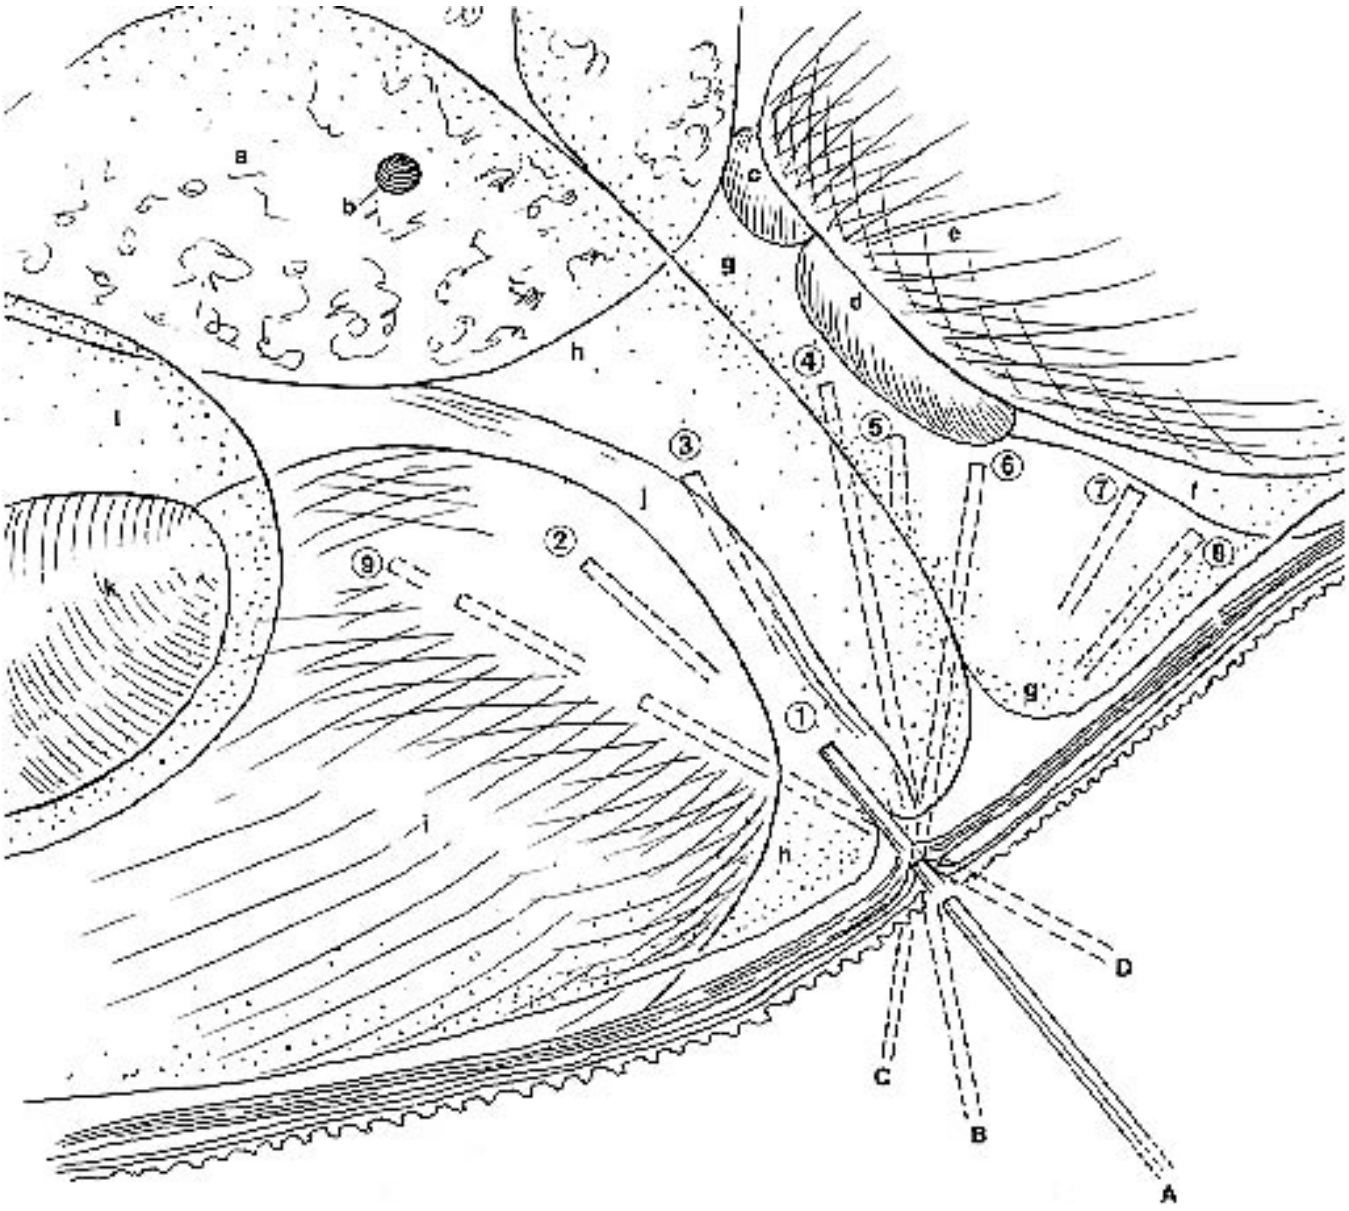

FIG 13.4 An artist's rendition of the anatomic features that are visible when the endoscope is placed in different directions and at different depths from entry site 6 (Figure 13.2). By matching the angle and depth of the endoscope, the endoscopist can develop an insight into the relative position of organs as viewed from entry site 6. The views are divided into four angles (A,B,C,D) and depths (1 through 9). Each color endoscopic picture has a corresponding angle and position marker to help the endoscopist envision the anatomic relationship of the endoscopic view. Thus, if the scope is oriented to B-4, the gonad, adrenal gland and kidney would be in view. Structures that will be used for orientation in the various endoscopic pictures include: a) lung b) ostium of the cranial thoracic air sac c) adrenal gland d) gonad e) kidney f) ureter, oviduct, vas deferens area g) abdominal air sac h) caudal thoracic air sac i) liver j) proventriculus k) heart and l) cranial thoracic air sac.

Endoscopic Examination and Biopsy Techniques

Understanding the relationship of structures is critical to effective endoscopy. This approach to endoscopic anatomy will guide the clinician through the evaluation of thoracoabdominal structures that can be viewed from various entrance points to the abdominal cavity. (All color photographs in this section © 1994 by Michael Taylor.)

Color 13.1
The left abdominal wall has been removed from an Amazon parrot. Note the tiered effect of the cranial thoracic (open arrows), caudal thoracic (arrows) and abdominal air sacs (a). The intestinal peritoneal cavity (IPC) has been infused with red dye. Other prominent organs include the lung (lu), heart (h), liver (li) and proventriculus (p).

Color 13.2
A bird is placed in right lateral recumbency with the leg extended cranially to show the insertion point to entry site 6 (see Figure 13.2). Dotted lines mark the caudal edge of the eighth rib (r), the flexor cruris medialis muscle (m) and the pubic bone (p). The entrance site is at the junction of the eighth rib and the flexor cruris medialis muscle.

Color 13.3
Endophotograph of entry site 6 to show the eighth rib (r), ventral border of the flexor cruris medialis muscle (m) and the penetration point in the lateral abdominal wall.

Color 13.4
(Position A-1 see Figure 13.4) Immediately after entering the abdominal cavity of an Amazon parrot, the caudal thoracic air sac can be visualized. The air sac should be transparent with minimal vascularity. The proventriculus (p) is ventral to the endoscope. The medial wall of the caudal thoracic air sac (a) becomes contiguous with the lateral wall of the abdominal air sac.

Color 13.5
(Position A-2 see Figure 13.4) Normal caudal thoracic air sac of an Amazon parrot. In this view, a clear, unobstructed view of the ostium (o) of the caudal thoracic air sac indicates that the tip of the endoscope is within this air space. Also visible are the dorsal edge of the left liver (li), lung (lu), proventriculus (p) and the confluent wall of cranial thoracic and caudal thoracic air sac (open arrow). The proventricular arteries are clearly visible (arrow).

Color 13.6
(Position A-3 see Figure 13.4) Normal organs and air sacs in an Amazon parrot. Ostium (o), lung (lu), proventriculus (p), liver (li), confluent wall of cranial and caudal thoracic air sacs (open arrow) and confluent wall of caudal thoracic and abdominal air sacs (arrow).

Color 13.7
(Position B-4 see Figure 13.4) Mature melanistic left testicle (t) of a Goffin's Cockatoo. Also visible are the left adrenal gland (a), ilium (i), cranial pole of the left kidney (k), left common iliac vein (arrow) and aorta (open arrow).

Color 13.8
(Position B-4 see Figure 13.4) Normal immature testicle (t) of a Quaker Parakeet. Also visible are the left adrenal gland (a), right and left common iliac veins (arrows) and the caudal vena cava (open arrow).

Color 13.9
(Position B-4 see Figure 13.4) Endoscopic view of the kidney (k) and immature melanistic ovary (o) of a six-month-old Blue and Gold Macaw. Note the sulci and gyri. Vessels are seen through the abdominal air sac in the peritoneal membrane overlying the gonads (arrows).

Endoscopic Examination and Biopsy Techniques

Color 13.10
(Position B-4 see Figure 13.4) Unpigmented, mature testicle (lt) in an Amazon parrot. Also noted are the lung (lu), cranial pole of the left kidney (k), epididymis (e), right testicle (rt), caudal vena cava (arrow) and right kidney (rk).

Color 13.11
(Position B-4 see Figure 13.4) Normal immature ovary (o) in a 14-week-old Amazon parrot. Also visible are the left adrenal gland (a), cranial pole of the left kidney (k), lung (lu), dorsal ligament of the oviduct (arrow) and common iliac vein (open arrow).

Color 13.12
(Position B-4 see Figure 13.4) Developing ovary (o), cranial pole of the left kidney (k), lung (lu), adrenal gland (a), dorsal ligament of the oviduct (arrow) and oviduct (open arrow). The vessels coursing across the oviduct, kidney and ovary are present in the abdominal air sac.

Color 13.13
(Position B-5 see Figure 13.4) Normal ovary in a 14-week-old Blue and Gold Macaw. The nondescript, fatty-appearing ovary (o) is difficult to identify, but the dorsal ligament of the oviduct (arrow) coursing across the kidney (k) confirms that this is a female. The vessels coursing across the kidney and ovary are in the peritoneal membrane and are seen through the abdominal air sac.

Color 13.14
(Position B-4 see Figure 13.4) Normal ovary of a mature cockatoo. The ovary (o) is melanistic and the developing follicles are translucent (arrow). The cranial pole of the left kidney (k), lung (lu), left common iliac vein (open arrow) and aorta (a) are also visible.

Color 13.15
(Position B-4 see Figure 13.4) Mature ovary of an Amazon parrot. Note the developing follicles (f) and the characteristic yellowish ("cooked egg") appearance of the involuted ovary, indicating previous ovulation sites (open arrow). The cranial pole of the left kidney (k) and dorsal mesentery (dm) overlying the right kidney are also noted. The cranial oviductal artery (arrow) is easily visualized. The vessels seen crossing the ovary are those that are present in the peritoneal membrane and are visible through the abdominal air sac.

Color 13.16
(Position C-6 see Figure 13.4) Normal epididymis (e) of an Indian Hill Mynah. Also visible are the kidney (k), caudal pole of the testicle (t) and a loop of intestines (i).

Color 13.17
(Position C-7 see Figure 13.4) Ductus deferens (arrow) of an immature macaw. Note that the ductus deferens is smaller than the ureter (u). The kidney (k) and aorta (a) are also visible.

Color 13.18
(Position C-8 see Figure 13.4) Ductus deferens (d) of a mature Amazon parrot. Also visible are the ureter (u), kidney (k), renal portal vein (arrow), synsacrum (s), ischium (i), aorta (a) and a loop of intestines (in).

Color 13.19
(Position C-7 see Figure 13.4) Oviduct (o) in a juvenile macaw. The ureter (u), kidney (k), and vessels in the abdominal air sac are also visible.

Color 13.20
Endoscopic appearance of chronic nephrosis and tubular dilation in a toucan. The abnormal kidney (k) and ureter (u) are clearly visible.

Color 13.21
(Insertion point 5 see Figure 13.2) A right abdominal (as opposed to the normal left abdominal) approach has been used to demonstrate the regression of the right ovary (ro) as the left ovary (lo) matures in an Orange-winged Amazon Parrot. Also visible are the cranial pole of the right kidney (k), the right adrenal gland (a), the caudal vena cava (arrow), the cranial mesenteric artery (open arrow) and the dorsal mesentery (dm).

Equipment

Rigid Endoscope

- ***Diameter Size:*** Fine-diameter, rod-lens endoscopes are the most suitable for avian work because of their small size, excellent optical resolution and superior light transmission capabilities. For diagnostic purposes, a 1.9 mm is the smallest diameter endoscope available with high quality optics. This endoscope is excellent for patients weighing less than 100 grams or in small anatomic sites (eg, sinus, trachea, oviduct). The major disadvantages of these very small endoscopes are their fragility, relatively small field of view and transmission of less light, which limit usefulness in larger body cavities. Because the 2.7 mm endoscope provides good light transmission capabilities with an adequate image size at a diameter that may be used in a wide range of birds, it is a good choice as the sole or principal endoscope in an avian practice[a] (Table 13.1).

  The 2.7 mm endoscope has been used in patients weighing from 55 grams to 4.0 kilograms. Intermediate-sized telescopes (eg, 2.2 mm) are available and may be preferred by some clinicians. Endoscopes (4.0 or 5.0 mm) can be employed in larger patients or when documentation demands. The advantages of the larger optics are greater light transmission and a bigger image circle. Most modern 4.0 or 5.0 mm endoscopes also incorporate new distal lens designs that provide a wider field of view; these are currently unavailable in telescopes less than 4.0 mm diameter. The author has used a 4.0 mm endoscope with wide-angle optics in birds as diverse as Golden Eagles, Crowned Cranes and Marabou Storks.

- ***Length:*** For general avian endoscopy, a length of the endoscope in the range of 170 to 190 mm is recommended. Shorter working lengths may give a more comfortable feel in use but often lack the reach desired for use in the trachea, esophagus or larger body cavities. An excessively long scope is more prone to bending or breaking.

- ***Angle of View:*** The final consideration when selecting an endoscope for avian diagnostics is the angle of view of the distal lens element. A 0° lens offset affords straight ahead viewing with a natural orientation. A 30° offset angles the field of view obliquely in the direction of the offset (Figure 13.5). This allows for improved viewing in confined areas, especially when the telescope is rotated. The bevelled distal lens element necessary to achieve this viewing angle enables easier and less traumatic passage through air sac and peritoneal walls. For these reasons endoscopes with a 30° offset are recommended for general diagnostic purposes. Specialized telescopes (eg, 70°, 90°, 130° angles) are not useful for general avian applications.

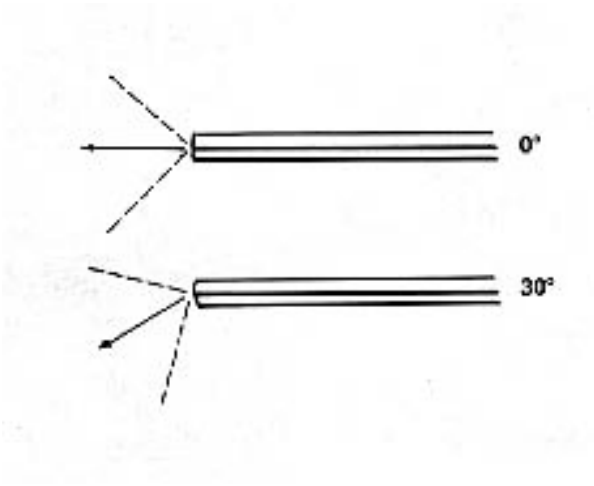

FIG 13.5 Endoscope lens with a 30° offset allows for improved vision in confined spaces.

In the late l970's, a laparoscopic technique was devised using a veterinary otoscope as the optical device.[12] Although this instrument had the advantage of relatively low cost, it soon became clear that it could not be compared to a rod-lens endoscope in either optical quality or size of the incision necessary

TABLE 13.1 Instrumentation for Avian Endoscopy

A. Diagnostic Examination
- 2.7 mm 30° view endoscope
- Glass fiber light cable
- Diagnostic light source (150 W)

B. Minimum Diagnostic Working Set for Examination and Biopsy
- Elements listed in "A" as well as:
- Diagnostic sheath for 2.7 mm endoscope incorporating a single 5 Fr instrument channel
- 5 Fr double spoon flexible biospy forceps (oval jaws)
- 5 Fr flexible grasping forceps

C. Expanded Capabilities
- Elements listed in"A" and "B" as well as:
- Diagnostic sheath incoporating a single 7 Fr instrument channel (for larger birds)
- 7 Fr double spoon flexible biopsy forceps (oval jaws)
- 5 Fr double spoon flexible biopsy forceps (round jaws)
- 3 Fr flexible grasping forceps
- 150 W Xenon high intensity light source
- Endovideo camera

D. Other Optics
- 1.9 mm endoscope, many different lengths are available
- 2.2 mm endoscope
- 4.0 mm endoscope, 0° to 30° viewing, excellent for photodocumentation or use in larger birds

to perform laparoscopy. In the l980's a tubular endoscope that attached to a handle-mount battery pack was introduced to the veterinary market as a less-expensive alternative to rod-lens endoscopes.[b] While this device had the advantages of lower cost, a focusing ocular and a length similar to a rod-lens endoscope, it had the disadvantages of poorer resolution, reduced light transmission and a limited field of view. The cost of a rod-lens endoscope system may be up to five times greater than less expensive instruments; however, the high optical quality, light transmission and field of view provide better long-term value when considered over the life of the endoscope. Before purchasing any endoscopic system the veterinarian is well advised to become familiar with the optical qualities of all systems under consideration. An endoscope must allow the clinician to examine tissues with accuracy and to recognize pathology or it is of no value. High quality optical systems are required to enable the clinician to achieve reliable, reproducible results. With appropriate care, modern rigid endoscopes should have a working life of five to ten years.

Veterinarians who see so few cases that they cannot justify the purchase of the appropriate equipment should refer endoscopy services to more experienced practitioners. Over the past decade, rod-lens endoscopes have become the standard for use in avian endoscopy.[2,8,21,23,27] The interests of clients and patients are best served by the use of quality optical equipment.

Flexible Endoscopes

Conventional flexible endoscopes are based entirely on fiberoptic systems for both illumination and imaging. Unlike modern rigid endoscopes, which employ solid rod-lenses, flexible endoscopes use many coherent, flexible, glass fiber bundles to transmit the image.[10] Rigid telescopes, particularly those with a small diameter, offer far better image resolution, illumination and quality than is technically possible to achieve with a flexible system. However, flexible endoscopes do provide a controllable distal tip, which allows manipulation that is not possible with a rigid rod-lens endoscope. They are most useful in examining tubular organs that are sinuous or folded. A l0 mm flexible colonoscope was found to be effective in removing lead shot from the proventriculus of Trumpeter Swans.[3] Fine-diameter, flexible endoscopes may have limited usefulness in smaller birds (eg, less than 800 g body weight) when compared to newer rigid systems.

The major disadvantage of a small-sized, flexible endoscope is that one cannot control the tip direction unless the instrument is located in a confined area such as the gastrointestinal tract. In an open area (such as the air sac), the scope cannot be manipulated or used to penetrate beyond the air sac walls without a probe. A specialty avian practice may have a small diameter flexible endoscope available to perform indicated procedures. Large flexible scopes with an operating channel for placement of grasping and biopsy instrumentation can be used in ratites.

Instrument Care

Flexible and rigid endoscopes are expensive, precision, optical instruments that will give excellent long-term performance if properly maintained. Rigid telescopes, especially those of small diameter, are fragile and must be carefully handled during transport and cleaning to avoid damage to the rod-lens elements. Torsional stresses upon the long axis of the endoscope must be avoided. This is most important when a fine-diameter telescope is being used without a protective sheath, as is frequently the case for diagnostic purposes. It is particularly important that the operator be sensitive to the amount of force being applied to the telescope during a procedure. Rigid endoscopes should always be picked up by the ocular (eyepiece) rather than the distal tip. One should lay the instrument flat to avoid bending the optical tip and fracturing the optic bundles. It is wise to clean the instrument immediately after a procedure is finished. A nonabrasive cleanser may be used to remove fat and debris. In many cases, simply washing the telescope in distilled water is all that is needed. A quality lens paper is used to clean the lens surfaces. An alcohol flush chemically dries the endoscope before it is placed in a padded storage container that

CLINICAL APPLICATIONS

- Rigid endoscopes should always be picked up by the ocular (eyepiece) rather than the distal tip.
- For office or field sterilization, sensitive endoscopic equipment may be soaked in a two percent solution of glutaraldehyde (of a type approved by the manufacturer of the equipment).
- Moderate to marked obesity leading to the intra-abdominal deposition of fat is the most frequent cause of difficulty in endoscopic visualization.
- Familiarity with anatomy, use of gentle tissue handling techniques and careful movements of the endoscope will reduce the risk of iatrogenic trauma.

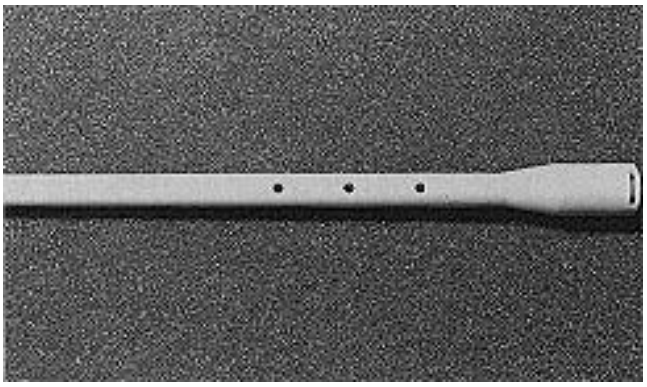

FIG 13.6 A sleeve should be placed over the endoscope for protection during movement or sterilization.

meets the manufacturer's recommendations. A simple but effective plastic endoscope sleeve is available to cover the shaft of the telescope for protection during transport and disinfection procedures (Figure 13.6).

Flexible endoscopes should also be handled with care. They should not be coiled tightly or have objects of any weight placed on the shaft, or the glass fiber bundles will be damaged. Instrument channels should be flushed thoroughly with warm soapy water to remove debris after use. Most manufacturers recommend that flexible endoscopes be stored suspended from the ocular end with the flexible shaft allowed to hang vertically. Detailed instructions for endoscope care are provided by most manufacturers. Technical staff should be properly trained in the handling and cleaning of these sensitive instruments before receiving the responsibility for their care.

Sterilization

Most endoscopic procedures require properly sterilized equipment. Even in the examination of noncritical areas such as the oral cavity or ear canal, it is prudent to remember that many animals (particularly carnivores) may harbor pathogenic organisms that can be physically transferred to another patient (particularly birds) if instrumentation is not disinfected between examinations. Due to the sensitivity of the rod-lens systems, sterilization by autoclaving is seldom recommended by the manufacturer. Expansion and contraction caused by the marked temperature extremes of steam autoclaving will damage or severely shorten the life of most telescopes. Some types of recently produced rigid endoscopes are steam autoclavable, although this process may also decrease their working life.

Two options provide safe yet consistently reliable sterilization for sensitive telescopes and light cables. Ethylene oxide gas is an extremely effective sterilant, but exposed materials must be aerated for a minimum of eight to twelve hours before use. Ethylene oxide is a human health hazard and must be used under carefully controlled conditions.

The most practical and safe alternative for the avian practitioner for office or field sterilization of sensitive endoscopic equipment is soaking in a two percent solution of glutaraldehyde (of a type approved by the manufacturer of your equipment).[c] The solution must be used according to the supplier's directions for soaking telescopes, hand instruments and light cables. The practitioner should be aware of the activated life of the product (usually 14 to 28 days) and change solutions accordingly. Stacking or layering instruments in the soak tray should be avoided so that the solution can properly reach all surfaces. Circulating the solution using a syringe is useful to ensure that all surfaces have been contacted. Minimum recommended soaking times in properly prepared glutaraldehyde solutions typically range from 15 to 20 minutes. Although greater germicidal effect is achieved the longer the equipment is soaked, many manufacturers caution against soaking for longer than two hours, as damage to glass fibers may occur.

After the soaking cycle has been completed, the equipment must be thoroughly rinsed in sterile water to prevent tissue-damaging glutaraldehyde from contacting the patient. Glutaraldehyde is extremely irritating to most tissues and may cause local irritation, tissue death, delayed healing and peritoneal reaction. Rinsing the equipment in a sterile container of sterile water for three to five minutes is most effective. The instruments are drained, immersed in a second container of sterile water for three to five minutes and wiped dry. A final alcohol wash may be used to chemically dry the equipment.

Other types of disinfectant solutions such as quaternary ammonium compounds, chlorhexidine and povidone iodine are not acceptable alternatives to two per cent glutaraldehyde solutions for soaking endoscopic equipment. With the number of resistant viruses and bacteria seen in many avian species, it is important for the endoscopist to ensure that only effective, approved products are used, or the result may be the unnecessary spread of disease.

Clinical Applications of Endoscopy

Pre-endoscopy Considerations

Indications

Endoscopic examination is indicated whenever the visual inspection of an organ or site may yield additional diagnostic information. Diagnostic endoscopy is usually preceded by less-invasive examinations such as a complete blood count, biochemistries or radiology. The patient's history, findings of the physical examination and the results of laboratory and radiologic studies may not be conclusive or may suggest endoscopic followup for additional diagnostic information (Table 13.2).

TABLE 13.2 Common Indications for Endoscopic Examination

- Loss or change in character of voice
- Acute or chronic dyspnea
- Acute or chronic sneezing
- Ingluvitis, crop burns or trauma
- Abnormal radiographic findings (plain or contrast); eg, lung, gastrointestinal tract, air sacs, organomegaly, granuloma
- Abnormal biochemical studies; eg, kidney (uricemia) or liver (elevated bile acids or liver enzyme activities)
- Persistent leukocytosis (nonresponsive to treatment)
- Acute or chronic systemic disease
- Reproductive system (suspected infertility)
- Polyuria, polydipsia
- Follow-up examination to check on lesion resolution ("second look")

- ***Diagnostic Uses:*** The endoscope and its light cable may be used to aid the physical examination.[8] The light cable may be used singly to offer additional illumination, to transilluminate a structure such as the trachea, sinus or crop, to augment examination of the oral cavity or for back lighting of overexposed radiographs. Fine-diameter endoscopes can be used in a variety of external sites where the properties of magnification, illumination and small optic diameter enhance diagnostic visualization. Many structures of the eye, ear canal, nares, oral cavity and upper respiratory tract may be examined without anesthesia. More thorough, noninvasive examinations of other body orifices are best completed under general anesthesia. The high quality optics of modern endoscopes allow visualization and inspection of tissues under magnification and are particularly useful in confined areas. Fine-diameter endoscopes introduced through a small incision, often referred to as laparoscopy,[2] permit excellent visualization of the coelomic cavities and air sacs, while creating minimal trauma.

Endoscopy has been compared to performing a necropsy on a live bird.[21] The endoscopist must become familiar with the normal and pathologic appearance of the tissues to be examined. Lesions should be described accurately regarding the location, color, size, shape and consistency. Photo or video documentation can be a tremendous aid in this process. In one study, the ability to review video recordings of examinations was believed to be an essential tool in understanding certain anatomic relationships in juvenile macaws.[29]

Improved instrumentation enhances the routine collection of specimens of suspect or abnormal-appearing tissue and debris for histologic, cytologic and microbiologic examination. Previous techniques for biopsy and specimen collection have relied on the manipulation of secondary instrumentation (eg, rigid biopsy forceps or cannulas for micro-swabs) separate from but in coordination with the endoscope. These techniques are awkward and can lead to iatrogenic trauma.[18,19,20] A new diagnostic endoscopy system for birds has recently been developed that greatly simplifies sample collection.[11,31] The system incorporates a 2.7 mm, 30° view endoscope with a single instrument port in a special sheath (Figure 13.7). Various flexible instruments may be introduced into the sheath, passed alongside the endoscope and guided to a specific site with great ease (Figure 13.8). Iatrogenic tissue trauma is markedly reduced because the instruments are directed to the visual field through the integral sheath, avoiding the blind manipulation required to place a second, rigid instrument.

- ***Surgery:*** Harrison[8] first suggested the use of the endoscope as an operating telescope in open avian surgery to enhance visualization of small structures.

Endoscopic surgery is currently one of the fastest growing areas in the human surgical specialties. Special hand instruments have been developed to enable tissue manipulation, suture and clip placement and radiosurgical techniques using the endoscope. The advantage of this type of surgery in humans has decreased patient trauma and hospitalization. The technology offers great promise if it can be adapted for avian surgery. In addition to decreased trauma, the magnification and illumination provided by a quality endoscopic system enable more precise techniques in small avian patients. Surgical procedures

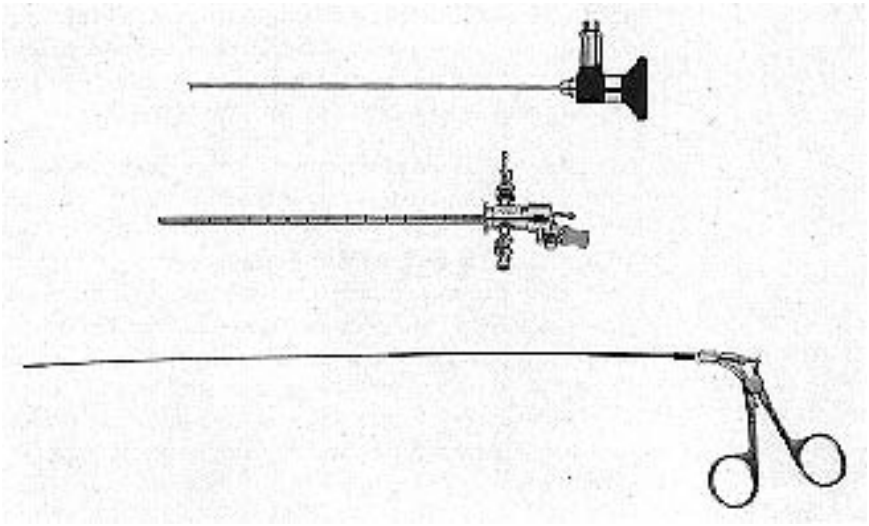

FIG 13.7 A specialized 2.7 mm endoscope that fits into a sleeve is ideal for most avian endoscopic procedures. The sleeve has been designed to accomodate the introduction of biopsy forceps and other flexible instruments to facilitate the collection of diagnostic samples (courtesy of Karl Storz Veterinary Endoscopy–America).

are under development for endoscope-guided hysterectomy, ulcer repair and egg removal.

- ***Identification of Gender of Monomorphic Birds:*** The use of endoscopy to identify the gender of monomorphic birds was the earliest widespread application of this technology in avian medicine; it has been the major force supporting the development and introduction of improved diagnostic capabilities utilizing endoscopy.

Contraindications

The general contraindications for endoscopy are those that would apply to general avian surgery and anesthesia. Moderate-to-marked obesity leading to the intra-abdominal deposition of fat is the most frequent cause of difficulty in endoscopic visualization. Large peritoneal fat reserves may make the examination of parts of the coelom impossible. In some cases, an improved diet is recommended for the patient (with reexamination in six to eight weeks).

The presence of ascites may cause difficulties if the peritoneum of the ventral hepatic peritoneal cavity (VHPC) or intestinal peritoneal cavity (IPC) is breached while entering the air sac. Fluid could drain from the peritoneal cavity into the air sac and from there into the lung, leading to aspiration and death. This is most likely to happen in a lateral approach to the caudal thoracic air sac. If ascites is suspected and an endoscopic examination of the liver is necessary, the ventral approach to the VHPC should be used. Fluid from the VHPC will drain from the incision site and can be safely suctioned without the concern for air sac involvement.

Left coelomic examinations should not be performed in the hen near the time of ovulation, as the ova greatly enlarges in size, virtually obliterating the abdominal air sac. The oviduct also increases in size and tortuosity, filling the left portion of the IPC. Use of the post-pubic approach to the abdominal air sac risks damage to the oviduct or an egg nearing oviposition. A left lateral coelomic approach is rendered less useful by the presence of large, developing ova that makes visualization difficult. Attempting passage into the abdominal air sac from the caudal thoracic air sac may be difficult and potentially risks damage to the ova.

Inexperience of the operator remains one of the most common causes of endoscopic complications.[8,21] Veterinarians considering the addition of endoscopic services to their avian practice are well advised to seek out appropriate continuing education and to become thoroughly familiar with normal avian anatomy. Experienced colleagues may be contacted for advice on practical equipment needs before purchasing new equipment. Necropsy specimens can be used to study endoscopic principles and are particularly useful in learning to identify tissue changes. Lectures and laboratories are available on endoscopic techniques.

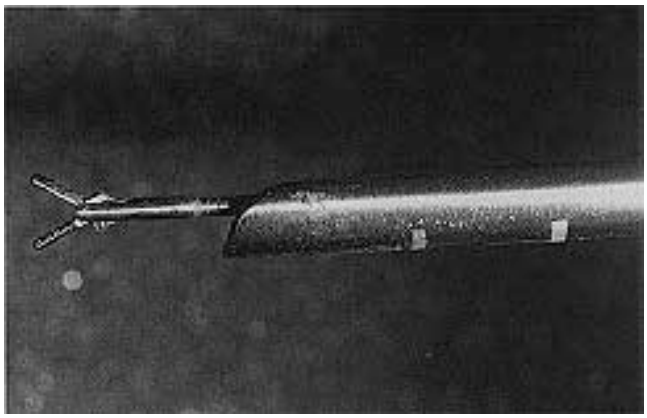

FIG 13.8 Biopsy forceps passing through a specially designed sheath for a 2.7 mm endoscope (courtesy of Karl Storz Veterinary Endoscopy–America).

Complications

As part of the informed consent process, the client must be made aware of potential complications of the endoscopic process. Anesthesia-related incidents are described in Chapter 39. Organ trauma is one of the most serious intraoperative endoscopic complications. The proventriculus may be punctured using a trocar and cannula or similar entry device from a lateral approach. Failure to identify and repair this injury can result in a fatal peritonitis. Laceration of a blood vessel or organ such as the liver or spleen is possible and may lead to serious or fatal hemorrhage. Liver or kidney contusions can be caused by the endoscope tip during excessively vigorous manipulation. These are infrequently the cause of serious clinical problems.

Familiarity with anatomy, use of gentle tissue handling techniques and careful movements of the endoscope will reduce the risk of iatrogenic trauma.

Subcutaneous emphysema is a potential (if rare) postoperative complication. Air may leak through the body wall at the point of the air sac entry and collect under the skin. Usually, the body wall opening will seal without incident, but occasionally the skin incision must be reopened and the body wall puncture sutured. This is most common when a large endoscope or sheath has been used. Endoscopic punctures may be routinely closed with a fine-diameter, absorbable, monofilament suture.

Air sac and peritoneal granulomas can occur by using instrumentation that has been improperly sterilized or in situations where poor technique or inadequate skin preparation has allowed contamination of the endoscope tip. The peritoneum of most birds seems to be quite forgiving of small insults. Many granulomas may not be appreciated clinically. The author and editors have never experienced a case of generalized sepsis related to endoscopic manipulation, although this may be possible in cases where the wall of an existing granuloma is damaged or where ineffective sterilization practices have been used. Cold disinfectant solutions such as chlorhexidine[2] are not appropriate, as some organisms such as *Pseudomonas aeruginosa* will survive this treatment. No comprehensive studies have examined the endoscopy and biopsy sites days to weeks following the procedure. However, preliminary work indicates that there was no local infection in patients where a two percent glutaraldehyde solution was used for instrument preparation and appropriate sterile technique was employed. The inability to perform proper sterilization of a single endoscope makes surgical sexing clinics obsolete. Transmission of viral infections (particularly Pacheco's disease virus and polyomavirus), resulting in the loss of numerous birds has been linked to "sexing clinics." The mixing of birds from multiple sources (particularly when an invasive procedure is performed) should be discouraged. It is possible, however, to safely perform endoscopy on several birds from a single client by utilizing two endoscopes, with one being sterilized while the other is in use.

Patient Preparation

Patients should be fasted a minimum of three hours. In some cases the length of the fast is extended, especially if the endoscopic examination will involve the gastrointestinal tract. Species that consume large boluses of whole foods (eg, raptors) may require fasting for 24 to 36 hours. Failure to do this may make examination of many portions of the coelom impossible due to distension of the proventriculus.

Surgical sites are prepared as for any avian surgery. Particular attention should be paid to the skin surface. The endoscope can transmit surface debris into the body cavity if the entry site is not properly prepared. Small, sterile, transparent, wound dressings[d] make excellent drapes for endoscopic procedures. They are available in a variety of sizes and are lightly adhesive so they stay in place without clamps; their transparency improves anesthetic monitoring in small patients.

- ***Anesthesia:*** Appropriate anesthesia is an essential part of good endoscopic practice. It is seldom possible to perform an endoscopic examination in the physically restrained bird without the risk of organ contusion or other trauma. Consistency in positioning of the patient is mandatory for anatomic orientation. Maintaining position is neither possible nor humane using physical restraint only. Clinical anesthesia has been thoroughly reviewed in Chapter 39. The anesthetic agent of choice for most endoscopic procedures remains isoflurane.[e]

Sites of Application

Air Sacs, Lungs

Birds are excellent subjects for endoscopic examination because the unique system of air sacs allows visualization of coelomic structures without artificial insufflation. Air sacs invaginate the thoracoabdomen of birds to facilitate examination of or access to specific organs. There are marked similarities in the

morphology of caudal air sacs among selected Passeriformes, Psittaciformes, Columbiformes, Gruiformes, Strigiformes and Falconiformes. In chickens, there are three paired air sacs (cranial thoracic, caudal thoracic, abdominal) and two single, median air sacs (cervical, clavicular).[17]

There is one published examination of air sac morphology in a psittacine bird (budgerigar).[4] The budgerigar has paired, unfused cervical air sacs but was otherwise similar to the chicken. The caudal thoracic air sacs of the pigeon extend farther caudally than in most Psittaciformes. In some diving birds, the caudal thoracic air sacs are much larger than in other species. This is assumed to be an adaption to increased air requirements while diving underwater.

For endoscopic purposes, it is preferable to consider the cranial and caudal thoracic and the abdominal air sac pairs together. In the parrot, the cranial thoracic air sacs are the smallest of the group and are located ventral and cranial to the caudal thoracic air sacs (Color 13.1). They are best accessed from the ventrolateral thoracic wall using the approach first described by Bush,[2] who suggested an entry site caudal to the last sternal rib in the area of the lateral notch (a "V"-shaped depression palpable between the sternum and the last rib).

The patient is placed in lateral recumbency with the wings extended dorsally. The wings may be taped to a restraint surface or they may be affixed with a short loop of non-adhesive, self-adhering tape[f] passed between the primary feathers and around the carpus. The landmarks are located and a small skin incision is made. The musculature of the body wall is bluntly separated and the endoscope is inserted in a craniodorsal direction. From this approach the pericardial sac and heart can be seen as well as the lobe of the liver and the caudal, ventromedial surface of the lung (Color 13.23).

The traditional left lateral surgical approach takes advantage of the air sac anatomy to approach the gonads by either directly entering the abdominal air sac or by entering the caudal thoracic air sac first and then passing into the abdominal air sac through a small incision (see Figure 13.2). This approach is similar to the early laparotomy techniques of field ornithologists.[1,26]

The patient is placed in true lateral recumbency with the wings extended dorsally. The upper leg is extended and held caudally. The point of insertion is located by palpating the triangle cranial to the muscle mass of the femur, ventral to the synsacrum and caudal to the last rib.[8,19,23] The body wall may be penetrated by a trocar and cannula or by blunt separation. In Psittaciformes, this entry site has been demonstrated to occur between the seventh and eighth ribs (not the behind the last rib). With this approach, the tip of the endoscope enters the mid to caudal portion of the caudal thoracic air sac in most birds.

As an alternative approach to the caudal thoracic air sac, the bird is restrained in lateral recumbency except that the leg is extended cranially.[15] The site of entry is the same as previously described in the upper part of the triangle formed by the proximal femur, the last rib and the cranial edge of the pubis.

A similar approach to the caudal thoracic air sacs that is based upon precise landmarks has been developed (see Figure 13.3).[29,30,31] The animal is positioned as described. The entry site is located by finding the point where the semimembranosus muscle (M. flexor cruris medialis) crosses the last rib (Color 13.2). The ventral fascia of the semimembranosus muscle is bluntly separated from the underlying body wall and the muscle is reflected dorsally. A blunt entry is made just caudal to the last rib, beneath the reflected semimembranosus muscle. Except in individuals with moderately to markedly increased fat reserves, the landmarks are located easily. The procedure is reproducible in members from a wide variety of orders including Psittaciformes, Passeriformes, Columbiformes, Gruiformes, Falconiformes and Strigiformes. A major advantage in placing the leg forward is that the lateral body wall can be more easily approached without the interference of the femoral musculature. This becomes particularly important in birds with heavily muscled upper thighs (eg, many Psittaciformes).

With either of these approaches the endoscope enters the caudal thoracic air sac at or near its caudal border. Color 13.4 was photographed from the left entry point of this caudal approach looking cranially. Visible from eleven to one o'clock is the caudal surface of the lung with its large ostium. From the two to three o'clock position is the transparent membrane formed by the confluent walls of the caudal thoracic air sac and the abdominal air sac. Passing through this wall would place the endoscope within the abdominal air sac. At four to six o'clock is the ventrolateral border of the proventriculus. The lateral edge of the left lobe of the liver may be seen at the seven to eight o'clock position. From nine to ten o'clock is

another transparent membrane. This one is composed of the walls of the confluent caudal thoracic air sac and cranial thoracic air sacs. Passing through this membrane would place the tip of the endoscope in the cranial thoracic air sac.

The abdominal air sacs of most birds are the largest air sacs. They extend from the caudal surface of the lung to the craniolateral borders of the cloaca. Entry into the abdominal air sacs may be gained through one of the previously described caudal thoracic air sac approaches or by direct access through the caudal body wall. Lumeij[21] was the first to describe a postpubic approach to the caudal portion of the abdominal air sac. The entry point is situated dorsal to the pubic bone and caudal to the ischium (see Figure 13.2). The endoscope generally first enters the most caudal portion of the intestinal peritoneal cavity and must be penetrated through this thin membrane to enter the abdominal air sac. The endoscope can then be moved cranially up the length of the abdominal air sac. From the left approach a large number of structures may be examined including the kidney, adrenal, gonad and associated structures, spleen, proventriculus, ventriculus and intestine (Color 13.26). The abdominal air sac may also be approached from a flank position. The entry site is located directly ventral to the acetabulum and just dorsal to the ventral border of the flexor cruris medialis muscle.

Reproductive Organs

In most avian species, only the left ovary and oviduct develop.[14,16] The development of the right ovary is normally arrested in a testis-like stage and can frequently be visualized near the right adrenal gland, along the caudal vena cava (Color 13.8). For this reason, endoscopy to examine gonadal structures is performed through the left side of the abdomen.

The testicle of the adult male bird is ellipsoidal to bean-shaped. In most species it is creamy white although it may be more or less pigmented (gray to black) in others (eg, cockatoos, mynahs, toucans) (Color 13.7). Under the seasonal influence of hormones, the mass of the testicle may increase from 10 up to 500 times.[14] The pattern of surface vessels increases and becomes more prominent. The epididymis enlarges, and the ductus deferens becomes very tortuous in preparation for storage and transportation of the spermatozoa (Color 13.16).

In contrast, the ovary of the mature female has the appearance of tapioca pudding with many small follicles visible during the nonbreeding season. Under appropriate hormonal stimulation, a hierarchy of follicles develops and matures giving the ovary the appearance of a cluster of grapes (Color 13.15). A follicle enlarges as it matures; simultaneously, the oviduct increases in size and becomes tortuous and folded in preparation to accept the ovum. A large ovum can be mistaken for a testicle, especially in an obese bird where other structures are difficult to see or where the surgeon fails to check related anatomic reference points.

The differences in the morphology of adult gonads are relatively distinct. In juvenile birds, gonadal tissue is less obvious and differentiation is more difficult. It is possible to endoscopically identify the correct gender of most species of birds at a young age if good optical equipment is used and a careful examination of the gonads and associated structures is performed.

In one study of juvenile macaws,[29] differentiation of the sexes was uniformly possible as young as six weeks of age when gonadal and oviductal or ductus deferens morphology were considered together. Testicles were tubular to ellipsoidal with distinct, rounded cranial and caudal poles. A paired right testicle could usually be seen through the dorsal mesentery (Color 13.10). The ductus deferens was a thin, white tubular structure, usually only one-third the diameter of the ureter (Color 13.17).

The juvenile ovary was comma-shaped, dorsoventrally flattened and closely applied to the adrenal and cranial pole of the kidney. The surface texture of the ovary was dependent on the age of the bird. Very young ovaries had a faintly granular surface with fine sulci (Color 13.13). As the birds aged, the sulci deepened, giving the ovary a furrowed, brain-like appearance (Color 13.12). With the maturation of the primary oocytes, the ovary began to take on a distinctly granular texture with a more three-dimensional shape, and the sulci disappeared (Color 13.14). The oviduct was pale white with a thicker, more substantial appearance than the vas deferens. The oviduct was generally two to four times the thickness of the ureter and on close inspection, fine, longitudinal, spiral bands were visible (Color 13.19). These may have represented the developing spiral folds of the mature oviductal mucosa. The most interesting finding of this study was the presence of the supporting ligament of the infundibulum, which was clearly visible crossing the cranial division of the kidney. This structure is part of the dorsal ligament of the oviduct and is absent in juvenile males (Color 13.11).

From this approach, it may be difficult or impossible to view the right side in mature birds. Examination of the right abdominal air sac (AAS) would be required to confirm the presence of abnormalities related to the remnant ovary or the right testicle such as ovotestes or hermaphrodism. While these conditions are uncommon, their presence may need to be ruled out in cases of infertility.

Caution should be exercised in estimating age, reproductive history or reproductive potential based upon a single endoscopic examination. During the nonbreeding times of the year, the adult gonads return to a quiescent state similar to those of the late adolescent bird. Several male Hyacinth Macaws in their teens had very small testicles, yet went on to breed within months of evaluation. A mature African Grey Parrot showed no evidence of follicular development at examination but ovulated 24 days later.

During the endoscopic examination for gender determination, the endoscopist is able to evaluate the air sacs, liver, lung, spleen, kidney, adrenal gland, proventriculus, ventriculus and the visual portions of the intestines. A systematic examination that may suggest a subclinical health problem can provide data of value to the aviculturist. This information is not available using cytogenetic or molecular biological techniques of gender determination.

Ear Canal

The external auditory meatus is hidden by specialized covert feathers that lack barbules. There is no pinna. The opening is usually rounded but can vary in diameter from small (2.0 to 15.0 mm in passerine and psittacine birds) to very large (up to 6.0 cm in owls). The ear canal is straight and short. The tympanum can usually be visualized clearly (Color 13.41). A 1.9 mm telescope is often needed to explore the deeper aspects of the canal. Unlike the dog and cat, birds infrequently suffer from otitis externa.

Oropharynx

The oral cavity is easily approached in most avian species. The bill may be held open manually or with a speculum. In species with strong mandibular musculature (such as Psittaciformes) it is recommended that the patient be anesthetized for most oral examinations. If manual restraint is used, extra care must be taken to prevent damage to the equipment.

The avian tongue may exhibit a number of adaptations for food prehension and manipulation. In many species it is a flat, triangular-shaped organ with a relatively smooth epithelium. Psittaciformes have large, fleshy tongues ideally suited to food manipulation. They are the only order with intrinsic lingual muscles[17] that allow a great variety of movement and flexibility. In many species, including parrots (Color 13.34), there are a group of mucus-secreting salivary glands at the base of the tongue. Inspissation of keratinized debris due to squamous metaplasia will be seen in birds suffering from hypovitaminosis A (Color 13.33).

Salivary glands are most prominent in species that eat primarily a dry diet (cereal grains) and may be absent in those that eat a moist, lubricated diet (fish). In the parrot, salivary glands are found along the roof and the floor of the mouth and on the tongue. The oropharynx is lined with stratified squamous epithelium and may be keratinized in areas of wear. In some species, the epithelium may be heavily pigmented. It normally has a smooth, unblemished surface except in areas where spike-like sensory papillae are present (Color 13.34). The mucosa should be examined for adherent exudate, debris or ulcers, as may be seen in certain protozoal (eg, *Trichomonas* sp.), fungal (eg, *Candida albicans*) or viral (eg, poxvirus) diseases.

The choanal slit is visible as a median "V"-shaped cleft in the palate. There is species variation in the width of the choanal borders. In pigeons and most raptors, the choana is slit-shaped (Color 13.35). In the parrot the borders are more widely spaced, forming a distinctive "V" shape. The borders of the choanal slit are lined with sensory papillae. By entering the choanal slit with the scope and moving craniodorsally, the nasal septum and conchae can be examined (Color 13.37). Just caudal to and on the midline of the choana is the small slit-like infundibular cleft. This is the common opening of the right and left pharyngotympanic tubes[17] also referred to as the eustachian tubes (Color 13.35).

The laryngeal mound is visualized at the base of the tongue on the midline of the caudal floor of the oropharynx. The paired, fleshy laryngeal prominences open and close to form the conspicuous glottis. There is no epiglottis (Color 13.31).

Trachea

The trachea may be entered at the larynx by passing through the glottis of an anesthetized patient. The avian larynx does not contain vocal cords. Tracheal rings of the bird are usually calcified and are completely circular. The tracheal mucosa consists of

smooth, stratified squamous epithelium. The syrinx is the site of sound production and is located where the trachea bifurcates into the primary bronchi. The syringeal membrane may be the site of opportunistic bacterial and fungal infection (aspergillosis).[25] Tracheoscopy to the level of the syrinx is possible in medium-to-large birds using a 180 mm long, 2.7 mm endoscope. Smaller patients (larger than cockatiels) may be examined with a l.9 mm endoscope. Visualization can be improved by extending the neck. In patients with acute to subacute dyspnea, tracheoscopy should be considered to rule out foreign objects or inflammatory debris.

In seed-eating birds, hulls or whole seeds may be aspirated into the larynx or syrinx. In carnivorous birds, small pieces of bone, tendon or cartilage may become lodged in the glottis. These may be removed using endoscopically guided grasping forceps. Tracheitis may be caused by bacterial or viral agents. Culture of the endoscope tip immediately after removal from the patient may be helpful in determining an etiologic agent.

Esophagus and Ingluvies

The esophagus is easily entered by passing the endoscope caudally into the pharynx and over the laryngeal mound. The surface of the esophagus is comprised of longitudinal folds that vary depending upon the dietary habits of the species (see Color 19). For example, the number and size of folds and the degree of distensibility are less in insectivores and seed eaters than in carnivores like hawks and owls (Color 13.38).

It is a common misconception that all birds have an ingluvies. Galliformes, Psittaciformes, Columbiformes and some Passeriformes have a true crop. The ingluvies can be examined with either a flexible or rigid endoscope after passing the instrument through the cervical portion of the esophagus. Insufflating the crop with air will help with visualization. To do this, a small-diameter, flexible feeding tube,[g] which has been attached to a 35 or 60 cc syringe, can be passed into the crop (Color 13.39). Alternately, the insufflation channel on a 4 mm or greater diameter flexible endoscope, or the instrument channel on the Storz rigid avian sheath[a] can be used to distend the ingluvies with air. Some pressure will need to be maintained around the proximal cervical esophagus to retain the infused air within the crop. Patients undergoing elective ingluvioscopy should be fasted for several hours before the procedure to reduce the effects of retained food materials upon visualization. With this technique the crop mucosa can be thoroughly examined and small foreign objects can be removed with grasping forceps. The grasping forceps can be endoscopically guided using either a flexible endoscope with an instrument channel or the rigid sheath with channel.

Proventriculus, Ventriculus

The proventriculus and the ventriculus may be examined using either flexible or rigid equipment. In a 250 to 600 g parrot it can be a difficult chore to guide a small-diameter, flexible endoscope down the cervical esophagus, across the crop and into the thoracic esophagus, although this equipment can be used successfully in larger parrots and in moderately large avian species that lack a crop (eg, owls and Anseriformes). A pediatric bronchoscope is required in smaller patients. The smallest practical flexible endoscopes with an instrument channel are pediatric bronchoscopes at 4.0 mm and 5.0 mm diameter. Human flexible colonoscopes (10.0 mm) have been shown to be useful in very large species such as swans and cranes.[3] Once the endoscope is positioned in the thoracic esophagus, the pathway becomes a relatively straight one continuing into the proventriculus (Color 13.40) and the ventriculus.

Preliminary studies using a midline ingluviotomy to enter the thoracic esophagus using the Storz 2.7 mm rigid endoscope and instrumented sheath have been performed.[a] Birds were anesthetized, intubated and placed in dorsal recumbency.

Care was taken to avoid the passage of proventricular contents into the trachea or choana by inserting an absorptive gauze tampon into the cranial cervical esophagus and ensuring that the endotracheal tube was secure. Whenever possible, patients were fasted for five to six hours in order to empty the proventriculus. In cases where fasting was not possible (eg, acute foreign body ingestion), the proventriculus was flushed with sterile saline and ingesta was forced out of the thoracic esophagus and into the crop, from which it was suctioned. Placing the patient with its head down facilitated this procedure. A small skin incision was made over the middorsal portion of the crop. The crop wall was incised. The entrance to the thoracic esophagus was located on the ventral midline border of the crop, and the telescope and sheath were introduced.

The sheath and endoscope were inserted into the thoracic esophagus. A 3-5 Fr rubber catheter connected to a syringe containing saline was inserted

into the instrument channel for use in flushing debris from the visual field. Grasping forceps (3 Fr or 5 Fr) can be inserted into the channel to manipulate and remove foreign objects. The crop incision was closed using standard techniques.

Ventral Hepatic Peritoneal Cavities

The liver of the bird is encapsulated within two paired peritoneal cavities: the ventral and dorsal hepatic peritoneal cavities. The paired ventral hepatic peritoneal cavities (VHPC) are the largest and of greatest clinical significance. The right and left VHPC are separated by the ventral mesentery. The right lobe of the liver is larger in most birds (Colors 13.22, 13.28).

To gain access to the liver, one or both of these ventral cavities must be entered. The liver can be visualized from the cranial and caudal thoracic air sacs (Colors 13.5, 13.24) and indeed seems tantalizingly close in most birds. In reality, the liver is covered by a layer of peritoneum that is contiguous with the overlying air sac. To access the liver, the ventral hepatic peritoneal cavity (VHPC) must be entered either laterally from the caudal thoracic air sac or by a direct, ventral midline approach. The ventral approach[16] is best for examining and sampling both lobes of the liver. A skin incision is made on the midline just caudal to the border of the sternum. The linea alba is incised and the caudal border of the VHPC is bluntly penetrated. A substantial fat pad may be present overlying the outer surface of the caudal border of the VHPC. Under conditions of health, the liver should not protrude past the caudal border of the sternum.

The VHPC may also be entered from the caudal thoracic air sac. This may be most convenient when a lateral approach has been used for a general diagnostic examination and liver lesions have been noted. An opening can be made in the confluent walls of the caudal thoracic air sac and the VHPC by using endoscopically guided forceps to pick up and tear a small hole in the membranes. The lateral border of the liver can then be grasped through this VHPC access (Colors 13.29, 13.42). This approach is contraindicated in patients with ascites because fluid will drain into the air sac and may be aspirated (Color 13.30).

Intercostal Approach to Lungs

An intercostal approach to the lung for biopsy has been recently described in the pigeon.[11] Entry was recommended through the dorsolateral portion of the third or fourth intercostal space where pulmonary tissue is the thickest in cross section. The third intercostal space is located by counting cranially from the last rib. The space is palpated just ventral to the scapula and a small skin incision is made. The intercostal muscles are bluntly separated to the level of the pleura. Care must be taken during dissection through the intercostal muscle to avoid deep penetration, which can traumatize the surface of the lung. The resulting hemorrhage may make visualization difficult and lead to sample artifact.

An instrumented sheath and rigid endoscope are inserted into the incision and maneuvered carefully between the ribs so that the surface of the lung can be visualized. The rounded edges of the sheath aid in atraumatically positioning the instrument. A 5 Fr flexible forceps is advanced into the lung parenchyma, the jaws closed rapidly and removed. Post-biopsy hemorrhage may vary from mild to moderate but is usually controlled by pressure. Intercostal muscle and skin are closed routinely with simple interrupted sutures.

While it is not essential to utilize an endoscope to biopsy the lung from this site, it was found that the sheath and endoscope combination greatly aided the collection of quality pulmonary biopsies with less risk of trauma to the patient.[11] Rigid cup biopsy forceps can be manipulated unaided through a similar intercostal incision, but trauma to the surface of the lung may be greater due to the short working distance and lack of magnification.

Intestinal Peritoneal Cavity

The intestinal peritoneal cavity (IPC) is the largest of the peritoneal cavities. It is a single, midline potential space that extends from the level of the kidneys caudal to the vent. It is somewhat subdivided by the several mesenteries formed by reflections of the peritoneum that suspend the proventriculus, intestines, gonads and supporting structures.[16,24] The gonads are actually suspended within the IPC and are not located within the abdominal air sac. The confusion in this positioning is understandable because the gonads are clearly visible from the abdominal air sac even though they are covered by the air sac wall and the confluent peritoneum (Color 13.12, 13.13). One method to demonstrate the relationship between the IPC and the abdominal air sac is to insert an endoscope into the IPC, optically guiding it toward the left gonad and then viewing this arrangement from the abdominal air sac via a second endoscope (Color 13.25). The thin but substantial air sac/peritoneal wall can be seen clearly covering the endoscope.

The intimate relationship between the abdominal air sac and the IPC is of greatest clinical significance in the female bird. The dorsal mesentery, the dorsal parietal peritoneum and the peritoneum covering the left abdominal air sac fuse to form a serous pocket surrounding the ovary.[24] This "ovarian pocket" is believed to help guide ova to the infundibulum.[6] It has been suggested[5] that extensive damage to both the right and left abdominal air sacs in female birds will lead to infertility and that trauma should be limited to only one of the abdominal air sacs. This suggestion ignores the presence of the IPC and simplifies the role of the abdominal air sacs. Under routine endoscopic examination from a lateral approach only the lateral wall of the abdominal air sac is penetrated. The confluent medial wall of the abdominal air sac and the IPC would not be penetrated under these circumstances. Thus, the ovarian pocket would not be disrupted. A hysterectomy (salpingohysterectomy) performed from a lateral approach will disrupt the left IPC membrane.

Cloaca

The cloaca is a unique, three-chambered structure that receives the terminal portions of the colon, ureters and reproductive tract. Endoscopic examination of the three parts of the cloaca is complicated by the presence of feces and urates. Flushing the proctodeum with saline and then insufflating the structure while closing the vent lips around the telescope will enhance viewing. Uroliths,[18] papillomatous inflammation and true prolapse have been documented with endoscopy. Bacterial and fungal cloacitis may also occur.

Distal Oviduct (Uterus)

Endoscopic examination of the distal oviduct (uterus) is possible in reproductively active birds and may be a useful procedure for the sampling and diagnosis of oviductal disease.

Biopsy Techniques

Patient Considerations

Indications

Open (surgical) and percutaneous techniques for biopsy of the liver have been described in avian medicine. Other internal organs have occasionally been biopsied using open techniques. The ability to obtain precise target biopsies of specific organs is a natural extension of endoscopic examination and offers a far less traumatic method for obtaining diagnostic specimens. Carefully selected biopsies of affected organs may be critical in establishing a diagnosis and allow more precise therapeutic decisions. Table 13.3 describes approaches and techniques for specific organ biopsies.

Indications for biopsy may include abnormal radiographic findings or biochemical parameters, chronic respiratory disease, polyuria and polydipsia (see Table 13.2). The endoscopist should be prepared to collect biopsies during routine examinations. It is not uncommon to find unexpected lesions in patients presented for gender determination. Specimens from obvious lesions are easily collected from the border zone where abnormal meets normal tissue. If the patient's history, physical examination or biochemical findings suggest renal or hepatic abnormalities, biopsy of the kidney or liver is indicated. Tissues will frequently appear grossly normal even though there are significant histologic lesions present.[20]

The decision to biopsy the liver or kidney (Color 13.43) is frequently made too late in the disease process to be truly helpful to the patient and client. Sampling the end stage liver is seldom illuminating beyond confirming a poor prognosis that should be otherwise clinically evident. Many birds with early cases of hepatic disease demonstrate few clinical signs. Recent advances in avian clinical biochemistry procedures, particularly the measurement of bile acids, promise to improve the clinician's ability to detect liver disease at an early stage. Bile acids determination is a sensitive and specific indicator of liver damage (see Chapters 11, 20). Histologic changes are seen in the livers of patients with persistent increases in the bile acids of two times or greater the normal reference intervals. A liver biopsy is recommended in cases where the bile acids measurement remains elevated following the completion of therapy for a systemic disease (eg, chlamydiosis) or where continued elevation of two weeks or more is confirmed.

Renal disease can also be challenging to recognize and diagnose in its early stages (Color 13.47, 13.48). Elevations in uric acid levels may not occur until a relatively large number of renal tubules have been damaged. Polyuria is frequently noted. Kidney biopsy is recommended when uric acid levels are consistently above reference values or show evidence of

TABLE 13.3 Specific Organ Biopsies: Approaches and Techniques

Organ	Approach	Technique
Liver	Best accessed from the VHPC but may also be approached through the left and right caudal thoracic air sac (caudal TAS).	In generalized diseases of the liver, samples can be most easily obtained from the hepatic border using a 5 or 7 Fr instrument. In focal disease (eg, granulomas, neoplasia), the lesion should be specifically targeted taking care not to open the jaws of the forceps too wide when pushing into the liver. This will reduce crush artifact. Larger, rigid forceps can be used but are not usually necessary.
Kidney	Through the caudal TAS into the cranial portion of the abdominal air sac (AAS) or via the AAS approach. May also be approached directly through the IPC, although this potential space would need to be insufflated. The caudal TAS approaches are most suitable for reaching the cranial and middle divisions of the kidney. Entry into the AAS is an excellent way to reach the caudal division of the kidney.	Depending upon the size of the patient, 3, 5 or 7 Fr forceps can be used. Cup-shaped forceps can be used to control depth of penetration. In some smaller birds, the 5 Fr round cup forceps may be more appropriate than those with a standard elliptical shape.
Air Sac	In most species, the caudal TAS is the one most frequently involved in air sac pathology. Lesions may be more prominent on one side than another or may involve the cranial TAS more extensively. Radiographs may be most helpful in selecting the preferred entry site.	Cup biopsy forceps may be used to grasp a small piece of air sac from the border of an air sac puncture site (eg, the caudal TAS/AAS entry site) or to harvest focal lesions directly from the surface of the air sac. Exudate may also be collected with the forceps for microbiology.
Lung	Two approaches to the avian lung were recently described.[11] An endoscopically-guided biopsy of the caudal surface of the lung can be collected from the caudal TAS using the Storz system. It is also possible to access the costal surface of the lung through an intercostal approach. The Storz system may be used to enter the intercostal space and visualize the lung, or a rigid forceps may be guided by the surgeon unaided.	5, 7 and 9 Fr forceps have been used to collect pulmonary biopsies. The degree of localized pulmonary hemorrhage is directly related to the size of the biopsy forceps used and the depth of penetration.
Spleen	The spleen is approached from the left AAS. The AAS may be entered through the caudal TAS or from the caudal approach. The spleen is located on the right side of the proventriculus near the junction with the ventriculus.	A 5 Fr elliptical cup is satisfactory for most patients.
Ventriculus	The greater curvature of the ventriculus, particularly the caudoventral surface, is best approached from the caudal TAS through the left paralumbar fossa.	A 7 or 9 Fr elliptical forceps is recommended. A minimum of two biopsies is collected from the caudoventral surface near a blood vessel to ensure the harvesting of nerve as well as serosa and muscularis.
Testes	The right or left testicle can be reached from its respective AAS or from the IPC.	A smaller forceps is less traumatic (eg, 5 Fr round) although testicular biopsy utilizing a 9 Fr elliptical cup instrument has been reported.[8]

an increasing trend or where polydipsia and polyuria persist without clinical explanation.

Air sac and pulmonary biopsies are indicated when clinical examination, radiographic studies or auscultation reveal persistent, nonresponsive respiratory disease. Dyspnea upon exertion is common in parrots with chronic respiratory disease but is not diagnostic because other thoracoabdominal pathology (eg, hepatomegaly, abdominal tumors) may also generate this clinical sign. Generalized pulmonary disease is best assayed with these techniques although specific types of focal lesions may also be sampled (Color 13.49).

Biopsies of the spleen are indicated in persistent systemic diseases where an etiologic diagnosis is lacking, in cases of unexplained splenomegaly and in granulomatous inflammation of the spleen.

Samples of the ventricular serosa and muscularis that include nerve tissue can be valuable in the definitive antemortem diagnosis of neuropathic gastric dilatation (NGD). A minimum of two specimens is obtained from the caudoventral surface of the ventriculus. A site near a branching blood vessel is chosen in an attempt to harvest nervous tissue. The thick ventricular muscularis prevents perforation of the viscus. These sites heal well, as only a portion of the serosa and outer muscularis is required. Ventricular biopsies are preferred for the diagnosis of NGD over proventricular biopsies because the serosa of the ventriculus can be harvested much more safely with less risk of perforation due to the thicker muscularis. The ventriculus is believed to be the most important site for NGD involvement due to its role in the motility of the gastrointestinal system. Biopsy of the proventriculus is contraindicated due to its thin

wall and the difficulty in preventing perforation with gastric spillage and peritonitis. Some researchers are investigating the possibility of identifying histopathologic lesions of NGD in biopsies of the crop.

Small, precise biopsies of the testicle may be useful in the documentation of reproductive failure due to dysfunction of the testes. Local and systemic infections may cause testicular lesions, although these have been poorly documented.

Contraindications

The specific contraindications for biopsy relate to blood clotting. Biopsy collection should be delayed in any avian patient that shows evidence of abnormalities of the hemostatic system. This usually becomes evident at the time of blood collection. Most birds should show clot formation in one to two minutes. Deficiency of vitamin K is the most common coagulation disorder, for which vitamin K_1h is administered pre-surgically (see Chapter 18). The blood film should be examined for the presence of adequate thrombocyte numbers.

A biopsy cup shape and diameter appropriate to the size of the patient and organ to be biopsied must be chosen. Forceps too large for the purpose may cause excessive organ trauma and hemorrhage.

Biopsy cups generally come in only two shapes: round or elliptical. The round shape does not penetrate as deeply into tissue as the same diameter elliptical cup and this may be indicated for use with certain organs such as the kidney or testes.

Inexperience with the instrumentation and approaches to the organ is a potential cause of biopsy complications.

Instrumentation

Table 13.4 lists selected sources of endoscopic and biopsy equipment.

A percutaneous technique to biopsy the avian liver using a 19 ga modified Jamshidi or Menghini needle has been described.[18] The larger, right lobe of the liver was approached through the sternal notch with the needle directed posteriorly to avoid puncture of the heart. The technique is relatively rapid to perform, but it is a blind procedure. The liver cannot be inspected nor can focal lesions be sampled. The proventriculus, heart and bile duct are at risk for organ trauma. Optically guided biopsies of the liver are superior.[20] A rigid cup biopsy forceps originally designed for otolaryngology[i] can be guided along the shaft of the endoscope to the visual field. Biopsies of the liver, kidney, spleen, air sacs, lung and testes can be obtained under direct observation. The 8150.00 forceps has a 3.0 mm (9 Fr) diameter cup and takes a relatively large, elliptical sample. This instrument should not be used in birds under 200 g. This forceps in combination with a 2.2 or 2.7 mm telescope has been the most widely utilized and accepted method for collecting optically guided biopsies in the avian patient. The forceps is "walked" into position along the shaft of the endoscope until it can be visualized.

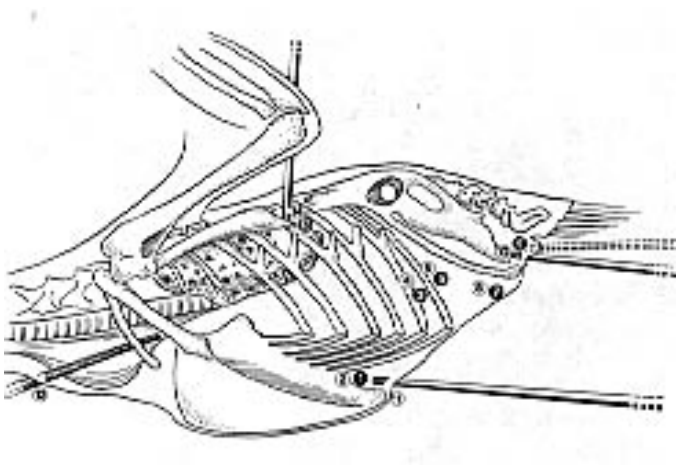
In an effort to improve the usefulness of endoscopically guided biopsies, a new endoscope and sheath set has been developed[a] in cooperation with Karl Storz Endoscopy. An instrument channel permits the use of implements up to 5 Fr (1.7 mm) diameter. Flexible forceps for biopsy and grasping as well as aspiration and infusion cannulas can be placed into the port of the channel and guided easily to the tip of the sheath and into the viewing field of the endoscope. This single puncture system simplifies the manipulation of instrumentation for the endoscopist and helps prevent additional patient trauma.

The system is appropriate for patients weighing approximately 150 g to 2000 g. In larger birds or at certain sites (eg, the ventriculus), a heavier biopsy forceps (eg, 7 Fr) is frequently required. This necessitates a larger sheath. The advantage of a systematic approach to endoscopic equipment employing one manufacturer is that a modular design can be



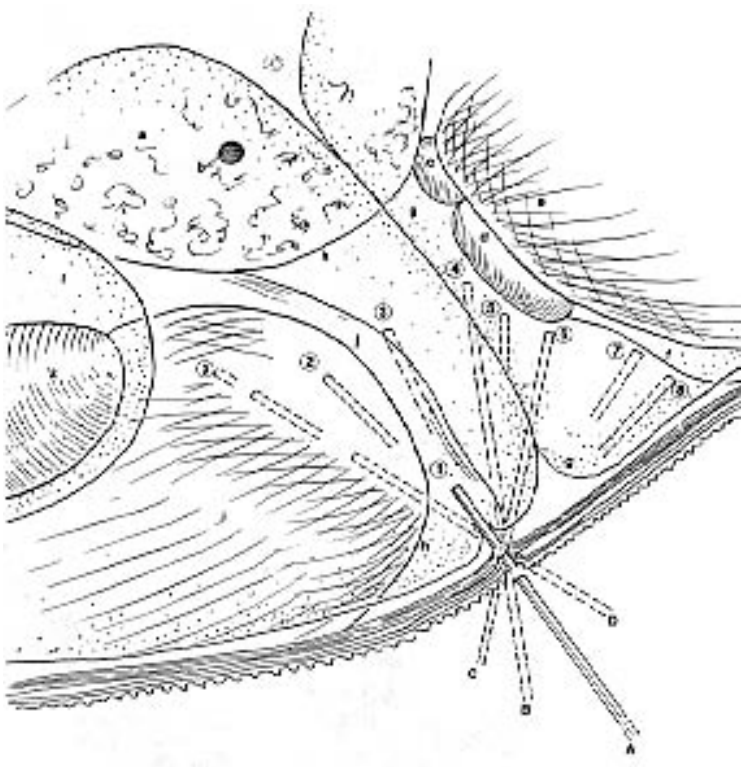


FIG 13.2 *(repeated)* Numbered endoscopic sites described for evaluation of the internal anatomy of birds. Entry sites are shown as either left-sided approaches (open) or right-sided approaches (solid).

FIG 13.4 *(repeated)* The endoscopist can develop an insight into the relative position of organs as viewed from entry site 6. The views are divided into four angles (A,B,C,D) and depths (1 through 9). Structures used for orientation include: a) lung b) ostium of the cranial thoracic air sac c) adrenal gland d) gonad e) kidney f) ureter, oviduct, vas deferens area g) abdominal air sac h) caudal thoracic air sac i) liver j) proventriculus k) heart and l) cranial thoracic air sac.

Endoscopic Examination and Biopsy Techniques

Color 13.22
Gross view from the end of the sternum in a cockatoo placed in dorsal recumbency. The sternum (s) has been elevated to accentuate the division of the cavities visible from endoscope insertion point 11 (Figure 13.2). The confluent wall of the right cranial thoracic air sac and right ventral hepatic peritoneal cavity (1), ventral mesentery (2) and confluent wall of the left cranial thoracic air sac and left ventral hepatic peritoneal cavity (3) are clearly visible. The right liver lobe (rl) and left liver lobes (ll) are also visible. The right ventral hepatic peritoneal cavity is marked by arrows; the left ventral hepatic peritoneal cavity is marked with open arrows.

Color 13.23
(Insertion point 2 see Figure 13.2) View inside the left cranial thoracic air sac of an Amazon parrot. For reference purposes, insertion point 2 would provide a similar view to position D-9 if entering through site 6 as shown in Figure 13.4. Easily identifiable structures include ribs (r), proventriculus (p), medial intercostal muscle (m), heart (h), attachment of pericardial sac (arrow), lung (lu), ostium of cranial thoracic air sac (open arrow) and liver (li).

Color 13.24
(Insertion Point 2 see Figure 13.2) The endoscope is in the cranial thoracic air sac, and the contiguous wall between the cranial and caudal thoracic air sacs is visible caudally (a). In this entry site, the heart (h) will be observed beating cranially. Other structures that can be visualized include ribs (r), lung (lu), liver (l), medial intercostal muscle (m) and the ostium for the cranial thoracic air sac (arrow).

Color 13.25
(Insertion point 10 see Figure 13.2) An endoscope placed in the left abdominal air sac was used to take a picture of a second endoscope guided into the intestinal peritoneal cavity. Note the membrane (arrow) covering the tip of the endoscope with the intestinal (in) tract under the membrane. Other visible structures include the lung (lu), cranial pole of the left kidney (k), transverse abdominal muscle (m), ilium (i) and proventriculus (p).

Color 13.26
(Insertion point 10 see Figure 13.2) This Amazon parrot had been endoscoped from insertion point 6 and the iatrogenic tear that was made in the contiguous wall of the caudal thoracic and abdominal air sac is clearly visible (arrow). Equipment used for endoscopy must be sterile to prevent air sac infections or peritonitis. The air sacs were originally clear and now are considered cloudy, and there is an increase in vascularization. When viewed from insertion point 8, a granuloma is evident in the air sac (g). Other structures that are visible include lung (lu), ilium (i), cranial pole of the left kidney (k), loop of intestines (in), proventriculus (p), external iliac vein (open arrow).

Color 13.27
(Insertion point 10 see Figure 13.2) A rent is visible in the contiguous wall of the caudal thoracic and abdominal air sac (arrow) showing the path of the endoscope when inserted at point 6 for gender determination. Other visible structures include lung (lu), external iliac vein (open arrow), cranial division of the left kidney (k1), middle division of the left kidney (k2), (i) ilium, loops of intestines (in) and proventriculus (p). This represents how a site should appear if the original entry was performed under aseptic conditions. Compare this to Color 13.26.

Color 13.28
(Insertion point 11 see Figure 13.2) The normal endoscopic anatomy of the ventral hepatic peritoneal cavity of a pigeon. This view provides clear visualization of the size, shape and texture of the liver. This position can be used to obtain endoscopically guided biopsies of the liver. Note that the right lobe of the liver (rl) extends further caudally than the left lobe of the liver (ll). Other structures that can be visualized include the sternum (s), deep pectoral muscle (m), proventriculus (p) and heart (h).

Color 13.29
A small tear (arrow) has been created in the caudal thoracic air sac to enter the underlying left ventral hepatic peritoneal cavity of a normal pigeon. Liver (li), proventriculus (p), lung (lu), ostium of caudal thoracic air sac (o), contiguous wall of the caudal thoracic and abdominal air sac (a), contiguous wall of the cranial and caudal thoracic air sac (open arrows).

Color 13.30
Left, ventral, hepatic peritoneal cavity distended with air (arrows) following biopsy of the liver. Other visible structures include the lung (lu) and proventriculus (p).

Endoscopic Examination and Biopsy Techniques

Color 13.31
An endoscope has been placed in the oral cavity of a Great Horned Owl showing the infundibular cleft (arrow), sphenopterygoid salivary glands (ssg), longitudinal folds of the esophagus (e), laryngeal mound (open arrow), tongue (t) and mandibular salivary glands (msg).

Color 13.32
An endoscope has been placed in the oral cavity of a normal African Grey Parrot. Note the dark pigmentation and uniform coloration and texture of the oral mucosa. Well formed papillae (arrow) are noted on either side of the choanal slit (c). Also visible are the lateral commissures of the mouth (open arrows) and the tongue (t).

Color 13.33
Lateral view of the oral cavity in a Yellow-crowned Amazon Parrot with hypovitaminosis A. Abscessation (open arrow) at the base of the tongue (t), and blunting and abscessation of the choanal papillae (arrow) are characteristic. Hyperkeratosis of the tongue and oral mucosa are also noted.

Color 13.34
An endoscope has been placed in the oral cavity of a normal Amazon parrot. Note the smooth texture of the tissues in the oral mucosa. All secretions are serous in nature. The choanal (arrow) and lingual papillae are sharp and well defined. Other structures that can be visualized include the tongue (t), oropharynx (o), infundibular cleft (open arrow) and choana (c).

Color 13.35
Endoscopic view of the palate in a Great Horned Owl. The cranial choanal slit (arrow) and sphenoptergoid salivary glands (ssg) are visible. Note that the choanal slit does not contain papillae, but that papillae are present on the caudal edge of the sphenopterygoid salivary glands.

Color 13.36
Caudal view of the choanal area in an African Grey Parrot. The visible structures include the choanal slit (c), infundibular cleft (arrow) and endotracheal tube placed in the trachea (open arrow). Note that the structure of the choanal papillae is different in an African Grey Parrot than in an Amazon parrot (see Color 13.34).

Color 13.37
Endoscopic view of the cranial margin of the choanal slit in a Moluccan Cockatoo. The nasal septum (n), left middle nasal concha (arrow) and nasal mucous membranes (open arrow) are visible.

Color 13.38
Normal esophagus of a Great Horned Owl showing longitudinal folds.

Color 13.39
Normal crop of a cockatoo. A red rubber feeding catheter (t) has been introduced into the crop and is just ventral to the opening from the crop into the thoracic esophagus (arrow). Normal, clear, bubbly mucus is seen covering the crop mucosa. Wrinkling of the crop mucosa (open arrow) is occurring in response to a peristaltic wave. Note the smooth, thin texture and even color of the crop mucosa.

Color 13.40
An endoscope has been passed into the fluid-filled proventriculus of a pigeon. Note the openings of the proventricular glands (arrow) and a pelleted food particle (open arrow).

Color 13.41
a) An endoscope has been inserted into the external ear canal of a Great Horned Owl to show the tympanic membrane (t), extracolumellar cartilage (e), cranial wall of the ear canal (arrow) and caudal wall of the ear canal (open arrow). **b)** Closer view of extracolumellar cartilage.

Color 13.42
Biopsy forceps are being used to take a sample from the caudal edge of the left liver lobe (l). The confluent wall of the caudal thoracic air sac and left ventral hepatic peritoneal cavity membrane are clearly visible (arrow).

Color 13.43
Post-biopsy view of the left liver lobe (l) in a pionus parrot with avian mycobacteriosis.

Color 13.44
Insertion 6. Post-biopsy photograph of the lung as viewed from within the left caudal thoracic air sac.

Color 13.45
Liver of an Amazon parrot showing severe biliverdin accumulation secondary to chlamydiosis.

Color 13.46
Endoscopic view of the liver (l) prior to biopsy of several white-to-yellow proliferative masses (arrow). Histopathology indicated bile duct carcinoma in an Amazon parrot. This bird had a history of cloacal papillomatosis.

Color 13.47
(Position B-4 see Figure 13.4) Endoscopic view of the cranial pole of the left kidney in an Amazon parrot showing several white, proliferative masses (arrow). Biopsy indicated lymphosarcoma. Other visible structures include the lung (lu).

Color 13.48
(Insertion point 6, postion B-4 see Figure 13.4) Endoscopic appearance of chronic glomerulonephritis in an Amazon parrot. The cranial pole of the left kidney (k), common iliac vein (arrow) and ovary (o) are clearly visible.

Color 13.49
Granuloma in the abdominal air sac of a pionus parrot. The substantial vascularity of the adjacent air sacs suggests a chronic reaction. The fact that the air sac tissue at the periphery of the mass is normal suggests that the infection has been contained. The spleen (s) is enlarged and pale.

used. Thus the 2.7 mm endoscope in the standard Storz avian set can be inserted into other sheaths such as the modified 26156 H, which permits the introduction and use of the larger 7 Fr biopsy forceps.

Preparation of Small Biopsies

The biopsies obtained with the types of forceps previously mentioned are small and must be handled with care so that they are not lost or damaged. Various techniques have been recommended in the past to enable the histotechnologist to locate and properly imbed small specimens for processing. Wrapping tiny pieces of tissue in filter paper or a very fine cloth before immersion in the fixative is one method. Or the specimens can be placed into a small stoppered blood collection container without anticoagulant.[k] This system is simple and effective, allowing the technician to clearly visualize the sample(s). No more than two to three specimens should be placed in each clearly labelled container. Small tissue samples require far less time to fix than larger samples (likely less than two hours in formalin). Specifically buffered, ten per cent formalin designed for tissue fixation must be used. Failure to do so will lead to precipitates and artifacts. If biopsies cannot be processed immediately, the specimens can be stored in a solution of 97% methyl alcohol after fixation in order to ensure sample quality. The laboratory should be contacted for specific recommendations.

Consulting Pathologists

The value of the clinical biopsy is directly related to the quality of the sample, the history provided and the experience of the pathologist. Reading small surgical biopsies from exotic avian species is a relatively specialized area of pathology. Best results are likely to be obtained by working with a consultant pathologist who has a real interest and expertise in this field. Timely reporting of results is essential to enable the clinician to make optimal use of the biopsy information.

NECROPSY EXAMINATION

Kenneth S. Latimer
Pauline M. Rakich

Necropsy examination of deceased patients should be an integral part of avian clinical medicine. Necropsy examination often is performed to determine the cause of an unexpected death. However, a thorough and systematic postmortem examination also may be used to confirm a clinical diagnosis, identify the etiology of a disease process, explain apparent unresponsiveness to treatment or reveal unrecognized disease processes. Integration of necropsy findings with clinical signs and laboratory data ultimately will enhance the clinician's understanding of disease processes and sharpen clinical diagnostic skills. In addition, necropsy will confirm radiographic interpretations and reinforce applied anatomy, which enhances surgical skills.

Necropsy examination is a relatively straightforward procedure that should follow a written protocol, thereby minimizing the possibility of overlooking important lesions. This chapter emphasizes the necropsy of psittacine and passerine birds; anatomic variations of other avian species such as ratites may be found by consulting appropriate chapters in this textbook and published articles in the veterinary literature.[3]

Maximum necropsy information can be obtained only by following a systematic approach and using ancillary support services as needed to establish a definitive diagnosis. Ancillary support services include histopathology, clinical pathology, microbiology, parasitology and toxicology.

Preparing for the Necropsy

Several excellent sources of information, in addition to this textbook, are available to help the clinician verify questionable anatomic structures, identify gross lesions and form a differential diagnosis.[6,12,14-17,22] The clinician should recognize certain limitations of the gross necropsy procedure. While recognition and interpretation of gross lesions may allow construction of a differential diagnosis as to the cause of death, few gross lesions are pathognomonic. Therefore, various ancillary services usually are required to determine the cause of death. Furthermore, communication of clinical, laboratory and necropsy findings to the pathologist will vastly improve interpretation of the tissues and histopathologic evaluation. A close working relationship with a veterinary pathologist who is interested in avian diseases is a definite asset. Lastly, the quality of the final diagnosis is directly proportional to the quality of the specimens submitted and the information provided with them.

Medical Precautions

When performing avian necropsies, the health and well being of the veterinarian and staff members should be considered. Zoonotic diseases of special concern include chlamydiosis, mycobacteriosis, salmonellosis and campylobacteriosis.[5,7,21,25,26,30] Therefore, appropriate protective measures such as surgical masks, eye protection, gloves and disinfectants are recommended. Wetting the carcass with soapy water or disinfectant solutions decreases the possibility of aerosol exposure to potential pathogens and irritating feathers or dander.[30,33] Ventilation hoods or downdraft necropsy tables provide an ideal environment for pathogen containment during avian necropsies; however, such equipment is seldom available in a private practice setting.

Equipment and Supplies

The equipment necessary to perform an avian necropsy will depend on body size, which may vary from a few grams for a Bumblebee Hummingbird to several hundred kilograms for an ostrich.[30] In the case of a small hummingbird, a dissection tray or board, ophthalmic instruments and a magnifying loupe or dissecting microscope may be helpful. With large ratites, rib shears and a Stryker saw will be required.

The body size of most birds encountered in practice will range from a finch to a duck. An assortment of instruments including scissors, poultry shears, scalpels, rongeurs, thumb forceps and hemostats will aid in tissue incision, dissection and specimen procurement. Such instruments should be dedicated for necropsy use only and be thoroughly cleaned and disinfected (eg, glutaraldehyde, phenol, gas, steam) after each use to maintain good functional integrity and prevent carryover of pathogens that could adversely influence future necropsy results. Furthermore, instruments that are sterilized in chemical disinfectants should be rinsed thoroughly before use to avoid killing pathogens in tissues intended for culture.

Ancillary equipment may include sterile swabs[a] and sealable plastic bags[b] to obtain microbiologic and parasitologic specimens; sterile collection tubes for blood, serum or body cavity fluids; and glass slides, stains and a microscope to examine cytologic and blood smear specimens. A camera, macro lens system, flash unit and copy stand can provide photographic documentation of unusual lesions.

The routine fixative for collection of tissue specimens for histologic examination is neutral-buffered 10% formalin solution. Buffering is important to prevent artifacts in the tissues, which can interfere with microscopic examination. Some formalin solution recipes, such as Carson's fixative, provide excellent tissue preservation for both routine histopathology and electron microscopy (see Table 14.2).[27] For more detailed information on sample procurement, refer to the section entitled "Specimen Collection for Ancillary Testing."

Lastly, a printed necropsy form (Figure 14.1) should be available to record important observations. Indelible marking pens should be used to legibly identify all specimen containers concerning patient identification and origin of the specimen(s).

Euthanasia

Euthanasia may be preferred to natural death to alleviate patient suffering. Acceptable methods of euthanasia include carbon dioxide or anesthetic gas

◁ **FIG 14.1** Use of a standard necropsy form (opposite) ensures that all organ systems are examined and important findings are documented.

administration, intravenous barbiturate administration (jugular vein or cerebral sinus) or anesthetic gas administration followed by exsanguination.[29] Of these various techniques, carbon dioxide administration is used least frequently because of excessive terminal motor activity. Anesthetic gas administration is beneficial because blood specimens may be obtained prior to death.

The clinician must realize that the method of euthanasia may have a bearing on gross and microscopic changes observed in necropsy tissues. For example, carbon dioxide-induced hypoxia may result in terminal involuntary motor activity with subsequent bruising, often noted at the base of the skull and misinterpreted as head trauma. Intravenous injection of caustic solutions may result in erythrolysis, edema and coagulative tissue changes, especially within the lungs.

Handling the Carcass Prior to Necropsy

Occasionally, a variable period of time will elapse between the point of death and performance of the necropsy. Examples include the unexpected death of a patient outside of regular clinic hours, delay in obtaining permission for necropsy from the owner or shipment of the carcass to a laboratory for necropsy examination. Unless precautions are taken to minimize autolysis, decomposition of the carcass will limit or preclude the benefits of histopathologic or gross examination of the carcass or various lesions, tissues and organ systems.

Rapid autolysis of avian carcasses is the result of a normally high body temperature (approximately 40°C in adults), body conservation of heat by insulating feathers, and use of incubators, heating pads or heating lamps to increase environmental temperatures of neonates and ill patients. Autolysis may be retarded by soaking the carcass thoroughly in cool soapy water, placing it in a thin plastic bag and storing the body under refrigeration before performing a necropsy or shipping the body to the diagnostic laboratory on ice. When shipping the carcass to a diagnostic laboratory, next-day courier service should be employed to minimize the delay of regular mail service.[6]

A carcass intended for necropsy *should not be frozen.* Placing a carcass directly on ice or dry ice during shipping also may result in freezing of the entire carcass or that portion in contact with the ice. Freezing induces artifactual changes, such as cell lysis and destruction of tissue architecture, which occur as a result of formation and thawing of ice crystals, and may render the tissue nondiagnostic histologically.

The Necropsy Examination

The necropsy examination should begin with a thorough review of the signalment, physical findings, medical history and pertinent laboratory data. An organized, standard necropsy technique is essential for a thorough necropsy examination without overlooking important lesions or organ systems. Because many more mistakes are made from lack of observation than lack of knowledge, a written necropsy protocol should be followed.

External Examination of the Carcass

Carcass identification should be verified by visual inspection based upon signalment (age, species and color) as well as leg band, tattoo or microchip implant data. Leg band numbers and other identifying marks should be recorded on the necropsy form. Palpation of the carcass may reveal fractures; swellings involving subcutaneous air sacs; masses of the skin, subcutis or underlying tissues; or physical deformities. An evaluation of general body condition also should be made, and body weight recorded. A prominent keel may indicate weight loss.

The integument including skin, mucocutaneous junctions, plumage, beak and nails should be examined carefully. Avian skin is generally thin and transparent, in contrast to that of mammals (see Color 24). Accumulations of scales and crusts on legs, feet and cere may indicate bacterial, viral, fungal or parasitic infections. Scabs or swellings involving the skin or mucous membranes may indicate neoplasia, bacterial granulomas or viral-induced lesions (see Color 25). Loss, deformity or color alteration of feathers or fracture of blood feathers could be the result of viral, bacterial, fungal or parasitic infection, as well as trauma or nutritional disease.[19] In birds such as cockatoos and African Grey Parrots, the presence or absence of powder on the beak, legs, feet and nails will provide information concerning proper function of powderdown feathers. Mites should be identified microscopically if present.

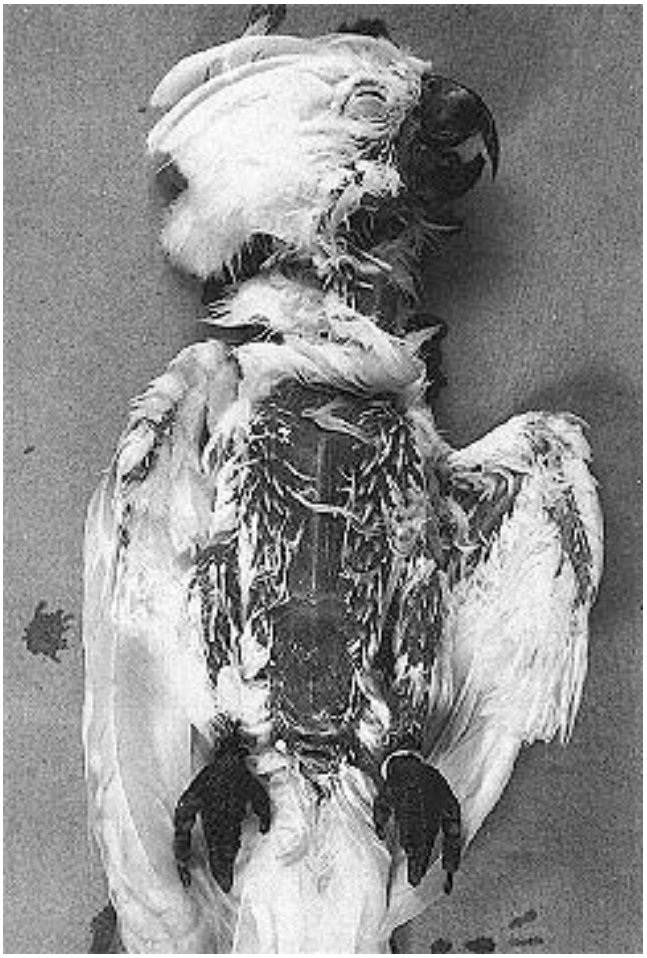

FIG 14.2 Following external examination of the carcass, the plumage has been dampened with soapy water to prevent aerosolization of feather debris and potential pathogens.

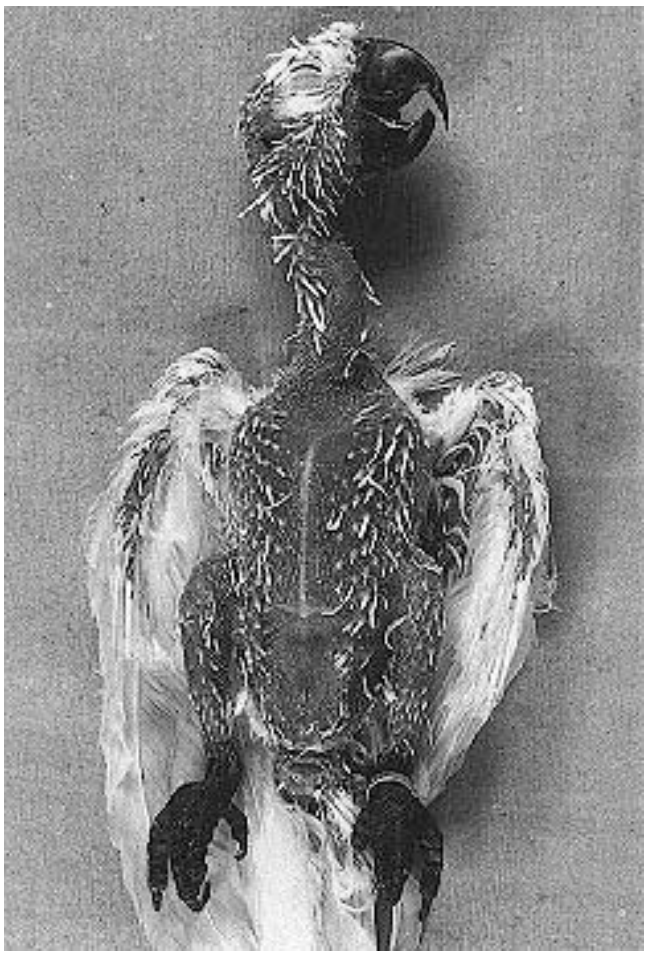

FIG 14.3 The feathers have been removed from the head, neck, ventral thorax and abdomen and legs; the bird is placed in dorsal recumbency.

The beak and nails should be examined for deformities, fissures, fractures or delaminations. Beak pathology could result in difficult prehension of food and subsequent malnutrition. Nail pathology could result in lameness.

All body orifices (eyes, external auditory meatus, nares, oral cavity and vent) should be examined for discharges, masses, foreign bodies, ulcers and plaques. Ocular discharge may be seen with chlamydiosis; bacterial, viral and parasitic infections; or mycoplasmosis. Periocular scabs and masses and oral plaques may be seen in poxvirus infections. Oral plaques alone may be caused by bacterial, viral and parasitic infections as well as by burns, trauma and vitamin A deficiency (see Color 8). Palatine and glossal (tip of the tongue) necrosis may be observed in some birds with psittacine beak and feather disease. Soiling of the vent may indicate enteric disease or cloacal dysfunction. Furthermore, yellow to green discoloration of urates may suggest hepatic or enteric disease (see Color 8). In Amazon parrots, cloacal masses may represent papillomas, which are frequently accompanied by cloacal prolapse. While the external auditory meatus should always be examined, aural pathology is rare, especially in parrots.

At this time, swabs of the choanal slit and vent may be taken for microbiological culture if desired. After cursory external inspection, the feathers may be wetted with soapy water to reduce feather dust and debris (Figure 14.2). The feathers subsequently may be removed to reveal subtle cutaneous pathology such as wounds or hemorrhages. Plucking feathers from the ventral cervical, thoracic and abdominal areas also facilitates further dissection and will avoid obscuring internal lesions (Figure 14.3).

Necropsy Examination

Color 14.1
The majority of the viscera have been removed from the carcass. The liver (l), spleen (s), proventriculus (p), ventriculus (v), duodenal loop (d) and pancreas (arrow) are visible.

Color 14.2
A 25-year-old Scarlet Macaw was presented for egg retention of three days' duration. The egg was surgically removed. The patient became depressed, anorectic and began to regurgitate two weeks postsurgery. Radiographs indicated dilated bowel loops suggestive of an intestinal obstruction. Exploratory laparotomy indicated a fibrous constriction of the ileum. A side-by-side anastomosis was performed, but the bird died postsurgically. Shown are the pancreas (p), inflamed serosal surface of the duodenum (d) and mesenteric hemorrhage (arrow) of the anastomosis.

Color 14.3
Gastrointestinal obstruction and peritonitis in a pheasant with proliferative typhlitis secondary to a *Heterakis isolonche* infection.

Color 14.4
Glistening, transparent membranes typical of normal air sacs in an Umbrella Cockatoo; left caudal thoracic air sac (arrow) and left abdominal air sac (open arrow). The heart (h), proventriculus (p), ventriculus (v) and right liver lobe (l) can also be visualized. Note the position of the reflection of the caudal thoracic air sac from the surface of the liver lobe (see Color 14.18).

Color 14.5
The pancreas (p) lies between the descending (dd) and ascending (ad) loops of the duodenum. In some species the pancreas is divided into three lobes: the dorsal lobe (arrow), the ventral lobe (open arrow) and the splenic lobe (see Color 14.6), which can be identified only from a dorsal view.

Color 14.6
Distended bile duct (open arrow) in an anorectic cockatoo. Some birds have gall bladders while others do not. In species that do not have gall bladders, bile may accumulate in the right bile duct and appear as though a gall bladder is present. From this dorsal view, the splenic head (arrow) of the pancreas and lateral edge of the liver (l) can also be identified.

Color 14.7
a) An enlarged, hemorrhagic spleen caused by *Pasteurella multocida* in a Common Black Bird (courtesy of R. Korbel). **b)** An enlarged spleen with multifocal granulomas caused by *Yersinia tuberculosis* in a toucan (courtesy of R. Korbel).

Color 14.8
Splenomegaly is a common finding in many bacterial and viral infections. In this case, the enlarged mottled spleen (s) was from a neonatal Blue and Gold Macaw that died from avian polyomavirus. Proventriculus (p), isthmus (i) and ventriculus (v).

Color 14.9
The thoracoabdominal viscera can be visualized by removing the sternum. The right lung (lu), both liver lobes (l), proventriculus (p), ventriculus (v), descending duodenum (dd), ascending duodenum (ad), pancreas (arrow) and colon (c) can be visualized from this view. Note the thin hepatic peritoneal membrane attached to the lobes of the liver.

Necropsy Examination

Color 14.10
The lungs (lu), kidneys (k), ovary (o) and adrenal glands (a) remain in the carcass following removal of the majority of the viscera. Normal lungs appear deep pink and kidneys appear red-brown. Note the inactive oviduct (arrow) and ureter (open arrow). In health, the kidneys appear dark red-brown and are embedded within the renal fossae. The adrenal glands are small, round, yellow structures at the cranial divisions of the kidneys. The quiescent ovary of this bird is granular and pigmented (melanin pigment) (courtesy of Ken Latimer).

Color 14.11
The left lung has been removed to demonstrate its normal anatomic position in the dorsal thoracic cavity. The lung is attached to the dorsal body wall and interdigitates with the spinal processes and ribs.

Color 14.12
Trauma-induced spinal cord hemorrhage (arrow) in a cockatoo. The ventral vertebral structures have been removed for visualization.

Color 14.13
Pale kidneys in an anemic male Amazon parrot. Cranial division of left kidney (k1), middle division of left kidney (k2), caudal division of left kidney (k3), lung (lu), common iliac vein (arrow), caudal renal vein (open arrow) and ureters (u).

Color 14.14
Hepatic rupture and hemorrhage (h) in a six-month-old emu with *Clostridium shovia*. Infected birds frequently die of exsanguination secondary to the tears in the liver (l) (courtesy of Brett Hopkins).

Color 14.15
A Barn Owl was presented with severe depression and weight loss. A palpable mass was present in the lower abdominal cavity. Abdominocentesis indicated the presence of a septic exudate containing numerous gram-negative bacteria. At necropsy, a perforating lesion was noted in the proventriculus (arrow), and the liver was enlarged, pale and mottled. Histopathology indicated a gram-negative septicemia with hepatitis and peritonitis.

Color 14.16
Cystic dilatation of the right bile duct (arrow) in an anorectic Amazon parrot. The accumulation of bile was detected radiographically as a fluid-filled mass slightly dorsal to the hepatic shadow. Lung (lu), heart with thickened, opaque pericardium (h), liver (l), proventriculus (p) and ventriculus (v).

Color 14.17
Congested, swollen kidneys in a male Scarlet Macaw with aspergillosis. Note the plaques (open arrows) on the right testicle. Note the plaques (arrows) and thickening of the dorsal wall of the intestinal peritoneal cavity.

Color 14.18
A mature Rose-breasted Cockatoo was presented with an acute onset of depression, dyspnea and syncope. The bird did not respond to supportive care. Necropsy findings included dark, congested lungs (lu), an enlarged, congested liver (l) (note the line of reflection of the lateral wall of the caudal thoracic air sac from the liver's surface, see Color 14.4), enlarged, congested kidneys (k) and an enlarged heart (h) with petechiation. Histopathology indicated *Sarcocystis* sp. The bird was housed indoors but the food was kept in an open container and was contaminated with roach feces.

Color 14.19
a) Proventriculus (p) and ventriculus (v) from a one-month-old ostrich. Note the hemorrhage and ulceration (arrows) at the isthmus, which is common in birds with *Clostridium perfringen* infections. This bacteria secretes an exotoxin that causes generalized vasculitis and is associated with atony of the proventriculus. **b)** Similar *C. perfringen*-induced lesions in the proventriculus of a 23-month-old ostrich (courtesy of Brett Hopkins).

Color 14.20
A mature cockatiel hen was presented with depression and severe abdominal distention. The bird did not respond to supportive care. At necropsy, multiple masses were identified in association with the pancreas and dorsal body wall. Histopathology indicated a pancreatic adenocarcinoma with carcinomatosis (arrows) of the abdominal cavity (courtesy of Cheryl Greenacre).

Color 14.21
Diffuse amyloidosis in the liver of an American Merganser. Focal granulomatous lesions characteristic of *Mycobacterium* sp. are also noted. Amyloidosis commonly occurs in waterfowl with chronic inflammatory diseases (courtesy of R. J. Montali).

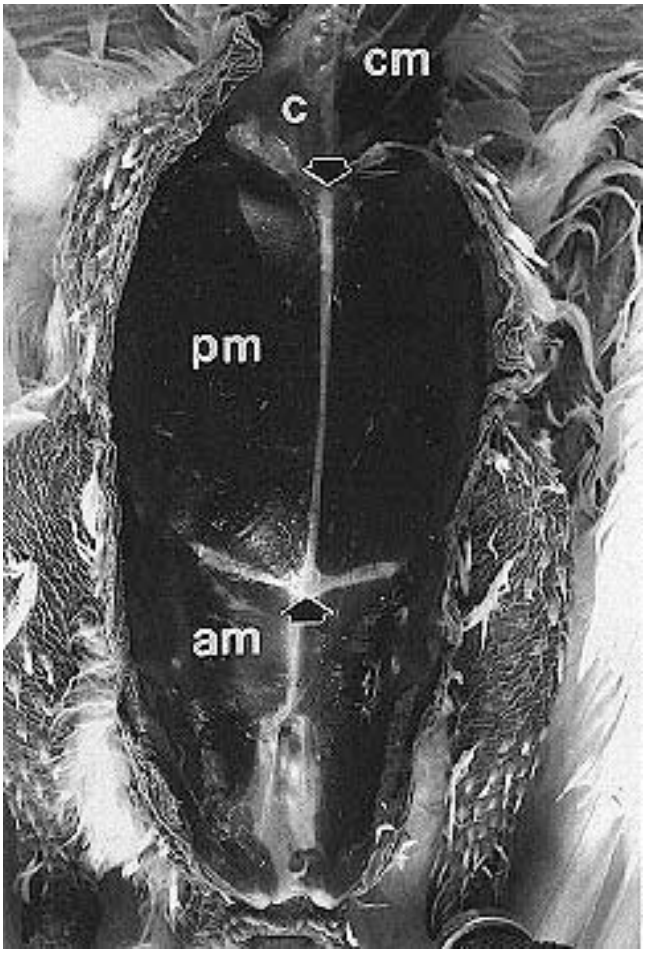

FIG 14.4 The skin has been incised and reflected. The proximal cervical musculature (cm), crop (c), pectoral musculature (pm) and abdominal musculature (am) have been exposed. The keel of the sternum identifies the ventral midline (arrows).

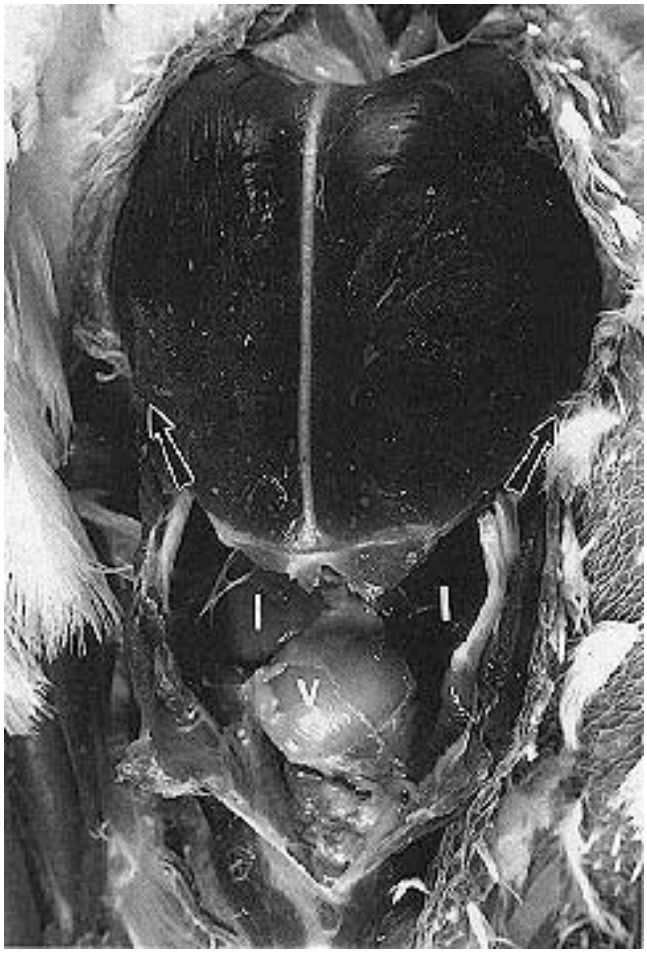

FIG 14.5 An incision has been made through the abdominal musculature and continued around the left and right margins of the sternal plate (arrows). The posterior portions of the left and right hepatic lobes (l) and ventriculus (v) are observed.

When external examination of the carcass is complete, survey radiographs may be taken if heavy metal toxicosis is suspected. These radiographs may assist the clinician in localizing metal densities that may be collected for analysis during the necropsy.

Initial Dissection

The bird is placed in dorsal recumbency for initial dissection (Figure 14.3). With very small birds, the wings and legs may be pinned to a dissecting tray or board to immobilize the carcass. With larger birds such as ducks or geese, the coxofemoral joints may be disarticulated by incising the skin, adductor muscles of the medial thigh and coxofemoral joint capsule. The knees are then forced craniolateral. Using a scalpel and scissors, a ventral midline incision is made from the intermandibular area to the pelvic area, encircling the vent. The skin is reflected by blunt dissection to reveal the underlying cervical musculature, trachea, crop, keel and pectoral and abdominal musculature (Figure 14.4).

Normal pectoral musculature of most companion birds is plump and appears red-brown. The musculature should be examined for hemorrhage, penetrating wounds, pallor, pale streaking or loss of total mass. Pallor or pale streaking may represent muscle necrosis, inflammation or neoplasia. Pale streaking of the pectoral musculature may be observed in feral birds with sarcocystosis. Muscle wasting is often a sign of inanition.

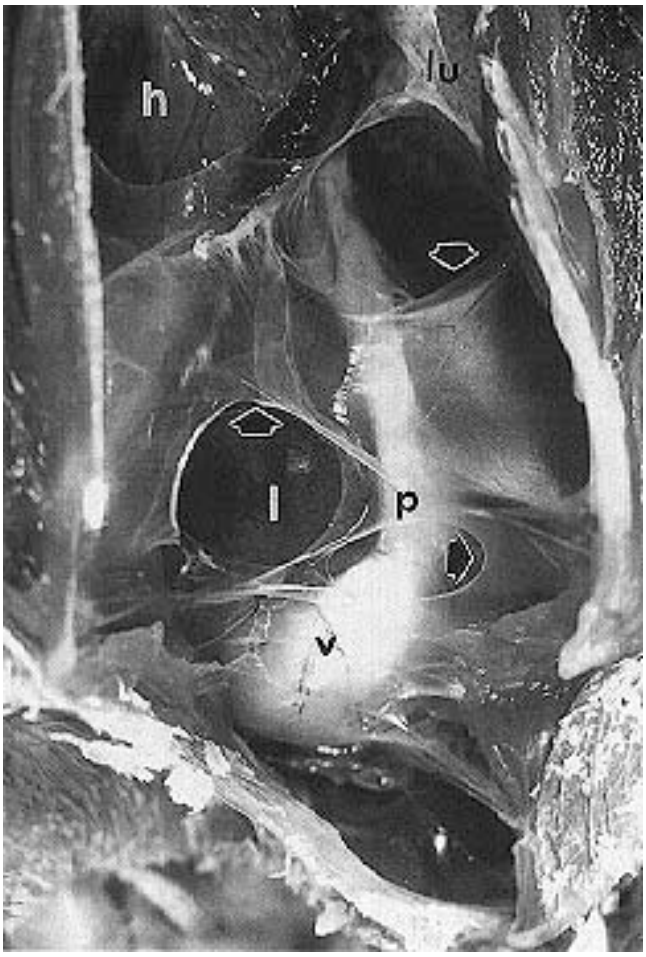

FIG 14.6 Normal air sacs (arrows) appear as glistening, transparent membranes that can be visualized as the sternal plate is lifted. Portions of the heart (h), lung (lu), liver (l), proventriculus (p) and ventriculus (v) also are visualized.

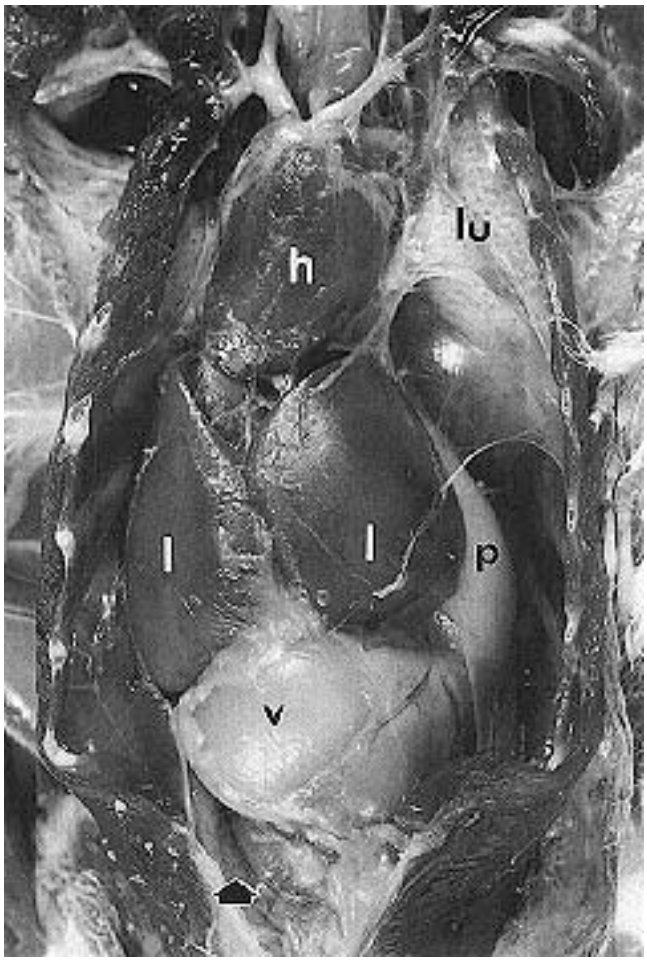

FIG 14.7 The sternal plate and a portion of the abdominal musculature have been removed to expose the thoracoabdominal viscera for gross examination. The heart (h), lung (lu), right and left hepatic lobes (l), proventriculus (p) and ventriculus (v) are identified. A small segment of the duodenum also is observed (arrow).

Exposure of the Thoracoabdominal Cavity

An incision is made through the abdominal musculature at the distal tip of the sternum. The incision is continued left and right through the pectoral musculature lateral to the sternum (Figure 14.5), which can be lifted craniodorsal to expose the thoracic and abdominal air sacs (Figure 14.6). Normal air sacs appear as glistening transparent membranes (Color 14.4). If air sacs appear opaque or contain accumulations of fluid or exudate, appropriate specimens should be obtained for microbiological culture or cytology before the field is contaminated (see Color 22). Air sac tissues collected for histopathology should be placed on a small piece of paper before fixation. This will facilitate identification of the tissue for processing and minimize the possibility that these transparent membranes will be discarded inadvertently.

The sternal plate is removed by continuing to incise the thoracic musculature and transecting the ribs, coracoid bones and clavicles using scissors, rongeurs or poultry shears (large pruning shears may be necessary for ratites). The midline incision is extended caudad through the abdominal musculature proximal to the vent; care should be taken to prevent incising the cloaca. The pectoral musculature of the sternal plate may be incised and examined; any abnormal tissue is collected for cytologic imprints and histopathologic evaluation. Abdominal wall musculature is then removed as necessary to expose the viscera within the body cavity (Figure 14.7).

Examination of Thoracoabdominal Viscera *In Situ*

Several gross observations should be made before the viscera are disturbed. The presence of fluid, exudates or fibrin tags within the thoracoabdominal cavity should be noted (minimal fluid is present in health). Air sac remnants can be examined further for opacity related to bacterial, chlamydial or fungal infection. Aspergillosis is observed commonly in the abdominal air sacs and appears as a velvet-like yellow to green mat (see Color 22). A small amount of fat may be observed normally in the abdomen, around the cloaca and within the coronary groove. Excessive fat may be present in obese companion birds, while serous (gelatinous) atrophy of fat may occur with inanition. The pericardial sac should be relatively transparent and contain little measurable fluid (Color 14.25). A white chalky discoloration may indicate visceral gout from urate deposition (see Color 21). White streaks occasionally are present on the pericardial sac and epicardium following euthanasia by intracardiac injection. Petechial epicardial hemorrhages may represent septicemia or be observed as an agonal event (Color 14.26).

The liver is mahogany brown and bilobed, extending around the left and right margins of the heart. In psittacine birds, the right lobe is larger, occasionally giving it an asymmetric appearance (Color 14.9). A swollen, pale-yellow liver may be observed in severe hepatic lipidosis or may represent a normal finding in neonates that are mobilizing egg yolk (see Color 30). Diffuse yellow-orange discoloration of the liver may be observed in severe hemosiderosis, which occurs with some frequency in mynah birds. Multifocal white-to-yellow discoloration of the hepatic parenchyma suggests necrosis secondary to chlamydial, bacterial or viral infection (see Color 20). Large umbilicated lesions in the liver, especially in peafowl, are strongly suggestive of histomoniasis. Pallor of the hepatic parenchyma may be observed in severely anemic birds. The gallbladder should be examined if present (some birds lack a gallbladder), and the patency of the common bile duct should be determined if possible (Color 14.16).

The heart and great vessels are examined next. The epicardium should be examined for petechiation. The heart is roughly triangular with the length slightly exceeding the width. Any alteration in the size or shape (eg, globose shape) of the heart should be noted.

As the great vessels are examined, any changes in the size of the thyroid and parathyroid glands also should be recorded. These glandular structures are located at the thoracic inlet lateral to the syrinx and adjacent to the jugular veins and carotid arteries. Normal thyroid glands are small, oval and reddish-brown (Color 14.22). The parathyroid glands are very small and best distinguished microscopically. In dietary-induced secondary hyperparathyroidism, the parathyroid glands will appear as enlarged circular off-white to yellow structures (Color 14.29).

A small portion of the ventriculus may be observed ventral to the liver. Much of the caudal portion of this organ is obscured by the duodenal loop and pancreas. The proventriculus is located beneath the left liver lobe and may not always be visible unless severely dilated (Color 14.9).[4]

FIG 14.8 The syringeal area is a common location for pathologic lesions of the respiratory tract. This area should be carefully examined and the trachea (t) and syrinx (s) should be opened under sterile conditions to collect samples for bacterial, fungal or viral isolation in birds with respiratory sounds. Note the reduction in size of the primary bronchi as they leave the syrinx (arrows). The thoracic esophagus (e) is dorsolateral to the trachea at the level of the syrinx and then courses from right to left to connect to the proventriculus. (vs) = ventral syringeal and (ds) = dorsal tracheobronchial muscles.

Disease-induced alterations in gastrointestinal morphology usually are quite subtle grossly and may be limited to congestion, hemorrhage or gas-filled intestinal loops (this latter change also is observed commonly following a long postmortem interval). Gas-filled intestinal loops and discoloration due to altered intestinal contents or hemorrhage should be noted. On rare occasions, gastrointestinal lesions may be quite striking. Examples include gastrointestinal tract obstruction and impaction in pheasants with proliferative typhlitis secondary to *Heterakis isolonche* infestation, severe nematode or trematode infestations, surgically-induced visceral adhesions, marked proventricular distention in birds with neuropathic gastric dilatation and severe egg-related peritonitis (Color 14.2, 14.3).

In hens, the viscera are reflected on the left side of the dorsal thoracoabdominal cavity to examine the communication of the colon and oviduct with the cloaca. The cloacal bursa may be partially visualized, especially in juvenile birds.

Removal and Examination of the Viscera

The heart is removed by transecting the great vessels. At this time the thyroid and parathyroid glands also may be collected while they are easily identified.

The epicardial surface should be examined for changes in size, shape and color. The heart of small birds may be transected near the apex and placed whole in formalin solution. In larger birds, the heart may be opened to inspect the valves and chambers; sections of tissue may be taken for formalin fixation.

The tongue and oral mucosa should be inspected for erosions, ulcers, plaques or masses. The tongue is freed by transecting the hyoid apparatus and pharyngeal tissues in the intermandibular region. Gentle traction is applied to remove the tongue, esophagus, crop, trachea and thymus with attached large vessels. The thymus may appear as pale tan to gray lobules of tissue extending along the cervical fascial planes adjacent to the trachea. This organ undergoes involution as sexual maturity is reached. The distal trachea is transected below the syrinx, leaving the lungs for later dissection (Figure 14.8). The esophagus is transected just below the syrinx and lifted upward. The ligamentous attachments, air sacs, blood vessels and ureters (including the oviduct if present) are transected and the vent area is excised with an intact margin of skin. The entire gastrointestinal tract, along with the liver and spleen, is removed from the carcass. The adrenal glands, gonads and kidneys remain in the carcass.

The spleen may be found dorsally in the angle between the ventriculus and proventriculus (Color 14.8). It appears as a variably-sized, round to elongate, red-brown structure. It should be removed and examined. Swelling and tan discoloration suggest inflammation or infection (viral, bacterial, chlamydial or protozoal such as atoxoplasmosis). Cytologic imprints may be made and a small portion removed for microbiological culture; the remainder is fixed in formalin solution.

The liver, gallbladder (if present) and patency of the bile duct connections to the duodenum should be examined. Excess accumulation of bile may cause gross distention of the bile ducts. The liver is removed, and its color, size and texture are examined in more detail. The parenchyma is examined by making several transverse slices through the organ with a sharp knife or scalpel. Lesions are imprinted and appropriate specimens are fixed for histopathologic examination, and fresh tissue is retained for other ancillary tests (microbiologic culture or toxicologic analysis) as necessary.

Lobules of thymic tissue, if present, are preserved for histopathologic examination. The esophagus, crop and trachea should be opened and the luminal surfaces and contents examined. Any abnormalities such as hemorrhage, erosion or ulceration and plaques or masses should be noted and appropriate portions of tissue imprinted, preserved in formalin solution and retained for other analyses (see Color 22). The crop contents should be examined carefully, especially in cases of unexplained death where poisonous plants may have been ingested. Crop contents may be collected for analysis if toxicosis is suspected.

The proventriculus and ventriculus are opened and examined for surface erosions or ulcers and foreign bodies. The morphology of the ventriculus varies

CLINICAL APPLICATIONS

- Maximum necropsy information can be obtained only by following a systematic approach and using ancillary support services as needed to establish a definitive diagnosis.
- The final diagnosis is directly proportional to the quality of the specimens submitted and the information provided with them.
- A telephone call or fax to the diagnostic laboratory prior to performing the necropsy is a prudent measure to ensure correct specimen collection, preparation and handling.

with the species of bird and its diet. The ventriculus of seed-eating and omnivorous birds has a thick muscular wall, and the mucosa has a koilin lining (thick horny material) that is often bile-stained. In carnivorous and piscivorous birds, the ventriculus may be fusiform, thinner-walled and blend with the proventriculus.[14]

The intestine may be opened in large birds and inspected for luminal hemorrhage, erosions, ulcerations or parasites. Direct visualization of parasites is noted and intact organisms may be preserved in appropriate fixatives for later identification (see Table 14.4). Wet mounts of intestinal contents and mucosal scrapings should be examined microscopically to identify protozoa (giardia, cryptosporidia), parasite ova or merozoites (coccidia). In large birds, various portions of the intestinal tract may be excised and preserved for histopathologic examination. In tiny birds, the intestine may be fixed *in toto* without gross examination, but it should be cut into multiple sections to allow adequate penetration of the formalin fixative. Portions of intestine also may be retained in a sealable plastic bag for microbiologic culture.

The terminal colon and cloaca should be examined externally and internally. Patency of the colon, ureters and oviduct, if present, should be determined. In some species of birds, such as pheasants and peafowl, the ceca should be examined for the presence of inspissated exudates, masses, parasites or other lesions.

The bursa of Fabricius generally may be found associated with the dorsal wall of the cloaca. Grossly, this organ may resemble a large lymph node in young birds (see Figure 5.6). In older individuals, the bursa may have involuted and will be difficult to identify. Histopathologic examination of formalin-fixed cloacal tissue may allow identification of bursal remnants following involution.

In juvenile hens, the reproductive tract will be minimally developed. The ovary will be small and have a slightly granular appearance (see Colors 13, 29). Adult hens that are sexually quiescent or severely stressed may experience atrophy of the reproductive tract, resembling a juvenile hen. In sexually active hens, the oviduct is a prominent, large, off-white, flaccid, vascular, hollow tubular organ with a rugose luminal surface.[17] Egg binding may induce inflammation wherein the distal wall of the oviduct will appear thickened. The oviduct also may be the origin of adenocarcinoma, especially in budgerigars. Hens that have undergone stress may have the uterus and ovaries reduced in size to that of juveniles due to alterations in hormonal secretions.

Removal of the majority of the viscera permits inspection of the lungs *in situ*. Normal lungs are deep pink. The lungs should be examined for areas of discoloration or other abnormalities. A dark red, wet appearance of the lungs suggests pulmonary edema and hemorrhage, which may accompany acute pulmonary sarcocystosis, polytetrafluoroethylene (Teflon®) toxicosis, inhalation of noxious gases, carbon monoxide asphyxiation or necrotizing bacterial pneumonia (see Color 22). Fungal pneumonia may present as cavitating nodules, the walls of which have a velvety green lining.

Because avian lungs are attached to the dorsal ribcage, removal requires gentle traction along with blunt and sharp dissection (see Chapter 22). The lung parenchyma should be transected at 0.5 cm intervals (as with the liver) to look for occult lesions such as bronchial exudates, particulate debris and areas of consolidation or cavitation. In small birds, use of a magnifying loupe may facilitate identification of particulate debris in aspiration pneumonia.

Next, the kidneys, gonads and adrenal glands are inspected *in situ* (Color 14.10). These organs are removed as a single unit by careful dissection, especially in regard to removing the kidneys from the renal fossae of the synsacrum. The sacral plexus is embedded within the kidney, which makes removal of the kidneys difficult. Normal kidney tissue is dark red-brown. The renal parenchyma is examined for discoloration, pallor, swelling or masses or linear white foci that may indicate renal gout. Removal of the kidneys may be impossible in some small birds; however, this portion of the synsacrum may be removed from the carcass and fixed *in toto*. The tissue subsequently may be decalcified, pro-cessed, embedded in paraffin and sectioned *en bloc*.

The testes of male birds are elongate to cylindrical organs near the anterior portion of the kidneys (Color 14.13).[15] Juvenile testes are yellow due to interstitial cell lipid.[17] These organs undergo cyclic atrophy and enlargement in sexually mature individuals and may be quite large in breeding birds.[14] The testes of adult male birds appear large and are commonly white with a vascular surface. Some species of male birds have melanistic testicles.

Only the left ovary normally persists in psittacine hens (Figure 14.9). In some species (eg, some raptors),

FIG 14.9 In a normal psittacine hen, only the left ovary and oviduct are present. Occasionally, the right ovary (ro) and oviduct will also be present. Note the large follicle (f) and enlarged left oviduct (arrows) indicative of a reproductively active hen.

the ovaries are frequently bilateral. The juvenile left ovary appears yellow and granular, resembling a piece of fat.[15] Variably-sized, vascular, yellow follicles are present in sexually active hens (see Color 13, 29). The yellow color is imparted by variable quantities of yolk.[17] In some species of female birds, the ovary may be pigmented.

The adrenal glands are identified as small, round, yellow structures to the left and right of the midline at the cranial pole of the kidneys. Adrenal gland enlargement may be observed in chronically stressed birds.

The remainder of the carcass consists of the musculoskeletal, integumentary and nervous systems. Specimens of skin, feather follicles and feathers may be taken for histopathology if they have not already been obtained. Abnormal, newly emerging feathers and associated follicles provide the best diagnostic specimens. Sections of the uropygial gland may be taken from appropriate species if masses are palpated or observed.

Examination of Special Organs and Tissues

Examination of the nervous system and associated tissues is governed by the presence or absence of neurologic or ocular disease. Although the brain and ischiatic (sciatic) nerves are routinely obtained for histologic evaluation, the spinal cord, brachial and sacral nerve plexuses and eyes are obtained only if pathology is present.

Brain

The brain is relatively accessible and is frequently obtained for routine histopathologic examination (Figure 14.10). The brain may be removed by plucking the feathers from the head, incising the scalp and reflecting it. A sagittal incision is made through the calvarium using a pair of blunt-sharp scissors. Using a forceps or rongeurs, the bony calvarium is removed as necessary to expose the brain.

Before removing the brain from the calvarium, it should be inspected for congestion or hemorrhage. Depending upon the rapidity of death or method of euthanasia, agonal hemorrhage may be observed in birds following severe terminal motor activity. Agonal hemorrhage must be distinguished from antemortem head trauma if possible.[6,14] Greenish bruising is more typical of old hemorrhage. The brain may be removed from the calvarium by severing the cranial nerves from rostral to caudal (Figure 14.11). The optic tectum (a bony plate that covers the large optic lobes) may present a problem in removing the brain from psittacine birds. In hatchlings, the calvarium is soft and may be transected through the midline with a scalpel. The halves of the calvarium may be fixed *in toto* or one-half of the calvarium may be retained for culture.

Vertebral Column

If neurologic disease involves spinal cord or nerve roots, appropriate sections of the vertebral column or synsacrum may be identified, removed *en bloc* and fixed in formalin solution.[6] The pathologist subsequently can decalcify these tissues and section them with a knife or scalpel to discern subtle gross lesions. These tissue sections can be processed and examined microscopically to evaluate nervous tissue, bone and attached soft tissues.

Necropsy Examination

Color 14.22
Normal thyroid glands (arrows) appear as small, oval, red-brown structures adjacent to the carotid arteries. The parathyroid glands are present at the caudal pole of the thyroid gland but are normally minuscule.

Color 14.23
A greater than 20-year-old Rosella was presented with a history of feather dystrophy and exercise intolerance. The bird was DNA probe-positive for PBFD virus. The bird died shortly after presentation, and at necropsy the great vessels were noted to be hard, irregularly shaped and yellow. The vessels were partially calcified and the histologic diagnosis was atherosclerosis.

Color 14.24
Normal heart (h), liver (l) and lungs (lu) demonstrating the relationship of these organs in the cranial portion of the thoracic cavity. Note the pericardial sac (arrow) and the left and right hepatic peritoneal membranes (open arrows). The ostium (o) of the caudal thoracic air sac is also clearly visible through the transparent, contiguous wall of the cranial thoracic and caudal thoracic air sacs.

Color 14.25
A mature Moluccan Cockatoo was presented for an acute onset of lethargy, dyspnea and weakness. The PCV was 12, and a large quantity of blood was noted in the right axillary and neck region. The bird was given a blood transfusion but did not survive. Necropsy indicated a pale heart and liver, and a ruptured brachial artery. The pale heart is shown resting in an increased quantity of clear pericardial fluid.

Color 14.26
A male duck from a zoological collection was found dead in its enclosure. Necropsy findings indicated multifocal, petechial hemorrhage in the epicardium. *Pseudomonas* sp. was isolated from the heart blood. Multifocal, myocardial, petechial hemorrhage can be an indication of septicemia or can represent agonal hemorrhage. Note the syringeal bulla (arrows) that is an extension of the trachea found in some male ducks.

Color 14.27
Pericardial effusion (arrow) can occur from several bacterial or viral diseases. In this case, hydropericardium was associated with avian viral serositis in a Blue and Gold Macaw neonate.

Color 14.28
A wild-caught Ducorps' Cockatoo was presented with abnormal feather development. DNA probe testing of a blood sample confirmed the clinical diagnosis of PBFD. During routine necropsy, filariid worms (arrows) were removed from the right ventricle. The parasites were identified as a new species of filariid worms, *Chandlerella* sp. (courtesy of Ken Latimer).

Color 14.29
A mature, female Amazon parrot with a history of an all-seed diet was presented for evaluation. The hen had been a consistent egg producer for several years. The bird was provided cuttlebone that was seldom consumed. The bird flew into a wall and sustained multiple fractures. Radiographs indicated metabolic bone disease and egg-related peritonitis. Finding enlarged hyperplastic parathyroid glands (pt) suggested nutritional secondary hyperparathyroidism. The normal syringeal muscles (s), trachea (t), thyroid (th) and thoracic esophagus (e) can be visualized. Note how the thoracic esophagus passes dorsally to the syrinx at the level of the heart.

Color 14.30
Pericarditis can be caused by many bacterial, fungal or viral pathogens. In this Amazon parrot, the pericarditis with plaques was secondary to a gram-negative bacterial septicemia. Note the congestion of the liver.

Color 14.31
A 32-year-old Green-winged Macaw was presented for progressive weakness of several weeks' duration. The bird was recumbent, depressed and severely dyspneic. The bird died shortly after presentation. Necropsy indicated a pale, mottled heart. Histopathologic changes included atherosclerosis and myocardial fibrosis.

Necropsy Examination

Color 14.32
Lobules of normal thymic tissue (arrows) within fascial planes adjacent to the cervical musculature in a young cockatoo (courtesy of Ken Latimer).

Color 14.33
Fibrotic areas of pectoral muscle (arrows) secondary to the injection of enrofloxacin. Note the yellowish discoloration of the subcutaneous tissue (open arrow) associated with the area where the bird had been vaccinated with an oil-emulsion vaccine.

Color 14.34
Normal brain. The cerebral hemispheres and cerebellum are exposed following removal of the posterior aspect of the cranial vault. Note that the tissues are moist but there is no accumulation of fluid (courtesy of Kenneth Latimer).

Color 14.35
Subdural hemorrhage (arrows) can be an indication of trauma or can occur as an agonal change.

Color 14.36
A mature Amazon parrot was presented with a progressive onset of ataxia and severe depression. The WBC was markedly elevated, and the bird did not respond to antibiotics and supportive care. Severe congestion and hemorrhage in the brain were caused by bacterial encephalitis.

Color 14.37
A ten-year-old Barn Owl was presented for a progressive head tilt and ataxia. Physical examination revealed numerous gram-negative rods in a necrotic discharge from the right ear canal. Auditory evoke potentials indicated a centralized inflammatory disease. Necropsy indicated an internal and external bacterial ear infection with progression to the brain.

Color 14.38
Acuaria skjabini is a common nematode parasite in finches maintained in aviaries in Australia. The nematode burrows into the koilin layer of the ventriculus, causing hypertrophy (arrows). A normal ventriculus is shown on the right to show the marked hypertrophy in the affected ventriculus (courtesy of Patricia Macwhirter).

Color 14.39
Proliferative, necrotic lesions (arrows) in the crop of a finch. These "turkish towel"-type lesions can be caused by candidiasis or aspergillosis.

Color 14.40
Proventricular dilatation (arrow) in a canary infected with megabacteria.

Color 14.41
a) Esophageal necrosis and diphtheritic membranes in a North American Black Duck caused by duck virus enteritis (duck plague) (courtesy of R. J. Montali). **b)** Necrotic, hemorrhagic bands of lymphatic tissues in the small intestines of a duck with duck virus enteritis (courtesy of John H. Olsen).

Color 14.42
Proventricular nodules in an Anseriforme caused by *Tetrameres* sp. (courtesy of R. J. Montali).

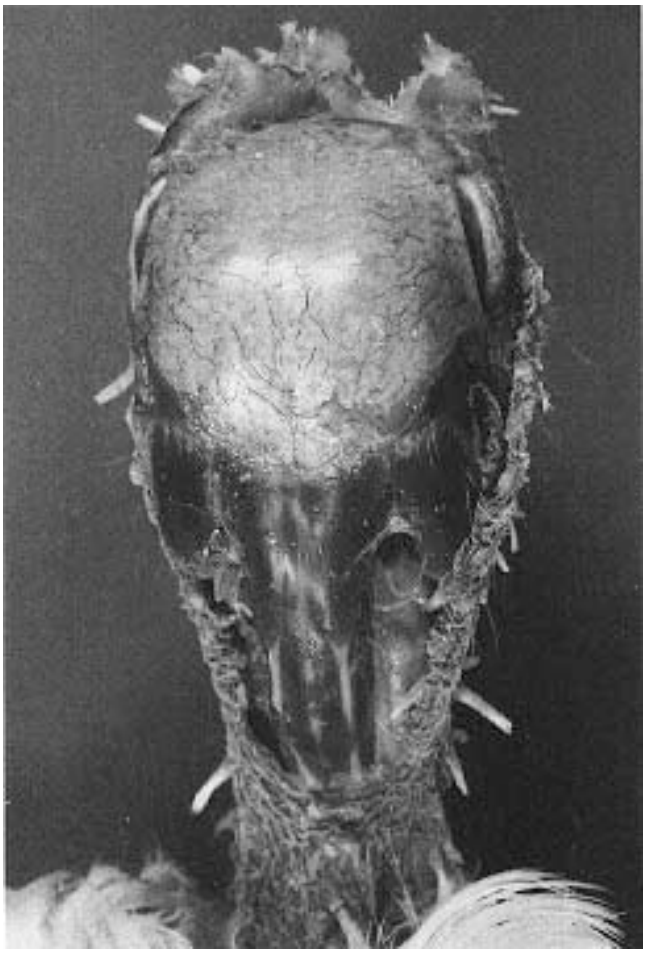

FIG 14.10 The scalp has been incised and reflected to expose the posterior portion of the skull.

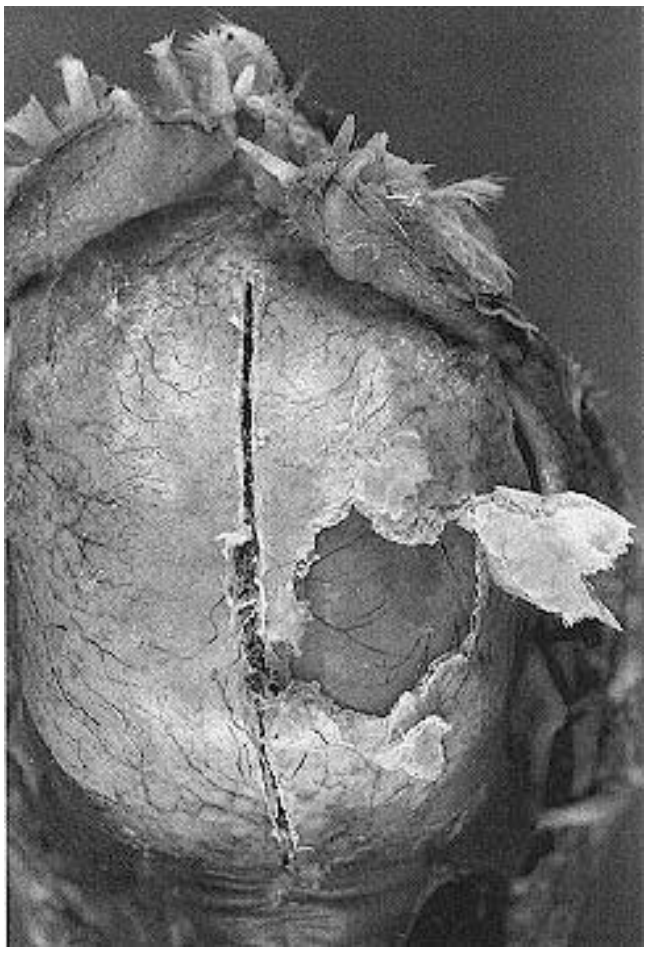

FIG 14.11 A midline incision has been made through the cranial vault using blunt-sharp scissors. The cranium is then peeled away to expose the brain.

Brachial Plexus

The brachial plexus lies lateral to the thyroid gland in the vicinity of the subclavian artery (see Anatomy Overlay). Although the plexus commonly is inspected at necropsy, dissection and collection of tissues is limited except in cases of suspected neurologic damage from penetrating wounds, inflammation, neoplasia or trauma resulting in avulsion of the plexus.

Sacral Plexus

The sacral nerve plexus should be examined carefully in instances where pelvic limb paresis or paralysis has been noted (see Anatomy Overlay). This plexus is best inspected when removing the adrenal glands, gonads and kidneys because it is embedded in the midportion of the kidney just anterior to the ischiatic artery (Figure 14.12). The ischiatic nerve, which innervates the pelvic limb, may be damaged in severe nephritis or renal neoplasia where compression or infiltration of the nerve occurs.

Ischiatic (Sciatic) Nerve

In instances of pelvic limb paresis or paralysis, the ischiatic nerve should be examined grossly and histologically. The ischiatic nerve can be found beneath the medial thigh muscles caudal to the femur (see Anatomy Overlay).

Removal of the Eyes

If intraocular disease is present, the eye(s) should be removed from the orbit(s) for histologic evaluation. This process is slightly more difficult in birds because of the relatively large size of the eye. The eyeball is removed by sharp and blunt dissection of orbital soft tissues and transection of the optic nerve.

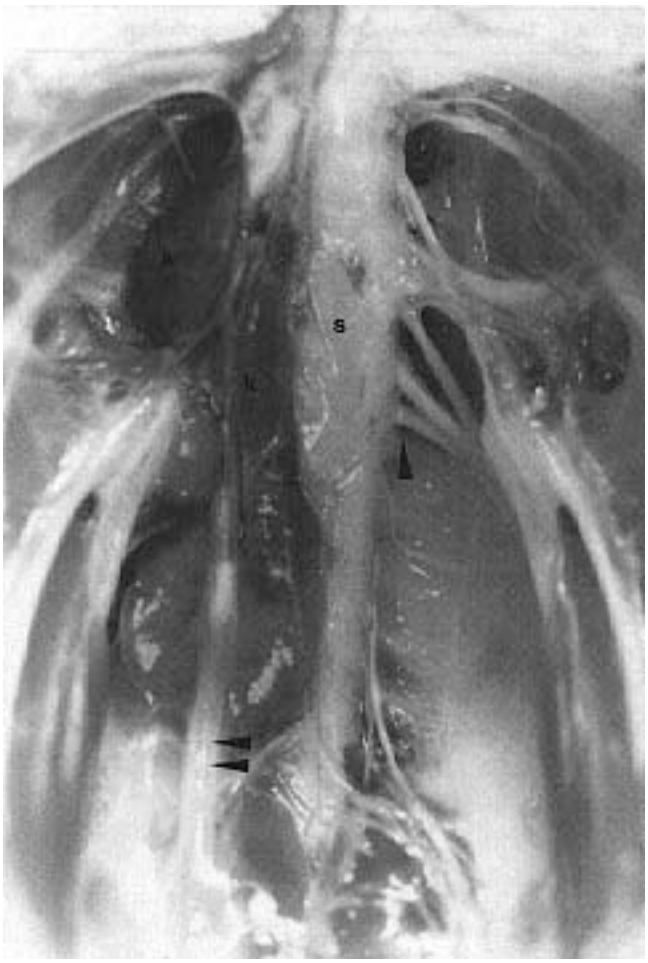

FIG 14.12 The sacral plexus (arrow) should be carefully examined in all cases involving weakness or ataxia (unilateral or bilateral) of the pelvic limbs. The sacral plexus and lumbosacral spinal column should be submitted for histopathology in these cases as well as those with clinical changes suggestive of neuropathic gastric dilatation. The left kidney has been removed to show the relationship of the kidneys and sacral plexus. The right kidney (k) and ureter (double arrow) are in their normal anatomic locations lateral to the spine (s).

Other Cranial and Skeletal Tissues

The nares, cere, beak, choanal slit, infraorbital sinus and ears should be examined. Abnormal tissues can be collected for formalin fixation or ancillary testing. Joints of the wings, legs and feet should be opened and examined. Articular surfaces should be off-white, smooth and glistening. If exudates are present, appropriate specimens should be taken for cytologic and microbiologic examination. White, chalky deposits may represent urate deposition. The presence of urate crystals can be confirmed by microscopic examination of cytologic preparations (under polarized light if available). Urate crystals will appear as refractile needles. Appropriate bony lesions may be collected with a dovetail saw, fixed in formalin, decalcified and processed for histopathologic examination.

Collection of Bone and Bone Marrow

Detailed examination of portions of the skeletal system may be necessary in instances of fractures, metabolic bone disease, osteomyelitis, arthritis or synovitis and anemia or blood cell dyscrasia. Collection of various skeletal tissues ultimately may be essential for a definitive diagnosis.

In the case of fractures, osteomyelitis and arthritis or synovitis, the tissues of interest may be localized with the assistance of survey radiographs. Blunt and sharp dissection will allow gross observations of these tissues. Callus formation, if present, should be noted and specimens for culture or cytology can be taken after the site is exposed by dissection. Cytology preparations will be useful to characterize inflammatory infiltrates, identify pathogens or identify urate crystals.

Joints can be disarticulated with a scalpel, knife or scissors. The joint capsule, ligaments and tendons can be inspected grossly. Articular surfaces should be examined for erosions of cartilage, eburnation of subchondral bone, tags of fibrin or the presence of exudates or hemorrhage. Rongeurs or a small dovetail saw can be used to excise portions of bone *en bloc* for histopathologic examination.

If the bird is anemic based upon laboratory studies or gross necropsy examination (pale liver and kidneys suggest anemia) or has a blood cell dyscrasia, bone marrow also should be examined. When bone marrow examination is necessary, it should be collected as soon as possible after death since bone marrow cells undergo rapid degeneration. Because many bones of the bird are pneumatized (including those of the thoracic girdle, humerus, sternum, sternal ribs and occasionally femur), the tibiotarsus or vertebral rib(s) should be used for collection. Because the tibiotarsus is larger, more marrow can usually be obtained for both cytology and histopathology. To obtain tibiotarsal marrow, the integument over the tibiotarsus is plucked and the skin is incised and reflected. The underlying musculature is dissected to reveal the shaft of the tibiotarsus. Using rongeurs, a portion of the shaft is excised. The cortex is cracked and small amounts of marrow are teased or gently squeezed from the marrow cavity. Smears or squash preparations of bone marrow are made for cytologic examination. Additional small segments of cortical

bone and marrow are taken for histologic examination. The cortex should be cracked to promote rapid penetration of fixative into the tissues.

Whole Carcass Submission

In instances where the entire carcass is extremely small, such as embryos, nestlings or very small adult birds, the entire carcass may be submitted for histologic examination. This is best accomplished by opening the thoracoabdominal cavity, gently separating the viscera and fixing the entire carcass in formalin solution.

Specimen Collection for Ancillary Testing

Ancillary testing often is essential to confirm or establish a definitive diagnosis. Tissue specimens should be collected routinely for histopathologic evaluation; however, additional specimens (eg, swabs for bacterial culture, fresh tissues for bacterial culture and virus isolation, crop contents for toxicologic analysis) are obtained as necessary based upon historical, clinical and necropsy findings. These latter specimens can be submitted along with the formalin-fixed tissues if the need for additional laboratory testing is obvious or they may be held under appropriate conditions for later submission if required. It is better to have taken specimens for ancillary testing and not need them, than to need the specimens and not have taken them. The following information is designed to expedite specimen procurement and handling to maximize the results obtained. A telephone call to the diagnostic laboratory prior to performing the necropsy is a prudent measure to ensure correct specimen collection, preparation and handling.

Histopathology

Tissue specimens for histopathology should be preserved in neutral-buffered ten percent formalin solution. Buffered formalin is necessary to prevent acid hematin formation, which can obscure microscopic examination. Furthermore, adequate preservation of tissues requires rapid and complete penetration of the fixative. This is best accomplished by procuring thin (four to five mm thick) slices of tissue. Excessively thick (one cm thickness) tissue slices or tissues that float (gas-filled intestine, fatty liver, lung) when immersed in formalin solution often do not fix and become autolytic. Representative tissue specimens from all organ systems should be collected (Table 14.1). When specific lesions are observed at necropsy, the tissue specimen collected should include a small margin of normal tissue adjacent to the lesion.

TABLE 14.1 Tissues Routinely Collected for Histopathology

Skin (including feathers, follicles)	Crop	Pancreas
Trachea	Proventriculus	Ovary and oviduct (female)
Lung	Ventriculus	Testis (male)
Air sac	Small intestine	Pectoral muscle
Heart	Large intestine	Bone marrow
Kidneys	Ceca (if present)	Cloacal bursa
Thyroid glands	Cloaca	Thymus
Parathyroid glands	Spleen	Brain
Adrenal glands	Liver	Ischiatic (sciatic) nerve
Esophagus	Gall bladder (if present)	

Selection of additional tissues will depend upon gross lesions observed at necropsy.

Specimens should be shipped to the laboratory in leak-proof containers that are well packaged. To decrease shipping weight, tissues that have been fixed in formalin solution for at least 24 hours can be wrapped in a formalin-soaked gauze square that is placed into a sealable plastic bag for shipment. In the authors' experience, a complete set of necropsy tissues provides the best diagnostic material. Because cost is often a consideration when submitting histopathologic specimens to the laboratory, the practitioner should consult a veterinary pathologist concerning the tissues to be submitted in a particular case. The remaining fixed tissues can be held for additional study if needed.

Hematologic and Cytologic Specimens

Preparation of blood and cytology specimens for microscopic examination is detailed in Chapters 9 and 10.[2] Smears of blood or exudates may be prepared in a routine manner by the wedge technique. Tissue scrapings may be smeared onto a clean glass slide, or squash preparations may be made if particles of tissue are present. Tissue imprints are prepared by blotting the tissue specimen on an absorbent surface (filter paper or paper towel) to remove excess blood and tissue fluid. The tissue specimen is then gently touched to a clean glass slide several times or vice versa. Imprints of liver and spleen can be prepared on a single slide and submitted for special stains (eg,

Macchiavello's or Gimenez staining for chlamydiosis, acid-fast staining for mycobacteriosis or fluorescent antibody staining for chlamydiosis or herpesvirus infection). Intestinal mycobacteriosis also may be diagnosed using cytologic imprints. Swab specimens are properly prepared by gently rolling the swab the length of the glass slide. Three such passes may be made on a single slide from top to bottom. All specimens are air-dried. If they are not stained before examination or submission to the diagnostic laboratory, they should be protected from excessive moisture or formalin fumes, which could cause cellular lysis or interfere with staining, respectively.

Microbiology

Microbiology includes culture and identification of bacteria, viruses and fungi as well as certain serologic assays to detect the presence of or exposure to these pathogens. Specimens procured for analysis may include culture swabs, fresh tissues, body fluids or exudates, cytologic smears and imprints (eg, fluorescent antibody staining for chlamydia and herpesvirus) and serum. These specimens are perishable and should be shipped to the laboratory without delay. Next-day courier service is recommended.

Fresh tissues submitted for bacterial culture should be at least two cubic centimeters to yield accurate results. At the laboratory the surface of the tissue is seared with a heated spatula to sterilize it, and a loop is inserted through the seared area into the center of the specimen to collect tissue for culture. If the tissue is too small, the entire specimen (including bacteria) is destroyed during the searing step, and a false-negative culture result is obtained. Tissues for routine bacterial culture can be placed in sterile, sealable plastic bags and submitted immediately or frozen if a delay of more than 12 to 24 hours before culturing is expected. If unusual pathogens are suspected, the diagnostic laboratory should be consulted regarding the best means of handling the tissue to optimize culture results.

Specimens for bacterial culture also may be obtained aseptically using swabs. Products such as Culturettes® are preferred because they are self-contained, minimize the possibility of specimen contamination and contain a transport medium that maintains organism viability while preventing saprophytic bacterial overgrowth.

Fresh tissues (especially liver, spleen, kidney, lung and brain) are collected for viral isolation. The selection of tissues for viral isolation depends in part upon the organ system affected. Tissue specimens may be placed in sealable plastic bags and frozen prior to shipment to the laboratory. If tissues are not sent to the laboratory immediately, they may be stored in the freezer until needed for diagnostic testing. After the definitive diagnosis has been made, remaining tissues can be discarded.

Tissue specimens for fungal culture and identification may be collected, placed in sealable plastic bags and refrigerated or frozen until analyzed. The choice of tissues is variable, depending upon the extent of infection.

Parasitology

Fecal flotation for detection of parasite ova is performed frequently as a portion of the minimum database to assess a patient's medical status. Additional fecal specimens may be taken for analysis at necropsy, especially in those patients with diarrhea, where protozoal infection is a consideration. Also, intact parasites such as cestodes, trematodes, nematodes or arthropods may be taken for specific identification when encountered in exotic birds or observed in unusual locations. Proper fixation of these parasites is essential for successful identification by a veterinary parasitologist.[20] Preferred fixatives for preservation of fecal material and parasites are detailed in Tables 14.3, 14.4.

Wet mounts of feces or a feces-saline slurry should be examined within minutes of death to detect organisms such as *Giardia* sp., which are identified by their characteristic rolling movement. Following initial examination, a small drop of Lugol's iodine can be added to kill and stain protozoa and their cysts for more detailed examination. These specimens are perishable and generally will not survive shipment to the diagnostic laboratory. Intestinal scrapings or imprints, which may be air-dried, stained and examined in-house or shipped unstained to the laboratory for examination, may be useful to diagnose coccidiosis, atoxoplasmosis and cryptosporidiosis.

Toxicology

Toxicologic analysis is generally labor-intensive, requires sophisticated analytical equipment and is often expensive. The clinician should have some suspicion of the substance involved before toxicologic analysis is requested, because tissue handling and the specimen(s) required vary with the type of toxi-

cologic analysis performed. A veterinary toxicologist or diagnostic laboratory should be contacted to ensure that the proper samples are collected and submitted for analysis. In addition, a particular laboratory may not perform a desired test or may not be equipped for analysis of small tissue specimens.

The most commonly ingested toxins in companion and aviary bird practice are heavy metals (eg, zinc, lead), aflatoxin-contaminated feeds and various ornamental houseplants. The most commonly inhaled toxins include the fumes of polytetrafluoroethylene produced from over-heated cooking pans or utensils and some varieties of red heat lamps.[1,9,11,13,18,24,28] The following discussion briefly covers sample submission for toxicologic analysis, especially for identification of certain heavy metals and aflatoxins (see Chapter 37).

Heavy Metals

Heavy metal toxicosis is most frequently associated with ingestion of zinc by companion or aviary birds and lead by foraging waterfowl. Sources of excess zinc include ingestion of particulate material from homemade galvanized wire mesh enclosures and ingestion of pennies thrown into captive bird displays.[9,13,23] United States pennies minted since 1982 are essentially copper-plated zinc wafers. Lead poisoning is usually due to ingestion of lead shot by waterfowl during normal feeding activities.[18] However, lead poisoning in companion birds may result from chewing leaded windows, lead-containing toys or costume jewelry, lead pellets and fishing sinkers.[32] Suspicion of heavy metal toxicosis may be based upon observing metallic foreign bodies in the crop and gizzard on routine survey radiographs or at necropsy.

Heavy metal toxicosis is best detected using graphite furnace atomic absorption spectrophotometry, which requires a small sample volume. Using this technique, quantitation of lead requires submission of 250 µl of blood in heparin or one-half gram each of liver and kidney. Quantitation of zinc requires 250 µl of serum (avoid hemolysis) or one-half gram each of liver and kidney. The above specimens may be submitted refrigerated or frozen. Blood and serum should be submitted in screw-cap plastic containers or stoppered test tubes. Control specimens are helpful in evaluating results because reference values have not been established for most birds. Liver and kidney specimens may be submitted in sealable plastic bags.

Aflatoxins

Aflatoxins B_1, B_2, G_1 and G_2 are metabolites of *Aspergillus flavus*. These substances may form in improperly stored feed and act as potent hepatotoxins. They may be identified in feed or tissue specimens using thin-layer chromatography or high performance liquid chromatography. An ELISA test is available for identification of aflatoxin B_1. Identification of aflatoxin in foodstuffs requires submission of 50 to 100 g of feed. The feed should be well mixed to prevent sampling errors, and should be derived from the same lot of material fed before the onset of disease. Detection of aflatoxin residues in tissues requires 100 g of fresh or frozen liver. Samples for analysis should be placed in sealable plastic bags. Although not ideal, tissues from several dead birds can be pooled for analysis if necessary.

Poisonous Plants and Chemicals

Suggestion of plant-induced toxicosis may be based upon the medical history and observation of crop contents. Although large lists of potentially toxic plants have been published, recent publications indicate that development of toxicosis is dependent on the species of bird, portion of plant ingested and season of plant growth.[1,8,28] Diagnosis of plant alkaloids or chemical-induced toxicosis should be pursued on an individual basis. A veterinary toxicologist should be consulted concerning appropriate specimens and handling prior to analysis.

Products Mentioned in the Text

b. Whirl-Paks, Fort Atkinson, WI

TABLE 14.2 Fixative Solutions for Tissue Specimens[27]

- **Neutral-buffered 10% formalin solution:** This solution is used as a common fixative to preserve tissue specimens for histologic examination. Proper fixation requires a ratio of one part tissue to 10-20 parts fixative solution.

Concentrated formaldehyde (37%)	100 ml
Distilled water	900 ml
Sodium phosphate monobasic, monohydrate	4.0 g
Sodium phosphate, dibasic, anhydrous	6.5 g

- **Carson's modified Millong's phosphate-buffered formalin:** This solution may be used for routine preservation of tissue specimens for both histopathology and electron microscopy. Proper fixation requires a ratio of one part tissue to 10-20 parts fixative solution.

Concentrated formaldehyde (37%)	100 ml
Deionized water	900 ml
Sodium phosphate monobasic	18.6 g
Sodium hydroxide	4.2 g

TABLE 14.3 Fixative Solutions for Fecal Material[20]

The following fixatives are intended for preservation of fecal material for storage or mailing to the diagnostic laboratory. Comments on the usefulness of each fixative solution follow.

- **PVA fixative:** This fixative is recommended because stained preparations of fecal material subsequently can be made for identification of protozoa.

  PVA, Elvanol 71-24 . . . . . 10.0 g
  95% ethanol . . . . . 62.5 ml
  Mercuric chloride, saturated aqueous . . . . . 125.0 ml
  Glacial acetic acid, concentrated . . . . . 10.0 ml
  Glycerin . . . . . 3.0 ml

  Mix all liquid ingredients thoroughly. Add the PVA powder without stirring and allow to soak overnight in a sealed beaker. Heat solution slowly to 75°C, remove from heat and swirl for 30 seconds until a homogeneous, slightly milky solution is observed. Using applicator sticks, mix approximately 1 g feces with 7-9 ml fixative and store in a labeled brown bottle.

- **10% formalin solution:** This fixative is used primarily to preserve ova for identification. Stained smears cannot be made for identification of protozoa.

  Concentrated formaldehyde (37%) . . . . . 100 ml
  Deionized water or 0.85% saline . . . . . 900 ml

  Best preservation is achieved by mixing 1 part feces with 10-20 parts of hot (60°C) fixative.

- **MIF preservative:** Fecal specimens may be stored indefinitely in MIF solution and ova may be harvested by common concentration techniques. This fixative is useful for large surveys where fecal materials are collected from many animals over a long period of time.

Solution A (store in a brown bottle):

  Distilled water . . . . . 50 ml
  Concentrated formaldehyde (37%) . . . . . 5 ml
  Thimerosal (tincture of merthiolate, 1:1,000) . . . . . 40 ml
  Glycerin . . . . . 1 ml

Solution B (Lugol's solution; good for several weeks in a tightly capped bottle):

  Distilled water . . . . . 100 ml
  Potassium iodide crystals . . . . . 10 g
  Iodine crystals (after above crystals dissolve) . . . . . 5 g

Combine 9.4 ml of solution A with 0.6 ml of solution B just before use in a small vial. Add feces (up to 1 g) and mix thoroughly. If the suspension is allowed to sit undisturbed for 24 hours, 3 well-defined layers will be apparent. The microscopic specimen is collected from the interface and bottom layers using a disposable Pasteur pipette.

TABLE 14.4 Fixative Solutions for Specific Parasites

- **Trematodes and Cestodes:** Platyhelminths may be fixed in 10% neutral-buffered formalin solution or alcohol-formalin-acetic acid mixtures. The parasites should be flattened under a slide and coverslip during fixation. Fixatives are best used hot (60°C) for more rapid penetration.

Alcohol-formalin-acetic acid fixative (Galigher's fixative):

  Concentrated formaldehyde (37%) . . . . . 10 ml
  95% ethanol . . . . . 70 ml
  Distilled water . . . . . 15 ml
  Glacial acetic acid, concentrated . . . . . 5 ml

- **Nematodes:** Living nematodes should be placed in boiling (60-63°C) alcohol glycerin fixative to rapidly kill the parasites and prevent contraction of the specimen. Nematodes can remain in this fixative indefinitely.

Alcohol-glycerin fixative:

  95% ethanol . . . . . 70 ml
  Distilled water . . . . . 25 ml
  Glycerin . . . . . 5 ml

- **Arthropods:** Arthropods can be preserved in 70% ethanol or 70% isopropyl alcohol solutions (formalin is unsatisfactory for arthropod fixation).

TREATMENT REGIMENS

CHAPTER

15

SUPPORTIVE CARE AND EMERGENCY THERAPY

Katherine E. Quesenberry
Elizabeth V. Hillyer

Knowledge of the principles and techniques of supportive care and emergency medicine is necessary for the successful medical management of avian patients. The basic concepts of emergency and supportive care of small animal medicine apply to birds, but modifications must be made to compensate for their unique anatomy and physiology. Supportive care including fluid therapy, nutritional support, and heat and oxygen supplementation is critical to both emergency and maintenance therapy.

Emergencies of many different types are seen in avian medicine. A common emergency is the extremely debilitated, cachectic, chronically ill bird that is too weak to perch or eat. Because certain syndromes are more common in certain species and at certain ages, the signalment of the bird is helpful in establishing a rule-out list. Recently obtained birds frequently present with acute infectious problems, including chlamydiosis and viral diseases.

Neonates that are being hand-fed commonly suffer from management-related problems (eg, crop burns, nutritional deficiencies) and certain fungal, bacterial and viral diseases such as candidiasis, gram-negative ingluvitis and avian polyomavirus. Birds that are long-term companion animals are more likely to have chronic infectious diseases such as aspergillosis, chronic nutritional diseases or toxicities. Egg binding and egg-related peritonitis frequently occur in companion budgerigars and cockatiels. Aviary birds can have a variety of infectious, metabolic, toxic and nutritional problems. Traumatic emergencies are common in all types of birds.

Critically sick or injured birds are often too weak for an extensive examination when first presented. Birds that are on the bottom of the cage and dyspneic need immediate medical attention with an organized, efficient approach to stabilization therapy. Physical examination, diagnostic tests and treatments should be performed in intermittent steps to decrease restraint periods and reduce stress.

Emergency Stabilization

Although each bird should be evaluated individually, some basic guidelines for emergency diagnostic testing and treatment can be followed. The bird should be observed carefully in its enclosure before handling, to assess the depth and rate of breathing. Birds with airway obstruction or severe respiratory disease are usually extremely dyspneic. Birds that are septicemic, in shock or weak from chronic disease may also have labored breathing. If respiration is rapid or difficult, the bird should be placed immediately in an oxygen cage. This is usually less stressful than using a face mask, especially if the bird is refractory to restraint. While the bird is allowed to stabilize, a complete history can be obtained from the owner, and a diagnostic and therapeutic plan based on the history, clinical signs and the initial physical findings can be formulated.

If the bird can be weighed without undue stress, an accurate pretreatment weight should be obtained. Otherwise, drug dosages are calculated based on an estimate of the body weight for the species (see Chapter 30). The most important treatments must be given first. If the bird shows any signs of stress during restraint, it may be placed back in oxygen or in a quiet enclosure until it is stable. Alternatively, the bird can be given oxygen by face mask while treatments are administered.

Some veterinarians prefer to use isoflurane anesthesia when treating very weak, dyspneic or fractious birds. For gradual induction in critically ill patients, low isoflurane concentrations (0.25%) are slowly increased to 1.5% or 2.5% over two to five minutes. Once the bird is anesthetized, lower maintenance concentrations (0.75% to 2%) can be used. Birds can be maintained with a face mask or intubated.

The use of anesthesia allows several procedures to be performed within a few minutes, including collection of a blood sample, placement of a catheter or air sac tube and radiographs. For each bird, the risk of anesthesia must be considered and weighed against the risks of stress associated with manual restraint. If anesthesia is chosen for restraint, the episode should be of short duration and the bird must be carefully monitored.

Pretreatment blood samples are valuable if appropriate to obtain. If intravenous fluids are given, a sample can be obtained through a butterfly catheter in the jugular vein immediately before fluid administration. The bird should be evaluated for anemia before blood is withdrawn. If the conjunctiva and mucous membranes appear pale, the packed cell volume (PCV) should be determined by taking a small blood sample from a toenail clip. If the PCV is 15% or less, collecting blood for a full biochemistry analysis or complete blood count can be life-threatening. Collecting a pretreatment blood sample is usually too stressful in extremely dyspneic birds unless anesthesia is used for restraint.

While the bird is resting after the initial treatments, necessary diagnostic samples collected during the restraint period (eg, fecal or crop cultures, chlamydia test, blood work) can be evaluated. Radiographs are usually postponed until the bird is stable. If radiographs are essential for establishing a correct diagnosis and initiating treatment, isoflurane anesthesia can be used to ensure that diagnostic radiographs are safely obtained.

Fluid Replacement Therapy

Fluid Requirements

The daily maintenance fluid requirement for raptors and psittacine birds has been estimated at 50 ml/kg/day (5% of the body weight).[42] This estimate is appropriate clinically for most companion and aviary bird species. However, water consumption may vary from 5 to 30% of body weight per day in many free-ranging species. The amount of water needed is generally inversely related to body size[3] and can also vary according to age, reproductive status, dietary intake and the type of foods consumed (Table 15.1).

TABLE 15.1 Variance in Water Intake

Adult chickens	5.5%	bw/day[15]
Cockatiels	5-8%	bw/day
Growing chickens	18-20%	bw/day
Laying hens	13.6%	bw/day[63]

An estimate of hydration status is based on the clinical signs and history. The turgescence, filling time and luminal volume of the ulnar vein and artery are good indicators of hydration status.[1] A filling time of greater than one to two seconds in the ulnar vein indicates dehydration greater than seven percent. Severely dehydrated birds (ten percent) may have

sunken eyes and tacky mucous membranes. The skin of the eyelids may tent when pinched.

As for mammals, anemia or hypoproteinemia can affect the accuracy of a PCV or total solids in detecting dehydration (Table 15.2).

TABLE 15.2 Findings with Dehydration[31,33]

Increased PCV	15 to 30%
Increased total solids	20 to 40%
Increased plasma urea	6.5 to 15.3 x normal

Changes will vary with the degree of dehydration.

Most birds presented as emergencies have a history of inadequate water intake and can be assumed to be at least five percent dehydrated. An estimation of the fluid deficit can be calculated based on body weight:

Estimated dehydration (%) x body weight (grams) = fluid deficit (ml)[18]

Half of the total fluid deficit is given over the first 12 to 24 hours along with the daily maintenance fluid requirement. The remaining 50% is divided over the following 48 hours with the daily maintenance fluids.

Lactated Ringer's solution (LRS) or a similar balanced isotonic solution warmed to 100.4° to 102.2°F (38° to 39°C) is recommended for fluid replacement and shock therapy. Using warm fluids is particularly important with neonates and with intravenous or intraosseous administration of fluids for hypothermia or shock.[1]

The exact fluid requirements of birds in shock are difficult to determine. In mammals in septic shock, a fluid volume of 0.5 to 1.5 times the estimated blood volume may be needed to correct peripheral vasoconstriction. Thirty minutes after treatment, only 25% of administered isotonic crystalloid fluids remains in the vascular compartment.[21] The remaining 75% redistributes to the interstitial fluid compartment. Consequently, circulatory improvement may be transient, requiring additional fluid therapy to prevent recurrence of hypotension and vasoconstriction.

As illustrated by this example, hemodilution is the primary limitation to crystalloid fluid therapy, making administration of colloids or blood necessary for effective shock therapy. Synthetic colloid solutions (dextran, hetastarch) have not been used to any extent in birds. These solutions contain large molecules that do not cross the endothelium and remain in the intravascular fluid compartment. Colloid solutions draw fluid from the interstitial fluid compartment into the intravascular space and are more effective blood volume expanders than crystalloids.[1,21] They are particularly useful in restoring circulating blood volume without aggravating hypoproteinemia or causing pulmonary edema in animals with low oncotic pressure and hypoproteinemia.

There is evidence that hemorrhagic shock does not occur in birds.[64] Severe blood loss is tolerated much better in birds than in mammals, especially in flighted birds. This tolerance is the result of an increased rate of absorption of tissue fluids to replace lost blood volume and baroreceptor reflexes, which maintain normal blood pressure. Prostaglandins, which potentiate shock in mammals, have been shown to have no effect in chickens.

Route of Fluid Therapy

Supplemental fluids can be given orally, subcutaneously, intravenously or by intraosseous cannula (Figure 15.1). Fluids can be given orally for rehydration and maintenance in birds that are mildly dehydrated. Oral rehydration is often used for waterfowl and other large species in which administration of intravenous or subcutaneous fluids is difficult. In pigeons, administration of an oral five percent dextrose solution has been shown to be more effective for rehydration than oral administration of lactated Ringer's solution.[33] This effect may be the result of glucose causing a more rapid uptake of water from the intestinal tract. Gatorade[w] is used by some veterinarians for oral rehydration and fluid maintenance. For effective rehydration, oral fluids need to be readministered within 60 to 90 minutes of the first treatment. Mixing oral fluids with pysillium[a] may increase fluid and calcium absorption from the intestinal villi. Oral fluids should not be given to birds that are seizuring, laterally recumbent, regurgitating, in shock or have gastrointestinal stasis.

Subcutaneous administration is used primarily for maintenance fluid therapy. The axilla and lateral flank areas are commonly used for injection. The intrascapular area is preferred by some clinicians in young birds that may be difficult to restrain for flank injection. The area around the neck base should be avoided because of the extensive communications of the cervicocephalic air sac system. A small (25 to 27 ga) needle is used to prevent fluids from leaking from the injection site. The total volume of fluids should be given in several sites (5 to 10 ml/kg/site) to prevent disruption of blood flow and subsequent poor absorption.[1] Subcutaneous fluids are less effective than intravenous or intraosseous fluids for shock therapy

FIG 15.1 Subcutaneous fluids can be administered in the lateral flank, axilla or intrascapular region (shown here) in cases of mild dehydration (five percent) to provide maintenance fluids. The area of the base of the neck should be avoided because of the cervicocephalic air sacs. Subcutaneous fluids are generally ineffective in cases of severe dehydration or shock.

because of peripheral vasoconstriction. Subcutaneous fluids may pool in the ventral abdominal area causing hypoproteinemia, overhydration or poor absorption. If ventral abdominal edema is noted, subcutaneous fluid administration should be decreased or discontinued.

Intravenous fluids are necessary in cases of shock to facilitate rapid rehydration. Intraosseous cannulas or use of the right jugular vein are the best access points to the peripheral circulation. Dyspneic birds and those with distended, fluid-filled crops should be carefully handled to prevent regurgitation and aspiration. Injection of a large fluid volume into the ulnar or metatarsal veins is difficult and frequently results in hematoma formation.

FIG 15.2 IV fluids and drugs can be slowly administered through a butterfly catheter in the right jugular vein. The biggest disadvantage to this technique is that fluids should not be given faster than 10 ml/kg over a five- to seven-minute period necessitating prolonged restraint for fluid administration (courtesy of Kathy Quesenberry).

A butterfly catheter (25 ga) with 3.5-inch tubing is ideal for fluid administration in medium-sized to large birds (Figure 15.2). A 27 ga needle can be used in small birds. The catheter allows pretreatment blood collection and "slow" administration of fluids, antibiotics or other medications with one venipuncture. Drug dosages and fluids should be prepared before the bird is restrained.

The amount of fluid that can be administered at one time depends on the size of the bird. Injections of ten ml/kg given slowly over five to seven minutes are usually well tolerated.[1] The bolus injections can be repeated every three to four hours for the first twelve hours, every eight hours for the next 48 hours, and then BID.[18]

Intravenous catheters (24 ga in medium to large birds) can be placed in the ulnar or medial metatarsal veins of some birds for continuous fluid administration. For placement in the ulnar vein, the catheter is inserted using sterile technique, secured loosely with elastic tape[24] and fixed in place using a tongue depressor that extends 1.5 inches beyond the catheter end. Both the proximal and distal ends of the tongue depressor are then firmly incorporated in a wing wrap to stabilize the catheter.[5] The risk of hematoma formation is probably greater using the ulnar vein than with the metatarsal vein.

Maintenance of an IV catheter can be difficult. Many birds will chew at the catheter, tape or extension set tubing.

FIG 15.3 A mature Umbrella Cockatoo was presented with a two-day history of vomiting and profuse diarrhea. The bird was estimated to be ten percent dehydrated (reduced ulnar refill time, tacky mucous membranes, dull sunken eyes). PCV=28 and TP=6.8. An intraosseous catheter was placed in the ulna and the bird was given warm LRS using an infusion pump. The clinical response to rehydration was dramatic. The bird had destroyed a plastic cup the day before clinical signs started. Large pieces of plastic were flushed out of the proventriculus by gastric lavage using warm LRS.

An intraosseous cannula can be used for administration of fluids, blood, antimicrobials, parenteral nutritional supplements, colloids, glucose and drugs used for cardiovascular resuscitation in birds.[36] Administration of hypertonic or alkaline solutions can be painful and should be avoided. The advantages of intraosseous cannulas include the ease of placement and maintenance, cannula stability, tolerance by most birds and reduced patient restraint once the cannula is placed. Continuous fluid administration by intraosseous cannula is less stressful than repeated venipunctures.

It has been shown in pigeons that 50% of the fluids administered in the ulna enters the systemic circulation within 30 seconds.[30] Over a two-hour period, the flow into the systemic circulation was almost equivalent to the administration rate.

Intraosseous cannulas can be placed in any bone with a rich marrow cavity.[36] A cannula may be placed in the distal ulna in medium-sized to large birds that will require several days of therapy (Figure 15.3). The proximal tibia is ideal in birds that will require shorter terms of therapy. Pneumatic bones such as the humerus and femur cannot be used. Isoflurane anesthesia is sometimes necessary for cannula placement in fractious birds. In medium-sized or larger birds, an 18 to 22 ga, 1.5 to 2.5 inch spinal needle[v] can be used as the cannula. In smaller birds, a 25 to 30 ga hypodermic needle is used.

For placement in the ulna, the feathers from the distal carpus are removed and the area is aseptically prepared. Using sterile technique, the needle is introduced into the center of the distal end of the ulna parallel to the median plane of the bone (Figure 15.4).[46] The entry site is ventral to the dorsal condyle of the distal ulna (Figure 15.4). The needle is advanced into the medullary cavity by applying pressure with a slight rotating motion. The needle should advance easily with little resistance once the cortex is penetrated. If resistance is encountered, the needle may have entered the lateral cortex. When seated correctly, a small amount of bone marrow can be aspirated through the cannula. This aspirate can be submitted for bone marrow analysis if desired. The

CLINICAL APPLICATIONS
Fluid Therapy Considerations

Oral Fluids
- Only effective with mild dehydration
- 5% dextrose may be better than lactated Ringer's solution
- Contraindicated with GI stasis
- Contraindicated with lateral recumbency
- Contraindicated with seizuring and head trauma
- Ineffective for shock

Subcutaneous Fluids
- Primarily used for mild dehydration
- Effective for providing maintenance fluids
- Given in axilla or lateral flank
- Divide dose among several sites

Intravenous or Intraosseous Fluids
- Rapidly expands circulatory volume
- Rapidly perfuses kidneys
- Indicated in shock
- Indicated with severe dehydration
- Right jugular vein - one time use
- Medial metatarsal vein - one time use
- Tibial intraosseous cannula - one time use

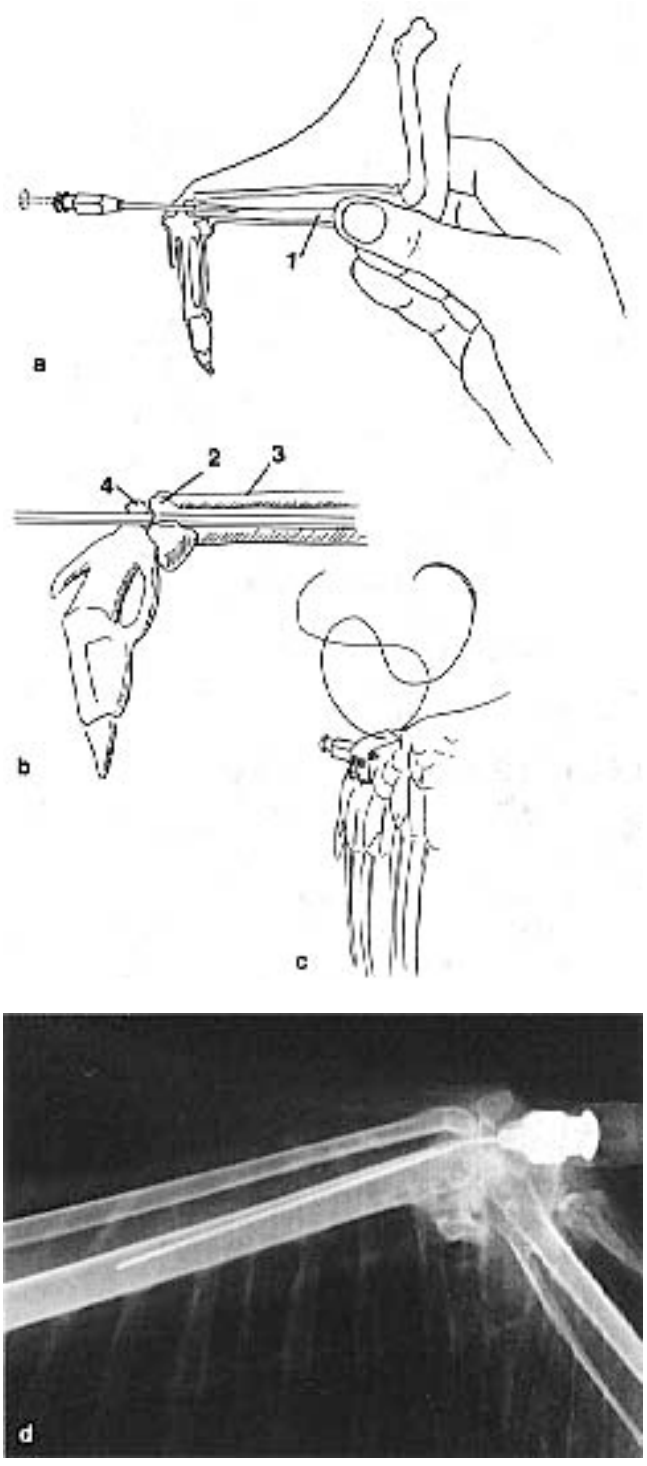

FIG 15.4 Technique for placing an intraosseous cannula in the distal ulna. If fluid or drug administration will be restricted to a single dose or a short period (eg, surgery), it is easier to place a catheter in the tibia. An intraosseous catheter placed in the ulna is easier to maintain if several days of continuous IV therapy are necessary. **a)** The thumb is placed in the center of the 1) ulna as a guide. **b)** The cannula is inserted slightly ventral to the 2) dorsal condyle of the distal ulna. The 3) radius and 4) radial carpal bone can be used for orientation. **c)** The cannula is sutured in place. **d)** Radiograph of properly inserted cannula.

cannula should be flushed with a small amount of heparinized saline, which should flow without resistance. Initial fluids should be administered slowly to check for subcutaneous swelling, which would indicate improper placement of the cannula. If the cannula is properly placed, fluid can be visualized passing through the ulnar vein. The cannula is secured in place by wrapping a piece of tape around the end and suturing the tape to the skin or by applying a sterile tissue adhesive[b] at the point of insertion (Figure 15.4). A gauze pad with a small amount of antibacterial ointment is placed around the cannula at the insertion site, and a figure-of-eight bandage is used to secure the wing. One to two loops of the extension tube should be incorporated into the bandage to decrease tension on the cannula.

Tibial cannulas are seated in the tibial crest and passed distally, similar to the technique used for obtaining a bone marrow aspirate. A light padded bandage or lateral splint is used to secure the cannula in place (see Figure 39.5).

Fluids are administered through the cannula using an infusion pump, buretrol[c] or Control-a-Flow regulator.[d] Unlike a vein, the marrow cavity cannot expand to accommodate rapid infusions of large fluid volumes. Consequently the rate of infusion into the marrow cavity is limited. The ideal infusion rate to avoid fluid extravasation in birds is unknown. In small mammals, fluids can be given at shock doses (90 ml/kg) at a pressurized flow rate of 2 l/hr.[36] Clinically, infusion rates in birds for shock therapy should probably be much lower. A flow rate of ten ml/kg/hr is suggested for maintenance. Excessively rapid infusion of the fluids may cause signs of discomfort or edema of the soft tissue in the area of the cannula. Fluid extravasation may occur if the infused volume is too large, or if several holes were made in the cortex while attempting to place the cannula.

Intraosseous cannulas are most successful in birds if used during the first 24 to 48 hours for initial rehydration and shock therapy. Cannulas can remain in place for up to 72 hours without complications if placed aseptically and maintained with heparinized flushings every six hours.[36] Clinically, after two to three days of use, many birds exhibit a painful response when fluids are given through an intraosseous cannula. This could result from pain associated with local edema or the extravasation of fluids around the marrow cavity. Some birds will not tolerate the cannula and will bite at the extension tubing or the wrap as their general condition improves.

The use of vascular access devices (VAD) in birds has recently been described.[20] A vascular access device consists of a catheter that is placed within a vessel, and a port that is implanted in the subcutaneous tissue. No portion of the catheter is externally exposed, reducing the incidence of bacterial contamination and infection. A specially designed needle (Huber needle) is used for access to the depot port by skin penetration. Use of a VAD allows repeated blood sampling and drug administration without repeated venipuncture, with minimal stress on the patient. Vascular access ports are used in humans primarily for long-term intravenous chemotherapy and total parenteral nutrition. More recently, vascular access devices have been used in dogs and laboratory animals.[2,37] Potential complications of the vascular access port include thrombosis, sepsis, local infection and drug extravasation.[2]

Vascular access devices have been used experimentally in pigeons and geese and clinically in an auklet.[20] The use of the device in small birds may be limited by the size of the animal and absence of an appreciable subcutaneous space. Other disadvantages of the device in birds include the necessity of surgical placement and removal and the difficulty of venotomy in small avian patients.

The system is usually implanted with the animal under general anesthesia (see Chapter 41). A skin incision is made over the jugular vein. The vein is isolated and occluded cranially for venotomy and insertion of the catheter. The catheter is secured in place in the vein with sutures above and below a retention ring on the catheter. A tunnel is made through the subcutaneous tissue to a site dorsal to the catheter where the port is sutured to the underlying muscle fascia. The extravascular portion of the catheter is left in a short loop to prevent tension during neck movement. The catheter is flushed with heparinized saline at regular intervals to ensure patency.

Antibiotics

Septicemia and bacteremia should be considered in any bird that is severely depressed. Prophylactic antibiotics are frequently used in birds that are immunocompromised from a noninfectious disease. Antibiotics are not necessary in all emergencies. Birds with simple closed fractures, uncomplicated heavy metal toxicity, hypocalcemia and other noninfectious problems may not require or benefit from the use of antibiotics. However, in many emergency patients the history and clinical signs are vague and inconclusive, and antibiotics may be indicated on a precautionary basis.

Parenteral antibiotics are recommended for the initial treatment of birds that are weak, sick, debilitated or in shock.[45] General peak plasma concentrations following parenteral drug administration vary with the route: IV = seconds; IM = 30 to 60 minutes; oral = 60 to 120 minutes.

Absorption following oral administration may be erratic in birds that are severely dehydrated, have gastrointestinal stasis or are regurgitating. Intravenous administration is recommended if septicemia is a primary concern. Intravenous drugs can be given during the initial fluid bolus or through an indwelling or intraosseous cannula. Intravenous drugs should be given slowly to avoid circulatory shock.

Intramuscular administration of antibiotics is used routinely for maintenance therapy. A small gauge needle (26 to 30 ga) is used to minimize muscle trauma. The pectoral muscles should be used for most injections (see Chapter 17).

The major disadvantage to intramuscular injection is the potential for muscle damage. In a study using hens, eight of thirteen injectable antibiotic preparations caused muscle necrosis, with the most severe damage being induced by tetracyclines and sulfonamides. Muscle damage was a common sequela to IM injections of almost 50 different medications in budgerigars.[13]

Subcutaneous administration of drugs is less traumatic to the muscle and is often used for maintenance therapy. Subcutaneous injections may be preferred in very small or cachectic birds with limited muscle mass and in birds with suspected coagulopathies. Disadvantages of subcutaneous injections include the possibility of leakage from the injection site and poor absorption.

The initial choice of an antibiotic depends on the clinical signs and history of the bird. Birds with suspected gram-negative septicemia should be treated with a bactericidal antibiotic effective against the most common avian pathogens, including *Escherichia coli, Enterobacter* spp., *Klebsiella* spp. and *Pseudomonas* spp.[45] Antibiotics commonly used for initial treatment of septicemia include piperacillin, cefotaxime, enrofloxacin, trimethoprim-sulfa, doxycycline and amikacin (see Chapters 17 and 18).

If chlamydiosis is suspected, the bird should be treated with a parenteral doxycycline to rapidly establish therapeutic blood concentrations and stop the shedding of the organism. After initial parenteral therapy (IV doxycycline in the United States,[e] IM doxycycline in the rest of the world[f]), the patient can be switched to oral medication for continued therapy (see Chapter 34).

Other Drug Therapy

Severe metabolic acidosis is common in mammals that are in shock or that are critically ill. In mammals in hemorrhagic shock, acidosis occurs secondary to inadequate tissue perfusion; however, acidosis has not been shown to occur in chickens following prolonged hemorrhage.[64] Bicarbonate replacement therapy has been recommended in birds if severe metabolic acidosis is suspected, but because it is not usually feasible to measure blood gases in birds, bicarbonate deficit must be estimated.[18] A dose of 1 mEq/kg given IV at 15- to 30-minute intervals to a maximum of 4 mEq has been recommended.[42] In small animals, bicarbonate must be administered slowly IV over 20 minutes or longer.[21] If administered too rapidly or given in excessive amounts, alkalemia, hypercapnia, hypocalcemia, hypernatremia, hyperosmolality, hypokalemia and paradoxical CNS acidosis may occur.[65] The result may be vomiting, hypotension or death.

Stress causes release of catecholamines, which have hyperglycemic effects. Consequently, birds with traumatic wounds or chronic, non-septic diseases may have normal to increased blood glucose concentrations and do not need initial supplemental glucose. Hypoglycemia is most common in sick hand-fed babies, septicemic birds, raptors or extremely cachectic birds in which body stores of glycogen have been depleted. In birds that have been determined to be hypoglycemic, an IV bolus of 50% dextrose at 2 cc/kg body weight can be given with fluids to restore blood glucose concentrations. Glucose can then be added to maintenance fluids in a 2.5% to 10% solution given intravenously or intraosseously. Intramuscular injections of hyperosmotic (75%) dextrose should not be given, because severe muscle irritation and necrosis can result.

Birds that are on poor diets or are chronically ill should receive a parenteral multivitamin on initial hospitalization. Vitamin A and D_3u should be administered with care in patients on formulated diets to prevent toxicities from over-supplementation. Vitamin B complex is suggested both initially and on a daily basis in anorectic or anemic birds. Iron dextran therapy is also recommended in anemic birds. Vitamin K_1 will improve clotting time and is important in birds with suspected hepatopathies or birds that may require surgery. Vitamin E and selenium should be considered in patients that have neuromuscular disease. Supplementation of calcium and iodine may be indicated in some cases.

Recently an injectable amino acid supplement[h] has been marketed for use in birds. The product has been recommended for use as an immune stimulant and a nutritional supplement in anorectic and compromised birds. Although no scientific studies have been conducted, some veterinarians report improvement in birds after using this product at recommended doses, and no detrimental side effects have been reported.

Corticosteroids

The use of corticosteroids in the treatment of shock is controversial. Shock is a very complex disease with many complicating factors, making it difficult to compare treatment results in clinical studies. In humans, there are numerous conflicting studies comparing mortality and reversal of shock in corticosteroid- versus non-corticosteroid-treated groups. Experimentally, pharmacologic doses of steroids have anti-shock effects in laboratory animals. These include improved microcirculation, organelle and cell membrane stabilization, improved cellular metabolism and gluconeogenesis and decreased production of endogenous toxins.[21] Hydrocortisone, prednisolone, methylprednisolone and dexamethasone are recommended in the treatment of hypovolemic and septic shock. There is no definitive evidence of one drug being superior to another.

Complications of steroid use include immunosuppression, adrenal suppression, delayed wound healing and gastrointestinal ulceration and bleeding. Except for immunosuppression, which may occur with one dose of dexamethasone, other negative side effects are primarily associated with chronic therapy using high dosages.

Prednisolone or dexamethasone are used routinely for central nervous system injuries in animals. Methylprednisolone sodium succinate (MPSS) has been shown to improve recovery in humans and cats with spinal cord injuries.[7,8] Dexamethasone was no better than a placebo in improving neurologic signs.[8] The beneficial effects of MPSS are primarily attributed to

the antioxidant effects in protecting cell membranes from lipid peroxidation. It was also found that improvement was strictly dose-dependent. The optimal dose was 30 mg/kg IV in cats and mice. Lower or higher dosages were ineffective or even promoted further lipid peroxidation. In mice, prednisolone sodium succinate was found to be equally efficacious, but half as potent, as MPSS when given five minutes after concussive head injury. Hydrocortisone was ineffective even at high dosages.

There are few studies detailing corticosteroid use in birds. In Red-tailed Hawks and Barred Owls, both intravenous and intramuscular injections of dexamethasone (3 mg/kg) produced peak plasma concentrations within 15 minutes of injection.[9] Intravenous injections resulted in a higher peak concentration. Serum half-life of dexamethasone varied with the species and was found to be 37.5 minutes in Red-tailed Hawks, 53.5 minutes in Barred Owls and 36 minutes in male broiler chickens.[4] Suppression of plasma corticosterone concentrations lasted for 24 hours in owls and for 18 hours in hawks following single-dose administration. Intramuscular injection of dexamethasone sodium phosphate (4 mg/kg) in Red-tailed Hawks was associated with elevations in AST and ALT. Elevations were 3.2 times normal values within 36 hours of single-dose administration.[26] No elevations in AST or ALT were seen following IV administration.

Corticosteroids are used in birds in the treatment of shock, acute trauma and toxicities. Clinically, birds receiving corticosteroids for head trauma and shock therapy seem to improve; however, clinical improvement may result from supportive care and fluid therapy rather than corticosteroid use.

Secondary fungal and bacterial infections are common in birds receiving steroids for longer than one week.[24] These findings suggest that birds are very susceptible to the immunosuppressive effects of corticosteroids; therefore, corticorsteroids should be used in birds on an infrequent, short-term basis.

Nebulization

Nebulization therapy may be beneficial in birds with bacterial or fungal respiratory infections, particularly those limited to the upper respiratory system (see Chapter 22). Air sacculitis is frequently associated with the accumulation of inflammatory cells and pathogenic organisms. The caudal thoracic and abdominal air sacs are more commonly involved, probably as a result of the directional air flow within the respiratory system.

The air sac wall consists of a thin layer of simple squamous epithelial cells supported by a small amount of connective tissue. Blood supply is extremely limited, and parenteral and oral antimicrobials that depend on the circulatory system for tissue distribution are ineffective in treatment of air sacculitis.[27] In effect, nebulization provides topical, localized treatment of the internal air sacs and is not dependent on absorption (see Chapter 22). Because of the anatomy of the avian respiratory tract and the lack of physical activity in the sick bird, nebulized drugs probably reach only 20% of the lung tissue and the caudal thoracic and abdominal air sacs.[13]

The particle size of nebulized medications must be less than 3 μm to establish local drug levels in the lungs and air sacs.[13] Particles from 3 to 7 μm generally deposit in the trachea and mucosal surface of the nasal cavity.[13,60] Many inexpensive commercial nebulizers do not produce a particle size small enough for penetration of the lower airways. Ultrasonic nebulizers are most effective in producing small particle size and are recommended for use in birds. The tubing and chamber of the nebulizer should be easy to clean after each use, and should be sterilized between birds to avoid introduction of bacterial or fungal organisms with the nebulized solutions.

In general, most parenteral antibiotics formulated for intravenous use can be used for nebulization. Bactericidal antibiotics appear most successful in nebulization therapy. With air sacculitis caused by an unidentified bacteria, the authors prefer to use cefotaxime (100 mg in saline) or piperacillin (100 mg in saline) for nebulization. The suggested protocol is to nebulize for ten to thirty minutes, two to four times daily for five to seven days.[61] Saline is preferred as the nebulizing fluid. Mucolytic agents should be avoided due to their irritant properties.[65] If amikacin is used, the patient should be carefully monitored for signs of polyuria. The effectiveness of treating mycotic air sacculitis with nebulization is not known.[13] In some cases, medications can be injected directly into the trachea or a diseased air sac.

Nutritional Support

Nutritional support is mandatory for the successful recovery of an anorectic bird. There are two main routes for providing nutritional support. Enteral feeding uses the digestive tract and is the simplest,

while parenteral feeding bypasses the digestive tract by supplying amino acids, fats and carbohydrates directly into the vascular system. In mammals, enteral feeding has been shown to be comparable to or possibly superior to parenteral feeding.[70] Parenteral nutrition is in its infancy in avian medicine, but may be necessary for birds with gastrointestinal disease.

Enteral nutritional support is generally provided in companion and aviary birds using a tube passed into the crop (Figure 15.5). Necessary equipment includes 10 to 18 ga stainless steel feeding needles with rounded tips, rubber feeding catheters of various diameters, plastic catheter adapters, oral beak specula and regular and catheter-tipped syringes. A "sterile" feeding needle or catheter should be used for each bird to prevent the transmission of pathogenic organisms. Feeding needles and catheters should be cleaned thoroughly and sterilized after each use. Raptors are usually hand-fed pieces of prey.

FIG 15.5 Tube-feeding is frequently necessary as part of the supportive care provided to anorectic patients that do not have gastrointestinal tract disorders that would prohibit oral alimentation (eg, crop stasis, ileus). Note that this African Grey Parrot's head is held upright and the tube is inserted from the left oral commissure (courtesy of Kathy Quesenberry).

Parenteral medications and fluids should be administered before gavage feeding. If given afterwards, there is a risk of regurgitation during restraint for the subsequent treatments. Oral medications can often be administered with the enteral feeding formula.

The crop should be palpated before each feeding to determine if residual feeding formula remains. Birds with ingluvitis or gastrointestinal stasis frequently have slow crop emptying times. If residual food remains, the crop should be flushed thoroughly with a warm, dilute chlorhexidine solution. The crop may need flushing for several days before motility returns to normal. "Crop bras" are sometimes used to support slow-moving, pendulous crops and will often improve crop emptying (see Chapter 30).

Tube-feeding is facilitated with the help of an assistant, but it can be done in small birds by one person. The handler holds the bird upright with the body wrapped in a paper or cloth towel (Figure 15.6). An oral speculum can be useful in large birds but is not usually necessary in small birds. A speculum must be used with care to prevent damage to the soft tissues at the lateral beak commissures.

The bird's neck is straightened vertically with the head grasped around the mandibles. An index finger is placed on top of the head to prevent the bird from throwing its head back. The second person then passes the tube into the left oral commissure (Figure 15.6). If the tube is passed directly from the front, the bird will try to chew at the tube. In medium-sized to large birds, the top beak can be pushed slightly to one side with one hand to open the beak for passage of the tube. Alternatively, the upper beak is inserted in the lower beak, preventing the bird from biting on the tube.[34a]

After entering the oral cavity, the tube is passed down the esophagus on the right side of the neck into the crop. Tube placement can be visualized by moistening the feathers on the right lateral neck region. The crop is palpated to check the position of the end of the tube before injecting the feeding formula. The total volume that can be given depends on the size of the bird (Table 15.3). The neck should be kept in full extension during feeding to discourage regurgitation.

After injection of the food, the tube is carefully removed to prevent reflux. The assistant continues to

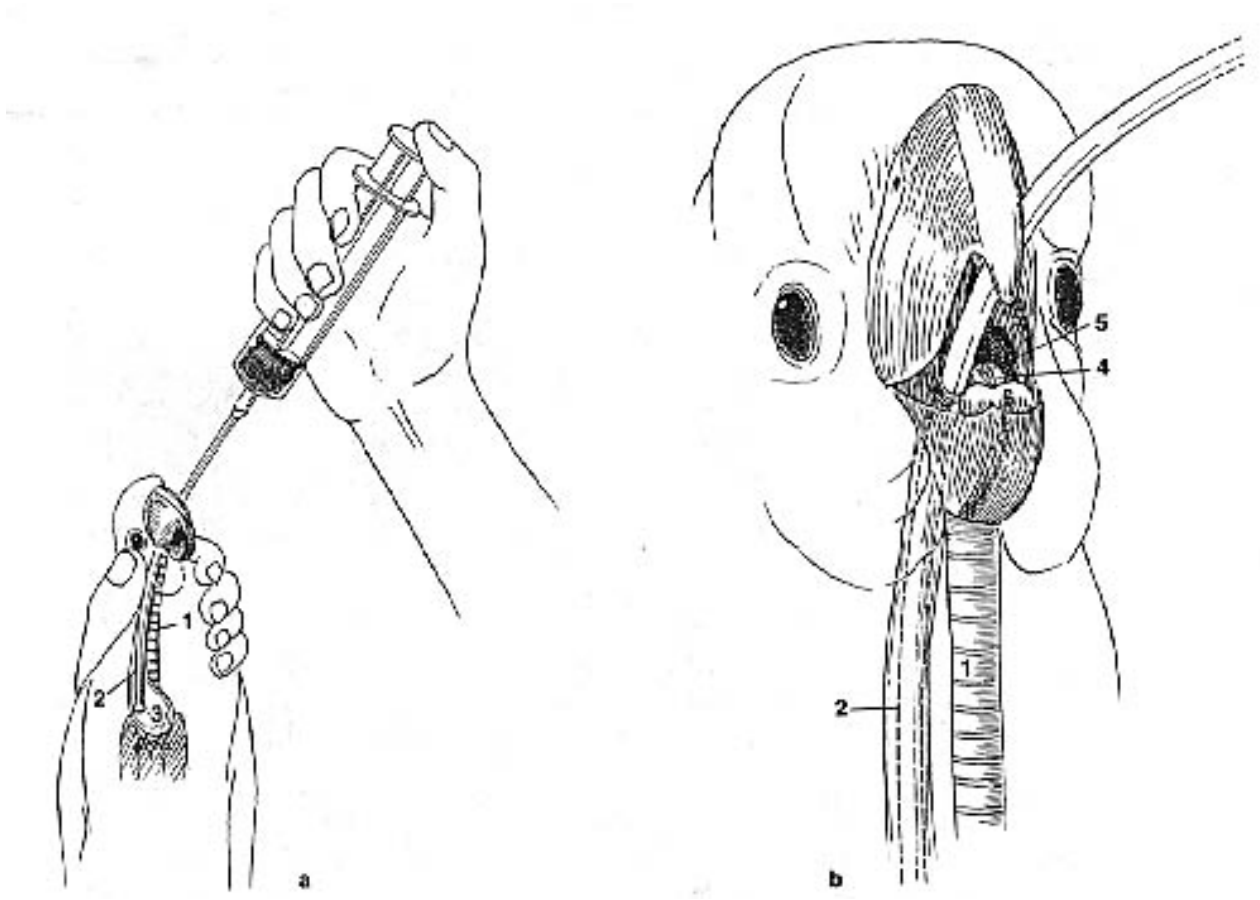

FIG 15.6 **a)** For tube-feeding or crop aspiration, the bird is held in an upright position with the neck in extension. **b)** The tube is passed through the left side of the oral cavity and down the esophagus in the right side of the pharyngeal cavity. The tip of the tube should be palpated to ensure that it is in the crop before delivering fluids or feeding formula. 1) trachea 2) esophagus 3) crop 4) laryngeal mound 5) rima glottis and 6) tongue.

hold the bird with the neck in extension until the bird is released into its enclosure. If reflux of formula occurs at any time during the tube-feeding process, the bird should be released immediately to allow it to clear the oral cavity on its own. Attempting to swab the oral cavity or turning the bird upside down will cause undue stress and may increase the possibility of aspiration.

TABLE 15.3 Suggested Volumes and Frequency for Tube Feeding Anorectic Birds

	Volume	Frequency
Finch	0.1 - 0.3 ml	Six times/day
Parakeet	0.5 - 1.0 ml	QID
Cockatiel	1.0 - 2.5 ml	QID
Conure	2.5 - 5.0 ml	QID
Amazon	5.0 - 8.0 ml	TID
Cockatoo	8.0 - 12.0 ml	BID
Macaw	10.0 - 20.0 ml	BID

Most hospitalized birds are tube-fed two to four times daily according to their clinical condition and caloric needs. Neonates and small birds may need to be fed more frequently (see Chapter 30).

If the crop or upper gastrointestinal system is dysfunctional (eg, crop stasis, crop burns, proventricular dilatation or ventricular impaction), a bird can be provided enteral nutrition by injecting food directly into the proventriculus or lower gastrointestinal tract through an esophageal gastric tube (pharyngostomy tube) or duodenal catheter (see Figure 41.10). The first method involves placing a soft feeding tube into the esophagus at the base of the mandible, through the esophageal opening at the right crop base and into the proventriculus. The tube is sutured in place. Cellulitis should be expected to occur at the interface of the tube and esophagus, but generally resolves when the tube is removed.

A second method for supporting enteral alimentation while bypassing the crop is the placement of a duodenal feeding catheter.[17] A small Foley catheter is surgically placed in the proximal duodenum and exited through the lower abdominal wall. The end of the tube is secured to the dorsum or intrascapular area with tape or sutures (see Chapter 41). An easily absorbed liquid diet is infused into the proximal small intestine.[1,41] The volume of liquid formula that can be infused at one time is small, and frequent feedings (as often as every one to two hours) are necessary to meet caloric requirements. Alternatively, food can be infused at a constant rate using an infusion pump. The authors have used this method in young birds for up to six days without complications. Duodenal tubes are not practical for use in small birds due to the difficulty of the surgical procedure and the need for a duodenal tube with a large enough diameter to allow easy infusion of a liquid feeding formula.

Total Parenteral Nutrition

Parenteral alimentation involves the intravenous administration of all essential nutrients including amino acids, lipids, carbohydrates, vitamins, electrolytes and minerals. Potential indications for the use of total parenteral nutrition (TPN) in birds include gastrointestinal stasis, regurgitation, some gastrointestinal surgeries, severe head trauma that precludes oral alimentation, malabsorption or maldigestion. In dogs, 50 to 60% of the calories are supplied by a 20% lipid solution, and the remaining calories are supplied by a 50% dextrose solution.[28] Daily protein requirements (1.5-6 gm/kg) are met by using amino acid supplements compounded into the TPN solution.

Difficulties associated with parenteral nutrition in birds include placing and maintaining a catheter, the necessity of multiple intermittent feedings to supply caloric requirements and potential metabolic complications associated with parenteral nutrition[41] (hypophosphatemia, hypo- or hyperkalemia, hyperglycemia and liver function abnormalities). Sepsis or bacteremia can occur from bacterial contamination of the catheter. Continuous infusion is the preferred method for administration of TPN, allowing for rapid dilution of the hypertonic solution, which minimizes irritation to the vascular endothelium.

The intraosseous cannula or a vascular access device can be used for parenteral alimentation.[12] Vascular access devices have been used experimentally for TPN in two geese.[20] The birds received the TPN formula in four daily infusions of twenty to thirty minutes each using an infusion pump set at 5 ml/min. Both geese showed marked hematologic changes after receiving TPN, including heterophilic leukocytosis; increases in SGPT, AP, cholesterol and CPK; and decreases in glucose, bile acids and triglycerides. One goose died on the second day of TPN. Acute renal ischemia and necrosis were cited as the cause of death. Histopathologic, microbiologic and clinical parameters implicated inflammation and bacteremia secondary to *Staphylococcus aureus* contamination of the VAD. The second goose was maintained on TPN for four days with no clinical abnormalities. Necropsy showed minor changes in the kidneys that were not associated with uric acid elevations.

Total parenteral nutrition administered by VAD was successful when given experimentally in pigeons.[12] The TPN was administered in four daily infusions over a five-day period. Clinical changes were mild including weight loss, regurgitation, transient hyperglycemia, polyuria, glucosuria and tachycardia.

Because the nutritional requirements for avian patients are not known, formulation of TPN diets is primarily extrapolated from mammalian diets and the nutritional requirements of poultry. Enteric liquid diets are estimated to be 90% bioavailable, while TPN solutions are 100% available.

Typically a 10% amino acid solution[i], a 20% lipid solution[j] and a 50% dextrose solution are used. The amino acid solution provides 100 mg protein/ml, the lipid solution provides 2 kcal/ml, and the dextrose solution, 1.7 kcal/ml. These three solutions can be mixed under clean conditions as a three-in-one TPN solution.[20] A 1000 ml bag of five percent dextrose solution is connected to an IV drip set and aseptically emptied. One day's supply of amino acid solution is injected through the port into the bag. The 50% dextrose solution is then added and mixed by inverting the bag. The lipid solution is added last. It should be added and mixed slowly over a two-minute period. This mixture should be used within 24 hours and should be stored in the refrigerator.[20]

Nutritional Requirements

Illness and stress cause a hypermetabolic state in animals and humans. Release of catecholamines, glucagon and glucocorticoids increases the rate of gluconeogenesis and glycogenolysis. When the increase in metabolic rate is coupled with a decreased nutritional intake, fat oxidation occurs at a maximum rate, and body proteins are used as an energy

source.[28] Blood glucose concentrations are increased. Intravenous infusion of isotonic glucose has little sparing effect on body proteins, and may actually be detrimental by increasing the release of insulin.[28] The antilipolytic action of insulin may decrease the use of fat stores and increase body protein breakdown.

Protein demand is high during periods of hypermetabolism. Proteins are necessary for tissue repair, white and red blood cell production, maintenance of blood proteins (albumin, fibrinogen, antibodies) and enzyme production. During periods of high demand, the body uses fatty acids preferentially for energy to spare protein. In the management of human patients, more than 40% of the total kilocalories in many enteral diets are derived from fatty acids.

The size, weight, reproductive status and season all affect the daily caloric needs of birds. The basal metabolic rate (BMR) is the minimum amount of energy necessary for daily maintenance. An estimate of the BMR for birds can be made based on metabolic scaling:[58]

$$BMR = K(W_{KG}^{0.75})$$

Passerine birds K = 129

Non-passerine birds K = 78

The K factor is a theoretical constant for kcal used during 24 hours for various species of birds, mammals and reptiles. The maintenance energy requirement (MER) is the BMR plus the additional energy needed for normal physical activity, digestion and absorption. The MER for adult hospitalized animals is approximately 25 percent above the BMR.[28] In passerine birds, MER varies from 1.3 to 7.2 times the BMR, depending on the energy needed for activity and thermoregulation during different times of the year.[72] With growth, stress or disease, animals are in a hypermetabolic state with daily energy needs that surpass maintenance. The amount of increased demand depends on the type of injury or stress and varies from one to three times the daily maintenance requirement (Table 15.4).

TABLE 15.4 Adjustments to Maintenance for Stress (as multiples of MER)[41]

Starvation	0.5 - 0.7
Elective Surgery	1.0 - 1.2
Mild Trauma	1.0 - 1.2
Severe Trauma	1.1 - 2.0
Growth	1.5 - 3.0
Sepsis	1.2 - 1.5
Burns	1.2 - 2.0
Head Injuries	1.0 - 2.0

Although not exact, metabolic scaling can be used to estimate the approximate daily caloric needs of birds.

Enteral Nutritional Formulas

In humans, diets used for enteral nutrition are chosen based on the clinical condition of the patient. For birds, a formula should be used that supplies basic protein, fat and carbohydrates, and is adequate in meeting the energy requirements of the patient.

Commercial enteral nutritional formulas marketed for humans are widely available. These diets are usually liquid formulations sold in 250 ml containers. The diets vary in caloric density, protein, fat and carbohydrate content and osmolality (Table 15.5). Formulas vary from meal replacement formulas, which require some digestion, to monomeric diets, which require little or no digestion. Almost all diets are lactose-free and are approximately 95 percent digestible. These diets have been successfully used for routine nutritional support in sick birds via an enteral route. Knowing the exact caloric density per millimeter is convenient for calculating daily maintenance requirements. Formulas range from less than 1.0 to 2.0 kcal/ml. With a calorie-dense formula (2.0 kcal/ml), the total volume of liquid can be given in two to four feedings per day. Maintaining adequate hydration is important in birds when using calorie-dense formulas. Once opened, enteral formulas can be refrigerated for two to three days. For feedings, the formulas can be heated gently, such as in a syringe under hot running water.

CLINICAL APPLICATIONS

Example of Metabolic Scaling to Estimate Approximate Daily Caloric Needs of Birds*

An Amazon parrot weighing 350 grams is presented for septicemia secondary to bacterial enteritis. Estimating MER as 1.5 times BMR, the daily caloric needs can be estimated as:

- $BMR = 78(0.35^{0.75})$ or 35 kcal/day
- 1.5 x 35 kcal/day = 53 kcal/day approximate MER
- 1.2 x 53 kcal/day = 63.6 kcal/day increase for sepsis

If the energy content of the feeding formula is known, the daily calorie needs are divided by the calories per ml of formula to calculate the total volume of formula needed daily. For example, using a formula that is 1.5 kcal/ml, the total volume of formula needed per day for the Amazon is:

- 63.6 kcal/day 1.5 kcal/ml = 42.4 ml needed daily

*See Appendix for instructions on using this formula.

FIG 15.7 Commercially available enteral nutritional products are superior to homemade formulas because they provide consistent nutritional and caloric content. Feeding needles can be used to deliver these products (courtesy of Kathy Quesenberry).

TABLE 15.5 Commercial Enteral Products: Nutrients per 100 kcal* Energy[41]

Product	Protein (g)	Fat (g)	Carbos (g)	kcal/ml
Isocal[k]	3.4	4.4	13.3	1.0
Isocal HCN[k]	3.8	5.1	10.0	2.0
Traumacal[k]	5.5	4.5	9.5	1.5
Pulmocare[l]	4.2	6.1	7.0	1.5
Ensure Plus[l]	3.6	3.5	13.0	1.5

* kcal = calories

Formula may curdle in the crop of birds with ingluvitis and gastrointestinal stasis, probably because of changes in the pH of the crop. Flushing the crop with warm water while gently massaging the crop will cause the curdled formula to break apart, allowing aspiration and removal. Multiple feedings of small amounts of an isotonic or diluted formula should be given until the crop motility is normal.

Commercial enteral formulas marketed for use in birds are available (Figure 15.7). These diets are either dry powders or liquids. They are consistent in nutritional content, easy to prepare and use and relatively low in cost. In general, these diets are relatively high in carbohydrate content when compared to human products. Some products are low in calorie content. Powdered products can curdle or sludge in the crop, especially if an inadequate amount of water is used for mixing.

Some veterinarians prefer to blend their own feeding formulas. Combinations of monkey chow, baby cereal, strained baby vegetables, vitamin and mineral supplements and water are used. Plant enzymes are sometimes added to improve digestibility (see Chapter 18). Homemade formulas may work but have the disadvantage when compared to commercial products of varying consistency and nutritional and caloric content. Formulas based on baby cereal are usually high in carbohydrates and low in fat and protein. Many homemade formulas are too high in water content and provide insufficient levels of energy. Following the bird's weight on a daily basis (in grams) is the best evaluation of enteral feeding.

Oxygen Therapy

An oxygen enclosure is highly recommended as standard equipment in an avian practice (Figure 15.8). There are several commercially available enclosures made specifically for use in birds. Most are designed as incubators with controls for heat and monitors for humidity. Human infant incubators with oxygen input ports can be adapted for use in birds. Oxygen levels within the enclosure can be monitored with an oxygen analyzer. Analyzers[m] are available with accuracy to within two percent. Administration of oxygen by face mask is effective for short-term treatment if an oxygen enclosure is not available, or during restraint while treatments or diagnostic tests are performed. If there is upper airway obstruction, oxygen can be infused through an air sac tube.

The actual benefits of oxygen supplementation in birds are unknown. Birds have a unique and efficient

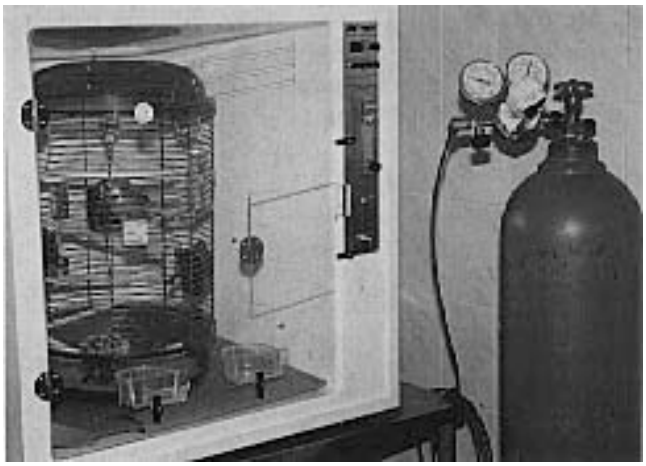

FIG 15.8 An oxygen enclosure should be standard equipment in any avian hospital (courtesy of Kathy Quesenberry).

respiratory system and may respond to oxygen supplementation differently than do mammals. Clinically, dyspneic birds appear to stabilize when placed in an oxygen enclosure and maintained at 40 to 50% oxygen concentration. Oxygen therapy is potentially toxic in mammals if given for prolonged periods at high concentrations. Oxygen can be supplemented in small animals at levels up to 100% for less than 12 hours without complications.[65] Canaries and budgerigars given continuous supplemental oxygen at concentrations of 82 to 100% and 68 to 93%, respectively, showed signs of lethargy, anorexia, respiratory distress and death after three to eight days.[62] Pathologic changes in the lungs included pulmonary congestion, histiocytic infiltration into the bronchi and deposition of proteinaceous material. Changes were consistent with those seen in mammals with oxygen toxicity.

Oxygen delivery to the tissues is dependent on adequate perfusion. Birds that are severely anemic or in circulatory shock need adequate volume expansion and red blood cell replacement for improved tissue oxygenation to occur.

Air Sac Tube Placement

Placement of an air sac tube is beneficial in birds with tracheal obstructions, or when surgery of the head is necessary. In companion birds the tube is normally placed in the caudal thoracic or abdominal air sac, allowing direct air exchange through the tube into the air sac. Following tube placement, dyspnea stops almost instantaneously in birds with upper airway obstruction. An air sac tube may also improve respiration in birds with air sacculitis, although the improvement in breathing is usually less dramatic (Figure 15.9).

An alternative site for air sac cannulation used in raptors is the interclavicular air sac.[43] In a study with Peking Ducks, there were no changes in heart rate, mean arterial blood pressure, PaO_2 or $PaCO_2$ when the clavicular air sacs were cannulated (see Chapter 39).[47] There were significant increases in the tidal volume and minute ventilation when compared to control birds. These increases may have resulted from a decrease in effective ventilation or an increase in respiratory dead space.

A shortened endotracheal tube, trimmed rubber feeding tube or plastic tubing from an IV extension set can be used for an air sac tube.[54] The diameter and length of the tube depend on the size of the bird. The tube can be placed in the lateral flank area in the same anatomic location as for lateral laparoscopy, or caudal to the last rib with the femur pulled forward (Figure 15.10). The bird is placed in lateral recumbency, prepped with a surgical scrub and a small incision is made in the skin. Mosquito forceps are used to bluntly penetrate the muscle wall and enter the air sac. The end of the tube is inserted into the air sac between the opened jaws of the mosquito forceps. If the tube is patent, condensation will appear on a glass slide held over the end of the tube. Tape is placed around the tube in a "butterfly" fashion and sutured to the skin, or a fingertrap suture technique is used. If a shortened endotracheal tube is used, the cuff can be slightly inflated just inside the abdominal wall to form a secure seal.

If placed correctly, the bird will immediately begin breathing through the tube. If anesthetized, the bird

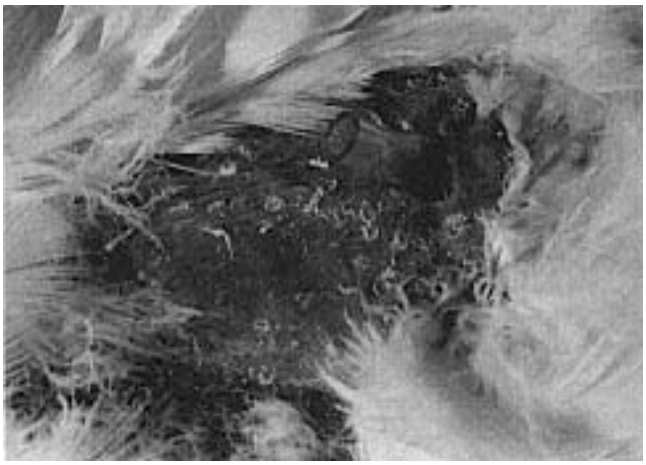

FIG 15.9 A Sulphur-crested Cockatoo was presented with an acute onset of severe dyspnea. The bird was in excellent overall condition. The bird was anesthetized with isoflurane and an air sac tube was inserted in the abdominal air sac. The bird began to breathe normally within two to three minutes of inserting the air sac tube. An Ayres T-piece was connected to the air sac tube and the bird was maintained on 1.5% isoflurane delivered into the air sacs. A small plastic ball was identified in the rostral part of the trachea by endoscopy. A needle was passed through the trachea distal to the ball to prevent it from descending further down the trachea. The ball was removed by holding the bird upside down and using suction.

CLINICAL APPLICATIONS

Air sac tubes can be used to:

- Alleviate dyspnea secondary to URD
- Deliver anesthesia for evaluation or surgery of the head or trachea
- Provide an immediate airway following apnea
- Deliver nebulized medications to a specific air sac

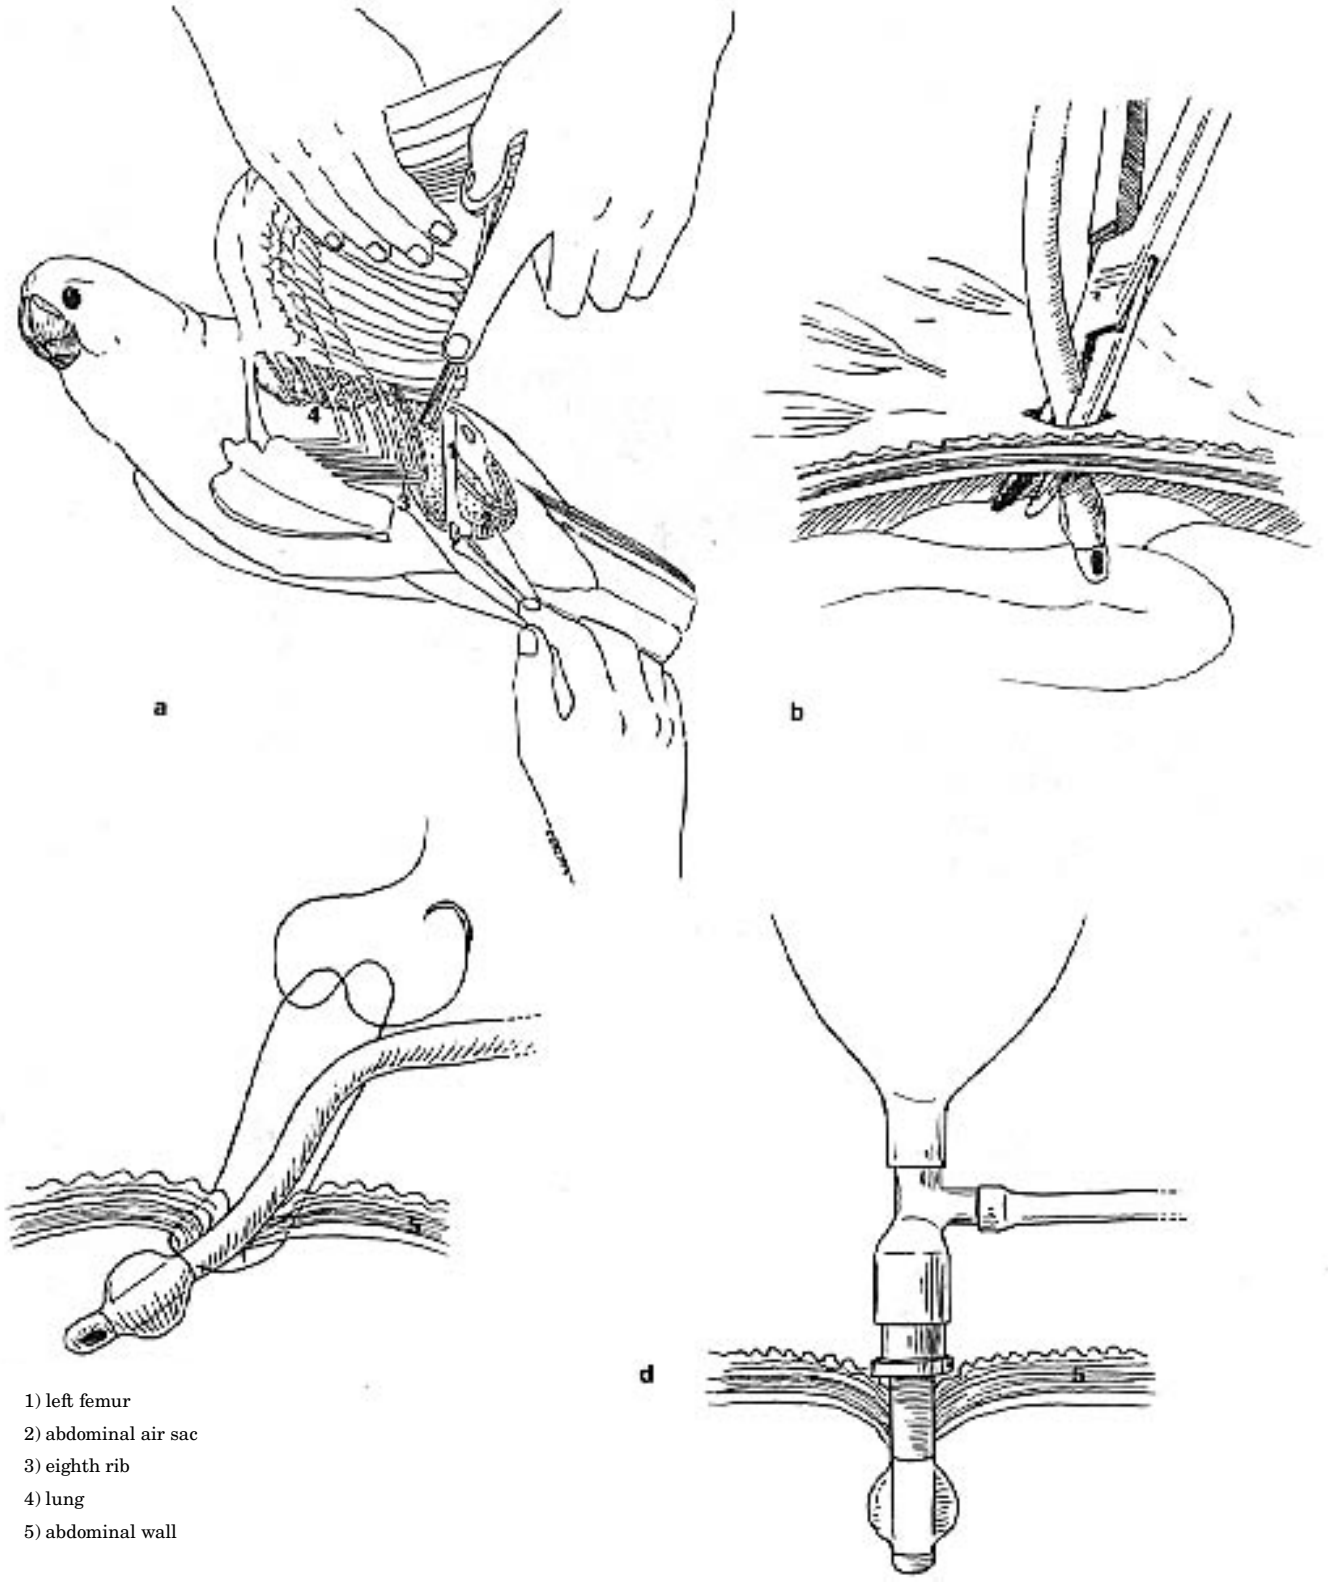

FIG 15.10 Placement of a tube in the abdominal air sac can be used to provide oxygen or isoflurane anesthesia. **a)** The tube is placed by making a small skin incision in the area of the sternal notch. **b)** A pair of hemostats is passed through the body musculature and the air sac tube is inserted between the jaws of the hemostats. **c,d)** A cuffed endotracheal tube can be sutured to the body wall if the tube will remain in place for several days.

will become light unless the end of the tube is occluded or attached to the anesthesia machine. The air sac tube can be left in place for three to five days. The effect of direct exchange of room air into the air sac and the potential for introduction of contaminants and infectious organisms into the cannulated air sac are unknown.

An air sac tube allows many treatment techniques to be performed that would otherwise be impossible in a dyspneic bird. Liquid medications can be instilled directly into the trachea for the treatment of bacterial or fungal tracheitis. The bird can be anesthetized through the tube for surgery or endoscopy of the trachea or head, and the tube can be used for positive pressure ventilation or resuscitation. Birds can be nebulized with the air sac tube in place, possibly increasing the concentration of antimicrobials in the air sacs. If apnea occurs, a needle can be used in place of a tube for providing a rapid source of oxygen.

Heat

A warm ambient environment is necessary for birds that are debilitated or in shock. Many commercial enclosures and incubators are available with floor or ceiling heating elements, side heating consoles or radiant heat systems. Floor heating elements may occasionally cause hyperthermia when debilitated birds are forced to stand or lie on the enclosure floor or in direct contact with the heating surface. Alternatively, heat can be provided by a hot water bottle or well insulated heating pad (preferably water). Birds receiving supplemental heat from any source other than a commercial incubator should be carefully monitored to prevent burns. Small, heated rooms that hold two to three enclosures allow birds to be treated in a temperature-stable environment, reducing the stress associated with being removed from a warm incubator to a cooler treatment area. It should be noted that none of the commercially available incubators with forced air heating systems can be properly sterilized with any procedure that does not involve the generation of formalin gas.

Enclosures should be equipped with thermometers to monitor ambient temperature. Many commercial enclosures also have humidity sensors. Ambient temperature for adult birds should be 85°F and humidity should be approximately 70%. Unfeathered baby birds less than ten days old need an ambient temperature of 94°F.[25] Older chicks can be maintained at 90°F. Birds in heated enclosures should be monitored for hyperthermia, which is clinically suggested by panting and holding the wings away from the body.

Housing

Many sick birds are too weak to perch. These birds should be placed in a smooth-sided enclosure or incubator without perches. Thick paper or non-woven towels can be used on the bottom of the enclosure. Many sick birds will not eat unless food and water are easily accessible. Seeds, fruits and vegetables can be spread around the bird to encourage eating. If the bird is still perching, food and water containers should be placed next to the perches to encourage food consumption. Millet spray is an attractive food item for many smaller species.

Although abrupt diet changes should not be attempted while the bird is sick, offering the bird a balanced diet in addition to any food it is accustomed to eating is appropriate, and may offer therapeutic benefits because of improved nutrient value. Food and water should be removed from the enclosure of birds that are seizuring, obtunded or post-anesthetic to decrease the danger of aspiration or drowning.

Birds with leg fractures or paralysis are best maintained in a wire enclosure on thick cage paper or toweling. These birds will grasp the wire siding with their beak to steady themselves. If perches are provided, they should be close to the enclosure floor to prevent injuries.

Emergency Problems

Cardiovascular System

Bleeding and Anemia

The emergency clinician is often presented with bleeding birds and sick birds that are anemic. Anemia in birds may be caused by blood loss, decreased red blood cell production and increased red blood cell destruction. As in mammals, anemias can be classified as regenerative or non-regenerative.

The most common cause of blood loss in birds is trauma (Figure 15.11). Other causes include gastrointestinal (GI) bleeding, genitourinary bleeding, hemolysis and idiopathic hemorrhage. Hematochezia and melena may occur from enteritis, gastro-

intestinal ulcers, coagulopathies, liver disease and GI foreign bodies. Cloacal bleeding may be caused by cloacal papillomas, cloacitis, egg laying, or cloacal or uterine prolapse. Heavy metal toxicity can cause hemolysis, which may result in dramatic hemoglobinuria in some birds, especially Amazon parrots. Conures may present for a sudden onset of weakness, ataxia, epistaxis, bloody regurgitation, bleeding from the oral cavity, hematochezia, hemorrhagic conjunctivitis or muscle petechiation.

Anemias resulting from decreased red blood cell production are common in birds, possibly because of the relatively short life-span (28 to 45 days) of the avian erythrocyte.[22] "Depression anemias" are usually caused by chronic infectious, toxic or nutritional disease. A rapidly fatal non-regenerative anemia seen in two- to four-month-old African Grey Parrots is suspected to be of viral etiology. Some birds with this problem have been shown to have polyomavirus or PBFD virus antigens in the bone marrow.

Diagnosis of anemia is based on clinical signs and documentation of a decreased PCV. Weakness is the most common clinical sign. Severely anemic birds may have a dull, almost dazed demeanor. Tachypnea and tachycardia may also be present. On physical examination, pallor of mucous membranes is evident in the oral cavity, palpebral conjunctiva and cloaca.

CBC and reticulocyte count, serum or plasma biochemistry analysis, blood heavy metal concentration and whole body radiographs should be considered in cases of anemia of unknown origin. Further testing might include chlamydia screening and a bone marrow aspirate. If an intraosseous cannula will be necessary for stabilizing the patient, a bone marrow sample can be obtained through the cannula at the time of placement. If the mucous membranes are pale, the PCV should be determined before drawing more blood. If the PCV is below 15%, further blood collection is inadvisable. It should be noted that the volume of serum or plasma relative to the volume of whole blood will be increased due to the anemia; the minimum amount of blood necessary to perform the desired diagnostic tests should be drawn.

If the bird is actively bleeding on presentation, localization of hemorrhage and hemostasis are the first priorities. Developing feathers are called "blood feathers" because of the rich vascular supply within the shaft. When one of these feathers is broken, it may continue to bleed until it is removed from its follicle. For removal, the base of the damaged feather is identified by parting the surrounding feathers. The base is grasped firmly with hemostats, and the feather is removed from its follicle by gently placing opposing pressure on the structure around the feather base (Figure 15.12). If any bleeding occurs from the dermis, it can be controlled by applying pressure to the area or packing the follicle with surgical gel. Chemical or radiosurgical cautery[o] should not be used inside the feather follicle because the subsequent inflammation and tissue damage can cause abnormal feather regrowth, resulting in the formation of feather cysts.

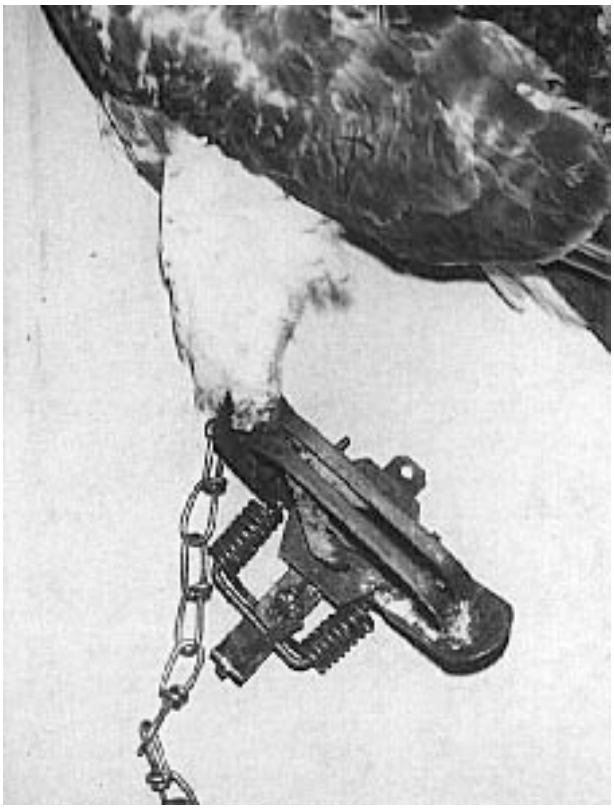

FIG 15.11 A mature female Red-tailed Hawk was presented after being found in a forest dragging a steel jaw trap. All of the soft tissues surrounding the metatarsus were destroyed. The metatarsus was black. The bird was euthanatized. Steel jaw traps are illegal in many states but are still used by poachers and individuals unconcerned with the inhumane destruction of free-ranging animals.

For home first aid, the client can be advised to wash any blood away with hydrogen peroxide, apply cornstarch or flour to the bleeding area and place the bird in a dark area until it can be presented to the clinician for evaluation. Bleeding from a nail can be arrested using ferric subsulfate, silver nitrate or bipolar radiosurgery. Application of bar soap or heat from a red-hot item can also serve as first aid measures.

FIG 15.12 Primary and secondary pin feathers have a substantial blood supply that arises at the base of the feather shaft where it is attached to the periosteum. Damaged pin feathers can result in substantial blood loss. Correctly removing the feather will allow the nutrient artery to collapse and will stop the bleeding. To remove a pin feather, the base of the feather is grasped with a pair of hemostats as close as possible to the skin edge. The skin is supported by applying gentle, opposing force around the feather

Persistent bleeding from soft tissue wounds is less common. If such bleeding occurs, it can be controlled by applying pressure to the area or through the use of bipolar radiosurgery. Surgical tissue adhesive[b] is often useful (Figure 15.13). Hemorrhage from oral and tongue lacerations may be difficult to control. Complete evaluation and suturing of these lacerations usually require general anesthesia.

The extent of blood loss can be gauged by the history or by the amount of blood present in the carrier. The capacity of birds to tolerate acute blood loss is often underestimated. In general, flighted birds tolerate blood loss better than mammals and non-flighted birds. Blood volume in birds averages ten percent of body weight. A healthy bird can lose as much as 30% of blood volume (about 3 ml/100 grams of body weight) with minimal clinical problems.[44] Because it takes roughly 24 hours following hemorrhage for the PCV to equilibrate, measurement of the PCV two days after the onset of blood loss is most useful as a diagnostic and prognostic indicator.

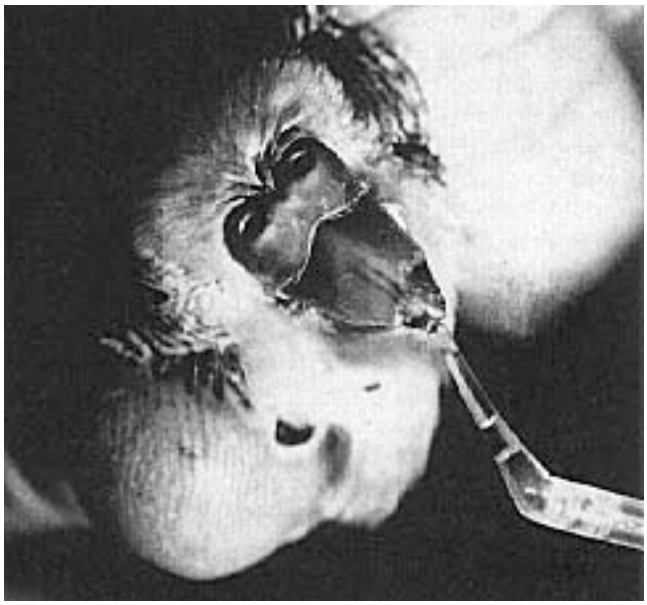

FIG 15.13 Careful application of tissue adhesives can be used to control bleeding of the beak or nails. Glue applied to the beak must not be allowed to run into the mouth or onto the eyelids.

Nonspecific treatment for blood loss includes volume replacement by subcutaneous or intravenous fluids, and the administration of iron dextran and B vitamins (see Chapter 18). The need for hospitalization and further supportive care depends on physical examination findings. Birds that are weak and in shock will require more aggressive therapy. Birds on an all-seed diet can be assumed to be nutritionally deficient and will benefit from an injection of vitamin K_1.

In birds with idiopathic hemorrhage, such as in conure bleeding syndrome, injectable vitamin K_1, vitamin D_3, calcium and antibiotics are indicated. The etiology of conure bleeding syndrome is unknown, but it is possible that a dietary lack of vitamin K, calcium and other nutrients may alter normal clotting mechanisms.[51,55] If hemoglobinuria is present, treatment should be initiated with calcium disodium edetate (CaEDTA) for possible heavy metal toxicity (see Chapter 37). If clinical signs are being caused by heavy metal toxicity, there will usually be clinical improvement within six hours of initiating CaEDTA therapy.

The benefits of blood transfusions in birds are controversial. In pigeons that lost 70% of blood volume, it

was determined that fluid replacement with LRS was more effective in resolving anemia than iron dextran, homologous blood transfusions or heterologous blood transfusions. All study birds had a normal PCV within six days following acute blood loss. Heterologous transfusions from chickens were not an effective treatment, but the authors concluded that a homologous blood transfusion might be useful in birds with a PCV <20%.[6] A similar controlled study is needed to evaluate blood transfusions in psittacine birds. Until a controlled study is performed, it is probably valid to assume that homologous blood transfusions are preferable to heterologous, and that in most instances, a blood transfusion will not greatly increase the survival rate in acute blood loss. However, in the authors' experience, even heterologous blood transfusions appear to be clinically beneficial to birds suffering from chronic anemia. The goal of the transfusion is to stabilize the patient while diagnostic tests can be used to determine the etiologic agent of the anemia. A transfusion volume of roughly 10 to 20% of calculated blood volume is ideal. A rough cross-match can be performed by mixing red blood cells from the donor with serum from the recipient; the absence of gross agglutination or hemolysis suggests compatibility.

Shock

The state of shock is difficult to determine in the avian patient. Clinical signs include weakness, pallor and poor perfusion of peripheral vessels. Vascular perfusion can be estimated by occluding the ulnar vein proximally on the medial surface of the wing and evaluating turgescence and filling time.[1] Decreased turgor and a filling time greater than 0.5 seconds are indications of reduced circulatory volume. Septic shock is a possibility in debilitated birds, and is clinically recognized as severe depression, particularly in birds with known exposure to infectious diseases.

Therapy for shock includes administration of fluids to expand the circulating blood volume and rapidly acting corticosteroids. If possible, corticosteroids and fluids should be administered intravenously or intraosseously. Intramuscular corticosteroids and subcutaneous fluids are beneficial but take more time to enter the circulation. In cases of shock, a state of metabolic acidosis may be present, and bicarbonate replacement therapy should be considered. Parenteral bacteriocidal antibiotics are given if bacterial infections are suspected.

Cardiac Failure

The field of avian cardiology is in its infancy, and cardiac failure is rarely diagnosed antemortem. Suspicious clinical signs include weakness, anorexia, tachypnea, dyspnea, coughing and abdominal distension due to hepatomegaly and ascites. The diagnosis is suggested by finding an arrhythmia or murmur on auscultation, and by radiographic changes including cardiomegaly, hepatomegaly and ascites (Figure 15.14). A single IM dose of furosemide, low-dose subcutaneous fluids and an oxygen-rich environment are indicated. Electrocardiography and ultrasonography are used to confirm cardiac disease and guide the selection of other cardiac medications (see Chapter 27).[35,48]

Cardiopulmonary Resuscitation (CPR)

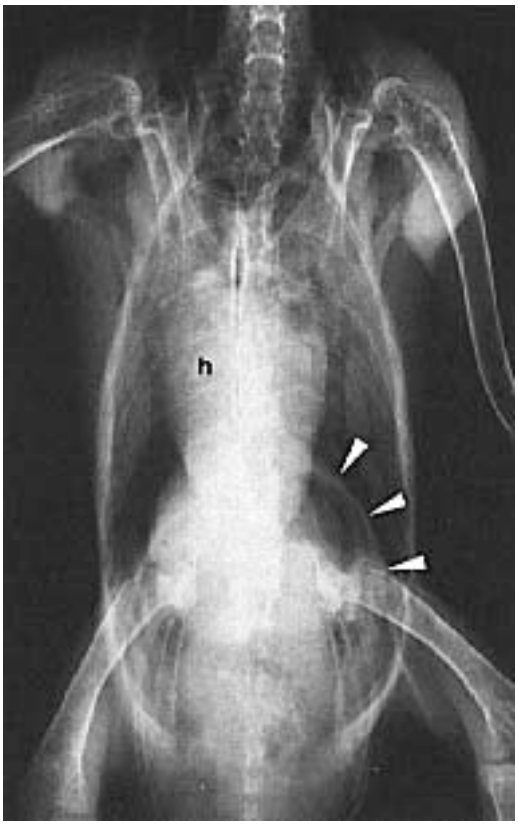
Avian CPR follows the same "ABC's" as mammalian CPR: Airway, Breathing and Circulation. In a bird that has stopped breathing, an airway must be established by placing an endotracheal or air sac tube. To avoid the danger of zoonotic disease, it is preferable to ventilate the bird in this fashion; alternatively, mouth-to-mouth respirations can be given by cupping the mouth over the bird's nares and beak opening. Positive pressure ventilation should occur once every four to five seconds. Once ventilation has been started, the heart beat or peripheral pulse should be determined. If neither is present, the heart should be massaged by firm and rapid compression of the sternum. Epinephrine and doxapram are given as necessary. The intratracheal, intracardiac or intraosseous routes (even spray into the thoracic cavity if open) for emergency drug administration should be considered when peripheral vascular access is not possible.[24]

Cardiopulmonary resuscitation should always be attempted in previously healthy birds that have collapsed; however, CPR is rarely successful in birds that are debilitated from long-standing, chronic disease.

Gastrointestinal System

Crop Burns and Injuries

Thermal burns of the crop are seen in hand-fed neonates, particularly psittacine birds. The most common cause is the occurence of "hot spots" in poorly mixed microwaved formulas. Birds will accept the overheated formula without showing discontent. A few hours after feeding, an erythematous area of skin is evident overlying the crop, generally on the right ventral portion. If the bird has feathers in this area, the burn is often not noted unless the crop and skin



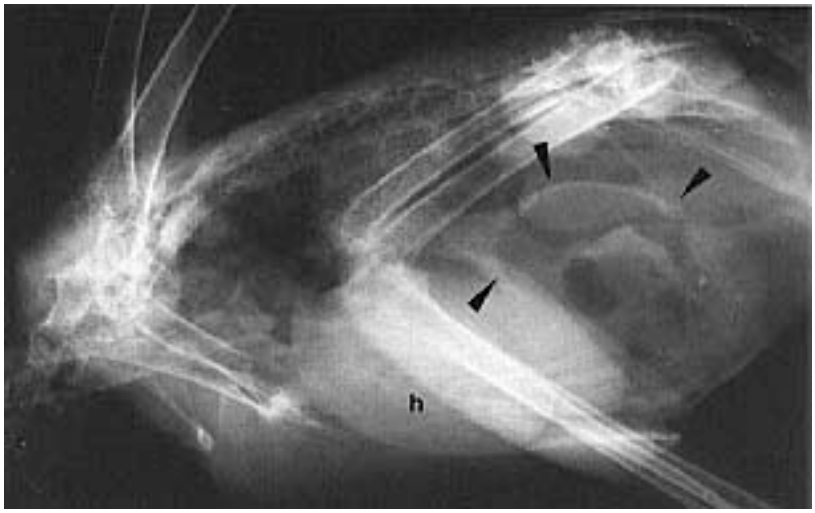


FIG 15.14 A one-year-old Umbrella Cockatoo was presented for emaciation (409 g) and depression. The bird had severed an electric cord the day before presentation and was having problems swallowing. Physical examination findings included harsh respiratory sounds (lung area) and dull "sunken" eyes. Abnormal clinical pathology findings included PCV=30, LDH=1400 and AST=850. Radiographic lesions included cardiomegaly (h), gaseous distension of the gastrointestinal tract (ileus) and enlarged radiodense kidneys. Note the gaseous distension of the proventriculus (arrows). The enlarged radiodense kidneys are suggestive of severe dehydration (consistent with physical examination findings), but microcardia is more characteristic of dehydration than cardiomegaly. The bird did not respond to emergency therapy. Histopathology findings included severe hepatocellular necrosis and pulmonary hemorrhage.

necrose, leaving a fistula from which formula drains out onto the breast feathers (see Color 30).

The presence of a fistula is alarming to most owners; however, it is a true emergency only if the fistula is so large that all formula drains out of the crop, leaving the bird in danger of dehydration and starvation. The frequency of feedings may have to be increased in the interim in order to replace the formula lost through the fistula. If the burn is discovered soon after it occurs, the crop area should be monitored daily. The use of anti-inflammatories (eg, corticosteroids) represents more of a risk than a benefit in young birds (see Chapter 41).[24] Some periesophageal burns, lacerations and other injuries may not result in fistula formation and are recognized clinically as crop stasis. In some cases, the feeding instrument may have punctured the crop, and the food is deposited between the skin and the crop wall. This is a true emergency because the bird can suddenly become toxic, exhibit massive edema and die.

Gastrointestinal Stasis

Gastrointestinal stasis is a common problem in pediatric medicine. Multiple factors that may affect GI motility in young birds include infectious disease, poor sanitation, low environmental temperature, low formula temperature and low humidity. Physical obstructions are usually caused by foreign body ingestion (bedding is a common culprit) or accidental ingestion of a feeding tube. Causes of GI stasis in adult birds include gastroenteritis (leading to ileus), neuropathic gastric dilatation, heavy metal toxicity and obstruction (see Chapter 19).

Delayed crop emptying is the most common presenting sign of GI stasis. Regurgitation or vomiting may occur also. Fecal output is reduced. If allowed to persist, the bird becomes dehydrated, loses weight and may become septic. Chronic cases in debilitated birds can be difficult to manage and treat effectively, and the client should be advised that therapy may be lengthy and that the prognosis is poor.

Physical examination begins with an assessment of hydration status and thorough palpation of the crop for the presence of foreign bodies or inspissated food material. Some crop foreign bodies, particularly linear ones, can be removed by carefully manipulating them back up the cranial esophagus and into the oropharynx, where they are visualized and grasped with forceps. Removal of other foreign objects and inspissated food material is most easily accomplished via ingluviotomy (see Figure 41.13). The bird is anes-

thetized with isoflurane and intubated to reduce the danger of aspiration. A small incision is made over the left lateral pendulous crop to ensure that the incision is not damaged should the bird require tube-feeding. The incision is closed in two layers using a 6-0 absorbable suture. Postoperative feedings should be small and frequent, beginning with clear liquids and gradually increasing the strength and amount of formula over the next 24 to 48 hours until a normal feeding schedule has been resumed.

If a crop foreign body cannot be palpated, food and water should be withheld until the crop is empty or the crop can be drained by the clinician. Usually it is difficult to empty the crop via gavage tube because crop contents tend to become thickened when the crop is static. Some clinicians hold the bird upside down and express the crop contents.[50] The authors believe that this technique in unanesthetized patients puts the bird in risk of aspiration, and that even when used in anesthetized patients, a finger should be placed over the choanal slit during the procedure to prevent reflux from entering the nasal passages. Another technique is percutaneous aspiration of the crop using an 18 to 22 ga needle.[24] Flushing the crop with 0.05% chlorhexidine solution is often beneficial. This can be done two to four times daily if the bird can tolerate the handling. After flushing, a small amount of LRS, followed in three hours with dilute formula or Isocal,[k] should be administered by gavage tube.

Radiographs and a barium series are indicated if impaction or extraluminal obstruction is suspected, particularly in adult birds. Before the series is begun, the crop contents should be removed and the anesthetized bird should be held upright until the esophagus can be packed with moist gauze. A finger placed over the cranial esophagus will help prevent reflux from entering the pharyngeal area.

A minimum database should include cytology of the crop contents and fecal wet mounts (see Chapter 10). Samples can be collected by crop lavage or by passing a flexible swab directly into the crop. Culture and sensitivity of the crop contents and feces are indicated if bacterial infection is suspected. An in-house blood glucose determination is important if the bird is weak.

In birds with GI stasis, restoring and maintaining hydration with subcutaneous, intravenous or intraosseous fluids is important, and should be considered prior to performing surgery or other stressful procedures. Parenteral antibiotics and metoclopramide[n] are often indicated (see Chapter 18). Oral medications are mostly ineffective because of slow passage into the intestinal tract. Oral aminoglycosides, however, may be beneficial in cases of bacterial overgrowth because they act locally with minimal absorption or side-effects. Parenteral feeding or placement of a duodenal feeding tube should be considered in critically ill birds (see Chapter 41).

Budgerigars with goiter often present with crop stasis and a history of regurgitation due to pressure of the enlarged thyroid glands on the caudal esophagus. These birds may also have a squeaky voice or an audible click with each respiration; tachypnea and tail-bob may be present. Diagnosis of goiter is based on clinical signs and history of an iodine-deficient diet. These birds should be hospitalized for parenteral fluids, steroids, antibiotics and iodine therapy. In mild cases, crop motility may be restored without the need for emptying and flushing the crop by gavage tube. Occasionally a bird may not respond to standard therapy, and thyroid gland neoplasia should be considered in these cases.

Regurgitation and Vomiting

The distinction between regurgitation and vomiting in birds is often difficult to make clinically and, for the purposes of this section, the term regurgitation will be used.

Regurgitation to a "mate" (often the owner) or mirror is a normal part of breeding behavior; this is seen most commonly in budgerigars and cockatiels but can occur in any psittacine bird. A clinical history that includes intermittent regurgitation when the bird is being handled or talked to will help differentiate this normal behavior from a pathologic problem. Pathologic regurgitation in birds is caused by primary GI problems, metabolic problems and toxicities that induce nausea. Primary GI problems include infection (bacterial, viral, fungal and parasitic) and both intraluminal and extraluminal obstruction. Metabolic problems include hepatic and renal disease (see Chapter 19). Toxins that may cause vomiting include ingestion of some plants, pesticides and heavy metals such as lead or zinc. Some birds will regurgitate from stress or from motion sickness (such as during a car trip). Iatrogenic regurgitation may occur when the crop is over-distended with gavage formula and during recovery from chemical sedation or anesthesia.

Birds that are regurgitating will make a head-bobbing and neck-stretching type of motion. If the owner

does not observe or recognize this characteristic motion, a sign of regurgitation is finding food caked on the head feathers, giving the bird a spiky, "punk-hairdo" appearance (see Figure 19.7). A bird will often shake its head when regurgitating, depositing the regurgitus about the face and head. The bird should be evaluated for hydration, and the crop and abdomen should be palpated for distension or the presence of a foreign body or a mass. Goiter is the most common pathologic cause of regurgitation in budgerigars over two years of age. Bloody regurgitation may be seen in conure bleeding syndrome.

Initial diagnostic testing should include swabbing or flushing the crop for a wet mount, cytology, Gram's stain and culture. Fecal examination by wet mount and Gram's stain is often informative also. Other diagnostic tests to consider include a CBC, biochemistry profile and blood heavy metal concentration. Whole body radiographs, a routine barium series, or a double contrast study of the upper GI tract may be useful (see Chapter 12).

Initial stabilization of the regurgitating patient involves parenteral fluid therapy, removal of foreign bodies or toxins, specific toxin antidotes and appropriate antimicrobials if bacterial or fungal infections are suspected. Flushing the crop with 0.05% chlorhexidine reduces local bacterial levels in cases of ingluvitis.

Severe Diarrhea, Hematochezia and Melena

Diarrhea in birds is clinically recognized by unformed feces, often in association with an increase in the fluid portion of the dropping (see Color 8). Stools may "normally" be loose from stress, excitement, over-consumption of dairy products and ingestion of foods with a high water content (vegetables and fruits). Pathologic diarrhea usually results from bacterial, viral, fungal, chlamydial or parasitic gastroenteritis. The presence of a foreign body in the GI tract can also cause diarrhea. Pancreatic or liver disease and ingestion of some toxins may cause diarrhea. The differential diagnosis list for the emergency patient with diarrhea includes gram-negative enteritis, hep-atopathy, chlamydial infection and heavy metal toxicity.

Physical examination of the bird with diarrhea should begin with careful evaluation of the hydration status and gross evaluation of droppings for evidence of blood, mucus, undigested food, plant material or gravel. Melena may be noted with problems of the upper GI tract (enteritis, foreign bodies, parasites, ulcers). Hematochezia may be present with disease of the colon or cloaca. Cytology or a dip stick for fecal occult blood should always be used to document GI bleeding before aggressive and unnecessary therapy is instigated. The cloacal mucosa can be examined by prolapsing it gently with a well lubricated cotton swab (Figure 15.15). The presence of yellow or green urates suggests involvement of the liver. Brown, pink, red or rust-colored urates are seen most commonly with acute heavy metal toxicity, particularly in Amazon parrots (see Color 8). Birds consuming heavily pigmented fruits (eg, blueberries, blackberries) may have dark feces that mimics melena or hematochezia (see Color 8).

The database for diarrhea includes fecal examination by wet mount, Gram's stain and culture. Cytology for *Giardia* sp., *Trichomonas* sp. or other protozoa should be considered. Other valuable diagnostic tests include a CBC, biochemistry profile, radiographs, blood heavy metal concentration and screening for chlamydia.

Parenteral fluids should be administered to meet maintenance levels and replace estimated fluid volume lost to diarrhea. Debilitated birds may benefit from intravenous or intraosseous fluids and one dose of rapidly acting corticosteroids. Parenteral administration of a bacteriocidal antibiotic with a broad gram-negative spectrum is indicated because bacterial enteritis is common with diarrhea either as a primary cause or as a secondary problem.

Cloacal Prolapse

Prolapse of the cloacal mucosa is associated with masses within the cloaca, neurogenic problems or conditions causing tenesmus (eg, enteritis, cloacitis or egg-binding). Idiopathic prolapses are seen also.

A prolapsed cloaca may not be immediately apparent to the owner unless the bird is seen self-traumatizing the area or there is blood on the droppings. The history should include questions about diarrhea, straining or previous egg laying. Abdominal palpation for a mass and checking for prolapse of the ureters or uterus should be a priority during the physical examination. Cloacal tumors, such as adenocarcinomas, tend to be single and discrete. An irregular, "raspberry-like" appearance of the mucosa suggests cloacal papillomatosis (see Color 19).

Diagnostics and treatment are best performed with the bird relaxed under isoflurane anesthesia. Fecal retention is a problem with long-standing prolapses and with neurogenic etiologies (see Color 19). Man-

FIG 15.15 A mature Amazon parrot was presented with chronic diarrhea. On physical examination, an accumulation of excrement was noted in the pericloacal area and on the tail feathers. The cloacal mucosa was examined using a moistened cotton-tipped applicator. A tentative diagnosis of papillomatosis was made by identifying small, pink nodules on the cloacal mucosa (courtesy of Elizabeth Hillyer).

ual massage of the caudal abdominal and cloacal regions promotes fecal evacuation. Parenteral fluid therapy and treatment for septic shock should be used in these cases.

A complete examination of the cloacal area must be performed. In larger birds, a vaginal speculum and strong light source permit examination deep into the cloacal region. Diagnostic tests to consider include fecal wet mount, Gram's stain, culture and radiographs. If cloacal papillomatosis is suspected, tissue excision with biopsy is necessary to confirm the diagnosis. A prolapsed cloaca caused by papillomas does not require a purse-string suture preoperatively. In fact, purse-string sutures in birds with cloacal papillomas may result in blockage of the cloacal opening and are thus contraindicated. Solitary tumors should be biopsied by excision if possible.

Prolapsed mucosa should be protected from damage and desiccation. The tissues should be flushed with saline and covered with a sterile lubricating jelly or ointment. The need for a retention suture will vary depending on the individual bird and the clinician's preferences. Retention sutures may complicate the prolapse by exacerbating straining and should be avoided if at all possible. If a retention suture is placed, it must not interfere with evacuation of the cloaca.[24] A cloacapexy may be necessary in some birds that chronically prolapse (see Chapter 41). It is important to treat any possible underlying cause of prolapse such as hypocalcemia or other nutritional or metabolic problems.

Liver Disease

As in mammals, liver disease is often difficult to diagnose and characterize in birds (see Chapter 20). Clinical signs of hepatitis are often nonspecific, including lethargy, inappetence, polyuria, polydipsia, diarrhea and ascites. Birds with ascites are often tachypneic or dyspneic. The presence of yellow or green urates is an indicator of probable liver disease (see Color 8). On physical examination, an enlarged liver may be palpable or, particularly in passerine birds, may be visible through the skin.

The basic database for suspected hepatitis includes a complete blood count, serum biochemistry profile, bile acids, fecal Gram's stain, fecal culture, cytology of the abdominal fluid, whole body radiographs and chlamydial testing.

While laboratory tests are pending, treatment for suspected liver disease includes basic supportive care, broad-spectrum antibiotics, oral lactulose and at least one dose of parenteral vitamin K_1. Doxycycline is the drug of choice for chlamydiosis. Metronidazole, cephalosporins and the penicillins are the antibacterials of choice for small mammal hepatic infections. Investigations to determine the best antibiotics for avian hepatitis have not been performed.

Pancreatic Disease

Primary pancreatitis is seldom diagnosed in birds, but is occasionally found at necropsy.[17a] Bacterial, viral and chlamydial infections of other organs may spread to the pancreas causing secondary problems. Acute pancreatic necrosis in an Umbrella Cockatoo[38] and pancreatic atrophy in a Blue and Gold Macaw[40] have been described. The underlying cause was not found in these two birds; however, it was speculated that obesity and a high-fat diet contributed to disease in the cockatoo.

Clinical signs of pancreatitis may include inappetence, lethargy, weight loss, polyuria, polydipsia, ab-

dominal distension and abdominal pain. Pancreatic exocrine insufficiency results in polyphagia, weight loss and bulky, pale droppings (see Color 8).

A CBC and a biochemical profile that includes amylase and lipase levels are indicated. In cases of acute pancreatitis, a radiograph may demonstrate a hazy or fluid-filled abdomen. Initial treatment should include aggressive parenteral fluid therapy and broad-spectrum antibiotics. One dose of rapidly acting corticosteroid may be beneficial in some birds. Plant enzymes (rather than canine pancreatic enzymes) can be added to the tube-feeding formula to help with digestion (see Chapter 18). Vitamin E and selenium should also be given, and the bird tested for zinc toxicosis.

Urogenital System

Egg Binding

Egg binding is most common in hens that are on a poor diet, are first-time egg layers or are prolific layers. Problems are most common and most severe in smaller species such as cockatiels, budgerigars and finches. Egg-laying is metabolically demanding, requiring large expenditures of protein, calcium and fat. Lack of sufficient dietary calcium, protein and trace minerals such as vitamin E and selenium will predispose to egg binding by resulting in soft-shelled eggs and uterine atony. Hypovitaminosis A is often a contributing factor due to alteration of mucosal integrity.

Clinical signs of egg binding include lethargy, inappetence, abdominal straining and remaining fluffed on the bottom of the enclosure. Owners often report "diarrhea." Droppings often tend to be large and wet due to cloacal relaxation associated with egg laying. In some birds there is a lack of droppings due to the egg's interfering with normal defecation. The owner should be questioned about previous egg laying activity and for clues that would suggest nesting behavior (eg, paper-shredding, hiding under papers or in dark places and nest building).

On physical examination, the hen may appear weak and quiet. Tachypnea is common. Unilateral or, less commonly, bilateral leg lameness or paresis occurs if the egg is pressing on the ischiatic nerve as it runs through the pelvic region. In most cases an egg is palpable in the abdomen. If the egg is poorly calcified, it may not be palpable but the abdominal region will be moderately swollen and soft. The cloacal region is often swollen also. Whole body radiographs can be used to confirm the diagnosis. Medullary bone formation, also termed hyperostosis or osteomyelosclerosis, occurs under the influence of female reproductive hormones and is seen especially in the femur, tibiotarsus, radius and ulna (see Figure 12.65).

Occasionally, the presence of an egg with a non-calcified shell may be difficult to distinguish radiographically from egg-related peritonitis or an abdominal mass. In this case, a repeat radiograph approximately one hour after the administration of barium may aid in localizing internal structures. An alternative is to administer supportive care, calcium, vitamins and antibiotics, and then to repeat the radiograph one to two days later, assuming that an egg would have calcified or passed in that time period. Uterine rupture is possible, and will negate this last assumption (see Chapter 41).

Conservative medical treatment for egg binding is often successful and should always be given a chance to work before more aggressive therapy is instigated. Decisions regarding therapy should be based on the bird's clinical condition, but in most cases, it is best to allow up to 24 hours of medical therapy before initiating more aggressive steps. Even with paresis of a leg, it is best to attempt medical therapy first because the paresis usually resolves once the egg is passed. Small birds such as finches may require earlier intervention.[19] The real emergency associated with a retained egg is that it may place excessive pressure on internal pelvic structures, such as the caudal poles of the kidneys, where ischemic renal necrosis may occur (Figure 15.16). In contrast, some birds are not clinically ill from egg binding. An example is an egg-bound budgerigar that the authors treated medically for six months because the owners refused surgery.

Medical therapy for egg binding includes fluids, lubricating the cloaca, supplemental heat and parenteral calcium, vitamin A and vitamin D_3. If the bird is anorectic, oral dextrose or a small gavage feeding may be given, and the bird should be placed in a warm, moist environment such as an incubator containing wet towels. (An old-fashioned, sometimes successful, therapy for egg binding is to submerge the caudal portion of the bird in a bowl of warm water for five to ten minutes!) After one or two doses of calcium, an injection of oxytocin may promote egg passage. Prostaglandin may be more effective in facilitating the passage of an egg than oxytocin (see Chapter 29).

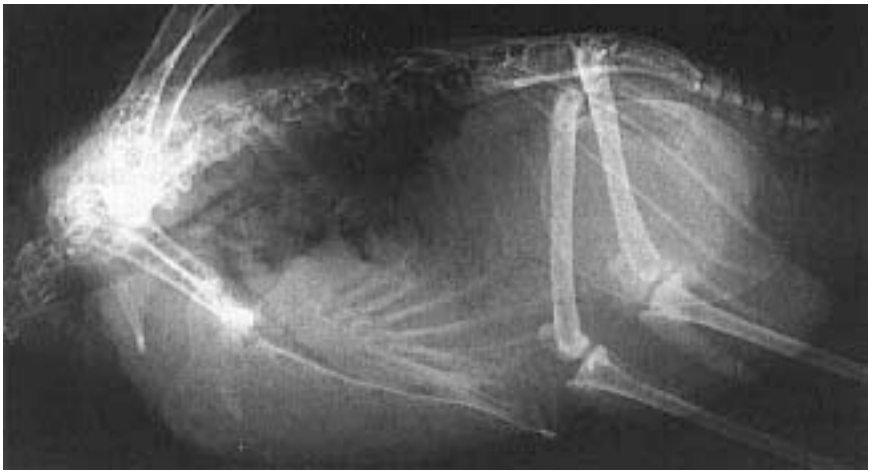

FIG 15.16 An adult Amazon parrot was presented with an acute onset of lethargy and mild dyspnea. Abnormal clinical pathology changes included WBC=22,400, Ca=28.5 and LDH=750. A hard mass, suspected to be an egg, was palpable in the caudal abdomen. Radiographs indicated a calcified egg in the caudal abdomen and hyperostosis. The high Ca level, elevated LDH activity and hyperostosis in the femur are all common with egg laying. This bird delivered a normal egg the day after evaluation.

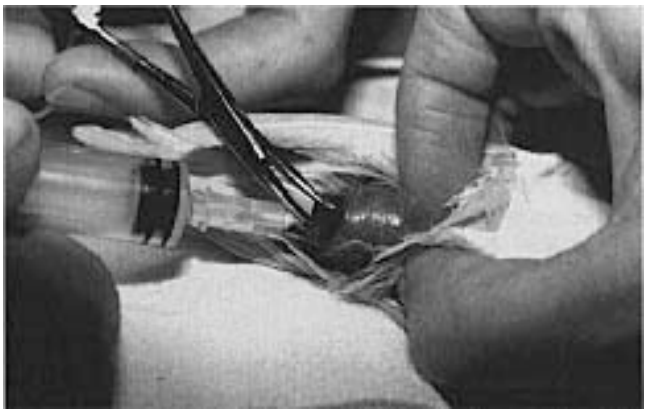

FIG 15.17 A cockatiel hen was presented for depression, straining to defecate and rear limb ataxia. A firm mass was palpable in the caudal abdomen and an egg could be visualized through the urodeum using a small otoscope cone. The bird was given five percent dextrose SC, calcium and oxytocin IM and the cloaca was lubricated with a water-soluble jelly. The bird was placed in a warm incubator. One hour later, the bird was re-evaluated and had not improved. The egg was gently pinched into the cloaca, the egg contents were removed with a needle and syringe, and the egg was collapsed. The fragments of the egg were removed with hemostats. The bird was given SC fluids and corticosteroids and placed back in the incubator. The bird had returned to normal and was eating within three hours (courtesy of Kathy Quesenberry).

If the egg has not passed in 24 hours, or if the bird appears to be weakening, two nonsurgical techniques can be considered. The first works best if the egg is low in the abdomen. With the bird under isoflurane anesthesia to achieve full relaxation, the egg may be manually pushed caudally so its tip is visible through the uterine opening into the cloaca (see Chapter 29). An 18 to 22 ga needle is inserted into the egg, the egg contents are withdrawn, the egg is carefully imploded and the egg shell fragments are withdrawn using a small hemostat (Figure 15.17). Generally, the hen will pass any remaining egg shell fragments within several days.

The second technique is transabdominal aspiration of egg contents using a large gauge needle (see Chapter 29). The egg is manipulated to the ventral body wall and the egg contents are removed with a syringe. The egg is then gently imploded, relieving pressure on pelvic structures. Supportive care and calcium are continued until the bird delivers the egg shell on its own. Some clinicians flush the uterus for several days to prevent feces from contaminating the tramautized uterus. The positive or negative effects of this procedure have not been studied. The disadvantage of this technique is that occasionally a hen does not pass the egg shell fragments, necessitating a hysterectomy.

Surgical removal of the egg via laparotomy is necessary if the uterus is ruptured, if an egg cannot pass due to adhesions or other causes, or if there are multiple eggs (see Chapter 41).

Uterine Prolapse

Uterine prolapse containing an egg is common, particularly in budgerigars. Occasionally the uterus will prolapse without the egg. Both conditions probably result from constant straining coupled with muscle weakness due to nutritional deficiencies or physical exhaustion.

The bird is anesthetized with isoflurane to allow careful examination of the prolapsed tissue. While the bird is anesthetized, SC or IV fluids, parenteral calcium, vitamins A and D_3 and a broad-spectrum bacteriocidal antibiotic are administered. One dose of a rapidly acting corticosteroid is appropriate if the bird appears to be in shock. The ureters, rectum and cloaca will sometimes prolapse with the uterus. The prolapsed tissue should be flushed with sterile saline and replaced with a lubricated blunt probang, sterile swab or other sterile, blunt instrument (see Color 29).

Oxytocin or prostaglandin (see Chapter 29) applied directly to the uterus will help reduce swelling and

control bleeding. If an egg is in the prolapsed tissue, the open end of the prolapse should be identified and the egg contents aspirated with a needle to gently collapse the egg. The egg is usually tightly adhered to the fine, transparent uterine tissue, which should be liberally moistened with warm sterile saline. A moist, sterile swab will help gently peel the uterine tissue from the egg without tearing. The prolapsed tissue should be flushed again and replaced as described. The need for a retention suture in the cloaca is based on clinical judgment.

The prognosis for recovery depends on the extent of tissue trauma. In the authors' experience, many hens respond well to therapy even if the replaced uterine tissue appears severely desiccated or inflamed. Antibiotic therapy for five to seven days is recommended. Any remaining necrotic areas should be exteriorized and amputated. The necrotic areas are sutured with 4-0 or 5-0 absorbable suture material, being careful to avoid the ureters.[19] Most birds will temporarily cease egg laying after the trauma and illness associated with uterine prolapse. After the bird is stable, a hysterectomy may be necessary to prevent future egg-related problems.

Egg-related Peritonitis

Egg-related peritonitis is thought to occur because of a failure of the ovum to enter the infundibulum. The peritonitis that occurs is usually sterile, but may be complicated by secondary bacterial infection. The condition is seen most commonly in cockatiels, lovebirds and budgerigars, but can occur in any hen.

The history usually includes a gradual onset of lethargy, weakness, inappetence, tachypnea and dyspnea. Nesting or egg-laying behavior often precedes the onset of illness. Occasionally, a bird will show no clinical signs other than tachypnea or dyspnea related to fluid accumulation in the abdomen. The clinical presentation of egg-related peritonitis varies with the species. Ascites is most common in cockatiels.

On physical examination, the bird is found to have a fluid-filled, distended abdomen. If the bird is dyspneic, it should be placed in an oxygen-rich environment prior to diagnostics and treatment. Abdominocentesis is performed with a 23 or 25 ga butterfly catheter or an appropriately sized needle and syringe (see Chapter 10). Only a sufficient volume of fluid to relieve the dyspnea should be removed. The needle is passed into the abdomen just below the end of the keel. Care should be exercised to prevent laceration of the liver if hepatomegaly is suspected. Fluid drainage can be attempted from several sites, choosing avascular areas of skin. Fluid may range from yellow to rust-colored and may be clear or cloudy. More than one abdominocentesis may be necessary. Some veterinarians prefer to place a Penrose drain to allow a continuous port for fluid removal.[19]

Fluid analysis and cytology, a CBC and whole body radiographs should be performed. Radiographic changes are characterized by a fluid-filled abdomen with loss of detail. Increased ossification in the long bones suggests that calcium is being stored for impending ovulation. Parenteral fluids, a broad-spectrum antibiotic and an anti-inflammatory dose of corticosteroid should be administered. Although corticosteroids should be used with caution in birds, low-dose corticosteroid therapy for two to five days in conjunction with antibiotics appears to be beneficial in birds with egg-related peritonitis. A course of medroxyprogesterone acetate is a common companion therapy to steroids (see Chapter 29). A laparotomy and abdominal lavage may be necessary in birds with severe or non-responsive egg-related peritonitis (see Chapter 41).

Renal Failure

Renal failure is uncommonly diagnosed in avian medicine (see Chapter 21). Possible causes include some toxicities, ureteral obstruction and trauma (such as occurs with egg binding) and bacterial, viral, fungal or parasitic infections.

Clinical signs include polyuria, polydipsia, inappetence, depression and dehydration. Uric acid deposits may be visible on joint surfaces. The basic database consists of a CBC, biochemistry analysis, urinalysis, fecal Gram's stain and fecal culture.[52] Radiographs are useful to evaluate the size and density of the renal shadows. Uric acid deposits are radiolucent but renal mineralization will be visible on radiographs.

Emergency treatment consists of subcutaneous or intravenous fluids, antibiotics and a multi vitamin injection. The latter would be contraindicated if hypervitaminosis is suspected (eg, vitamin D toxicosis in macaws).

Respiratory System

Dyspnea

Dyspnea in birds is characterized by open-mouthed breathing, prominent abdominal excursions and tail-bobbing with respiration. Causes of dyspnea can be

divided into two categories: primary respiratory and extra-respiratory disease. Primary respiratory disease occurs in the trachea, lungs or air sacs and may be caused by viral, bacterial, fungal, parasitic, chlamydial and mycoplasmal infections, inhaled toxins or foreign body aspiration. Extra-respiratory diseases can cause dyspnea by interfering with normal air flow patterns through the respiratory tree or by limiting expansion of the lungs and air sacs. This category includes thyroid enlargement, abdominal masses, abdominal fluid and oral masses such as papillomas. Birds with severe rhinitis, impacted nares, choanal atresia or sinusitis may also show open-mouth breathing and a tail-bob because they cannot breathe through the nares. Anemia may also induce dyspnea (see Chapter 22).

A thorough history should include questions regarding the possibility of exposure to other birds or to air-borne toxins, the possibility of foreign body aspiration and recent evidence of crop stasis or ileus, which may lead to aspiration. Before a dyspneic bird is handled, it should be carefully observed for conjunctivitis, swollen sinuses, nasal discharge and respiratory sounds. Budgerigars with goiter may have a high-pitched voice or a squeak with each respiration. These birds are also prone to crop-emptying problems and may have a dilated crop. Birds with infectious respiratory conditions often have conjunctivitis, swollen sinuses or nasal discharge. Mynah birds and toucans may develop cardiomyopathy or iron-storage hepatopathy, resulting in ascites and dyspnea. Egg binding or egg-related peritonitis should be considered as a cause of dyspnea if the bird has a history of egg laying. The bird should be placed in an oxygen-rich environment while diagnostic and treatment plans are being formulated.

Some birds may benefit from immediate placement of an air sac tube (see Figure 15.10) while diagnostic tests are performed. If a bacterial pneumonia or air sacculitis is likely, antibiotics may be administered by nebulization in order to minimize handling. Alternatively, the bird may be anesthetized with isoflurane to collect diagnostic samples and initiate therapy. Initial diagnostic tests should include radiographs, CBC, biochemistry profile, abdominal fluid analysis (if present) and tracheal wash. Birds with ascites or egg-related peritonitis will often improve once the abdominal fluid is removed. Early in the course of therapy, enough fluid should be withdrawn to relieve dyspnea and provide a diagnostic sample. In theory, sudden withdrawal of too much fluid can cause hypovolemia and shock;[11,19] however, in practice, the authors have not experienced this problem. A 23 to 25 ga butterfly catheter or fine-gauge needle and syringe are used to aspirate from several sites through areas of avascular skin.

A tracheal wash should be performed just before the bird recovers from anesthesia. A sterile catheter or tube is passed into the tracheal opening. With the bird held parallel to the floor, sterile saline (up to 10ml/kg) is infused into the trachea and immediately aspirated. Cytology and bacterial and fungal culture can be used to evaluate the aspirated material.

General supportive care, including fluid therapy, heat, vitamins and nutritional support, is administered according to the patient's ability to withstand handling. Specific therapy is given according to the differential diagnosis (see Chapter 22).

Acute Dyspnea

Acute onset of dyspnea in a previously healthy bird is usually due to one of three causes: 1) inhalation of a toxin, 2) plugging of the trachea by dislocation of an infectious plaque from the choana or tracheal bifurcation or 3) inhalation of a foreign body such as seed or bedding material. Inhalation of small seeds by cockatiels is common.

When a blockage of the upper respiratory tract is suspected, an air sac tube will provide immediate relief of dyspnea. The bird can be anesthetized by administering isoflurane through the air sac tube, making it possible to examine the trachea endoscopically. In smaller birds, transillumination of the trachea may be used to identify tracheal foreign bodies. Radiographs often demonstrate the site of obstruction and will also allow for evaluation of the lungs and air sacs. Removal of a tracheal foreign body is accomplished using suction or a biopsy forceps. In some cases it may be necessary to perform a tracheotomy by incising between tracheal rings just distal to the foreign material. The foreign body is retrieved with biopsy forceps or pushed up and out of the trachea using a blunt probang.[19]

Air Sac Rupture

Rupture of an air sac often results in a balloon-like deformity of the skin (see Figure 22.12). While the clinical appearance is quite alarming to owners, the problem is rarely a true emergency. Rupture of a cervicocephalic air sac in small birds is most common. The rupture is usually acute, but gradual onset is seen also. Most birds are reported to be otherwise normal and the cause of the rupture is not identified.

On physical examination, a soft, air-filled swelling is palpable. The swelling will involve the head and neck region when the cervicocephalic air sacs are involved. A small needle and syringe can be used to aspirate some air and confirm the diagnosis. A medical workup should be considered if the bird is showing clinical signs of illness, particularly those associated with respiratory disease.

Initial treatment for air sac rupture involves making a percutaneous fistula to allow for continued drainage of air. This relieves pressure on the site of rupture to allow for healing. A rapid, simple technique is to use a hand-held ophthalmic cautery[o] to make a one to two centimeter opening in an avascular area of skin over the swelling, causing rapid deflation. Occasionally the swelling may recur when the fistula closes and the technique must be repeated, making a larger fistula. Surgical repair may be necessary in some birds if initial treatment fails (see Chapter 41).

Neurologic System

Head Trauma

Companion birds are often presented with head trauma caused from flying into ceiling fans, mirrors, windows and walls. Free-ranging birds may be injured by colliding with buildings, windows or automobiles.

Birds frequently recover from seemingly severe head trauma. Examination should include visual assesment for alertness and neurologic signs, an evaluation for shock, and examination of the cranium, eyes, nares and ears for evidence of fractures, hemorrhage or bruising. If the trauma is recent, treatment consists of IV or IM rapidly acting corticosteroid and placement of the bird in a dark environment maintained at a comfortable (cool) temperature. A warm environment may potentiate intracranial vasodilation. If the bird is in shock, IV fluids are given at one-half to two-thirds of the normal volume to avoid overhydration and cerebral edema. The use of diuretics is controversial in mammals with head trauma,[59] but mannitol or furosemide may be beneficial if the bird does not respond to initial therapy. Short-term monitoring consists of neurologic evaluation and measurement of blood glucose.

Birds may be presented with severe neurologic abnormalities from head trauma that occurred several days earlier. If the trauma occurred over 24 hours previously, an empirical course of antibiotics and short-term corticosteroids can be attempted, but this is usually ineffective. Neurologic impairment may be permanent if the injury is several days old and no improvement is noted following 48 hours of therapy. Long-term corticosteroid therapy should be avoided in such birds.[24]

Seizures

Although the study of avian neurology is in its infancy, most seizure disorders in birds can be managed effectively, even if the exact cause is not determined. Avian seizures have not been classified according to the criteria used in mammals; however, several different types of seizure activity are seen clinically. Mild seizures are characterized by a short period of disorientation with ataxia and inability to perch. Generalized seizures are characterized by a loss of consciousness, vocalizing, wing flapping and paddling. Partial seizures are characterized by persistent twitching or motor activity of the head or one of the extremities. They can be continuous and chronic, and frequently go unrecognized by the owner because they are less dramatic than generalized seizures.

Causes of seizures in birds include primary central nervous system (CNS) disease resulting from trauma, hyperthermia, vascular accidents, infection or neoplasia, and metabolic problems such as hypocalcemia, hypoglycemia, hepatoencephalopathy, toxin exposure and fat emboli. Idiopathic epilepsy, a diagnosis of exclusion, has been reported in Peach-faced Lovebirds, Red-lored Amazon Parrots, Double Yellow-headed Amazon Parrots and mynah birds.[53,55,56,68] A syndrome of hypocalcemia causing weakness and seizures occurs in African Grey Parrots.[55] Cockatiels and lovebirds may show neurologic signs with an undiagnosed, fear-induced mild flapping of the wings, or occasionally with chlamydiosis. Egg-laying birds often have severe lipemia and may develop fat emboli with resultant neurologic abnormalities including seizures and paralysis. Hypoglycemic seizures occur most commonly in raptors and neonates of other species.

The history should include questions regarding diet, egg laying and possible toxin exposure. Owners rarely can verify heavy metal exposure although it is common in psittacine birds due to their propensity for chewing on toys and household objects. Even toys manufactured expressly for birds should not be assumed to be safe.[67] If the bird is not actively seizuring, a full physical and neurologic examination including a CBC, biochemical analysis and blood metal concentration should constitute the minimum database in most cases (see Chapter 37). Radiographs are

useful to evaluate bone quality and screen for metallic particles in the gastrointestinal tract. If the bird is weak or actively seizuring, an in-house blood glucose test should be performed. Abnormal values are less than 50% of the published normal reference interval for the species (see Appendix).[44]

While laboratory results are pending, treatment for birds not actively seizuring consists of general supportive care. If the bird is seizuring on presentation, the first goal of therapy is to stop the seizure activity with IM or IV diazepam. Intravenous phenobarbital should be underdosed and used with caution in birds.[19] If lead or zinc poisoning is a possibility, treatment with CaEDTA should begin immediately. Hyperthermia should be evaluated and treated, and hypoglycemia should be corrected with IV dextrose. Suspected chlamydiosis or other infectious diseases should be treated accordingly.

Seizure activity associated with hypocalcemia is most common in African Grey Parrots and young birds on a poor diet. The African Grey hypocalcemic syndrome is thought to occur because of a lack of compensatory mechanisms to maintain serum calcium levels.[55] The syndrome may actually represent a deficiency of vitamin D_3; however marginal dietary calcium levels seem to play a role.[68] These birds can have a serum calcium concentration as low as 2.5 mg/ml. Radiographically, the skeletal mineralization appears normal, indicating an inability to mobilize skeletal calcium. Other species that develop hypocalcemia will show decreased bone density, folding fractures and pathologic fractures. Treatment for hypocalcemia consists of parenteral calcium, vitamin D_3 and supportive care.

Coma

Coma can result from head trauma, toxin ingestion, hyperthermia, CNS infection or neoplasia, cerebral ischemia due to a vascular accident, or severe metabolic disease such as hepatic encephalopathy or uric acidemia. The history should include questions related to the onset of clinical signs and possible trauma, toxin ingestion or inhalation (carbon monoxide) and exposure to viruses or parasites (eg, *Sarcocystis* spp. , *Baylisascaris* sp.).

Ensuring a patient's airway and adequate ventilation are of primary importance. Establishing an airway with a tracheal or air sac tube and placing the bird in an oxygen-rich environment or applying positive-pressure ventilation may be necessary. The bird should be given dextrose IV if an in-house test indicates hypoglycemia. Emergency treatment consists of IV fluids (low dose if cerebral edema is a possibility), parenteral corticosteroids and treatment for hyperthermia as necessary. The use of IV diuretics such as mannitol or furosemide should be considered in birds with head trauma and hyperthermia. Bacteriocidal antibiotics or doxycycline for chlamydiosis may be indicated in some patients. The bird should be placed in a dark, cool enviroment after treatment to discourage cerebral vasodilation and edema.

The prognosis for recovery depends on the patient's progress during the first two days of therapy. Supportive care should include lubrication of the eyes and frequent turning of the recumbent bird as necessary.

Paralysis of Acute Onset

Paresis or paralysis of one or both legs is seen more commonly than problems with the wings. Possible causes of leg paresis include soft tissue trauma, fractures, osteoporosis, neural infections or vertebral trauma or neoplasia. Fractured leg bones are usually associated with reversible paresis of the foot and toes. Another cause of unilateral or, less commonly, bilateral leg paresis is pressure on the pelvic portion of the ischiatic nerve caused by egg binding or renal or gonadal tumors (see Color 25). Paresis of a wing is indicated by a wing droop. This is most commonly caused by soft tissue or bony trauma. Occasionally lead or other heavy metal toxicity will cause peripheral neuropathy resulting in wing or leg paresis.

A neurologic examination of affected birds should include assessment of cloacal tone, grasping strength of the feet and ability to move the tail (see Chapter 28). Muscles may undergo atrophy in the affected limb. The feathers should be parted with alcohol in order to examine the skin for evidence of bruising or wounds. This technique is useful for detection of fractures. The skin overlying the skull and spine should also be examined.

In many cases, the cause of the paresis or paralysis is evident on physical examination but radiographs may be useful to detect or assess intra-abdominal masses, metallic densities in the GI tract, coxofemoral luxations, or fractures of the spine, long bones or shoulder girdle. If heavy metal poisoning is a possibility, blood levels of lead or zinc can be determined.

Treatment is tailored to the specific condition. Egg binding and fractures are managed routinely. Paretic toes must be taped in the proper perching position to avoid knuckling and resultant damage to the top of the foot. One to three days of corticosteroid therapy

may be indicated in cases of head or vertebral trauma. In general, birds have a good capacity for return to function after the cause of the paresis or paralysis is resolved. An Amazon parrot with a pelvic plexus avulsion, incurred when its foot was trapped between the cage bars, had no perceptible sensation or function of the leg or foot. Treatment consisted of one dose of rapidly acting corticosteroid and seven days of a broad-spectrum antibiotic. A gradual return of sensation began around one month and the bird was back to normal at three months. It is impossible to predict the possibility of recovery with most avian neurologic injuries.

Chronic Disease With Acute Presentation

Birds are able to hide subtle signs of disease from owners until illness is advanced. The most common avian emergency presented to avian clinicians is a chronically ill bird that has decompensated to the point where the owner finally becomes aware of the illness. These birds are usually debilitated, dehydrated and cachectic. It is important with these patients to minimize stress (eg, loud noises, bright lights and excess handling). These birds generally require therapy for severe dehydration and cachexia. Emaciated birds are frequently anemic. Some birds begin to eat on their own within a short time after the initiation of therapy. Birds that refuse to eat should receive an easily digestible enteral preparation such as Isocal-HCN.[k]

Occasionally a cachectic bird will be presented that is alert and relatively active with a good appetite. The owner may not be aware of the weight loss and may have brought the bird in for another problem. This is a common presentation in birds with tuberculosis and some neoplasias. Although the bird may appear strong, its body fat and glycogen stores are depleted and it may decompensate as easily as birds that appear weaker. Prognosis for cachectic birds is grave.

Physical Injury

Animal Bites

Birds that have been attacked by a mammal or another bird are often presented for emergency evaluation. Bite-induced injuries are typically of the crushing and tearing type, often necessitating surgical repair or debridement of damaged tissue (see Chapter 16). Mammal bites are usually from a pet dog or cat. These are true emergencies and require immediate attention due to the pathogenic oral bacteria that are introduced deep into bite wounds. Cat attacks, in particular, are especially dangerous because many cats carry *Pasteurella multocida* on the gingival tissue and teeth.

Shock therapy is instituted if necessary. For a carnivore bite, treatment with a bacteriocidal antibiotic should begin immediately. Penicillins are the antibiotics of choice for cat bites because of their efficacy against *P. multocida*. All wounds must be flushed with copious volumes of warm sterile saline or 0.05% chlorhexidine. If they are difficult to find, small amounts of alcohol may be used to part the feathers, keeping in mind that there are usually two wounds, one from either jaw, associated with a bite. Puncture wounds must be left open for drainage, but large gaping lacerations may require partial closure.

Burns

The most common burns in birds occur on the legs and feet. These result when free-flighted birds land in hot cooking oil, hot water or on a hot surface. Burns to the oral mucosa and tongue may occur when birds bite on electric cords (see Color 24).

The treatment for burns involves basic supportive care, topical therapy and prevention of secondary infection while the wounds are healing. Secondary invaders are typically *Staphylococcus intermedius*, streptococci, coliforms and *Pseudomonas* spp. Systemic antibiotics and corticosteroids should be avoided during initial therapy because their use may predispose the patient to immunosuppression and nosocomial infection.[57]

Diligent topical therapy is the key to burn management. The burned areas should be flushed with copious amounts of cool water or saline. Feathers surrounding the wounds should be removed to allow for aeration. Water-soluble, topical antibacterial creams such as silver sulfadiazine[x] should be used instead of greasy or oily medications. If the wound is not infected (Gram's stain of cleansed wound negative for organisms), a hydroactive dressing[p] is beneficial to prevent water loss and promote granulation tissue (see Chapter 16). Wounds should be flushed twice daily and debrided once a day.

Gram's staining and culture and sensitivity of burned tissue may be indicated to monitor for infection. Systemic antibiotic therapy is initiated based on positive culture results. In humans, early surgical closure of burn wounds is beneficial. Perioperative antibiotic therapy may prevent surgically induced bacteremia or endotoxemia.[57]

Glue Traps

Free-flighted companion birds can become caught in glue traps intended for rodents. Trapped birds usually struggle, entangling many contour and primary feathers in the glue. Unless the bird can be removed from the trap with relative ease, the client should be instructed to bring the bird to the hospital still attached to the glue device.

Removing a bird from the glue entails gentle restraint of the body while freeing one extremity at a time. Feathers may be cut or gently removed. Shock therapy and supportive care should be given as needed. To prevent ingestion, the glue remaining on the bird must be removed before preening activity is allowed. Ether, acetone and water are ineffective. A commercial automobile protectant[q] is nontoxic and can be rubbed gently on affected feathers to remove the glue. This material can be rinsed away with warm water. These agents should be used with caution because some products contain lead (see Chapter 37).

Exposure

Oil

The avian veterinarian may be called on to treat free-ranging birds caught in an oil spill, companion birds that have flown into household oils, or birds whose owners have applied greasy, over-the-counter medications as topical mite or wound therapies (see Color 24). Large quantities of oil on the feathers disrupt normal thermoregulatory mechanisms and may result in hypothermia and coma (Figure 15.18). Oil-contaminated birds may also suffer from blockage of the nares and conjunctivitis. Systemic toxicity and GI upset may occur if the oil is ingested during preening.

The goals of treating oil-soaked birds are to reverse shock, prevent or treat hypothermia, provide basic supportive care and remove the oil from the feathers, nares and oral cavity. The bird is wrapped in a towel or thermal blanket to conserve body heat, and shock therapy is initiated if needed. The eyes are lubricated and oil is removed from the nares and oral cavity with a swab. Depending on the bird's tolerance for restraint, it may be necessary to alternate rest periods in a dark, heated environment (95°F) with warm baths (100 to 105°F) to remove the oil. A commercial dish-washing detergent[r] is a safe and effective solvent and is used in decreasing concentrations in sequential baths with thorough warm water rinses in between.[71] When the feathers are clean, the bird is dried with a blow-dryer and placed in a warm environment.

FIG 15.18 The most life-threatening concern with an oil-contaminated bird is hypothermia. Oil should be removed from the nostrils and oral cavity with cotton-tipped applicators and from the feathers with repeated baths in warm dish-washing detergent (courtesy of J Assoc Avian Vet).

Hyperthermia

Panting and holding the wings away from the body indicate hyperthermia in birds. Birds do not have sweat glands and do not dissipate heat efficiently. If allowed to progress, hyperthermia results in ataxia, seizures and coma.

The first goal of emergency therapy is to reduce body temperature by placing the feet and legs in cool water and wetting the feathers down to the skin with water or alcohol. If the bird is severely overheated, cool water can be infused into the cloaca, taking care not to induce hypothermia by overzealous cooling. Flunixin meglumine may be used to reduce hyperthermia rapidly and safely. A bird in shock should be given low doses of IV or SC fluids, and one dose of rapidly acting corticosteroid. Mannitol or furosemide may help control cerebral edema.

Frostbite

Frostbite injuries in birds generally occur on the feet and toes, but may also occur around large metal identification bands that are exposed to freezing temperatures. If the injury is recent, the frozen tissues appear pale, dry and avascular, sometimes with a swollen area proximally. If left untreated, the frozen tissue will become necrotic with an erythematous line of demarcation separating it from viable tissue. Ascending infections and gangrene do not appear to be complications of frostbite in birds.

Treatment of a recent frostbite injury involves gradual warming of the extremity by placing the affected tissue in circulating water baths and increasing the water temperature over a 20- to 30-minute period. If

QUICK REFERENCE FOR EMERGENCY TREATMENT

ANIMAL BITES
- Parenteral penicillin ASAP
- Clean wounds

BLOOD LOSS/ANEMIA
- Stop bleeding
- Volume replacement (IV or IO fluids)
- Iron dextran
- B vitamins
- Vitamin K_1
- Blood transfusion (PCV <20%)

BURNS
- Gently remove feathers
- Clean wounds
- Antimicrobial creams
- Hydroactive dressing if not infected

CACHEXIA
- Fluids - IV or IO
- 5% dextrose IV or IO
- Oral or parenteral alimentation

COMA
- Ensure patent airway
- Oxygen-rich environment
- Low dose fluids if dehydrated
- Single-dose corticosteroids
- Mannitol or furosemide

CPR
- Establish airway - air sac tube
- Ventilate every 4 to 5 secs
- Rapidly press on cranial sternum
- Epinephrine and doxapram IC, IO, IT

DIARRHEA
- Fluids (IV, IO)
- Bactericidal antibiotics
- Shock therapy if necessary

DYSPNEA
- URD - air sac tube
- Oxygen-rich enclosure
- Removal of some ascitic fluid
- Remove tracheal foreign bodies (suction or surgery)

EGG BINDING
- Medical therapy initially:
- Subcutaneous fluids
- Lubricate cloaca
- Prostaglandin
- Parenteral calcium and oxytocin
- Dextrose
  - oral (50%)
  - SC (5%)
- Vitamins A and D_3
- Supplemental heat
- If medical therapy fails:
- Assisted cloacal delivery
- Percutaneous ovocentesis
- Ventral laparotomy

FROSTBITE
- Gradual warming in water bath
- Increase temperature

HEAD TRAUMA
- Corticosteroids - IV, IO
- Dark, cool environment
- Minimal fluids - correct shock only

HYPERTHERMIA
- Wet with cool water
- Flunixin meglumine
- Mannitol
- Single dose corticosteroids
- Dry and keep at 85°F

LIVER DISEASE
- Fluids (IV, IO)
- Lactulose
- Vitamin K_1
- Doxycycline - if suspect chlamydia
- Parenteral penicillin - if suspect bacteria

OIL
- Shock therapy
- Prevent hypothermia
- Bathing in warm detergent

PANCREATITIS
- Fluids (IO)
- Bactericidal antibiotics
- Single-dose corticosteroids
- NPO if possible

PROLAPSED CLOACA
- Keep tissues moist and clean
- Replace cleansed tissue
- Correct underlying urogenital or GI problem
- Retention suture if necessary

PROLAPSED UTERUS
- Clean with sterile saline
- Topical oxytocin or prostaglandin to reduce swelling
- Lubricate with water-soluble gel
- Replace with blunt probang
- Retention suture if necessary

REGURGITATION
- Fluids (IV, IO)
- Remove foreign bodies or toxins
- Gastric lavage
- Specific toxin antidotes
- Appropriate antimicrobials

SEIZURES
- Diazepam - IV or IM
- Supportive care
- African Grey Parrots - calcium and vitamin D_3
- Raptors and neonates - glucose if needed

SHOCK
- Fluids (IV or IO)
- Corticosteroids (IV or IO)
- Bicarbonate if acidotic
- Bactericidal antibiotics if septic

SUPPORTIVE CARE
- Fluids
- Heat
- Vitamin/mineral supplements
- Nutritional support

TOXINS
- Treat for shock
- Remove ingested foreign bodies
- Oxygen for inhaled toxins
- Specific antidotes (see Chapter 37)

the tissue becomes necrotic, it can be surgically amputated at a later date (see Chapter 41).

General Emergency Principles of Toxin Exposure

Toxicity problems in companion birds are extremely common, with heavy metal poisoning leading the list.[24] Toxins that may enter by the alimentary route include lead, zinc and other heavy metals, various plants, rodenticides and some foods like chocolate (see Chapter 37). Birds are also very sensitive to aerosolized toxins, which include overheated polytetrafluroethylene (Teflon or other non-stick coatings), tobacco smoke, hair spray, pesticides, paint fumes, naphthalene, ammonia and carbon monoxide. Leaded fumes or dust can cause lead toxicity by inhalation in mammals. Iatrogenic drug toxicities may occur due to species or individual differences in drug metabolism or errors in administration or dosing.

Ingestion of prey animals or contaminated water may expose free-ranging birds to potential toxins, the most common being organophosphates, botulism toxin and lead.[39]

Clinical signs of toxicity vary widely and may include depression, anorexia, diarrhea, regurgitation, dyspnea and neurologic signs including ataxia, seizures, head tilt and peripheral neuropathy. Amazon parrots may have hemoglobinuria with acute lead toxicity. Occasionally a bird will be exposed deliberately or allowed unrestricted access to substances such as chocolate, alcohol or marijuana. Careful and specific questioning is usually necessary to delineate potential toxin exposure.

The first step in treatment of any toxin exposure is to stabilize the patient as necessary with shock and anticonvulsant therapy. If a known toxin was recently ingested, a crop lavage is the quickest method of removal. An ingluvotomy may be necessary to remove solid toxins (see Chapter 41). If more than one-half hour has passed since ingestion, a poison control center should be contacted (see Chapter 37).

Most often, an exposure to a specific toxin cannot be identified. A CBC and biochemistry analysis, blood lead and zinc concentration and radiographs are indicated. Nonspecific treatment for suspected toxicosis includes decreasing further absorption of the toxin from the GI tract, hastening elimination of the toxin and providing supportive care. If heavy metal toxicity is a possibility, treatment with Ca EDTA should be initiated.

TABLE 15.6 Suggested Equipment for Avian Emergency Practice (items not commonly found in a standard small animal practice)

- Incubator with temperature control, temperature and humidity sensors, oxygen port
- Nebulizer (ultrasonic)
- Anesthesia machine with isoflurane
- Bipolar radiosurgical unit
- Hand-held ophthalmic cautery devices
- 5-0 and 6-0 absorbable and nonabsorbable suture material
- Endotracheal tubes (2.0 and larger)
- Pre-sterilized air sac tubes of different sizes (shortened endotracheal tubes, red rubber tubes, others)
- 18 to 22 ga spinal needles (for use as intraosseous cannulas)
- 24 ga short, indwelling catheters
- 25 ga butterfly catheters with 3.5 inch tubing
- Buretrol or Control-a-Flow extension sets
- Low-dose insulin syringes (for accurate measuring down to 0.01 cc)
- Leg band cutters
- Metal feeding needles
- Various sizes of red rubber tubes (for crop and GI lavage)
- Catheter-tipped syringes
- Catheter-tip adapters
- Enteral feeding formula
- Seeds, spray millet, other foods for inpatients

If the ingested toxin is still in the GI tract, lavage is performed with saline or activated charcoal. Crop, proventricular and ventricular lavage are best performed with the bird intubated and under isoflurane anesthesia. A tube is passed into the proventriculus per os or a small crop incision is made and a red rubber tube is passed distally. The bird can be held with the head tilted down, and foreign objects and toxins can be retrieved by flushing.[67] The administration of activated charcoal helps to bind toxins and decrease GI absorption.

Saline and osmotic cathartics are used to speed elimination of toxins. Saline cathartics (eg, sodium sulfate [Glauber's salt])will precipitate heavy metal in the GI tract, decreasing absorption. Psyllium is an osmotic cathartic.[29] For specific toxin therapies see Chapter 37.

CHAPTER

16

TRAUMA MEDICINE

Laurel A. Degernes

Proper management of traumatic injuries in birds significantly decreases complications and wound-healing time. Many of the principles and techniques for wound management and bandaging in mammals apply to birds; however, anatomic differences require modifications and adaptations. Treatments and bandaging techniques for soft tissue wounds and nonsurgical fractures in birds will be discussed.

An understanding of wound healing is important in order to devise a treatment plan for optimal results. Wound healing is a complex interaction of host responses to an injury leading to regeneration of connective tissue, vascular supply and epithelium.[1] The three basic phases of wound healing are inflammatory (exudative), collagen and maturation.

Inflammatory Phase: The hemodynamic and cellular responses of the acute inflammatory response in birds have been studied in chickens and pigeons[2,6,10,19,22] (see Chapter 40). The response is similar in both mammalian and chicken skin in the first 12 hours. Immediate vasoconstriction to control hemorrhage is followed by vasodilation within 30 minutes.[22] Polymorphonuclear leukocytes and monocytes infiltrate the margins of the injured and necrotic tissue within the first 2 to 6 hours, causing active phagocytosis of necrotic cellular debris and bacteria.[10,22]

By 12 hours post-injury, the ratio of polymorphonuclear to mononuclear cells shifts toward a predominance of mononuclear cells.[22] During the next 36 hours, necrotic leukocytes that were active in phagocytosis accumulate at the periphery of the necrotic tissue and are phagocytized by macrophages and multinucleated giant cells. Fibroblasts appear in the wound during this period and continue to proliferate during the next few days, signaling the end of the first phase of the healing process.

Collagen Phase: Beginning the third or fourth day following injury in chickens, fibroblasts synthesize collagen in the form of microfibrils, which aggregate into larger fibers over time.[10] During this phase, which lasts approximately two weeks, capillaries develop from bud-like structures from nearby vessels and penetrate the wound. Wound contraction occurs, and epithelial cells proliferate and migrate across the wound surface.[20,21]

Maturation Phase: The final phase of wound healing may take weeks to months, and is marked by remodeling of the collagen bed and a decrease in the number of fibroblasts.[21] The weak, poorly developed collagen is replaced by thicker, stronger collagen fibers, which become oriented relative to the normal tension on the wound margins (see Chapter 40).

Principles of Wound Management

Impediments to Wound Healing

There are many factors that can impair or prevent normal wound healing.[8] Dehydration, starvation, severe protein deficiency and chronic anemia may have adverse effects on wound healing (Figure 16.1). Necrotic tissue or blood clots may harbor bacteria and physically impede epithelial cell migration. Infection by pathogenic bacteria may significantly delay wound healing. Dirt, debris, dead bone and even suture material[6] may cause host reaction leading to the development of fistulous tracts.

Tissue destruction resulting from desiccation, severe trauma (eg, crushing or projectile injuries) or poor surgical technique will delay healing. Wounds of the distal extremities (reduced vascular supply) and non-immobilized injuries over joints, the axilla and the patagia tend to heal more slowly.

Initial Assessment

Preliminary assessment of the injured avian patient will determine if immediate life-saving treatments are necessary.[11] A complete history is taken to determine the cause of injury, followed by a thorough physical exam. It is important to avoid overlooking less obvious injuries and unrelated problems. Traumatized birds often have multiple injuries and may be further compromised by dehydration, malnutrition and other problems, especially if there has been a delay (hours to days) between injury and presentation. Shock, fluid and nutritional therapy are critical in the early management of traumatized birds. Overzealous wound and fracture treatment before stabilization of the patient may result in the patient's death. Anesthesia may be necessary with fractious birds or in birds with extensive soft tissue or orthopedic injuries. However, if the bird is not stable, partial wound management and bandaging may have to suffice until more thorough treatment can be safely completed.

FIG 16.1 A mature female Sulphur-crested Cockatoo was presented for a unilateral non-weight-bearing lameness noted the day before presentation. The bird was reluctantly willing to use the affected limb but when she did, she ambulated on the distal tibiotarsal area with the foot closed and held in extension. A large blue-black wound was located on the caudal tarsometatarsus. Radiographic findings were limited to soft tissue swelling. The wound was thoroughly cleaned with chlorhexidine scrub and flushed with copious quantities of warm lactated Ringer's solution. A Gram's stain of the wound after cleansing revealed a few gram-positive cocci. The wound was placed in a sterile bandage that incorported a ball bandage to keep the foot open. The bandage was changed every two to three days. By the fourth bandage change, a healthy granulation bed had formed, and a primary skin closure was performed. The bird was returned to the aviary with no further complications.

When assessing a wound, one should note the location, extent and age of the injury. Associated orthopedic injuries and the vascular and nerve supply to the area should also be evaluated (Figure 16.2). It is common to have underlying fractures or luxations associated with soft tissue wounds of the limbs. Wounds can be located by parting or wetting the feathers and viewing the normal translucent avian

skin. Greenish discoloration of the skin is normal in bruised birds due to accumulation of biliverdin pigment following breakdown of hemoglobin. This discoloration develops two to three days post-injury and may persist for a week or more.

The vascular integrity may be evaluated by palpating the warmth of the limb, checking the capillary refill time of the skin, clipping a toe nail or pricking the skin. Other diagnostic tests used to assess an injured bird include microbiological cultures, hematology, radiology and ophthalmologic examination. Biopsies may be indicated in chronic, non-healing or self-inflicted wounds.

Surface Preparation and Wound Treatment

The initial goal in treating contaminants or infected wounds is the removal of devitalized tissue, foreign material and bacteria. The feathers surrounding the wound should be gently plucked or trimmed to allow more thorough cleansing and to prevent feather matting during the healing phases. Plucking feathers will allow for earlier regrowth of feathers, but caution should be used to prevent additional trauma to friable skin while plucking.

Wound lavage using a curved tip irrigating syringe will remove foreign material, reduce bacterial numbers and rehydrate soft tissues. Sterile isotonic saline with or without 0.05% chlorhexidine[a] or 0.5-1.0% povidone iodine[b] solution is recommended for wound lavage.[33] Cultures should be obtained after surface contaminants have been removed and before any antiseptics have been applied. Hydrogen peroxide has been shown to be ineffective for bacterial infections, but may be effective as a sporicide in cases of suspected clostridial infections, or for initial cleansing of dirty wounds.[3] The volume of solution required will depend upon the severity and location of the wound and the degree of contamination.

FIG16.2 An immature Red-tailed Hawk was found beside a highway, unable to fly. A severe wing droop was noted on physical examination. Radiographs indicated a fractured coracoid. The bird was placed in a figure-of-eight bandage. Fracture repair was uneventful, but when the bandage was removed, a severe wing droop was still evident and muscle atrophy had occurred to the wing musculature. EMG findings indicated denervation of all of the muscles in the wing. Necropsy indicated a brachial plexus avulsion.

Wound debridement following lavage involves removal of as much of the devitalized and necrotic tissue as possible until viable, vascularized tissue is recognized. In complicated or older wounds, the debridement process may have to be repeated over a period of a few days.

Topical medications in certain wounds may be beneficial; however, use of non-water-soluble medications should be avoided due to loss of insulation with soiled feathers. Bacitracin, neomycin and polymyxin are effective against a wide spectrum of bacteria.[33] One percent silver sulfadiazine[c] is effective for thermal burns and other wounds.[27] Topical use of hemorrhoid creams containing live yeast cell derivatives[d] (LYCD) has been shown to stimulate epithelialization and collagen synthesis in human[23] and canine[33] wounds. LYCD has been successfully used in raptors with granulating wounds and pododermatitis (bumblefoot) lesions.[12] A topical medication commonly used for pododermatitis in raptors and other birds is dimethyl sulfoxide (DMSO), used either alone or with a combination of dexamethasone and an antibiotic, such as carbenicillin or piperacillin.[30]

Products that have been shown to retard wound healing in mammals include nitrofurazone, which slows epithelialization,[13] and gentamicin sulfate, which impairs wound contraction.[24] Although similar studies have not been conducted in birds, it is advisable to avoid these products in avian wounds.

After lavage and debridement, the wound should either be sutured, managed by second intention healing or managed as an open wound with delayed closure.[8] Wounds less than eight hours old and not heavily contaminated, or wounds that were surgically created under sterile conditions should be sutured. Older, infected or more complicated wounds should be managed as open wounds and allowed to heal by second intention.

Bandaging Principles

Properly applied dressings and bandages will provide an optimal environment for epithelialization and wound contraction with the fewest complications.

The functions of bandages[32] are to:

- Apply pressure to reduce dead space, swelling, edema and hemorrhage
- Protect the wound from pathologic microorganisms
- Immobilize the wound and underlying fractures, if present
- Protect the wound from desiccation and additional trauma from abrasions or self-mutilation
- Absorb exudate and help debride the wound surface
- Provide comfort for the patient.

The three layers of a bandage are the primary layer (or dressing that is in contact with the wound), the secondary layer for absorption and the tertiary layer, which serves to hold the other layers in place.

Primary Layer

The primary layer is the most critical layer for optimal wound healing. This layer should be sterile, remain in place even with patient movement, provide a moist wound environment and assist with the debridement process.[32]

The two basic groups of dressings include adherent and non-adherent dressings. Adherent dressings such as fine mesh or open weave gauze pads are indicated during the initial phase of wound treatment when there is a large amount of necrotic debris that cannot be surgically debrided, or with excessive exudate production. Wet-to-dry bandage techniques involve the application of sterile saline-soaked, warm gauze pads over the wound surface.[8,9] The exudate and necrotic debris will be mechanically removed with daily dressing changes during the first few days of treatment, at which time the type of dressing used can be changed to a non-adherent one. Disadvantages of wet-to-dry bandages may include tissue maceration and bacterial colonization with the moist environment, and disruption of the wound healing surface with each dressing change.[8]

Non-adherent dressings, by definition, do not adhere to the healing wound surface,[25] and include a variety of products. Traditional non-adherent products commonly used in veterinary wound management include cotton film dressings[e] and petrolatum-impregnated fine mesh gauze pads[f]. Advantages of these products for use in avian medicine include availability and low cost. However, disadvantages include disruption of the healing surface when the dressing is removed after being in place for more than two to three days, soiling of feathers (petrolatum-impregnated products), slippage of dressings under the bandage and difficulty in bandaging certain anatomic locations.[11]

Increased understanding of wound healing processes has resulted in the development of many new synthetic adhesive, non-adherent dressings for use in humans.[4,5,14,15] These new dressings keep the wound surface moist and prevent scab formation, which significantly increases the rate of re-epithelialization, compared to air-exposed and wet-to-dry gauze dressings.[1] Adaptation of these products to avian wound management has resulted in elimination of many of the problems outlined earlier, and significant improvements in the rate and quality of wound healing.[11] The two product groups discussed include hydrocolloid dressings and moisture vapor permeable (MVP) dressings.

Hydrocolloid dressings or hydroactive dressings (HAD)[g,h] are semi-flexible, opaque membranes that are impermeable to moisture vapor and oxygen, and absorb fluid and exudate to develop a moist, gelatinous cover over the wound. These dressings adhere to normal skin and not wounds, but generally require additional bandaging material to be held in place. Hydrocolloid dressings have been used successfully in a variety of avian species,[9,11,12,17] and are most useful for extensive wounds with greater than normal exudate production, wounds that require debridement or for slow healing wounds (Figure 16.3).

Moisture vapor permeable (MVP) dressings[i,j,k] are thin, flexible, transparent polyurethane membranes that are oxygen permeable, impermeable to water and bacteria, allow accumulation of fluid and exudate under the dressing and are adhesive to normal skin but not wounds.[26] The maintenance of a moist, aerobic environment under the dressing promotes leukocyte debridement of the wound surface, prevents desiccation and scab formation and reduces pain associated with desiccation of raw nerve endings.[4] Epithelialization is more rapid when scabs are not present to impede cell migration from the wound margins.[1,4,5]

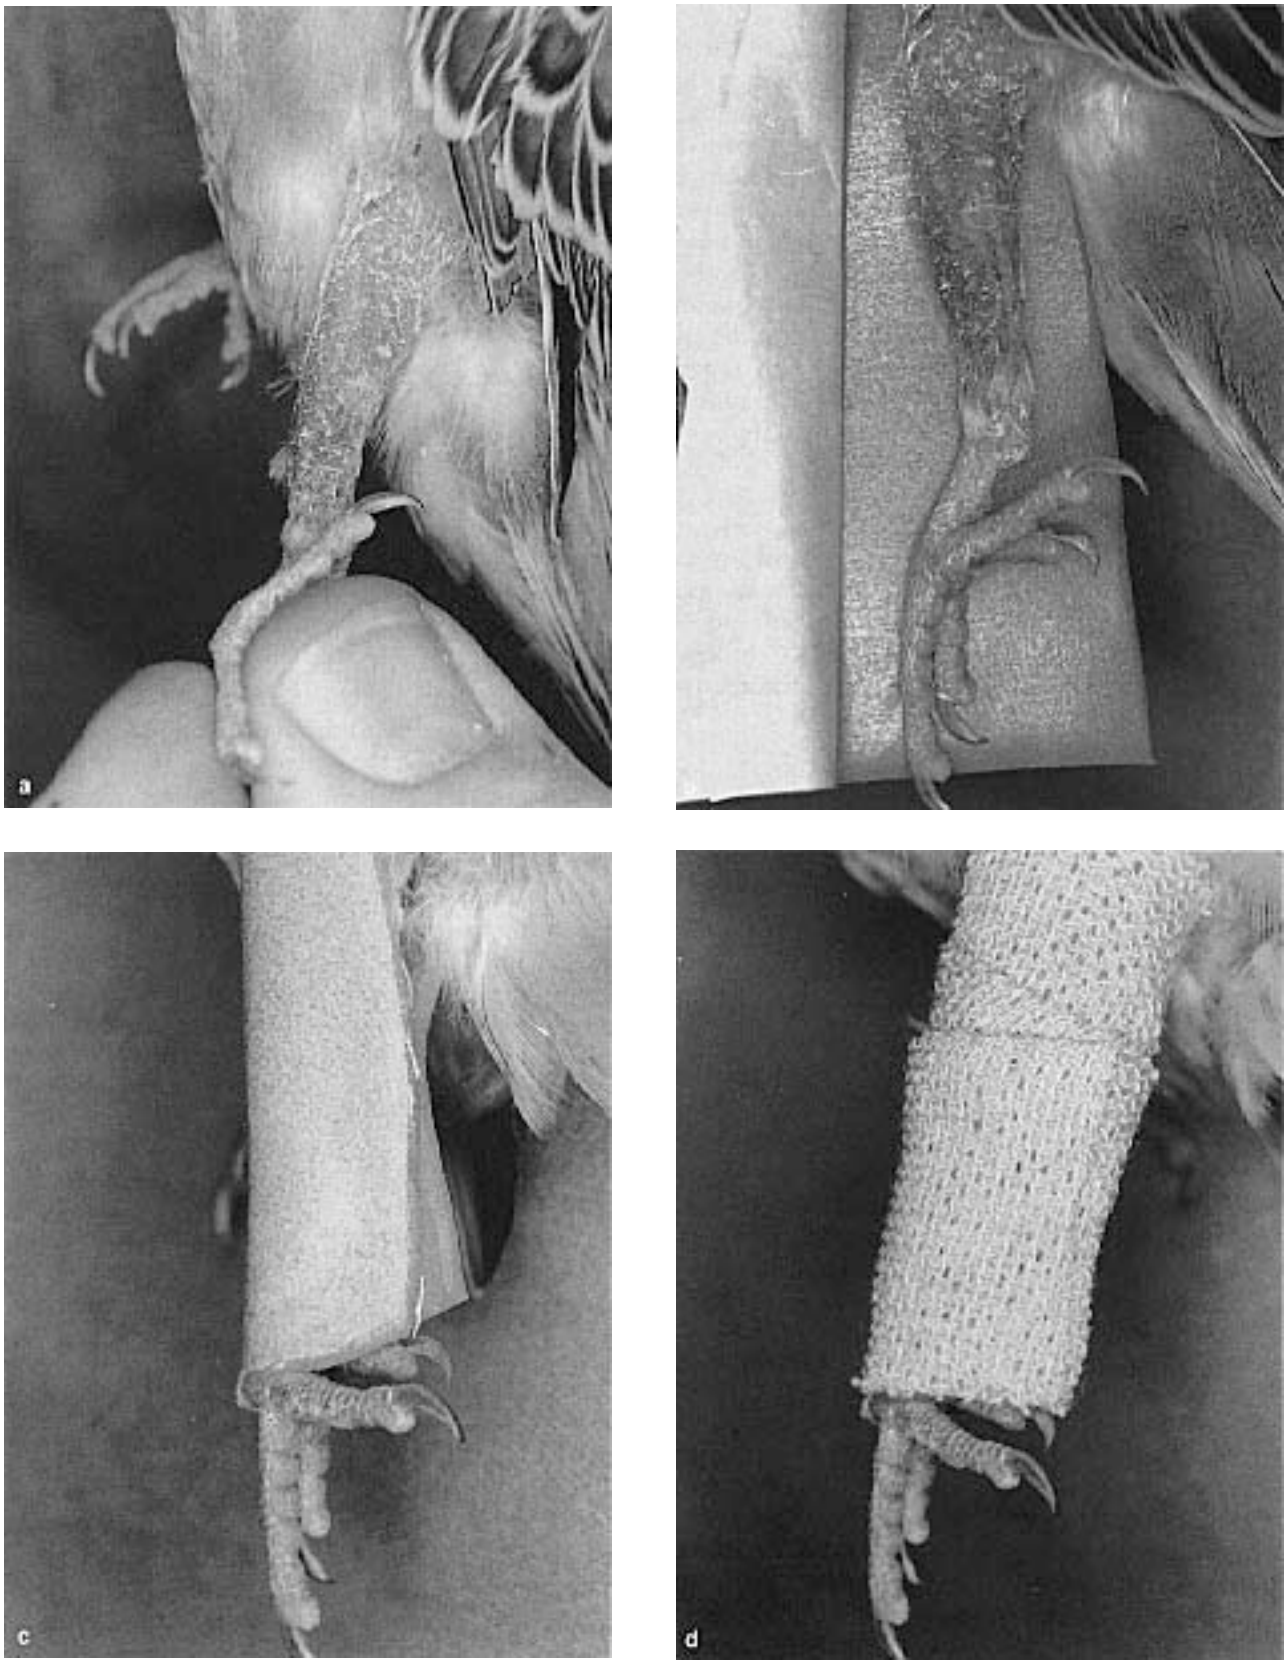

FIG 16.3 In birds that weigh less than 150 g, hydrocolloid dressings can be used as a splint material for distal tibiotarsal fractures. This material is superior to tape because it is more rigid. **a)** Note the bruising associated with this distal tibiotarsal fracture. **b,c)** A hydrocolloid dressing is wrapped around the leg incorporating the femur and the tarsometatarsus. **d)** The hydrocolloid dressing is covered with self-adherent bandage materials.

Both MVP and hydrocolloid dressings are indicated for a variety of avian wounds, but MVP dressings are more suited to areas that are impossible to bandage (eg, head wounds) because of the superior adhesive quality and flexibility of the material. The dressings are changed every two to three days initially, or more often if excessive exudate production results in fluid leakage from underneath the dressing. Once a healthy granulation bed is established, dressings can be changed weekly. Wounds treated with these dressings appear to heal more rapidly and with fewer complications compared to conventional non-adherent dressings.[11] Patient acceptance is usually very good, even with psittacine species.

Secondary Layer

The functions of the secondary bandage layer are to absorb fluids and wound exudate, pad the wound from trauma, and immobilize the wound and underlying fracture during the healing phases.[8] Conforming gauze material[l] or cast padding is most commonly used.

Tertiary Layer

The tertiary or outer layer serves to hold the other layers of the bandages in place. Most bandages consist of conforming stretch tapes with or without an adhesive. Self-adherent bandages[m] are excellent for birds because they are light-weight and breathable, are well tolerated by most birds, and the material adheres to itself cohesively without problems associated with tape residues on feathers. In cases where patient acceptance is poor, white adhesive tape, duct tape, neck braces or Elizabethan collars may be required for bandage protection.

FIG 16.4 A maxilla fracture occurred in this budgerigar when it was bitten by a larger bird. Placement of a wire suture in a mattress pattern was used to oppose the maxilla. Beak injuries of this magnitude should be handled as emergencies. The sooner the damaged area is repaired, the more likely the beak is to heal.

FIG 16.5 Necrosis of the metatarsal skin in a cockatiel that caught its band in an unsafe toy. If a bird hangs by the leg for prolonged periods, microvascular damage may occur that results in necrosis 10 to 14 days post-injury. In severe cases, amputation of the most proximal joint and application of a hydroactive dressing to the stump is necessary.

Specific Traumatic Injuries and Their Management

Lacerations and Abrasions

Lacerations and abrasions in companion birds are commonly caused by enclosure wires, inappropriate toys, collisions during flight, other birds or household pets (Figure 16.4). Specific management of a laceration is determined by the size, location and age of the wound. In birds with breast or wing tip lacerations that result from frequent falls, additional therapy may include pulling improperly clipped wing feathers to stimulate their replacement.

Band Injuries

As useful as leg bands are for individual identification, they are not totally innocuous. Open style steel quarantine bands may cause serious problems if the band gap is large enough to allow the bird to get hung up on the cage wire. Resulting injuries may include soft tissue bruising, swelling or lacerations, leg fractures or luxations and occasionally death. Even captive-raised birds with closed bands may get their bands caught on toys, clips or enclosure wire (Figure 16.5). Inappropriately sized bands may cause soft tissue swelling and vascular compromise to the distal leg and toes if young birds outgrow bands that are too small. Some birds on a marginal diet will collect excessive quantities of desquamated skin under a band, resulting in a constrictive injury. Soft tissue swelling of the tarsometatarsus associated with fractures or other injuries may be further complicated by vascular constriction caused by the band. Large psittacines may crimp aluminum bands with their beaks,

causing a tight constriction of the distal limb, making band removal difficult. Abrasions and swelling underneath the band may develop when the leg is bandaged.

Band injuries should be prevented by anticipating potential problems, especially with open bands that have large gaps and with inappropriately sized bands (too small or too large). Prophylactic band removal or crimping to reduce the gap is preferable to treating a band injury (see Chapter 1). Once an injury or associated problem with a band is recognized, extreme caution should be exercised with band removal to avoid additional injury to the bird. The owner should always be warned of potential risks to the bird whenever a band is removed, even when the procedure is elective and not associated with trauma. Complications may include fractures, dislocations and lacerations. If a wound is already present, avascular necrosis may complicate the band removal procedure. Specific treatment options following band removal involve wound debridement and cleansing, surgical closure if indicated and coverage with appropriate dressing and bandaging material as needed.

Feather, Toenail and Beak Injuries

Significant hemorrhage may occur with broken blood feathers, especially broken flight and tail feathers. Direct digital pressure over the bleeding feather should be applied immediately to prevent excessive blood loss. A first-aid home procedure involves putting flour over the bleeding feather stub. This conservative treatment may be adequate in some cases, but most broken blood feathers require timely removal. The feather should be grasped at the base with a hemostat (needle-nosed pliers can be used on large birds) or fingers and pulled from the follicle while applying counter pressure to the area surrounding the follicle, to prevent tearing the skin (see Figure 15.12).

It is critical to remove the entire feather shaft from the follicle and continue to apply pressure over the follicle until the hemorrhage stops. Products intended for hemorrhage control during nail and beak trims, such as silver nitrate and ferric subsulfate powder[n] should never be used in a feather follicle to stop bleeding, due to the irritation caused by these products and the possible foreign body reaction that may occur (granuloma or feather cyst formation). Radiocautery should also not be used to blindly cauterize the interior of a follicle.

Broken or torn toenails can be managed by trimming the exposed portion with a nail trimmer to make a smooth surface, and packing ferrous subsulfate or silver nitrate into the exposed nail bed pulp cavity. If the keratin sheath of the toe nail has been pulled off to expose the underlying bone, direct pressure should be applied to control hemorrhage. The exposed bone can be protected with liquid bandage products,[o,p] or light bandaging.

Beak injuries occur most often from bites from other psittacines, or from collisions during flight. Cockatoo males often become extremely aggressive toward the females, sometimes inflicting lethal injuries (see Chapter 4). Head trauma is common with mate aggression and may be associated with beak fractures, punctures or avulsion of the maxillary or mandibular beak, in addition to soft tissue trauma. Hemorrhage may be controlled with direct digital pressure or by applying clotting products such as silver nitrate or ferric subsulfate. For specific beak repair see Chapter 42.

Self-mutilation

Many factors may induce self-mutilation behavior (see Chapters 4 and 24). A thorough diagnostic workup to rule out predisposing factors should be considered. Appropriate antibiotic, antifungal or anthelmintic treatment is combined with soft tissue wound management and protection of the wounds from further trauma. The wounds should be cleansed and debrided, and surrounding feathers carefully plucked or trimmed to prevent them from becoming matted in the wound. Aloe vera preparations may help in soothing the pain and irritation caused by massive self-trauma.

Application of moisture vapor permeable dressings is very effective in promoting rapid wound healing, and is well tolerated by most avian species including psittacines. The use of topical non-water-soluble wound medications is discouraged due to feather soiling, and is not necessary when MVP dressings are used. In severe cases of self-mutilation, an Elizabethan collar or neck brace collar may be indicated to protect the wounds from further trauma (Figure 16.6).

Burns

The most common thermal burns occur in the crop of neonates fed improperly heated hand-feeding formula (microwaved without proper stirring). Further discussion of medical and surgical management of crop burns is covered in Chapter 30. Accidental burns

FIG 16.6 A mature Quaker Parakeet was presented with a one-month history of feather picking that progressed to self-mutilation. Note the numerous emerging pin feathers that many bird owners mistakenly identify as mites. The cause of this bird's self-mutilation was undetermined.

FIG 16.7 An Amazon parrot was presented four days after flying into a pot of hot liquid on the stove. The bird had been treated at home with a topical burn ointment. On presentation, several phalanges were missing, and the foot and leg distal to the mid-metatarsal region were cold, firm and black. Tissue fluids were oozing from the margin of the burned area. Because four days had passed since the initial injury, the only effective therapy was amputation of the necrotic limb. The prognosis for burn wounds is best if they are treated on an emergency basis.

may occur when pet birds come in contact with hot liquids, hot surfaces or electrical wires (Figure 16.7). The feathers provide some measure of insulation; however, the extent of the trauma depends upon the cause and the duration of exposure. Damage may range from singed feathers, ocular irritation or mild erythema of the feet or other exposed skin, to severe destruction of the toes or feet, melted beaks or death (see Color 24). Treatment action to be taken includes immediate cooling and rinsing of the affected areas, followed by supportive care, topical wound management and systemic antibiotic therapy. Topical medications may include DMSO for acute inflammation and silver sulfadiazine[c] cream for antibacterial protection.

Chemical burns secondary to contact with caustic solutions, acids or other irritants may be seen occasionally. The affected areas should be thoroughly washed and the compound neutralized by either sodium bicarbonate solution for acidic compounds, or dilute vinegar for alkaline compounds.[27]

Frostbite

Frostbite injuries are more common in cooler climates, but may occur in warmer regions during unexpected cold snaps when birds are not acclimated or do not have adequate shelter and supplemental heat. Injuries may range from mild redness, swelling and pain of the affected digit(s) or limbs, to gangrenous necrosis and death (Figure 16.8). Treatment requires supportive care including supplemental heat, fluid therapy, anti-inflammatory agents or topical DMSO, bandaging and treatment of secondary complications (see Chapter 15). Loss of soft tissue viability may be assessed by discoloration of the skin, loss of neuromuscular control, cooler skin temperature, odor, leakage of serosanguinous fluid and disruption of blood flow to distal extremities. The prognosis for saving a frozen digit or foot is extremely guarded, and amputation may be necessary if gangrenous necrosis develops.

Degenerative Joint Disease

Degenerative joint disease (DJD) is a chronic inflammatory condition involving the joint and surrounding tissues. Bony changes and reduced function in the joint may be secondary to trauma, bacterial infection, malnutrition or neoplasia. Radiographs, microbiologic cultures and biopsies are indicated to determine the cause and severity of the problem. The prognosis for successful treatment and return to normal joint function is extremely guarded, even with long-term antibiotic treatment.

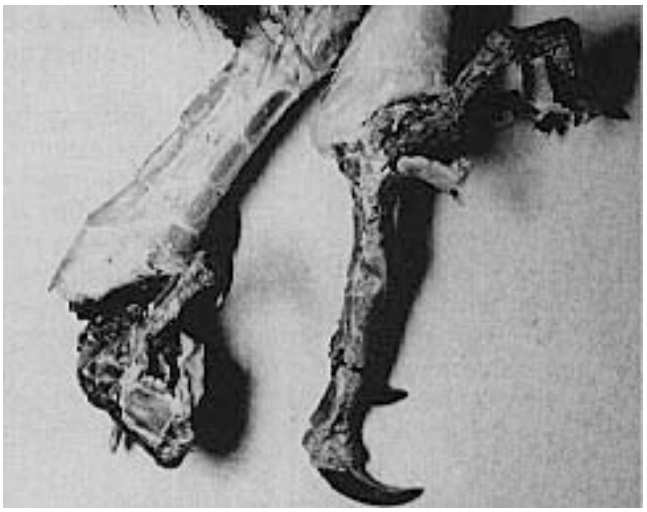

FIG 16.8 An adult toucanette hen was presented for a bilateral non-weight-bearing lameness. The bird had not been seen for several days and was presumably incubating eggs. Dry gangrene secondary to frostbite was evident in both legs distal to the tarsometatarsal joint. Temperatures the week before presentation were below freezing. The bird was euthanatized.

Bumblefoot

Bumblefoot or pododermatitis is a general term for any inflammatory or degenerative condition of the avian foot and may range from very mild redness or swelling to chronic, deep-seated abscesses and bony changes.[12,16,18,29,30] Considerations for prevention of bumblefoot include proper perches (size, shape and texture), flight pen or cage construction (wall components, substrate, perch arrangements), nutrition, general health of the bird and sanitation of facilities.

Classification and Causes of Bumblefoot

With the common occurrence of bumblefoot in companion and aviary birds, it seems appropriate to classify bumblefoot in a new manner, combining the concepts described by Halliwell[18] with subtle clinical changes that alter the management and prognosis of the disease (Table 16.1). A classification scheme grading from minor early clinical signs progressing to severe lesions is proposed (Harrison GJ, unpublished). The clinical progression of the disease varies based on the species of bird (eg, Psittaciformes, Passeriformes, raptors or Anseriformes) and the factors that contributed to the infection (Figure 16.9).

Grade I to III lesions may not be recognized in raptors that are commonly presented with Grade IV or V lesions. Older budgerigars and cockatiels (five to ten years old) may have a Grade V to VI lesion if precipitating factors are not corrected early. Bony changes and osteomyelitis may be present. Prognosis for full recovery of Grades I to IV is usually more favorable than Grade V to VI lesions.

Grade I to III lesions are common in Psittaciformes and Passeriformes that are on all-seed or over-supplemented fruit and vegetable diets, overweight, have no exposure to sunlight or are kept on improper perches (covered with sandpaper, too small or too large, no variance in size) (see Color 8).With proper husbandry and nutrition, most cases recover. Substrate perch size, shape and covering material may all influence the bird's weight distribution on the toes and metatarsal pad and the amount of skin wear on the plantar surface.[12,16,18,29] For example, a perch that is too wide and flat may cause excessive weight-bearing on the toe pads, while one that is too small may cause excessive weight-bearing on the metatarsal pads.

Bruising and abrasions on the plantar surface of the feet may develop when raptors persistently bate (jump) from a perch onto a hard surface or hang from the cage wire,[18] or when they are forced to stand on perches or cement. Any soft tissue or orthopedic injury involving one leg or foot may cause excessive weight bearing and secondary bumblefoot on the contralateral foot. Overgrown talons cause improper weight distribution on the plantar surface of the foot (especially in falcons and finches) or self-inflicted puncture wounds of the metatarsal pad.[16] Other traumatic injuries to the foot include bite wounds from prey, punctures from thorns or quills and trap inju-

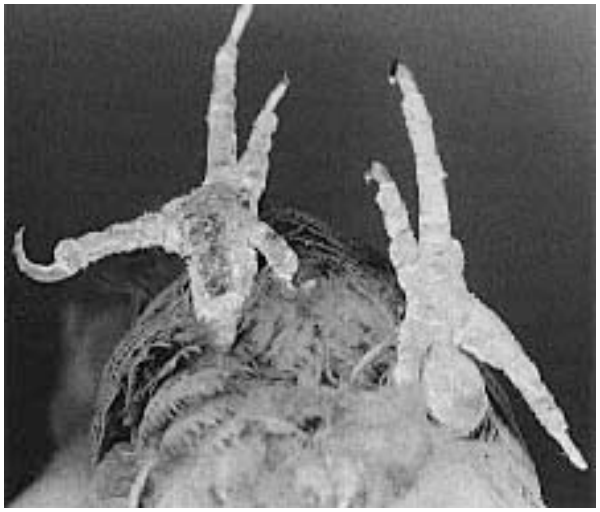

FIG 16.9 A 12-year-old cockatiel was presented with a non-weight-bearing lameness. Grade III bumblefoot is common in older inactive birds that are fed inadequate diets. Early lesions (smoothing of the plantar foot surface and hyperemia) are frequently missed, and the birds are not presented until they are lame.

TABLE 16.1 Clinical Grades of Bumblefoot

Grade I	Desquamation of small areas of the plantar foot surfaces represented clinically by the appearance of small, shiny pink areas - peeling or flaking of the skin on the legs and feet.
Grade II	Smooth, thinly surfaced, circumscribed areas on the plantar metatarsal pads of one or both feet with the subcutaneous tissue almost visible through the translucent skin. No distinct ulcers are recognized.
Grade III	Ulceration of the plantar metatarsal pads. In some birds a peripheral callus may form.
Grade IV	Necrotic plug of tissue present in ulcer. Most species with ulcers and accumulation of necrotic debris exhibit pain or mild lameness.
Grade V	Swelling and edema (cellulitis) of the tissues surrounding the necrotic debris. The digits or foot may also be edematous. Necrotic debris may start to accumulate in the metatarsal area, suggesting infection of the tendon sheaths. Severe lameness is common. The entire metatarsal pad may be affected. This is generally a chronic lesion.
Grade VI	Necrotic tendons recognized clinically as swelling in the digits and ruptured flexor tendons. Ankelosis and nonfunctioning digits usually present in recovery.
Grade VII	Osteomyelitis.

ries. Pathogenic bacteria introduced at these sites may lead to abscessation, osteomyelitis or joint changes.[31] Other causes of bumblefoot include severe poxvirus lesions with secondary bacterial infections, frostbite injuries and thermal burns.[29,30]

The precise pathogenesis of bumblefoot in various avian species remains undetermined. It is theorized that dry, flaky hyperkeratotic skin on the feet (possibly precipitated by malnutrition, environmental deficiencies and systemic disease) changes the mechanics of weight bearing on the metatarsal pads, leading to reduced circulation, micro-epithelial damage, localized impairment of the immune system and invasion of opportunistic pathogens. A bird's inactivity in an enclosure (inability to fly) may be a major precipitating factor. In one group of raptors, birds that were housed outdoors and were able to exercise did not develop bumblefoot regardless of their perching surface. By comparison, a group of raptors maintained indoors on the same diet developed bumblefoot irrespective of the perching material (Redig PT, unpublished).

Prevention and Treatment

Prevention of bumblefoot involves constant vigilance for early signs of hyperkeratosis, baldness, flaking of the skin of feet and legs, redness or swelling and correction of the underlying causes. The walls of an enclosure should be designed with vertical bars or solid barriers to minimize the tendency for hanging from the wire. Selection of proper perch size, shape and cover for a particular species of bird is very important.[29] Perches wrapped with hemp rope or covered with Astroturf work well for most raptors. Falcons do best on flat shelf or block perches covered with short Astroturf or cocoa mats. Strict sanitation of the facilities and feet is important to minimize bacterial infections. Feeding some formulated diets and providing fresh water for bathing prevents or reverses early bumblefoot in Psittaciformes (Harrison GJ, unpublished).

The goals of advanced bumblefoot treatment are to reduce inflammation and swelling, ensure an adequate diet, establish drainage if needed, begin antibacterial therapy to eliminate underlying pathogens, manage the wound to promote rapid healing and address dietary deficiencies.[29,31] Surgical excision of the abscess or amputation of a severely traumatized digit may be indicated. Treatment for Grade V to VI lesions must be vigorous, and the prognosis is guarded. Treatment for Grade IV should include drainage, irrigation and closing the wound when the infection has been resolved. The prognosis is fair. Grade I to III lesions generally respond to keeping the foot clean and correcting underlying management or nutritional deficiencies. With Anseriformes, this frequently involves changing the dimension, shape and surface of the enclosure, including the addition of adequate swimming areas.

Conservative treatment options may include changing the diet and padding the perchs, applying topical medications and, if needed, bandaging. Many topical products have been used, such as softening agents (udder balm or lanolin-based lotions) for dry, scaly feet; topical dimethylsulfoxide (DMSO) for acute inflammation and swelling;[29] hemorrhoidal ointment with live yeast cell derivative for granulating wounds;[12,23] and liquid bandage products for minor skin cracks or torn talon sheaths.[12]

Moisture vapor permeable dressings or hydrocolloid dressings should be applied topically to enhance wound healing for open, granulating wounds or postoperative incisions.[11] Bandaging of affected Psittaciformes may go on for several months until the bird responds to the new diet. Bandaging options include simple toe bandages, interdigitating bandages and ball bandages (Figures 16.10, 16.11).

FIG 16.10 Ball bandages can be used to protect the foot while plantar lesions are healing.

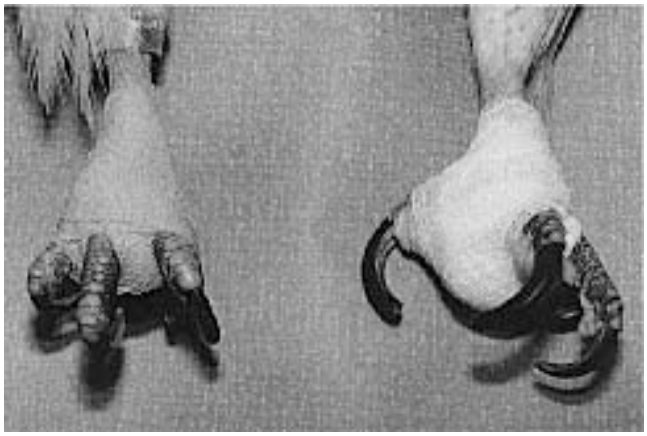

FIG16.11 Interdigitating foot bandages are used when a wound needs to be protected or padding is needed for the bottom of the foot, yet it is desirable for the bird to perch.

In raptors, therapy for Grade IV to V lesions include a DMSO preparation that is made by combining piperacillin (1 g) with dexamethasone (4 mg) and DMSO to make a 10 ml mixture. This is refrigerated and discarded after one week. Resolution of Grade IV to VI lesions is slow, and complete healing may take several months. Initial treatment also includes systemic antibiotics for seven to ten days. The entire foot should be cleaned with surgical scrub and any scabs should be soaked free without applying pressure to the wound. A swab taken from deep within the abscess should be cultured for bacteria and fungus. *E. coli*, staphylococcus and candida are commonly isolated pathogens. The wound should be flushed with copious quantities of one percent povidone iodine solution and allowed to soak for five minutes. The wound should then be flushed with large quantities of sterile saline, the defect packed with a sterile gauze 2 x 2 soaked in povidone iodine solution and a large soft bandage applied. On the second day, the flushing of the wound, gauze pack and bandaging are repeated. Most can be done without anesthesia.

On the third day, swelling may be reduced and much of the exudate gone. Any fibrotic material is removed and the foot is prepared for sterile surgery. A wide exposure of the affected area is made and the abscess wall is dissected out. Any devitalized ligaments or tendons must be removed in their entirety. A tourniquet may be required to control hemorrhage. The wound should be vigorously irrigated with povidone iodine followed by sterile saline. If hemorrhage returns after removing the tourniquet, pressure, epinephrine or selective radiocautery may be used for control, and the wound should be flushed to remove all free blood. The wound is partially sutured shut to allow for drainage, packed with a seton soaked in saline and rebandaged with a large soft wrap. If hemorrhage was poorly controlled, the bandage should be changed in four to six hours.

The bandage should be removed daily and the foot scrubbed and flushed with iodine solution and sterile saline until a "dry socket" is obtained (see Color 24). This may take a week or more. Then the bandage can be changed at two- to three-day intervals. Each time the bandage is changed, the wound should be flushed and kept open as long as there is serum seepage. Mechanical debridement of the wound with a sterile swab will prevent premature closure. The wound may be sutured closed when there is no apparent infection or drainage. Appearance of granulating tissue around the edges of the wound indicates healing is occurring, which may take up to two to five weeks. A week after closure, bandaging can be reduced to only a light wrap. After healing is complete, the foot may still be tender for several weeks. Prevention of trauma and maintaining the patient on soft footing are important to prevent recurrence. Waterfowl should be returned to water as soon as possible to prevent other problems. Modifications and compromises to this procedure may be necessary depending on the species involved and the individual situation.

Nonsurgical Immobilization of Fractures

There are many indications for bandaging avian limbs: nonsurgical immobilization of fractures, soft tissue and joint injuries, and following orthopedic fracture repair. The following bandages and splints have been developed and modified to meet specialized anatomic requirements for avian limb immobi-

lization.[7,28] Specific indications, contraindications and application techniques will be discussed for each type of bandage or splint.

Bandaging Materials

Bandage materials used in birds should be soft, pliable and not have adhesive materials that can adhere to or damage feathers. Cast padding is an ideal base for slings, bandages and wraps. Self-adherent bandage materials are best for the outer layer. When necessary, wooden splints, aluminum rods or lightweight casting materials can be used to reinforce bandages. Some human orthopedic products have been excellent support materials for use in birds. Orthoplast[r] and Hexcelite[s] are excellent support materials for use in birds. At room temperature, these materials are firm, but when placed in hot water they become malleable and can be manipulated to conform to the shape of a bird's limb.

Fracture Stabilization

To be effective, an external coaptation device must immobilize the joint above and below a fracture. Once in place, bandages should be carefully monitored for tissue abrasions, slipping, seepage or swelling in the distal part of a limb, all of which would indicate that the bandage needs to be replaced.

Figure-of-Eight Wing Bandage

The indications for figure-of-eight wing bandages include wing fractures distal to the elbow, luxations of the elbow or carpal joint and soft tissue wounds in these areas that require bandaging and immobilization.[28] There are no rules to dictate which wing fractures can be adequately repaired with external coaptation, which fractures require surgical repair and which are simply not repairable. In general, external coaptation in the form of a figure-of-eight wing bandage can be considered for the following fractures: most closed fractures of the ulna and radius, when the fragments are relatively well-aligned (Figure 16.12); most fractures of the major and minor metacarpals; fractures that are too close to a joint or too comminuted to surgically repair; fractures in birds that may not require full return to flight capability; fractures in small or very young birds; and following most orthopedic surgeries of the wing. It is contraindicated to apply a figure-of-eight wing bandage for a humerus fracture without also immobilizing the shoulder with a wing-body wrap.

Application of a figure-of-eight wing bandage is shown in Figure 16.13. It is important to incorporate the scapular or tertiary covert feathers in the bandage and apply the bandage as high in the axillary region as possible to prevent the bandage from slipping below the elbow. The bandage should not extend more than approximately one-half bandage width beyond the elbow joint and should not be applied too tightly. A bandage that is applied too tightly may cause vascular compromise of the wing distal to the carpal joint and sloughing of flight feathers. If the primary and secondary flight feathers have a crisscrossed appearance following bandaging (instead of lying parallel), the bandage is too tight. The bandage should not be so bulky that it causes balance problems in the patient. It may be advantageous to tape the tips of the primaries to the tail feathers in birds with long primary feathers.

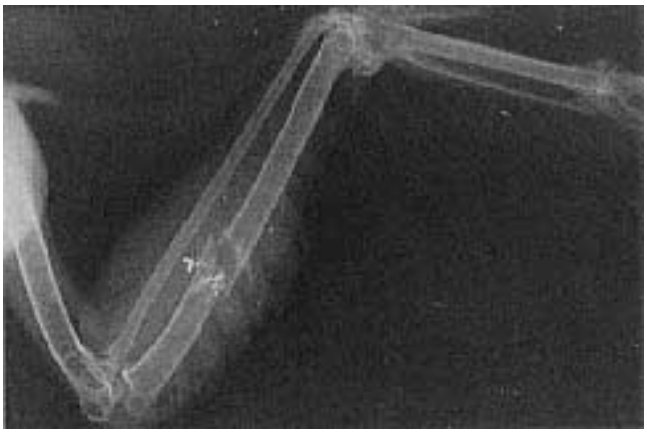

FIG16.12 Wing fractures, in which either the radius or ulna remain intact, can be successfullly managed with a figure-of-eight bandage.

The length of time a wing bandage is left on is determined by the underlying problem. Most fractures require three to five weeks of bandaging, and soft tissue wounds may require a few days to two weeks of immobilization. Complications of prolonged bandaging are joint stiffness, bony changes, disuse muscle atrophy and occasionally sloughed flight feathers.[28] Weekly bandage changes with physical therapy on the wing, proper bandage application and removal of the bandage as soon as possible after healing will minimize these problems.

Wing-Body Wrap

Fractures or luxations involving the humerus, coracoid, furcula or scapula should be immobilized with a wing-body wrap,[28] as shown in Figure 16.13. Humerus fractures are often immobilized with both figure-of-eight and wing-body wrap bandages, and most of these fractures require orthopedic repair.[7] The legs should be extended to pull the stifle joints away from

the keel, and the wing should be folded in a normal flexed position and held to the body using a self-adherent bandage[m] or adhesive tape that does not harm feathers (masking tape or Durapore[q] tape). The bandage should be positioned approximately halfway between the top and bottom of the keel to avoid interference with the legs and the vent. It is important to apply the body wrap tight enough to prevent wing motion, but not tight enough to compromise respiration.

Schroeder-Thomas Splint

The use of a Schroeder-Thomas splint is limited to fractures of the tarsometatarsus and the distal one-third of the tibiotarsus[26] (Figure 16.14). Indications for these splints include fractures of the tarsometatarsus in psittacine birds in which the bone is too small to apply any form of orthopedic repair, fractures too close to the tibiotarsal-tarsometatarsal (hock) joint or foot, uncomplicated fractures in small birds, and following internal surgical fixation of distal tibiotarsal fractures. Contraindications for Schroeder-Thomas splints include all fractures of the femur and proximal two-thirds of the tibiotarsus, because the extreme flexion at the ileal-femoral joint and the wide inguinal skin web in birds results in the proximal portion of the splint acting as a fulcrum and interfering with immobilization.

The wire or rod material of the splint should be made with two right-angle bends next to the ring at the top so that the splint is parallel to the long axis of the leg (Figure 16.14). The leg should be positioned with some flexion at the hock joint, with the splint angles bent to conform to the angles of the leg. The splint should be slightly longer than the partially

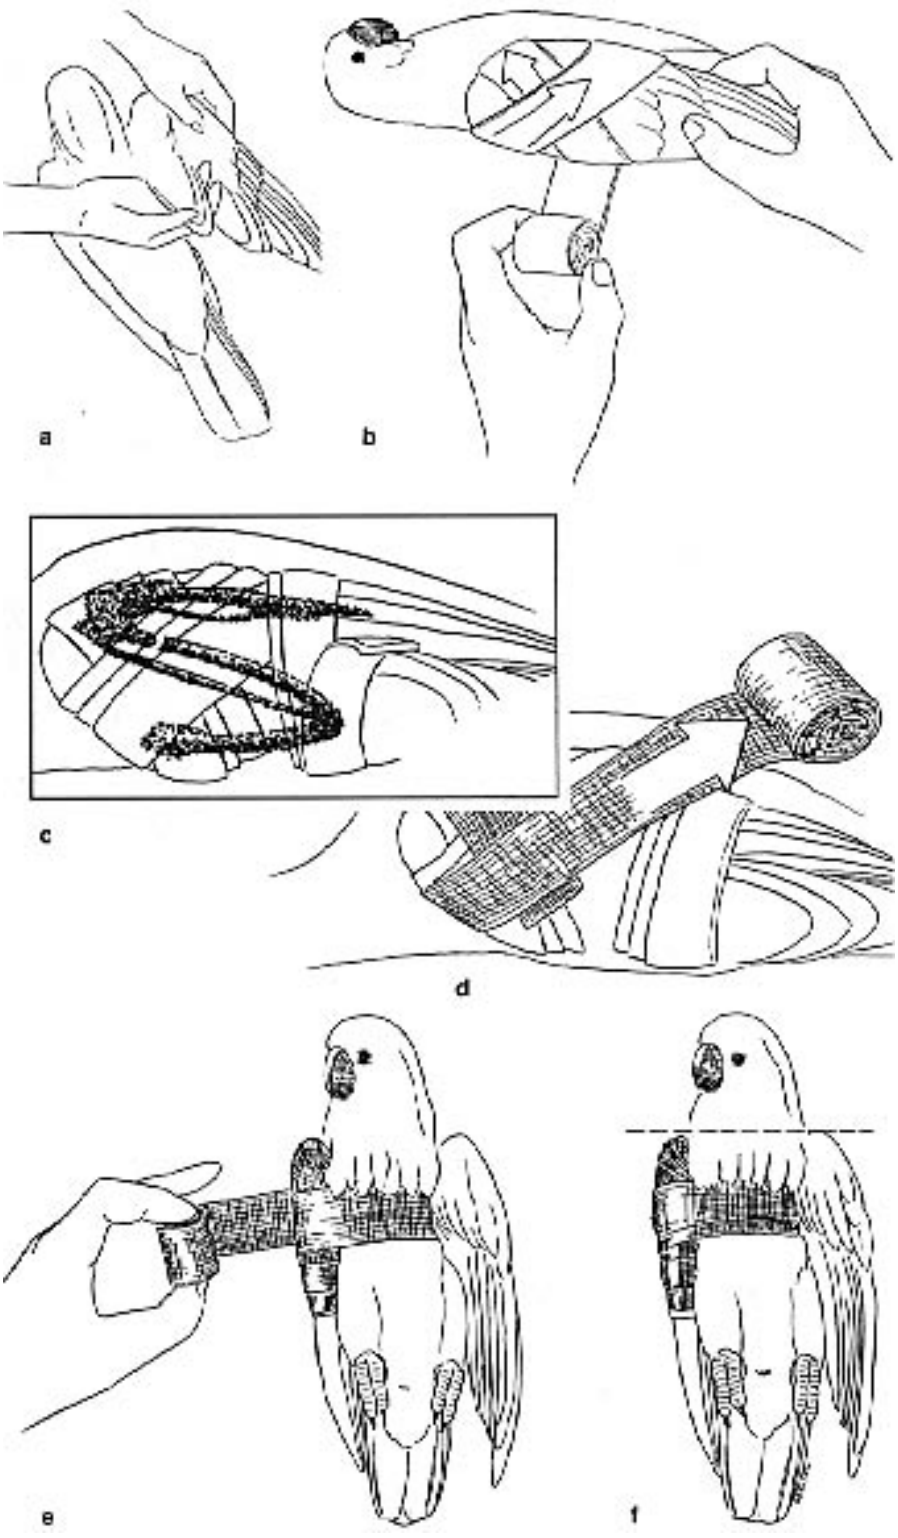

FIG16.13 a,b,c) Rolled cotton padding is used for the initial layer of a figure-of-eight bandage **d,e)** followed by the application of a self-adherent bandage material. **f)** If the bandage is properly applied, the carpus of the injured wing will be positioned neither higher nor lower than the unbandaged carpus. In addition, the primary and secondary feathers will be in a normal anatomic association. If the primary tips are medial to the secondary feathers, the carpus is being excessively flexed and the bandage is too tight.

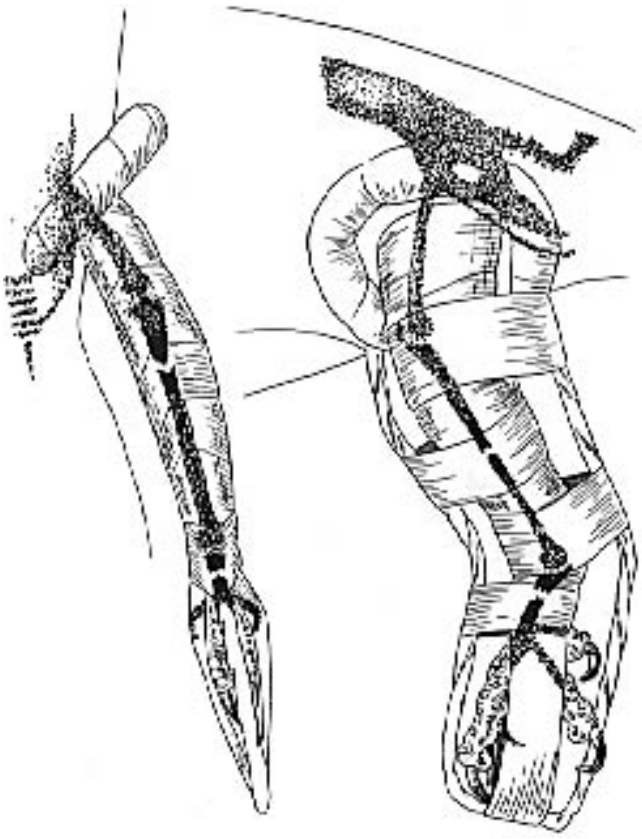

FIG16.14 Craniocaudal and lateral views of a Schroeder-Thomas splint, which can be used to temporarily stabilize fractures of the tarsometatarsus and distal tibiotarsus.

FIG 16.15 Lateral view of a Robert Jones bandage, which can be used to temporarily stabilize fractures of the distal tibiotarsus and tarsometatarsus.

flexed leg and extended toes. The leg is lightly bandaged with gauze and tape and is suspended within the splint by alternating strips of tape placed cranially and caudally with the toes extended to the end of the splint. The splinted leg is then covered with bandaging material. Weekly or bimonthly bandage changes with passive physical therapy should be conducted until the fracture heals in four to six weeks. The bird should be provided a low perch so that the splinted leg can hang below or be propped on the perch. With all leg injuries, bumblefoot lesions in the contralateral, weight-bearing foot should be prevented through the use of soft flooring materials, adequate nutrition and, in some cases, ball bandages.

Robert Jones Bandage

The Robert Jones bandage (Figure 16.15) should be limited to simple fractures of the distal one-third of the tibiotarsus and tarsometatarsus, injuries involving the hock joint, soft tissue wounds of the tibiotarsus or tarsometatarsus, or following orthopedic repair of the distal two-thirds of the leg. These heavily padded leg bandages can be used with or without additional splinting material, such as tongue depressors, aluminum splints or orthopedic casting material[r,s] (Figure 16.16). Fractures involving the tarsometatarsus should be combined with a ball bandage to immobilize the foot. The Robert Jones bandage is contraindicated for leg fractures of the femur, proximal two-thirds of the tibiotarsus and in larger birds (eg, over 500 g) because of inadequate immobilization.

A thick layer of casting material is wrapped from the top of the foot to the most proximal point of the leg. The leg is slightly flexed, conforming gauze material is tightly wrapped around the cast padding, additional splinting material is incorporated into the bandage and tape or self-adherent bandaging material is used to cover the bandage. The toes should be monitored for swelling and discoloration if they are not incorporated within the bandage.

FIG 16.16 An adult male Amazon parrot was presented for an acute onset of a non-weight-bearing lameness. The bird's wing had been improperly trimmed, and it fell from the top of its enclosure to a concrete floor. Radiographs indicated an oblique fracture of the mid-tibiotarsus. The owner chose a cast repair (right) over the application of an external fixator. In this case, with a calm bird and a minimally displaced fracture, casting was sufficient coaptation to allow bone repair.

Spica Splint

Spica splints may be used for simple, aligned fractures of the femur in smaller birds, but generally need to be combined with orthopedic fracture repair in larger birds (eg, over 300 g).[7,28] Splint material can be molded from orthopedic casting material[r,s] or padded aluminum finger splints. This splint is a modification of the Robert Jones bandage, except that the padded, molded splint extends from the tibiotarsus proximally and over the bird's pelvis in an inverted U-shape to immobilize the femur against the body of the bird.

Ball Bandage

Indications for ball bandages (Figures 16.17) include moderate to severe forms of pododermatitis (bumblefoot), toe fractures and other soft tissue injuries involving the toes or feet in perching birds.[12,29]

The toes should be conformed around a stack of gauze sponges, and wrapped snugly with conforming gauze material to form a teardrop-shaped bandage. There should be adequate padding and support around the distal tarsometatarsus to allow the bird to be able to stand upright on the bandaged foot. It is also important to make sure that the bandage is not applied too tightly around the tarsometatarsus at the top of the bandage, which can cause vascular compromise of the foot. Birds with one or both feet in ball bandages should be placed in an enclosure with a padded surface.

Other Leg and Foot Bandages and Splints

Various tape splints have been devised for immobilizing simple tibiotarsal and tarsometatarsal fractures in small birds.[26] Additional splinting material such as paper clip wire or toothpicks, balsa wood, pipe cleaners or wooden applicator sticks can be used to provide more stabilization. Such support must be properly padded over bony protuberances to avoid pressure ulcers. The joint above and below the fracture should be immobilized.

Toe fractures can be immobilized by taping two toes together, by splinting with a padded tongue depressor or cardboard in a modified "snowshoe" splint using two or more toes, or by using thermoplastic coated casting material[s] to mold a "shoe splint" to fit the entire foot (Figure 16.18). For small birds, hydrocolloid dressings can be used as splint material for tibiotarsal and tarsometatarsal fractures (see Figure 16.3). The hydrocolloid dressing should be covered by another bandage material to prevent chewing, and should be changed on a daily basis if it becomes moist. When the wound is dry, the dressing can be left in place for up to ten days.

Soft tissue wounds involving the plantar surface of the foot can be effectively bandaged with an interdigitating bandage that leaves the toes exposed for perching (Figure 16.19). It is important to avoid applying the bandage too tightly, or using too much bandaging material between cranial digits. The lightest possible bandage would be used in finches and other small birds to prevent loss of balance.

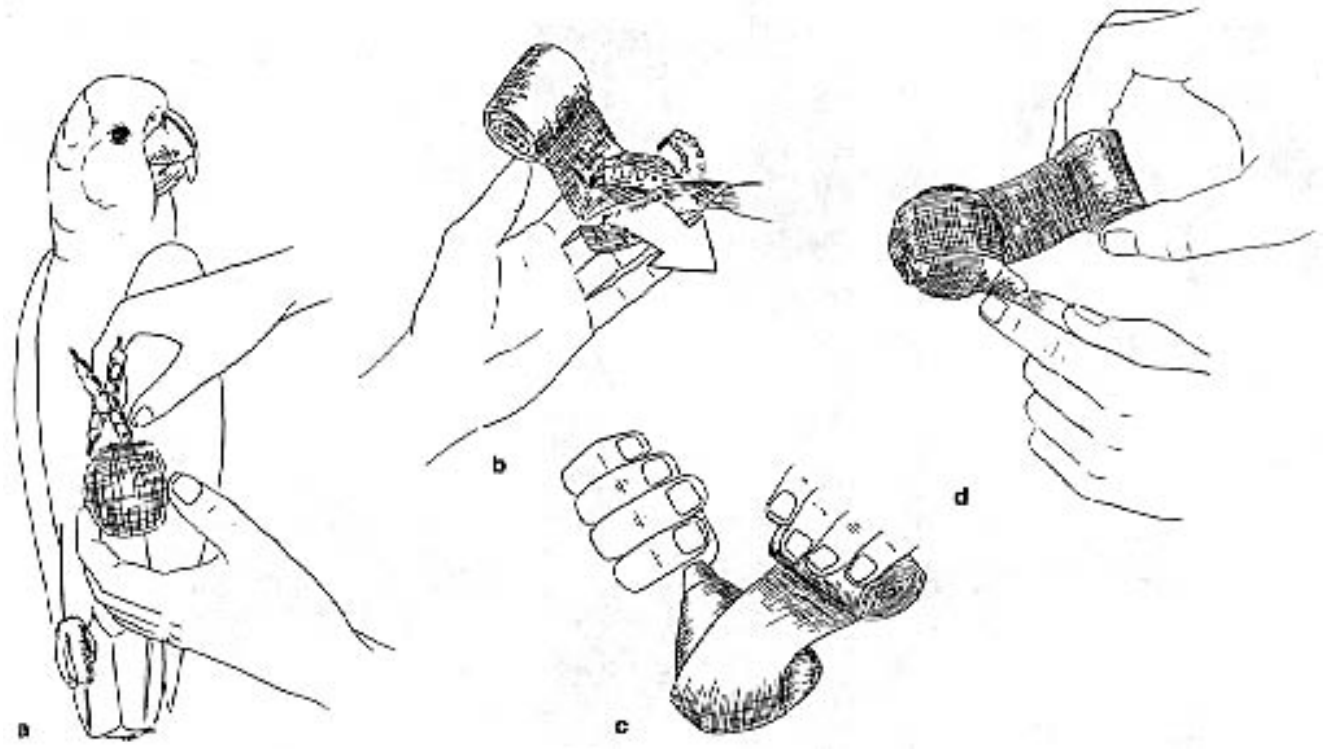

FIG16.17 Ball bandages can be used to protect foot injuries while they heal. A stack of gauze pads or a piece of cardboard cut to fit the bottom of the foot is covered with cotton padding and placed on the plantar surface of the foot. The foot is then wrapped with a layer of rolled cotton padding and covered with a self-adherent bandage material.

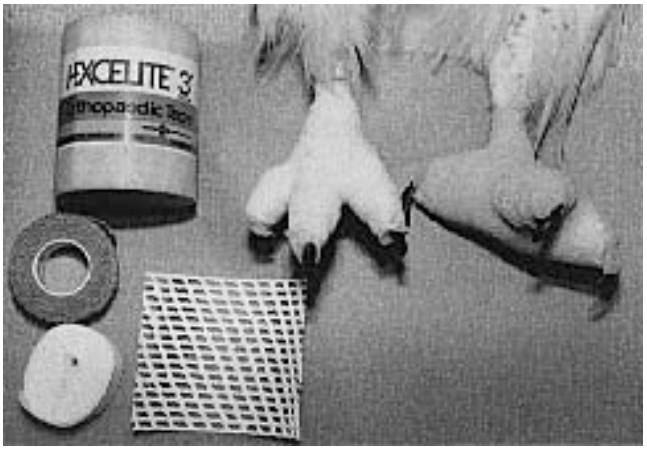

FIG 16.18 A snowshoe splint can be used to provide primary support for phalangeal fractures. The bandage is applied by wrapping the toes and foot in a protective layer of cotton padding. A "snowshoe"-shaped splint is fashioned out of Hexcelite and placed onto the plantar surface of the foot. The splint is held in place with cotton padding covered with a self-adherent bandage material.

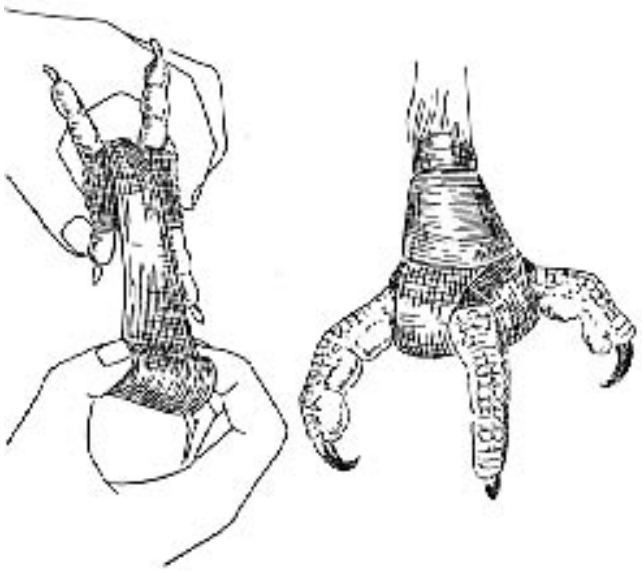

FIG 16.19 An interdigitating bandage is applied by placing gauze on the metatarsal pad and wrapping it in place with cotton padding, which is then covered with a self-adherent bandage.

CHAPTER

17

ANTIMICROBIAL THERAPY

Keven Flammer

Microbial diseases are common in companion and aviary birds, and careful drug selection and delivery can greatly influence the outcome of many clinical cases. In contrast to mammals in which it may be possible to try an empirical treatment regimen, birds are often presented in an advanced state of illness, necessitating immediate and correct diagnosis and treatment. For best results, antimicrobial therapy should be maximized early in the disease process.

Published avian drug doses are often based on clinical experience or data extrapolated from other species. Suggested doses may or may not be optimal, and avian veterinarians should be attentive to the possible toxic effects or lack of efficacy when treating birds with empirically derived doses. Sub-therapeutic dosing can result in treatment failure and encourage the development of microbial resistance. Excessive drug treatment may be toxic and damage the kidneys or liver. In particular, care should be extended when treating rare birds in which the effects of a specific drug have not been investigated.

The goal of antimicrobial therapy is to aid elimination of the infecting organism from the host. Antibiotics play only a partial role in this process, and the host immune system is usually required to resolve an infection. Supportive care is therefore an important component of the overall therapeutic plan. The clinical outcome of using an antimicrobial agent depends upon the intrinsic susceptibility of the agent and microbiological activity of the drug (efficacy), the ability of the drug to reach the site of infection at adequate concentrations (pharmacodynamics), and the ability of the drug to kill the pathogen without harming the host (selective toxicity). Other considerations include the route and frequency of administration, cost and ability of the bird owner to accomplish the treatment regimen. Because birds are often presented in a state of advanced illness and immunosuppression, the best drug should be given via the best route to maximize the chances for treatment success. A general approach to the treatment of microbial diseases is provided in Table 17.1.

Factors Influencing Selection of an Antibiotic

There are no exact criteria to determine which antibiotic is best for each situation. Some of the important factors influencing the rational selection of an antibiotic are discussed below.

TABLE 17.1 General Approach to Treatment of Bacterial Diseases

1. **Identify** the pathogen and location of infection.
2. **Determine** the antimicrobial susceptibility of the isolate if the susceptibility cannot be predicted.
3. **Select** an antimicrobial drug based on susceptibility, ability to reach the site of infection, available routes of administration, required frequency of administration and minimal toxicity to the host.
4. **Determine** if it is feasible for the bird owner to complete the treatment regimen.
5. **Treat** with appropriate antibiotics.
6. **Maintain** host defenses by reducing stress and maximizing supportive care.
7. **Find** and **eliminate** the source of bacteria.
8. **Decontaminate** the bird's environment.

Antimicrobial Spectrum

The target organism must be susceptible to the antibiotic at concentrations achievable at the site of infection if treatment is to be effective. Some microbial organisms have predictable susceptibility. For example, all strains of chlamydia are presumed to be susceptible to tetracyclines. If chlamydiosis is diagnosed, it is rational to begin therapy without a susceptibility test. Unfortunately, the most common infectious agents in psittacine birds (gram-negative bacteria, streptococcus and staphylococcus) have unpredictable antimicrobial susceptibilities, and an in vitro susceptibility test is required to aid drug selection.

Laboratories can determine the antimicrobial susceptibility of a bacterial isolate by two primary methods: disk diffusion and dilution tests. The Kirby-Bauer disk diffusion susceptibility test is a semiquantitative method, and the test organism is classified as susceptible, of intermediate susceptibility, or resistant to the drug. It is important to understand that the classification "susceptible" is based on the

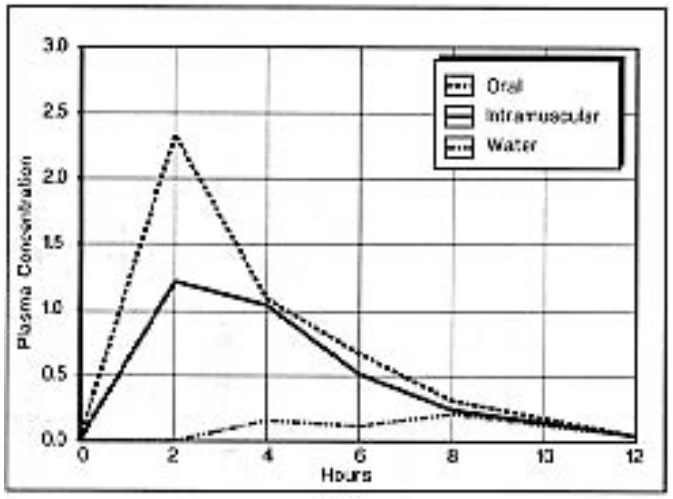

FIG 17.1 Plasma concentrations of enrofloxacin in African Grey Parrots vary with the route of administration. Bacteria must be highly susceptible (MIC <0.05 μg/ml) to be effectively treated with water-based administration.

antibiotic serum concentrations that are achieved by a *standard treatment regimen in humans* (or a test animal if the drug is veterinary-labeled). A pathogen that is classified as susceptible by an *in vitro* test will be susceptible in the bird only if similar concentrations are maintained at the site of infection. As explained below, the achievable drug concentrations are influenced by many factors including dose, frequency and route of administration. Therefore, if a disk diffusion susceptibility test indicates that an organism is resistant, treatment with that drug will not be successful. If the test indicates the organism is susceptible, then treatment *may* be successful if drug concentrations similar to those in humans are achieved in the bird.

Antimicrobial susceptibility tests using dilution methods determine the minimal inhibitory concentration (MIC) of the antibiotic. Since the MIC is quantitative, it allows the clinician to select the drug to which the organism is *most* susceptible and provides a better prediction of treatment success. An example illustrates how disk diffusion and dilution tests differ. When using a disk diffusion test to determine microbial susceptibility to enrofloxacin, all isolates with a zone of inhibition corresponding to an MIC of 2 μg/ml (based on achievable concentrations in dogs) would be reported as susceptible. It would not indicate if the organism was at the low end of susceptibility (0.03 μg/ml) or the high end (2.0 μg/ml). If a dilution susceptibility test were performed, the precise MIC for that organism would be determined. Figure 17.1 illustrates the plasma concentrations

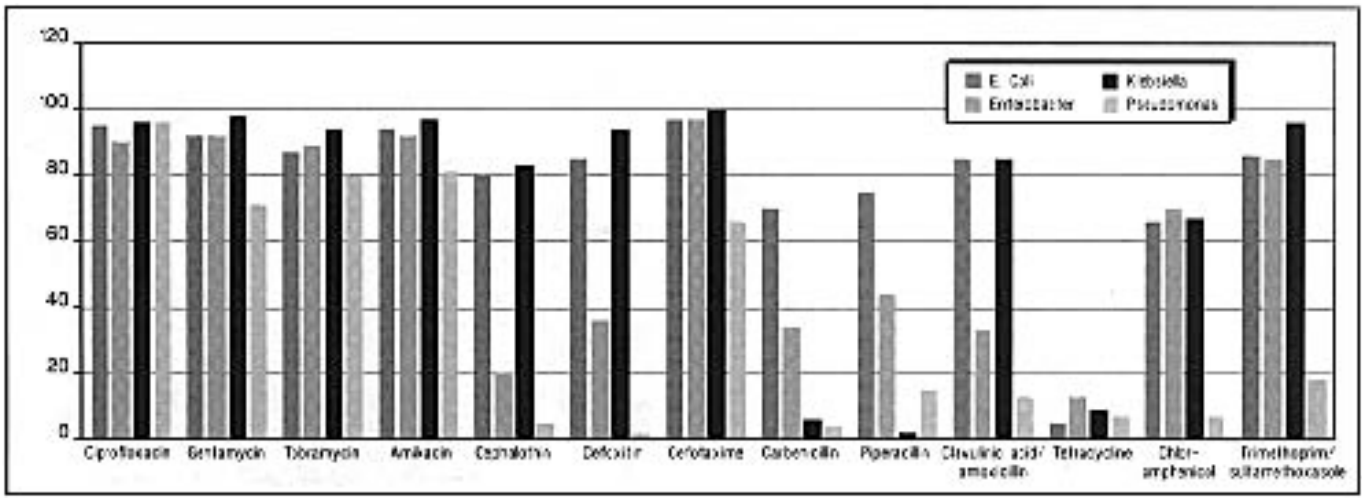

FIG 17.2 Susceptibility of gram-negative bacteria to commonly used antibiotics in one study of psittacine birds.

achieved when enrofloxacin is administered to African Grey Parrots by intramuscular, oral (gavage) or water route. This data shows that isolates with an MIC of 1-2 μg/ml would not be successfully treated by enrofloxacin in African Grey Parrots under any circumstances; oral and IM administration would be effective against isolates with an MIC < 1.0 μg/ml; and water administration would be effective only against isolates with an MIC < 0.05 μg/ml. The dilution test enables selection of a drug and route of administration that will have a high likelihood of success. Information on the pharmacokinetics of antibiotics in avian species is expanding, making decisions based on MIC data increasingly possible and effective.

In a severely ill patient, or in one that has an infection in an area that is difficult to culture, it may be necessary to start treatment without the benefit of a culture and susceptibility test. In these cases it is helpful to know the common causes of infection and the antimicrobial drugs most likely to be effective. There are many exceptions to the comments made below; however, following these suggestions can result in successful therapy. Figure 17.2 displays the predictive efficacy for using various antimicrobial drugs to treat gram-negative bacteria isolated from psittacine patients at the Veterinary Teaching Hospital, College of Veterinary Medicine, North Carolina State University. Antimicrobial susceptibility patterns vary geographically, so this data may not be applicable to all areas.

The most common causes of primary and secondary microbial infections in psittacine birds are gram-negative bacteria, chlamydia and yeast. Gram-negative bacteria are frequently resistant to routine antibiotics (eg, ampicillin, tetracycline, chloramphenicol and erythromycin); however, most isolates are susceptible to trimethoprim/sulfa combinations, enrofloxacin, amikacin, and the advanced generation cephalosporins (eg, cefotaxime) and penicillins (eg, piperacillin). Yeast are usually confined to the alimentary tract and can be readily identified by performing a Gram's stain of a fecal smear. Most yeast are susceptible to treatment with nystatin, ketoconazole or fluconazole. Chlamydia are susceptible to treatment with tetracyclines.

CLINICAL APPLICATIONS

- Prolonged tetracycline therapy may be catabolic, cause immunosuppression, reduce normal gut flora or render a bird more susceptible to secondary pathogens.
- Nystatin must come in direct contact with yeast to be effective. If nystatin is delivered by gavage tube, infections in the mouth will not be treated.
- Medicated food and water are traditionally favored routes for poultry but seldom achieve therapeutic drug concentrations in companion and aviary birds.
- Birds receiving antibiotics should be monitored for secondary infections with cloacal cultures and fecal Gram's stains.
- Trimethoprim/sulfadiazine is often effective for treating gram-negative infections in nestling birds.
- Critically ill birds should be treated via parenteral routes to establish effective drug concentration quickly.
- On a body weight basis, a 0.05 ml injection in a canary is equivalent to a 40 ml injection in a 25 kg dog.
- Given orally, the IM formulation of enrofloxacin produces therapeutic plasma concentrations.

Less common infectious agents of psittacine birds are gram-positive bacteria (*Staphylococcus aureus* and some *Streptococcus* spp.), mycoplasma, systemic fungi and mycobacteria. Many of the *S. aureus* and streptococcus isolates tested by the author are susceptible to cephalexin or cephalothin. Mycoplasma are presumed to be susceptible to enrofloxacin, tetracyclines and tylosin. Systemic fungal infections are difficult to treat under any circumstances and require multiple drug therapy with amphotericin B and itraconazole, fluconazole or flucytosine. Mycobacteria are extremely difficult to eliminate. *Mycobacterium avium* can cause fatal infections in immunosuppressed humans, and therapeutic management must be considered with caution (see Chapter 33). A summary of the susceptibilities of common avian infectious agents to antimicrobial therapy is given in Table 17.2.

Pharmacodynamics of the Drug

Antibiotics penetrate tissues differently, so the site of infection will also influence drug selection. Most bacteria remain extracellular while causing infection; however, there are a few notable exceptions (eg, salmonella, mycobacteria and some staphylococci). Treatment of intracellular infections may require drugs that are highly lipophilic and can penetrate cells (eg, chloramphenicol). Polar drugs (eg, the beta lactams and aminoglycosides) are frequently excluded from pharmacologically privileged spaces such as the cerebrospinal fluid (CSF) and ocular fluids.

Conditions at the site of infection are also important. Exudates, abscesses and granulomas create a hostile environment for the action of antibiotics. Perfusion of fibrous tissue is limited, and this may prevent the drug from reaching the site of infection. Changes in pH, oxygen tension, binding by intracellular proteins and slow microbial division may reduce antimicrobial activity. Surgical drainage or removal of an infected mass may be required before antibiotics can be effective.

The pharmacokinetics of the drug are also important. With bacteriostatic drugs, it is desirable to maintain the concentration of drug above the bacterial MIC for at least half of the dosage interval, and preferably throughout the interval, if this is attainable and not toxic. With most bacteriocidal drugs, it is not necessary to maintain the drug above the MIC for the entire dosage interval; however, if concentrations drop below the MIC for too long, the bacteria will multiply, and a "break-through bacteremia" may occur. Drugs with a short half-life, like the beta lactams, must be given frequently to maintain effective concentrations.

Pharmacokinetic information is invaluable and has become available for specific drugs in some avian species, but it is likely that the use of extrapolated drug treatment regimens to untested species will continue to be a common practice in avian medicine. The extrapolation of pharmacokinetic data to untested species is complicated by the fact that there may be differences in the way that even individuals and closely related species absorb and excrete antimicrobial drugs.[15] For example, the aminoglycosides are excreted unchanged by the kidney, and the pharmacokinetics are similar across species lines. The recommended dose and elimination half-life are similar in cockatiels and macaws despite a 10-fold difference in body weight. The pharmacokinetics of drugs that are metabolized show greater variability.

For some drugs there is good correlation between dose and metabolic rate calculations based on body size. It has been suggested that the techniques of "allometric scaling" be used to extrapolate the doses of these drugs from human and mammalian medicine to birds.[15,55] Although allometric scaling has validity for some compounds, veterinarians should be aware of its limitations. Evaluation of drug excretion and potential metabolic pathways are important, as numerous exceptions to scaling exist — some with potentially toxic results. For example, the elimination half-life of chloramphenicol in budgerigars is twice as long as in macaws, despite a 30-fold difference in body weight. In this instance, scaling a dose from a macaw to a budgerigar would result in toxic doses, while scaling from a budgerigar to a macaw would result in completely ineffective doses. Unexpected differences are also seen with doxycycline. The elimination half-life of orally administered doxycycline in Goffin's Cockatoos is approximately 20 hours, but in similarly sized Orange-winged Amazon Parrots it is approximately 10 hours.[19] Finally, scaling of a compound with a narrow therapeutic range such as gentamicin could result in potentially lethal dosage recommendations if the drug is scaled from doses from small to large species. Allometric scaling is a useful tool when pharmacokinetic data is not available, but it should be used with caution and the effects of dosing closely monitored. The adverse effects of improper antimicrobial therapy are discussed below in the section on toxicity and side effects.

Route of Administration

Selecting the route of drug administration in birds requires careful consideration. Available routes include medicated water, medicated food, oral, intramuscular, intravenous, subcutaneous, intraosseous, intratracheal, inhalation and topical. Factors to consider when selecting a route include: 1) The severity of the infection. Critically ill birds should be treated with parenteral medications to establish effective drug concentrations quickly. 2) The number of birds to be treated. Medicated food or water may be the only practical way to treat multiple-bird flocks (Figure 17.3). 3) The availability of appropriate drug formulations. 4) The frequency of administration, resultant stress to the bird and the labor involved in completing the treatment regimen. 5) The ability of the owner to complete the treatment regimen.

As noted previously, the route of delivery greatly influences the drug concentration achieved in the host. For example, Figure 17.1 shows that the concentration of enrofloxacin achieved in African Grey Parrots by offering medicated water is one-tenth of that achieved by oral or parenteral administration. This data must be considered when interpreting antimicrobial susceptibility tests, as the achievable drug concentrations will depend on the route of administration.

The advantages and disadvantages of various routes are discussed below. In general, medicated food and water are traditionally favored routes for poultry but seldom achieve therapeutic drug concentrations in companion and aviary birds. Most serious microbial infections must be treated by the oral or a parenteral route.

Water-based Drug Administration

- ***Advantages:*** It is easy, handling of the birds is not required and the birds will self-medicate several times daily. The presence of medication may decrease disease transmission via contaminated drinking water.

- ***Disadvantages:*** Consumption is erratic and therapeutic serum concentrations are rarely achieved, especially during the night when less water is consumed. Medicated water is often unpalatable, and reduced water consumption not only decreases therapeutic drug concentrations but may also result in decreased water consumption and dehydration. Many antibiotics are not stable or soluble in water.

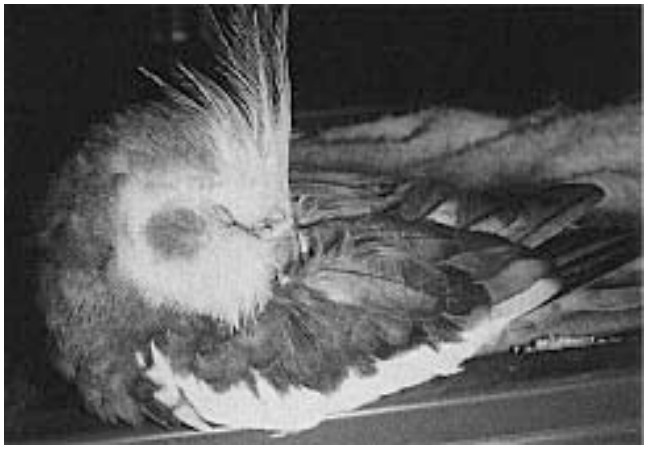

FIG 17.3 An adult cockatiel with a three-day history of anorexia was found on the bottom of the enclosure. Depression is a hallmark clinical sign of septicemia. These emergency cases usually require parenteral administration of broad-spectrum antibiotics, parenteral fluid therapy and corticosteroid administration to prevent endotoxic shock due to degenerating gram-negative bacteria.

- ***Comments:*** At first glance, medicated water would appear to be the ideal way to medicate many avian species. Unfortunately, with a few exceptions, medicated water will not adequately treat most companion and aviary bird diseases. Psittacine birds simply fail to drink enough water to consume adequate doses of most antimicrobial drugs, especially if they are ill. If water is consumed, low drug concentrations are usually sustained in the bird because small amounts of drug are consumed often. Only highly susceptible bacterial infections in a stable patient should be treated in this manner. Water-based drugs should not be used in sick birds where the rapid establishment of therapeutic drug concentrations is required. Water-based medications can be used as an adjunct to direct drug administration or in situations where direct medication is impossible. Water-based drugs are most successful against mild infections of the alimentary tract where the drug may have a local effect in the gut.

There are some specific drugs and therapeutic situations where water-based administration may be successful. Enrofloxacin may successfully treat highly susceptible gram-negative bacteria (MIC <0.05 μg/ml). Sulfachlorpyridizine may be effective against alimentary tract infections caused by highly susceptible strains of *Escherichia coli*. Spectinomycin may be effective against alimentary tract infections caused by highly susceptible strains of *E. coli*. Nitrofurazone may slow the spread of salmonella within a flock. Aminoglycosides (eg, gentamicin, neomycin and amikacin) are not absorbed but may have

a local effect against pathogens in the gut. Tetracyclines may slow the spread and alleviate clinical signs in birds with chlamydiosis but will not consistently clear birds of infection. Tetracyclines degrade rapidly in water. Chlorhexidine may inhibit the spread and severity of candida infections of the alimentary tract.

Food-based Drug Administration

- ***Advantages:*** It is easy, the birds will self-medicate several times daily, capture and handling are not required and food consumption is often more consistent than water consumption. It may be possible to medicate nestling birds by adding medication to the food of their parents.

- ***Disadvantages:*** Food often reduces drug absorption and sick birds consume less food, especially if the medicated ration is unpalatable. As with medicated water, it is difficult to achieve therapeutic concentrations with food-based administration. Psittacine birds are notorious for refusing new foods and may reject even palatable medicated rations if the diet must be changed to provide a food that will carry the drug.

- ***Comments:*** Powders, ground tablets and oral suspensions can be added to a palatable food vehicle such as cooked mashes, rolled corn, canned and frozen vegetables or fruit mixtures. A cooked mash containing 13% dry oatmeal and 29% each cooked kidney beans, rice, and corn is nutritious and well accepted by many psittacine birds. If a favorite treat food is well accepted and quickly consumed, it may be possible to lace it with the divided daily drug dose and offer it several times daily. If the drug must be added to food consumed on an intermittent basis throughout the day, the total daily dose plus extra (based on wastage and estimated reduced drug availability) should be placed in the amount of food the bird will consume in one day. As with medicated water, the achievable serum drug concentrations are usually much lower than those reached with oral or parenteral administration, so only highly susceptible bacteria should be treated with food-based medications.

  Formulated diets containing chlortetracycline are commercially available and can be used to treat chlamydiosis. Chlortetracycline-impregnated millet seed[a] is also available and is readily accepted by budgerigars and finches. These products sustain chlortetracycline blood concentrations of 0.5-1.5 μg/ml when fed with diets containing < 0.7% calcium. It is also possible to prepare a medicated mash using powdered chlortetracycline.

  Research on developing doxycycline-medicated diets illustrates the importance of standardizing the components of a medicated ration. Consumption of the diet determines the amount of drug ingested and is dependent on energy content, palatability and familiarity of the diet. For example, cockatoos receiving ad libitum diets medicated with identical concentrations of doxycycline (0.1%) achieved toxic plasma concentrations (8-10 μg/ml) when fed a medicated corn and soybean mash, adequate concentrations (1-2 μg/ml) when fed a medicated rice, corn, bean, and oatmeal mash, and low concentrations (< 0.5 μg/ml) when fed medicated pellets. The primary difference among these diets is the energy content. Drug concentrations for medicated feed cannot be extrapolated from one diet to another without knowing the energy content and palatability of the diets.

Oral Medication

- ***Advantages:*** A precise dose can be administered and, because many drugs are available as oral suspensions in flavored pediatric strengths, dosing is easy. Sick birds frequently require assisted feedings, and these drugs can easily be added to the feeding formula.

- ***Disadvantages:*** Unless the bird is tame and finds the medication palatable, the bird must be captured and fully restrained to deliver the medication. This is stressful, and some birds will refuse to swallow medications or may aspirate them into the nasal passages. It is often necessary to pass a tube and deliver oral drugs into the crop of recalcitrant birds. Drug selection is restricted since not all drugs are absorbed orally (eg, aminoglycosides, advanced generation penicillins and cephalosporins). Some birds, (eg, macaws) may regurgitate medications delivered per os.

- ***Comments:*** It is surprisingly difficult to force psittacine birds to accept oral medications. Bird owners may initially be able to administer the drug, but as treatment progresses the bird may become more difficult to medicate. Sometimes the stress of handling exceeds the benefits of the drug itself. Acceptance can be improved if the drug is mixed with a palatable vehicle such as lactulose syrup or fruit juice. Oral suspensions and solutions are appropriate for use in all birds; tablets and pills are probably not appropriate for use in birds with a crop. Capsules that rapidly dissolve can be used in those birds that are "pillable" (eg, pigeons, waterfowl and gallinaceous birds).

Intramuscular Injection

- ***Advantages:*** An exact dose can be administered, and absorption is usually rapid. The bird must be captured, but restraint time is minimal.

- ***Disadvantages:*** Not all antibiotics can be given IM, and injections may be painful and cause muscle necrosis (Figure 17.4). The volume of injected fluid must be carefully monitored in small patients.

- ***Comments:*** Intramuscular injection is often the quickest and least stressful method of directly administering drugs to companion birds. It is often easier to administer drugs IM than orally, and most bird owners can be taught to perform this procedure. The proximal two-thirds of the pectoral muscles provide the optimal injection site. Drugs injected into the muscles of the legs may pass through the renal portal system first, clearing the drug before it can reach the systemic circulation. Injection sites can be rotated to avoid excess trauma in one area. Short, 26 ga x 3/8" intradermal needles or insulin syringes work well.

  Intramuscular injection may not be feasible in all birds. Nestling birds of all species have relatively little pectoral muscle mass, and it is easy to pierce the sternum, which is non-ossified at this age. Ratites, even as adults, lack large pectoral muscles. Owners of racing pigeons, raptors and some game birds may refuse to give medications IM in the breast because they fear muscle damage will interfere with flight or normal activity.

  The injection volume in relation to body size must also be considered. For example, on a body weight basis, a 0.05 ml injection in a canary is equivalent to a 40 ml injection in a 25 kg dog. Injection volumes in psittacine birds should be small but permit accurate measurement of the medication.

Subcutaneous Injection

- ***Advantages:*** An accurate dose and large volumes can be administered. This is a good site for fluid administration if the bird is not volume depleted or severely dehydrated. The best sites are the groin and dorsal cervico-thoracic area.

- ***Disadvantages:*** Full restraint is required. Birds have very thin skin and fluid will often leak out of the injection site. Irritating drugs may cause skin necrosis and ulceration.

- ***Comments:*** The subcutaneous route is not ideal but can be used for irritating drugs when muscle necrosis or injection trauma is to be avoided. This site is often used by pigeon and game bird breeders.

FIG 17.4 Muscle necrosis secondary to a single IM injection of ticarcillin. Many of the drugs available for parenteral administration in birds can cause mild to severe muscle necrosis.

Intravenous Injection

- ***Advantages:*** An exact dose can be given and therapeutic levels are rapidly achieved.

- ***Disadvantages:*** The bird must be fully restrained; anesthesia may be helpful. Because avian veins are fragile, leakage of drug from the vessel and hematoma formation are common.

- ***Comments:*** Intravenous injection should be reserved for emergencies and one-time drug administration. Veins may also be needed for blood withdrawal for diagnostic tests. The right jugular, superficial ulnar, basilic vein on the ventral humerus and superficial plantar veins are most accessible. Intravenous catheters are available but are potentially dangerous to leave in unattended birds. Intravenous fluids can be delivered as a slow bolus at a dose of 10 ml/kg without pulmonary compromise.

Intraosseous Injection

- ***Advantages:*** If repeated drug administration is required the intraosseous route may be selected (Figure 17.5). The intraosseous route allows stable access to the intravascular space. A cannula can be inserted and used for repeated fluid or drug administration. If properly bandaged, psittacine birds will usually tolerate cannulas for short periods of time. Intraosseous cannulas are well tolerated in raptors, pigeons, waterfowl and other less temperamental species. The

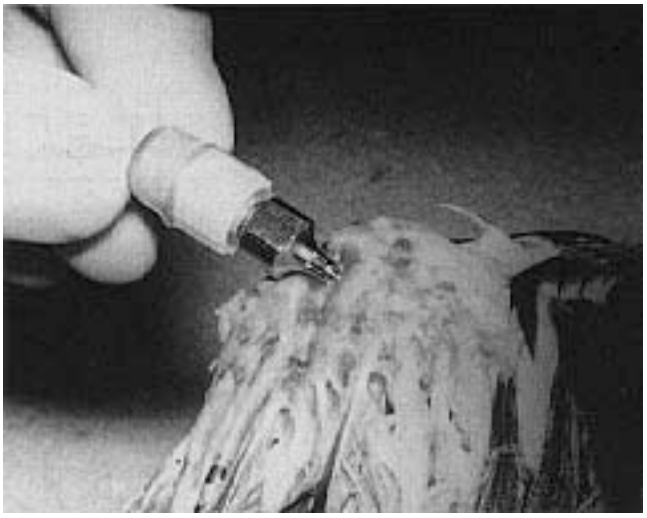

FIG 17.5 It may be safe to deliver some drugs designed for IV administration through indwelling intraosseous cannulas. If several days of therapy are necessary, the cannula can be placed in the ulna. For birds that need only a single administration of a drug that must be given slowly (most IV products), a cannula can be placed in the tibia. It has not been determined which of the IV drug preparations can safely be delivered through IO cannulas.

distal ulna and proximal tibia are the best locations for cannulation.

- ***Disadvantages:*** Only fluids or non-irritating drugs should be delivered via intraosseous cannulas. Sterility is critical, as infection may result in osteomyelitis.

Nebulization

- ***Advantages:*** Nebulized antibiotics are useful for pulmonary, sinus and trachea infections, and are often combined with mucolytic and penetrating agents (eg, DMSO) to break down caseous material and increase antibiotic uptake. Simple humidification of the lungs is also helpful. Therapeutic serum levels are seldom achieved but effective concentrations may be achieved in restricted sites in the upper respiratory tract.

- ***Disadvantages:*** At rest, there is little or no air exchange in much of the respiratory tract. It has been suggested that only 20% of the respiratory tract would be reached by nebulization.[2] The nebulized particle size should be less than 1-3 μm. Nebulization should usually be combined with systemic therapy.

Topical Medications

- ***Skin:*** Topical medications should be used carefully and sparingly. Oily and toxic compounds should be avoided, as they will mat the feathers and be ingested when the bird preens. A water-soluble formulation should be selected if available. If it is necessary to use greasy compounds, the site should be bandaged or the bird collared to prevent preening and ingestion. Propylene glycol can be added to some preparations (eg, ivermectin) to allow systemic absorption of cutaneously applied drugs.

- ***Eye:*** Liquid eye drops retard corneal healing less than ointments but must be given more frequently. Ointments should be applied very sparingly, as excess ointment will cause matting and loss of feathers surrounding the eye. Misting the eye with a water-soluble, topical spray may also be effective. Subconjunctival injections may be considered for delivering repository drugs.

- ***Nasal Flushes:*** Nasal irrigation can be very helpful for treating upper respiratory infections. Antibiotics can be added to flushing solutions, but in many cases unmedicated saline works as well. Isotonic solutions should be delivered with minimal pressure to avoid damage to inflamed tissues.

- ***Infraorbital Sinus Injection:*** Sinus injection is useful for flushing and delivering medication into the infraorbital sinus in birds with sinusitis. The injection is made at the level of the commissure of the beak, just ventral to the zygomatic arch, the same site as for cytologic sampling (see Chapter 10). Care must be taken not to penetrate the globe of the eye. If sinusitis has resulted in blockage of the outflow tracts, low volumes of fluid must be slowly injected to prevent exophthalmus. Only non-irritating drugs should be used.

- ***Intratracheal*** (through the glottis): This is an effective route for delivering amphotericin B to birds suffering from tracheal and pulmonary aspergillosis.

Toxicity and Adverse Effects of Antimicrobial Therapy

All antimicrobial drugs have the potential to harm the host. Direct toxic effects and the reduction of normal alimentary tract flora can occur even when antibiotics are used properly, requiring that birds should be monitored during treatment. Treatment failure and the development of resistant strains of bacteria occur most often when drugs are used improperly. Because the interplay between effective treatment, toxicity and adverse side effects is complex, the use of antimicrobials in birds should be pursued with caution, and routine prophylactic treatment of birds without a clear indication of infection is not suggested in any circumstance.

Misuse of antimicrobials can have serious consequences, especially in an avicultural facility or multiple-bird household. Selection of the wrong agent can result in treatment failure and spread of disease-causing organisms by the inappropriately treated bird. Use of low-dose administration (eg, drinking water-based) often generates resistant strains of bacteria that may become established in the aviary. This, coupled with the stress and adverse effects of drug delivery on normal flora, can actually make a disease problem worse rather than better. When prescribing antimicrobials, it is important to explain to the client the necessity of giving the full treatment regimen without skipping doses, even if the bird improves before treatment ends. This is necessary to prevent a recurrence of the infection and generation of resistant strains of bacteria.

Direct Toxic Effects

Drug toxicity varies with the compound, dose and physiologic status of the patient. Toxic effects of specific agents are listed in the section below, but some generalities can be made. The beta lactam antibiotics have relatively few direct toxic effects. The aminoglycosides are nephrotoxic at therapeutic doses and should be used with extreme caution in juvenile and dehydrated birds. Sulfa drugs should also be used cautiously in birds that are uricemic, because they are potentially nephrotoxic in dehydrated animals and are metabolized via the same metabolic pathway in the liver as uric acid. The fluroquinolones cause defects in the articular cartilage of some species of growing animals (eg, dogs, pigeons and horses) but not others (eg, cats). These effects are both species- and dose-dependent. To date, toxic effects have not been proven in psittacine birds treated with recommended doses of fluroquinolones.

Adverse Effects on Normal Alimentary Tract Flora

Most of the antibiotics used in avian practice are broad spectrum and their use will reduce or eliminate normal alimentary tract flora. Normal flora help reduce infection by potentially harmful microorganisms by competing for nutrients and occupying cellular attachment sites. Eliminating normal flora may render the bird more susceptible to colonization by potential pathogens such as yeast, viruses and gram-negative bacteria. Birds receiving antibiotics should be monitored for secondary infections with cloacal cultures and fecal Gram's stains.

Inappropriate antimicrobial therapy may potentiate an infection if the pathogen is resistant but the drug selected eliminates normal flora. This will favor growth of the pathogen in a competition-free environment (eg, digestive tract, skin, nasal passages). For this reason, drugs and the route of administration should be selected with care, and non-specific prophylactic use of antimicrobials should be avoided. It may also be advisable to culture the cloaca prior to antimicrobial treatment of all birds, even if the alimentary tract is not the primary site of infection. If potential pathogens are isolated, the treatment regimen should include a drug that will be effective for these organisms as well as the primary pathogens; otherwise minor alimentary tract pathogens may proliferate and cause illness if the competition from normal flora is eliminated. Environmental sources of harmful microorganisms should be eliminated during antimicrobial treatment by improving husbandry. Young and immunocompromised birds should be monitored every day during antimicrobial therapy to prevent potential yeast infections.

Treatment Failure

Birds are perceived to be masters at hiding their signs of disease and are often in an advanced state of illness by the time they are presented for treatment. It is important to establish a correct diagnosis and implement an effective treatment plan early in the disease process because there is seldom time to simply try a drug and see what happens. If the wrong drug or route of administration is selected, or if the problem is not due to a microbial infection, the bird may die while waiting to determine if prophylactic therapy is successful.

Some pet stores may sell over-the-counter (OTC) antibiotics with label claims that they are beneficial for treating a variety of avian respiratory and gastrointestinal complaints. Most of these products contain tetracycline, erythromycin or a sulfa drug, and are compounded for water administration. These products are *seldom* effective at the doses and routes recommended, and many bird owners waste valuable time attempting treatment with these products before consulting an avian veterinarian. By the time the bird receives appropriate care, it is usually too late. Bird owners should be educated to avoid these useless medications and to use more effective diagnostic and therapeutic methods with their pets.

Development of Resistant Strains of Bacteria

Bacteria develop resistance to drugs by two primary methods: transfer of plasmids and chromosomal mutation. These methods may: 1) induce production of an enzyme that degrades the antibiotic; 2) alter membrane permeability and therefore prevent the

antibiotic from penetrating the bacteria; or 3) create an alternate metabolic pathway that bypasses the action of the antibiotics. Plasmids are cytoplasmic bundles of nucleic acid that can be transferred among different species of bacteria, and are therefore the most important mechanism of developing, maintaining and transferring resistance in a bacterial population. Resistance is most common among gram-positive and gram-negative bacteria and less common in anaerobes, chlamydia and yeast.

Sub-therapeutic treatment can encourage the development of resistant bacteria. If low antibiotic concentration is achieved at the site of infection (such as typically occurs with water-based treatment regimes), only the highly susceptible bacteria will be killed. The remaining resistant bacteria will then multiply to use the space and nutrients formerly consumed by the susceptible bacteria. Over time, resistant bacteria may become established in a hospital or aviary. Sub-therapeutic or random non-specific treatment would be considered worse than no treatment at all if resistant bacterial strains are generated at the same time normal alimentary tract flora is reduced.

Cost

The small size of most avian patients makes it possible to economically use antibiotics that would be too expensive in traditional small animal species. This permits use of a variety of advanced generation antibiotics, especially among the beta lactams. In appropriate situations, these antibiotics are quite effective; however, they should not be used inappropriately, or microbial resistance will occur.

Antibacterial Therapy

The following sections were written to provide concise, practical information about the pharmacology and use of antimicrobial drugs in birds, primarily psittacines. More exhaustive reviews of drug pharmacology and use in poultry are available in the references (see Chapter 18).[47,51]

Fluoroquinolones

Pharmacology

The fluoroquinolones are a relatively new class of antimicrobial drugs that inhibit bacterial gyrase, the enzyme responsible for coiling DNA within the bacterial nucleus. They are bactericidal, widely distributed to tissues and the extracellular space, and are excreted primarily through renal tubular secretion and glomerular filtration. There is some hepatic metabolization, and enrofloxacin is partially metabolized to ciprofloxacin, an equipotent metabolite. Fluoroquinolones are generally well tolerated, although gastrointestinal upset and anorexia have been occasionally reported, and they may induce seizures in seizure-prone animals. High-dose or prolonged treatment may cause permanent articular defects in growing juveniles of certain species, including dogs, pigeons and horses.[36]

Use in Companion Avian Medicine

- ***Enrofloxacin:*** Enrofloxacin is currently the only veterinary-labeled fluoroquinolone. It has excellent activity against mycoplasma, some gram-positive bacteria and most gram-negative bacteria. Resistance of *Pseudomonas* spp. is occasionally seen. Enrofloxacin is highly active against most Enterobacteriaceae recovered from psittacine birds. It reduces clinical signs in birds infected with *Chlamydia psittaci*, but anecdotal comments indicate that enrofloxacin treatment does not routinely clear the carrier state. Currently, only tablets and IM preparations are available in the United States. A water-soluble liquid is available in some countries.

Studies on the single-dose kinetics of enrofloxacin in healthy African Grey Parrots, Blue-fronted and Orange-winged Amazons, and Goffin's Cockatoos indicate that a dose of 7.5-15 mg/kg administered IM or PO BID should maintain effective concentrations in these species.[26,27] Elimination in the African Grey Parrot was more rapid than in the Amazon parrot or cockatoo. For highly susceptible bacterial infections (MIC ≤ 0.03 μg/ml) in the Amazon parrot and cockatoo, SID therapy may be adequate. Intramuscular injection achieves greater peak concentrations (3-5 μg/ml versus 1-1.5 μg/ml with oral administration at 15 mg/kg), but concentrations after two to four hours are similar to those achieved with oral administration of the water-soluble solution. The IM formulation causes irritation at the site of injection, but given orally, the IM formulation induces higher peak plasma concentrations (1.5-2.5 μg/ml at 15 mg/kg) than the water-soluble formulation.

FIG 17.6 A duck with osteomyelitis of the tibiotarsal/tarsometatarsal area. Surgical debridement and long-term antibiotic therapy are usually required to resolve bone infections.

Mean plasma concentrations of approximately 0.1 μg/ml were maintained in African Grey Parrots fed drinking water medicated at 0.19-0.38 mg/ml. These concentrations might be effective for highly susceptible gram-negative bacteria.[25] Effective clearance of gram-negative bacteria from psittacine birds has been reported using IM (10 mg/kg SID) or water-based administration (100-200 ppm) for ten days.[36] Combination therapy in Senegal Parrots treated with enrofloxacin-medicated drinking water (100 ppm) and ketoconazole (30 mg/kg PO SID) for 10 days produced evidence of renal toxicity.[36] The half-life of enrofloxacin in pigeons was 2.6-4.7 hours with tissue concentrations exceeding those of serum in one hour. Recommended doses are 5 mg/kg, BID IM, PO or SC, or 100-200 ppm (0.1-0.2 mg/ml) in the drinking water for highly susceptible bacteria.[14]

Enrofloxacin and ciprofloxacin have been widely used in psittacine nurseries without reports of side effects. However, the drug should be used with caution in growing birds since toxic effects are species-specific and dose-related, and the drug has not been studied in all species. There have been scattered, anecdotal reports of aggressive, irritable behavior in adult Amazon parrots treated with quinolones.

- ***Ciprofloxacin:*** Ciprofloxacin is a human-labeled fluoroquinolone with an antibacterial spectrum and pharmacology similar to enrofloxacin. Ciprofloxacin tablets appear to be more water soluble than enrofloxacin. Ciprofloxacin has not been shown to have a therapeutic advantage over enrofloxacin.

Comments

The fluoroquinolones, especially enrofloxacin, are among the most effective drugs for treating gram-negative bacterial infections (Figure 17.6). Effective treatment with BID (or in some species, SID) administration is a clear advantage over some other antibiotics. Enrofloxacin can be administered orally but is bitter, and many birds will refuse to accept it. It may be necessary to dilute the drug in a palatable vehicle such as fruit juice or lactulose syrup, or to deliver it via a gavage tube. The major disadvantage to parenteral administration is intramuscular pain and irritation at the site of injection.

Penicillins

- ***Characteristics:*** The penicillins are beta lactam antibiotics. They inhibit the formation of the bacterial cell wall and are bactericidal for growing and dividing organisms. The spectrum and route of administration vary with the generation of the product. Older agents, such as ampicillin and amoxicillin, are effective against many gram-positive and some gram-negative organisms, and are available in oral and injectable formulations. Later-generation penicillins such as ticarcillin and piperacillin have enhanced activity against gram-negative bacteria, including *Pseudomonas* spp., but are primarily available in parenteral formulations.[40]

Penicillins are widely distributed to the extracellular space but poorly penetrate the CSF. Excretion is rapid (half-lives are usually less than 60 minutes) and is accomplished primarily through renal tubular secretion and glomerular filtration. Penicillins are considered relatively nontoxic, although allergic reactions (anaphylaxis) can occur. Procaine penicillin may cause adverse reactions in small patients (eg,

finches, canaries, budgerigars and cockatiels) due to the procaine component. Penicillins have reduced efficacy in the presence of overwhelming numbers of organisms ("inoculum effect"). Penicillins are synergistic when combined with aminoglycosides, and this combination can be used to treat severe infections, especially those caused by *Pseudomonas* spp.. These two agents should not be combined in the same syringe or the aminoglycoside will be inactivated.

Use in Companion Avian Medicine

- ***Natural Penicillins:*** Natural penicillins have a narrow spectrum restricted to *Pasteurella* spp. and some gram-positive organisms with MIC's less than 1 μg/ml. They are rarely used in avian medicine due to the availability of more effective drugs.

- ***Ampicillin / Amoxicillin:*** Many gram-positive bacteria are susceptible to ampicillin and amoxicillin, but most gram-negative isolates are resistant at concentrations achievable in birds. Oral absorption of ampicillin is highly erratic, so treatment failures are common even when laboratory tests suggest the isolated organisms are susceptible. Tests in chickens and ducks indicate that oral amoxicillin induces double the plasma concentrations of oral ampicillin.[37] Parenteral administration results in much higher and more consistent plasma concentrations. Ampicillin sodium doses of 100 mg/kg IM induced mean peak plasma concentrations of 60 μg/ml that declined to 0.65 μg/ml in four hours in Blue-naped Parrots. Based on this study, and another in Amazon parrots, it was recommended that ampicillin be dosed at 150 mg/kg PO QID.[17] Clark suggested that ampicillin in birds may be eliminated via hepatic and intestinal routes, in addition to renal excretion.[9]

- ***Ticarcillin:*** The pharmacology of ticarcillin is similar to that of carbenicillin; however, it is often two to four times more active against *Pseudomonas* spp. It is available for parenteral administration only.

- ***Piperacillin:*** In humans, piperacillin has greater activity against more gram-negative bacteria than other penicillins. It is widely used by avian veterinarians to treat systemic gram-negative bacterial infections. It is available for parenteral administration only. Serum and intestinal concentrations of piperacillin after an IM dose of 100 mg/kg in budgerigars were very high, and doses up to 1000 mg/kg did not induce clinically apparent toxic effects.[32] The half-life of piperacillin in Blue-fronted Amazon Parrots dosed with 100 mg/kg IM was less than 30 minutes, and doses of 75-100 mg/kg IM administered three to six times daily have been recommended.[23] Higher and more frequent doses should be used in more severe infections.

- ***Clavulinic Acid:*** Clavulinic acid has no antimicrobial activity of its own, but when combined with a penicillin, it inhibits beta-lactamase, a bacterial enzyme that inactivates many penicillins. Formulations combining clavulinic acid with amoxicillin or ticarcillin are available. Reports of use in birds are rare, but this drug may offer safe, effective activity against gram-negative and gram-positive pathogens.

Comments

Early generation penicillins are appropriate for treating infections caused only by highly susceptible pathogens. The advanced generation penicillins have an excellent gram-negative spectrum and are appropriate for treating severe infections caused by these organisms. Penicillins have a very high therapeutic index, an advantage when treating patients with compromised renal or hepatic function. A major disadvantage of using penicillins is the frequency of administration required to maintain effective concentrations.

Cephalosporins

Pharmacology

Like penicillins, the cephalosporins are beta lactam antibiotics; they share similar pharmacology but differ in spectrum.[41] Cephalosporins inhibit the formation of the bacterial cell wall and are bactericidal for growing and dividing organisms. They are widely distributed in the extracellular space, but most products poorly penetrate the cerebrospinal fluid and other pharmacologically privileged spaces. Excretion is primarily through renal tubular secretion and glomerular filtration. Cephalosporins are considered to be relatively nontoxic. They are classified into first, second and third generation products. In general, first generation products are effective against many gram-positive and some gram-negative bacteria, while increasing generations demonstrate enhanced gram-negative activity but reduced activity against gram-positives. Like the penicillins, cephalosporins also suffer from the "inoculum effect," and show reduced activity in the presence of overwhelming numbers of organisms. They are potentially synergistic when combined with aminoglycosides.

Use in Companion Avian Medicine

- ***First Generation Agents*** (eg, cephalexin and cephalothin): The antimicrobial spectrum of first genera-

tion agents includes most gram-positive cocci, some gram-negative bacteria and some anaerobes. Oral cephalexin is readily absorbed after oral administration in quail, ducks, cranes and emus. Doses of 35-50 mg/kg QID for larger birds and BID to TID for smaller birds have been recommended.[42] Cephalothin is available as a parenteral formulation, and, based on single-dose studies, therapeutic concentrations should be maintained with doses of 100 mg/kg IM QID in pigeons, cranes and emus, and BID to TID in quail and ducks. The author has successfully treated psittacine birds with cutaneous infections caused by *S. aureus* using administration of cephalexin at a dose of 100 mg/kg PO TID for 14-21 days.

- ***Second generation agents*** (eg, cefoxitin and cetaxitin) have increased gram-negative activity and are available primarily in parenteral formulations. There are few reports of their use in birds. Presumably, the pharmacology would be similar to first and third generation products.

- ***Third generation agents*** (eg, cefotaxime and ceftriaxone) have an expanded gram-negative spectrum (including increased activity against *Pseudomonas* spp.) and variable activity against gram-positive bacteria. Cefotaxime is unusual among cephalosporins because it penetrates the CSF in effective concentrations. Ceftriaxone has an extended half-life in humans (eight hours versus one hour for most other cephalosporins); however, the half-life is the same as other cephalosporins in Amazon parrots.[23] Doses of 75-100 mg/kg IM given three to six times daily should maintain effective plasma concentrations. These agents are mostly available in parenteral formulations; the use of newer drug preparations that can be given orally has not been reported in birds.

Comments

Recommendations are similar to the penicillins. First generation products have shown good activity against staphylococcus infections of the alimentary tract and skin of birds. The third generation products have an excellent gram-negative spectrum. Cephalosporins have a high therapeutic index, an advantage when treating patients with compromised renal or hepatic function. A major disadvantage of using cephalosporins is the frequency of administration required to maintain effective plasma concentrations.

Aminoglycosides

Pharmacology

The aminoglycoside antibiotics interfere with bacterial protein synthesis and are bactericidal.[42] They are not absorbed from the GI tract and must be administered parenterally. Aminoglycosides are confined to the extracellular space and poorly penetrate the eye and cerebrospinal fluid. Excretion is almost exclusively by glomerular filtration. Aminoglycosides must penetrate the bacterial cell wall to interfere with protein synthesis. This process requires oxygen, so aminoglycosides are not active against anaerobes or at sites with low oxygen tension (eg, large abscesses). Although aminoglycosides are poorly bound to blood proteins, they are extensively bound to intracellular proteins and may be inactivated in proteinaceous environments such as abscesses and exudates.

The aminoglycosides are relatively toxic when compared to other antibiotics. Nephrotoxicity and ototoxicity are relatively common, even in humans where dosage regimens are tailored for individual patients. The nephrotoxicity associated with recommended dosage regimens and short-term treatment is usually reversible once treatment stops. Chronic renal dysfunction occurs when high-dose or prolonged therapy is attempted. Since excretion is dependent on glomerular filtration, aminoglycosides should be used with caution in dehydrated patients. Another side effect, neuromuscular synaptic dysfunction and paralysis, can occur if the drug is given intravenously at a rapid rate.

Use in Companion Avian Medicine

- ***Early Generation Aminoglycosides:*** Streptomycin, dihydrostreptomycin, neomycin and kanamycin have limited spectrum and greater toxicity, and are seldom used systemically in birds. Neomycin is used in topical and ocular formulations and can be administered orally to sterilize the gut.

- ***Gentamicin:*** Gentamicin is effective against many gram-negative and gram-positive bacteria. It is more toxic than amikacin, and signs of nephrotoxicity (eg, polyuria and polydipsia) are often encountered even when birds are treated with low doses. The degree of toxicity varies with individuals and species. For example, toxic reactions were more severe in Rose-breasted Cockatoos than in Scarlet Macaws treated with 5 mg/kg IM BID for seven days (Figure 17.7). The cockatoos remained polyuric for more than 30 days after treatment ended.[24] Based on these studies, gentamicin doses of 2.5-5 mg/kg IM BID should pro-

vide efficacious plasma concentrations and reduce toxicity. Variability in toxicity has also been demonstrated in raptors. Renal toxicity was found in Lanner Falcons treated with 5 mg/kg/day for four days,[18] and doses of 10 mg/kg administered BID for five days in Great Horned Owls produced reactions ranging from no signs to death. Doses similar to those in psittacine birds (2.5 mg/kg IM TID) are recommended for raptors.[4] Previously recommended doses (10 mg/kg IM TID) are excessive and may cause severe toxicity and death.

- ***Tobramycin:*** The pharmacology of tobramycin in mammals is similar to that of gentamicin, but it has greater activity against *Pseudomonas* spp. and some other gram-negative bacteria. Pharmacology studies in birds are lacking, but it is probably similar to gentamicin. In dogs and humans, tobramycin is considered slightly less toxic than gentamicin but more so than amikacin. The estimated dose for tobramycin is 2.5-5 mg/kg IM BID.

- ***Amikacin:*** Amikacin has excellent activity against many gram-negative bacteria, including some strains that are resistant to gentamicin and tobramycin. Amikacin is approximately four times less active than gentamicin but is correspondingly less toxic, so higher doses can be used safely. Amikacin causes fewer toxic side effects and is the aminoglycoside of choice for use in birds.

  Pharmacokinetic studies have been completed in several psittacine species. Doses of 13 and 20 mg/kg IM in healthy Blue-fronted Amazon Parrots produced peak plasma concentrations of 40 and 75 μg/ml respectively that declined to zero by eight hours.[20] When these doses were administered for seven days, mild signs of toxicity (polyuria) occurred but rapidly resolved when treatment ended. Similar single-dose pharmacology was observed in cockatiels, Goffin's Cockatoos,[20] and Orange-winged Amazon Parrots and in African Grey Parrots.[28] Based on these studies, amikacin doses of 10-15 mg/kg IM administered BID or TID should provide effective plasma concentrations for most susceptible gram-negative bacteria. The higher end of the dosage range should be used with more resistant organisms, sites of infection with poor perfusion or in critically ill patients. In dehydrated birds and those with compromised renal function, the dose should be reduced or a less toxic drug selected.

Comments

The aminoglycosides are excellent drugs for treating resistant gram-negative bacterial infections in birds. They are active against *Pseudomonas* spp., especially when combined with a third generation cephalosporin (eg, cefotaxime) or late generation penicillin (eg, piperacillin). However, these two agents must not be combined in the same syringe. Aminoglycosides should be avoided or used with care in dehydrated patients. Amikacin is currently the aminoglycoside of choice for avian use because of its broad spectrum and reduced toxicity compared to other aminoglycosides.

Tetracyclines

Pharmacology

Tetracyclines interfere with bacterial protein synthesis and are bacteriostatic.[43] In mammals, they are effective against a broad spectrum of gram-positive and some gram-negative bacteria. It is difficult to achieve concentrations that are effective for treating bacterial infections in companion and aviary birds, and tetracyclines are primarily used to treat chlamydiosis and mycoplasmosis. Tetracyclines are lipid soluble and are widely distributed to tissue. They are mostly available as oral formulations. Injectable formulations are available for some compounds but cause necrosis at the site of injection. Oral absorption is generally good except in the presence of cations such as calcium or magnesium, which chelate tetracyclines. The route of excretion varies with the compound. Oxytetracycline and chlortetracycline are excreted primarily by hepatic metabolism and renal excretion; minocycline is metabolized by the liver and excreted in the bile; and doxycycline is excreted as an inactive conjugate in the feces. Toxicity varies with the compound used, species of animal and duration of treatment. Tetracyclines will chelate calcium in the teeth and bone. GI upset and photosensitization have been reported. Prolonged treatment may have catabolic and immunosuppressive effects, reduce normal gut flora and render the animal more susceptible to opportunistic infections.

Use in Companion Avian Medicine

- ***Chlortetracycline:*** Diets containing 1% chlortetracycline are recommended for treating psittacine chlamydiosis in the United States.[12] Diets containing 0.5% chlortetracycline have been shown to be effective in Europe. Powdered chlortetracycline can be added to a cooked mash, or medicated pellets are commercially available. The efficacy of these diets

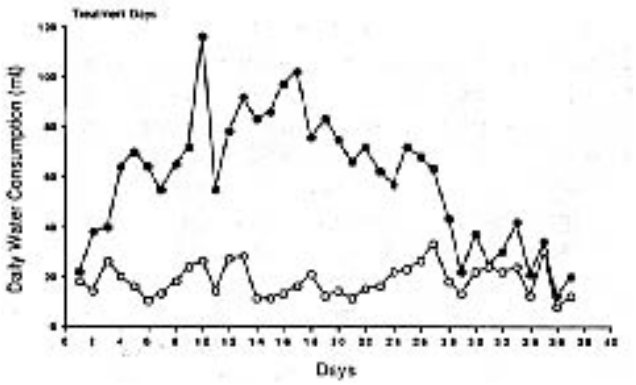

FIG 17.7 Adverse effects of gentamicin in Scarlet Macaws (open circles) and Rose-breasted Cockatoos (Flammer, et al: Am J Vet Res 51[3]:406, reprinted with permission).

will vary with the nutritional composition of the ration. Birds will tend to consume less of a diet with a high-energy content (eg, formulated diets) and more if the energy content is reduced (eg, cooked corn mashes). Although medicated diets may be successful in reducing the clinical signs of chlamydiosis, common sequelae to treatment include diet refusal, starvation, treatment failures and secondary microbial infections.[21]

- ***Oxytetracycline:*** Water-soluble formulations of oxytetracycline are available, but oral absorption is poor. A long-acting injectable formulation[c] is available and may maintain plasma concentrations effective for controlling chlamydiosis in Goffin's Cockatoos for two to three days; however, this drug preparation is irritating and will cause necrosis at the injection site.[22] The single dose kinetics of intramuscular injection has been investigated in pheasants, Great Horned Owls and Amazon parrots.[59] It can be nebulized for treating respiratory infections, but must be dosed every four to six hours.[16]

- ***Minocycline:*** This drug has an extended half-life in mammals. It has been used experimentally to coat millet seeds and treat chlamydiosis in small psittacine birds.[54]

- ***Doxycycline:*** Doxycycline has a prolonged half-life and differs from conventional tetracyclines because it is more lipophilic. The half-life varies with the species. At oral doses of 50 mg/kg, the half-life averages ten hours in cockatiels and Amazon parrots and greater than 20 hours in cockatoos and macaws.[19] This is the drug of choice for treating chlamydiosis, and oral dosage recommendations are: 40-50 mg/kg PO BID in cockatiels and Blue-fronted and Orange-winged Amazons; 25 mg/kg PO BID in African Grey Parrots, Goffin's Cockatoos and Blue and Gold and Green-winged Macaws. In untested species it is impossible to precisely extrapolate dosages; however, 25-30 mg/kg is the recommended starting dose in cockatoos and macaws, and 25-50 mg/kg is recommended in other species.

If regurgitation occurs, the dose should be reduced by 25% or divided and administered BID. Hepatotoxicity, as detected by elevated AST and LDH tests, may occur in macaws. Dosage recommendations for treating chlamydiosis in psittacine birds with injectable doxycycline (Vibravenös formulation only!) is 75-100 mg/kg IM every five to seven days. In macaws, the lower dose and more frequent administration should be administered in the last three weeks of treatment.[29] There have been anecdotal reports of use of pharmacist-compounded injectable doxycycline products; however, kinetic studies are lacking and it is impossible to extrapolate dosage schedules from one formulation to another.

Comments

In companion and aviary birds, tetracyclines are primarily used to treat chlamydiosis and, to a lesser extent, mycoplasmosis and pasteurellosis. Dosage regimens are based on attaining sustained blood concentrations of 1 μg/ml — a concentration thought to inhibit chlamydiosis.[1]

Trimethoprim / Sulfonamide Combinations

Pharmacology

A combination of trimethoprim and a sulfonamide is synergistic, as both drugs interfere with microbial folic acid synthesis.[7] This combination has good efficacy against many gram-positive and gram-negative bacterial pathogens, with the exclusion of *Pseudomonas* spp. Use of these drugs in combination has largely replaced use of either component alone for treatment of systemic bacterial infections. This combination is probably bacteriostatic at the doses used in birds. Oral and parenteral formulations are available and readily absorbed. The sulfa drugs are primarily distributed to the extracellular space, while trimethoprim is more lipophilic and has good tissue penetration. Excretion is primarily renal, and the degree of hepatic metabolism varies with the species. A number of side effects, including rashes, photosensitization, arthritis and hepatic disorders, have been reported in mammals but not in birds.

Use in Companion Avian Medicine

The pharmacology of trimethoprim/sulfonamide combinations has been investigated in poultry,[65] geese[52] and pigeons,[13] but not in psittacine birds. Empirical doses of 16-24 mg/kg trimethoprim/sulfonamide (oral solution) administered BID, and 8 mg/kg IM (40 mg/ml trimethoprim + 200 mg/ml sulfadiazine) BID have been widely used clinically with good success.

Trimethoprim and sulfonamide combinations have few toxic effects, but many birds (especially macaws) suffer GI upset and will regurgitate one to three hours after an oral dose. The incidence of GI upset can be reduced if the drug is added to a small amount of food or if the dose is reduced. Sulfonamides form crystals and damage renal glomeruli in dehydrated birds and those with compromised renal function. The injectable product may cause irritation and necrosis at the site of injection.

Two formulations are available, each combining trimethoprim with a different sulfa drug. There is no clear advantage for either preparation. Trimethoprim/sulfadiazine (veterinary formulation) is available in injectable and oral forms. Trimethoprim/sulfamethoxazole (human formulation) is available in oral suspension.

Comments

Trimethoprim/sulfadiazine is an excellent broad-spectrum bacteriostatic drug. It is often the drug of choice when using the oral route to deliver antibiotics (eg, treating gram-negative infections in nestling birds).

Macrolides and Lincosamides

Pharmacology

The macrolides and lincosamides interfere with bacterial protein synthesis, are bacteriostatic and share similar pharmacology.[6] Their spectrum of action includes gram-positive bacteria, pasteurella, bordetella, some mycoplasma and obligate anaerobic bacteria. Injectable formulations are available but are seldom used in birds due to irritation and necrosis at the site of injection. Oral absorption is good in mammals, but there are few pharmacokinetic studies in birds. All are well distributed to tissues and eliminated primarily by hepatic metabolism. Toxicity is usually limited to gastrointestinal irritation and vomiting.

Use in Companion Avian Medicine

The primary uses for the macrolides are to treat gram-positive infections in finches, suspected or confirmed mycoplasma in psittacine birds and gram-positive or anaerobic osteomyelitis. These drugs are also active against *Campylobacter* spp. and *Clostridia* spp. Clindamycin is the most active of the listed drugs.

- ***Tylosin:*** The pharmacokinetics of intramuscularly administered tylosin has been studied in quail, pigeons, cranes and emus.[38] Peak concentrations of 3-5 μg/ml were achieved, and doses of 15-25 mg/kg TID to QID were recommended, with the cranes receiving the lower dose. Unfortunately, tissue necrosis at the site of injection would preclude a multi-day treatment regimen using the IM formulation at this frequency. Effective pulmonary concentrations were achieved with nebulization of 1 gram tylosin in 50 ml dimethyl sulfoxide (DMSO) for one hour.[39] Treatment of conjunctivitis in cockatiels with a tylosin and water spray has been suggested.[33]

- ***Erythromycin:*** Erythromycin is active against campylobacter and mycoplasma. Dosages have been investigated in pigeons,[44] but it is rarely used in companion and aviary birds. In humans, erythromycin is active against chlamydia, but it is not likely to eliminate this organism in birds at accepted avian dosages. A water-soluble powder has been used to treat mild respiratory infections in psittacine birds at a rate of 500 mg/gallon of water but is of questionable efficacy. A popular over-the-counter product[b] is available for medicating drinking water, but it is doubtful that this product achieves plasma concentrations effective for treating most microbial infections in companion birds.

- ***Clindamycin:*** Clindamycin is the most active of the macrolides mentioned. It is used to treat anaerobic infections and osteomyelitis caused by susceptible gram-positive pathogens. The author treated osteomyelitis in a macaw with a combination of enrofloxacin and clindamycin for seven months without detectable toxic effects.

- ***New Macrolides:*** Research on treating *Chlamydia trachomatis* infection in humans has focused on the use of new macrolide (azalide) antibiotics (ie, azithromycin and clarithromycin). These drugs are well tolerated and have a prolonged tissue half-life. Studies in humans have demonstrated that a single dose of either drug is as effective in eliminating *C. trachomatis* infection as a seven-day course of doxycycline. The

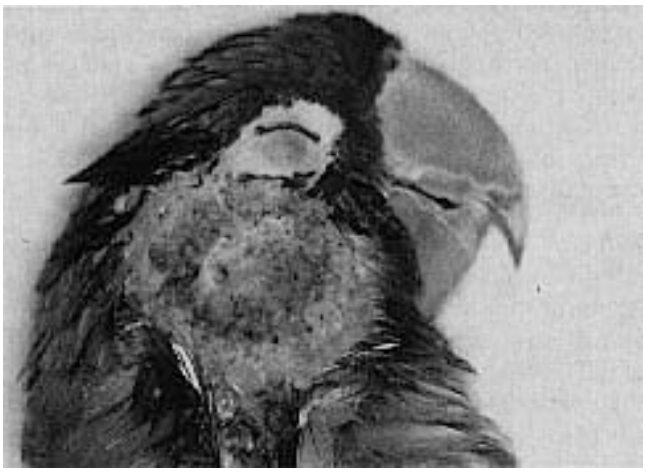

FIG 17.8 Bacterial-induced pruritic dermatitis that was responsive to systemic antibiotic therapy. Many cases of bacterial dermatitis recur when therapy is stopped (photo courtesy of Louise Bauck).

disposition and safety of these drugs in birds remain to be investigated.

- ***Lincomycin:*** Lincomycin is usually combined with spectinomycin and has been used in finches to treat respiratory and alimentary tract infections caused by gram-positive bacteria and mycoplasma in other species.

Chloramphenicol

Pharmacology

Chloramphenicol interferes with bacterial protein synthesis and is bacteriostatic.[58] Its antimicrobial spectrum includes many gram-positive and some gram-negative bacteria. It will inhibit chlamydial growth and alleviate clinical signs in infected birds, but will not routinely clear a bird of infection. Oral and parenteral formulations are available; however, oral absorption is highly erratic. Chloramphenicol is highly lipid-soluble and is widely distributed to most tissues, including the central nervous system. Tissue concentrations often exceed serum levels. The route of excretion varies with different species, but in most cases it is metabolized by the liver.

Potential toxic effects include reversible dose-related bone marrow depression, inhibition of hepatic microsomal enzyme synthesis, inhibition of host protein synthesis resulting in decreased wound healing and decreased immunoglobulin synthesis.[58] In a small percentage of the human population, non-dose-related, irreversible, aplastic anemia may occur, even with mild cutaneous contact. For this reason, clients are instructed to handle this drug carefully and wear gloves when treating birds.

Use in Companion Avian Medicine

- ***Oral Formulation*** (palmitate ester): This formulation is readily accepted by most birds but achieves erratic blood concentrations.[10] It is infrequently used in avian medicine due to the potential toxicity in humans and the availability of more effective oral drugs (eg, trimethoprim/sulfa combinations and enrofloxacin).

- ***Injectable Formulations*** (succinate, propylene glycol-based): These formulations yield more predictable serum concentrations than the oral preparations. The succinate formulation yields lower serum concentrations, but is less irritating to muscle. There is wide pharmacokinetic variation among species. For example, the elimination half-life in budgerigars was longer than in macaws.[10] Doses of 50 mg/kg IM TID are recommended for most psittacine birds.

Comments

Use of chloramphenicol has been largely replaced by other antibiotics that are more effective and can be administered less frequently. Chloramphenicol is still useful for treating infections caused by susceptible intracellular bacteria (eg, salmonella) and where penetration into the central nervous system is desired. Chloramphenicol is bacteriostatic and is probably not the drug of choice for initial treatment of severe, life-threatening infections.

Antifungal Therapy

The most common fungal infections encountered in psittacine birds, raptors and waterfowl are candidiasis (usually confined to the alimentary tract) and aspergillosis (respiratory and cutaneous).[47] Other fungal infections such as cryptococcosis, sporotrichosis, blastomycosis and histoplasmosis are infrequently encountered.

Historically, nystatin, flucytosine and amphotericin B have been widely used in birds. Development of the orally active, broad-spectrum azole antifungals (first

ketoconazole and more recently, fluconazole and itraconazole) may offer similar or greater efficacy, easier administration and lower toxicity. The major drawback to the use of azoles is the lack of pharmacokinetic and toxicologic information to guide dosage selection. However, empirical doses have been established, and use of these drugs is becoming established in avian medicine. As with antibacterial agents, spectrum, ability to reach the site of infection, route of administration and potential toxicity are important considerations when selecting an antifungal agent.

Nystatin

Pharmacology

Nystatin is a polyene antimicrobial that disrupts the fungal cell membrane by substituting for ergosterol.[48] It is effective against most strains of candida and some other yeasts, although clinical evidence suggests resistant yeast strains may occur in some psittacine nurseries.[46] It is not absorbed from the GI tract and is available for oral or topical use only. Nystatin is relatively nontoxic due to the lack of systemic absorption, and is suitable for treating alimentary tract infections caused by candida and other susceptible yeast. It must come in direct contact with the yeast to be effective. Treatment failures may occur if the nystatin is delivered via a tube or syringe to the back of the oral pharynx, bypassing more rostral sites of infection in the mouth.

Use in Companion Avian Medicine

Nystatin is a highly useful drug for yeast infections that are confined to the alimentary tract. It has low toxicity and is safe for use in nestling birds. Some birds suffer GI upset and may regurgitate following repeated or large doses. With oral infections, nystatin or a more potent topical drug (eg, amphotericin B cream) can be applied directly to the lesions. If resistance or a non-alimentary tract infection is encountered, a systemically active antifungal should be used.

Nystatin dosage recommendations have been empirically derived but are supported by effective, long-term clinical use. Individual birds can be treated with 300,000 IU/kg orally BID or TID for five to ten days. Nystatin can also be added to hand-feeding formulas for prophylactic treatment in nurseries experiencing chronic yeast problems. If the yeast is highly susceptible to nystatin, food-based administration will be effective. A nystatin feed premix[d] has been used to medicate a mash diet to treat flocks.

Amphotericin B

Pharmacology

Amphotericin B is a polyene antimicrobial drug that disrupts the fungal cell membrane by substituting for ergosterol.[3] It is active against most of the yeast and fungi of medical importance. Resistance by some strains of *Aspergillus* spp. has been reported in man and other animals. Comparison studies in humans have shown that amphotericin B is still one of the most efficacious antifungal drugs, especially for chronic infections and infections in immunocompromised hosts. Clinical data demonstrating improved efficacy when amphotericin B is combined with flucytosine or an azole antifungal are conflicting, but combination therapy is a common practice for treating serious fungal infections in humans. Amphotericin B is not well absorbed after oral administration and is too irritating for intramuscular or subcutaneous injection; thus, it must be delivered intravenously or used topically. It is widely distributed to tissue and extracellular spaces where it is metabolized and slowly excreted in the urine. Amphotericin B is highly nephrotoxic in mammals, although this can be reduced by instituting a step-wise dosing scheme based on renal function calculated from creatinine clearance levels.

Use in Companion Avian Medicine

Amphotericin B is one of the drugs of choice for initially treating serious, systemic fungal infections. Major disadvantages are potential toxicity and the need for IV administration. It has been used in combination with flucytosine in raptors and swans with fair results.[48] A new, orally active azole, itraconazole, may offer similar activity or may potentiate the effects of amphotericin B.

Amphotericin B can be nebulized or injected into an affected air sac for respiratory infections. It can also be injected through the glottis or administered transtracheally to treat tracheal and syringeal aspergillosis. A topical cream in a plasticized base is available for treatment of topical lesions and oral candidiasis.

The pharmacokinetics of amphotericin B in turkeys and selected raptors indicate that these birds eliminate the drug much more rapidly than mammals.[52] Based on these findings and clinical experience, doses of 1.5 mg/kg IV BID are recommended. Pharmacokinetic data in psittacine birds is lacking. Long-term use in raptors was not associated with nephrotoxicity, so the drug may be safer in avian than mammalian species.[49] However, until more informa-

tion on avian use is available, patients receiving this drug should be monitored for signs of nephrotoxicity (polyuria and uricemia).

Flucytosine

Pharmacology

Flucytosine is converted by the liver to 5-fluorouracil, and exerts its antifungal effect by inhibiting DNA synthesis.[34] It is always used in combination with amphotericin B in humans, and this combination is considered useful for treating candida and cryptococcus infections. Resistance develops quickly when the drug is used alone. It is well absorbed orally, shows little protein binding and is widely distributed to tissues that are difficult to penetrate such as the CSF, eye and joints. This drug is excreted almost entirely unmetabolized in the urine, and dosage modifications are necessary in patients with reduced renal function. Dose-related, reversible bone marrow depression is the major toxic change seen in humans, presumably due to the conversion of flucytosine into 5-fluorouracil by GI tract bacteria. Hepatotoxicity and GI toxicity are occasionally reported in mammals.

Use in Companion Avian Medicine

Flucytosine has been used singly as a prophylactic treatment to prevent aspergillosis in highly susceptible avian species undergoing stress (eg, hospitalization of swans) and in combination with other drugs to treat respiratory aspergillosis. *In vitro* susceptibility of eleven strains of *Aspergillus fumigatus* indicated that flucytosine doses of 20-30 mg/kg QID would maintain inhibitory plasma concentrations.[49] Because reported *in vitro* susceptibility data varies greatly, a combination of flucytosine, amphotericin B and rifampin has been suggested for treating respiratory aspergillosis in raptors.[48] Clinically, doses of 50 mg/kg orally BID for two to four weeks appears to prevent aspergillosis when prophylactically administered to swans (Degernes L, unpublished). Flucytosine has been safe for long-term use (two to four weeks) in raptors and waterfowl.[49] Rosskopf, et al. reported successful treatment of esophageal and subcutaneous aspergillosis in a cockatoo using a combination of flucytosine (65 mg/kg orally BID) and ketoconazole (20 mg/kg orally BID) for approximately one month.[53]

Recently available azole compounds may replace flucytosine with drugs that are safer and more effective.

Ketoconazole

A major breakthrough in antifungal therapy occurred in 1979 with the release of the azole drug ketoconazole, the first orally active, systemic antifungal with a broad spectrum. Further research resulted in release of fluconazole in 1990 and itraconazole in 1992. All three of these drugs are labeled for human use only. Older azole antifungals, miconazole and clotrimazole, are suitable for intravenous and topical use only and are more toxic than more recently available drugs.

The use of the azole antifungals in veterinary medicine has been reviewed.[30] They inhibit synthesis of the primary fungal sterol, ergosterol, which is important in fungal cell membrane integrity. This is accomplished by inhibition of a P_{450} enzyme system, and the relative potency of the azoles is determined by their affinity for this P_{450} enzyme moiety. Vertebrates also have a P_{450} enzyme system, and the selective toxicity of the azoles depends on their relative specificity for binding fungal P_{450} enzymes. Potential toxic effects of interfering with vertebrate P_{450} enzymes include decreased synthesis of cholesterol, cortisol and reproductive steroid hormones. Ketoconazole has the least affinity and specificity and is therefore considered less active and potentially more toxic than fluconazole and itraconazole; however, it is still a highly useful drug. All three azoles are fungistatic and several days of therapy are needed to achieve steady-state concentrations.

Pharmacology

Ketoconazole is effective against many of the yeast and fungi of medical importance, but *Aspergillus* spp. are often resistant.[45] It is readily absorbed in an acid environment such as exists in the stomach following a meal. It is widely distributed to tissues but is highly protein-bound and does not significantly penetrate into the cerebrospinal or ocular fluids. It is eliminated via hepatic metabolism, and significant interactions occur with drugs that inhibit or induce hepatic enzyme metabolism (eg, rifampin and barbiturates). Ketoconazole is considered more toxic than either itraconazole or fluconazole. Reports of toxicity are rare in birds, but anorexia, vomiting, jaundice and elevated liver enzymes have been reported in other animals. Long-term use in dogs has resulted in decreased cortisol levels and decreased testosterone synthesis.

Ketoconazole is available in 200 mg tablets. Crushed tablets can be compounded with 0.15% methylcellu-

lose into an oral suspension that is stable for six months if refrigerated. Ketoconazole is water insoluble unless in an acid environment. Medicated water is therefore of questionable benefit except for infections caused by highly susceptible yeast that are limited to the GI tract.

Use in Companion Avian Medicine

Ketoconazole is currently the most widely used, least expensive, orally available and systemically active antifungal. It is useful for treating resistant yeast infections and yeast infections where systemic drug delivery is required. It is not usually effective against aspergillosis alone, but may have a synergistic effect when combined with other antifungals.

Limited pharmacokinetic studies have been performed in pigeons and cockatoos.[35] Following oral administration at 30 mg/kg, peak concentrations were achieved in 0.5 to 4 hours and the elimination half-life was 2 to 3.8 hours in pigeons and 3.8 hours in Moluccan Cockatoos. No significant toxic reactions were seen in pigeons given 30 mg/kg orally BID for 30 days or Amazon parrots treated with 30 mg/kg BID for 14 days. Because absorption is increased in an acid environment, ketoconazole should be administered with food. It is not necessary to pre-dissolve the drug in acid.

Tracheal aspergillosis in an Amazon parrot was treated using ketoconazole (approximately 25 mg/kg orally BID for 14 days) and intratracheal amphotericin B (50-75 mg/kg SID for seven days).[53]

Itraconazole

Pharmacology

Itraconazole is a triazole that was recently licensed for use in humans in the United States.[30] It is similar to ketoconazole but has 5 to 100 times greater potency, better *in vitro* and *in vivo* activity against aspergillus infections and meningeal cryptococcoses, and fewer side effects. It is insoluble in water, highly lipophilic and is well absorbed if taken with a meal. It is highly protein-bound and widely distributed to tissues. Tissue concentrations (especially fat, liver, adrenal cortex and skin) are substantially greater than plasma concentrations, and therapeutic concentrations are maintained longer in tissue than in plasma. The volume of distribution greatly exceeds body water (11-17 l/kg). It is poorly distributed to CSF, ocular fluids and plasma. It is degraded by hepatic metabolism, and the primary route of elimination is via the bile. Elimination half-life in man is longer than for ketoconazole (17 to 25 hours versus 8 hours), and steady-state concentrations are achieved in approximately six days. Itraconazole is considered safe for long-term treatment in humans at a dose of approximately 4-6 mg/kg/day, and dogs receiving up to 40 mg/kg/day for three months did not show signs of toxicity.[60] Maternal toxicity, embryo toxicity and teratogenicity were absent in mice treated with 10 mg/kg/day, but did occur when the dose was increased to 40 and 160 mg/kg; use in pregnant animals is not recommended.[61]

In man, itraconazole has shown promising results for treating aspergillosis; however, there are conflicting reports when efficacy is compared to other drugs (primarily amphotericin B and flucytosine). Even with prolonged treatment (eg, several months), relapses and treatment failures are common. If reports in the literature are any indication, itraconazole alone or in combination with amphotericin B appears to be the treatment of choice for aspergillosis in humans.

There is limited data on the use of itraconazole in animals. It was as effective as ketoconazole when used for three months in cats with cryptococcosis, but less toxic.[44] Variable success has been seen with itraconazole used to treat superficial dermatophyte infections and systemic blastomycosis.[5] It was unsuccessful as a sole treatment in resolving four cases of canine nasal aspergillosis; better success was achieved in another study when itraconazole was combined with topical enilconazole infusion.[64]

Use in Companion Avian Medicine

Reports of itraconazole use in birds are limited, but it has been used to treat aspergillus and candida infections in macaws and penguins.[31] A severe *Candida krusei* tracheitis was resolved in a Blue and Gold Macaw that received itraconazole at 10 mg/kg/day for 35 days. Presumed ocular aspergillosis in a King Penguin was successfully resolved after treatment with 8 mg/kg/day for 29 days. Two penguins with candida infections of the uropygial gland were successfully treated with 10 mg/kg/day for 20 days. A Gentoo Penguin with a pulmonary aspergilloma showed marked improvement and reduction in the size of the aspergilloma after receiving itraconazole at 8.3 mg/kg for 30 days and 17 mg/kg for an additional 19 days. However, the bird died from cerebral aspergillosis three weeks after therapy ended. In man, pulmonary aspergillosis is treated for six to nine months, so the treatment failure in this case may have been due to the short duration of therapy.

Fluconazole

Pharmacology

Fluconazole is a synthetic bistriazole that became available in the United States in 1990.[30] *In vitro* potencies are up to 100 times greater than ketoconazole. Most yeast and fungi of medical importance are susceptible to fluconazole *in vitro*. *In vivo*, it has excellent activity against yeast and variable activity against aspergillus. In contrast to ketoconazole and itraconazole, fluconazole is highly water soluble and is readily absorbed from the GI tract regardless of acidity or food intake. It is not highly protein-bound and penetrates the CSF, brain tissue, ocular fluids and sputum; the volume of distribution is similar to body water (0.7 l/kg). It is eliminated primarily by the kidney, and the prolonged serum half-life of 4 to 5 hours in rats and mice, 14 hours in dogs, and 22-30 hours in humans is presumably due to tubular reabsorption. The dose should be modified if renal function is impaired. Fluconazole alters the kinetics of drugs that undergo hepatic metabolism, but not to the degree described with ketoconazole. The manufacturer recommends giving a double loading dose during the first 24 hours, because five to seven days are needed to achieve steady-state concentrations in man. Fluconazole is well tolerated in humans, although mild GI, CNS and skin reactions are occasionally reported. Hematologic abnormalities are rare. Doses of 30 mg/kg/day in dogs caused increased hepatic fat and hepatic weight.

Clinical studies in humans are still investigating the efficacy of fluconazole *in vivo*. It has been highly successful for treating tissue candida and coccidiomycosis infection and variably successful for treating pulmonary aspergillosis. It is probably the drug of choice in situations where penetration into the CSF is desirable.

Clinical studies in animals with fluconazole are even more limited. Six of ten dogs with nasal aspergillosis were successfully treated with 2.5-5 mg/kg/day orally for eight weeks.[56] Fluconazole was considered effective treatment in animal models for blastomyces, cryptococcus, candida, coccidioides and histoplasma infection. As with clinical trials in humans , fluconazole was variably effective against aspergillosis.[30]

Use in Companion Avian Medicine

Juvenile psittacine birds treated with fluconazole were found to be fecal negative for yeast as determined by Gram's stain; clearance of yeast required 48 hours.[2] Based on this limited study, dosage recommendations of 2-5 mg/kg/day were suggested. Transient regurgitation, increased AST and LDH levels were observed in some birds. Further studies are needed to establish the safety and efficacy of fluconazole in birds.

Enilconazole

Pharmacology

Enilconazole is an imidazole antifungal agent with a broad spectrum. It is not approved for use in the United States. It is poorly soluble and its use is limited to topical application and inhalation. Inhalation of burned enilconazole has been used to treat aspergillosis in poultry.[50] It has also been infused into the nasal passages and sinuses to treat canine nasal aspergillosis.[57] Reports of use in companion and aviary birds are lacking.

Summary of Antifungal Treatment

Spectrum, ability to reach the site of infection, route of administration and potential toxicity are important considerations when selecting an antifungal agent. Spectrum is difficult to determine for antifungal drugs because the methods for *in vitro* testing are expensive, are poorly standardized and there is often little correlation between *in vitro* and *in vivo* efficacy. This makes drug selection somewhat empirical, but some generalities can be made. Most candida are susceptible to nystatin, and almost all yeast of medical importance are susceptible to ketoconazole, itraconazole, fluconazole and amphotericin B. In human and animal studies, itraconazole and fluconazole are more active than ketoconazole, with itraconazole showing greater activity against aspergillosis, and fluconazole showing greater activity against yeast infections. A combination of amphotericin B and flucytosine or an azole, or an azole and flucytosine may provide better efficacy than either drug alone.

The ability of the drug to reach the site of infection is also important. Nystatin is not absorbed from the alimentary tract and must come in contact with the yeast. Systemic infections by hypheal fungi (eg, aspergillus) usually cause a granulomatous response that inhibits drug penetration to the site of infection. Ketoconazole and itraconazole are highly protein-bound and develop high tissue concentrations, but are found in low concentrations in the CSF and ocular fluids. In contrast, fluconazole is water-soluble, minimally protein-bound, and able to treat the CNS, eye and sputum. In general, fungal infections require

TABLE 17.2 Susceptibility of Common Avian Infectious Agents to Antimicrobial Therapy

longer treatment periods than bacterial infections. Sometimes many months of therapy are needed to control aspergillosis.

Finally, the route of administration and potential toxicity are important considerations. All of the antifungal drugs mentioned are delivered orally with the exception of amphotericin B, which must be administered IV. Nystatin is virtually nontoxic. Ketoconazole has greater potential toxicity than either itraconazole or fluconazole, especially if long-duration and high-dose therapy are used. Drug interactions should also be considered. Ketoconazole and fluconazole may significantly alter the hepatic metabolism of drugs such as barbiturates and rifampin.

Nystatin is the drug of choice for uncomplicated yeast infections of the alimentary tract. It is inexpensive and virtually nontoxic. Resistant or severe yeast infections can be treated with ketoconazole or fluconazole. Ketoconazole is less expensive but potentially more toxic; few side effects have been observed when used for fewer than two to three weeks. Systemic yeast infections can be treated with either ketoconazole, fluconazole or itraconazole, depending on the site of infection.

Drug selection for treatment of aspergillosis infections is more problematic. Cutaneous aspergillosis is probably best treated with fluconazole or itraconazole (ketoconazole might be effective in limited cases). Topical administration of enilconazole or miconazole may also be effective. Severe pulmonary or disseminated aspergillosis carries a poor prognosis for recovery regardless of the treatment program. Amphotericin B is the primary drug of choice for chronic infections and infections in immunocompromised patients because it rapidly develops fungicidal concentrations. Prior to the availability of the new azole antifungals, a combination therapy with amphotericin B, flucytosine and rifampin was recommended. Based on human clinical studies, it is probably more effective to use amphotericin B in combination with itraconazole for initial treatment, and then continue long-term treatment for months with itraconazole alone. Flucytosine also has substantial anti-aspergillus activity and may be preferable if there is CNS involvement. Intratracheal ad-

ministration of amphotericin B is very useful when treating syringeal or tracheal infections. Systemic infections caused by other fungi (eg, mucormycosis and cryptococcosis) can be treated in the same manner as systemic aspergillosis.

Antifungal drug research is currently an active field, spurred by the increasing numbers of opportunistic fungal infections in immunocompromised human HIV patients. New drugs may soon be available.

CHAPTER

18

FORMULARY

Branson W. Ritchie
Greg J. Harrison

This chapter provides an overview of the unique characteristics of various drugs used in avian species. All suggested drug uses are for companion (non-food) birds only. Complete reviews of all the drugs discussed in this book are available through a variety of desk references and product information forms provided by the manufacturers. The clinician is referred to these references for a review of the general pharmacology and specific contraindications of any drug discussed. The suggestions of the manufacturer should always be followed. A drug should never be used for which the clinician is not fully aware of the indications, contraindications and potential side effects. Some drugs administered concurrently will potentiate toxicity, and the clinician should review any potential drug interactions before placing a bird on more than one drug at a time.

In this chapter, commonly used drugs and their associated doses are provided in table form for easy reference. The information concerning the use of the drugs listed in the table should be reviewed before administering any therapeutic agent. If a drug is not discussed, either insufficient data is available to warrant its use in birds, or it has been used but has little applicability.

The doses and material presented for each drug have been compiled from numerous reference sources, including the various chapters in this book. Some of the recommended doses are based on pharmacokinetic information, and some are based totally on observation. An asterisk in the formulary table indicates that the suggested dose is based on pharmacologic data obtained in some species of birds other than poultry. Notes on any adverse drug reactions should be forwarded to the *Journal of the Association of Avian Veterinarians* to keep colleagues informed of any problems that occur with commonly used therapeutic agents. Representative manufacturers listed in the formulary are for reference purposes only. Other manufacturers may produce similar products of equal efficacy.

ACETYLCYSTEINE - Mucomyst (Apothecon)
Neonates treated with nebulized Mucomyst developed dyspnea, lethargy, edema of the eyelids and tachycardia 20 minutes after therapy.

ACETYLSALICYLIC ACID - Aspirin (Butler; Vedco)
Available as tablets (5 or 60 grain) for oral administration. Also available as 1.25 grain orange-flavored chewable tablets. May be effective as an analgesic, antipyretic and anti-inflammatory agent in some avian species. May be indicated to prevent clot formation and embolisms secondary to egg-related peritonitis, granulomatous diseases and shock. Uricosuric at low doses and may be effective in some cases of acute and chronic gout. A five grain tablet can be mixed in 30 ml of diluent and administered at a dose of 0.5 ml/kg, TID (or 1 tablet per pint of drinking water).

(ACTH) ADRENAL CORTICOTROPIC HORMONE - (Vedco; Phoenix; Butler)
Available as an injectable solution (40 or 80 units/ml) for IM administration. Used to test stimulation of the adrenal glands in suspected cases of adrenal insufficiency. Glucocorticoid administration may falsely elevate endogenous cortisol levels. Prolonged administration induces adrenal gland hyperplasia.

ACTIVATED CHARCOAL, KAOLIN - Toxiban (Vet-A-Mix)
Available as a suspension (104 mg/ml activated charcoal and 62.5 mg/ml kaolin) for oral administration. Can be used to absorb some ingested toxins (many insecticides, pesticides, lead, mercury, inorganic arsenic and chemotherapeutic agents) from the gastrointestinal tract. High therapeutic index. Can be mixed with sodium sulfate in cases of heavy metal ingestion to form lead complexes that are not absorbed. Sodium sulfate can cause osmotic diarrhea and should be used with extreme caution in birds that weigh less than one kg. Can be mixed with hemicellulose to function as a bulk laxative and aid in the passage of ingested toxins.

ACYCLOVIR - Zovirax (Burroughs Wellcome)
Available as a soluble powder (50 mg/ml when reconstituted) for IV administration and as a capsule (200 mg), tablet (200 mg) or suspension (40 mg/ml) for oral administration. Has been shown to be effective in decreasing mortality associated with flock outbreaks of Pacheco's disease virus. Appears to be most effective if treatment is initiated in an individual bird before clinical signs occur.

Acyclovir is preferentially absorbed by herpesvirus-infected cells and primarily inhibits herpesvirus DNA polymerase. Acyclovir is effective in preventing herpesvirus replication in only those strains of herpesvirus that code for their own DNA polymerase. Acyclovir also has varying effects on different strains of susceptible herpesviruses. Low level of effect on uninfected host cells results in a high therapeutic index. It has been suggested for treatment of poxvirus, but there is no conclusive evidence to support its efficacy.

The injectable product may cause severe muscle necrosis if administered IM and may cause phlebitis (common) and neurologic signs (rare) when administered IV. Oral administration may cause vomiting. Acyclovir has been shown to interfere with spermatogenesis and is mutagenic when administered at high doses in some mammals.

ALCOHOL
An excellent solvent for many drugs as well as a popular skin disinfectant. Bactericidal for most common pathogenic bacteria with variable activity for viruses and fungi. Will cause a dramatic decrease in core body temperature when applied to large areas of the skin as a presurgical dressing. Consumption of alcoholic beverages or absorption of ethanol through open wounds can result in lethargy, incoordination and regurgitation in most avian species.

ALLOPURINOL - Zyloprim (Burroughs Wellcome)
Available as a tablet (100 or 300 mg) for oral administration. Used for the treatment of gout. Well absorbed from the gastrointestinal tract. Functions to inhibit purine catabolism, which prevents the production of uric acid. A 100 mg tablet can be crushed and dissolved in 10 ml of sterile water. Up to 1 ml of the diluted suspension may be added to 30 ml of drinking water. A fresh solution of drinking water should be provided several times per day. A reduction in serum and urinary uric acid levels should be noted within two to three days of administration.

Birds being treated with allopurinol should be thoroughly hydrated at all times. It has been found to *cause* gout in Red-tailed Hawks, and may cause a skin rash, urticarial lesions or hepatitis. In birds with severe gout, the initial dose should be 25% of the recommended dose, with a gradual increase over several days. Should be used in conjunction with colchicine in severe cases of gout.

ALOE VERA - George's Aloe Vera (Warren Laboratories)
Available as a lotion or for topical application on pruritic lesions or as a liquid for oral administration. Solution for treating pruritic skin lesions is made by mixing 0.5 oz of aloe vera oral liquid with 1 tsp of Penetran, 2 drops of Woolite and 1 pint of water.

AMIKACIN SULFATE - Amiglyde (Aveco); Amikin (Bristol Labs)
Available as injectable solutions (50 mg/ml and 250 mg/ml) for IM or SC administration. Limited activity against gram-positive organisms. Should be used only in birds when absolutely necessary to treat gram-negative bacteria (*Pseudomonas, Klebsiella* spp.) that are resistant to other, less toxic antibiotics. Very effective when used in combination with synthetic penicillins.

Birds should be thoroughly hydrated throughout the treatment period to decrease the possibility of nephrotoxicity. Use in conjunction with furosemide may potentiate renal damage. Toxic effects of aminoglycosides may be potentiated when used in combination with cephalosporins (see Chapter 17).

AMINOPENTAMIDE HYDROGEN SULFATE - Centrine (Aveco)
Available as an injectable solution 0.5 mg/ml for SC or IM administration for controlling vomition.

AMINOLOID - (Essex; Schering Corporation)
Has been used to induce molt in raptors. Should induce complete molt within 2 months of administration.

AMITRIPTYLINE HCL - Elavil (Stuart); Endep (Roche)
Available as a tablet (10, 25, 50, 75, 100, 150 mg) for oral administration or as an injectable solution (10 mg/ml) for IM administration. Tricyclic antidepressant with a sedative effect that has been suggested for use in some cases of feather picking. Appears to be rarely effective. Should not be used in conjunction with monoamine oxidase inhibitors. May cause depression, arrhythmias, tachycardia, vomiting or muscle rigidity.

AMMONIUM SOLUTION - Penetran (Trans Dermal Technologies)
Available as an ointment for topical application. Used as a topical analgesic or antipuritic (see Aloe Vera).

AMOXICILLIN - Amoxi-drops, Amoxi-Inject (SmithKline)
Available as a suspension (50 mg/ml, Amoxi-drops) for oral administration or as an injectable solution (250 mg/ml, Amoxi-Inject) for IM administration. Palatable and easy to administer but rarely effective against the bacterial organisms that affect birds. Absorbed from the gut more effectively than ampicillin, resulting in higher blood levels than are achieved with oral ampicillin. Injectable solution stable one year after reconstitution if refrigerated. Oral suspension stable for 14 days if refrigerated (see Chapter 17).

AMPHOTERICIN B - Fungizone (Squibb)
Available as an injectable solution (5 mg/ml) for slow (over several hours) IV administration. Functions by binding to sterols in the membrane of fungi, causing alterations in permeability. Rapid administration may cause arrhythmias and death. Can also be given intratracheally. Has been suggested to be effective if administered SC, but efficacy is unknown. Can be nebulized in conjunction with systemic flucytosine or ketoconazole therapy for fungal infections in the upper respiratory tract. Intratracheal or intra-air sac administration does not result in systemic absorption and is effective only against aspergillosis localized to the site of infection. May be effective in treating megabacteria. A lotion or cream (3%) is available that can be used for fungal dermatitis and for oral candidiasis that is resistant to nystatin.

May cause renal damage and bone marrow suppression. May potentiate toxic effects of flucytosine when used in combination. Depression, vomiting and irritation at the injection site are common side effects. Amphotericin B injected into the sinuses of an African Grey Parrot caused a severe granulomatous sinusitis and death. If used in combination with imidazoles may result in fungi that are resistant to amphotericin B. Stable one week after reconstitution if refrigerated. Stable only 24 hours at room temperature. Can be mixed, divided into small aliquots and frozen (see Chapter 17).

AMPICILLIN - Polyflex (Fort Dodge)
Available as an injectable suspension (100 mg/ml) for subcutaneous or IM administration. This drug has minimum activity for the common gram-negative bacteria that infect birds. IM administration for treatment of "cat bite" injuries in which pasteurella septicemia is common. Ampicillin administered orally is poorly absorbed and the drug that is absorbed is rapidly excreted by the kidneys. Oral administration is limited to highly sensitive pathogens restricted to the gastrointestinal tract. May be effective in treating salmonella arthritis in gallinaceous birds. May be effective against some L-form bacteria when used in conjunction with erythromycin (see Chapter 17).

AMPROLIUM - Corid (MSD-Agvet)
Available as a solution (9.6% - 96 mg/ml) for oral administration. Structurally related to thiamine and competitively inhibits thiamine utilization by some parasites. May be effective against some strains of coccidia. The strains that infect mynahs and toucans appear to be particularly resistant. Resistances may develop following repeated use in an aviary. Not as effective in Galliformes and cranes as monensin. Must be used in conjunction with thorough aviary cleaning to prevent reinfection following treatment.

ASCORBIC ACID - Vitamin C (Phoenix; Vedco)
Available as an injectable solution (250 mg/ml) for IM administration. May be beneficial support for avian patients with infectious or debilitating metabolic diseases.

ATROPINE - (Butler; Vedco; Phoenix)
Available as an injectable solution (0.5 mg/ml or 15 mg/ml) for IM or SC administration. More concentrated solution used as a treatment for organophosphate poisoning. Used with caution in birds as a preanesthetic. May thicken secretions in the trachea resulting in blockage of the endotracheal tube. Does not cause pupil dilation as occurs in mammals. Inappropriate or excessive use can result in cardiac arrhythmias and gastrointestinal stasis.

AVIPRO - (Vetark Animal Health)
Mixture of bacteria, enzymes, electrolytes and vitamins that may be an effective adjunct therapy in debilitated birds.

AZITHROMYCIN - Zythromax (Pfizer)
Available as capsules (250 or 500 mg) for oral administration. Used for the treatment of chlamydiosis. Should be administered on an empty stomach. A 250 mg capsule is mixed with 0.25 oz of lactulose and dosed at one drop per gram of body weight BID for 14 days.

BISMUTH SUBSALICYLATE - Pepto-Bismol (Procter and Gamble)
Available as a suspension (1.75% subsalicylate) for oral administration. Indicated for gastrointestinal irritation, ulcers or to aid in the removal of some ingested toxins.

BOTULISM ANTI-TOXIN - (Schering Plough Animal Health; United Vaccine Inc.)
Clostridium botulinum Type C for use in mink. Dose at one-half the mink dose.

BUTORPHANOL TARTRATE - Stadol (Bristol Labs)
Available as an injectable solution — Torbutrol (10 mg/ml) IV; or as tablets — Torbugesic (1, 5 or 10 mg) PO. Synthetic opiate that is used for its antitussive effects and to control abdominal pain. May be helpful in suppressing a non-productive cough and for post-surgical pain. May cause vomiting at 10 mg/kg in some species. Should be used with caution in patients with liver disease.

CALCIUM - (Vedco; Phoenix; Butler)
Available as a solution (23 mg/ml - Vedco, Phoenix) for oral administration; as an injectable solution (5 mg Ca glycerophosphate and 5 mg Ca lactate/ml - Butler) for IM, SC or IV administration and as a powder for oral administration. Oral administration is recommended for long-term therapy of calcium deficiencies and for supplementation during bone healing, bone development and egg laying. Parenteral administration is recommended for the treatment of hypocalcemia, hypocalcemic tetany, egg binding and soft-shelled eggs. Oral calcium will chelate some tetracycline preparations. Toucans being treated with tetracyclines should receive parenteral calcium supplementation to prevent bone deformities. Supplemental calcium may help prevent hypocalcemia in some African Grey Parrots.

CALCIUM DISODIUM VERSENATE - Calcium EDTA (3M Pharm.)
Available as an injectable solution (200 mg/ml) for IM administration. Used to chelate circulating lead or zinc. Can be used orally to prevent lead or zinc from being absorbed from the gastrointestinal tract. Long-term treatment (over two weeks) can result in unacceptable chelation of normal cations from the blood. May cause renal tubular necrosis and its use should be discontinued if polyuria and polydipsia occur. May cause muscle necrosis when administered IM.

CAPRILLIC ACID - Kaprycidin A (Ecological Formulas)
Available as a capsule containing 325 mg of calcium, magnesium and zinc carprylates for oral administration. May be effective as an adjunct therapy with imidazole antifungals for the treatment of aspergillosis.

CARBARYL - Sevin (Southern Agricultural Insecticides)
Available as a 5% powder. Used to lightly dust birds for treatment of some ectoparasites. May be added to the nest litter to control mites and ants (one tsp is effective for a small nest box; two tsp may be needed for a larger box). Should be used in conjunction with thoroughly cleaning the box. Should be used only when necessary. May be helpful in reducing ant infestations in the aviary.

CARNIDAZOLE - Spartrix (Wildlife Laboratories)
Available as a tablet (10 mg) for oral administration. Single dose treatment for trichomoniasis, hexamitiasis and histomonas in pigeons. High therapeutic index in pigeons. Birds did not develop

any signs of toxicity even when treated with 640 mg/kg (32 times the therapeutic dose).

CEFOTAXIME - Claforan (Hoescht-Roussel)
Available as an injectable solution (10 to 300 mg/ml depending on reconstitution) for IM or IV administration. The less concentrated solution should be used for slow IV administration. Broad-spectrum activity for many gram-negative and gram-positive avian pathogens. Penetrates CSF. Reconstituted solution is stable for ten days refrigerated or six months frozen. Cannot be thawed and refrozen (see Chapter 17).

CEFOXITIN - Mefoxitin (Merck)
Available as an injectable solution (10 to 400 mg/ml depending on reconstitution) for IM or IV administration. The less concentrated solution should be used for slow IV administration. Reconstituted solution is stable for ten days refrigerated or six months frozen. Cannot be thawed and refrozen (see Chapter 17).

CEFTRIAXONE - Rocephin (Roche)
Available as an injectable solution (10 to 250 mg/ml depending on reconstitution) for IM or IV administration. The less concentrated solution should be used for slow IV administration. Reconstituted solution is stable for ten days refrigerated or six months frozen. Cannot be thawed and refrozen (see Chapter 17).

CEPHALEXIN - Keflex Pediatric Suspension (Dista)
Available as an oral suspension (25-100 mg/ml). Varied efficacy for many gram-negative bacteria. Frequent dosing makes treatment in all but hand-feeding neonates impractical. Reconstituted suspension stable for 14 days if refrigerated. May be effective in cases of staphylococcus dermatitis where long-term therapy is necessary (see Chapter 17).

CEPHALOTHIN - Keflin (Lilly)
Available as an injectable solution (100 mg/ml) for IV or IM (painful) administration. This drug is not absorbed from the gastrointestinal tract (see Chapter 17).

CEPHRADINE - Veloself (Squibb)
Available as a suspension (25 or 50 mg/ml) for oral administration. Similar in activity and spectrum to cephalexin.

CHLORAMPHENICOL - (Parke-Davis; Fort Dodge)
Available as injectable solution (100 mg/ml, succinate) for IV administration or as a suspension (30 mg/ml - chloramphenicol palmitate) for oral administration. May cause bone marrow suppression in humans, and clients should be warned to avoid skin contact. A dose of 1000 mg/kg may cause death in most avian species. Should be used with extreme caution in patients with renal or liver disease. Rapidly excreted by pigeons, necessitating a dosing frequency that makes therapy impractical.

Chloramphenicol succinate administered IV is excreted rapidly by the liver. May be useful in suppressing bacterial replication in cases of severe bacterial septicemia.

Chloramphenicol palmitate is erratically absorbed from the gastrointestinal tract. This drug should not be used in critical cases of bacterial septicemia. Usually well accepted by hand-feeding birds. May be useful in some cases of enteritis in young birds. If gastrointestinal stasis has occurred, a parenteral antibiotic should be chosen. Suspension or powder from capsules can be used to lace favorite foods or to mix into a mash for flock treatment of some highly susceptible bacteria. Particularly effective in the flock treatment of salmonella. Has been associated with temporary infertility in male pigeons. Must be used with caution. Chloramphenicol has been associated with contact dermatitis and pernicious anemia in some people (see Chapter 17).

CHLORHEXIDINE - Nolvasan (Fort Dodge; Bio-Ceutic)
Available as a disinfectant solution (2% = 20 mg/ml). Off label use for oral or topical administration. Also available as an ointment or cream for topical administration. Commonly used to clean skin wounds and as a surgical scrub. May be used to prevent further cases of candidiasis in a flock while hygiene problems that caused the outbreak are corrected. Is not absorbed from the gut. May be effective in reducing the spread of some enteric viruses. The scented form added to water may prevent birds from drinking and result in death from dehydration, especially finches. Some preparations contain alcohol that may cause local skin irritation.

As a disinfectant, mix six tablespoons (3 oz or 90 ml)/gallon of water. Not effective for pseudomonas or gram-positive cocci. Extremely toxic to aquatic environments (lakes, ponds, streams). Waste products must be carefully handled. May irritate eyes or mucous membranes.

CHLORINE - Household bleach
Available as a 10% solution (100 mg/ml) that can be used to disinfect water (8 drops/gallon). May also be used as a disinfectant when mixed 1:10 with water. The longer the chlorine is in contact with an organism the more efficient it is as a disinfectant. Clorox, like most disinfectants, is not effective if organic debris is present.

Exposure to fumes may cause epiphora, coughing, sneezing, rhinorrhea and dyspnea in most avian species, particularly neonates. Should not come in contact with some metals. May react with some basic cleaners. Must always be used with adequate ventilation. Difficult to rinse out of porous materials (eg, wooden perches).

CHLOROQUINE PHOSPHATE - Aralen Phosphate (Sandoz)
Available as tablet (500 mg) for oral administration. Rapidly and completely absorbed from the intestinal tract. Used to treat the circulating forms of plasmodium (avian malaria). Must be used in conjunction with primaquine phosphate.

Overdose may be fatal. May cause retinal damage, vomiting, diarrhea or CNS problems.

CHLORTETRACYCLINE (CTC) - Aureomycin (Cyanamid)
Available as a feed additive (100 g/lb), tablet (25 mg) or powder (200 mg/teaspoon) for oral administration. Also available in pelleted feeds (Zeigler Brothers, Lafeber Co., Bird Life), in impregnated millet (Keet Life - Hartz) and for oral administration. Soybean meal base and CTC soluble powder may be added to cooked mashes containing rice, beans, chick starter ration and ground monkey biscuit for the flock control of chlamydiosis. Mixture must be made fresh each day. Addition of CTC to water for the flock treatment of chlamydiosis should not be considered effective. Pelleted foods may be useful in controlling chlamydiosis outbreaks in flocks of large psittacine birds. Tetracyclines are known to have immunosuppressive effects in other animals and the indiscriminate or periodic use of CTC in a flock of birds is not recommended. CTC chelates divalent and trivalent cations and interferes with normal bone development in mammals. No evidence to support the theory that annual treatment with CTC-impregnated pellets increases productivity as has been reported in the lay literature. Impregnated millet seeds may be helpful in treating chlamydiosis in flocks of budgerigars and cockatiels. The use of chlortetracycline for the treatment of chlamydiosis should be considered inferior to the use of doxycycline and enrofloxacin (see Chapter 17 and 34).

CHLORSULON - Curatrem (MSD Agvet)
Available as a suspension (8.5%, 85 mg/ml) for oral administration. Has been suggested as a treatment for tapeworms and liver flukes. Leads to death of the parasite by inhibiting glycolytic enzymes and incapacitating the parasite's primary source of energy.

CIMETIDINE - Tagamet (SmithKline Beecham)
Available as tablets (200, 300, 400, 800 mg) or liquid (60 mg/ml) for oral administration. Also available as an injectable solution (150 mg/ml) for IM or IV administration. Inhibits gastric acid secretion by inhibiting the effects of histamine at the H_2 receptor of the parietal cells. Indicated in cases of gastric ulceration and to decrease gastric acidity if the cloacal pH is low, a common problem with tenesmus and cloacal papillomas. May cause depression, diarrhea, tachycardia and respiratory failure.

CIPROFLOXACIN - Cipro (Miles)
See enrofloxacin. Available as a tablet (250, 500 or 750 mg) for oral administration, as an injectable solution (200 or 400 mg/ml) for slow IV administration or as an ophthalmic solution (3 mg/ml). Well absorbed from the gastrointestinal tract. Tablet can be crushed and added to liquid but must be shaken well before administration. May cause irritability in some birds. May cause CNS problems. Has been associated with crystalluria and joint abnormalities in some mammals (see Chapter 17).

CLAZURIL - Appertex (Janssen)
Available as a tablet (2.5 mg) for oral administration. Used for coccidiosis in pigeons. Not as effective in Galliformes and cranes as monensin.

CLINDAMYCIN - Antirobe (Upjohn)
Available as a suspension (25 mg/ml) or capsule (25, 75, or 150 mg) for oral administration. Primarily indicated in cases of osteomyelitis where long-term therapy is often required. Renal and hepatic function should be monitored during long-term use. Patients should be monitored for secondary yeast infections.

CLOMIPRAMINE HCL - Anafranil (Baker Cummins)
Available as a capsule (25, 50, or 75 mg) for oral administration. Tricyclic antidepressant. Used in humans to control compulsive behavior disorders. May be effective in some cases of feather picking and self-mutilation. Initial dose should be low with a gradual increase over a four- to five-day period. Clinical impressions suggest that this drug is rarely effective in controlling mutilation behavior in birds.

Numerous metabolic side effects. Regurgitation and drowsiness may occur in some birds. One cockatoo developed ataxia following administration.

COLCHICINE - (Merck; Lilly)
Available as a tablet (contains 0.5 mg colchicine and 0.5 mg probenecid) for oral administration or as an injectable solution (0.5 mg/ml) for IV administration. Both colchicine and probenecid have anti-gout activity. Inhibits release of histamine-containing granules from mast cells. Injectable solution used as an inhibitor of collagen production and may stimulate collagenase activity. May be indicated in some cases of hepatic fibrosis. Will not reverse fibrosis but may be helpful in preventing further damage.

May potentiate gout formation in some cases. Numerous metabolic side effects. Administration should be discontinued if vomiting or diarrhea occur.

COPPER SULFATE - Caustic Powder (Phoenix; Butler)
Available as a powder (51%) for topical application. Used for treating cases of ulcerative dermatitis.

CYANOCOBALAMIN - Vitamin B_{12} (Butler)
Available as an injectable solution (1 or 3 mg/ml) for IM or SC administration. Birds being treated with B_{12} may develop pink droppings.

DEXAMETHASONE - Azium (Schering)
Available as an injectable solution (2 or 4 mg/ml) for IM or IV administration. Anti-inflammatory that may be useful in debilitated animals. Dexamethasone is 20 times more active as an anti-inflammatory than prednisolone. Higher dose is used for treatment of shock and to reduce the effects of gram-negative endotoxemia that may occur when patients with bacteremia are treated with antibiotics. Higher dose may be immunosuppressive and a lower dose should be used for repeated therapy. Induces rapid glucocorticoid and anti-inflammatory response. May be useful as an adjunct therapy (with iodine) for treating goiter in budgerigars.

Has been associated with congenital deformities when administered to pregnant mammals. May cause increased levels of liver enzymes, polydipsia, polyuria and diarrhea. AST and ALT activities may increase to three times normal values within 36 hours of IM administration. Doses of three drops/gallon of water were found to be immunosuppressive in pigeons.

DEXTROSE 5 to 50% - (Fort Dodge; Butler)
Available as an injectable solution (5% - 50 mg/ml to 50% - 500 mg/ml) for slow IV administration. Used for the treatment of hypoglycemia. Must be given slowly to prevent circulatory collapse. 50% solution is hypertonic and cannot be given IM. Must be diluted to 5% solution for IM administration.

DIAZEPAM - Valium (Roche)
Available as an injectable solution (5 mg/ml) for IM or IV administration or as a solution (1 or 5 mg/ml) for oral administration. Can be used to control some seizures and feather picking (0.6 mg/kg IV, IM) in birds. Birds should be carefully supervised. May become so drowsy that they fall from an enclosure or perch.

DIETHYLSTILBESTROL DIPHOSPHATE - Stilphostrol (Miles)
Available as a tablet (50 mg) and as an injectable solution (0.25 mg/ml) for IM or IV. Low therapeutic index. Overdosing may cause anemia.

DIGOXIN - Cardoxin (Evsco); Lanoxin (Coopers)
Available as a solution for oral administration: Cardoxin = 15 mg/ml; Lanoxin = 0.05 mg/ml. Limited studies in birds. Suggested dosages based on studies in Quaker Conures, sparrows, parakeets and ducks. A dose of 0.01 mg/kg was found to reduce right ventricular enlargement in chickens. A dose of 0.02 mg/kg daily was considered safe and produced satisfactory plasma levels in parakeets.

Low therapeutic index. A dose of 0.1 mg/kg was found to induce arrhythmias in pigeons. Patients receiving digoxin should have regular ECG evaluations. Toxic reactions include depression, ataxia, vomiting, and diarrhea.

DIHYDROSTREPTOMYCIN - Azimycin (Schering)
Intramuscular injection has been associated with paralysis and death in some avian species.

DIMERCAPROL - BAL (Becton Dickinson)
Available as an injectable solution (100 mg/ml) for IM (painful) administration. Dimercaprol is a chelating agent that binds heavy metals including lead, gold, arsenic or mercury. Binding is reversible and a decreased activity occurs in an acidic environment. Less toxic than calcium EDTA and can be given orally. More rapid reduction in blood lead levels than occurs with calcium EDTA. Considered the drug of choice for removing lead from the CNS;

however, D-penicillamine is also effective and has a higher therapeutic index. Tachycardia is the most common side effect.

DIMETHYLSULFOXIDE - Domoso (Syntex)
Available as a liquid or gel (90% - 900 mg/ml) for topical application. Has been suggested as a method of reducing swelling and as a vehicle for carrying some antibiotics into difficult-to-reach sites of infection (joints, cellulitis, bumblefoot). May be helpful in reducing the swelling of prolapsed cloacal tissue prior to surgical correction. May cause local skin irritation. Has been associated with birth defects when used in pregnant mammals. Avoid contact with human skin.

DIMETRIDAZOLE - Emtryl (Jensen Salsbury)
Available as a soluble powder (182 g/6.42 oz) for oral administration. Used to treat giardiasis, trichomoniasis, histomoniasis, and hexamitiasis. Dimetridazole has activity against some anaerobic bacteria and may be useful in some cases of bumblefoot, ulcerative dermatitis, chronic sinusitis and metritis.

Low therapeutic index. Toxic to Pekin Robins and may be toxic in some other Passeriformes. Breeding birds should be treated only by gavage. If dimetridazole is added to the food or drinking water, a toxic level may be consumed or fed to a mate or nestlings. At a dose of one tsp/gal of drinking water, cockatiels, budgerigars and pigeons have been reported to develop incoordination, acute seizures and death. Extended therapy or excessive dosing may result in toxicity. Acute hepatitis has been reported in cockatiel fledglings. Some affected birds may respond to treatment with B vitamins. Is no longer available in the United States.

DINOPROST TROMETHAMINE - Lutalyse (Upjohn)
Available as a solution (5 mg/ml) for IM administration. Contains naturally occurring prostaglandin F2 alpha. Prostaglandins may be effective in some cases of egg retention. This agent would be expected to relax the vagina and increase uterine tone, which may facilitate the passage of an egg. Prostaglandins may prove also to have a therapeutic benefit in removing necrotic debris from the uterus in cases of salpingitis.

DIPHENHYDRAMINE HCl - Benadryl (Parke Davis)
Available as a capsule (25 or 50 mg) for oral administration or injectable solution (10 or 50 mg/ml) for IM or IV administration. May be effective in calming some feather pickers or excessively anxious birds. Has sedative, antihistamine and anti-depressant activity. Dose may need to be altered based on clinical response. Has atropine-like action and toxic side effects.

DOXAPRAM HCl - (Fort Dodge)
Available as an injectable solution (20 mg/ml) for IV or SC administration. Has been used in birds as a respiratory stimulant. May be helpful in reversing the respiratory depressant effects of ketamine and xylazine.

DOXEPIN HCl - Sinequan (Roerig)
Available as capsules (10, 25, 50, 75, 100, or 150 mg) or suspension (10 mg/ml) for oral administration. Tricyclic anti-depressant that may be helpful in some cases of feather picking. May cause severe lethargy.

DOXYCYCLINE - (Pfizer; Henry Schein; Roerig)
Available as a suspension (5 mg/ml, Vibramycin monohydrate), syrup (10 mg/ml, Vibramycin calcium syrup) or capsules (100 mg, Henry Schein) for oral administration. Also available in the US as an injectable solution (10 mg/ml, Vibramycin hyclate) for IV administration. In Europe and Canada, an injectable solution (20 mg/ml, Vibravenös) is available that can be administered IM. A doxycycline for IM administration produced by a compounding pharmacist has been suggested for use in individual birds.

Doxycycline is the therapeutic agent of choice for the treatment of chlamydiosis. This agent has greater activity, less immunosuppression and fewer side effects with fungal overgrowth than other tetracycline preparations. Calcium and zinc have little effect on the absorption of doxycycline. Iron decreases absorption substantially. Calcium and zinc may reduce the half-life of doxycycline by binding excreted doxycycline and thereby preventing enterohepatic circulation. A bird's feces may turn red when being treated with oral doxycycline.

Vibramycin hyclate IV is the therapeutic agent of choice for treating acute and severe cases of chlamydiosis in the United States. Once a patient is stabilized with IV administration, it can be switched to an oral suspension (monohydrate or syrup). Vibravenös, available in Europe and Canada, administered IM, is the preparation of choice for treating chlamydiosis where available. Vibramycin monohydrate designed for IV administration may cause severe muscle necrosis when administered IM.

Injectable doxycycline should be used within six hours of being reconstituted. The drug may remain stable if refrigerated for 72 hours. Reconstituted IV injectable (hyclate only) solution can be maintained in the freezer. In general, the time-related degeneration of tetracyclines results in the formation of toxic by-products. If vomiting occurs with the higher recommended dose of oral doxycycline, the dose should be split and administered BID. If vomiting continues, the dose should be reduced in 5 mg/kg intervals until vomiting stops. Macaws appear to be particularly sensitive to doxycycline and are the most frequent species to regurgitate following oral administration. Consumption of doxycycline-medicated food caused an increase in AST and LDH activities in Goffin's Cockatoos. Gram's stains of the feces should be monitored for proliferation of candida when any tetracycline is being administered. Doxycycline does persist and may stop oviposition in egg-laying hens. Toucans, particularly young birds, are sensitive to tetracyclines and may develop bone deformities following its use (see Chapter 17).

D-PENICILLAMINE - Cuprimine (Merck); Depen (Wallace)
Available as capsules (Cuprimine, 125 or 250 mg); or tablets (Depen, 250 mg) for oral administration. Used as a chelating agent. Particularly effective for copper. May also reduce blood and tissue concentrations of lead, zinc and other heavy metals. Low therapeutic index. May cause aplastic anemia, agranulocytosis, vomiting and diarrhea.

D-TUBOCURARINE
Mydriatic (3 mg/ml strength) (see Chapter 26).

ECHINACEA - (BioBotanica Inc.)
Available as a solution (a derivative of *Angustifolia purpurea*) for oral administration. Used as an immunostimulant. May speed recovery in some cases of poxvirus and in debilitated birds.

EDTA - TRIS Lysozyme Solution
Must be prepared from a chemical base. Best obtained from a compounding pharmacist. Materials to prepare the solution are available from Sigma Chemical Co. The solution is made by mixing 3.07 g Trizma HCL, 3.71 g Trizma base, 1.12 g disodium EDTA and 0.045 g lysozyme in 1000 ml of water. Solution can be used intratracheally, intranasally or to lavage wounds. Toxic if administered orally or parenterally. Particularly effective in treating pseudomonas dermatitis and sinusitis. EDTA - TRIS solution can be mixed and frozen. The lysozyme component should be added just before use.

The impermeability of the cell wall of gram-negative bacteria results in some of the antibiotic resistance seen with this group of bacteria. EDTA binds bivalent cations, which are required for

formation of the lipopolysaccharide layer of the cell wall. Lysozyme catalyzes the hydrolysis of peptidoglycans found in the bacterial cell wall. The damaged cell wall is more permeable to antibiotics.

ENILCONAZOLE - Clinafarm (Sterwin)
Available as a solution (13.8% - 138 mg/ml) for topical use on hatchery and farm equipment for the control of aspergillosis. Corrosive and may cause irreversible damage to the eyes.

ENROFLOXACIN - Baytril (Haver/Diamond)
Available as a tablet (5.7, 22.7 or 68 mg) for oral administration or as an injectable solution (22.7 mg/ml) for IM administration. Baytril is the veterinary-labelled form of a fluroquinolone class of antibiotics (human product = ciprofloxacin). The injectable solution can be administered orally. IM injection may result in severe muscle necrosis in some species. There is no advantage to using ciprofloxacin in place of enrofloxacin. Inability of bacteria to develop resistance is over-rated. Many gram-negative bacteria, particularly pseudomonas, are resistant to enrofloxacin and ciprofloxacin. Early studies show encouraging results in chlamydia therapy (see Chapter 34). Birds should be monitored for the development of secondary yeast infections.

Enrofloxacin may cause irritability in some birds. Long-term enrofloxacin treatment in pigeons was well tolerated; however, a dose-dependent increase in embryonic mortality was associated with drug administration to breeding pigeons. Hens receiving 800 ppm of enrofloxacin passed the drug in their crop milk, causing decreased weight gains and occasional joint abnormalities in squabs. A Senegal Parrot treated with enrofloxacin and ketoconazole for ten days was found to have renal damage. This drug should be used with caution in young birds. Quinolones have been suggested as a cause of joint problems in young psittacines and pigeons in Europe (see Chapter 17).

EPINEPHRINE (1:1000) - (Webster; Vedco; Butler; Phoenix)
Available as an injectable solution. Dilute with 10 parts LRS. This drug should be used with caution in birds. The therapeutic index for this drug is low. Clinical indications are confined to desperate attempts at restoring cardiac function in cases of peracute death from anesthesia.

ERGONOVINE MALEATE - Ergotrate maleate (Lilly)
Available as an injectable solution (0.2 mg/ml) for IM administration. Causes firm contractions of the uterus. Used in conjunction with calcium gluconate to induce the passage of an egg from the oviduct. Contraindicated if the egg is adhered to the wall of the oviduct or if a mechanical blockage is preventing egg passage.

ERYTHROMYCIN - (Sanofi; Lextron)
Available as an injectable solution (100 or 200 mg/ml) for IM or IV administration or as tablets (250 or 500 mg) or solutions for oral administration. Most gram-negative bacteria that affect psittacines are resistant to this drug. May be effective in cases of sinusitis and air sacculitis caused by mycoplasma. Injectable solution can be used in a nebulizer to treat upper respiratory infections caused by mycoplasma. Injectable solution administered IM can cause severe muscle necrosis (see Chapter 17).

ETHAMBUTOL HYDROCHLORIDE - Myambutol (Lederle)
Available as tablets (100 or 400 mg) for oral administration. Used for the treatment of *Mycobacterium* spp. infections, particularly strains that are resistant to isoniazid.

FENBENDAZOLE - Panacur (Hoechst-Roussel)
Available as a suspension (10% -100mg/ml) for oral administration. Can be used for ascarids, some microfilaria, flukes and capillaria. Fenbendazole should not be used while active feather development is occurring (may damage developing feathers). Has not been found to be effective against the gizzard worm that infects finches. May not always be effective against capillaria. May be effective against *Syngamus* spp. The drug has a low therapeutic index in some species of finches. A dose of 10 ml/liter of water has been associated with death three to five days following administration. This dose may cause ataxia, depression and mydriasis in canaries.

FERRIC SULFATE - Monsel's Solution
Available as a liquid or powder for topical application. Used for chemical cauterization of minor bleeding caused by damage to beak or nails. Should not be used to stop bleeding associated with soft tissue or damaged pin feathers. Placing a foreign compound into a feather follicle can cause the formation of feather cysts.

FLUCONAZOLE - Diflucan (Roerig)
Available as tablets (50, 100 or 200 mg) for oral administration or as an injectable solution (2 mg/ml) for IV administration. *In vitro* activity for aspergillosis, candida and cryptococcus. Passes blood-brain barrier.

May not be compatible with other antifungals. Transient regurgitation may occur in some species, particularly cockatoos and cockatiels. Elevated AST and LDH levels have been reported in some species being treated with fluconazole (see Chapter 17).

FLUCYTOSINE - 5-fluorocytosine, Ancobon (Roche)
Available as a capsule (250 and 500 mg) for oral administration. May be indicated for the long-term treatment of aspergillosis infections or for severe candidiasis infections that are resistant to nystatin. Because nystatin is not absorbed from the gut, flucytosine may be used to treat candida infections in other organ systems (particularly respiratory infections).

Flucytosine is toxic to the bone marrow and frequent CBCs should be used to monitor for evidence of bone marrow damage.

FLUNIXIN-MEGLUMINE - Banamine (Schering)
Available as an injectable solution (50 mg/ml) for IV or IM administration. Derived from nicotinic acid. Potent cyclo-oxygenase inhibitor that functions as a non-steroidal analgesic, anti-inflammatory and antipyretic agent. May be helpful in some cases of shock and trauma. May also be useful as an antipyretic in cases of hyperthermia. May cause vomiting and diarrhea in some birds.

FURAZOLIDONE
Has been associated with congestive heart failure and death in chicks, ducklings and turkey poults.

FUROSEMIDE - Lasix (Hoescht-Roussel)
Available as an injectable solution (5% - 50 mg/ml) for IM or IV administration or as a syrup (1% - 10 mg/ml) for oral administration. Used as a diuretic. Furosemide should be considered to have a low therapeutic index in birds. Some avian species (particularly lories) are extremely sensitive. Overdose may cause severe dehydration and electrolyte abnormalities. Toxic reactions are characterized by neurologic signs and death.

GENTAMICIN SULFATE - (Butler; Schering)
Available as an injectable solution (50 mg/ml) that may be used orally, intranasally, topically or for nebulization. Also available as ophthalmic ointment or as otic solution (3 mg/ml) that can be used intranasally or topically. For nebulization, 1 ml of injectable solution is mixed with 10 ml of saline and nebulized for 15 minutes TID.

Experimental data indicate that the doses needed to maintain therapeutic blood levels and the doses that cause nephrotoxicity and ototoxicity vary widely among avian species. A transient polyuria indicative of renal damage is common. The dose that is considered nephrotoxic has not been determined for all birds.

Prolonged use in any bird can cause permanent renal damage. Owls appear to be particularly sensitive to the toxic effects of gentamicin, as are some cockatoo species. A dose of 20 mg/kg IM, subcutaneously or IV can cause collapse, respiratory arrest and death in some avian species, particularly lories. Parenteral administration of amikacin is safer in birds. Gentamicin ophthalmic solution must be used with caution in small birds to prevent overdosing and nephrotoxicity. Gentamicin should be used only in life-threatening infections that have been shown to be resistant to less toxic antibiotics or amikacin.

Gentamicin is not absorbed from the gut and can be given orally to sterilize the gut or to treat severe cases of enteritis in which an infection is localized to the gastrointestinal tract. Oral administration is generally needed only for two to three days. This drug can be nebulized for the treatment of upper respiratory infections (sinuses, trachea, lungs). Topical preparations may impair wound contraction and retard healing. The toxic effects of aminoglycosides may be potentiated when used in combination with cephalosporins or furosemide (see Chapter 17).

GENTIAN VIOLET - GV-11 (Noremco)
Available as a powder or solution (1.6% - 16 mg/ml) for oral administration. Can be used to treat gastrointestinal candidiasis that is resistant to nystatin. Acts as a drying agent, which may be helpful in treating moist dermatitis. Will stain clothing, feathers and hands.

HALOPERIDOL - Haldol (Henry Schein)
Available as a solution (2 mg/ml) for oral administration or as an injectable solution (50 or 100 mg/ml) for IM administration. Used in humans to treat compulsive, obsessive behavior. Has a tranquilizing effect in humans with mental confusion. May be effective in some cases of feather picking and self-mutilation in birds. Appears to work best in cockatoos. African Grey Parrots and Quaker Parakeets may be disoriented or neurotic following administration. The IM product may provide two to three weeks of activity. Should be used in conjunction with behavioral modification to correct the inciting cause of the destructive behavior. The dose should be adjusted by increasing or decreasing 0.01 ml every two days. Administration should be discontinued if anorexia, ataxia or vomiting occur. Quaker Parakeets and Umbrella and Moluccan Cockatoos appear to be particularly sensitive to this drug and may respond to much lower doses (0.08 mg/kg, SID).

HALOXON
Often combined with piperazine for the treatment of capillaria in pigeons. Low therapeutic index in Psittaciformes, Anseriformes and raptors. Antidote for toxicity is atropine.

HEMICELLULOSE - Psyllium; Metamucil (Searle)
Found as a fiber source in some formulated diets. May be effective in controlling glucosuria, hypocalcemia and hypercholesterolemia. Can be administered as a bulk laxative to aid in the passage of foreign bodies. Large doses may precipitate out in the crop or upper intestinal tract causing an impaction.

HYDROCHLORIC ACID
A one M/l solution is mixed at a rate of 30 ml/pint of drinking water. May be effective in some cases of enteritis that are not responsive to traditional therapy. Preliminary findings suggest that this treatment may help in some cases of megabacteriosis.

IMMUNOREGULIN - (Immunovet)
Available as a solution for IV administration. Has been suggested as an immunostimulant in birds, but there is no scientific documentation that it is effective. Anaphylactic reactions and death have been reported in some birds.

IODINE - Lugol's Solution (Butler); Renografin-76 (Solvay)
Available as a solution (50 mg/ml free iodine and 100 mg/ml potassium iodine). Used in water to prevent goiter in iodine-deficient areas. Will oxidize if exposed to light and must be stored in dark-colored bottle. Concentrated solution is made by mixing two ml of Lugol's solution in 30 ml of water. Working solution is mixed fresh daily by mixing one drop of concentrated solution in 250 ml of drinking water. Organic iodines (diatrizoate sodium, 37% iodine) can be administered IM (122 mg/kg) in budgerigars with goiter.

IPRONIDAZOLE - Ipropan (Roche)
Available as a soluble powder (61 g/2.65 oz) for oral administration. Used to treat trichomoniasis, histomoniasis and giardiasis.

IRON DEXTRAN - (Butler; Lextron; Vedco)
Available as a solution (100 mg/ml) for IM injection. Indicated in some cases of anemia and hemorrhage. Must be used with caution in toucans and mynah birds that are prone to hemochromatosis.

ISONIAZID - INH (CIBA Pharmaceuticals)
Available as a tablet (300 mg) Also available as a capsule in combination with rifampin (Rifamate - 300 mg isoniazid and 300 mg rifampin). Destroys actively growing tubercle bacilli. May cause a fatal hepatitis, vomiting, depression and ataxia.

ITRACONAZOLE - Sporanox (Janssen)
Available as capsules (100 mg) for oral administration. *In vitro* activity for aspergillosis, candida and cryptococcus. Used successfully in Europe for aspergillosis in waterfowl and penguins. This drug is considered to be more effective against aspergillosis and less toxic than other anti-fungals.

Has been associated with anorexia and depression in African Grey Parrots given 8-10 mg/kg BID. Other reports indicate that it is effective against aspergillosis in Psittaciformes with few side effects at a dose of 10 mg/kg BID for months. Has been associated with hepatitis in mammals (see Chapter 17).

IVERMECTIN - Ivomec, Eqvalen (Merck Agvet)
Supplied as an injectable solution (10 mg/ml) for IM, topical or oral administration. Effective for some nematodes, mites and lice. Most effective therapy for *Knemidokoptes*. Calculated dose can be used topically on affected areas or can be given orally.

May also be effective for *Oxyspirura*, some coccidia, some nematodes, gapeworms and sternostamatosis. May not be effective against all coccidia. Toxic in bullfinches and goldfinches when used topically at 0.4 mg/kg. Propylene glycol is used as a carrier in the solution designed for cattle and pig use. This product will precipitate out if diluted with sterile water. The propylene glycol-based product may cause toxic reactions when administered IM, particularly in small birds. Ivermectin diluted in propylene glycol will settle out and the diluted product should be thoroughly mixed before administration. The water-soluble preparation designed for use in horses is easier to work with and appears to be safer. However, deaths in finches and budgerigars have been reported when Eqvalan (the water based formula) was administered IM at the recommended dose.

Ivermectin is environmentally stable and is highly toxic to fish and crustaceans. The drug or its metabolites should not be allowed to contaminate lakes, streams or rivers.

KETOCONAZOLE - Nizoral (Janssen)
Available as a tablet (200 mg) for oral administration. Used for the treatment of severe candidiasis in which other therapies have been ineffective. This drug is water-soluble and is easiest to dissolve in acid. Tablets can be dissolved in 0.8 ml one M hydrochloric acid and 3.2 ml of water for administration by gavage. The mixture normally turns light pink.

Crushed tablets can also be added to mashes or mixed in orange juice, aloe vera, lactulose or pineapple juice if accepted by the patient. Crushed tablets can be mixed with methyl-cellulose by a compounding pharmacist to produce a stable product that is easy to administer. This drug impairs synthesis of ergosterol, which is a critical component of the fungal cell membrane. May cause hepatocellular necrosis (see Chapter 17).

LACTATED RINGER'S SOLUTION (LRS)
Available as an isotonic solution for IV administration. Can also be administered orally if gastrointestinal stasis or vomiting are absent. In cases of mild dehydration (5%), oral administration may be effective. Absorption may be enhanced by mixing with psyllium and sugar. In more severe cases, parenteral administration of fluids is required. Fluid replacement is calculated by: body wt in g X % dehydration = quantity of fluid in ml. The maintenance fluid requirement for birds is considered to be 50 ml/kg/day.

LACTOBACILLUS - Probiocin (Pioneer)
Contains *Lactobacillus planatarum, Streptococcus faecium, L. casei* and *L. acidophillus*. Multi-dose application may be effective in establishing flora that can act to prevent pathogenic gram-negative bacteria from colonizing the gastrointestinal tract. Should be considered as adjunct therapy in any bird that has received antibiotics, has bacterial enteritis or has a reduced population of intestinal microbes as determined by Gram's staining.

LACTULOSE - Cephulac (Marion Merrell Dow)
Available as a suspension (667 mg/ml) for oral administration. Acts as an osmotic retardant to the absorption of potential toxins from the gastrointestinal tract. Palatable and usually well tolerated by patients. Can be used as a carrier for many less palatable drugs. Indicated in cases of liver disease to decrease the load of metabolites that must be processed by the liver. May be effective as an appetite stimulant in some birds. May also be effective in establishing a gastrointestinal environment that favors the growth of autochthonous flora. Can be used daily for weeks if needed. The dosage should be reduced if diarrhea occurs.

LEVAMISOLE - Levasole (Pittman Moore); Tramisol (American Cyanamid); L-Spartakon (Janssen)
Available as an injectable solution (13.65% - 136.5 mg/ml) for IM, SC, or PO or as tablets (20 mg) in Europe for PO in pigeons. May be effective for intestinal nematodes. Experimental studies in chickens suggest that a dose of 1.25-2.5 mg/kg administered PO or SC increases immune response in immunosuppressed birds. However, there is no work to confirm a positive immunostimulatory effect in other birds. Suggested dosing when used as an immunostimulant is 2 mg/kg IM or SC every 14 days for three doses. May cause swelling at the injection site.

Low therapeutic index. This drug is not recommended for use in debilitated patients. Parenteral administration of 2 to 4 times therapeutic dose may cause vomiting, neurologic problems and death. A dose of 40 mg/kg SC or IM has been associated with ataxia, depression, regurgitation and mydriasis in some cockatoos, budgerigars and mynah birds. Clinical signs are most severe when administered IM. A dose of 25 mg/kg IM has been associated with hepatotoxicity in budgerigars. Death has been reported in pigeons administered 35 mg/kg IM, Peach-faced Lovebirds administered 66 mg/kg IM and White Ibis administered 22 mg/kg IM.

LEVOTHYROXINE SODIUM - Thyroxine L (Butler)
Available in tablet form (0.1, 0.2, 0.3, 0.5, or 0.8 mg) or suspension (0.4 mg/ml) for oral administration. Can be mixed with drinking water (mixed fresh daily) to treat goiter and hypothyroidism. A tablet (0.1 mg) is crushed and mixed with 4-12 oz of drinking water. Response to therapy is widely variable. May induce molt. T_4 levels should be monitored with long-term therapy to maintain proper blood levels and prevent overdose. Should be used with extreme caution except in cases of documented hypothyroidism. Overdose causes an iatrogenic hyperthyroidism (tachycardia, polydipsia, polyuria, vomiting, weight loss, convulsion and death) (see Chapter 23).

LINCOMYCIN HCL - Lincocin (Upjohn)
Available as a solution (50 mg/ml) for oral administration or as an injectable solution (100 mg/ml) for IM or IV administration. This drug has poor activity against most gram-negative bacteria but does have good activity for many gram-positive organisms. May be effective in treating chronic respiratory infections caused by mycoplasma. May be useful in cases of chronic dermatitis caused by gram-positive organisms. Has been associated with death in some birds when administered IV. Patients should be monitored for secondary yeast infections.

LEUPROLIDE - Lupron (TAP Pharmaceuticals)
Available as lyophilized microspheres (7.5 mg/vial) for IM injection. Has been shown to cause cessation of ovarian activity for up to 14 days in cockatiels. May be used in cases of egg-related peritonitis to stop ovarian function. Reduces levels of testosterone to castration levels. Has been used to stop aggressive male behavior.

LORELCO - Probacoll (Merrell Dow)
Available as tablets (250 or 500 mg) for oral administration. Used in mammals to lower blood cholesterol levels. Has been used in birds to control lipemia and suppress the growth of lipomas. In humans, drug administration is discontinued if a patient has a prolonged QT interval.

MANNITOL - (Webster; Vedco)
Available as an injectable solution (20 mg/ml or 180 mg/ml) for slow IV administration. Functions as an osmotic diuretic and may be effective in reducing intraocular and intracranial pressure. Used primarily to reduce brain swelling following head trauma.

MEBENDAZOLE - Telmintic, Telmin (Pitman Moore)
Available as a soluble powder (Telmintic, 40 mg/g) or suspension (Telmin, 33.3 mg/ml) for oral administration by gavage or by lacing food. Primarily used for capillaria. Has been associated with hepatitis in some mammals and raptors. Death and intestinal obstruction caused by dead nematodes have been reported at all doses in some finches and some psittacine birds. Reported to be toxic in pigeons, cormorants, pelicans and raptors. Commonly mixed in the food of geese and pheasants. A dose of 12 mg/kg may cause death in Columbiformes.

MEDROXYPROGESTERONE ACETATE - (Upjohn)
Available as tablets (2.5, 5, or 10 mg, Provera promone) for oral administration or as an injectable suspension (100 mg/ml, Depoprovera) for IM or SC administration. Intramuscular injection may cause muscle necrosis. Can be used to inhibit ovulation and as an antipyretic. Inhibits secretion of pituitary gonadotropin and prevents follicular development and ovulation. In some birds, one dose may be effective in suppressing ovulation for six months. The dose of medroxyprogesterone varies with the size of the bird (150 g [0.05 mg/g]; 150-300 g [0.04 mg/g]; 300-700 g [0.03 mg/g]; 700 g [0.025 mg/g]; Umbrella Cockatoo [0.018 mg/g]).

There are numerous metabolic side effects. A single dose may cause lethargy, obesity, polydipsia, polyuria and fatty liver syndrome in some species. Cockatoos and Quaker Parakeets appear to be very sensitive and require a reduced dose (see Chapter 29).

METHRIDINE -
Used to treat capillaria in raptors only. Commonly causes vomiting which helps expel parasites in the pharynx and esophagus. Should not be stored in plastic.

METHYLPREDNISOLONE ACETATE - Depo-Medrol (Upjohn)
Available as an injectable solution (20 or 40 mg/ml) for IM administration. Has been associated with birth defects when administered to pregnant mammals.

METOCLOPRAMIDE HCl - Reglan (Robins)
Available as tablets (10 mg) or syrup (1 mg/ml) for oral administration. Also available as an injectable solution (5 mg/ml) for IV or IM administration. Thought to sensitize tissues to acetylcholine. In mammals, stimulates gastrointestinal motility without increasing gastric, biliary or pancreatic secretions. Indicated in birds with gastrointestinal motility problems, slow crop-emptying, regurgitation and vomiting that is not associated with blockage of the gastrointestinal tract.

Has been associated with hyperactivity in some birds. Should not be used when gastrointestinal stasis is caused be intraluminal or extraluminal masses that are preventing the movement of ingesta. Also contraindicated in cases of gastrointestinal bleeding or perfor-ation.

METRONIDAZOLE - Flagyl (Searle)
Available as tablets (250 or 500 mg) for oral administration or as an injectable solution (5 mg/ml) for slow IV administration. Used for treatment of giardia, hexamita and for anaerobic bacterial infections. Resistant organisms may require two daily injections followed by two more doses in 14 days.

Contraindicated in finches. Injectable solution can be administered IM but may cause necrosis at the site of injection. Needles and IV sets containing aluminum should not be used with some preparations.

MIBOLERONE - Cheque (UpJohn)
Available as a solution (100 μg/ml) for oral administration. May be effective in stopping oviposition. The experimental dose is 10 μg/kg.

MICONAZOLE - Monistat (Janssen)
Available as an injectable solution (10 mg/ml) for slow IV administration or as an ointment or cream (1 or 2%) for topical administration. Used for the treatment of systemic mycosis, particularly candida and cryptococcus. Must be given slowly to prevent tachycardia, cardiac arrhythmia or death. Ointment can be used for nasal or dermal fungal infections. High therapeutic index in mammals.

MINERAL OIL
Administered by gavage as a laxative and to aid in the removal of intraluminal foreign bodies (eg, lead, zinc, plastics). Aspiration pneumonia is common if administered orally.

MONENSIN SODIUM - Coban (Elanco)
Available as a feed additive (45 or 60 g/lb) for oral administration. Used to prevent coccidiosis in Galliformes, quail, cranes and pigeons. Has been shown to be safe in cranes at five times the therapeutic dose. Monensin was more effective than clazuril or amprolium for treating coccidiosis in Galliformes and cranes. May be lethal if consumed by mature turkey or guinea fowl.

MORPHINE
Sensitivity and response varies with species. In Galliformes, 2.5 - 30 mg/kg produces analgesia.

NALOXONE - (Pitman; Moore)
Available as an injectable solution for slow IV administration as a narcotic and tranquilizer antagonist.

NATAMYCIN - Natacyn (Alcon)
Available as a 5% solution for ophthalmic use. Used for ocular and periocular fungal infections. Patients receiving this medication should be slowly weaned off the drug by a gradual reduction in dosing.

NEOMYCIN - Biosol (Upjohn)
Available as a solution (50 mg/ml) for oral administration. The drug preparation that contains methscopolamine bromide (BiosolM) can be toxic. Not absorbed from the gastrointestinal tract. Drug preparation used mainly for sterilizing the gut in infections localized to the gastrointestinal tract.

NEOMYCIN TOPICAL - (Schering)
Available as an ointment or cream for topical administration. Some preparations may also contain other antibiotics, steroids, trypsin, and chymotrypsin. The preparations containing trypsin and chymotrypsin are particularly useful for debriding and providing antimicrobial activity to necrotic areas of skin.

NICLOSAMIDE - Nicloside (Miles)
Available as a tablet (500 mg) for gavage or by lacing food. Primarily used for tapeworms. Causes the expulsion of the parasite, which can be a diagnostic aid in difficult-to-detect infections. The ground tablets are not soluble in water and must be added to a gruel. Has been used in a baked bread type of food for administration to finches in Australia. Tablets can be administered directly to some larger species. All doses have been associated with death in pigeons, geese and some other Anseriformes.

NITROFURAZONE - Furacin (SmithKline Beecham)
Available as a soluble powder (9.2% - 92 mg/ml) for oral administration or as a solution or ointment (0.2% - 2 mg/ml) for topical application. May be effective in preventing the spread of *E. coli* and salmonella-induced enteritis on a flock basis. Has been used to treat some strains of coccidia in psittacine birds. The coccidia that infect toucans and mynahs appear to be less susceptible. Topical preparations slow epithelialization and retard wound healing.

Nitrofurazone has a low therapeutic index and should not be mixed in nectar. Overdose may cause neurologic signs or death. If neurologic signs occur, treatment should stop immediately. A dose of 1 tsp/gallon of drinking water may cause screaming, incoordination, vomiting, and death in mynahs, lorikeets and lories. Topical preparations slow epithelialization of damaged tissues. Furacin powder should not be used on wounds that could be open to the pneumatic bones or to the abdomen or thorax. May cause severe granulation formation if it enters the air sacs.

NITROTHIAZOLE - Enhaptin (American Cyanamid)
All doses administered orally have been associated with death in finches.

NORTRIPTYLINE HCL - Aventyl HCL (Lilly)
Available as a tablet (25 mg/ml) or syrup (2 mg/ml) for oral administration. A tricyclic anti-depressant that is used in humans as a mood elevator to treat depression. May be effective in treating some cases of feather picking. If a bird becomes hyperactive, the drug dose should be reduced and if it remains hyperactive, treatment should be stopped. Clinical experience suggests that this drug is rarely effective in cases of feather picking.

NYSTATIN - Mycostatin (Apothecon); Myco 20 (Squibb)
Available as a suspension (100,000 units/ml) or as a feed premix (Myco 20) for oral administration. Used for the treatment of sus-

ceptible strains of candida localized to the gastrointestinal tract. Nystatin must come in contact with candida to be effective and is not absorbed from the gastrointestinal tract. Oral lesions must be treated topically and will not resolve if nystatin is administered by gavage. Neonates that are receiving antibiotics should be monitored by Gram's stains for the early detection of candida overgrowth. If candida is found to be proliferating, nystatin therapy should be initiated. Some strains of candida are resistant to nystatin and Gram's stains should be used to monitor therapeutic results.

Nystatin feed premixes contain high levels of calcium and should not be used in conjunction with tetracycline therapy (see Chapter 17).

OXFENBENDAZOLE - Synanthic (Syntex)
Available as a suspension (90.6 or 225 mg/ml) for oral administration. May be effective for some nematode infections.

OXYTETRACYCLINE - Liquamycin - LA200 (Pfizer)
Long-acting tetracycline available as an injectable solution (200 mg/ml) for IM or IV administration. It may be effective in treating chlamydiosis, but severe muscle necrosis may occur in some species following IM administration. Secondary yeast infections may be a problem (see Chapter 17).

OXYTOCIN - (Butler; Lextron; Vedco)
Available as an injectable solution (20 units/ml) for IM, IV or SC administration. Used in conjunction with calcium gluconate for the treatment of uncomplicated uterine stasis. Should not be used if an egg is adhered to the oviduct, if the uterus is ruptured or if passage of an egg is mechanically inhibited.

2-PAM
Available as an injectable solution for IM injection as an antidote to cholinesterase inhibitor toxicosis as seen in many insecticide toxicities.

PANCREATIC ENZYMES - Viokase V (Fort Dodge); Hi-Vegi-Lip (Freeda Vit, Inc.)
Available as a powder for oral administration. Contains lipase, protease and amylase. Can be mixed with food or administered by gavage. Primarily indicated in cases of pancreatic insufficiency but may also help in the digestion of food in some cases of weight loss, enteritis or slowed crop-emptying. Viokase has been developed for use in mammals. Hi-Vegi-Lip may be more effective for assisting in the digestion of high-cellulose diets consumed by grain-eating birds. This product is available in 2400 g tablets. One-fourth of a tablet may be mixed with water or hand feeding formula and gavaged in a 250-500 g bird with each meal.

PANCURONIUM BROMIDE - (Astra)
Synthetic, non-depolarizing, neuro-muscular blocking agent used to dilate the pupil. Dose of 0.06 mg/kg injected into the anterior chamber of the eye of an eagle resulted in tachycardia, dyspnea and depression within 20 minutes.

PARCONAZOLE
Used as a food additive in Europe to control candida.

PHENOBARBITAL - Donnatal (Robins)
Available as a tablet (16.2 mg), elixir (3 mg/ml), or solution (4 mg/ml) for oral administration. Has a peripheral anticholinergic, antispasmodic and mild sedative effect. Should not be used in patients with gastrointestinal blockage. May cause depression, vomiting and ataxia.

PHENYLBUTAZONE - Butazolidin (Coopers)
Available as an injectable solution (200 mg/ml) for IV administration or as a tablet (100 or 400 mg) for oral administration. Non-steroidal anti-inflammatory anti-pyretic agent. Not for SC or IM administration.

PIPERACILLIN - Pipracil (Lederle)
Available as an injectable solution (200 mg/ml) for IM or IV administration. Lower end of dose range used when combined with aminoglycoside administration.

Piperacillin is unstable (48 hours when refrigerated) once it is reconstituted. It can be reconstituted, transferred into sterile vials and frozen for one month (see Chapter 17).

PIPERAZINE - (Agrilabs)
Available as a suspension (17% - 170 mg/ml or 34% - 340 mg/ml) for oral administration. Has been used for ascarids in gallinaceous birds. Has not been shown to be effective in psittacine birds and finches.

POLYMYXIN B
A dose of 5-10 mg/kg has been associated with weakness, incoordination, vomiting and death in Amazon parrots.

POTASSIUM CHLORIDE
Available as an injectable solution for slow IV administration in concert with electrolyte analysis and electrocardiography. Can cause arrhythmias.

PRAZIQUANTEL - Droncit (Haver/Diamond)
Available as tablets (23 or 34 mg) for oral administration or as an injectable solution (56.8 mg/ml) for IM, SC or PO. Used for treating tapeworm infections. Can be administered by gavage or by lacing food. May stop the shedding of tapeworm eggs but not eliminate the adults. Discussed as treatment for liver flukes but may not be effective (see chlorsulon).

Injectable form may be toxic in some species, particularly finches. A dose of 100 to 250 mg/kg IM has been associated with depression and death in some species.

PREDNISOLONE SODIUM SUCCINATE - Cort Sol (Butler); Solu-Delta-Cortef (Upjohn)
Available as a tablet (5 mg) for oral administration or as an injectable solution (10 or 50 mg/ml) for IM or IV administration. For oral administration, mix one (5 mg) tablet in 2.5 ml of water (makes a solution of 2 mg/ml). Dose is 6 mg/kg BID. Can be mixed with lactulose for oral administration. Used as an anti-inflammatory in cases of shock and trauma. Long-term therapy should be avoided. Also effective in reducing the effects of endotoxins released from the destruction of gram-negative bacteria.

PRIMAQUINE PHOSPHATE
See chloroquine phosphate. Used in combination with chloroquine for the treatment of avian malaria (*Plasmodium* sp.).

PROCAINE PENICILLIN G AND PENICILLIN BENZATHINE - Ambi-pen (Butler); Benza-pen (SmithKline Beecham)
Available as an injectable solution (150,000 units penicillin G procaine and 150,000 units penicillin benzathine) for IM or SC administration. Maintains therapeutic blood levels up to 48 hours in some species. Most effective in gallinaceous species and Anseriformes that are difficult to catch for more frequent drug administration. Should not be used in small birds because of a high incidence of procaine overdose and death in these species. A dose of 1 mg/kg has been associated with paralysis and death in some species.

PROPRANOLOL - Inderol (Wyeth-Ayerst)
Available as a tablet (10, 20, 40, 60, 80 mg) for oral administration or as an injectable (1 mg/ml) for slow IV administration. Beta adrenergic receptor blocker that has antihypertensive and antiar-

rhythmic effects. Used in cases of tachycardia. May cause depression, vomiting, heart failure or bradycardia, and patients should be carefully monitored during administration.

PYRANTEL PAMOATE - Strongid T (Pfizer)
Available as an oral suspension (4.5 mg/ml). High therapeutic index. Effective for many intestinal nematodes.

PYRETHRINS
Used topically for the treatment of external parasites that are resistant to carbaryl. Therapy for lice is the primary indication for use. Lice frequently inhabit the axillary regions, and the wings should be extended during treatment to ensure that pyrethrin is properly applied to the axillary regions.

PYRIMETHAMINE - Daraprim (Burroughs Welcome)
Available as a tablet (25 mg) for oral administration. To facilitate administration, tablets can be mixed in 21 ml of water and 4 ml of KY jelly, creating a suspension containing 1 mg/ml. Used to treat plasmodium, toxoplasma and sarcocystis. The drug is a folic acid antagonist and its effects are potentiated by the administration of sulfonamides.

QUINACRINE HCL- Atabrine (Sanofi; Winthrop)
Available in a tablet (100 mg) that can be crushed and administered by gavage. Effective for the treatment of *Haemoproteus*; however, this parasite is not currently considered to be pathogenic, and treatment is not recommended. Low therapeutic index. Dose of 50-150 mg/kg (five times the recommended dose) causes hepatotoxicity in cockatoos.

RAFOXANIDE
For treatment of cestodes in Falconiformes. May be effective against some trematodes. Dose is 40 mg/kg orally.

RIFAMPIN - Rifadin (Marion Merrell Dow)
Available as a capsule (150 or 300 mg) for oral administration. Also available in combination with isoniazid (Rifamate). Inhibits DNA-dependent RNA polymerase activity. Interferes with bacterial but not mammalian RNA polymerase. Destroys growing tubercle bacilli. May cause a fatal hepatitis, CNS signs, depression or vomiting.

SODIUM SULFATE - GoLYTELY (Braintree Laboratories)
Osmotic cathartic that can be used to evacuate the gastrointestinal tract. Used in heavy metal poisoning to prevent absorption from the gastrointestinal tract by forming insoluble complexes. Should not be used in cases with impaired gastrointestinal function. Contraindicated with dehydration.

SPECTINOMYCIN - Spectam (Sanofi; Syntex)
Available as an injectable solution (50 or 100 mg/ml - Spectam) for IM administration or as a water-soluble solution (50 mg/ml) for oral administration. Used with some success for the flock (Galliformes) treatment of enteritis caused by gram-negative bacteria.

STA SOLUTION
Salicylic acid (3 g), tannic acid (3 g) qs in ethyl alcohol to 100 ml. Used as a topical treatment for moist and fungal dermatitis.

STANOZOLOL - Winstrol V (Upjohn)
Available as a tablet (2 mg) for oral administration or an injectable solution (50 mg/ml) for IM administration. For oral administration, a 2 mg tablet is crushed in 4 oz of water. Anabolic steroid used to increase weight gain and improve recovery from debilitating disease. Should be used with caution in birds with hepatic or renal disease. The effects of administration to gravid hens is unknown. A controlled substance in some states.

STREPTOMYCIN SULFATE
Used frequently in Columbiformes and Galliformes. Low therapeutic index. Appears to be highly toxic in most species of companion birds.

SUCRALFATE - Carafate (Marion Merrell Dow)
Available as a tablet (1 g) for oral administration. Can be mixed in 10 ml of water for administration. Disaccharide that reacts with stomach acids to form a complex that binds to the proteins associated with an ulcer, producing a protective layer that protects the ulcerated mucosa from gastric acids and microbial pathogens. Indicated in cases of gastrointestinal bleeding.

SULFACHLORPYRIDAZINE - Vetisulid (Solvay)
Available as an oral suspension (5% - 50 mg/ml) for oral administration or as an injectable solution (215 mg/ml) for IV administration. Used for treatment of *E. coli*-induced enteritis in Galliformes. Can cause hypersensitivity reaction resulting in a hemorrhagic syndrome. Repeated use of sulfonamides can induce hypersensitization and toxicity (hemorrhagic crisis).

TESTOSTERONE CYPIONATE - (Henry Schein; Upjohn)
Available as a tablet (10 mg or 25 mg, Methyltestosterone) for oral administration or as an injectable solution (200 mg/ml, Depo-testosterone) for IM administration. Incorrectly used to increase male reproductive activity and for some cases of feather loss. May be useful in some cases of reproductive-associated feather picking and chronic egg-laying. Prolonged use is not advised. Contraindicated in cases of renal or liver disease. For water administration, 100 mg is added to one oz. of water. Five drops of the stock solution is added to one oz of drinking water and is mixed fresh daily.

TETRACYCLINE
Available as a soluble powder, capsules (250 mg), suspension or solution (100 mg/ml) for oral administration. Also available as an eye ointment that is particularly effective in many cases of idiopathic conjunctivitis in cockatiels. Ineffective for many of the avian pathogens frequently found in pet birds. Immunosuppressive in many animal species. Potentiates secondary fungal infections. Few therapeutic uses in birds. Toucans, particularly young birds, are sensitive to tetracyclines and may develop bone deformities following its use. See Chapter 34 for chlamydia indications.

THIABENDAZOLE - Equizole (MSD AgVet)
Available as a suspension (4 mg/30 ml) for oral administration. Used for the treatment of ascarids and *Syngamus trachea*. May be toxic in ostriches, diving ducks and cranes.

THIAMINE - Vitamin B_1 (Butler; Phoenix; Vedco)
Available as an injectable solution (200 or 500 mg/ml) for IM administration. Also available as a powder to be added to the feed of birds consuming fish that contain thiaminase.

TICARCILLIN - Ticar (SmithKline Beecham)
Available as an injectable solution (30 to 400 mg/ml depending on reconstitution) for IM or IV administration. Lower concentration is used for IV injection. Good activity against many *Pseudomonas* spp. Wide therapeutic index. Good synergistic effect with aminoglycosides for use in difficult-to-treat gram-negative bacteria. Can be reconstituted and held in refrigerator for 72 hours or mixed into individual doses and frozen. IM infection in conjunction with tobramycin was associated with hepatotoxicity in a Rose-breasted Cockatoo (see Chapter 17).

TOBRAMYCIN - Nebcin (Lilly)
Available as an injectable solution (40 mg/ml) for IM administration. Low therapeutic index. Reserved for use in life-threatening infections caused by pseudomonas that are resistant to combina-

tion therapy with other aminoglycosides and synthetic penicillins (see Chapter 17).

TRIMETHOPRIM/SULFADIAZINE - Bactrim (Roche); Tribrissen (Coopers)
Available as a suspension (8 mg trimethoprim and 40 mg sulfamethoxazole/ml, Bactrim) for oral administration or as an injectable solution (Tribrissen 48%; 80 mg trimethoprim and 400 mg sulfadiazine/ml) for IV administration or (Tribrissen 24%; 40 mg trimethoprim and 200 mg sulfadiazine/ml) for IM or SC administration.

Oral suspension is one of the drugs of choice for treating gastrointestinal and respiratory infections in hand-feeding babies that do not have gastrointestinal stasis. May be effective in treating some cases of coccidiosis, particularly in toucans and mynahs.

Regurgitation, facial flushing and GI stasis have been noted in some birds (particularly macaws). Should not be used in patients with liver disease or bone marrow suppression (see Chapter 17).

TSH - Dermathycin (Jen-Sal Laboratories)
Used for thyroid stimulation testing.

TYLOSIN - (Butler; Elanco)
Available as an injectable solution (50 mg/ml or 200 mg/ml Tylan 200) for IM injection. Also available as a soluble powder (Elanco) for oral administration. Soluble powder can be mixed with sterile water (mixed 1:10) and used as an eye spray. Tylosin 200 mg/ml injectable solution can be mixed with DMSO (1 ml tylosin/50 ml DMSO) and used for nebulization. May be effective in the initial therapy of upper respiratory infections, particularly when nebulized. May be useful as an eye spray for the frequent treatment of conjunctivitis (particularly if mycoplasma is suspected). Tissue concentrations of tylosin may last for three hours following an hour of nebulization in quail and pigeons. High therapeutic index (see Chapter 17).

VERCURONIUM BROMIDE
Available as an injectable solution. Used topically to induce mydriasis. Suggested dose in raptors is 4 mg/ml every 5 min x 3 (see Chapter 26).

VITAMINS, MULTIPLE - Injacom (Hoffman LaRoche)
A mixture of vitamins A, D, and E, in an aqueous emulsion for IM or SC injection. Indicated in the treatment of Vitamin A and D_3 deficiencies, bone healing, egg binding and other reproductive or debilitating diseases. Should be used with caution in species that appear to have problems with Vitamin D_3 and calcium metabolism including macaws and African Grey Parrots. Must be used with caution in birds on formulated (heavily fortified) diets.

VITAMINS, MULTIPLE - Injacom + B (Hoffman LaRoche)
A mixture of vitamins A, D_3, E, and B available in an aqueous emulsion for IM or SC injection. Indicated in the treatment of Vitamin A and D_3 deficiencies, bone healing, egg binding and other reproductive or debilitating diseases. Should be used with caution in species that appear to have problems with Vitamin D_3 and calcium metabolism including macaws and African Grey Parrots. Must be used with caution in birds on formulated (heavily fortified) diets.

VITAMIN B COMPLEX - (Butler; Lextron; Vedco)
Available in injectable solution for IM administration. Indicated for cases of neuromuscular disease, debilitating illness of the liver, kidney and gastrointestinal tract, and anemia. Overdosing may cause an anaphylactic reaction.

VITAMIN E AND SELENIUM - Seletoc (Schering)
Available as an injectable solution (1 mg Se and 50 mg vit E/ml) for IM or SC administration. Used in cases of neuromuscular disease. May be helpful in some cockatiels with jaw, eyelid and tongue paralysis. Can be given before or shortly after stressful event (capture) to reduce the chances of capture myopathy in long-legged birds. Selenium can cause toxicity if administered in high doses.

VITAMIN K_1 - (Butler; Phoenix; Vet-A-Mix; Vedco)
Available as injectable solution (10 mg/ml) for IM or SC administration or as tablets (25 mg) for oral administration. May be effective in cases of severe and pathologic hemorrhage. Can also be used to offset the effects of drugs that cause hemorrhage (eg, sulfas, amprolium).

YEAST CELL DERIVATIVES - Preparation H (Whitehall Laboratories)
Stimulate epithelialization. Used to treat wounds that are not healing. Can be used in the eye.

TABLE 18.1 Conversions and Formulas for Drug Dose Calculations

mg/g X wt divided by mg/ml = dose in ml
(wt in g/1000) X (mg/kg) divided by mg/ml = dose in ml
1 ppm (dry weight) = 1 mg/kg
1 ppm (liquid) = 100 μg/dl
1 oz (dry) = 28.35 g
1 oz (liquid) = 29.5 ml
1 lb = 454 g
1% = 10 mg/ml
16 oz = 480 ml = 1 pint
1 cup = 8 oz = 237 ml
1 TBS = 15 ml
1 tsp = 5 cc
1 oz = 30 ml
1 ml = 1 cc

TABLE 18.2 Therapeutic Agents

DRUG	SPECIES	ROUTE	DOSAGE
Acetylsalicylic acid	Most	Oral	1 tablet in 250 mls of water; see formulary
ACTH	Pigeon	IM	50-125 μg
Activated charcoal	Most	Oral	2-8 g/kg as needed
Acyclovir	Most	Oral	80 mg/kg TID, up to 240 mg/kg of food
Allopurinol	Budgerigar	Oral (water)	See formulary
Aloe vera	Most	Topical	0.5 ounce/pint of water, use as spray
Amikacin*	Most	IV, IM, SC	10-15 mg/kg BID or TID
Aminopentamide Hydrogen Sulfate	Most	IM, SC	0.05 mg/kg q 12 hrs - 5 doses maximum
Aminolid	Raptors	IM	0.25-0.75 mg/kg, repeat 10-14 days
Amitryptyline HCl	Psittaciformes	Oral	1-2 mg/kg SID to BID
Ammonium solution	Most	Topical	See formulary
Amoxicillin	Most Pigeons Pigeons	Oral IM Oral	150-175 mg/kg SID or BID 150 mg/kg every 4 hrs 150 mg/kg QID
Amphotericin B	Raptors, Psittacformes Raptors, Psittaciformes Raptors, Psittaciformes Most	IV Intratracheal Nebulize Topical	1.5 mg/kg BID to TID 1 mg/kg BID to TID 1 mg/ml saline (15 min BID) BID
Ampicillin*	Pigeons Pigeons Psittaciformes Psittaciformes Galliformes	IM Oral Oral IM Oral (drinking water)	150 mg/kg every 2 hrs 150 mg/kg QID 100-200 mg/kg TID to QID 100 mg/kg every 4 hrs 250 mg/8 ounces of water
Amprolium	Most	Water	2-4 ml/gallon for 5 days
Ascorbic acid (vitamin C)	Most	IM	20-40 mg/kg, daily to weekly
Atropine	Most	IM, SC	0.01-0.02 mg/kg as needed; see formulary
Avipro	Psittaciformes	Oral	4 g/200 mls of water
Azithromycin	Most	Oral	See formulary
Butorphanol tartrate	Psittaciformes	IV, oral	See formulary; 3-4 mg/kg
Calcium gluconate	Most Most Most Most	Water IM, SC IV Feed	1 ml/30 mls of water to effect 5-10 mg/kg, BID as needed 50-100 mg/kg, slowly to effect 1/8 tsp/kg feed, as needed
Calcium disodium versonate (CaEDTA)	Most	IM	20-40 mg/kg BID-TID
Caprillic acid	Most	Oral	1/4 capsule/300 g
Carbaryl	Most	Topical	See formulary
Carnidazole	Pigeons	Oral	Adults 200 mg/kg once Newly weaned 100 mg/kg once
Cefotaxime*	Most	IM, IV	75-100 mg/kg TID, QID; see text
Cefoxitin*	Most	IM, IV	See formulary
Ceftriaxone	Most	IM, IV	75-100 mg/kg TID, QID or every 4 hrs; see formulary
Cephalexin*	Most Pigeons, Cranes, Emus	Oral Oral	35-50 mg/kg QID to every 4 hrs 100 mg/kg QID to every 4 hrs
Cephalothin*	Most	IM, IV	100 mg/kg QID
Cephradine	Most	Oral	See cephalexin
Chloramphenicol*	Pigeons Most Psittaciformes Galliformes	Oral (with grit) Oral (without grit) IM IV, IM Oral	95 mg/kg QID 30 mg/kg QID 80 mg/kg BID or TID 50 mg/kg TID or QID 50 mg/kg TID or QID
Chlorhexidine	Most Most Finches	Oral Topical Oral	10-30 ml/gallon O.5% as wound lavage Very sensitive, toxic, may not drink
Chlorine	Most	Oral, topical	See formulary

DRUG	SPECIES	ROUTE	DOSAGE
Chloroquine phosphate	Penguin	Oral	10 mg/kg once, then 5 mg/kg at 6, 18, 24 hrs
Chlortetracycline	Psittaciformes	Oral	See formulary and Chapter 34
Chlorsulon	Psittaciformes	Oral	20 mg/kg, 3 times, two weeks apart
Cimetidine	Psittaciformes	Oral	300 mg/5cc
Ciprofloxacin	Most (see enrofloxacin)	Oral	20-40 mg/kg BID
Clazuril	Pigeons	Oral	1 tablet/pigeon
Clindamycin*	Pigeons	Oral	100 mg/kg SID
Clomipramine HCl	Psittaciformes	Oral	0.5-1 mg/kg SID or BID
Colchicine	Psittaciformes	Oral	0.04 mg/kg/day, BID
Copper Sulfate	Most	Topical	As needed
Cyanocobalamin (vitamin B_{12})	Most	IM	250-500 μg/kg once/week
Dexamethasone	Most Raptors	IM, IV IM, IV	2 mg/kg SID or BID 1 mg/kg
Dextrose - 50%	Most	IV	50-100 mg/kg, slowly
Diazepam	Most Psittaciformes	IM, IV Oral	0.5-1 mg/kg BID, TID 2.5-4 mg/kg as needed
Diethylstilbestrol	Most	IM Oral	0.1-0.3 ml/kg 1 drop/30 mls of water
Digoxin	Conures, parakeets	Oral	0.02-0.05 mg/kg SID
Dimercaprol (BAL)	Most	Oral	25-35 mg/kg BID 5 days per week for 3-5 weeks
Dimethylsulfoxide	Most	Topical	1 ml/kg, BID as needed for swelling
Dimetridazole	Budgerigars Most Lories, mynahs	Oral (gavage) Oral (drinking water) Oral (drinking water)	Stock solution: 1 tsp/pint of water Dose: 0.5 ml/30 g repeat at 12 and 24 hrs 1 tsp/gallon 0.5 tsp/gallon
Dinoprost tromethamine	Most	Intracloacal, IM	0.02-0.1 mg/kg once
Diphenhydramine HCl	Psittaciformes	Oral	0.5 tsp/8 ozs water or 2-4 mg/kg BID
Doxapram	Most	IM, IV	5-10 mg/kg once
Doxepin HCl	Psittaciformes	Oral	0.5-1 mg/kg BID
Doxycycline*	Pigeons Pigeons Pigeons Cockatiels, Amazons, African Greys, cockatoos Macaws Other Psittaciformes	IM Oral (with grit) Oral (without grit) Oral Oral IM (Vibravenös) IV	10 mg/kg QID 7.5 mg/kg QID 25 mg/kg BID 150 mg/kg SID 3 mg/kg QID 7.5 mg/kg BID 25 mg/kg SID 40-50 mg/kg SID or BID 25 mg/kg SID or BID 75-100 mg/kg every 5-7 days 25-50 mg/kg; see formulary
D-penicillamine	Most	Oral	52 mg/kg BID
D-tubocurarine	Raptors	Ophthalmic	Every 5 min x 3
Echinacea	Psittaciformes	Oral Water	2.5 drops/kg 5 drops/cup of drinking water
EDTA-TRIS	Most	See formulary	See formulary
Enilconazole	See formulary		
Enrofloxacin*	Greys, Amazons Cockatoos Pigeons Psittaciformes	IM, Oral IM, Oral, SC Oral Oral (food)	7.5-15 mg/kg SID to BID 5 mg/kg BID 15 mg/kg BID 250-1000 ppm; see Chapter 34
Epinephrine	Most	IV, IO, IT, IC	0.1 mg/kg
Ergonovine maleate	Most	IM	0.06 mg/kg, once
Erythromycin	Most Most Psittaciformes	Oral (Powder) Nebulize injectable Oral (Suspension)	500 mg/gallon of drinking water 1 ml/10 ml saline 15 min TID 10-20 mg/kg BID
Ethambutol	Most	Oral	15 mg/kg BID

table continued on next page

DRUG	SPECIES	ROUTE	DOSAGE
Fenbendazole	Anseriformes Most	Oral Oral	5-15 mg/kg daily for 5 days For ascarids 20-50 mg/kg - repeat 10 days For flukes 20-50 mg/kg SID for 3 days For capillaria 20-50 mg/kg SID for 5 days
Ferric subsulfate	Most	Topical	As needed for hemorrhage
Fluconazole	Most	Oral	2-5 mg/kg SID, 7 days
Flucytosine	Most Raptors Psittaciformes, mynahs	Oral (gavage) Oral (gavage) Oral (feed)	20-50 mg/kg BID for 21 days 20-30 mg/kg QID 250-550 mg/kg of feed
Flunixin-meglumine	Most	IM	1-10 mg/kg
Furosemide	Most (see text)	IM, SC	0.15-2 mg/kg, SID-BID
Gentamicin*	Most	Ophthalmic solution intra-nasally	Several drops/nostril TID
Gentian Violet	Psittaciformes	Oral (feed), topical	0.5-1.0 g/kg of feed
Haloperidol	Psittaciformes	IM Oral	1-2 mg/kg every 2-3 weeks 0.2 mg/kg BID for birds < 1 kg 0.15 mg/kg SID-BID for birds > 1 kg; see formulary
Haloxon	Pigeons	See formulary	See formulary
Immunoregulin	Most	See formulary	See formulary
Iodine	Budgerigars	Water, IM	See formulary
Ipronidazole	Most Psittaciformes	Water Oral	500 mg/gallon for 7-21 days 0.25 tsp/gallon
Iron dextran	Most	IM	10 mg/kg, repeat in 7-10 days if needed
Isoniazid	Most	Oral	15 mg/kg BID
Itraconazole	Penguins, waterfowl Psittaciformes	Oral	5-10 mg/kg BID
Ivermectin	Most	IM, oral, topical	200 μg/kg, repeat 10-14 days
Ketoconazole*	Most Most Most	Oral (gavage) Oral (water) Oral (feed)	20-30 mg/kg BID for 21 days 200 mg/l 10-20 mg/kg
Lactated Ringer's solution	All	IV	See formulary
Lactobacillus	Psittaciformes	Oral	1 pinch/day/bird 1 tsp/ quart of hand-feeding formula
Lactulose	Most	Oral	0.3 ml/kg
Levamisole	Anseriformes Australian parakeets Most Most	Oral (gavage) Oral (gavage) Oral (drinking water) IM, SC	20-50 mg/kg 15 mg/kg, repeat 10 days 5-15 ml/gallon, 1 to 3 days 5 mg/kg, repeat 10-14 days
Levothyroxine	Most	Oral	20 μg/kg SID to BID; see formulary
Lincomycin	Budgerigar Amazon parrots Raptors Most	Oral Oral Oral Water	1 drop BID 75 mg/kg BID 100 mg/kg SID 1/8 - 1/4 tsp/pint of water
Leuprolide	Psittaciformes	IM	See formulary
Lorelco	Psittaciformes	Oral	0.25 tsp/day for 2-4 months
Mannitol	Most	IV	0.5 mg/kg slowly SID
Mebendazole	Anseriformes Raptors, Psittaciformes	Oral Oral	5-15 mg/kg daily for 2 days 25 mg/kg BID for 5 days
Medroxyprogesterone acetate	Pigeons Most	Oral (feed) IM, SC	0.1% of ration, continuous 5-25 mg/kg, every 4 to 6 weeks; see formulary
Methylprednisolone acetate	Most	IM	0.5-1 mg/kg
Metoclopramide	Most	IM, IV, oral	0.5 mg/kg
Metronidazole	Psittaciformes	Oral IM	10-30 mg/kg, BID for 10 days 10 mg/kg SID for 2 days
Miconazole	Psittaciformes	IV, topical	20 mg/kg TID
Mineral oil	Most	Oral	6-10 ml/kg, repeated as needed

DRUG	SPECIES	ROUTE	DOSAGE
Monensin	Galliformes, cranes	Oral (feed)	90 g/ton of feed
Morphine	Galliformes	IM, SC	2.5-3 mg/kg
Naloxone	Most	IV	2 mg 14-21 hours
Natamycin	Most	Ophthalmic	1 drop QID; after 14-21 days, taper off
Neomycin	Most	Water	1-8 drops/oz water; 5 g/gallon
Neomycin ointment	All	Topical	BID to QID as needed
Niclosamide	Most Finches, see text	Gavage Gavage	50 mg/kg, repeat 10-14 days 500 mg/kg, weekly for 4 weeks
Nitrofurazone	Most Psittaciformes Lories, Lorikeets, Passeriformes	Water Water	1 tsp/gallon of water 0.5 tsp/gallon water
Nortriptyline HCl	Psittaciformes	Oral	1 ml/4 oz drinking water
Nystatin	Most Most	Oral (gavage) Oral (feed)	1 ml/300 g BID to TID, 7 days
Oxytetracycline*	Pheasants Owls Psittaciformes Cockatoos	IM IM IM IM, SC	43 mg/kg, every 24 hrs 16 mg/kg, every 24 hrs 58 mg/kg, every 24 hrs 50-100 mg/kg, every 2-3 days
Oxytocin	Most	IM	0.01-0.1 ml, once
2-PAM	Most	IM	10-30 mg/kg SID
Pancreatic enzymes	Most	Oral (feed)	1/8 tsp/kg; see formulary
Phenobarbital	Most	Oral	1-5 mg/kg BID
Phenylbutazone	Psittaciformes Raptors	Oral	3.5-7 mg/kg BID to TID 20 mg/kg TID
Piperacillin*	Most Amazon parrots	IM, IV IM	100-200 mg/kg TID to QID 75-100 mg/kg QID to every 4 hrs
Piperazine	Galliformes Anseriformes	Oral	100-500 mg/kg; repeat 10-14 days 45-200 mg/kg
Potassium chloride	Most	IV	0.1-0.3 mg/kg
Praziquantel	Most	Oral IM	10-20 mg/kg; repeat 10-14 days 9 mg/kg (flukes: SID for 3 days then oral for 11 days; tapeworms: once, then repeat in 10 days)
Prednisolone	Most	IM or IV	0.5-1 mg/kg once (anti-inflammatory) 2-4 mg/kg (immunosuppressive)
Primaquine	Penguins	Oral	0.03 mg/kg, SID for 3 days
Procaine penicillin G	Galliformes	IM	100 mg/kg SID every 2 days
Propranolol	Most	IM IV	0.2 mg/kg 0.04 mg/kg slowly
Pyrantel pamoate	Most	Oral	4.5 mg/kg, repeat 10-14 days
Pyrethrins	Most	Topical	See formulary
Pyrimethamine	Most	Oral	0.5 mg/kg BID
Quinacrine	Psittaciformes	Oral	5-10 mg/kg, SID for 7 days
Rifampin	Most	Oral	10-20 mg/kg BID
Sodium bicarbonate	Most	IV	1-4 mEq/kg slowly over 15-30 minutes - do not exceed 4 mEq/kg
Sodium sulfate	Large birds	Oral	2 g/kg, slurry for 2 days; see Chapter 37
STA solution	Most	Topical	As needed
Stanozolol	Most	IM	25 to 50 mg/kg, 1 to 2 times weekly
Streptomycin	Most larger birds	IM	10-30 mg/kg BID or TID
Sucralfate	Psittaciformes	Oral	25 mg/kg TID
Sulfachlorpyridazine	Most	Water	0.25 - 1 tsp/gallon
Testosterone	Most	IM	8 mg/kg, weekly as needed
Tetracycline	Most	Water Oral	0.25 - 1 tsp/gallon 200-250 mg/kg BID

table continued on next page

DRUG	SPECIES	ROUTE	DOSAGE
Thiabendazole	Most	Oral	For ascarids; 250-500 mg/kg, repeat 10-14 days For *Syngamus*; 100 mg/kg, SID for 7 to 10 days
Thiamine	Raptors, penguins, cranes	Oral	1-2 mg/kg, daily
Ticarcillin	Most	IM, IV	150-200 mg/kg TID or QID
Tobramycin	Pheasants, cranes, Psittaciformes	IM	2.5-5 mg/kg BID
Trimethoprim and Sulfamethoxazole*	Psittaciformes Toucans, mynahs Psittaciformes	Oral Oral (for coccidia) IM	16-24 mg/kg BID or TID 25 mg/kg SID 8 mg/kg BID
TSH	Psittaciformes	IM	1-2 IU/kg; see Chapter 23
Tylosin*	Most Quail, pigeons, emus Cranes Most Cockatiels, Psittaciformes Most	IM IM IM Water Eye spray Nebulization	10-40 mg/kg TID or QID 15-25 mg/kg TID or QID 15 mg/kg TID or QID 2 tsp/gallon BID or TID (see formulary) One hour BID (see formulary)
Vitamin A, D_3, E (Injacom 100)	Most	IM	0.1-0.2 ml/300 g, weekly as needed
Vitamin B complex	Most	IM	1-3 mg thiamine/kg, weekly
Vitamin B complex (Methiscol)	Most	Oral	1-2 g/kg food, daily
Vitamin E/Selenium (Seletoc)	Most	IM	0.05 to 0.1 mg/kg, every 14 days
Vitamin K_1	Most	IM	0.2-2.5 mg/kg, as needed
Yeast cell derivatives	Most	Topical	See formulary

* Pharmacological data are available to support doses in avian species other than poultry.

Brand Names and Nonproprietary Names (brand names in italics)

Acetylcysteine - *Mucomyst*
Acetylsalicylic acid - *Aspirin*
ACTH - *Adrenal Corticotrophic Hormone*
Activated charcoal/kaolin - *Toxiban*
Acyclovir - *Zovirax*
Adrenal Corticotrophic Hormone - **ACTH**
Allopurinol - *Zyloprim*
Ambi pen - **Procaine Pen. G and Pen. Benzathine**
Amiglyde - **Amikacin Sulfate**
Amikacin Sulfate - *Amiglyde*
Amitriptyline HCl - *Elavil*
Ammonium Solution - *Penetran*
Amoxi-drops - **Amoxicillin**
Amoxi-Inject - **Amoxicillin**
Amoxicillin - *Amoxi-drops, Amoxi-Inject*
Amphotericin B - *Fungizone*
Ampicillin - *Polyflex*
Amprolium - *Corid*
Anafranil - **Clomipramine HCl**
Ancobon - **Flucytosine**
Antirobe - **Clindamycin**
Appertex - **Clazuril**
Aralen Phosphate - **Chloroquine Phosphate**
Ascorbic Acid - *Vitamin C*
Aspirin - **Acetylsalicylic acid**
Atabrine - **Quinacrine HCl**
Aventyl HCl - **Nortriptyline HCl**
Azimycin - **Dihydrostreptomycin**
Azithromycin - **Zythromax**
Azium - **Dexamethasone**
Bactrim -**Trimethoprim/Sulfadiazine**
BAL - **Dimercarprol**
Banamine - **Flunixin Meglumine**
Baytril - **Enrofloxacin**
Benadryl - **Diphenhydramine HCl**
Bismuth subsulicylate - *Pepto-Bismol*
Biosol - **Neomycin**
Butazolidin - **Phenylbutazone**
Butorphanol Tartrate - *Torbutrol, Torbugesic*
Calcium EDTA - **Calcium Disodium Versenate**
Calcium Disodium Versenate - *Calcium EDTA*
Caprillic Acid - *Kaprycidin A*
Carafate - **Sucralfate**
Carbaryl - *Sevin*
Cardindazole - *Spartix*
Cardoxin - **Digoxin**
Cart Sol - **Prednisolone Sodium Succinate**
Caustic Powder - **Copper Sulfate**
Cefotaxime - *Claforan*
Cefoxitin - *Mefoxitin*
Ceftriaxone - *Rocephin*
Cephalexin - *Keflex Pediatric Suspension*
Cephalothin - *Keflin*
Cephrandine - *Veloself*
Cephulac - **Lactulose**
Cheque - **Mibolerone**
Chlorhexidine - *Nolvasan*
Chlorine - *Household Bleach*
Chloroquine Phosphate - *Aralen Phosphate*
Chlorsulon - *Curatrem*
Chlortetracycline - *CTC*
Cimetidine - *Tagamet*
Clindamycin - *Antirobe*
Cipro - **Ciprofloxacin**
Ciprofloxacin - *Cipro*
Claforan - **Cefotaxime**
Clazuril - *Appertex*
Clinafarm - **Enilconazole**
Clomipramine HCl - *Anafranil*
Coban - **Monensin Sodium**
Copper Sulfate - *Caustic Powder*
Corid - **Amprolium**
CTC - **Chlortetracycline**
Cuprimine - **D-Penicillamine**
Curatrem - **Chlorsulon**
Cyanocobalamin - *Vitamin B_{12}*
D-Penicillamine - *Cuprimine*
Daraprim - **Pyrimethamine**
Depo-Medrol - **Methylprednisolone Acetate**
Dermathycin - **TSH**
Dexamethasone - *Azium*
Diazepam - *Valium*
Diethylstilbestrol Diphosphate - *Stilphostrol*
Diflucan - **Fluconazole**
Digoxin - *Cardoxin, Lanoxin*
Dihydrostreptomycin - *Azimycin*
Dimercarprol - *BAL*
Dimethylsulfoxide - *Domoso*
Dimetridazole - *Emtryl*
Dinoprost Tromethamine - *Lutalyse*

Diphenhydramine HCl - *Benadryl*
Domoso - **Dimethylsulfoxide**
Donnatal - **Phenobarbital**
Dopram - **Doxapram HCl**
Doxapram HCl - *Dopram*
Doxepin HCl - *Sinequan*
Droncit - **Praziquantel**
Echinacea - *Echinacea angustifolia*
Echinacea angustifolia - **Echinacea**
EDTA - *TRIS*
Elavil - **Amitriptyline HCl**
Emtryl - **Dimetridazole**
Enhaptin - **Nitrothiazole**
Enilconazole - *Clinafarm*
Enrofloxacin - *Baytril*
Enzymes - see pancreatic enzymes
Equizole - **Thiabendazole**
Eqvalen - **Ivermectin**
Ergonovine Maleate - *Ergotrate maleate*
Ergotrate maleate - **Ergonovine Maleate**
Ethambutol - *Myambutol*
Fenbendazole - *Panacur*
Ferric Sulfate - *Monsel's Solution*
Flagyl - **Metronidazole**
Fluconazole - *Diflucan*
Flucytosine - *Ancobon*
Flunixin - *Banamine*
Fungizone - **Amphotericin B**
Furacin - **Nitrofurazone**
Furosemide - *Lasix*
Gentian Violet - *GV-11*
GoLYTELY - **Sodium Sulfate**
GV-11 - **Gentian Violet**
Halodol - **Haloperidol**
Haloperidol - *Halodol*
Hemicellulose - *Psyllium*
Hi-Vegi-Lip - **Pancreatic Enzymes**
Inderol - **Propranolol**
Injacom + B - **Vitamins, Multiple**
Iodine - *Lugol's Solution, Renografin 76*
Ipronidazole - *Ipropan*
Ipropan - **Ipronidazole**
Itraconazole - *Sporanox*
Ivermectin - *Eqvalen*
Kaprycidin A - **Caprillic Acid**
Keflex Pediatric Suspension - **Cephalexin**
Keflin - **Cephalothin**
Ketoconazole - *Nizoral*
L-Spartakon - **Levamisole**
Lactobacillus - *Probiocin*
Lactulose - *Cephulac*
Lanoxin - **Digoxin**
Lasix - **Furosemide**
Leuprolide - *Lupron*
Levamisole - *Levasole, Tramisol, L-Spartakon*
Levasole - **Levamisole**
Levothyroxine Sodium - *Thyroxine L*
Lincocin - **Lincomycin HCl**
Lincomycin HCl - *Lincocin*
Liquamycin LA200 - **Oxytetracycline**
Lorelco - *Probacoll*
Lugol's Solution - **Iodine**
Lupron - **Leuprolide**
Lutalyse - **Dinoprost Tromethamine**
Mebendazole - *Telmintic, Telmin*
Mefoxitin - **Cefoxitin**
Meglumine - *Banamine*
Methylprednisolone Acetate - *Depo-Medrol*
Metoclopramide HCl - *Reglan*
Metronidazole - *Flagyl*
Mibolerone - *Cheque*
Miconazole - *Monistat*
Monensin Sodium - *Coban*
Monistat - **Miconazole**
Monsel's Solution - **Ferric Sulfate**
Mucomyst - **Acetylcysteine**
Myambutol - **Ethambutol**
Mycostatin - **Nystatin**
Natacyn - **Natamycin**
Natamycin - *Natacyn*
Nebicin -**Tobramycin**
Neomycin - *Biosol*
Niclosamide - *Nicloside*
Nicloside - **Niclosamide**
Nitrofurazone - *Furacin*
Nitrothiazole - *Enhaptin*
Nizoral - **Ketoconazole**
Nolvasan - **Chlorhexidine**
Nortriptyline HCl - *Aventyl HCl*
Nystatin - *Mycostatin*
Oxfenbendazole - *Synanthic*
Oxytetracycline - *Liquamycin LA200*
Panacur - **Fenbendazole**
Pancreatic Enzymes - *Hi-Vegi-Lip, Viokase V*
Penetran - **Ammonium Solution**
Pepto-Bismol - **Bismuth subsalicylate**
Phenobarbital - *Donnatal*
Phenylbutazone - *Butazolidin*
Pipercillin - *Pipracil*
Pipracil - **Pipercillin**
Polyflex - **Ampicillin**
Praziquantel - *Droncit*
Prednisolone Sodium Succinate - *Cart Sol*
Preparation H - **Yeast Cell Derivatives**
Probacoll - **Lorelco**
Probiocin - **Lactobacillus**
Procaine Penicillin G and Penicillin Benzathine - *Ambi pen*
Propranolol - *Inderol*
Psyllium - **Hemicellulose**
Pyrantel Pamoate - *Strongid T*
Pyrimethamine - *Daraprim*
Quinacrine HCl - *Atabrine*
Reglan - **Metoclopramide HCl**
Renografin 76 - **Iodine**
Rifadin - **Rifampin**
Rifampin - *Rifadin*
Rocephin - **Ceftriaxone**
Seletoc - **Vitamin E and Selenium**
Sevin - **Carbaryl**
Sinequan - **Doxepin HCl**
Sodium Sulfate - *GoLYTELY*
Spartix - **Cardindazole**
Spectam - **Spectinomycin**
Spectinomycin - *Spectam*
Sporanox - **Itraconazole**
Stanozolol - *Winstrol V*
Stilphostrol - **Diethylstilbestrol Diphosphate**
Strongid T - **Pyrantel Pamoate**
Sucralfate - *Carafate*
Sulfachlorpyridazine - *Vestisulid*
Synanthic - **Oxfenbendazole**
Tagamet - **Cimetidine**
Telmin - **Mebendazole**
Telmintic - **Mebendazole**
Thiabendazole - *Equizole*
Thiamine - *Vitamin B_1*
Thyroxine L - **Levothyroxine Sodium**
Ticar - **Ticarcillin**
Ticarcillin - *Ticar*
Tobramycin - *Nebicin*
Torbutrol - **Butorphanol tartrate**
Torbugesic - **Butorphanol tartrate**
Toxiban - **Activated charcoal/kaolin**
Tramisol - **Levamisole**
Trimethoprim/Sulfadiazine - *Bactrim*
TRIS - **EDTA**
TSH - *Dermathycin*
Valium - **Diazepam**
Veloself - **Cephrandine**
Vestisulid - **Sulfachlorpyridazine**
Viokase V - **Pancreatic Enzymes**
Vitamin B_{12} - **Cyanocobalamin**
Vitamin E and Selenium - *Seletoc*
Vitamin C -**Ascorbic Acid**
Vitamin B_1 - **Thiamine**
Vitamins, Multiple - *Injacom + B*
Winstrol V - **Stanozolol**
Yeast Cell Derivatives - *Preparation H*
Zovirax - **Acyclovir**
Zyloprim - **Allopurinol**
Zythromax - **Azithromycin**

175.0													
200.0									0.02		0.01		0.008

The quantity of drug to administer for agents listed in Table 18.1 can be quickly and easily calculated by knowing the bird's weight in grams, the drug concentration and the drug dose. A bird's weight in grams is multiplied by the factor that corresponds to a drug's concentration and its respective dose. For example, the dose for enrofloxacin administered orally is 15 mg/kg. This drug is available in an injectable solution (23 mg/ml) that can be administered orally. The factor that corresponds to 23 mg/ml and 15 mg/kg is 0.00065. The drug dose for a 100 gram bird would be 0.00065 X 100 = 0.065 mls. The drug dose for a 600 gram bird would be 0.00065 X 600 = 0.39 mls.

DRUG DOSING CHART

Drug Dose (mg/kg)	Drug Concentration (mg/ml or mg/unit)										
	30.0	40.0	50.0	75.0	85.0	100.0	104.0	150.0	200.0	250.0	400.0

19

GASTRO-ENTEROLOGY

J. T. Lumeij

Diseases of the alimentary tract occur frequently in birds. Nonspecific clinical signs of gastrointestinal diseases may include anorexia, dysphagia, regurgitation, vomiting, constipation, diarrhea and tenesmus. With polyuria, the feces are normal and are surrounded by a large volume of clear fluid, while with diarrhea the feces are abnormal (see Color 8). The composition and quality of food and ingestion of bedding material, poisonous plants or chemicals may influence gastrointestinal signs. Weight loss and generalized weakness are characteristic of chronic diseases.

Fecal evaluation, hematology, blood chemistry, radiology and esophago-ingluvio-(gastro)scopy or laparoscopy are considered indispensable diagnostic tools in avian gastroenterology. Diseases that may affect the gastrointestinal system are listed in Table 19.1.

Cytologic examination of a fresh ingluvial aspirate is best for detecting flagellates (*Trichomonas* spp.). Examination of freshly voided feces is essential to detect *Histomonas meleagridis, Hexamita* spp., *Giardia intestinalis, Cochlosoma* sp. and *Chilomastix gallinarum*. Direct microscopic examination of feces may reveal helminthic ova and protozoal oocysts. Flotation and sedimentation techniques are best for detecting the low number of eggs or oocysts that occur in an early parasitic infection (see Chapter 36). Parasites infecting the liver, kidney, uterus and pancreas can deposit ova or oocysts that can be detected in the feces. Parasite ova originating from the respiratory tract may be coughed up, swallowed and found in the excrement.[28,78]

TABLE 19.1 Differential Diagnosis of Clinical Signs Associated with the Gastrointestinal Tract

Regurgitation or Vomiting in Adults

- Iatrogenic - apomorphine, levamisole, trimethoprim/sulfadiazine (macaws), ketoconazole, doxycycline suspension (particularly macaws and Amazons)
- Fear and excitement (vultures, pelicans, penguins)
- Courtship behavior (male psittacines)
- Crop milk feeding in pigeons
- Physiological cast formation - (raptors)
- Goiter (particularly budgerigars)
- Callus formation after coracoid fracture
- Neuropathic gastric dilatation (NGD)
- Food allergies
- Motion sickness
- Viral diseases - looping ill virus, Pacheco's disease virus, pigeon herpesvirus, avian polyomavirus, avian viral serositis (togavirus), poxvirus (diphtheritic form)
- Bacterial diseases - megabacterial infection, most Enterobacteriaceae, Pasteurella, Serratia
- Mycotic diseases - candidiasis, aspergillosis
- Helminths (oropharynx/ingluvies/esophagus) - capillariasis, serratospiciliasis
- Protozoal disease - trichomoniasis of upper digestive tract, Plasmodium (penguins, gyrfalcon)
- Poisoning - alcohol, arsenic, copper, lead, organochlorine (lindane), organophosphate, carbamate, organomercurial, rotenone, phosphorus, polytetrafluoroethylene (Teflon), sodium chloride, thallium, zinc
- Plants - Yew (Taxus baccata), Philodendron spp., Rhododendron spp. (azalea), Solanaceae (green berries and roots)
- Obstructed alimentary tract - stricture, foreign body, neoplasia, intussusception, volvulus, hernia, stenosis, parasites, impaction, paralytic ileus
- Organopathy - renal disease, hepatopathy, pancreatitis, peritonitis, egg binding, electrolyte disturbances

Regurgitation in Neonatal Psittacines (Sour Crop)

- Overgrowth of bacteria or yeast (improper food storage)
- Overheated formula
- Underheated formula
- Crop burns
- Foreign body ingestion (eg, substrates)
- Improper formula consistency
- Over-stretching the crop
- Aerophagia
- Fear and excitement
- Infectious agents
  - Avian polyomavirus
  - Avian viral serositis
  - Candida spp.
  - Gas-producing bacteria

Diarrhea[28,78]

- Use of antibiotics
- Dietary changes
- Bowel obstruction
- Toxins
- Obstruction
- Foreign bodies
- Organopathy - hepatopathy, renal disease, pancreatitis
- Viral diseases - Newcastle disease virus, paramyxovirus type 3, influenza, adenovirus, astrovirus, calicivirus, coronavirus, enterovirus, Pacheco's disease virus, pigeon herpesvirus, duck virus enteritis, herpesvirus (Ciconiidae), herpesvirus (gruiformes), Marek's disease virus, orthoreovirus, parvovirus, reovirus, rotavirus, togavirus-like agent, retrovirus (leukosis/sarcoma group)
- Bacterial diseases - borreliosis, spirochaetosis, most Enterobacteriaceae, Campylobacter spp., Streptococcus spp., Erysipelothrix rhusiopathiae, Listeria monocytogenes, megabacteria, Clostridium spp., Mycobacterium avium, Yersinia pseudotuberculosis, Aeromonas hydrophila, Pasteurella multocida, Pasteurella anatipestifer (new duck disease)
- Chlamydia
- Mycoplasma
- Candida albicans
- Protozoa - Histomonas meleagridis, Hexamita spp., Giardia spp,, Cochlosoma sp., Chilomastix gallinarum, coccidiosis
- Helminths - nematodes, trematodes, cestodes

Hematochezia

- Cloacal papillomas
- Egg laying
- Ulcers
- Hepatitis
- Infectious enteritis - bacterial, viral, parasitic
- Aflatoxicosis
- Coagulopathies
- Heavy metal intoxication
- Foreign bodies
- Cloacal neoplasias

Passing Undigested Food

- Gastric foreign body
- Gastrointestinal dysfunction
- Neuropathic gastric dilatation
- Enteritis - bacterial, viral, parasitic
- Pancreatitis
- Use of antibiotics
- Food allergies
- Hepatitis

Tenesmus

- Egg-laying problems (binding)
- Abdominal mass
- Goose venereal disease
- Cloacal pathology
- Prolapse
- Papilloma
- Stricture
- Cloacolith
- Cloacitis
- Intestinal obstruction (eg, constipation)
- Uterine prolapse
- Rectal prolapse
- Enteritis - diarrhea
- Bacteria
- Parasites
- Fungi
- Viruses
- Toxins
- Decreased bacteria (eg, indiscriminate antibiotic use)

Bacteriologic cultures of the gastrointestinal tract must be interpreted with respect to the normal flora.[78] Gram-positive microorganisms including lactobacilli, staphylococci, streptococci and *Bacillus* spp. are common in the oropharynx of healthy psittacine birds. *Mycoplasma* spp. and *Aspergillus* spp. are sometimes encountered.[168,176] Enterobacteriaceae are normally not found in the feces of Psittaciformes and Passeriformes, where gram-positive organisms, especially *Corynebacterium* sp. and *Bacillus* sp., predominate.[17] The isolation of a large number of Enterobacteriaceae in pure culture from Psittaciformes or Passeriformes is suggestive of a primary or secondary infection. *E. coli* and other Enterobacteriaceae are normal inhabitants of the gastrointestinal tract in Galliformes, Columbiformes, Falconiformes, Strigiformes and Corvidae.[140]

Routine bacteriologic examination of the feces may fail to reveal some important microbes that can cause diarrhea, including mycobacteria, campylobacter and chlamydia. A technique for identifying mycobacteria is described in Table 19.2. Detection of campylobacter can be augmented by the use of Hemacolor; the bacteria appear S-shaped or in gull-wing form. Chlamydia is best detected using an antigen capture system.[21,102]

TABLE 19.2 Detection of Acid-fast Bacteria in Feces[78]

- Combine 4 grams of feces and 12 ml of 15% sputofluol (Merck)
- Gently mix for 30 minutes
- Centrifuge for 5 minutes 10,000 rpm
- Make smear of sediment
- Stain with Ziehl-Neelsen

The Beak

Anatomy and Physiology

The avian beak is a continuously growing, dynamic structure composed of bone, vascular layers, keratin, dermis, joints and a germinative layer. In psittacine birds, the upper and lower jaws are connected to the skull via a kinetic joint. The keratinized sheath covering the upper and lower beaks is called rhamphotheca and can be divided into the rhinotheca (maxillary keratin) and the gnatotheca (mandibular keratin). The median dorsal border of the rhinotheca is called the culmen, and the median ventral border of the gnatotheca is called the gonys. The cutting edges of the rhamphotheca are called the tomia. The rhinotheca is perforated by the paired nostrils. Aviculturists classify caged birds into hardbills (eg, most psittacine birds) and softbills (eg, mynahs, starlings).

In ducks and parrots, the tip of the bill contains well developed mechanoreceptor nerve endings. The beak is used for prehension, for the physical preparation of food, and in some species such as parrots, for locomotion.[130]

The rate of keratin replacement is strongly dependent on the use of the beak. In large parrots, the complete rhinotheca is replaced in about six months, while in toucans the rhinotheca grows approximately 0.5 cm over a two-year period. The rate of growth of the gnatotheca is about two to three times faster than that of the rhinotheca.[38] Shedding and replacement of the rhinotheca has been described in capercaillie (annually)[4] and Suriname finches.

Beak Diseases

A variety of congenital and acquired defects, including scissor beak and mandibular prognathism, can interfere with normal beak function. In gallinaceous birds, a deformed upper mandible has been associated with embryonic deficiencies of folic acid, biotin or pantothenic acid. Crusty, scab-like lesions in the corners of the mouth are considered a definite sign of biotin or pantothenic acid deficiency in these birds.[5] Examples of acquired lesions that can lead to malformations or necrosis of the beak include punctures, lacerations, splits and avulsions. Traumatic fractures, especially of the mandible, occur frequently in psittacine birds that get caught in hooks suspended from the ceiling of their enclosures or as a result of fighting.

Any bacterial, mycotic, viral or parasitic pathogen that damages the germinative layers of the beak can cause developmental abnormalities.[108] Examples include *Candida albicans*, psittacine beak and feather disease virus, *Knemidokoptes* spp. in Psittaciformes or *Oxyspirura* spp. in cranes. Rhinothecal overgrowth in psittacines, especially budgerigars, has been associated with liver disease (Figure 19.1).[133] The rhinotheca may overgrow in hardbills maintained in an indoor environment and provided soft foods. "Rubber bill," caused by insufficient mineralization of the upper beak, has been described with

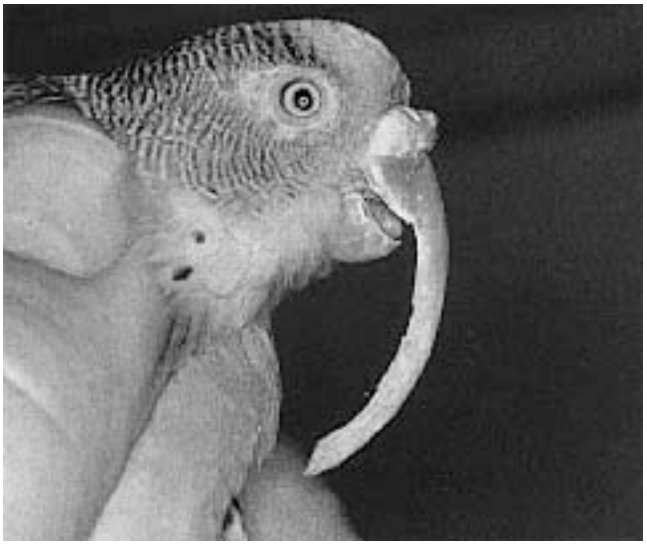

FIG 19.1 A two-year-old budgerigar, maintained on an all-seed diet in a strictly indoor environment, was presented for a beak trim. The bird was obese and was passing bile-tinged urates. This clinical presentation is suggestive of a hepatopathy.

FIG 19.2 An eight-year-old Umbrella Cockatoo was presented with a nine-month history of progressive sneezing and nasal discharge. The feathers around the beak were moist from a serous nasal discharge. The rhinotheca had a deep groove that extended from the nostril to the rostral commissure of the upper beak (arrows). The extent of this defect suggests that the germinative layer of the rhinotheca had been involved in a disease process for over six months. This bird belonged to a heavy smoker. A mixed population of gram-positive and gram-negative bacteria were cultured from a sinus aspirate. The bird responded to nasal flushing, systemic antibiotics, frequent exposure to fresh air and sunlight and being removed from a smoke-filled environment.

vitamin D and calcium deficiencies. Necrotic lesions at the commissure of the beak have been described with trichotecene mycotoxicosis, avian poxvirus and trichomoniasis (cockatiels).[137]

Beak deformation consisting of loss of normal epithelium on the surface of the beak, upturning of the tomia and shortening of the upper beak have been reported secondary to photosensitization in ducks following ingestion of seeds from *Ammi visnaga, A. majus* and the plant or seeds from *Cynopterus watsonii* and *C. longipes*.[152] Photosensitization has been suspected in many cases of vesicular dermatitis, but the precise etiologic agents are frequently undetermined.

Chronic rhinitis may lead to permanent defects in the adjoining germinative layer of the rhinotheca (Figure 19.2). Dysphagia, which may be recognized clinically as an accumulation of food under the tongue, can be an indication of rhamphothecal dysfunction.

The Oropharynx and Salivary Glands

Anatomy and Physiology[49,101]

Birds lack an oropharyngeal isthmus, and the oral and pharyngeal cavities are combined to form an oropharynx. The walls of the oropharynx contain numerous mucus-secreting salivary glands (Figure 19.3). The palate contains a median fissure called the choana, which connects the sinuses to the glottis. Just caudal to the choana is the infundibular cleft, which is the common opening of the auditory tubes. Tongue anatomy varies widely among avian species. Parrots have intrinsic muscles in the tongue, while other birds have only extrinsic tongue muscles. Swallowing involves a rapid rostrocaudal movement of the tongue and the larynx, assisted by sticky saliva and caudally directed papilla on the tongue, laryngeal mound and palate. During swallowing, the choana, infundibular cleft and glottis are closed. The salivary glands secrete mucus and, in some species, amylase. During the breeding season, the salivary gland of swifts temporarily enlarges to produce an adhesive liquid used in nest construction. The nests of some of the cave swiftlets of Southeast Asia are made entirely of this edible secretion (birds' nest soup). The Grey Jay produces large quantities of mucus that are formed into boluses and stored on the sides of trees as a winter food supply. The mucosa of the oral cavity

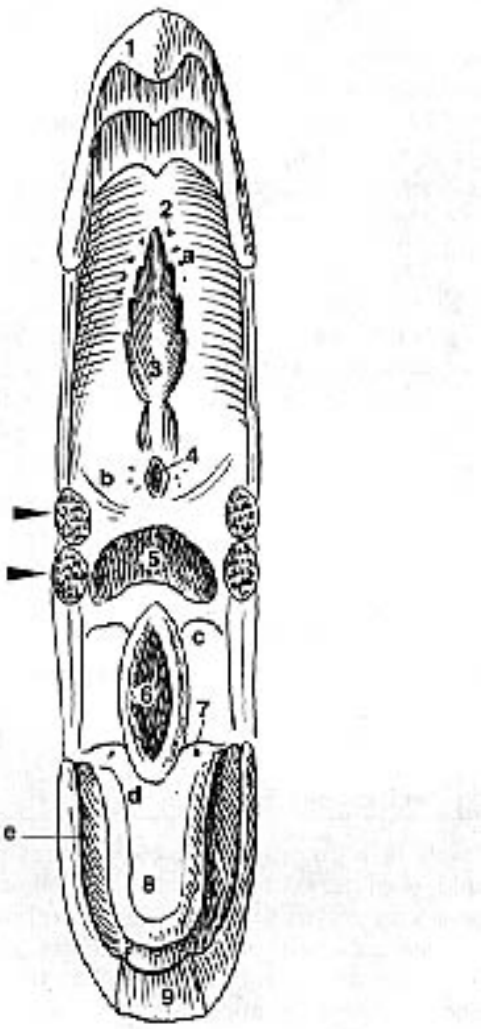

FIG 19.3 Anatomy of the oral cavity of an Umbrella Cockatoo. The depressor mandibulae muscles (arrows) have been transected bilaterally to allow the jaws to be opened, revealing the 1) upper beak, 2) openings of the seromucous glands, 3) choana, 4) rima infundibuli, 5) esophagus, 6) rima glottis, 7) salivary orifice, 8) tongue, 9) lower beak. Abscesses occur in multiple locations including a) perichoanal, b) pharyngeal, c) periglottal, d) lingual, e) lateral-ventral lingual and f) sublingual tissues.

in some passerine chicks is brightly colored, with distinctive markings that disappear when the chick is weaned. These markings appear to stimulate the parents to feed the chick.

Oropharyngeal Diseases

Table 19.3 lists common upper gastrointestinal tract diseases, the typical anatomic sites affected, the types of lesions induced and the common species affected.

Poxvirus

Poxvirus may cause proliferative caseous lesions (diphtheritic form) in the mouth and esophagus in a variety of avian species. Diagnosis can be achieved by identifying elementary bodies (Bollinger bodies) in impression smears prepared from lesions and stained with Wright's stain or by the Gimenez method. Trichomoniasis lesions may have a similar gross appearance.

Pigeon Herpesvirus Infection (Smadel's Disease)

Pigeon herpesvirus (PHV) infection has been associated with pharyngeal and esophageal diphtheritic membranes, which are attached to the underlying tissues. Lesions are most severe when secondarily infected with *Trichomonas* spp.[105] Other clinical signs include dyspnea, mucopurulent rhinitis and conjunctivitis. Histologic identification of basophilic and eosinophilic intranuclear inclusion bodies is suggestive.

Granulomas

Granulomas caused by *Mycobacterium* spp. or other bacterial or fungal agents frequently occur in the oral cavity. A diagnosis can be made by staining suspected material with the Gram's or Ziehl-Neelsen methods (see Table 19.2).[50,71,202] Surgical removal in conjunction with appropriate antimicrobial agents is usually effective in resolving non-mycobacterial-induced granulomas. A case of malignant fibrohistiosarcoma located on the tip of the tongue in a seven-year-old Brown-throated Conure was successfully removed by radiosurgery.

Nematodes

Various *Capillaria* spp. may infect the mucosa of the tongue, pharynx, esophagus and ingluvies of Falconiformes, Psittaciformes, Galliformes, Passeriformes and Anseriformes.[78,91,174] Characteristic lesions include hemorrhagic inflammation in the commissure of the beak and diphtheritic membranes in the pharynx and tongue. Parasites can be found embedded in inflammatory material. Typical bipolar eggs may be found in esophageal smears or ingluvial washings. In Strigiformes, *Synhimanthus* (*Dispharynx*) *falconis* has been reported in the oropharynx.[109]

Spirurid infections have been reported in diurnal and nocturnal birds of prey. Lesions containing the adult nematodes can be found in the mouth, esophagus and crop. The embryonated eggs are thick-walled. Ascarides belonging to the genus *Contracaecum* have been found in fish-eating birds, and severe infections of the oral cavity have been documented in young Pelecanidae. In birds of prey, *Seratospiculum amacu-*

TABLE 19.3 Upper Gastrointestinal Tract Diseases[22, 24, 51, 76, 191, 220, 221]

Organism	Location	Lesion Type	Species Susceptibility
Candida spp.	Oral cavity Esophagus	Ulcerative, necrotic, diphtheritic	Most species, particularly neonates, immunosuppressed animals
Duck enteritis virus	Oral cavity Sublingual salivary glands	Ulcerative	Ducks
Herpesvirus	Oropharynx, Esophagus Proventriculus	Diphtheritic	Owls
Lice (*Piagetiella peralis*)	Oral cavity	Stomatitis	Penguins
Leeches (*Theromyzon* spp.)	Nasal cavity, Conjunctiva Oropharynx	Hyperemia at attachment site	Anseriformes
Mycobacterium spp.	Tongue, Frenulum Hard palate	Granulomas	Psittaciformes, Falconiformes Galliformes
Neoplasias	All locations	Masses, ulcerative	Most species
Papillomas	Oropharynx, Esophagus Proventriculus	Masses	Psittaciformes
Pigeon herpesvirus	Pharynx, Esophagus	Diphtheritic	Pigeons
Poxvirus	Mouth Esophagus	Diphtheritic	Galliformes, Psittaciformes, Passeriformes, Raptors, Columbiformes
Trematodes (*Cathaemasia* spp. *Clinostomum* spp.)	Oral cavity	Stomatitis	Ciconiiformes
Trichomoniasis	Oral cavity, Esophagus Crop	Ulcerative Proliferative	Raptors, Psittaciformes, Columbiformes, Passeriformes

latum can cause lesions that resemble those of oral trichomoniasis.[212] The adult worms are found in the air sacs. Eggs may be found in the oral mucus or feces.

Hypovitaminosis A

In psittacine birds, a typical clinical sign of hypovitaminosis A is metaplasia of the submandibular or lingual salivary glands and clubbing of the choanal papillae (see Color 8). Affected birds are usually fed all-seed diets with a large percentage of sunflower seeds. Treatment should include parenteral vitamin A and the use of a formulated diet. Keratogenic cysts in the lingual salivary glands should be differentiated from lingual abscesses by biopsy.

Lesions associated with hypovitaminosis A in gallinaceous birds first appear in the pharynx and are largely confined to the mucous glands and their ducts. The epithelium is replaced by a stratified squamous epithelium that occludes the ducts of the mucous glands, causing accumulations of secretions and necrotic debris. Small, white, hyperkeratotic lesions (up to 2 mm in diameter) may be seen in the nasal passages, mouth, esophagus, pharynx and crop.

Some authors suggest that hypovitaminosis A is unlikely in pigeons because these birds efficiently metabolize this vitamin.[155,223] Other authors suggest hypovitaminosis A frequently occurs in pigeons but it is seldom recognized because the histologic lesions are limited to inflammation of the mucous glands.[194] As the condition progresses, the duct systems fill with masses of degenerate lymphoid and inflammatory cells, amorphous debris and mucus.

Sialoliths in Pigeons

Mucosal lesions that appear similar to those caused by hypovitaminosis A have been described on the palate of pigeons and are referred to as sialoliths (see Color 13).[223] Sialoliths consisting of a proteinaceous substrate mixed with cellular debris are clinically recognized in approximately one percent of pigeons. The etiology of sialoliths remains unknown. However, based on their histologic, histochemical, chemi-

cal and physical characteristics, they are not thought to be caused by hypovitaminosis A.[223] An association with pigeon herpesvirus infection has been suggested and seems plausible.[110,206,223]

Foreign Bodies

Clinical signs of foreign bodies in the upper GI tract can include respiratory distress, head shaking, scratching the head with the feet, dysphagia or anorexia. A thorough oropharyngeal examination and radiographs may reveal the foreign body.

A string looped around the base of the tongue and passing down the esophagus has been associated with dysphagia and respiratory distress in gallinaceous birds.[71,151] The string tightens and cuts further into the tongue with each swallowing movement, causing edema of the glottis. Ring-shaped foreign bodies (eg, tracheal rings of prey eaten by raptors) can become lodged around the tongue, causing avascular necrosis. Wooden, plastic or metal splinters (originating from toys or enclosures) may lodge in the mouth or esophagus of psittacine birds (Figure 19.4). Waterfowl frequently ingest baited fishhooks, which can be lodged anywhere in the upper or lower digestive tract. Fish bones may lodge in the pharynx or proximal part of the esophagus causing dysphagia. Plant hairs that lodge in the oral or esophageal mucosa can cause granulomas.

Stomatitis

Stomatitis in birds has been associated with the consumption of hot foods, ingestion of oil and ingestion of caustic substances.[51] Birds that chew on silver nitrate sticks may have extensive chemical burns of the oropharynx and crop.[131] Use of bipolar radiosurgery is superior to silver nitrate sticks for controlling hemorrhage of the beak and nails. Stomatitis may occur secondary to food accumulations caused by beak deformities (eg, PBFD) (Figure 19.5). Beak necrosis has been described in pigeons and gallinaceous

FIG 19.4 A mature Umbrella Cockatoo was presented for evaluation of palatine beak necrosis. The bird's feathers were in poor condition, and the bird appeared to be hungry but would eat reluctantly. The referring veterinarian had diagnosed PBFD based on the combination of beak necrosis and feather abnormalities. On physical examination, the defect in the palatine area of the beak appeared to contain a foreign body. Magnification indicated that the bird had a large wood splinter lodged in the occlusal surface of the upper beak. The splinter was removed and the wound was debrided and flushed. The bird's appetite improved within several days of presentation, and it began to preen normally within a week. The bird was DNA probe-negative for PBFD virus and polyomavirus.

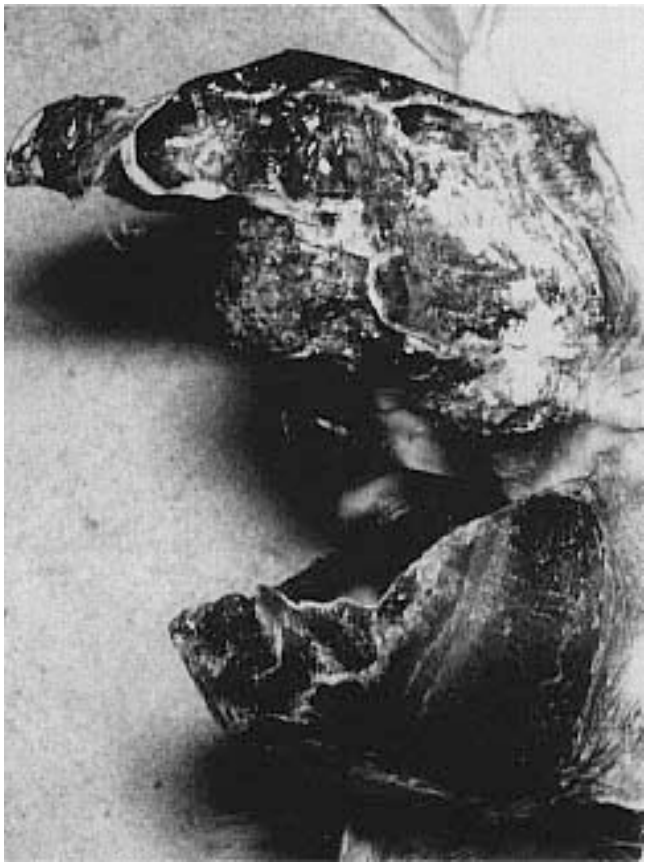

FIG 19.5 Palatine beak necrosis may occur in some birds with PBFD virus. Once a defect in the oral mucosa occurs, food may accumulate in the damaged tissues and create a nidus for secondary bacterial and fungal pathogens. In this Umbrella Cockatoo, the rhinotheca was completely necrotic and separated from the underlying bone. The bird had relatively minor feather pathology. This bird was euthanatized.

birds fed a finely ground, high-gluten food. The gradual accumulation of fine particles of food along the inner edge of the lower beak leads to secondary infection and necrosis of the beak. Feeding pelleted rations prevents the problem. The tongue of turkey poults fed a finely ground mash may be curled backward by an accumulation of food on the floor of the mouth.[151]

Many trichotecenes, notably T_2 toxin, can cause caustic injury to the alimentary mucosa. Yellow erosive and exudative plaques with underlying ulcers located near the salivary duct openings on the palate, tongue and buccal floor are characteristic lesions. Thick crusts of exudate may accumulate along the anterior margin of the beak. Anorexia is probably caused by the painful lesions in the beak.[87,219]

Spirillum pulli may cause stomatitis in chickens.[127] The organism can be demonstrated cytologically in fresh scrapings from diphtheritic lesions or salivary glands. Experimental transmission occurs by inoculation of tissue suspensions and by direct contact. Moist, slick mucosal membranes have been described in pheasants with Newcastle disease virus and in chronic cholera.

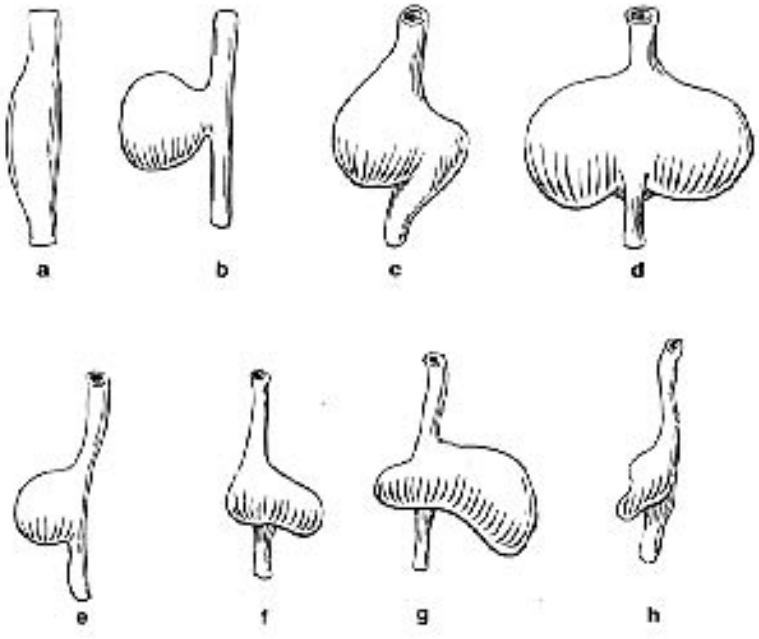

FIG 19.6 The shape of the crop varies dramatically depending on the species and the amount and shape of the ingesta. Some crop shapes include **a)** Great Cormorant, **b)** peafowl, **c)** budgerigar and **d)** domestic pigeon. **e-h)** Various shapes noted in a cockatoo. Modified in part from King and McLelland.[101]

Lacerations of the Tongue

Lacerations of the tongue have been encountered in psittacine birds and may be due to mate-induced trauma, automutilation during the excitement phase of post-anesthetic recovery or gnawing on sharp objects. The tongue is highly vascular and bleeds profusely if damaged. Anesthesia, magnification and radiocautery are usually necessary to control bleeding and repair the laceration.

Glossitis Gelatinosa Circumscripta

A gelatinous mass may be found on the dorsal aspect of the tongue in five- to twelve-week-old ducklings and goslings. The precise etiology is undetermined, but a multi-deficient diet has been suggested.[103]

The Esophagus and Crop

Anatomy and Physiology[31,49,101]

The esophagus lies immediately under the skin and to the right of the trachea (see Color 13).[16] The internal surface of the esophagus is longitudinally folded, increasing its distensibility and allowing carnivorous and piscivorous birds to consume large food items. From a clinical perspective, the anatomy of the avian esophagus allows for easy introduction of instruments or endoscopes for foreign body removal from the esophagus, crop and proventriculus. In most birds, the esophagus is divided by the crop or ingluvies (some birds do not have a crop) into a cervical and a thoracic component.

In Galliformes and Falconiformes, the crop forms a ventral enlargement of the esophagus at the thoracic inlet. In Psittaciformes, the crop is stretched transversely across the neck. In canaries and ducks, the crop is absent, but there is a spindle-shaped swelling of the esophagus at the thoracic inlet. In pigeons, the ventral diverticulum of the esophagus that forms the crop is divided into two large lateral sacs. The esophagus is lined with partly kerat-

inized stratified squamous epithelium. Mucous glands are located in the lamina propria, and are numerous in the thoracic esophagus. The structure of the crop resembles that of the esophagus, except that the mucous glands are restricted to an area adjacent to the esophagus. The function of the crop is to store food when the ventriculus is full (Figure 19.6). When the ventriculus is empty, food can bypass the crop and move directly into the proventriculus. The entire length of the esophagus can be used to store food in species that do not have a crop (eg, penguins and gulls). The esophagus and crop produce mucus, which softens and moisturizes the food in preparation for mechanical and chemical digestion lower in the gastrointestinal tract. Initial stages of carbohydrate digestion (mediated by salivary amylase) may occur in the crop of some species. The highly developed crop of the Hoatzin is unusual in having a large cervical component and two thoracic components. In this species, the ventriculus is small, and the muscular crop is the main site for the mechanical dissociation of food.

Adult pigeons of both genders produce a secretion called crop milk that is regurgitated and fed to the squabs during the first week after hatching. Other food items gradually replace the crop milk as the babies mature. Prolactin controls the production of crop milk, which consists of desquamated cells of the proliferated stratified squamous epithelium of the crop. Crop milk physically resembles mammalian milk and contains a high concentration of fat (6.9-12.7%) and protein (13.3-18.6%), but lacks carbohydrates and calcium. The crop of Psittaciformes and finches may also produce some secretions that are regurgitated and fed to neonates. The male Emperor Penguin feeds its chicks a fluid produced by desquamation of the esophageal epithelial cells, while the merocrine esophageal glands of both genders of Greater Flamingos produce a red nutritive juice that is regurgitated and fed to the young.

The crop of some birds may be involved in courtship behavior. Regurgitation is a common courtship behavior in some psittacine birds, particularly budgerigars, cockatiels and macaws. Males of some avian species (eg, pigeon, Great Bustard, ostrich, Sage Grouse) have inflatable esophageal diverticula that act as resonating chambers or display devices.

Investigative Methods

Clinical signs of esophageal or ingluvial disorders may include dysphagia, anorexia, retching, regurgitation or vomiting. In budgerigars, vomiting may be accompanied by a rapid flick of the beak, which frequently deposits vomitus on top of the bird's head (Figure 19.7).[8] A history of recent drug administration, assisted feeding, poor hygiene or access to toxic compounds may suggest an etiology for esophageal problems.

FIG 19.7 A two-year-old male budgerigar was presented with a three-week history of regurgitation. The bird was in overall good condition and would regurgitate when handled by either of the female members of the family. The bird would flick its head when it regurgitated, causing vomitus to land on the head feathers giving them a stiff, displaced appearance. Rhinorrhea can cause similarly appearing feather changes. The regurgitation in this bird was linked to courtship behavior.

The skin and feathers overlying the crop should be examined for abnormalities. Wetting of the feathers will help in visualizing lacerations, discolorations or necrosis of the crop. Hypermotility or hypomotility may occur with crop disorders.[96] In domestic fowl, peristaltic waves occur in the cervical esophagus at intervals of 15 seconds and in the thoracic esophagus, at intervals of about one minute. A psittacine crop that is partially filled with food should average one or two contractions per minute.

The esophagus and crop are thin-walled structures that are difficult to palpate unless abnormally thickened (Color 19.16). The crop can be palpated when it is full of food, fluid, air or abnormal masses. An enlarged crop with a dough-like consistency that fails to empty is suggestive of a crop impaction (Color 19.17). Occasionally, large deposits of fat, and in some cases lipomas, can occur near the crop and should not be misdiagnosed as a full or impacted crop. The use of improperly designed feeding cannulas to provide supportive nutrition to birds can result

in esophageal lacerations, with food being deposited into the subcutaneous, periesophageal tissues (see Color 30.8). Discolored necrotic areas, swelling and edema are common clinical findings.

For diagnostic purposes, an esophageal or ingluvial aspirate can be obtained by inserting a catheter and washing the mucosa with sterile isotonic saline solution. Luer-lock syringes should always be used when tube-feeding or collecting samples from psittacine birds to prevent them from swallowing the tube. Immediate microscopic examination of a wet mount slide is best for diagnosing trichomoniasis. Material aspirated from the crop should be centrifuged, and microscopic examination of the sediment may reveal nematode eggs or *Candida* spp. (see Color 30 and Color 10). Air-dried smears can be stained with Diff-Quik, Gram's stain, Wright's stain, Hemacolor or other stains for specific cytologic examination (see Chapter 10).

A fecal flotation and crop aspirate should be performed to detect parasite ova that might indicate an esophageal or ingluvial nematode or trematode infection. Flotation is more likely to detect low concentrations of eggs than a direct smear. Endoscopy is useful for examining the gastrointestinal mucosa and for removing some foreign bodies (Color 19.1).

Diseases of the Esophagus and Crop

Trichomoniasis

Trichomonas gallinae infections commonly occur in pigeons and raptors, and may also occur in Passeriformes (particularly canaries and Zebra Finches)[115] and Psittaciformes (particularly budgerigars and cockatiels).[8,61,137] In pigeons, the proliferative necrotic lesions caused by trichomoniasis are called "canker," while in falcons the disease is called "frounce." Trichomoniasis lesions appear similar to those caused by poxvirus; however, in cockatiels, poxvirus infections are uncommon.[137] Table 19.4 compares the clinical presentation of trichomoniasis in budgerigars and pigeons.

TABLE 19.4 Differences in Clinical Presentation of Trichomoniasis in Budgerigars and Pigeons

	Budgerigars	Pigeons
Anatomic Location	Esophagus, crop	Mouth, cloaca, umbilicus, liver, generalized
Lesions	Proliferative	Diphtheritic
Age	Mainly adults	Squabs

Samples for detecting *T. gallinae* can best be collected by introducing a slightly moistened cotton-tipped applicator into the esophagus, and moving it up and down several times against the mucosal lining. The cotton tip is then compressed between the thumb and index finger to produce one drop of fluid, which is placed on a slide for direct examination. A clinical diagnosis in Psittaciformes can be difficult because of low parasite numbers in the early stages of the disease[137] and the intracellular location of the parasite.[8]

Trichomoniasis can cause inflammation of the upper intestinal tract and mouth resulting in dysphagia or vomiting, and may be an underdiagnosed cause of ingluvitis in budgerigars. Historically, idiopathic vomiting, diarrhea and death with yellow caseous plaques and papilliform projections in the esophagus and crop have been defined in many budgerigars. These lesions resemble those caused by trichomoniasis.[3,154] Trichomoniasis was documented in 70% of a group of budgerigars with clinical signs of vomiting and diarrhea.[8] There was no gender predisposition, but the majority of cases occurred in birds from one to three years of age. The cervical part of the esophagus was most frequently affected, but many birds also had crop involvement. Histologic examination revealed that the increased thickness of the crop and esophagus was the result of an increase in depth of the mucosa. The intracellular occurrence of trichomoniasis has not been reported in other avian genera, and this unique feature of infection in budgerigars may contribute to the underdiagnosis of trichomoniasis as a cause of morbidity and mortality in Psittaciformes.

Trichomoniasis-induced ingluvitis and stomatitis have been reported in a cockatiel and budgerigar flock, respectively.[138,162] Trichomoniasis was considered the cause for 80% morbidity and 72% mortality in a flock of 60 cockatiels exhibiting regurgitation, diarrhea and depression.[222] A large caseous mass in the distal trachea caused by *Trichomonas* sp. was reported in a ten-week-old Blue-fronted Amazon parrot.[61]

Trichomoniasis was diagnosed in neonatal cockatiels, Lilac-crowned Amazon Parrots, Mexican Red-headed Amazon Parrots, Sun Conures and Blue-crowned Conures that were fed from a single food source with three syringes. Clinical signs included necrotic dermatitis at the commissure of the beak, depression, crop stasis and white caseous plaques on the tongue and pharynx. Histopathology was negative in all cases. The diagnosis was made by identifying tricho-

Gastroenterology

Color 19.1
A >20-year-old Amazon parrot was presented with a six-month history of intermittent dyspnea that had become progressively worse. Survey radiographs indicated a soft tissue mass in the area of the caudal thoracic esophagus. Laparoscopy indicated a diffuse air sacculitis (that was not detected on radiographs), and the soft tissue mass was determined to be a dilated portion of the esophagus. Endoscopy of the trachea revealed thick mucus from which *Klebsiella* spp. and *Pseudomonas* spp. were recovered. The bird responded to systemic antibiotics but would relapse with the cessation of antibiotic therapy. Endoscopy of the esophagus revealed a large mass in the esophagus. Histologically, the surface of the mass contained hyperplastic mucus-producing cells. The etiology of the mass remains undetermined.

Color 19.2
An eight-year-old Sulphur-crested Cockatoo was presented with a five-week history of vomiting and progressive weight loss. Contrast radiographs indicated a mucosal filling defect in the proventriculus. Gastroscopy with a 3.5 mm flexible endoscope was performed. **a)** The opening from the crop into the thoracic esophagus is clearly visible. **b)** The opening from the proventriculus to the ventriculus is visible. Note the koilin layer (dark green areas), which can partially extend into the proventriculus. **c)** Bile-stained koilin layer of the ventriculus. **d)** Ulcers on the proventricular mucosa. Note barium sulfate is still adherent to some of the sites of ulceration. The bird did not respond to supportive therapy. Histopathology indicated marked myocardial degeneration and necrosis of undetermined etiology.

Color 19.3
A mature Scarlet Macaw was presented for intermittent regurgitation and weight loss. The bird was maintained in an outdoor environment and was frequently exposed (every hour) to an automatic pesticide fogger. The bird had been in this environment off and on for several years. Abnormal clinical pathology findings included WBC=22,000, AST=750 and LDH=800. Radiographs indicated a rough appearance to the dorsal serosal surface of the proventriculus, suggestive of inflammation. The client chose to treat the bird at home with only antibiotics. The bird died several days after presentation. At necropsy, a large perforating ulcer was present in the proventriculus.

Color 19.4
Hemorrhagic, necrotizing, gram-negative bacterial colitis in an Umbrella Cœkatoo with a chronic PBFD virus.

Color 19.5
Several different nematodes can cause nodular-type lesions and mucosal hypertrophy in the proventriculus and ventriculus. In this case, proventricular hypertrophy was caused by *Dyspharynx* sp. in a crane that died following a period of weight loss, depression and anemia (courtesy of Robert E. Schmidt).

Color 19.6
A cockatoo with PBFD virus was found dead in its enclosure. The bird was in excellent overall condition and was of normal weight. Necropsy findings included hyperemia of the intestinal tract with distended vessels. Histopathology indicated a gram-negative bacterial enteritis and septicemia.

Color 19.7
A mature Yellow-collared Macaw hen died following a period of unseasonably low temperatures well below freezing. The bird had exhibited several days of depression before death. At necropsy, the cloaca and lower intestinal tract were filled with blood-tinged, poorly digested food. Histopathology indicated severe necrosis of the villi and crypt cells with a minimum inflammatory response. An etiologic agent was not identified.

Gastroenterology

Color 19.8
The pericloacal area of birds is normally dry and the feathers are of normal color. Accumulations of excrement or bile-stained feathers are indications of enteritis or cloacal dysfunction. In this case, a mature cockatiel had biliverdinuria from hepatopathy and enteritis associated with giardiasis.

Color 19.9
a) A cloacal papilloma appears as multiple, pink-to-red masses on the cloacal mucosa. Large lesions may protrude from the cloaca and be misidentified as a cloacal prolapse. Five percent acetic acid will cause papillomatous tissue to appear white while normal mucosa will stay pink. Stage cauterization with silver nitrate may be the easiest and most efficacious way to remove papillomatous tissue. Large masses should be removed with repeated treatments several weeks apart to prevent excessive damage to the cloacal mucosa. **b)** The silver nitrate stick is placed in direct contact with the papillomatous tissue and moved gently over the lesion. When the tissue turns grey, the silver nitrate is inactivated by flushing with water. The undiluted silver nitrate must not be allowed to run inside the cloaca, or nonspecific chemical burns will occur.

Color 19.10
A mature pigeon was presented for depression and anorexia of two days' duration. The feathers around the vent and lower abdomen were covered with excrement and fly larvae. The contaminated feathers were removed. The cloaca was impacted with dry, firm feces and urates. The feces were removed from the cloaca with forceps, and the cloaca was flushed with dilute chlorhexidine solution. A Gram's stain of the rostral cloacal wall revealed a moderate number of short, gram-negative bacteria. The bird responded to parenteral enrofloxacin.

Color 19.11
A female Amazon parrot was presented three days after egg laying when she was found on the bottom of the enclosure. The bird was depressed and emaciated. A cloacal prolapse had occurred, and the mucosa had multifocal, dry, necrotic areas. The necrotic tissues were cleansed with a dilute chlorhexidine solution and surgically removed. The cloaca was placed back in the abdomen and was held in place with a cloacopexy. The bird was placed on oral enrofloxacin, and the cloaca was flushed BID with dilute chlorhexidine solution followed by the installation of Preparation H. The bird responded to the therapy. The prolapse was considered to have occurred following the passage of an unusually large egg.

Color 19.12
A mature male budgerigar was presented with a three-week history of intermittent regurgitation. Several masses (ingluvioliths) were palpated and were removed surgically from the crop.

Color 19.13
A mature budgerigar was presented for a swelling in the thoracic inlet area. The crop was severely distended with food, and the bird had an audible click on inspiration. Goiter was the presumptive diagnosis and the bird responded to iodine therapy (courtesy of Elizabeth Hillyer).

Color 19.14
A >25-year-old rosella died acutely. The gastrointestinal tract was dilated and contained poorly digested ingesta. The bird died from severe atherosclerosis.

Color 19.15
Typical "turkish towel" appearance of the crop in a bird with a severe *Candida* spp. ingluvitis. Compare to Color 19.16 in which the crop is transparent.

Color 19.16
In Psittaciformes, the normal crop and esophagus are thin, milk-colored, partially transparent membranes with a few distinguishable, small blood vessels. Note that the trachea can be seen through the crop.

Color 19.17
A 15-week-old Hyacinth Macaw was presented for necropsy following a brief period of depression. The client had noticed that the bird's crop had not emptied over a twelve-hour period. The bird was being fed a commercial hand-feeding formula supplemented with a liquid vitamin and mineral supplement. At necropsy, the crop was hyperemic and distended with food, and the vessels were congested. The kidneys were calcified. Macaws appear particularly sensitive to hypervitaminosis D_3. This bird's diet was estimated to have four to six times the necessary level of vitamin D_3.

Color 19.18
A 23-year-old Scarlet Macaw hen was presented two weeks after the referring veterinarian had surgically removed an impacted egg from the distal uterus. The bird was severely depressed and emaciated, and the abdomen was distended. Radiographs indicated gaseous distention of the intestinal tract. Abnormal clinical pathology findings included WBC=45,000 (toxic heterophils), PCV=25, TP=2.2 and AST=900. Fluid collected by abdominocentesis was characteristic of an exudate (SpGr=1.025, Protein=4.5 g/dl and numerous heterophils). An exploratory laparotomy was performed, a section of strangulated colon was removed and a side-to-side anastomosis was performed. The bird did not recover from the surgery. Note the congested, distended bowel loops and the presence of granulation tissue on the abdominal wall.

monas in impression smears of the lungs of a bird that died one hour before examination.[137]

In another case, six Yellow-naped Amazon Parrot babies were affected. Clinical signs included whitish gray plaques on the tongue, choana and pharynx. Wet mount examination of scrapings from these lesions, crop lavage and transtracheal wash were negative. Postmortem examination of one of the Amazon parrots revealed a caseous plaque partially occluding the syrinx and lungs and filled with a yellowish, clear exudate containing abundant trichomonads that were demonstrated by a wet mount impression smear.[137] These cases suggest that trichomoniasis is a severely underdiagnosed cause of upper gastrointestinal disease in psittacine birds. Histopathologic examination is of limited diagnostic value because the causative organisms float away from the tissue in formalin.[137] Nitroimidazole drugs like metronidazole, ronidazole, dimetridazole and carnidazole are usually effective in treating trichomoniasis; however, nitroimidazole-resistant strains of trichomoniasis occur in The Netherlands because of the improper use of these drugs by pigeon fanciers.[56]

Nematode and Trematode Infections

Many nematodes including *Capillaria* spp., *Echinura uncinata*, *Gongylonema ingluvicola* and *Dis-pharynx nasuata* can invade the esophageal or crop mucosa. The thorny-headed worm (*Oncicola canis*) has been reported in turkeys.[78,174]

Ingluvial/Esophageal Stasis and Dilatation

The suggestive causes of crop stasis include heavy metal toxicity, crop impaction, callus formation after a coracoid fracture, thyroid enlargement, atonic crop, sour crop, overstretching of the crop, esophagitis (candidiasis, trichomoniasis, capillariasis, serratospiciliasis), ingluvioliths and esophageal stenosis (Color 19.13). If the fluid in the crop remains stagnant, it will decay and have a foul odor (often referred to as sour crop). Regurgitation of proventricular fluid may be a contributing factor. Feeding a liquid formula to granivorous birds can induce crop stasis, possibly as a result of a lack of mechanical stimulation.

In turkeys, there is thought to be a hereditary predisposition to developing a pendulous crop after increased liquid intake during the first wave of seasonal hot weather. The majority of affected birds do not recover, but continue to have pendulous crops. It has been shown that feeding cerelose as a substitute for starch increases the incidence of pendulous crop in gallinaceous birds. Affected birds had large quantities of the gas-producing yeast *Saccharomyces tellustris*. Large quantities of gas may have initiated the crop dilatation.[151]

Crop Impaction

Crop impaction is occasionally seen in Galliformes and Anseriformes that have sudden access to an abundant supply of lush grasses and sprouted grains.[79,122] Dried oatmeal and soybeans swell when they absorb water and can impact the crop. This is a major cause of mortality in free-ranging Canada Geese.[80,92] About 2000 Canada Geese died from impaction of the cervical esophagus accompanied by necrosis and ulceration of the esophageal mucosa following the ingestion of fox tail grass (*Setaria lutescens*). Lead poisoning, acute fowl cholera and ventricular worm infections can cause similar clinical signs.[122] Crop impactions can occur in birds provided ad libitum grit. Food substances that are difficult to digest, such as raw potatoes, beets, apple skins, sausage skins and large pieces of animal tissues, may also cause crop impaction. In captive raptors, ingluvial impaction may occur when roughage is suddenly added to a low roughage diet, or when the moisture content of the diet is inadequate. Crop impaction may be complicated by secondary *Clostridium perfringens* infection in the European Kestrel.[91]

Impacted material in the crop can be softened by the administration of warm water followed by massaging the crop. However, an ingluviotomy will generally be the method of choice for removing impacted material. Foreign bodies may be removed endoscopically. Expressing the ingluvial contents through the mouth by turning the bird upside down is a dangerous procedure that may lead to irritation of the nasal mucosa, sinusitis or aspiration pneumonia. Packing the choana with cotton and intubating with an endotracheal tube will help eliminate this problem.

Ingluvioliths

Ingluvioliths have occasionally been reported in birds (Figure 19.8).[3,10,12] Urate (excreta) calculi with seed husk centers were described in the crops of several budgerigars.[12] It was speculated that the calculi originated from the ingestion of excreta and seed husks in birds provided no food. Other ingluvioliths have been found to contain potassium phosphate, oxalate and cystine, and were not considered to have occurred secondary to urate ingestion (Color 19.12).[3]

Foreign Bodies

Unweaned psittacine neonates (especially macaws and Eclectus Parrots) frequently ingest foreign bodies.[11] Any ingested foreign body, including rubber or metal feeding tubes, should be removed immediately from the ingluvies before it has an opportunity to align with the thoracic esophagus and pass into the (pro)ventriculus. The type of foreign body is dependent on the species (Figure 19.9). Fishing hooks are common in waterfowl. Perforating or obstructing bones are encountered in raptors.

Crop and Esophageal Lacerations and Fistula

Penetration of the pharynx or esophagus by feeding cannulas, or esophageal-ingluvial burns caused by ingestion of overheated feeding formulas or caustic materials can result in deposition of food subcutaneously and lead to extensive foreign body reactions. In birds of prey, sharp bones from prey animals may cause an esophageal or ingluvial fistula.[20,153] Traumatic lacerations of the chest including the ingluvies are often seen in racing pigeons. The most likely cause for these lacerations is a collision with antenna wires. Bite wounds from mates or cats and dogs may also cause crop lacerations. A bird with a crop fistula may be presented with weight loss despite a ravenous appetite. The feathers surrounding the fistula are usually matted with dried food. Subcutaneous pockets of food should be surgically drained and frequently flushed. A feeding tube can be passed from the esophagus directly into the proventriculus to allow enteral feeding while the esophagus and crop heal (see Chapters 15, 16 and 41).[81]

Esophageal Stricture

A ten-year-old Hyacinth Macaw developed a stricture in the thoracic esophagus after ingesting several large pieces of hard plastic. The most obvious clinical sign was regurgitation of mucus. A barium study revealed a filling defect in the caudal esophagus. Endoscopic examination through an ingluvial incision revealed an annular ring of exudate and hyperplastic tissue. The stricture was resolved by periodic mechanical dilation.[203] Esophageal strictures may also occur secondary to burns. A cockatoo with severe self-mutilation syndrome damaged the perieso-

FIG 19.8 An ingluviolith is evident in these radiographs of a cockatiel (courtesy of Jean Paré).

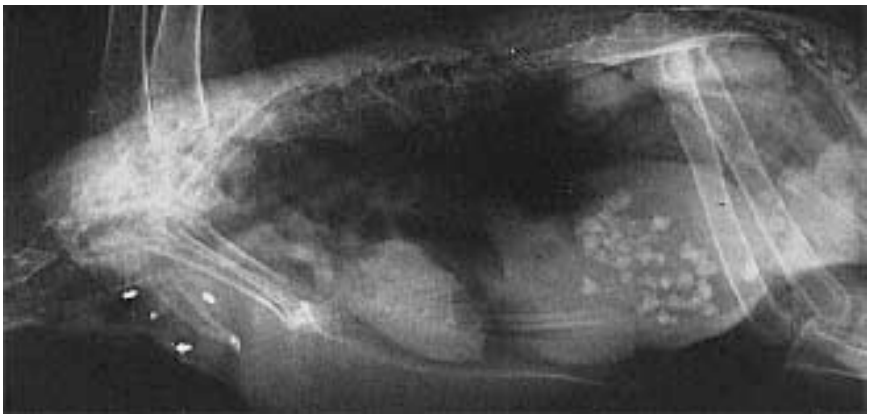

FIG 19.9 An adult female Umbrella Cockatoo was presented with an acute onset of lethargy and regurgitation. Several small solid masses could be palpated in the crop. The bird was producing small amounts of excrement and had tenesmus. The bird was maintained in an earthen-floored flight enclosure and was fed wild bird seeds. Abnormal clinical pathology findings were limited to hypokalemia and mild anemia (PCV=34%). Radiographs indicated several metallic densities in the crop. In addition, an excessive number of mineral densities (small rocks, grit) were present in the ventriculus and intestinal tract. The metallic densities (pieces of wire) were removed using an endoscope and forceps. The ventriculus was flushed with copious amounts of warmed LRS, which resulted in the removal of about 20 to 30 small rocks. The bird was given corn oil by crop tube three times a day for three days, and rocks were noted in the stool on the day after the first corn oil treatment. The bird's diet was corrected and no further problems were noted.

phageal skin to such a degree that the esophagus was occluded and the bird died from asphyxiation.

The Proventriculus and Ventriculus

Anatomy and Physiology[55,101]

The avian stomach consists of a cranial glandular part (proventriculus) and a caudal muscular part (ventriculus). The proventriculus in birds is situated in the left dorsal and left ventral regions of the thoraco-abdominal cavity, and is covered ventrally by the fat-laden posthepatic septum (see Color 14). The pyloric part of the ventriculus joins the duodenum and is located on the right side of the midline. In granivorous, insectivorous and herbivorous birds, the muscular wall of the ventriculus is highly developed and is clearly distinct from the proventriculus. The two organs are divided by an intermediate zone, or isthmus, which can be seen grossly as a constrictive band (Figure 19.10). The ventriculus can be palpated in granivorous birds on the left ventral side of the abdomen just caudal to the sternum.

The proventriculus has two types of glandular epithelial cells. Mucus-producing, columnar epithelial cells line the proventricular mucosa and the lumina of the ducts from the proventricular glands. These cells contain numerous periodic acid Schiff (PAS)-positive mucin granules. The multilobular glands of the proventriculus are lined by oxynticopeptic cells. These cells have ultrastructural features similar to both the parietal (acid-secreting) and the peptic (enzyme-secreting) cells of the mammalian stomach, and secrete both pepsinogen and hydrochloric acid. The ducts from these glands empty from numerous papillae that can be found in the proventricular wall. These oxynticopeptic cells possess a very eosinophilic and somewhat granular cytoplasm and do not contain PAS-positive mucin granules.

The wall of the ventriculus is composed of smooth muscle arranged into four semi-autonomous masses. The caudodorsal and cranioventral thick muscles and the craniodorsal and caudoventral thin muscles attach to the right and left tendinous centers in the lateral walls of the ventriculus. The asymmetric arrangement of the muscles enables rotary and crushing movements during ventricular contractions. The thin muscles form the cranial and caudal blind sacs. The caudal blind sac is a good point for gastrotomy incision in granivorous birds because incisions in the thick muscles heal poorly. The inner surface of the ventriculus of granivorous birds is lined by a carbohydrate-protein complex (koilin layer or cuticle). This koilin layer is composed of vertical rods secreted by the mucosal glands of the lamina propria and a horizontal matrix, which is a secretion of the surface epithelium that hardens after spreading around the rods. Desquamated cells of the surface epithelium are trapped within the horizontal matrix. Hydrochloric acid from the proventriculus causes precipitation of the protein complex to form a tough, water-resistant lining. The brown, green or yellow color of the koilin is caused by regurgitation of bile through the pylorus.

The intermediate zone that divides the proventriculus and ventriculus has histologic characteristics

FIG 19.10 The isthmus (arrow) is distinguished as a constrictive band separating the proventriculus (p) from the ventriculus (v). The proventriculus can be seen laying dorsal to the caudal thoracic air sac. This bird died from myocardial degeneration.

similar to both organs. Compound glands are absent, and the internal surface is relatively smooth. The columnar epithelium lining the proventriculus gradually changes into ventricular glands. There is a mixture of proventricular-like mucoid secretions and ventricular-like glandular secretions. Most gastric neoplasms in birds occur in the intermediate zone, and use of PAS stains appears useful in determining the types of epithelial cells that have been transformed.[113,161]

The ventriculus is the site of gastric proteolysis, and in many species also of mechanical digestion. In carnivorous and piscivorous birds, the proventriculus is more adapted for storage than for physical digestion. In these species, the ventriculus is thin-walled and sac-like, and the ventriculus and proventriculus are difficult to differentiate grossly. The koilin layer is relatively thin and softer than in granivorous birds. The muscularis is relatively thin. In raptorial species (eg, owls), the ventriculus is involved in the formation and regurgitation of pellets or "castings," which are composed of undigestible fur, feathers or bones. Intermediate forms of proventricular and ventricular differentiation are found in many avian species including frugivorous (fruit-eating) and testacivorous (shellfish-eating) birds.

In certain frugivorous pigeons, the koilin layer is composed of rows of hard, pointed, conical projections that facilitate crushing firm fruits such as nutmeg. In some species (magpie and starling), massive shedding and excretion of the koilin layer occur periodically. Male hornbills may regurgitate the koilin layer as a seed-filled sac that is fed to the nesting female.

The proventriculus in an ostrich is a large, thin-walled structure. In contrast to other birds, the oxynticopeptic cells are restricted to a patch on the greater curvature. The distal extremity of the ostrich proventriculus passes dorsal to the ventriculus and empties on the caudal aspect of this organ. The ostrich ventriculus is a thick-walled muscular organ. The isthmus between the proventriculus and ventriculus is large, which makes it easy to remove foreign bodies from the ventriculus through a proventricular incision. In emus and nandus, the proventriculus is large and spindle-shaped, and the ventriculus is slightly larger and more lightly muscled than that of the ostrich.

Proventricular and Ventricular Diseases

Most diseases of the proventriculus or ventriculus produce similar clinical signs and make differentiation difficult. For example, an enlarged proventriculus may be found in many of the diseases in Table 19.1. The following is a discussion of some of the diseases that affect the proventriculus and ventriculus.

Megabacterial Proventriculitis

"Going light" syndrome in budgerigars, a disease characterized by emaciation, weakness, high morbidity and low mortality, has been described in canaries and budgerigars. Vomiting of slimy material is seen in advanced stages of the disease.[64,177,197,201] Postmortem findings include proventriculitis and proventricular dilatation. Histologically, gram-positive, PAS-positive, acidophilic (with Giemsa), rod-shaped bacteria can be identified, especially in the area between the proventriculus and ventriculus. The organisms have been characterized as large bacteria (not fungi), hence the name "megabacteria" (see Figure 33.13).

A diagnosis can be made by cytologic demonstration of the organisms in a proventricular washing. The pH of the proventriculus is markedly elevated in affected birds. The pH of the proventriculus from normal canaries was found to range from 0.7 to 2.4 compared to severely infected canaries in which the pH was 7.0 to 7.3. In birds with moderate numbers of megabacteria, the pH of the proventriculus ranged from 1.0 to 2.0.[201] The most important differential diagnosis is trichomoniasis.

Proventricular and Ventricular Nematodes

Many nematode species have been reported to occur in the proventriculus (*Echinura uncinata, Gongylonema ingluvicola, Cyrnea* spp., *Dyspharynx nasuata* and *Tetrameres* spp.). *Amidostomum* spp., *Cheilospirura spinosa* and *Epomidiostomum uncinatum* are found under the horny layer of the ventriculus (Color 19.5).[60,174,179] Lesions vary considerably depending on the host and the parasite, and may be quite extensive (see Chapter 36). Clinical signs may be absent or include emaciation, anemia and mortality. Diagnosis can often be made by detecting parasite eggs using a fecal flotation technique. Treatment can be attempted with levamisole (20 mg/kg orally, or 10 mg/kg parenterally) or ivermectin (200 μg/kg parenterally). It should be stressed that experience with ivermectin in many avian species is absent. Acute death has been reported after the use of ivermectin in some mammalian and reptilian species.

Neuropathic Gastric Dilatation and Encephalomyelitis of Psittacines

Neuropathic gastric dilatation (NGD)[123] has been given many names since it was first recognized as a clinical entity in 1971 (Table 19.5).

The descriptive term myenteric ganglioneuritis and encephalomyelitis of Psittaciformes best defines the following histologic lesions that can be observed in affected animals: lymphocytic and monocytic infiltration of intrinsic and extrinsic splanchnic nerves of the muscularis tunics of the alimentary tract; in some cases, leiomyositis in organs innervated by affected nerves and non-suppurative encephalitis, myelitis and radiculoneuritis have been described.[68] Many psittacine species can be affected, including macaws, cockatoos, conures, African Grey Parrots, Senegal Parrots, Amazon parrots, Eclectus Parrots, Thick-billed Parrots and cockatiels.[68]

Clinical signs are related to (pro)ventricular and sometimes neurologic dysfunction, and may include anorexia, regurgitation, undigested seeds in the feces and weight loss. The occurrence of neurologic signs is variable. In advanced cases, proventricular dilatation can be visualized on abdominal radiographs, with or without contrast media (Figure 19.11). In the clinical patient, a tentative diagnosis of NGD can be made based on clinical signs and radiographic findings. It should be stressed that other diseases can mimic NGD and should be ruled out before a definitive diagnosis is considered (Table 19.6).[69,90,197] NGD

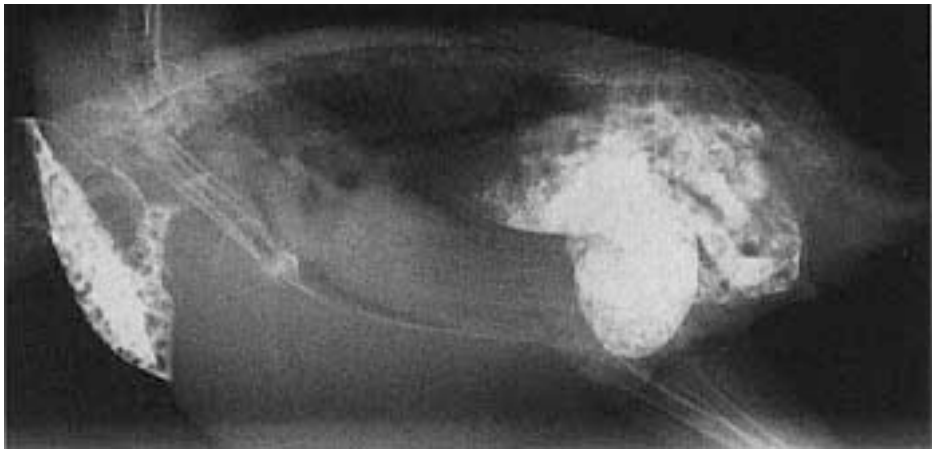

FIG 19.11 A three-year-old female cockatiel was presented with a two-week history of passing undigested seeds. Survey radiographs suggested a dilated proventriculus. Barium contrast study indicated a slowed gastric emptying time (VD and lateral radiographs eight hours after the administration of barium by crop tube). Note the numerous filling defects (ingesta and undigested seeds) in the crop, proventriculus and intestines. The client chose to have the bird euthanatized. Histopathology confirmed a diagnosis of neuropathic gastric dilatation.

TABLE 19.6 Differential Diagnosis of Neuropathic Gastric Dilatation

- Intestinal papillomatosis
- Proventricular and ventricular neoplasia
- Vitamin E and selenium deficiencies

can be confirmed by histologic identification of characteristic lesions in the splanchnic nerves from a ventricular biopsy (Figure 19.12). However, a negative result derived from a small biopsy of the ventricular wall does not rule out NGD.[68]

Although the etiology is presently unclear, a viral etiology has been suggested because of epidemiologic histories of affected aviaries and the demonstration of intranuclear and intracytoplasmic inclusion bodies in affected tissue of some birds.[26,63,84,123] Paramyxovirus-like inclusions have been described by some researchers[123] but could not be identified by others.[68] The "avian viral serositis" virus produces experimental lesions that are similar to those described with NGD (see Color 32).

Affected animals invariably die after a more or less protracted course of the disease. Controlled studies to document the effects of treatment on the prognosis of NGD have not been reported. General therapy including supportive care, a liquid diet, vitamin supplementation and treatment of secondary diseases has been recommended. It has been suggested that birds can survive on a liquid diet,[78] but no case reports could be found that document long-term survival of birds confirmed by ventricular biopsy to have NGD. Treatment of NGD should be considered with caution, given that the disease may be caused by an infectious agent.

It has been suggested that a virus may induce an autoimmune reaction that would be responsible for the lesions observed in NGD.[67] The inciting virus would no longer be present when the disease became clinically obvious or was diagnosed at necropsy. If this scenario is true, then administration of an anti-inflammatory dose of corticosteroids might be indicated.[161]

Ganglioneuritis and Encephalitis in Geese

Proventricular impaction with non-suppurative encephalomyelitis and ganglioneuritis morphologically similar to NGD in psittacine birds has been reported in two Canada Geese.[43]

Proventriculitis in Chickens

Proventricular enlargement and infiltration of the proventricular interglandular tissue with mononuclear cells has been described[106] as part of the infectious runting and stunting syndrome in broiler chickens.

Gastric Impaction and Gastric Foreign Bodies

Gastric impaction is common in psittacine babies that consume bedding material such as crushed walnut shell, ground corncob, shredded paper pulp, styrofoam packing, kitty litter and excess grit. These bedding materials should not be used with neonates.[35,39]

Ventricular impaction secondary to litter ingestion has been reported to cause high mortality during the first three weeks of life in turkey poults. Affected animals were emaciated and had empty intestinal tracts, distended impacted ventriculi and foreign bodies in the first part of the duodenum.[170]

Gastric obstruction caused by phytobezoars or detachment of the koilin layer of the ventriculus has been reported in chickens, a goose, ducks and a pigeon.[51] Gastric rupture may occur secondary to an impaction. In raptors, ventricular impaction caused by a hard mass of fur can also occur. Gastric impaction is more common in captive raptors fed early during the day in hot weather. Those fed late in the day are less likely to retain their casting.[66]

In ostriches, (pro)ventricular impaction is a serious management problem.[209] The condition occurs usually two to three weeks after moving the birds to a new environment containing a novel substrate or food. Most affected birds are under six months of age, but the condition can also occur in adults. Clinically the birds are sluggish and produce small, firm fecal balls. Some affected birds may be lame. Cloacal prolapse may occur in young birds several days to four weeks old. Early diagnosis through abdominal palpation and radiographs followed by immediate surgical correction are imperative for successful resolution.[88,187] A 17-inch string of beads could be palpated

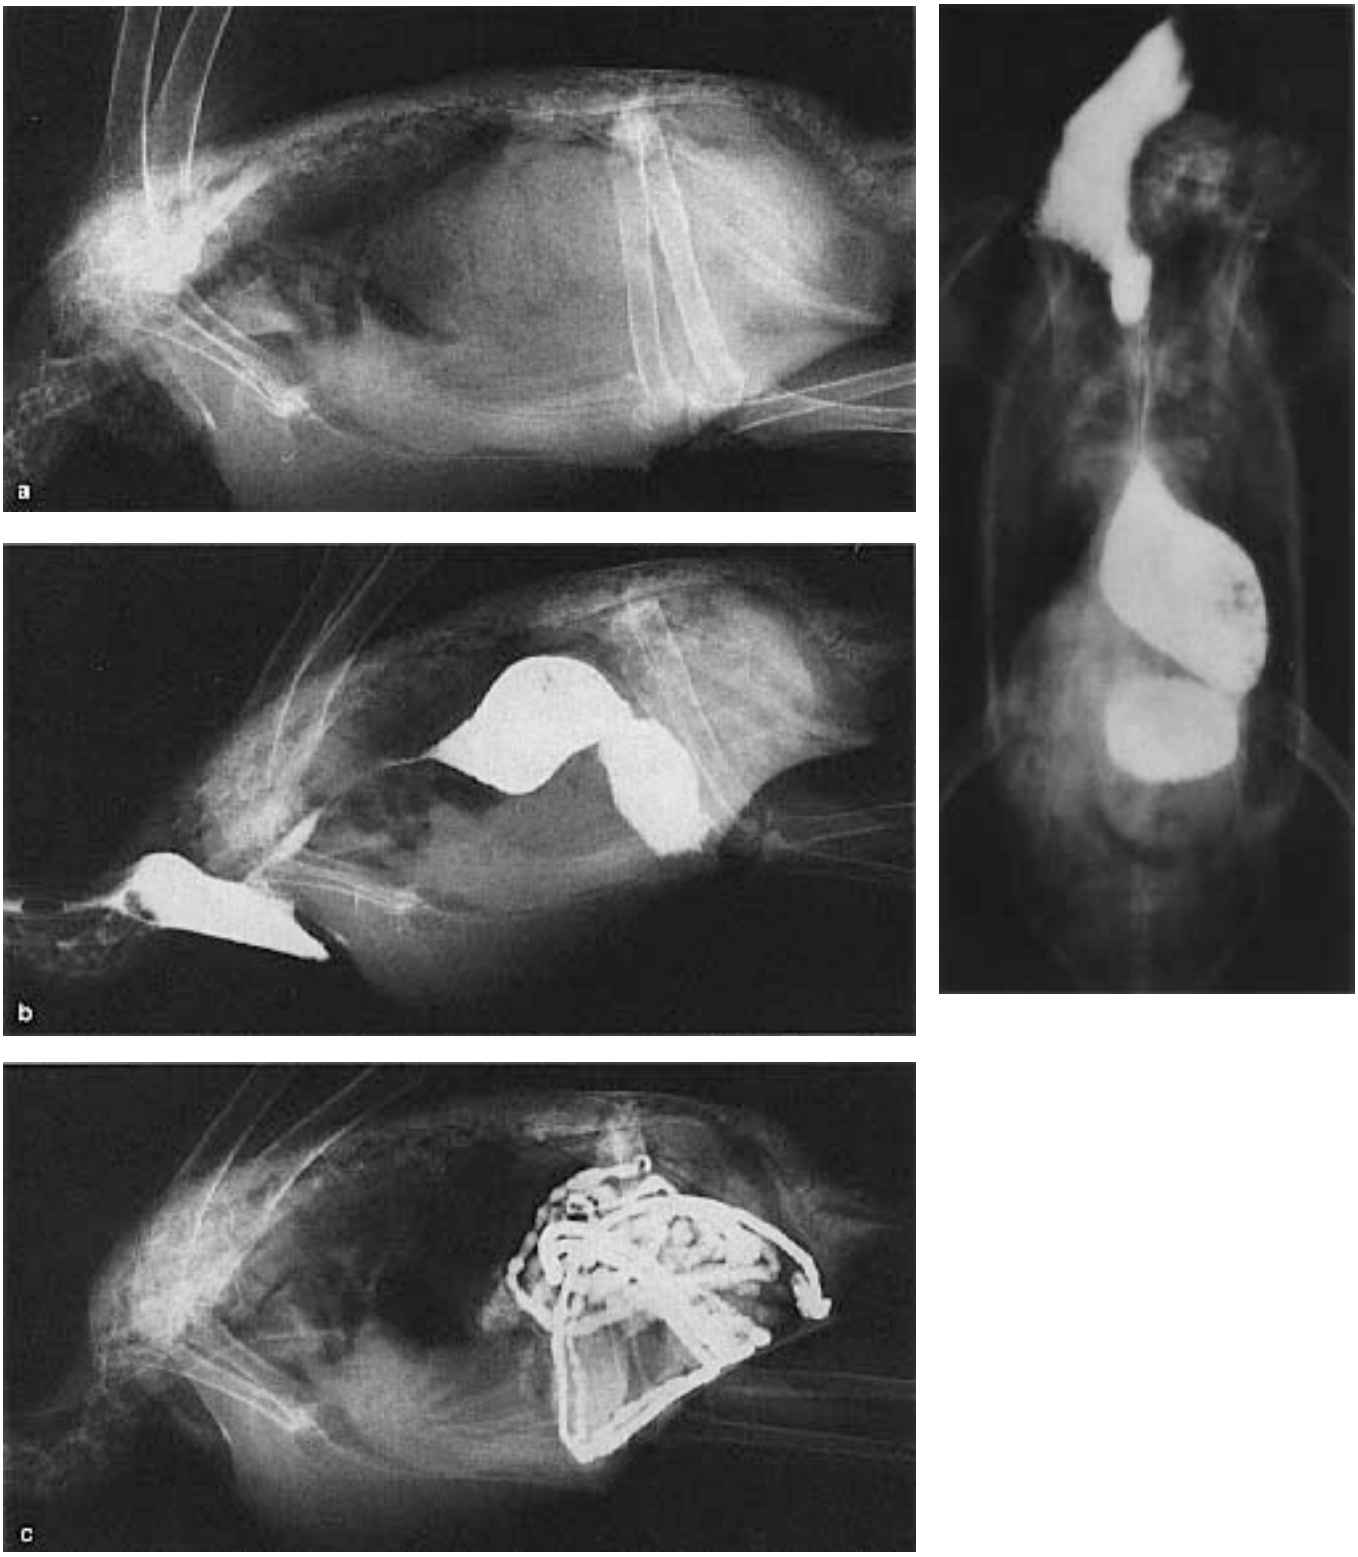

FIG 19.12 A one-year-old male Eclectus Parrot was presented for severe emaciation, depression, diarrhea and a distended abdomen. The bird had a ravenous appetite. Abnormal clinical pathology findings included AST=1637, LDH=4049 and WBC=3000. **a)** Survey radiographs indicated a severely dilated proventriculus and hepatomegaly. The bird was fasted for eight hours and a barium contrast study was performed. **b)** Ventrodorsal and lateral radiographs were taken two hours post-barium administration and **c)** lateral radiograph represents eight hours post-barium administration. The proventriculus was markedly reduced in size following fasting. Contrast studies indicated a delayed gastric-emptying time, hepatomegaly (causing the proventriculus to be displaced dorsally) and retention of barium in the proventriculus, suggestive of mucosal inflammation. The bird responded to treatment with broad-spectrum antibiotics and lactulose. It should be stressed that the survey radiographs were suggestive of NGD; however, a dilated proventriculus and slowed gastric-emptying time are not pathognomonic for NGD. A biopsy is necessary to confirm a diagnosis.

in the crop of an Amazon parrot. Barium contrast radiographs were used to confirm that the string of beads passed into the small intestines. The string was extracted through the mouth using sponge forceps.[213]

Although poorly documented in birds, emetics might be useful to remove foreign bodies that would not damage the gastrointestinal mucosa during the regurgitation process. Apomorphine induced emesis in 55% of treated birds[36] and in another study, a 0.5% solution of tartar emetic was effective.[114]

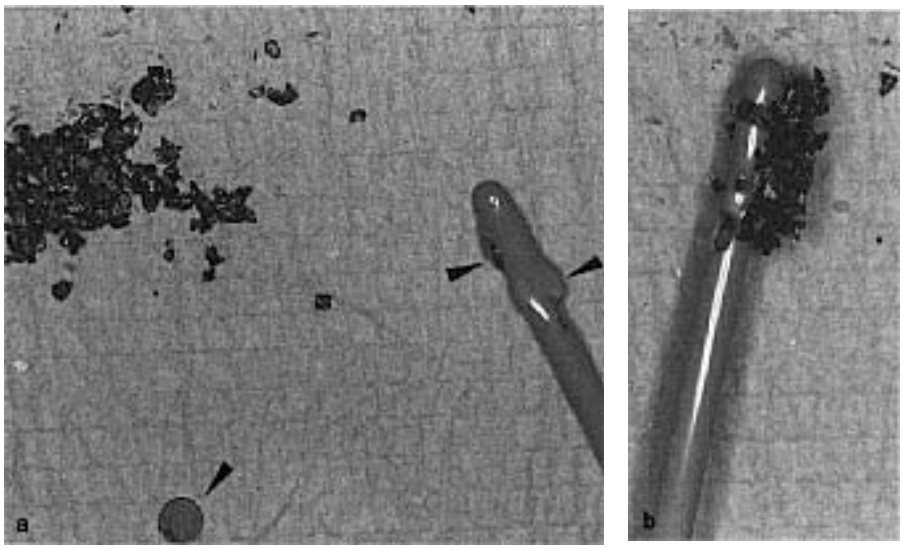

FIG 19.13 A mature African Grey Parrot was presented for evaluation of depression and anorexia several days after destroying a panel of chicken wire placed over a screened-in-porch. Radiographs indicated that the ventriculus was full of metallic densities. Because the wire was composed of a ferrous metal, **a)** the foreign bodies were removed by repeatedly inserting a red rubber feeding catheter equipped with several neodymium-ferro-borium alloy magnets (arrows). **b)** The metal removed from the bird is firmly attached to the magnet contained within the tube.

Metallic Foreign Bodies: Traumatic Gastritis, Heavy Metal Poisoning

Ingestion of metallic foreign bodies is relatively common in Galliformes, Anseriformes, Columbiformes, Gruiformes, Pelecaniformes, Psittaciformes and ratites.[51,71,205,209,210] In captive Psittaciformes and free-ranging Anseriformes, ingestion of lead is extremely common. Paralysis of the intestinal tract from nerve damage may occur secondary to lead poisoning. In Anseriformes, this is clinically recognized as esophageal and proventricular dilatation. In the other orders, ingestion of ferrous metal objects, such as nails, wire, hairpins and needles, account for the majority of cases. This is particularly common in gallinaceous birds.[151] In one case, each affected bird had a piece of one-inch wire penetrating the ventriculus (see Figure 45.2). It was discovered that the owner used a wire brush to clean the water container.

Ingestion of ferrous objects may cause perforation of the ventriculus (majority of cases) or proventriculus, leading to an acute, generalized, purulent peritonitis or to a local peritonitis with abscess formation on the serosal surface of the (pro)ventriculus or duodenum. The powerful contractions of the ventriculus muscles in the domestic fowl can result in a pressure of 100-200 mmHg, which can easily force sharp objects through the tough muscular wall. Occasionally, penetration of a large (hepatic) artery or vein can result in fatal hemorrhage. In some rare cases, the ferrous foreign body will be resorbed by the inflammatory reaction without permanent deleterious effects. Cases have been documented in which a foreign body was exteriorized by penetration through the body wall.[51,205]

Foreign body penetration of the ventricular wall causes a decrease in ventricular contraction and an insufficient digestion of food, which may be recognized clinically by the passage of undigested seeds in the feces. In the racing pigeon, passing undigested seed is considered pathognomonic for a traumatic gastritis. In chronic cases, anorexia, weight loss and a palpable abscess on the left side of the abdominal wall may be noted.[205] Radiology is the method of choice to confirm a tentative diagnosis.

Noninvasive treatments for removal of gastric metal foreign bodies should be attempted before (pro)ventriculotomy. Ferrous metals may be removed from the (pro)ventriculus using a powerful magnet of neodymium-ferro-borium alloy (The Magnet Store 1-800-222-7846) attached to a small-diameter polyvinyl catheter with a removable steel guide wire (Figure 19.13).[120] The size of the polyvinyl probe and magnetic disk can be varied according to the size of the animal. A probe with a length of two meters, a diameter of 18 mm and an attached cylinder magnet of 17 x 70 mm (derived from a bovine cage magnet) has been used to remove thirteen large staples from the ventriculus of an ostrich. Fluoroscopy or endoscopy can be used to guide grasping forceps in the

removal of gastric foreign bodies.[117,119] Most cases of lead and zinc ingestion can be managed medically and do not require surgery.

Myoventricular Dysgenesis

Proventricular dilatation secondary to ventricular abnormalities caused by feeding finely ground food low in fiber is commonly observed as an incidental finding in chickens. The enlarged proventriculus has a distended thin wall and is full of food. The ventriculus in affected birds is poorly developed, and there is no sharp demarcation between the proventriculus and ventriculus.[169] The postmortem findings are similar to those with pyloric obstruction or gastroesophageal paralysis (ie, dilatation of the food-filled ventriculus, proventriculus, esophagus and crop). In the latter condition, the ventricular muscles are of normal thickness.

Vitamin E and Selenium Deficiencies

Vitamin E and selenium deficiencies may cause degenerative lesions in the smooth muscle of the ventriculus of domestic and free-ranging Anseriformes.[135,178,219]

Gastric Ulceration, Ventriculus Erosion, Gastritis, Koilin Dysgenesis

Idiopathic proventricular ulcers do occur in psittacine birds. Many affected animals are "high strung" or in what could be called stressful environments (Figure 19.14); (Color 19.3).

High dietary levels of certain types of fish meal or finely ground, low-fiber diets can cause erosions and ulcers in the koilin layer of gallinaceous birds.[71,144] Infectious and parasitic agents may damage the ventricular wall causing dysfunction. Penetration of foreign bodies may cause localized lesions. Zoalene (DOT) toxicosis may cause gastric erosion.[71] Ventriculus erosion with a heavy infiltration of heterophils has been reported with zinc poisoning.[46,48,216]

Copper Poisoning

Excessive dietary copper leads to roughening and thickening of the koilin layer. The marked thickening and folding may have a wart-like appearance. Hemorrhages may be seen under the koilin layer.[53,216]

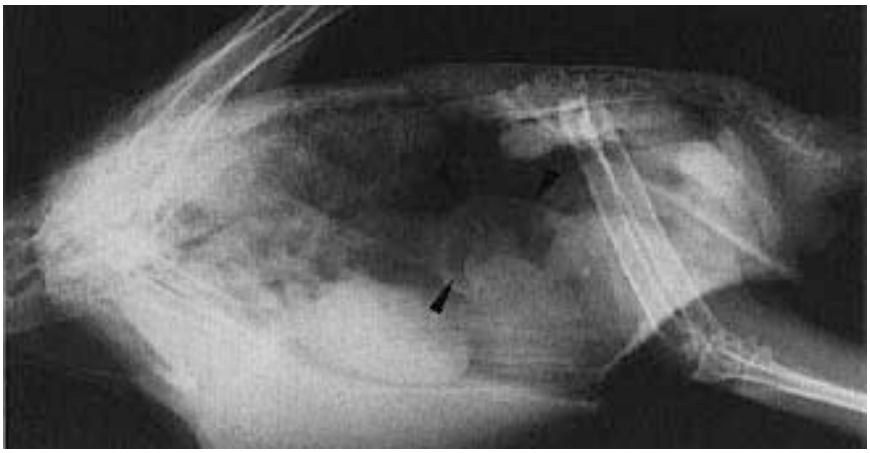

FIG 19.14 An eight-year-old Sulphur-crested Cockatoo was presented with a five-week history of vomiting and progressive weight loss. Survey radiographs indicated gaseous distention of the proventriculus (arrows). Contrast radiographs indicated mucosal filling defects in the proventriculus. Gastroscopy with a 3.5 mm flexible endoscope indicated numerous proventricular ulcers (Color 19.2). The bird did not respond to supportive therapy. Histopathology indicated marked myocardial degeneration and necrosis of undetermined etiology.

Neoplasias[2,68,74,113,161]

The clinical effects of (pro)ventricular neoplasia may vary, depending on the size of the tumor and the presence or absence of active bleeding from the ulcerated tumor. Clinical signs may include weight loss, vomiting, passing of whole seeds in the feces, regenerative anemia, hypoproteinemia and melena. Although hypoproteinemia may occur, the albumin/globulin ratio is not affected, which together with the anemia and melena is strongly indicative of gastrointestinal blood loss (Table 19.7). Death usually ensues when massive gastric bleeding occurs following erosion of a major vessel. Contrast radiography using both positive and negative contrast may be helpful in outlining the (pro)ventricular neoplasm.[196] Endoscopic-guided biopsy may be used to confirm a tentative diagnosis.

Tumors are frequently located at the isthmus on the boundary between the proventriculus and ventriculus. Gross lesions in the (pro)ventriculus may be subtle, and histologic examination is needed to differentiate tumors from other causes of ulceration or hypertrophy. The use of specific staining methods (Alcian blue and periodic acid Schiff) facilitates differentiation between tumors of proventricular and ventricular origin.[113,161]

Presently, no reports of successful treatment of (pro)ventricular tumors have been published, but it has been suggested that early diagnosis and surgical excision are feasible.[161]

Squamous cell carcinomas are the most common tumor in the oral cavity of Galliformes. Oropharyngeal tumors may be painful, ulcerative and infiltrative but rarely metastasize. Clinical signs may include dysphagia, regurgitation, vomiting, diarrhea, tenesmus and cloacal prolapse. A definitive diagnosis can be made by biopsy. Prognosis depends on the location of the tumor, the degree of tissue infiltration and the occurence of metastasis. Many connective tissue tumors in gallinaceous birds may be caused by the leucosis sarcoma group of viral infections.[149] There is a high incidence of pharyngeal and esophageal squamous cell carcinoma in humans and chickens in northern China suggesting a common etiology.[34, 180] The incidence of gastric neoplasia seems higher in psittacine birds compared to otherspecies. Intestinal tumors must be differentiated from metastatic oviductal or ovarian tumors by demonstrating that no primary tumors of these organs exist and that the tumor originates from intestinal mucosal epithelium or glands, rather than growing inward from the serosal surface.[29] Obstruction of the pancreatic ducts can occur with pancreatic neoplasias. Islet cell carcinomas can cause diabetes mellitus.[74, 196]

The Small and Large Intestines

Anatomy and Physiology[101]

In the majority of avian species, the duodenum is a narrow, U-shaped organ that originates from the pylorus on the right side of the ventriculus. The pale pink or yellow lobulated pancreas is located between the proximal descending and distal ascending duodenal loops (see Color 14). In some species (eg, White-tailed Sea Eagle and Jackass Penguin), secondary folds are present in the duodenum. In the Black Stork, the duodenum is twisted, while in other species (eg, Northern Fulmar and Gannet), the duodenum consists of more than one loop. The bile and pancreatic ducts often open near each other at the distal end of the duodenum. There are one, two (ducks and geese) or three (domestic fowl) pancreatic ducts and two bile ducts. When a gallbladder is present, this organ drains the right liver lobe via the right hepatocystic duct and empties into the duodenum via the cysticoenteric duct. In species where a gallbladder is absent (most pigeons, many parrots and the ostrich), the right liver lobe drains directly into the duodenum via the right hepatoenteric duct. In gallinaceous birds, the common hepatoenteric duct drains bile from both liver lobes to the duodenum. The jejunum and ileum are arranged in a number of loops, and are suspended by a long, distal mesentery on the right side of the abdominal cavity.

The vitelline diverticulum (Meckel's diverticulum), which is the remnant of the yolk duct, is located opposite the distal end of the cranial mesenteric artery. The duct of the yolk sac opens into the small intestine on a small papilla. The yolk provides nourishment, minerals, fat-soluble vitamins and maternal immunoglobulins to the embryonic bird and to the chick during the first few days of life. Just before hatching, the yolk sac is internalized and the umbilicus is closed. Precocial birds have a yolk sac that ranges from 10 to 25% of body weight at hatching, while in altricial species these values range from 5 to 10% of body weight.[99] Precocial birds must learn to eat during the first few days of life, while altricial birds are fed by their parents. In altricial species, resorption of the yolk is faster than in precocial species and takes about four days.

In gallinaceous birds, the yolk sac should not persist beyond six to nine days and should not be larger than pea-size between six to eight days of age.[71] In the ostrich, yolk sac absorption may require eight or more days. In the emu and cassowary, a yolk sac can be palpated for at least one week, but it should be reduced in size. It should be noted that at hatching, the liver of some birds is a bright yellow color due to absorption of pigments from the yolk sac (see Color 30). The liver gradually changes to the mahogany color of the adult between eight and fourteen days of age in gallinaceous birds.[130] In the adult chicken, the vitelline diverticulum has been found to contribute to extramedullary myelopoiesis, and it has been suggested to have a lymphoepithelial function.[130]

The large intestine usually consists of paired ceca and a short, straight rectum. The ceca arise at the ileorectal junction. The anatomy of the ceca varies among species. In Galliformes, the ceca are large and curve in a caudodorsal direction. Tetraonids (eg, capercaillies grouse that eat branches and twigs of trees) have the largest ceca of any species because of their high cellulose diet.[4] The ostrich has a large sacculated cecum while other ratites have only vestigial ceca. Passeriformes, Columbiformes and some Psittaciformes also have vestigial ceca. Budgerigars have no ceca. Vestigial ceca usually contain large amounts of lymphoid tissue. In Galliformes, the lymphoid cecal tissue is located in the proximal part of each cecum and is called the cecal tonsil. Large ceca are involved in the bacterial fermentation of cellulose, and are also important in water reabsorption from ureteral urine. The type of food consumed by a bird influences intestinal length. Red Grouse fed a pelleted ration have a cecal length 50% shorter than those of free-ranging birds.[136] This is extremely important when one considers the problems with digestion that could occur if captive-raised birds were released into the wild.

The rectum lies in the dorsal part of the abdominal cavity and is a continuation of the ileum. It is usually a short, straight organ, but in some species, including the rhea, the rectum is looped or folded. In the emu, the rectum is adapted to preserve water. The high resorptive capacity may be related to increased folding of the mucosal surface, which increases the surface area by a factor of five. The emu has a limited renal concentrating ability with a maximal urine:plasma osmotic ratio of only 1.4:1.5.[182]

Intestinal Diseases

Enteritis

Many infectious agents can cause enteritis. Table 19.1 lists some infectious causes of diarrhea. Infectious stunting syndrome (ISS) in chickens (probably of viral etiology) is associated with an enteritis and inflammation of the pancreatic ducts. Most affected birds recover completely after a period of diarrhea. However, some birds develop exocrine pancreatic deficiency secondary to blockage of the pancreatic ducts (Colors 19.4 and 19.6).[93]

Ileus

Ileus (intestinal obstruction) can be defined as a condition wherein the passage of intestinal contents is arrested or severely impaired. The cause of intestinal obstruction may be physical or it may be due to impaired motor function (paralytic ileus) (Color 19.18). Physical causes may be located within the lumen, in the intestinal wall or outside the intestine. Occlusion of the intestinal lumen may be caused by foreign bodies, enteroliths or parasites. Intestinal wall lesions that have been reported to cause stenosis in birds include tumors, granulomas and strictures (eg, cicatrization tissue induced by foreign bodies). Extraluminal compression may occur from intussusception, volvulus mesenterialis, volvulus nodosus, incarcerated hernia mesenterialis, pseudoligaments and adhesions due to tumors or peritonitis. Vascular causes of ileus include embolism and thrombosis of a splanchnic artery or vein with infarction of a bowel segment.

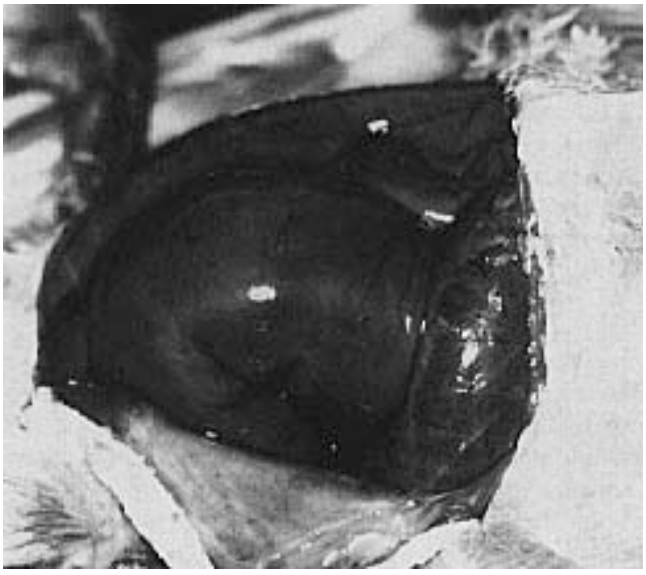

FIG 19.15 A twelve-week-old Blue and Gold Macaw chick was presented for anorexia, depression and regurgitation of three days' duration. The abdomen was severely distended and doughy. Heart sounds were muffled dorsally, and severe dyspnea occurred following minimal exercise. A modified transudate was collected by abdominocentesis. Abnormal clinical pathology findings included: WBC=4500, AST=800 and LDH=1200. Radiographs indicated gaseous distention of the bowel. The bird did not respond to supportive care. At necropsy, the abdomen was filled with yellow fluid, and the bowel loops were distended with gas and were blue-black in coloration. Histologic findings were suggestive of avian viral serositis. The bird's sibling died following a similar clinical disease.

Neurogenic causes (paralytic ileus) include lead poisoning, peritonitis, neuropathic gastric dilatation and enteritis (Figure 19.15).

Once the intestine is obstructed it dilates, and fluid is collected in the intestinal lumen and lost from the circulation. Clinical signs depend on the site and severity of the obstruction. The birds become rapidly dehydrated and are severely depressed. In many conditions ischemic necrosis of the intestinal wall occurs, leading to increased permeability and protein loss into the intestinal lumen. Resorption of intestinal contents, including endotoxins released from gram-negative bacteria, can cause shock. Usually complete intestinal obstruction in birds caused by intussusception or volvulus is fatal within 24 to 48 hours. A more protracted course is common with other causes of intestinal obstruction. Vomiting is usually present in complete mechanical obstruction, although this sign may be absent when the obstruction is in the caudal part of the intestinal tract. The passage of feces is diminished or absent. Diarrhea may be present with partial obstruction. Emaciation is seen when the obstruction occurs gradually from a progressive disease.

Plain radiographs may show the extent and location of the gas-filled intestinal loops. A barium enema or upper GI contrast study may be used to determine the exact location of the obstruction. The use of double contrast techniques facilitates visualization of lesions in the intestinal wall. Early diagnosis and rapid surgical correction may successfully resolve many intestinal obstructions. Birds should be stabilized with fluids and antibiotics before surgery.

Intussusception

Intussusception of the distal part of the small intestine is occasionally reported in young gallinaceous birds secondary to enteritis or spasmodic antiperistalsis caused by a nematode infection or coccidiosis. The affected part of the intestine rapidly becomes necrotic, inducing adhesions with neighboring tissues. Death usually occurs from peritonitis and toxemia.[93]

In 19 cases of intestinal intussusception in gallinaceous birds and ducks, 15 cases involved the small intestine, three cases involved the ceca and one case involved the rectum. The middle and distal parts of the small intestine were usually involved. The beginning of the intussusception was usually located about 30 cm proximal to the ileocecal junction in chickens and 10-20 cm proximal in ducks. In one bird the distal end of the small intestine was invaginated into the rectum, while in another bird, 5 cm of the small intestine was prolapsed through the cloaca. In one case of cecal intussusception, the cecum passed through the rectum, and the black-red color of the apex could be seen in the cloaca. In the other cases of cecal invagination, part of the cecum was invaginated into itself. Invagination leads to partial obstruction with accumulation of fluid and gas proximal to the affected site. Rectal intussusception, which can lead to rectal prolapse, has been reported in gallinaceous birds and has been noted in Psittaciformes.[51]

Volvulus Mesenterialis

Volvulus mesenterialis can be defined as the twisting of a portion of the intestine around its mesenteric attachment. Volvulus mesenterialis jejuni has been reported in chickens, ducks and pigeons.[51] The presence of stalked tumorous egg follicles with associated adhesions and stalked mesenteric cysts are common predisposing factors. In one case (pigeon), a heavy ascarid infection was present. In the other cases, enteritis was present, which may have predisposed the birds to mesenteric torsion. In one case, a fecalith caused obstruction and torsion of the rectum just proximal to the junction with the cloaca. The entire rectum was filled with fecal material and gas. In the ostrich, torsion of the large bowel has also been reported.[209] It is speculated that an abrupt change in feed may be a predisposing factor.

Volvulus Nodosus

Volvulus nodosus can be defined as twisting of an intestinal loop around itself. Volvulus nodosus is usually seen in conjunction with a volvulus mesenterialis jejuni but may occur independently. Predisposing factors include adhesions and antiperistaltic movements induced by intestinal ulcerations, heavy ascarid infestations, accumulation of sand, foreign bodies and tumors.

Occlusion of the bowel can occur if intestinal loops herniate through tears in the mesentery or through the abdominal wall.[51] Abdominal herniation is particularly common in egg-laying hens, and may be associated with trauma, abdominal masses, egg binding, tenesmus or endocrine abnormalities.

Other reported causes of intestinal obstruction include a stone lodged near the boundary between the duodenum and jejunum, sloughed koilin layer in a pigeon obstructing the distal part of the rectum where it joins the cloaca, and phytobezoars lodged in the distal part of the ileum or distal part of the rectum. Acute death was caused by rupture of an intestinal diverticulum in two of these cases and intestinal hemorrhage in one case. Other affected birds died eight to ten days after developing clinical signs, probably due to shock and absorption of intestinal toxins.[51] Sarcoma of the small intestine, an abscess or a cyst in the distal part of the rectum, diphtheritic enteritis with obstruction in the distal part of the small intestine and a stenosis caused by circular cicatrization tissue in the small intestine or rectum have also been reported as causes of intestinal obstruction.

Persistently feeding voluminous feedstuffs of poor nutritional value caused intestinal impaction in a group of Galliformes, Anseriformes and Columbiformes. In some cases, the entire gastrointestinal tract was involved. In others, the small intestine, rectum or cecum was the major site of impaction. Obstruction of the small intestine, which may progress to rupture, may be caused by ascarids or cestodes in Galliformes, Anseriformes, Falconiformes, Psittaciformes or Passeriformes (see Figure 36.30).[91,93,154] Esophageal and intestinal perforations in turkeys occurred following the ingestion of grasshoppers.[215] Intestinal perforation by fir cones and glass have been reported in Tetraonidae.[4]

Coligranuloma: Hjarre's Disease

A coliform-induced granulomatous disease (Hjarre's disease) has been reported in captive[75] and free-ranging Galliformes. Clinical signs are not specific and include emaciation and diarrhea. Large lesions may cause intestinal obstruction. Granulomas may also occur in the liver, ceca (which may be very large), duodenum and mesentery. The lesions should be differentiated from leukotic neoplasms and tuberculosis.

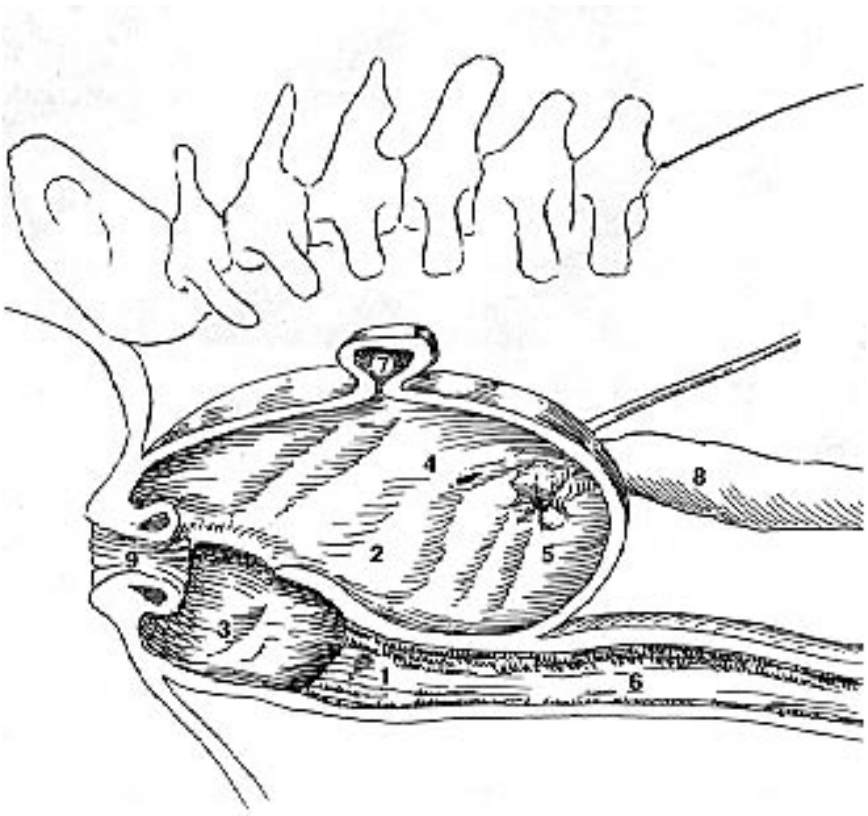

FIG 19.16 The cloaca is composed of the 1) coprodeum, 2) urodeum and 3) proctodeum. The 4) openings of the ureter and 5) vagina can be seen in the urodeum. Other structures associated with the cloaca include the 6) rectum, 7) cloacal bursa, 8) oviduct and 9) vent.

The Cloaca

Anatomy and Physiology

The cloaca consists of three compartments: the coprodeum, which is directly continuous with the rectum; the urodeum, which contains the openings of the ureters and genital ducts; and the proctodeum, which opens to the outside through the lips of the vent.[130] The coprodeum is separated from the urodeum by the coprourodeal fold, while the urodeum and proctodeum are separated by the uroproctodeal fold (Figure 19.16). A striated sphincter muscle controls the action of the vent. In the cock, the phallus, if present, lies on the crest of the ventral lip of the vent. It consists of a median phallic body flanked on either side by a lateral phallic body and lymphatic folds. Tumescence of the phallus is due to lymph, which flows from the paracloacal vascular bodies that lie in the ventrolateral walls of the urodeum. In the detumescent state, the phallus is directed toward the interior of the cloaca. This type of phallus is called non-intromittent, because it does not enter the cloaca of the female but is merely applied to the protruded oviduct of the female. In adult male ducks and ratites, a distinct phallus is present that is inserted into the female cloaca during coitus. The male Vasa Parrot also has a large copulatory organ that swells considerably during the breeding season. This physiologic phenomenon in the Vasa Parrot should not be confused with cloacal pathology.

The cloacal bursa (bursa of Fabricius) is a dorsomedian pear-shaped diverticulum of the cloacal wall (see Figure 5.6). In chickens, it reaches its maximum size at six weeks when it measures 3 x 2 x 1 cm and weighs about 4 grams. It then begins to regress at about 8 to 12 weeks of age, and by 20 months it weighs only 0.5 g. In the adult, a nodular remnant of the bursa can be identified. In ratites, the neck of the bursa has a wide lumen, which does not occur in other avian species. In these birds, the proctodeum and cloacal bursa form one single cavity. The unusually wide entrance to the bursa is often incorrectly identified as a urinary bladder. The bursa is the site of differentiation of B-lymphocytes, which play an important role in the humoral defense system of the body (see Chapter 5).

During defecation, the coprourodeal fold protrudes through the vent to prevent fecal contamination of the urodeum and proctodeum. Similarly, the uroproctodeal fold protrudes through the vent during egg laying. Urine deposited in the urodeum moves retrograde into the rectum (and ceca, if present), where reabsorption of water takes place. Often birds will have watery excreta when they are excited, because they defecate before water reabsorption is complete.

Clinical Examination

Clinical signs indicative of cloacal disorders may include flatulence, tenesmus, soiled pericloacal area,

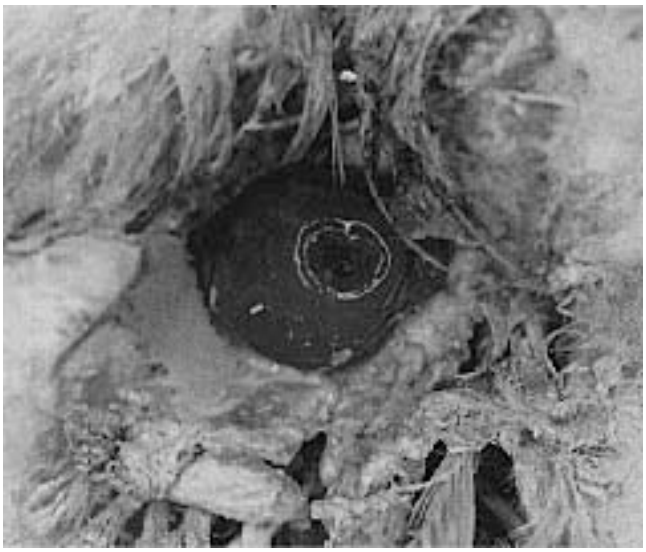

FIG 19.17 A two-year-old Umbrella Cockatoo was presented with a four-day history of tenesmus. The bird was fed a seed-based diet and was constantly demanding affection from its owner. Physical examination findings included the accumulation of excrement around the vent and protrusion of a smooth, glistening, pink cloaca. The bird had a moderate number (15%) of gram-negative bacteria in the feces and was placed on injectable enrofloxacin and medroxyprogesterone acetate. The mucosa of the cloaca was coated with apple cider vinegar to check for papillomas. None were detected. The bird responded to the antibiotic and hormone therapy as well as to a change in diet to a formulated product and behavior modification. The tenesmus stopped, and there were no further problems with cloacal prolapsing.

protruding tissue from the cloaca and foul-smelling feces. Examination of the cloaca should start with the feathers and skin around the vent. Normally these structures should be clean, and there should be no signs of inflammation (Color 19.8). An abnormal acidic smell can be a sign of cloacitis, which is often associated with cloacal papillomatosis.

Cloacal Diseases

Cloacal Prolapse

A prolapse involving the cloaca may contain intestines, oviduct and one or both ureters. The appearance of smooth, glistening, pink tissue is an indication that the cloaca has prolapsed, which may be caused by sphincter problems, chronic irritation of the rectum or tenesmus. A cloacal prolapse may cause severe constipation and toxemia (Color 19.10). In gallinaceous birds, cannibalism by cage mates may result in cloacal rupture and evisceration of the affected individual.

Acute cloacal prolapse associated with egg laying generally responds to manual reduction, followed by application of two simple transverse stay sutures perpendicular to the vent. Postoperative straining can be prevented by applying xylocaine gel in the cloaca BID. The cause of the straining or increased abdominal pressure should be corrected to prevent further prolapsing.

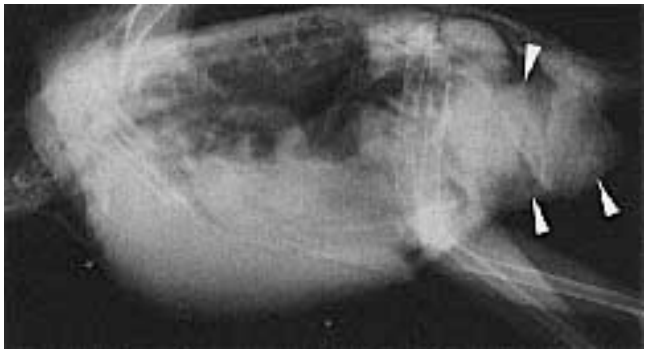

FIG 19.18 A four-year-old male Amazon parrot was presented with a history of straining to defecate and emitting a foul odor. A large pericloacal mass was palpable on physical examination. The mass was ulcerated, hyperemic, moist and associated with a yellowish-green discharge. Cytologic evaluation of samples collected from within the mass revealed gram-negative rods, degranulating heterophils and macrophages containing bacteria. Radiographs showed an extensive pericloacal mass that was causing cloacal distention (arrows) and cranial displacement of the intestines. The mass was surgically debrided, and the bird was successfully treated with piperacillin.

In cockatoos, chronic cloacal prolapse may be associated with sexual behavior in the presence of the owner, or can be caused by idiopathic straining (Figure 19.17). A combination of ventral cloacopexy[173] and cloacal mucosal "reefing" has been used to correct chronic cloacal prolapse (see Chapter 41).

Cloacitis

A sporadically occurring, chronic inflammatory process of the cloaca with a very offensive odor, commonly known as "vent gleet," may occur in laying hens and occasionally in males. A yellow diphtheritic membrane may form on the mucosal surface, and urates and inflammatory exudate contaminate the skin and feathers around the vent. The cause is unknown. Treatment consists of cleaning the area and applying a local antibiotic ointment.[93]

A similar condition has been reported in ducks. Scarring, which reduces the elasticity and diameter of the cloaca and may prevent egg laying and, in extreme cases, defecation, is a complication of cloacitis (Figure 19.18).[71,93]

Neisseria, Mycoplasma spp. and *Candida albicans*

Bacteria (especially *Neisseria* and *Mycoplasma* spp.), and *Candida albicans* have been associated with a venereal disease affecting ganders.[9,14,188] It seems likely that the cloacitis observed in drakes has a similar etiology, but an association has not been confirmed.

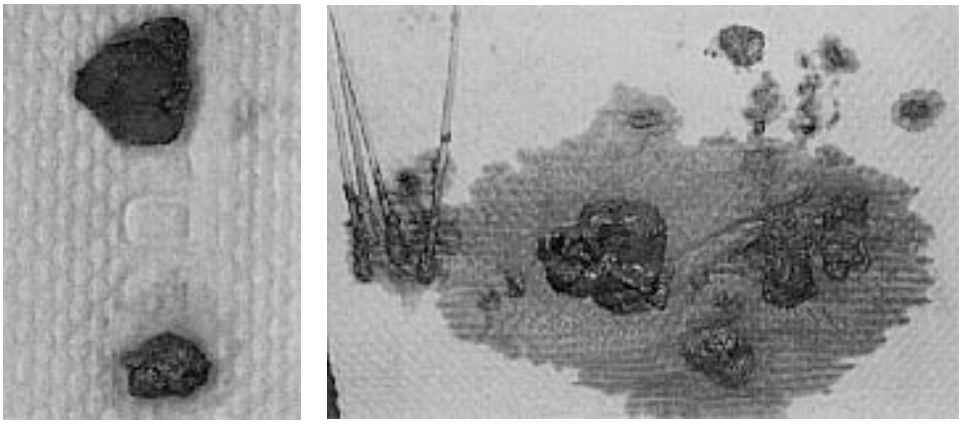

FIG 19.19 A mature Amazon parrot was presented with a two-day history of depression, anorexia and straining to defecate. The abdomen was distended. When a cotton swab was inserted into the cloaca, excrement would "squirt" out. When the swab was removed, no excrement would be released. Several uroliths that were functioning as a valve were identified at the opening of the cloaca. When the uroliths were removed, the bird was able to defecate normally.

Cloacal infections may occasionally be observed in other species and may result from trauma, surgery or infectious diseases. Uroliths or fecaliths may form during the process. Cloacitis is often seen in psittacine birds suffering from cloacal papillomatosis.

Phallus Prolapse and Venereal Disease in Anseriformes

The phallus may not retract into the cloaca in some sexually mature drakes. The problem is usually associated with an extensive infection in the erectile tissue at the base of the phallus. It has been suggested that the etiology of this condition is traumatic, because the incidence is higher under conditions where the drakes have to mate with the females out of the water.[71] Drakes with females that have cloacitis may have a phallus infection, suggesting that an infectious agent can play a role in phallus prolapse.

Cloacal Stricture

Infections, surgical manipulation of the cloaca (particularly for removal of papillomas) and trauma may cause stricture of the vent, requiring surgical recreation of an opening and appropriate aftercare to prevent a recurrence.[173]

Cloacal Impaction

Cloacal impaction may occur from foreign bodies (eg, potato chunks in Galliformes), fecaliths, concrements of urates and retained necrotic eggs (Figure 19.19). Uroliths can vary from six to eight millimeter-thick concrements on the cloacal wall to solid masses the size of a chicken egg. In any case of cloacal impaction, passing excrement is difficult or impossible and can cause congestion of the ureters and dilatation of the intestines as far proximal as the duodenum. Renal failure and visceral gout may occur if the ureters are blocked.[51]

Cloacoliths composed of urates have been observed in numerous psittacine birds, particularly macaws and Amazon parrots.[173] The etiology is unknown. Treatment consists of segmenting and removing the concrements. Cloacal impaction may also occur secondary to cloacal infections and cloacal stricture (Figure 19.20).

Cloacal papillomatosis is a well known disease in psittacine birds and is recognized clinically as a glistening red or pink cauliflower- or strawberry-like mass rising from the cloacal orifice (Color 19.9).[42,67,86,112,173,190,196,200] Early lesions are characterized by a rough-appearing mucosa at the mucocutaneous junction of the cloaca. Other presenting signs may include tenesmus, melena, foul-smelling feces, flatulence, pasting of the vent and cloacoliths. The abnormal odor is likely to be caused by bacterial proliferation in the crypts caused by the papillomas. The incidence of disease is higher in New World parrots, but Old World parrots may also be affected.[69] The condition is frequently misdiagnosed as a cloacal prolapse. Applying an acetic acid solution (apple cider vinegar) to cloacal epithelium will change the color of papillomatous tissue to white. A definitive diagnosis can be made after histopathologic examination of a biopsy. Cloacal papillomas are often associated with similar lesions in the oropharynx, choana, esophagus, crop, proventriculus, ventriculus and occasionally mucosa of the eye and nose.[67] The etiology is presently unknown. There seems to be a high correlation between neoplasia of bile ducts and pancreatic ducts and papillomatosis in psittacine birds.[41,69,86,159]

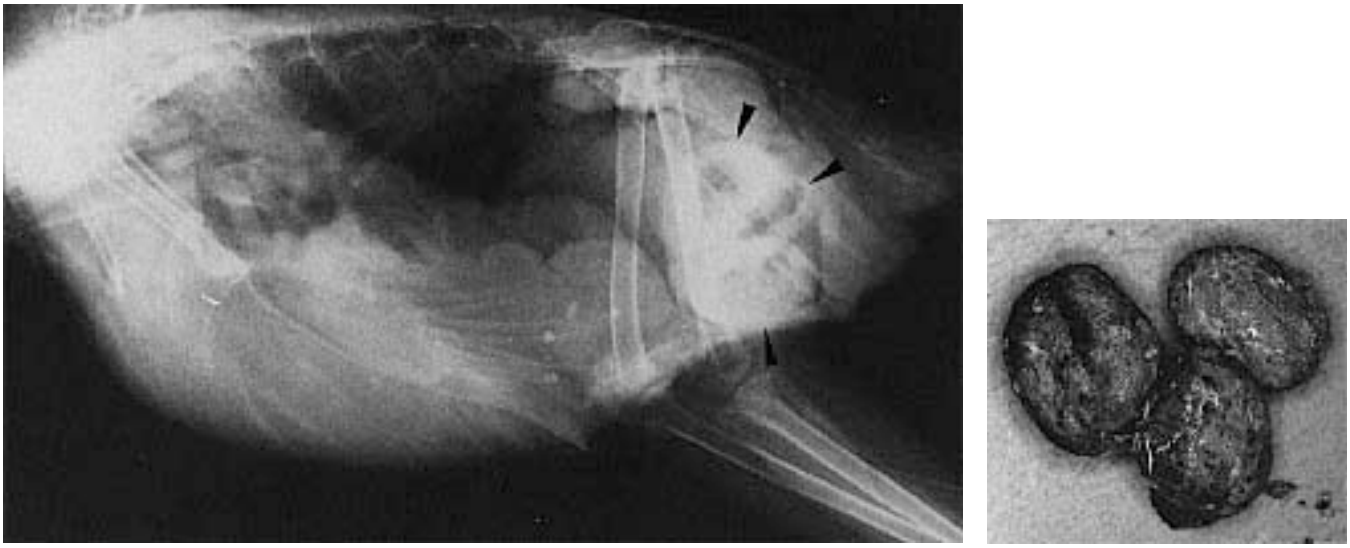

FIG 19.20 A ten-year-old Blue-fronted Amazon Parrot was presented with depression, failure to defecate and a distended abdomen. The referring veterinarian had placed a purse-string type suture to correct what was diagnosed as a cloacal prolapse three days before presentation. The abdomen was distended and tight. Unproductive tenesmus was noted by a constant "winking" of the cloaca. The purse-string suture was removed and the bird released a large quantity of excrement; however, the tenesmus continued. Survey radiographs revealed several elongated mineralized masses in the cloacal area (arrows). Three large uroliths were removed from the cloaca with forceps. The cloacal mucosa was hyperemic and ulcerated. A large cloacal papilloma was evident in the left lateral wall of the cloaca. The papilloma was cauterized by specific application of silver nitrate, and the cloaca was flushed with a dilute povidone-iodine solution. Removal of the papilloma required two further treatments. Papillomas that protrude from the cloaca must not be confused with a cloacal prolapse, as initially occurred in this case.

Various techniques have been used to treat cloacal papillomas, including cryosurgery, chemical cautery, radiosurgery and autogenous vaccination,[173] but the reported spontaneous remissions and intermittent nature of the disease[67,69,129,200] makes evaluation of the various treatments difficult. The introduction of birds with papillomas to a breeding facility should be prevented by performing a thorough physical examination at the beginning and end of the quarantine period. Of 41 papillomatous lesions, growth was benign in 40, but one single case was diagnosed as carcinoma *in situ*.[190] Other tumors should be considered in the differential diagnosis.[13,58,15,163] Papillomas are most easily removed from the cloaca with careful, staged cauterization with a silver nitrate stick. The silver nitrate must come in contact only with the tissue intended to be removed to prevent severe burns of normal cloacal mucosa (Color 19.9).

The Pancreas

Anatomy and Physiology

The pancreas is situated on the left ventral side of the abdominal cavity between the descending and ascending loops of the duodenum. There are three lobes: dorsal, ventral and splenic. The dorsal and ventral lobes are usually connected (except in the Mallard and pigeon). The splenic lobe extends cranially from the dorsal or ventral lobe. There are one, two or three pancreatic ducts, which usually drain the pancreatic secretions into the ascending part of the duodenum. The exocrine pancreatic enzymes that are present in the duodenum include amylase, lipase, trypsin and chymotrypsin, which facilitate degradation of carbohydrates, fats and proteins, respectively. Trypsin and chymotrypsin are secreted as inactive precursors, and they become active only when they enter the duodenum. The activator is the locally produced enzyme, enterokinase, which changes trypsinogen to trypsin. This prevents the pancreas from being digested by its own enzymes.[49]

Diagnostic Considerations

The pancreas has both endocrine and exocrine functions. The former are discussed in Chapter 23. Many postmortem lesions have been reported in avian pancreata.[70] There are two major clinical manifestations of pancreatic disease. If no pancreatic enzymes are available in the duodenum, maldigestion and passing of feces with excessive amylum and fat will occur. Affected animals may have voluminous, pale or tan, greasy feces (see Color 8). Fat in the feces can be demonstrated by Sudan staining. Interpretation of microscopic examination of feces for undigested food such as fat, starch grains and muscle fibers is complicated by variation in diets and by changes due to intestinal causes of malabsorption. Measurement of fecal proteolytic activity can be performed in several ways. The X-ray film gelatin digestion test is an unreliable assay of fecal proteolytic activity.[217] A test for fecal proteolytic and amylase activity is probably more reliable for use in birds.[214]

Pancreatic Diseases

Acute Pancreatic Necrosis/Acute Pancreatitis

The pathogenesis of acute pancreatitis involves the activation of pancreatic enzymes in and around the pancreas and in the bloodstream, resulting in coagulation necrosis of the pancreas, and necrosis and hemorrhage of peripancreatic and peritoneal adipose tissue (see Color 14). Affected birds may be in shock, and radiographs may show loss of abdominal detail due to peritonitis and fluid accumulation in the peritoneal cavity. Dilatation of the small intestine may be visible due to an accompanying ileus. Increased plasma amylase activity (secondary to destruction of exocrine pancreatic cells) has been reported in chronic active pancreatitis in birds. Elevated plasma amylase may also occur with occlusion of the main pancreatic duct,[164] and might be a component of the infectious stunting syndrome in chickens.[181] Lipemia may be present. A diagnosis of pancreatitis can be confirmed by endoscopy or exploratory laparotomy.

Obesity seems to be a predisposing factor of pancreatitis in birds. Treatment should include withholding food and oral medication for 72 hours, correction of fluid and electrolyte balance and prophylactic use of antibiotics. Dietary fat intake should be restricted to decrease the secretory load of the pancreas.[70,158]

Chronic Pancreatic Fibrosis/Chronic Pancreatitis/ Pancreatic Exocrine Insufficiency

A decrease in pancreatic glandular tissue or fibrosis may occur as the result of a chronic inflammatory process and cause clinical changes suggestive of pancreatic exocrine insufficiency (PEI).[70,160] Further studies on the relation between pancreatic disease and plasma amylase and plasma lipase activities in birds are needed to facilitate clinical diagnosis; however, birds with a malabsorption syndrome and high amylase and lipase levels may respond to therapy with pancreatic enzymes, suggesting PEI. Frequently, the cause of PEI is undetermined. Pancreatic fibrosis was reported in two psittacine birds with chronic chlamydiosis.[70]

High dietary levels of zinc may cause dilation of acinar lumina and degenerative changes in acinar cells including depletion of zymogen bodies, cytoplasmic vacuolization, the presence of hyaline bodies and other electron-dense debris, necrosis of individual acinar cells and fibrosis.[46,48,98,204,216] Excess levels of zinc also interfere with exocrine pancreatic function.[118]

Pancreatic atrophy and fibrosis accompanied by impaired fat digestion have been reported in chickens on a selenium-deficient diet.[192,193] It has been shown that addition of 0.1 ppm selenium to the diet could reverse the clinical signs and cause complete pancreatic acinar regeneration.[72]

Infectious Stunting Syndrome (ISS)

Infectious stunting syndrome (ISS)[93,1709] has many synonyms including runting and leg weakness,[104] runting syndrome,[147] infectious stunting,[19,171] pale bird syndrome,[65,116,142] malabsorption syndrome,[142] brittle bone disease,[199] diarrhea and stunting,[93] runting and stunting syndrome,[165] and stunting and runting syndrome.[125] Clinical signs include growth retardation, steatorrhea, polyphagia, coprophagia, soft bones, swollen tibial epiphyses, rachitic ribs and abnormal feather development. The latter is possibly related to decreased circulating concentrations of thyroxine (see Chapter 23).[93,170]

Although the etiology of this disease is not known, a virus is likely to be the etiologic agent,[170] but mycotoxins, other toxins, *Campylobacter* spp. and spirochetes may also be involved.[93,189] Chickens, turkeys and guineafowl have all been documented with this disease. Most birds develop enteritis and inflammation of the pancreatic ducts and recover completely after a prolonged period of diarrhea.[93]

Pancreatic lesions are thought to be incited by inflammatory reactions in the pancreatic ducts, which may result in complete blockage of the pancreatic ducts in a small proportion of affected birds. Blockage leads to vacuolization and shrinkage of exocrine cells and atrophy of the acini. As the disease progresses, much of the exocrine tissue is obliterated by fibroplasia. The changes are similar to those induced after experimental ligation of the pancreatic ducts.[124,126] The resulting exocrine pancreatic insufficiency leads to maldigestion,[173] steatorrhea and inappropriate absorption of fat-soluble vitamins. The skeletal changes are likely to be related to reduced absorption of vitamin D and calcium, the latter being bound to the excessive amounts of fat and excreted in the feces.[93]

Paramyxovirus Infections in Psittaciformes and Passeriformes

Paramyxovirus type III is a common infection in *Neophema* spp. and *Platycerca* spp., and is also encountered in some passerine birds, especially Estrildidae.[184,198] Torticollis, other neurologic signs, cachexia and death are common. Some infected birds develop a yellow-to-white chalky stool that contains large amounts of starch. In almost all cases, a pancreatitis can be detected. Histologically, the lesions can vary from a few lymphoid follicles to massive infiltration with lymphocytes and plasma cells. In some cases, this is clinically manifested as pancreatic exocrine insufficiency.

Campylobacter infections in Estrildidae cause similar discoloration of the feces. Histologically, atrophy of the microvilli of the small intestine, which may cause a malabsorption syndrome, can be found.[47]

Pancreatic Tumors

A high correlation between neoplasia of bile ducts and pancreatic ducts and internal papillomatous diseases in psittacine birds has been suggested.[41,69,86,159]

The Pleuro-peritoneum

Anatomy and Physiology[101,130]

The coelomic cavity in birds is subdivided by peritoneal, pleural and pericardial reflections into eight different cavities, excluding the eight cavities that are formed by the air sacs. Birds do not have a diaphragm. They have two pleural cavities and five peritoneal cavities (Table 19.8). Clinically, these cavities dictate the location and spread of pathologic processes within the coelomic cavity and are important when considering surgical approaches to the abdominal organs (see Color 13, Anatomy Overlay).

TABLE 19.8 Reference Guide to the Coelomic Cavities in Birds

- Right pleural cavity (RPC)
- Left pleural cavity (LPC)
- Pericardial cavity (PC)
- Left ventral hepatic peritoneal cavity (LVHPC)
- Right ventral hepatic peritoneal cavity (RVHPC)
- Left dorsal hepatic peritoneal cavity (LDHPC)
- Right dorsal hepatic peritoneal cavity (RDHPC)
- Intestinal peritoneal cavity (IPC)

As in mammals, both the parietal and the visceral pleura are reflected over the lungs, but in birds a large surface of the parietal pleura is joined to the visceral pleura by fibrous strands. The degree of obliteration of the pleural space depends on the species. In some birds, including the domestic fowl, extensive areas of pleural cavity persist in the adult (in the chicken, dorsolateral). In these areas the lungs can collapse inward when the pleural cavity is opened. Some fluid can accumulate in these areas under certain disease conditions.

The pericardium in birds is essentially similar to that in mammals. Because the lungs are situated dorsally and there is no diaphragm, the heart is not enclosed by the lungs. The liver lies on both sides of the heart, and the parietal pericardium becomes continuous with the peritoneum. During embryonic development, the pleural cavity becomes separated from the peritoneal cavity by the pulmonary fold, which is a double-layered sheet formed by the parietal pleura (dorsal) and the parietal peritoneum (ventral). The cranial and caudal thoracic air sacs develop as dilatations from the bronchi and penetrate into this double-layered sheet, splitting the dorsal from the ventral layer. The dorsal layer becomes fused with the adjacent wall of the thoracic air sac, becomes tough and tendinous and acquires fascicles of striated muscle along its lateral edge that attach to the ribs (costoseptal muscle). This is called the horizontal septum, saccopleural membrane or pulmonary aponeurosis. The ventral layer becomes fused with the ventral walls of the thoracic air sacs and is called the oblique septum, which occurs bilaterally.

Unlike the horizontal septum, the oblique septae or saccoperitoneal membranes remain thin and look like air sac walls.

The partitions in the peritoneal cavity proper are formed by five sheets of peritoneum which, apart from the mesentery, do not occur in mammals.

The combined dorsal and ventral mesentery form a continuous midline vertical sheet from the dorsal to the ventral body wall as far caudally as the ventriculus. Caudal to this level, only a dorsal mesentery is present supporting the intestines. Cranially, the mesentery is continuous with the pericardium.

The posthepatic septum is composed of a left and a right double-layered sheet. It extends caudal to the liver from the last thoracic vertebra in a ventrocaudal direction to the caudal wall of the peritoneum. The posthepatic septum has connections with the visceral peritoneum enclosing the liver.

The ventriculus is enclosed between the two layers of the left sheet of the posthepatic septum. The principal peritoneal fat depot is located between the two peritoneal layers of the posthepatic septum. The lateral layers of the right and left sheet form the medial wall of the right and left hepatic peritoneal cavities. Because the right and left sheets are fused cranially and unite in the midline ventrally, the liver is separated from the rest of the viscera by this posthepatic septum. The posthepatic septum (together with the mesentery) divides the peritoneum into three principal cavities: the intestinal peritoneal cavity dorsomedially, and two lateral hepatic cavities that enclose the liver. The left and right hepatic cavities are further subdivided by the left and right hepatic ligaments, which run horizontally and are continuous with other peritoneal sheets (medially with the mesentery, cranially with the parietal peritoneum, caudally with the posthepatic septum and laterally with the oblique septum), thus forming the LDHPC, LVHPC, RDHPC and RVHPC, respectively. The LVHPC and RVHPC are large, elongated cavities extending from the left and right liver lobe, respectively, to the caudal body wall. The LDHPC and RDHPC are much smaller and are in contact with the craniodorsal aspects of the left and right liver lobes. The IPC is enclosed between the left and right hepatic cavities and extends from the liver to the vent. The intestines and gonads are suspended by mesenteries within the IPC. Each peritoneal cavity is blind and has no connections, except for one that exists between the IPC and the LDHPC. The peritoneum plays an important role in the defense system of the body by closing perforations, containing infection and providing blood supply. The peritoneum heals rapidly after damage. Peritoneal injuries normally heal without the formation of adhesions, but in the presence of infection, ischemia or foreign bodies, fibrous adhesions may occur. The peritoneal surface allows the passive diffusion of water and solutes of low molecular weight between the peritoneal cavities and the subperitoneal vasculature. Larger molecules and particulate matter enter the bloodstream via the lymphatics. Healthy birds have a thin film of fluid in the peritoneum, which facilitates organ movement. The presence of free fluid in the peritoneal cavities is considered pathologic.

From the anatomic relationships outlined above, it is clear that diseases associated with the female genital tract (ovarian adenocarcinoma with implant metastasis on the peritoneum, egg-related peritonitis) are often confined to the IPC and LDHPC. Peritonitis from gastric perforation may be restricted to the LVHPC. Rupture of the liver can lead to accumulation of blood in one of the hepatic peritoneal cavities. Accumulation of transudate is most often seen in the LVHPC and the RVHPC and the PC, although the dorsal hepatic and peritoneal cavities may sometimes be involved. It is even possible to see some fluid accumulate in the RPC and LPC.

Ascites

Ascites is defined as the accumulation of serous fluid within one or more of the peritoneal cavities and may be caused by peritoneal and extraperitoneal diseases. Accumulation of fluid in one or more peritoneal cavity can result in abdominal distention. Large amounts of ascitic fluid may compress the pulmonary air sac system, causing dyspnea. During physical examination, abdominal distention can be recognized by the increased distance from carina to pubic bones. A bird with ascites should be handled carefully to prevent rupture of the air sacs, which can lead to immediate asphyxiation. Clinical signs may or may not occur with abdominal fluid accumulations. In liver disease, yellow or green feces may be seen. In neoplastic or liver disease, palpable masses may be present in the abdomen (Figure 19.21).

In ascites associated with liver disease (including hepatic congestion due to cardiac disease), increased portal venous hydrostatic pressure and decreased portal venous colloid osmotic pressure are important factors. Increased subperitoneal capillary permeabil-

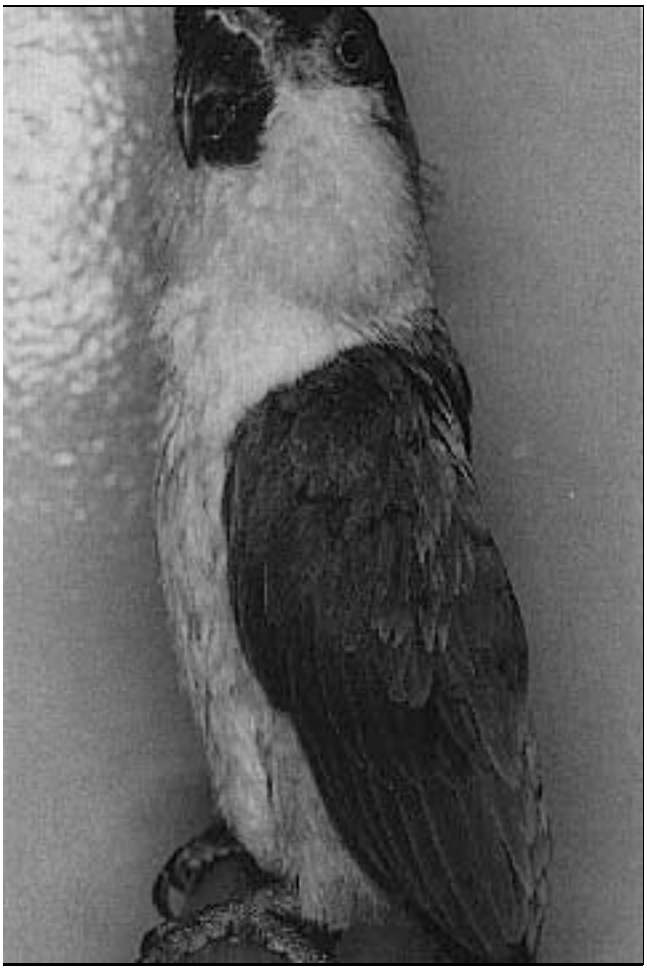

FIG 19.21 A mature caique was presented with a two-week history of progressive dyspnea and abdominal swelling. Note the distal protrusion of the abdomen. Fluid collected by abdominocentesis was yellow and was characterized as a transudate (SpGr=1.012, Protein=1.8 mg/dl, few cells). The liver was swollen and the blood was lipemic. An exploratory surgery was performed, at which time a soft-shelled egg was removed from the uterus. Soft-shelled eggs are most often related to a primary etiology of malnutrition, which results in the fatty liver, lipemia and dystocia leading to possible egg-related peritonitis.

ity, decreased peritoneal lymphatic drainage and leakage from disrupted abdominal viscera (bile, urine) may cause non-liver-related ascites. Sometimes the definition of ascites is restricted to non-inflammatory transudate,[44] but the distinction between transudate and exudate is not always clear under clinical conditions. Conditions where an inflammatory exudate is present can be defined as peritonitis.

Although it has been suggested that chylous ascites (ascites due to the presence of lipoproteins and chylomicrons in the peritoneal cavity) can occur in birds,[44] current information on avian physiology suggests that the absorption of fat from the intestine in birds is different from what occurs in mammals. The lymphatic system is not as well developed in birds as in mammals. The lymphatic vessels are small, the largest being hardly more than 1 mm in diameter, and the thoracic duct is only 1.5 mm across.[148] Because there is no functional intestinal lymphatic system in birds, absorbed lipids enter the portal system as large, very low-density lipoproteins. These lipoproteins have been defined as "portomicrons" in contrast to "chylomicrons" (the fat-rich particles that are absorbed by mammals).[16] Chylous peritonitis, which occurs in mammals secondary to rupture of the lymphatic vessels or lymphatic congestion, is therefore theoretically not possible in birds.

Blockage of lymph drainage can be an important factor in the development of ascites in birds. For example, implantation of oviduct carcinoma on the intestinal peritoneal cavity rapidly induces ascites from portal hypertension secondary to pulmonary hypertension. Right ventricular failure with valvular insufficiency results in increased pressure in the vena cava where the lymph ducts connect to the circulatory system.[93]

Pseudochylous ascites is the condition whereby turbid or milky abdominal fluid is seen. This may be caused by cellular debris and is associated with abdominal malignancies and infections.[57] A goose with a severe fatty degeneration of the liver accompanied by extreme hepatomegaly and hyperlipemia developed severe dyspnea secondary to pseudochylous ascites of unknown origin. A milky-appearing ascitic fluid was demonstrated in the ventral hepatic peritoneal space by laparotomy. Removal of 0.5 liter of ascitic fluid and diuretic therapy decreased the dyspnea. The concentration of total triglycerides in the ascitic fluid was 55 mmol/l, while total triglycerides in the plasma was 77 mmol/l. The ascitic fluid:plasma triglyceride ratio in this bird was opposite to what would be expected in chylous ascites, although the physical characteristics of the fluid were highly suggestive for this condition.

Edema may occur in organs and tissues in conjunction with ascites caused by hypoalbuminemia. It may be recognized clinically as edema of subcutaneous tissues of the abdomen or pitting edema on the feet (ducks with amyloidosis).

Diagnostic Methods

Radiographically, ascites is characterized by a diffuse, ground-glass haziness in the abdomen, and specific organs are often impossible to delineate. Administration of furosemide for several days or abdominocentesis will increase the diagnostic value of the radiographs. The cardiohepatic silhouette may appear widened, and the air sacs may appear narrowed laterally on the ventrodorsal view. Occasionally, ileus or enlargement of the heart, liver, spleen or other abdominal organs may be detected, providing information with respect to the primary disorder. Ultrasonography is a noninvasive technique that is valuable in the differential diagnosis of abdominal enlargement and ascites (see Chapter 12).[27,100]

Abdominocentesis provides diagnostic information in birds with ascites (see Chapter 10).[33] Peritoneal lavage is possible, but extreme caution should be practiced to prevent iatrogenic puncture of the pulmonary air sac system and asphyxiation of the bird. Abdominocentesis should be performed when one is certain that free fluid is present to prevent inadvertent organ puncture. Transudate is characterized by a clear to pale-yellow color, a low specific gravity (<1.020), low protein (1 g/dl) and a low cellularity. Exudate is characterized by a high specific gravity (>1.020), a high protein content (3 g/dl) and possible presence of many inflammatory and mesothelial cells. Exudates may clot during sampling and may require an anticoagulant for proper cytologic examination. Septic exudates contain intracellular bacteria. Identifying a wide variety of bacteria suggests perforation of the gastrointestinal tract or the abdominal wall.

Clinical Biochemistry and Hematology

Laboratory investigations in birds with ascites should include plasma chemistries for hepatic and renal disease (AST, CPK, LDH, bile acids, protein electrophoresis, uric acid, urea). Renal protein loss should be evaluated by a quantitative determination of protein in the urine. Additionally, a PCV and total WBC and differential are indicated. When peritonitis is present, a marked leucocytosis can be observed, with the predominant cell type being heterophilic leukocytes. Juvenile heterophils (band cells) are normally not present in the peripheral blood and indicate severe inflammation. Granulomatous diseases and avian tuberculosis are often associated with monocytosis.

In neoplastic disease, exfoliated neoplastic cells may be encountered. Hemorrhagic effusions may have the appearance of peripheral blood and have leukocyte and erythrocyte numbers comparable to peripheral blood. Chronic hemorrhagic effusions may show signs of erythrophagocytosis. Urine in the abdominal cavity can be recognized by the presence of spherical urate crystals.

In mammals, LDH and the ascites serum protein and LDH ratios are helpful in differentiating between exudates and transudates.[15] The ascitic fluid amylase:plasma amylase ratio is useful for the diagnosis of pancreatic ascites. Ascitic fluid with a milky appearance and a triglyceride:plasma triglyceride ratio <1 is suggestive of pseudochylous ascites because chylous ascites does not occur in birds.

Differential Diagnosis[44,62,71,89,97,112,170]

Abdominal enlargement due to ascites should be differentiated from other causes of abdominal enlargement such as obesity, neoplasia, herniation, egg-related peritonitis, granuloma, gravid uterus, gastrointestinal dilatation, hepatomegaly, splenomegaly and renomegaly. A cystic right oviduct can also pose a diagnostic challenge to the clinician because these fluid-filled cysts may reach a size up to 10 cm in diameter and may compress the abdominal viscera, mimicking ascites.

Chronic liver disease can cause ascites through intrahepatic portal hypertension due to hepatic fibrosis (aflatoxicosis, coal tar poisoning, plant toxins from *Crotalaria* spp. or rapeseed, bacterial or viral cholangiohepatitis). The accompanying hypoalbuminemia contributes to ascites formation. Blood chemistries, bile acids, low plasma albumin and liver biopsies are useful diagnostic techniques. Ascites from chronic liver disease is common in Anseriformes with amyl-oidosis and in mynahs, toucans and birds of paradise with iron storage disease.

Ascites may occur as part of generalized edema secondary to hypoalbuminemia caused by chronic liver disease, nephrotic syndrome and protein-losing enteropathy.

Neoplasias, particularly abdominal carcinomas (especially ovarial adenocarcinoma with implants on intestinal peritoneal cavity), may block lymph drainage, causing ascites with a high-protein content that contains neoplastic cells.

Congestive heart failure (right ventricular failure; RVF) is a common cause of ascites in gallinaceous birds and ducklings that are raised at high altitudes

and forced to grow at a rapid rate. Low environmental temperature and high-sodium diets have been associated with RVF and ascites in chickens and turkeys. Furazolidone causes cardiomyopathy in turkeys, ducks and chickens. *Fusarium moniliforme var. subglutans* produces the mycotoxin moniliformin that induces myocardial degeneration with associated hydropericardium and ascites in chicks, ducklings and turkey poults. RVF and ascites may also be associated with rickets. Congenital ventricular septal defect can cause a left to right shunting of blood and result in RVF and ascites. Numerous drugs have been shown to cause cardiovascular malformations in chick embryos.

Exposure to chlorinated biphenyls, dioxin (toxic fat syndrome), creosol and coal tar products can damage the endothelial lining of blood vessels, causing hydropericardium and ascites.

Viral infections such as Marek's disease tumors may occur in the heart, and viruses of the leukosis-sarcoma group can cause various tumors associated with ascites (hemangioma and hemangiosarcoma of mesentery, erythroblastosis, mesotheliomas). Other viruses including avian polyomavirus and avian viral serositis can cause myocarditis and pericarditis leading to RVF and ascites.

Bacterial endocarditis and myocarditis may result in cardiac insufficiency (RVF) and ascites. *Staphylococcus*, *Streptococcus* and *Erysipelothrix* spp. have been associated with endocarditis, while bacterial myocarditis may occur in listeriosis, pullorum disease, fowl typhoid and other bacterial infections. *E. coli* peritonitis may be associated with ascending infections from the female genital tract.

Mycobacterium spp. infections can cause blockage of lymph drainage in some cases. Acid-fast (Ziehl-Neelsen) staining organisms may be noted in ascitic fluid. Peritonitis can occur from foreign bodies penetrating the intestinal tract and secondary to infections in the lungs, air sacs, pericardium, female reproductive organs and gastrointestinal tract. *E. coli*, staphylococci and streptococci can often be isolated in serofibrinous peritonitis in females as a result of ascending infections from the uterus. Aspergillosis air sacculitis can also involve the peritoneum.

Penetrating or nonpenetrating trauma to the abdomen can cause urate ascites, bile ascites, pancreatic ascites and hemoperitoneum (rupture of liver, spleen or kidney). Enlargement of an organ or other space-occupying masses can block lymph drainage, resulting in ascites.

Cystic right oviduct occurs if the right Muellerian duct does not regress normally. The oviduct remnant is attached to the cloaca by a narrow stalk. Ultrasonography can differentiate between free fluid and fluid encapsulated within a cyst (see Chapter 12).

Therapy for ascites should be aimed at the primary disorder. Therapeutic removal of ascitic fluid is indicated only if ascites is accompanied by a life-threatening dyspnea. If hypoproteinemia is present, abdominocentesis will remove protein from a bird that may have compromised liver or kidney function. Diuretic therapy (furosemide) can be administered to effect. Low-sodium diets may be helpful.

Accumulation of fat in the peritoneal cavity can cause dyspnea through compression of the thoracic and abdominal air sacs. Obesity is an important differential diagnosis in birds with dyspnea and abdominal enlargement. It is commonly seen in parrots, cockatoos and pigeons on high-energy diets with restricted exercise, but many other species can be affected.

Ventral abdominal hernias are common in budgerigars and racing pigeons (particularly hens). A causal relationship with hyperestrogenism, which causes weakening of the abdominal muscles, has been suggested. The hernia may contain fat, loops of bowel or other abdominal organs. Incarceration of the intestinal tract is a rare but possible complication. A diagnosis can be made by physical examination and radiology. Treatment involves surgical closure of the abdominal hernia. Removal of excess fat that is primarily located between the sheets of the posthepatic septum facilitates the procedure. A perineal hernia containing a persistent right oviduct was observed by the author in a budgerigar.

The most common causes of peritonitis in birds are foreign bodies (from alimentary tract or through abdominal wall) and egg-related peritonitis. The latter condition can be the result of oviduct or ovarian dysfunction. Conditions such as false layer, internal layer, impaction of oviduct and torsion of egg yolk followed by infarction should be considered. Abdominocentesis is indicated to collect samples for further examination (cytology, culture).

CHAPTER

20

HEPATOLOGY

J. T. Lumeij

The avian liver is bilobed and relatively large in comparison to the size of the bird. The left hepatic duct connects to the duodenum. The right hepatic duct connects to the gall bladder in those species that have this organ (gallinaceous birds, ducks, geese). If the gall bladder is absent (pigeons, parrots, ostriches), the right hepatic duct drains directly into the duodenum. If this duct dilates, it may appear as though a gall bladder is present (see Color 14). Birds have no mesenteric lymph nodes, and patients with chronic enteritis may also have periportal hepatitis. The liver in a normal Psittaciforme rests ventrally against the sternum, wraps cranially around the base of the heart and wraps dorsally along the lateral margins of the proventriculus (see Anatomy Overlay). The size of the liver varies among species. In Galliformes, the liver lobes are of similar size while in Psittaciformes, the right lobe is generally larger. Bile acids secreted by the liver function to emulsify fats and activate pancreatic lipase and amylase, all of which aid in digestion. The liver also metabolizes fats, proteins and carbohydrates and detoxifies metabolites and ingested toxins.

Diagnostic Considerations[22]

Physical findings associated with liver disease are often nonspecific, and are generally not sufficiently diagnostic to establish a clinical diagnosis. A green coloration of the urine and urate fractions in the excreta is a strong indication of liver disease (Color 20.4). Dyspnea is a common finding in birds with hepatomegaly or ascites. Occasionally, an enlarged liver can be palpated and in the smaller Passeriformes, an enlarged liver may be visible through the transparent abdominal wall. Abnormal coloration of the liver is also sometimes visible, particularly in small species and neonates. Polydipsia and vomiting are sometimes associated with liver disease. Pruritus occurs commonly in icteric humans and is thought to be caused by the deposition of irritant bile salts in the skin. Clinical signs suggestive of pruritus and feather picking have been reported in birds with liver disease. Other integumentary disorders that are loosely discussed in association with liver disease include pigment changes of feathers (Color 20.2), abnormal molting and softening, flaking and overgrowth of beak and nails (Figure 20.1).

Because liver diseases may be associated with many physical findings and may even be asymptomatic, fecal examination, hematologic examination (PCV, WBC and differentiation, buffy coat for parasites), total protein, plasma protein electrophoresis (A:G ratio), AST, LDH, bile acids and a total body radiograph are considered the ideal database for evaluating a sick bird. The history should involve questions concerning contact with birds outside the premises, which might indicate exposure to infectious diseases that cause hepatitis like Pacheco's disease virus or chlamydia.

FIG 20.1 Liver disease should always be considered in the differential diagnosis list for birds with beaks and nails that consistently overgrow.

Clinical Pathology

Bile Pigments

Green-colored urates are suggestive of liver disease.[5,20,38] This discoloration is the result of increased excretion of biliverdin (biliverdinuria), which is the most important bile pigment in birds. Icterus or jaundice, which is caused by a hyperbilirubinemia, is seen very infrequently in birds. In chickens, if both bile ducts are ligated, the concentration of plasma bile pigments rises immediately but stabilizes after two weeks at about 85 μmol/l. This is a much lower concentration than is found in mammals with total biliary obstruction. In sera of healthy ducks, low levels of bilirubin may be detected, and significantly elevated levels have been reported after experimental infection with duck hepatitis virus; however, the observed levels of about 17 μmol/l were well below the serum concentration of 34-51 μmol/l, which is considered the level above which jaundice becomes apparent in man. The infrequent occurrence of icterus in birds may also be explained by the fact that the enzyme biliverdin reductase, which converts biliverdin to bilirubin, is absent in the bird species that have been tested.[18,19,39] It has been suggested that in birds, some biliverdin may be converted to bilirubin by bacteria or nonspecific reducing enzymes.[17]

Avian plasma may be colored yellow because of the presence of carotenoids, and this normal color should not be misinterpreted as icteric plasma. Some avian species, such as Hyacinth Macaws, have a normal yellow coloration of the skin that could be misinterpreted as icterus (see Color 8). A few hours after birds have received an intramuscular multivitamin injection, the urate fraction can be yellow-brown in color, which should not be confused with liver-induced changes in the urates (see Color 8).

Clinical Enzymology

The application of clinical enzymology in human and veterinary medicine is a common method for estab-

lishing a diagnosis in certain disease conditions. Increases in plasma enzyme activities are usually related to leakage of enzymes from damaged cells, but sometimes there may be increased production in affected tissues. The increased concentration of a particular enzyme in plasma depends on factors such as the activity of enzyme in the cells, the rate of leakage and the rate of clearance of the enzyme from the plasma. Rational interpretation of elevated plasma activity of intracellular enzymes due to cellular damage can be performed only if the enzyme profiles of the various organs of the species under investigation and the elimination half-lives of these enzymes are known. The most reliable way to investigate the specificity and sensitivity of various plasma enzymes for detecting liver disease is to establish reference intervals in healthy individuals, and to monitor plasma enzyme changes after selective experimental liver damage. These data are compared to changes associated with diseases of other organs.

Enzyme profiles of the various organs have been investigated in chickens, Mallard ducks, turkeys, racing pigeons, budgerigars and African Grey Parrots.

The elimination half-life of an enzyme can be calculated from the exponential decline in activity during recovery from acute tissue damage. Alternately, it can be determined by measuring the decline in activity after intravenous administration of purified enzymes. After intravenous injection, most enzymes follow a biphasic exponential decline. The rapid primary phase is related to distribution of enzymes by diffusion from plasma into other extracellular body fluids, and the slower secondary phase is related to the actual clearance of enzyme from the body fluids. During the secondary phase, a constant fraction of the enzyme present is eliminated per unit of time, making the decline linear on a logarithmic scale (first order kinetics). The time required for 50 percent completion of the latter process is defined as the elimination half-life ($t_{1/2\beta}$).

Plasma enzyme profiles have been studied in a number of avian species following experimentally induced or spontaneously occurring liver disease. Unfortunately, there is a large interspecies variation in data and the type of liver disease. Additionally, the presence of concomitant injury to other organs that could alter the results of enzyme activity measurements may occur. The results of experimental studies of liver-specific enzymes in racing pigeons are listed in Table 20.1.[22,27,28] Information on enzyme activity in other tissues may be found in Chapter 11 and in the Appendix.

Glutamate dehydrogenase (GLDH) is the most liver-specific enzyme in the racing pigeon. Since GLDH is localized within the mitochondria of the liver cells, elevated plasma GLDH activities are seen only after severe liver cell damage (necrosis). Liver cell degeneration without necrosis will not cause elevated GLDH activities. In the budgerigar, GLDH activity in liver tissue is relatively low when compared to man and most other birds tested, including cockerel, duck, turkey and pigeon.[31] However, increased GLDH activities were observed in Amazon parrots with extensive liver necrosis due to Pacheco's disease virus, suggesting that this enzyme may be useful for the detection of liver necrosis in at least some psittacine species.

Aspartate aminotransferase (AST, formerly GOT) is the most sensitive indicator of liver disease in the pigeon. This variable, however, is not specific because elevated AST activities can also be seen with muscle damage.

Despite relatively low alanine aminotransferase (ALT, formerly GPT) activities in liver tissue of racing pigeons, this enzyme is useful for detecting liver cell damage because the elimination half-life in plasma is relatively long.

Lactate dehydrogenase (LDH) disappears rapidly from plasma, making it a poor indicator of liver damage, despite relatively high concentrations of this enzyme in liver tissue. Neither ALT nor LDH is specific for the liver because these enzymes, like AST, also occur in muscle.

Gamma glutamyl transferase (τ-GT), has been found to be a specific indicator of liver disease in the racing pigeon. The fact that no activity of this enzyme can be found in supernatants of liver tissue homogenates may be due to the synthesis of τ-GT during cholestatic liver disease, as has been reported in mammals. This enzyme is not as sensitive as AST.

Alkaline phosphatase (AP) and creatine kinase (CK) are never elevated after liver cell damage, while activities of these enzymes in liver tissue are negligible.

It should be emphasized that elevated activities of "liver enzymes" in plasma may indicate recent damage to liver cells and does not give information on liver function.

Intramuscular injections given within one to five days before collection of a blood sample may cause an elevation of some plasma enzyme activities due to damage of muscle tissue. This can lead to an erroneous diagnosis of liver disease.

TABLE 20.1 Plasma Chemical Variables in Liver and Muscle Disease Based on Experimental Studies in Pigeons.[22]

Variable	Liver Disease		Muscle Disease	
	Specificity	Sensitivity	Specificity	Sensitivity
Bile acids	+++	+++	–	–
τ–GT	+++	+	–	–
AST	–	+++	–	+++
ALT	–	+	–	+++
AP	–	–	–	–
GLDH	+++	+*	–	–
CK	–	–	+++	+++
LDH	–	+	–	+

– low, + some, ++ moderate, +++ high
*Only with liver and kidney cell necrosis.

Bile Salts

Plasma bile acids and bile salts are formed in the liver from cholesterol. It is likely that there is a continuous secretion of bile into the intestine in birds, with or without a gall bladder. A slight increase in secretions would be expected postprandially due to the intrahepatic effects of intestinal hormones like secretin, avian vasoactive intestinal peptide (VIP) and cholecystokinin (CCK). These hormones are released after the consumption of food.

The exact site responsible for increased bile secretion and the regulatory mechanisms involved are presently unknown.[24] Bile acids secreted by the liver enter the small intestines, are absorbed in the lower small intestines, enter the portal vein and are extracted from the blood by the liver. Enterohepatic recirculation accounts for over 90% of the secreted bile acids being reabsorbed in the jejunum and ileum.[9] Plasma bile acid concentrations (PBAC), including their salts and corresponding glycine and taurine conjugates, are a reflection of the clearing capacity for bile acids by the liver. All liver functions (extraction, conjugation and excretion) are involved in this process, and determination of plasma bile acid concentration provides information on the combined effectiveness of these functions.

Due to the development of specific and sensitive enzymatic assays for bile acids, bile salts and their corresponding glycine and taurine conjugates, there has been substantial progress with respect to the use of PBAC for the diagnosis of hepatobiliary disease. Circulatory levels of bile acids increase if the liver is damaged and cannot extract bile from the portal vein or if the enterohepatic cycle is blocked and blood from the portal vein does not reach the liver. PBAC should be considered a sensitive and specific variable for testing liver function in birds as it is in mammals.[3,12,23,36] Reference intervals for PBAC have been established for the racing pigeon and the most common psittacine species found in captivity (see Appendix). Experimental studies[22] indicate that PBAC is the single most useful, available test for determining liver dysfunction in the racing pigeon. In experimentally induced liver disease, five- to ten-fold increases of PBAC over the upper limit of the reference interval are common.

Food consumption significantly increased PBAC in granivorous birds with a gall bladder (Mallard Duck) and granivorous birds without a gall bladder (racing pigeon).[24] The same effect was seen in carnivorous birds.[30] Although up to a 4.5-fold postprandial increase of PBAC was seen in individual birds, the concentrations were never elevated more than 1.65-fold over the upper limit of the reference range. In hepatobiliary disease, five- to ten-fold increases over the upper limit of the reference range were common.[27] Although postprandial increase might complicate interpretation of PBAC, differentiation between postprandial elevations and elevations due to hepatobiliary disease is possible. Experimental findings suggest that values >70 μmol/l in fasted racing pigeons and most psittacine species, and values >100 μmol/l postprandially should be considered elevated, and therefore suggestive for hepatobiliary disease. In Amazon parrots, PBAC values >145 μmol/l are considered elevated.[24,28,29]

Hepatic Encephalopathy

A tentative diagnosis of hepatic encephalopathy is often made when neurologic signs are seen in birds with documented liver disease; however, this syndrome has not been well documented in avian species. In man and other mammals, hepatic encephalopathy and hepatic coma are mostly seen in portosystemic shunting as a result of a portocaval anastomosis. It is not a disease in itself but a medical condition characterized by neurologic symptoms caused by intoxication of the brain by products of protein digestion, which enter the portal circulation and are not detoxified in the liver. It is believed that degradation products from protein catabolism act as false neurotransmitters. For this reason, protein-rich

Hepatology

Color 20.1
A mature Blue and Gold Macaw was presented with a history of developing necrotic lesions in the beak. The bird was severely obese (1300 g) and had thick, white serum. The bird's cholesterol level was 1700 mg/dl. A biopsy of the liver indicated severe fatty degeneration. The obesity and lipemia were controlled by switching the bird to a formulated diet supplemented with fresh fruits and vegetables. The formulated portion of the diet was offered on a limited basis and the bird's exercise was increased. The beak lesion was theorized to have occurred secondary to a vascular accident that caused an area of ischemic necrosis.

Color 20.2
The occurrence of black discolored feathers in Amazon parrots and macaws is frequently discussed as a clinical change indicative of hepatitis. While a connection between the appearance of black feathers and hepatitis has not been confirmed, clinical experience suggests that hepatitis should be included in the differential diagnosis list.

Color 20.3
An obese Amazon parrot was presented for exercise intolerance (dyspnea) and intermittent depression. The bird weighed 700 g and had difficulty ambulating because of fat in the inguinal and abdominal regions. The bird's blood was yellow; a normal Amazon parrot's blood is provided for comparison. The bird's cholesterol level was 2300 mg/dl. Most other blood parameters were considered non-diagnostic because of the lipemia. Radiographs indicated severe hepatomegaly. Histopathology of a liver biopsy confirmed fatty liver degeneration.

Color 20.4
Yellow-to-green urates are suggestive of biliverdinuria and are most commonly associated with hepatitis.

Color 20.5
Normal liver of an adult Umbrella Cockatoo hen with PBFD virus. Note the reddish-brown color, smooth consistency of the surface and sharp defined margins of the normal liver lobes. In Psittaciformes, the right liver (rl) lobe is slightly larger than the left liver (ll) lobe. The lung (lu) can be seen lying under the transparent, contiguous wall of the cranial and caudal thoracic air sacs (open arrow). The transparent ventral hepatic peritoneal membrane can also be seen (arrows). Other organs that should be noted include the heart (h), proventriculus (p) and ventriculus (v).

Color 20.6
A breeding toucanette was found dead in its enclosure. The abdomen was severely distended. Characterisitics of fluid collected by abdominocentesis at necropsy were consistent with a transudate. The enlarged liver was orange and rough in appearance. Histopathology was suggestive of hemochromatosis, and the disease was confirmed using a Prussian blue stain to demonstrate iron-laden hepatocytes.

Color 20.7
Swollen, pale-yellow liver from an Amazon parrot with severe hepatic lipidosis. Neonates that are mobilizing egg yolk will have a similarly appearing liver for the first two to three weeks of life. Note that the heart is also pale and rotund.

Color 20.8
A Blue and Gold Macaw chick was presented for evaluation. The bird was in a comatose state and was the sixth baby from a psittacine nursery to die acutely. The bird had subcutaneous hemorrhages, hepatomegaly and swollen, hemorrhagic kidneys, all suggestive of avian polyomavirus. A polyomavirus infection was suspected by identifying basophilic intranuclear inclusion bodies in the liver, spleen, kidneys and heart, and was confirmed by DNA probe detection of viral nucleic acid on a swab taken of the cut surface of the liver and spleen. Note the petechial to ecchymotic hemorrhages in the liver and heart.

Color 20.9
An Amazon parrot with severe dyspnea was found on the bottom of its enclosure. The bird died while en route to the emergency clinic. At necropsy, the bird's muscle tissue was extremely pale. Exsanguination had occurred secondary to a tear in the liver capsule. Note the pale heart and left liver below the blood clot.

Color 20.10
A Blue and Gold Macaw that was being treated for aspergillosis air sacculitis was presented with an acute onset of anorexia, depression and abdominal swelling. Radiographs indicated a soft tissue density filling most of the abdominal cavity. Abdominocentesis was unproductive. An exploratory laparotomy was performed. When the abdominal cavity was opened, unclotted blood flowed from the incision with each breath. The bleeding originated from a tear in the right lateral liver lobe (arrow). The hemorrhage was controlled with pressure. Both liver lobes had multiple, raised, white lesions that were suspected to be fungal granulomas. The client elected euthanasia. At necropsy, the liver was firm and had multiple, granulomatous-like lesions. Similar lesions were noted in the lungs, and the right caudal thoracic air sac was thickened and necrotic. Histopathology confirmed *Aspergillus* sp. in the lung and air sac. The liver lesions were characterized by massive hepatocellular necrosis and biliary hyperplasia. These lesions are suggestive of aflatoxicosis. Interestingly, the LDH=397, AST=141 and bile acids=1.9, determined two weeks before surgery, did not reflect the severity of the liver damage.

Color 20.11
Cut surface of the liver from the Blue and Gold Macaw in Color 20.10. Note the substantial involvement of the liver and the scarcity of normal-appearing liver tissue.

Hepatology

Color 20.12
Severe fatty liver degeneration and bacterial hepatitis in a 23-year-old Amazon parrot hen with ovarian cysts.

Color 20.13
Multifocal, white-to-yellow discoloration of the liver is characteristic of hepatocellular necrosis. The lesions in this African Grey Parrot were caused by *Chlamydia* sp. Bacterial and viral infections can cause similarly appearing lesions.

Color 20.14
Hepatomegaly and multifocal, white-to-yellow foci in the liver and heart of a mynah bird that died from atoxoplasmosis (courtesy of Carol Partington).

Color 20.15
Iron storage hepatopathy in a mynah bird. Small brown-black foci were clearly visible throughout the liver parenchyma. The lesions can be more clearly visualized using a magnifying glass (courtesy of Robert E. Schmidt).

Color 20.16
Histomonas meleagridis (blackhead) lesions in the liver of a gallinaceous bird. Multiple round foci with central depressions extending into the liver parenchyma are considered pathognomonic (courtesy of R. Korbel).

Color 20.17
Mycobacteriosis hepatitis in a Sandhill Crane. *Mycobacterium* spp. infections frequently affect the liver and gastrointestinal tract in birds. Unlike in mammals, infections rarely occur in the lungs. Mycobacteriosis should be considered in any bird with granulomatous hepatitis. A quick diagnosis can be achieved by acid-fast staining of an impression smear of the cut surface of the liver (courtesy of Robert E. Schmidt).

Color 20.18
An Amazon parrot was presented with anorexia, dyspnea, depression and weight loss of three days' duration. Radiographs indicated severe hepatomegaly. Abnormal clinicopathologic findings included WBC=25,000, LDH=700, AST=600 and bile acids=150. A fecal antigen test for *Chlamydia* sp. was positive. Doxycycline therapy was initiated, but the bird did not respond and died the following day. Necropsy indicated a severely enlarged, firm, irregular yellow liver. The histopathologic diagnosis was lymphosarcoma. Chlamydia was not detected in any tissues, suggesting that the fecal antigen test result was a false positive.

Color 20.19
Multiple, disseminated granulomas in the liver of a gallinaceous bird. These lesions were caused by *Mycobacterium tuberculosis* (courtesy of R. Korbel).

Color 20.20
Plasmodium sp. infection in a Peregrine Falcon. The liver (l) and spleen (s) are both enlarged, but the characteristic change is the black discoloration of both organs. Other easily distinguishable organs include the lung (lu), proventriculus (p), ventriculus (v), heart (h) and intestines (i) (courtesy of Robert E. Schmidt).

diets in patients with liver disease frequently trigger neurologic symptoms.

Fasting plasma ammonia levels and plasma ammonia levels 30 minutes after oral loading with NH_4Cl (100 mg/kg in a gelatine capsule) have been used in dogs to establish the ability of the liver to convert ammonia into urea. Fasting plasma ammonia concentrations in healthy psittacines have shown values ranging from 36 to 274 μmol/l, which are well above the fasting concentrations described in dogs. Furthermore, some avian species will normally show up to an eight-fold increase of plasma ammonia concentration on oral ammonia tolerance test (ATT) using the canine protocol, and therefore an abnormal ATT is not diagnostic for portosystemic shunting in these species.[26] Further work is needed to properly diagnose and document the occurrence of hepatic encephalopathy in birds.

Avian Hemochromatosis

Limited work has been done on the clinical pathology associated with avian hemochromatosis. The iron status of an individual bird is determined by measuring three main areas of iron: storage iron, transport iron and erythrocyte iron. Storage iron can be semiquantitated by histologic examination of liver biopsies for stainable iron. In humans with hemochromatosis, urinary iron excretion in the six hours following injection of an iron chelating agent, desferrioxamine or diethylenetriamine pentacetic acid (DTPA) is significantly higher compared to normal individuals. Serum concentration of the iron storage protein ferritin is directly related to the available storage iron in the body and is clinically the most useful method for assessing iron stores.[14]

Transport iron in man is determined by measuring serum iron concentration and the total iron binding capacity (TIBC). The latter estimation is performed by determining the amount of iron required to saturate fully the iron-binding protein present in the serum sample. Reference values for serum or plasma iron concentration and TIBC in man are 10-34 μmol/l and 45-72 μmol/l, respectively.[37] In pigeons these values are 11-33 μmol/l and 30-45 μmol/l, respectively.[25] In Ramphastidae, total serum iron concentrations should be below 63 μmol/l, while TIBC should fall below 100 μmol/l.[42] Total serum iron in a mynah bird with confirmed hemochromatosis exceeded 360 μmol/l, while control birds had values that were about 36 μmol/l.[32] (See update on need for biopsy in Chapter 47.)

Erythrocyte iron can be evaluated by determining the red blood cell morphology and the various red cell parameters, such as PCV, hemoglobin concentration, mean corpuscular volume, mean corpuscular hemoglobin and mean corpuscular hemoglobin concentration. Low erythrocyte iron will be reflected by abnormalities in these parameters. Treatments of patients with hemochromatosis using repeated phlebotomies require frequent evaluation of red cell parameters to detect excessive iron depletion.

Plasma Chemistry and Liver Disease

To facilitate interpretation of plasma chemistry, it is advisable to include specific and sensitive indicators of both liver and muscle disease in the plasma chemistry panel (eg, GLDH, AST, CPK, bile acids). It should be stressed that elevated plasma enzyme activities are a sign of recent cell damage and not necessarily of impaired organ function. Most enzymes are not specific for one particular organ. Furthermore, in chronic conditions, extensive damage occurring in the past may have led to major dysfunction of an organ while enzyme activities may have returned to normal. This is a common finding in birds with liver fibrosis (normal AST, but elevated bile acids and extremely low protein and albumin) (Figure 20.2). When periodic blood chemistry is performed in a bird with liver disease, fluctuation of plasma enzymes and bile acids are often noted. Enzymes may be elevated while bile acids are not, and vice versa. Occasionally both variables may be found to be within established reference intervals. Repeated plasma chemistries are recommended when evaluating liver disease to prevent misinterpretation of results.

Radiology

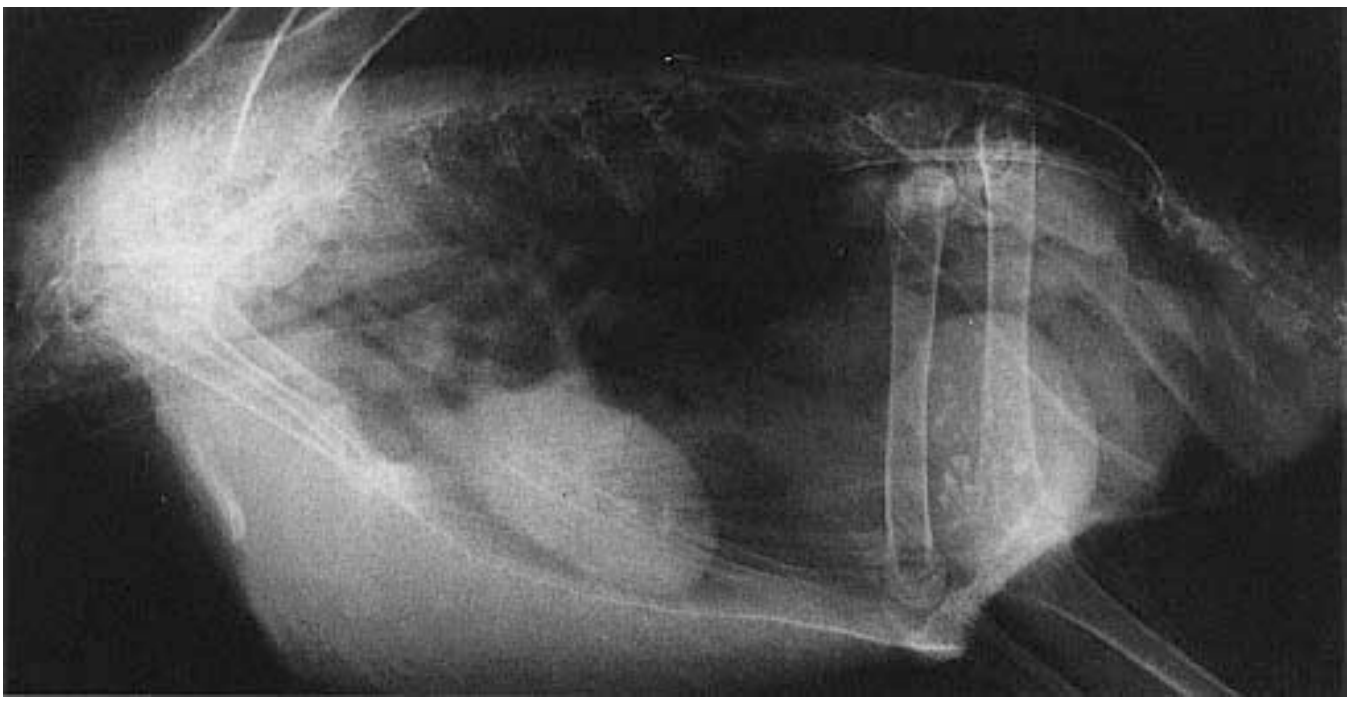
Both hepatomegaly and ascites due to liver disease may be diagnosed radiographically. Hepatomegaly and microhepatia are common findings in birds (see Chapter 12). It is important to differentiate between hepatomegaly and cardio-hepatomegaly, because the latter indicates the presence of cardiac failure and secondary congestion of the liver. Caudal displacement of the ventriculus on a lateral radiograph is often caused by enlargement of the liver or associated structures (eg, bile duct or gallbladder in those species that possess one). Loss of the hourglass appearance between the heart and the liver on a ventrodorsal radiograph and widening of the liver beyond a line between the scapula and the acetabulum indicate hepatomegaly. Caudodorsal displacement of the ventriculus is also possible with hepatomegaly.

Ascites and peritonitis may complicate radiographic interpretation and obscure hepatic enlargement by overshadowing the liver. Repeat radiography of the abdomen after removal of peritoneal effusion fluid by paracentesis or diuretic treatment may be needed to visualize an enlarged liver and heart.

Liver Biopsy

In order for the clinician to establish a definitive diagnosis of liver disease, it is essential to take biopsies for histologic examination. Indications for liver biopsy include biochemical and radiographic changes suggestive of liver disease. Laparoscopic examination and biopsy of the liver through a midline ventral approach just caudal to the sternum is the method of choice to confirm a diagnosis of liver disease (see Chapter 13).[8,16,22] Alternatively, the liver can be exposed through a ventral laparotomy incision and a small wedge of liver tissue can be excised with small surgical scissors. The possibility of severe, life-threatening hemorrhage secondary to liver congestion should be considered prior to biopsy in cases

FIG 20.2 A one-year-old Scarlet Macaw was presented with blood-tinged feces two days after destroying a plastic bowl. Radiographs indicated severe microhepatia (arrows). Abnormal clinicopathologic findings included WBC=18,500, TP=3.1 and bile acids=130. AST=50 and LDH=130 were both normal. High bile acid levels with normal AST and LDH activities suggest liver dysfunction in the absence of ongoing cellular injury. Histopathologic evaluation of a liver biopsy indicated severe hepatic fibrosis of unknown etiology.



showing radiographic signs of congestive heart failure or electrocardiographic abnormalities indicative of cardiac disease. A liver biopsy site will usually clot without complication, but caution should be exercised when performing biopsies in birds that have prolonged bleeding times after blood collection. Routine tests to determine the efficiency of the avian clotting mechanism are presently not available. In birds with ascites, it is important to perform a biopsy by entering just caudal to the carina to avoid damaging the air sacs and asphyxiating the bird with its own ascitic fluid.[4] Liver biopsies should be examined histologically and cultured for bacteria. Acid-fast staining is of importance for the detection of mycobacteria.

Liver Diseases

Liver disease occurs frequently in companion birds. Clinical and clinicopathologic signs may indicate liver disease that can be confirmed by histologic examination of a liver biopsy. The following liver diseases discussed below have been documented in gallinaceous, companion or aviary birds.[1,2,6,7,10,13,15,33,34,40] This review is based on known etiologies of avian liver disease, but it should be stressed that an etiologic diagnosis for many hepatopathies cannot be determined.

Infectious Diseases

Bacteria

Many bacterial species can cause hepatitis in birds (Color 20.12). A diagnosis can be made by culturing the organisms from a biopsy specimen. If bacteremia occurs, the same organisms can be isolated by blood culture. Elevated white blood cell counts and monocytosis are common with hepatitis caused by *Mycobacterium avium*. Bacteria that have been associated with hepatitis in birds include: *Borrelia*, *Escherichia coli*, *Salmonella typhimurium*, *Yersinia pseudotuberculosis*, *Acinetobacter*, *Serratia marcescens*, *Staphylococcus*, *Campylobacter*, *Corynebacterium*, *Streptococcus zooepidemicus*, *Pseudomonas*, *Citrobacter*, *Pasteurella haemolytica*, *P. multocida*, *Mycobacterium avium*, *M. bovis*, *M. tuberculosis* (Colors 20.17 and 20.19). In gallinaceous birds, bacterial cholecystitis has been reported. *Eubacterium tortuosum* has been associated with hepatic granulomas and ulceration of the lower intestines in turkeys.

Chlamydiosis

Chlamydia psittaci is an extremely common cause of hepatitis in psittacine birds (Color 20.13). Hepatosplenomegaly on radiographs of a bird that has been in recent contact with infected birds is a characteristic clinical presentation (Figure 20.3). A tentative diagnosis can be made by using an ELISA-type antigen capture test for the detection of chlamydial organisms in a fecal swab. Liver biopsies can be screened for chlamydiosis with a Stamp, Giemsa or Macchiavello's stain, or by fluorescent antibody IFA or ELISA.

Viruses

Many viruses that infect birds can cause hepatitis alone or in combination with other systemic changes. Elevated plasma GLDH activity has been shown to occur with Pacheco's disease virus infections and should alert the practitioner to extensive liver necrosis. Other herpesviruses are known in other avian species. Pacheco's disease virus, adenovirus, polyomavirus, reovirus, coronavirus and avian serositis virus have all been associated with hepatitis in companion birds (Color 20.8).

Duck virus hepatitis is a highly fatal, rapidly spreading viral disease of young ducklings that can be caused by either of one of the three known duck hepatitis viruses: DHV types 1 (worldwide distribution, classified as a picornavirus), 2 (only in England, classified as astrovirus), or 3 (only in USA, classified as picornavirus, unrelated to type 1). The sudden onset, rapid spread and acute course of this disease, in combination with hemorrhagic lesions in livers of ducklings up to three weeks of age, are practically pathognomonic.

Turkey viral hepatitis is a highly contagious, often subclinical disease of turkeys that produces lesions only in the liver and pancreas (hence the suggested name hepatopancreatitis). The presence of stress factors is considered to be essential for manifestation of the disease. Mortality is usually very low and does not occur over six weeks of age.

Helminths

Trematode infections have been reported in the liver and bile ducts of cockatoos (*Platynosomum proxillicens*), penguins (*Renicola* sp.), cormorants (*Amphimerus elongatus*), ducks and turkeys. A diagnosis can be made by examination of the feces for trematode eggs.

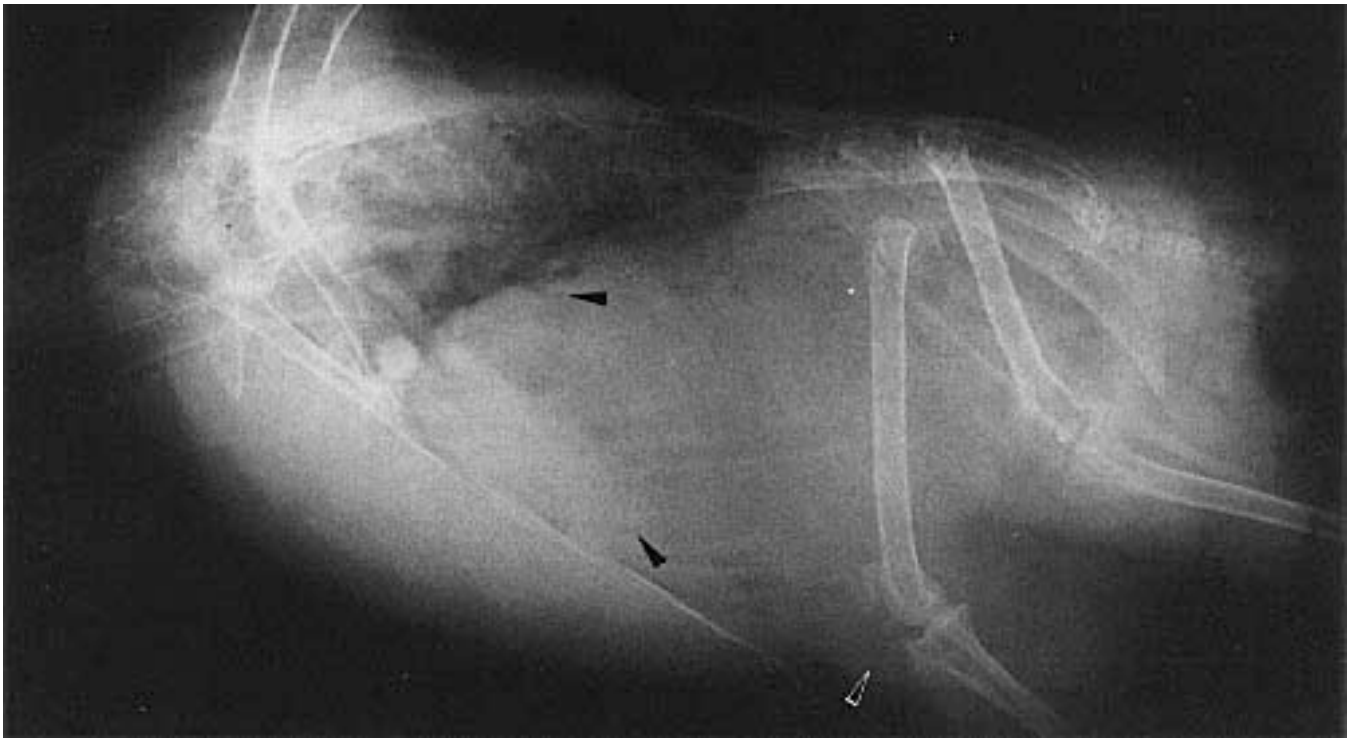


FIG 20.3 A young Double Yellow-headed Amazon Parrot was presented with lethargy, dyspnea and lime-green excrement. Radiographs indicated massive hepatomegaly causing cranial displacement of the heart (arrows), abdominal swelling (open arrow) and compression of the abdominal air sacs. The bird was positive for chlamydiosis by serology and responded to doxycycline therapy (courtesy of Marjorie McMillan).

It should be noted that in birds, trematode eggs in the feces do not always originate from parasites in the liver. In pigeons and ducks, trematodes can also be found in the alimentary tract (*Echinoparyphium* and *Echinostoma* spp.) or the kidney (*Tamerlania bragai* in the pigeon). In various avian species (including chickens, Passeriformes and Anseriformes), trematodes can be found in the oviduct (*Prosthogonimus ovatus*). Pancreatic trematodes have also been reported in birds.

Protozoa

A variety of protozoa can cause hepatopathies. *Trichomonas gallinae*-induced hepatic necrosis has been reported in Columbiformes, Falconiformes and Passeriformes.

Histomonas meleagridis is a common cause of hepatitis in captive Galliformes (Color 20.16). Sulfur-colored feces in turkeys, bloody cecal discharge in chickens, leucocytosis with heterophilia, a decreased albumin/globulin ratio and elevated liver enzymes are all suggestive of histomoniasis.

Leucocytozoon simondi is a well known cause of mortality in ducks and geese; however, the infection can also occur in other species. Hepatosplenomegaly is common, and parasites can often be detected in a peripheral blood smear.

Atoxoplasma (*Lancesterella* sp.) and toxoplasma infections are common in Passeriformes, but the latter also occurs in Psittaciformes (Color 20.14). An enlarged liver can often be seen through the transparent abdominal wall in Passeriformes with atoxoplasmosis. Sporozoites may be seen in small lymphocytes in a peripheral blood smear.

Microsporidian infections have been associated with hepatitis in lovebirds.

Noninfectious Diseases

Metabolic Disorders

In zoological collections, Psittaciformes show a high prevalance of fatty infiltration of the liver (Color 20.7). Hepatic steatosis, hepatic lipidosis and fatty degeneration have all been used to describe the condition. It has been well established that an unbalanced diet (biotin, choline and methionine deficiencies) or excessive consumption of high-energy diets with restricted exercise may lead to fatty degeneration. It should be stressed that many companion

psittacine birds are fed high-energy, multi-nutrient-deficient, all-seed diets that predispose them to fatty liver degeneration.

Fatty liver hemorrhagic syndrome in laying hens has been associated with high-energy diets fed to birds with restricted exercise. The dramatic estrogen-induced increase in liver lipogenesis to supply the developing ova has been suggested as the etiology of this condition. Reticulolysis and fibrosis of hepatic parenchyma is sometimes associated with a fatty liver. Reticulolysis is associated with rupture of intrahepatic portal veins and liver hemorrhage. Affected chickens have greatly elevated serum calcium and cholesterol concentrations. The condition can be artificially induced with estrogen injections.

Fatty liver and kidney syndrome of young broilers or layer pullets is associated with diets with a marginal biotin content. Extensive fatty infiltration occurs in the heart, liver and kidney without inflammatory or degenerative changes. There is a failure of hepatic gluconeogenesis which may lead to an acute hypoglycemia in biotin-deficient, otherwise healthy birds, if normal food intake is interrupted for a short time.

Iron Storage Disease

Hemosiderosis has been defined as an accumulation of an increased amount of hemosiderin in tissues without alteration of tissue morphology, while hemochromatosis is associated with pathologic lesions in hemosiderin-containing tissues (Color 20.6).[21] Hemosiderin is an iron-containing pigment derived from hemoglobin. The abnormal storage of iron is most frequently seen in the liver, but other organs may be involved. It has been suggested that excessive iron in the diet may be the cause of iron storage disease but this hypothesis has not been confirmed.

Hemochromatosis is most frequently described in Rampastidae (see Chapter 47), Sturnidae (birds of paradise), mynahs and quetzals, but has also been reported in Psittaciformes. Rampastidae are generally clinically normal prior to death, but occasionally affected birds are listless 24 hours prior to dying. Cardiac disease has been reported in mynahs due to iron storage in the myocardium. Electrocardiographic changes are possible due to cardiomegaly. In mynahs, generalized weakness, dyspnea and ascites are common. Radiography may reveal (cardio)hepatomegaly and ascites, and blood chemistry may indicate a liver function disorder (Figure 20.4). A specific diagnosis can be made by histologic examination of a

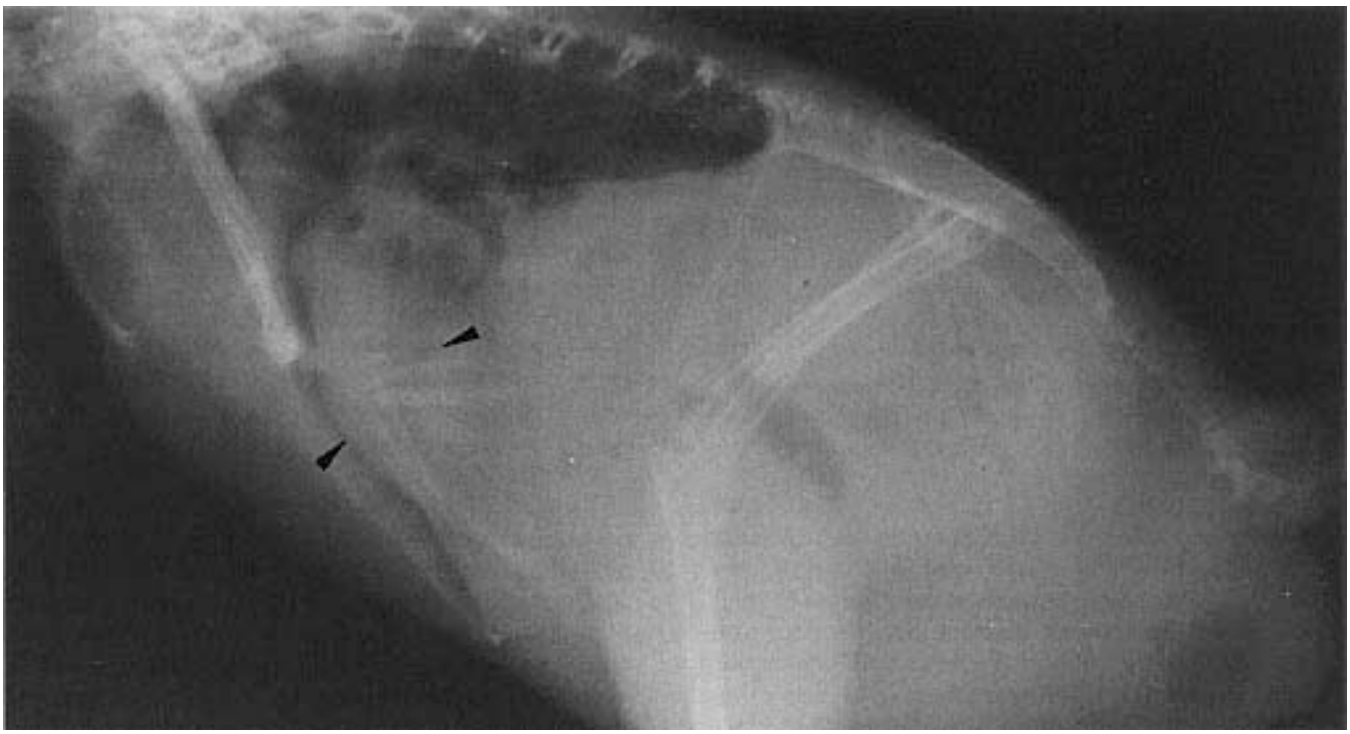

FIG 20.4 A four-year-old mynah bird fed predominately a seed-based diet was presented for severe dyspnea, lethargy and abdominal swelling. Radiographs indicated a diffuse soft tissue opacity in the abdomen suggestive of hepatomegaly and ascites. The heart was displaced cranially (arrows). Fluid collected by abdominocentesis was characterized as a transudate (low cellularity, SpGr=1.012 and TP=2 gm/dl). These findings are typical for iron storage disease.

liver biopsy after specific staining for iron (see Chapter 10). Total serum or plasma iron and TIBC may not be helpful in evaluating the iron status of the animal.

Circulatory Disorders

Portal hypertension can occur as the result of right atrioventricular valvular insufficiency. Portal hypertension may cause hepatic congestion. In the acute stage, the liver is swollen; as the disease progresses, the organ may be fibrotic and have a shrunken appearance. When liver enlargement is caused by congestion, a liver biopsy may result in fatal hemorrhage. The use of an artificial substrate (eg, Gelfoam) at the biopsy site to facilitate clotting may help control bleeding.

Anemic infarctions of the liver, especially of the caudal margins, can be seen as a result of bacterial endocarditis. Streptococci or staphylococci are often involved, but other bacteria like *Erysipelothrix rhusiopathiae* (formerly *E. insidiosa*) and *Pasteurella* spp. have also been associated with these lesions.

Hepatotoxins

Many plants are known to be hepatotoxic in some birds including: rapeseed (*Brassica napus*), ragwort (*Senecio jacobea*), castor bean (*Ricinus communis*),

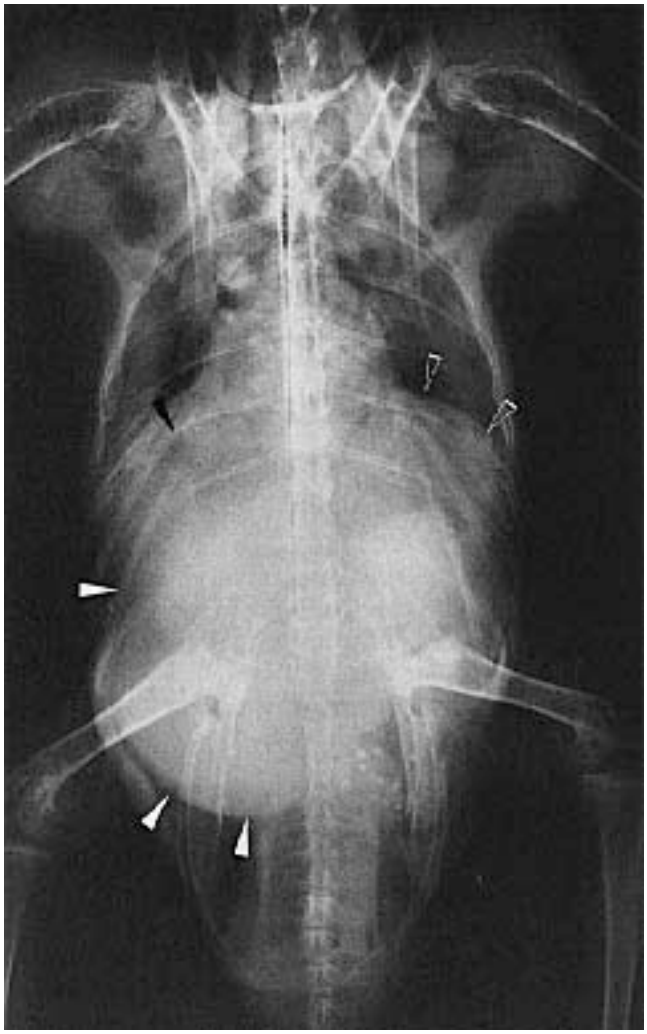

FIG 20.5 A mature Blue and Gold Macaw with a history of aspergillosis air sacculitis that was being treated with systemic antifungals became depressed and anorectic (see Color 20.10). Radiographs indicated a diffuse soft tissue opacity throughout the abdomen (arrows). Gas is seen in the dorsally displaced proventriculus (open arrows).

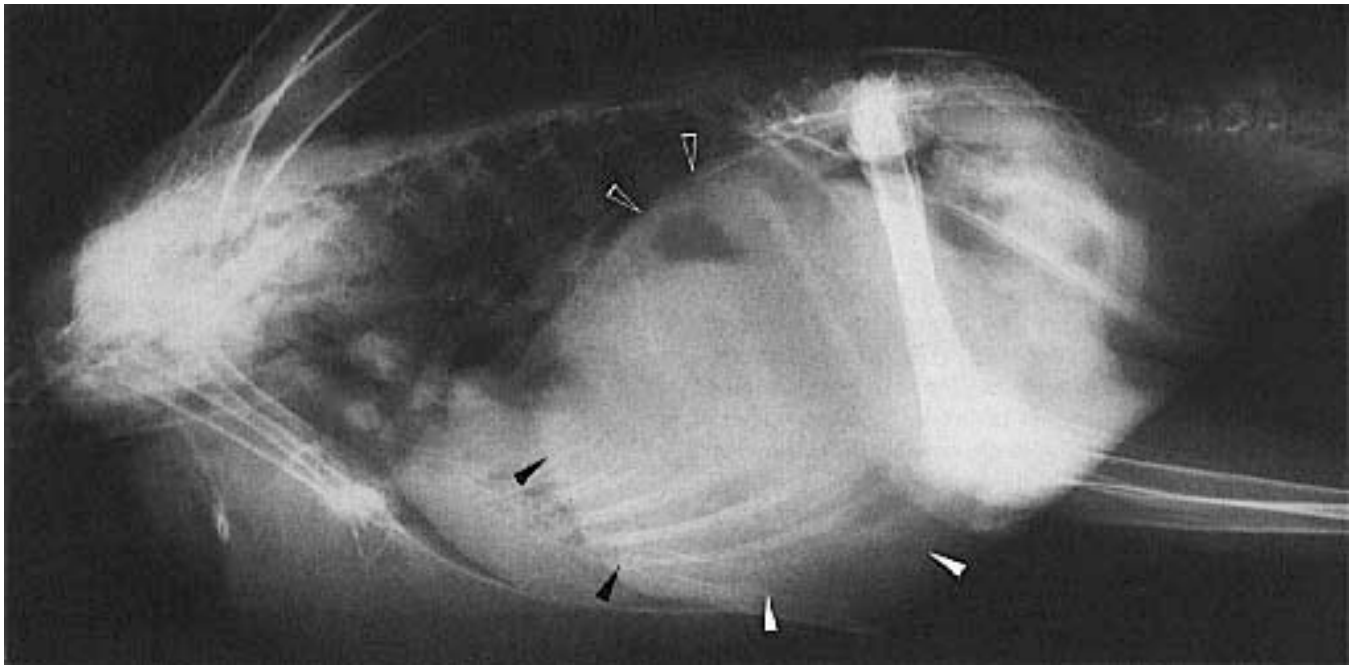

hemlock (*Conium maculatum*), oleander (*Nerium oleander*), *Oxalis* spp., *Grantia* spp., *Crotalaria* spp., *Daubentonia* seed and cotton seed (*Gossypium* spp.). Interestingly, canaries are routinely fed rapeseed and do not appear to be affected by its toxins.

The following substances are hepatotoxic: arsenic, phosphorus, carbon tetrachloride, toxins from certain blue-green algae, halothane, methoxyflurane and mycotoxins (especially aflatoxin from *Aspergillus flavus*, *A. parasiticus* and *Penicillium puberulum*) (Figure 20.5). Degeneration and necrosis of hepatocytes are typical with aflatoxicosis. Bile duct proliferation and fibrosis leaving only islands of hepatocytes are common in chronic cases (Colors 20.10 and 20.11).

Fatty degeneration and the feeding of feeds contaminated with mycotoxins causing aflatoxin hepatosis are likely to be involved in the high incidence of liver disease in birds. Peanuts and Brazil nuts are notorious sources of aflatoxins, but many other seed mixtures can be contaminated. Chemical analysis of food for aflatoxin is possible (see Chapter 37).

Neoplasia

Liver tumors can be classed as primary and multicentric (metastatic) (see Chapter 25). Examples of the former are hepatoma, hepatocellular carcinoma, cholangioma, cholangiocarcinoma, lipoma, fibroma, fibrosarcoma, hemangioma, and hemangiosarcoma. Examples of metastatic tumors are leukosis/lymphosarcoma, rhabdomyosarcoma, renal carcinoma, and pancreatic carcinoma (Color 20.18).

It has been suggested that there is an association between cholangiocarcinoma and the presence of cloacal papillomatosis in Amazon parrots (see Chapter 19). Likewise, it has been suggested that hemochromatosis in mynah birds and aflatoxicosis in ducks are associated with hepatomas.

Amyloidosis

Amyloidosis is commonly seen in Anseriformes, gulls and shorebirds. It is caused by deposition of amyloid A (a waxy, transluscent substance) in various organs, including liver and kidney (see Chapter 21). Amyloid A is a degradation product of an acute phase, reactant protein. Amyloidosis is often seen in birds with chronic infections (bumblefoot, tuberculosis and aspergillosis). Severe hypoalbuminemia caused by glomerular and hepatic damage can cause ascites and peripheral edema of the feet and legs.

Traumatic Rupture

Rupture of the liver is most likely to occur secondary to liver diseases, such as fatty degeneration, amyloidosis, mycobacteriosis and neoplasia, but can also occur as a result of trauma (Color 20.9). The reticulolysis that is associated with some liver diseases makes the liver more sensitive to traumatic insult. When the bleeding is limited or confined to a subcapsular hematoma, survival is possible. Birds can also survive liver hemorrhage confined to one of the hepatic peritoneal cavities. This is based on clinical cases and the documentation of blood clots in these cavities during laparotomies.

In the acute phase, bleeding birds may show signs of shock. Radiographically, liver enlargement is indistinguishable from perihepatic hematoma (Color 20.10). A diagnosis is usually made during endoscopy or exploratory laparotomy. Ultrasonography is a useful diagnostic tool in these cases.

Treatment of Liver Disorders

Generalities about treating avian liver disease can be extracted from known etiologies. The single most important treatment seems to be the administration of a well balanced diet free of hepatotoxins. Moldy foods and seed-based diets, particularly those containing peanuts (unless certified mycotoxin-free), should be avoided. The use of lactulose, hemicellulose and supportive care including IV fluids and assisted feeding are indicated in many cases of hepatitis. Special attention should be given to known causes of fatty degeneration or fatty infiltration of the liver (biotin, choline and methionine deficiencies or excessive consumption of high-energy diets in birds with restricted exercise). A multivitamin injection is indicated when malnutrition is suspected. In birds with hemochromatosis, the iron content of the diet should be drastically reduced (<100 ppm), although high iron content of the diet may not be the only cause of excessive iron storage in the body.

The treatment of choice for hemochromatosis in man is to remove excess iron from the body by phlebotomy (one percent of body weight once a week for six months, then twice a month for two years). Frequent

monitoring of hemoglobin and serum iron level is essential.[35] A few birds with hemochromatosis have responded to phlebotomy therapy (see Chapter 47).[32,41]

When a microbiologic cause of liver disease can be diagnosed, a specific treatment against the causative organism is possible. Doxycycline is the treatment of choice for chlamydiosis (see Chapter 34). Pacheco's disease virus infections can be treated with acyclovir. Liver flukes may be susceptible to praziquantel.

Outbreaks of duck hepatitis virus can be controlled by IM injection of DHV antiserum into each duckling at the time the first deaths are noted.

Ascitic fluid should not be removed from birds with liver disease. Removal of this fluid will further deplete body stores of protein in a bird with an already compromised liver function. The author's preference for treating ascites is to use a potent diuretic, such as furosemide, to effect, and to take only a small amount of ascitic fluid for diagnostic purposes.

Corticosteroids are occasionally used for the treatment of hepatopathies in man (eg, viral hepatitis, chronic active hepatitis) and may result in a dramatic clinical improvement. Limited experience with prednisolone in cases of chronic active hepatitis of unknown etiology in African Grey Parrots suggests that this drug may also be beneficial for treating some avian liver disorders. The use of corticosteroids in mycotoxicosis may limit the formation of fibrosis; however, corticosteroids may exacerbate an underlying infection and may be contraindicated in cases of infectious hepatitis. Colchicine has been used to prevent the progression of hepatic fibrosis in a conure.[11]

CHAPTER

21

NEPHROLOGY

J.T. Lumeij

Confirming a diagnosis of renal disease in birds is often difficult because clinical signs are generally nonspecific and are frequently complicated by secondary changes caused by renal dysfunction. Lethargy, with a diminished appetite leading to emaciation, is typical of renal disease. Birds may appear unable to fly, while in reality they are too weak to fly. A distended abdomen with or without ascites may be seen with renal tumors. In over 50% of renal neoplasms, the tumor can be palpated (Color 21.11).[2] Renal masses and ascites may prevent normal air flow and cause dyspnea because of compression on the abdominal and caudal thoracic air sacs (Color 21.4). Urinary output may vary from anuria to polyuria. In oliguric patients, the possibility of acute nephrotoxic renal failure should be considered, and the client should be carefully questioned concerning the administration of nephrotoxic drugs (eg, allopurinol, aminoglycosides, polypeptide antibiotics and sulfonamides) or exposure to sodium chloride (eg, saline as drinking water, sea sand for bedding material, heavily salted foods) or other nephrotoxic substances (eg, heavy metals, ethylene glycol, carbon tetrachloride).

Clinical findings can be quite suggestive of renal disease. During the physical examination, signs of dehydration or shock may suggest a diagnosis of prerenal renal failure. Dehydrated birds have a reduced skin elasticity and dry mucous membranes. Subcutaneous urate tophi or urate accumulations in joints are signs of articular gout (Color 21.3), a clinical sequela to hyperuricemia, which in birds is caused by a renal disorder. Unilateral or bilateral paresis of the legs is often the first clinical sign of renal neoplasm in psittacine birds (particularly budgerigars). Neurologic signs are seen in about one-third of renal neoplasms, but may also be caused by other space-occupying lesions in the ipsilateral kidney (eg, iatrogenic hematoma, renal aspergillosis) (Color 21.2). Neurologic changes are secondary to compression or inflammation of branches of the lumbosacral plexus, which pass through the kidneys (Color 21.1). Constipation may also occur if the renal mass compresses the large intestine. In large birds, a lubricated, gloved finger can be inserted and moved dorsally in the cloaca in order to palpate the caudal division of the kidney. Any swelling, asymmetry or tenderness may be an indication of renal disease.[4]

Clinicopathologic changes in the blood and urine depend on location and severity of the renal lesions (eg, glomerulopathies may lead to severe protein loss and hypoalbuminemia, while tubular lesions may lead to hyperuricemia or polydipsia).

Anatomy and Physiology of the Kidney

The paired kidneys are located dorsally in a depression of the pelvis. Each kidney is made up of three divisions that are frequently referred to as lobes (cranial, middle and caudal). The divisions are composed of lobules with a large cortical mass and a small medullary mass. It is difficult to demarcate between the cortical and medullary portions of the lobules. The cortex is composed of both reptilian-type nephrons that do not contain loops of Henle and mammalian-type nephrons that do contain loops of Henle. The reptile-type nephrons are most numerous, and birds are less efficient in the excretion of electrolytes than mammals. The cortical-type nephrons are uricotelic and the medullary-type produce urine. The former are located on the surface of the kidney, and the latter are located in a deeper orientation. The nephrons' collecting ducts and ureters are contiguous. The kidneys of birds are larger by weight than in mammals. There are three pairs of renal arteries. The anterior branch arises from the aorta, and the middle and posterior branches arise from the sciatic artery or external iliac artery. The anterior branch supplies the cranial division of the kidney, and the middle and posterior branches supply the middle and caudal divisions of the kidney.

Birds have a renal portal system in which the renal portal vein functions like an artery by carrying blood to the tubules. Flow of blood into the kidneys from the renal portal system is controlled by valves. These valves are bilateral and are located at the junction of the external iliac vein and the renal vein. Studies suggest that acetylcholine causes the valves to close and epinephrine causes them to open. If agents excreted by the renal tubules are injected into the legs, they are excreted by the tubules on the injection side of the body before entering the general circulation.

Glucose is completely filterable and is normally absorbed by the kidney. Glucosuria indicates that renal absorption is damaged or that excessively high levels of glucose are being presented to the kidneys. The avian kidney has a reduced capacity to secrete creatinine in comparison to uric acid.

Renal output varies with the water intake and stress levels of the bird, but is generally considered to be 100 to 200 ml/kg/day. By comparison, dehydrated birds may have a renal output of 25 ml/kg/day. There is a physiologic polyuria that occurs a few hours before egg laying.

Some urine water that is excreted into the cloaca is passed by antiperistaltic movement of the cloaca into the colon where absorption of the liquid occurs. In dehydrated birds, 15% of urine water may be reabsorbed from the colon. The amount of water absorbed by the colon is decreased with polyuria or with a stress-induced defecation creating a moist-appearing excrement.

Pathophysiology

Etiology of Gout

Uric acid (UA) is produced in the liver and is the major end product of deamination of amino acids in birds. It constitutes approximately 60 to 80% of the total excreted nitrogen in avian urine. Uricotelism permits excretion or storage of nitrogen waste in a small volume of water. Uric acid is relatively nontoxic when compared to urea or ammonia. This method of handling nitrogenous waste is essential for embryo development within an egg. Uricotelism may also be viewed as an adaptation for water conservation.

Uric acid is synthesized in the liver. Ninety percent of its excretion is via tubular secretion from reptilian-type nephrons and therefore largely independent of urine flow rate. The clearance of uric acid surpasses the glomerular filtration rate by a factor of eight to sixteen and is occasionally even higher. The rate of secretion is largely independent of the state of hydration because UA excretion is independent of tubular water reabsorption. Very high concentrations of uric acid can be found in ureteral urine in dehydrated birds. Renal function disorders can eventually lead to elevated uric acid concentrations. However, non-protein nitrogen substances in plasma, such as uric acid, creatinine and urea will be elevated only when renal function is below 30% of its original capacity.

Hyperuricemia is defined as any plasma uric acid concentration higher than the calculated limit of solubility of sodium urate in plasma and is an indication of nephrosis or impaired renal function. An ordinary aqueous solution at 37°C, with a sodium concentration equal to that of normal human plasma is saturated when the urate concentration reaches 383 to 407 μmol/l. It is generally accepted that the upper limit of solubility of urate in human plasma, is 420 μmol/l.[3] Urate solubility increases with higher sodium concentrations and higher temperatures. When the higher body temperature of birds (up to 43°C) is taken into account, the theoretical limit of solubility would be about 600 μmol/l. Because avian species have a higher plasma sodium concentration than humans (136-145 mmol/l), the theoretical limit of urate solubility is even higher. Hyperuricemia can result in urate precipitation in joints (articular gout) (Colors 21.10 and 21.12) and in visceral organs or other extra-visceral sites (visceral gout) (Color 21.7). The exact mechanism of deposition or the predilection for gout to occur in certain sites is unknown. Gout should not be regarded as a disease entity, but as a clinical sign of any severe renal dysfunction that causes a chronic, moderate hyperuricemia.

When birds are provided with dietary protein in excess of their requirements, the surplus protein is catabolized and the nitrogen released is converted to uric acid. The total amount of uric acid formed may surpass the clearing capacity of this substance from the body, and hyperuricemia and articular gout may result. The use of high-protein poultry pellets as the bulk food in psittacine aviaries may result in an increased incidence of gout (See Chapter 3).

- ***Articular and Visceral Gout*** There is no consensus on the different etiologies of articular and visceral gout in birds. The following hypothesis seems to explain all known facts.

A plasma uric acid concentration that is slightly above the solubility of sodium urate will lead to uric acid precipitates in the body. Predilection sites are those areas where the solubility of sodium urate, for whatever reason, is lower than in other areas (Figure 21.1). The joints and synovial sheaths may be predilection sites because of a lower temperature than the rest of the body. Once uric acid deposits have occurred in a specific area, these deposits will grow with time, forming tophi (accumulations of uric acid) (Color 21.8).

FIG 21.1 A six-year-old male budgerigar was presented for lameness of several days' duration. Multiple, firm, raised nodules (tophi) were noted at several periarticular locations. The severe articular gout was considered unresolvable and the bird was euthanatized. Histopathology revealed severe nephritis.

If, for whatever reason, uric acid crystals precipitate in the tubules or collecting ducts of the kidney (eg, severe dehydration of long duration, hypovitaminosis A) or the ureters, an acute obstructive uropathy (postrenal obstruction) will occur (Color 21.3). These birds develop anuria or gross oliguria, and tubular secretion of uric acid is severely compromised or stops. This results in a rapid and severe elevation of plasma uric acid concentration with precipitation of urates on many visceral surfaces, including those predilection sites for articular gout. Visceral gout will rapidly lead to death of the affected animal. This hypothesis is supported by the fact that inflammation and tophi formation are rare with visceral gout, because the condition has a rapidly fatal course. There is simply no time for an inflammatory reaction or tophi to develop. The kidney tubules, collecting ducts and ureters may contain uric acid deposits.

Acute, renal tubular failure, which would lead to acute abolishment of uric acid secretion, would result in a similar course of events. In this situation, visceral gout could develop without uric acid deposits forming in the tubules, collecting ducts and ureters.

The acute mortality seen in birds with visceral gout is probably not due to the effects of hyperuricemia, because uric acid is generally a nontoxic, insoluble substance. It is likely that these birds die from cardiac arrest caused by hyperkalemia, although this hypothesis needs confirmation.

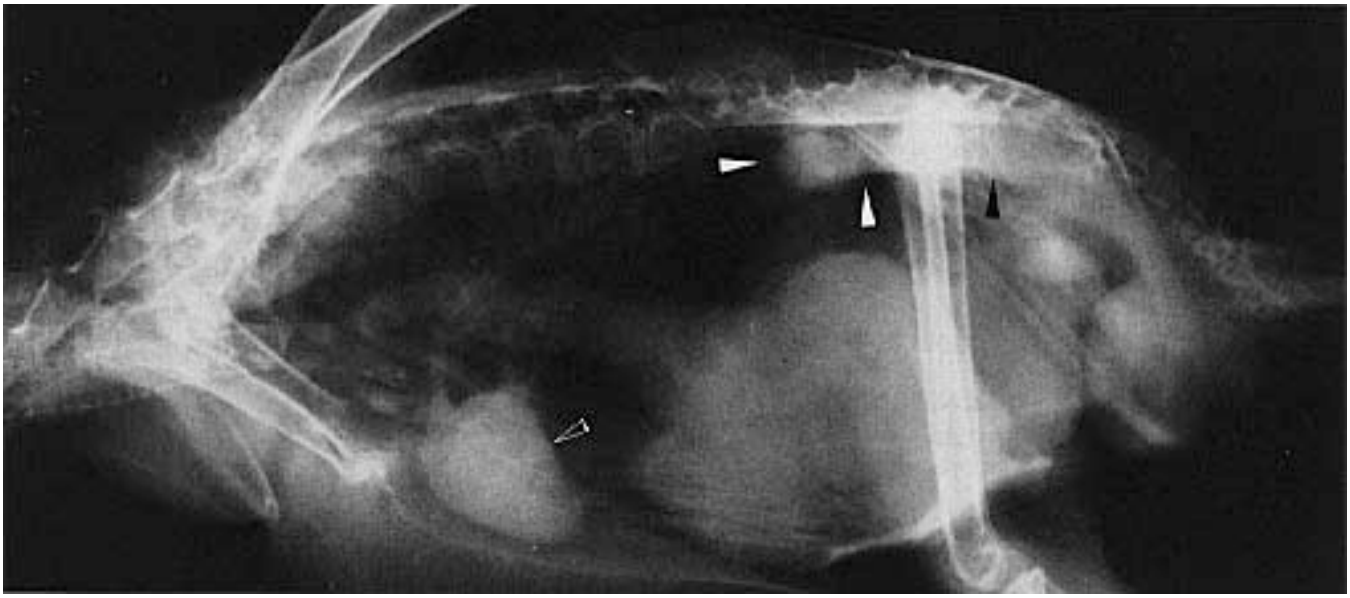

FIG 21.2 An adult male Umbrella Cockatoo was presented with severe depression, emaciation (470 g) and putrid, watery diarrhea. Abnormal clinical pathologic findings included WBC=46,000, PCV=34%, TP=7.5 and LDH=500. Radiographic lesions included a microcardia (open arrow) and radiodense kidneys (arrows), both of which are indicative of dehydration and hypovolemia. Necropsy findings included small irregular kidneys with multiple granulomas and granulomatous tubulointerstitial nephritis.

Acute and Chronic Renal Failure

Renal dysfunction may result from any progressive destructive condition affecting both kidneys (chronic renal failure), but can also occur in conditions wherein the function of the kidneys is rapidly and severely, but often reversibly, compromised (acute renal failure) (Figure 21.2). In the latter condition, oliguria usually occurs, while in the former situation, polyuria is normally seen. Dehydration and shock (prerenal renal failure), urolithiasis (postrenal renal failure) and urinary tract infections and the administration of nephrotoxic drugs can all cause changes that mimic irreversible chronic renal failure. Appropriate and timely treatment of the former conditions can often prevent further damage and in some cases result in improved function. Extrarenal factors such as infection, gastrointestinal hemorrhage and hypovolemia can disturb an otherwise stable, well compensated, asymptomatic patient with chronic renal disease and precipitate a life-threatening, acute clinical change.

Prerenal Azotemia

Prerenal azotemia can be defined as the clinical condition associated with reduced renal arterial pressure or perfusion leading to oliguria and retention of

nitrogenous urinary waste products in the blood. It is often seen during shock or severe dehydration. In clinical textbooks, it is commonly stated that dehydrated birds have elevated plasma uric acid concentrations. In recent experimental studies, elevated plasma uric acid concentrations were not observed in racing pigeons that were deprived of water for four days, while plasma urea concentration showed a significant 6.5- to 15.3-fold increase above reference values. Urea is normally present in low concentration in avian plasma and determination of this has traditionally been considered of little value in evaluating renal function in birds; however, plasma urea appears to be the single most useful variable for early detection of prerenal causes of renal failure (dehydration).[21]

These observations can be explained by the fact that urea is excreted in the kidneys by glomerular filtration, while tubular reabsorption is dependent on tubular urine flow, which in turn depends on the state of hydration. In a hydrated bird, almost all of the filtered urea is excreted. When a bird is dehydrated, nearly all of the filtered urea is reabsorbed. The tubular reabsorption of urea in conditions of renal failure, accompanied by a low urine flow (eg, dehydration) in combination with a nearly unchanged excretion of uric acid, causes a disproportionate increase in plasma urea concentration, which results in an elevated urea:uric acid ratio.

Chronic, progressive dehydration may eventually lead to hyperuricemia. This might be caused by reduced tubular blood supply that leads to reduced uric acid secretion or by uric acid precipitation in the tubuli caused by active tubular secretion of uric acid in the absence of urine flow. The latter condition appears similar to acute uric acid nephropathy described in man.

Postprandial Effects

It has been demonstrated that a significant postprandial increase in plasma uric acid (UA) and urea concentration occurs in Peregrine Falcons and Redtailed Hawks.[24,25]

Postprandial plasma UA levels were similar to those in birds suffering from hyperuricemia and gout and were well above the theoretical limit of solubility of urate in plasma. It is not clear why at least twelve hours of postprandial hyperuricemia does not result in uric acid deposition in the tissues. The fact that Peregrine Falcons have relatively high plasma sodium concentrations might partially explain their tolerance of high plasma UA levels. In order to prevent misinterpretation of high plasma UA levels caused by the ingestion of food, it is recommended that repeat samples be evaluated following a fasting period in any bird that initially has a high plasma UA or urea concentration.

Evaluation of Urate Tophi

Macroscopically, the aspirated material from articular gout looks like toothpaste (Color 21.10). The presence of urate can be confirmed by performing the murexide test or by microscopic examination of aspirates from suspected tophi. The murexide test is performed by mixing a drop of nitric acid with a small amount of the suspected material on a slide. The material is dried by evaporation in a flame and allowed to cool. One drop of concentrated ammonia is added, and if urates are present, a mauve color will develop. Microscopically, sharp, needle-shaped crystals can be seen in smears. A polarizing microscope is helpful in identifying the typical crystals.

Blood Changes

Apart from elevated concentrations of nonprotein nitrogen substances, a number of other variables are known to change in mammals as a result of acute or chronic renal failure. Hyperkalemia, which may lead to severe electrocardiographic changes and cardiac arrest, is a particular problem in acute renal failure. Hyperkalemia (5.2 mmol/l) was described in a Redtailed Hawk with acute renal failure.[24] In man, plasma potassium concentration can be lowered promptly and for a number of hours by infusion of one liter of 10% glucose solution containing 10 to 20 IU insulin; however, in birds, insulin may cause acute hypoglycemia, CNS swelling and death. Infusion of 10% calcium gluconate solution may reverse the cardiotoxic effects of severe hyperkalemia without affecting plasma potassium concentration. Hypocalcemia and hyperphosphatemia are common in mammals with renal failure. The former may lead to hypocalcemic tetany, especially with rapid correction of acidosis. Because these variables have significant therapeutic implications, documentation of their occurrence in avian renal disease is necessary. Anemia has also been documented in birds with chronic renal failure.

Clinicopathologic Diagnosis of Renal Dysfunction

Urinalysis

Analysis of urine has been shown to be a valuable diagnostic tool in veterinary medicine. Examination of urinary sediment and determination of urinary protein concentration are the most valuable procedures in the differential diagnosis of renal diseases. Renal function tests provide information on the degree of functional impairment. Urinalysis may give an early warning of renal damage or impaired renal function long before there is an increase in plasma nonprotein nitrogen concentrations. Signs of renal damage or impaired renal function include proteinuria, glucosuria without hyperglycemia and casts or cells in urinary sediment.

Despite its high diagnostic value, urinalysis is not routinely performed in avian medicine, perhaps because it seems difficult to separate urine from feces. Practical guidelines for urinalysis in companion birds have been developed and are an indispensable part of the diagnostic workup in polyuric birds.[38,39] The identification of casts in urinary sediment is strongly suggestive of renal disease. In polyuric cases, collection of a urine sample is relatively simple and can be performed by aspirating the fluid part of the excreta into a syringe from a clean enclosure floor covered by wax paper. It is important that the urine sample be relatively free of urates to ensure the diagnostic value of microscopic examination of the sediment. Sediments obtained from the total renal fraction of the excreta will contain excessive urates; the results are of limited diagnostic value. Clinically normal birds have a tendency to become polyuric when in a stressful environment (eg, the veterinary clinic). In these birds, a urine sample is easy to obtain because of the bird's tendency to increase the frequency of cloacal emptying when nervous (Color 21.13). This will result in the excretion of urine fraction that has not moved retrograde into the large intestine where absorption of water and salts typically occurs.

Urate-free urine samples should be examined for specific gravity or osmolality, color, clearness, pH, protein, glucose, hemoglobin and the sediment should be examined microscopically.

Several methods for collecting avian urine from nonpolyuric birds have been reported. The modified cloacal cannula method[5,15] is the most appropriate for clinical use in docile birds (eg, racing pigeons) because it is the least invasive and is useful under clinical conditions. Reference values for twelve chemical and physical variables established in supernatants of pigeon urine (7000 G for 2 minutes) collected with the cloacal cannula method have been established (Table 21.1) and might provide a new perspective for the application of urinalysis in avian medicine.

TABLE 21.1 Reference Values ($P_{2.5}$- $P_{97.5}$) for Pigeon Urine[15]

Variable	Reference Values (SI units)
Urine production	2.3-19.7 ml/kg/h
Osmolality	27-193 mOsmol/kg
Flow-osmol factor	237-1847mOsmol/ml/kg/h
Glucose	0-3.2 mmol/liter
Total protein	0.11-1.99 g/liter
Uric acid	1.2-10.1 mmol/liter
pH	5.5-6.9
Na^+	2.0-27 mmol/liter
K^+	4.0-27 mmol/liter
Inorganic P	0.2-10.9 mmol/liter
Cl^-	5.0-56 mmol/liter
NH_4+	4.6-39.5 mmol/liter

Osmolality and Specific Gravity

The low urine osmolality as reported in Table 21.1 can be explained by the fact that birds can produce urine with a considerably lower osmolality than the osmolality of blood plasma, due to the presence of reptilian-type nephrons as well as mammalian type nephrons.[29,44] High urine osmolalities are common in avian species that are adapted to desert situations (Zebra Finch and budgerigar). Budgerigars can survive long periods (up to a month) without water under certain conditions;[41] however, domesticated budgerigars and finches that are provided free-choice water may lose much of their compensatory ability. Maximum urine osmolalities in birds vary from 500 to 1000 mOsmol/kg.[41] The emu is adapted to the Australian semidesert and has a low turnover rate of water, but has a limited renal concentrating ability with a maximal urine:plasma osmotic ratio of only 1.4:1.5. In this species, the large intestine has been adapted to preserve water. The high resorptive capacity may be related to increased folding of the mucosal surface, which increases the surface area by a factor of five.[43]

Nephrology

Color 21.1
In health, the kidneys are dark red-brown and consistent in color. Cranial (k1), middle (k2) and caudal (k3) divisions of the kidney adhere tightly to the synsacrum in the dorsal abdominal wall. The right kidney has been removed to show the relationship of the kidneys with the synsacrum (s) and the sacral nerve plexus (arrow). Other structures that are easily identified include the lung (lu), left ovary (o) and oviduct (open arrow).

Color 21.2
A Black Palm Cockatoo with a history of progressive rear limb ataxia died and was presented for necropsy. The walls of the left abdominal and caudal thoracic air sacs were thickened, and a velvet-like yellow material was present on the surface of the membranes (arrow). The cranial and middle divisions of the left kidney and the ischiatic nerve (open arrow) were also involved. Aspergillosis air sacculitis with extension to the kidneys and nerves was the cause of death in this bird.

Color 21.3
Birds with decreased renal function may develop uric acid deposits (gout) in visceral organs or in joints. The linear white streaks within the renal parenchyma in this African Grey Parrot are characteristic for gout. This was a breeding male that died after a brief period of severe depression. Uric acid deposits were also present in the pericardium and liver (see Color 21.7). Structures that are clearly visible are cranial (k1), middle (k2) and caudal (k3) divisions of the kidney, right and left testicles (t), lung (lu), ureter (open arrow), caudal renal vein (arrow).

Color 21.4
A mature, female African Grey Parrot was presented for evaluation of severe dyspnea. Radiographs indicated a large mass in the left thoracic cavity. Histologic evaluation of a fine-needle aspirate was suggestive of adenocarcinoma in the lung. A renal mass identified at gross necropsy was confirmed to be a renal adenocarcinoma. This bird had no clinical changes suggestive of rear limb ataxia or weakness, which frequently accompany renal masses. The ovary (o), oviduct (open arrow), ischium (i), external iliac vein (arrow) and ureter (u) are clearly visible.

Nephrology

Color 21.5
Hemorrhage and swelling of the right cranial division of the kidney (arrow) in a juvenile Umbrella Cockatoo. The left kidney (k) is unusually pale.

Color 21.6
Iron storage disease is a common cause of death in toucans and mynahs. Excessive accumulation of iron is usually present in the liver but can also occur in the kidney (k), as seen in this toucan. These affected kidneys are swollen and orange in color. Other structures that are clearly visible include the ovary (o), oviduct (arrow) and the caudal renal vein (open arrow) (courtesy of Robert E. Schmidt).

Color 21.7
Deposits of uric acid in the pericardium and liver of an African Grey Parrot with renal failure (see Color 21.3).

Color 21.8
Multiple urate masses in the kidney of an immature gallinaceous hen in end-stage renal failure. Note the immature ovary (o) and oviduct (arrow) coursing over the left ureter; urates are visible near the bottom of the photo (courtesy of R. Korbel).

Color 21.9
Gout in a five-day-old rhea chick. Note that the tubules are white and filled with urates (courtesy of Brett Hopkins).

Color 21.10
A mature pigeon was presented for lameness and an inability to fly. Prior to dissection, the firm, white, periarticular masses could be visualized through the skin (as in Color 21.12). Cytology of material collected from the masses revealed numerous uric acid crystals. Articular gout is common in some birds secondary to renal dysfunction.

Color 21.11
A three-year-old budgerigar was presented with a two-week history of progressive ataxia and inability to stand. The bird was first noted with dyspnea about three months prior to presentation and was severely dyspneic during the physical examination. A large mass could be palpated in the caudal abdomen. Necropsy revealed large cystic kidneys. Histologic changes in the right kidney (rk) were consistent with a renal adenocarcinoma, and the left kidney (lk) had undergone cystic changes.

Color 21.12
Articular gout in the elbow of a pigeon with renal failure (see Color 21.10).

Color 21.13
Polyuria can be caused by excitement, polydipsia, high-moisture diets (fruits) or renal disease. In this case, polyuria in a juvenile Blue and Gold Macaw occurred secondary to the excitement associated with handling.

Color 21.14
Hematuria is occasionally seen in birds. The blood can originate from the kidney and ureters, which is rare, or from the gastrointestinal tract or cloaca, which is common. In this African Grey Parrot, hematuria was occurring secondary to a bacterial nephritis.

Color 21.15
The presence of a large concentration of WBCs can cause urine to appear cloudy. In this cockatiel with severe metritis, both WBCs and RBCs were identified in the urine by cytology.

As an alternative to the cloacal cannula method, the fluid part of the excreta (urine) can be recovered immediately after excretion. The values for urine osmolality in excreted samples tend to be higher than those obtained from cloacal cannula samples. This might be explained by water resorption from the urine in the large intestine, which occurs under physiologic conditions[41] but is prevented when using the cloacal cannula method. The cloacal cannula method would be expected to provide a better impression of the renal concentrating capacity of a patient.

A test for urine concentrating capacity of the racing pigeon has been developed as a model for differentiation of polyuric disorders in birds.[1] It was concluded that urine osmolality of 450 mOsmol/kg is indicative of the normal concentrating capacity of the kidneys. In polyuric birds without a diminished concentrating capacity, one day of water deprivation should be sufficient to cause a demonstrable rise in urine osmolality.

Because the specific gravity of urine has a positive correlation with the osmolality, it should be possible to determine specific gravity of avian urine with a refractometer. Further work is needed to establish the correlation between refractometric readings and osmometric values before refractometry can be recommended. Some practitioners believe that they can make an empirical prognostic determination based on the specific gravity of the urine in a patient.

Polyuria is confirmed by demonstrating hypotonic urine (osmolality, mOsmol/l or specific gravity).

Flow-osmol Factor

The flow-osmol factor can be defined as the product of the osmolality and urine volume per hour per kilogram. This value provides the limits within which the combination of both factors can be considered to be normal. There is a negative correlation between osmolality and urine flow. In this way, a low urine osmolality and a low urine flow, while both within their respective limits, should be considered abnormal when their combined value is below the normal values of the flow-osmol factor.

Nonprotein Nitrogen and pH

Uric acid concentrations, as mentioned in Table 21.1, are those that are found in supernatants of pigeon urine. The sediment has a much higher concentration of uric acid.

It is known that large quantities of cations are trapped in uric acid precipitates.[32,33,44] The degree of cation trapping varies from 3-75% for Na^+, 8-84% for K^+ and 17-32% for Ca^+ and Mg^{++}. This should be considered when evaluating the values for these cations provided in Table 21.1. The Cl^- concentration in the urine mainly depends on the concentration of sodium chloride in the food.

Dietary protein does influence the total ammonia excreted but it has little effect on the urine ammonia concentration.[31] Dehydration produces an increased ammonia concentration in urine, which is caused by the role of ammonia in regulating the acid-base balance.[20] Table 21.1 provides an indication of the pH range to be expected in the urine of granivorous birds. Determination of urine pH can be helpful in the diagnosis of acidosis in birds.[a]

Protein

In healthy pigeons, protein concentrations in urine collected with the cloacal cannula method can be as high as 2 g/l. The excretion of mucoproteins and glycoproteins in the distal portion of the nephrons and the ureters is responsible for this low level proteinuria.[30] Severe, persistent proteinuria is a sign of increased glomerular permeability (eg, glomerulonephritis). Proteinuria is usually minimal or absent in diseases that primarily involve the tubules or interstitial tissue. Extreme protein loss through the kidneys can lead to severe hypoproteinemia.

Most urine dip-sticks are too insensitive to distinguish between moderate and severe proteinuria and may not properly detect proteinuria in polyuric patients. A false-positive protein result is common in psittacine birds that have had an alkaline urine. The use of the Ponceau S method[16] for determination of urine protein concentration is recommended. With this method, protein is precipitated with trichloroacetic acid in the presence of the dye Ponceau S. The precipitate is then dissolved in sodium hydroxide, and the color intensity is measured spectrophotometrically at 545 nm.

Glucose

Glucose is normally absent from chicken urine,[6,45] though small quantities (1.6 mmol/l) of monosaccharides have been described in ureteral urine samples collected from birds.[42] The glucose concentrations mentioned in Table 21.1 are too low to be detected by rapid screening tests like Testape.[b]

Polyuria and polydipsia accompanied by glucosuria do not always indicate diabetes mellitus. Diabetes mellitus can be diagnosed only if elevated plasma glucose concentrations have been demonstrated. In

mammals, Fanconi's syndrome is characterized by renal glucosuria, hyperaminoaciduria and hyperphosphaturia, as well as renal loss of potassium, bicarbonate, water and other substances conserved by the proximal tubule. Fanconi's syndrome should be considered as the final result of any one of many possible primary insults to proximal tubular function. The syndrome may be inherited or acquired. A case of renal glucosuria and proteinuria in an African Grey Parrot with severe renal damage was considered to be similar to the Faconi's syndrome. Glucosuria is frequently seen in psittacine hens with egg-related peritonitis. The problem is transitory if the peritonitis can be successfully managed.

Ketonuria

Ketonuria in mammals occurs when fatty acids are used instead of carbohydrates as the body's main energy source. It has been stated that ketonuria is a poor prognostic sign in birds, suggesting that catabolic processes lead to mobilization of fat and ketoacidosis.[39] This statement is probably incorrect for migratory birds. The primary energy source during migration is fat. In the premigratory state, the dry weight basis of some migratory birds is two-thirds fat. When this fat is used for energy during migration, it is broken down to fatty acids and glycerol. The body of migratory birds seems to have a metabolic system for preventing the accumulation of ketone bodies.[12] Diabetes mellitus has been mentioned as a cause of ketonuria in birds;[11,38] however, in the author's opinion, the clinical importance of ketonuria needs further clarification.

Color

The color of urine varies but is generally white or off-white, pale yellow or light beige. Pigmented food items and medications may alter urinary color. B-complex vitamins can cause a yellow or brownish discoloration of the urine that can be misinterpreted as bilirubinuria (see Color 8). Berries in the diet can cause a blue-red discoloration of the urine (see Color 8). In liver diseases, biliverdinuria may result in a green-tinged urine (see Color 8).

Microscopic Examination of Urinary Sediment

Microscopic examination of urine sediment is diagnostic only when evaluating urine that contains relatively little uric acid. Furthermore, contamination of the urine with nonrenal components, such as feces or blood originating from the cloaca, must be considered. If performed properly, microscopic evaluation of the urine and protein determination are the most important methods for early detection of renal disease. Various cast types and cellular elements can be encountered in urinary sediment (Color 21.15). Cellular casts can contain epithelial cells, erythrocytes, leukocytes, bacteria and fungi. Granular casts are composed of degraded cellular components. Casts that have no cellular elements but have a yellow-orange color are suggestive of hemoglobin casts.[38] Eosinophilic tubular casts were suspected to contain myoglobin in an ostrich with acute muscle necrosis and toxic nephropathy.[37] Clinical experience suggests that the transition from cellular or granular casts to hemoglobin casts is a favorable prognostic sign and indicates resolution of the inflammatory process.[39]

Microorganisms found in urine sediments are usually from fecal contamination; however, high bacterial counts in a relatively clean sample, together with urinary cast formation, is indicative of urinary tract infection. In male birds, sperm cells may be seen on routine microscopic examination of urinary sediment. Avian urine contains many amorphous urates, but other crystals may sometimes be noted.

Urinary Enzymes

Tissue enzyme profile studies in racing pigeons[22] and budgerigars[26] have shown that renal tissues of these birds contain relatively high amounts of various enzymes. LDH, AST, CPK, AP, GLDH and ALT can be found in decreasing concentrations in renal tissue. From studies in dogs,[18] it is known that the enzymes that are released during renal damage do not enter the systemic circulation but are voided with the urine. For this reason, determination of urinary enzyme activities could be of value for the diagnosis of renal cell damage, and the severity of cell damage might be judged by considering the site of origin of the various enzymes. For example, GLDH is known to be a mitochondrial enzyme and is expected to be released only after renal cell necrosis in which the cell organelles are damaged. In renal cell degeneration only the release of cytoplasmic enzymes is expected to occur. Further experimental studies in birds are needed.

Abnormal Urine Coloration

Hematuria is macroscopically visible when 0.1% of the urine contains blood (Color 21.14). Chemical test strips, like Hemastix,[c] will show a positive reaction when 0.002-0.001% of the urine contains blood. The combination of microscopic examination of the sediment and the use of a test strip is more sensitive for the detection of hematuria than when either test is used alone. In mammals, hematuria is always pathologic. Red blood cells can originate all along the

urinary tract. In birds, hematuria is also possible when blood cells from the gastrointestinal and genital tract or cloaca are mixed with the urine sample. In carnivorous birds, the meat diet frequently results in a positive reaction. Both hematuria and hemoglobinuria can be demonstrated using test strips for hemoglobin. Hemoglobinuria will be seen when there is an increased erythrolysis.

Myoglobinuria can also cause a red coloration of urine, which cannot be distinguished from hemoglobinuria on routine chemical urinalysis. Myoglobinuria can be demonstrated spectrophotometrically. Exertional rhabdomyolysis is well known in a number of mammalian species (eg, man, horse, whippet, kangaroo) and has also been reported in flamingos[9,10] and ostriches.[37] The resulting myoglobinuria can induce a severe toxic nephropathy.

Porphyrinuria is another cause of red coloration of the urine. In birds, the most common cause of porphyrinuria is lead poisoning. Amazon parrots with lead poisoning often produce a red or brown urine, which is assumed to be hemoglobinuria.[38] Lead is known to inhibit the activity of various enzymes involved in heme synthesis, which leads to porphyrinemia and porphyrinuria. Urine that contains high concentrations of porphyrins is wine-red in mammals. It is possible that the red or brown urine seen in Amazon parrots with lead poisoning is caused by porphyrins mixed with urates rather than hemoglobinuria. Porphyrins in urine will show a red fluorescence in ultraviolet light. When the test is negative, a blue fluorescence will be seen.

Radiology of the Urinary Tract

Survey radiographs provide information about the size, location and radiopacity of the kidneys. The paired kidneys are located in the ventral renal fossae of the synsacrum. The kidneys are surrounded by the abdominal air sacs, which extend as diverticuli between the kidneys and the pelvis. This finding explains why, at least in Psittaciformes, a rim of air can be seen dorsal to the kidneys. The loss of this dorsal rim of air is seen during pathologic swelling of the kidneys.[28] On a lateral radiograph, the kidneys appear as bean-shaped structures posterior to the last rib. The cranial part is more easily visualized radiographically because the caudal part is superimposed by the intestinal tract and pelvis. On a ventrodorsal radiograph, the kidneys are superimposed by the liver and the intestinal tract. Abnormalities that can be detected on survey radiographs include swelling and crystalline inclusions indicative of urate deposits (Figure 21.3).[19] Nephrocalcinosis or concrements in the kidney, ureters or cloaca can also be detected. Barium sulphate contrast of the gastrointestinal tract may be helpful in localizing intra-abdominal space-occupying lesions such as renal tumors. Occasionally, urate tophi of articular gout are visible on radiographs.[8]

Endoscopy and Biopsy

Endoscopy allows direct visualization of the complete urinary system (kidneys, ureters and cloaca). The endoscopic approach of choice is through a puncture site dorsal to the pubic bone and caudal to the ischium on the left side of the bird (see Chapter 13).[23] Although it is feasible to take renal biopsies in healthy birds,[23] there is considerable risk of fatal hemorrhage from this procedure, and it should always be performed with the appropriate equipment and ample experience.

In visceral gout, urate deposits can be seen on visceral organs, especially the pericardium and cranial border of the liver capsule (Color 21.7). A ventral midline approach just caudal to the sternum is preferred to endoscopically evaluate these structures.[23]

Diseases of the Kidney[2,7,13,14,35,37,40]

Infectious Diseases

Bacterial Infections

Bacterial infections of the kidney often occur secondary to septicemia but may also result from bacteria that ascend from the cloaca. *Staphylococcus*, *Streptococcus*, *Listeria*, *Escherichia coli*, *Klebsiella*, *Salmonella*, *Yersinia*, *Proteus*, *Citrobacter*, *Edwardsiella*, *Enterobacter*, *Morganella*, *Providencia*, *Serratia*, *Pasteurella* and *Mycobacterium* spp. have all been associated with nephritis. Diagnostically, WBC evaluation, total protein and protein electrophoresis provide useful information on the systemic inflammatory reaction. Bacterial cultures of blood and urine may reveal the causative organism. Mycobacterial infections often cause monocytosis that can be demonstrated on a peripheral blood smear.

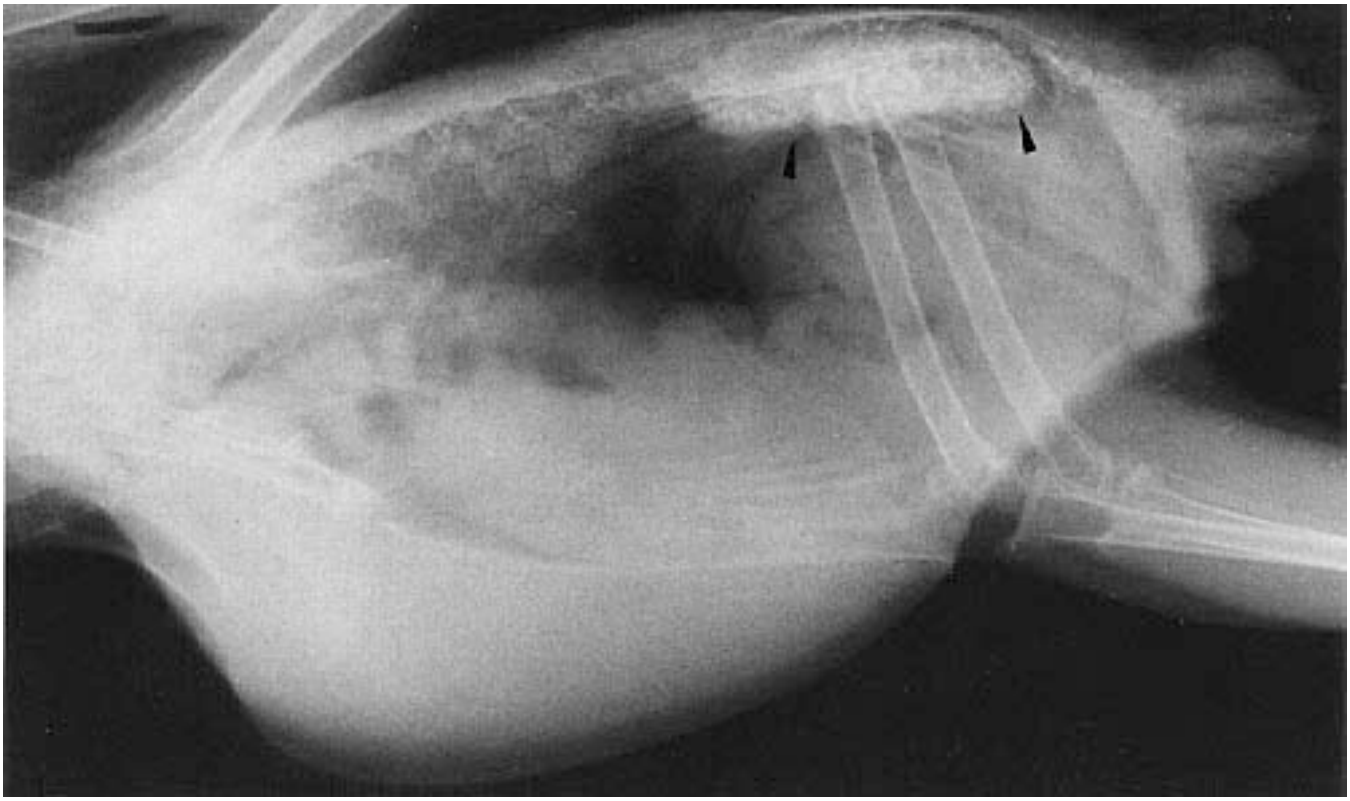

FIG 21.3 An African Grey Parrot of unknown age was presented for a pre-purchase examination two years after being imported into the country. A CBC and avian profile were unremarkable. Radiographs indicated nephrocalcinosis (arrows). This is considered an abnormal finding that occurs frequently in African Grey Parrots. Nephrocalcinosis has been associated with hypervitaminosis D.[37]

Viral Infections

Viral infections are usually multisystemic, although some viruses like avian polyomavirus and infectious bronchitis virus in chickens demonstrate a trophism for the kidney. Other viruses that have been associated with renal lesions include Newcastle disease virus, paramyxovirus of pigeons, reoviruses, viruses belonging to the leukosis/sarcoma group and herpesviruses (eg, Pacheco's disease virus and pigeon herpesvirus).

Mycotic Infections

Renal infarction as a complication of mycelium invasion of blood vessels secondary to pulmonary mycotic disease is common. Abdominal air sac aspergillosis with renal involvement *per continuitatem* has also been reported (Color 21.2). In the latter case, ischiatic nerve involvement resulted in unilateral paralysis.

Parasitic Infections

Granulomatous nephritis due to *Isospora*, *Cryptosporidium*, *Microsporidium* and *Encephalitozoon* spp. has been reported in a variety of avian species. *Eimeria truncata* is a well known cause of renal coccidiosis in geese. Adult trematodes of *Tanaisia bragai* can be found in collecting ducts of chickens, turkeys and pigeons.

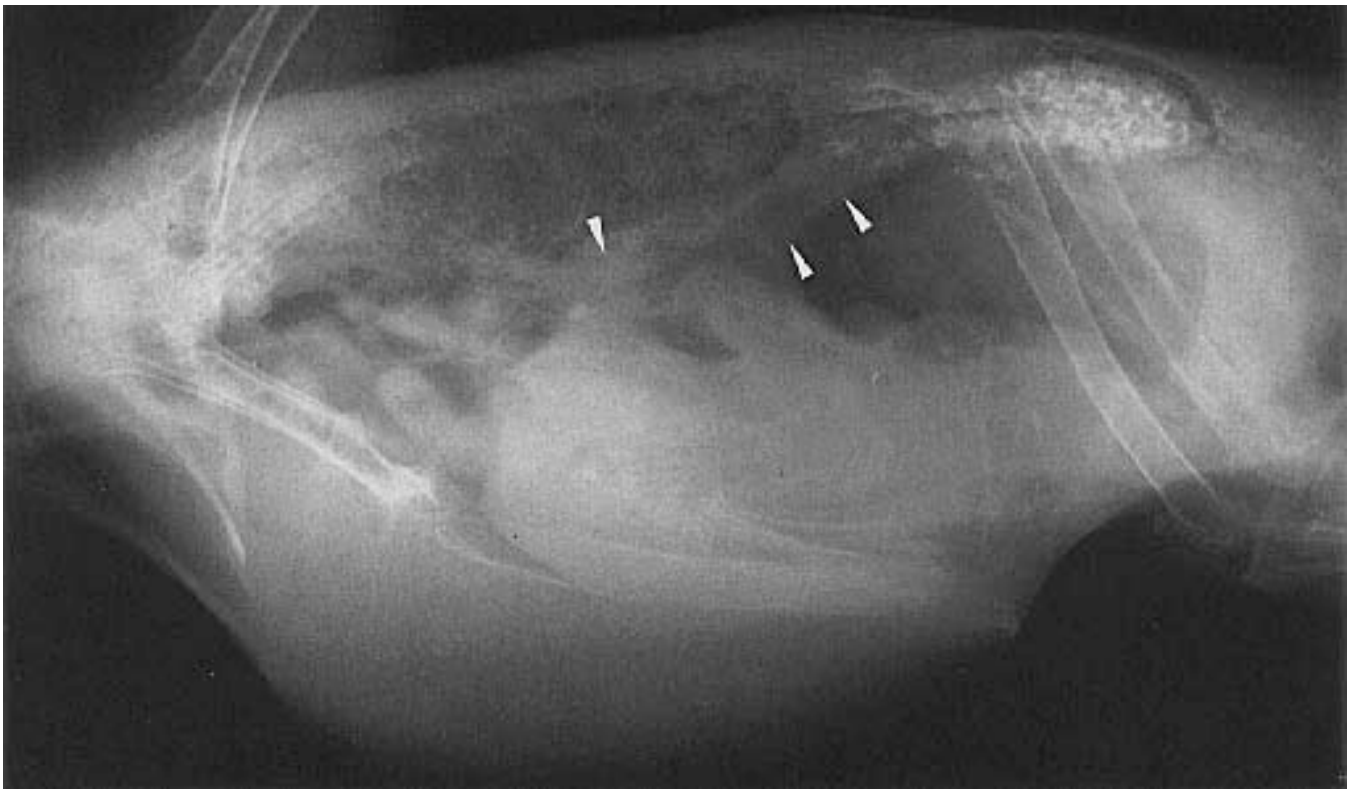
Noninfectious Diseases

Congenital Defects

Agenesis and hypoplasia of part of the kidneys have been described in birds. Compensatory hypertrophy of the intact poles is common (Figure 21.4). Renal cysts have also been described and may be congenital in origin (Color 21.11). Diagnosis can be made with urography and laparoscopy.

Metabolic Disorders

Hypervitaminosis D and elevated dietary calcium can both cause hypercalcemia and lead to deposition of calcium salts in the renal parenchyma (nephrocalcinosis). Calcinosis of other organs may also be noted. This condition can be detected radiographically, and the history may indicate oversupplementation of calcium or vitamin D in the diet. Nephrocalcinosis should not be confused with urolithiasis. The latter



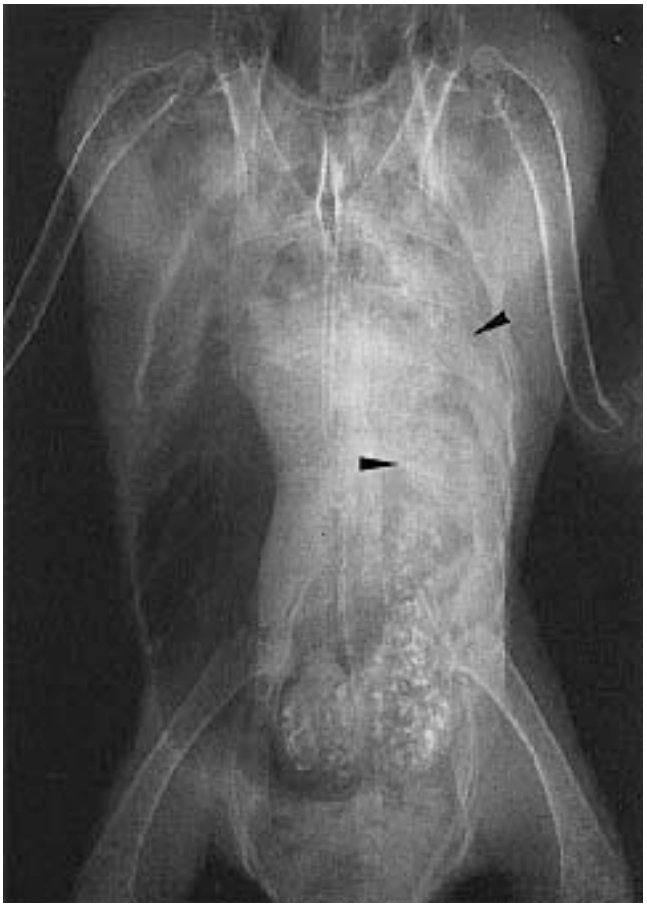


FIG 21.4 An African Grey Parrot with agenesis of the cranial and middle divisions of the right kidney. Visualization of the kidneys is enhanced by the presence of calcium phosphate crystals. Pneumonia and consolidation of the left air sacs (arrows) are also present (courtesy of Marjorie McMillan).

condition is the most prevalent renal disorder of laying hens. Suggested causes include excess dietary calcium, low phosphorous and infectious bronchitis virus. Unilateral or bilateral ureteral concrements of calcium urate can lead to postrenal renal failure. A diagnosis may be possible with cloacal palpation, radiography, excretory urography and endoscopy.

Hypovitaminosis A can cause metaplasia of the epithelium of the ureters and collecting ducts and decreased secretions of mucus in these structures. This may lead to precipitation of urates and ureteral impaction.

Amyloidosis

Renal amyloidosis often occurs in Anseriformes in conjunction with amyloidosis of other organs (eg, liver) secondary to chronic inflammation. There is a deposition of amyloid A, a degraded fragment of an acute phase reactant. In ducks, renal amyloidosis can lead to massive proteinuria and nephrotic syndrome due to severe glomerular damage. Clinically, this may be recognized as ascites, or edema of the feet and legs.

Toxic Nephropathies

Many nephrotoxins cause renal tubular necrosis including aminoglycosides, heavy metals, and mycotoxins such as aflatoxin (*A. flavus* and *A. parasiticus*), ochratoxin (*A. ochraceus* and *Penicillium viridicatum*), oosporein (*Chaetomium trilaterale*) and citrinin (*P. citrinum*).

Salt (NaCl) poisoning has been documented in various species. Salt poisoning via drinking water can lead to right ventricular failure and ascites. Salt poisoning via food leads to acute renal failure with urate impaction of the ureters. Clinical signs include polydipsia and polyuria, or anuria if urate impaction of the ureters occurs. The principal toxic effect is an imbalance in sodium and potassium homeostasis. Right ventricular failure should be suspected with ascites and can be diagnosed by ECG (see Chapters 27 and 37).

Neoplasia

Budgerigars have a high incidence of primary renal tumors, especially adenocarcinoma and nephroblastoma (younger birds) (Color 21.11). A viral origin has been suggested.[35] The kidney is a potential metastatic site for tumors of nonrenal origin, especially lymphoproliferative diseases (leukosis). Unilateral or bilateral paralysis caused by compression of the ischiatic nerve is a common clinical sign associated with renal malignancies in birds (Color 21.4). Abdominal enlargement is common when a renal mass causes caudoventral displacement of the ventriculus or ascites. A renal tumor may be radiographically detectable with or without the use of barium sul-phate to differentiate the margins of the gastrointestinal tract.

Ureteral Obstruction

Displacement or obstruction of ureteral orifices can occur due to intestinal or cloacal prolapse or cloacal obstruction caused by fecaliths, uroliths, foreign bodies, tumors or inflammatory processes. A bilateral obstruction will rapidly lead to visceral gout. Unilateral obstructions will lead to atrophy and compensatory hypertrophy of the contralateral kidney.

Renal Hemorrhage

Renal hemorrhage can be caused iatrogenically during endoscopy if improper technique is used. Sporadic renal hemorrhage in male turkeys and Psittaciformes has been documented with extravasated blood remaining confined under the renal capsule or retroperitoneally (Color 21.5). It can also occur as a complication of renal pathology (eg, tumor). Peracute mortality is common.

Therapeutic Considerations

Prerenal Renal Failure

Treatment of prerenal renal failure caused by dehydration or shock is usually successful; however, the challenge is diagnosing and treating the initial cause of dehydration. Rapidly expanding the circulatory volume with intravenous fluids will usually restore normal renal function within hours (see Chapter 15).

Postrenal Renal Failure

The treatment of postrenal renal failure caused by urolithiasis requires removal of the uroliths. This is a substantial surgical challenge. Successful extracorporeal shock wave lithotripsy for removal of uric acid concrements in the urinary tract has been reported in a Magellanic Penguin and may be attempted in other affected birds.[27]

Acute Renal Failure

Once a diagnosis of acute (reversible) renal failure is made, immediate and aggressive therapy is indicated to prevent further damage. Suggested therapy for managing uric acid nephropathy in mammals provides some insight into the treatment of birds with a similar condition but different etiology. Acute oliguric renal failure associated with hyperuricemia and marked hyperuricaciduria in man occurs sporadically due to the precipitation of uric acid crystals in the distal parts of the renal tubules, the collecting ducts, the renal pelvis or the ureters.

This condition most frequently occurs secondary to the administration of cytotoxic drugs or irradiation, whereby the dissolution of a neoplastic mass liberates a heavy load of nucleic acid that must be catabolized and excreted by the kidneys. The uric acid excretion rises suddenly, uric acid precipitates in renal tubules and acute oliguric renal failure ensues. Contributing factors include excretion of an acid urine secondary to metabolic acidosis, dehydration and the use of uricosuric drugs (adrenocorticosteroids). Plasma uric acid concentrations may be as high as 4770 μmol/l (80 mg/dl). Treatment includes maintaining a high alkaline urine flow by infusing mannitol 20% (1000 mg/kg) every 15-20 min and sodium bicarbonate supplemented with intravenous fu-

rosemide. The prognosis for recovery of renal function is good if diuresis can be achieved.[46]

Successful treatment of a Red-tailed Hawk with acute obstructive nephropathy that was induced by administration of allopurinol has been reported.[24] The bird showed signs of depression 18 hours after the third dose of allopurinol was given. Plasma chemistry revealed hyperuricemia (uric acid 5,721.6 μmol/l). A diagnosis of renal tubular nephrosis caused by oxypurinol, xanthine or uric acid deposits in the tubuli was made. Intravenous and subcutaneous saline, corticosteroids and furosemide (1 mg/kg) were administered twice daily in an attempt to restore renal function. Urine production was restored and, after 24 hours, plasma uric acid concentration had decreased to 3,814 μmol/l. Fluid therapy, corticosteroids and diuretics were continued. Plasma uric acid had decreased to 1,639 μmol/l 72 hours later. The bird fully recovered after two weeks of intensive treatment with intravenous fluids and supportive alimentation. Although corticosteroids were used in this case, these drugs have been shown to be uricosuric in man and should be considered contraindicated in most cases of renal failure.

In anuric/oliguric renal failure, fluid intake in the patient should be restricted to fluid loss (renal loss, loss from the gastrointestinal tract and insensible loss of about 20 ml/kg/day). Assessment of fluid requirements can be based on this general outline but must be monitored by daily weight determination and observation for clinical signs that would indicate overhydration or dehydration. In patients that are anorectic and not receiving assisted feedings, some allowance should be made to account for tissue catabolism. Losses of 2.5% body weight per day are possible in totally anorectic parrots. Sodium, potassium and protein intake should be discontinued and calories should be given in the form of fat and carbohydrates. Alternatively, a low-protein diet containing all essential amino acids can be given. Furosemide should be used in an attempt to restore or increase urine flow and potassium excretion.

In the polyuric phase that follows the anuric phase, fluid and electrolyte balance should be carefully monitored to prevent dehydration, hyponatremia and hypokalemia. Intravenous and subcutaneous infusions with lactated Ringer's solution should be continued on a daily basis. Because bacteria are often incriminated as the cause of renal failure, use of non-nephrotoxic bactericidal antibiotics that are effective against the most commonly encountered bacteria are indicated. A combination of piperacillin and claforan has been suggested, although these drugs have a similar mode of action.[39] Vitamin A supplementation is always indicated in hyperuricemia, because hypovitaminosis A is a common cause of renal failure.

Effects of Drugs

Allopurinol

A recent study[24] has demonstrated that oral administration of allopurinol does not prevent the occurrence of physiologic postprandial hyperuricemia in Red-tailed Hawks. Contrary to expected findings, administration of allopurinol caused a severe hyperuricemia and induced gout in three out of six, clinically normal Red-tailed Hawks. This drug is known to reduce plasma uric acid concentration in man with hyperuricemia. The results of this study seem to indicate that allopurinol is contraindicated for the treatment of hyperuricemia in Red-tailed Hawks. Previous reports discussing effective therapy in parrots with allopurinol may have been coincidental[36] and related to physiologic variations in plasma UA concentrations in relation to food intake. Further work is needed in carnivorous and granivorous birds to establish fasting and postprandial reference intervals of plasma UA concentrations and the possible effects of allopurinol in birds. Recommendations for therapy based on single observations in individual birds must be cautiously applied to the management of any avian disease (including gout) until research can determine that a therapy is safe.

The extreme renal tubular nephrosis observed following allopurinol administration in Red-tailed Hawks[24] might be explained by the formation of oxypurinol, the relatively insoluble and nephrotoxic endproduct of allopurinol. Alternatively, renal damage might have been caused by the deposition of xanthine crystals. Xanthine and hypoxanthine are precursors of uric acid, and concentrations of these substances increase when the xanthine oxidase inhibitor, allopurinol, is administered. High-pressure liquid chromatography is necessary to determine which metabolic product is being deposited in the tubules. Histologic techniques are not sufficient to determine the character of the deposits in the tubules, because they are generally washed away during preparation of the tissues for sectioning.

Corticosteroids

Corticosteroids are known to be uricosuric in man[46] and may be contraindicated in avian hyperuricemic

conditions. Prednisolone has been used in budgerigars with renal tumors. The author states that although she does not know whether the prednisolone prolongs life, it may improve the quality of life by diminishing the pressure on the ischiatic nerve and stimulating appetite.[2]

CHAPTER

22

PNEUMONOLOGY

Thomas N. Tully, Jr.
Greg J. Harrison

Companion bird clients frequently seek veterinary care when abnormal respiratory signs are noted in their pets.[1] The rapid progression of many avian respiratory diseases makes early recognition by the client and rapid diagnosis and effective treatment by the practitioner critical. Conversely, chronic rhinitis and air sacculitis can fulminate for many years with subtle clinical changes. The difficulty in distinguishing between clinical signs originating from the upper versus the lower respiratory system makes the diagnosis and treatment of these problems challenging.[52] Successful respiratory therapy depends on rapid diagnosis.[36] The primary cause of a respiratory disease may be complicated by a more severe opportunistic infection that takes advantage of damaged respiratory epithelium. Diagnosis and treatment of avian respiratory disease depend on an understanding of the unique anatomy and physiology of the avian respiratory system and the effect these adaptations have on the clinical signs and the progression of disease. Respiratory health is best maintained by frequent exposure to fresh air and sunlight, a proper plane of nutrition and flighted exercise.

During the initial physical examination, the avian patient should be observed from a distance to evaluate subtle changes in posture, wing position, respiratory rate and respiratory pattern that may indicate an abnormality. A bird uses its intercostal musculature to expand and depress its chest, creating a "bellows" action that moves air into and out of the respiratory system. Any compromise in inspiratory or expiratory effort can affect the bird's posture.[24,35,59,64] Normal respiratory effort in the bird should not be noticeable, and the mouth should remain closed. An increase in abdominal effort or head movement may be recognized in association with increased respiration following exercise, but should return to normal within minutes of ceasing exertional activity. See Chapter 8 for normal avian respiratory rates.

Mild upper respiratory or lung-induced dyspnea is frequently accompanied by open-mouthed breathing with a dilated glottis. Lung and lower respiratory tract problems are usually associated with a rhythmic jerking of the tail (tail-bob). A bird in severe respiratory distress may also move its head forward in an effort to increase air intake. If the respiratory problem is associated with excessive fluid production, bubbling and gurgling sounds are common on both inspiration and expiration (Table 22.1).

Overt signs of respiratory disease are easy to identify and include oculonasal discharge, stained or matted feathers around the nares, sneezing, coughing, dyspnea or audible inspirations or expirations (Figure 22.1). Changes in pitch or vocalization of the patient may indicate problems in the glottis, trachea or syrinx.[24] Shallow, labored breathing in a bird with a weak, altered or absent voice is common with acute zinc toxicosis. Many psittacine birds may mimic the sneeze or cough of household members, which should not be misinterpreted as a sign of respiratory disease.

Dyspnea may be caused by chronic lung or air sac consolidation or by an acute reduction in the amount of air being delivered to the lungs. When dyspnea is induced by protracted respiratory disease, it is usually associated with other clinical signs including weight loss, depression, ocular or nasal discharge, sneezing or wheezing. Acute dyspnea in an apparently healthy bird usually results from exposure to aerosolized toxins, dislocation and movement of plaques in the trachea (from malnutrition or infectious agents) or aspiration of foreign bodies (particularly seed husks or cage litter material). Dyspnea may also be caused by rhinoliths, air sac granulomas, tracheal parasites (particularly in canaries, gallinaceous birds, finches), obesity (loss of air sac volume) or thyroid enlargement secondary to an iodine-deficient diet (Table 22.2).

The Respiratory Tract

Clinically important components of the avian respiratory system include the external nares, operculum, nasal concha, infraorbital sinus, choanal slit, glottis, trachea, syrinx, bronchi, lungs, parabronchi and air sacs (see Anatomy Overlay).

FIG 22.1 A six-month-old Blue-crowned Conure was presented for suspected sinusitis that was not responsive to antibiotics. The bird had moist, matted feathers and dried debris over most of the head region. The area was thoroughly cleaned and severely matted feathers were removed. The discharge was found to be associated with conjunctivitis and not sinusitis. It was determined that the bird had no nasolacrimal ducts. It also had secondary bacterial and fungal conjunctivitis. The bird was successfully managed by frequently flushing the eyes with sterile saline.

Nares

The first areas to examine for respiratory disease are the nares and surrounding tissues. Unilateral or bilateral diseases of the upper respiratory tract are indicated by matted or mildly stained feathers around the nostrils, occluded nares, nasal discharge or a growth or change in size of the nasal opening. Bacterial, fungal, chlamydial and viral infections, neoplasia and trauma are common etiologic agents of upper respiratory disease.[24,35,59] Chronic inflammation may lead to disfiguring lesions of the nares, beak and cere (Figure 22.2).[36] Severe *Knemidokoptes* spp. infection may cause proliferation of the cere that blocks the external nares and causes respiratory difficulties (see Color 24).[50]

Some Arabian falconers dilate the nares in their birds to facilitate air intake and improve hunting performance. With the efficiency of the air exchange system in birds, it is unlikely that this procedure is of any value.

The operculum can be seen just inside the nostril; this cornified flap of tissue (frequently referred to

FIG 22.2 A mature, male Major Mitchell's Cockatoo was presented for a proliferative mass involving the right nostril and beak. No other abnormalities were noted by physical examination, radiography or clinicopathologic evaluation. The mass was removed and was determined to be a well encapsulated fungal granuloma. The presence of a beak defect from the cere to the tip indicates the chronicity of the problem.

improperly as bone) should not be mistaken for a foreign body. The operculum should be smooth and dry. Cellular debris can accumulate between the operculum and the wall of the nasal cavity, leading to substantial necrosis of the rostral nasal passages and its associated bone (see Chapter 41).

A septum divides the nasal cavity into two halves, each containing a rostral, middle and caudal nasal concha in most avian species. Air that enters the external nares is warmed and moistened by the highly vascular rostral and middle nasal concha (turbinates), which lie rostral, caudal and ventral to the operculum. The caudal nasal concha does not connect directly to the nasal cavity; instead, it opens dorsally into the infraorbital sinus, which is divided into five diverticuli (rostral, periorbital, infraorbital, mandibular and postorbital) that extend into the upper beak, mandible and portions of the pneumatic skull (see Anatomy Overlay). The infraorbital sinus opens caudally into the cranial and cervical portions of the cervicocephalic air sac and dorsally into the middle nasal concha.[44] The fact that the openings from the caudal nasal concha to the infraorbital sinus and from the infraorbital sinus to the middle conchae are both in a dorsal position may contribute to the common accumulation of pus and cellular debris in the infraorbital sinus in birds with upper respiratory tract disease (Colors 22.2, 22.3, 22.5).[44]

In mammals, the sinuses are contained within the bones of the skull. By contrast, avian sinuses are restricted laterally by the skin and subcutaneous tissues of the face. The sinuses have simple mucous glands and are lined by stratified squamous and ciliated columnar epithelium. Hypovitaminosis A commonly causes squamous metaplasia and hyperkeratosis of the sinuses and nasal passages, leading to granuloma formation.

Sinuses

The infraorbital sinus is the only paranasal sinus in birds and is located lateral to the nasal cavity and surrounding the eyes ventrally.[72] In some birds (insectivorous Passeriformes, Anseriformes and Psittaciformes), the right and left infraorbital sinuses communicate, while in other species (non-insectivorous Passeriformes), the right and left infraorbital sinuses are independent.

The interconnection of the nasal cavity, infraorbital sinuses and the porous calvaria creates a situation in which inflammatory reactions in the sinus or nasal passages can involve most of the anatomic structures of the head. The numerous pockets and extensions of the nasal system make sinus infections difficult to treat. With severe chronic sinusitis, the accumulation of caseous necrotic debris can cause destruction of the nares, nasal cavity, operculum and nasal conchae. This degree of destruction is particularly common in Amazon parrots and African Grey Parrots with aspergillosis sinusitis. Inflammation or accumulation of debris in the infraorbital sinus can lead to periorbital swellings (Color 22.2).

The tube-like nasal cavity turns ventrally at the sinuses, and the air exits the two choanae (internal

TABLE 22.1 Clinical Considerations of Respiratory Disease

UPPER RESPIRATORY DISEASE

Clinical Signs
- Open-mouthed breathing
- Change in voice
- Sneezing
- Sinus swelling
- Rhinorrhea
- Nasal granulomas
- Exercise intolerance
- Dyspnea
- Head-shaking
- Mucopurulent nasal discharge
- Inflamed swollen cere
- Stretching the neck
- Yawning
- Epiphora
- Periophthalmic swellings
- Plugged nares

Diagnostic Protocol
- Thorough review of nutritional status
- Thorough history (exposure to smoke, PTFE)
- Gram's stain of feces; direct fecal smear for parasites; special pathology stains
- Sinus flush
- Cytology of affected area (sinus aspirate, flush, scraping for parasites); Gram's stain
- Radiographs (whole body, sinus views)
- Rhinoscopy (foreign body examination)
- Culture and sensitivity
- Special bacterial and viral diagnostic testing (also for chlamydia, mollicutes)
- Biopsy of lesion
- CBC, biochemistry panels

Normal Flora
- Gram-positive bacteria (eg, *Lactobacillus* spp., *Streptococcus* spp. and *Micrococcus* spp.)
- Small numbers of gram-negative organisms (eg, *E. coli, Bordetella*)
- Occasional non-budding yeast

Abnormal Flora
- Large numbers of gram-negative bacteria (over 5%)
- 10 budding yeast per oil immersion field examined

LOWER RESPIRATORY DISEASE

Clinical Signs
- Tail-bobbing
- Loss of voice
- Change in vocalization
- Labored respiration
- Exercise intolerance
- Coughing
- Sounds on auscultation

Diagnostic Protocol
- Radiographs of lungs, air sacs
- Transtracheal lavage (cytology of sample)
- Laparoscopy; tracheoscopy
- Biopsy of lungs, air sacs
- Suction and cytology
- Culture of trachea, lungs and air sacs
- Surgical intervention (air sac granuloma; tumor; tracheal foreign body)
- Compression reduction of air sacs

Fluid Obtained by Tracheal and Air Sac Lavage
- Normal
  Low cellularity and very few pulmonary macrophages or inflammatory cells
- Abnormal
  Large numbers of heterophils, pulmonary macrophages and other inflammatory cells, bacteria or yeast

nares) at the level of the palate. The middle choanae are just cranial and dorsal to the choanal slit, which courses longitudinally in the dorsal oral cavity or roof of the mouth. The choanae are separated into right and left openings by the nasal septum or vomer bone. The paired entrances of the nasal cavity can be viewed with a rigid or flexible endoscope by directing it through the rostral end of the choanal slit (see Color 13). The choanal slit represents the incomplete fusion of the two bony plates of the hard palate (see Color 8). Birds do not have a soft palate. Instead, air moves from the nasal cavity through the choana via the choanal slit (oropharynx) and then into the rima glottis of the trachea. The configuration of the choanal slit varies with the species, but in all cases the slit should be slightly moist. On the ventral surface of the palate and along the choana are numerous caudally directed choanal papillae, which are most pronounced in gallinaceous species but are also found in most birds (see Color 13).

Swollen, inflamed choanal tissues, with a sloughing of the protruding papillae, are common with upper respiratory tract infections (particularly chlamydiosis),[30] and secondarily infected with candidiasis in immunosuppressed states following prolonged illness, malnutrition or improper antibiotic administration. The presence or absence of papillae is not a diagnostic indicator of current respiratory disease, as they seldom regrow after sloughing. Laryngeal le-

TABLE 22.2 Clinical Presentations of Avian Respiratory Disease with Associated Differential Diagnoses

Clinical Presentation	Differential Diagnosis
Sunken eye	Chronic bacterial sinusitis
Enlarged cere	Chronic rhinitis; foreign body; trauma; allergy; airborne irritants (eg, cigarette smoke); malnutrition (chronic); avian poxvirus; knemidokoptes mites; normal female budgerigar
Enlarged cere with or without granuloma formation	Bacterial, mycotic, mycoplasmal, chlamydial; nutritional rhinitis
Rhinorrhea or sneezing	Bacterial infection; mycotic infection; foreign body; toxic insult (smoke); allergy; virus; malnutrition;; chlamydia
Serous sinusitis	Chlamydia or mycoplasma infection; nutritional rhinitis; foreign body; papillomatosis; occluded choana (atresia); uncomplicated viral infections
Mucopurulent sinusitis	Bacterial infection with predominantly gram-negative organisms; mycotic infection (often secondary to serous sinusitis)
Irritated swollen cere with sloughed papillae	Chronic mycotic, bacterial or viral sinusitis; chronic exposure to airborne irritants; chlamydiosis; malnutrition; hypovitaminosis A
Coughing (chronic)	Bacterial, viral, fungal, chlamydial, parasitic, yeast, mycobacterial; ascites; abscess or granuloma; malnutrition; air sac mites; mimicry of humans; airborne toxins (eg, cigarette smoke)
Coughing (acute)	Foreign body inhalation; trauma; upper respiratory infection; abscess or neoplasia in lungs or body cavity; air sac mites; infectious tracheitis; avian viral serositis; mimicry of humans; bleeding into body cavity;sarcocystosis; syringeal granuloma; airborne toxins - PTFE gas
Dyspnea (acute)	Aspergillosis syringeal granuloma; infectious disease; foreign body inhalation; internal bleeding; allergy; toxin inhalation; plugged nares; avian viral serositis; sarcocystosis; anemia
Dyspnea (chronic)	Infectious disease; liver disease; kidney disease; ascites; heart disease; neoplasia; airsacculitis; malnutrition; sarcocystosis (lung edema); proliferative tracheitis; Pacheco's disease virus; pericardial effusion; egg-related peritonitis (binding); hemochromatosis; anemia; obesity; thyroid enlargement, tumors, goiter
Subcutaneous swelling	Overinflation of cervicocephalic air sac; trauma (bite wound); normal (pelicans)
Neonatal sneezing, coughing, dyspnea	Inhalation pneumonia; respiratory foreign body; infections (eg, chlamydia); avian viral serositis; mycotic infection

sions may occur from viral infections (poxvirus, herpesvirus), hyperkeratosis secondary to hypovitaminosis A, candidiasis, trichomoniasis, papillomatosis and neoplasia (Figure 22.3).[24,25,35,36,57,61] Seeds may also become lodged in the choanal slit and cause respiratory signs or constant movement of the tongue in an effort to dislodge the seed.

Trachea

The opening of the larynx, or rima glottis, is not covered by an epiglottis as it is in mammals. The laryngeal cartilages are reduced or absent. The largest laryngeal cartilages are the coracoid cartilages.[3] The larynx does not function for sound production in birds. When a bird breathes, the mouth is closed and the mobile glottis seals with the choanal slit, allowing air to pass into the trachea from the nares (see Anatomy Overlay). There are no vocal cords in the larynx.

The trachea is loosely found on the right side of the neck, ventral to the esophagus. The trachea courses under the crop at the thoracic inlet and terminates into the syrinx. It is the syrinx that serves as the vocal organ (see Anatomy Overlay). The trachea of birds differs from mammals in that it is longer and has a larger diameter — two anatomic considerations for anesthesia. The trachea consists of complete cartilaginous rings in most avian species. These cartilaginous rings may calcify as the bird grows older.[7] The length, configuration and anatomic position of the trachea vary widely among genera. Some birds, like the Whooping Crane, have a trachea that extends to the cloaca, where it doubles back and returns to the thoracic inlet before connecting to the syrinx. Other species (Helmeted Curassow) have a similar configuration, but the trachea courses subcutaneously outside the confines of the sternum.

At the distal end of the trachea is the syrinx, which can be classified as tracheal, tracheobronchial or bronchial depending on the location of fusion of the cartilages.[51] Most psittacine birds have a tracheobronchial-type syrinx in which the last of the tracheal rings fuse into a syringeal box, which joins to the first of the bronchial rings. The shape of the syrinx and the sound it emits are controlled by the bronchial muscles that attach to the syrinx, the first bronchial rings and the bronchotracheal muscles, which extend from the bronchus to the trachea. Sounds are believed to be produced in the syrinx by

FIG 22.3 Proliferative lesions of the pharyngeal or oral mucosa (arrows) may be caused by some viruses, hypovitaminosis A, *Trichomonas* spp. or *Candida* spp. (this case). Cytology is a useful technique to establish a clinical diagnosis (courtesy of Louise Bauck).

the turbulent flow of expelled air that is forced through syringeal membranes, which form slots.[44] The pitch of the sound is also controlled by the length of the trachea and whether the air sacs are inflated or flattened. A long trachea and inflated air sacs produce a loud, booming, low-frequency sound.

Pathology involving the syrinx is best diagnosed and treated when signs of disease are first recognized. If a bird stops talking or has a voice change it should be evaluated immediately for lesions developing in the perisyringeal area (frequently aspergillosis). Progressive changes recognized clinically as dyspnea, coughing or tracheal discharge are more difficult to successfully resolve (Figure 22.4). The trachea and primary bronchi contain goblet cells and are lined with pseudostratified, ciliated, columnar epithelium. The syringeal mucosa contains bistratified squamous or columnar epithelium that is subject to squamous metaplasia and granuloma formation.[4]

Lungs

The lungs of birds are much different than those of mammals, both morphologically and physiologically (Table 22.3). The paired lungs lie dorsally in the thoracic cavity, extending from the first through the seventh ribs in Psittaciformes; however, the boundaries of the lungs vary, and they may extend to the ilia in some species. The lungs are attached dorsally against the thoracic ribs and vertebrae, where they fill the intercostal space throughout their margins (see Color 14). When removed, the coastal surface of the lung will have an impression of the vertebral ribs (costal sulci). The sixth rib creates the most caudal sulci in Psittaciformes (see Anatomy Overlay).

There are frequent and inaccurate suggestions that the avian lung is fixed and not expandable. While changes in the size or position of the avian lung are limited, it is a dynamic organ that does undergo expansion and contraction during the respiratory cycle.[44]

The lungs are connected to the distal trachea (syrinx) by the primary bronchi, which progressively divide into secondary bronchi and tertiary bronchi (parabronchi) (Figure 22.5). Parabronchi connect to the secondary bronchi and other parabronchi, which have shallow depressions (atria) evenly displayed along their walls. Each depression has three to six funnel-shaped ducts (infundibula), which lead to the air capillaries. The air capillaries form an anastomosing three-dimensional network.[44] The air capillaries are intermittently interwoven with the blood

TABLE 22.3 Differences in Avian and Mammalian Respiratory Systems

Bird	Mammal
No diaphragm	Active diaphragm
Air sacs	No air sacs
Communicating air capillaries	Alveoli (blind sacs)
Syrinx	No syrinx
Complete tracheal rings	Open tracheal rings
No thyroid cartilage	Thyroid cartilage
No laryngeal vocal cords	Laryngeal vocal cords
No epiglottis	Epiglottis
Limited lung expansion	Highly expansible lungs

Pneumonology

Color 22.1
Chronic sinusitis may cause the globe of the eye to retract into its socket (sunken sinus syndrome). The problem is usually unilateral but on occasion may occur bilaterally. The pathogenesis of this lesion is unclear. Some cases will resolve when the sinusitis is resolved (courtesy of L. Karpinski).

Color 22.2
An advanced case of mycoplasmosis in a Galliforme associated with symblepharon, infraorbital sinusitis and rhinitis. The avian sinuses are not restricted laterally by bone (as they are in mammals), and sinusitis is frequently associated with facial swelling (courtesy of R. Korbel).

Color 22.3
Inflammatory reactions in the sinuses can involve most of the structures of the head. In this Blue-fronted Amazon Parrot, chronic sinusitis is associated with an infraorbital sinus fistula, nostril damage, a beak deformity, conjunctivitis and keratitis. Because of the complex extensions of the nasal system, treatment for chronic sinusitis usually requires surgical drainage (courtesy of R. Korbel).

Color 22.4
Cockatiels frequently develop an upper respiratory disease characterized by sinusitis, conjunctivitis or both. *Mycoplasma* spp. and *Chlamydia* sp. are frequently implicated in these cases. Conjunctival scrapings collected for cytology and culture are most useful in identifying an etiologic agent. If an infectious agent cannot be determined, these birds frequently respond to long-term treatment with tylosin eye wash and lincomycin/spectinomycin in the drinking water or an ophthalmic solution containing chlortetracycline (conjunctivitis only) or doxycycline (conjunctivitis and sinusitis).

Color 22.5
An adult cockatiel was presented with a two-week history of sneezing, lethargy and a nasal discharge. The bird had been receiving over-the-counter medications in the water for ten days. A severe conjunctivitis and mucopurulent rhinitis were noted on physical examination. Additionally, several periocular masses were evident. Cytology of samples collected from the masses indicated an accumulation of mixed gram-negative bacteria. The bird did not respond to therapy. At necropsy, granulomatous infraorbital sinusitis was evident.

Color 22.6
A gallinaceous bird was presented with a three-day history of progressive lethargy, anorexia and upper respiratory disease. The bird was part of a backyard flock in which intermittent deaths had been occurring in birds with similar clinical signs. This bird did not respond to therapy. Newcastle disease virus was isolated from the bird. A vaccination program was initiated in the flock.

Color 22.7
A herpesvirus that is serologically distinct from Pacheco's disease virus has been isolated from Amazon parrots with proliferative tracheitis. **a)** The diphtheritic membranes in the trachea cause severe dyspnea and death. In this case, the pharyngeal mucosa is covered with necrotic tissue. **b)** Bronchopneumonia and the presence of necrotic casts in the trachea and bronchi are characteristic (courtesy of Helga Gerlach).

Color 22.8
A cockatoo neonate died seconds after being hand-fed. The chick had placed its glottis on the ending of the feeding tube, and food was deposited in the trachea and lungs.

Color 22.9
A five-month-old ostrich had been losing weight for several days. In an attempt to provide supportive care, the client passed a feeding tube and delivered a liquid-based product. The bird began stretching its neck and became frantic. It died several minutes later. The client had passed the tube into the trachea instead of the esophagus, resulting in asphyxiation (courtesy of Brett Hopkins).

Color 22.10
Mycobacterial pneumonia in a Border Canary (courtesy of Louise Bauck).

Color 22.11
A breeding Umbrella Cockatoo was found dead in its nest box. The bird was in excellent overall condition and had blood-tinged fluid in the mouth. The lungs were edematous and hemorrhagic. Sarcocystosis was diagnosed histologically. Inhalation of noxious gases and fumes from non-stick cooking surfaces can cause similar gross lesions in the lung.

Pneumonology

Color 22.12
Normal air sacs should be completely transparent and lack vascularity. Heart (h), liver (l), ventriculus (v), cranial thoracic air sac (cr), caudal thoracic air sac (ca), abdominal air sac (ab) (image is reversed).

Color 22.13
Several white proliferative masses were noted on the cranial thoracic air sac during a routine necropsy of a cockatoo with PBFD. Impression smears stained with new methylene blue revealed branching septate hyphae characteristic of *Aspergillus* spp. These plaques were considered an incidental finding.

Color 22.14
A five-month-old Amazon parrot was presented with a history of progressive dyspnea. The bird had a severe tail-bob, was open-mouthed breathing and was in severe distress. The bird was anesthetized with isoflurane and an air sac tube was placed in the abdominal air sac. Radiographs indicated a soft tissue mass in the right thoracoabdominal cavity. The client chose euthanasia because of the extent of the mass. At necropsy, a large, yellow mass that involved portions of the lung and thoracic air sacs was identified. Histopathology indicated bacterial pneumonia and air sacculitis. Ingesta was also noted, confirming a diagnosis of aspiration pneumonia.

Color 22.15
a) Four white plaques suggestive of aspergillosis in a relatively normal thoracic air sac from an ostrich. **b)** Severe, necrotic fungal air sacculitis in a 22-month-old ostrich. The primary isolate was *Aspergillus* sp., although other unisolated fungi were suspected to be the cause of the black discoloration. This fungal infection was secondary to aspiration of ingesta. Note kernels of corn (courtesy of Brett Hopkins).

Color 22.16
Aspergillosis granulomas in the trachea of a Pintail Duck (courtesy of R.J. Montali).

Color 22.17
Aspergillosis will frequently produce proliferative fluffy lesions in the air sacs. Colonies in the oxygen-rich areas of the lungs and air sacs frequently produce characteristic conidiophores. The aspergillosis lesions in this case were present on the abdominal air sacs of a Buttlehead Duck (courtesy of R.J. Montali).

Color 22.18
Aspergillus spp. pneumonia in a six-month-old emu with progressive dyspnea that was not responsive to antibiotic therapy. Note the multiple white-tan granulomas. The depressions in the lung (costal sulci) represent the areas where the lung folds around the ribs (courtesy of Brett Hopkins).

Color 22.19
Pseudomonas spp. can cause severe respiratory disease in ratites. A two-year-old ostrich hen with a history of respiratory disease had fibrinonecrotic pharyngitis (courtesy of Brett Hopkins).

Color 22.20
a) Severe emphysema and collapse of the secondary bronchi and **b)** hemorrhagic pseudomembranous tracheitis caused by *Pseudomonas* spp. in an ostrich (courtesy of Brett Hopkins).

capillary network to form the exchange tissue of the lung.[44] On the ventral surface of the lung, secondary bronchi connect directly to the caudal thoracic and abdominal air sacs through ostium that can be visualized during endoscopy (see Color 13).

Surfactants in the parabronchi function to keep fluids from entering the air capillary area and prevent transudation. These functions combine to maintain the integrity of the delicate blood gas barriers.[44] Dilation and contraction of the bronchi and ostium are controlled by smooth muscles. The innervation to these muscles is non-vagal and can be relaxed with adrenergic drugs.[44]

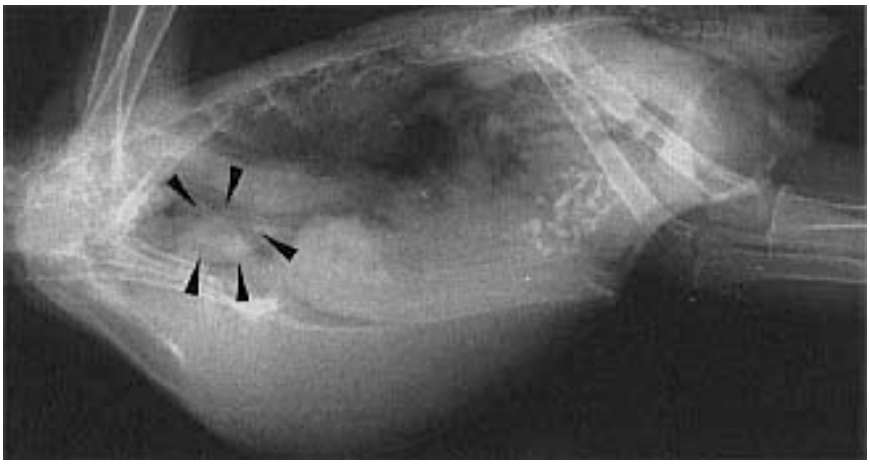

FIG 22.4 An adult African Grey Parrot was presented with acute onset of severe dyspnea accompanied by open-mouthed breathing. Radiographs revealed a soft tissue mass at the level of the syrinx (arrows). The lungs and air sacs were considered radiographically normal. Tracheoscopy was performed with a 2.7 mm endoscope while the animal was maintained on isoflurane anesthesia delivered through an air sac tube. Cultures taken from a syringeal granuloma were positive for *Aspergillus* spp. (courtesy of M. McMillan).

From a functional standpoint, the avian lung is divided into a paleopulmo (which all birds have and which constitutes at least 75% of the lung) and the neopulmo (which some birds have and which makes up no more than 30% of the lung). The neopulmo is absent in penguins, minimally developed in emus, further developed in ducks and psittacine birds and maximally developed in pigeons and gallinaceous and passerine birds. The reasons for this division have not been clearly established, but it has been determined that the neopulmo is less efficient at gas exchange than the paleopulmo.[40] The fact that the neopulmo is less efficient is interesting, considering it is highly developed in one of the fastest flying birds, the pigeon.

Air Sacs

Pulmonary

Most birds have four paired and one unpaired pulmonary air sacs that connect to the lung and create a large respiratory capacity (see Anatomy Overlay). The configuration of the air sacs varies with the species. Most birds, including Psittaciformes, are believed to have four paired air sacs that include the cervical, cranial and caudal thoracic and abdominal air sacs. An unpaired clavicular air sac lies dorsal and caudal to the crop in the thoracic inlet and has both intra- and extrathoracic components. The intrathoracic component surrounds the great vessels, esophagus and syrinx with diverticula into the sternum and sternal ribs. The extrathoracic component represents diverticula into the thoracic girdle (see Anatomy Overlay).

The cranial air sacs are composed of the cervical, clavicular and cranial thoracic air sacs; the caudal air sacs are composed of the caudal thoracic air sac and abdominal air sac. The cranial thoracic air sacs receive air via the medioventral parabronchi and are physiologically components of the paleopulmonic air sac system. The caudal thoracic air sac, on the other hand, gets its air from lateroventral parabronchi and, along with the abdominal air sacs, is part of the neopulmonic air sac system.[44]

Cervicocephalic

The cervicocephalic air sacs are not connected to the lung and are divided into cephalic and cervical portions; they connect to caudal aspects of the infraorbital sinus (see Anatomy Overlay). Extensive cervicocephalic air sac development has been noted in budgerigars, cockatiels, conures, Amazon parrots, macaws and cockatoos. This air sac is absent in diving birds, partially developed in ratites, pigeons and chickens and is well developed in strong-flying avian species. The cervicocephalic air sacs may function as insulating air layers for the retention of heat, to control buoyancy, to reduce the force of impact with the water in fish-eating birds and to support the head during sleep or flight.[44]

In some species, the cephalic portion is large, and in others it is minimally developed. Studies involving budgerigars, conures and cockatiels suggest that the cephalic air sacs arise from the infraorbital sinus and extend dorsally to cap the dorsum of the skull.[72] In the Amazon parrot, the cephalic portion of this air sac

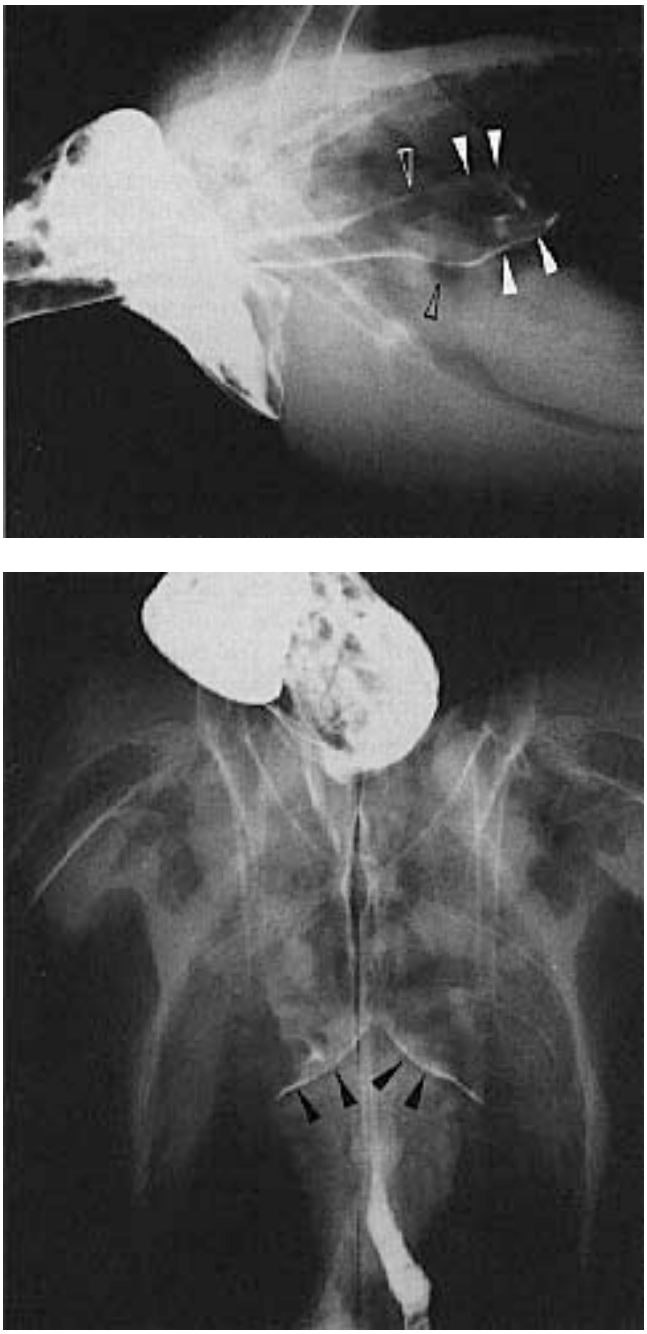

FIG 22.5 The syrinx (open arrow) and primary bronchi (arrows) are clearly visible in this macaw that aspirated barium. The barium could not be detected in the respiratory system on a subsequent radiograph taken 90 minutes later.

extends dorsally adjacent to the occipital bone. The cervical portion extends bilaterally dorsolaterally in the neck from the head to the distal neck (Figure 22.6).[72] The cervical division of the air sac communicates with the cephalic part by a small median pathway. The cervicocephalic air sac covers the lateral aspect of the head and extends caudally over the dorsal cervical region to the shoulder area.

No direct connection has been found between the cervicocephalic air sac system and any of the pulmonary air sacs. All air sacs are thin-walled and lack vascularity. The air sacs of a normal bird are completely transparent (appear similar to clear plastic wrap) (Color 22.12). Any alteration in transparency should be considered abnormal. The presence of blood vessels in the air sacs may be an indication of early inflammation. Blood vessels that transverse inflamed abdominal air sacs must be avoided during surgical procedures.[61] Air sac lesions that are localized and do not alter the flow of air in or out of the air sacs may not cause clinical changes (see Color 13.).

The trachea, primary bronchi and larger secondary bronchi are lined with pseudostratified or simple columnar ciliated epithelium, whereas the air sacs distal to the connection with the lungs are lined with a single layer of simple squamous epithelial cells. The area of the air sacs near the lung may contain simple cuboidal and columnar ciliated epithelium.[44] The poor vascular supply and lack of ciliary transport system within the air sacs hinder parenteral treatment of air sacculitis.[52]

Depending on the species of bird, the humerus, clavicles, coracoids and cervical vertebrae are connected to the respiratory system through extrathoracic diverticula. The sternum and sternal ribs are pneumatized through the intrathoracic diverticula that lie between the coracoid bones. The lungs connect directly to the thoracic vertebrae and their associated ribs. The femur may be pneumatized through a connection with the air sac (see Anatomy Overlay).

Respiratory Physiology

Birds have no functional diaphragm. The thoracic cavity is separated from the abdominal cavity by a thin membrane called the oblique septum. Birds breathe by using the six inspiratory muscles (principally the external intercostales) to pull the ribs cranially, laterally and ventrally and to move the sternum ventrally and cranially, increasing the volume of the thoracoabdominal cavity. These changes in the body wall create a negative pressure with respect to

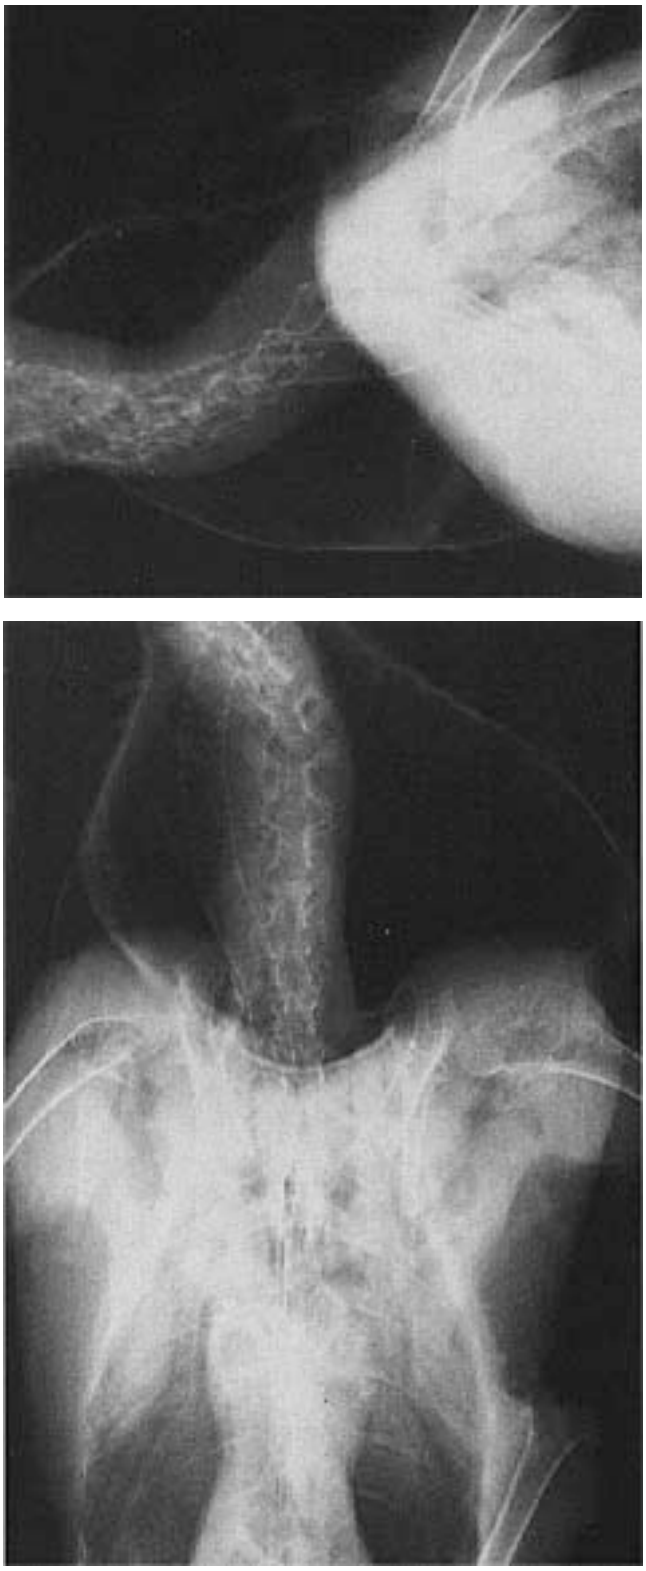

FIG 22.6 A Yellow-naped Amazon Parrot was presented for a persistent swelling in the cervical area. Radiographs indicated gaseous distension of the cervical air sac with no other evidence of respiratory disease. Biopsies and cultures of the air sac were unremarkable. A permanent opening (stent) was created in the air sac to resolve the problem (courtesy of Marjorie McMillan).

the atmospheric air pressure surrounding the bird, causing air to pass through the respiratory system and into the inspiratory portion of the respiratory tract.

The nine expiratory muscles (principally the internal intercostals and abdominals) pull the ribs caudally, raising the sternum and pulling the ribs inward, causing expiration by creating increased internal pressure within the air sacs. This forces air out of the air sacs and back through the parabronchi (caudal air sacs) or trachea (cranial air sacs).[44]

It is frequently discussed that the oxygen (O_2) and carbon dioxide (CO_2) content of air in the caudal air sacs is similar to that in the environment. In reality, the caudal air sacs contain air that is higher in CO_2, possibly because of some dead space gases that remain in the caudal air sac following expiration.[44] The O_2 and CO_2 content of air in the cranial air sacs is similar to that of expired air. The rapid influx of inspired air into the caudal air sacs and the similarity of this air to environmental air have been used to explain the apparent prevalence of air sac infections and pathology in the caudal air sacs versus the cranial air sacs; however, it should be noted that half the inspired air enters the lungs. The prevalence of caudal air sacculitis may be a reflection of the air layering that occurs in this location.

In pigeons, barely detectable tail movements have been shown to be associated with inspiration (minimally) and expiration. The M. caudofemoralis, M. pubocaudalis internus and M. pubocaudalis were found to be involved with expiration by depressing the pelvis and uropygium and compressing the thoracoabdominal cavity. The M. longissimus dorsi was found to be involved in inspiration.[6] These findings would suggest that tail-bobbing is an exaggerated movement of a normal component of inspiration and expiration and is a reflection of an increased amount of work necessary to ventilate the lungs. The tail muscles seem to be most involved in respiration when a bird is resting on its keel, or the sternum is fixed in position.

If a bird is unable to move its ribs, it will rapidly suffocate. This can occur with an overly aggressive restraint or by the surgeon resting his hands on the body cavity during surgery. Bandages that encompass the body cavity can also interfere with breathing, particularly if they are wrapped tightly around the caudal portion of the sternum or ribs.

It is frequently discussed in veterinary literature that inspired air flows through the parabronchi or primary bronchus and directly into the caudal air sacs, thus bypassing the gas exchange portion of the lungs. This statement is not completely accurate. On inspiration, one-half of the inspired air volume goes to the lung and the other half goes to the caudal air sacs. The air that is already in the lungs enters the cranial air sacs. On expiration, the ambient air that is in the caudal air sacs enters the lungs. Although not clearly stated in any physiology reference, the air that is in the lungs must exit through the trachea along with the air that is in the cranial air sac. For this system to function, the volume of the caudal air sacs, the lungs and the cranial air sacs must be equal (each contains one-half of a total volume of inspired air at any one time) (Figure 22.7).

Two respiratory cycles are necessary for the one-half volume of air that enters the air sacs to move totally through the avian respiratory tract. Superficially, this would appear to be relatively inefficient, but in reality, it is much more efficient than the mammalian system. In birds, fresh air (fresh air delivered directly to the lungs on inspiration or fresh air delivered directly to the lungs on expiration from the caudal air sacs) enters the lungs on both inspiration and expiration.[44]

Some studies suggest that birds have a fluid valving system that controls the unidirectional air flow through the lungs and air sacs.[45] Other authors suggest that pressure differentials between the cranial and caudal air sac systems control the movement of air through the respiratory tract.[44]

Gas Exchange

The air capillaries are present in all birds. In some species, the parabronchi are divided into two systems. In these birds, the paleopulmonic parabronchi are the major sites of gas exchange, and air flows unidirectionally through these passages on inspiration and expiration. In the neoplumonic parabronchi, air passes bidirectionally through both phases of the respiratory cycle. Gas exchange occurs in the air capillaries. These air tubes branch and anastomose with each other, creating an extensive network. They are richly entwined with blood vessels, which form a blood gas barrier.[60] The pulmonary artery transports the less oxygenated blood into the interperibronchial arteries of the lungs. The interperibronchial arteries are located in the area of gas exchange and are arranged so that blood flows perpendicular to the air capillaries.

TABLE 22.4 Influences on Respiratory Rate

Increase Respiration	Decrease Respiration
Restraint	Anesthesia
Hyperthermia	Hypothermia
Low CO_2 levels in inspired air	Inhalation of toxic fumes
Increased respiratory dead space	High CO_2 levels in inspired air
Obesity	Severing of vagus nerve(s)
Pain	Air sac oxygen administration
Exercise	Sleep

This barrier has the same three components as in mammals; however, it is anatomically not as thick as in mammals due to the reduced width of the epithelial cells and decreased tube size, which is much smaller that the mammalian alveolus. The efficiency of gas exchange is thus greater. However, with infection and its associated inflammation, a greater ventilation perfusion mismatch can occur.

In the paleopulmonic system, a current of parallel tubes of air moves in one direction counter to pulmonic vessels, allowing gas exchange to occur with greater efficiency than in the neopulmonic system or in the alveolus of mammals. In the latter case, air moves in both directions in the parabronchi, mixing oxygenated air with air having a higher partial pressure of carbon dioxide. These physiologic and anatomic components account for a 20% increase in the diffusion capacity for oxygen in birds when compared to mammals.[44]

The respiratory cycle is controlled principally by sensitive CO_2 pulmonary receptors. Interestingly, these receptors have been shown to be inhibited by halothane.[44] Other receptors that are integrally involved in controlling respiration include dermal pain receptors, thermoreceptors (control panting), chemoreceptors, baroreceptors in the aorta and mechanicoreceptors in the respiratory tract (see Chapter 39).[44]
