CHAPTER

38

MYCOPLASMA AND RICKETTSIA

Helga Gerlach

The mycoplasmatales constitutes one order within the class Mollicutes that replicates mainly by binary fission. Strains that produce mycelia-like forms may propagate by dissociation of these "mycelia." Morphologically, colonies and single organisms can exist in multiple forms (coccoid, rods, ring-forms), depending on the physical properties of the media in which they are growing. In most cases, morphology is unsuitable for species differentiation. In contrast to bacteria, mycoplasmatales have no cell wall and are bound by a three-layer membrane. Thus, they are resistant to antibiotics that inhibit cell wall development (eg, penicillins, cephalosporins, bacitracin) and sulfonamides. Mycoplasmatales are fastidious and must obtain most of the nutrient requirements from the growth media because of their relatively small genome. They grow on agar media in small, fried egg-shaped colonies, which in many instances, can be recognized only under the microscope. Generally, specialized laboratories are necessary for isolation and identification. The lack of a cell wall makes the organism sensitive to inactivation outside the host (it survives only hours on dry surfaces, two to four days in water); therefore, transport media are necessary for shipping infected tissues intended for isolation attempts. Mycoplasmatales that are free in the environment are susceptible to all commonly used disinfectants. Organisms within host excretions are protected from contact with the disinfectant. Secretions and excretions must be removed before disinfecting procedures are effective.

The mycoplasmatales consist of three genera, which can be distinguished roughly by the following properties:

Mycoplasma need cholesterol for growth (production of the cellular membrane).

Acholeplasma do not need cholesterol for growth, but many strains can be inhibited by the thallium acetate that is commonly used for inhibiting gram-negative bacteria in media used for the isolation of mycoplasma.

Ureaplasma were formerly called T-strains because of their tiny colony sizes. They require urea for their energy metabolism and also cholesterol for growth.

Many isolates from companion and aviary birds have not yet been fully identified and have no valid name. In addition, the pathogenicity and epizootiology of these strains have not been defined to date.

Mycoplasmatales are distributed worldwide in connection with the poultry industry. There is little information on the prevalence of mycoplasmatales in captive or free-ranging Psittaciformes or other groups of birds. Isolations have been rare, and the importance of the majority of the strains is unknown. With intensified aviculture, increased farm sizes and population densities on these farms, more problems with mycoplasmatales can be expected.

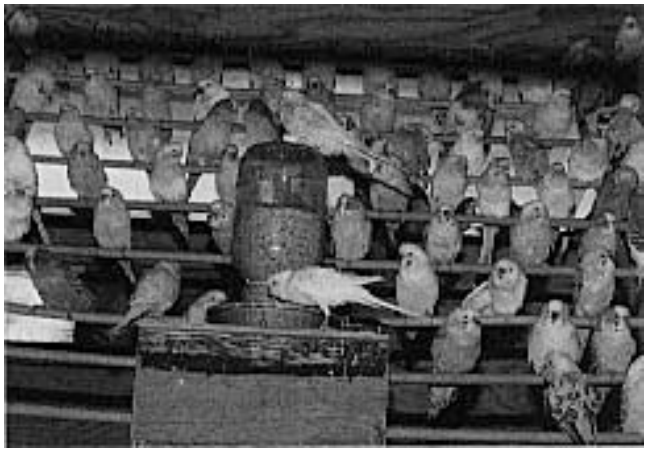

FIG 38.1 High density, confined, indoor breeding operations increase the exposure of individual birds to a mixture of microorganisms that may include *Mycoplasma* spp. Damage to the respiratory tract caused by increased dust, dry-heated air and respiratory viral infections predispose birds to mycoplasma infections. Most infectious diseases are less of a problem in birds maintained in low density outdoor breeding facilities (reprinted with permission *J Assoc Avian Vet*).

Mycoplasmatales

The host spectrum of the mycoplasmatales is rather narrow (see Table 38.1), with the exception of *Mycoplasma cloacale* and the genus *Acholeplasma*. Reports suggesting isolates of well known species from unusual hosts should be met with skepticism. The various mycoplasmatales have similar biochemical properties and serologically cross-react with other species of the order, creating a high number of false-positive results (low specificity). The reason for these cross reactions is that the lack of a cell wall diminishes the antigenicity, which is probably governed by enzymes within the microorganisms. Because these enzymes are phylogenetically old and highly conserved, they do not vary much between genera. Physical methods such as electrophoresis (combined with blot methods) are more reliable than serologic methods for differentiating between species or strains.[28]

Transmission

Mycoplasmatales are relatively low in infectivity. Close contact between individuals is necessary for transmission, and infections are most common in dense populations (Figure 38.1). The respiratory and genital tracts are the primary portals of entrance. The organism is spread by respiratory excretions and by the gonads of both sexes as well as hematologically through the body. Infected air sacs can lead to contact transmission of the ovary (and developing follicle). Transovarian transmission is epornitically important, although in clinically healthy breeders, the egg transmission rate is low (between 0.1 and 1.0 %); however, there are some exceptions. The egg transmission rate of *M. meleagridis* in turkeys can be as high as 25%. This species causes predominantly a venereal disease. Infected breeders may be asymptomatic. Close contact is the primary mode of transmission in neonates. Offspring feeding on contaminated crop regurgitations (eg, crop milk in pigeons) may also become infected.

Pathogenesis

Primary pathogenic strains, ie, strains that can damage epithelial cells and cause disease without additional factors, have to be distinguished from secondary pathogenic strains that need predamaged epithelium, and from strains that are assumed to be apathogenic. Mycoplasmatales preferably colonize the mucosa of the respiratory and the genital tracts. Strains capable of inducing systemic infections can be found in the brain and joints. Infections start with the adsorption of the organism to the surface of host cells (including erythrocytes with hemagglutinating strains). Multiplication takes place on the cell surface, and both the membrane integrity as well as the function of the host cell can be altered. Because the agent may be hidden in the recesses of the host cell membrane, it can remain rather inaccessible by therapeutics and the host defense mechanisms. As a consequence, only negligible amounts of humoral antibodies, if any, are produced. *M. gallisepticum* (and

TABLE 38.1 Avian Host Spectrum of Mycoplasmatales[13,17]

Species	Host Spectrum	Signs of Disease
M. gallisepticum	Chicken, turkey, guineafowl, peafowl, pheasants, partridge, rock partridge, Red-legged Partridge, Japanese Quail, Bobwhite Quail, House Sparrow, domestic duck and goose,[5] Canada Goose[5]	Rhinitis, sinusitis, tracheitis, air sacculitis, pneumonia, arthritis, encephalitis, ophthalmitis
M. gallinarum	Chicken, pheasant, Chinese Bamboo Partridge, House Sparrow, Demoiselle Crane, Domestic Goose, Bewick's Swan	Mild respiratory signs in geese also infected with parvovirus
M. pullorum	Chicken, Turkey, Pheasant, Partridge	Asymptomatic
M. gallinaceum	Chicken, Turkey, Pheasant, Hoopoe	Asymptomatic: complicated with PMV1
M. iners	Chicken, Turkey, Domestic Goose,[2] Golden Pheasant[31]	Asymptomatic
M. gallopavonis	Turkey, (Chicken?)	Mild respiratory signs only in turkeys
M. meleagridis	Turkey	Sinusitis, air sacculitis, infection of the genital tract
M. iowae	Chicken, Turkey, Yellow-crowned Amazon Parrot	Mild air sacculitis, in turkeys veneral transmission and reduced hatchability
M. columbinasale	Pigeon	Rhinitis, pharyngitis
M. columborale	Pigeon (Chicken ?)	Rhinitis, pharyngitis
M. columbinum	Pigeon	Asymptomatic
M. synoviae	Chicken, Turkey,[23] Guineafowl, Red-legged Partridge, Japanese Quail,[2] House Sparrow,[31] Tree Sparrow,[31] Domestic Duck and Goose	Sinusitis, synovitis, air sacculitis, hepatitis, splenomegaly
M. anatis	Domestic Duck, Greater Scaup, Common Teal and other Teals,[31] Domestic Goose,[2] Coot,[31] Common Shoveler[31]	Rhinitis, sinusitis, air sacculitis only if triggered by influenza virus
M. glycophilum	Chicken	
M. lipofaciens	Chicken	
M. cloacale	Turkey,[2] Domestic Duck and Goose,[2] Tufted Duck, European Pochard, Muscovy Duck, Skylark, Starling, Cockatiel, Lesser Spotted Woodpecker[4]	
M. anseris	Domestic Goose	Together with *M. cloacale* lesions in geese
M. spp. *n.n.* (7 different types)	Domestic Duck	Mild respiratory signs
M. sp. *n.n.*	Budgerigar	Air sacculitis
A. laidlawii B (*var. inocuum*)	Chicken, Pigeon, Greater Adjutant Stork, Night Heron	Asymptomatic
A. laidlawii A	Domestic Duck and Goose	Air sacculitis, conjunctivitis, cloacitis
A. axanthum	Domestic Goose Domestic Duck	Embryonal death, peritonitis, salpingitis, air sacculitis Conjunctivitis, cloacitis
A. equifetale	Chicken	
A. spp. *n.n.* (2 different types)	Pigeon	Rhinitis, pharyngitis
U. gallorale	Chicken, Red Junglefowl	Air sacculitis, pneumonia
U. spp. *n.n.*	Turkey, Jungle Bush Quail	Respiratory signs
Unidentified (3 different types)	Severe Macaw, Cockatoo spp., Cockatiel, Canary	Chronic conjunctivitis, rhinitis, sneezing, sinusitis, dyspnea, arthritis
Several types ?	Saker Falcon, Peregrine Falcon, Prairie Falcon, Rough-legged Buzzard, Common Buzzard, Griffon Vulture,[31] Common Kestrel	Synovitis, air sacculitis, catarrhal tracheitis, serofibrinous pneumonia, sitting on paralyzed hocks,
One type	Phasianinae	See text
Several types ?	Black-headed Gull, Brown-eared Bulbul, Phasianinae, White-fronted Goose	Asymptomatic

probably other strains of avian mycoplasmatales) has a special organelle for attaching to the host cell.

Depending on the virulence of the strain in question, cellular damage may be caused at the site of colonization. The host reacts with a serofibrinous inflammation and activation of the cell-mediated defense system. The excessive response of the latter (which is genetically determined) governs the type and magnitude of pathologic changes.

Many mycoplasmatales cause transformation of the host lymphoblasts (mainly T-cells) by excreting a mutagenic substance. Affected cells function improperly and there is a severe proliferation of immature lymphocytes in local lymph follicles with invasion of the lymphoid cells into the infected area. These altered lymph follicles can appear similar to those described for lymphoma. Other pathogenicity factors are cytotoxins (exotoxins, H_2O_2) and polysaccharides. Triggering factors for mycoplasmatales are immature epithelial membranes, environmentally induced dyspnea (heat, dry air) and damage to the respiratory epithelium (excess NH_3, paramyxovirus, reovirus, adenovirus, infectious bronchitis virus and *E. coli*). The involvement of several different factors in a flock outbreak creates a high variability in clinical and pathologic changes.

Incubation Period

Incubation periods for *M. gallisepticum* are 6-21 days in chickens and 7-10 days in turkeys.[43] In other avian species and with other mycoplasmatales, long latency periods, egg transmission and the involvement of environmental factors make the determination of an incubation period difficult.

Clinical Disease and Pathology

Red Junglefowl

U. gallorale has been isolated from the pharynx of this species. Although the strain is serologically identical with isolates from the chicken, experimental infections did not cause disease in chickens.

Phasianinae

The Common Pheasant and its subspecies, *Crossoptilon* spp., the Golden Pheasant and probably other pheasants are susceptible. The main host is the Common Pheasant, which is typically maintained in large flocks. The strains of mycoplasma that are infectious to pheasants have been incompletely studied and documentations in the literature provide conflicting information.[13] The author's experience suggests that the Phasianinae have host-adapted strains, one that is apathogenic and another that experimentally reproduces typically defined signs of the disease. Clinical signs are most common in large groups of chicks at the age of two to eight weeks. Adults are rarely affected. A seasonal peak can be observed between June and August. The disease spreads slowly and not all aviaries are always affected. Morbidity is high. Mortality depends on secondary factors and can range from 30 to 90%. Blinking the eyes and scratching at the eyelids are the first clinical signs. Deterioration of the general condition, photophobia and swelling of the eyelids are followed by exudation, blepharoconjunctivitis and sometimes keratitis; approximately 25% of the corneal surface is affected. Death can be caused by cachexia as a result of blindness. Voluminous expansion of the infraorbital sinus, which contains only a small amount of exudate, may be observed. Birds are frequently dyspneic, particularly when agitated. At postmortem, the air sacs may be mildly inflamed or grossly normal.[13]

Japanese Quail

Experimental infections indicate that Japanese Quail are less susceptible to *M. gallisepticum* than are chickens. Isolation of the organism is possible from the trachea, lung and brain for weeks post-infection. The course is subclinical. Infections derived from contact with infected chickens or egg transmission have been documented.

Bobwhite Quail

This species is raised in large numbers in the southern parts of the United States. Dyspnea and anorexia have been observed. An isolate assumed to be *M. gallisepticum* from Bobwhite Quail caused typical lesions in turkey poults. However, a strain of *M. gallisepticum* experimentally given to Bobwhite Quail chicks did not result in lesions, and no antibodies were produced.

CLINICAL APPLICATIONS

- Mycoplasmatales are most important in dense populations of birds where direct transmission can easily occur. Control can be enhanced through sound hygiene.
- Mycoplasma are resistant to antibiotics that inhibit cell wall development (eg, penicillins, cephalosporins, bacitracin and sulfonamides).
- Mycoplasmatales that are free in the environment are susceptible to all commonly used disinfectants. Organisms within host excretions are protected from contact with the disinfectant. Secretions and excretions must be removed before disinfecting procedures are effective.
- With intensified aviculture, increased farm sizes and population densities on these farms, more problems with mycoplasmatales are to be expected.

Partridge

It is assumed that the same strains as in Phasianinae cause disease in the partridge, although this has not been proven. Affected birds develop infections that are similar to those seen in pheasants, but there is no defined seasonal peak. Birds up to 11 weeks of age show a swelling of the infraorbital sinuses which, in contrast to pheasants, are filled with a fibrinous, cheesy exudate (Figure 38.2). Free-ranging Red-legged Partridge usually develop clinical disease in August to December. Isolates are assumed to be identical to strains removed from pheasants and other partridges.

Rock Partridge

Disease has been described only in chicks and not in the respective breeding flock. Emaciation and swollen sinuses are the main clinical signs. Isolates assumed to be *M. gallisepticum* were experimentally apathogenic for chickens and turkeys.

Peafowl

Affected birds are lethargic, shake their heads to remove sticky nasal exudates, have swollen infraorbital sinuses and make gurgling respiratory sounds. Latent infections are thought to occur.

FIG 38.2 A young partridge was presented with a five-day history of progressive ocular irritation, photophobia, dyspnea and periocular swelling. Large, bilateral, periocular masses were noted on physical examination. Large quantities of necrotic debris were surgically removed from both intraorbital sinuses. *Mycoplasma* sp. was isolated from culture samples taken from the sinus cavities. The bird responded to postsurgical therapy with tylosin (courtesy of Helga Gerlach).

Guineafowl

An outbreak of infectious synovitis caused by *M. synoviae* in guineafowl could not be distinguished clinically or pathologically from the lesions that occur in chickens and turkeys.[26] In contrast to chickens and turkeys, affected guineafowl (including experimentally infected birds) developed severe amyloidosis and did not develop sinusitis.[29] Strains isolated from guineafowl are more virulent for guineafowl than for chickens.

Domestic Duck

A variety of *Mycoplasma* and *Acholeplasma* strains can be isolated from domestic ducks. In the few isolates that have been evaluated experimentally, pathogenicity is limited to mild respiratory lesions, conjunctivitis and cloacitis. *M. anatis* may cause enzootic rhinitis, sinusitis, conjunctivitis and lacrimation in association with concommitant influenzavirus A infections. Morbidity may be as high as 50-80%, but mortality remains below 5%. As a rule, affected ducks recover spontaneously without therapy. Experimentally, the clinical disease can be produced using *M. anatis* and influenzavirus A,[32] although both infectious agents alone have been proven to be apathogenic. The role of *M. cloacale* as the cause of a cloacitis in ducks has not been fully studied. Most of the *Mycoplasma* and *Acholeplasma* strains described are capable of causing increased embryonic mortality.

Domestic Goose

Geese suffering from cloacitis and necrosis of the phallus were found to be infected with mixed cultures of *M.* spp. (mostly *M. cloacale*, but also *M. anseris* and strain 1220). Phallus lesions are characterized by serofibrinous inflammation of the mucous membrane of the lymph sinus, the glandular part of the phallus, and occasionally the cloaca and the peritoneum. Necrosis of the affected phallus can be severe if secondary pathogens are present. Mortality is less than 1%. *M.* spp. can be isolated from the phallic lymph secretion as well as the spleen, testes, air sacs, peritoneum and liver. The incidence of affected ganders in some flocks can be as high as 40-100%. High numbers of infertile eggs and a high incidence of embryonic death are common in affected flocks.[36,40]

A. axanthum may cause embryonic mortality (up to 60%) around the 13th day of incubation. The organism can be isolated from the respiratory tract and feces of breeding birds showing embryonic mortality. Infected adults develop fibrinous peritonitis, salpingitis and air sacculitis. Goslings from infected flocks and experimentally infected neonates can suffer from

mild to severe air sacculitis (depending on the virulence of the strain in question).[37] The pathogenicity of *A. axanthum* can be potentiated by concommitant infection with parvovirus, even if antibody titers are high enough to prevent the parvovirus from causing clinical disease.[22]

Domestic Pigeon

At least six different species of mycoplasmatales have been isolated from domestic pigeons.[13,15] All of them apparently are incapable of causing primary disease. Following natural or experimental infection with all except *M. columbinum* and *A. laidlawii* (which have not been tested), the agents can be isolated from various organs including brain, eye and joints of asymptomatic birds. The frequent colonization of the pharyngeal mucosa is epizootiologically important because pigeons feed their offspring crop milk. During the act of regurgitation the crop milk passes over the infected mucosa and may be contaminated. Although egg transmission has been proven, this means of transmission might play the most important role.

Clinical signs of rhinitis, sinusitis, tracheitis and conjunctivitis are generally chronic in nature and vary with secondary factors such as concomittant infections with *Salmonella* spp. or *Chlamydia psittaci*. Under these conditions, mycoplasmatales can be isolated from the lower third of the trachea, air sacs and occasionally lung, and birds frequently have persistent respiratory sounds and serofibrinous inflammation of these organs. The association between the colonization of the meninges and synovial structures by mycoplasmatales and the frequency of arthritis and meningoencephalitis caused by salmonellosis has not been determined. Further evidence for the apathogenicity of uncomplicated mycoplasmatal infections in pigeons is the fact that humoral antibodies only occasionally develop following natural or experimental infections. In contrast to some older reports, experimental infection of chickens with pigeon mycoplasma strains does not lead to clinical disease. *M. gallisepticum* does not affect pigeons. *M. columborale* was recovered from a pigeon flock with respiratory signs that responded to treatment with tylosin. Experimentally infected three-week-old chicks developed mild to severe air sacculitis, but were clinically asymptomatic. There is no report of natural infection in chickens with *M. columorale*.[25]

Other Pigeons

In addition to domestic pigeons, infections with mycoplasmatales have also been described in the Wood Pigeon,[20] Collared Dove[14] and Crowned Pigeon.[13] The isolation of *M. columbinum* and *M. columborale* has also been recovered from healthy "feral pigeons."[21]

Saker Falcon

Mycoplasma was isolated from the trachea of a Saker Falcon with insufflation of the soft tissues around the eye and between the rami mandibulares following each expiration. Similar respiratory signs occured in two contact birds.[10] A definitive connection between the clinical signs and the *M.* isolate was not established. Mycoplasma-induced synovitis has also been described in this species.[19]

Peregrine Falcon

A *Mycoplasma* sp. was isolated from the trachea of two Peregrine Falcons with anorexia, vomiting, respiratory sounds and tachypnea (60-70 beats per minute).[10] The animals responded to treatment with tylosin.

Budgerigar

A *Mycoplasma* sp. was isolated from a budgerigar with air sacculitis.[1] The serum of five contact birds revealed humoral antibodies against the homologous strain with titers between 1:160 and 1:640. Antibodies were not detected against *M. gallisepticum* and *M. meleagridis*. The budgerigar strain propagated in the embryonated chicken egg and showed no embryonal pathogenicity. Budgerigars experimentally infected with *M. gallisepticum*[6] and *M. synoviae*[3] developed clinical signs. Budgerigar are not considered to be a natural host of *M. gallisepticum* and *M. synoviae*.

Cockatiel

It has been assumed that conjunctivitis in cockatiels can be caused by mycoplasmatales, (see Color 26) as wet sneezes and sinusitis are common in those birds. Although mycoplasmatales can be isolated from some of these cases, their importance in the disease process has not been determined. From the clinical course and response to treatment it can be concluded that chlamydiosis and infections with polyomavirus are the main pathogens in these conditions.[9,12] Many cockatiels in Florida with symptoms of mycoplasmosis respond to tylosin (as an eyewash) or lincocinspectinomycin (Harrison GJ, unpublished).

Severe Macaw

An epornitic of mycoplasma was described in Severe Macaws with clinical and pathologic lesions in the respiratory tract. Although mycoplasmas were iso-

lated, no causal relationship between the agent and the disease could be established.[11]

Yellow-crowned Amazon

A flock of Yellow-crowned Amazon Parrots experienced high mortality (200 of 1100 birds) with an upper respiratory tract disease. Lesions were complicated by the presence of many bacteria and also some fungi. A mycoplasma strain (assumed to be *M. gallisepticum*) was isolated and used for experimental infections in budgerigars and chickens. Mild air sac lesions were induced in budgerigars, but the strain was apathogenic for chickens. The serologic evidence for *M. gallisepticum* was questionable.[3]

Cockatoo

An unidentified strain of mycoplasma was isolated from a group of cockatoos with severe air sacculitis.[12]

Canary

An unidentified strain of mycoplasma was recovered from a flock of canaries with a high incidence of wheezing and "tail-bobbing." The affected flock had suffered from canarypox.

Pathology

At necropsy, lesions caused by various mycoplasmatales in respective hosts vary in degree but not in presentation. Serous to serofibrinous conjunctivitis, rhinitis, sinusitis, tracheitis, air sacculitis and focal bronchopneumonia have all been described.[18] The nasal cavity and the infraorbital sinus frequently display a unilateral, seromucoid (later fibrinous) exudate that also fills the choanal fissure. In ducks and turkeys, the exudate is often semigelatinous, fibrinous or caseous, and leads to distension of the infraorbital sinus. The mucous membranes are swollen and may show petechiation. The tenacious exudate can be mixed with fibrinous debris.

Histopathologically, the disease is initially characterized by severe distension of the mucous glands, the swollen cells of which have particularly large nuclei. Subsequent proliferation of epithelial cells leads to multilayered, glandular epithelium, pressure on the glands themselves and mucoid degeneration. The superficial mucosal epithelia lose their cilia, proliferate to 10-15 cellular layers and finally show vacuolization and karyorrhexis. In contrast to various viral diseases, desquamation and necrosis of the epithelium are mild.

From the second week after infection, an infiltration of the lamina propria with lymphocytes and histiocytes is seen. Round-to-oval, up to 400 μm in diameter nodules that consist mainly of lymphocytes appear in the submucosa. The proliferation of the lymph follicles persists in the lower part of the trachea and the syrinx from the 2nd to the 12th week after infection. This is generally a longer course of reactions than are noted with other infections of the respiratory tract. As healing occurs, there is a proliferation of connective tissue in the submucosa. The histopathomorphologic changes vary depending on the presence of secondary bacterial or viral infections. Secondary fungal infections are rather rare.

Lesions of the air sacs start with edema between the inner and outer epithelial layers. The cellular reaction consists initially of subepithelial infiltrates of heterophils. The capillaries are engorged. Progression is marked by increased edema and growing numbers of heterophils followed by lymphocytes, macrophages and plasma cells. The normally flat epithelium becomes cubic, loses its cilia and is finally desquamated. Inflammatory exudate, mainly in the form of fibrin, appears on both sides of the air sac membrane. The host responds with proliferation of the endodermal epithelial layer and necrotic foci of epithelial cells and proliferation of fibrocytes and mononuclear cells (80% can be lymphocytes). A granulomatous reaction characterized by the formation of multinucleated giant cells occurs by the third week post-infection. Lymph follicles and diffuse mononuclear infiltrations govern the pathologic picture. Pneumonia is a rare complication in avian mycoplasmosis, and in most instances is caused by secondary infections with *E. coli*.

Mycoplasma colonization of the mucosa of the urogenital tract can cause pathologic lesions, although colonization of the phallus may be inconspicuous. Histologically, lesions are mainly seen in the part of the mucosa where the majority of the glands are situated (species-specific differences). Submucosal proliferation of lymph follicles and disseminated infiltration of lymphocytes into the tissue are the main lesions. In ganders, the phallus is enlarged and covered with fibrinous exudate, and may finally become necrotic if secondary infections occur. Synovial membrane lesions have been rarely reported in companion and aviary birds.[23]

Differential Diagnosis

The rule-out list includes many viral, bacterial and fungal diseases. In Psittaciformes, pigeons, ducks and geese, chlamydiosis is the main rule-out. The genital tract can be infected by other microorganisms as well. Embryopathologic lesions and embryonal death are suggestive. With mycoplasmatales, infected embryos generally die late in incubation. Embroyos that die after pipping frequently have air sacculitis of the left thoracic air sac group (exceptions are geese that have air sacculitis bilaterally). After hatching, chronic lymphofollicular proliferation can be so severe that lymphoma must be considered in the rule-out list.

Diagnosis

A tentative diagnosis can be made by histopathologic examination. Isolation of the agent is necessary for identification and biologic assays. Because of the fastidious nature of this organism and the difficulties in identifying the agent, specialized laboratories are necessary to isolate *Mycoplasma*. In addition, the mycoplasmatales need to be differentiated from bacterial L-forms. Swabs from the upper respiratory tract, or the phallus in males, can be taken from live birds. Endoscopic biopsies of affected air sacs are useful diagnostic aids. Samples from air sacs, salpinx, lungs and spleen should be collected for postmortem evaluation. Transport media are necessary for shipping samples. They should contain heart infusion broth, mycoplasma broth or another similar medium with penicillin (2000 IU/ml). Because the organisms are primarily to be protected from drying during transport and are not supposed to grow, the pH is not of particular importance (however, it should be around 7 or slightly above). Penicillin does not affect acholeplasma, but thallium-acetate does; therefore, mycoplasma broth that contains thallium-acetate should not be used for material from geese.

Indirect diagnosis of mycoplasmatales by serology is hampered by false-positive (cross-reactions) and false-negative tests. The presence of a mycoplasmatales on a mucosal surface usually does not stimulate production of humoral antibodies. Antigen-recognizing cells become active only after the mucosa has been penetrated. The most frequently used tests are: serum slide agglutination (SSA), HI test (for the hemagglutinating species), growth- or metabolic-inhibition test, immunodiffusion test, immunofluorescence test, ELISA, and recently the polymerase chain reaction.

Treatment

Clinical infections can be treated with tylosin, spiramycin and erythromycin or spectinomycin in combination with clindamycin or pleuromutilin. The efficacy of tetracyclines against avian mycoplasmatales has yet to be proven. However, in Psittaciformes, the tetracyclines are recommended because of the clinical similarities between mycoplasmosis and chlamydiosis. The pigeon strains are highly resistant to erythromycin and, to a lesser extent, tylosin. Only pleuromutilin was able to inhibit 57 of 65 strains recovered from pigeons.[15] The LD_{50} for pleuromutilin in pigeons is 440 mg/kg, considerably less than for chickens and turkeys. This drug must be carefully used when treating pigeons that are feeding offspring or if used in the water during hot weather.

Spiramycin given parenterally to Ploceidae, Estrildae and even canaries may lead to sudden death from unknown causes. The same dose given via drinking water is well tolerated. Spiramycin is one of the macrolid antibiotics and is given at a dose of 100 mg/kg body weight IM, or 100-200 mg/kg body weight orally. Since the primary patent has expired, several manufacturers produce it. Enrofloxacin has been used to treat mycoplasmosis in poultry. There have been no reports of success in treating mycoplasmosis with enrofloxacin in other birds. Treatment is designed to allow clinically affected birds to recover. The organism is difficult to eliminate.

Control

Recovery from mycoplasmosis results in the production of a low antibody level and a persistent infection. *In vitro*, mycoplasmatales can propagate in the presence of homologous antibodies, indicating that humoral antibodies are not correlated with immunity. The disease is governed by the excessive reactions of the cell-mediated immune system. Therefore, vaccinations might sensitize a bird to the organism and cause a severe reaction to a field exposure. Theoretically, vaccines that prevent mycoplasmatales from attaching to the mucus cells might give protection.

Rickettsia

Little information is available on rickettsial infections in birds. Rickettsia form a group of microorganisms, the taxonomy of which has still not been fully determined. They are obligatory cellular parasites, and can be differentiated from chlamydia by the absence of a developmental cycle and the capacity to synthesize energy-rich compounds (ATP). Rickettsia are small rods or coccoids with an average size of 0.3 to 0.5 μm in diameter and 0.8 to 2.0 μm in length. They may also be pleomorphic, and are generally nonmotile. Multiplication takes place by binary fission. The organism parasitizes reticuloendothelial cells, vascular endothelial cells or erythrocytes. Infections may occur in arthropods, which can serve as vectors or as primary hosts. The mutualistic forms in insects are considered to be essential for development and reproduction of the host.[47] Rickettsia may cause disease in humans, many vertebrates and insects. The organisms can be cultured in embryonated chicken eggs or metazoan cells. The chlamydial staining procedures may be used, although some changes are made particularly in fixation.

The rickettsia have historically been divided into three families:[47] Rickettsiaceae, Bartonellaceae and Anaplasmataceae. The latter two families are no longer considered to be Rickettsia and are "phylogenically unaffiliated bacteria" (Gothe, unpublished).

Rocky Mountain Spotted Fever (RMSF)

RMSF is a mammalian disease caused by *Rickettsia rickettsii*. Prior to the availability of antibiotics (tetracyclines), infections were characterized by high mortality rates. The pathogenicity (for many other rickettsia as well) involves a toxin-like action that damages endothelial cells, inducing increased capillary permeability, plasma flow into the tissue, hemoconcentration and eventual circulatory collapse. Cytotoxicity is thought to be the mechanism by which rickettsia gain access to the cytoplasm of the host cells.[41]

RMSF is transmitted by ticks (mainly *Dermacentor* spp.) and rodents. Dogs and opossum are thought to be reservoirs. Birds, including chickens, several Columbiformes, pheasants, Falconiformes and the Magpie, are susceptible to experimental infection and may also serve as reservoirs. Pigeons may be particularly important reservoirs.[24] Clinical abnormalities have not been described in infected birds.

Q-Fever

Q-fever, caused by *Coxiella burnetti*, is an aerosolborne disease in humans with worldwide distribution. Direct and indirect transmission (arthropods) can occur in humans and other host species. This agent differs considerably from other members of the Rickettsiaceae. The cells are smaller (0.2 to 0.4 μm by 0.4 to 1.0 μm) and replicate in vacuoles of the host cells. In contrast to chlamydia, *C. burnetti* infections result in the formation of phagolysosomes. Two different phase variations are distinguished. Phase I is more virulent, presumably because of the high amount of lipopolysaccharides, and occurs naturally. Phase II appears following repeated passages in the yolk sac of embryonated chickens. The occurrence of plasmids has been established. The replication cycle includes production of endospore-like bodies, which are probably the cause of the high tenacity of *C. burnetti*. This organism is resistant to chemical disinfectants and high temperatures that might kill other rickettsia. Metabolic activity in these endospore-like bodies is extremely low outside the host. Survival, which can be several years in the feces of ticks, is augmented by dryness. Chlorine-containing preparations are recommended for disinfection. The effects of phenol and formaldehyde products are debatable.[35]

The host spectrum of *C. burnetti* is wide, and includes arthropods (particularly ticks), birds and mammals. An infectious cycle in free-ranging animals, arthropods, birds and mammals is differentiated from an infectious cycle in domesticated animals (sheep, goats, cattle, dogs). Cross transmission, including in man, is possible from both cycles.[35]

Avian susceptibility to *C. burnetti* seems to be high, and this organism has been demonstrated in at least 49 avian species.[8,30,39] The type of feeding behavior, breeding areas and seasonal migrations are the main factors for the spread of the organism. Carrion-eating birds may be infected by ingesting the infected placenta of ruminants from endemic areas. The feeding location of granivores and insectivores is more important than their food preferences. Birds that live in close contact with humans (synanthrops) are exposed more frequently to *C. burnetti* than birds that avoid civilization (exanthrops). The susceptibility to infec-

tion in domesticated birds is variable.[8,38,39] Chickens are apparently most susceptible and may shed the agent in the feces for 7 to 40 days post-infection. Vertical transmission via the egg may also occur. Domesticated pigeons are next in susceptibility. Domesticated turkeys, ducks and geese are rarely infected. All the free-ranging urban pigeons that were examined (125) in the Netherlands showed CF titers of ≤1:20 against *C. burnetti*.[7] In experimentally infected domesticated pigeons, the agent could be isolated from the spleen and lung 58 days post-infection.[34] No clinical disease has been observed in any susceptible avian species.

C. burnetti can be identified in tissues using various staining methods (Giemsa, Macchiavello, Castañeda) as for chlamydia. The organism replicates in embryonated chicken eggs and various cell cultures. Antibodies can be demonstrated using the CF test or the ELISA. Not all exposed domestic pigeons have been found to produce CF antibodies.[34] Antibody production is not related to immunity.

Therapy with tetracyclines is effective for the clinical disease, but elimination of the organism is not possible. Treatment for infected birds is not encouraged because of the high immunosuppressive side effect of the tetracyclines.

Aegyptianella (Ae.)

Ae. pullorum is the causative agent of anemia and hepatitis in chickens and other birds. It is an erythrocytic parasite that produces endocytoplasmic inclusions, which stain using the Giemsa or Pappenheim procedures. The inclusions measure 0.3 by 4.0 μm, and each can contain up to 26 initial bodies (reproducing form up to 0.8 μm in diameter). In many instances, the inclusions are polymorphic (round, oval, ring- or horseshoe-shaped) and are separated from the plasma by a single-layered membrane. Infection of the cell starts with an endocytosis-like process followed by vesiculation in the erythrocyte. Exocytosis is one way in which the organism is released from the infected host cell. However, the host erythrocytes are usually damaged by the parasite, leading to lysis and release of the parasite into the plasma. Arthropods, mainly ticks of the genus *Argas*,[16] are essential for transmission.

The organism is most common in tropical and subtropical regions including the Mediterranean. The host spectrum is probably incomplete but certainly includes chickens, quail, Columbiformes, Strigidae, Falconidae, Accipitridae, crows, canaries, ostriches, ducks, geese and some Psittaciformes such as *Agapornis* spp.[16,17,33]

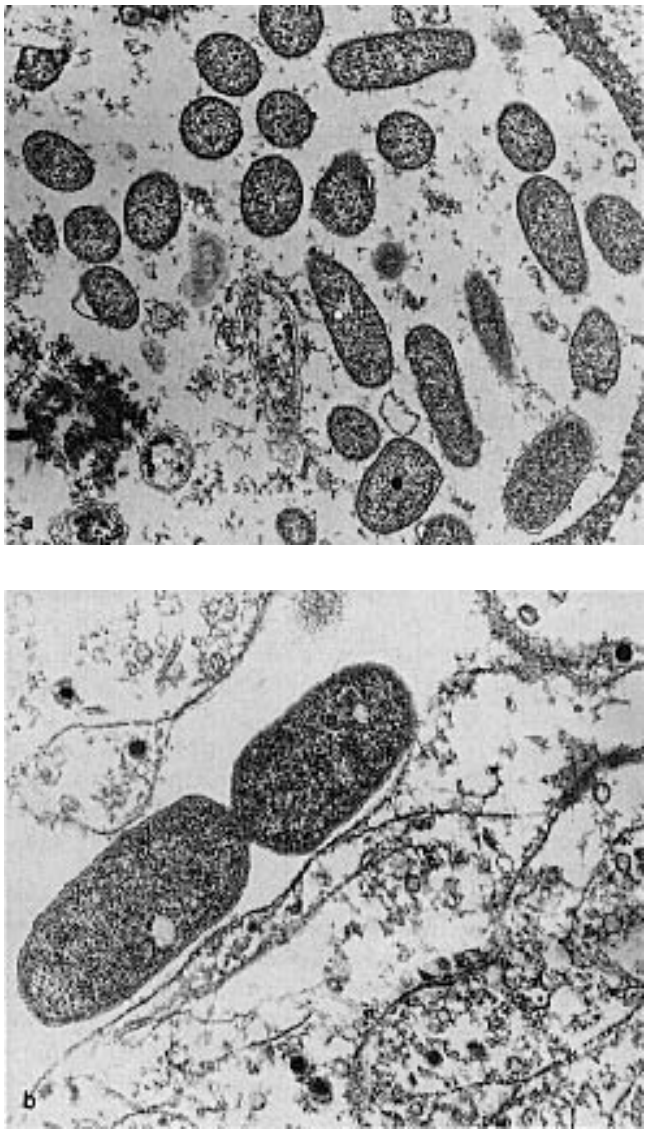

FIG 38.3 **a)** A group of Gouldian Finches died following an onset of clinical signs that included depression, dyspnea and coughing. Electron microscopy of tracheal epithelial cells revealed intracytoplasmic inclusion bodies with organisms morphologically suggestive of rickettsia. Magnification: x 22,250. **b)** Same cell type with rickettsia in binary fission; magnification: x 52,500; (courtesy E. Göbel).

Clinical signs in young birds are characterized by an acute onset of anemia, anorexia, weakness, weight loss, greenish diarrhea and death.[33] Chronic infections in older birds are characterized by icterus, which may not be clinically recognizable. The post-

mortem examination reveals anemia as well as a considerable enlargement of the liver and spleen.

Small inclusion bodies were demonstrated in the majority of the mature erythrocytes in two domestically raised Eclectus Parrot neonates (six weeks old) with heterophilia (toxic heterophils) and anemia. These intracellular parasites resembled those identified as *Aegyptianella* in several imported African Grey Parrots. Following a long-term course of doxycycline therapy, the parasites were no longer identifiable in the erythrocytes. The parents that produced these neonates were also positive for aegyptianella and responded to long-term doxycycline therapy.[33]

In gallinaceous birds, the age and condition of the host govern the pathogenesis and outcome of the infection. Up to 60% of the erythrocytes may be infected in one-day-old chicks, while by one year of age less than 1% of the erythrocytes may be infected.[16] Mortality is higher in chicks less than two days of age.

The rule-out list includes internal bleeding, chlamydiosis and chronic diseases of various etiology. For diagnosis, a blood smear stained according to Giemsa or Pappenheim shows the parasites in the erythrocytes. Tetracyclines are effective for treatment. Tick control is mandatory to prevent reinfection and epizootics.

Unclassified

There are indications that diseases caused by rickettsia other than aegyptianella may occur. Tracheal epithelial cells in Gouldian Finches with severe respiratory disease were filled with cytoplasmic "inclusions." Many of the affected birds died. Electron microscopy of the epithelial cells revealed particles that were morphologically compatible with rickettsia (Figure 38.3). Treatment with tetracyclines was successful. Isolation was not possible because the material had been prepared for histopathology.[27]

ANESTHESIOLOGY

Leslie C. Sinn

With the refractory attitudes of many birds toward even mild restraint, sedatives and local anesthetics are of little use in most avian species. General anesthesia, however, with appropriate agents, can enable clinicians to safely and rapidly perform fluid administration, emergency procedures, blood collection and radiography, or to perform prolonged invasive surgical procedures in avian patients.

Historically, avian anesthesia has been a problem fraught with continuous debate. Many clinicians have had their preferred drug "cocktails," and there were many conflicting views with regard to dosage ranges and choice of anesthetic regime. Anesthesia machines have been altered in an attempt to meet the specialized needs of avian patients, and numerous modified endotracheal tubes, non-rebreathing bags and delivery systems have been implemented. Sophisticated monitoring systems and equipment designed for or found to be suitable for avian patients are now commercially available.

As in other animal species, general anesthesia in birds can be accomplished with either injectable or inhalant anesthetic agents. The goal of anesthetizing a patient is to select the safest drug that allows the minimum amount of physiologic changes. (The reader is referred to Section Seven for use of anesthetics in non-psittacine species.) Injectable anesthetics are far inferior to gas anesthetics for use in avian patients, and for private avian practice, isoflurane is the only recommended anesthetic. This is particularly true given that the vast majority of patients are anything but healthy and are less tolerant of the physiologic compromises induced by most injectable and other inhalant anesthetics.

The basic principles of risk assessment and patient support used for mammalian anesthesia are also applicable to the avian patient. Ability to assess the condition of avian patients has improved, as has the ability to provide physiologic support during the anesthetic episode.

Anesthetic Agents and Equipment

The ideal avian anesthetic agent is one that creates minimal stress in administration, has a high therapeutic index, provides for rapid induction and recovery, induces minimal physiologic changes, provides adequate restraint for the desired procedure and can be safely used in critical cases. Contraindications for anesthetizing an avian patient should include severe obesity, fatty liver, liver or kidney failure, dehydration, shock, anemia, dyspnea and fluid in the crop. Unfortunately, patients presented with many of these problems are those that require anesthesia for proper resolution of the case. The choice of anesthetic agent must be based on the patient's status and the working conditions that the clinician faces (eg, field vs. hospital anesthesia). In all situations, the anesthetic of choice is isoflurane.[a,b] There are some indications for the use of injectables in the field, and recent work with reversal agents may make the use of injectables more appealing to some avian practitioners. However, an isoflurane anesthetic unit designed for field use will fit into a small tool box (10" x 12" x 20"); the only other necessary equipment is an oxygen source (Figure 39.1).

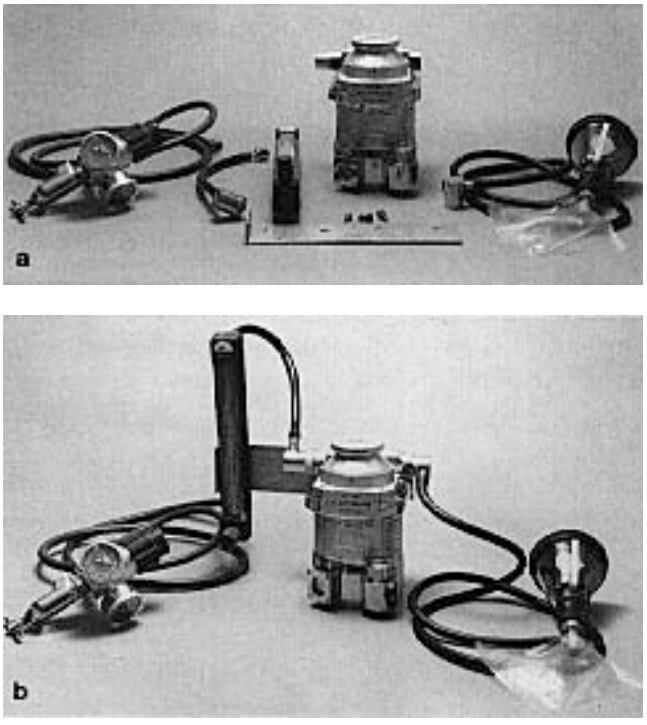

FIG 39.1 An isoflurane anesthesia circuit for use in birds that will fit into a small tool box is commercially available. **a)** The components of the system are shown separated and **b)** connected to form a functional circuit (courtesy of Exotic Animal Medical Products).

When compared to injectable anesthetics, inhalation agents have numerous advantages. They can be titrated to effect, have a more consistent therapeutic index and provide for rapid induction and smooth, rapid recoveries. Additionally, the anesthetic episode can be maintained for variable durations as dictated by the procedure and, particularly with isoflurane, effects can be instantly reversed.

Physiologic Effects of Inhalant Anesthesia

In administering avian inhalant anesthetics, there are several important differences between the mammalian and avian respiratory system that should be addressed. The paramount difference is that the avian lung does not have alveoli. Instead, the air capillaries function as the anatomic location of gas exchange.[28] Avian species also lack a diaphragm, and inspiration is totally dependent on the correlative movement of the coracoids, ribs and sternum. The total lung capacity of avian species is much less than that of an equivalent-sized mammal; however, due to the air sac system, the total respiratory volume is substantially greater. There is also a high gas exchange surface-to-volume ratio that accounts for more efficient gas exchange. This efficiency accounts for the rapid equilibration of inspired components with arterial blood and for the rapid induction, rapid changes in depth of anesthesia and speed of recovery when inhalant anesthetics are used in birds. Recovery from isoflurane is primarily a function of the excretion of the gas by the lungs. Full recovery with agents such as methoxyflurane that are highly metabolized depends on the biotransformation of the agent by the liver. Birds are very sensitive to CO_2 concentrations, and if the blood is depleted of CO_2, the patient will become acutely apneic. The minimum level of CO_2 in the blood that is necessary to stimulate respiration in birds has been suggested to be 25 torrs.[6]

Because of the anatomy and structure of the avian respiratory system, even healthy birds may not be properly oxygenated when anesthetized and placed in dorsal recumbency.[6] It may be impossible for some species that have a large pectoral muscle mass (eg, Galliformes and Anseriformes) to adequately ventilate. Because of their unique respiratory anatomy, intubation and the use of gentle intermittent positive

pressure ventilation (IPPV) (20 to 40 per minute at 15 mm H_2O) is strongly recommended in anesthetized patients.[28]

Isoflurane

Isoflurane is rapidly replacing halothane and methoxyflurane as the gas anesthetic of choice for small animal patients. This surge in popularity is based on isoflurane's rapid induction time, rapid and smooth recoveries, rapid change in anesthetic level, high margin of safety for both the patient and hospital staff, reduced arrhythmogenic properties, reduced cardiovascular depression and reduced respiratory depression. The drug can also be safely used to obtain diagnostic information from high-risk and critically ill birds. Recovery from even long surgical procedures requires only minutes.

Isoflurane can have a dose-related depressant effect on the respiratory and cardiovascular system. Fortunately, there is a substantial interval between respiratory and cardiac arrest.[1,9,11,27] The hypotensive effects of isoflurane have been shown to be severe in cranes. The effect was dose-dependent and was potentiated by spontaneous respiration when compared to assisted ventilation (IPPV).[19] Isoflurane is only 0.3% metabolized compared to 15% for halothane and 50% for methoxyflurane; thus, isoflurane does not produce the hepatic damage induced by halothane and methoxyflurane. However, it has been evaluated in the field for only 12 years, and precautions should still be used with this anesthetic gas. The low metabolism rate also means that when the gas is expired by the lungs, few residues or toxic metabolites remain to further hinder the patient's recovery. Isoflurane has a blood solubility of 1.4 compared to 13 for methoxyflurane and 2.4 for halothane. Because the solubility is so low, the agent is not dissolved in the blood, and the speed of induction and recovery are extremely rapid. Minimum alveolar concentration (MAC) has been found to be approximately 1.3 (cranes and ducks).[18,19] This would indicate that higher settings for isoflurane delivery might predispose the patient to apnea, cardiac arrhythmias and cardiac arrest.

Methoxyflurane

Methoxyflurane is 50% metabolized, has a high degree of organ toxicity and produces prolonged effects on physiologic parameters. This gas is highly soluble in blood, which accounts for its relatively long periods of induction and recovery (may take hours). This solubility prevents the rapid change in anesthetic depth, which makes the anesthetized bird easier to maintain. However, the quantity of gas dissolved in the blood also prolongs the time required to lighten a bird in critical situations. Methoxyflurane is known to induce major hepatic and renal dysfunction in chronically exposed hospital personnel, and scavenging systems should be used to remove waste gas from the hospital setting. Because of methoxyflurane's low volatility, techniques have been described for administering the gas in open anesthetic systems. This is an extremely dangerous method of providing anesthesia in birds, and if an adequate oxygen supply is not assured, it will result in rapid death of the patient.

Halothane

Halothane is a relatively nonirritating gas that requires a precision vaporizer for proper delivery. The blood:gas coefficient for mammals is 2.3, which, when combined with the rapid arterial gas exchange that occurs in the avian respiratory system, accounts for a rapid induction and recovery. Induction is usually achieved within two to five minutes at a two to three percent level; recovery time depends on the length of the procedure but generally varies from 5 to 20 minutes. Halothane will induce a rapid decrease in the heart rate that returns to normal shortly after ceasing anesthetic administration. Maintenance is usually achieved between 1 to 1.5%, which decreases as the length of the procedure increases, and decreases with the degree of induced hypothermia. Halothane is only 15% metabolized. Disadvantages of halothane in the avian patient are that 1) apnea and cardiac arrest often occur at the same time, and 2) the gas does sensitize the heart to catecholamines, which may induce arrhythmias, particularly with longer surgical procedures. The agent can cause liver disease in chronically exposed hospital personnel, and scavenging systems should be used to remove waste gas from the hospital setting. Recoveries with halothane are more prolonged than with isoflurane.

CLINICAL APPLICATIONS

Isoflurane is an ideal anesthetic in birds because of its:

- High therapeutic index
- Rapid induction and recovery
- Minimal physiologic changes
- Adequate restraint for many procedures
- Safety in critical patients
- Reduced toxicity

Oxygen

The oxygen flow should be high enough to ensure that a precision vaporizer is accurate in its delivery of the anesthetic gas. For most precision vaporizers, the minimum flow rate is 500 ml/min. Some vaporizers function adequately at low settings but the manufacturer's recommendations should always be followed. If a semi-open system is used, the oxygen flow should be three times the respiratory minute volume, which for a 450 g bird is about 275 ml/min. As a general guideline, this ratio can be used to determine the respiratory minute volume of any avian species. For most psittacine birds, the oxygen flow rate during induction is 1 l/min and maintenance is 0.5 to 1 l/min depending on the size of the patient.

Nitrous Oxide

Nitrous oxide (N_2O) has successfully been used in birds in combination with isoflurane anesthesia. N_2O is not potent enough to induce anesthesia on its own; however, it does allow for the reduction in the percentage of isoflurane necessary for anesthetic maintenance. Because cardiovascular and respiratory depression caused by isoflurane are dose-dependent, N_2O is an important addition to the anesthetic regime. N_2O does have the characteristic of diffusing into closed gas spaces faster than nitrogen (room air) can diffuse out. This means that N_2O is contraindicated in situations where dead gas spaces are present. Because the avian respiratory system including the air sacs freely intercommunicate, the use of N_2O is not contraindicated. Some species differences do exist. For instance, diving birds have naturally occurring subcutaneous air pockets, and the use of N_2O in these birds may lead to subcutaneous emphysema.[3]

Pre-anesthetics

The routine use of atropine as a pre-anesthetic has been avoided in avian patients because it thickens respiratory secretions, slows gastrointestinal motility and increases the heart rate. The thickening of respiratory secretions could contribute to a life-threatening occlusion in patients intubated with small-diameter endotracheal tubes. Additional elevation of the heart rate is not desirable in patients that already have a rapid rate. Glycopyrrolate does not have as marked effect on the heart, but it too causes thickening of respiratory secretions. Consequently, these drugs are used only as specific therapy for bradycardia. Further studies on the use of these drugs in birds are needed.

Injectable Anesthetics

Injectable anesthetics in birds have the same disadvantages that are recognized in mammalian species. There is a tremendous variability in therapeutic dosages and physiologic effects, both at the species and individual patient levels. Likewise, many injectable anesthetics do not provide an adequate plane of anesthesia without reaching tissue levels that threaten the life of the patient. There is minimal ability to titrate injectable agents to effect, so levels of anesthesia may be insufficient to perform a procedure or may be so deep that the patient is in danger. With most commonly used injectable agents, the anesthetic level cannot be rapidly decreased, and the recovery is prolonged because the drug must be totally removed by metabolic pathways. Increased recovery times create excessive stress, increase the period of hypothermia and prolong the deviation from a physiologically normal state. With any anesthetic episode, a major goal should be to minimize the time between induction and recovery, and injectable anesthetics do not effectively meet this criteria. Unfortunately, when using parenteral anesthetics, the period of recovery may be far longer than the duration of useful anesthesia.

The most commonly reported injectable anesthetics used in birds are combinations of ketamine and xylazine and, less frequently, ketamine and diazepam. Etorphine, methoxymol, propafol, midazolam, tiletamine/zolezapam and barbiturates have all been used in birds.[4,7,12,15] Initial data are promising for some of these drugs, but in many cases actual clinical trials are not available. In general, phenobarbital, methohexital, thiobarbiturates and barbital should not be used in companion birds. They have a low margin of safety, produce prolonged violent recoveries, must be given IV to prevent perivascular damage and at best provide radically variable levels of anesthesia.

Ketamine, a cyclohexamine, produces a cataleptic state that inhibits movement, but does not provide adequate analgesia for major surgical procedures. This drug has a highly variable effect in different avian species. It is metabolized by the kidneys and is therefore contraindicated in patients with renal insufficiency. Dose ranges for various species are reported from 5 to 75 mg/kg. The drug is most commonly administered IM, and the first signs of incoordination occur within three to five minutes. The typical duration of anesthesia is 10 to 30 minutes, and recovery may take from 30 minutes to several hours, which is completely dose-dependent.

Ketamine anesthesia is typified by cardiac and respiratory depression, increased blood pressure, reduced body temperature, slow violent recoveries and prolonged physiologic changes.

Ketamine is rarely used alone. Because of the muscle rigidity produced by this drug and the inadequacy of the analgesia achieved, ketamine is most often used in combination with either xylazine or diazepam.[12,20] The ratio for both ketamine/diazepam or ketamine/xylazine combination is 10:1 on a mg/kg basis. Either combination provides for more rapid induction, smoother maintenance and less violent recovery than when ketamine is used alone.

Xylazine produces good muscle relaxation and transient analgesia. It can cause bradycardia and heart blocks.[20]

Diazepam is an excellent sedative and provides some muscle relaxation.[20] Ketamine/diazepam combinations can be useful when mild restraint is required.

The dosages for the drugs to be administered in combination are calculated based on a ketamine dosage of 5 to 30 mg/kg IM (or 2.5 mg to 5.0 mg IV) mixed with xylazine 1.0 mg to 4.0 mg IM (or 0.25 to 0.50 mg IV). Alternatively, diazepam (0.5 mg to 2.0 mg/kg IM or IV) may be substituted for the xylazine.[2,4,5,8,12,28] The two drugs chosen are mixed together and administered either intramuscularly or intravenously. Reduced doses are necessary in seriously ill, pediatric and geriatric patients and for intravenous administration. Ratites require only 3 mg/kg of ketamine. Because these drugs have a narrow therapeutic index and the species and individual dose responses vary widely, clinicians are advised to start at the lower end of the dosage range. The intravenous route is preferred, as the dose can be titrated to effect.[12] Both xylazine and diazepam can be mixed in the same syringe with ketamine. Care must be taken, especially with smaller doses, to eliminate all air pockets from the syringe and to thoroughly mix the two drugs. Recovery from intravenous administration of these injectable anesthetic combinations may take 15-45 minutes, while recovery from intramuscular administration, especially if additional dosages have been necessary, may take hours. Recovery may be violent. Yohimbine has been shown to be an effective reversal agent for ketamine/xylazine anesthesia in raptors. A dosage of 0.1 mg/kg yohimbine was effective in reversing anesthesia caused by the administration of intravenous ketamine (4.4 mg/kg)/xylazine (2.2 mg/kg).[5] Tolazoline (15 mg/kg IV) has been used to successfully reverse ketamine/xylazine anesthesia in turkey vultures.[2] The use of these reversal agents may make the use of ketamine/xylazine safer and more practical for birds.

Etorphine has been successfully used in large birds such as ostriches and cassowaries. A dosage of 0.02 to 0.03 mg/kg IM is utilized for restraint. This can then be reversed with 0.04 to 0.06 mg/kg IV of diprenorphine.[15]

Midazolam (same group as diazepam) (15 mg/kg IM) was successfully used to reduce the percentage of isoflurane necessary for general anesthesia in racing pigeons. It was then effectively reversed with the drug flumazenil (0.1 mg/kg IM).[29]

Gas Anesthetic Equipment and Delivery

Anesthetic Machines and Vaporizers

Most of the available models of anesthetic machines are adequate for an avian practice. What is required is an out-of-circuit, precision vaporizer for the administration of isoflurane. The vapor pressure of isoflurane (261 mm Hg) is so close to halothane (243 mm Hg) that the same type precision vaporizer can be used for both agents (Figure 39.2). However, once converted to isoflurane, a machine should no longer be used for halothane. A vaporizer can be purchased that is manufactured specifically for use with isoflurane, or a halothane vaporizer can be cleaned with ether and re-calibrated for use with isoflurane. A vaporizer cannot be used for halothane and isoflurane at the same time. Switching back and forth

FIG 39.2 The vapor pressure of isoflurane and halothane are similar so isoflurane can be delivered through a halothane vaporizer; however, once a vaporizer has been converted to isoflurane use, it should not be used with halothane.

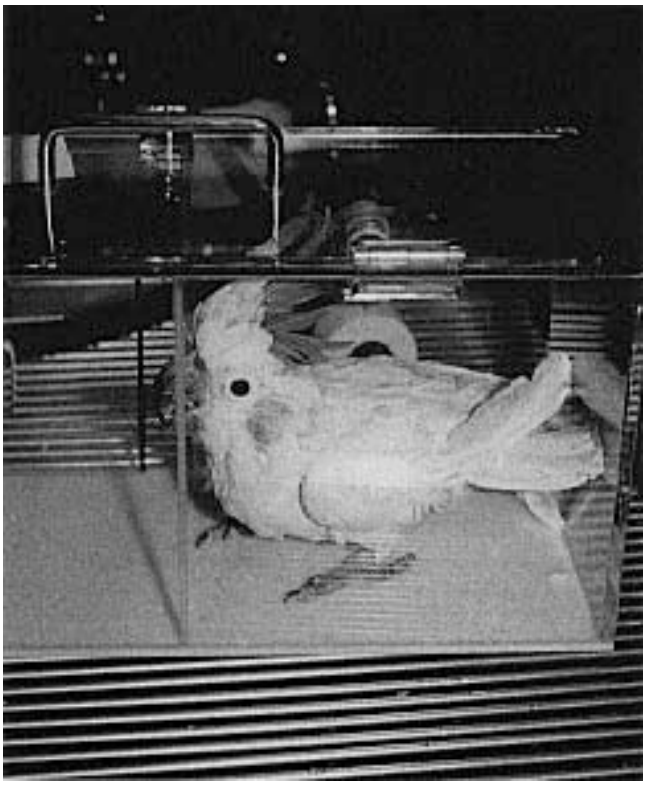

FIG 39.3 Tank systems should not be used for inducing anesthesia in birds.

between these agents will destroy the vaporizer. Calibration of the vaporizer is necessary after a conversion has occurred from halothane to isoflurane. Once isoflurane is in use, the vaporizer should be cleaned and re-calibrated on a yearly basis.

Breathing Systems

Gas anesthesia can be achieved through either an open, semi-open or semi-closed system. Open systems rely on the animal's being placed in contact with an absorbent material soaked in the anesthetic liquid. There are descriptions of methoxyflurane being administered in a drip cone system. With the highly volatile anesthetics like halothane and isoflurane, very high concentrations of the gas will rapidly occur in the inspired air, causing acute anesthetic overdose and death. Tank systems used to induce anesthesia in small mammals should not be used in birds. These chambers prevent monitoring of the patient, create a potential for beak, head, neck or spinal trauma and release high concentrations of gas into the environment when the top is opened (Figure 39.3).

Semi-open systems rely on an Ayres T-piece, Y-piece, Norman elbow or Kuhn circuit that prevents the rebreathing of expired gases. Because of the relatively low resistance to air flow present in these systems, they are ideal for avian patients.

Semi-closed systems rely on the complete rebreathing of expired gases. The resistance inherent in the circuit makes them impractical for birds.

A non-rebreathing anesthetic system is recommended for patients under seven to eight kilograms (most birds). This reduces dead space and decreases the effort that the patient must exert in order to breathe. This is especially important in birds, because both expiration and inspiration involve active use of the trunk muscles. Either an Ayer's T-piece or Bain's circuit can be effectively used with most birds. Some clinicians prefer the Bain's circuit because in theory, the patient's expired gases warm the in-flowing gases and reduce the loss of body heat. This can be critical in birds because their small size predisposes them to hypothermia, and respiration is one of the major routes through which body heat is lost. In patients over seven to eight kilograms, conventional human pediatric supplies are adaptable, easy to obtain and easy to maintain. In larger avian patients (eg, ostriches), standard small animal anesthetic equipment and supplies are applicable.

A standard 0.5 liter reservoir bag can be used in some larger avian patients, but better control and monitoring of respiration can be achieved with a smaller volume bag specifically designed for birds. These can be handmade from plastic bags, or an inexpensive, disposable avian anesthesia bag is commercially available (Figure 39.4).[c]

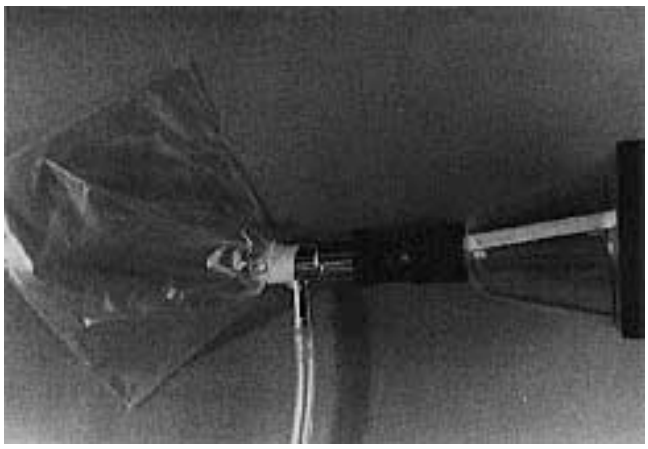

FIG 39.4 Anesthesia bags (50 ml, 100 ml and 250 ml) are commercially available for use in birds. These inexpensive bags account for the reduced tidal volumes of birds, allow for precise IPPV and are disposable, which prevents nosocomial infections. The bags can be adapted to any Ayres T-piece-type semi-open anesthetic delivery system (courtesy of Exotic Animal Medical Products).

An appropriate scavenging system is the best protection for operating room personnel from secondary gas exposure. Once the scavenging system is in place, gas exposure can be reduced by quickly intubating patients, minimizing the time the patient is wearing a mask and keeping flow rates as low as possible to prevent gas from escaping via the pop-off valve. End valves placed in the reservoir bag can be vented directly into the scavenging system.

Endotracheal Tubes

Non-cuffed infant, Magill or Cole (smallest size = 2 mm) endotracheal tubes can be used in medium- to large-sized birds (Figure 39.5). Cuffless tubes are used because birds have complete tracheal rings that cannot expand if excessive amounts of air are introduced into a cuffed tube. Alternatively, some clinicians choose to make their own endotracheal tubes out of red rubber feeding tubes. The end of the tube is snipped off and small holes are cut in the surface of the tube to allow for air exchange. The tip of the tube should be blunted by heating it with a flame and pressing it on a hard surface. These tubes are less costly than purchased tubes and have the added bonus of being disposable. In any situation, a tube with the maximum internal diameter that will fit in a bird's trachea should be used.

Face Masks

The delivery of inhalant gases from a precision vaporizer can best be achieved by manually restraining the patient and placing the nostrils and mouth in a face mask connected to an Ayres T-piece anesthetic circuit. Common canine or feline anesthetic masks, while not ideal, can be used for induction. Most small animal masks fit avian patients poorly, resulting in dilution of the anesthetic gas with room air. With these leaks, higher gas and oxygen settings are necessary in order to compensate for leakage (Figure 39.6). To avoid nosocomial infections, a disposable plastic drinking cup, with soft paper products placed between the cup and the patient's neck to prevent gas leaks, can be used as a face mask (Figure 39.7). In birds less than 150 g, an effective mask can be made by covering the end of a 12 cc syringe case with a section of latex glove. The syringe case can then be slipped over an Ayres T-piece with a 50 ml anesthesia nonrebreathing bag (Figure 39.8).

FIG 39.6 A small animal face mask can be used to induce gas anesthesia in medium and large companion birds.

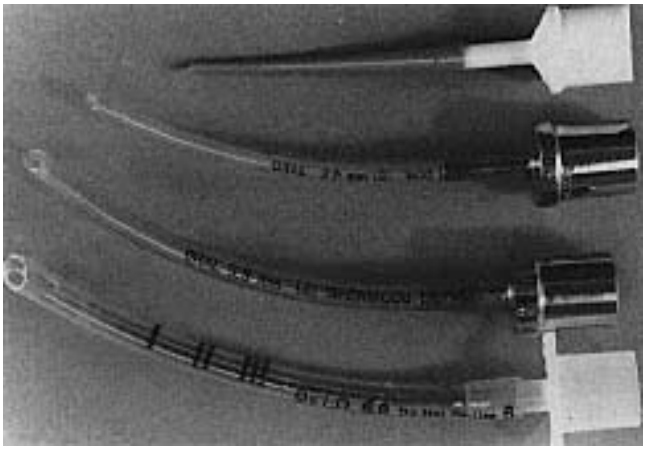

FIG 39.5 Non-cuffed, 2 mm endotracheal tubes are commercially available. These are generally small enough for use in birds over 150 g. In smaller birds, a red rubber feeding catheter with several holes cut in the end can be used as an endotracheal tube.

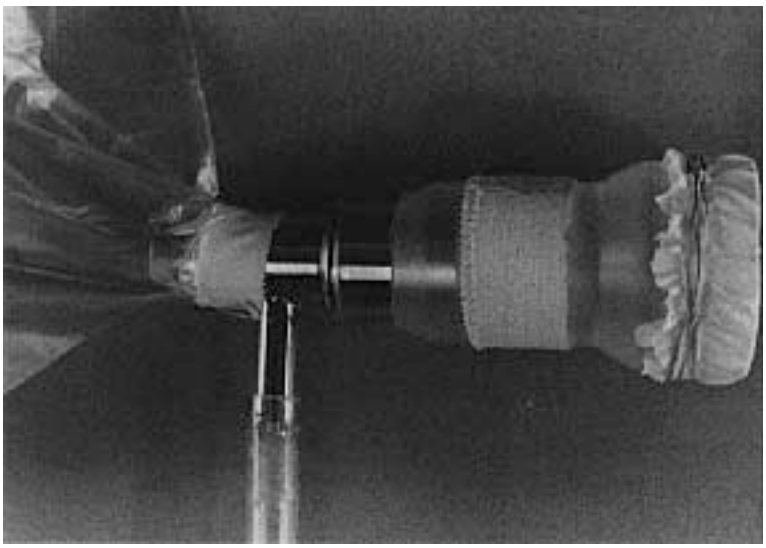
FIG 39.7 Using a disposable plastic cup as an induction mask prevents the transmission of respiratory pathogens (eg, chlamydial, viral, fungal) between patients. If small animal face masks are used, they must be cleaned and sterilized between avian patients.



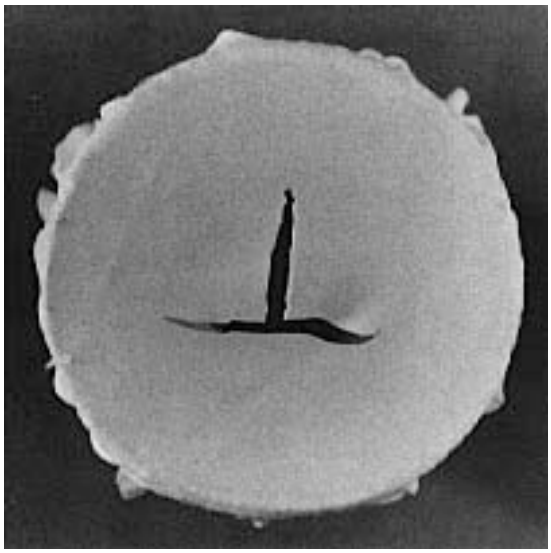


FIG 39.8 A 12 cc syringe case can be cut to fit over an Ayres T-piece and covered with a latex glove to be used as a disposable face mask in small avian patients.

Care of Equipment

The proper use and maintenance of anesthetic equipment is an often overlooked area.

With the large number of infectious bacterial, fungal and viral agents encountered in avian patients, any equipment used during anesthesia, including tubing and endotracheal tubes, should be thoroughly disinfected to reduce the chance of nosocomial infections. Equipment should not be used for other companion animals and then used for birds without sterilization. While the face mask and Ayres T-piece can be easily disinfected in cold sterilization solutions, anesthetic bags are much more difficult to disinfect.

Tubing, reservoir bags, face masks and endotracheal tubes should be thoroughly cleaned with soap and water, then rinsed with clear water. They should then be disinfected using a chemical disinfectant and rinsed again with clear water. Finally, they should be allowed to air-dry in a clean, dust-free location. Alternatively, they may be sterilized using ethylene oxide or, with some endotracheal tubes, a heat autoclave. Because this cleaning regime must be used with every anesthetic episode, a large reserve of equipment is necessary to handle a sizable avian patient case load. Many clinicians feel it is more economical to use disposable anesthetic supplies than to use technician time for cleaning equipment. Disposables, however, are more expensive and they contribute to the medical waste problem.

Delivery of Inhalant Anesthetics

Two methods of anesthetic induction with isoflurane have been discussed. One method is to place the bird in a face mask and slowly increase the gas to a level of 2.5 to 3%. However, the editors believe that the rapid induction achieved by using a 5% setting initially, followed by a decrease to maintenance levels of 1 to 2% is a better method. The amount of isoflurane delivered will vary with the patient, the individual anesthetic machine and the delivery system. Some macaws, owls and Galliformes appear to be particularly sensitive to gas anesthesia and may become apneic even with the use of isoflurane. Maintenance levels of anesthesia may be as low as 0.25% in sensitive individuals.

After induction, any patient that will be anesthetized for more than ten minutes should be intubated with an appropriately sized endotracheal tube (Figure 39.9). The amount of dead space should be minimized by ensuring an adequate gas flow and by using tracheal tubes of the proper length. The appropriate endotracheal tube length can be determined by measuring the distance from the thoracic inlet to the tip of the beak. The laryngeal structure of birds is highly mobile and can be manipulated from below the mandible to improve access for intubation.

Following intubation, the endotracheal tube can be connected directly to the semi-open system. If there is a possibility of regurgitation, the tongue and glottis should be pulled cranially, and the esophagus

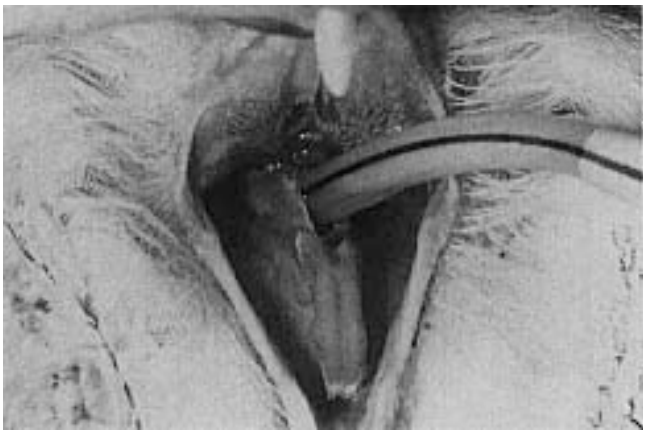

FIG 39.9 In some birds (like this owl), it is easy to visualize the glottis for intubation. In others (many psittacine birds), it is more difficult to visualize the glottis. Intubation can be simplified by placing a finger in the intermandibular space and gently lifting the glottis into view.

should be packed with moistened cotton to prevent aspiration.

Air Sac Administration

For surgery of the head, trachea or syrinx, anesthesia can be delivered by placing a short endotracheal or red rubber tube into the clavicular or caudal thoracic air sacs.[25,26] The placement procedure is rapid and may be indicated as an emergency tactic when an animal is presented with respiratory arrest or when severe dyspnea has been induced by foreign body aspiration. To place an air sac tube, the animal is positioned with the leg extended to the rear as for a surgical sexing procedure. A small skin incision is made over the sternal notch, and hemostats are used to produce an entrance through the body wall and into the left abdominal air sac (see Chapter 13). A shortened endotracheal tube can then be inserted into the air sacs and the Ayres T-piece connected directly to the tracheal tube.

A study in pigeons and common buzzards indicated that isoflurane could be safely administered through the air sacs to maintain a surgical plane of anesthesia for 60 minutes. These birds were monitored for changes in temperature, pulse rate, oxygen saturation, blood pressure and $paCO_2$ levels (Table 39.1). In this study a persistent period of apnea was noted when the air sac tube was perfused with oxygen. It was suggested that the loss of CO_2 present in the lungs and air sacs decreased the stimuli to the respiratory centers and induced the apnea. No assisted respiration techniques were used during the 60-minute period of apnea.[16]

At the end of the 60-minute study, the birds were flushed with oxygen to remove residual isoflurane and their $paCO_2$ levels dropped to 19. This hypocapnia was followed in four minutes by the return of spontaneous respiration, which was associated with an increase of $paCO_2$ levels (40 in the pigeons, 31.7 in the buzzards). Arrhythmias were common in the pigeons starting around 50 minutes after induction. The part that hypothermia played in inducing arrhythmias could not be determined. The mean recovery time to standing was 10 to 12 minutes. A metabolic alkalosis occurred throughout the anesthetic episode that was attributed to the decrease in $paCO_2$.[16]

TABLE 39.1 Mean Effects of Air Sac Anesthesia with Isoflurane[16]

	Pigeon	Buzzard
Temperature (°C)	37.3 (41.5)	38.7 (41)
ApH	7.62 (7.36)	7.67 (7.51)
paO_2	426 mm Hg	360 mm Hg
$paCO_2$	19.2	19.1
Pulse rate	93.1 (172)	232 (301)
Blood pressure	64.6 mm Hg (106)	119.7 mm Hg
O_2 saturation (pulse oximeter)	98.1%	99%

Normal is listed in parenthesis. ApH = arterial pH, paO_2 = partial pressure of oxygen, $paCO_2$ = partial pressure of carbon dioxide.

Management of the Anesthetic Patient

Patient Evaluation

Isoflurane can be used for two distinct purposes in the avian practice. One is for long-term general anesthesia needed to perform difficult diagnostic procedures and surgeries. The other is as an anesthetic to provide short-term restraint and to facilitate the ease of performing fluid administration, blood collection, radiography, endoscopy or bandage changes (Figure 39.10).

The goal of a preanesthetic evaluation is to detect and correct any underlying pathology prior to inducing anesthesia. In some cases, several days or weeks of supportive care may be needed in order to ade-

FIG 39.10 Isoflurane is generally safe to use for short procedures (eg, radiography, endoscopy, blood collection) in patients with only a history and a physical examination. If a bird will be anesthetized for more than ten minutes, a complete database should be obtained to assess the stability of the patient.

quately stabilize a compromised patient before anesthesia can be safely administered. In other cases, eliminating abnormalities may not be possible, and consequently, adjustments must be made in inducing and monitoring anesthesia to ensure a successful outcome.

The minimum database is designed to help the anesthetist develop a list of risk factors associated with general anesthesia in a given patient and to develop evaluation methods or supportive care techniques that decrease the anesthetic risk. The patient evaluation associated with the use of isoflurane for short-duration procedures (five to ten minutes) is generally limited to a thorough history and physical examination. The theory in using isoflurane for short-term procedures with a limited database is that this drug has a wide therapeutic index and has consistently been shown to be relatively safe even in severely compromised patients.

If a bird is going to undergo anesthesia for more than ten minutes, then in addition to the history and physical examination, a minimum database ideally should include a fecal parasite check, Gram's stain of feces and choana, PCV, TP, WBC with differential, a platelet estimate, estimated clotting time, bile acids, AST, LDH and UA. Additional tests may be indicated depending on the initial assessment and the type of procedure requiring anesthesia.

Risk Classification

Successful risk classification depends on conservative evaluation of the minimum database. Practically, risk assessment allows one to estimate the duration of safe anesthesia, the intensity of monitoring required and the supportive care and technical assistance needed to ensure patient safety. It also provides the clinician with a prognostic perspective to be discussed with the owner (see Table 39.2).

It can be successfully argued that few avian patients requiring anesthesia are Class I. Most patients are Class IV and V. With careful supportive care, a clinician can reduce the anesthetic risk factors of many Class IV and V patients to those of Class II or III patients.

A commonly encountered complication of anesthesia in birds is liver dysfunction. Hepatopathies may be suspected when performing the initial physical examination and confirmed with findings of lowered protein levels, elevated or depressed bile acids and tissue enzyme values, and radiographic findings of hepatomegaly, or conversely, a loss of liver mass. Liver dysfunction may reduce a patient's ability to metabolize anesthetic agents and may also be associated with coagulopathy. The use in these patients of any anesthetic drug that is dependent on the liver for metabolism is contraindicated (most injectables, halothane, methoxyflurane). Supportive care designed to improve liver function may be necessary before anesthesia. If anesthesia cannot be postponed to allow

TABLE 39.2 Risk Classification of Potential Anesthesia Patients

Class I *(minimal risk)*	Young, healthy patient undergoing an elective procedure.
Class II *(some risk)*	Young, healthy patient undergoing a non-elective procedure, or a healthy patient undergoing an elective procedure.
Class III *(risky)*	Patient with an ongoing health problem undergoing a procedure for this or another problem.
Class IV *(very risky)*	Patient with a major health problem (unstable in nature) undergoing a procedure.
Class V *(moribund)*	Last ditch effort to save bird's life.

sufficient stabilization, then anesthetic agents that are minimally metabolized by the liver (eg, isoflurane) and vitamin K injections to help promote clotting are suggested.

Obesity is common in companion birds. Excess fat deposits interfere with the patient's ability to ventilate. Respiratory effort is further compromised when a bird is anesthetized and placed in abnormal body positions for surgery. With elective procedures, dietary changes and treatment for underlying metabolic disorders are indicated before general anesthesia is performed.

Surgery is frequently required for egg-related peritonitis, especially in small species (eg, cockatiels, lovebirds, budgerigars). These patients should be carefully stabilized prior to anesthesia. This stabilization process may take weeks and in some cases render surgical intervention unnecessary. An abdominal tap and diuretic therapy are indicated prior to anesthesia to reduce the volume of fluid in the abdomen and to improve the patient's ability to breathe.

These patients should be maintained in an upright position to prevent abdominal fluid and debris from entering the lungs through rents in the air sacs. The surgery table should be tilted so that the patient's head is slanted up.

In non-elective procedures on obese patients or those with an abdominal fluid accumulation, proper intubation is mandatory to ensure a patent airway. Gentle IPPV will help maintain adequate oxygenation. Keep in mind when providing IPPV that the avian lungs inflate minimally, and pressure placed on a breathing bag should be less than 15 mm H_2O to prevent rupture of the air capillaries.

Preanesthetic Stabilization and Preparation

Nutritional Therapy

For elective procedures, inadequate diets should be corrected three to four weeks before surgery. For specific nutritional requirements and nutritional support of surgical patients, see Chapters 3, 15 and 40.

Fluid Therapy

Fluid therapy is an important aspect of supportive care that should be provided to avian patients. Many sick birds presented for evaluation have been off food and water for at least a day, often longer. With their high metabolic rate, birds rapidly become dehydrated. Correcting dehydration will dramatically improve the patient's ability to physiologically cope with anesthesia.

It has been suggested that all birds suffering from trauma and disease can be assumed to be at least ten percent dehydrated, and that the following formula should be used to calculate their fluid requirements: normal body weight (grams) x 0.1 (10%) = fluid deficit in ml. The dose for maintenance fluid is estimated at 50 ml/kg/day.[24]

Calculated fluid requirements can be administered in severely dehydrated patients by an intravenous or intraosseous route (see Chapter 15) (Figure 39.11).[17,30] Fluids administered by oral or subcutaneous routes are not as effective in restoring or maintaining circulating volume.

FIG 39.11 Placing an intraosseous cannula in the tibiotarsal bone is an excellent way to provide fluids to a patient during surgery. In comparison to catheters in peripheral vessels, intraosseous cannulas are much easier to maintain. Intraosseous cannulas placed in the tibiotarsus can also be used in critically ill patients for intermittent fluid, blood or drug administration.

Lactated Ringer's solution is the fluid of choice. This balanced electrolyte solution protects renal function better than sugar solutions.[23] Five percent dextrose is not a satisfactory replacement solution because the dextrose is metabolized, leaving free water.[23] Fluids administered to anesthetized birds should be heated (96°F) to prevent hypothermia.

Fluids must be carefully administered to birds to prevent volume overload. The maximum acute fluid load that can be tolerated by healthy patients is 90 ml/kg/hr.[14] In a cockatiel this would be a maximum of 9 mls in an hour or 0.15 mls per minute. Most avian patients, however, are unstable and cannot tolerate such a high rate and volume of fluid administration.

Electrolyte levels and acid-base balance should always be of concern in the anesthetic candidate. Some newer analyzers use small volumes (10 µl) of serum, providing clinicians access to actual values to use in assessing the status of their patients. If no means of determining the bicarbonate deficit is available and the patient is dehydrated or critically ill, the administration of 1 mEq/kg of bicarbonate at 15 to 30 minute intervals to a maximum of 4 mEq is suggested.[24]

Fasting

Recommendations concerning fasting of birds prior to anesthesia have varied from no fasting to an overnight fast.[12,13] Practically speaking, the patient should be kept off food long enough for the upper gastrointestinal system to become empty. This process takes overnight in large birds and four to six hours in smaller birds. One should palpate the crop and postpone surgery if it is not empty. In an emergency, a patient with food in the crop should be held upright during the induction procedure, with a finger blocking the esophagus just below the mandible. Once the animal is anesthetized, the crop can be emptied by placing a finger covered with cotton or gauze over the choanal slit to prevent food entering the nasal cavity, turning the bird upside down and manually emptying the crop and esophagus. The esophagus can then be packed with gauze, and the head and neck positioned on an upward slant to minimize the chances of passive regurgitation. The trachea should be intubated using an appropriately sized tube.

Patient Monitoring

The goal in any anesthetic episode is to maintain the lowest possible level of anesthesia to achieve necessary restraint. Anesthetic planes in birds are difficult to observe from outward signs, and depth should be monitored by combining information obtained from heart rate monitored by either an ECG or doppler, respiratory rate and effort, toe pinch, palpebral and corneal reflexes and wing tone. The rates will vary depending on the species (Table 39.3). A doppler can be placed on either the cranial tibial or medial metatarsal arteries.

TABLE 39.3 Heart Rates and Respiratory Rates in Birds Anesthetized with Isoflurane

	Beats Per Minute	Breaths per Minute
Budgerigar	600-750	55-75
Cockatiel	450-604	30-40
Pigeon	93.1±5.4[16]	15-25
Parrot	120-780	10-20
Ostriches[4]	60-72	2-20

Anatomic locations to evaluate the reflex response to pain or touch in avian patients include palpebra, cornea, cloaca, propatagium, cere, interphalangeal area, pupils (response to light) and pectoral muscles.[16]

In a light plane of anesthesia, the patient has a palpebral, corneal and pedal reflex but has lost voluntary motion. The ideal anesthetic level, as described in one study,[16] was when the bird's eyelids were completely closed and mydriatic, the pupillary light reflex (pupillary response to light) was delayed and the nictitating membrane moved slowly over the entire cornea. The muscles were relaxed and all pain reflexes were absent. The loss of a corneal reflex (no reflex closure of the lid after touching the peripheral cornea with a dry swab) was considered to indicate deep anesthesia.[16]

The respiratory rate should be slow and deep. If a patient becomes too deep, all reflexes will be lost and the respiratory rate will be slow and irregular. Wing flutter is often an early indicator that an animal is

CLINICAL APPLICATIONS

Anesthetic planes may be monitored by:

- Rate and depth of respiration
- ECG
- Heart rate — doppler
- Toe pinch
- Palpebral reflex
- Temperature
- Wing flutter
- Lid closure
- Pupillary dilation
- Pupillary reflex
- Corneal reflex

becoming light. An excellent plane of anesthesia for most procedures can be accomplished by reaching a depth of anesthesia where wing tone has just disappeared. If injectable agents have been used, the traditional planes of anesthesia may not be present, making evaluation of the patient more challenging.

Body Temperature

Physiologically, birds are actually less efficient homotherms than mammals and as a result undergo more rapid changes in body temperature during anesthesia. Loss of heat during surgical anesthesia is a very important factor in anesthetic survival and in the rate of return to a physiologic normal state following anesthesia. Besides a loss of physiologic responses to reduced core temperature, hypothermia is also induced during surgery by removal of large areas of feathers to expose surgical sites, by the constant flow of cool anesthetic gases through the respiratory tract, by the liberal use of alcohol, by body contact with a cold conductive surface and by the length of the procedure. Even with supplemental heat, it is not unusual to have rapid reductions in core temperature during anesthesia. Any degree of hypothermia compromises the patient's ability to recover from anesthesia. While supplemental heat will not prevent the drop in core temperature seen with anesthesia, it does tend to reduce the speed of heat loss.

All patients undergoing long surgical procedures should be placed on water circulating heating pads. Keep in mind that these devices need at least a 20-minute warmup period before they reach the preset temperature. The clinician may choose to minimize the amount of alcohol used in the surgical scrub and instead use chlorhexidine or povidone iodine to minimize heat loss through evaporation. Body temperature loss may also be minimized through the use of heat lamps, heated lavage solutions, heated IV fluids or hot towels wrapped around non-rebreathing tubes. Hypothermia occurs in birds despite their being placed on water circulating pads.

Body temperature (normal=105 to 107°F[28]) can be constantly monitored during anesthesia to properly evaluate the degree of heat loss. A patient under anesthesia will experience a time-related reduction in body temperature (maybe as much as 10°F), which can predispose to cardiac arrhythmias and increased recovery times. If severe hypothermia (loss of greater than 10°F) occurs, the patient may not recover at all. Traditional thermometers can be used to record this data, but they require cloacal insertion and take three to five minutes to give an accurate reading. Electronic thermometers also require cloacal insertion and take two to three minutes to give a reading. A more practical option is a tympanic scanner,[d] which gives a reading in five to six seconds. The monitors are easy to use by applying the probe to the outer surface of the ear. Tympanic temperatures are consistently slightly higher than cloacal temperatures.[21]

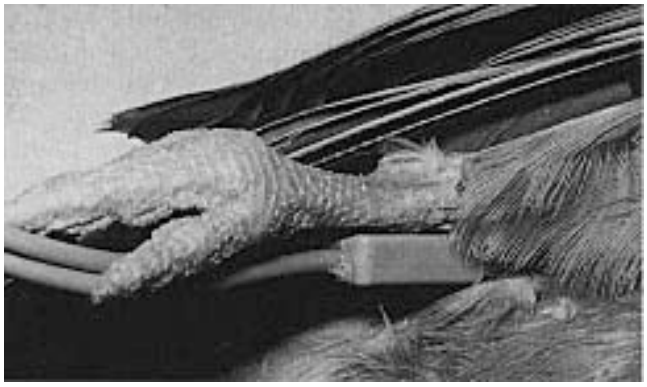

FIG 39.12 A doppler probe placed on the medial metatarsal artery can be used to monitor the heart rate during anesthesia.

Heart Monitoring

Heart rate in avian patients can be monitored in several ways. Palpation at the point of maximum intensity is possible in some patients (see Table 39.3). Peripheral pulses can be used but are often difficult to detect in smaller patients. Auscultation via a stethoscope is possible, although the chest may be difficult to reach once the patient is draped for surgery. Esophageal stethoscopes equipped with pediatric tubing can be used for auscultation of the heart in avian patients the size of Amazon parrots and larger. This monitoring system allows direct auscultation of the heart without having to go near the surgical field. If correctly positioned, the esophageal stethoscope can also be used for monitoring respiration. Dopplers can be used, but are extremely positional in nature and difficult to maintain in birds (Figure 39.12). Some oximetry units provide pulse rates up to 250 bpm; these units are easy to use and are not positional like the doppler. In a group of cockatiels maintained in a surgical plane of anesthesia, the heart rate remained above 450 bpm.[12] In one study with pigeons and common buzzards, the pulse rates determined by the oximeter were consistent with those determined through a direct arterial line.[16] In an emergency situation, a heart rate can be quickly obtained by placing the doppler probe on the globe of the eye. An ECG is an excellent way to monitor the

depth of avian anesthesia. As a bird gets deeper, the T-waves become smaller and may totally disappear. As the depth further increases, the R-wave will increase in magnitude and the S-wave is reduced.

Respiratory Rate

Respiratory rates during anesthesia should be slow and regular (see Table 39.3). Hyperventilation or rapid jerky motions are indications of ensuing problems. An increase in the respiratory rate may indicate that a bird is entering a lighter plane of anesthesia, that the bird is having difficulty breathing (occluded tracheal tube) or that the bird has an elevated $paCO_2$. Because surgical patients are draped, it is often difficult to observe respiratory effort. Direct visualization of chest movement as an indication of respiration can be facilitated by using clear sterile surgical drapes.[e] An anesthetic bag[c] designed to deal with the lower tidal volumes of birds will also make it easier to monitor respiration.

When using halothane or methoxyflurane, apnea and cardiac arrest may develop at the same time without prior warning. With isoflurane, apnea usually proceeds cardiac arrest by several minutes. Halothane typically induces a rapid decrease in heart rate that returns to normal shortly after ceasing gas administration.

Apnea monitors do work in birds; however, less expensive units may not be sensitive enough to detect the respirations of smaller patients. The monitoring device that attaches to the endotracheal tube is heavy, and precautions must be taken to keep the weight of the monitor from kinking small diameter tubes. These units also require that the patient be intubated. A unit intended for use in birds should be evaluated on avian patients prior to purchase.

Blood Pressure

Blood pressure can be monitored directly or indirectly and should remain above 100 mm Hg. Except in a research situation, it is unlikely that most practitioners are going to opt for direct blood pressure monitoring due to the cost and invasiveness of the procedure. Although indirect monitors that use pediatric cuffs are available and offer some promise for use in avian patients, they are less reliable for smaller patients. Appropriate responses to patients with decreased blood pressure values include reduction of anesthetic levels, administration of IV fluids, correction of hypothermia and evaluation and correction of blood loss.

CLINICAL APPLICATIONS

Emergency Steps for Respiratory Arrest

- Disconnect bird from anesthetic
- Press on sternum 40 to 50 cycles/min
- Intubate or apply air sac tube
- IPPV through tube

Blood Gases

Arterial blood gases can be assessed directly by running arterial samples on a blood gas machine. This is not practical for most practitioners and it may involve taking multiple blood samples, a procedure that smaller patients cannot tolerate. Indirect assessment of blood oxygenation can be done via an oximeter. An oximeter records the percentage of circulating oxygenated blood via a noninvasive probe.[10] The unit works by spectrometrically measuring the difference in absorbance between reduced hemoglobin and oxyhemoglobin. Oximeters are not as sensitive at direct determination of arterial blood gases, and oximeter readings at 98% saturation are common in birds that are actually 100% saturated.[16] The author has found that the oximeter probe can be attached to the wing web, toe, tongue or the area over the tibiotarsal bone. The tibiotarsal area seems to give the most consistent and reliable readings. The probe is small and requires only one wire so it is easily used during surgery. Additionally, many oximeters are actually pulse oximeters that produce an audible beep, allowing the anesthetist to monitor heart rate as well as oxygen saturation levels. Ideally, oxygen saturation levels should be above 90%. A reading below 80% should be considered life-threatening. Most birds will maintain an oxygen saturation between 80 to 85% when self-ventilating. Use of IPPV to increase oxygen saturation is, therefore, valuable. Normal blood gas values of $paCO_2$=19, paO_2=400 and ApH=7.4 have been reported.[20]

Anesthetic Emergencies

With careful assessment of patients, conscientious supportive care and thorough monitoring, many anesthetic-related emergencies can be prevented.

Respiratory Arrest

If respiratory arrest occurs, the anesthetic system should be disconnected from the bird and the chest should be lightly pressed and released to induce air intake, or fresh air can be gently delivered into the tracheal tube. If the patient is not intubated, an air sac tube should be placed or the animal should be immediately intubated. The practitioner must keep mind that air sac intubation may result in apnea while the paO_2 is increasing and the $paCO_2$ is decreasing.

If respiratory arrest occurs in response to injectable anesthetics, the reversal agent should be administered intravenously. The administration of doxapram HCl on the tongue may help stimulate respiration. The pulse rate should be carefully monitored and resuscitation should continue until the bird is breathing unassisted. Birds that show respiratory arrest should be rescheduled for the procedure; a second or third episode of apnea in these cases is often followed by cardiac arrest.

Cardiac Arrest

Cardiac arrest represents a poor prognosis. Resuscitation efforts are often unsuccessful. If success is to be achieved and cardiac arrest truly does exist, the clinician should be aggressive and utilize open heart massage. The rate should be 60 or more compressions per minute and they should be accompanied by coordinated artificial ventilation. These efforts should be continued for up to five minutes. Although rare, some birds may recover following cardiac arrest.

Hemorrhage

If hemorrhage occurs during surgery, a significant portion of that loss can be replaced via fluid therapy using isotonic solutions. If hemorrhage is severe, a transfusion will be necessary (see Chapter 15).

Postanesthetic Monitoring and Recovery

Anesthetic recovery should occur in a pre-heated environment, preferably a pediatric or avian incubator. The safest approach to post-anesthetic monitoring of a patient is to leave all of the monitoring devices in place until the patient absolutely will not tolerate them. Patients should be recovered where they can be easily observed. Birds should not be left unsupervised until they are perching without difficulty.

Recovery from injectable anesthetics will be much more prolonged and if ketamine has been used, potentially traumatic. Anesthetic recovery is best accomplished by wrapping the bird in a towel to prevent wing-flapping and self-inflicted trauma. The lights should be dimmed and the noise level kept to a minimum to prevent violent reactions. The patient should be rolled over every few minutes, and the pharynx should be monitored for the accumulation of mucus or vomit. In severely depressed birds, IPPV can be continued until the patient is no longer willing to tolerate the tracheal tube. Recovery from even long anesthetic episodes with isoflurane generally requires less than five minutes. The administration of a reversal agent is indicated when appropriate.

CHAPTER

40

SURGICAL CONSIDERATIONS

R. Avery Bennett

Many avian patients are small and delicate, increasing the risks associated with surgery. Seemingly minor hemorrhage can be life-threatening in patients with such a small blood volume. Their high metabolic rate, small body size, and high ratio of body surface area to body volume predispose them to intraoperative hypoglycemia and hypothermia, the risks of which increase as the duration of anesthesia and surgery increases. These factors make it crucial that the avian surgeon not only have the procedure well thought out, but also have any necessary equipment ready and accessible. Exactness, precision, advanced preparation and minimal anesthesia time are the keys to success in avian surgery.

Avian blood vessels are relatively thin-walled, tend to course in a more superficial manner and are less protected by surrounding tissues than in mammals. Because there is less perivascular tissue in birds, vessels are prone to move within the tissues and retract from the surgeon's view. Even after radiocoagulation, vessels may relax and begin to leak blood after they retract into the tissues. The avian surgeon must frequently re-evaluate vessels for recurrence of hemorrhage and should be meticulous with hemostasis to prevent surgically induced hypovolemia. With the aid of magnification, small blood vessels can be identified, isolated and coagulated, minimizing the risk of recurrent hemorrhage.

Surgery is frequently a life-prolonging procedure when applied correctly to a properly conditioned avian patient; however, birds with severe nutritional and metabolic abnormalities do not have the capacity for long-term recovery from many anesthetic and surgical episodes. The most common cause of problems associated with elective surgeries is inadequate presurgical evaluation of the patient, which prevents proper post-surgical recovery. Although some surgical procedures must be performed on an emergency basis without the benefit of a complete medical evaluation and preconditioning, in many situations there is adequate time to accumulate clinical data. In some cases, surgery should be delayed in the patient's best interest.

Patient Evaluation

When possible, a clinical database acquired prior to surgery should include a complete history, physical examination and laboratory data. A minimum database for any preoperative evaluation should include hematocrit, total serum solids and WBC. If possible, a complete blood chemistry profile, whole body radiographs, electrocardiogram and cultures, if indicated, should be obtained. A blood glucose is useful in Anseriformes and raptors.

Patients with blood glucose of <200 mg/dl should receive 5% dextrose IV intraoperatively. Patients with total serum solids of <2 mg/dl are usually severely debilitated and are poor candidates for surgical recovery. A hematocrit >60% is indicative of dehydration, and fluid therapy should be instituted. If the hematocrit is <20%, surgery should be delayed or a whole blood transfusion should be administered. Blood transfusions are best made from donors of the same species; however, heterologous transfusions appear to be safe and efficacious.[7,26] A serum uric acid of >30 mg/dl indicates dehydration (prerenal) or renal disease. Surgery should always be postponed until a patient is adequately hydrated. The hematocrit and total serum solids can be used to determine whether primary renal disease is a factor.

Serum cholesterol, AST and LDH activities may be helpful in evaluating the preoperative condition of a patient. Of 54 birds used to evaluate various anesthetic agents, three deaths occurred, two of which had preanesthetic serum parameters: AST=>650 IU/l, LDH=>600 IU/L and cholesterol=>700 mg/dl. Many of the birds that survived had high AST and LDH activities but not in combination with a high serum cholesterol level.[17]

Respiratory recovery time is determined by the time it takes a bird to return to a prestressed respiratory rate following two minutes of handling. A return to normal respiratory rate within three to five minutes indicates respiratory stability adequate for most anesthetic and surgical procedures. Periods longer than five minutes indicate severe respiratory compromise.

The bird's nitrogen balance should be addressed, especially in birds that have been anorectic for several days. In a properly hydrated bird, an increase in body weight is a good indicator of a positive nitrogen balance.

Birds have relatively little glycogen stored in the liver. A decrease in blood glucose and insulin combined with an increase in glucagon stimulate hepatic glycogenolysis. Liver glycogen stores may decrease as much as 90% during a 24- to 36-hour fast and potentially quicker in smaller birds.[21] Vomiting and regurgitation may occur if the patient is not fasted, and can result in aspiration pneumonia (see Chapter 39). A short fast of five to eight hours will help decrease the probability of aspiration pneumonia and will have minimal effects on blood glucose.[20] In emergency situations when the digestive tract is full, it should be partially emptied before the bird is placed in dorsal recumbency (see Chapter 39).

When significant hemorrhage is anticipated, intraoperative IV fluid therapy should be provided. A patient may be suspected to have a clotting disorder if perifollicular bleeding occurs during surgical preparation. When a mature feather is removed, there should be virtually no hemorrhage around the follicle.

Nutritional Support

Little is known about the nutritional requirements of the various species of companion and aviary birds. Even less is known about how stress, such as surgery, increases the nutritional and caloric requirements of avian patients. In contrast to starvation, stress may cause an initial hypometabolic state followed by hypermetabolism,[32] which increases the body's need for protein. Protein is necessary for tissue repair, antibody production and blood cell production, all of which are necessary for postsurgical recovery. Carbohydrates (not fats) are nitrogen-sparing energy sources that best correct a stress-related negative nitrogen balance.[32] The postoperative surgical patient must have a positive nitrogen balance to facilitate tissue repair, and a source of nonprotein energy to meet increased caloric requirements.

The basal metabolic rate (BMR) of inactive animals may be determined using the formula BMR kcal/kg/24 hr = $K(BW_{kg}^{0.75})$ (see Chapter 15). Additional energy is required for growth, reproduction, disease and tissue repair and is defined as productive energy (the amount of energy a bird mobilizes above the requirements for existence).[41] Stresses such as severe trauma, head injury and sepsis increase the patient's energy requirements 1.5 to 3.0 times the minimum energy requirement.[13,32] Birds have a higher

requirement for protein,[13,32] and their amino acid requirements are different from those of mammals.

Liquid diets that can be used to provide assisted alimentation to pre- or postsurgical patients are commercially available.[13,14,32] Hyperosmolar diets should be diluted (1:1) with water. Only 25% of the calculated requirements should be provided initially in order to prevent diarrhea. Over a period of two to three days, the concentration and volume of formula are gradually increased as the intestines adapt to the hyperosmolar solution.[40]

The patient's water requirements must also be met. When using hyperosmolar diets, water may be pulled into the intestine, which contributes to dehydration. Water requirements vary with species, diet, size, age and environmental temperature (see Chapter 15).[32]

Patient Preparation

Feather Control

In preparing the skin for surgery, feathers surrounding the proposed surgical site should be gently plucked for a distance of two to three centimeters. The contour and covert feathers of the body grow in pterylae or tracts, which are separated by featherless areas (apteria). These feathers may be easily and safely removed individually if plucked in the same direction as their growth. The large flight feathers (remiges and retrices) are attached to the periosteum of the underlying bone and have highly developed feather muscles and ligaments. Removing these feathers is painful and is best accomplished while the patient is anesthetized. When flight feathers must be removed, they should be removed individually by holding the feather at its base and pulling in the direction of feather growth. To avoid injury to the skin, muscles and periosteal attachments, the other hand is used to carefully secure the tissues at the base of the feather while it is being removed (see Figure 15.12).[28]

Small feathers should be pulled in groups of three or four in a direction opposite their growth.[1,18,28] If the skin has been damaged or torn, the feathers in this area can be cut to avoid further damage to the skin.[10] Cut feathers are replaced only during the normal molt cycle.

Excess feather removal will reduce a bird's insulating ability, increase metabolic demand during the recovery period (energy used to regrow the feathers)[28] and, if primary or secondary feathers are removed, the bird will not be able to fly until they regrow. The removal of primary and secondary feathers should be avoided because it is easy to damage the follicle, resulting in the growth of malformed replacement feathers. Flight feathers are molted one at a time and require the structural support of the adjacent feathers for proper growth. Because the skin of birds is very fragile and tears easily, removal of feathers is a delicate procedure, and attempting to remove too many feathers too quickly may result in bruising and tearing of the skin. Feathers in adjacent pterylae can be retracted using a stockinette, masking tape or water-soluble gel.[1,18,28] Water-soluble gels will prevent clear plastic drapes from properly adhering to the skin and should not be used in this situation.

Creating a Sterile Field

Standard aseptic technique[30,39] must be adhered to when performing surgery on avian patients. Poor technique may have devastating consequences. Skin preparation solutions are used to decrease the number of bacteria present on the skin surface to minimize the risk of bacterial contamination of the surgery site. They should accomplish this objective without damaging the skin and predisposing the patient to dermatitis.[27]

Concentrations of chlorhexidine diacetate (0.05%)[a] and povidone iodine (1.0%)[b] are effective for skin preparation. Although studies have shown these concentrations to be cytotoxic *in vitro*, they do not have a significant clinical effect on wound healing. Chlorhexidine gluconate (4%)[c] is equally effective when rinsed with saline or alcohol. A saline rinse has been found to leave sufficient residual chlorhexidine gluconate bound to the skin to be effective. This is beneficial in avian patients where the use of alcohol predisposes to hypothermia. When povidone iodine (1%) was used as a skin preparation, approximately

CLINICAL APPLICATIONS

Clinical pathology parameters for which postponement of surgery may be necessary include:

- PCV: <20% - delay surgery or provide blood transfusion
  >60% = dehydration; give fluid therapy
- Total solids: <2 mg/dl = severe debilitation
- Blood glucose (raptors, Anseriformes): <200 mg/dl - give 2.5-5% dextrose
- Uric acid: >30 mg/dl = dehydration (prerenal) or renal disease
- AST: >650 IU/dl
- LDH: >600 IU/dl
- Cholesterol: >700 mg/dl

50% of the treated dogs developed erythema, edema, papules, wheals and "weeping" of serum from the skin surface.[27] Chlorhexidine is generally preferred over povidone iodine solution as a patient preparation[27] because it has a broader spectrum of antimicrobial activity, longer residual antimicrobial activity, is efficacious in the presence of blood and organic matter and is nontoxic and hypoallergenic. However, in clinical settings, the type of scrub solution used has not been found to affect the rate of wound infections.[34]

It is challenging to create a sterile field of the wing because of the large flight feathers, which should not be removed unless absolutely necessary. The primary and secondary flight feathers can be wrapped together with masking tape. The surgeon can then cover the entire wing with a sterile stockinette or self-adherent bandage material[d] creating a sterile field (Figure 40.1).[28]

Patient drapes are currently available in a variety of sizes, shapes and materials. With avian patients clear drapes are recommended, as they allow the surgeon and anesthetist to visually monitor the patient during the procedure. Clear plastic drapes are commercially available[e] with or without povidone iodine impregnation. These drapes have an adhesive that will stick to dry avian skin and create a sterile field, but must be removed with care to prevent damaging the tissue. These drapes conform closely to the patient's body, are lightweight, disposable and inexpensive, and allow the anesthetist to monitor respiratory movements. As an alternative, a clear plastic drape can be made from plastic kitchen wrap. The border of the plastic should be edged with masking tape, making it easy to find the edges and open the drape. These drapes can be folded with a sheet of plastic but must be gas sterilized and are not adhesive.

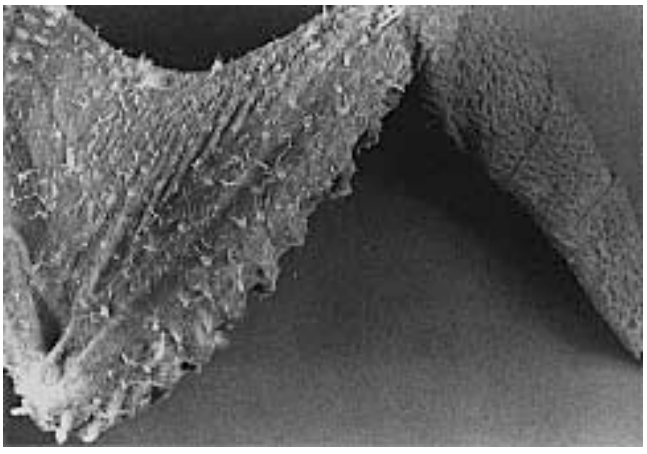

FIG 40.1 Feather removal in preparation for surgery should be sufficient to allow the establishment of a sterile field but not so severe that the bird is predisposed to hypothermia. In this case, the feathers from the mid-diaphysial humerus to the carpus were removed to prepare the bird for the placement of an external fixator to repair a fractured ulna. The primary feathers were clipped and wrapped in a self-adherent bandage material to facilitate the creation of a sterile field without removal of the primary feathers.

In most cases, the plastic drape is small and does not allow the surgeon to create a sterile field incorporating the entire surgery table and instrument stand. In order create such a field, the clear plastic drape is placed over the patient and a large drape sheet with a central fenestration large enough to allow the draped patient to be exposed, is placed over the entire field. This will prevent accidental contamination of the arms and elbows by touching them to an undraped table.

Perioperative antibiotic therapy involves the use of antibiotics such that there are therapeutic tissue levels of the agent present at the time of exposure to bacteria. With most antibiotics, parenteral administration one to two hours preoperatively, and maintaining therapeutic doses for 8 to 16 hours postoperatively, will accomplish this goal. Unless there is infection or significant contamination, use of antibiotics beyond this period is not indicated and has been shown not to decrease the incidence of surgical wound infections.

Wound Healing

Wound healing has been thoroughly studied in mammals, and five phases have been described: the inflammatory stage, the fibroblastic phase, the epithelialization phase, the contraction phase and the remodeling phase.[29,31] The cellular and vascular events of the inflammatory phase have been studied in chickens.[2,8,10,24,25] The inflammatory response in birds is similar to that classically described in mammals with early vasoconstriction to initiate hemostasis, followed by vasodilation within 30 minutes.[25,31] Bradykinin, histamine, 5-hydroxytryptamine and other chemical mediators initiate the acute inflammatory phase of wound healing in birds.[2] During the first two to six hours, large numbers of heterophils, basophils and monocytes migrate into the wound margins.[8,25] Phagocytosis of cellular debris and bacteria begins during this phase. After 12 hours there is a shift in the cellular response from one of primarily polymorphonuclear leukocytes initially to one of primarily mononuclear cells such as lymphocytes, plasma cells, macrophages and monocytes.[25] During the next 36 hours, macrophages and multinucleated giant cells begin to phagocytize those leukocytes that

have been involved in the early phagocytosis of tissue debris and bacteria. Fibroblasts begin to appear at the wound margins and proliferate over the next few days.

As soon as necrotic tissue, blood clots and other debris are removed by phagocytic cells, fibroblasts move into the damaged tissue. In the inflammatory phase, the exudate contains fibrinogen, which is converted to fibrin by the release of tissue enzymes. This acts as a hemostatic barrier and a scaffolding for other repair elements such as the incoming fibroblasts. New capillaries enter immediately behind the migrating fibroblasts. They contain plasminogen activator that is necessary for the breakdown of the fibrin. Collagen is synthesized during this fibroblastic phase beginning on the third or fourth day in birds[8] and on the fourth or fifth day in mammals.[31] The collagen bundles are initially small, but gradually enlarge to form dense collagen networks that bind the edges of the wound together. The fibroblastic phase of healing lasts two to four weeks. As the content of collagen increases, the number of fibroblasts decreases, and the capillaries begin to regress. Eventually, the rate of collagen production roughly equals the rate of collagen destruction.[31]

The epithelialization phase is characterized by the migration of epithelial cells from the wound margin. The epidermal basal cells are normally adhered to each other. These adhesions break down, allowing the cells to be mobilized. The cells enlarge and migrate down and across the wound. These cells do not begin to proliferate until the entire wound surface has been covered by a single layer of epithelial cells. Eventually, the normal epithelial thickness is restored.

The contraction phase is described as "the process by which the size of a full-thickness open wound is diminished and is characterized by the centripetal movement of the whole thickness of surrounding skin."[29] Several mechanisms have been theorized to be responsible for this action.[31]

The remodeling phase is described in terms of early wound strength and late wound strength.[31] There is no appreciable gain in wound strength during the first four to six days of healing. However, the fibrin clot, epithelialization and ingrowth of new capillaries occur early and provide some support to the wound. After the early fibroblastic phase, wound strength increases to an early maximum at 14 to 16 days, paralleling the rise in collagen content of the wound.[31] Late wound strength occurs as a result of collagen maturation. The collagen content stabilizes after the third week. Wound strength may continue to increase for a period of years following the stabilization of the collagen content resulting from the intramolecular and intermolecular cross linking of collagen fibers.

Freshly created (within eight hours), uncomplicated wounds should be treated by primary closure with anticipated first intention healing;[5] however, this is not appropriate for the treatment of open, contaminated wounds.

Instrumentation

Instuments for avian surgery should be appropriate to the patient's size. In many cases, ophthalmic instruments are suitable and should be included in the standard avian surgery pack. Iris scissors (curved and straight), forceps with fine teeth, micro Halstead mosquito forceps, jeweler's forceps (curved and straight), iris hooks, eyelid retractors for abdominal retractors, retinal forceps, adventitia scissors, spring handled scissors and Castroviejo needle holders are particularly useful (Figure 40.2). Because avian tissues are delicate, the use of toothed forceps is seldom appropriate. Debakey-type forceps are relatively atraumatic and serve well in avian surgery. Penrose drains or other sterile rubber materials may be used to wrap around structures for elevation or retraction, and eyelid retractors work well as wound retractors (Figure 40.3). A sterile gavage or feeding tube can be used for irrigation or for flushing out hollow viscera (such as the proventriculus during proventriculotomy). Various sizes of bone curettes are useful to retrieve foreign bodies from the ventriculus or proventriculus. A tuberculin syringe with an attached 25 ga needle can be fashioned into a tissue hook by bending the tip of the needle 45 to 90° under the operating microscope.

A mini-Frazier suction tip is well suited for avian surgery because of its small, delicate size. This type of suction tip also has a small hole at the finger rest, which the surgeon may use to adjust the amount of suction created at the tip. Red rubber urinary catheters and infant feeding tubes are available in varying sizes and may be cut off and adapted for use as a

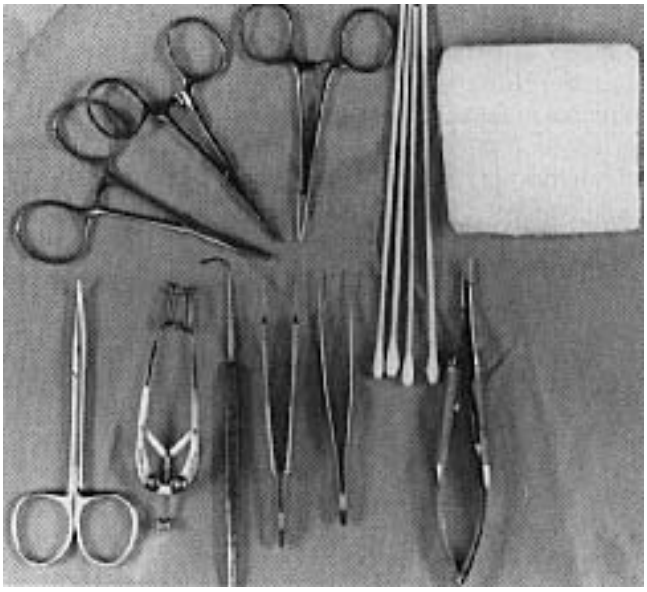

FIG 40.2 Ophthalmic instrumentation is best suited for use in birds.

suction tip. Care must be taken with this type of tip and a powerful suction unit in order not to damage viscera inadvertently suctioned against the tip. The strength of suction can be controlled on most suction units and should be adjusted so that fluids can be evacuated without damaging tissues. A Poole-type suction tip can be fashioned from a catheter by cutting multiple fenestrations along the terminal two to three centimeters of the catheter. By having many fenestrations, the suction force is distributed among the inlets, decreasing the force at any one hole. Additionally, if some of the holes are occluded by tissue, the remaining inlets continue to evacuate the celomic cavity.

A one- to three-millimeter rigid endoscope is helpful for visualizing areas that the surgeon may not be able to access with the operating microscope (eg, lumen of hollow viscera). Abdominal retractors appropriate for small avian patients should maintain retraction but not have blades that extend deep into the body cavity. Mini-Balfour retractors are useful in large patients such as macaws and cockatoos, Alm retractors are appropriate for medium-sized patients like Amazons and conures, and Heiss retractors work well in small avian patients including cockatiels and budgerigars.

In many situations, the placement of ligatures in deep surgical sites is unachievable or results in unacceptable tissue damage due to the relative inaccessibility and delicate nature of avian tissues. Hemostatic clips[h,i] are best for controlling bleeding in these

FIG 40.3 Various types of lid retractors are ideal for use in maintaining access to the abdomen of birds. In this photograph, a lid retractor is being used to maintain an opening in the left abdominal wall. The seventh rib (r) has been isolated and cut ventrally to facilitate its removal for better access to the proventriculus. Several rents can be seen in the relatively clear caudal abdominal air sac (arrow) just to the left of the rib. The proventriculus (p) and ventriculus (v) can be seen deep to the surgical site.

cases. Multiple-sized clips should be available to address varied-sized patients and different surgical needs. The major expense is encountered in purchasing the applier, as the clips themselves are relatively inexpensive. The appliers are available either straight or with a 45° bend. The bent-tipped applier is useful for deep clip placement; however, the bent-tipped instruments are about twice the size of the equivalent straight-tipped applier, making them more cumbersome to use. Generally, the small and medium clips are used most frequently.

Number 15 and No. 11 scalpel blades are most appropriate for avian surgery. Small gauze pads (2 x 2) and sterile cotton-tipped applicators should also be available (see Figure 40.2). Surgical spears[j] are small, wedge-shaped, highly absorbent, synthetic sponges attached to a stick. The point of the spear provides critical control when working under magnification.

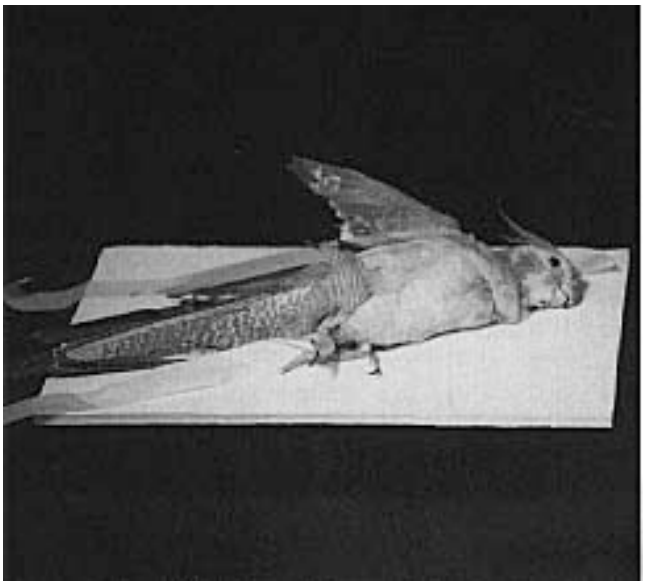

FIG 40.4 Surgical boards made of sterilizable materials are helpful to facilitate the movement of patients undergoing microsurgical procedures. An anesthetized cockatiel hen has been taped to a surgical board in preparation for a hysterectomy.

Absorbable gelatin sponges[k] are valuable for controlling hemorrhage, as is oxidized regenerated cellulose[l].

With avian patients it is best to place the patient on a restraint board, which is then placed on the operating table. This allows the surgical assistant to move the patient intraoperatively to acheive proper visualization of structures. This is especially important when using the operating microscope as it is much easier to move the patient than to move and refocus the microscope (Figure 40.4). Such boards are commercially available[m] or can be easily constructed from a plastic container lid, a piece of styrofoam or a section of cardboard. Any material that is used should be disposable or sterilizable. Tape restraints are preferred over velcro restraints because they are disposable and minimize the risk of disease transmission.

An ideal monitor for the surgical patient would be easy to apply, unaffected by the surgical environment, economically priced and provide data on the patient's heart rate, respiration, body temperature and hemoglobin oxygen saturation. The high heart rate and small tidal volume of small avian patients are not easily detected by traditional monitors. Pulse oximeters have become standard in human anesthesia but may be unable to detect the high pulse rate of some smaller patients. Sensitive respiratory monitors that have a thermistor that extends to the end of an endotracheal tube[n] are effective in intubated patients but do not function properly if the patient is maintained using a face mask (see Chapter 39). Remote thermometers are available at a reasonable price.[o] The best monitor for surgical anesthesia is still a well trained and experienced surgical technician.

Radiosurgery (Electrosurgery)

Radiosurgery employs high frequency (two to four mHz), alternating current to generate energy waves, which create vibration and molecular heat inside individual cells, causing water to vaporize and the cells to rupture while the active electrode remains cool (Figure 40.5).[15,16,19,33,38] Most electrosurgical units generate wave forms in the frequency range of radio waves, making the term *radiosurgery* applicable. The frequency can be varied to achieve either cutting of tissues or coagulation of vessels. Coagulation occurs when the current density is sufficient to dehydrate cells and coagulate their organic contents.[16,19,33,38]

When set for monopolar operation, a radiosurgery unit employs two electrodes (an active electrode and an indifferent electrode or ground plate), which concentrate the current density at the tip of the smaller (active) electrode. Monopolar radiosurgical techniques are acceptable for gross tissue manipulations in avian patients weighing more than two kilograms. These are analogous to a broadcast antenna (active electrode) and a receiving antenna (indifferent electrode) for radio transmission. The ground (indifferent electrode) should be large and placed as close as possible to the surgical area, and the contact with the patient should be improved using an electrode paste. It is important to keep the active electrode clean and free of char and debris. A dirty electrode will drag

FIG 40.5 Radiosurgery units are indispensable in avian practice. Versatile units are available that also have numerous applications in mammalian surgery (courtesy of Ellman Intl. Mfg. Inc.).

through the tissue, inhibiting the cutting action and increasing tissue coagulation, which can delay healing and predispose the wound to dehiscence.[15,16,19] Many types of active electrode tips are commercially available. Ball-type electrodes create a lot of tissue destruction and are used for fulguration and coagulation of large vessels. Loop electrodes are used to contour tisses, obtain organ biopsies and remove large masses in a piecemeal fashion. Skin incisions and incisions into other fine tissues are best accomplished with fine wire electrodes.

Bipolar Forceps

Bipolar radiosurgical forceps are superior to monopolar forceps in patients weighing less than two kilograms and when manipulating tissues in the realm of microsurgery. With bipolar forceps a ground plate is not needed as one of the tips serves as the active electrode and the other as the indifferent electrode (Figure 40.6). Compared with the fine-needle or wire monopolar electrodes, the tips of the bipolar forceps are broader, allowing the current to be dispersed just enough to accomplish the tissue welding that is critical for hemostasis. The current passes from one tip (active electrode), through the contacted tissue and to the other electrode (indifferent) without passing through the entire patient. In avian patients, bipolar forceps induce less reflex hemorrhage and provide improved tissue control. With the two electrodes in such close proximity, the transmitted wave currents are different from those generated with the monopolar system, resulting in precise control of energy application.

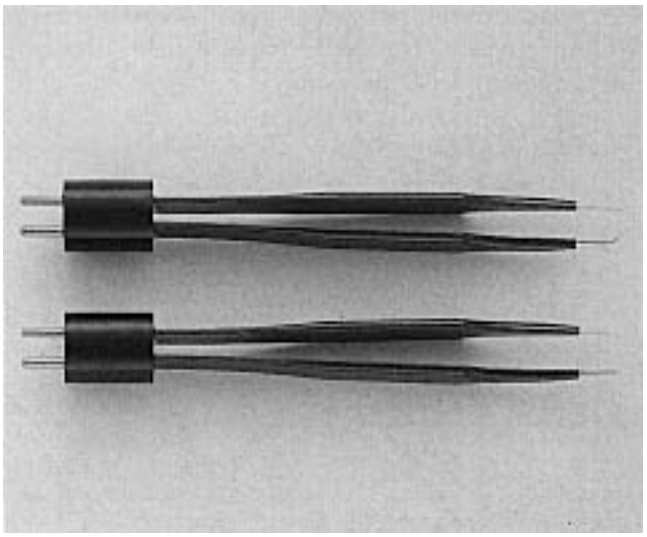

FIG 40.6 Several styles of bipolar forceps are available. The top one has been specifically designed for avian microsurgical application. These tips are thinner than normal bipolar tips and the active electrode has a 45° bend to facilitate cutting of avian tissues (courtesy of Ellman Intl. Mfg. Inc.).

Some commercially available bipolar ophthalmic forceps are slightly wider than is ideal for avian surgery. These forceps can be made more appropriate for avian surgery by using a fine sharpening stone to reduce the width of the tips. It is best to make the active electrode tip slightly narrower than the indifferent tip. Forceps with the active electrode slightly bent are commercially available and are best for avian surgery.[p] The energy passes through the tissue between these tips in a manner not attainable with unmodified, straight-tipped bipolar forceps. A lower energy setting can be used with these forceps. With the Surgitron,[q] the fully filtered wave pattern of the *cutting* settings are used most commonly. The unit is set at 1 for vessel coagulation, 2 for muscle transection, and 3 for incision of dry skin. For vessels that are difficult to coagulate, the *cutting/coagulation* settings may occasionally be indicated. The *coagulation* setting is used primarily for tissue fulguration (such as the destruction of cloacal papillomas).

Incision Techniques

The Harrison modified bipolar forceps[p] may be used to make primary skin incisions, coagulate cutaneous vessels prior to blade incision and coagulate individual vessels. These forceps may also be used with or without current for tissue dissection. Skin incisions should be planned in a manner to minimize the effect on feathers and feather tracts and to avoid the major blood supply to feathers. The skin is tented with thumb forceps and grasped with the bipolar forceps at the location of the proposed incision (Figure 40.7).

The current is activated (using a foot switch) precisely as the grasp on the tissue is relaxed slightly, and with a smooth, rapid motion, the forceps are pulled off the tissue.[15,16] When correctly applied, a fine, white blanching of the tissues occurs with a barely discernible separation of the skin that can be seen under magnification. This will create a small incision in the tissue that may then be parted to allow introduction of the indifferent electrode of the bipolar forceps (non-bent tip). The electrode is inserted subcutaneously to the extent of the proposed incision. The electrodes of the bipolar forceps are lightly apposed, the current is activated and the forceps withdrawn. This creates a skin incision with minimal damage. If properly performed, the skin should remain a normal color except immediately adjacent to the incision (which should be white), and there should be no hemorrhage.[15]

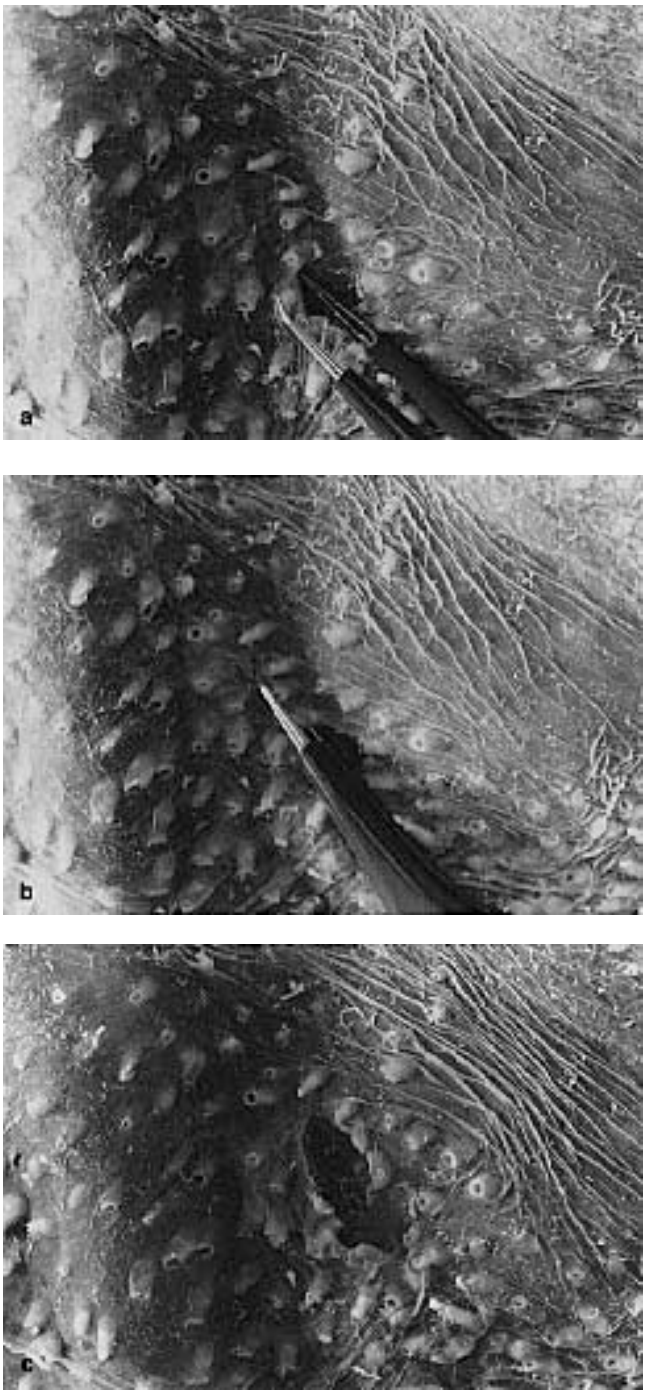

FIG 40.7 **a)** When possible, the site for a skin incision is chosen by selecting an area that does not pass directly through a feather follicle. A small nick incision is made with a scalpel or by raising the skin slightly with a pair of forceps and grasping the tissue with the bipolar forceps. **b)** The indifferent electrode of the bipolar forceps is then inserted under the skin, the tips are gently apposed and the forceps are pulled out of the nick incision in a straight line. **c)** The length of the bloodless incision line can be increased as needed. Note that the skin is incised between, not through, the feather follicles.

When thicker tissue is to be transected, small bites of tissue are grasped with the bipolar forceps, the current is activated and the forceps are withdrawn through the tissue, creating a small nick. This process is repeated until the tissue is completely transected, stroke by stroke.

Coagulation Techniques

If hemorrhage is encountered, a sterile cotton-tipped applicator is used to dry the area for radiocoagulation, which cannot be achieved in a wet field. The swab is rolled toward the source of blood flow with gentle pressure to serve as a tourniquet (Figure 40.8). The pressure is relaxed slightly to identify the source of hemorrhage. Once the vessel is identified, the slightly broader, flat indifferent electrode is placed under the vessel, and the bent-tipped, active electrode is loosely apposed to occlude the vessel. The current is activated as the forceps are relaxed, sealing the vessel. At high current or coagulation settings, the vessel frequently retracts within the tissue due to vasospasm. This results in temporary hemostasis only. As the vessel relaxes, the hemorrhage recurs.

When using monopolar radiosurgery, the power settings vary with the type and size of the electrode, the area of electrode surface in contact with tissue, the nature of the tissue, the operation performed (cut or coagulation) and the depth of the incision desired. Higher settings are necessary with tough tissues, deep incisions and large electrodes. Healing after radioincision is by first intention. When used correctly for creating an incision, the current should be activated *before* touching tissue, and the electrode should glide effortlessly, producing only a slight color

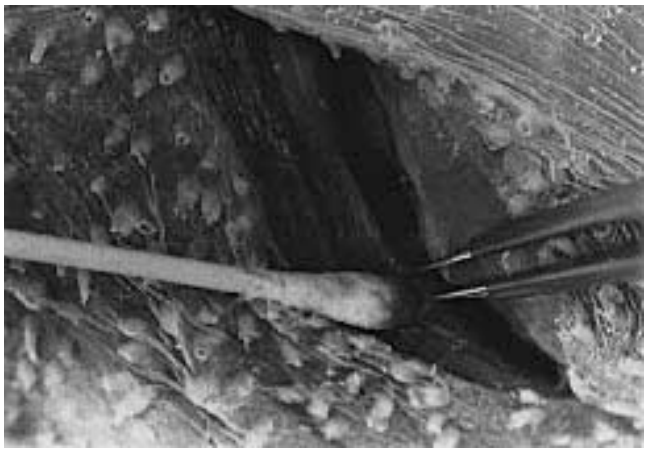

FIG 40.8 A cotton swab is used to roll toward a bleeding vessel and, with gentle pressure, to occlude the vessel, stop the bleeding and allow the identification and coagulation of the severed vessel.

change in the tissue. When used for coagulation, the electrode should be activated *after* contacting the tissue and should produce a white spot at the site of energy transfer. Current applied repeatedly to the same area will cause excessive heating and damage to underlying tissues.

A radio current may pass through any portion of the exposed metal portion of the electrode. When the current is activated, it is important to be certain that only the tissue to be cut or coagulated is in contact with the metal portion of the electrode tip. This is especially important when attempting to coagulate vessels in the abdominal cavity through a small incision in a small bird. If the electrode inadvertently touches other structures (abdominal wall, parenchymous organs), the current will pass from the electrode through the first tissue it touches and exit at the ground plate, potentially without even contacting the intended tissue. Most bipolar forceps are insulated such that only the tips are exposed. This reduces the likelihood of errors causing unwanted damage to adjacent structures.

The fine-tipped monopolar electrode requires a higher setting when used on avian tissues than when used on thicker mammalian skin. When a vessel is encountered at these high settings, the electrode has a tendency to cut rather than coagulate the vessel, resulting in hemorrhage. A second effort must then be made to locate the vessel and coagulate it separately, creating the potential to induce more damage to the vessel and surrounding tissues. In mammals, the tissues surrounding vessels will heat slightly with the application of radiocurrent, which helps seal any transected vessels.

The application of a bipolar radiosurgical unit to avian practice and to veterinary practice in general is limited only by the time that the clinician spends in practicing with this equipment. Each radiosurgical unit requires precise adjustments that must be performed by the surgeon who will be using the instrument. Time invested in practicing with a radiosurgical unit will be well worth the improvement in clinical results.

Magnification

The hands and fingers are able to accomplish tasks of intricate detail, and vision is generally the limiting factor in surgical procedures. Therefore, some form of magnification is recommended for avian surgery[33] and is an integral part of an avian specialty practice.

Operating Microscope

In patients weighing less than a kilogram, an operating microscope and microsurgical instrumentation are mandatory and would be considered advantageous in larger birds. Using microsurgical techniques, severed nerves and vessels, which if left unrepaired would result in a dysfunctional post-fracture limb, can be anastomosed. Binocular magnification loupes of 2.5x to 8x are adequate for many procedures. Head sets with higher magnification usually create disorientation because of the constant micromovements of the head. Attaching a fiberoptic lamp to the loupe facilitates vision. With the use of magnification, individual vessels are more easily identified for coagulation, minimizing the degree of hemorrhage associated with a procedure.[1,19,33] Because minor hand tremors are magnified, it is recommended that microsurgeons abstain from the use of alcohol, caffeine, other stimulants and heavy exercise prior to surgery.[16] The major disadvantage of performing surgery under an operating microscope is that it generally requires more time to complete a procedure than when a magnification loupe is used.

The operating microscope should have a lens objective of approximately 150 mm with 12.5 mm ocular lenses.[12] An electronic zoom is advantageous. A fiberoptic ring light can be attached to the lens for improved illumination of the surgical field. This type of ring light can be connected to most standard endoscope light sources. Bright white light is critical for visualization during microsurgery. Microscopes are expensive, but used and reconditioned models are becoming more readily available.

Microsurgical Instruments

There are four requirements for microsurgical instruments: they should be long, be counterbalanced, have round handles and have miniaturized tips (Figure 40.9).[16] It is important that only the tips of microsurgical instruments are miniaturized. The handles should be of normal length to help provide stability to the tips and diminish the effect of hand tremors. The handles should be long enough to rest comfortably in the hand between the thumb and index finger. The instrument should be held like a fine writing instrument and be manipulated with minimal pressure. Gripping the instrument will fatigue the hand and fingers, causing motion at the tips. Microsurgical instruments have a counterbalance and are contoured to rest in the groove between the thumb and index finger. They should lie in the hand and not fall out when the grip is released (Figure 40.10). The handles should be round (except for scissors) to facili-

FIG 40.9 A microsurgical needle holder with long, rounded, counter-balanced handles and miniaturized tips is compared to a standard needle holder.

tate a rolling action that results in smooth, precise, flowing movements at the tip. This rolling motion is especially important for delicate cutting, suturing and knot-tying. It is important to note that totally miniaturized instruments (older generation of ophthalmic instruments) are not appropriate for microsurgery. These instruments have short shanks and handles, and their use under the operating microscope results in loss of balance and control leading to fast, jerky movements.

The microsurgical pack should include micro-scissors, micro-needle holders and a variety of micro-forceps. Needle holders should not have a clasp or box lock, as the motion that occurs when the lock is set and released is enough to cause the needle to tear tissues. Inexpensive forceps can be fashioned by placing vulcanized silicone on the handles of jewelry forceps. Layers of liquid plastic (dispensed from a hot glue gun) may be applied to the handles to achieve the necessary round shape. An ophthalmic Castroviejo needle holder can be modified for microsurgery by grinding the tip narrower, removing the box lock and making the handle round.[12,16]

For microvascular work, specialized clips are used to maintain the severed ends of the vessel in approximation. A colored background is placed under the vessel to improve contrast and make identification of the vessel easier. These backgrounds are commercially available[r] or can be made from pieces of balloon appropriately sterilized. Vessel dilators are also necessary. A vascular irrigation system can be made using a 27 or 30 ga needle, the tip of which has been cut off and polished smooth so it will not damage the vascular intima. A motorized rotary tool and the operating microscope are used to modify the needle. Heparinized irrigation solution in a hand syringe with the modified needle attached is used to clear the vessel of clots and debris.[12,16] Suture material for small avian patients usually is of 6-0 to 10-0 size, while for microvascular work, 10-0 nylon suture on a 75 micron needle is routinely used.[12]

Developing Microsurgical Skills

The avian surgeon should take advantage of every opportunity to gain experience. Human plastic surgeons and microvascular surgeons are valuable resources. Continuing education courses and opportu-

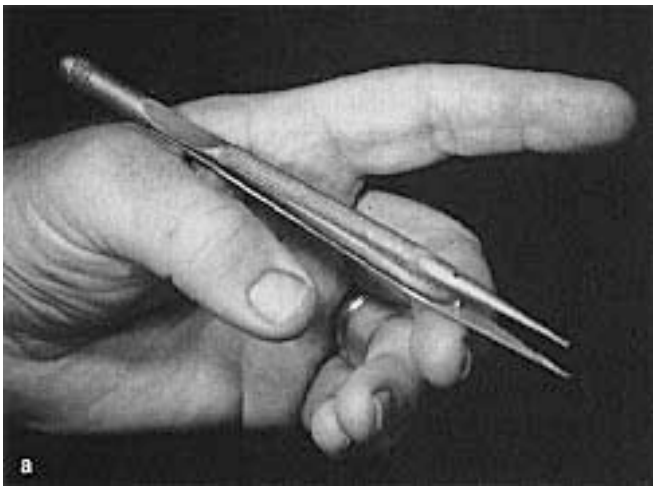

FIG 40.10 **a)** The handles of microsurgical instruments should be of sufficient length to allow them to rest comfortably in the groove between the thumb and index finger. **b)** Miniaturized instruments are difficult to manipulate and cause increased fatigue of the hands during use.

nities to practice on cadaver specimens are also valuable. Prior to practicing on tissues, it is helpful to gain experience manipulating objects under magnification by picking up and moving small objects (eg, canary seeds) with the microsurgical instruments. A slit can be placed in a latex glove to practice suture placement and knot tying. Initially, the clinician must develop new eye-hand coordination, and it is important to develop dexterity with both hands under the operating microscope. Microsurgery is tedious, time-consuming work, and it is imperative that the surgeon be comfortable. Prior to the onset of the procedure, the height of the table and chair should be adjusted for the surgeon's maximum comfort. Motion from the shoulders and arms should be minimized by resting the mid-antebrachium along the edge of the table to serve as a fulcrum. The fourth and fifth fingers should also rest on the table to provide a second fulcrum and additional stability. The hands should be relaxed, and any motion should originate from the wrists and fingers, resulting in smooth, accurate paint brush-type movements. Breathing patterns should be natural. Breath-holding results in tremors at the instrument tips.[16]

Suture Materials

The goals of incision repair are to limit the adverse effects of the repair technique and to restrict the loss of tissue function. In routine avian surgery, suture sizes of 3-0 to 6-0 are most commonly used.[18] For small patients and microsurgery, sutures of 10-0 may be necessary. Companion birds may have a rather formidable beak that could easily remove the toughest materials; however, they generally do not traumatize suture lines.[1] This characteristic allows the use of continuous patterns in the skin of many avian patients. Topical medications, splints and bandages are not well tolerated by companion birds.

Many factors should be considered when selecting an appropriate suture material for a given procedure. The tissue characteristics, the presence of contamination or infection and the characteristics of the suture material influence the selection. The ability of suture material to potentiate infection is roughly proportionate to the inflammatory reaction caused by the suture.[36] The inflammatory response and reaction to various suture materials differ between birds and mammals. A number of factors influence the amount of inflammation a suture material induces including the surface area of material exposed to the tissue, the tissue in which the material is used (ie, fascia does not react to silk while intestines and skin react strongly), the method of placement (tight sutures strangulate tissue), the length of time the material has been present (some sutures stimulate a reaction shortly after placement but become inactive within a few months) and the chemical properties of the material.[36,37]

Suture is a foreign material in a surgical wound and may potentiate infection. Bacteria may be protected from the body's defenses within the suture material. By reducing the amount of material implanted (the fewest number of sutures and the smallest diameter possible to accomplish the task) and minimizing surgical tissue trauma, the risk of suture-related infection may be diminished.[36,37] Braided sutures should not be used in contaminated or infected wounds as they delay the clearance of bacteria, prolonging and promoting inflammation.[36] Bacteria are better able to bind to braided materials than monofilament suture made of the same material. Where there is contamination or infection, a monofilament, nonreactive material such as nylon is indicated, as it will not allow bacterial wicking and will retain its tensile strength long enough for resolution of the infection and completion of tissue healing. In a study of the ability of bacteria to adhere to suture material it was found that monofilament, nonabsorbable materials have the least capacity for adherence while polyglycolic acid and polyglactin 910 have the most.[36]

Sutures that act as a wick to allow transport of serum and bacteria are called capillary sutures.[37] They may potentiate the spread of infection from a contaminated or infected tissue into a sterile area.[36] Multifilament sutures are also more likely to cause the formation of suture sinus tracts and granulomas than monofilament materials. The advantage of braided sutures is that they generally have better handling characteristics.

The extent of tissue damage during suture placement also influences the reaction and the risk of infection. Sutures should be placed with a minimum amount of both intrinsic (tension on tissue within the loop of suture material) and extrinsic (tension on surrounding tissues) tension. Knots must be securely tied, yet the surgeon must attempt to use the least amount of suture material to decrease the foreign body reaction. It is important to use the fewest throws to create a secure knot, which will fail by suture breakage and not by knot failure. For chromic catgut, polyglactin 910, polyglycolic acid and polypropylene, three throws are required and four are required for polydioxanone and nylon.[35] When starting and finishing a

continuous pattern, a different number of throws is required to create a secure knot. To start a continuous pattern with polygycolic acid, polyglactin 910 and polypropylene three throws are required. Four are required for chromic catgut and five for polydioxanone. When ending a continuous pattern, it takes five throws for polypropylene, chromic catgut and polyglycolic acid, six for nylon and polyglactin 910, and seven for polydioxanone to create a secure knot.

After considering suture characteristics, tissue interaction and the processes of wound healing, the final factor in suture selection is personal preference. The technique of suture placement and tissue handling remains more important for uncomplicated wound healing than the selection of suture material.[37] The placement of sutures in a manner that allows accurate tissue apposition appears to be more critical in avian patients than in mammals. Tension and the resultant tearing of tissue in birds dictates the use of more sutures per centimeter, less intrinsic tension (within the suture loop) and atraumatic insertion. Most avian tissues have low tensile strength. It is important to use the smallest swaged-on atraumatic needle that is available for a particular suture. Many visceral organs are very delicate and require that the surgeon develop specialized handling techniques.

Evaluation of Suture Materials in Birds

The tissue reaction to five suture materials (polyglactin 910, polydioxanone suture, monofilament nylon, medium chromic catgut and monofilament stainless steel) in pigeons was evaluated at 3, 7, 15, 30, 60, 90 and 120 days following implantation in the body wall.[4] In mammals, it is known that chromic catgut is absorbed by the action of proteolytic enzymes released from monocytes. The pigeons in this study developed a marked granulocytic inflammatory response the the catgut that diminished during the period of evaluation; however, the material was still present at the end of the study indicating prolonged absorption of the material. Polyglactin 910 is considered nonreactive in mammals. It is absorbed by the process of hydrolysis and does not require enzyme degradation. In this study, polyglactin 910 caused the most intense inflammatory reaction but it was absorbed the most quickly (completely gone by day 60). Polydioxanone is a monofilament material, which, like polyglactin 910, is absorbed by hydrolysis. It is considered nonreactive in mammals and is usually completely absorbed by 180 days after implantation. This material behaved similarly in the pigeons studied. It caused minimal tissue reaction and absorption was underway at the close of the study.

Nylon and stainless steel cause minimal tissue reaction but are nonabsorbable. In the pigeons, they caused minimal tissue reaction but, because they are stiff and potentially more mechanically irritating to surrounding tissues, they were more often associated with hematoma, seroma and caseogranuloma formation. Based on the findings reported in this study, chromic catgut should be avoided in avian surgery. Slowly absorbed monofilament, synthetic materials absorbed by hydrolysis rather than proteolysis are most appropriate when wound healing is expected to be prolonged. Rapidly absorbed, braided, synthetic materials absorbed by hydrolysis are best used when the benefit of rapid absorption outweighs the disadvantage of a pronounced inflammatory reaction.

(The editors have experienced some adverse reactions with Polyglactin 910 in psittacine birds; therefore they personally use nylon for subcutaneous sutures and stainless steel wire for skin.)

Tissue Adhesives

Tissue adhesives of cyanoacrylate have many applications in avian medicine and surgery. The cyanoacrylate monomer is a liquid that polymerizes in the presence of the small amount of water present in tissues. The time required for the liquid to become solid and bond tissues depends on the amount of water (more water present will delay curing) and the thickness of the acrylic applied (thicker will delay curing). Medical grade adhesives[s] are biologically inert and cause minimal tissue reaction. Some prefer to use the less expensive commercial grade of glue (eg, SuperGlue); however, these contain substances that are toxic to tissues[6,19] and are not recommended for medical use.

These materials hold tissues in approximation to allow healing to progress; however, cells cannot penetrate the adhesive. It is important not to allow the adhesive to run between the tissues to be apposed as the presence of the acrylic will delay healing by creating a physical barrier. In some cases, especially with water birds, the acrylic may be applied in a thin layer over the apposed incision to create a seal yet allow epithelial cells to migrate under the acrylic during the healing process. These adhesives may also be used to secure IV catheters in place, to attach the limbs or digits of tiny patients to splints for orthopedic problems and various other purposes. Caution should be exercised when using these materials in the presence of anesthetic gases with which they are synergistic and may cause ocular irritation and vomiting in avian patients.[19]

Postoperative Care

The patient should be placed in an incubator at 85°F with supplemental oxygen during recovery from surgery. It is best to continue maintaining the postsurgical patient in a small, controlled environment during the convalescent period (see Chapter 39). The patient's activity level should be kept to a minimum to allow proper tissue healing. A square, box-type enclosure is preferred and in most circumstances perches should be removed or lowered to decrease the likelihood of falling. Food and water should be placed where they are easily accessed by the patient. Toys and extraneous objects within the enclosure should be removed.

Postoperative antibiotic therapy should be instituted when there is a specific indication, such as with open, contaminated wounds or where there has been intraoperative contamination of the surgical field. IM perioperative antibiotic therapy is recommended for general prophylaxis in these cases.

In general, avian patients do not traumatize their surgical incisions, and they poorly tolerate bandages and other devices. Elizabethan collars or neck braces should be reserved for the most desperate cases. If an Elizabethan collar is considered necessary, the patient's neck should first be wrapped so the collar will be held in position against the mandible. Using this technique, a smaller, looser collar may be utilized.[22] In some patients, the center core of cardboard from a roll of bathroom tissue may be padded and used as a neck brace alone or in conjunction with an Elizabethan collar. The first day, the Elizabethan collar should open rostrally in the traditional manner. This will allow the patient time to become accustomed to the collar, and it will not damage the wings while the patient is struggling to escape the device. The second day, the collar should be reversed such that the cone opens caudally. This will allow the patient more ready access to food and water. The patient should be kept in a plain box with nothing to trap and hold the collar. Food and water should be placed on a pedestal for easy access. The patient's weight should be closely monitored to assure that an adequate amount of food and water is being consumed. The collar should be regularly evaluated for evidence of pressure or esophageal obstruction.

Analgesics

Historically, it has been considered that birds have a remarkable capacity to deal with pain, although the assessment of what animals perceive as pain is difficult. Research in the area of avian pain perception has been minimal. Companion birds have a well developed sense of touch and react by loud vocalization and withdrawal when potentially painful stimuli are applied. Clients expect that analgesia will be provided for their pet, and it is the responsibility of the entire staff to relieve a patient's postoperative pain and suffering.

Some research has been conducted with respect to pain in pigeons and poultry. One study was conducted in budgerigars[3] to evaluate the effect of high doses of butorphanol tartratet and flunixin meglumine[u] on heart rate, motor control and respiratory rate.

Butorphanol is an opioid analgesic with both agonist and antagonist properties, resulting in a "ceiling effect" such that above a maximum effective dose, neither beneficial nor deleterious effects are noted. The action and potency of opiates and opioids is related to the specific receptor sites to which a given agent binds.[3]

There are three major types of opiate receptors. Mu receptors mediate analgesia and euphoria. They are also responsible for physical dependency, sedation and respiratory suppression. Kappa receptors also are involved in analgesia and, to a lesser degree, with sedation and respiratory depression. Sigma receptor stimulation results in cardiac and respiratory stimulation, anxiety and hallucinations.

Butorphanol exerts its effects at mu and kappa receptors. Doses of 3 to 4 mg/kg of butorphanol given to budgerigars had no statistically significant effect on heart rate or respiratory rate;[3] however, some treated birds lost motor control. This effect was considered minor and all birds remained alert. Return to normal motor coordination occurred within two to four hours post-administration. No gastrointestinal effects were observed with this agent. This study did not evaluate the minimum and maximum effective doses. It would be advisable to start with a standard dose of 0.2 to 0.4 mg/kg of butorphanol, recognizing that doses up to ten times this dose are safe in birds.

Buprenorphine hydrochloride[v] is another opioid with agonist/antagonist activity that appears to be effective in controlling pain in avian patients. A dose of

0.01 to 0.05 mg/kg IM appears to provide adequate postoperative analgesia.[23]

Flunixin meglumine is a nonsteroidal anti-inflammatory agent that is a potent analgesic for certain types of pain; however, surgical pain is rarely responsive to this class of analgesic, and it is more appropriate for use in the treatment of inflammatory conditions. It has been recommended for use as an analgesic in companion birds at 1 to 10 mg/kg SID IM or IV.[9,23] Flunixin at 10 mg/kg had no effect on respiratory or heart rates in budgerigars.[3] Additionally, motor function remained normal following IM administration of flunixin. Regurgitation or vomiting occurred within two to five minutes after administration in five of six patients. Tenesmus was also observed several minutes after administration of flunixin. Aspirin has been recommended at a dose of one 5 gr tablet dissolved in 250 ml drinking water. These nonsteroidal agents have the potential to cause serious gastrointestinal side effects and may prolong clotting time. They should be used with caution until their benefits and limitations are better understood.

CHAPTER

41

SOFT TISSUE SURGERY

R. Avery Bennett
Greg J. Harrison

Soft tissue surgical techniques that can be performed in birds have increased substantially over the last decade because of the widespread use of isoflurane anesthesia, the introduction of microsurgical techniques to the avian practice, improvement in microsurgical instrumentation, improvements in bipolar radiosurgical instrumentation and the growing expertise of avian surgeons. Board certified surgeons are becoming attracted to the field for the purpose of developing and refining avian procedures. Procedures that were once considered impossible are now performed on a routine basis.

The most substantial limitation to soft tissue surgery of the abdomen is the small size (<100 grams) of many avian patients. Some of these problems can be overcome with the use of magnification, but others are a result of having limited surgical access to an area, and are difficult to overcome. Surgery of the thoracic area, even in large companion birds, presents a similar problem, in that the organs of interest are covered by the sternum and heavy musculature. Continued improvements in the endoscopic surgical equipment available in human medicine will undoubtedly improve the surgeon's ability to perform surgery in difficult-to-reach areas of the avian body.

The avian surgeon should practice surgical techniques on cadavers prior to performing the procedures on clinical patients. The delicate avian tissues tear in the presence of slight autolysis; therefore, the use of fresh specimens will give the surgeon an appreciation of avian tissue characteristics and allow the surgeon to explore the capabilities of surgical instrumentation.

When necropsies are necessary, the clinician should approach this procedure from the perspective of a surgeon rather than of a pathologist, by dissecting and reviewing anatomy from a regional approach rather than by performing the necropsy strictly from the traditional ventrodorsal approach.

Surgery of the Skin

The skin and subcutaneous tissues of birds differ from those of mammals. Birds have relatively thin, dry epidermis, and the dermis is attached to the underlying muscle fascia with little subcutaneous tissue.[19,33] In feathered areas, the skin is generally only ten cells thick. Compared to mammals, the skin is only loosely attached to underlying structures, except in the distal extremities where it is firmly adherent to underlying bone.

Passerine Leg Scales

Passerine leg scale syndrome is characterized by the development of abnormally large scales of the legs and feet, possibly as a result of mite infection or malnutrition (see Chapter 43). These scales can coalesce and act as a constricting band. They also predispose the bird to bacterial pododermatitis (usually *Staphylococcus* spp). If present, the shiny, convex carapace of the female *Knemidocoptes* mite can usually be visualized, with the aid of the operating microscope, inside the burrows they create. In most instances, lesions resolve after treatment with ivermectin or correction of nutritional deficiencies. In severe cases, it may be necessary to surgically debride the proliferative scales to prevent vascular compromise. A 22 or 25 ga needle with the point bent to a 90° angle can be used to lift the scales and scabs, which can then be grasped with the micro-forceps. Skin softeners may also be beneficial.

Toe Necrosis (Constricted Toe Syndrome)

Avascular necrosis of digits may occur secondary to circumferential constriction caused by fibers, scabs or necrotic tissue (see Color 24). These constrictions cause edema and if untreated, sloughing of the digit distal to the constriction.[4] This condition is generally not life-threatening, and amputation should be considered only after less aggressive therapies have failed. Removal of the offending tissue or fibers and supportive care are frequently successful. Avascular necrosis of the digits has been described in passerine birds and Amazon parrots. Scabs should be debrided or incised to prevent vascular compromise, and hydroactive dressings should be applied to the affected digits to prevent the formation of additional scabs. Complete healing may require weeks to months.

In small birds (eg, Passeriformes), constricting fibers may be visualized using the operating microscope (see Figure 43.4). A bent 25 ga needle is helpful for removing constricting fibers. The tip can be used to elevate the fiber, which can then be cut by gently rolling the needle such that the beveled edge severs the fiber. Microsurgical forceps may be used to untangle the fibers. Even severely swollen digits with exposed tendons may heal without incident once the fibers are removed. A hydroactive dressing should be placed on any wounds created by the fibers to prevent desiccation and the formation of a constricting scab.

Neonates (especially macaws and Eclectus Parrots) may develop constrictive toe lesions that can result in avascular necrosis of the digit (see Color 30). Proposed etiologies for these include low humidity, egg-related strictures or ergot-like intoxication.[25] Increasing the environmental humidity or providing hot moist compresses and massage may be effective in resolving lesions in the early stages.[25] More advanced lesions require surgical intervention. The circumferential indentation is treated using magnification to remove the constricting tissue (Figure 41.1).

A tourniquet fashioned from a rubber band held tightly with a mosquito hemostat may be used to control hemorrhage for short periods until the injury is properly treated. Hemostatic agents including radiocoagulation should be avoided. The blood supply to the digits is minimal, and anything that interferes with proper blood flow may predispose the digit to postoperative necrosis.

A circumferential anastomosis of the skin is then performed by placing one or two sutures in the subcutaneous tissues to provide skin apposition without tension. Skin sutures should be placed shallow below the epidermis and be sufficiently tight to appose the skin edges without disrupting the blood supply. Sutures placed too deeply will cause the skin edges to evert, exposing subcutaneous tissue and delaying healing. When the skin edges are apposed, a two to three millemeter release incision should be made at the site of the anastomosis on both the lateral and medial aspects of the digit. These incisions allow swelling without constriction. A hydroactive dressing is applied to prevent scab formation, which could result in reformation of the constriction.

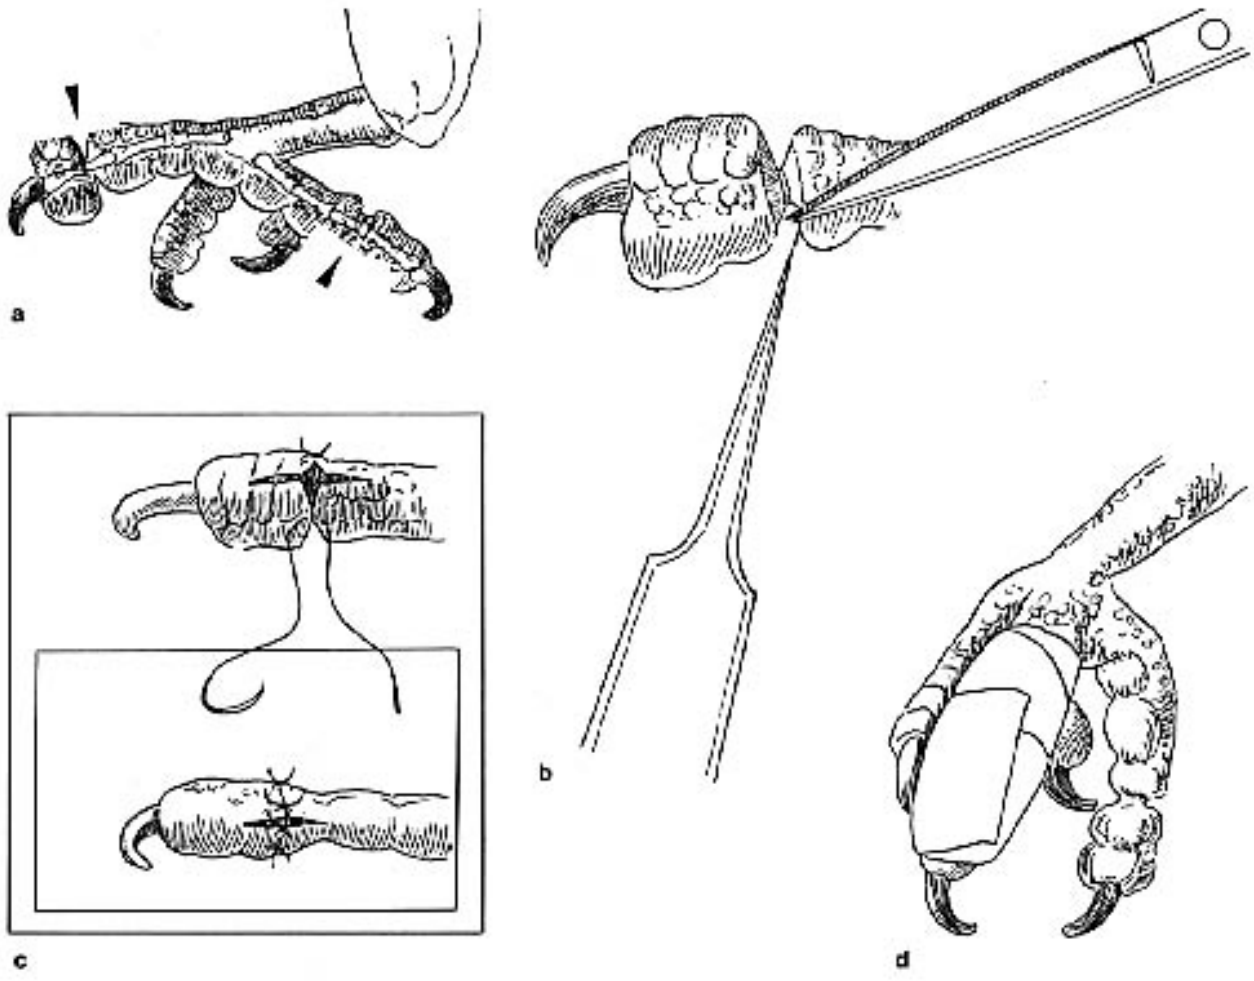

FIG 41.1 **a)** Constriction of the digits (arrows) is common in some macaw and Eclectus Parrot neonates. **b)** The lesion is repaired by using an operating microscope to remove the circumferential scab and create a fresh tissue margin. **c)** The wound edges are then apposed with shallowly placed sutures, and longitudinal incisions are made through the constriction on the medial and lateral sides of the digit to compensate for swelling and growth. **d)** The wound is covered with a hydroactive dressing to keep it clean and prevent dehydration.

Feather Cysts

Feather cysts are generally the result of trauma to the feather shaft, feather follicle or, as in the case of "soft-feathered" canaries, the result of abnormally developed feathers (see Color 24).

Feather cysts may occur within any feather follicle, but those on the wing and tail are the most challenging to the surgeon. In canaries, feather cysts are most common in Norwich, Gloucester and their crossbreeds. These birds have been genetically selected to produce an extra downy type of feather (soft feathering) that may predispose them to this syndrome (see Color 24).[3] In other birds, malformed and cystic feather development have been associated with trauma, malnutrition and viral, bacterial or parasitic infections. If damage is sustained to one side of the follicle, feather growth becomes asymmetrical and the feather may grow in a curled fashion inside the follicle, resulting in a feather cyst.

Feather cysts on the wing that are treated by lancing and curettage frequently recur. Fulguration with a radiosurgical unit has been reported to be successful in some cases; however, the depth of destruction is difficult to control, resulting in damage to adjacent follicles. These damaged follicles can then develop feather cysts. Use of laser for follicle excision does not appear to improve the long-term clinical results.

Blade excision appears to be the treatment of choice. A tourniquet can be applied to aid in hemostasis. The entire follicle, including any bony attachments, should be excised. Adjacent follicles and their blood supply should be carefully avoided. In the postop-

erative period, the wing should be bandaged to prevent movement at the site of follicle excision while healing occurs by second intention. As adjacent feathers begin to regrow, debris should be gently removed by flushing with warm sterile saline several times daily.

With a single cyst or a large feather, the follicle may be saved by marsupializing the lining of the cyst with the skin surrounding the follicle. An incision is made centered on the cyst, parallel to the direction of feather growth. Hemorrhage is controlled with 6-0 ligatures, not with radiocautery. The lining of the cyst is cultured and the debris is removed. Redundant tissue is excised and the follicle is thoroughly lavaged with sterile saline. The margin of the cyst is then sutured to the skin using a simple continuous pattern of fine suture. New feather growth must be closely monitored.

Feather cysts of the tail may be severe and disfiguring, requiring amputation of the pygostyle. Blunt dissection to the coccygeal vertebrae allows disarticulation at the sacrococcygeal junction without entering the cloaca. Soft tissues are closed routinely.

Feather cysts on the body are easily removed using elliptical or fusiform excision followed by primary skin closure.[3] Treatment of individual feathers is generally unrewarding in cases where an entire feather tract is involved. A technique for radical excision of an entire pteryla of affected feathers in canaries has been described.[3] A fusiform incision is made from the flank to the thoracic inlet around the affected pteryla. The main vascular supply to the tract is located centrally at the cranial third of the pteryla. Large cysts may be supplied by relatively large individual vessels that should be coagulated or ligated. Despite the significant-sized defect, skin apposition is easily accomplished using a monofilament suture in a simple continuous pattern (braided material may damage the skin). Removal of one or more pterylae from the body wall does not seriously affect the cosmetic appearance of the bird.

CLINICAL APPLICATIONS

- Feather cysts are particularly common in line-breed canaries.
- Feather cysts may occur secondary to any factor that damages the follicular epithelium.
- For feather cysts on the wing, blade excision appears to be the treatment of choice.
- Feather cysts of the tail may require amputation of the pygostyle.
- Feather cysts on the body are removed using elliptical or fusiform excision followed by primary skin closure.

Xanthomas of the Wing Tip

Xanthomatosis is characterized by the deposition of a rubber-like proteinaceous material within the skin and is frequently associated with inflammation of underlying tissues (see Color 25). Xanthomas at the wing tip may cause the wing to droop, resulting in trauma to the mass. Probucola (25 mg/day for an Amazon parrot) and dietary management should be used in combination with surgical excision of the mass. Medical management is ineffective alone but may help prevent recurrence. Serum cholesterol levels should be closely monitored because they are usually elevated in birds with xanthomatosis and should be medically reduced to a normal level prior to surgery. The diet should be low in protein (13%) and fat (5.5%).

A monopolar, wire electrode functions well for removal of xanthomatous masses. The wound is left to heal by second intention. The wound may be protected with tissue adhesive or a hydroactive dressing, which should be changed every three to five days. Complete healing often requires several weeks. If subcutaneous tissues are involved (especially bone), the affected wing may require amputation.

Excision of the Uropygial Gland

Impaction of the uropygial gland may respond to medical management using hot, moist compresses and gentle expression of the contents. In some cases, the gland may rupture, causing inflammation and scar tissue formation in the surrounding tissues. Chronic debilitation and death may follow.[31] Excision of the gland should be considered in cases where impaction recurs, the gland has ruptured, a tumor is present or chronic infection of the gland is not responsive to medical management.

A fusiform incision is made along the dorsal midline to incorporate the papillae of the gland. The skin is reflected with the aid of blunt dissection and radiocoagulation of damaged vessels. The gland is bilobed, and each lobe receives its blood supply from a vessel that branches at the cranial, middle and caudal portions of the gland. The gland may extend deeply to the synsacrum and caudally to the insertion point of the tail feathers. The vessels are identified and coagulated or ligated. Bipolar coagulation should be used to minimize damage to the follicles of the rectrices. Dissection is continued, beginning at the cranial extent of the gland proceeding circumferentially until its removal is possible. The deep fascia is closed

with monofilament absorbable material in a continuous or interrupted pattern, depending upon the amount of tension present. Subcutaneous and skin closures are routine.

Extensive dissection and debridement are necessary if the gland has ruptured. An additional caudal incision perpendicular to the dorsal midline incision may be necessary.[31] In these cases, extensive tissue trauma increases the likelihood of postoperative dehiscence and damage to the follicles of the rectrices.[31] Dehiscence usually occurs at the junction of the two perpendicular incisions. If possible, it is preferable to remove a diseased uropygial gland prior to its rupture.

Surgery of the Eye

Lateral Canthoplasty for Inferior Ectropion

Idiopathic paralysis of the inferior eyelid occurs with some degree of frequency in cockatiels and occasionally in Umbrella Cockatoos (see Color 26). Clinical signs generally include exposure keratitis with secondary epiphora and corneal ulceration. Symptomatic treatment involves the use of ophthalmic ointment to lubricate and protect the cornea. A lateral canthoplasty will create a smaller aperture, reducing the risk of exposure keratitis and associated conditions (Figure 41.2). Postoperatively the eye is medicated with an antibiotic ophthalmic ointment TID to QID, and the eye is cleaned as needed with an appropriate eye wash solution.

Conjunctival Masses

Masses involving the palpebral conjunctiva occur with some frequency in cockatiels. These may be the result of tissue edema, cyst formation or discrete masses. They are usually easy to remove with radiosurgical bipolar forceps. These masses may be secondary to chlamydiosis, mycoplasmosis, eyelid paralysis or oropharyngeal abscessation from hypovitaminosis A (see Chapters 22, 26).

Indolent Corneal Ulcers

Successful treatment of indolent corneal ulcers in birds appears to require debridement of the entire superficial layer of the cornea. Under the operating microscope, a cotton-tipped applicator moistened with 10% acetylcysteine[b] is used to gently debride the edge of the ulcer toward the limbus. Once the affected epithelium has been debrided, it should be excised using a #11 scalpel blade or a corneal knife. Standard ulcer treatment is instituted postoperatively. The corneal surface will re-epithelialize from the limbus.

Lens Removal

Trauma (blunt or penetrating) and senile lenticular degeneration have been speculated as causes for cataract formation in birds.[7,27] In canaries, cataracts are inherited, and surgical removal has been recommended.[50] The avian eye is large, conforms closely to the orbit and has limited mobility.[52] Scleral ossicles help support the eye and prevent collapse during surgery.

In a study of older macaws, immature cataracts were present in at least one eye of most birds over the age of 35.[7] In many cases, the cataracts remained immature for several years without completely obstructing vision. The change from an incomplete, immature cataract progressed rapidly to a complete, mature cataract seemingly skipping a complete, immature stage. Those birds with rapidly developing cataracts frequently became blind due to phacolytic uveitis. Lens removal was performed on 13 eyes in 8 birds because of visual impairment or uveitis.[7]

For lens removal in these macaws, no attempt was made to dilate the pupil preoperatively. The macaw cornea is approximately seven millimeters in diameter, which is too small for phacoemulsification instrumentation, and the cataracts were removed using standard surgical technique (Figure 41.3). In the immediate postoperative period, the eyes were treated with a topical steroid-antibiotic ointment,[c] followed by weekly subconjunctival injections of triamcinolone[d] for up to a total treatment period of four weeks. Hemorrhage, synechiae of the iris and sloughing of the corneal epithelium were reported complications; however, postoperative inflammation was minimal in most cases.

Ten of the 13 eyes were visual after surgery. One bird had bilateral posterior synechiae and pigment migration that obstructed vision. A third eye remained blind because of a pre-existing intraocular inflammation that caused a change in consistency of the lens material and retention of the lens protein.[7]

Ultrasonic phacoemulsification may be successful in removing the lens of birds with large eyes (such as

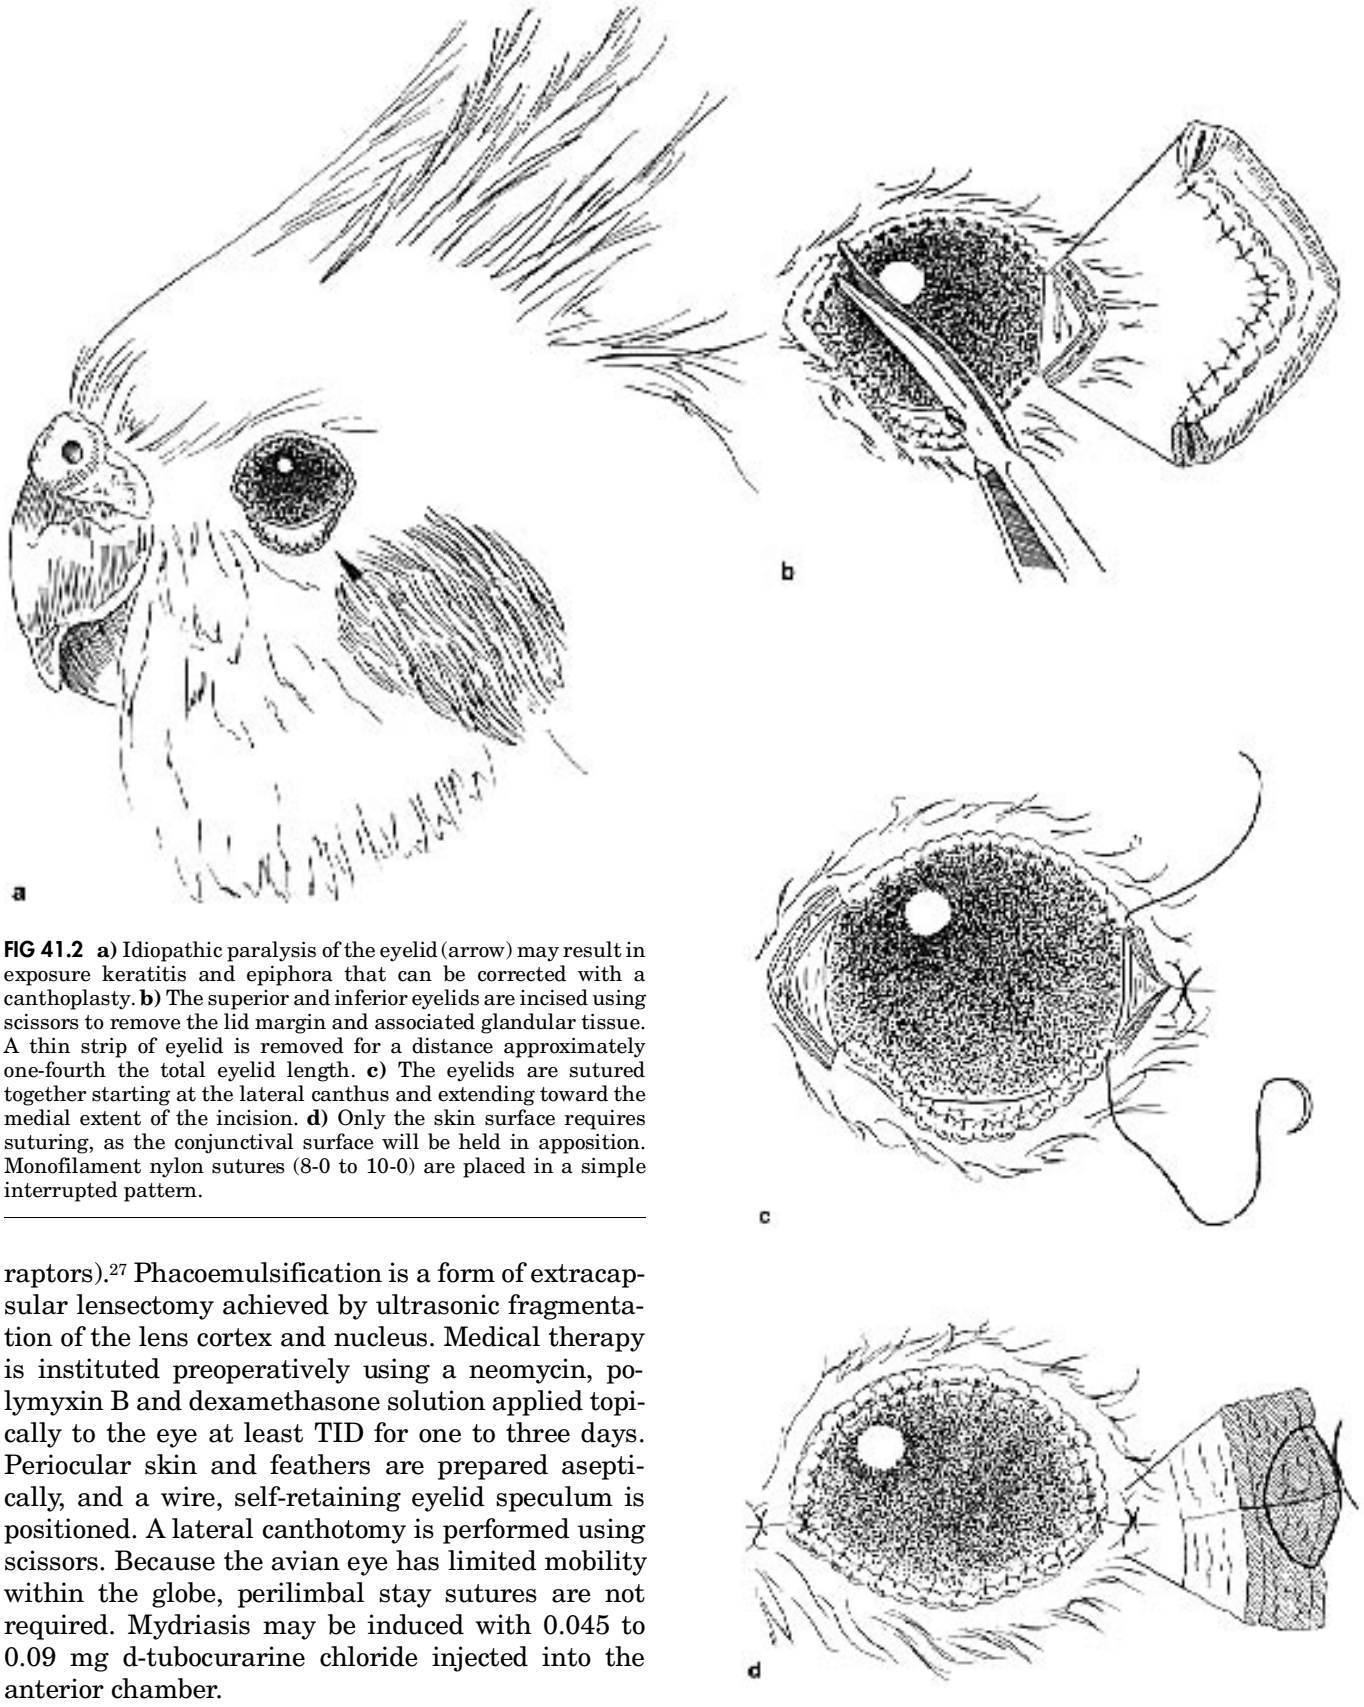

FIG 41.2 **a)** Idiopathic paralysis of the eyelid (arrow) may result in exposure keratitis and epiphora that can be corrected with a canthoplasty. **b)** The superior and inferior eyelids are incised using scissors to remove the lid margin and associated glandular tissue. A thin strip of eyelid is removed for a distance approximately one-fourth the total eyelid length. **c)** The eyelids are sutured together starting at the lateral canthus and extending toward the medial extent of the incision. **d)** Only the skin surface requires suturing, as the conjunctival surface will be held in apposition. Monofilament nylon sutures (8-0 to 10-0) are placed in a simple interrupted pattern.

raptors).[27] Phacoemulsification is a form of extracapsular lensectomy achieved by ultrasonic fragmentation of the lens cortex and nucleus. Medical therapy is instituted preoperatively using a neomycin, polymyxin B and dexamethasone solution applied topically to the eye at least TID for one to three days. Periocular skin and feathers are prepared aseptically, and a wire, self-retaining eyelid speculum is positioned. A lateral canthotomy is performed using scissors. Because the avian eye has limited mobility within the globe, perilimbal stay sutures are not required. Mydriasis may be induced with 0.045 to 0.09 mg d-tubocurarine chloride injected into the anterior chamber.

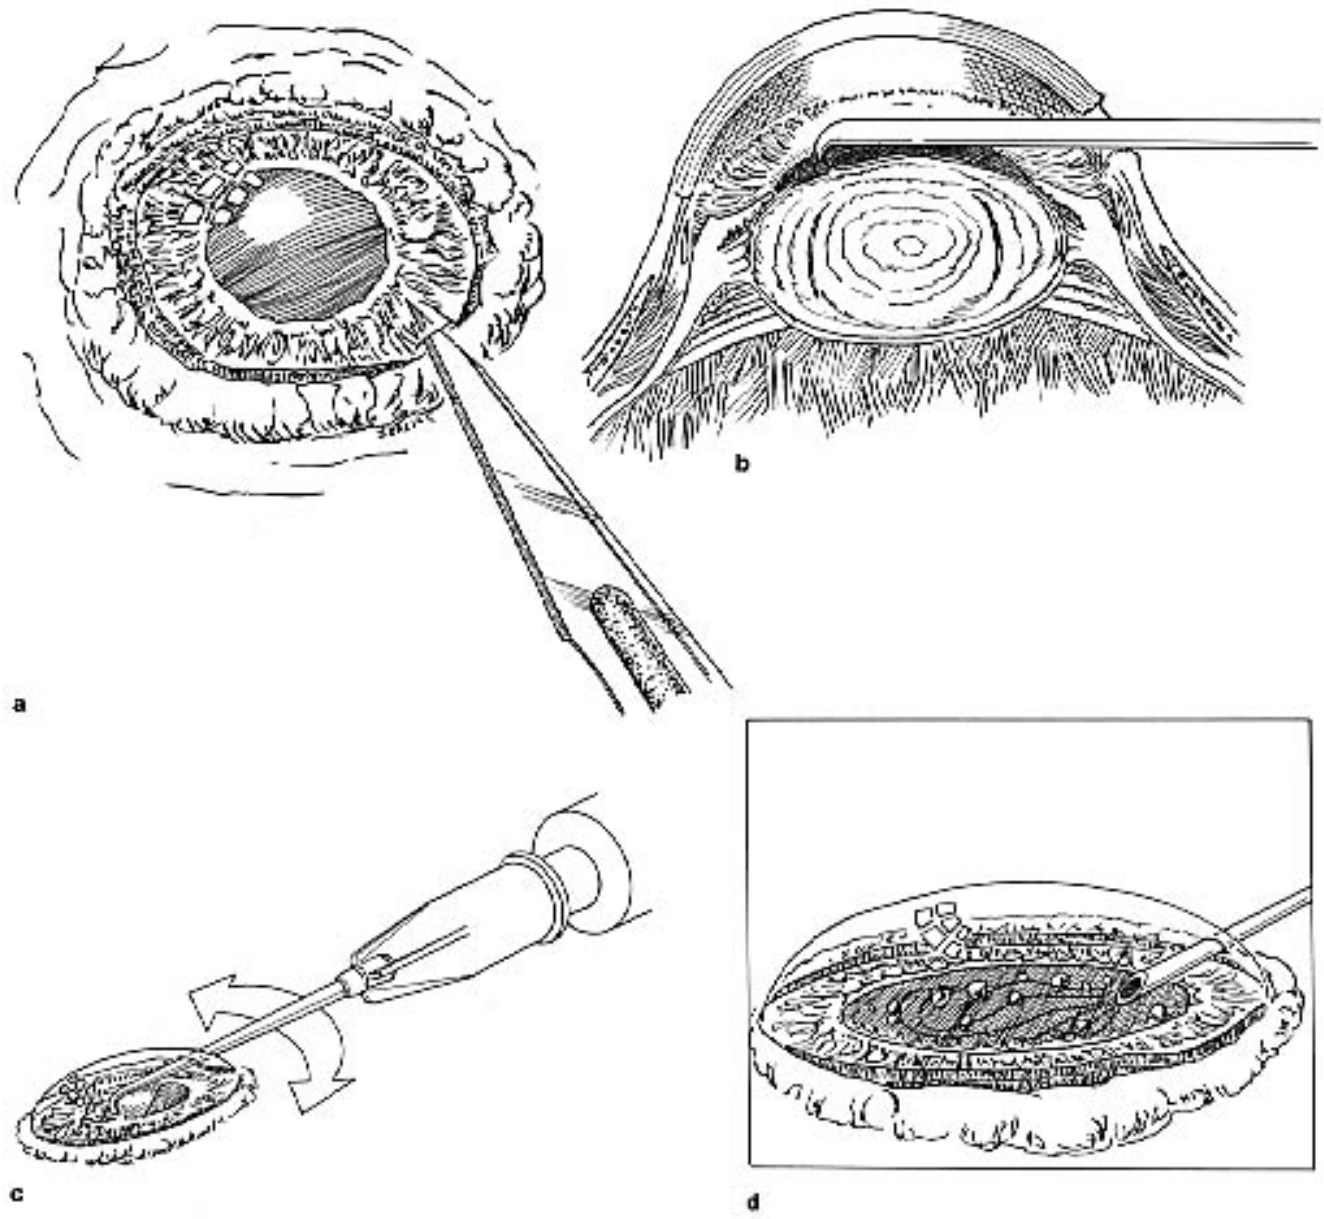

FIG 41.3 Cataract removal can be performed using phacoemulsification in most raptorial birds with large eyes. For most companion birds with small eyes, standard surgical techniques are used. **a)** Under the operating microscope, a small corneal incision is made. **b)** A 26 ga one-inch needle with the tip bent is inserted into the anterior chamber and used to tear the anterior lens capsule. **c)** A needle is then inserted into the lens through the anterior capsule to break down the lens and **d)** it is flushed out of the anterior chamber with lactated Ringer's solution. The corneal incision is closed with one or two simple interrupted sutures.

The phacoemulsification tip requires a 3 mm incision at the limbus or perilimbus at approximately the 10 and 3 o'clock positions. A #11 scalpel blade or a von Graefe cataract knife is used to make these incisions. Prior to making the second incision, a 22 ga needle connected to an IV set (containing lactated Ringer's solution supplemented with aqueous sodium bicarbonate without preservative to a final concentration of 25 mEq/l) is inserted through the first incision. The depth of the anterior chamber is maintained using a continuous infusion of this solution while the second incision is made.

A cystotome or 27 ga needle with a bent tip is inserted through the second incision and used to create a tear in the anterior lens capsule at its periphery. The anterior capsule is not removed in order to help contain the fragments of lens material. After the capsulotomy is created, the needle is removed and

the phacoemulsification tip is inserted through the second incision, through the capsulotomy incision and under the anterior capsule. The tip is hollow with a 0.75 mm internal diameter and is used to aspirate materials or vibrate at 40,000 cycles/second. It is preferable for the lens to be removed without the use of ultrasonic waves. The posterior lens capsule is left intact. Once the entire lens is removed, the anterior capsule is removed by grasping it with Colibri forceps or the cystotome and tearing it from its attachments. The incisions are closed with 8-0 polyglactin 910 in a simple interrupted pattern. The first incision is closed while the infusion needle is maintained. Some fluid is lost during closure of the second incision but the depth of the anterior chamber is reestablished within a few minutes. The lateral canthotomy is closed using 5-0 polyglactin 910 in a simple interrupted pattern. At present, lens replacement devices are not commercially available in a size appropriate for avian patients.

Postoperatively, topical neomycin-polymyxin B-dexamethasone is applied at least TID for approximately 14 days and exercise is restricted for several weeks. Minimal evidence of uveitis has been noted in the postoperative period.[27,38] Corneal edema generally occurs only at the corneal incision sites. Optimum results are achieved when minimal surgical trauma occurs. The corneal endothelium must not be disturbed by touching the inner corneal surface with instruments or by directing the flow of the irrigation solution toward the cornea.

The ciliary processes fuse to the lens capsule in the region of the annular pad (see Chapter 26). The posterior capsule is adhered to the anterior vitreous. Care must be taken to avoid shearing the fused ciliary processes and producing hemorrhage. Posterior capsule opacification may occur as a sequela to extracapsular lensectomy, possibly due to retained lens cortex or iris pigment migration from synechiae.

Enucleation

Enucleation is indicated for treatment of conditions that cannot be managed by other methods, such as neoplasia, overwhelming infection and severe trauma (Figure 41.4). The technique is similar to that described for mammals, except that birds have a very short optic nerve, and excessive traction on the globe can result in pressure trauma to the brain. Visualization of the muscles and blood vessels is enhanced by collapsing the globe at the start of the procedure. After the cornea is incised, the lens and vitreous are expressed through the incision. The lid margins must be excised to eliminate glandular tissue and provide a cut edge for the blepharoplasty. It is also important to remove all conjunctival tissues and any secretory tissue.

One enucleation technique involves suturing the eyelids together to improve the precision of the incision of the skin, which needs to be made a few millimeters from the lid margin circumferentially (Figure 41.5). The dissection is continued subcutaneously around the globe such that the palpebral conjunctiva will be excised with the globe. Hemorrhage is controlled with the bipolar radiosurgical forceps. Once all attachments have been transected except for the optic nerve and associated vessels, hemostatic clips are placed on this neurovascular bundle. Two clips should be applied to assure hemostasis. Curved appliers facilitate placement of the clips caudal to the globe and minimize traction on the optic nerve. The optic nerve is severed and the globe is removed. Any remaining hemorrhage is controlled using radiosurgery. An ocular prosthesise may be used to prevent the sunken appearance characteristic of avian enucleation. The skin margins are sutured together routinely. Drains or bandages are not indicated in most cases.

FIG 41.4 A mature female cockatiel was presented several days after a traumatic injury that resulted in rupture of the globe. The eye was necrotic, and multiple gram-negative bacteria were detected by cytologic examination of periocular discharge. The eye was not salvageable and was removed. Enucleation is a cosmetic solution to ocular neoplasia and severe unresponsive ocular infections.

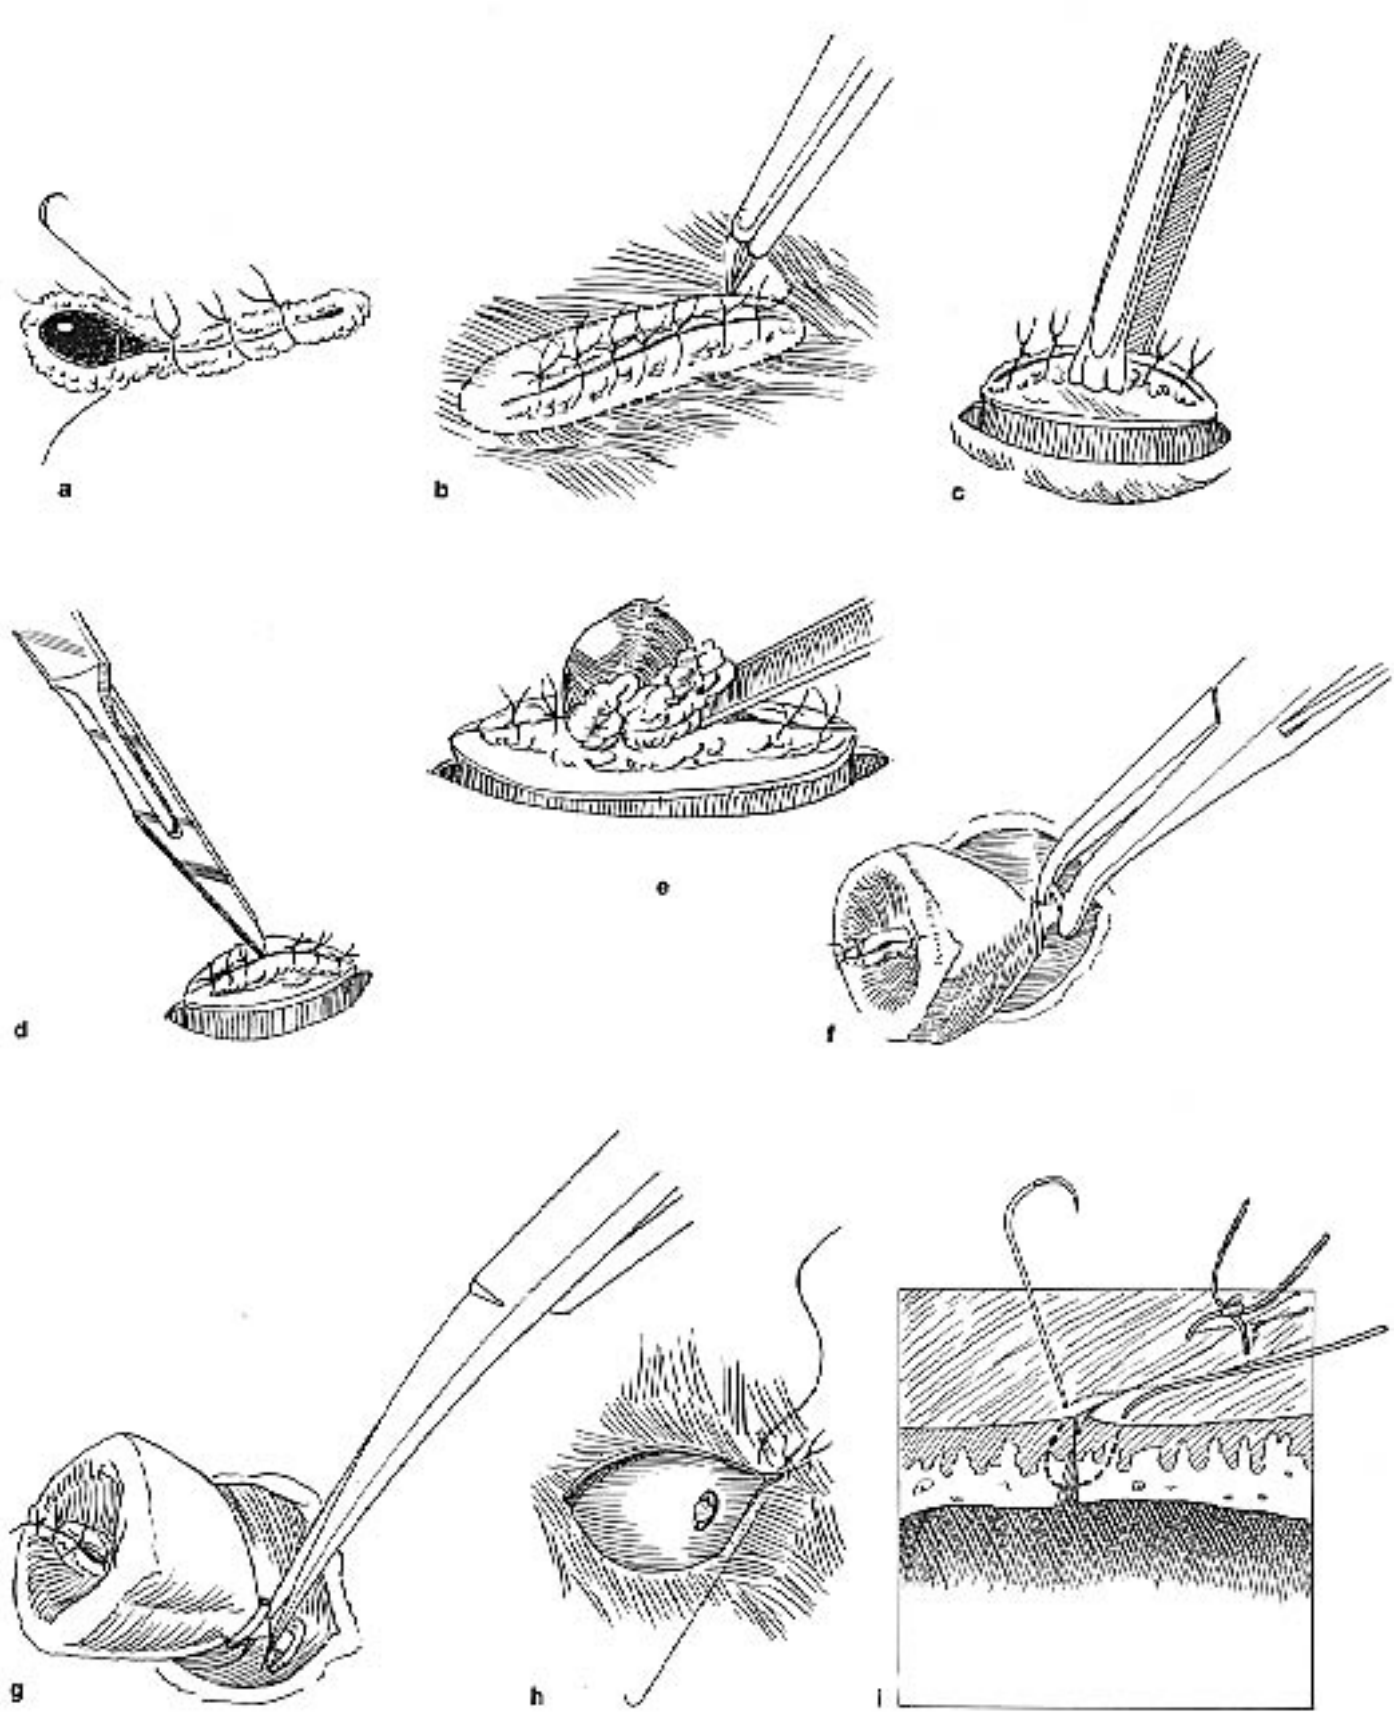

FIG 41.5 A technique for enucleation in birds: **a)** The eyelids are sutured together. **b,c)** The lid margins are incised circumferentially so that the palpebral conjunctiva are excised with the globe. **d,e)** The globe is collapsed and eviscerated. **f)** Two hemostatic clips are placed around the neurovascular bundle at the base of the globe. **g)** The optic nerve is then cut between the clips. **h,i)** The skin margins are closed.

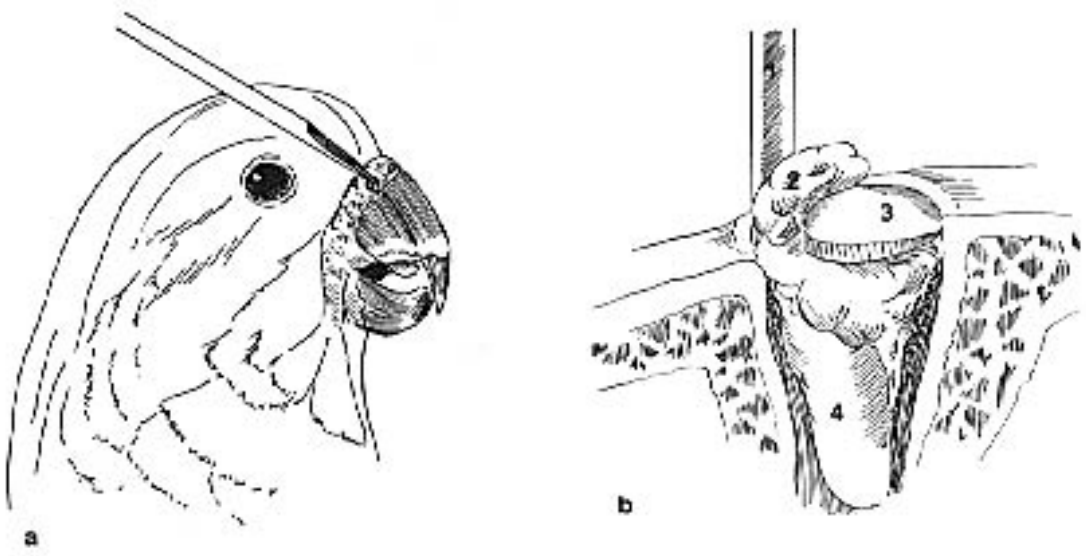

FIG 41.6 **a)** A feathered wooden applicator stick can be used to gently break apart and remove rhinoliths. **b)** These masses start as an accumulation of debris frequently located caudal to the operculum. 1) probe 2) rhinolith 3) operculum 4) conchae.

Surgery of the Respiratory System

Rhinoliths

Rhinoliths may occur secondary to chronic malnutrition and rhinitis (Figure 41.6). These masses, formed of desiccated secretions and debris, cause a physical obstruction to respiration, which may result in respiratory distress and disfiguring atrophy of the nares (Figure 41.7). Clinical signs include sneezing, upper respiratory sounds and inflation of the infraorbital air sac during expiration. Rhinoliths are difficult to diagnose, and identification requires probing under magnification and a strong light source. Once the technique for visualizing these concretions has been mastered, their occurrence will seem quite common.

Removal of rhinoliths requires magnification. Nasal tissues are friable and bleed easily when traumatized, which also predisposes the mucosa to infection. A wooden applicator stick broken to create a long bevel works well to begin the gentle removal of the mass (Figure 41.6). The beveled applicator stick is used to elevate the concretion from the margin of the naris followed by slow, precise, gentle probing with pressure to separate the mass from the wall of the

FIG 41.7 **a)** A conure was presented with a three-week history of progressive dyspnea and inflation of the sides of the face on expiration. The right nostril was partially occluded with dried crusty material, and the area around the nostril was hyperemic; the left nostril shown in this view is relatively normal. **b)** The necrotic material was removed and the nostrils were flushed daily with sterile saline. **c)** Rhinoliths that are allowed to persist can cause disfiguring atrophic rhinitis-type lesions.

nasal cavity. Once the margins of the mass are clearly identified, a slightly thicker metal spatula may be used to finish the dissection. The lith usually breaks during manipulation and is retrieved in fragments. Fragments may fall caudally into the nasal cavity and must be flushed from their resting place behind the turbinates.

Once the rhinolith is removed, the lining of the nasal cavity should be swabbed and evaluated cytologically and by culture for mycotic and bacterial pathogens. The nares should be flushed with dilute chlorhexidine, and any fungal or bacterial component should be treated systemically with appropriate antimicrobial medications.

Infraorbital Sinusitis

Infraorbital sinusitis in birds may lead to secondary lacrimal and conjunctival infections, chronic rhinorrhea and other upper respiratory problems. Effective treatment requires a definitive diagnosis. Frequently, nutritional problems such as hypovitaminosis A predispose a bird to secondary infections with bacteria, yeast and fungi. A sinus flush technique can be used to obtain samples for cytology and cultures (see Chapters 10 and 22).

If untreated, mild infraorbital sinusitis may progress to abscessation that requires surgical exploration and curettage (see Color 22). Clinical signs may include sneezing, rhinorrhea, swollen eye, other ocular diseases, periorbital swelling and conjunctivitis. In some cases, purulent material can be visualized below the conjunctiva of the eyelid or the globe itself (Figure 41.8).

The infraorbital sinus is initially opened in the same location described for sinus flushing (see Chapter 10). This area is highly vascular, and laser, if available, is best for providing hemostasis. Bipolar radiosurgical units on higher coagulation settings may also be effective. Pressure may be applied to the area with a cotton-tipped applicator to allow visualization of the vessels. The sinus must be thoroughly and deeply explored, as purulent debris may be located within the nasal cavity, the recesses of the beak and even between the sinus and the nasal cavity caudal to the turbinates. It may be necessary to remove affected portions of the periorbital bone.

Supraorbital sinus trephination may be used to gain access to the dorsal and caudal-most areas of the sinus that cannot be accessed using nasal flushes and sinus injections.[46] The purpose of sinus trephination is to create an opening in the sinus through which irrigation and antimicrobial solutions may be instilled over a long period of time. Its major disadvantage is the risk of ocular injury. The site for trephina-

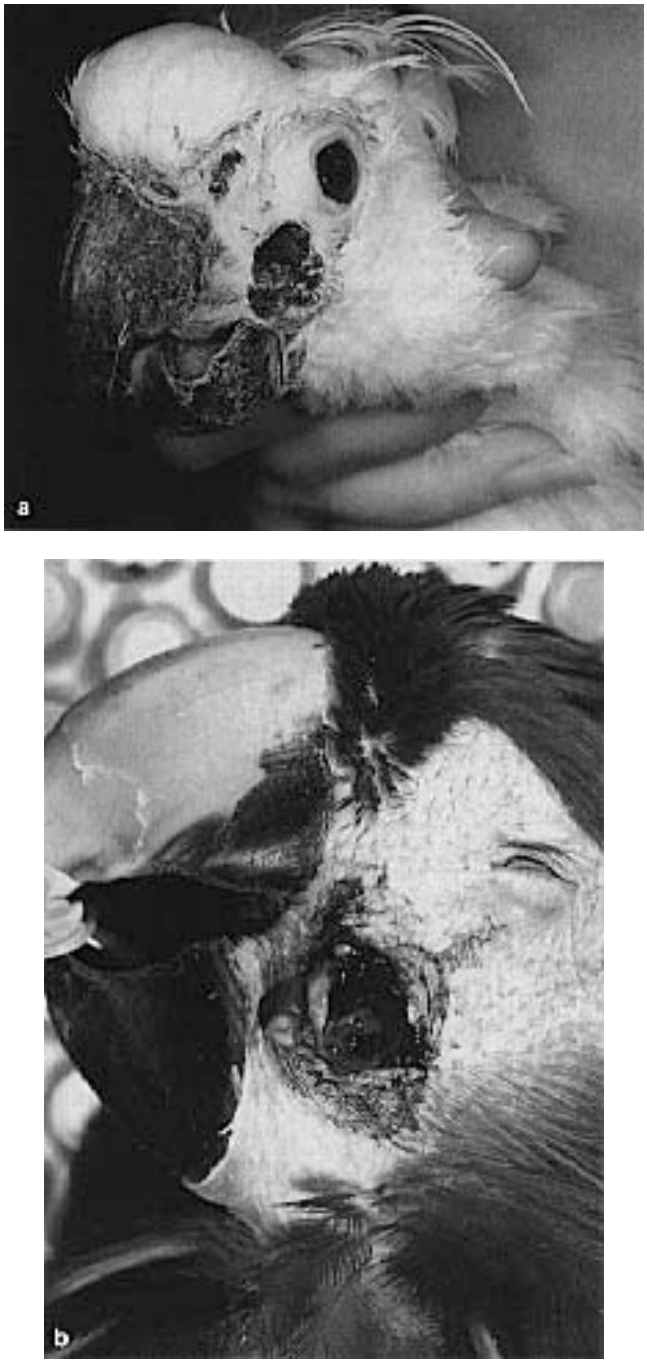

FIG 41.8 If left untreated, infraorbital sinusitis can progress to abscessation with necrosis and discharge from the side of the face as noted in this **a)** Sulphur-crested Cockatoo and **b)** Green-winged Macaw.

tion varies with the species, and the anatomy should be carefully studied prior to attempting this procedure.

To create an opening in the supraorbital sinus, the skin is incised exposing the frontal bone. Holes are made in the bone with a sterile rotary toolf about one-half to two-fifths the distance between the rostral-most plane of the eye and the naris. The hole is angled toward the midline. Cortical bone is removed until the cancellous bone above the supraorbital sinus is visualized. Drilling proceeds into the supraorbital sinus and may then be widened to an appropriate diameter. Samples for cytology and culture are obtained, and the sinus is flushed with irrigation solution. The passage of irrigation solution through the choana and into the oral cavity confirms that the hole is properly placed. The periorbital tissue will bulge when fluids are introduced, and these tissues should not be over-distended. If indicated, this procedure may be performed bilaterally in some Passeriformes, whereas a single trephination site is sufficient in Psittaciformes in which the infraorbital sinuses communicate (see Chapter 22).

The trephination sites may be irrigated as often as indicated with appropriate antimicrobial solutions. The incisions heal rapidly and may need to be opened periodically. When therapy is no longer indicated, the trephination sites heal with minimal scarring.

Hyperinflation of the Cervicocephalic Air Sac

This condition is thought to occur secondary to trauma, but the location of leakage of air into the subcutaneous space is generally not identifiable. Generalized subcutaneous emphysema usually occurs in small birds, while in larger species the emphysema is generally confined to the dorsum of the neck (see Figure 22.11). A procedure for surgically implanting a cutaneous stent at the poll of the head to allow the air to escape (in a location where the bird cannot remove the device) has been described.[12] A Teflon stent,[h] with a 5 mm outer rim that allows the skin to be placed under its edge to prevent the dermis from closing over the opening, is used for the procedure.

A skin incision is made just large enough for the insertion of the stent. Sutures are pre-placed through the four pairs of holes in the flange of the stent such that the suture enters one hole from the external side, doubles back and passes through the other hole from the internal side. Once all four sutures are placed, the stent is implanted. A 22 ga needle is inserted through the skin at the proper location for one tail of suture material to be inserted through the needle to be exteriorized through the skin. This procedure is repeated so that each of the four sutures passes through the skin, one hole of the stent, doubles back, passes through the other hole of the stent and exits the skin. The four sutures should be placed one on each of the four sides of the incision. The sutures can then be tied. The main postoperative problem is a transient occlusion of the stent with dried tissue fluids, which is easily resolved using a swab or needle.

This syndrome has also been treated in an Amazon parrot using a one-way valve connecting the cervicocephalic air sac to the clavicular air sac. The approach is through the left lateral thoracic inlet, and the tube is inserted into the hyperinflated air sac. It is then directed caudally along the esophagus, through the thoracic inlet and into the cranial aspect of the clavicular air sac. The tube is sutured to the longus coli muscles to prevent migration. No attempt is made to suture the air sac around the tube. Skin closure is routine.

Thoracic Surgery

Tracheal/Syringeal Obstruction

Seed or other foreign body aspiration,[9,19] fungal granulomas resulting from aspergillosis or candidiasis[36] or concretions of epithelial cells and mucus may occlude the trachea or syrinx resulting in respiratory distress. Some birds present with no premonitory signs, while others have a history of voice change and a more gradual onset of dyspnea.

Therapy depends upon the size of the patient and the configuration of the trachea. The trachea of some birds such as swans and cranes is coiled and encased within the sternum, making retrieval of distal tracheal foreign bodies extremely difficult (see Figure 12.17).[19] Care must be taken not to push the foreign body into the sternal portion of the trachea. In a Sarus Crane, a 22 ga spinal needle was passed transversely through the trachea to prevent a kernel of corn from migrating farther down the trachea while it was being surgically removed.[19] The avian trachea is composed of complete tracheal rings, which are generally cartilaginous, although calcified rings have been reported in adult Amazon parrots and adult cranes.[19] Annular ligaments connect adjacent rings.[40] In some species, the pessulus (a midline laryngeal cartilage) may be present, providing an additional challenge to foreign body retrieval.[19]

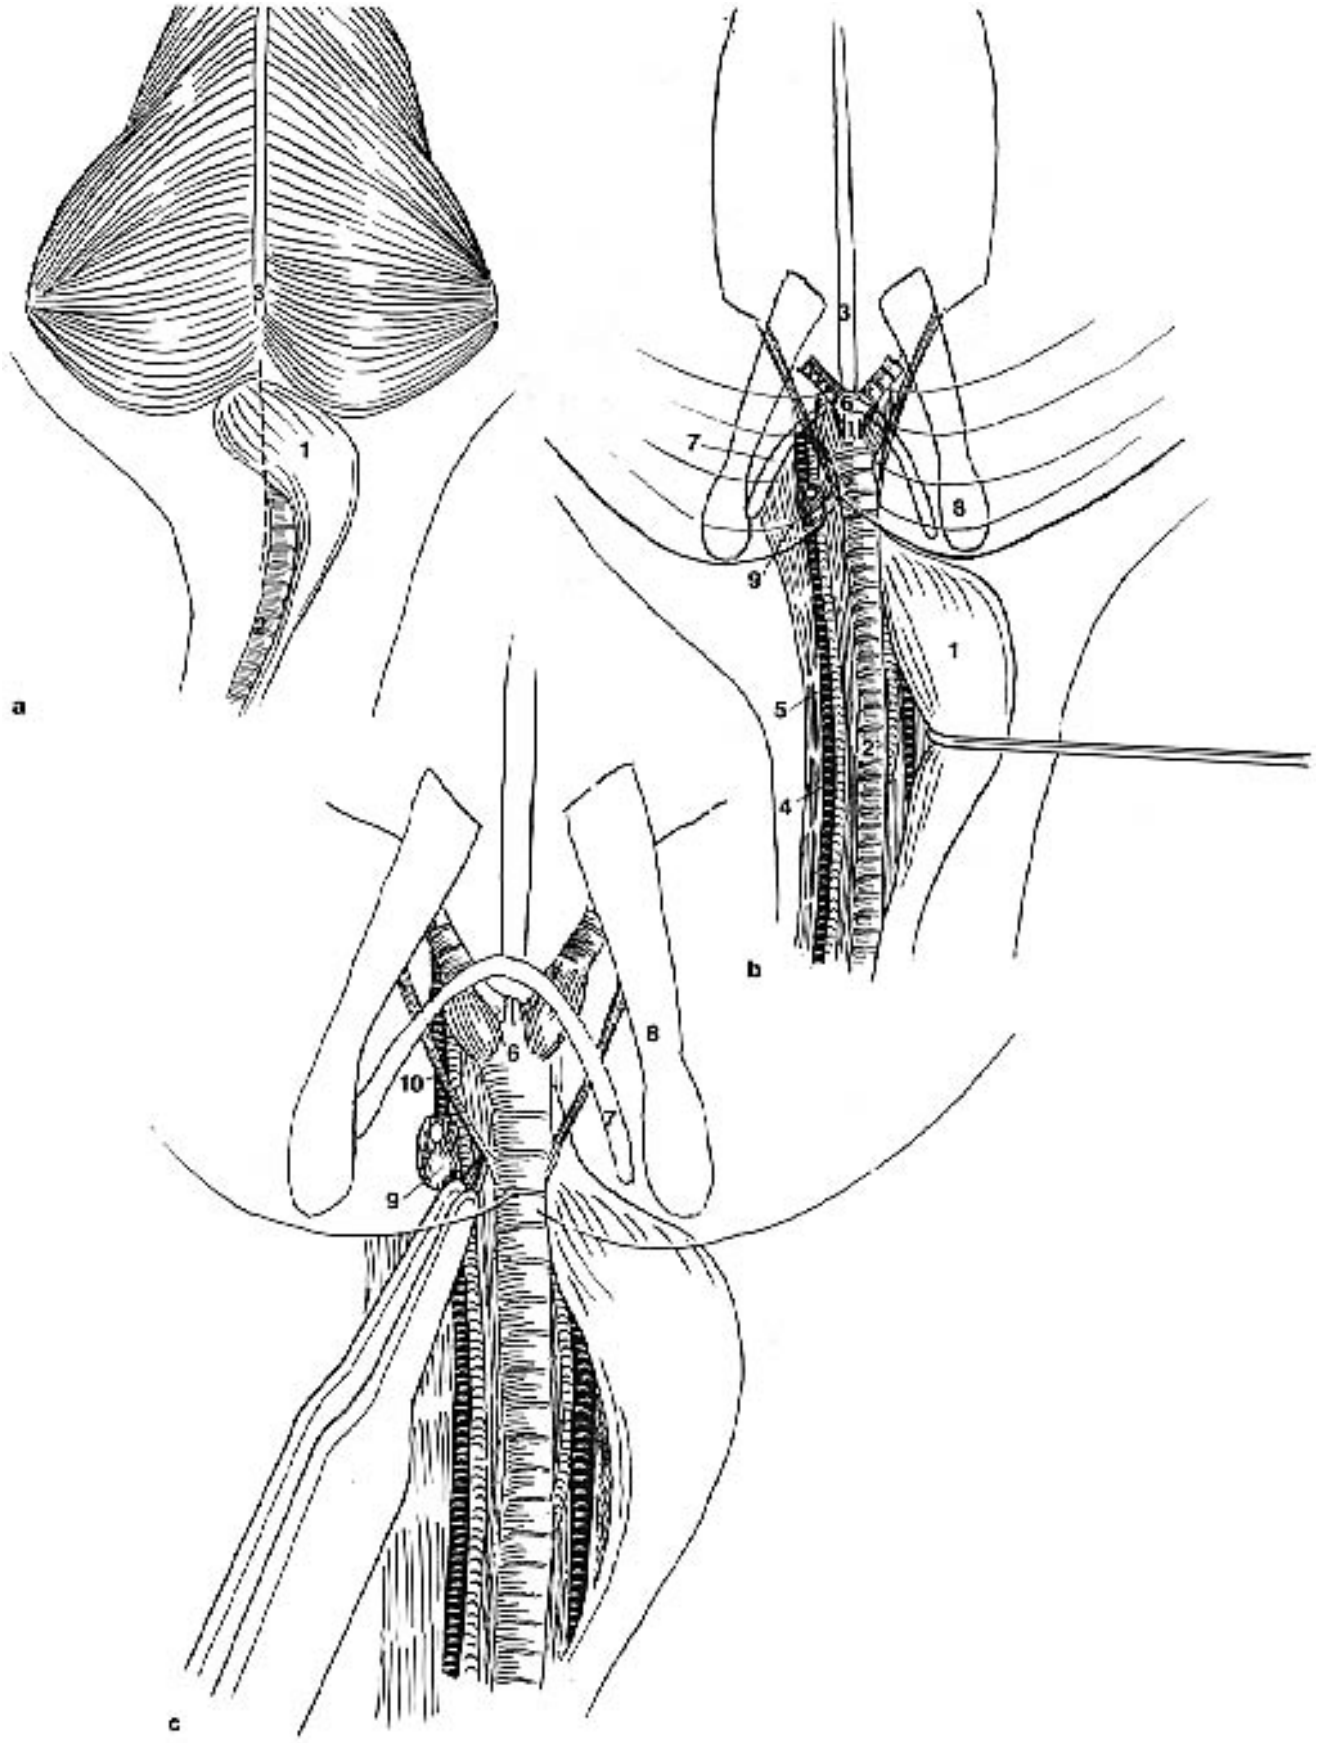

FIG 41.9 If all other techniques for removal fail, some foreign bodies and granulomatous plaques can be removed from the trachea and syrinx using a tracheotomy. **a)** An incision is made over the crop on the ventral midline. **b)** The crop is retracted laterally to the right. **c)** The tracheal muscles are transected using bipolar radiosurgery. *(continued on next page)*

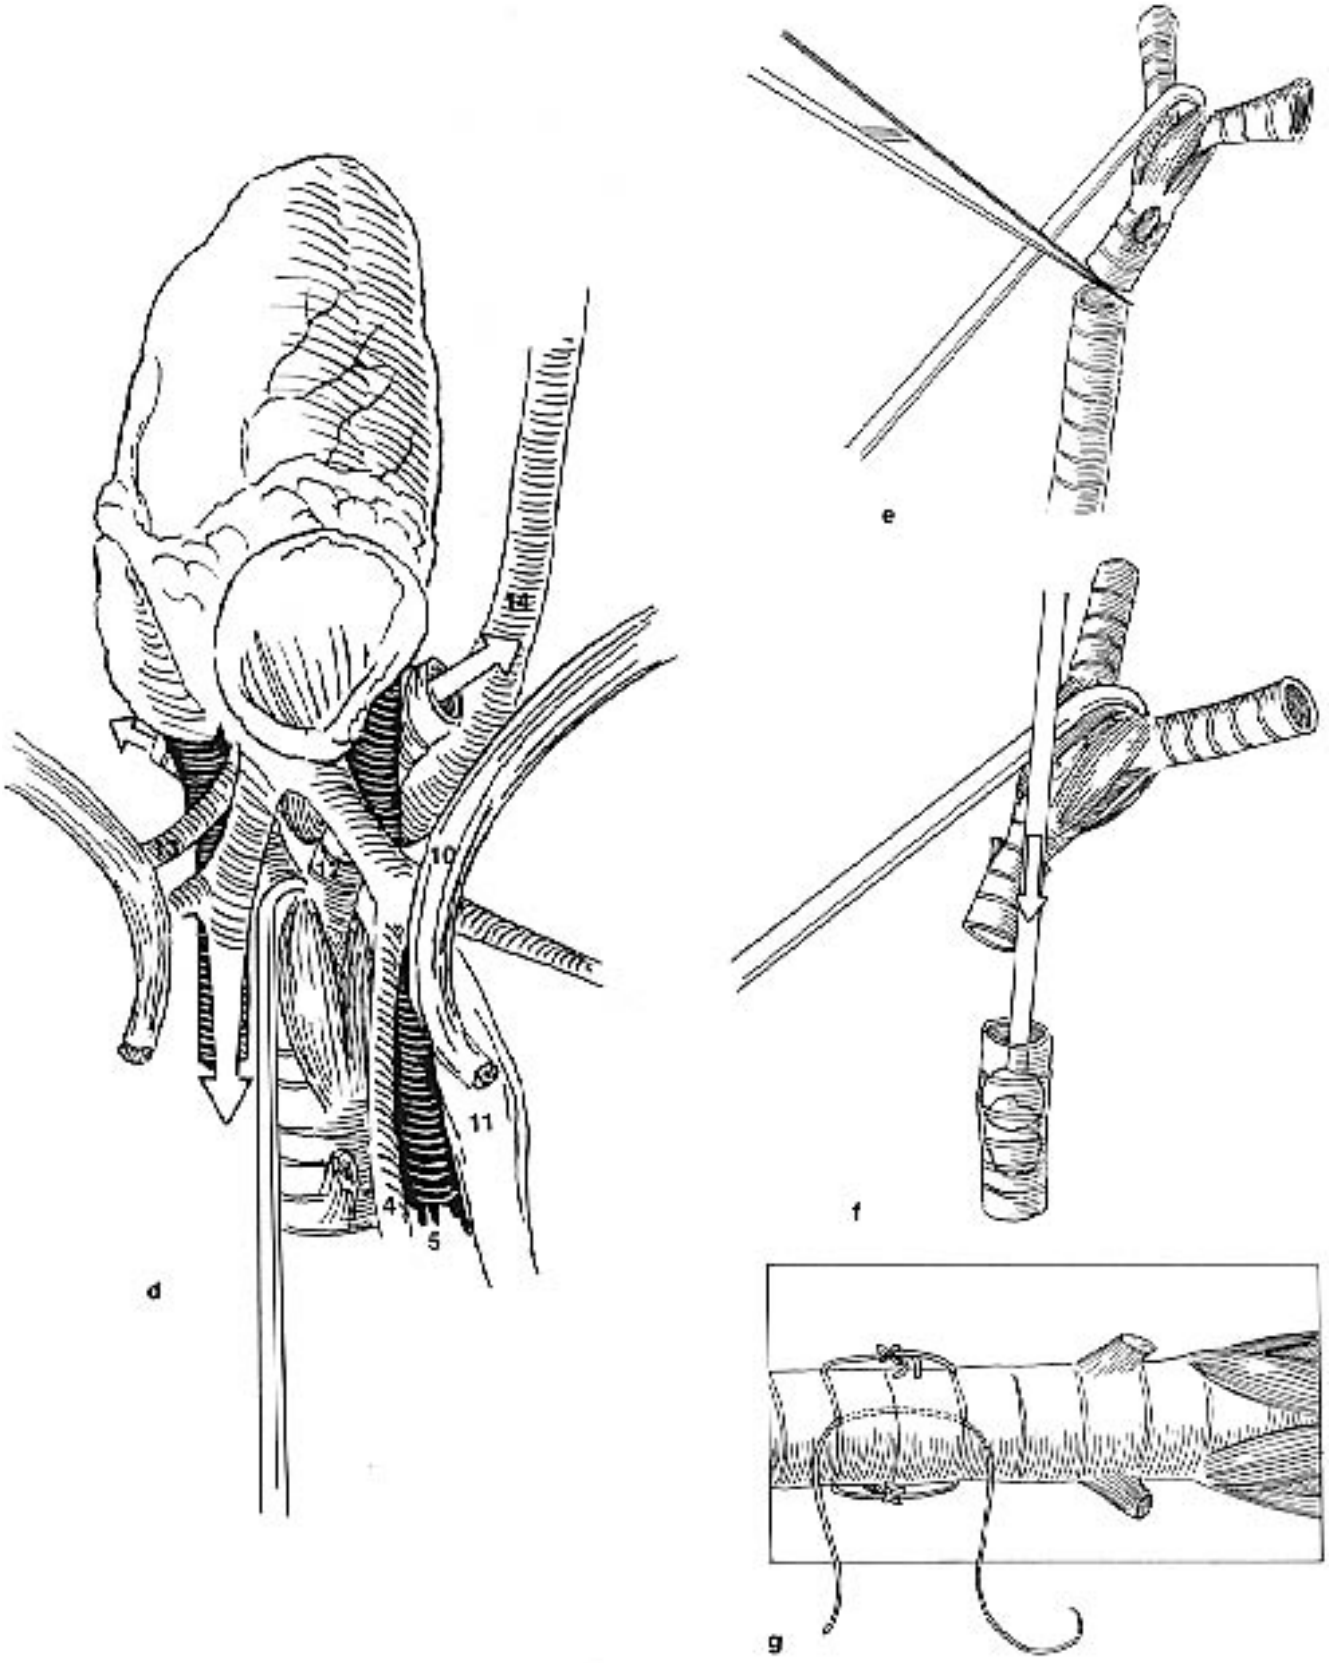

d) A spay hook is used to gently pull the syrinx into the thoracic inlet. **e)** The trachea is transected. **f)** A blunt probang or suction device can be used to remove debris. **g)** Closure is completed by apposing the tracheal rings. 1) crop 2) trachea 3) sternum 4) internal carotid artery 5) jugular vein 6) syrinx 7) clavicle 8) coracoid 9) thyroid 10) sternotracheal muscle 11) esophagus 12) primary bronchi 13) pulmonary artery and 14) aorta; lateral arrows show primary bronchi to lungs.

Establishment of a patent airway is crucial. Placement of an air sac cannula will allow the patient to ventilate through an alternate airway until the obstruction can be removed. It may be beneficial to place the bird in an oxygen-enriched environment prior to manipulating the patient for placement of the air sac cannula.

In small birds (cockatiels and smaller), the tracheal diameter (approximately 1.5 mm for cockatiels) precludes use of an endoscope to retrieve a foreign body or granuloma. If the obstruction is the result of a granuloma or inspissated cells and mucus, a suction tube (urinary catheter) slightly smaller than the diameter of the trachea may be utilized to remove material from the trachea and syrinx (see Chapter 22).[30] By maintaining anesthesia with an air sac cannula, the trachea may be occluded with the suction tube without compromising respiration. If squamous metaplasia secondary to hypovitaminosis A is suspected, dietary modification and vitamin A supplementation should be instituted.

In medium to large birds, a rigid or flexible endoscope can be used to evaluate the cause of an obstruction and potentially aid in its removal. In some cases, the endoscope may allow visualization of the object, but the tracheal diameter may be too small to use a wire basket or grasping forceps to remove the object.[19] In these cases, the endoscope can be used to brush off plaques or physically alter lesions sufficiently to open the airway, and the loosened plaques can be removed with a suction tube. Cytologic evaluation of samples obtained from the suction tube, or the end of the endoscope, may be used to determine the identity of an etiologic agent. Following this procedure, the patient should be treated using nebulization, intratracheal medications and systemic therapies as indicated (see Chapter 22).

In some cases, tracheal foreign bodies may be retrieved using grasping forceps, a Foley catheter[i] or a Fogarty catheter[28] with the aid of an endoscope. The size of the patient's tracheal diameter will determine which catheter is most appropriate. The catheter is passed beyond the foreign body and the balloon is inflated sufficiently to occlude the airway but not to prevent it from being withdrawn. With the balloon inflated, the catheter is withdrawn, resulting in removal of the foreign body.[19,28]

As a last ditch effort in medium- to large-sized birds (parrots, raptors, doves, pheasants and peafowl), the thoracic inlet may be approached surgically for removal of tracheal or syringeal foreign bodies (Figure 41.9). The patient is positioned in dorsal recumbency on a surgical restraint board. A tube should be placed in the esophagus to allow for its easy identification to prevent iatrogenic trauma. The skin is incised from the right clavicular/sternal junction to the clavicular/coracoid junction just cranial to the crop. The skin is elevated from the crop, and the right lateral aspect of the crop is gently dissected from surrounding tissues. Major blood vessels are easily avoided using blunt dissection. Once the crop is freed from its clavicular attachments, it should be reflected to the right. The trachea is identified by its complete cartilage rings. The sternotracheal muscles are identified traversing obliquely to their caudolateral attachments, and both sets of sternotracheal muscles are transected. A large blood vessel between the muscle bellies should be coagulated prior to transection of the muscles. A small canine vaginal speculum may aid in visualization.

At this point, the use of the operating microscope becomes essential. The restraint board should be elevated at the cranial end such that the operating microscope can be used to visualize the structures deep in the thoracic inlet. It may take some time and patience to achieve proper positioning and focus, but this technique allows the surgeon to visualize critical structures while having both hands free for manipulations.

The interclavicular air sac is bluntly dissected to expose the syrinx. A blunt hook is looped over the syrinx, which is gently pulled into view. In Amazon parrots, small macaws and smaller birds, this procedure may result in avulsion of the bronchi from the lung. For these patients, a left lateral approach to the syrinx is recommended as a last desperate attempt.

A transverse tracheotomy (50% of diameter) can also be created on the ventral surface to allow retrieval of the foreign material. Foreign bodies have been removed through longitudinal tracheal incisions;[35,36,44] however, these incisions provide limited visibility and access due to the inward twisting of the cut rings, and are more prone to iatrogenic trauma during manipulation, are more difficult to close than a transverse tracheotomy and are more prone to stricture formation.[15,46] Unless absolutely mandatory, the trachea should not be completely transected in order to maintain its alignment, reduce tension on the closure and prevent complete disruption of the blood supply.[19] Stay sutures placed around the tracheal rings adjacent to the tracheotomy allow atraumatic manipulation of the trachea. Foreign materials located

cranial to the tracheotomy site can be pushed out of the trachea with a sterile probang. Those located caudal to the tracheotomy site can be removed by suction. If the trachea completely separates during manipulations, anastomosis may be performed. The incision should be closed with a small-sized, monofilament, absorbable suture material encompassing at least one tracheal ring on each side of the tracheotomy incision.[19] A simple interrupted pattern is best performed by pre-placing the encircling sutures. Knots should be placed external to the tracheal lumen. Intraluminal granuloma formation at the sutures is common. Soft tissue, skin and subcutaneous closure are routine.

A lateral thoracic approach to the trachea can be used in very small birds where there is no other means to approach and evaluate the syringeal area. Practice and microsurgical techniques are essential for this procedure. The patient is positioned in right lateral recumbency. An incision is made over the second and third ribs. These ribs are exposed using blunt dissection, and they are transected at both ends to allow their complete removal. This will expose the cranial portion of the lung. Using a moistened cotton-tipped applicator, the cranial extent of the lung is gently dissected and reflected from its attachments. The jugular vein, pulmonary artery and branches of the subclavian artery may be identified and should be avoided. Dissecting between these vessels allows visualization of the syrinx, which is incised (2 to 3 mm) using bipolar radiosurgical forceps at its junction with the left primary bronchus. A foreign body may then be removed using a combination of tracheal endoscopy, visualization and suction through the syringeal incision.

The syringeal incision is allowed to close by second intention. The ribs are not replaced. The lung is repositioned in its normal location. Soft tissues are apposed and the remainder of the closure is routine. This is a difficult procedure that should be used only as a life-saving technique when all other methods for foreign body removal have failed.

Devocalization

The authors and editors consider devocalization a cruel and unethical practice; therefore, a procedure will not be described. Birds with vocalization patterns that are unacceptable to a client should be placed in new homes.

Pneumonectomy

Removal of lung tissue may be indicated in the treatment of abscesses or granulomas. In some instances, a surgical lung biopsy may be required instead of an endoscope-guided biopsy for diagnosis of a respiratory disease.[20]

In birds, there is no distinct pleural space, and the visceral and parietal pleura are in close approximation. The pulmonary parenchyma is contoured to the dorsal aspect of the ribs and the intercostal spaces. This makes the lungs easy to approach surgically. Compared with mammalian lungs, those of birds are more vascular and the intrinsic clotting mechanism appears to be less efficient.

The lungs can be approached through the caudal thoracic air sac or the intercostal space by removing one or more ribs as described for the lateral approach to the syrinx. The affected lung tissue is elevated from the ribs and surrounding structures using a moistened cotton-tipped applicator or a spatula. The affected area is isolated using vascular clips, and the tissue to be removed is incised such that the clips remain with the viable portion of lung. No studies have been conducted to determine the amount of lung that may be removed or the physiologic effects of partial pneumonectomy; however, clinically, partial pneumonectomy patients appear to function normally.[20]

Closure is accomplished using wire suture to oppose the intact ribs on each side of the thoracotomy site. For a caudal thoracotomy, the pubis may be utilized to aid in closure of the gap created by the removal of ribs.

Surgery of the Gastrointestinal System

Pharyngostomy Feeding Tube

Pharyngostomy feeding tubes are indicated when it is necessary to aliment the patient while bypassing the oral cavity, esophagus or crop. The technique is simple and straightforward. The right side of the neck at the caudal extent of the lower mandible is prepared for surgery. A small incision is made through the skin, and the esophagus is identified. A moistened cotton-tipped applicator is inserted per os into the esophagus to aid in identification and to prevent the incision from penetrating the opposite side of the esophagus. A small (1 to 2 mm) stab incision is made into the esophagus to allow passage

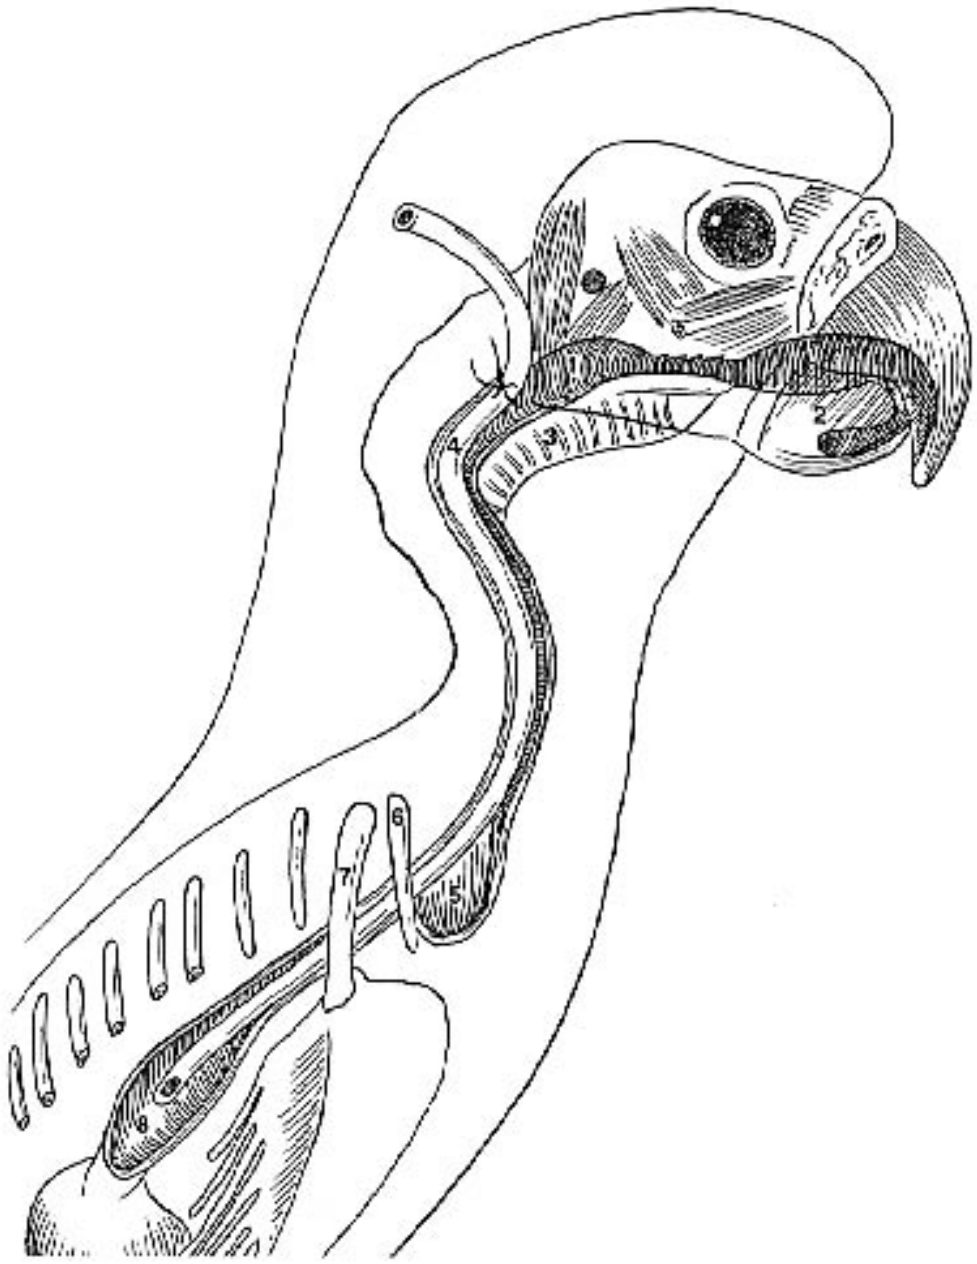

FIG 41.10 A pharyngostomy tube can be used to supply food to the proventriculus and bypass the oral cavity, esophagus and crop. 1) pharynx 2) tongue 3) trachea 4) tube in esophagus 5) crop 6) clavicle 7) coracoid and 8) proventriculus.

of a feeding tube. The tube is advanced into the crop or lower esophageal sphincter and sutured in place (Figure 41.10). A bandage is used to protect the site and to direct the tube to the dorsal cervical area away from the patient's field of vision. When it is no longer needed, the tube is removed, and the esophagus and skin defects are allowed to heal by second intention.

Oropharyngeal Abscesses

Oropharyngeal abscesses in birds frequently occur secondary to hypovitaminosis A (see Color 13). Abscessation occurs following squamous metaplasia and the development of a bacterial infection. These may be located at the base of the tongue, the intermandibular space, the choana, the pharynx or the larynx (see Color 8). These abscesses are often highly

vascular necessitating careful dissection and hemostasis for removal.

Surgical management of an oral abscess involves pretreatment with antibiotics and vitamin A (if indicated). A fine-needle aspirate may be used for culture and sensitivity. In cases of hypovitaminosis A, parenteral vitamin A administration will help encapsulate the abscess and reduce inflammation and vascularization. In some cases, beta carotene therapy has resulted in complete resolution of the abscess without the need for surgical intervention.

Abscesses that are lanced and curetted frequently recur because minute fragments of material may be located within the tissue surrounding the abscess. The abscess will reform when the mucosa heals over the trapped necrotic debris. Removing the tissue surrounding the abscess is preferable. In some locations, such as with intermandibular abscesses, the abscess and its capsule may be removed intact. Dissection is meticulous and time-consuming, and accurate hemostasis is imperative.

Choanal abscesses must be lanced to remove necrotic material followed by surgical removal of the abscess. Laser or radiosurgery are best for controlling hemorrhage in this highly vascular area. Invasive abscesses may erode the palatine artery and result in severe hemorrhage.

Oropharyngeal Papillomas

Oral papillomas are uncommon except in some macaw species. These masses can be removed using cryosurgery, radiosurgery or chemical cautery (silver nitrate). Papillomatous growths that extend into the crop and proventriculus are currently considered untreatable, and are eventually fatal.

Esophageal Perforation

Esophageal perforation may occur from using a rigid feeding tube for supportive alimentation in a struggling bird, in enthusiastic, violently bobbing neonates or from feeding overheated formula (see Color 30). As the tube penetrates the esophagus, food or medication may be deposited in the subcutaneous tissues (Figure 41.11). Additional material may accumulate during subsequent feedings. Edema, sepsis and toxemia occur in response to the foreign material. Emergency and supportive care should be instituted. A proventricular feeding tube should be placed to bypass the damaged esophageal tissue. Fasciotomy, copious irrigation, debridement, topical antiseptics and systemic antimicrobials are indicated. Surgical debridement and closure may be possible in three to five days when the affected tissues begin to granulate and appear healthy. Extensive fasciotomy and copious irrigation are probably the most important portions of the initial treatment.

Esophageal Strictures

A case of esophageal stricture of undetermined etiology in a Hyacinth Macaw was successfully treated by bougienage.[56] The stricture was located in the thoracic esophagus and was believed to be obstructing the flow of ingesta to the proventriculus. Initially a 5 Fr rubber feeding tube was the largest bougie that could be inserted. Three sessions of bougienage separated by a few months produced an increase in lumen size to accommodate an 11 Fr bougie. Attempts to pass larger tubes produced an intense vagal response. Following this treatment, the patient was able to eat solid food. No steroids were administered; however, the owner instituted therapy involving nonsteroidal anti-inflammatory medications (ibuprofen and naprosyn).

Crop Fistula Repair

The primary function of the crop is storage of food. When the crop is full of food, it is often prominent and pendulous, making it more susceptible to trauma.[16] Penetrating wounds can result in the formation of a fistula in the crop. Such wounds are often the result of animal bites, improperly assisted feeding technique, foreign body ingestion, trauma and consumption of excessively hot food items.[16] A permanent fistula may form because food will pass continuously from the crop through the defect in the crop and skin and out into the environment (see Color 30).

Crop fistulae occur most commonly in neonates being hand-fed. The crop of neonates is more fragile and susceptible to injury than the adult ingluvies.[16] One source of injury to the neonatal crop is penetration resulting from improper or careless gavage tube-feeding. This allows food to escape from the esophagus or crop and collect under the skin, creating an abscess and potential toxemia. Early diagnosis and treatment are essential for optimum recovery.[1,16,25] Crop burns may also occur if a hair dryer is used to dry a wet bird.[1] Crop burns most frequently occur when food is warmed in a microwave oven and not thoroughly mixed.[1,4,25] Microwave ovens do not heat

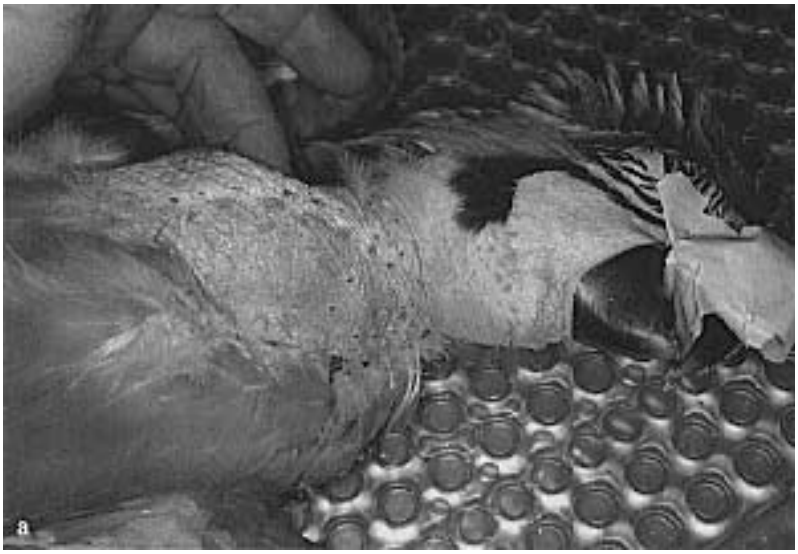

FIG 41.11 **a)** A 15-week-old Blue and Gold Macaw chick that was still being tube-fed was presented with a soft, mobile swelling of the right lateral neck area and thoracic inlet. The bird was depressed, regurgitating and losing weight. **b)** An esophageal tear that was allowing food to collect subcutaneously was located in the mid-neck area. The skin tissues overlying the accumulated food were excised, and the subcutaneous tissues were flushed with copious amounts of warm LRS. Penrose drains were placed to facilitate flushing of the subcutaneous tissues.

food uniformly and generate areas where the food is excessively hot.

Crop burns may be small or very extensive. Immediate treatment consists of removing the hot food and replacing it with cool water.[25] The patient should be placed on antifungal medication and a systemic antibiotic. Small frequent feedings should be used to minimize the stretching force placed on the crop. Small burns may not be noticed immediately and may develop fistulae. Birds with crop burns may present in the acute phase when it is difficult to determine the extent of the injury, or in the chronic stage when a well developed fistula is present.

Chronic crop fistulae are generally easier to deal with than acute crop burns (Figure 41.12). Because a fistula has developed, the serosa of the ingluvies and the skin have healed together as one tissue. These must be separated using scissors to circumferentially excise the edge of the fistula. Using meticulous dissection, the tissue plane between the ingluvies and the skin is identified and separated. The skin is normally adherent to the crop, being attached by two layers of striated muscle that form a sling-like support for the diverticulum of the crop.[1,37] Once the two tissues are separated, closure is as described for ingluviotomy. It is important to repair the crop as a separate structure from the skin to minimize the chance of dehiscence, which is more likely to occur if the two are closed as one tissue. Placement of a tube from the mouth through the crop into the distal esophagus or into the proventriculus will aid in identifying the crop lumen.

In some cases, the crop may develop a defect while the skin remains intact,[16] causing an accumulation of food in the subcutaneous space that may be misdiagnosed as crop stasis (Figure 41.11). The affected skin should be opened, the subcutaneous tissues debrided, the crop and esophagus closed and the skin defect managed as an open wound. The wound should be evaluated periodically and debrided of any food material or necrotic tissue accumulates. Once the subcutaneous tissues are healthy, the skin defect may be closed or it may be left to heal by second intention.

Cases of acute crop burn are significantly more challenging than chronic crop injuries. Severe cases of crop burn may be fatal as a result of metabolic changes, sepsis and absorption of toxins from necrotic tissues. Initial treatment should be supportive and should include shock therapy, broad spectrum antibiotic therapy and antifungal medication. In cases of severe burns with significant edema, fasciotomy may be beneficial.[13] The affected area should be

liberally opened, copiously irrigated and left to heal by second intention or a delayed closure performed at a later date. In less severe cases, clinical signs may simply be consistent with a "sick bird:" lethargy, anorexia and fluffed appearance.[16]

The feeding regimen will need to be changed in order to bypass the damaged tissues. This can be accomplished using a needle catheter intestinal feeding tube[11] or by tube-feeding directly into the proventriculus. It is important to instruct the owner on proper methods for tube-feeding, and it must be stressed that the proventriculus cannot hold the same volume of food as the ingluvies; therefore, feedings will be more frequent and of smaller volume.

In most cases, it will be three to five days before the delineation between healthy and devitalized tissues becomes apparent,[1] and it may take as long as 7 to 14 days.[45] Prior to this, it will be difficult to determine what tissue should be removed and what is viable and should remain. Burned tissue becomes pale and edematous and then becomes dry, dark and leathery. Eventually, the devitalized tissue will separate from viable tissue and the edges of the crop and skin will heal together, forming a fistula (see Color 30).

Any tissue that is obviously necrotic should be debrided to reduce the body's burden of necrotic tissue. If a skin and crop defect result from this debridement, this defect can be used to intubate the proventriculus for nutritional support and also to cleanse and apply topical antiseptics to reduce the chances of developing fungal or bacterial infections.

The definitive correction should be postponed until approximately five days after the injury when the demarcation between healthy and devitalized tissue is apparent.[1] It is often beneficial to endoscopically examine the crop prior to planning the surgery. A small catheter can be used to inject air and dilate the crop, and an endoscope can be used to detect avascular, darkened areas. It is important to evaluate the entire crop, because devitalized mucosa may occur away from the primary burn. The aboral extent of the crop at the thoracic inlet is a location where devitalized areas are often missed.

At surgery, all necrotic tissue must be removed and the tubular structure of the esophagus and ingluvies reestablished. In some cases this may be very challenging, as major portions of crop may be devitalized. If possible, the length of the crop should be maintained even if only a thin strip of esophageal tissue remains. Esophageal strictures are more likely to occur if a resection and anastomosis have been performed than if a thin strip of normal esophagus is preserved and allowed to granulate over a stent. If enough viable tissue remains, it may be sutured around a pharyngostomy feeding tube, through which the patient can receive alimentation while the crop is healing. The crop will stretch in time, but the patient must be fed frequently small volumes of soft or liquid diets until the capacity of the ingluvies increases.[1] Where indicated, a Penrose drain may be placed to provide postoperative local drainage and may also be used for wound irrigation.[16]

In cases where there is extensive tissue loss, the defect may be allowed to heal by second intention while maintaining the patient with a pharyngostomy feeding tube. If the defect is so large that wound contraction cannot occur, a dermoplasty may be performed once there is a healthy bed of granulation tissue. A rotating skin flap will generally provide tissue to cover the defect.

Ingluviotomy

Neonates are susceptible to ingestion of foreign objects such as substrate materials, especially if they are underfed. Feeding tubes, small toys and unhulled seed may also be ingested.[4] These objects may interfere with the passage of food and may irritate the lining of the ingluvies.[4] Palpation of a persistent lump in the crop, food retention, delayed crop emptying and regurgitation are clinical signs associated with crop foreign bodies.

Small objects may be retrieved from the crop using a flexible endoscope and a biopsy instrument. Many foreign bodies including feeding tubes can be pal-

CLINICAL APPLICATIONS

How to Repair a Crop Fistula (Figure 41.12)

- Intubate the patient and pack the esophagus with moistened gauze to prevent flush solution from entering the pharyngeal area.
- Remove any necrotic tissue and thoroughly clean the underlying bed of granulation tissue with a dilute chlorhexidine solution.
- Once the tissue defect is thoroughly cleaned, debride the edges of the fistula to remove granulation tissue and completely separate the crop from overlying skin.
- Separate the skin and crop further by careful blunt dissection with strabismus scissors.
- Perform the closure in two layers. The crop is initially closed with an inverting suture pattern making certain that the incision line extends past the defect on both ends. The skin can be closed in a simple interrupted pattern.

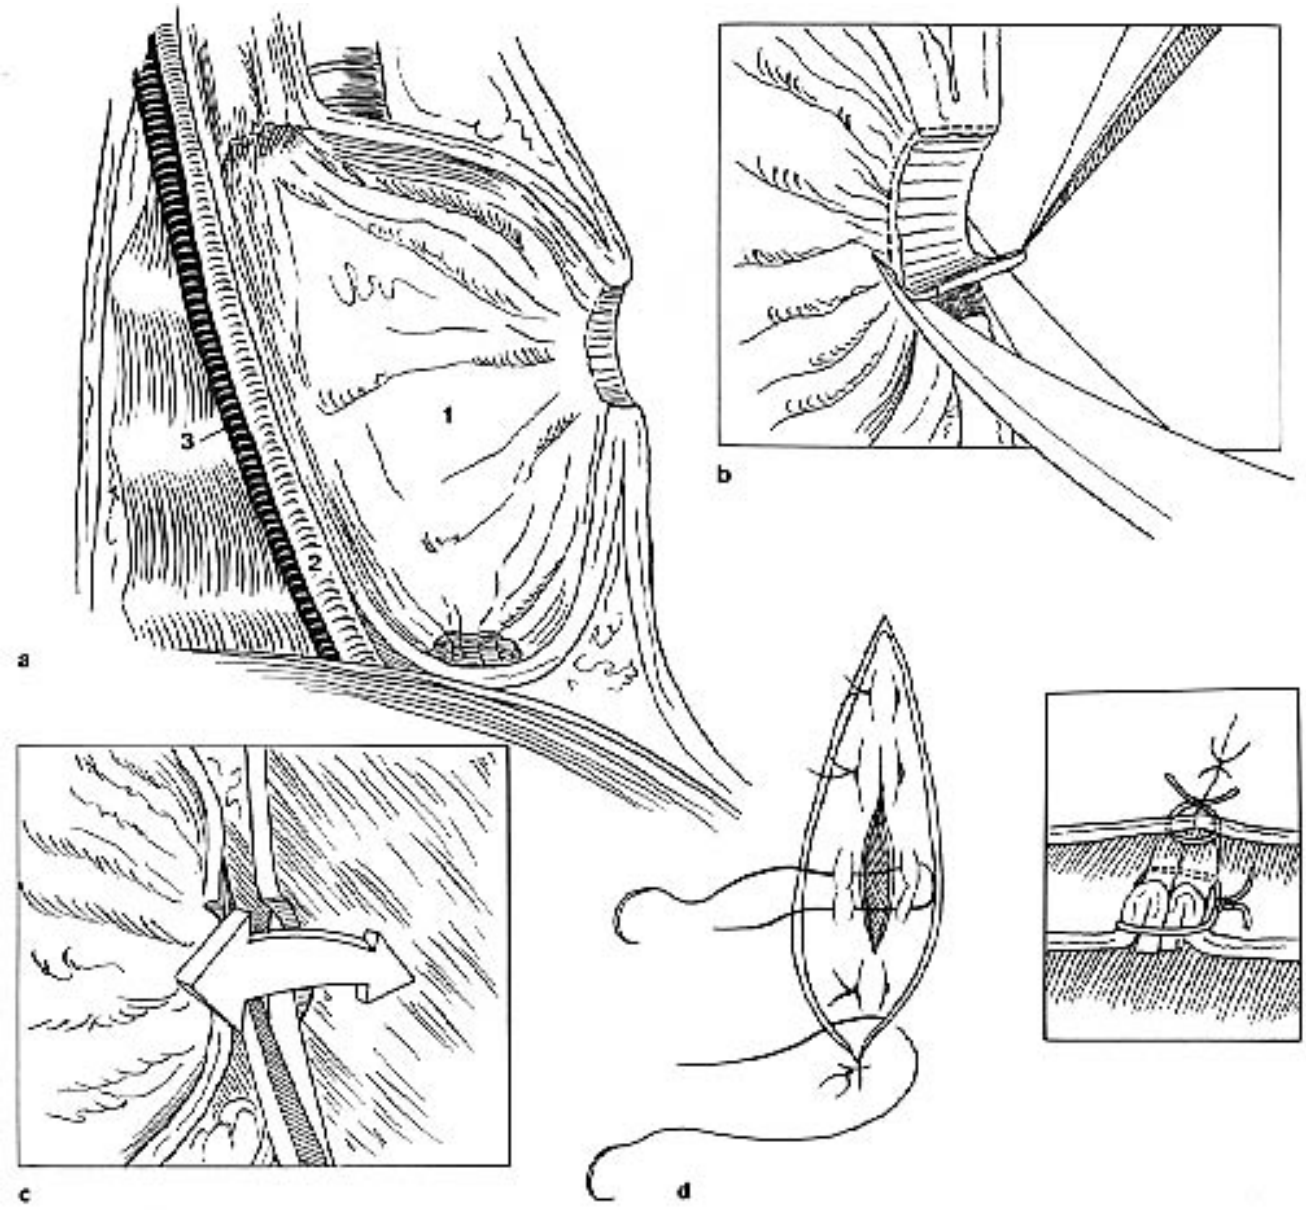

FIG 41.12 Crop burns frequently result in the formation of fistulas that must be surgically repaired. The surgical closure of a burn should be delayed as long as possible to allow the body to differentiate between healthy and devitalized tissue. **a)** Fistula in the crop. **b)** The wall of the fistula is debrided and **c)** the skin and crop are separated by blunt dissection. **d)** The crop is sutured with an inverting suture pattern and the skin is closed with a simple interrupted pattern. 1) crop 2) internal carotid artery and 3) jugular vein.

pated and removed using a hemostat. Instilling a dilute water-soluble lubricant into the crop may help prevent iatrogenic injury to the crop and esophageal wall.[25] If the object is to be digitally manipulated out the pharynx, traction on the head can be used to stretch the neck, allowing the object to be pushed into the pharynx. This is not as easy as it sounds, and care must be taken to prevent iatrogenic injury to the crop, esophagus and mouth.[4]

Indications for ingluviotomy include foreign body removal,[1,29] placement of a feeding tube and gaining endoscopic access to the proventriculus and ventriculus.[55] To perform an ingluviotomy (Figure 41.13), the patient is positioned in dorsal recumbency with the head elevated and the esophagus occluded with moist cotton to prevent fluids from refluxing into the oral cavity. An incision is made through the skin, only over the cranial edge of the left lateral sac of the crop. The skin incision can be made using a radiosurgical

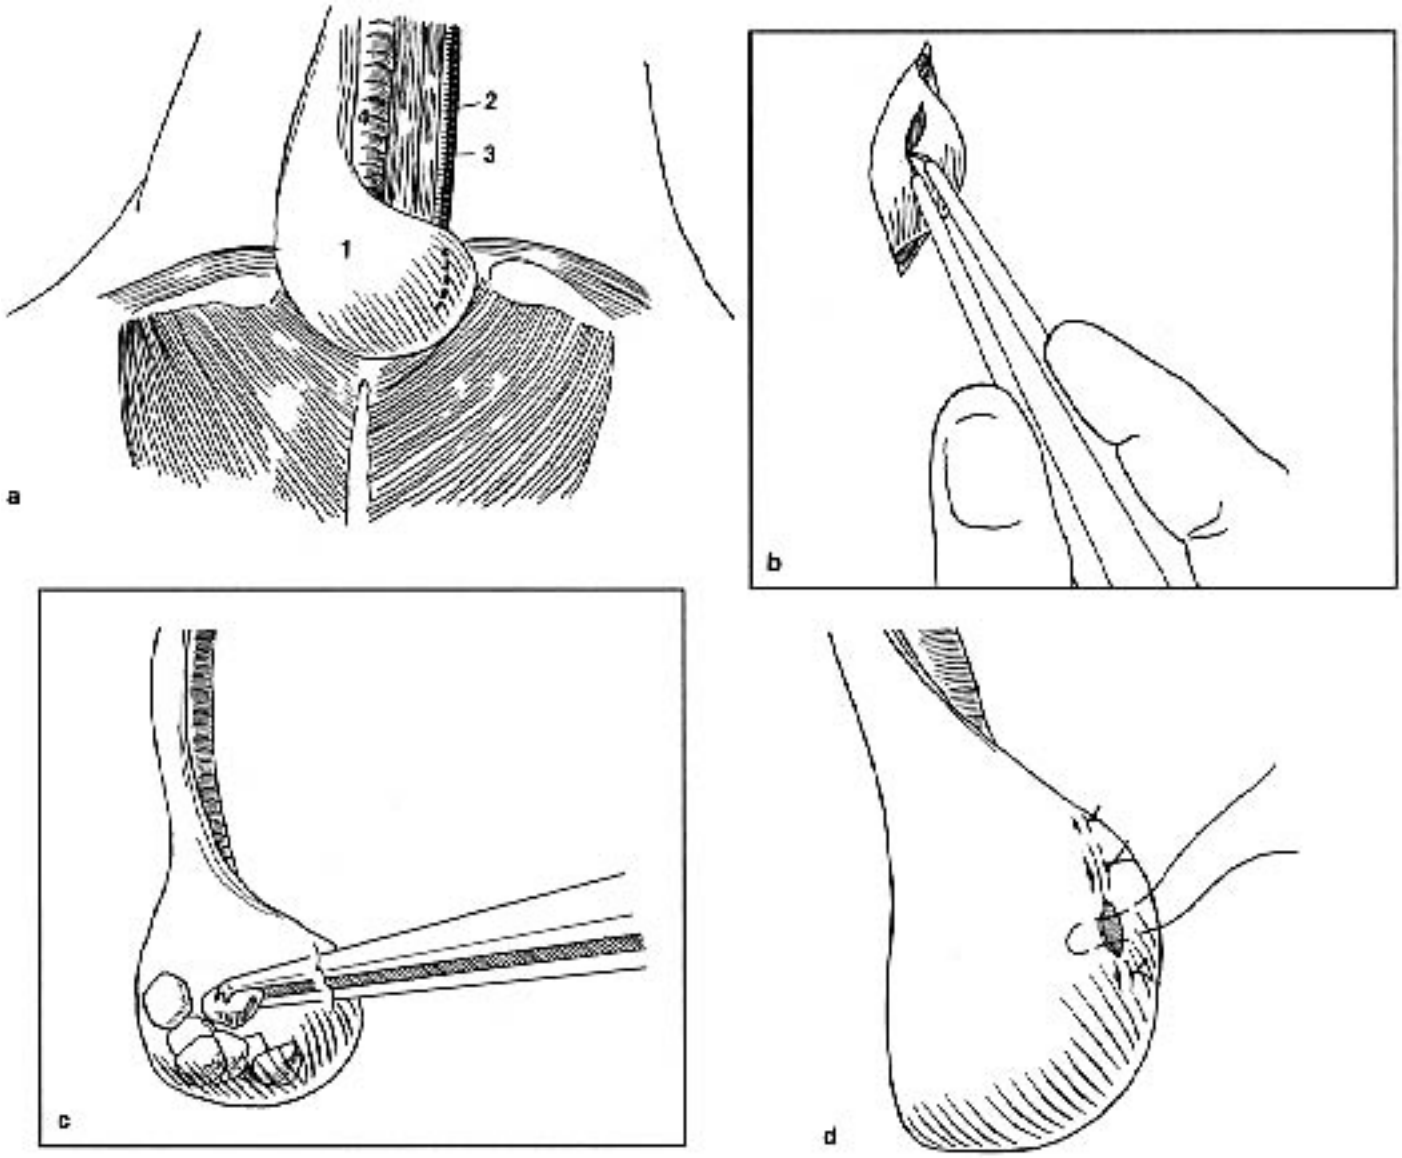

FIG 41.13 Ingluviotomy may be indicated to remove foreign bodies or to gain endoscopic access to the proventriculus and ventriculus. **a)** A skin incision is made over the left lateral portion of the distended crop. **b)** A sharp incision is made into the crop. Specific bleeding can be controlled with radiosurgery, but the incision in the crop should not be made using this unit. **c)** Foreign materials can be removed with forceps or by flushing with dilute chlorhexidine. **d)** The crop and skin are closed in separate layers. 1) crop 2) internal carotid artery 3) jugular vein and 4) trachea.

unit. This area of the crop is less subject to stress as the crop fills and is out of the path of a feeding tube. Because of the ability of the ingluvies to stretch, the incision should be made only about half the size necessary to accomplish the procedure; however, having adequate exposure is more important than having a small incision, and retrieval of large foreign bodies through small ingluviotomy incisions should not be attempted. The crop generally heals without complication. The crop incision should be made with a blade in an avascular area. Radiosurgery should be used to seal only specific vessels. Use of the radiosurgical forceps will result in unnecessary tissue trauma. The opening can be enlarged as needed. The incision is closed using an inverting technique with an absorbable material swaged on an atraumatic needle. Two-layer inverting patterns are frequently recommended;[4] however, one layer of simple continuous appositional sutures over-sewn with an inverting pattern is effective and is less compromising on the size of the crop lumen. The crop may be inflated with saline or air to check for leakage prior to skin closure. Foreign bodies can be removed manually or impacted material can be removed by flushing.

Celiotomy

Surgical approaches to the abdomen involve invasion of the air sac, allowing anesthetic gas to escape through the celiotomy site. This effect can be minimized by packing the borders of the incision with saline-moistened gauze sponges. Additionally, an air sac cannula may be introduced into the abdominal air sac on the side contralateral to the surgical incision. This will allow anesthetic gas to enter an intact air sac, pass through the lung and out the trachea. Using this technique, anesthetic gas does not escape from the surgery site, and waste gas can be scavenged from the trachea. For any celiotomy, the patient should be positioned with the cranial part of the body elevated 30 to 40° to prevent irrigation fluids from flowing craniad and entering the lungs following incision of the air sacs. Similarly, patients with ascites should have the fluid removed from the coelomic cavity prior to opening the air sacs. Moistened cotton may be placed in the caudal pharynx to occlude the esophagus and prevent proventricular reflux from entering the oral cavity and causing aspiration pneumonia. The celiotomy approaches used for access to the avian abdomen include left lateral, ventral and transverse. Skin incisions can be made in varying arrangements and combinations depending on the surgical procedure and the degree of abdominal exposure that is required (Figure 41.14).

Left Lateral Celiotomy

A left lateral celiotomy provides the best exposure of the proventriculus, the ventriculus, the female reproductive tract and the left kidney (Figure 41.15).[15,24] With the patient in right lateral recumbency, the caudodorsal border of the sternum can be palpated. The pelvic bones, including the cranial extent of the pubis, should be identified. The left leg should be retracted as far caudally as possible, creating a fold of skin (knee web) in the flank extending from the stifle to the lateral margin of the sternum. In small patients, lung tissue can be visualized per cutaneously through the intercostal spaces between the fifth, sixth and seventh ribs. In larger birds, the latissimus dorsi and iliotibialis cranialis muscles obscure visualization of the lung. The skin incision will extend from the cranial extent of the pubis to just dorsal to the uncinate process of the fifth or sixth rib. The incision is started in the knee web and continued ventral and caudal following the boundaries of the postventer and postlateral regions, passing through the groove of the groin web caudally to the region of the pubic bone. Care should be taken to incise only the skin, which is easily accomplished using the modified bipolar radiosurgical forceps. Once the skin is incised, the left leg may be further retracted caudally and somewhat dorsally to expose the abdominal wall. A branch of the superficial medial femoral artery and vein should be identified passing over the lumbar fossa toward the pubis. These vessels should be sealed or ligated prior to incising the musculature. The radiosurgical body wall incision is initiated in the external abdominal oblique muscle, just caudal to the last rib. The incision is extended caudally through the internal abdominal oblique and transversus abdominis muscles to the cranial extent of the pubis.

The intercostal vessels coursing along the cranial border of the last two or three ribs should be ligated or coagulated. In small birds, these vessels may be sealed by inserting the indifferent electrode inside the thoracic wall, lightly opposing the electrodes, withdrawing the electrodes until the cranial aspect of the rib is encountered, then activating the electrodes. In larger birds, it is best to cut the rib, clamp the vessel cranial to the rib to achieve hemostasis, then identify the vessel visually and apply a hemostatic clip. In larger birds, the caudal-most two or three ribs will need to be transected at their dorsal and ventral extents and removed to achieve adequate visualization of the viscera. In small birds, excision of the ribs may not be required. They may be fractured and retracted dorsally to provide proper exposure. This method is preferred, because closure of the incision is easier. Once the incision is made through the musculature, the shiny surface of the caudal thoracic or the abdominal air sac is visualized. In some patients, the lung extends caudally as far as the seventh rib. Care must be taken to prevent lacerating the lung, which can be gently elevated using a moistened cotton-tipped applicator if necessary.

A Heiss, Alm or mini-Balfour retractor should be positioned to maintain retraction of the body wall. Entering the air sac, the surgeon can visualize the lung parenchyma and the hilus of the caudal thoracic air sac entering the lung at its craniodorsal extent. Dorsally, the liver lobes become thin at their margins, and the wall of the proventriculus can be observed. If the abdominal air sac is entered instead of the caudal thoracic air sac, the lung is not visible, but will lie dorsolateral to the incision rather than cranial as observed when entering through the caudal thoracic air sac. Medially, the proventriculus can be seen suspended by the air sacs and suspensory ligaments. Often the intestines are the first structures encountered. They can be gently retracted using a cotton-

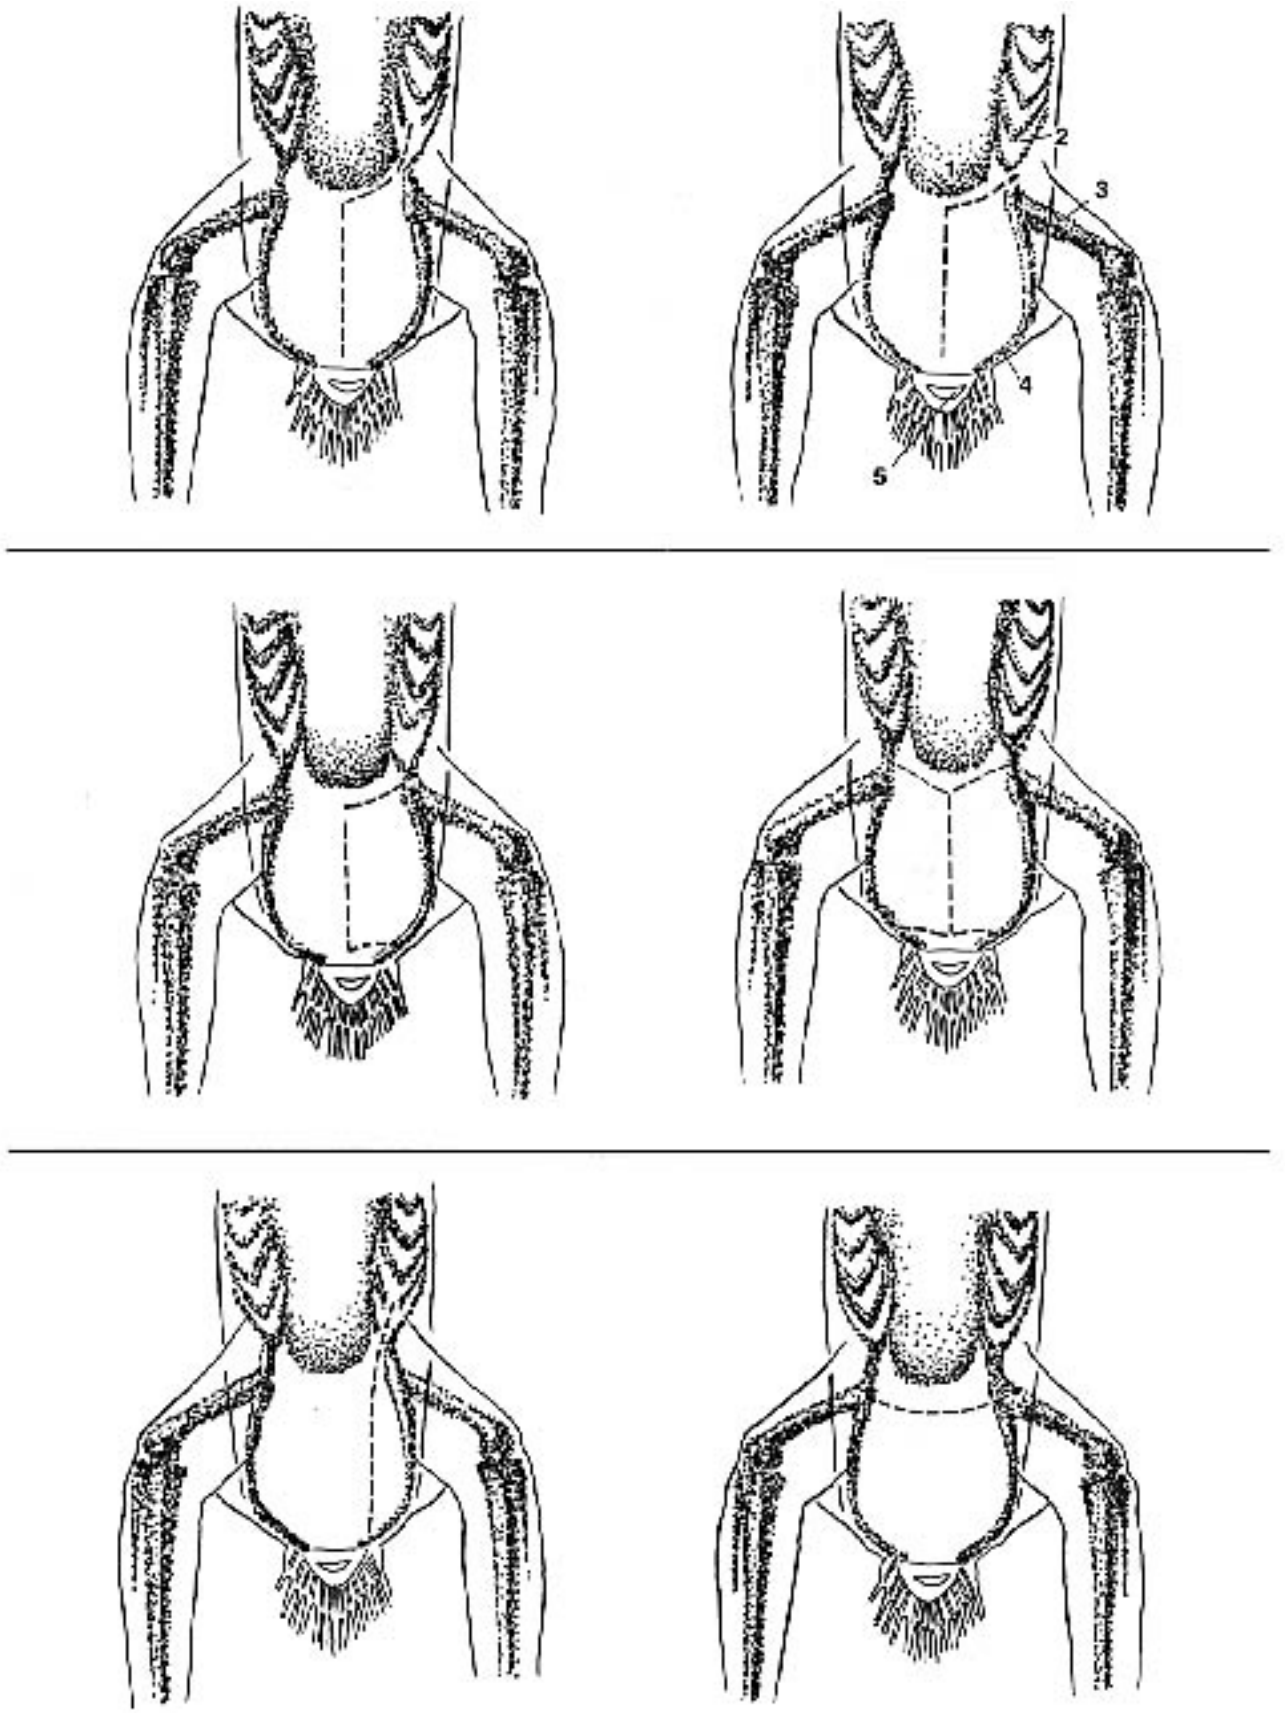

FIG 41.14 Several different celiotomy incisions can be used to gain access to the abdomen of birds. 1) sternum 2) eighth rib 3) femur 4) pubis and 5) vent.

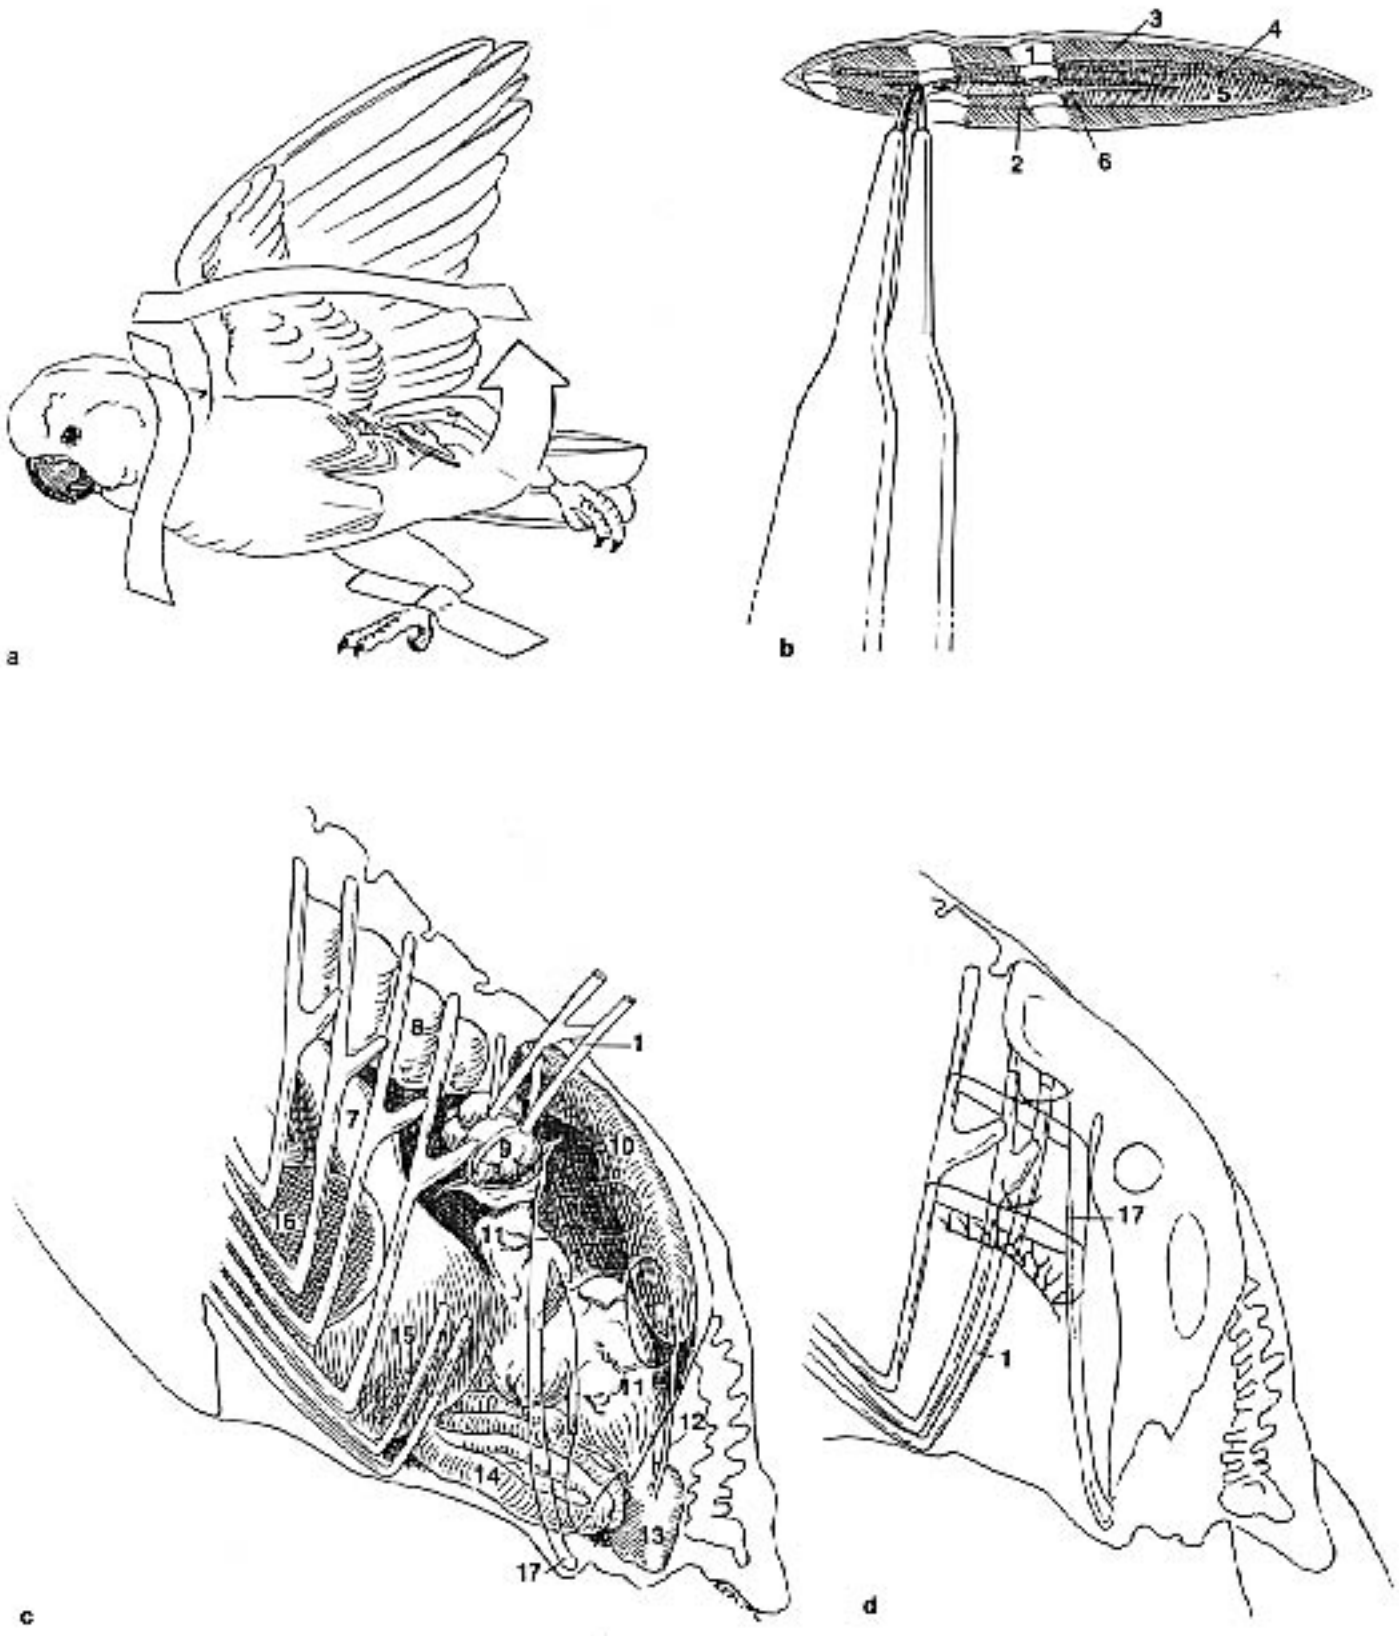

FIG 41.15 **a)** To perform a left lateral celiotomy, the bird is placed in right lateral recumbency, the leg is retracted caudally and a skin incision is made as shown. **b)** The intercostal vein and artery on the edge of the ribs are coagulated using bipolar radiosurgery. **c)** This approach provides the best access to the proventriculus, ventriculus, female reproductive tract and left kidney. **d)** Closure of the skin and muscles can be facilitated by placing sutures between the rib and the pubis to reduce pressure on the incision line. 1) eighth rib 2) intercostal artery, vein and nerve 3) external oblique muscle 4) internal oblique muscle 5) transversus abdominis muscle 6) air sac 7) proventriculus 8) lung 9) ovary 10) kidney 11) oviduct 12) ureter 13) cloaca 14) intestine 15) ventriculus 16) liver and 17) pubis.

tipped applicator. The intestines are fragile and should not be manipulated with toothed forceps, which will create severe bruising and potential perforation. Once the intestines are retracted caudally, the kidney may be identified at the dorsomedial aspect of the coelom. The ovary or left testicle should be encountered at the cranial division of the kidney. The adrenal gland is located between the gonad and the cranial division of the kidney, but may be obscured if the gonad is large. Obesity and hepatomegaly result in topographical changes in the abdominal anatomy, emphasizing the need to practice on a variety of cadavers with a variety of conditions prior to performing a celiotomy in a clinical patient.

If the seventh and eighth ribs have been removed, closure will require the placement of tension sutures from the abdominal musculature to the sixth rib. Sutures passed around the pubic bone may be necessary when closing large incisions.

Ventral Midline Celiotomy

A ventral midline celiotomy is used primarily for surgery of the small intestines, liver biopsy, egg-related peritonitis, abdominal masses, egg binding and repair of a cloacal prolapse. This approach provides access to both sides of the coelomic cavity.

The skin is incised in the midpostventer region from the sternum to the interpubic space (see Figure 41.14). The linea alba is usually broad and easily identified. It must be incised carefully because the duodenum crosses from left to right just inside the body wall. It is best to initiate the incision between the pubic bones over the cloaca. Once a two millimeter incision is initiated, it may be extended craniad to the level of the sternum. If exposure is limited, the incision may be extended to one or both sides approximately two millimeters from the sternal border creating a muscular flap. Further exposure is achieved by extending the incision along one or both sides of the pubic bones in a similar fashion. This approach provides the best exposure to mid-abdominal masses, uterine masses and generalized abdominal disease (peritonitis). The size of the incision should be sufficient to allow a procedure to be performed, but as small as possible to minimize tissue damage and air sac disruption, and to make it easier to maintain anesthesia. If it is necessary to approach a large area of the abdomen, it is often best to open and close each area before proceeding on to another area.

Closure of the body wall is accomplished using simple interrupted or simple continuous, monofilament, synthetic, absorbable suture material. Skin closure is routine.

Transverse Celiotomy

Transverse celiotomy provides exposure to a large area of the abdomen.[1,24,51,53] The bird is positioned in dorsal recumbency and the postventer region is prepared. A transverse skin incision is made midway between the sternum and the vent (see Figure 41.14).[1] The abdominal wall is lifted and incised with care to avoid lacerating the underlying intestines. The ventriculus and duodenum are the first organs encountered, but may be reflected to expose the cranial aspect of the cloaca, the middle and caudal lobes of the kidneys and the lower reproductive tract of hens. The abdominal wall and skin are sutured separately using 4-0 to 6-0 synthetic, monofilament, absorbable material in a continuous or interrupted pattern.

Proventriculotomy and Ventriculotomy

The stomach of birds is divided into an orad, glandular portion (the proventriculus) and the aborad muscular ventriculus (gizzard). The isthmus or intermediate zone separates these two structures, and the pylorus controls the emptying of ingesta from the ventriculus into the duodenum. In carnivorous birds, the crop is underdeveloped so the bird relies on the stomach for digestion and as a storage organ. These birds often have a large, thin-walled stomach with a poorly developed isthmus and little distinction between the proventriculus and ventriculus. The proventriculus tears easily when excessive tension is applied. The ventriculus is composed of dense muscle and fascia and holds sutures well, but is more difficult to seal with suture and cannot be inverted.

Proventriculotomy is most often indicated for the removal of foreign objects or toxic materials (such as lead or zinc-containing coins) from the proventriculus or ventriculus that cannot be retrieved using rigid or flexible endoscopes.[10] A definitive diagnosis of neuropathic gastric dilatation requires a ventricular biopsy, although there are some discussions that biopsies of the crop may provide similar information. In an Umbrella Cockatoo that had ingested sticks, the proventriculus was determined to be distended based on radiographs.[21] The tentative diagnosis of neuropathic gastric dilatation could not be confirmed by biopsy of the ventriculus. Several pieces of glitter and 72 small green sticks were surgically removed. Although techniques for ventriculotomy have been de-

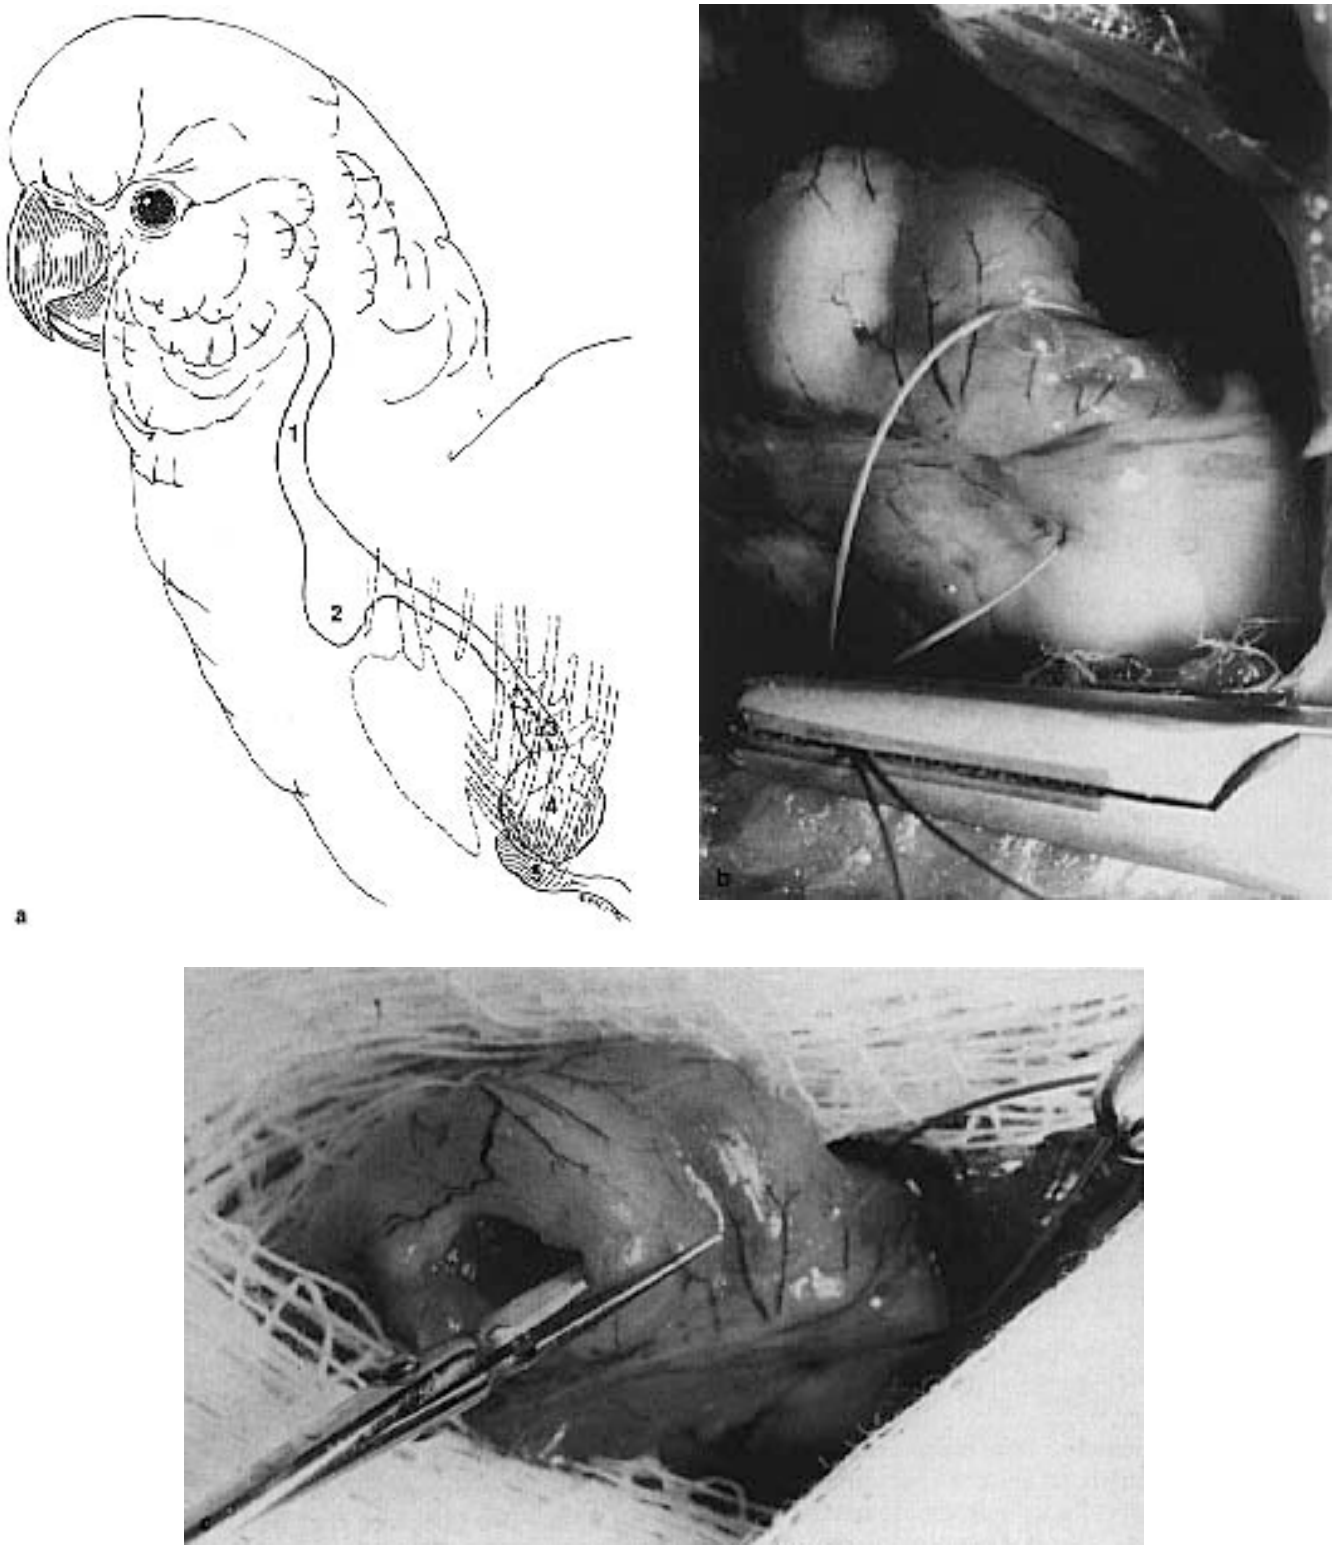

FIG 41.16 **a)** A proventriculotomy is indicated in patients with foreign bodies that cannot be removed by lavage or endoscopy. The proventriculus is approached through a left celiotomy incision site as shown. **b)** Stay sutures can be placed in the ventriculus (not the proventriculus) to improve control over the position of the organ. **c)** The incision into the proventriculus should be made with a blade and extended into an avascular area with scissors. Note that stay sutures are used to exteriorize the proventriculus, and the abdomen has been isolated with moistened gauze pads. *(continued next page)*

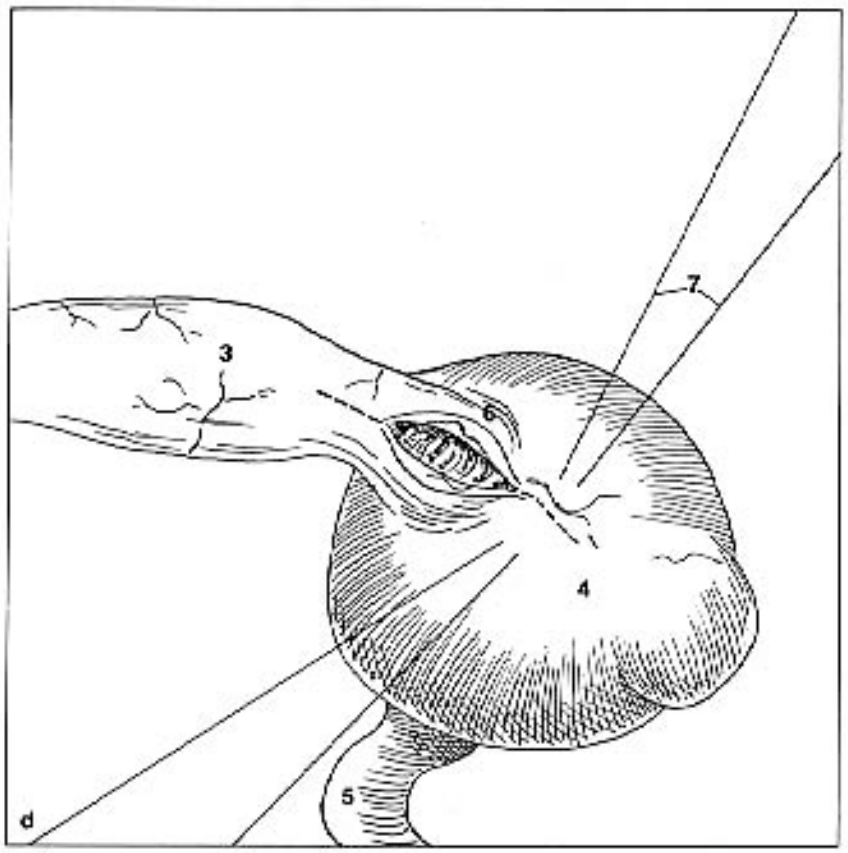

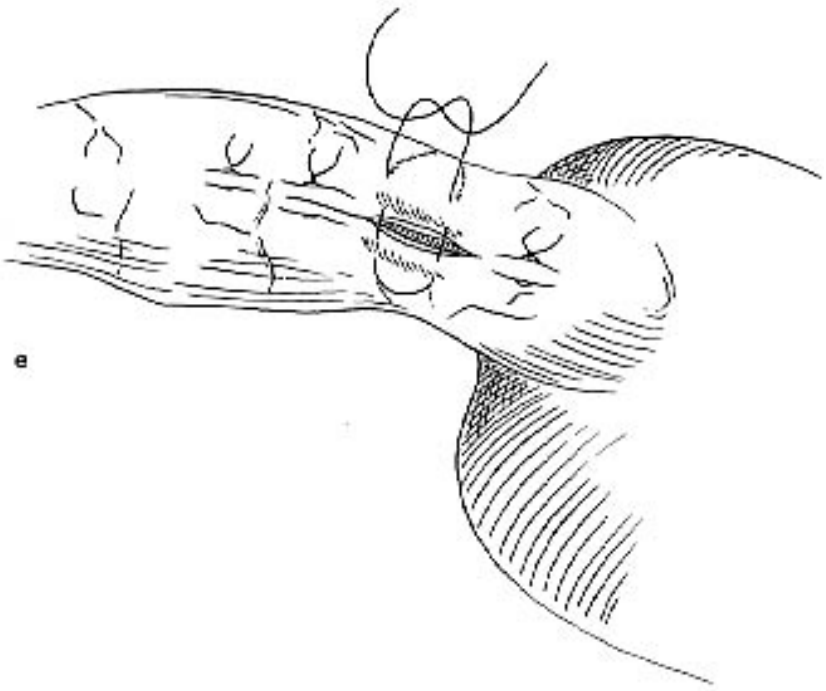

d) Radiosurgical forceps should be used only for controlling hemorrhage and not for making incisions into viscera. **e)** Closure is routine, using an inverting suture pattern. 1) esophagus 2) crop 3) proventriculus 4) ventriculus 5) duodenum 6) isthmus 7) stay sutures.

scribed they are generally avoided because of the vascularity and slow healing characteristic of this organ.[1,5,6,10,22]

A left lateral celiotomy approach will provide exposure of the ventriculus and proventriculus (Figure 41.16). The ventral suspensory structures are bluntly dissected to allow the proventriculus to be retracted caudally. The proventriculus in some birds is quite fragile and toothed forceps should be avoided. Stay sutures may be placed in the ventriculus to aid with exteriorization and manipulation of the proventriculus. Stay sutures should not be placed in the proventriculus. The coelomic cavity should be packed off with moist gauze sponges to prevent contamination of the abdominal cavity with gastric contents.

The isthmus or intermediate zone is identified as a constriction between the ventriculus and the proventriculus. The vessels on the surface of the proventriculus are easily identified and avoided. The proventriculotomy incision is initiated at the isthmus and extends orad into the body of the proventriculus. Hemorrhage from the cut edge of the proventriculus may be controlled using radiocoagulation. Thumb forceps may be used to gently clamp the cut edge to occlude the vessel, allowing it to be identified and appropriately coagulated. Proventricular contents should be removed using suction. Small spoons or curettes may be used to remove solid contents. A combination of irrigation and suction is useful to completely evacuate the proventriculus and ventriculus. A small diameter flexible endoscope may be used per os, or through the proventriculotomy to assure that all foreign objects have been removed.

The proventriculotomy is closed using a simple continuous appositional pattern of a fine, synthetic, monofila-

ment, absorbable material over-sewn with a continuous or interrupted inverting pattern such as a Cushing or Lembert pattern. The inverting pattern should extend beyond the actual incision to ensure an adequate seal. The closure may be evaluated for leakage using an orogastric tube to insufflate the proventriculus with air or sterile saline.

Food and water should be offered in the immediate postoperative period. The wound strength immediately following suture placement is stronger than during the debridement phase of wound healing, which occurs three to five days postoperatively. Unless one intends to withhold food until wound strength begins to increase again (the phase of fibroplasia), fasting for one to two days postoperatively is not indicated. Incisional leakage of gastric contents occurs with some frequency in birds.[35] The lack of an omentum may be partially responsible for this complication. Meticulous attention to proper closure is vital to prevent leakage. A small, atraumatic needle should be used with a continuous suture pattern to provide the best seal. If the proventricular wall appears thin and friable, the potential for postoperative incisional leakage may warrant placement of a duodenal feeding tube. This will allow enteral alimentation of the patient while bypassing the gastric incision.

The ventriculus is best approached through a proven-triculotomy incision. The incision in the isthmus is extended aborad toward the ventriculus. The opening into the ventriculus can be gently dilated to allow the introduction of instruments appropriate for removal of ventricular contents. Some surgeons suggest that a ventriculotomy (transverse abdominal approach) is easier than a proventriculotomy (left lateral approach). The lighter-colored, elliptical area of the ventriculus, where the muscle is thin and the fibers can be seen to course in a different direction from the remainder of the ventriculus, is the location where the incision is made (see Anatomy Overlay).[1] The incision is made transversely across the muscle fibers into the lumen. At closure, sutures must be placed close together to prevent leakage, because a serosal seal cannot be created by using an inverting suture pattern.

Intestinal Surgery

Surgery on the intestines may be necessary to repair an accidental enterotomy created during a ventral midline celiotomy or to debride necrotic bowel secondary to constrictions caused by adhesions (see Color 14). These cases generally carry a poor-to-grave prognosis. A midline, flap or transverse celiotomy may be appropriate, depending on the location of the lesion. In most circumstances, microsurgical technique is indicated due to the extremely thin nature of the avian intestine. The blood supply to the small intestine is via the celiac artery (to the duodenum) and the cranial mesenteric artery (jejunum and ileum). The technique used to anastomose the bowel requires microsurgical manipulation of 6-0 to 10-0 monofilament suture on a one-fourth circle atraumatic needle. Typically, six to eight sutures are used for an end-to-end anastomosis in a simple interrupted appositional pattern. Side-to-side anastomosis may prove to be more appropriate in birds and is easier to perform.

Intestinal Feeding Tubes

Enteral feeding tubes may be indicated for a variety of conditions in which a diseased portion of the alimentary tract must be bypassed to provide nutritional supplementation to anorectic and debilitated patients. A variety of medical and surgical conditions including crop infections, impaction, injury or inflammation, esophageal perforation or laceration, proventricular dilatation, beak disorders, pharyngeal disorders and any condition resulting in hypophagia or anorexia places a nutritional demand on the patient that may not be met by oral alimentation. Proper attention to the patient's nitrogen balance can make the difference between success and failure of therapy (see Chapters 15 and 40).

A technique for placement of a duodenostomy tube has been described in domestic pigeons.[11] Four of the five catheterized birds had minor weight loss after 14 days of total nutritional support through the enterostomy tube (4% to 10%). Within seven days of tube removal, all the birds had regained their normal weight.

The catheter is placed through a ventral midline incision. The ascending duodenum is easily identified by its close association with the pancreas (see Anatomy Overlay). A "through-the-needle" catheter (indwelling jugular catheter) is used with the needle passing first through the left abdominal wall, then into the descending loop of duodenum. The catheter diameter should be less than one-third the diameter of the intestine.[11] The catheter is advanced through the descending and ascending loops of duodenum (4 to 6 cm), and the needle is withdrawn from the intestine and body wall. One or two sutures are placed between the left body wall and the duodenum at the entry site of the catheter to secure the intestine to the body wall and allow a seal to form (monofila-

ment 5-0 prolene). The midline celiotomy is closed routinely.

The catheter is secured to the outside left abdominal wall using a "finger trap" technique. The needle is protected within its "snapguard," and the snapguard is bent to conform to the contour of the bird's body. The snapguard is then sutured to the skin to secure it in place. The catheter is brought caudal to the leg and under the wing. The excess is coiled and the catheter is secured to the lateral and dorsal body wall using two sutures. The catheter is flushed with saline to assure patency, and an injection cap is placed to create a sealed system for alimentation.

Once the caloric need is calculated (see Chapter 40), the amount of liquid diet required is calculated based on the caloric density of the diet (usually 1 ml = 1 kcal). A variety of liquid diets is commercially available and their compositions have been described (see Chapter 15).[41] The amount should be divided into equal volumes and injected four to six times daily at a rate of approximately 1 ml/15 seconds to allow the intestine to accommodate the volume. The catheter should be flushed with water or LRS (1 to 2 ml) before and after injection of the diet to prevent plugging.

The catheter should be maintained a minimum of five days to allow a seal to form between the intestine and the body wall.[11] If the catheter is dislodged prematurely, leakage of intestinal contents may occur. Once the catheter is no longer needed, the finger trap suture is cut, the catheter removed and the defect left to heal by second intention.

Hypertonic diets may cause osmotic diarrhea. Daily weight and biochemistry changes can be used to alter the volume and content of the liquid diet. Patients that have a tendency to disturb the catheter should be fitted with a neck brace.[k]

Cloacal Prolapse

Cloacopexy is indicated to correct problems with chronic cloacal prolapsing. This condition appears to be most common in Old World psittacine birds, especially cockatoos, and is associated with reduced sphincter tone. Chronic gram-negative enteritis may be an initiating factor,[2] underscoring the need for cloacal cultures as part of the patient evaluation process. The attachments of the cloaca are damaged, allowing the entire structure to prolapse, which may cause occlusion of the ureters and colon. Minor prolapses may respond to placement of a mattress suture on either side of the cloaca; however, when the entire organ prolapses, this method of treatment is ineffective. If mattress sutures are used, they must allow for the passage of droppings. An alternative method involves the placement of two sutures transversely across the vent. These must be placed close enough together to prevent recurrence of the prolapse, but far enough apart to allow the normal passage of droppings. These sutures may be left in place from a few days to several weeks depending on the clinical situation. Purse-string sutures are contraindicated due to frequent postsurgical cloacal atony secondary to nerve damage.

A percutaneous cloacopexy may be performed as a temporary or definitive treatment for cloacal prolapse.[33] The prolapse is reduced using a moistened cotton-tipped applicator. The applicator is maintained within the cloaca to help identify its limits, and two or three sutures are placed percutaneously through the skin, body wall and urodeum. The sutures should be removed in two to four weeks. This procedure carries the risk of inadvertently entrapping or perforating the ureters, rectum, duodenum and pancreas.

In some cases, prolapse is due to atony of the vent sphincter. This condition may be treated by surgically narrowing the vent opening. One-half to three-fourths of the margin of the circumference of the vent is incised to provide a cut surface for healing. Simple interrupted sutures are placed from one side of the vent to the other in order to partially close the opening. This will decrease the size of the vent opening permanently, preventing prolapse of the cloaca.

A rib cloacopexy is an effective treatment for severe cloacal prolapse.[47] A ventral midline celiotomy is performed and the cloaca is identified (Figure 41.17). This approach provides exposure to the entire cloaca and its associated structures. It may be necessary to use a moistened cotton-tipped applicator or the finger of a gloved assistant to reduce the prolapse and define its limits intraoperatively. Fat on the ventral surface of the cloaca should be excised. This appears to be crucial for a successful surgery.[48] The ribs are pushed caudally using the thumb, and the surgical incision is elevated with the index finger, bringing the ribs into view to facilitate suture placement. A suture is placed around the last rib on each side of the bird and passed through the full thickness of the ventral aspect of the craniolateral extent of the urodeum. The suture should be tied with enough tension to slightly invert the vent. Large sections of

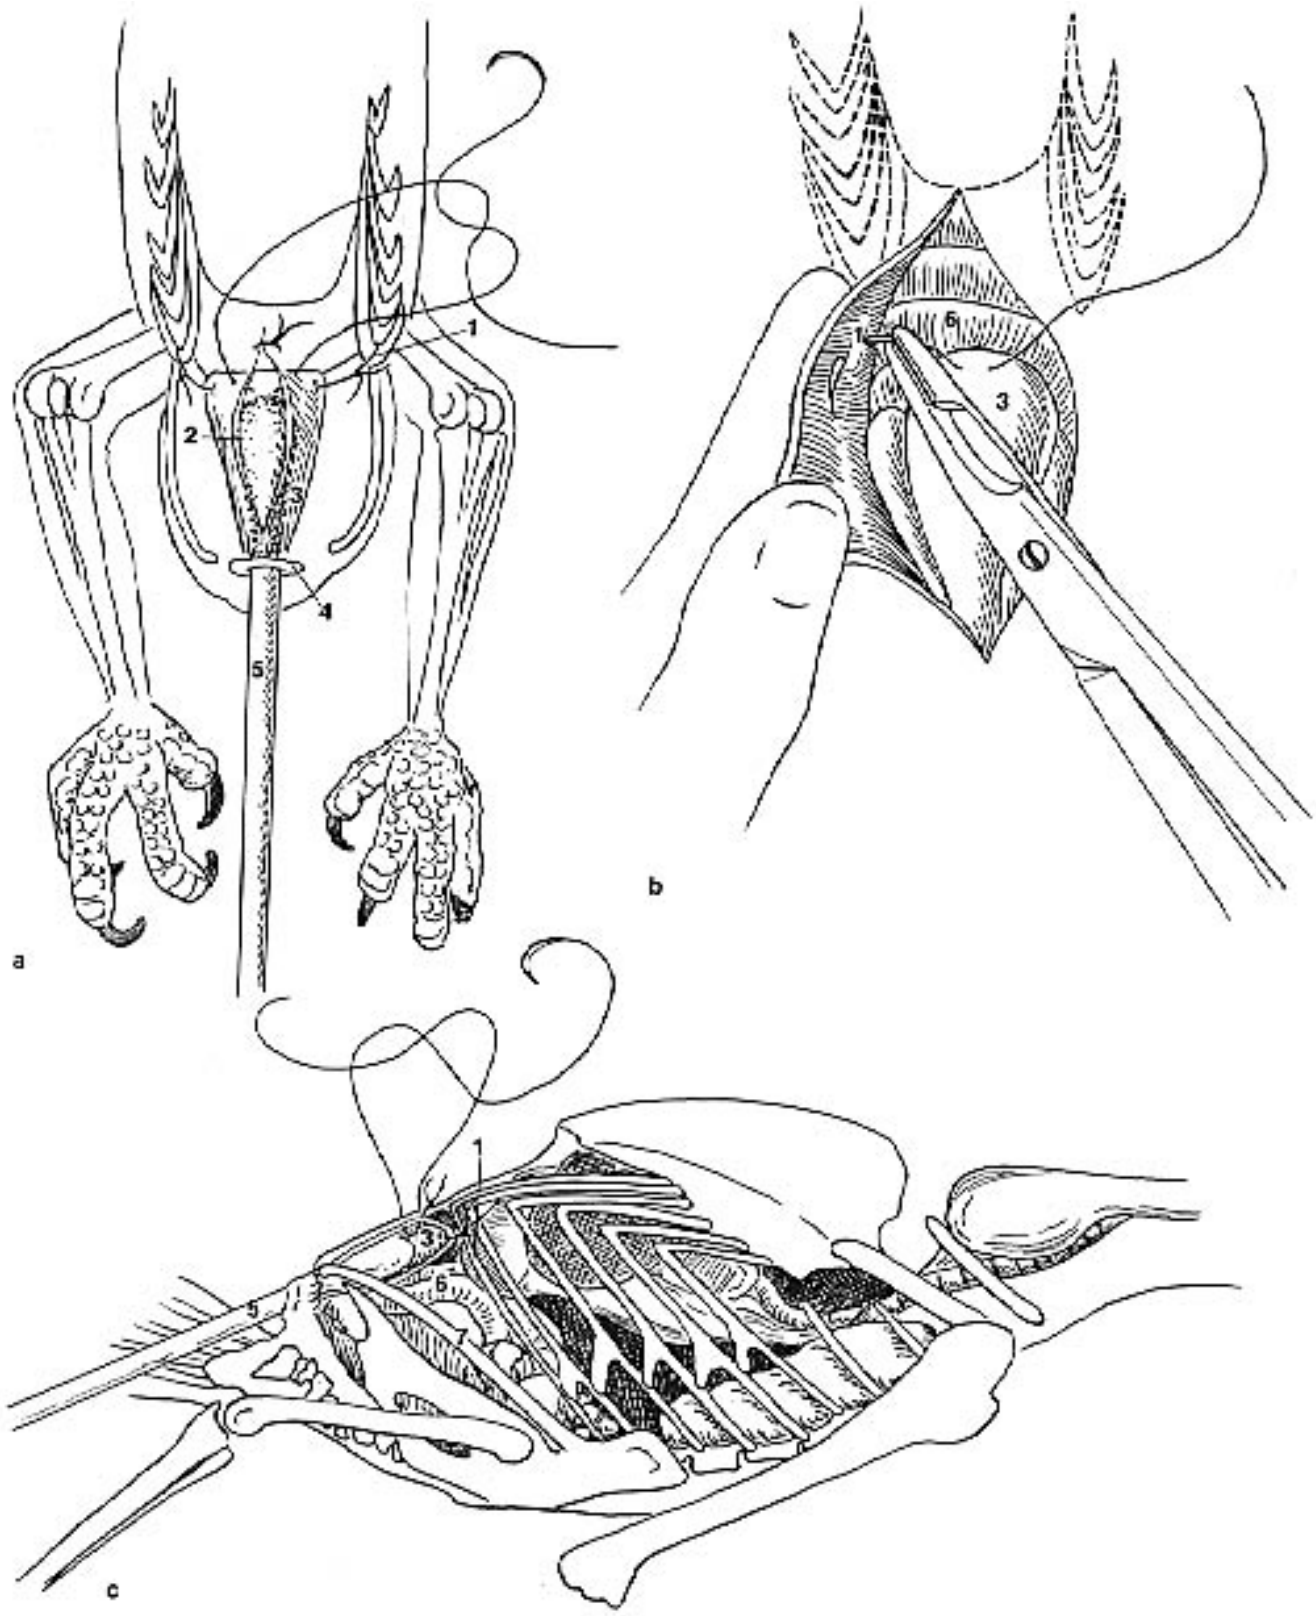

FIG 41.17 A rib cloacopexy is indicated to permanently correct chronic cloacal prolapse. **a)** The cloaca is pushed cranially with a moistened cotton-tipped applicator and sutures are placed between the cranio-lateral border of the cloaca and the eighth rib. **b)** Pushing the eighth rib caudally with a finger will help in the placement of sutures. **c)** Lateral view of the cloacopexy procedure showing the placement of the suture between the cloaca and the eighth rib, and the suturing of the cloaca to the abdominal wall during closure. 1) eighth rib 2) skin incision 3) cloaca 4) vent 5) swab 6) intestines and 7) pubis.

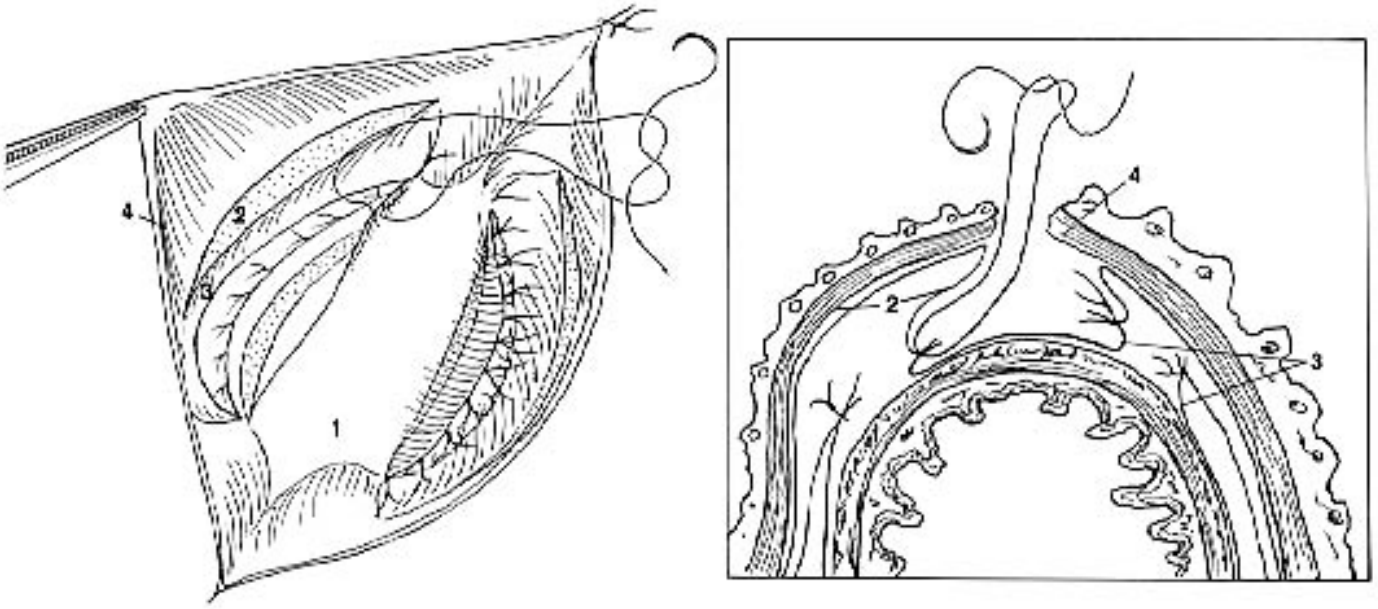

FIG 41.18 An alternative cloacopexy technique is to make a ventral midline incision and place three or four sutures that appose the subserosal surfaces of the cloaca and internal body wall. 1) cloacal wall 2) pleuro-peritoneum 3) seromuscular layer of the cloaca and 4) body wall.

tissue must be used for suture placement, and it appears to be important to penetrate the cloacal lumen. Several other sutures are then placed between the body wall and the wall of the cloaca. The cloaca may be sutured to the caudal border of the sternum instead of the ribs, if the rib sutures place excessive inverting tension on the cloaca. This procedure may not be effective in birds with a thin-walled cloaca.

Another method for performing a cloacopexy has been described.[23] A 2 to 5 mm incision is made in the serosal surface of the coprodeum parallel to its length and 5 to 10 mm from the midline (Figure 41.18). A corresponding paramedian incision is made in the peritoneal surface of the body wall at a point that will maintain the cloaca in a position that will result in slight inversion of the vent. Three or four sutures are placed between each side of the two incisions such that the serosal surfaces are sutured and the subserosal surfaces of the two structures are apposed. This procedure is repeated on the contralateral paramedian side.

Alternatively, a routine ventral midline incision may be made, the cloaca reduced and the associated fat excised. The abdomen is closed incorporating the cloaca. The suture passes through one side of the body wall, through the full thickness of the cloaca and through the other side of the body wall in a simple interrupted pattern (Figure 41.19). Skin is closed over this layer.

A transverse abdominal cloacopexy may provide more even distribution of tension than a ventral midline approach.[2] The transverse incision is made

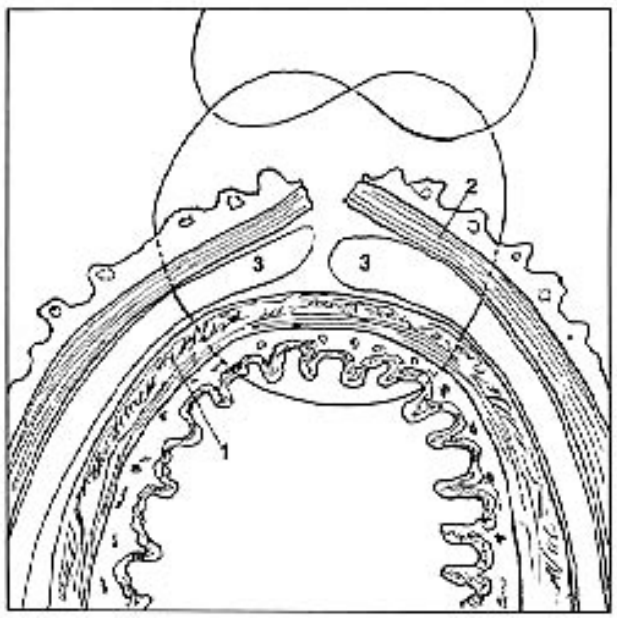

FIG 41.19 A simple cloacopexy technique that involves full-thickness suturing of the cloaca into a ventral midline incision may be effective in resolving mild cases of cloacal prolapse. 1) cloacal wall 2) body wall and 3) peritoneal cavity.

through the skin and abdominal musculature in the postventer region. The cloaca is incised to the level of the submucosa, and the seromuscular layer is then sutured to the incision in the abdominal wall. The abdomen and skin are closed routinely.

Surgery of the Reproductive Tract

Surgery on the female reproductive tract is most often indicated in cases of egg binding, ectopic ovulation, soft-shelled eggs, congenital atresia of the oviduct, damage to the uterus, salpingitis, neoplasia, abnormal egg production, biopsy and culture of the oviduct and egg-related peritonitis.[8,14,24,42,48,57] Generally, only the left side of the female reproductive tract is functional. The right oviduct may become cystic in older fowl,[43] and this condition has been reported in a budgerigar (see Color 29).[18] A left lateral flap or ventral midline celiotomy approach may be used, depending upon which portion of the reproductive tract is to be evaluated.

Egg Binding

Egg binding occurs commonly in companion birds and has been associated with a genetic predisposition, improper nutrition, atony of the uterus, oversized eggs, inexperience of the hen, tumors of the reproductive tract and extraluminal compression of the reproductive tract by abdominal masses.[14,18,34,48,53] In one case of egg binding, a cystic right oviduct was compressing the left reproductive tract, preventing normal migration of the egg.[18] Both oviducts were successfully removed, relieving the dystocia. In an Isle of Pines Amazon Parrot, an oviduct defect allowed deposition of uncalcified eggs into the abdominal cavity. Five eggs were successfully removed from the coelom. A hysterectomy was performed after two more eggs were deposited into the abdomen and surgically removed the following year.[57]

Egg binding in birds is most commonly the result of malnutrition. If the egg remains in the uterus (shell gland), it will continue to deposit shell material onto the egg, further lowering systemic calcium levels. Any bird presenting for egg binding should be evaluated for hypocalcemia prior to planning surgery, and any abnormalities should be addressed. Medical management including ovocentesis should be attempted prior to considering surgical intervention.

Prolapse of oviduct or uterine tissue occurs with some degree of frequency in egg-bound birds, especially budgerigars and cockatiels.[47,48] It may occur following egg binding or from straining. The tissue may have been expelled through the vaginal opening into the cloaca and potentially externalized through the vent. As the tissue protrudes through the cloaca, it undergoes axial torsion, making it difficult to identify the lumen. Exposed uterine tissue becomes dry and necrotic within 30 to 60 minutes.

Ovocentesis

If medical management of egg binding fails, ovocentesis and collapsing the egg may be successful. Under general anesthesia, the opening of the vagina into the cloaca is identified. A blunt probe is used to dilate the opening. Once the egg is visualized, a needle can be inserted into the egg to aspirate its contents. Following ovocentesis, the egg can be collapsed and the shell fragments removed (see Chapter 29). The vagina and uterus should be flushed repeatedly to verify that all egg material has been evacuated. It is prudent to reconstruct the egg to be certain that all shell fragments have been retrieved. Alternatively, a radiograph may be valuable to rule out the presence of another egg or remaining fragments.

If the lumen is not identifiable, the prolapsed tissue may be incised to deliver the egg. Once the egg is removed, the layers of uterine wall should be sutured with a fine (6-0 to 10-0) monofilament, absorbable material on an atraumatic needle in a simple appositional or inverting pattern. If the patient's condition permits, necrotic tissues should be excised and viable tissues reconstructed. With critical patients, the damaged tissue should be replaced into the cloaca after removal of the egg, and debridement should be postponed until the patient's condition improves. If an egg or shell fragments remain in the oviduct, a celiotomy is indicated.

If the egg is near or within the pelvic canal, it may be delivered using an episiotomy-type incision.[33] The incision is made on the ventral midline through the cloacal sphincter extending craniad through the urodeum. If necessary, the incision may extend into the uterus. After the egg is removed, the uterus and cloaca are closed with a simple interrupted or simple continuous pattern of a slowly absorbable material. Closure of the body wall and skin are routine. This is

a radical procedure and is indicated only in critical cases in which the hen is likely to die or the egg is of major importance for species propagational purposes.

In cases where the egg is lodged farther cranial in the oviduct, it may be best to perform a midline celiotomy, and hysterotomy may be the best technique for removing the egg. The hysterotomy incision should be closed with a simple appositional continuous or inverting pattern of a fine monofilament synthetic absorbable material. Postoperatively, hormone therapy or photoperiod regulation should be used to prevent subsequent laying until the hysterotomy has healed. If hysterectomy is indicated, a left lateral approach is preferred to gain access to the entire oviduct.

Salpingohysterectomy

This procedure involves removal of both the uterus (shell gland) and the oviduct; therefore, the term salpingohysterectomy is most appropriate. Although hysterectomy is the term commonly used to refer to this procedure, the ovary is not removed. Salpingohysterectomy is indicated to terminate pathologic egg laying, alleviate egg binding, remove an infected or ruptured oviduct and to treat a prolapsed oviduct and recurring egg-related peritonitis.

Salpingohysterectomy carries a significant degree of risk and is generally not recommended as a preventive measure. Although cockatiels continue to have copulatory, nesting, territorial and egg-laying behavior following salpingohysterectomy, there is no evidence that problems related to the deposition of yolks into the abdomen occur.[14,34] Presumably, a hormonal feedback loop from the uterus to the ovary prevents follicular development and release of ova.[15,33,48] In a retrospective study of 30 birds on which salpingohysterectomy was performed, five were evaluated laparoscopically several months postoperatively.[34] Follicular development was noted; however, no large follicles were observed. Continued yolk release with subsequent yolk-related peritonitis was reported in a California Quail and a duck following routine salpingohysterectomy.[48]

The size of the oviduct and uterus varies with the reproductive and physiologic status of the patient. The reproductive tract of a cockatiel that is not in breeding condition is narrow (2 to 3 mm). A bird in poor condition may also have a small, inactive ovary. A young bird in good condition with exposure to a male may have a well developed ovary with large follicles and a large reproductive tract.

Salpingohysterectomy may be accomplished through a left lateral celiotomy (Figure 41.20). The ovary may be visualized following lateral and ventral retraction of the proventriculus. The oviduct and uterus lie convoluted along the dorsal aspect of the body cavity. The oviduct is identified and elevated away from the large caudal vena cava. Minor damage to this vessel will result in life-threatening hemorrhage. The ventral ligament causes the convolutions in the uterus and oviduct. The ligament courses caudally and collects as a muscular cord at the vagina. There are no vessels in this ligament, and it should be dissected to allow the oviduct and uterus to be stretched into a linear configuration.

The fibria of the infundibulum lie caudal to the ovary and may be elevated to expose the dorsal attachments. At the base of the infundibulum and coursing caudally along the uterus, the dorsal ligament suspends the uterus and a branch of the ovarian artery. A small blood vessel can be identified coursing from the ovary through the infundibulum. This vessel should be coagulated or a hemostatic clip should be applied to control hemorrhage. If it is inadvertently transected or broken, it will retract under the ovary in a virtually unretrievable location. A small piece of absorbent gelatin sponge[g] may be packed against the ovary to achieve hemostasis. The remainder of this suspensory structure may then be dissected with the bipolar radiosurgical forceps.

Once the infundibulum is free, the oviduct is retracted ventrally and caudally, exposing the dorsal suspensory ligament. Several small blood vessels, branches of the ovarian artery, can be seen in this structure perpendicular to the oviduct and uterus. These should be identified and coagulated. Each vascular stump should be inspected for residual hemorrhage before closure. As this dissection is continued caudally toward the cloaca, the ureter can be identified as a white tubular structure extending from the kidney to the cloaca. This structure should be avoided. As the dissection approaches the cloaca, the uterus courses along with the terminal colon and enters the cloaca (see Anatomy Overlay). The uterus should be ligated at its junction with the vagina by placing one or two hemostatic clips a short distance from the cloaca. In cases where the vaginal tissue has been damaged, the clips may be applied at the cloaca, being careful not to entrap the ureter. The clips should be secure with the entire width of the uterus

within the clips to prevent leakage. If the clips become dislodged or do not completely occlude the uterus, feces and urates may reflux into the abdomen.

Egg-related Peritonitis

Egg-related peritonitis occurs most commonly in cockatiels, budgerigars, lovebirds, ducks, gallinaceous birds and macaws (see Color 29).[48] Diagnosis is made by clinical signs, hematology, radiography, abdominocentesis and laparotomy. A severe inflammatory response is typical of the hemogram.

Mild cases may respond to antibiotic therapy and supportive care (see Chapter 29). Surgical intervention is usually necessary to resolve severe cases.[33,48] In some cases, surgery should be postponed and the patient treated medically until the condition stabilizes. A ventral midline celiotomy is preferred because fluids are easily drained out the incision rather than down into the air sacs, and potentially into the lungs. Once the celiotomy is performed, the intestines should be retracted using moistened cotton-tipped applicators or other suitable atraumatic instruments. Any yolk or tissue debris should be removed. The cavity should be copiously irrigated prior to closure. Implantation of Penrose drains may be indicated in some cases, but do not generally provide adequate coelomic drainage. This condition warrants a guarded-to-poor prognosis. Birds that recover frequently have abdominal adhesions, distention and muscular dysfunction.

Removal of the Gonads

Carbon dioxide laser destruction of gonadal tissue has been attempted; however, the procedure is very time-consuming and costly, and controlling damage to surrounding tissues, especially the adrenals, is very difficult. Removal of the gonads with laser in companion birds is often followed by severe hemorrhage either intraoperatively or postoperatively.

Alternatively, the vascular supply to the ovary may be destroyed using vascular clips, but this is a difficult procedure, performed without being able to visualize vital structures. Microsurgical equipment is essential. Clients should be informed that this procedure is extremely difficult and the possibility of complications is higher. The patient should be treated medically to reduce the size of the ovary and improve visualization. Through a left lateral celiotomy, the ovary is identified. A hemostatic clip is applied dorsal to (under) the ovary to occlude all ovarian vessels. In small birds, one clip applied from a caudal to cranial direction is adequate. Two clips, one from a cranial direction and the other from a caudal direction, may be required for large birds. Angled appliers should be used to place the clips under the ovary parallel to the spine, which reduces the possibility of inadvertently entrapping the aorta or peripheral nerves.

Orchidectomy

Neutering a male is theoretically easier than neutering a female because the testicles are not as adherent to deeper structures as the ovary, making clip application easier and safer. However, orchidectomy must be performed bilaterally, making a ventral approach more applicable than a left lateral approach. The placement of vascular clips is similar to that described for the ovary. Orchidectomy in companion birds is extremely difficult and many birds do not survive the surgery.

A technique for orchidectomy in ostriches has been described.[49] The procedure is indicated to control aggressive behavior in birds that present a danger to keepers, handlers, the public or other birds. The surgical approach is through the costal notch and lumbar fossa on each side. The skin and body wall are incised adequately to allow introduction of a gloved hand. The testicle on the corresponding side is palpated, grasped and twisted until it is torn from any attachments. It is recommended that the procedure be performed at the onset of breeding season when the testicles have begun to increase in size so they can be easily located. If performed during the breeding season, excessive hemorrhage may result from avulsion of the hypertrophied testicular vascular supply. Body wall, subcutaneous tissue and skin are closed routinely. The procedure can be accomplished through a single, lateral celiotomy incision if the surgeon has hands small enough to reach through to the contralateral testicle. Minor postoperative subcutaneous emphysema and occasional incisional dehiscence are the only reported complications.

Miscellaneous Surgical Procedures

Abdominal Hernias

Abdominal hernias in birds may be congenital or acquired. They are characterized by a separation of the aponeurosis of the abdominal musculature at the ventral midline. This gives the bird a pot-bellied appearance with the abdominal viscera visible directly beneath the skin (Figure 41.21). Abdominal hernias frequently develop in female budgerigars and cockatiels, which may be related to a hormone imbalance causing a weakening of the abdominal muscles.[40,48] It has been suggested that altered calcium metabolism in chronic egg-laying hens may contribute to muscular atony and over-distention in the caudal abdomen near the cloaca.[32]

In most cases, the hernia is of little clinical consequence. The defect in the body wall is large with little risk of organ entrapment. As a result, herniorrhaphy may carry more risk than the potential benefit. Because of the extensive system of air sacs (on which birds rely heavily for respiration), efforts to close the body wall defects frequently result in respiratory compromise. In birds with chronic or large hernias, the resulting respiratory compromise can be life-threatening. As closure proceeds caudad, the abdominal viscera are forced craniad. This results in compression of the thoracic and abdominal air sacs. In these cases, a mesh implant should be considered. If the hernia is small or acute, primary closure may be successful.

Herniorrhaphy is necessary if secondary clinical problems such as cloacal urolithiasis or egg binding occur. A fusiform section of skin and urodeum was excised and the body wall closed to repair a hernia containing urate concretions in a cockatiel. The hernia recurred, but a second surgery was not attempted, and the owner was instructed to manually express urates out of the cloaca as needed.[32]

Abdominal Masses

Surgical excision may be considered for treatment of neoplastic diseases of birds.[3,54] Removal of abdominal tumors is rarely successful. Their removal requires meticulous attention to detail, strict hemostasis with blood transfusions and a prolonged anesthesia time, predisposing the patient to hypothermia and severe metabolic compromise. Carbon dioxide laser surgery shows the greatest promise for removal of neoplasms.

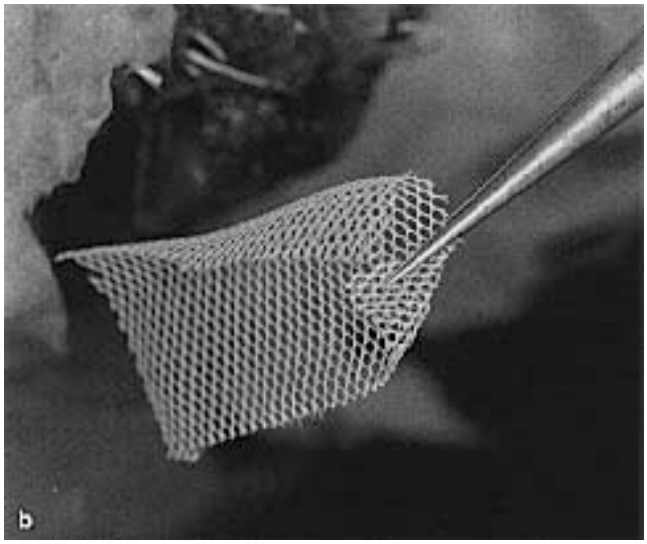

FIG 41.21 **a)** An adult African Grey Parrot hen was referred for surgical removal of an egg that was thought to be causing a distended abdomen. On physical examination, a sizable abdominal swelling that was soft and contained palpable tubular structures was identified. Contrast radiography indicated that the hen had an abdominal hernia. **b)** The hernia was repaired using a surgical mesh to add strength to the damaged abdominal wall.

Lipomas

Lipomas are frequently the expression of obesity. Central necrosis and ulceration may occur. Some lipomas are covered by xanthomatous skin. Efforts should be made to reduce the size of the mass medically before attempting surgical extirpation. Diet and exercise are effective over a period of several months. Lipomas are generally well encapsulated and shell out easily.

Leg Amputation

When a leg must be amputated, it is best performed at mid-femur. If the stump is too long, the bird may continue to use it for ambulation, causing trauma and granuloma formation to the stump. A mid-femoral amputation allows adequate soft tissue coverage of the end of the bone and prevents the patient from traumatizing the surgical site. Because the majority of the femur is contained within the skin of the body wall, a mid-femoral amputation is also cosmetic. Most companion birds with one leg are able to function normally. Psittacine birds compensate particularly well because they use their beak as an aid to ambulation. Pododermatitis of the contralateral foot, as occurs commonly in raptor amputees, is rarely a problem in companion birds on a formulated diet.

The skin incision should be made along the knee web to conform to the contour of the abdomen. A semicircular incision is created both medially and laterally at about the level of the stifle. This will allow adequate skin for tension-free closure. The muscles should be transected at the stifle. Use of the radioscalpel will aid in hemostasis. The muscles are elevated from the femur to the mid-diaphyseal region using a periosteal elevator. The ischiatic nerve should be injected with lidocaine or bupivacaine prior to transection for temporary postoperative analgesia. The femur may be cut with a bone cutter, an osteotome, a gigli wire, a sagittal saw or other suitable instruments appropriate for the patient's size. Following the osteotomy, the muscles are sutured over the end of the bone to provide padding. Subcutaneous tissues and skin are closed routinely.

Toe Amputation

Indications for toe amputation include avascular necrosis, trauma and infection. Hemostasis is aided by the use of a tourniquet. Hemostatic agents should be avoided. The heavily keratinized scale surfaces may be gently debrided exposing the more supple epidermis below. This improves tissue handling for suture placement. The site of amputation should be at the joint proximal to the affected area. The skin should be incised distal to the joint to provide adequate skin for closure (Figure 41.22). A hydroactive dressing will promote healing and prevent contamination (see Chapter 16).

Wing Amputation

Amputation of the humerus at the junction of the middle and proximal thirds of the bone provides adequate soft tissue coverage and creates a stump short enough to prevent self trauma. The skin incision should be made at the distal humerus, just proximal to the elbow. If additional skin is needed for closure, the patagium may be utilized. The muscles are transected at their musculotendinous junctions near the elbow. The radial and medianoulnar nerves should be injected with lidocaine or bupivacaine for short-term postoperative analgesia prior to their transection. Brachial musculature is mobilized by blunt dissection to remove attachments from the humerus. The humerus should be transected at the proximal third, to provide sufficient muscle distally to be sutured over the stump. Subcutaneous and skin closure are routine.

In situations where use of the wing for balance is important, it may be beneficial to amputate as distally as possible.[19,39] This function is especially important when working with birds to be used in breeding programs and as surrogate parents. It may be difficult to obtain adequate soft tissues for stump coverage with distal amputations.

Vascular Access Devices

In avian patients, intravenous catheters are viable only for short-term therapies. Avian veins are relatively small, thin-walled and fragile, with a propensity for hematoma formation following venipuncture. The intraosseous placement of a needle provides access to the vascular space for administration of fluids and therapeutics for up to 72 hours. Vascular access devices provide a route for long-term administration of therapeutics into the vascular system.[8,17] They have been used for long-term administration of amphotericin B in a Cassins Auklet[17] and Magellanic Penguins and for total parenteral nutrition in pigeons.[8]

Vascular access devices are subcutaneously implanted devices with a reservoir that is accessed through surgically prepared skin using a non-coring

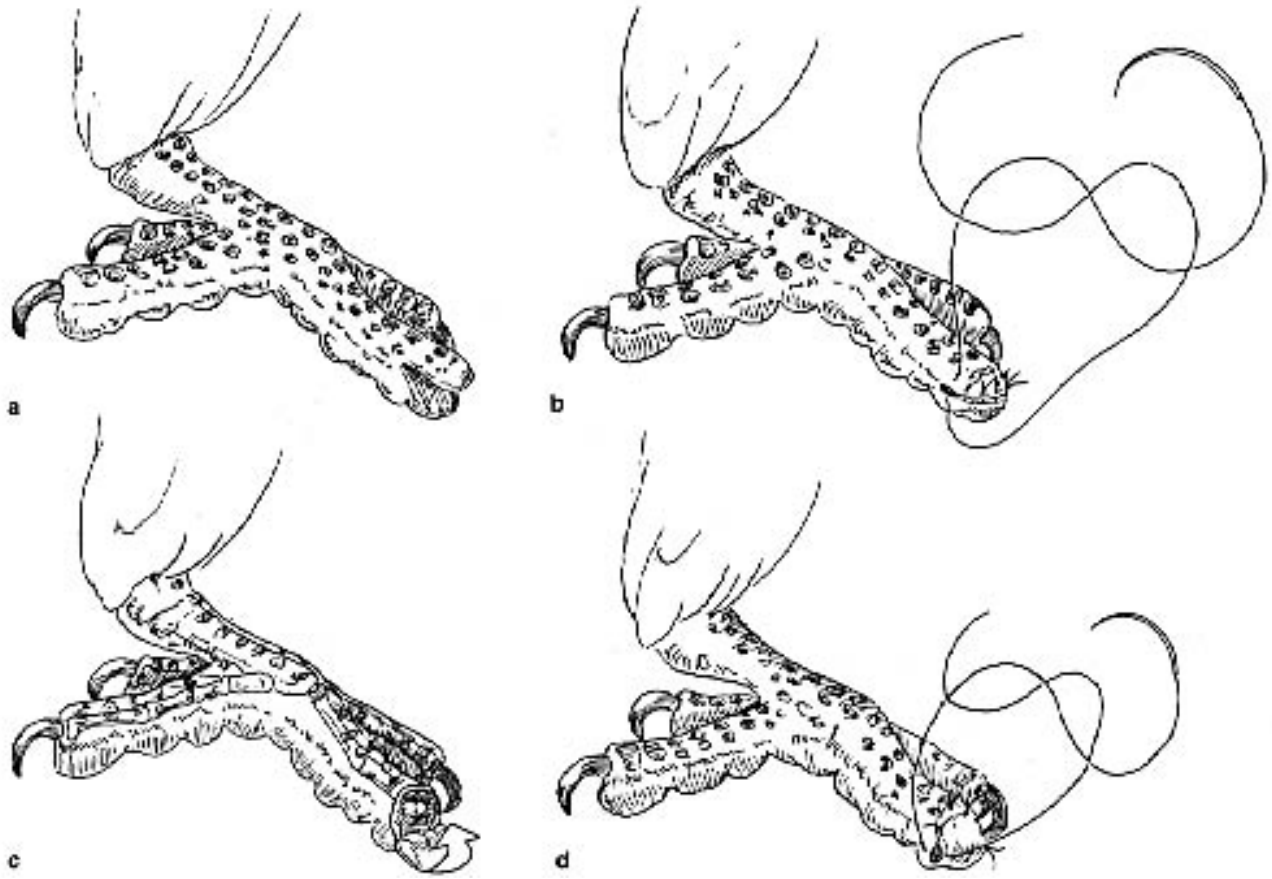

FIG 41.22 Two techniques may be used for toe amputation: **a,b)** The skin may be incised, creating a semicircular flap on both the dorsal and the plantar surfaces of the digit. This skin pattern will provide adequate tissue for closure over the distal end of the bone. **c,d)** Alternatively, the plantar skin may be incised to create a flap of plantar skin that will cover the end of the bone. The plantar skin is somewhat stronger than the dorsal skin, providing additional protection over the end of the bone. Because the metaphysis and epiphysis of the phalanges are larger than the diaphysis, it may be beneficial to remove the exposed joint surface with rongeurs prior to skin closure. The skin is sutured as described for the repair of toe necrosis (see Figure 41.1).

needle (Huber point needle). Risk of sepsis and thrombosis is minimized because the catheter is not exposed to the environment. These have been maintained in humans for years and in birds for up to 12 weeks.[17] Vascular access devices have a number of synonyms, some of which are proprietary names, such as portacath, infusaport, dome, vascular access port and subcutaneous port.

The material, construction, surface finish and tip configuration influence the thrombogenicity of the catheter. Silicone and hydromer-coated polyurethane are considered the least thrombogenic materials currently in use. The catheter can be implanted into a vein, artery or other hollow organ and connected to the reservoir.

The right jugular vein is the preferred site for implantation. The patient is positioned in left lateral recumbency, and the area over the right jugular vein is prepared for surgery. In many avian patients, there is no need to remove feathers because there is an apterium in this location. The skin is moved dorsally and an incision is made over the jugular vein. When the skin is released, the incision site will be ventral to the jugular vein and not over the reservoir. The jugular vein is identified and isolated for a distance of approximately 15 mm. Dissection must proceed cautiously as the vein is very fragile. Two ligatures are placed around the vein, one at the cranial extent and the other at the caudal extent of the isolated area. The caudal suture is elevated to occlude blood flow. The jugular vein will distend and the cranial suture is then tied off permanently occluding jugular flow. This does not seem to affect cerebral hemodynamics.

At this point, a small segment of the jugular vein remains distended. Using fine iris scissors and magnification, a transverse venotomy is created in the distended portion of the vein. This incision will not transect the vein but will allow the catheter to be inserted. After the blood from the distended segment is cleared, the end of the catheter is inserted into the venotomy site. The tension on the caudal ligature will have to be loosened to allow the catheter to pass, but enough tension should be maintained to prevent reflux hemorrhage. The venotomy may be widened using fine forceps or a vascular introducer. The catheter is advanced to the right atrium and secured in place by suturing above and below the retention ring at the venotomy site to prevent the catheter from advancing or backing out.

A Huber needle attached to a three-way stopcock and a saline-filled syringe is used to test the ease of injection and withdrawal of a sample. The position of the catheter tip should be evaluated using contrast radiography. Some catheters are radiopaque. With those that are radiolucent, the position can be evaluated by injecting a vascular contrast medium.

A subcutaneous pocket is created dorsal to the jugular vein large enough to accommodate the reservoir, which is placed into the pocket and sutured in place to the fascia of the neck musculature. A 2 to 4 cm loop of catheter is left to allow for neck movements. Subcutaneous and skin closure are routine. During recovery, feathers over the reservoir should be removed and the skin aseptically prepared. The device should then be filled with heparin at 100 IU/ml. Only non-coring needles should be used with these devices. With a minimal amount of practice, these devices can be implanted in 10 to 15 minutes.

The skin area above the port must be aseptically prepared before each use. Chlorhexidine has been shown to be three to four times more effective at preventing bacterial colonization of the catheter than povidone iodine.[17] The individual administering the therapy should wear sterile gloves and use sterile equipment. The non-coring needle is inserted into the reservoir until it hits the base plate and the injection can then be made.

These devices can be maintained for extended periods of time but require some maintenance.[17] Catheters were maintained in chickens for 12 weeks using a 1000 IU/ml heparin lock and weekly flushing. In geese, the catheters were flushed every four days with 1.0 ml physiologic saline and locked with 0.25 ml heparin at 100 IU/ml. When catheters are used daily or several times daily, there is no need for heparin locks, which eliminates the potential for heparinizing the patient. However, there is a higher potential for thrombus formation with small gauge catheters, and a heparin lock may still be necessary.[17]

Removal of the device requires a surgical approach to the vein and the reservoir. The sutures holding the reservoir are removed as is the suture holding the catheter in the vein. A ligature is pre-placed around the vein and the catheter is removed. The ligature is tightened to prevent reflux of blood. Closure of the skin and subcutaneous tissues is routine.

Perinatal Surgery

Many aviculturists do not seek veterinary assistance with embryonal and neonatal matters, attempting to manage problems themselves. Rarely are these attempts successful. Neonatal tissues are challenging to suture. Compared with adult tissues, they have a high moisture content, making them very friable, with reduced tensile strength. With practice and management, fine suture (8-0 to 10-0) and an atraumatic needle can be used for closure of the umbilicus. However, hemostatic clips are more appropriate for application to the umbilicus than suture ligatures. Featherless neonates are highly prone to developing hypothermia. Anesthesia and surgery time should be less than 15 minutes, and the operating room temperature should be elevated to 75 to 85°F.[1] Body temperature should be carefully monitored throughout the procedure, and supplemental glucose should be provided through an intraosseous cannula as necessary.

Because of their small blood volume, perinatal patients are more likely to require transfusion if major blood loss occurs or if the hematocrit is below 20 to 25%. Respiratory movements may be difficult to observe in perinatal patients, making the use of clear drapes and small non-rebreathing bags essential. The crop of altricial avian neonatal patients is usually full, increasing the risk of regurgitation and aspiration. The patient may be fasted until the crop volume has diminished or the contents may be removed by aspiration. Elevating the head and packing the thoracic esophagus with moist cotton will also help prevent reflux of crop contents.

Yolk Sac Removal

The yolk sac is a diverticulum from the small intestine attached by the yolk stalk and accompanying

vasculature. It is normally internalized prior to hatching. Yolk is absorbed during incubation through the endodermal cells of the yolk sac and, at least in chickens, nutrients are absorbed through a duct that connects the yolk stalk to the intestines. Yolk provides nourishment, minerals, fat-soluble vitamins and maternal antibodies to the developing embryo and the neonatal bird. After the yolk has been completely absorbed, the remnant of the yolk sac becomes the vitelline or Meckel's diverticulum.

A procedure for removal of unabsorbed yolk sacs has been successful in decreasing mortality in affected chicks (see Chapter 48). Candidates for surgery demonstrate one or more of the following clinical signs: abdominal distention, exercise intolerance or dyspnea, weight loss and anorexia, failure to grow or inability to stand or walk. Abdominal palpation and radiography support the diagnosis of unabsorbed yolk sac. Radiographically, the yolk mass displaces the viscera cranially into the thoracic space, compromising the caudal air sacs. This results in exercise intolerance and dyspnea. Yolk sac removal is most effective if performed before the chick becomes dyspneic. Percutaneous aspiration of the yolk should not be attempted as the yolk sac is very thin and will leak yolk into the coelomic cavity resulting in peritonitis. Injecting antibiotics directly into the yolk sac carries the same risk. Systemic antibiotics are not effective alone.[26]

CHAPTER

42

ORTHOPEDIC SURGICAL TECHNIQUES

Howard Martin
Branson W. Ritchie

Numerous approaches have been used to repair fractures and luxations in avian species. Typically, these techniques have been adapted from those used for small mammals and humans. Regardless of the specific techniques employed in fracture repair, it is important to:

- Treat contaminated and infected wounds.
- Preserve soft tissue structures.
- Appose, align and control rotation of fractures and reduce luxations.
- Rigidly immobilize the fracture site.
- Maintain range of motion in all joints affected by the fracture or fixation technique.
- Return the affected limb to "normal function" as soon as possible.

The presence of a fracture certainly suggests major trauma, and a thorough physical examination should be performed to determine other injuries.

Subcutaneous emphysema may be noted in birds with ruptured air sacs or with fractures of the humerus, thoracic girdle or some ribs (the pneumatic bones). The emphysema will generally resolve within a few days. In many cases, birds may require several days of stabilization with fluids, steroids, antibiotics or supportive alimentation before anesthesia and surgery can be safely performed (see Chapter 40).

It is common for subtle injuries to occur that are difficult to detect by physical examination. Survey radiographs of affected skeletal areas as well as the abdomen and thorax are needed to assess any bony or soft tissue changes that may have occurred during a traumatic episode. Recommendations for other evaluation procedures are similar to those described in soft tissue surgery (see Chapter 41).

Fracture stabilization techniques used in free-ranging birds must be designed to increase the likelihood that a rehabilitated bird can be released. Repair of a wing fracture, particularly near a joint, must be nearly perfect with no ankylosis and minimal soft tissue damage to ensure return to full flight. For these avian patients, maintenance and protection of soft tissues is the single most important aspect of successful surgery. The degree and type of soft tissue damage may be more critical in determining the potential for postsurgical return to function than specific osseous injuries. Native avifauna with injuries that will prevent their release must be repaired to a functional level that allows them to adapt to a zoo, breeding program or educational facility. Injured native birds that cannot be repaired to sufficiently achieve one of these goals may require euthanasia.

Birds that are maintained in aviary situations or in breeding facilities must have adequate postoperative use of a fractured limb to allow them to function effectively in their respective environments. Most companion birds can tolerate a substantial loss of function of the wings and still function normally. Leg injuries that alter weight-bearing in one or both feet can predispose a bird to bumblefoot or arthritis. Some birds will tolerate postoperative surgical hardware while others will not.

Therapeutic Strategies

The fracture should be classified as to anatomy, shape, whether it is open or closed and its chronicity. The type of fracture will frequently dictate the type of specific therapy and stabilization procedures that are used. Patient preparation for surgery, preparing the surgical site and draping are discussed in Chapter 40.

TABLE 42.1 Types of Fixation

- **External coaptation** - Sling, splint, bandage
- **Internal fixation** - IM pins, cerclage wires, bone plates
- **External fixation** - pins passed through bone from skin surface and connected to stabilizing bars

TABLE 42.2 Principles of Fracture Stabilization[31,30,38,39]

- Minimal soft tissue damage
- Maintenance of length, rotation, angular orientation
- Anatomic alignment
- Rigid stabilization
- Minimal disturbance of callus formation
- Neutralization of forces:
  - Rotation, bending (transverse fractures)
  - Shear, rotation, bending (oblique or spinal fractures)
  - Compression, shear, rotation, bending (comminuted fractures)

Developing a Surgical Plan

The method of fixation selected should suit the patient's injury, natural behavior, activity levels and future needs (Tables 42.1, 42.2). A thorough understanding of the location of major nerves, arteries and veins ensures that the surgeon can properly perform any necessary stabilization procedure. Bipolar radiosurgery is necessary to control blood loss and allow thorough visualization of a relatively small surgical field (see Chapter 40).

Avian bones have a high calcium content, and a thin, brittle nature.[31,35] In addition, portions of the medullary canal of the humerus in many birds are connected to the air sacs (pneumatic), which reduce the weight of the bone and are believed to contribute to the respiratory cycle during flight (see Anatomy Overlays). It is best to cover the medullary canal of the proximal fragment of a humeral fracture before irrigating the surgical site. Fluids or necrotic debris that are flushed into the pneumatic bones may cause asphyxiation, air sacculitis or pneumonia.

The distal legs and wings of birds have relatively little soft tissue (ie, tendons, ligaments, skin and muscles). Bone in these areas are, therefore, particularly susceptible to impact-related injuries (see Anatomy Overlays). Aggressive tissue manipulation can cause increased damage of already compromised blood supply and soft tissues, which increases the healing time and likelihood of unsuccessful function post-repair.

FIG 42.1 Primary and secondary remiges (arrows) are attached to the periosteum of the metacarpal bones and ulna, respectively. Periosteal stripping and damage to the primary and secondary feather follicles should be avoided during a surgical procedure (courtesy of Laurel Degernes).

Gentle manipulation and frequent irrigation of soft tissues and bones with sterile saline will help maintain the integrity of vascular and neural structures and speed return to normal function. If exposure of a fracture site requires the transection of a muscle, it is best to do so near the muscle's origin or insertion in order to minimize trauma and hemorrhage and to facilitate reattachment. Periosteal stripping and damage of soft tissue attachments to the bone should be avoided, particularly in the wings, where the primary and secondary feathers are attached to the periosteum (Figure 42.1).

Open Versus Closed Reduction

Thin skin, scarce soft tissues and sharp bone fragments frequently result in open fractures in birds. Even if bones are not protruding from the skin at the time of presentation, the presence of any wound associated with the fracture would indicate previous violation of the skin barrier. If any skin wound is present, the fracture should be considered open.

Closed reduction involves the manipulation of the fracture through application of traction and countertraction to stretch the soft tissues and appose and align the bone fragments. It is difficult to achieve adequate alignment and reduction of fractures with closed reduction techniques without causing significant soft tissue trauma, except in those fractures that are minimally displaced.

The advantages of open reduction include reduced soft tissue trauma (as traction is applied directly to the bones), visualization of the fracture site (and therefore the ability to attain optimal reduction as well as cleansing of the fracture site) and removal from the fracture site of interposed soft tissues, contaminated or infected debris and necrotic or devitalized bone.[11]

Prognosis

Companion and aviary birds rarely require full mobility following fracture repair, and the post-fracture prognosis for return to function with these birds is generally excellent. By comparison, free-ranging birds (particularly raptors), which can be viewed as finely tuned athletes, must have near perfect wing function in order to survive in the wild. A slight rotation in the wing (particularly in the distal wing) can alter flight. The ulna and radius normally slide by each other longitudinally. If trauma causes the ulna and radius to fuse (preventing this sliding motion), a bird will be unable to properly supinate or pronate the carpus and may not be able to fly.[21,41]

Fractures near a joint usually result in ankylosis, which prevents normal limb function. Open comminuted fractures are more likely to be infected, resulting in secondary osteomyelitis.[21] A 20 to 30% decrease in leg function may be acceptable in birds released to the wild as long as the dysfunction does not dramatically affect the flexion or extension of the foot or the prehension of food.

Postoperative Care

Postoperative radiographs should be taken at two- to four-week intervals to assess bone healing. The radiographic changes associated with bone healing can appear similar to those that occur with osteomyelitis including periosteal reaction, sclerosis and increased radiodensities in the medullary canal (Figure 42.2).

To improve vascular supply to damaged tissue and to speed the bone healing process, active and passive

FIG 42.2 A minimally displaced mid-diaphyseal tibiotarsal fracture in a Green-winged Macaw was stabilized with a cast. Radiographs three weeks after the fracture occurred show a loss of detail at the fracture ends and a smooth, well defined periosteal response characteristic of a normal healing process. This lateral radiograph indicates slight malalignment and over-riding of the fragments (courtesy of Marjorie McMillan).

rehabilitative techniques should be instigated as soon as possible after an orthopedic surgery. The physical therapy program should be based on the bird's injury, behavior and required degree of post-surgical function. Initial physical therapy may involve only a bird's daily activities of perching and prehending food. Physical therapy should evolve to include a variety of regimented exercises designed to maintain or increase cardiovascular endurance, to maintain or increase range of motion of joints and to maintain or increase muscular flexibility tone and fitness.[10] The physical therapy program is dictated by the exact nature of the injury and species of injured bird.

FIG 42.3 Radiographic findings suggest that primary bone healing occurs in birds if a fracture is properly aligned and rigidly stabilized. An adult Amazon parrot was presented with a history of having fractured the right tibiotarsus three months before presentation. This fracture was repaired with a Robert Jones bandage. Three weeks before presentation, the bird had fractured the left tibiotarsus and the limb was cast. The bird had not improved during the three-week period, and the case was referred for evaluation. The severely displaced right tibiotarsal fracture was stable and a substantial periosteal callus was evident radiographically. At presentation, the left tibiotarsus was displaced (bone ends were not touching) and there was excessive soft tissue swelling. The fracture site was approached medially, and a large amount of fibrous connective tissue was removed to allow the bone ends to be reduced. The fracture was stabilized using positive profile threaded pins connected with methylmethacrylate. The bird was placed in a light Robert Jones-type bandage and was using the leg several hours after surgery. Radiographs taken four weeks postsurgery indicated a bony union with minimal callus formation.

Bone Healing

Controlled studies evaluating the healing process of avian bone are scarce. In general, it is assumed that the rate of fracture repair is dependent on the displacement of the bone fragments, the amount of damage to the blood supply, whether an infectious agent is present and the amount of motion at the fracture site.[14] In mammals, primary bone healing (bone growth through the Haversian system with minimal callus formation) occurs with rigid fixation and does not occur if there is a gap or motion at the fracture site. In these cases, secondary bone healing characterized by maximum callus formation occurs (Table 42.3). In birds where fractures were repaired with bone plates (maximum stabilization), callus formation was found to be minimal, suggesting that primary bone healing had occurred (Figure 42.3).[19]

Callus formation appears to be similar in birds and mammals.[19] Endosteal callus provides rapid stabilization in bones that are properly aligned. Periosteal

FIG 42.4 In comminuted fractures, bone fragments that maintain a blood supply heal rapidly. Devitalized, uninfected fragments should be left at the fracture site to provide additional support for callus formation (courtesy of Laurel Degernes).

callus formation is minimal if the bones are rigidly fixed. The blood supply to the bones is believed to arise from periosteal (originating from soft tissues and muscles), medullary (originating from nutrient artery), metaphyseal and epiphyseal vessels.[7]

Stable, properly aligned fractures appear to heal more rapidly in birds than in mammals.[6,7,30,31,45] It has been suggested, but not confirmed, that pneumatic bones heal slower than medullary bones.[31] Clinical stability of a fracture (two to three weeks) may precede radiographic evidence that the bone is healed (three to six weeks).[7,31,45] The healing of unstabilized humeral fractures in pigeons was characterized by increased radiolucency in the medullary canal and endosteal and periosteal calluses that were present histologically by nine weeks. Poorly aligned fractures changed little between four and twelve weeks,[31] while properly stabilized bones remodeled rapidly during that time period.

Minor forces that cause undetectable levels of movement can damage the growth of small capillary beds and impede fracture stabilization. Fracture stabilization is most likely to fail in comminuted fractures that have the greatest number of forces that must be neutralized.[30] In these fractures, bone fragments that maintain a blood supply should heal as rapidly as the intact distal and proximal fragments. Devitalized, uninfected fragments should be left in place to provide structural support for callus formation (Figure 42.4).[33]

TABLE 42.3 Secondary Bone Healing

Induction and Inflammation
- Fibroblasts proliferate
- Osteogenic cells migrate from periosteum and endosteum and proliferate at fracture site

Callus Formation
- Collagen and mucopolysaccharide produced
- Calcium deposited in callus
- Soft callus becomes bone (endochondral ossification)

Remodeling
- Accelerated deposition and resorption of bone
- Change in shape of bone
- Function and strength restored

Osteomyelitis

Avian heterophils lack the proteinase necessary to liquify necrotic tissue, and birds tend to form granulomas that wall off infectious agents and necrotic material. Consequently, osteomyelitis is characterized by caseous, dry, non-draining lesions that are frequently restricted to the site of infection and rarely induce secondary systemic infections.[33] With mild infections, it is common for the host defense mechanism to wall off the necrotic debris and form callus around the infected tissue. However, these granulomatous osteomyelitis lesions can serve as a nidus for infection that can cause a fatal septicemia if a bird becomes immunosuppressed.

Large quantities of necrotic debris may prevent bone healing and should be surgically removed if successful fracture stabilization is expected to occur.[33,46] Debridement and flushing should be used to remove necrotic tissue and debris from all open fractures to reduce the chances of postoperative osteomyelitis. Samples for culture and sensitivity should be collected from the fracture site at the time of surgery. The use of intraoperative, broad-spectrum antibiotics with good tissue penetration (trimethoprim-sulfa, cephalosporins, chloramphenicol, tetracyclines) should be considered in these cases.

Placement of stabilizing hardware at or near an open fracture site should be avoided to decrease the likelihood of osteomyelitis and improve the speed of bone healing. External fixators are recommended in these cases. It has been suggested that fractures in pneumatic bones would be predisposed to osteomyelitis from contaminated air entering the fracture site. There is no evidence to support this theory.[7,31]

Malunions

Viable and nonviable malunions can occur in birds (Table 42.4). Malunions occur when the ends of fractured bones heal but not to each other. Stabilization

requires removing necrotic debris, freshening the bone ends and compressing and rigidly stabilizing the fracture site.[41] Electrical current stimulation was used to repair a nonunion fracture (six months' duration) in the radius and ulna of a Rough-legged Hawk. A direct-current stimulator[a] was implanted and delivered 0.83 volts at 20 uA to the fracture site. Callus formation was evident radiographically at 21 days post-implantation and the fracture was healed by 80 days post-implantation.[27]

Ossification[13]

The maturation process of the long bones of birds is different from that of mammals. In the majority of raptors, ossification of the limb bones occurs within 60 days of hatching and bones appear to mature thereafter. The diaphysis, or shaft, is that portion of a long bone between the ends (Figure 42.5). The metaphysis is the wider part of the extremities of the shaft, adjacent to the epiphyseal disc (physis). The epiphysis is the end of a long bone and is formed from a secondary center of ossification. The physis, or growth plate, is that segment of tubular bone concerned with growth. It is divided into four distinct zones:[11]

- **Zone of resting cartilage:** Small chondrocytes are dispersed in an irregular pattern.
- **Zone of cell proliferation:** Chondrocytes are somewhat larger and tend to form columns; this is the area of chondrocyte proliferation and mitotic figures are usually present.
- **Zone of cell maturation:** Cells are larger still and arranged in columns. As the cells enlarge and mature, they accumulate glycogen and begin producing phosphatase, which initiates calcification.
- **Zone of calcification and ossification:** With maturity, the columns of chondrocytes die and disintegrate, leaving spaces between partitions within the cartilage. Capillaries invade the spaces and osteoblastic activity takes place on the surface of the partitions. Longitudinally oriented bony trabeculae develop, which give a jagged appearance to this zone on histologic and radiographic preparations.

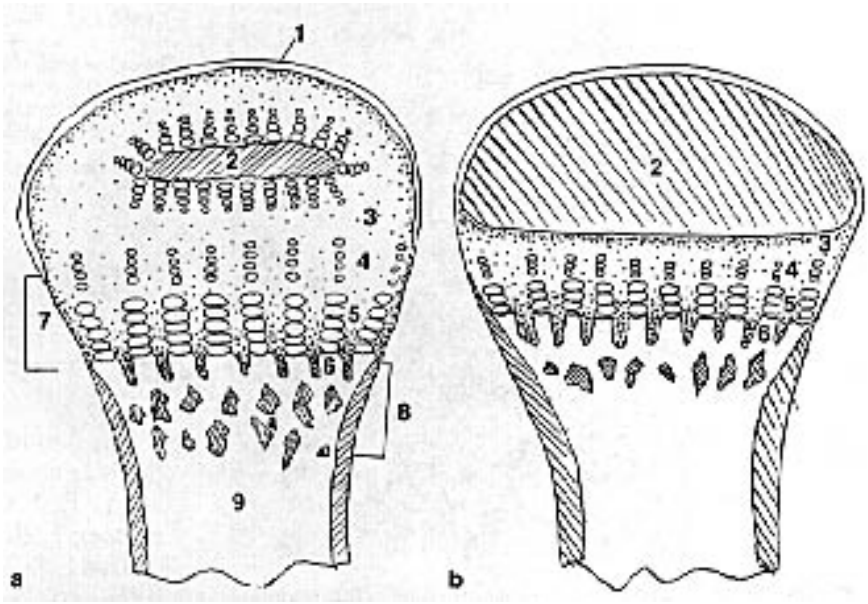

FIG 42.5 **a)** Mammalian long bone ossification during early development and **b)** after the epiphysis has reached maximum size. 1) articular cartilage 2) secondary center of ossification 3) zone of resting cartilage 4) zone of cell proliferation 5) zone of maturation 6) zone of calcification and ossification 7) physis 8) metaphysis and 9) diaphysis (modified with permission from Fowler[13]).

TABLE 42.4 Types of Malunions[3]

Viable – Sufficient blood supply

Hypertrophic
- Abundant callus and blood vessels
- Fractures filled with fibrocartilage
- Caused by inadequate fixation or premature loading

Oligotrophic
- No evidence of callus
- Biologically, fracture can heal
- Hypervascularized fragments
- Rounded, decalcified fragment ends

Nonviable – Insufficient blood supply

In mammals, most long bones have one or more epiphyseal or secondary centers of ossification. Their formation is similar to endochondral ossification with proliferation occurring in all directions until a predetermined size is reached. The epiphyseal center is covered distally by hyaline articular cartilage and proximally by an epiphyseal plate or physis until the animal reaches maturity.

The tibiotarsus of birds appears to follow a classic mammalian ossification pattern. The ends of the bones grow rapidly and establish secondary centers of ossification (epiphyses). The growth in length takes place at the epiphyseal layer, and when growth ceases, the layer of cartilage ossifies. The avian hu-

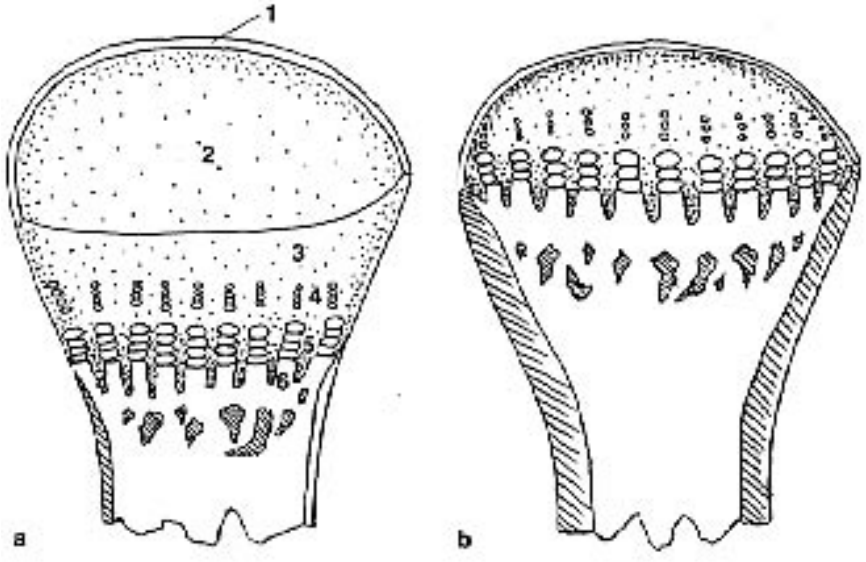

FIG 42.7 **a)** In contrast to mammals, the epiphyseal center of the avian long bone remains cartilaginous (day-old chick). **b)** After the maximum bone size is reached (in this case a 155-day-old chick), the epiphyseal cartilage undergoes endochondral ossification. 1) articular cartilage 2) epiphyseal cartilage 3) zone of resting cartilage 4) zone of proliferation 5) zone of maturation and 6) zone of calcification and ossification (modified with permission from Fowler[13]).

merus, radius, ulna and femur appear to have different patterns of ossification.

The basic progression of ossification in long bones has been described in chickens (Figure 42.6). In the femur of a 9-day-old embryo, a sheath of bone has begun to form beneath the perichondrium of the original hyaline cartilage. At 13 days, the central diaphyseal cartilage has been replaced by bone, and the marrow cavity has formed. Endochondral ossification progresses toward both extremities.

In the day-old chick, the diaphysis has elongated by replacement of the cartilage model at the metaphysis. There is also a cartilage model analogous for the mammalian epiphyseal center of ossification (Figure 42.7), but the epiphyseal cartilage does not undergo endochondral ossification in the femur of chickens as it does in mammals. Instead, it persists as a wide basophilic hyaline zone covered by a narrow strip of eosinophilic articular cartilage. Elongation of the cartilage model is accomplished by interstitial growth of chondrocytes.[11]

At a predetermined time (may be controlled by age, species, nutrition), the growth cartilage becomes exhausted. The invading marrow tissue then enters the epiphyseal cartilage (Figure 42.8). Individual chondrocytes undergo hypertrophy allowing final endochondral ossification of the epiphyseal cartilage. By 190 days, ossification is essentially complete. At each end of the bone, a dense terminal bone plate is covered by an articular hyaline cartilage. It is possible for slight elongation of a long bone to take place by cartilage proliferation and ossification at the junction of the bone and articular cartilage. This is typical of the long bones of the humerus, radius, ulna and femur.

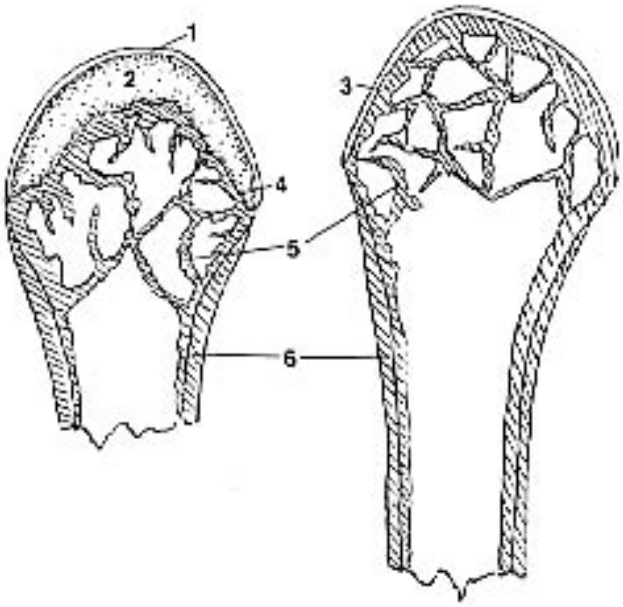

FIG 42.8 Progression toward mature bone in a 190-day-old chick. 1) articular cartilage 2) epiphyseal cartilage 3) dense layer of bone beneath articular cartilage 4) physis 5) bone trabecula and 6) cortex (modified with permission from Fowler[13]).

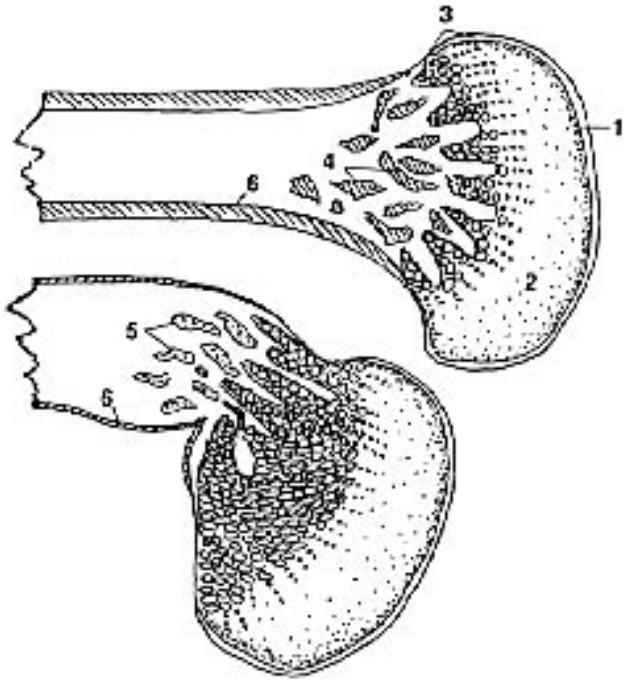

FIG 42.9 Comparison of normal avian ossification and ossification in a bone affected with metabolic bone disease. 1) articular cartilage 2) epiphyseal cartilage 3) physis 4) bone spicules 5) osteoid spicules 6) cortex, and folding fracture (modified with permission from Fowler[13])

The ossification of the tibiotarsal and tarsometatarsal bones is different. The epiphyseal center of ossification of the proximal end of the tibiotarsus becomes visible radiographically at 35 days in the chicken. The fibular and tibial tarsal bones, which make up the hock of mature mammals, fuse in avian embryos to the tibial cartilaginous model and appear as two epiphyseal centers in the seven-day-old chick. Likewise, the epiphyseal center at the proximal end of the tarsometatarsus corresponds to the distal row of tarsal bones in mammals. The carpals, metacarpals and phalanges of the wing ossify from a diaphyseal center in the same manner as long bones of the wing.

Metabolic Bone Disease

Metabolic bone disease in the tibiotarsus and tarsometatarsus (bones with epiphyseal centers of ossification) appears similar to that described in mammals. If growth of the long bone continues by interstitial cartilaginous growth in the zone of proliferation without a sufficient supply of calcium and phosphorus, calcification of the intracellular substance between the mature cells ceases. Without calcification, the chondrocytes continue to live, causing thickening of the whole growth zone (Figure 42.9). Osteoblastic activity continues with the production of unmineralized osteoid tissue in the metaphysis. The stimulus for osteoid production is intensified because of the relative structural weakness of the unmineralized growth zone. This excessive osteoid production occurs subperiosteally, resulting in knobby growth centers. The radiographic changes are characterized by rickets, increased width of the physis, increased trabeculation in the metaphysis, lipping of the metaphysis and swollen distal extremities.[40]

The femur and wing bones lack epiphyseal centers of ossification. However, histologically, the same pattern of abnormal development takes place in the growth zone of a femur or wing bone in a bird with metabolic bone disease. The epiphyseal cartilage in birds corresponds to the epiphyseal ossification center in mammals.[13]

Bone Grafts

Bone grafts promote fracture healing through osteogenesis (production of new bone), osteoinduction (recruitment of mesenchymal cells that differentiate into chondroblasts and osteoblasts) and osteoconduction (osteoblast ingrowth from the host into the graft providing structural and mechanical support). In general, cancellous bone is better than cortical bone

for grafting because the former has a larger surface area and a large number of viable cells for stimulating new bone production.

Autogenous medullary bone (collected from the tibiotarsus), corticocancellous bone (collected from the sternum or ribs) and cortical bone (devitalized fragments from the fracture site) have been shown to augment bone healing in birds.[33,35,41] Cortical allografts (same species, different individual) and xenografts (different species) were not found to stimulate nor inhibit bone healing when applied in an overlay fashion to humeral fractures in pigeons. There was less callus formation in the fractures supported by a graft but these birds also had a significantly higher occurrence of dehiscence, sequestration and foreign body reactions than birds with no grafts.[28] These findings suggest that the positive effects of cortical bone grafts in birds are limited to added fracture stabilization.

Fracture Repair Techniques

It is best to have a command of a variety of fracture fixation techniques and to be ready with alternative plans at the time of surgery (see Table 42.1). Reassessment of the injury intraoperatively may necessitate a change in the surgical procedure. Each avian fracture is unique and may require a variety of maneuvers, techniques and instruments to achieve optimal reduction and immobilization.

Many closed fractures may heal without any type of coaptation or fixation. However, with unsupported long bone fractures, excessive callus formation, malalignment of the bone ends and shortening of the limb (overridden fractures) will dramatically reduce normal function. Non-displaced fractures of the pelvic girdle, coracoid, clavicle and scapula will generally heal with minimal support.[21,39,46] Displaced fractures of the coracoid must be surgically repaired or the fracture will usually result in an inability to fly.[46] Fractures of the radius or ulna, in which the other bone is intact, can generally be repaired with external coaptation and forced rest (Figure 42.10).[38]

FIG 42.10 Minimally displaced fractures of the radius or ulna in which the other bone is intact can generally be repaired with a figure-of-eight wing-body wrap and forced rest; **a)** before and **b)** after coaptation (courtesy of Laurel Degernes).

External Coaptation: Bandages and Splints

External coaptation is an inexpensive and rapid method of providing increased comfort to a patient (decreased movement of bone ends) and minimal stabilization of a fracture. Bandages and splints should be made of the lightest weight materials with the minimal amount of padding needed to compensate for swelling of damaged soft tissue. External coaptation is acceptable as a primary stabilization technique only when a limited post-fracture range of motion is satisfactory, a patient is too small to facilitate surgical repair, a fracture is minimally displaced or anesthesia and surgery would jeopardize the patient's life (eg, liver failure, kidney failure, heart disease, head trauma).

Fracture disease (malalignment of bone ends, muscle atrophy, joint ankylosis, shortened bone length and tendon contraction) is common in fractures repaired by external coaptation (Figure 42.11). In general, external coaptation should be considered an emergency method of stabilizing fractures until surgery can be performed or for providing additional support for fractures repaired by other methods.

Some companion birds may not require full return to flight; in these patients, some wing fractures can be effectively managed with external coaptation. Bandages or splints can be used to repair fractures of the distal legs and feet if the fracture can be properly

FIG 42.11 VD radiograph of a falcon with post-traumatic degenerative joint disease of the elbow. Improper fracture repair techniques are frequent causes of fracture disease in birds.

aligned and if any decrease in bone length does not alter the weight-bearing capacity of either limb and predispose the patient to arthritis or pododermatitis (see Chapter 16). Additionally, if leg function is altered, the companion bird may not be able to ambulate or adequately prehend food.

External Fixators

Bony injuries in the avian patient tend to heal in a reasonable manner and are amenable to a variety of fixation methods. In contrast, maintenance of soft tissues and joint mobility, the most vital components of return of full function for birds, may be hindered by many of the techniques used for immobilization of fractures and luxations. External fixators are generally considered the best stabilization technique for immobilizing fractures in birds that require a full return to function.

Numerous types of external fixation devices have been described for use in birds (Table 42.5). A variety of Kirschner wires and Steinman pins may be passed into the bones, and a variety of connecting bars and acrylic cements can be used for stabilizing the pins.[6,16,25,26,37,45] These devices are inexpensive, lightweight, easy to remove and are well tolerated by many avian species. An external fixator can be easily removed from a calm patient without anesthesia. When properly used, external fixators provide rigid stabilization and preserve joint and periarticular structure, while neutralizing rotational, bending and shear forces.[14,21,24,25,26,35,46] The approach to the surgical site can be minimal and, therefore, decreases soft tissue damage and reduces post-fixation dysfunction of the limb.[16,18,19] In many cases, external fixators allow a bird to use a repaired limb within several days of surgery (Figure 42.12).

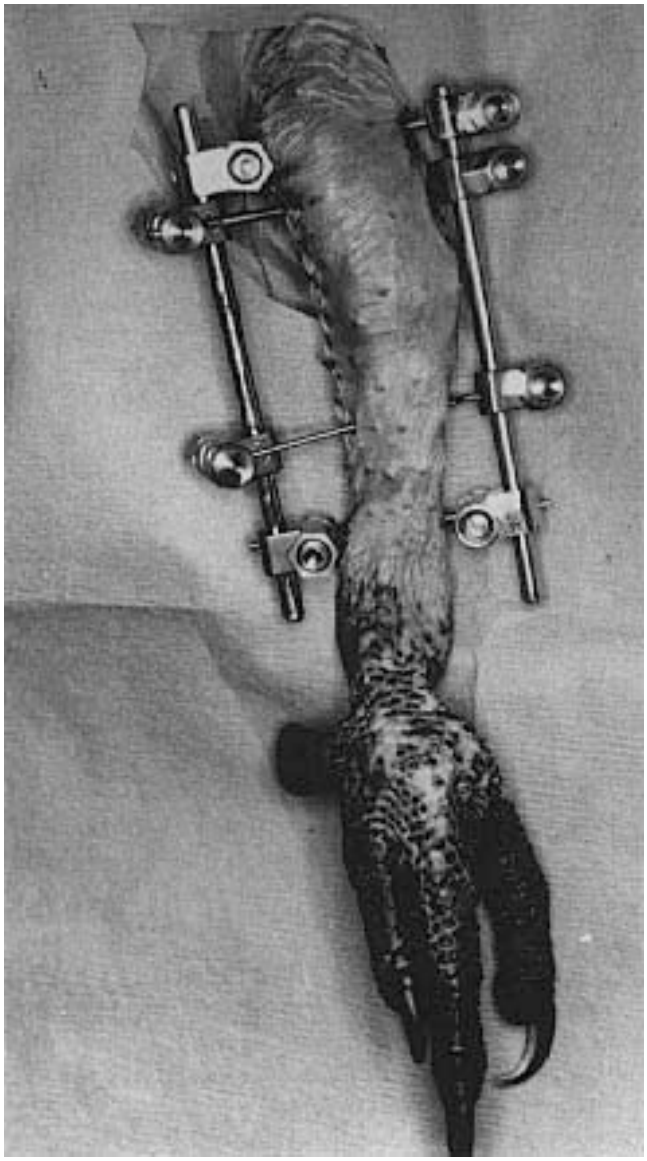

FIG 42.12 An external fixator is an ideal way to repair many fractures in birds. Either KE connectors, various cements or casting materials can be used to connect the stabilizing pins. In this case, a valgus deformity of the tibiotarsus was corrected with a dome osteotomy and stabilized with a Type II external fixator. The connecting bars should be as close to the skin edge as possible.

External fixators can be applied in conjunction with IM pins to further neutralize rotation and increase stability.[43]

Type II (through-and-through) fixators are more stable and stronger than Type I fixators, which tend to loosen rapidly (Table 42.5).[6] The use of positive-profile threaded pins in a Type I fixator configuration is

particularly useful in repairing fractures of the proximal humerus and femur, where interference with the body wall makes it difficult or impossible to place a Type II fixator (Figure 42.13).

External fixators are ideal for corrective osteotomies and open, comminuted fractures. In the latter situation, the fixator can be placed so that an infected wound can remain open for several days for flushing and evaluation.

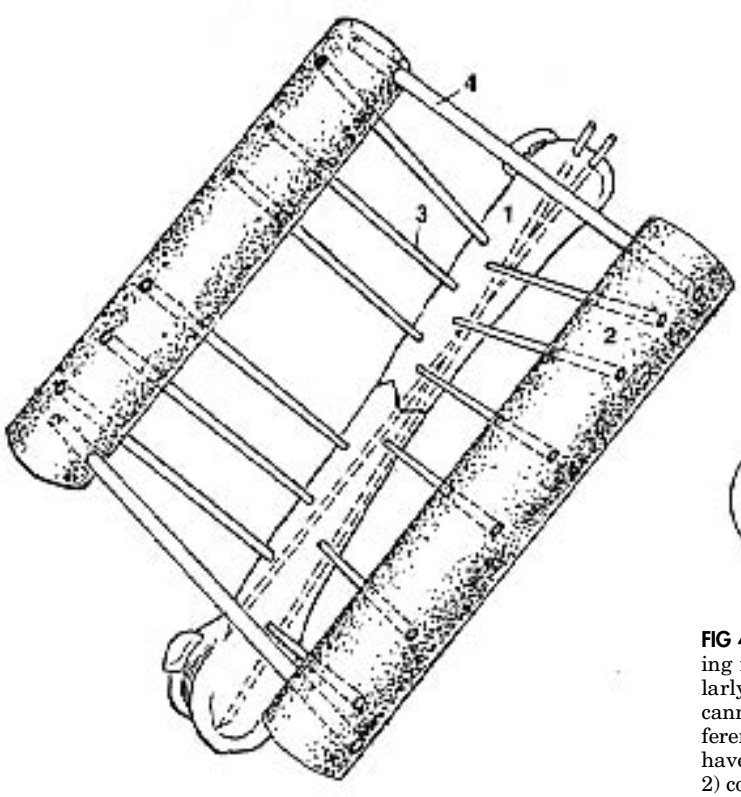
Application of an External Fixator

External fixator pins should be placed by making a small incision in the skin, and should not be placed through a primary incision site or open wound. This placement technique will decrease the likelihood that the pins will promote an infection at the surgical site. Pins should be inserted so that they avoid large muscle masses (minimizes loosening) and should be passed through pre-drilled holes to decrease wobble (improperly increases the size of the hole) and increase pin purchase on the cortices. It is best to place from three to four pins on each side of a fracture to decrease the stresses on any one pin. A minimum of two pins must be placed in each bone segment to ensure that the fixator will provide adequate fixation without rotation.

TABLE 42.5 Fixator Types Listed in Increasing Strength

Type I	Half-pin splint - Pins penetrate one skin surface and both cortices. Connecting bars only on one side of the limb.
Type II	Full pin splint - Pins pass through both skin surfaces and both cortices. Connecting bars on both side of the limb in one plane.
Type III	Type I and Type II splints placed at a 90° angle to each other. Fixators are connected to each other. Creates a three-dimensional frame.

Positive-profile threaded pins inserted through predrilled holes have been found to maintain solid bone-to-pin interfaces for prolonged periods (up to three months) in some birds (Aron DN, unpublished). By comparison, other types of threaded or unthreaded pins are frequently loose in the cortex within three to six weeks of insertion. The diameter of positive-profile threaded pins is not reduced by the threading process and these pins are less likely to fail from the stress-riser effect than other types of threaded pins.[2] Placing unthreaded pins at an angle (35 to 55°) perpendicular to the bone will decrease the chance that the fixator will slip from side to side, but



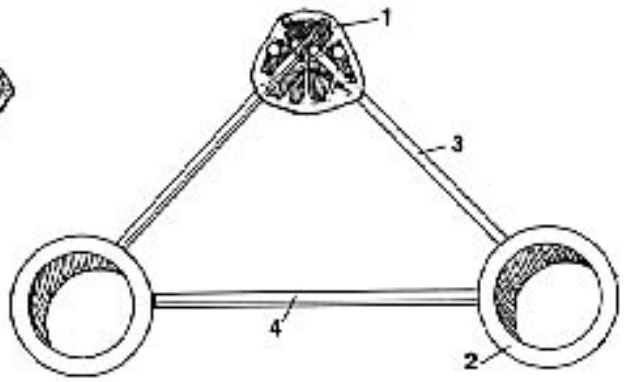


FIG 42.13 Type III fixators provide maximal stability by correcting fracture motion in two planes. Biplanar fixators are particularly useful for repairing femoral fractures where a connecting bar cannot be placed on the medial side of the bone because of interference with the body wall. In this drawing, the connecting bars have been moved away from the skin for clarity purposes. 1) femur 2) connecting bars 3) stabilizing bars and 4) cross bar.

would not be expected to be as effective as positive-profile threaded pins.

The connecting bar for the fixator pins should be placed as close as possible to the skin (taking into account anticipated swelling) to increase the strength of the apparatus. Standard Kirschner-Ehmer (KE) fixator hardware can be used to stabilize fractures in medium- or large-bodied birds. Their primary limitations are their size and weight.

It is extremely difficult to properly align a group of stabilizing pins that are passed free-hand. If they are not properly aligned, the pins cannot be attached to the connecting bars by KE fixator hardware. The easiest way to apply a KE fixator is to place the most proximal and distal stabilizing pins through the bone. The connecting bar is equipped with the desired number of clamps (minimum of four), and the first and last clamps are connected to the already inserted proximal and distal pins. The interior clamps are then used as a drill guide for placement of the remaining stabilizing pins.

In addition to KE clamps, stabilization pins can be connected with polymethylmethacrylate,[b] cast material[c] and dental acrylic.[26,29,36,38,45] In comparison to KE clamps, these materials are inexpensive, lightweight and are malleable so that pins that are not in perfect alignment can be easily connected. The tips of the stabilizing pins can be carefully bent parallel to the long axis of the bone to increase their holding strength in the connecting material. During the bending process, the pin should be stabilized to ensure that no forces are applied to the fracture site, the bone pin interface or associated joints.

Polymethylmethacrylate (PMM) can be attached to the stabilizing pins by mixing the material until it is the consistency of dough and then molding it around the stabilizing pins. The material can also be used by passing the stabilizing pins through a hole in a clear plastic tube (eg, clear straw). The plastic tubes used for a mold should be thin-walled to ensure that the methylmethacrylate column is of adequate diameter (approximately equal to that of the bone). When the pins are properly positioned (fracture site reduced and in proper alignment), the PMM is placed in a syringe and injected into the straw while it is still liquid. The fracture is held in place until the PMM hardens (generally ten minutes).

A soft metal connecting bar with numerous holes has recently become available.[d] The stabilizing pins are passed through the holes in the connecting bar, which is then crimped to firmly secure the pins. These connecting bars are light-weight and inexpensive.[16]

In birds that weigh less than 200 g, hypodermic needles can be used as stabilizing pins and these can be attached with cyanoacrylate glue (SuperGlue) to other needles or tooth picks that function as temporary connecting rods. An index card can be fashioned into a V-shaped trough and placed over the pins. Five-minute epoxy cement is then poured into the trough to firmly bind the stabilization pins and connecting bars.

Intramedullary Fixation

Intramedullary Pins

Generally, intramedullary pins neutralize bending forces and provide adequate fracture alignment, but they do not protect the fracture from rotational or shear forces.[6,21,33,46] Minimal rotational deformities in the wing bones can inhibit flight by altering the dynamics of the wing aerofoil.[9,19,46] Techniques that use IM pins in combination with external coaptation have been frequently discussed in the literature; however, the combination of these two fixation techniques should be avoided to prevent ankylosis of the associated joints.[6,8,14,16,19] Because of the relatively thin cortices of birds, the use of threaded IM pins has been suggested to provide better bone purchase than non-threaded pins.[36,37,42] However, IM pins are primarily used to counter bending force which would not be influenced by the degree of purchase in the cortex.[21]

Editors' note: Intramedullary pins have several disadvantages when compared to external fixators. They have the inherent potential to cause articular and periarticular damage resulting in ankylosis of the joints. Even properly placed pins that exit near a joint can cause sufficient tendon or ligament damage, resulting in a partially dysfunctional limb. Unless an IM pin can be placed so that it does not exit through or near a joint, it is best not to use this method of internal fixation in birds that require full post-fixation use of a limb. Even pins that do not exit near a joint can still injure the vasculature and significantly alter the growth pattern of the bone.[13]

Retrograde placement of pins through the distal humerus, normograde placement from the lateral or medial epicondyle of the humerus, placement through the distal ulna or retrograde placement from the elbow can cause severe periarticular fibrosis and wing dysfunction.[17,46]

The use of IM pins, with or without interfragmentary wires, is effective for stabilizing some fractures in companion birds when clients are not concerned with postsurgical return of flight. When IM pins are used, they should be of sufficient size to fill about one-half to two-thirds of the medullary canal.[12,36-38] In mammals, current theories suggest that the pin should occupy approximately 60% of the medullary canal; however, in birds, excessively large pins can interfere with endosteal blood supply, which may cause avascular necrosis or iatrogenic fractures.[6,8,14] In order to compensate for these problems, stack-pinning, cross-pinning or Rush-type pinning with multiple, small-diameter pins has been recommended for use in birds. However, placement of the pins with any of these techniques induces excess cortical damage.

Cerclage, hemicerclage and interfragmentary wires can be used as an adjunct to internal or external coaptation to neutralize rotational and shear forces. They are most useful for adding stability to long oblique and spiral fractures and for holding fragments of bone in apposition during the application of other fixation devices.[41]

Long bone fractures fixed with intramedullary pins alone are often immobilized with bandages or splints for 10 to 21 days. A significant loss in post-surgical range of motion should be expected when bandages are used in combination with intramedullary pinning.[3]

Intramedullary Polymer Pins

Several techniques have been described for the insertion of high-density polymer rods, polypropylene welding rods or polymethylmethacrylate into the medullary canal.[17,24-26] Plastic and acrylic rods have been successfully used in combination with external fixators for additional stability. The polymer rods are lighter than IM pins, inexpensive, biologically inert, provide for stable fracture repair and do not require removal when the fracture is healed.[4,21,24]

In one study, fractures of the wing repaired with IM polymer rods allowed rapid post-fixation exercise (seven to ten days) and most birds were able to fly 14 to 21 days postsurgery. [24] However, because the rods must be inserted using a shuttle technique (technically difficult), the length of the pin is limited to the longest fracture segment and the pin may not be passed into the shorter fragment segment to a sufficient depth to provide adequate stability.[24-26] Additionally, these techniques dictate that a foreign material remain in the medullary canal, which is likely to alter the biomechanical response of a portion of the wing to stresses induced by flight.[24]

Intramedullary PMM

Polymethylmethacrylate has been used in the intramedullary canal of birds to aid in fracture stabilization. This material comes as a liquid monomer and a powdered polymer that, when mixed together, undergoes polymerization that is exothermic (100°C).[16,19] The high temperatures associated with polymerization do cause bone necrosis, and application of cool water has been suggested as a method of dissipating heat.[18,35] The material generally hardens in ten minutes. This method of fracture fixation does have the advantage of being fast and inexpensive, providing rapid stability and allowing almost immediate return to function without joint insult.

The inhibition of endosteal callus formation, endosteal blood supply (that is theorized to occur) and the intramedullary bone necrosis (that is known to occur) have not been shown to interfere with the clinical outcome of fracture healing.[18,19,21,35] The most significant interference with healing occurred when polymethylmethacrylate was allowed to pass between the bone ends and inhibit callus formation. If the humerus or femur are overfilled with PMM, the material may enter the connecting air sacs.

Methylmethacrylate should not be used in open wounds where infectious agents are likely. If the methylmethacrylate is contaminated with bacteria, the material can serve as a chronic source of infection.[18,19] The necrosis that occurs during the polymerization process and the damage to the endosteal blood supply would theoretically predispose an affected limb to osteomyelitis.[35] In humans, heat-stable antibiotics (cephalothin, potassium penicillin) have been added to the polymer to provide up to five years of bacteriostatic activity.[35,44] The effects of long-term exposure of birds to these antibiotics have not been investigated.

Given the uncertainties about the long-term effects of IM PMM (particularly in the wing bones of free-flighted birds), this technique should be used with caution. Techniques have also been reported using polymer rods in conjunction with IM PMM.[10,22,23] The advantages and disadvantages of these techniques are similar to those described with either technique alone.

Bone Plates

Bone plates have been infrequently discussed for use in birds because of their thin cortices (undetermined whether a real or perceived concern) and their relative lack of soft tissue.[6,14,24,41,46] In addition, traditional bone plating equipment is expensive and the technique requires specialized training and prolonged anesthesia times.

The availability of small, lightweight bone plates has made these devices more worthy of consideration for repairing some avian fractures. Small finger plates designed for humans, cuttable metal plates[e] and acrylic plates are available in sizes useful for fractures of long bones in birds of 350 g or more. [5,15,19]

Bone plates have been successfully used to achieve what clinically and radiographically appear as primary bone healing in larger birds (ratites).[20,41] When they are used, bone plates have the advantage over other fixation techniques of providing rigid fixation with minimum callus formation and joint involvement.[18,19,33,35] Another advantage of plates is that they are completely internal and therefore are well tolerated by birds.

The stress junction at the end of the plate is susceptible to fracture. In raptors, plates used for the repair of closed fractures resulted in long healing times and rehabilitation periods, but produced excellent reduction and alignment of the fractures and a high level of return to full function.[9]

Some avian fractures are not conducive to being repaired with bone plates. Plates can serve as a nidus for infection and are not recommended for use in open fractures. Plates usually require a relatively long healing and rehabilitation time because of the "shielding effects" the plate induces with respect to underlying bone. After a plate is removed, the underlying bone may fracture (usually through the screw holes) if normal use is resumed immediately. Therefore, gradual physical therapy programs should be instituted. Movement should be limited for the first seven to ten days following removal of the plate, and then the bird should be allowed to gradually return to normal function. Plates can conduct cold and lead to deep bone pain as well as frostbite of surrounding tissues and should generally be removed in birds that will be released to the wild. Plates can remain in place if the bird is not exposed to freezing temperatures or the plate does not cause any specific problems.

CLINICAL APPLICATION

- The long-term effect of infusing polymethylmethacrylate into the medullary canal of birds has not been determined. The presence of any foreign material in the medullary canal of a bone would be expected to change its response to applied forces (particularly those involved with flight).

Doyle Technique

A fracture fixation method has been developed (Doyle JE, unpublished) that combines intramedullary pinning concepts with those of external fixation (Figure 42.14). In both the distal and proximal fracture segments, a pin is placed through one cortex and angled to bounce off the opposite cortex and remain in the medullary canal (Figure 42.15). Hooks are fashioned on the external end of each pin, and the fracture site is then compressed and stabilized by stretching a dental impact type rubber band[f] over the hooks of each pin. The technique requires that the smallest fracture segment be of sufficient size for the safe placement of a stabilizing pin. Kirschner wires (0.028, 0.035, 0.045 or 0.062 cm) are adequate for most avian fractures. In small birds, various-sized catheter needles or hypodermic needles can be used in place of the K wires.

This technique compensates for several problems that typically occur with intramedullary pinning techniques:

- The pins placed in the medullary canal do not damage periarticular tissue.
- Smaller pins can be used in order to prevent trabecular damage and excessive fixator weight.
- Maximum compression of the fracture site is achieved.

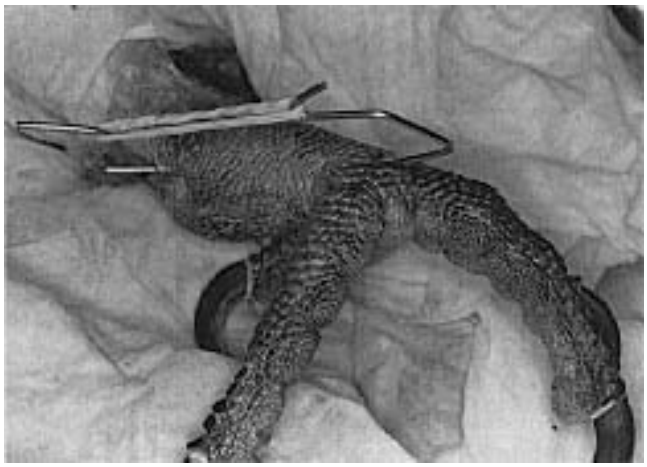

FIG 42.14 Use of the Doyle technique to repair a diaphyseal tarsometatarsal fracture in a cockatoo.

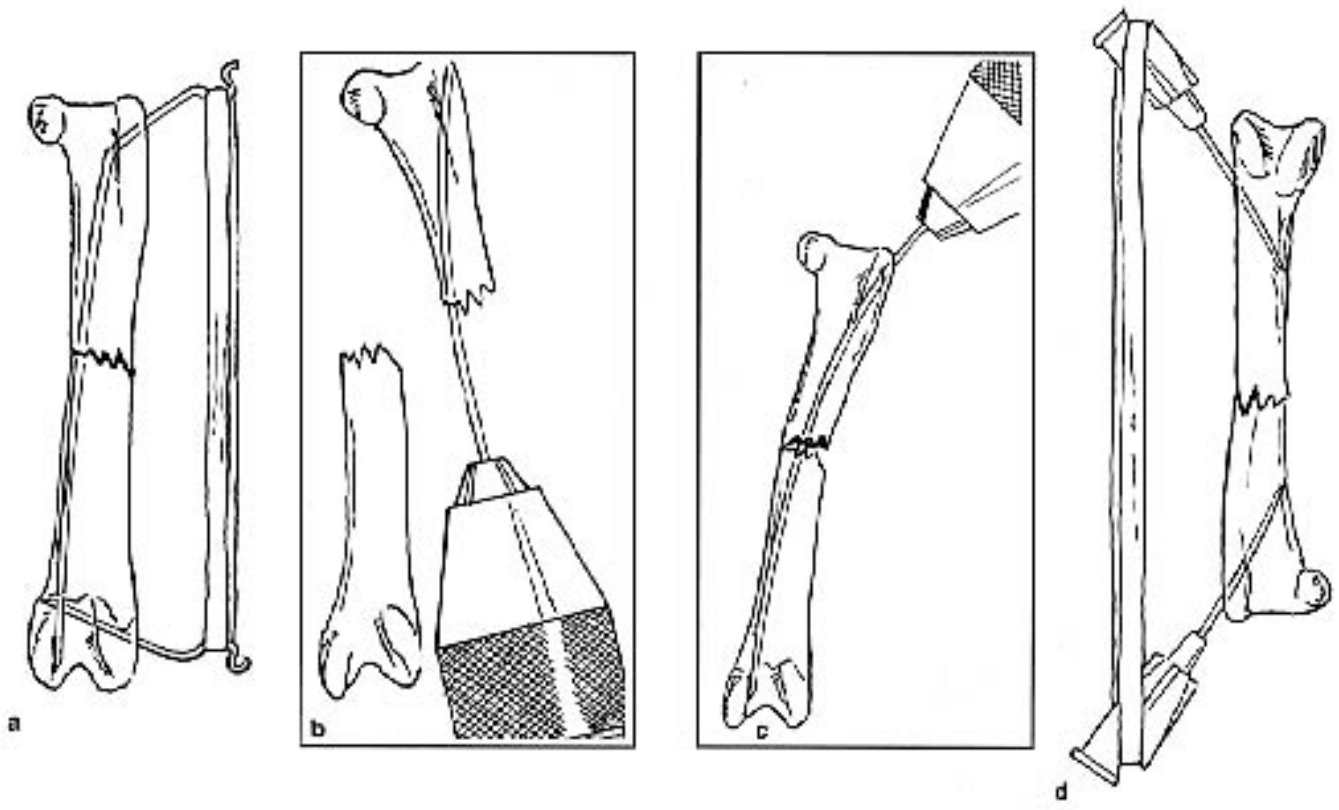

FIG 42.15 **a)** Doyle technique to repair long bone fractures. This technique allows for the use of intramedullary pins while reducing the degree of perivascular and trabecular damage and providing the maximum compression of the fracture site. Note that the longest pin does not penetrate the cortex of the bone, and that the shortest pin is placed into the cortex. **b,c)** A battery- or air-driven drill is used to place the pins. A dental rubber band attaches the cupped ends of the pins. **d)** In small birds, side cutters are used to notch the hubs of hypodermic needles, which are used in place of intramedullary pins.[14a]

- The joint is not involved in the repair process.
- The bird will have less of a problem with fixation-induced fracture disease.

As with any pin that is placed through the cortex, the stabilizing pins used in this technique should be inserted through pre-drilled, appropriately sized holes (smaller than the pin size). The pin is inserted as far away from the fracture as possible without compromising the periarticular tissues. Once the pin has entered the cortex, the angle is changed so that the pin bounces off the opposite cortex and can be threaded into the medullary canal, past the fracture site and as deep as possible into the smaller fracture segment (the long pin should not penetrate through the cortex in the smaller segment) (Figure 42.15).

The exterior portion of the pin is bent in two places using locking pliers. A right angle bend is placed in the pin as it exits the skin so that the pin is relatively perpendicular to the bone. A semicircle (hook) is fashioned in the end of the pin about 1 cm from the skin. A second pin is placed in the smaller fracture segment. This pin is inserted at a 45° angle to the long axis of the bone and parallel to the initial pin. This pin should penetrate but not exit the opposite cortex. A rubber band is placed around the hooks to compress the fracture. Postoperatively, several opened gauze pads are placed between the skin and the rubber band to prevent irritation. The affected appendage is placed in an appropriate bandage (leg: Robert Jones; wing: figure-of-eight body wrap). The rubber bands can generally be removed within 10 to 21 days, and the pins between 21 and 40 days after surgery.

Fractures that are minimally displaced and have recently occurred can be repaired in a closed fashion. Fractures that are several days old or that are displaced must be repaired in an open fashion, and any tissue debris or fibrous connective tissue should be removed from the bone ends. Either cerclage wires or fracture transversing staples can be used to minimize over-riding or rotation in oblique and comminuted fractures (Figure 42.16). Transverse fractures

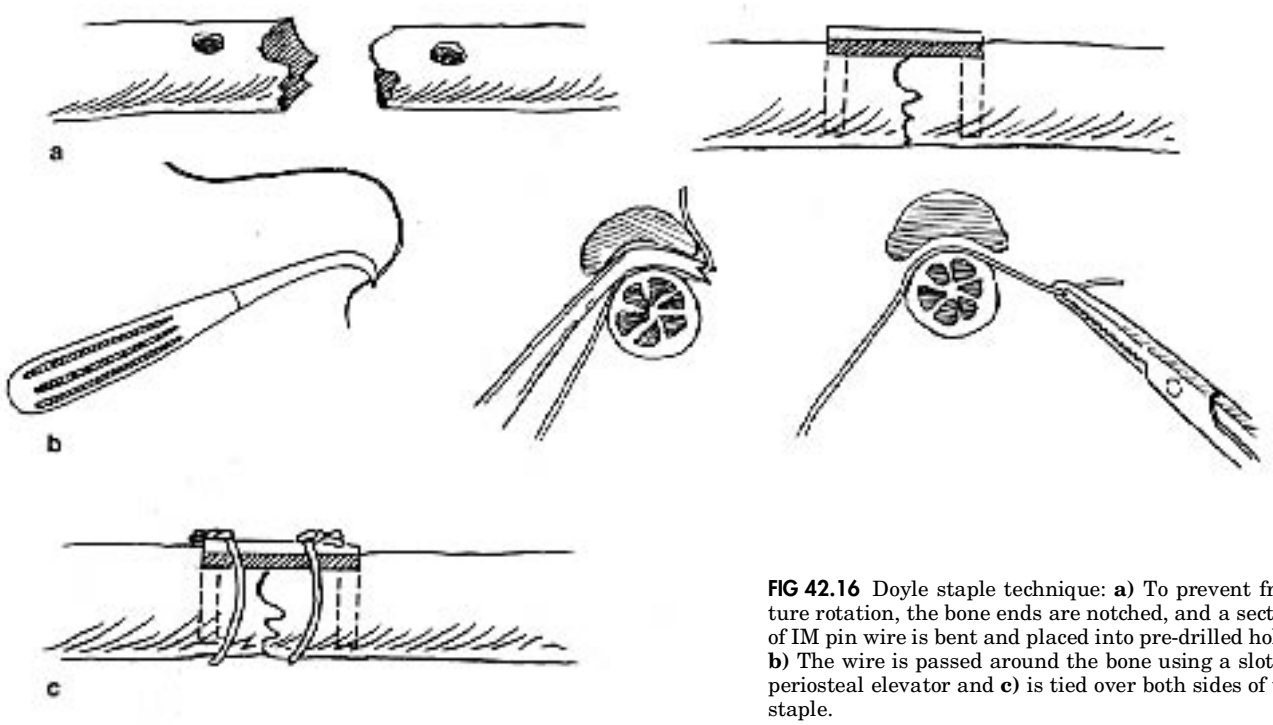

FIG 42.16 Doyle staple technique: **a)** To prevent fracture rotation, the bone ends are notched, and a section of IM pin wire is bent and placed into pre-drilled holes. **b)** The wire is passed around the bone using a slotted periosteal elevator and **c)** is tied over both sides of the staple.

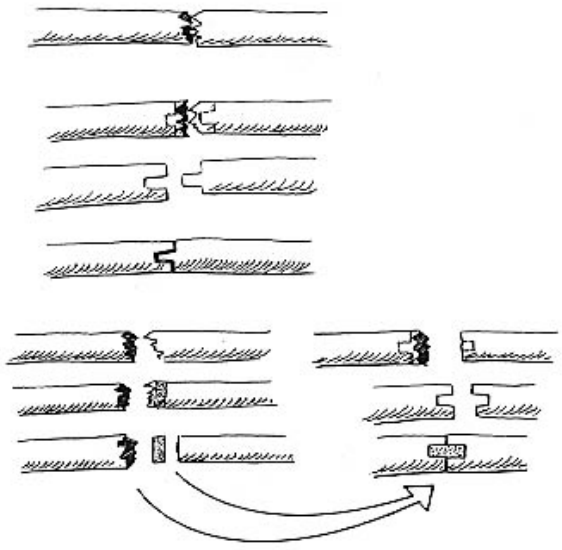

FIG 42.17 Doyle technique for slotting the end of fractures to reduce rotation. The bone ends are most easily notched using a sagittal saw. For additional stability, a section of the bone end can be removed (arrow) and placed in a slot created in the end of both fracture segments.

FIG 42.18 **a)** A bite wound to the mandible in a conure resulted in rhamphothecal damage. A Doyle apparatus was applied to stabilize the fracture. are most likely to rotate. This rotation can be reduced by notching the ends of the bone fragments with a sagittal saw and then applying a Doyle compression apparatus (Figure 42.17).

The Doyle technique can be used in combination with cleaning, calcium hydroxide and acrylics to repair the beak and fractures of the mandible. Pins are placed into the fracture segments and connected with rubber bands. The fracture site and beak defect are covered with calcium hydroxide paste to prevent dental acrylic from entering the defect and causing a malunion. The fracture is then covered with dental acrylic or a hydroactive dressing. The defect and fracture will generally require six weeks to heal (Figure 42.18).

Surgical Approaches

During a surgical procedure, every attempt should be made to identify and follow the natural separations between muscles and along fascial planes. In most instances, surgical approaches can be planned to avoid muscles completely, which will reduce the degree of surgically induced soft tissue damage. Incision or bruising of the propatagium should always be avoided.

The Wing

The Carpometacarpus

Figure 42.19 illustrates the anatomy of the wing. Repair of metacarpal fractures is meticulous. If the single artery and vein located between the third and fourth metacarpal bones are damaged, avascular necrosis to the distal portion of the wing can occur.[41] The most direct approach to fractures of the carpometacarpus is the dorsal approach. The bone can be visualized immediately beneath a dorsal skin incision. A ventral approach requires that soft tissues, tendons and blood vessels be separated in order to approach the main, or primary, metacarpal bone. Minimally displaced closed fractures of the carpometacarpus may be repaired with a figure-of-eight bandage (see Chapter 16). The clinical drawback to bandages is the loss in range of motion of the carpal joint while the fracture is healing.

Fractures of the carpometacarpus are ideally suited for small, lightweight external fixators that allow freedom of movement in the carpal joint. These are usually applied using small K wires or hypodermic needles and then attached by a connecting bar composed of plastic tubing filled with methylmethacry-

late cement. IM pins may be added to help with alignment; these are usually placed through the fracture site and normograded distally and then retrograded back to the proximal fragment. Passing IM pins normograde from the carpus reduces the damage to the carpal joint.[41]

In larger birds, small plates may also be used; however, wound closure may be difficult due to the lack of subcutaneous tissues.

The Radius and Ulna

Occasionally, birds are presented with fractures of the radius alone. Given the larger size of the ulna, radial fractures are often anatomically stabilized and splinted by the larger ulna. Bandages or simple enclosure rest may result in adequate fixation of minimally displaced radial fractures. If displaced, IM pins introduced through the fracture site and normograded out toward the carpus (avoiding the joint) and then retrograded back through the proximal fragment may be useful in reducing the fracture. External fixators may be used alone or in combination with IM pins. External fixators are easily applied to ulnar fractures.

Traumatic injuries frequently cause fracture of both the ulna and radius. For minimally displaced midshaft fractures, bandaging or external coaptation (figure-of-eight to immobilize the elbow and carpus) may be adequate. However, given the resulting decrease in range of motion of the elbow and carpal joints, it is preferable to repair these fractures with external fixators. Concomitant use of intramedullary or shuttle pins to provide alignment and increased stability is helpful. Plates may also be used on fractures that are closed.

The dorsal approach to the radius and ulna is preferred. An incision is made on the dorsocranial aspect of the ulna just cranial to the insertion point of the secondary feathers (Figure 42.20). In some cases in which both bones are broken, repair of the ulna alone is sufficient. However, with severely displaced fractures, the surgeon may need to stabilize the radius to allow proper healing. The same incision may be useful for stabilizing both bones depending on the location of the radial fracture. The intraosseous space between the radius and ulna houses the radial nerve and the radial artery, both of which should be avoided. The ulna can be easily identified and exteriorized for debridement and repair through the dorsal incision. If intramedullary pins are used, they are introduced through the fracture site and retrograded out the olecranon (avoiding the elbow) and then normograded into the distal fragment.

To approach the radius separately, an incision is made over the dorsal aspect of the radius between the extensor metacarpi radialis muscle anteriorly and the extensor digitorum communicans over the intraosseous space. IM pins placed in the radius can be retrograded out through the distal radius and then normograded back into the proximal fragment. Badly displaced radial and ulnar fractures can usually be repaired by applying an external fixator or shuttle pin in the ulna, and placing a simple intramedullary shuttle pin in the radius. Plates can be used to repair ulnar fractures.

The Humerus

Humeral fractures usually require open fixation because contraction of the pectoralis and biceps brachii muscles pulls the distal bone fragment proximally, creating a displaced fracture (Figure 42.21). A dorsal approach is recommended for most fractures of the humerus (Figure 42.22). This procedure avoids transection of the basilic vein and artery over the ventral aspect of the bone, as well as the medianoulnar nerve. However, the surgeon must cautiously incise dorsally over the midsection of the humerus to avoid the radial nerve. Once the incision is made through the skin, the radial nerve should be immediately identified and retracted. The humerus is exposed immediately beneath the skin. Proximally, the muscles of the biceps and deltoids will overlie the humerus. For a ventral approach, the surgeon makes an incision over the cranioventral aspect of the humerus, taking care to avoid the medianoulnar nerve and the brachial artery and basilic vein. The easily separable muscles of the biceps and the triceps converge proximally (see Figure 42.19).

A variety of methods may be used to repair fractures of the humerus. The choice of fixation technique is based on the nature of the fracture, the type of patient and the surgeon's experience. External fixators in combination with shuttle pins or intramedullary pins are preferred for free-ranging birds. Type II external fixators should be carefully applied to prevent pins and connecting bars from inducing soft tissue trauma medially on the trunk of the animal. Threaded pins in a Type I or biplanar Type I external fixator will reduce the chances of fixation-induced injuries to the animal. Stabilizing splints and bandages must immobilize the shoulder joint as well as the elbow and, therefore, must be wrapped around the body of the bird. Some birds may be highly intolerant of this type of bandaging.

FIG 42.21 Contraction of the pectoralis and biceps brachii muscles usually pulls the distal fragment of a humeral fracture proximally. The resulting displacement of the bone necessitates open reduction and repair (courtesy of Laurel Degernes).

The Coracoid

Birds can fracture the coracoid by flying into large, solid objects such as walls, windows or cars. Minimally displaced fractures may be stabilized successfully by bandaging the wing to the body. Surgical correction is necessary if the fracture is markedly displaced. A skin incision is made along the caudal edge of the furcula starting laterally and then continuing medially along the lateral edge of the keel for the first one-fifth or one-sixth of the length of the keel bone (Figure 42.23).

The superficial pectoral muscle is encountered, and an incision is made through the superficial pectoral muscle along the caudal edge of the furcula. This muscle can then be elevated from the keel bone medially. Radiosurgery is necessary to control hemorrhage from the clavicular artery, which supplies part of the pectoral muscle. This vessel is usually encountered at the caudal midpoint of the furcula. An incision or blunt dissection is used to penetrate the deep pectoral muscle. The coracoid is located immediately beneath the deep pectoral muscle and runs from the point of the shoulder at approximately a 45° angle to

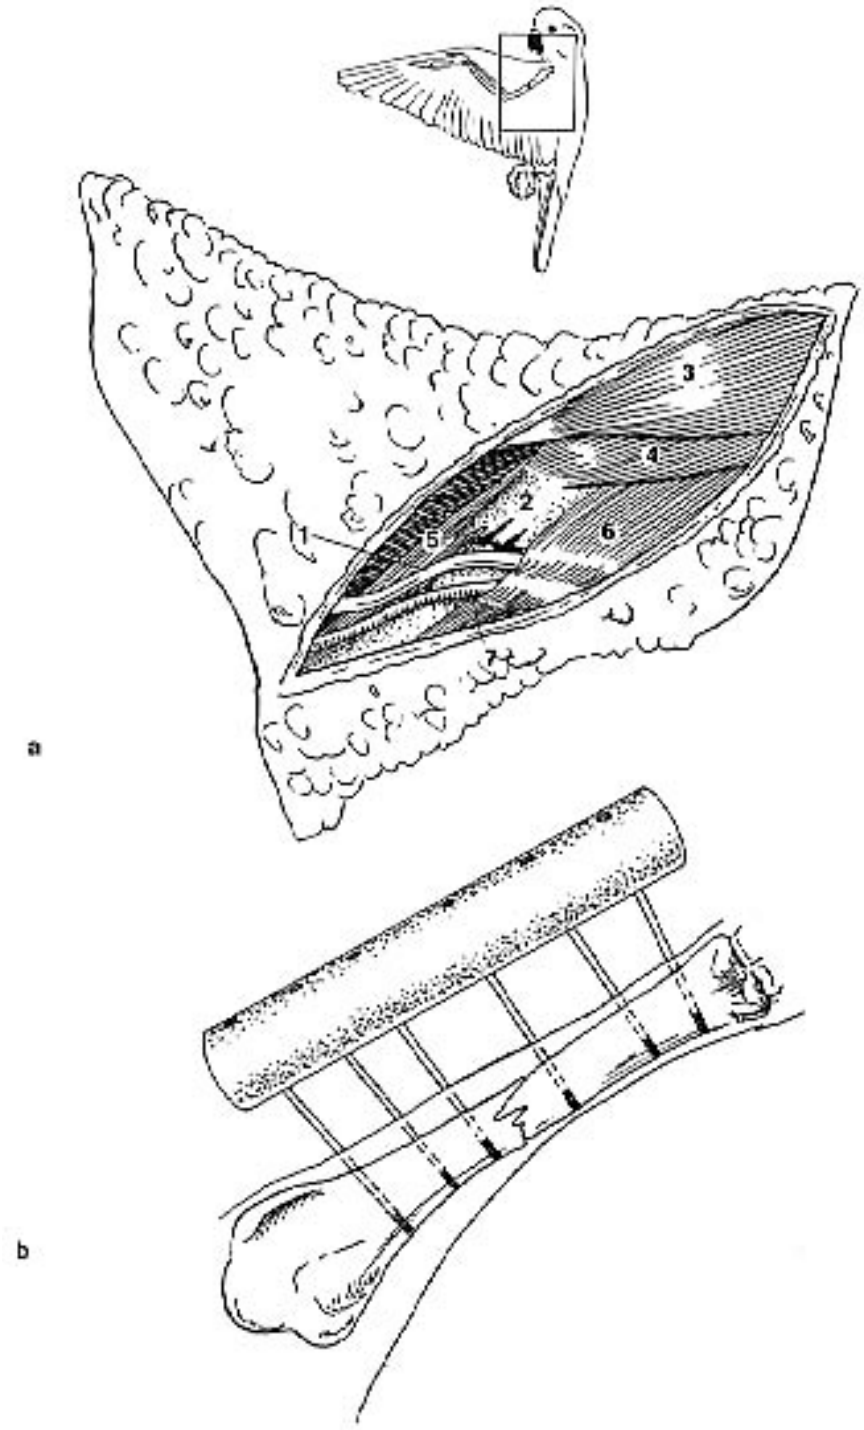

FIG 42.22 Dorsal approach to the left humerus. **a)** The skin over the dorsal humerus should be carefully incised to avoid cutting the 1) radial nerve. The 2) humerus is visible immediately beneath the incision. Exposure to the proximal humerus is prevented by the 3) M. tensor propatagialis and the 4) M. deltoideus. The 5) M. biceps brachii is seen on the cranial edge of the humerus and the 6) M. triceps scapularis is located caudally. The 7) radial artery runs caudal to the nerve. **b)** A Type I external fixator in conjunction with positive-profile threaded pins can be used for stabilization of humeral fractures. The connecting bar has been raised from the skin edge for clarity purposes.

the cranial aspect of the sternum. Trauma associated with a fractured coracoid can be significant, resulting in massive soft tissue damage and hematoma formation. Because of the location of the coracoid, the surgeon works in a small, deep hole, and radiosurgery as well as irrigation are mandatory to keep the surgical field clean.

The proximal fragment of the coracoid should be grasped and rotated into the incision. Following cleaning and debridement, multiple small intramedullary pins are introduced at the fracture site and exteriorized through the point of the shoulder. The distal fragment is rotated up into view and cleaned, and the fracture is aligned. Intramedullary pins must be carefully normograded back into the distal fragment. If the pins are advanced too far caudally and penetrate the sternum, the pins may perforate the pericardium and the heart. This problem can be prevented by carefully measuring the length of the distal fragment and using this distance to advance the pins. Muscle bellies are re-apposed using a simple continuous pattern and absorbable suture material. The superficial pectoral muscle may also be secured to the furcula. The wing should be wrapped to the body for five to ten days following surgery.

The Leg

Fractures of the tibiotarsus, tarsometatarsus and phalanges are best repaired using external fixation techniques (Figures 42.25, 42.26).

The Tarsometatarsus

The approach to the tarsometatarsus is simple because of the lack of soft tissues in this area. A lateral dorsal or medial dorsal approach may be used. A straight dorsal approach is generally not used because of the scutes overlying this area and the extensor tendons beneath. The sur-

geon should be aware of the concave nature of the caudal aspect of the tarsometatarsus (Figure 42.25). A groove, which houses the flexor tendons of the foot as well as the dorsal metatarsal artery, runs dorsomedially along with the vein and should be avoided when approaching the tarsometatarsus.

Any number of fixation methods may be utilized for fractures in this area (Figure 42.26). However, external fixators are ideally suited, and Type II configurations are easy to apply and provide excellent stability. If IM pins must be used, they are generally introduced through the fracture and exteriorized in a

retrograde fashion laterally or medially to the joint, then normograded back into the distal fragment. Small plates may also be used; however, there are scant soft tissues or skin in this area that can be used to cover the plate.

The Tibiotarsus

A skin incision over the craniomedial aspect of the tibiotarsus provides access to the distal two-thirds of the underlying bone (Figure 42.27). The medial belly of the gastrocnemius muscle may have to be retracted from the cranial tibial muscle and fibularis longus craniolaterally to achieve access to some fractures. The cranial tibial artery, which runs over the mid to distal tibiotarsus in a craniolateral position, should be avoided when making this approach.

External fixators are ideally suited and easy to apply in this area. IM pins may be introduced from the tibial crest and normograded down through the proximal and then into the distal fragments. This positioning prevents the pin from penetrating the stifle. Plates may be used in midshaft closed fractures. External fixation can be used to repair metaphyseal fractures by placing stabilizing pins on both sides of the affected joint.

The Femur

The lateral approach to the femur is initiated by making a craniolateral skin incision (Figure 42.28). The greater trochanter proximally and the stifle joint distally can be used as landmarks. The cranial and caudal bellies of the iliotibialis muscle are separated using blunt and sharp dissection. The iliofibularis muscle is located caudally. With this approach, the femorotibialis medialis muscle will be located craniolateral and ventral to the pubo-ischio-femoralis muscle will be located caudally. Distally, a branch of the lateral genicular artery may require attention when working around the epicondyles and condyles.

Branches of the femoral artery may be encountered in the cranial proximal region of the femur. However, the femur is generally easy to approach except in those species that have a well developed femorotibialis medialis muscle that originates on the lateral aspect of the femur (eg, Anseriformes). In these species, the muscle is transected and elevated cranially and caudally to expose the femur.

A variety of fixation methods may be used for femoral fractures. Plates provide excellent stabilization especially in closed fractures. Type I or biplanar external fixators may be used alone or in combination with intramedullary pins. IM pins are passed through the fracture site and retrograded out through the greater trochanter laterally and then normograded back through the distal fragments. Shuttle pins are also ideally suited for this area.

Some surgeons have described a medial approach to the femur (Figure 42.29).[3,16] With this procedure, care must be taken to avoid the ischiatic nerve, artery and vein, which lie caudomedially. The bone is approached by separating the pubo-ischio-femoralis muscle medially. IM pins can be successfully used to repair proximal and metaphyseal fractures of the femur.[21,41] Retrograde insertion through the trochanteric fossa and normograde insertion from the same anatomic area can be accomplished.

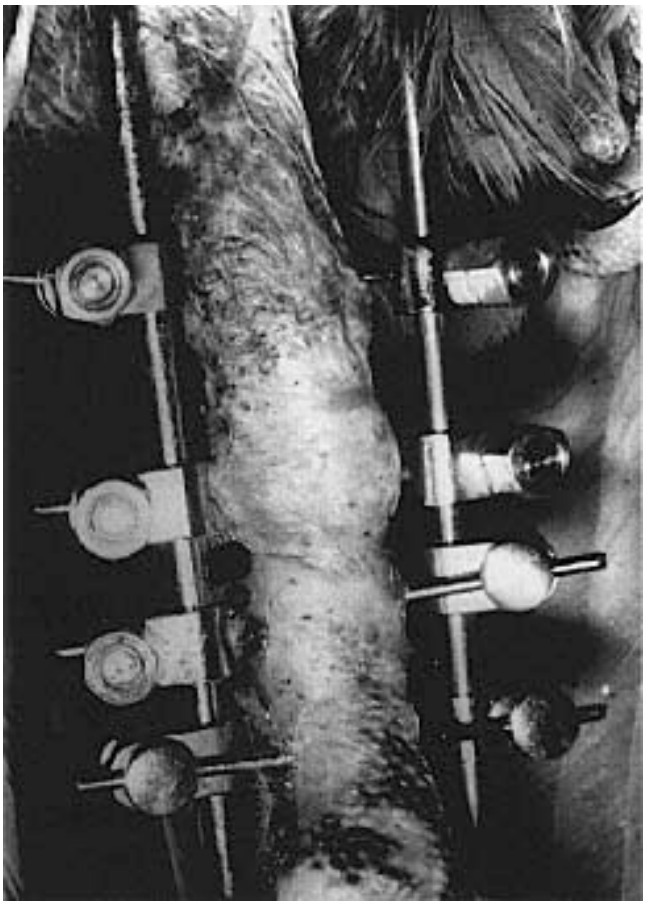

FIG 42.26 Type II external fixators are ideal for repairing tibiotarsal or tarsometatarsal fractures. A recently imported Military Macaw was presented with an open comminuted fracture of the distal tibiotarsus. The fracture was reduced through an open approach and stabilized using an external fixator. Two pins were placed in the large proximal fracture segment, one pin was placed in the small distal fracture segment and a pin was placed in the metatarsal bone, with the joint in a normal flexed position to ensure stability of the fracture. The bird was using the limb within 24 hours after surgery and healing was uneventful. The medial side of the KE apparatus was removed in three weeks, and the entire KE apparatus was removed six weeks after surgery.

Dome Osteotomy

Several techniques have been described for correcting angular limb deformities including transverse, oblique, wedge and dome osteotomies. Dome osteotomies have been successfully used to correct angular limb deformities in Psittaciformes, Falconiformes and Strigiformes, and offer several advantages over other osteotomy techniques. These include ease of planning and implantation, maintenance of maximum bone length and maximum bone-to-bone contact to facilitate healing. In addition, the dome osteotomy technique allows three-dimensional correction of the deformity while ensuring bone-to-bone contact in all three planes. This technique can also be used to successfully repair fractures that have healed, producing an incorrect bone angle.

The procedure is planned from a tracing of a radiograph of the affected limb. The radiographic view that indicates the most severe angular deformity should be used for planning the procedure. Lines are drawn sagittally through the center of the distal and proximal ends of the bone. The point where the two lines intersect is the location for the dome osteotomy. The osteotomy is performed by using a drill to make a series of small holes in a half-circle fashion at the osteotomy site. The holes are then connected using a high-speed air drill and a side cutting bit. The distal bone segment can then be rotated freely in the proximal segment to allow proper bone alignment.[42] Appropriate fixation, generally an external fixator, is then used to stabilize the fracture during healing. Radiographic findings in birds suggest that when properly applied, a dome osteotomy site will undergo primary bone healing with minimal to no callus formation (Figure 42.30).

Repair of Luxations

Luxations have been infrequently reported in birds. Those that have been reported usually involve coxofemoral luxations secondary to a companion bird getting a leg trapped in enclosure accessories or as a consequence of struggling during restraint. Luxations of the elbow are probably the most common luxation in free-ranging raptors and are the result of trauma to the distal wing while in flight. Repair requires reduction of the luxation and stabilization of the joint. The sooner the luxation is detected, the better the chances for reduction without secondary joint damage.

Femoral head luxations are generally craniodorsal to the acetabulum. Open reduction may be successful in repairing acute cases. A femoral head osteotomy has been recommended for repair of chronic luxations of the hip. Coxofemoral luxations may be approached laterally or medially for stabilization. Spica-type splints are recommended, as well as supporting sutures, which are placed from the greater trochanter to the ilium and to the ischium. These sutures, usually of nonabsorbable materials, support the reduced hip in its normal location and are recommended in those avian species with a gliding hinge-type coxofemoral joint (noncursorial species such as most psittacine birds and raptors). It is important to remember that some cursorial species of birds (eg,

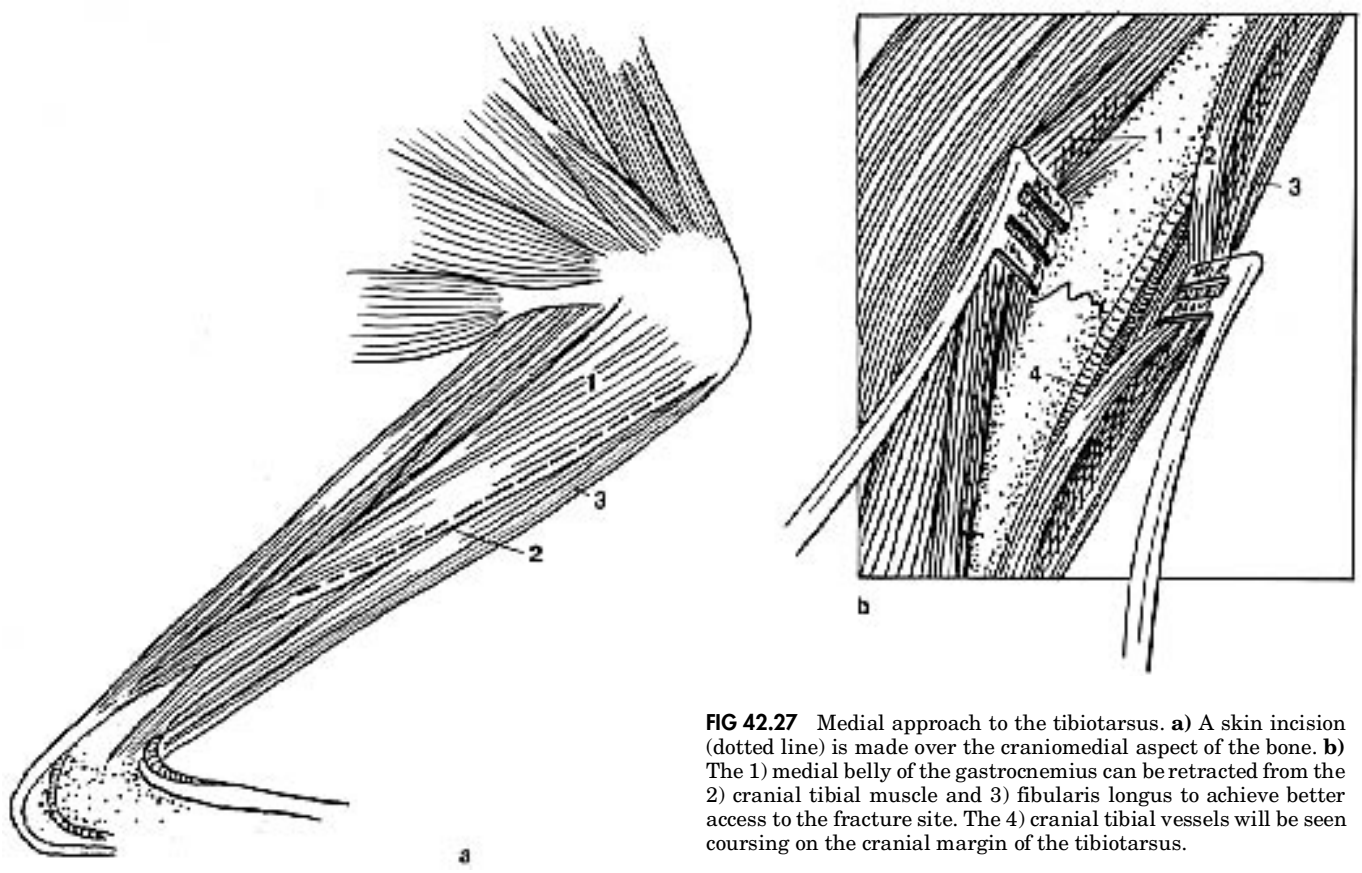

FIG 42.27 Medial approach to the tibiotarsus. **a)** A skin incision (dotted line) is made over the craniomedial aspect of the bone. **b)** The 1) medial belly of the gastrocnemius can be retracted from the 2) cranial tibial muscle and 3) fibularis longus to achieve better access to the fracture site. The 4) cranial tibial vessels will be seen coursing on the cranial margin of the tibiotarsus.

ratites), have a ball and socket-type coxofemoral joint and these sutures would not be appropriate.

Elbow luxations in raptors usually result in a straight caudal or dorsocaudal displacement of the ulna. If treated early, closed reduction of these luxations can be made and then supported with external fixators or bandages. In one report, five of nine raptors with elbow luxations were successfully returned to the wild following closed reduction and support with external fixators or bandages for seven to ten days.

Luxations of the shoulder have also been reported in raptors. These are usually accompanied by an avulsion fracture of the ventral tubercle of the proximal humerus. These can be stabilized by application of a figure-of-eight bandage to immobilize the wing to the body for 10 to 14 days. A surgical approach may be warranted to reduce and reattach the ventral tubercle with wires or lag screws. It is important to note that luxations do not necessarily suggest a hopeless prognosis for return to complete function, particularly if addressed soon after the injury occurs.

The collateral ligaments of the knee may be damaged following many traumatic events. A positive drawer sign is characteristic. Techniques used to repair collateral ligament damage in mammals can also be used for birds.

Repair of the Beak

A healthy beak is critical to the everyday survival of a bird, and minor injuries to this tissue can be serious depending upon the degree of associated soft tissue damage. Initially, therapy for any beak injury should be provided to control hemorrhage, maintain nutritional support and prevent secondary infection. Several approaches may be used to correct these injuries, and the therapeutic plan is chosen based upon the size of the patient and the nature of the fracture. Birds with beak injuries that result in defects can also readily adapt to soft diets. Prosthetic beak devices require continuous replacement as the beak grows, and must be carefully monitored to prevent bacterial or fungal infections.

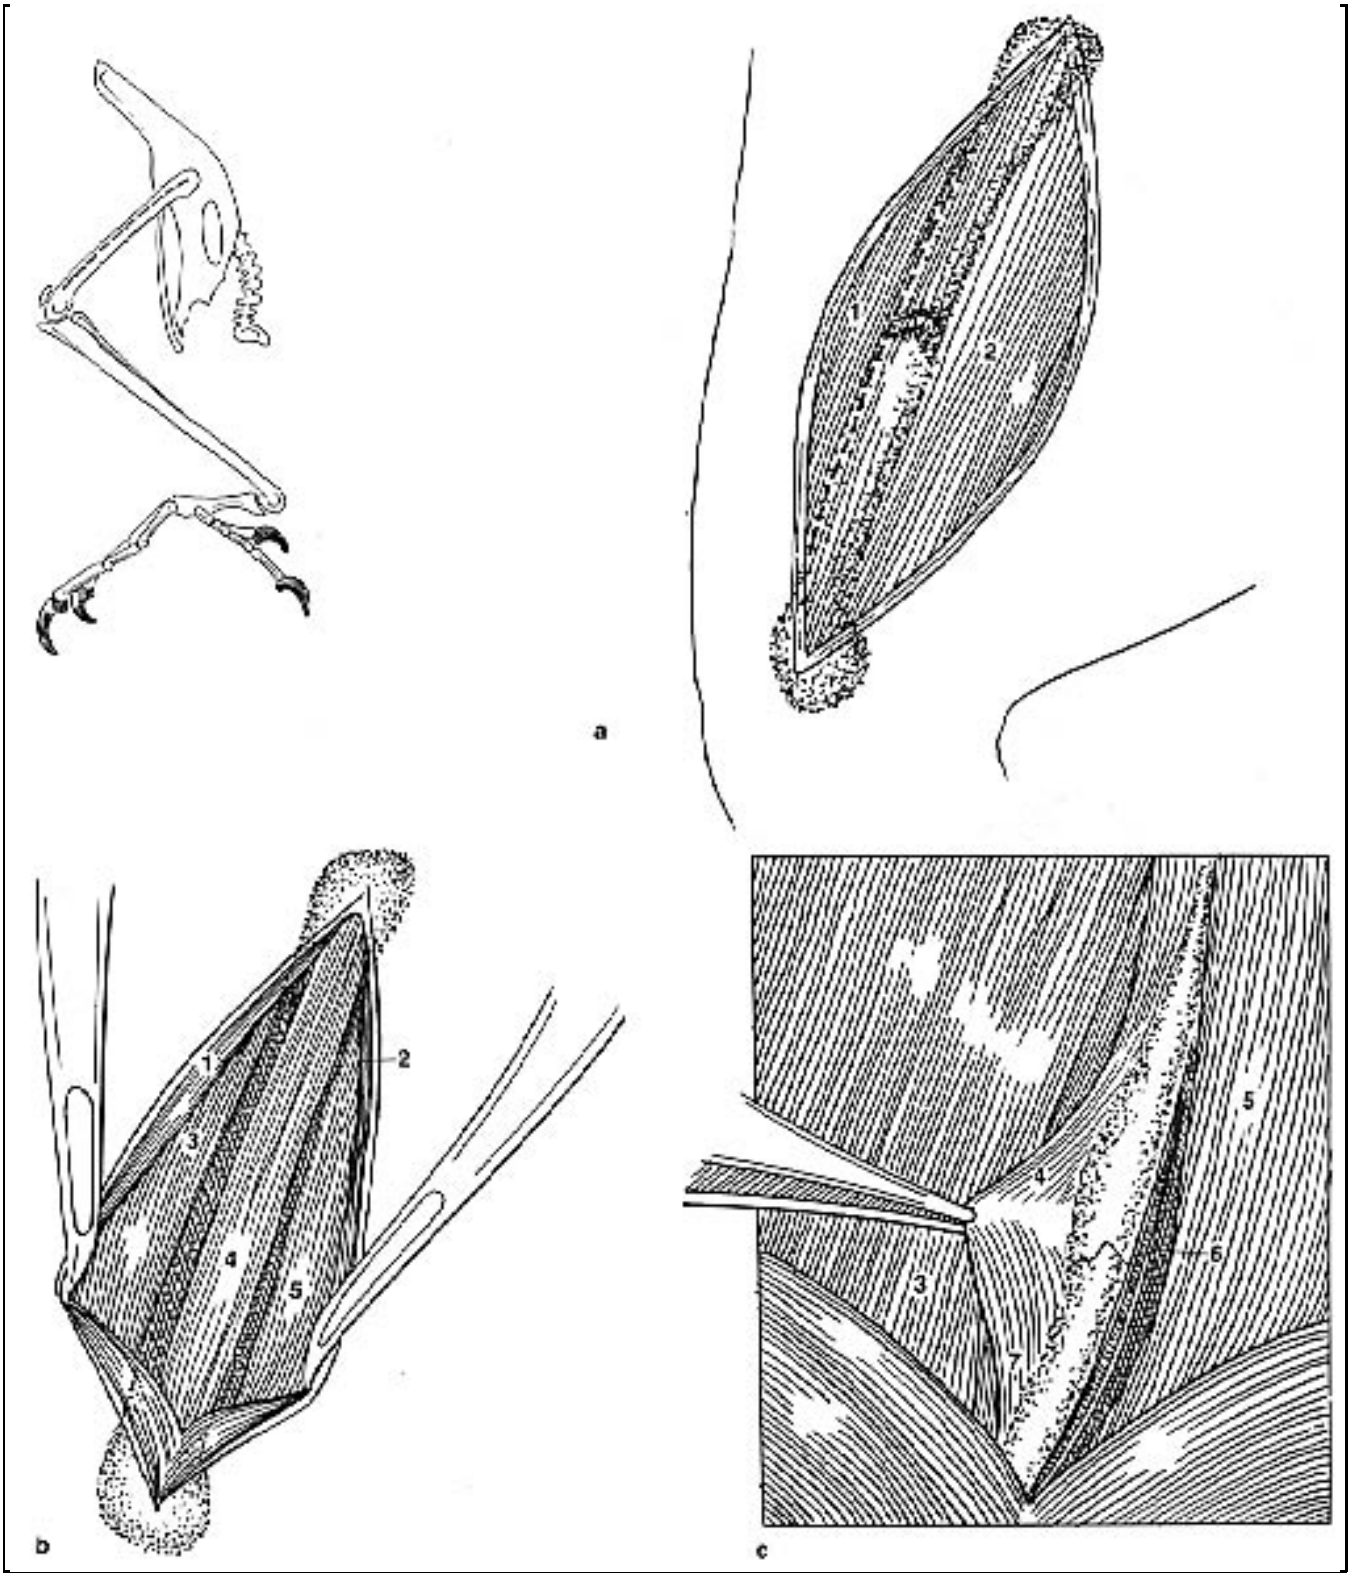

FIG 42.28 Lateral approach to the femur. **a)** A skin incision is made from the greater trochanter to the stifle joint as needed. Fractures

Mandibular fractures are the most common injury and should be addressed in two stages: repair of the bone, and repair and realignment of the keratinized beak. Fractures through the beak will not heal side-to-side. Forces encountered by the beak must be neutralized or they will be transferred to the underlying bone and interfere with healing (Figure 42.31).

Depending upon patient size and the location of the fracture, pins, wires, cements, screws and plates may be useful in repairing mandibular fractures. For most smaller birds, hypodermic needles and cerclage wires are useful. The primary goals are realignment and stabilization of the fracture site. Pins and hypodermic needles may be inserted into the body of the mandible, antegraded across the fracture site from the rostral point of the beak, and stabilized with cerclage wires (plus or minus cements) (Figure 42.32).

Once the fracture is repaired, soft tissue injuries must be treated. If the injury is of a degloving type, every attempt should be made to reappose the displaced skin. Tissue glues are useful for facilitating this repair. If glues are not applicable, the fracture site should be dressed with a self-adherent wet/dry type dressing.[g]

Fractures of the upper beak are generally more difficult to manage due to the presence of small bones and the kinetic nature of the maxilla. These fractures frequently involve the quadrate and jugal bones, which are thin structures that are difficult to immobilize. The use of small hypodermic needles is usually necessary to facilitate repair, but their effectiveness is limited. Healed fractures often result in beak abnormalities such as lateral deviation of the maxillary beak.

Beak Deformities

Beak defects that require repair may occur secondary to trauma, nutritional deficiencies or congenital abnormalities. The beak is constantly growing and any prosthesis that is applied will migrate and loosen over time. The beak

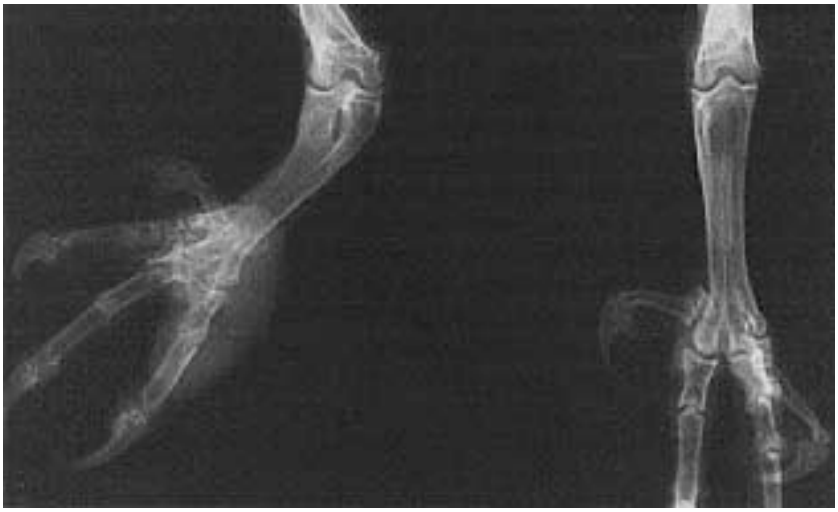

FIG 42.30 A free-ranging Great-horned Owl neonate was presented with a valgus deformity of the right tarsometatarsus. Note the soft tissue swelling on the medial side of the foot induced by improper ambulation. A dome-shaped cut was made in the metatarsus at the point of maximum deformity. The angle of the limb was so severe that even though a dome-shaped cut was made, it appears on radiographs as an oblique osteotomy site. The osteotomy site was stabilized with a Type III external fixator. The bird had full postsurgical use of the foot and was released.

is similar in structure to a hoof, with sheets of protein overlying a substantial vascular supply and bone. The keratin layers of the bone can regenerate only if the underlying vascular bed is viable. If the vascular tissue is destroyed, a permanent defect will be present in the beak.

Two common defects in psittacine neonates are scissors beak (lateral deviation of the upper beak) and mandibular prognathism. The etiology of these problems is only speculative. If mandibular prognathism is recognized early, it can be corrected by applying gentle outward pressure to the beak for ten minutes, six to eight times daily. The same technique can be used to correct some early cases of scissors beak. If cases are allowed to progress, they must be corrected using various beak prostheses or surgical techniques to redirect the forces applied to the beak and its underlying bones.

Scissors Beak

A severe case of scissors beak can prevent the prehension of food and will cause abnormal wear on both sides of the gnathotheca. The gnathotheca on the side of the deviation will wear excessively, and the gnathotheca on the contralateral side will grow unabated. This problem may occur in most species of psittacine birds but appears to be most common in cockatoos and macaws. In poultry, scissors beak can be caused by inappropriate egg incubation temperatures, fungal toxins, vitamin D_3 toxicosis, teratogens and genetic defects.[1]

In theory, any slight injury to the cere or germinal beds during early development could cause scissors beak (Figure 42.33). The theory that scissors beak is caused by constantly feeding a neonate from the same side of the mouth has been disproven.[1] Keratin normally migrates rostrally along the surface of the beak and laterally from the vascular bed. Any change in the rate of keratin migration between these two sites, any change in the premaxilla that changes the orientation of the tip, or a malformation of the frontal bone could cause the beak to deviate laterally.

Correction procedures are designed to change the forces that direct the anterior growth of the rhinotheca (Figure 42.34). Redirected growth is achieved by applying a prosthesis to the lower beak on the affected side or by placing pins in the calvarium and

FIG 42.31 **a)** An adult Blue and Gold Macaw was presented with a malaligned beak after attempting to bite a large wooden dowel. Radiographs indicated a dislocated palatine bone dorsal and rostral to the vomer bone. **b,c)** The dislocation was repaired by placing a pin through the frontal sinus over the maxilla and pushing caudally. The dislocation was stabilized for healing by placing wire sutures around the suborbital arch and the jugal bone ventral to the globe. The bird returned to normal function.

using rubber bands to apply pressure to the tip of the beak (similar to orthodontic techniques used in humans).

Scissors beak is easiest to repair in a young bird because the bones and beak are actively remodeling. The prosthetic device must be sufficiently anchored to the lower beak to prevent normal beak occlusion from dislocating the prosthesis. The keratin of the gnathotheca on the affected side is grooved with a Dremel tool. The grooves should be deep enough to increase the surface area for prosthetic attachment but should not be so deep as to induce hemorrhage.

The scored gnathotheca is cleaned and disinfected, and a light coat of cyanomethacrylate is applied to the area and allowed to dry. Stainless steel or nylon dental screen mesh is molded to the gnathotheca. The mesh should be extended to create a ramp that redirects the beak tip to the midline with each bite. The ramp is covered with cyanoacrylate and smoothed with a Dremel tool. When the defect is corrected, the implant is removed.

Bragnathism

Bragnathism can be repaired by placing a KE wire into the frontal bone just caudal to the maxilla joint and caudal to the nares (Figure 42.35). A caudally directed hook is bent into the external portion of the pin. A second pin is placed in the maxilla midway down the beak at the point at which the internal rotation of the maxilla is most severe. Acrylic is applied to the area, incorporating the pins to supply extra support. A rubber band placed between the two pins will pull the beak tip into proper apposition. When the rhinotheca is properly positioned on the outer surface of the gnathotheca, the rubber band can be removed. The pins can remain in place for several more days until it is apparent that the bragnathism will not recur. When it is apparent that the problem is permanently corrected, the acrylic and pins can be removed.

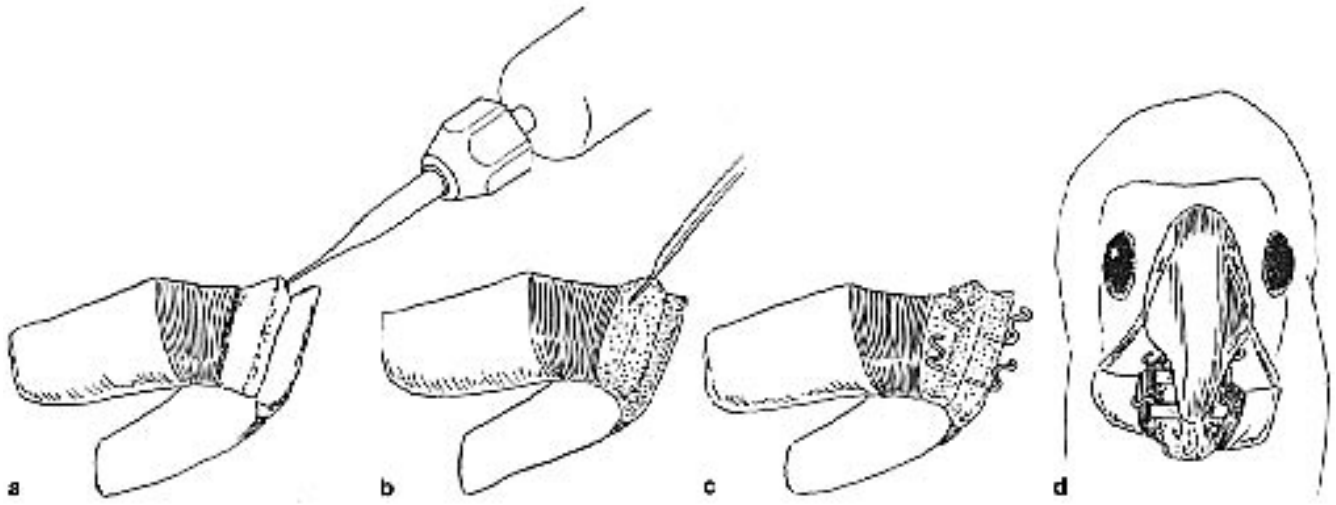

FIG 42.32 Doyle technique for repair of a mandibular symphyseal fracture. **a)** The gnathotheca is scarified with a dental burr. **b)** The scarified area is coated with calcium hydroxide. **c)** Pins are placed through the mandible and hooks are fashioned in their ends. **d)** Rubber bands are placed around the hooks and the hardware is coated with methylmethacrylate.

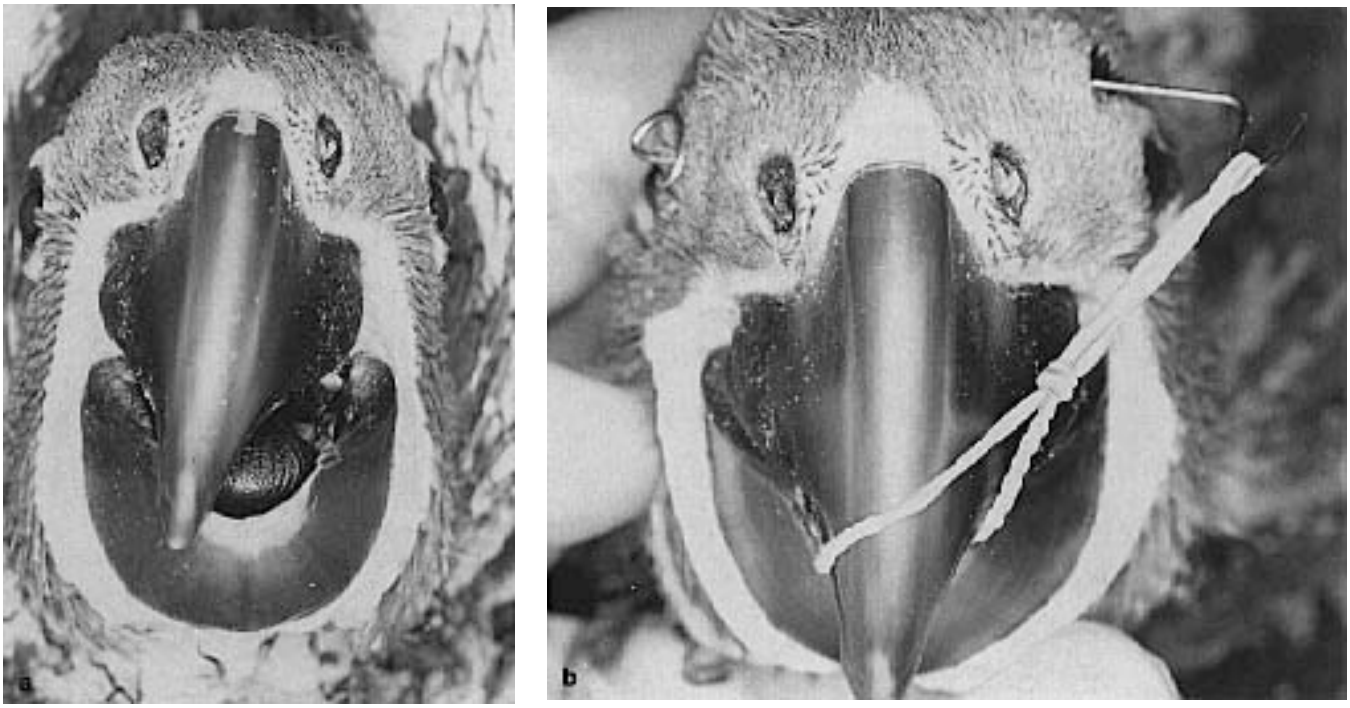

FIG 42.33 **a)** Scissors beak in a Hyacinth Macaw chick. **b)** The defect was corrected by placing a KE wire through the frontal bone and using a rubber band to place correcting pressure on the beak tip. The upper beak was properly aligned within seven days of applying the apparatus.

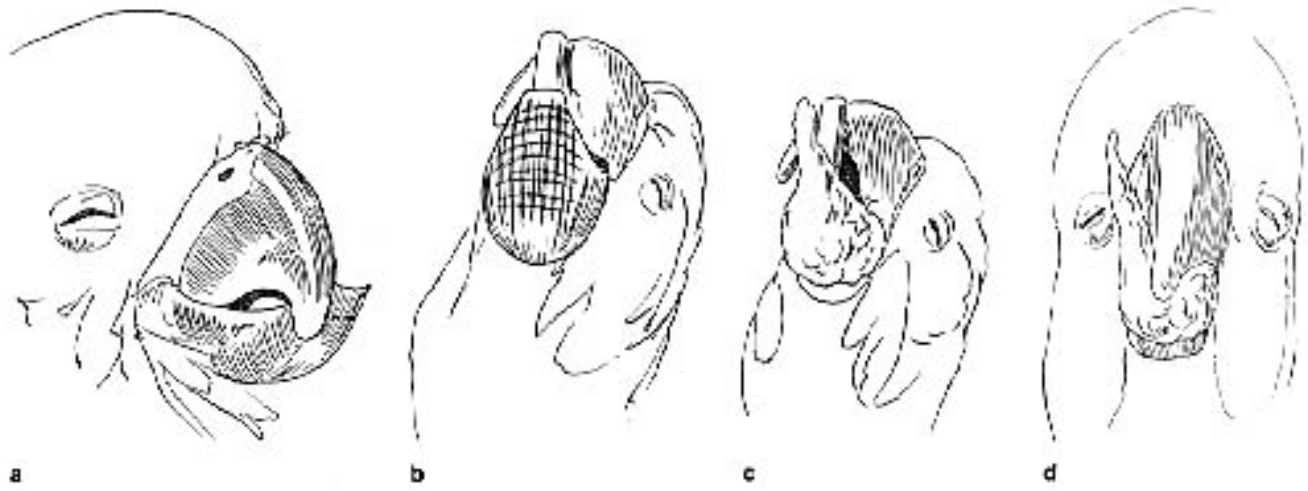

FIG 42.34 **a)** Scissors beak can be corrected by using pins placed through the frontal bone or by using a prosthetic device attached to the gnathotheca. **b)** The gnathotheca is scarified with a dental burr and cleaned and covered with a light coat of dental acrylic. **c)** Nylon dental mesh is covered with dental acrylic to create a ramp that pushes the tip of the beak into proper alignment. **d)** The prosthesis after being shaped with a Dremel tool.

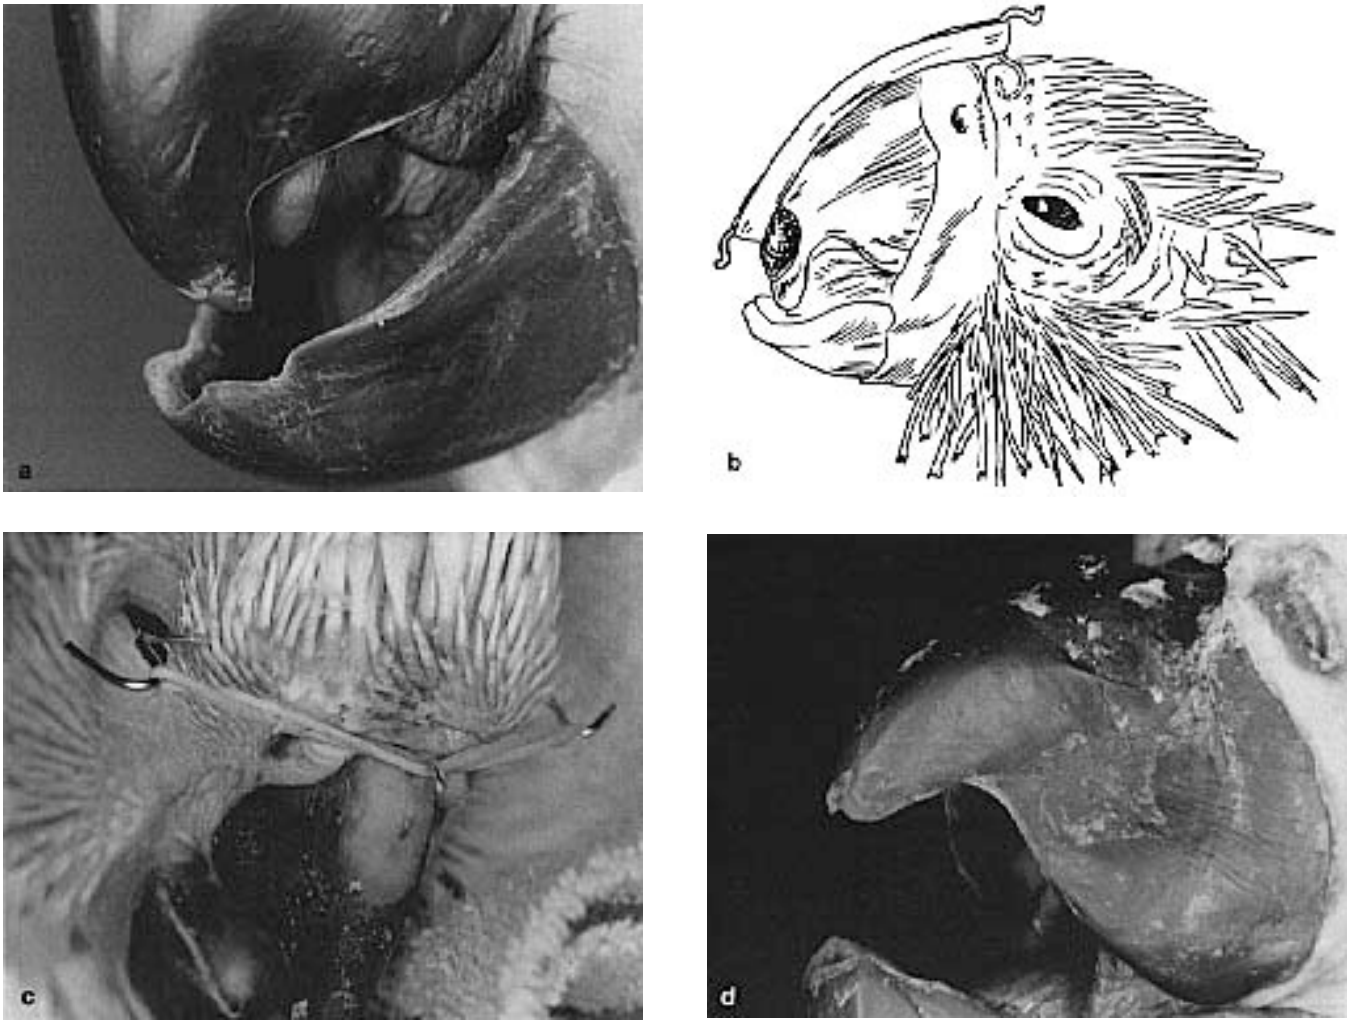

FIG 42.35 **a)** Bragnathism in a cockatoo neonate before repair. **b,c)** Repair of bragnathism using a principle (modified Doyle technique) similar to those used in human orthodontics. A KE wire is passed through the frontal bone and hooks are fashioned in both ends. A second pin is placed into the maxilla midway down the beak. The pin in the maxilla is supported with dental acrylic. The tip of the beak is pulled into proper apposition using a rubber band. **d)** Patient after correction of bragnathism.

PASSERIFORMES

Patricia Macwhirter

Passeriformes (perching and songbirds) is the largest order of birds. It contains nearly 60 percent of all bird species ranging in size from the tiny Weebill (80 mm in length) to the Superb Lyrebird (130 cm long, including a 72 cm tail). Canaries, finches, starlings and mynahs are examples of passerine birds that are common in captivity. Passerines are widely distributed throughout the world, and all passerines share a common anisodactyl foot structure with three unwebbed toes pointed cranially and one caudally. The altricial young are usually naked when hatched and are reared in a nest.

The order is believed to have originated in Gondwana, the ancient southern continent. Convergent evolution makes differentiating species based on morphologic grounds difficult, and in the past, the anatomy of the syrinx has been a primary means of classification. Recent DNA hybridization and protein electrophoresis studies are modifying traditional views. One group of passerines is now believed to have evolved and radiated in eastern Gondwana, proto-Australasia (these include such species as bowerbirds, lyrebirds, birds of paradise, honeyeaters, Australian grass finches and fairy wrens). Another group, the suboscines or primitive songbirds are believed to be of western Gondwanan origin (current-day South America). These include such primitive South American species as contingas, manikins, antbirds and gnateaters. More advanced songbirds like Fringillidae finches, sparrows, warblers, starlings, thrushes and sunbirds may also have evolved via western Gondwana and migrated from this area to become widely distributed.[10]

While Passeriformes are widespread in the northern hemisphere, there are very few endemic families and many of the species are migratory.[56]

Anatomy and Physiology

Passeriformes have become adapted to a wide variety of ecological niches. The anatomic and physiologic differences expressed within the order reflect these specific evolutionary patterns (Table 43.1).

Digestive System

The basal metabolic rate (BMR) of passerine birds is generally about 65% greater than that of non-passerines, and their body temperature is about two degrees Centigrade higher (around 42°C). While some desert passerines such as the Zebra Finch have been known to survive months without drinking water, most small passerine birds drink from 250 to 300 ml/kg body weight of water each day and may eat up to 30% of their body weight daily. These figures are higher than those for most non-passerines, which tend to be larger birds.

Most passerine species have a narrow, triangular tongue compared with the thick blunt tongue of parrots. The tongue is rarely involved in clinical problems. The tongue of passerines may become hyperkeratotic at the tip and extend rostrally through the beak. The syndrome appears to cause few clinical problems, but the hyperkeratotic tissue can be slowly trimmed back with a pair of strabismus scissors, taking care not to cut healthy mucosa. Other parts of the digestive tract differ depending on the species' feeding patterns. A ventriculus is present in granivorous and insectivorous species such as finches, but not in species such as honeyeaters that consume nectar and soft foods. If present, cecae are generally small and vestigial.

Inexperienced Passeriformes breeders may present chicks for evaluation of a "sore" or "swelling" on the neck. This clinical sign is usually determined to be the crop distended with seeds and visible beneath thin, featherless skin.

There is no production of crop milk in passerines as there is in pigeons, but some finches will regurgitate crop contents to feed their young. Pathogens can be transmitted from parent to offspring during this process, particularly with foster-raised chicks that probably did not receive yolk-derived antibodies against microorganisms from their foster parents' digestive system. For example, although *Cochlosoma* sp. may cause inapparent infections in adult Bengalese (Society) Finches, significant mortality may occur in juvenile Gouldian Finches being fostered by Bengalese parents.[15]

Nestling Estrilid finches (eg, Gouldian and Zebra Finches) normally have characteristic luminous mouth markings. Mucosal patterns are species-specific and help to guide parents to their own chicks within the recesses of dark nests.

The spleen in most passerines is oblong, not spherical, as it is in Psittaciformes.

Respiratory System

In most Passeriformes, unlike in Psittaciformes, the right and left nasal sinuses do not communicate. In passerine birds, separate samples for rhinal disease (bacterial, viral, chlamydial) cytology examination should be taken from each sinus if a bilateral nasal discharge occurs (Figure 43.1).[9]

Singing ability is highly developed in many passerine species and is related to the complexity of the syringeal anatomy. Some species have the capacity to sing duets with themselves by alternately using op-

FIG 43.1 Passeriformes, like this canary, have right and left paranasal sinuses that do not communicate as they do in Psittaciformes. If bilateral oculonasal discharge suggestive of sinusitis is occurring, it is wise to collect samples from both the right and left sinuses for culture and cytologic evaluation. Conjunctivitis in this canary was responsive to tylosin therapy (courtesy of Michael Murray).

TABLE 43.1 Distinguishing Features of Selected Passerine Birds

Family	General Composition	Approx. Number of Species	Characteristics
Emberizidae	New World finches, cardinals, buntings, Cuban finch	550	Cup-shaped open nest, female incubates, diverse group, 9 primary feathers
Estrildidae	African, Asian and Australian finches, waxbills, nunias, parrot finches	125	Palatal markings in young, monogamous, dome-shaped nest with side entrance, 10 primary feathers
Fringillidae	True finches, canaries, goldfinch, chaffinch	125	Cup-shaped open nest, female incubates, 9 primary feathers, 12 long tail feathers
Passeridae	Sparrows, finches	32	Bulky domed nest of dried grass, breed in colonies, seed-eating, finch-like birds
Ploceidae	Weavers, whydahs, queleas	145	Dome-shaped, covered, woven nest, do not sing, some species parasitic
Sturnidae	Starlings, mynahs	108	Dark, iridescent, or brightly colored, colonial, nest in holes, long straight bills, mimicry ability

FIG 43.2 A hand-raised European starling can develop an extensive vocabulary and have a voice quality that is similar to its relative, the mynah bird (courtesy of Mark Spreyer).

posite bronchi. Roller canaries are specifically bred and trained for their singing ability.

The ability to mimic the human voice is well developed in some passerines, notably mynahs, starlings and corvids (Figure 43.2). Among Australian passerines, lyrebirds are legendary in their ability to mimic the calls of other bird species, and rain forest gullies will re-echo with an apparent chorus of calls that can be traced to a single individual bird. The American mockingbird has similar abilities and may mimic the sounds of companion Psittaciformes.

Like psittacine birds but unlike ratites and penguins, passerine birds have a highly developed neopulmonic and paleopulmonic parabronchi. This allows for highly efficient oxygen exchange. In most passerines, the cranial thoracic air sacs are fused to the single median clavicular sac, making a total of seven air sacs as opposed to the nine air sacs of psittacine species.

Reproductive System

In general, only the left ovary and oviduct develop in normal female passerines. Occasionally a nonfunctional right ovary will develop in female sparrows. Both testicles develop in males and during the breeding season these may reach enormous proportions in relation to the size of the bird. These physiologically enlarged testicles should not be mistaken for pathologic conditions.

Role of Light in Reproduction

Temperate-evolved species (including canaries) are usually dependent on daylight intervals for reproductive performance. Increased daylight hours trigger the release of luteinizing hormone (LH) in responsive individuals. The precise light interval varies among species but the physiologic control mechanism appears to be similar. Light stimulates photoreceptors in the brain, probably in the hypothalamus, where there is a circadian rhythm of photosensitivity. If light coincides with the period of sensitivity, luteinizing hormone releasing factor (LHRF) is released and gonadotrophin secretion is increased. If light coincides with the insensitive phase of the rhythm there is no response. Gonadotrophin release in turn, triggers the release of sex hormones.

There must be a rest period following a long light exposure to allow the photoreceptive system to reac-

tivate and once again be responsive to increasing day length. Stimulation of the reproductive cycle is best accomplished by a progressive increase (four-week period) of exposure to light. In general, the maximum effect of increasing day length will occur when a passerine individual is exposed to 10-14 hours of light. In males, the release of testosterone may occur in less than 24 hours following exposure to appropriately increased daylight hours. This in turn can result in rapid development of secondary sexual characteristics and breeding display (territorial calling, testicular and cloacal enlargement, courtship behavior).

Courtship behavior is the culmination phase of the reproductive cycle. Response of females to increased photoperiod is less dramatic, and it may require the presence of a male in breeding condition to trigger appropriate nesting and egg laying responses.[60] By gradually increasing the light exposure, a more natural reproductive cycling occurs, and a male is less likely to brutalize a slowly responsive hen. This also accounts for the common aviculture practice of separating males and females during the non-breeding season.

Many aviculturists use a "breeder" cage with a removable partition that allows the male to feed the female through an opening. At various intervals, the partition separating the two sexes is removed, and if the female "accepts" the male, they are left together. The nest is put in the male's side of the cage along with a source of nest material, which he collects in the nest as part of the courtship activity. An experienced canary breeder can remove the partition at precisely the right time for the female to accept the male.

This photoresponsive mechanism is very sensitive, and some species of birds indigenous to high latitudes commence breeding at almost the same week from one year to the next. The fact that many Psittaciformes hens produce eggs within a one- to two-day period on an annual basis suggests a similar, well defined control system of the reproductive cycle. This is obviously an advantage where suitable conditions for raising chicks are restricted to a very limited season. In indoor breeding aviaries, it is important to mimic appropriate daylight patterns in order to stimulate breeding. Appropriate daylight-hour patterns will vary from species to species. In canaries, 14 hours of light is commonly recommended to induce reproductive behavior in a responsive bird. Longer light periods may cause a shorter breeding period and early molting. Molting causes an immediate cessation of breeding activity.

After a period of long daylight hours, birds become refractory to photostimulation, and plasma concentrations of both LH and FSH begin to fall. In male White-crowned Sparrows, for example, this occurs after 50 days of long daylight hour exposure. Following the molt and period of decreasing daylight hours (fall), the breeding season starts again with the increasing daylight hours in the late winter and early spring. Following the molt and several months of reconditioning, the process starts over (in the United States, this occurs in December with January breeding).

Testosterone-induced Singing

Male canaries will usually sing best in the spring in response to the endogenous testosterone "surge." If a bird becomes ill, it may stop singing and may not recommence vocalizations until the following spring, even though the initial illness has resolved. In contrast, some canaries (even some females) sing year round and birds that stop singing because of illness re-commence singing as soon as their general condition improves. Injectable testosterone has been suggested as a method of inducing singing in birds that have stopped after a period of illness. This is a practice that should be discouraged because the testosterone has a negative feedback that causes shrinking of the testes and reduced fertility.

Avicultural Considerations

Husbandry

Dietary and husbandry requirements for passerines are diverse. There are primarily seed-eating species such as the canary and Bengalese Finches that have been domesticated for centuries, are easy to care for and breed well in captivity. Many varieties of these domesticated species bear little resemblance to their free-ranging ancestors. Java Finches, Zebra Finches and Gouldian Finches have somewhat shorter histories of domestication but are also bred intensively in captivity, and many mutations have occurred.

Many Passeriformes are critically endangered because of habitat destruction and human interference. By developing a better understanding of these spe-

TABLE 43.2 Breeding Characteristics of Selected Passerine Birds

	Eggs Per Clutch	Incubation (days)	Fledging
Australian Grass Finches	4-8	12-17	21-25
Birds of paradise	1-2	17-21	17-30
Bowerbirds	1-2	19-24	18-21
Bulbuls	2-5	12-14	14-18
Canaries and Frigillid finches	3-5	12-14	11-17
Cardinals	2-5	11-14	9-15
Crows and jays	2-8	16-22	20-45
Java Finch	4-8	14-14	26-28
Sparrows and weavers	2-5	13-14	21-24
Starlings and mynahs	2-7	11-18	18-30

cies and pressuring local, national and international leaders to preserve all remaining natural habitat, the aviculturist and avian veterinarian can have a dramatic impact on the health of the planet.

Table 43.2 lists the breeding characteristics of selected passerine species.

Housing

Aviaries for Passeriformes should provide adequate protection from the elements, with tropical species requiring the greatest degree of protection. In mild climates, hardy species of Passeriformes do well in carefully planned, planted aviaries that provide adequate protection as well as visually attractive surroundings (Figure 43.3). Indoor, temperature-controlled rooms may be necessary to raise finches in harsher climates or when artificial lighting control is necessary to increase production.

Planted aviaries are popular for passerines because these birds cause less damage to vegetation than psittacines and the vegetation provides observers a more natural view of a bird's behavior. Care must be taken to ensure that the plant species are nontoxic.

Some passerine birds require special materials for nesting or to stimulate display behavior. Care must be taken that the type of objects provided for these birds are safe. Any contact with fine synthetic fibers should be avoided because these may become entangled around the birds' feet, toes or other body areas and cause damage, loss of limb or death. Burlap (hessian) cut into small squares, torn strips of facial tissue or coconut fiber make suitable, safe nesting materials (Figure 43.4) (see Color 24).

Male Satin Bowerbirds will build intricate display nests that they decorate with blue objects if suitable materials are provided. At one time in Australia, blue plastic rings were used to seal milk bottle tops, and free-ranging bowerbirds would selectively collect these rings from rubbish dumps and elsewhere to decorate their bowers. The rings would occasionally slip over the bowerbird's neck with fatal results. Manufacturers changed the color of the rings from blue to white or red, ending the strangulation deaths.

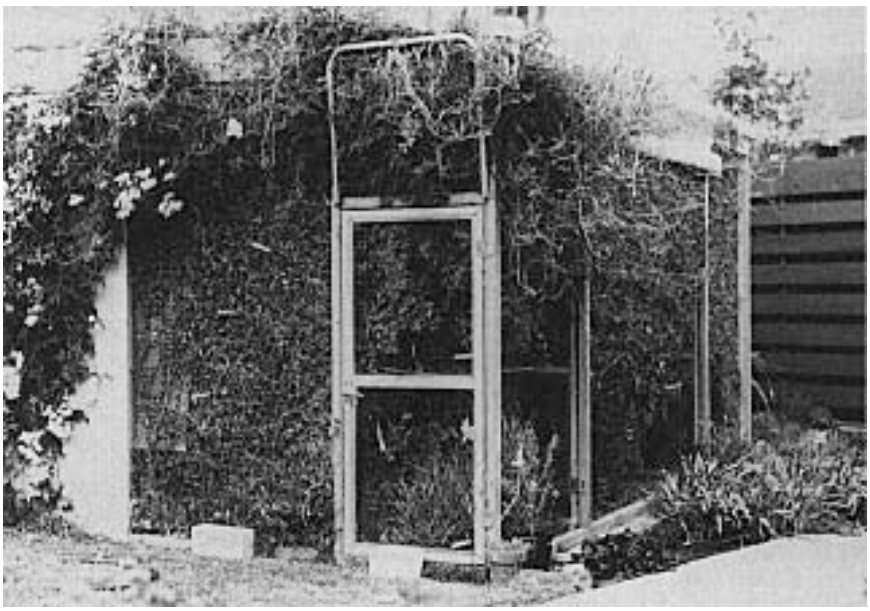

FIG 43.3 Depending on the climatic conditions and the durability of the species, many Passeriformes can be maintained in attractive, planted outdoor aviaries.

Disease Control

Disease control in planted aviaries can be challenging because of the difficulties involved in controlling microorganisms and in medicating individual birds. Because it is difficult to eliminate infectious agents once they are introduced into a planted aviary, it is critical that any new birds be quarantined, tested and treated for parasites and infectious diseases prior to introduction.

Free-ranging birds should be excluded from aviaries to prevent the transmission of microorganisms. Sparrows, for example, may transmit poxvirus, *Plasmodium*, feather lice, mites and *Haemoproteus* to canaries.

FIG 43.4 Only natural substitutes (burlap, coconut fiber) should be used for nesting material in Passeriformes. Synthetic fibers (particularly yarn) may wrap around a digit, leg or wing causing avascular necrosis distal to the constriction. In some cases, the fibers are grossly visible, while in others, magnification is necessary to see and remove the constricting fibers. A 26 or 30 ga needle makes an excellent cutting tool for removing small fibers under magnification (courtesy of Michael Murray).

Nutrition

Passeriformes may be granivorous, nectivorous, fructivorous, insectivorous, omnivorous or carnivorous. Some species adapt readily to commercially available diets, while others may require live food and are thus difficult to maintain in captivity. Some free-ranging species have specific dietary preferences (Gouldian Finches prefer sorghum) but may adapt to diets provided in captivity. Even finches that are considered omnivorous or carnivorous can be successfully raised on properly balanced vegetable-based diets (Figure 43.5).

Recommended dietary levels of vitamins and minerals developed for poultry are used as a base in small passerines. Finches may consume up to 30% of their body weight daily in food compared with 10% for larger parrots. If dietary supplementation is based on a percentage of particular ingredients in the diet, finches may be consuming greater amounts on a per gram body weight basis than larger species. Overdosage of vitamins and minerals may occur, resulting in infertility, renal calcification, gout and general poor condition; thus, only diets specifically formulated for finches should be used.

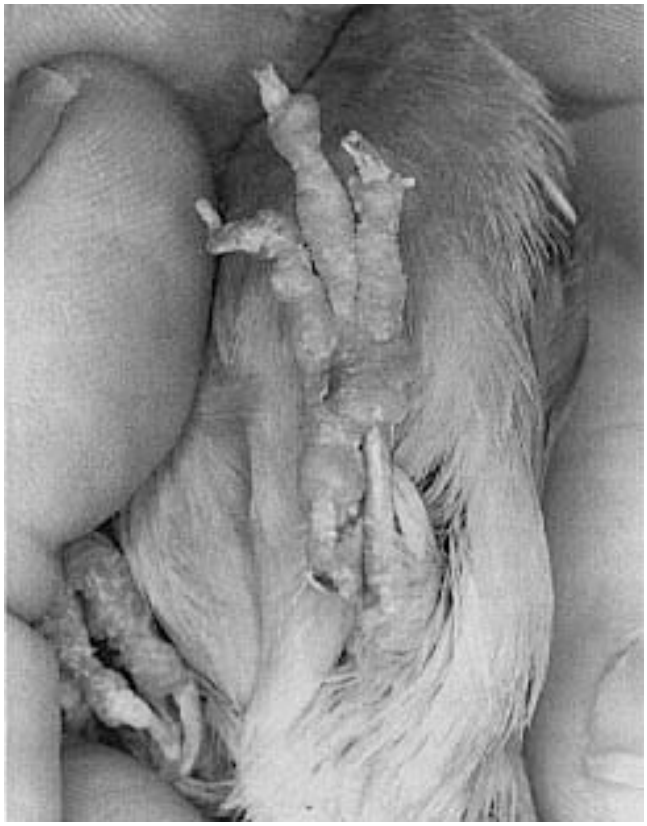

FIG 43.5 A mature canary was presented with a four-month history of progressive lameness. The bird was maintained on an all-seed diet in a small enclosure and had no exposure to water for bathing or sunlight. Note the generalized edema, hyperkeratosis, dry brittle nails and poor feather quality suggestive of chronic malnutrition.

Feather color is dietary-dependent in species with carotenoid pigmentation. Red factor and new color canaries have genotypes that require exogenous sources of carotenoids or related compounds to enable full development of yellow, orange and red pigments in feathers. Foods for these birds contain carotenoids and xanthophylls to enable proper color development. Reduced or absent carotenoids during feather formation produces pale or whitish feathers while excess carotenoids will cause a deepening of yellow and red pigments.[8] Commercial diets that contain algae (spirulina) should have sufficient levels of naturally occurring carotenoids to maintain proper feather coloration. In the United States, "colored" foods generally contain carotene-soaked stale bakery products and should be avoided in favor of more natural sources of carotenoids.

Free-ranging Green Finches may be bronze or reddish if they are exposed to excessive carotenoids. Their natural color will return when they are placed

on a more natural diet. Cardinals may fade in color when fruits, berries or greens that contain canthexanthin are scarce.

Vitamin A lacks color even though it is related to carotenoid pigments. Birds that have yellow feathers (honeyeaters) may become pale in captivity in spite of being given access to grated carrot and other sources of vitamin A precursors, due to the nutrient's being bound to undigestible cellulose. Consideration should be given to the bird's natural diet. Pollen, for example, may be a source of utilizable carotenoids such as apocarotenol, a pigment associated with golden-orange shades.

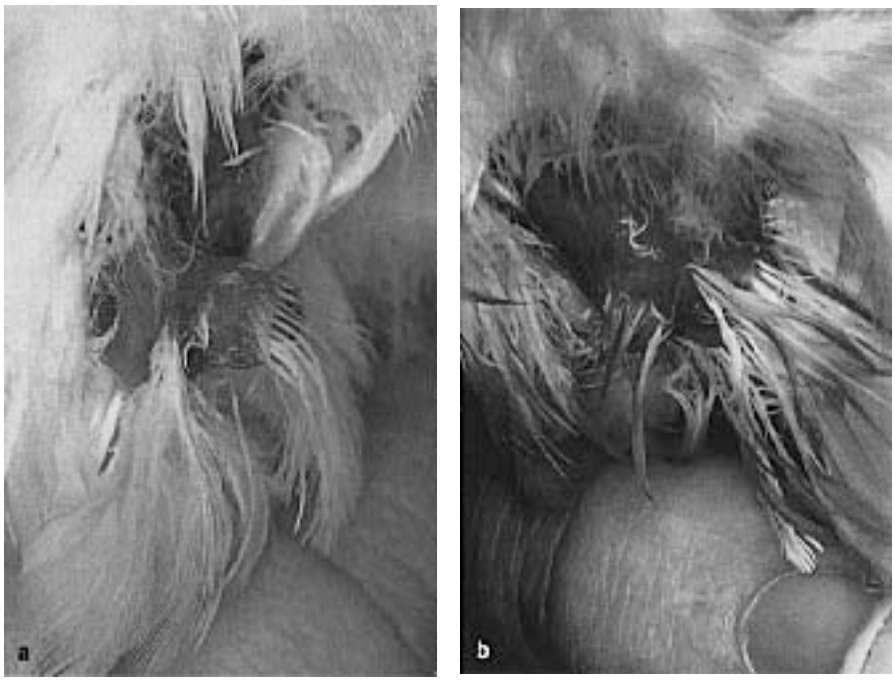

FIG 43.6 In many male Passeriformes, the seminal glomerulus swells and pushes the cloaca caudally during the breeding season. The cloacal promontory is **a)** present in the male and **b)** absent in the female, which has a flatter vent.

Seasonal Feeding Practices

In passerines indigenous to tropical or arid regions, seasonal changes related to daylight hours are less important to the reproductive cycle than the periodic availability of food and water. Most successful breeders of these species mimic natural conditions by lowering the caloric, protein and fat content of diets and maximizing the birds' physical condition by allowing free flight in open aviaries during the non-breeding season. At the beginning of the breeding season, the birds are "flushed," or encouraged to come into a breeding condition by increasing the plane of nutrition. Misting some species with water (to mimic rainfall) and providing green, fresh foods and foliage may stimulate breeding, particularly those species from desert environments such as the Australian grass finches. Birds must not become chilled during the misting process. Depending on the species, birds may be transferred in pairs to smaller breeding enclosures or left in flights to colony breed.

Sexing Passerines

In some passerines, there are obvious or subtle morphologic differences between the genders. Males are generally brightly colored or elaborately marked, particularly during the breeding season. Differences in singing, courtship or nesting behavior may also provide clues as to gender. Males usually have a melodious song and are more active during courtship with dancing, hopping and assuming of various unusual postures in addition to building the nest. The females usually have more of a chirp or single-note call and are more passive in the courtship role.

In males of many species, the caudal end of the ductus deferens forms a mass of convolutions called the seminal glomerulus. During the culmination phase of the breeding cycle, the seminal glomerula pushes the cloacal wall into a prominent projection, the cloacal promontory. This can be observed by blowing the feathers on the bird's vent cranially (Figure 43.6). Hens do not develop this projection and have a flatter vent. In the non-breeding season and with immature birds, these differences are less obvious.

Laparoscopy can be used to determine gender in monomorphic passerine birds, but the small size of many species may increase the risk of this procedure. Newer methods of gender determination using DNA technology are proving useful and will probably be used more extensively in the future. The cost of these procedures tends to limit their application to more expensive species.

Vasectomy in Finches

Estrilid finches may be vasectomized by making a 3 mm bilateral incision 5 mm lateral to the cloaca. The skin and muscle layers are incised and adipose tissue

is displaced to reveal the seminal glomus. A portion of each seminal glomus is removed. The incisions are closed with single sutures and the bird placed on antibiotics postoperatively. The procedure generally takes less than 15 minutes.[5]

Combating Aggression

While passerine species may be small, some are quite territorial and others have well developed pecking orders. Head trauma, feather picking, other injuries or death may occur in individuals that have been attacked by a companion (Figure 43.7). Self-mutilation, poor body condition and increased susceptibility to disease can be indirect results of such aggression in birds that are psychologically stressed because of their low social position. Aggression is more likely to occur if the birds are overcrowded in small, open enclosures where less dominant birds have few opportunities to escape from dominant birds. Aggression-related injuries can be particularly pronounced if new birds are introduced into collections where a social order has already been established.[3]

Appropriate measures to prevent combat aggression will vary depending on individual circumstances. Suggestive control measures include:

- prevent overcrowding; the fewer birds, the better
- keep stocking densities low
- clip the wings or remove particularly aggressive individuals
- provide extra vegetation or visual barriers (burlap sheets) to provide less dominant birds with an escape area
- provide multiple perches, feeding locations and nesting sites
- maintain subdued lighting in indoor areas
- simultaneously introduce all birds into a new environment.

Parents that become aggressive toward their chicks are preparing to lay a second clutch of eggs and the chicks should be removed.

Sick or injured birds should be housed separately from other birds to prevent them from being injured by their healthier companions.

Successfully establishing aviaries containing psittacine, passerine and other bird species requires a working knowledge of individual behavioral characteristics and interspecies tolerance. Parrots from the genera *Neophema* (Bourke's or Scarlet-chested Parrots) or *Polytelis* (Princess Parrots) are usually sedate and will mix well with finches. In contrast, rosellas (except for the Western Rosella) or *Psephotus* parrots (Hooded or Blue Bonnet Parrots) are usually aggressive and will kill other birds that are in their space.

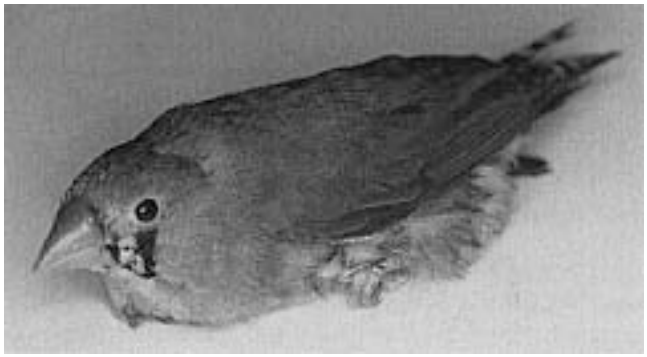

FIG 43.7 A Zebra Finch female was presented after having been involved in an episode of territorial aggression in an overcrowded enclosure. The bird had bilateral rear limb paresis with some deep pain. The finch responded to therapy that included corticosteroids and being placed in a dark, cool (72°F) environment.

Cross-fostering Techniques

Species with long histories of domestication, such as Bengalese (Society) Finches, will usually breed freely in captivity without the use of specialized techniques. Members of this species are sometimes used as foster parents to incubate and raise other finches. Similarly, Border Canaries may be used as foster parents for other canary varieties. Cross-fostering is practiced to increase the production of a particular pair of birds. Many species will breed and lay but may require certain foods to raise the young. Many birds will immediately re-lay when eggs are pulled to foster, thereby increasing production.

One of the inherent problems in cross-fostering is that it does not enable selection for good parenting ability in the offspring. The problems that gave rise to the need for fostering in the first place are often perpetuated into future generations. Some organisms such as *Campylobacter* spp. and *Cochlosoma* spp. may cause inapparent infections in foster parent birds but be transmitted to cross-fostered juveniles where disease may result. By comparison, using foster parents may prevent some infectious diseases that are transmitted from infected parent to offspring. For example, colonies of Gouldian Finches that are air sac mite-free have been established by

using Society Finches, which are not susceptible to air sac mites, as foster parents.

Cross-fostering has also been used as a technique to enhance breeding populations of endangered species. The Helmeted Honeyeater, state bird of Victoria, Australia, is endangered. In an effort to save this bird, eggs are collected from free-ranging Helmeted Honeyeaters and are incubated in captivity by the closely related Yellow-tufted Honeyeater. This induces the free-ranging Helmeted Honeyeaters to produce a second clutch of eggs and increase the annual production of chicks from a single pair. Similar techniques have been used to save other endangered passerines such as the Black Robin (fostered under Chatham Island Robins). However, preservation and rehabilitation of suitable natural habitats must also be a priority if captive breeding and subsequent release to the wild is to be effective.

Imprinting

One of the major disadvantages of fostered birds is that they imprint on the foster parents and may be less likely to breed with their own species. Experimental work in Bengalese and Zebra Finches has shown that development of sexual orientation and adult song patterns occur during a defined period in early juvenile life. Male finches reared by foster parents of a different species or color variety preferentially choose females of the foster species as they sexually mature. If only male members of the foster species were available, the cross-fostered males formed homosexual pairs with these birds rather than heterosexual pairs with birds of their own variety. The critical sensitive period for sexual orientation from imprinting lasts from about the 15th to the 40th days of life. Acquisition of adult song follows a similar pattern: birds raised by foster parents learn the song of the foster parent, even if this song was audible only some weeks prior to the young bird's beginning to sing.[35] For species-specific imprinting to occur, a finch should be exposed to its own species from the 15th to 40th days of life.

Parallels of the imprinting behavior that occur in finches have been defined in humans and other animal species. For example, adult humans retain accents acquired during childhood even when they move to new locations. By comparison, children will quickly change an original accent and acquire the one characteristic to a new location. As an example in other birds, Whooping Cranes in the United States that were foster-raised by Sandhill Cranes did not learn appropriate Whooping Crane courtship behavior, yet were rejected by Sandhill Cranes during the breeding season.

Finches are an inexpensive experimental animal and are being used as a model to study neurophysiologic controls of imprinting.

Breeding Parasitic Species of Passerines

Some finch enthusiasts relish the challenge of breeding parasitic species (birds that lay their eggs in the nests of other species) such as Paradise Whydahs (parasitize various species of the *Pytilia* family) and Broad-tailed Whydahs (parasitize Aurora Finches). Whydahs are generally bred in large planted aviaries where the parasitized finch species has first been firmly established and is breeding freely. The parallels between the appearance and behavior of the whydah chicks and the finch chicks that they mimic are striking even though the adults of the two species are very different.

If male and female whydahs do not originate from the same geographic area, they may not enter breeding condition simultaneously, preventing successful reproduction. The male whydah develops a long, flowing tail during the breeding season.

Special Considerations in Managing Passerine Patients

Passeriformes are increasingly presented for veterinary evaluation as aviculturists recognize that successful medical and surgical treatment can be performed, even in tiny patients. However, owner financial constraints and difficulties in collecting samples from small birds may limit diagnostic and treatment options. Veterinary care in these species is frequently directed toward appropriate preventive husbandry measures and approaching medical problems from a flock perspective. As importation of wild-caught Passeriformes (eg, African finches) ceases, the cost of acquiring pairs warrants further financial investment in their care.

Restraint and Handling

A "lights out/perches out" approach to capture is often useful for small active birds. Birds will generally not move in a dark room and can easily be removed from an enclosure with minimal stress. Once out of the enclosure, the bird can be restrained by placing the head between two fingers so that the body rests in the palm of the hand, or it can be restrained by holding the head gently between the thumb and first finger. The latter can be difficult to execute (Figure 43.8).

Blood Collection Techniques

The right jugular vein is generally the best site for collecting blood or giving intravenous fluids. It is surprisingly large even in very small birds. A nail clip, medial metatarsal vein or cutaneous ulnar vein are alternative blood collection sites but they frequently provide insufficient sample volumes. A skin prick technique from these sites or from the external thoracic vein (which courses on either side of the rib cage just behind the shoulder) can be used. The blood is collected directly from the skin into a micro-collection tube.[71]

The lymphocyte is the predominant white cell in most passerine species, and lymphocytes rather than heterophils tend to increase in stress-related conditions.

Treatment Techniques

Therapeutics

Although the right jugular vein can be used for administering intravenous fluids, intraosseous catheterization using a 26 ga needle is a practical means of fluid administration in a finch.

Hemorrhage may be a problem following intramuscular injections into the pectoral muscles in small birds. To minimize risk, the injection site should be located in the caudal third of the chest muscles, and a fine gauge needle should be used (25 ga or less). Aspiration should be performed prior to injecting any drug to ensure that a blood vessel has not been cannulated. After the needle has been removed the site should be observed for hemorrhage, and pressure should be applied digitally if bleeding does occur.

Drug dosing in small patients must be based on an exact weight (as determined by a gram scale) and should be delivered with precise microliter or insulin syringes to avoid overdose. There is little room for a dosing error in a small bird.

FIG 43.8 Passeriformes can be restrained by **a)** placing the head between the second and third fingers and letting the body rest in the palm of the hand, or **b)** by holding the head between the thumb and first finger. Note the clean, dry nostril and perinasal area, relatively smooth beak, dry sleek feathers and clear bright eye suggestive of a healthy Gouldian Finch.

Fiber Removal

It is common to see canaries and finches with fine fibers (cotton or synthetics) wrapped around their feet or legs. Swellings associated with the feet and legs should be examined using magnification to determine if fibers are involved. Individual digits or the whole foot may be lost from untreated or chronic vascular constriction (see Figure 43.4) (see Color 24).

If there are only a few fibers, it may be possible to remove them using magnification and gentle teasing with fine scissors, a needle and forceps under magnification. If numerous fibers are present, it is best to cut through all the fibers down to the skin, keeping the incision parallel to the long axis of the leg or digit. The incision should be made on the lateral side of the appendage or wherever the fibers are least imbedded. Pulling on deeply imbedded fibers can cause them to further constrict vascular structures. Once all the fibers have been severed, they may be removed with reduced risk of iatrogenic damage.

Splinting

In small birds, lower limb fractures can often be repaired with a sandwich adhesive or masking tape splint (see Figure 16.3). The limb should be positioned in moderate flexion to enable the bird to move and to prevent bending that may occur if the leg is splinted straight. Several layers of tape may be needed. This type of splint is also used to provide support to weakened or damaged bones following the removal of tight leg bands.

Diseases

Table 43.3 lists the most common diseases of captive Passeriformes that are likely to be seen by avian practitioners.

Mutations and Genetic Diseases

Some passserines, such as Gouldian Finches, new color canaries and Zebra Finches, are bred for their color mutations. Other varieties (eg, Norwich, Glouster and Yorkshire canaries) are bred for morphologic characteristics. Some of these mutations may be associated with genetic disease (Figure 43.9).

FIG 43.9 Linebreeding and inbreeding to achieve color or morphologic mutations produce a weaker bird with greater potential for genetic abnormalities. This color mutation Gouldian Finch will have a reduced life-span in comparison to its wild-type conspecifics.

FIG 43.10 Feather cyst formation is believed to be hereditary although infectious agents have not been ruled out as an etiology. Severe localized feather cysts, like this one in a canary, generally require surgery to remove the cyst and all affected feather follicles. Less aggressive therapy generally results in recurrence of cyst formation with subsequent molts (courtesy of Michael Murray).

Feather Cysts (Hypopteronosis Cystica)

Heavily feathered canaries, particularly those with "double buff" soft feathers, may develop feather cysts. Norwich, Crested, Crest-bred and dimorphic new

color canaries are most frequently affected with this condition but it may occur in other varieties as well. The condition is believed to be hereditary but the mode of inheritance is not simple, and other factors apart from genetics may play a role in the development of the condition. The possibility of a vertically transmitted virus infection causing folliculitis with secondary cyst formation has been suggested.

Feather cysts may occur as isolated or multiple lumps. Often they affect the wings, back or chest. They may be bilaterally symmetrical or occur randomly on the body (Figure 43.10). Badly affected birds have irregularly directed feathers all over their bodies (see Color 24). The cysts may involve one or more feather follicles, and occasionally whole feather tracts are affected. The texture of the material within the cyst will vary depending on the stage of molt. Actively growing feather cysts will have vascular walls and contain blood and gelatinous material. Mature cysts will contain drier keratinous material, and the cyst wall may be more expansive, thickened and reduced in vascularity (see Color 24).

Medical treatment for feather cysts is generally unrewarding. Some canary breeders believe that iodine given at 0.1 ml to 50 ml drinking water will hasten the maturation of feather cysts and allow some to desiccate and slough naturally. Controlled trials to verify this mode of therapy have not been performed, and some feather cysts will heal without treatment. Once mature, the material can be expressed from small cysts but the problem will recur with the subsequent molt.

Surgical options for feather cysts include excision of individual cysts, removal of complete feather tracts or lancing and curetting individual cysts (Figure 43.11). Excision will remove the affected follicle and may be useful for solitary cysts, particularly those located on the body. This therapy is not practical if there are numerous cysts and will not prevent new cysts from developing at remote sites. In birds with numerous cysts it may be more practical to remove a complete feather tract[2] (see Color 24).

The author's preference for treating feather cysts is to place hemostats at the base of the cyst and remove

TABLE 43.3 Common Clinical Presentations and Diagnoses in Companion Passerines

Clinical Presentation	Common Diagnoses
Canaries	
Open-mouthed breathing, moist rales	Air sac mites, upper respiratory tract infections (bacteria, mycoplasma), inhalant toxins, lymphoproliferative disease
Masses on head	Pox, caseated sinus abscesses, mycoplasma
Masses on wings and body	Feather cysts
Masses on legs and feet	Pox, insect bites, swelling from strangulating fibers, Knemidokoptes mites
Digit necrosis	Strangulating fibers, Staphylococcus infections
Scale on legs, swollen feet	Knemidokoptes mites, genetic, nutritional, associated with aging in some birds
Diarrhea in nestlings	Bacterial infections, Isospora, atoxoplasmosis
Black spot (enlarged, dark liver visible through skin)	Atoxoplasmosis, bacteremias, Plasmodium
Deaths in adults (both sexes)	Bacterial septicemias (especially colibacillosis and yersiniosis)
Abdominal enlargement	Egg binding, leukosis
Deaths in breeding hens	Egg peritonitis (often due to *E. coli*)
Feather loss from head	Feather mites, male baldness, aggression, malnutrition
Torticollis	Paramyxovirus, listeriosis, cerebral vascular accident
Finches	
Open-mouthed breathing, moist rales	Air sac mites (Gouldian Finches), upper respiratory tract infections
Masses on legs and feet	Knemidokoptes (esp. European Goldfinches), swelling from strangulating fibers, insect bites
Scale on legs	Knemidokoptes (may also be genetic/nutritional in some birds)
Diarrhea in nestlings	Bacterial infections, coccidiosis, atoxoplasmosis, polyomavirus (in Gouldians), Cochlosoma (in Gouldians cross-fostered on Bengalese)
Voluminous white droppings	Campylobacteriosis, pancreatic insufficiency
Seed in droppings	Cochlosoma infections, vitamin E or selenium deficiency, enteritis, lack of grit
Deaths in adults (both sexes)	Bacterial septicemias (especially colibacillosis and yersiniosis); tapeworms or gizzard worms (in insectivorous finches); mycobacteriosis (esp. siskins); avian malaria (parrot finches)
Feather loss from head	Feather mites, aggression from enclosure mates
Mynahs (and other Sturnidae)	
Ascites, dyspnea	Iron storage disease, hepatic cirrhosis or neoplasia, congestive heart failure
Seizures	Epilepsy
Nasal discharge, sinus swelling, rales	Bacterial upper respiratory tract infections, malnutrition
Chronic weight loss, dyspnea	Aspergillosis, mycobacteriosis

FIG 43.11 Surgically removed feather cyst from a canary (courtesy of John Cooper).

all tissue to the base of the hemostats with a radiosurgical unit. With this technique, the contents of the cyst are removed along with the skin that forms the wall of the cyst but the cyst is not totally excised. The hemostats are removed, and any remaining keratinous material is curetted from the base of the cyst. The small remaining part of the interior lining is cauterized with the radiosurgical unit. An elastic adhesive bandage is used to control minor bleeding. The advantages to this technique are that it is quick, economical and can be performed without anesthesia. Stitches are generally not required. The cosmetic effect is preferred to what occurs when cysts are simply lanced, and damage to surrounding tissue is less than with total excision. If the base of the cyst has been adequately cauterized, there is generally no recurrence at that site.

Birds with feather cysts should not be used for breeding. Unfortunately, cysts may not develop in a bird until after it is reproductively active.

Crested Canaries

Crested varieties of Norwich or Glouster canaries are occasionally kept for show or pets. Depending on the variety, birds with crests are referred to as "coronas" or "crested" while those of the same conformation but without crests are referred to as "consorts" or "crest-bred." The desirable crested phenotype is heterozygous for the autosomal crested gene. Birds that are homozygous for the crested gene die. Crested canaries are produced by breeding crested birds (coronas) with non-crested (consorts or crest-bred) canaries. This mating will result in 50% crested birds (Cc) and 50% non-crested birds (CC). If crested birds are mated to crested birds, normal Mendelian genetics will result in 25% non-crested, 50% crested and 25% dead chicks.

Dominant White Lethal Factor

Canaries that are homozygous for the dominant white gene die, while heterozygous individuals are white. Two dominant white birds should not be mated or all the chicks will die. If white birds are mated with other color varieties, 50% of the chicks will be heterozygote-dominant white and 50% of the chicks will be other colors.

Straw Feathers

Canaries and Zebra Finches occasionally show retention of the feather sheath and incomplete development of the barbs and barbules. The disease may affect first-molt fledglings or adult birds in a symmetrical fashion; it is believed to be genetically determined (see Color 24).[18,58]

Cataracts

Cataracts are occasionally seen in canaries, particularly in Norwich and Yorkshires. Affected birds will often be found on the bottom of the cage or aviary, possibly avoiding flight after a previously misjudged landing. Histologically, there may be disorganization of lens cortex, fragmentation of fibers, globule formation and lens resorption. Cataracts are reported to be caused by a recessive gene in Yorkshire and Norwich canaries. They may be removed surgically.[36,67]

Viral Diseases

Poxvirus

- ***Clinical Presentation:*** The clinical appearance of poxvirus in passerine birds varies with the virulence of the strain, the mode of transmission and susceptibility of the host. Canaries and House Sparrows are particularly susceptible and may show the cutaneous, septicemic or diphtheroid forms of the disease (Figure 43.12). The cutaneous form of poxvirus has also been reported in a variety of free-ranging Passeriformes, eg, starlings, juncos, silvereyes and Australian magpies.[26,57] Poxvirus infections are usually self-limiting in free-ranging birds.

Poxvirus may be transmitted from free-ranging starlings to other members of the Sturnidae family. In one instance, all of a group of Rothschild's Mynahs exposed to infected starlings died. In Greater Hill Mynahs, poxvirus has been associated with low mortalities, but chronic eye, wattle and oral lesions occur. These include proliferative lymphocytic conjunctivitis, keratitis, chronic corneal ulcers, lid depigmentation, cataracts, eyelid distortion and scar tissue with feather loss on the head.[37]

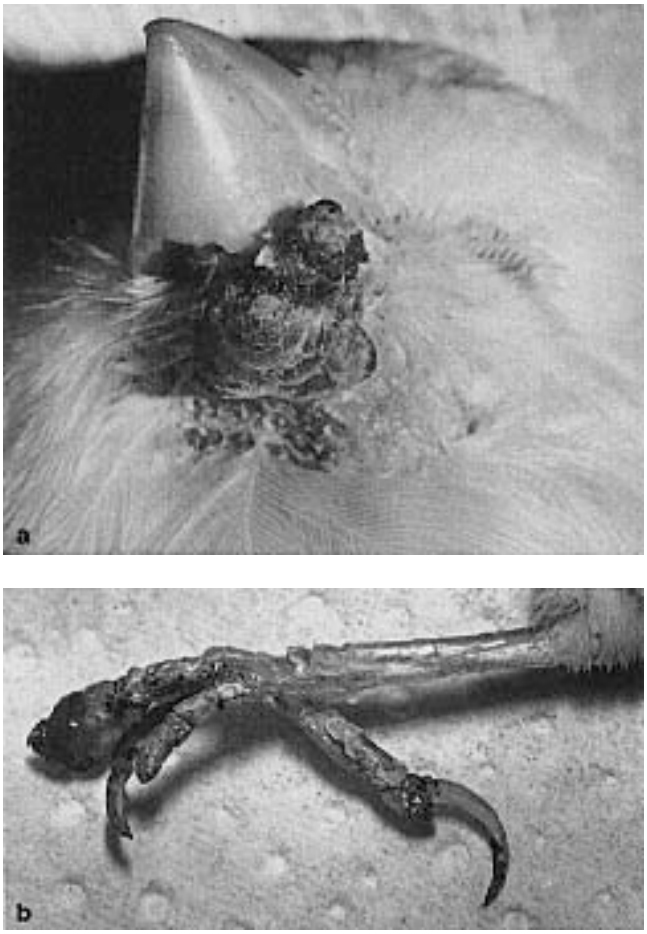

FIG 43.12 Poxvirus infections are common in canaries that are maintained outdoors in areas with high densities of mosquitoes. Depending on the species of bird and virulence of the virus, either cutaneous, diphtheritic or septicemic forms of the disease may occur. Cutaneous lesions are common on **a)** the face or **b)** feet and legs (courtesy of Michael Murray).

Mortalities of up to 100% have occurred in some outbreaks of canary pox. Acutely affected birds may show lethargy, ruffled feathers, open-mouthed breathing and death in two to three days. In less acute cases, birds may show conjunctivitis, blepharitis and lacrimation before the appearance of characteristic proliferative lesions around the eyes and mouth. Death may result if these lesions cause pharyngeal obstruction. On necropsy, birds dying acutely may show cloudy air sacs and pneumonia with proliferative necrotizing bronchitis, while those dying later in the course of the disease are more likely to show proliferative skin lesions and typical intracytoplasmic inclusions in the epidermis and respiratory epithelium. The skin lesions should be differentiated from mosquito bite abscesses, which result in discrete lumps that contain caseous material when lanced.[18,40] An uncomplicated pox lesion is a contained fibrous reaction without a necrotic, expressible center.

A much milder form of cutaneous canary pox is also seen in southeastern Australia and California. Periodically more virulent strains erupt and high mortalities occur, particularly in birds kept in outdoor aviaries in areas with dense mosquito populations.

While birds affected with poxvirus will typically show intracytoplasmic Bollinger bodies, intranuclear inclusions have been demonstrated in the junco. Concurrent infections with other viruses have also been noted. Retrovirus-like particles have been found in the brains of some poxvirus-infected canaries.[11] Adenomatous tumors in the lungs have occurred as a sequel to poxvirus infections.

Serologic cross-reactions between strains of poxvirus in Passeriformes have not been demonstrated, but some strains will affect more than one passerine species. For example, in one outbreak, canaries and House Sparrows were the only species to show clinical signs of poxvirus or mortality even though ten species of passerine birds were present in the aviary (see Chapter 32).

- ***Treatment and Control:*** There is no specific treatment for poxvirus. Antibiotics may be useful to control secondary infections, and vitamin A or its natural precursor may aid in the healing process. Scarifying individual pox lesions may result in spontaneous remission. Topical application of astringent solutions such as mercurochrome or alcohol may be useful. Adenine arabinoside ointment[a] has also been recommended. Mild baby shampoo may be gently applied to any lesions around the eyes to remove scabs. Immune stimulants such as PEP-E[b] and echinacea may be of possible value.

Avian poxviruses can be transmitted by mosquitoes, mites or by contact through damaged epithelial surfaces. Bird rooms should be mosquito-proofed and treated with insecticides to eliminate vectors, and affected birds should be isolated until fully recovered. Recovered birds generally have lasting immunity to the disease but may become carriers and shed the virus. A modified live virus canary pox vaccine[c] is available in some countries.[15,18]

Herpesvirus

Herpesviruses have been isolated from Estrildid finches, Ploceid finches (weavers and whydahs) and canaries, but in most cases they have not been asso-

ciated with disease. Outbreaks of conjunctivitis in Gouldian Finches associated with herpesvirus-like particles have been reported in Europe.[64]

Cytomegalovirus

An epidemic of conjunctivitis with respiratory distress and a 70% mortality rate was reported in Australian grass finches maintained in Europe. Basophilic intranuclear inclusions were seen in karyomegalic epithelial cells of conjunctiva, esophagus and trachea. Cytomegalovirus-like particles were identified by electron microscopy.[12]

Polyomavirus

Polyomavirus-like infections have been associated with several clinical presentations in passerine birds. Sporadic deaths have occurred in adult finches of various species, particularly in birds that have been stressed by transport or other factors. Ventricular mycosis has been reported as occurring concurrently with polyomavirus in many of these birds.[40]

In color mutation Gouldian Finches, polyomavirus-like infections have been reported to cause acute mortality in two- to three-day-old babies, and poor growth, dirty feathering and late fledging in older nestlings. Many affected birds had an abnormal lower mandible that was long and tubular (Figure 43.13). Nonspecific illness and mortality occurred in slightly older birds. Concurrent *Candida* infections were common.[46]

In a separate report, deaths in fledgling and immature Gouldian Finches occurred without any concurrent feathering or beak defects. The most consistent gross lesion was a swollen, pale liver.[22] Currently there is no effective treatment for polyomavirus. Controversy exists as to whether it is best to depopulate, rest breeding stock or to continue to breed with the expectation that birds will develop immunity (see Chapter 32).

While polyomavirus-like intranuclear inclusion bodies have been described in finches in North America, Europe and Australia, the virus has not yet been cultured from passerine species. Gross lesions that have been associated with polyomavirus infections in finches include perirenal hemorrhage, serosal or subserosal intestinal hemorrhage, splenomegaly, and swollen or mottled liver. Histologically, amphophilic intranuclear inclusion bodies are typically seen in the kidneys, heart, spleen, gastrointestinal tract or liver. Cellular necrosis may occur in the bone marrow, gastrointestinal tract, spleen or hepatocytes.

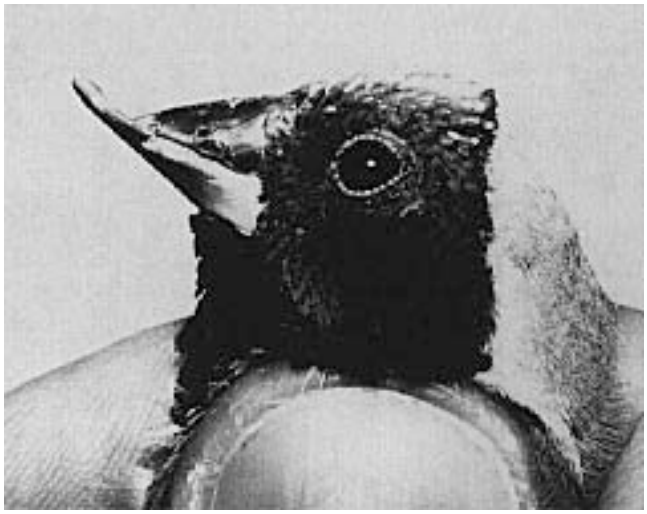

FIG 43.13 Long, tubular lower beaks have been reported in Gouldian Finches with polyomavirus-like infections.

Diagnosis is based on the histologic presence of large, clear-to-amphophilic, intranuclear inclusion bodies in one or more organs. Fluorescence should occur using polyclonal antibody FITC-labelled conjugate specific for polyomavirus antigen. Electron microscopy should reveal polyomavirus-like particles.[75]

Papillomavirus

Avian papillomavirus has been demonstrated in association with papillomas on the legs of wild European chaffinches. Three hundred and thirty birds out of approximately 25,000 birds examined were affected. The virus was purified and its physicochemical properties characterized.[42,51]

Viral papillomatosis has also been described in canaries from Argentina. The disease occurred seasonally during late summer and autumn over a three-year period, and the outbreaks were controlled using hygienic measures and an autogenous vaccine.[45]

Paramyxovirus

Passerines are known to harbor paramyxoviruses of groups 1,2 and 3.[26]

- ***Group 1 (Newcastle Disease Virus):*** Many weaver finches are susceptible and show conjunctivitis, pseudomembrane formation in the larynx and death. Neurologic signs are rare. Canaries rarely develop clinical signs, and infected birds should be considered asymptomatic carriers. Because species susceptibility varies, mortality patterns in an aviary may be sporadic and an infectious agent may not be considered as the cause.

- ***Group 2:*** Free-ranging passerines, particularly weaver finches in North Africa, are considered to be carriers of this virus. Many infected birds are asymptomatic but others may die following a period of emaciation and pneumonia.
- ***Group 3:*** This virus has been isolated from a variety of passerines including canaries, Gouldian Finches and weaver finches. It is generally associated with an overall poor condition and central nervous system signs (tremor, paralysis or torticollis).

Leukosis

Sporadic deaths associated with enlarged pale livers and spleens and histopathologic lesions suggestive of leukosis have been reported in canaries in Europe, Australia and North America. A viral etiology has been proposed but has not been confirmed.[1,15,18] Treatment with prednisolone may slow the progression of the disease.

Chlamydia Infections

Passeriformes are less susceptible to chlamydiosis than Psittaciformes. Chlamydia has been isolated from the droppings of clinically normal finches in households in which clinical cases of chlamydiosis occurred in psittacine species. Active disease outbreaks are intermittent, and infection rates of less than ten percent of the at-risk population are typical.[16] Chlamydiosis should be suspected in passerines with recurrent respiratory disease especially if they are exposed to psittacine birds.

Mycoplasma

Mycoplasma spp. have been isolated from canaries with wheezing, respiratory signs including tail-bobbing and conjunctivitis. Many cases of conjunctivitis and upper respiratory disease in canaries are responsive to tylosin. However, there has been no conclusive experimental work proving that mycoplasma is associated with this syndrome[25] (see Figure 43.1).

Tetracyclines are believed to be effective against many mycoplasma isolates as well as chlamydia. Both of these infectious agents are difficult to identify in a live bird, and a therapeutic trial with tetracyclines may be appropriate if they are suspected of being part of a disease complex. Tylosin or tiamutilin are other drugs that may be considered if mycoplasmal disease is suspected.

Bacterial Infections

Some investigators believe that bacteria and other microorganisms should seldom be found in stained fecal smears from normal canaries and finches. Others believe that low levels of gram-positive rods or cocci are considered normal. There is generally no bacterial growth on routine aerobic microbiological cultures taken from passerine birds.[15,21]

The general principles for treating and controlling bacterial infections in passerines are similar to those discussed in psittacines (see Chapters 17, 33). Passerines are frequently maintained in planted aviaries and medicating individuals can be extremely impractical. If a decision is made to use water-based medication, frequently used drugs include tri-methoprim and sulfamethoxale, amoxicillin, chlor-amphenicol, tetracyclines and enrofloxacin. Some passerines are particularly sensitive to certain antimicrobial agents (dimetridazole, furacin) and care should be exercised when administering any medication to a finch or canary (see Chapter 18).

Gram-positive Flora

- ***Staphylococcus* spp.** are normal inhabitants of the gastrointestinal tract and the skin but occasionally virulent strains may cause disease in susceptible hosts (see Chapter 33). Staphylococcal infections are commonly associated with the occurrence of thrombi in arterioles. This lesion can be particularly dangerous in small birds because collateral circulation is more limited than with larger birds. Digit necrosis, gangrenous dermatitis and pododermatitis are likely outcomes. Other clinical syndromes that have been associated with staphylococcus infections in passerines include high embryonic mortality, omphalitis, septicemia and arthritis.[27]

Streptococcal infections have also been associated with embryonic mortality, omphalitis, septicemia and arthritis in passerines, although, like staphylococcus, these bacteria are often part of the normal autochthonous flora.

- ***Enterococcus fecalis*** (formerly *Streptococcus fecalis*) has been associated with chronic tracheitis, pneumonia and air sac infections in canaries. Experimental infections are possible following subcutaneous or intrathoracic air sac injections but not by simple aerosol administration. Clinically affected birds have harsh respiratory sounds, voice changes and dyspnea. These changes are similar to those caused by the tracheal mite *Sternostoma tracheacolum*. Concurrent infections are possible.[13]

- ***Mycobacterium avium:*** Passerines are susceptible to *Mycobacterium avium* and may show nonspecific signs similar to those seen in other avian species: chronic wasting, diarrhea, polyuria, anemia, dull plumage and leukocytosis. Classic tubercles rarely develop, and gross necropsy findings usually reveal minimal changes. Two histopathologic conditions have been noted: small focal granulomas may be found in the lungs or high numbers of acid-fast bacteria may be noted in the lamina propria of the intestine.[27,47,61]

  Red-hooded Siskins may be particularly susceptible to tuberculosis. Treatment of companion birds for *Mycobacterium* spp. is not recommended because of the public health concerns.

- ***Erysipelothrix rhusiopathiae*** may cause disease in passerines as it does in other avian species but infections are not common.

- ***Listeria monocytogenes*** is a ubiquitous organism that may be transmitted by the oral route. Canaries are particularly susceptible to listeriosis and flock outbreaks may occur. Clinical signs include torticollis, tremors, stupor, paresis or paralysis. A marked monocytosis may occur. Tetracyclines may be useful therapy in the early stages of the disease but treatment is usually ineffective in birds with CNS signs.[21]

- ***Clostridium perfringens*** was isolated from a canary that died after eating contaminated food. Other reports of clostridial infections in Passeriformes are scarce but there is no reason to believe that birds of this order would not be susceptible.[31]

- ***Megabacterium:*** A large, rod-shaped, gram-positive bacteria that was difficult to culture and was associated with a proliferative, inflammatory reaction in the proventriculus of canaries was described in Europe. In affected birds, the proventriculus had an increased pH and altered synthesis of mucopolysaccharides. The koilin lining of the ventriculus was thinner in affected canaries than in a control group, possibly as a result of the increased pH in the proventriculus. The organism identified in these birds appeared to be very similar, if not identical, to the organism defined as "megabacterium" in psittacine birds (see Color 14).[69]

Enterobacteriaceae and Other Gram-negative Bacteria

Enterobacteriaceae are generally considered secondary pathogens. The predisposing factors that allowed organisms to colonize the bird should be identified and corrected. Oral neomycin or spectinomycin may be useful for infections localized to the gastrointestinal tract.

- ***Escherichia coli*** has been associated with a variety of disease problems in passerine birds including diarrhea, septicemia and ascending oviduct infections. Ascending oviduct infections are usually rare; however, *E. coli*-induced egg-related peritonitis and metritis have been associated with high mortality in some canary flocks in southeastern Australia. Juveniles and cock birds on the same premises were not affected. Mortalities stopped when the birds were placed on appropriate antibiotics (as indicated by sensitivity testing). Interestingly, bacteria isolated from Australian birds are frequently sensitive to a wider range of antibiotics than are commonly reported with similar organisms in the United States.[44]

- ***Salmonella typhimurium var copenhagen*** is commonly isolated from finches in Europe that develop a characteristic granulomatous ingluvitis, which can be confused with crop candidiasis or capillariasis. Histologic lesions are nonspecific and include intestinal inflammation and focal necrosis in the heart, lung, liver, spleen and kidney. Granulomas may occur in chronic cases. *Salmonella* spp. have also been isolated from cases of osteomyelitis and subcutaneous granulomas in canaries.[54,62]

- ***Citrobacter* sp.** is commonly found as a secondary invader in weaver finches and waxbills. It has also been associated with acute septicemia and death.[21]

- ***Yersinia pseudotuberculosis*** is a common cause of peracute mortality in finch and canary aviaries as well as causing general ill health, diarrhea and dyspnea. The organism is believed to have originated in Europe with worldwide dissemination occurring through rodents on ships. Yersiniosis is a widespread problem in Australian aviaries where rodent control is poor. Infections occasionally occur in free-ranging birds. Enteritis and pinpoint or large abscesses throughout the liver and spleen are characteristic gross findings. Affected birds are often too sick to respond to therapy but treatment of exposed birds with antibiotics based on sensitivity testing will usually stop an outbreak. Decontaminating the aviary and rodent-proofing food and water supplies should accompany any antibiotic therapy.[27,44]

- ***Klebsiella, Pasteurella and Haemophilus* spp.** are occasionally isolated from Passeriformes. Pasteurella is often associated with fatal septicemias following cat bite wounds. Even if injuries seem mi-

nor, birds that have been bitten or scratched by cats should receive antibiotics immediately.

- ***Campylobacter fetus var. jejuni*** has been associated with pale, voluminous droppings ("popcorn poohs") in canaries and finches of a variety of species (particularly Gouldian Finches). European investigators have suggested that adding animal protein, minerals and vitamins (soft food) to the diet may strengthen the bird's immune system and protect against repeated infections. Antibiotics (particularly erythromycin and tetracyclines) may also be useful.[70]
- ***Pseudomonas*** sp. infections may originate from the consumption of contaminated drinking water, misting bottles or inappropriately prepared soaked seed. The organism may cause foul-smelling diarrhea or mucopurulent pneumonia and air sacculitis. Treatment should be based on sensitivity testing, as the bacteria is often resistant to routinely used antibiotics. Steps should be taken to identify and remove environmental sources of contamination.
- ***Aeromonas*** sp. has been isolated from European rooks and House Sparrows.[29]

Fungal Infections

Candida albicans

Identifying candida in fecal swabs from passerines should be evaluated with caution. Many passerine species are fed bread products that are made with yeast. Yeast blastospores may pass through the gastrointestinal tract unchanged and appear in large numbers in the feces. These organisms do not reflect disease. Small numbers of candida blastospores may also be present as a part of autochthonous flora.

Candida albicans is occasionally associated with upper gastrointestinal tract infections in passerines, particularly in immunosuppressed or hand-fed neonates. Vomiting, anorexia, weight loss and diarrhea are characteristic findings. The lining of the crop may be thickened and covered with whitish "turkish towel" coating (see Color 14). Yeast blastospores or hyphae may be identified on Gram's stain of material from a crop wash. Systemic candidiasis has also been reported in canaries.[17] Nystatin or ketoconazole may be useful in infections confined to the gastrointestinal tract (see Chapter 15).

Aspergillus spp.

Aspergillosis may cause weight loss, respiratory distress, anorexia, vomiting or diarrhea in infected passerines. Immunosuppression, usually from malnutrition, along with contaminated environmental conditions are primary factors in the development of the disease. Captured free-ranging birds are often stressed, suffering from poor nutrition and kept in unclean surroundings with decaying organic material. It is not surprising that aspergillosis occurs under these conditions. Aspergillosis is also a common postmortem finding in sporadic deaths in free-ranging passerine birds. A granulomatous form of this disease occurs in which nodules varying in color from yellow to white may be seen in the liver, lungs, kidneys, muscles and subcutaneous tissues. Most Passeriformes should be considered susceptible.[57]

Aspergillosis was a major cause of mortality in hatchling Helmeted Honeyeaters. Mortality was controlled by nebulizing the birds with amphotericin B.

Captive mynahs are reported to be particularly susceptible to aspergillosis, possibly because of their moist, messy droppings and the tendency for these birds to be maintained in small enclosures[39,63] (see Chapter 35).

Cryptococcus neoformans var. neoformans

Respiratory or systemic cryptococcosis has been rarely diagnosed in passerine birds, even though the organism has been isolated from seed and droppings of canaries. It has been suggested that the fungus might persist from year to year on the wood of poorly cleaned enclosures. The organism has been associated with deaths in munia finches[53] (see Chapter 35).

Zygomycosis (Mucormycosis)

Multiple fungal granulomas have been identified in the lung, liver or brain in canaries and Gouldian Finches fed damp, germinated seeds (sprouts). Histologically, fungal hyphae are frequently associated with blood vessel walls.

Superficial Mycoses

Dermatomycoses are occasionally reported in passerines and generally cause as alopecia (especially of the head and neck) or hyperkeratosis. *Microsporum gallinae* and *Trichophyton* spp. are the most common etiologic agents, but other saprophytic fungi may also be involved. Whole body dermatomycosis has occasionally been seen in free-ranging Red Wattle birds (a type of honeyeater) presented at the author's practice. In one case, the client also developed dermatomycosis. Treatment with ketoconazole and griseofulvin provided some improvement but did not eliminate the infection. Topical baths with chlor-

hexidine and tamed iodine washes were irritating but they did lead to some improvement. One bird died when the owner attempted home treatment by applying a propylene glycol-based product over extensive areas of the bird's body.

Protozoa

Cochlosoma

Cochlosoma spp. are flagellates that inhabit the gastrointestinal tract of some finches. Bengalese Finches may be inapparent carriers of this organism; when they are used to foster species of Australian finches (such as Gouldians), they may pass the organism on to juveniles, causing high mortality in nestlings. Typical clinical signs include debility, dehydration and passing whole seeds in the droppings. At necropsy the intestine may be filled with a yellow suspension or whole undigested seeds. Most affected birds are six to twelve weeks of age.

The organism may be identified by direct wet preparation of fresh warm droppings or at necropsy using intestinal contents. Cochlosoma has six anterior flagella with a helicoidal, anterior ventral sucker.[38]

Treatment with ronidazole at 400 mg/kg in egg food and 400 mg/liter of drinking water for five days has been suggested. After a two-day rest period, the treatment is repeated. Dimetridazole may also be used at no more than 100 mg of active ingredient per liter of water for five days. Water containers should be disinfected and rinsed clean (the organism is sensitive to most common disinfectants) and the aviary should be kept clean and dry.[15]

Trichomonas

Trichomonas spp. infections are occasionally seen in finches, particularly those housed near infected budgerigars. Clinical symptoms include gagging, neck stretching, regurgitation, respiratory distress, nasal discharge, green diarrhea and emaciation. Diagnosis is made by identifying the flagellate on a wet smear prepared from a crop wash. At necropsy, caseous material may be seen lining the crop and esophagus, and flagellates may be identified from this material provided that it is fresh.

Giardia

Giardia sp. has also been reported to be associated occasionally with gastrointestinal tract infections in finches. Treatment is the same as for cochlosomiasis.

Coccidiosis

Coccidia infections in passerine birds may be asymptomatic or associated with diarrheal syndromes (sometimes with blood in the droppings), emaciation, general ill health and systemic disease. Systemic protozoal disease is occasionally diagnosed in avian species, but it is difficult to classify the causative organism based solely on histologic appearance. Fresh tissues for transmission studies, blood for serology and hematology and feces for parasitologic evaluation should be saved from patients where protozoal disease is suspected.

Coccidia in the Eimeriidae family have a single host. Development of the endogenous stages occurs within host cells to produce a resistant oocyst. Sporulation of oocysts usually takes place outside the host and oocysts of different genera have a characteristic number of sporocysts, each with one or more sporozoites[68] (see Chapter 36).

Eimeriidae genera affecting passerines include:

- *Eimeria* (oocysts with four sporocysts each containing two sporozoites)
- *Isospora* (oocysts with two sporocysts each with four sporozoites)
- *Dorisiella* (oocysts with two sporocysts each with eight sporozoites)
- *Wenyonella* (oocysts with four sporocysts each with four sporozoites)
- *Sarcocystis* (oocysts with four sporozoites)
- *Toxoplasma* and *Cryptosporidium* (same as *Isospora*, but sporocysts are usually found individually instead of inside membrane-like oocyst wall)

When examining fresh fecal material, it is often not possible to classify coccidial oocysts because sporulation may take several days to occur (see Chapter 36).

Atoxoplasmatidae are single-host coccidia with merogony in the blood and intestinal cells, gametogeny in the intestinal cells of the same individual and sporulation outside the host. This family contains a single genus, *Atoxoplasma*. Early work suggested that *Atoxoplasma* spp. could be transmitted between different bird species, particularly between House Sparrows and canaries, by an arthropod transport host (particularly the red mite *Dermanyssus gallinae*). More recent investigations have shown that these findings were incorrect, and that the parasite is transmitted directly via oocysts in the feces and that it is host-specific.[21,38,43,68]

Coccidia in Canaries

Oocysts from *Atoxoplasma* or *Isospora* spp. may be found in the feces of infected canaries. Isospora is less pathogenic and completes its life cycle within the intestines while atoxoplasma develops asexually in mononuclear blood cells and spreads hematogenously to other organs including the liver, spleen and lungs.

Canaries with atoxoplasmosis may be defined as having "black spot," referring to the enlarged, dark liver that is visible beneath the skin. Diarrhea, nonspecific illness and death sometimes occur. The organism can be diagnosed by identifying sporozoites on Giemsa-stained impression smears of the spleen, liver or buffy coat. The sporozoites are found in the cytoplasm of lymphoid-macrophage cells and appear as oval structures containing pink-staining chromatin. Indentation of the host nucleus often occurs (see Chapter 36). Table 43.4 is useful for differentiating between these two species.[20]

Sulpha drugs or amprolium are usually effective for *Isospora* sp. but *Atoxoplasma* sp. is resistant to treatment. Maintaining clean surroundings to reduce the birds' exposure to the infective oocysts may help control infections, but will probably not eradicate the organism from an aviary.

Coccidia in Other Passerine Species

Morphologically similar *Isospora* species of coccidia have been identified in over 50 species of passerine species throughout the world. This species has been named *Isospora lacazei* although it represents more than a single species. Many other morphologically distinct species of *Isospora* have also been identified. Life cycles are believed to be similar to *Isospora canaria*.[68]

Eimeria spp. generally follow the same pattern as *Isospora* and complete their life cycle in the intestinal tract. One species, *Eimeria grallinida*, has been described in a wild-ranging Australian Magpie-Lark in which the parasite was found in the liver. The affected bird had been found in a moribund state and died shortly thereafter. On necropsy, the bird showed marked hepatic enlargement with small white foci. Various stages of the life cycle including schizogony, gametogony and oocysts were found in the bile ducts. Sporulated oocysts were consistent morphologically with *Eimeria* sp.[60]

Coccidia of the genus *Dorisiella* have been identified in a number of passerine species including munias, avadavats, hawfinches and a Fohkein Grey-headed Crow Tit. Pathogenicity appears to be minimal. *Wenyonella* sp. has been recovered from Pied Wagtails in India.[68]

TABLE 43.4 Characteristics of *A. serini* and *I. canaria*

Characteristic	*A. serini*	*I. canaria*
Oocyst length	20.1 (13-23) μm	24.6 (17-30) μm
Oocyst width	19.2 (13-23) μm	21.8 (17-30) μm
Length:width	1.05	1.13
Prepatent period	9-10 days	4-5 days
Patency	10 ->95 d	5-18 d post-infection
Duration of infection	4 months	2-3 weeks

Sarcocystis

Sarcocysts are common in the skeletal muscles of passerines from many geographic regions. North American cowbirds, grackles and other Passeriformes have been shown to be the intermediate hosts of *Sarcocystis falcatula*, for which opossums are the definitive host. In Australia, sarcocysts are incidental findings at necropsy and a definitive life cycle has not been determined. Cysts can sometimes be observed through the skin.[33,38]

Toxoplasmosis

Toxoplasma gondii is occasionally identified in passerines and in isolated cases may cause death. In one outbreak, all 23 mynahs in a shipment died with visceral toxoplasmosis. It was postulated that the birds had been exposed to the organism at some time prior to shipment and that the stress of transportation had reactivated latent infections.[14]

Cats and other members of the Felidae family are definitive hosts for *Toxoplasma gondii,* and birds must ingest oocysts from cat droppings or visceral cysts from other animals in order to be infected. Feral cats in Australia have damaged native bird populations from direct killing and by spreading *Toxoplasma* sp. In one Tasmanian study, over 30% of free-ranging ravens were found to carry the organism. Carnivorous marsupials, many of which are threatened or endangered, are extremely susceptible to toxoplasmosis. If a free-ranging bird infected with toxoplasmosis is eaten by one of these species, the marsupial is likely to die. Birds infected with toxoplasmosis may be asymptomatic or show neurologic symptoms, ophthalmitis or sudden death. Such birds are easy targets for free-ranging carnivores. To avoid fecal contamination and the risk of toxoplasmosis, cats should be prevented from entering bird food storage areas.

Cryptosporidiosis

Cryptosporidium sp. has been associated with acute onset, severe diarrhea and death in a Diamond Firetail Finch. At necropsy the bird showed focal cuboidal metaplasia of glandular epithelial cells of the proventriculus and amyloid deposits at the base of the glands, as well as renal amyloidosis.[6] Proventricular cryptosporidiosis has also been identified in canaries with concomitant salmonellosis. Renal cryptosporidiosis has been diagnosed in a Black-throated Finch.[24]

Cryptosporidium sp. has a direct life cycle but oocysts have not been identified in the droppings of clinically affected passerines. The true clinical significance of the organism is not known, as it is often associated with other disease entities.

Blood Parasites

Blood parasites may be detected on routine screening of apparently healthy passerines, but they are occasionally implicated as the primary cause of disease or death. Life stages of the coccidian parasite *Atoxoplasma* sp. may also be seen in monocytes and lymphocytes. The occurrence of blood parasites varies from time to time and region to region. There is some evidence that the incidence of blood parasites in birds has decreased in some areas as a result of decreased numbers of invertebrate vectors.[4]

Passerine families reported to be most commonly infected with hematozoa in one European study included Paridae (tits, 8% affected), Sylviidae (warblers, 14% affected) and Turidae (thrushes, 10% affected). The most commonly encountered parasites included *Haemoproteus* sp. (4%), *Leucocytozoon* sp. (1.8%), *Trypanosoma* (0.9%), *Plasmodium* (0.8%), *Atoxoplasma* (0.2%) and microfilaria (0.1%). *Haemoproteus* sp. is also the most common blood parasite encountered in birds in North America and Australia.[4,43]

Other blood parasites that are occasionally seen in passerines include the small tick-borne erythrocytic parasites *Aegyptianella* and *Nuttallia* spp.

Plasmodium

Plasmodium spp., the cause of avian malaria, are mosquito-borne protozoa of the family Plasmodiide that occur worldwide. Sporogony occurs in the invertebrate host, schizogony occurs in erythrocytes and pigment is formed from the host cell hemoglobin. Each of the avian plasmodia has a limited host range but they do not appear to be particularly host-specific. *Plasmodium* spp. have been described in free-ranging wild tits, Fringillid finches, Old World warblers, thrushes, starlings, sparrows and in Australian magpies.[4,43]

The parasite has been associated with significant mortalities in Blue-faced Parrot Finches in the Taronga Zoo in Sydney. Free-ranging house sparrows are believed to have been asymptomatic carriers of the organism. No other species of captive birds at the zoo were affected. The parrot finches showed signs of lethargy, anorexia, labored respiration and death. A darkened, enlarged liver could be observed as a "black spot" through the skin and muscle of the abdominal wall. Treatment with chloroquine or pyrimethamine was successful in some cases but the birds did not have any lasting immunity and were susceptible to repeated infections. Controlling mosquito vectors is necessary to prevent infections. Avian malaria has also been reported to cause deaths in canaries and other species.[23,71]

Haemoproteus

Like *Plasmodium* sp., *Haemoproteus* spp. are found worldwide and are capable of infecting a variety of birds. Each species appears to have a limited host range but they are not particularly host-specific and generally cause only mild or inapparent clinical symptoms. Diagnosis is based on identification of typical pigment containing gamonts in erythrocytes. For most species of *Haemoproteus* the intermediate hosts are hippoboscid flies, biting midges (*Culicoides* spp.) or tabanids.

Passerine species in which *Haemoproteus* spp. have been reported are numerous and include mynahs, Fringillid finches, swallows, fly catchers, tits, sparrows, weaver finches, warblers and thrushes. In one outbreak, canaries were believed to have been infected following exposure to free-ranging house sparrows.[38,43,57]

Schizonts have a predilection for development in skeletal and cardiac muscle, lung and spleen. One form of schizont is sausage-shaped and often branches during development within capillary endothelium. Megaloschizonts may develop in the absence of circulating gamonts and reach sizes of up to 200 μm. Extensive myopathy and myonecrosis may be associated with intramuscular megaloschizonts (eg, commonly seen in free-ranging infected Pied Currawong around Sydney, Australia). These birds show multiple, yellow streaks in pectoral and other muscles, and most are presented thin, weak and unable to fly.[57] Treatment with antimalarial drugs

(chloroquine at 250 mg/120 ml drinking water for one to two weeks) may be useful. Orange juice may be added to the drinking water to make the drug more palatable.[71]

Leucocytozoon

Leucocytozoon spp. occur worldwide except for South America (where appropriate simuliid vectors are absent). These parasites may infect either erythrocytes or leukocytes. Parasitized cells are so distorted by the organism that it may be difficult to determine their origin. Pigment is not produced by leucocytozoon and schizonts do not appear in peripheral blood. Megaloschizonts can be found in brain, liver, lung, kidney, intestinal tissue and lymphoid tissue.

Most leucocytozoon infections are subclinical, although vague signs of illness and death were reported in infected Crested Oropendolas from a zoo in Florida. These birds hemorrhaged from protozoal cysts within hepatic and renal tissue. It was thought that the leucocytozoon may have been transmitted from free-flying black flies infected by feeding on local leucocytozoon-infected crows. The oropendolas, which had been trapped in South America, may have been particularly susceptible because of lack of previous exposure to the parasite.[52]

Leucocytozoon-like megaloschizonts have also been described in association with acute and fatal hepatocellular necrosis in canaries in Texas. Outbreaks of the disease were controlled with dimetridazole.[55]

Some other passerine species that have been reported to harbor *Leucocytozoon* spp. include Fringilid finches, swallows, tits, warblers, thrushes, starlings, blackbirds, canaries and lyrebirds.[38,43,57]

Trypanosoma

Trypanosomes are found worldwide but their incidence is low and they may only be found during summer months in temperate climates. Vectors are thought to include hippoboscid flies (*Ornithomyia avicularia*), red mites (*Dermanyssus gallinae*), simuliids and mosquitoes. Evidence suggests that the parasites may be transmitted by contamination rather than inoculative routes. Diagnosis is by finding the parasites on stained blood smears.[38] High prevalence levels of this parasite (8.3%) have been reported along the coast of the Baltic Sea in Europe.[72] Treatment is not warranted.

Trypanosomes have been identified in over 14 passerine families, including Fringillid finches and canaries, swallows, tits and pipits.[38,43]

Avian Piroplasmosis

Piroplasmosis is an important tick-borne infection that has been identified in many species of birds in the Mediterranean, Asia and Africa but it has not yet been found in Australia. *Aegyptianella* sp. is a rickettsial organism that appears as a small, signet ring-shaped structure in the cytoplasm of infected erythrocytes. Clinical signs of infection may include anemia, fever, lethargy and occasionally jaundice. Some passerine species in which piroplasmosis has been identified include crows, rooks, larks, sparrows and buntings.[38] Treatment with doxycycline or antimalarial drugs may be useful.

Filarial Worms

Microfilaria and adult filiarial nematodes (*Seratospiculum amaculata* and *Diplotriaena* sp.) have been reported at a low prevalence in a variety of species of passerines such as lyrebirds, Estrilid finches, honeyeaters, thrushes, grackles, sparrows and corvids. Most infections have not been associated with any disease and the parasites have been found incidentally in blood smears (microfilaria) or at necropsy (adults). *Splendidofilaria passerina* may be pathogenic in sparrows. Treatment is not generally warranted but levamisole may be useful.[38,43,57]

Internal Parasites

Acanthocephalans

Both adult and intermediate stages of acanthocephalan parasites may be found in free-ranging passerines. Adult worms are generally susceptible to benzimidazole anthelmintics. Genera affecting passerines include *Polymorphous, Plagiorhynchus, Prosthorhynchus* and *Centrorhynchus.*

The Superb Lyrebird, the largest passerine species, is a ground-dwelling inhabitant of rain forests in southeastern Australia. The acanthocephalan parasite *Plagiorhynchus menurae* has been identified in lyrebirds showing weakness, emaciation and respiratory distress. Duodenal necrosis has been demonstrated at necropsy. Invertebrates are postulated to be the intermediate hosts.[48,50]

Small cysts, 2 to 3 mm long and shaped like rice grains, may sometimes be found in the subcutaneous tissues of the neck and thorax in a wide variety of Australian passerine birds. These cysts are intermediate stages of the acanthocephalan *Oncicola pomatostomi*, the adult stages of which are found in the intestines of dingos and feral cats. The initial host is postulated to be scavenging insects.[50]

Cestodes

Because tapeworms require arthropods as intermediate hosts, they are predominately a problem in softbill and insectivorous finches. They are normally not seen in canaries or exclusively seed-eating birds (such as Gouldian Finches), except in situations where parent birds feed insects to their offspring or the insects are accidentally consumed with the seeds.

Many different tapeworms have been described in passerines but in most cases, infectivity levels are low, and the parasites cause no clinical disease. Emaciation, diarrhea, general debilitation and death may occur in birds that are stressed and are continuously exposed to infected intermediate hosts. Proglottids or hexacanth larvae may be noted on gross or microscopic examination of droppings, but these are passed only intermittently. Certain finch species, eg, parrot finches and Diamond Firetails, are particularly prone to developing intestinal obstructions from heavy *Choanotaenia* sp. infections. These high levels of infectivity are common in densely planted aviaries with compost heaps or other sources of infected intermediate hosts.

Tapeworms can be avoided by limiting access to intermediate hosts and by using insect-proof screening. Other sources of protein (such as commercially available formulated diets, insectivore mixes, egg food or grated cheese) may replace live invertebrates as food items. However, some birds may not accept these alternative foods and may die or be left susceptible to disease because of poor nutrition. Others will be reluctant to breed without live food or may desert their nestlings.

Effective anthelmintics for passerines include praziquantel and oxfendazole. In cases where it is not appropriate to prevent access to intermediate hosts, a regular deworming program will lower the infection rate.[18]

Trematodes

These parasites have complicated life cycles that typically involve snails as initial intermediate hosts and other invertebrates as secondary intermediate hosts. It is unlikely that appropriate conditions for completion of the life cycle will be found, except possibly in planted aviaries.

Trematodes are seen occasionally in wild-caught passerines.[38,50] *Collyriculum* sp. may be found encysted in the skin of birds. *C. faba* forms 4 to 6 mm cysts on passerine birds such as sparrows and starlings, as well as gallinaceous birds. These cysts have been reported to cause death in wood thrushes by obstructing the cloaca.

Schistosomes are trematodes that live in blood vessels. *Gigantobilharzia huronensis* is a blood fluke that has been reported in North American goldfinches and cardinals. It has also been experimentally transmitted to canaries.

Prosthogonimus sp. are trematodes affecting the intestinal tract, cloaca, bursa or oviduct. These parasites have been found worldwide in passerine species such as sparrows, corvids, starlings and thornbills.[38] They are not particularly pathogenic, and if clinical signs occur they are generally nonspecific. Dragonflies and snails are intermediate hosts. Praziquantel may be useful in treating trematodes.

Nematodes

- ***Ascaridia:*** Two main types of roundworms affect passerines: *Ascaridia* spp., which have direct life cycles, and *Porrocecum* spp., which have indirect life cycles with invertebrates such as earthworms as the intermediate host. Both types of roundworms may be associated with weight loss, diarrhea, general debility and sometimes neurologic symptoms. *Ascaridia* spp. are uncommon in passerines.

  Porrocecum spp. have been found in a variety of free-ranging passerines, for example pipits, quail-thrush, thrush, blackbirds, Australian magpies, currawongs and corvids. Fibrous tumors, believed to have been induced by larval *Porrocecum* spp. have been described in blackbirds on the peritoneal surface of the intestine.[38,50] Fenbendazole, piperazine and levamisole are useful in treating ascarid infections.

- ***Capillaria:*** *Capillaria* spp. are cosmopolitan in their distribution and affect a range of passerine species. The life cycle is direct or may involve earthworms as paratenic hosts. Susceptibility does not depend on dietary preferences, and the parasite has been found to cause disease in a variety of seed-eaters (such as canaries), insectivorous and omnivorous species (such as weavers, whydahs, jays and mynahs) and honeyeaters.

  Birds with low numbers of capillaria may be subclinical. Higher parasite loads may lead to weight loss, diarrhea, general ill health and death. These worms may localize to a variety of sites along the gastrointestinal tract. They may be associated with white or cream plaques in the buccal cavity or pharynx and swelling and lumen distension of the crop, proven-

triculus, intestine or bowel. Typical bi-polar plugs may be found by directly swabbing lesions or by fecal flotation.

Capillaria are often more difficult to treat than ascarids. Aviary hygiene and removal of earthworms are important control measures. Levamisole, fenbendazole and oxfendazole may be effective in some cases.

- ***Spiruroid:*** *Acuaria skrjabini* has been associated with significant mortalities in Australian aviaries housing both native and imported finches. This ventricular and proventricular worm parasite does not affect psittacine birds. The parasite lives under the koilin lining of the ventriculus, and characteristic embryonated eggs are passed in the feces. Attempts to identify intermediate hosts in this species have been unsuccessful, but other species of *Acuaria* are believed to be transmitted by arthropod vectors. The parasite is resistant to treatment with many common anthelmintics, but oxfendazole may be effective.

  Acuaria spp. have been reported in a variety of free-ranging passerines in Australia, eg, bushlarks, trillers, thrush, flycatchers, whistlers, shrike-thrush, honeyeaters, Australian magpies, currawongs and corvids.[50]

  Other spiruroid worms that occur worldwide and may be found in the proventriculus or ventriculus of passerine species include *Dispharnyx nasuata* (which has been described in the House Sparrow, starling, catbird and gallinaceous birds) and *Spiroptera incerta*. These worms have been reported to cause swelling of the proventricular mucosa and may inhibit the passage of food.[74]

- ***Eye Nematodes:*** *Oxyspirura mansoni* has been reported in mynahs, sparrows and other passerines. The parasite is found behind the nictitating membrane or in the conjunctival sac or the nasolacrimal duct. The intermediate host is the cockroach. Worms should be mechanically removed and any inflammation treated symptomatically. Ivermectin is effective.[36]

- ***Respiratory Nematodes:*** *Syngamus trachea* (gapeworm) affects a range of passerine species as well as birds from other orders. Corvids, starlings and blackbirds are particularly susceptible. Earthworms may act as transport hosts. Levamisole, ivermectin and fenbendazole are effective in treating this parasite, but caution should be exercised when treating birds with heavy infections. Tracheal obstruction may occur when the parasites are killed. Mechanical removal of worms and treatment with low doses of anthelmintics over several days is an effective therapeutic plan.

Arthropod Parasites

- ***Respiratory Mites:*** Respiratory acariasis ("air sac mite infection") caused by *Sternostoma tracheacolum* is a common cause of dyspnea, open-mouthed breathing and wheezing respiration in canaries and Gouldian Finches. "Air sac mites" is a misnomer given that these parasites are frequently found in the trachea, particularly near the syrinx. Occasionally, the mites may be visualized by wetting the feathers of the bird's neck with alcohol and transilluminating the trachea with a bright source of light. If mites are present, they may be visible as tiny, dark, moving, pinhead-sized spots. Failure to see the mites does not rule out their occurrence because the mites may be present lower in the respiratory tract.

  There are several options for treating this mite. Ivermectin may be used orally or topically. A dichlorvos pest strip may be placed (according to manufacturer's directions) near but out of reach of the birds. Birds may also be sprayed with pyrethrin synergized with piperonyl-butoxide insecticide spray.

  Other species of passerines apart from canaries and Gouldian Finches may harbor *S. trachaeacolum*, but they are less frequently affected and less likely to show severe clinical symptoms. Other species of *Sternostoma* mites have been recorded in passerines including *S. sialiphilus* in Eastern Bluebirds, *S. spatulatum* in Olive-backed Thrush and *S. cryptohyncheum* in sparrows. A nasal rhynonyssid mite *Speleognathus sturni*, which occasionally causes nasal discharge, has been recorded in starlings.

  Cytodites nudus is another mite that has been associated with respiratory disease in free-ranging passerines. It is much less common than *Sternostoma* sp. and may be found in the abdominal cavity as well as the respiratory system. Heavy infections have been associated with granulomatous pneumonia, peritonitis and obstruction of the respiratory passages.[38] Treatment is as described for other air sac mites.

External Parasites

Skin and Feather Mites

- ***Scaly Mites:*** *Knemidokoptes pilae* (and several other less common species) tend to cause hyperkeratotic lesions on the feet in passerines. This is in contrast

to infections in psittacine birds, which are primarily associated with beak lesions. Hyperkeratosis caused by scaly mite needs to be differentiated from generalized hyperkeratosis of the feet and legs that occurs with malnutrition and age in some canaries and other passerines (see Color 24). Scaly mite lesions start as crusts on the plantar surface of the foot and gradually get thicker. Flexion of the joints of the digits causes the thickening keratin to split and gradually enlarge, making it difficult for the bird to perch. Scaly mite lesions in passerines are sometimes referred to as "tassel foot" because of this characteristic appearance (Figure 43.14). European goldfinches and canaries are particularly susceptible to *Knemidokoptes* spp. but the condition has been reported in a wide range of Passeriformes (Figure 43.15).

Knemidokoptes spp. may be treated with topical ivermectin. A single dose may be effective in mild cases. A repeat dose three weeks later may be needed in more severe cases.

- ***Feather Mites:*** *Dermanyssus* sp. (red mites) and *Ornithonyssus* sp. (fowl mites) are not host-specific and may be found on a variety of Passeriformes including canaries, starlings and mynahs. These mites commonly cause irritation and anemia. Deaths have been reported with heavy infections in small birds. Nonpathogenic feather mites of a variety of genera (*Anlages*, *Megninia* and *Rivoltasia*) may also occur. Lightly dusting birds with pyrethrin or carbaryl powders may be effective. Placing the powder in a salt shaker and "lightly salting" is sufficient.

- ***Quill mites*** are not particularly species-specific and may attack both passerine and non-passerine species. *Dermoglyphus*, *Syringophilus, Picobia* and *Harpyhynchus* are genera that have been reported on Passeriformes. *Harpyhynchus* sp. has been associated with extensive dermatitis as well as cysts and skin tumors on hawfinches and a Lanceolate Warbler. Hanging a dichlorvos pest strip near birds affected with quill mites has eliminated the parasite in some cases. Treating the bird with ivermectin should be effective.

- ***Epidermoptic Mites,*** which may be carried mechanically by hippoboscid flies, cause a depluming dermatitis followed by scale formation (Figure 43.16). *Myialges* sp. (from a Blue Tit and Pekin Robin),

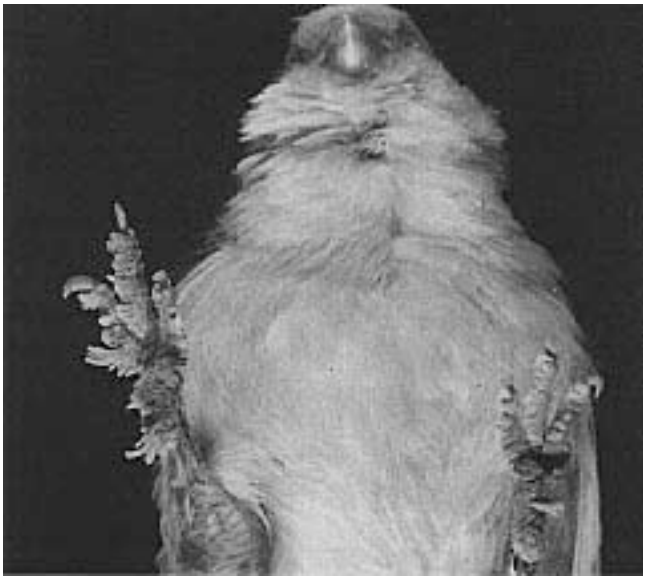

FIG 43.14 A mature female canary was presented with a three-week history of anorexia and lying on the bottom of the enclosure. The proliferative hyperkeratotic lesions on this canary's foot are characteristic for a *Knemidokoptes* sp. infection ("tassel foot") (courtesy of Terry Campbell).

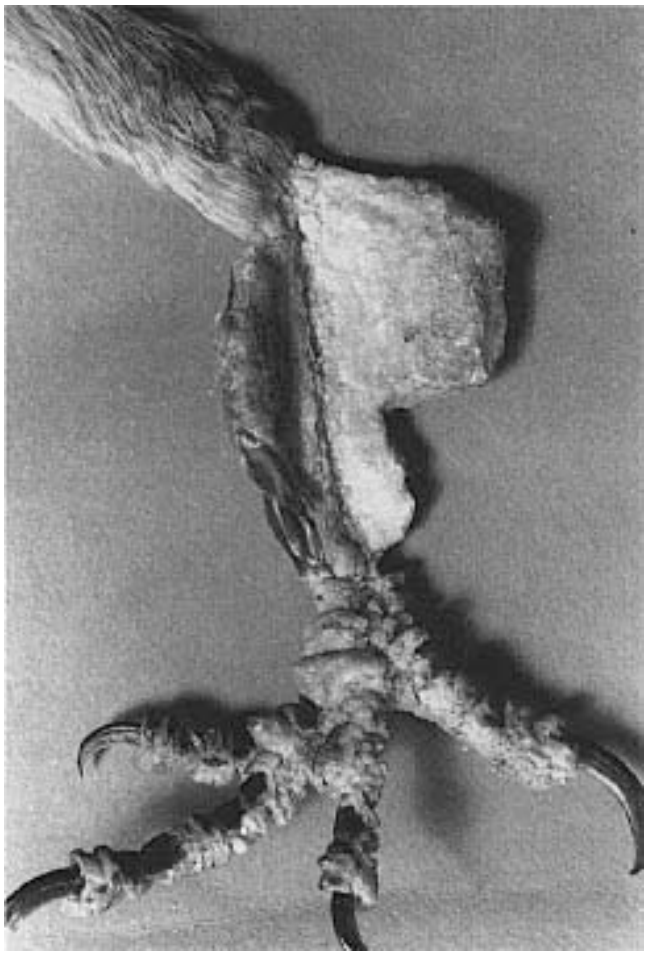

FIG 43.15 A group of several hundred robins died following the ingestion of pesticide-contaminated worms. Several of the birds had hyperkeratotic lesions on the feet and legs. These were confirmed to be caused by *Knemidokoptes* sp. by demonstrating the mite on skin scrapings.

Epidermotes bilobatus (from canaries) and *Microlichus avus* (from canaries, House Sparrows and mynahs) have been described in Passeriformes. Epidermoptic mites may be easily identified on microscopic examination of skin scrapings. Trombidiform mites of the genus *Neocheyletiella* have also been reported to cause depluming mange in canaries and Pekin Robins. Treatment options are like those described for quill mites.[38]

Lice

Lice are more common on Passeriformes than they are on Psittaciformes. Some of the genera of biting lice (*Amblycera*) that occur on passerines include *Colpocephalum, Menacanthus, Machaerilaemus, Mysidea* and *Rininus*. These lice are not specialized for life on particular feathers and are able to move quickly. Chewing lice (*Ischnocera*) are often specifically adapted to a particular part of the bird's body and are generally more sluggish than biting lice. Some genera that affect passerines include *Bruelia* (on canaries and House Sparrows), *Sturnidoecus* (on starlings and other passerines), *Degeeriella* and *Philopterus*. Signs of the presence of lice include restlessness and biting, excessive preening and damage to plumage. Some cases of baldness in canaries are caused by lice.

Lice undergo a complete life cycle on the bird, and a weekly dusting with pyrethrin is an effective method of control.

FIG 43.16 A number of external parasites including quill mites, epidermoptic mites and lice can cause skin irritation, pruritus and plumage damage.

Metabolic Diseases

Iron Storage Disease and Related Entities

Various Passeriformes species including Indian Hill Mynahs, Rothschild's Mynahs, quetzals, Birds of Paradise, Green Cat Birds and tanagers have been reported to be susceptible to excessive accumulation of iron in the liver.[28,30,59] In a group of 11 mynah birds that varied from five to ten years in age, clinical signs associated with hepatomegaly and ascites included a three-day to three-month history of listlessness, regurgitation, dyspnea, weight loss, diarrhea, coughing, wheezing and syncope. Most of the birds died within several days of presentation.[59]

Radiographs may reveal hepatic enlargement and ascites in affected birds. Liver enzymes are typically elevated while total serum protein is low. Diagnosis using biopsy is discussed in Chapters 13 and 20.

At necropsy birds may show an enlarged, congested liver which may be tan in color (see Color 20). Histologically the distinction is made between hemosiderosis, where there is no visible tissue alteration but an increased amount of hemosiderin, and hemochromatosis, where there are pathologic changes in the hemosiderin-containing tissues. Hepatic pathology may include congestion, focal necrosis, accumulation of inflammatory cells and fibrosis. Iron-processing cells are absent from the spleen and the spleen does not contain iron pigments.[28,30,34]

Neoplasia including lymphosarcoma, hepatocellular carcinoma and erythroblastosis has been associated with iron storage disease. The neoplastic cells do not contain iron.

Iron storage disease is believed to be associated with high dietary iron levels in avian species with problems in processing iron. Susceptible species should be kept on low-iron diets such as fresh fruit and commercially available formulated rations that are low in iron (less than 60 parts per million) (see Chapter 20).

Amyloidosis

Amyloidosis is common in Gouldian Finches and is occasionally seen in other Passeriformes species.[39] Affected birds may be found dead, have a chronic nonspecific history of illness or suffer from concurrent infections (polyomavirus, cryptosporidio-

sis). Social stress may play a role in the development of the disease. The liver and kidneys may appear normal at necropsy even though they may be severely affected histologically. More often they will appear pale and yellowish. A hereditary predisposition is suspected.[18,46]

Hepatic Lipidosis

Fatty livers are occasionally seen in Estrilid finches (Zebra Finches, parrot finches and Star Finches) and may be associated with inadequate exercise and high-energy diets such as soft foods and mealworms. The liver is swollen, yellow or tan in color and may float in formalin.[18] The use of some formulated diets may help resolve or prevent hepatic lipidosis.

Toxicosis

Canaries and finches are particularly susceptible to inhalant toxins because they breathe more air per gram of body weight than larger birds, and they have a highly efficient gas exchange system (see Chapter 22). Carbon monoxide exposure from any source (car exhaust, gas furnace leaks, kerosene stoves) can be rapidly fatal. There may be minimal changes at necropsy or the lungs and blood may appear bright red. Carbon dioxide poisoning may occur in crowded, poorly ventilated shipping boxes. Passerines, like psittacines, are very susceptible to the gases released from overheated polytetrafluoroethylene[65] (see Chapter 37).

Certain varieties of avocado may be toxic to some Passeriformes. Postmortem findings in intoxicated birds include hydropericardium and subcutaneous edema in the pectoral area.[32] Deaths have occurred in American Goldfinches after consuming green almonds, presumably from cyanide released by hydrolysis of amygdalin, a cyanogenic glycoside.

Ethanol toxicity has been reported in free-ranging passerines (especially Cedar Waxwings) following the ingestion of hawthorn pommes or other fruits that have frozen and then thawed allowing yeast fermentation of sugars to produce ethanol. Birds are lethargic, ataxic or may be in a stupor ("drunk"). Many intoxicated birds die from accidents that occur while they are "flying under the influence." Diagnosis is based on analyzing crop contents for ethanol concentrations.[19]

Heavy metal toxicities caused by the consumption of wire are uncommon in passerines because they have limited capacity to damage metal objects. Lead or zinc toxicosis has occasionally been seen when galvanized wire has been use in the construction or repair of enclosures. Heavy metal particles may be identified on radiographs, but most affected birds die quickly. Removing the source of heavy metals and administration of chelation therapy are recommended. The occurrence of "new wire disease" can be reduced by scrubbing galvanized wire with a dilute acetic acid solution and allowing it to weather before it is used for enclosure construction; however, even wire that is washed may still be toxic (see Chapter 37).

Neoplastic Diseases

Passeriformes have one of the lowest incidence of tumors of any order of birds or mammals. Neoplasms that have been regularly reported include leukosis in canaries, adenomas associated with poxvirus, papillomas in finches and neoplasia associated with iron storage disease.

COLUMBIFORMES

Curt Vogel
Helga Gerlach
Mait Löffler

Columbiformes are among the most ancient domesticated animals in the world. They were initially used as utility birds (meat, fertilizer and feather products), were later used for sport and as carriers of information, and more recently, as laboratory animals. The history of the domesticated pigeon starts in the early Stone Age, approximately 10,000 to 2,000 years B.C.[17] Pigeons can be termed cosmopolitan birds because, with the exception of the northern and southern polar regions, they occur on all continents and in all the countries of the world. More than half the species are native to Asia and Australia; the second highest number of species is found in the tropics of the Americas.[36]

Of special interest and importance is the Rock Pigeon, from which a whole variety of domestic breeds and color variations have been developed via mutations and recombinations throughout the millennia. Worldwide, millions of pigeon fanciers breed or keep more than 800 varieties of the domesticated pigeon, although the number of breeders of wild-type or nondomesticated pigeons and doves is still rather small.[16] Pigeon breeding is considered a hobby and, as such, provides pleasure and an interesting combination of genetics, behavior, physiology and endocrinology.

Zoologic Taxonomy

The order Columbiformes consists of 8 families, 67 genera and 296 living as well as 11 extinct species (including 3 species of the genus *Dodo*). The Passenger Pigeon, which populated the North American continent, became extinct in the last century. Other dove and pigeon species, particularly populations on small islands, are in danger of extinction.[1,36]

Domesticated Pigeons

Distinctive Pigeon Groups

The species Rock Pigeon is divided into 14 subspecies and is the original genetic stock for domesticated pigeons and for domesticated pigeons that have returned to the wild. These are called city or street pigeons or incorrectly, feral pigeons, and are considered a special variety. The number of these city or street pigeons worldwide is estimated at approximately 500 million. The so-called Field Pigeon, a direct progeny of the Rock Pigeon, became accustomed to humans during the sixth and fifth millennium B.C.[21]

There are at least 800 varieties of the domesticated pigeon globally. These can be systematically differentiated from the Rock Pigeon by body morphology, size and weight; deviations of the skeleton, musculature beak and cere; coloration and design of the plumage (in particular feather structure) and feather morphology; and breed-specific behavior.[33] Nine groups of domesticated pigeons have been distinguished (Table 44.1).[33]

Families of Columbiformes[36]

Caloenadidae	The Nicobar Pigeon is a large 38 to 40 cm bird that develops a mane (long, thin body contour feathers around the neck) and a short white tail. The color of the plumage is mainly a dark, coppery-shimmering green, which shows blue and black at the head and the upper breast. Nicobar Pigeons have a strong beak with small wart-like protuberances at the base. The beak is used to burrow into soil to forage for seeds and fruits. This species needs frost-free shelters for the winter.
Gouridae	The Blue-crowned Pigeon is a large 76 cm bird that may weigh more than 1 kg. A large, light-blue crest is characteristic. There are several subspecies, which show differences in coloration and in size. The beak of the male has a prominent hook, while that of the female is straight.
Otidiphabidae	The Pheasant Pigeon is a 38 to 40 cm pigeon with a relatively large tail. The bird's gait and colorful plumage are similar to those of pheasants. This tropical bird requires a warm environment.
Columbidae	These are true pigeons with 47 genera and 173 species. This is the largest group of pigeons and contains the best flyers. They may consume small seeds or large grains, depending on their body size, which ranges from 12.5 to 40 cm.
Duculidae	"Fruit-eating" pigeons range from 20 to 47 cm in size, live exclusively in trees, and appear awkward when ambulating on the ground.
Treronidae	Green Pigeons are 25 to 40 cm birds that are indigenous to high altitudes (2,500 m) where they inhabit trees in light woods and are occasionally found on the ground.
Didunculidae	Tooth-billed Pigeon

TABLE 44.1 Nine Distinguishing Characteristics of Groups of Domesticated Pigeons

- Colored pigeons, eg, German toys (These birds are selectively bred for coloration and plumage morphology.)
- Medium-sized varieties (with a body mass of up to 500 to 700 g)
- Heavy-sized varieties (with a body length of up to 55 cm, a wing spread of up to 105 cm, and body weight of over 700 g)
- Trumpeters (with their characteristic vocal expressions)
- Frillbacks, Fantails, Jacobins and Monks, Owls, Dewlaps and Swifts (each with a particular feather structure and design)
- Tumblers (These birds are considered flight sports breeds and represent the largest group with several hundred varieties worldwide.)
- Wattled Pigeons (They have a characteristic bulged, distended or wart-like cere, as well as more or less prominently developed naked or wart-like rings around the eyes.)
- Pouters (including the ringbeaters) with a singularly developed round, egg-shaped, pear-shaped or sac-like crop area, which varies according to the breed.
- Hen Pigeons (with their fowl-like body morphology and body posture.)

Pigeon Fanciers

There are several groups of pigeon fanciers whose interests and objectives differ.[33] In decreasing number of enthusiasts, these groups include: 1) the racing pigeon fanciers; 2) breeders of fancy pigeons for exhibition; 3) tumbler pigeons (high flyers, sustained flyers, flying tipplers, purzelers and rollers); 4) producers of meat pigeons (may be raised for individual consumption or as part of a large breeding facility) and breeders of wild pigeon and dove species.

Forty-two countries belong to the International Racing Pigeon Association (Fédration Colombophile International - FCI). There are almost 590,000 members and more than 20 million leg band registrations annually. With average flocks of approximately 50 birds, the FCI members would possess about 30 million pigeons.[33] In Europe alone, there are approximately 205,000 pigeon breeders who raise birds for exhibition and maintain approximately 6.6 million birds.[33]

Unique Characteristics of Columbiformes

Despite the many families, genera and species, which vary in size, weight, plumage and coloring, pigeons have some uniform features.[21,33]

The size of Columbiformes ranges from that of sparrows to that of chickens. They can move effectively on the ground and in the air. The birds have a droplet-shaped rump and an oval front. Their streamlined morphology and their closed plumage, which covers almost the whole body, reduces air resistance during flight and allows the air to pass around the aerodynamic body almost free of turbulence.[1] They have a relatively short neck, small head, small tail and four (in some species, five) short toes.

Columbiformes produce varied vocalizations including cooing, howling, buzzing, tittering or whistling sounds. A chirp-whistling noise is produced mainly by nestlings.[1] Pigeons may live 20 to 30 years.

Selected Anatomy and Physiology

Integument

A particular feature on the beak of the Columbiformes is the cere (ceroma).[16a,21,30]

The plumage of the pigeon does not have the powder down (plumae) found in many other avian groups. The powder found in pigeons is produced by modified semiplumes as well as downs (semiplumae), which can be generally called pulviplumes. Pulviplumes are distinguished from the small body contour feathers by their finer pennaceous barbs, which consist only of the upper part of the vane, while the lower part shows plumulaceous barbs that unfurl more slowly. Semiplumae are found in several genera of pigeons and doves, particularly on the sides of the body.

The powder is derived from cells that surround the differentiating cells of the barbules of a growing feather. They are not a fragment of the sheath or the feather itself. Powder is shed only while the feathers are emerging from their sheaths. Pulviplumes are characterized by a slow exsheathing process, decreased thickness of the rachis and increased reduction of the barbules, resulting in larger quantities of powder. The number of pulviplumes and the amount of powder produced vary significantly with the species.

The feather powder is composed entirely of keratin. The keratin particles inhibit abrasion of the feathers, provide the plumage its silky gray gleam and keep the ends smooth and pliable. The feather powder protects the pigeon from being waterlogged in the rain and from losing body heat in the cold. Powder enables the flight sport breeds to fly more quickly and with greater endurance. There also seems to be a correlation between high powder production and the reduction of the uropygial gland in some species and breeds.[16a]

The most highly modified powder feathers, the fat quills, are found in only some breeds of domesticated pigeons (ie, German toys such as the Nuremberg Swallows and the South German Shield Pigeons). Instead of powder, these feathers contain homogenous, yellow, organic fat. The fat is distributed throughout the plumage during preening, creating the “silky” appearance.[16a]

Frequent exposure to feather powder has been associated with allergic alveolitis (pigeon breeder’s lung) in some susceptible, genetically predisposed humans. The same pathogenesis has been determined for the feather powder coryza.[1a,32] Recent investigators working on a causative relationship between exposure to feather dust and human lung cancer misinterpreted the results, because of the failure to recognize that avian feather dust is not only created by companion birds but also by geese, ducks and chicken feathers in numerous pillows and quilts.

The uropygial gland is absent or poorly developed in many species and in some breeds of the domesticated pigeon.[21] The secretions contain the precursor of vitamin D. Most Columbiformes enjoy getting wet in the rain and bathing in shallow water. Other anatomic characteristics are the absence of a gall bladder and the presence of a highly rudimentary ceca.[1,21,30]

Vascular Plexus

The Columbiformes have an anatomic characteristic called the plexus arteriosus et venosus intracutaneous seu subcutaneous collaris. This plexus of anastomosing vessels extends from the cranium to the crop and base of the neck (Figure 44.1). It is divided dorsally into left and right portions, where it is separated by a 1 mm-wide gap in the median plane. The plexus is thicker (more vessels) in the male than in the female. The venous part of the plexus is composed of manifold twirled and tangled vessels that can be distended or narrowed. In scanning electron microscope pictures, the engorged blood vessels appear to be arranged like roofing tiles.

The plexus is used for sexual and territorial display and regulates circulation and body temperature in both genders.[6] The plexus engorges at high ambient temperatures to prevent hyperthermia through the dissipation of excess body heat through the skin. In flight, the head, underside of the wings, breast, legs and toes radiate heat. At temperatures over 25°C, surplus heat is also dissipated by hyperventilation. Injections in or damage of this plexus, especially during display and in hot weather, can cause fatal hemorrhage.

Gastrointestinal Motility

Gastrointestinal transient times vary with the species and amount and type of food but generally include crop (3 to 17 hours), ventriculus (5 to 19 hours) and intestine (9 to 14 hours).[1] The length of the intestinal tract varies depending on the species, composition of diet and amount and frequency of food consumed. Length ranges from approximately 35 cm in pygmy doves to 70 to 120 cm in domesticated pigeon varieties. Thus, the intestines are 2.5 to 3.5 times longer than the body. Fasted pigeons will defecate between 2.5 and 3.5 hours after consuming food. The majority of excrement (up to 80%) is produced within 24 hours, and the rest is excreted over three to four days.[1]

Physiologic Parameters

The body temperature of the Rock Pigeon and the descendant domesticated pigeon breeds and varieties is not as uniform as in mammals (eg, Wood Pigeon = 41.8°C, African Collared Dove = 41.0°C, Mourning Dove = 42.6°C).[11] The internal temperature varies with the state of excitement, vigor of flight and ambient temperature. The cloacal temperature averages 39.8 to 43.3°C. The diurnal body temperature varies by approximately 2°C.[1,31] During flight, the metabolic rate is increased to 10 to 12 times the basal

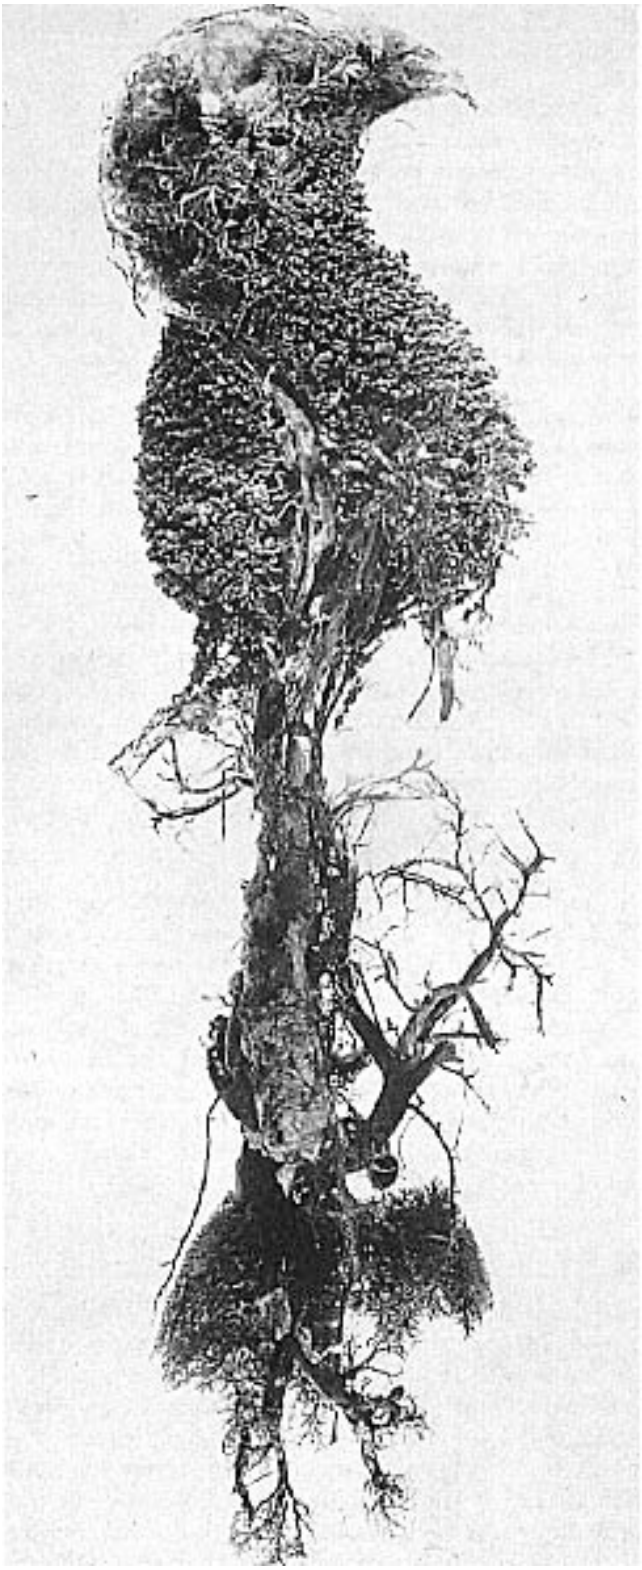

FIG 44.1 Latex cast of the vasculature of a male pigeon demonstrating the plexus arteriosus et venosus intracutaneous seu subcutaneous collaris. Note the extensive network of anastomosing vessels. This plexus is involved in territorial displays and thermoregulation (courtesy of D. Brückner[6]).

level and the body temperature increases by about 1.5 to 3°C.

In Rock Pigeons and domesticated pigeons, there is a thermo-neutral zone between 25 to 30°C where the regulation of the body temperature between 39.8 to 43.3°C is almost independent of changes in the ambient temperature. These pigeons can withstand extremes in ambient temperature of 42°C to minus 40°C. Resting pigeons begin to shiver at an ambient temperature of approximately 20°C, independent of whether or not they have adapted to the cold.

The heart rate of Rock and domesticated pigeons ranges from 180 to 250 beats per minute; the respiratory rate is 20 to 35 breaths per minute.[30] During sustained flight, the heart rate may reach 5.2 to 6.2 beats per second with a high of 9.4 beats per second at the time of take off.[1]

The blood volume of pigeons is approximately 0.1-0.01 ml/g body weight.[30] The prothrombin time, which is a sensitive indicator of hepatopathies, is 15.1 minutes (range of 11.5 to 18.7) for undiluted pigeon plasma. Pigeons generally have a lymphocytic blood differential. Hematologic and clinical chemistry values are listed in the Appendix.[11,17] Electrocardiographic data are provided in Chapter 27.[19,35]

In contrast to most avian species (except hummingbirds and some finches), pigeons and doves drink water by placing the beak up to the nares in water and sucking it up like a vacuum pump. The drinking cycle consists of combined mechanisms of the beak tip, tongue, palate, laryngeal mound and the pressure differences that occur in the anterior and posterior oropharynx while drinking.[37] With each drinking cycle, domesticated pigeons ingest approximately 0.6 ml of water.

Behavior

Although considered the international symbol for peace, pigeons and doves are by no means docile creatures.[1] Columbiformes are rather aggressive, particularly during the reproductive cycle, and have no behavioral inhibitions against killing members of their own species or their offspring. In free-ranging birds, one of the combatants can usually escape, which is not always possible in captivity. This behavioral trait should be considered when designing flight enclosures and constructing lofts. Birds should always have a place that they can use to escape from an aggressive male. Many pigeon and dove species can also be aggressive toward other avian species.

Homing Abilities of Racing Pigeons

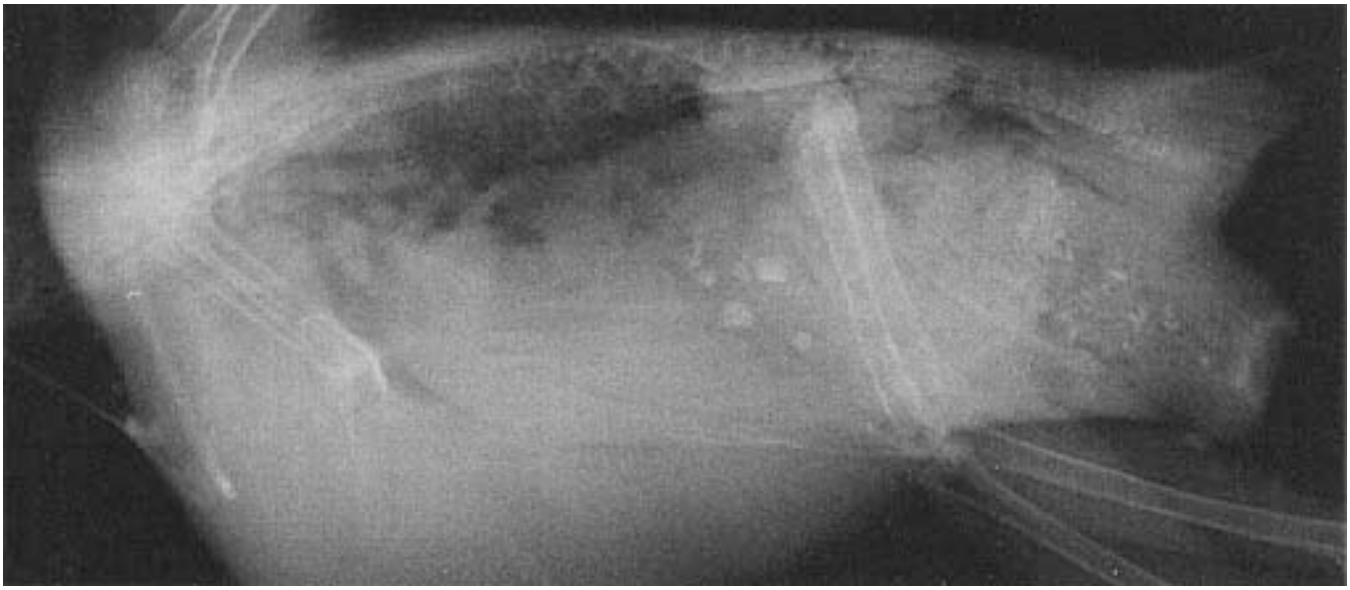
Only racing pigeons have an innate homing ability that has been enhanced through selective breeding and continuous training.[34] Their capacity to return home is based on special senses that enable them to determine the direction of home as soon as they are released. Their methods of navigation detect each divergence from the correct course immediately.[27]

Three distinct parts of the orientation system have been defined in pigeons and migratory birds: the inborn magnetic compass, the acquired sun compass and the star compass (not in homing pigeons).[1,13,15,26,27,28,33,34] The magnetic compass and the sun compass function independently, but they function together to monitor a bird's progress.[13,28] Probably a computer-like mechanism has stored a variety of data, which can be used for reaching the "home loft" target as well as finding the navigational data to get there. Four to five training flights can provide the necessary data.

Other important senses enable a bird to find its way home.[1,15] Homing pigeons can perceive infra-acoustic waves of below 0.06 Hz; they recognize ultraviolet light as well as the plane of polarized light; they sense small changes in air pressure of less than 1 microbar and altitude variations of only 10 m or less; they can detect small variations in the earth's magnetic field; they react to the slightest deviations in the earth's gravitational field.

According to recent findings, racing pigeons obviously do not rely on any one single sense to find their way home, but are assumed to use a combination of orientation factors.[15,33,34] Pigeons can see the sun even when it is invisible to human eyes. Pigeons react to polarized light and probably use this to indirectly determine the sun's position. They are particularly sensitive to the ultraviolet light spectrum and can detect polarized ultraviolet light even through heavy clouds.[15] On the other hand, it is known that homing pigeons are not able to navigate correctly under inverison layer air conditions.

Racing pigeons have iron oxide (magnetic particles) both in the cranium and in the neck musculature that may enable them to gauge the earth's magnetic field by means of special detectors that can recognize the density of the magnetic field.[15] It has been speculated but not proven that olfactory navigation is also of importance for racing pigeons.[1,8,13,15,18,26,28,33,34]



Husbandry

Nutrition

With the exception of fruit-eating pigeons (Duculidae) and green pigeons (Treronidae), the natural feed of other families (including the Columba) consists of the seeds of cultivated plants such as cereals, peas, beans, lentils and oil-fruit.[33] Many doves, free-ranging pigeons and domesticated pigeons feed on other cultivated plants, the seeds of weeds, green parts of many plants, berries and other fruits and animals (insects, snails, earthworms). In addition, they pick up small stones, grit and earth particles, which are necessary for grinding the seeds and other grains (Figure 44.2).[1,33] Domesticated pigeons have been observed to perform as many as 35,000 pick actions a day as a response to visual stimuli.[1]

Diets for pigeons should be rich in concentrated nutrients but should not contain high amounts of water or fiber. Effective formulated diets are readily available for domesticated pigeons[33] (nutritional requirements are listed in Tables 44.2-44.5). Commercially available mixed seeds used for many pigeon and dove species can be enriched by adding brewer's yeast, vegetables and vitamin preparations.[33] Pigeons that are allowed free flight will find additional foodstuffs and are usually well nourished.

FIG 44.2 An adult dove was presented for evaluation of progressive tenesmus of several days' duration. Physical examination indicated a firm mass in the caudal abdomen. Radiographs indicated that the cloaca was impacted with a granular material. A large amount of straw, grit and excrement was removed from the cloaca (courtesy of Marjorie McMillan).

TABLE 44.2 Suggested Mineral Mixture for Pigeons (%)

Components	Breeding Pairs	Squabs
$CaCl_3$	84.79	61.32
Ca_2PO_4	9.21	31.58

Nicotinic acid (niacin) (mg)	3	1.5	35
Pantothenic acid (mg)	0.70	0.35	15

*Body weight
**Body weight approximately 500 g for a racing pigeon

The nutritional requirements and quantity of food consumed vary, based on species, body mass, season, climatic conditions (temperature, relative humidity), type of husbandry (free-flying or restricted to pens), stage of reproduction (egg or sperm production, incubation, raising squabs), stage of growth or molting, amount of exercise, type of feed (seeds, formulated diet) and method of feeding.[33]

The daily feed consumption of pigeons and doves is approximately 1/5 to 1/20 of their body weight. The feed intake of squabs ranges from 10 to 100% of their body weight, depending on their age. The daily amount of drinking water varies between 5 and 8% of the body weight.[1]

The feed quality is of the utmost importance. Grains, seeds or formulated diets should be stored in a dry, clean, pest-free location. Fungi, particular mycotoxins, feed mites and toxic seeds from weeds should be avoided.[33]

TABLE 44.4 Recommended Diet for Pigeons*

Component	Quantity per kg feed
Crude protein	30 - 150 g
Crude fat	20 - 35 g
Crude fiber	50 g
Metabolizable energy	12 ME
Methionine	3.5 g
Methionine and cystine	6.5 g
Lysine	8 g

Housing

When constructing lofts, it is necessary to consider particular requirements for individual pigeon varieties and the number of birds to be housed.[21-23] Breeds maintained for their flying ability must have the opportunity to fly freely in order to maintain a proper level of health.

Optimal environmental conditions increase the productivity, performance and health of Columbiformes of all species and varieties. The housing (lofts, dove-

cots, aviaries, pens and flypens) criteria for pigeons are listed in Table 44.6. Pigeons must be protected from raptors, cats, dogs, foxes, opossums, raccoons, skunks, martens, weasels and rats.[21]

Pigeon lofts or dovecots should be partitioned so that several pens are provided.[21-23] There should be an entrance room that can be used for storing the necessary equipment, tools and feed, as well as one or more pens for breeding pairs.

For tumblers and other flight sport breeds, room should be provided for the bird's flight training (the exact specifications can be requested from local breeder associations for those breeds). Each loft should have compartments for newly weaned birds. Excrement should be removed on a routine basis or the birds should be placed on gratings (steel bar, metal lattice or rip-wire frames) so that the feces can drop through the grate.

Many countries require that domestic pigeons be kept indoors during certain times of the year. In the northern geographical regions, this period extends from April and May, when the cultural grains are sprouting in the fields.

Preventive Medicine

For pigeons to be at the peak of health and performance, it is necessary to provide them an optimal environment. Practicing sound preventative medicine techniques is far superior to treating disease. Birds involved in racing may be exposed to infectious agents in the race basket and then bring these pathogens back to the flock. This necessitates an ongoing disease surveillance and management program. Pathogens are best recognized and treated before the breeding and racing season.

CLINICAL APPLICATIONS

Pigeon lofts should be equipped with:[16,17,33]

- Appropriate nests (single coops, double coops or batteries). The latter can be equipped for automatic fecal removal by means of a conveyor belt.
- Hoppers, aisle feed troughs or cafeteria feeders and small dishes for feeding mineral.
- Drinking vessels such as bottle fountains or float-valve fountains that work automatically.
- Baths.
- Multipurpose pens.

TABLE 44.6 Design Criteria for Pigeon Lofts

Floor area/kg body weight	0.25-0.5 m^2
Air space/kg body mass	0.25-0.5 m^3
Hourly air exchange/kg body weight	270-320 ml
Maximum content of dust	10 mg/m^3 air
Maximum content of toxic gases:	
CO_2	2000 ppm
NH_3	20 ppm
H_2S	10 ppm
Room temperature	5-28°C

Each bird in the loft should be visually examined daily to determine its overall state of health. Pigeons that appear abnormal should be isolated, observed and evaluated by an experienced avian veterinarian. Birds that cannot be treated are euthanatized immediately and submitted for a complete veterinary and laboratory examination.

Good hygiene demands that excrement and discarded food be removed from the loft and flypens daily. Drinking containers, hoppers, cafeteria troughs and gutters should be thoroughly cleaned at least three times per week or better, daily.

Lofts should be designed with well drained concrete floors to facilitate proper cleaning and disinfection. The concrete floor can be covered with clean litter, sand, gravel or grasses planted in removable flat boxes. If natural soil is used as a floor, excrement should be removed regularly. The upper layer should be removed and replaced with sand or gravel once a year. Flypen floors covered with grass should be cut regularly and the clippngs discarded. The lawn should be chalked with unslaked lime, and holes in the surface should be reseeded.

Recently purchased birds must be placed into quarantine before being added to the flock. This includes birds with veterinary certificates stating that they are free of the most important pathogenic agents. There are many pathogenic organisms, particularly viruses, chlamydia and salmonella, which are not regularly excreted and are not always recognizable by antibodies. Therefore, sentinel birds, preferably very young birds, are placed together with the new ones in the quarantine room. If the sentinel and quarantined birds remain healthy for eight weeks, they can be introduced to the flock.

Any free-ranging pigeons that appear in the loft should be isolated immediately, provided food and water and then released. Birds that do not leave should either be treated according to legal regula-

tions or, if these do not exist, euthanatized or placed into quarantine.

Substandard environmental conditions increase the possibility of microbial enrichment and impair the bird's defense mechanisms.

Factors that may increase a pigeon's susceptibility to disease include:[21,22,33]

- Aviaries, lofts and flypens that are overcrowded, too small, dark, insufficiently ventilated, have accumulated toxic gases and dust, and are not kept clean.
- Equipment and supplies that are not kept clean.
- Feeding birds from impractical hoppers or cafeteria troughs.
- Drinking vessels that are difficult to clean and disinfect and hold stale, dirty water or none at all.
- Litter contaminated with too much feces may be either moist (fungal spores) or dry (dust).
- Squabs weaned too early or fed insufficient quality or quantity of food.
- Failure to separate the weaned squabs from the parents.
- Nutritional deficiencies and food contamination with mycotoxins or feces from insects and rodents.
- Overexertion of birds during the flight and race season and exhibition periods.
- Transport baskets and carriers that are dirty and poorly ventilated.
- Immunosuppression caused by viral, bacterial, fungal, parasitic, toxic or metabolic diseases as well as corticosteroids, some antibiotics, coccidiostats and chemotherapeutic agents (see Chapter 5).
- Corticosteroids should be considered highly immunosuppressive (not only in pigeons).

Special Management Considerations

During the Racing Season

During the racing season (May to September in the northern hemisphere), active racing pigeons should have a veterinary certificate indicating that they are clinically free of salmonella, helminths and other contagious agents. The veterinary certificate should be based on clinical examinations and laboratory testing. Many organizations in Europe request that pigeons be vaccinated against paramyxovirus-1-pigeon.

Young birds should be properly conditioned before they are entered in races. This is accomplished by gradually increasing the flight distance without causing the birds to overexert themselves. Racing pigeons that return from strenuous flights should be provided energy-rich foods and a mixture of electrolytes, glucose and amino acids. Many racing pigeon fanciers feed their own preparations, which are usually kept secret. Racing pigeons that return very late to the loft or appear weak without any obvious reason should be isolated and may be reintroduced to the flock only after successfully passing through quarantine. Birds involved in races should be considered exposed to infectious agents.

The transport baskets and boxes should always be cleaned and disinfected following each transportation. It is imperative that these containers be kept extremely clean to prevent the transmission of infections. Shipping boxes for racing pigeons should offer adequate space for each bird. Only birds that are in excellent condition should be flown. Racing pigeons should be transported to their release destination as quickly as possible. Birds being shipped long distances should be provided food and water and should have at least a three hours' rest before being released.

Prior to the Breeding Season

Fecal samples should be collected from pigeons in all lofts, compartments or flypens and evaluated for bacteria (salmonella) and parasites (coccidia, helminthic eggs) prior to the breeding season (January and February in the northern hemisphere). Groups in which salmonella, protozoa or helminths are identified should be treated. Between treatments, the loft, flypens and all equipment should be cleaned and disinfected as dictated by the respective agent.

Vaccination with avian paramyxovirus-1-pigeon is recommended, and in appropriate regions, vaccination with pigeon poxvirus should also be considered. The latter is usually administered in the late summer but should be available on all appropriate occasions. There is still no efficacious vaccine for *Salmonella typhimurium var. cop*. A vaccine against pigeon herpesvirus is available commercially in Hungary, but the effectiveness of this vaccine remains undetermined.

During the Breeding Season

Approximately two weeks before the first clutch of eggs hatches, all breeding pigeons should be treated with carnidazole, dimetridazole, metridazole or ronidazole to control trichomoniasis. One tablet of carnidazole might be an effective treatment. The tablet should be administered into an empty crop to reduce

the chances of regurgitation. For large flocks, a second prophylactic treatment for trichomonas is recommended from mid-April to the beginning of May. A breeding pair with massive trichomonas should be retreated two weeks before the subsequent clutch hatches. Trichomoniasis should be considered a secondary disease, and the initiating factors that allow an infection to occur should be identified (see Chapter 36).

During the warm season, it is especially important to observe pigeons and their environment for ectoparasites, in particular the red mites, northern feather mites, pigeon ticks, bed bugs, pigeon bugs, pigeon flies and chicken and pigeon fleas. Many of these parasites are found on the birds only at night. If necessary, the animals and their environment should be treated with carbaryl powder or pyrethrin.

Squabs should be placed together in compartments immediately after separation from their parents. If necessary, the weaned squabs should be tested for bacteria (particularly salmonella) and parasites as well as for antibodies against paramyxovirus-1-pigeon. If necessary, the youngsters should be vaccinated.

In the northern hemisphere, all young racing pigeons should be vaccinated for pigeon pox around the end of July. The breeding pairs should be separated from each other at the end of the breeding season.

During the Non-breeding Season

Pigeons that will be involved in exhibition should be removed from the nesting area at the beginning of September to induce an undisturbed molt. During the main molt period, pigeons should be provided food that is high in energy, essential amino acids, minerals, trace elements and vitamins.

Until the middle of October, pigeons for exhibition are separated by gender and are allowed to fly free in segregated groups. Most exhibitors require a veterinary certificate indicating that the birds are free of salmonella and parasites; some also require vaccination again for paramyxovirus-1-pigeon.

A complete physical examination should be performed on each breeding pair and their offspring. Any bird that does not meet breeding target or that is determined to be abnormal should be removed from the flock.

Reproduction

All Columbiformes are monogamous. They differ substantially from gallinaceous birds in reproductive characteristics. In contrast to chickens, female pigeons must at least be able to see a sexual partner for egg production to occur. If a male is not present, another female or a mirror image may stimulate ovulation.

Most of the Columbiformes construct a nest consisting of twigs or similar material in trees, shrubs or other hiding places. Some particular genera are cavity or ground breeders. The Nicobar Pigeon will nest in colonies. The design of enclosures for breeding pigeons should provide a dry, warm, draft-free area.

Pigeons generally are sexually mature by four to six months of age and will select a mate for the breeding season. Pigeons generally breed from spring to late summer when they stop oviposition and enter the main molt that lasts several months. Breeding may start again in late winter. In temperate areas, pigeons may produce offspring year round.

The females of large species lay a single egg; medium-sized species, two and small species occasionally three. Domestic female pigeons lay two eggs, the first at about 5:00 p.m. on one day, and the second approximately 40 hours later (ie, at 2:00 p.m. two days later).[1] Incubation periods and weaning ages are listed in Table 44.7. The hen and cock share incubation duties and two eggs hatch after 17 to 19 days of incubation. The female incubates from the late afternoon until morning, and the male sits on the nest for the rest of the day. The offspring are fed by both parents.[4,5,12,23,24] Information on all stages of embryonal development is still incomplete.[25]

Production of Crop Milk

For two weeks before the squabs hatch, the mucosa of the crop in the hen and the cock proliferates, producing increasingly large amounts of exfoliated crop epithelial cells known as “crop milk.” Columbiformes feed their offspring exclusively “crop milk” for the first days of life and as a supplemental food until they are 16 days of age.

Crop milk is a holocrine secretion of the epithelium of the crop and consists of 75% water, 12.5% protein, 2.5% non-protein, 8.5% lipids and 1.5% minerals. In addition, it contains all essential amino acids, fatty acids, gammaglobulins (IgA), vitamins, minerals and trace minerals. Carbohydrates are present only in small amounts, if at all.[1] Recent research has shown that crop milk is essential for squabs and cannot be replaced by other material, at least not during the first six days of life. Artificial incubation of pigeon eggs is simple; successful hand-feeding remains difficult.

Crop milk is formed in pigeons under the influence of prolactin. The changes in the epithelium of the crop that allow the production of crop milk can be demonstrated microscopically starting on the sixth day of brooding.[1] In the domestic pigeon, the proliferation of the crop epithelium is macroscopically distinguishable by the twelfth day of brooding. The crop wall is thickened ten to twenty times (1.5 to 3 mm) its normal thickness (0.15 mm) and may appear hyperemic.

The offspring of pigeons and doves are considered to be particularly fast-growing vertebrates. Their body mass doubles within 34 hours following hatch, and their growth curve is steep.[31] Both genders of domesticated pigeons reach sexual maturity as early as 120 days of age. The thyroid gland governs molting patterns in the squab, which start around the 50th day of age, and are completed by the sixth or seventh month when the bird is fully grown.[1]

TABLE 44.7 Incubation Period and Fledging Age for Pigeons (in days)

Common name	Incubation Period	Fledging Age
Nicobar Pigeon	28-30	90
Blue-crowned Pigeon	28-30	28
Domestic Pigeon	17-18	21-28

Banded Imperial Pigeon	18	14-16

Gender Determination

Only a few of the Columbiformes, eg, the Namaqua Dove, Plain-breasted Ground Dove, Emerald Dove, Luzon Bleeding-heart Dove and the Galapagos Dove, are sexually dimorphic. In these species, the males are noticeably larger than the females.

With most other Columbiformes, including the domesticated pigeons, there are few differences between the secondary sexual signs in the male and female. The sexes cannot always be distinguished with certainty by body size or morphology, the shape of the head, cere or neck, or by differences in specific behavior. Evaluation of differences in the structure of the cloacal lips according to the Japanese method[21] for gender determination has been shown to be ineffective in practice. Endoscopy might be necessary for definitive determination of gender (see Chapter 13).[19]

Gender can be determined in most Columbiformes using a modified nose speculum to examine the inside of the cloaca.[21] The lateral part of the speculum is ground off and smoothed so that the ends are only 17 to 25 mm long and 3 to 5 mm wide. To perform this procedure, the bird is held in a vertical restraint position with the head upside down and the feet toward the examiner. The speculum is inserted carefully about 1 cm into the cloaca (depending on the size of the bird), then opened and slowly advanced dorsally and cranially. The cloacal lips widen and some of the internal cloacal structures become visible. The female is identified by visualization of the orifice of the oviduct on the left side, while the male has bilateral papillae where the vas deferens open into the cloaca. This method of gender determination is reliable for adult birds, but less so for younger pigeons. Injection of either testosterone or follicular hormones has been suggested in juveniles to improve the success of cloacal gender determination. However, considering the accuracy and safety of endoscopy, the use of therapeutic agents that could alter a bird's natural development is not encouraged.

FIG 44.3 A pigeon was presented with conjunctivitis and a mass in the lower eyelid. Cytology of a fine-needle biopsy indicated that the mass was characterized by epithelioid cells packed with acid-fast rods, suggestive of *Mycobacterium* spp. (courtesy of Helga Gerlach).

Artificial Insemination

Managing the Male

The best males to use for semen donors are mature birds that are with hens eight days before, or up to four days after, egg laying. Two people are required for collecting the semen. One person restrains the bird upside down with the tail toward the examiner. The other person holds a Pasteur pipette in one hand, and the tail is lifted up and held between the thumb and index finger of the same hand. The opening of the cloaca is literally pressed together to push the spermatozoa out of the papilla of the ductus deferens.

This pressure also causes blood plasma to pass from the capillaries under the cloacal epithelium. This blood plasma collects in the median part of the cloaca and combines with the spermatozoa to produce 0.1 to 0.2 ml of semen.

Managing the Female

The most suitable females for artificial insemination are those that have been sexually stimulated by a sterile male.[2,33] Males are sterilized by transecting the ductus deferens, which are visible as meandering whitish cords between connective tissue folds of the peritoneum (cave ureters) (see Color 13). The cranial end of the transected vas deferens should be permanently closed with an ethicon clip to prevent the spermatozoa from being released into the abdominal cavity. Spermatozoa are still produced following sterilization and may initially occlude the seminal duct and vas deferens. The accumulated spermatozoa will eventually be phagocytized by leukocytes.

The collected semen is used to directly inseminate the female. The oviductal mucosa contains glands that store sperm and keep it viable for several days. Insemination is best performed around 8:00 p.m. four days before the first egg of a clutch would be laid. This method maximizes the chance that any eggs produced will be fertilized. Insemination is achieved by restraining the hen in the same manner as described for semen collection. An assistant opens the proctodeum with a short vaginal speculum. The orifice of the oviduct is identified on the left side of the urodeum, and should not be confused with the opening of the cloacal bursa or the entrance to the coprodeum.

The salpingeal orifice is relatively large in older hens but is difficult to visualize in young hens before the first egg has been laid. Two small papillae that represent the vestiges of the Wolffian duct can also be identified. These structures disappear shortly before the first egg is laid. Insemination is most successful if performed with undiluted ejaculate immediately or shortly after collection. The pipette is positioned relatively deep into the distal section of the salpinx and the semen is released, while simultaneously and slowly withdrawing the pipette. If properly performed, semen should not reflux into the cloaca.

Clinical Examination

The clinical examination might involve a single pigeon or the entire flock. The physical appearance of a healthy pigeon, examination procedures for the loft and examination procedures for the individual pigeon are similar to those described for Psittaciformes (see Chapters 2, 8). A bird's feathers should be carefully protected during the examination procedure. Damage to the feathers of a racing or exhibition bird can substantially affect their performance.

It is necessary to determine the breeds and color varieties, because some groups of pigeons are more susceptible to certain diseases. For example, the German toy pigeons, many pouters, trumpeters, frillbacks, fantails, jacobins, owls, tumblers, certain homers, strassers, kings and runts are very suscepti-

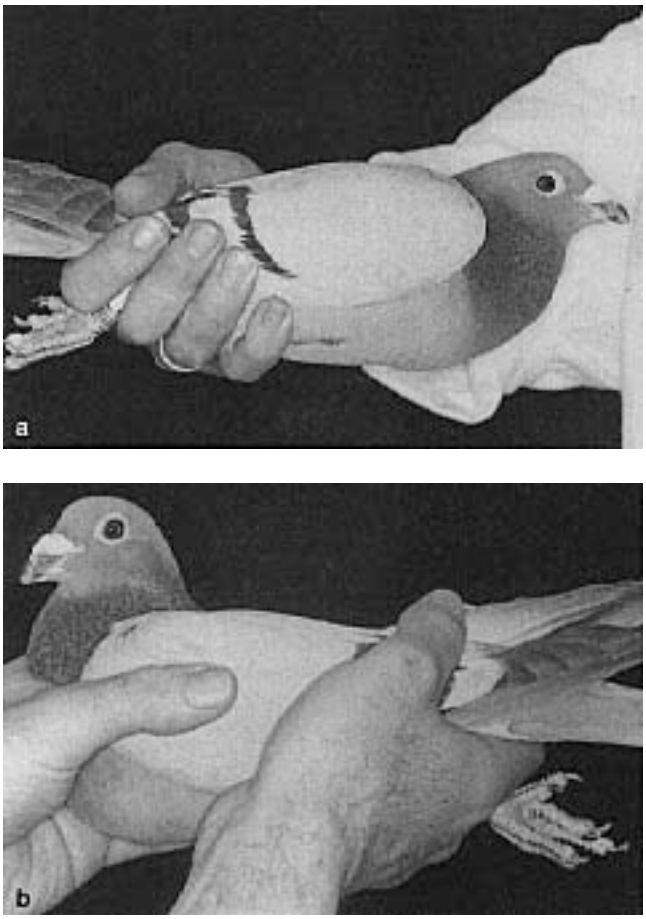

FIG 44.4 The basic method of restraint in Columbiformes is the horizontal hold. **a)** The bird's feet are stretched caudally and are held between the index and middle fingers. At the same time, the thumb and the other fingers fix the end of the wings and the base of the tail. The restrained pigeon lies flat in the inside of one hand. The other hand is free for examining the bird. **b)** Large pigeons may require both hands for proper restraint, and in this instance a second person is needed to facilitate the physical examination (courtesy of R. Korbel).

FIG 44.5 With a vertical restraint technique, the bird is held upright with the thumb, index and middle fingers placed at the end of the wings and the remaining fingers restraining the feet and base of the tail (courtesy of R. Korbel).

ble to salmonella and viral infections. Restraint techniques for Columbiformes are described in Figures 44.4 to 44.7.

Therapeutic Methods

The subcutaneous connective tissue of the caudal third of the neck is most suitable for subcutaneous injections. The skin near the base of the neck should be gently lifted to create a fold, and the needle should be directed strictly dorsomedian with a relatively flat cranial orientation.[39] The animal is restrained in the horizontal hold. The exact location of the needle is checked by injecting a small fraction of the drug and watching for a bubble of fluid in the tissue. The plexus arteriosus et venosus intracutaneous collaris must be avoided. Injection into this area can cause fatal hemorrhage. Infusing large volumes of fluid or injecting caudally can damage the clavicular air sac, the jugular vein and the vagus nerve. Large volumes of fluid can be administered into the subcutaneous connective tissue on the side of the thoracic wall and behind the wings.[39]

Pigeon poxvirus vaccines can be administered by feather follicle or wing web method. A feather follicle vaccine is applied by removing approximately ten feathers on the lateral thigh and rubbing the vaccine into the follicles using a brush provided by the manufacturer (Figure 44.8).[31,32,39] This method should not be used for emergency vaccination because field virus can infect the traumatized skin. The wing web method employs a puncture through the propatagium with a special needle provided by the manufacturer. Both methods should be used only as recommended by the manufacturer.[10,39]

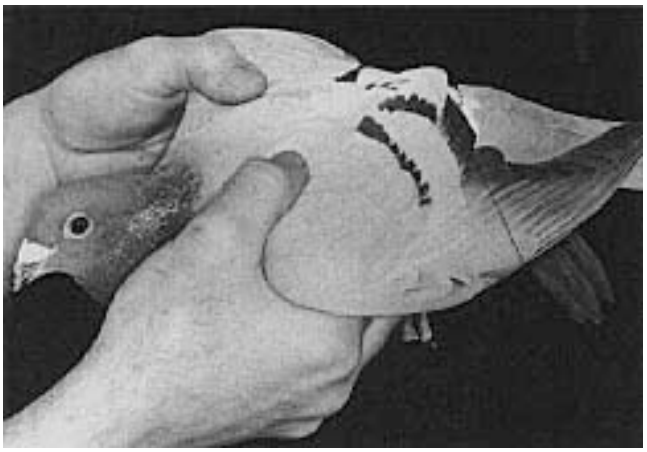

FIG 44.6 The wings are best examined using horizontal restraint. Another method for restraint when examining the wings is to hold both wings with the head facing the examiner. The thumb is on the upper surface of the wings, the other fingers on the lower side, and both wings can be palpated simultaneously. For examining the legs, the pigeon is held against the body of the person who is restraining it, and the hands press gently down on the body while the hind limbs are examined and compared between the thumb and index finger (courtesy of R. Korbel).

FIG 44.7 To examine the crop and neck region, the animal is restrained in one hand using the horizontal hold. The other hand is used to palpate the regions in question and to open the beak. This can be done by fixing the upper beak between the thumb and middle finger while carefully pressing down the lower beak with the index finger. It is easier, particularly with larger pigeons, if an assistant restrains the bird while it is being examined (courtesy of R. Korbel).

The iliotibialis muscle of the thigh is a good site for intramuscular injections in some pigeons or doves. The bird is restrained inside the palm of one hand, the head and the leg to be injected are fixed between the middle and index fingers, and the other leg is held between the ring and little fingers. The injection is administered at the middle of the femur, and the needle runs distally. The pectoralis muscle is used for IM injections in larger Columbiformes that require a higher injection volume.[39] The injection site is approximately parallel to the cranial third of the mediana sterni, close to the carina with a cranio-dorsal needle angle of approximately 70°. The needle must be advanced approximately 5 to 7 mm into the muscle, not too flat or too far laterally. Although the injection volume depends on the body size, it should generally be restricted to less than 0.5 ml. The smallest possible needle gauges that are compatible with the viscosity of the therapeutic agent should be used to prevent hemorrhage.

For intravenous injections, the ulnar vein or medial metatarsal veins can be used (Figure 44.9). Postvenipuncture hemorrhage can be reduced by using the thumb to tighten the propatagium at its insertion, directing the needle as far proximally as possible and releasing the propatagium before withdrawing the needle. This reliably prevents bleeding without the need to apply continuous compression.[39]

Anesthesia

General Anesthesia

Isoflurane is the anesthetic of choice for use in pigeons (see Chapter 39).[11,14]

Several protocols for injectable anesthetics have been suggested including the IM administration of ketamine hydrochloride (20 to 40 mg/kg body weight) in combination with diazepam (0.5 to 1.5 mg/kg body weight) or xylazine (2 to 5 mg/kg body weight).[14,11] The use of methomidate (10 to 20 mg/kg body weight intramuscularly) has also been reported in pigeons. However, the use of injectable anesthetics in pigeons is fraught with problems that include widely variable responses and levels of safety among patients.[9]

If injectable anesthesia must be used, it is best to use 25 mg/kg body weight ketamine hydrochloride together with 12.5 mg/kg body weight clamazolam IM.[9] Combined ketamine/clamazolam injection anesthesia has been shown to have minimal adverse effects on the physiologic regulation systems of the pigeon. An excitation phase will occur during the induction

FIG 44.8 Application of a feather follicle pox vaccine in a pigeon. The feathers from the medial area of the thigh have been removed, and the vaccine is applied to the follicles with a brush according to the manufacturer's recommendations (courtesy of Curt Vogel).

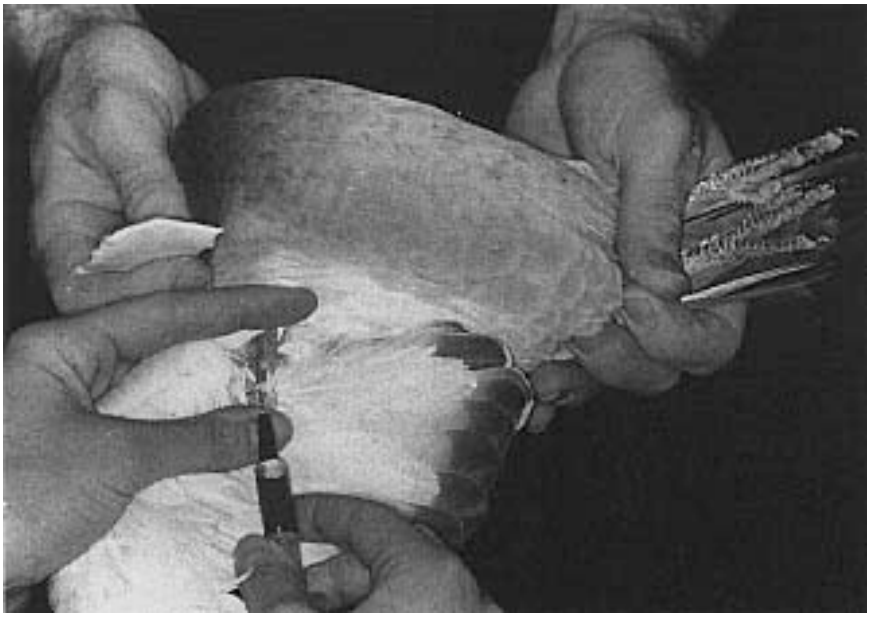

FIG 44.9 The ulnar vein can be used for blood collection or IV injections, but tends to hemorrhage more than the medial metatarsal vein. Using the thumb to tighten the propatagium before inserting a needle may help reduce post-cannulation bleeding (courtesy of Curt Vogel).

and recovery phases with this combination, but in general it appears to provide satisfactory restraint for about 25 minutes. There are no known anesthetic recovery problems. The recovery phase can be shortened to 10 to 20 minutes by administering benzodiazepine antagonists IV.

Local Anesthesia

Columbiformes are sensitive to many local anesthetic agents and may develop adverse drug reactions or die following the administration of 0.5 ml/kg of 2% procaine or lidocaine hydrochloride. Local anesthesia can be achieved with 1% procaine or 2% lidocaine hydrochloride with the addition of adrenalin 1:20,000. The addition of adrenalin increases safety, decreases absorption and prolongs anesthetic duration.[29] Local anesthesia is achieved within two to ten minutes of application.

Diseases

The primary disease problems are due to infectious agents. The corresponding clinical and pathologic features, as well as some suggestions for control and therapy, are mentioned in the pertinent chapters. Table 44.8 provides a checklist of infectious diseases. Noninfectious ailments are also discussed in other chapters.

Two special problems with pigeons should be mentioned here.

Pigeons frequently have trichomoniasis (canker) of the oropharynx and the crop as well as occasional systemic infections, which cause lesions in the liver, base of the heart and lungs. Native preparations (swab from the crop) for demonstrating trichomonas are taken for direct microscopic examination. One-half to one hour after collection of the sample, the agent will no longer be recognizable. With cooling down of samples or cadavers, the agent becomes invisible. Therefore, sending samples to a diagnostic laboratory is of no benefit.

In pouters, so-called sour crop (ingluveitis) is a common problem. Sour crops have to be emptied and

TABLE 44.8 Check List of Infectious Agents in Pigeons

VIRUS
Pigeonpox
Herpesvirus
– Inclusion body hepatitis in pigeons (syn. Infectious esophagitis)
– Contagious paralysis (syn. pigeon herpes encephalomyelitis)
Avian adenovirus
Avian parvovirus
Avian reovirus
Eastern and western equine encephalomyelitis
Venezuelan equine encephalomyelitis
Rubivirus
St. Louis encephalitis
West-Nil-Virus
Avian paramyxovirus, serotype 1
Newcastle disease, serotype 1
pigeon, serotype 7
Avian influenzavirus A
Avian retrovirus
– Type C retrovirus group (Avian leukosis-related viruses) including avian sarcoma and leukemia viruses
– Avian reticuloendotheliosis virus

CHLAMYDIA
Chlamydia psittaci

MOLLECUTES
Mycoplasma spp.
Acholoplasma spp.

RICKETTSIA
Coxiella burnetii
Aegyptianella pullorum

BACTERIA
Staphylococcus spp.
Streptococcus spp.
Mycobacterium avium-intracellulare
Erysipelothrix rhusiopathiae
Listeria spp.
Clostridium spp.
Enterobacteriaceae
Pseudomonas aeruginosa
Aeromonas hydrophila
Alcaligenes faecalis
Bordetella spp.
Campylobacter spp.
Vibrio spp.
Borrelia anserina
Pasteurella spp.
Actinobacillus spp.
Haemophilus spp.
Cytophaga anatipestifer (*syn. Pfeifferella, Moraxella, Pasteurella*)
Acinetobacter calcoaceticus

FUNGI
Microsporum spp.
Candida albicans
Cryptococcus neoformans
Histoplasma capsulatum
Aspergillus spp.

ECTOPARASITES
Argas spp.
– (*A. reflexus* = Pigeon tick)
Ixodes spp.
Dermanyssus gallinae
– Roost mite syn. chicken mite
Ornithonyssus
– Northern fowl mite
Syringophilus columbae
– Quill mite
Sarcopterinus nidulans
Cytodytes nudus
– Air sac mite
Laminosioptes cysticola
– Forms nodules within the subcutis
Neonyssus spp.
– In nasal and sinus cavities
Speleognathus striatus
– As above
Cheyletiella heteropalpa
– Feather mite
Falculifer spp.
– Feather mite
Megninia spp.
– Feather mite
Analges bifidus
– Feather mite
Hemialges anacentros
– Feather mite
Knemidocoptes mutans
– Scaly-leg mite
Neoknemidocoptes laevis
– Depluming scabies

FLUKES (Trematodes)
Echinoparyphium spp.
Echinostoma spp.
Hypoderaeum conoideum
Cotylurus cornutus
Ribeiroia ondatrae
Apatemon gracilis
Brachylaema spp.
Harmostomum spp.
Postharmostomum spp.
Cryptocotyle concavum
Amphimerus elongatus
Tanaisia bragai

ROUNDWORMS (Nematodes)
Ascaridia columbae and other *A.* spp.
– Common or large roundworm
Ornithostrongylus quadriradiatus
Trichostrongylus tenuis
Tetrameres spp.
Dispharynx nasuta
– Spiral stomach worm
Pelucitus spp.
– Filaria in the subcutis of the neck
Capillaria spp.
– Thread worms
Syngamus trachea
– Red worm syn. forked worm

INSECTS
Columbicola columbae
– Slender pigeon louse
Campanyulotes bidentatus
– Golden feather louse
Colocera spp.
– Little feather louse
Hohorstiella spp.
– Large body louse
Neocolpocephalum spp.
– Narrow body louse
Bonomiella columbae
Physconelloides spp.
Cimex spp.
– Bedbugs
Haematosiphon inodora
– Adobe bug
Oeciacus vicarius
Triatoma spp.
– Assassin bug
Ceratophyllus spp.
– Fleas
Echidnophaga gallinacea
– Stick-tight flea
Tenebrio molitor
– Yellow mealworm
Dermestes lardarius
–Larder beetle
Neocrophorus vestigator
Silpha spp.
– Carrion or Sexton beetle
Pseudolynchia canariensis
– Pigeon louse fly
Ornithomyia spp.
– Louse fly
Ortholfersia spp.
– Louse fly
Stribometapa podostyla
– Louse fly
Lynchia spp.
– Louse fly
Microlynchia pusilla
– Louse fly

TAPEWORMS (Cestodes)
Aporina delafondi
Choanotaenia infundibulum
Hymenolepis spp.
Raillietina spp.
Cotugnia spp.
Diphyllobothrium mansoni (only larvae)

PROTOZOA
Eimeria spp.
Toxoplasma gondii
Sarcosporidia spp.
Haemoproteus spp.
Plasmodium spp.
Leucocytozoon spp.
Trypanosoma hannai
Spironucleus columbae
Trichomonas gallinae

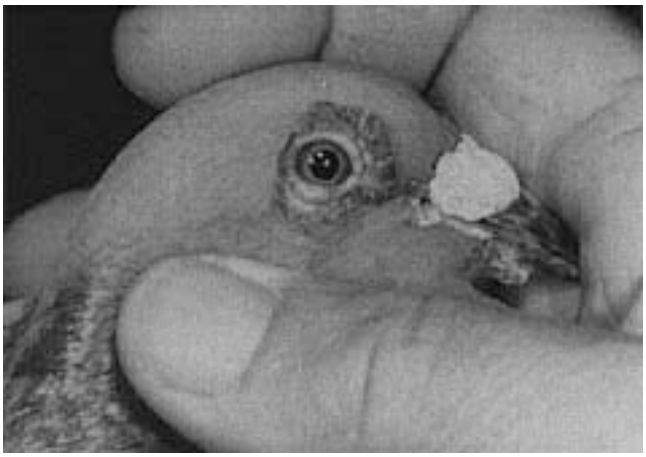

FIG 44.10 Mild conjunctivitis is characteristic of chlamydiosis in adult Columbiformes.

rinsed with saline at body temperature, possibly with some added antibiotic. Pouters must be fed in small portions to avoid overloading the crop. This is particularly important after transport, when the animals start eating again.

FIG 44.11 Poxvirus infections can cause high morbidity in some flocks. Squabs are particularly susceptible to the virus and may develop the cutaneous or diphtheroid forms of the disease. This squab had characteristic papules on the beak and oral mucosa.

CHAPTER

45

GALLIFORMES

Christian Schales
Kerstin Schales

Members of the order Galliformes occur on every continent except Antarctica. The Red Junglefowl, Common Turkey and Helmeted Guineafowl have been domesticated for centuries and are of considerable economic importance. Some varieties reach monstrous proportions and some members of the order, like the Japanese Quail and various pheasants, are approaching a level of complete domestication.

Many Galliformes are commonly maintained as game birds, some of which are stable in captivity, easy to breed and inexpensive. Other species are from niches with specific environmental requirements and need specialized diets, humidity or temperature to survive.

In this chapter, "domestic fowl" means *Gallus gallus, forma domestica* (domestic form of the Red Junglefowl); "domestic turkey" is *Meleagris gallopavo, forma domestica* (domestic form of the Common Turkey) and "domestic guineafowl" is *Numida meleagris, forma domestica* (domestic form of the Helmeted Guineafowl) (Table 45.1).

Maintaining, breeding, treating or dealing with gallinaceous birds may be regulated by laws that govern the protection of animals, property rights, exchange of goods, liability, epornitics, food for human consumption, hunting and (international) transport of animals.

Several gallinaceous birds have anatomic or physiologic peculiarities that should be discussed.[7] In the circulatory system, for example, most gallinaceous birds have right and left internal carotid arteries; however, the megapodes have only the right internal carotid artery.[28] The respiratory rates, heart rates and rectal temperatures of some gallinaceous birds are listed in Table 45.2

Anatomy and Physiology

Integument

Many gallinaceous species develop a durable, vascularized thickening of the corium in the ventral thoracic region called a brooding spot. The feathers in this region are temporarily lost, and body heat is transferred directly from the brooding bird to the eggs.[34]

The preen gland in the domestic fowl consists of two bilateral symmetric lobes, each with one secretory duct opening into the uropygial teat. Some breeds of domestic fowl have two uropygial teats. Tail-less breeds of the domestic fowl and the argus pheasants have no preen gland. A brush-like feather tuft that absorbs secretions from the gland is present on the uropygial teat (see Figure 24.7).[34] This feather tuft is absent in the megapodes.[28]

Some gallinaceous birds have unique skin appendages. Junglefowl possess marked unpaired carneous combs consisting of a wide intermediate layer, which is formed of a fibrillar network filled with mucus-like substances that impact elastic stability to the comb. The intermediate layer is covered by the strongly vascularized corium and the epidermis. Feathers are present on the comb bonnet in some domestic fowl breeds. The paired wattles of the throat are similar in structure to the comb (Figure 45.1). Like the comb, the size of the wattles is influenced by hormones, and both are better developed in cocks than in hens. Paired cheek or ear lobes are located ventral to the auditory canal and are red or white if subepithelial capillary sinusoids are absent.[34]

The structure of the skin appendages on the head and neck of turkeys varies from those described in junglefowl. These appendages have no elastic intermediate layer but do have superficial, muscular and vascular layers. The dewlaps of turkeys are smooth, can increase and decrease in size and can change color. Turkeys have a single snood on the forehead that can increase or decrease in length. Numerous red caruncles are located on the poorly feathered blue skin of the head. A beard consisting of tough dark bristles is present at the border between the neck and chest. Turkey hens have smaller skin appendages than cocks, and a beard is found occasionally in older hens[34] probably as a result of hormonal changes.

FIG 45.1 Fly bite dermatitis in the comb of a Rhode Island Red Rooster.

In New World quail, the edge of the lower bill is serrated or slightly toothed. An osseous process, which can be large in some species or subspecies, exists near the junction of the upper bill and cranium of Helmeted Guineafowl and some cracids.[28] This helmet consists of a cone of spongy bone covered by the corium and a keratinized epidermis. The wattles of the Helmeted Guineafowl are white to light-blue and, like the helmet, are larger in cocks than in hens.[34] Some other phasianids, some megapodes and some cracids also possess ornamental appendages of the head and the neck. In some species, these appendages are visible only during mating displays. Some breeds of the domestic fowl, some megapodes, some francolins, some tragopans and some pheasants have completely featherless heads and necks or featherless areas of the head or neck. Unfeathered areas of skin are frequently colored.[28] Many grouse species have red-colored supra-ocular combs. These unfeathered regions become swollen during the mating season.[5,17]

TABLE 45.1 Families and Subfamilies of Gallinaceous Birds[41]

Family Subfamilies	No. of Genera	No. of Species
Cracidae (cracids)	10	43
Megapodiidae (megapodes)	7	12
Phasianidae (phasianids)	70	203
Numidinae (guineafowl)	4	6
Pavoninae (peafowl)	2	3
Meleagridinae (turkeys)	1	2
Argusianinae (peacock pheasants and argus pheasants)	3	8
Phasianinae (pheasants)	8	21
Lophophorinae (monals)	1	3
Pucrasiinae (Koklass)	1	1
Ithagininae (Blood Pheasant)	1	1
Gallinae (junglefowl)	1	4
Tragopaninae (tragopans)	1	5
Galloperdicinae (spurfowl)	1	3
Ptilopachinae (Stone Partridge)	1	1
Perdicinae (partridges, snowcocks, francolins, Old World quail)	27	98
Odontophorinae (New World quail)	9	31
Tetraoninae (grouse)	9	16

The cocks of many gallinaceous birds have spurs, which are osseous eminences originating from the tarsometatarsus and are covered by keratinized epidermis (see Figure 12.34). If spurs occur in hens, they are generally smaller than in cocks and often have no osseous component.[34] The cocks' spurs are frequently sharp and can easily injure rivals, females, clients or veterinarians. Cracids and grouse do not have spurs.[5] In the Common Pheasant, annual rings are formed in the epidermis at the base of the spurs and can be used to determine the minimum age of the bird.[20]

Adaptations to Low Temperatures

The feet and toes of grouse are feathered. In ptarmigans, even the plantar surface of the foot is covered with fur-like feathers. Long nails and keratinous pins on both sides of the digits facilitate locomotion on snow. Dense plumage and a thick layer of subcutaneous fatty tissue help protect against the cold. Hair-like feathers cover the nostrils. In ptarmigans, shivering for the active production of body heat starts only below -12°C.[5,17,28]

Plumage

The chicks of all gallinaceous birds are nidifugous and hatch with a downy plumage.[33] The contour feathers of the plumage are formed of the deck feathers (tectrices), the flight feathers (remiges) and the tail feathers (rectrices). The number of rectrices varies among different species: the domestic fowl has 7 pairs; the Bulwer's Wattled Pheasant has 12 to 16 pairs. Ornamental feathers can originate from different portions of the plumage including tail coverts (peafowl), rectrices (many pheasants) and chin feathers (capercaillies). Birds that are indigenous to open terrain often have a patterned plumage that serves as camouflage.[28,34] Some species like the Golden Pheasant show polychromatism of the plumage.[28,33]

The eyes of many gallinaceous birds are hidden by dark periorbital feathers. Attempting to escape from predators by running or flying in open terrain is poor defense; thus, most ground-dwelling gallinaceous birds remain immobile when predators approach and flee only as a last ditch effort to escape.

Gallinaceous birds generally have well developed afterfeathers (hypopennae). Peafowl do not have afterfeathers. In some cracids, the vanes of the first primaries are curved and narrow, which, when a bird flies, produce a unique sound that is used to mark its territory.[28]

Most gallinaceous birds molt once a year, generally after the breeding season. Gallinaceous birds retain their ability to fly during a molt. The secondaries are molted in a divergent pattern from an inner starting point. The rectrices are molted randomly.[33] The Willow Ptarmigan lives in a subarctic-type habitat and molts three times a year in order to adapt to color changes in the environment, with the winter plumage being mainly white. Some grouse (capercaillies and ptarmigans) even molt the horny sheath (rhamphotheca) of the bill (in small pieces) after the breeding season. Ptarmigans also replace their nails.[17]

Some birds (notably grouse, pigeons) undergo a stress-induced physiologic response when attacked by predators that results in release of the feathers (the shock or fright molt). The predator or handler is left with a collection of feathers and the bird escapes.[14]

Gallinaceous birds normally fly at a low level, have a high frequency wing flap and tire quite rapidly. Their flight is often limited to gliding for short distances. Some species lead a nomadic life. Birds that dwell in high mountainous regions in the summer usually move to lower altitudes in the winter. The only true

migratory gallinaceous birds are the Common Quail and the Japanese Quail. Some gallinaceous birds move by running, which is assisted by quick flapping of the wings. A normal cruising speed for the Common Pheasant would be 20.5 mph (= 33 km/h) while the Common Turkey cruises through the forest at 15 mph (= 24 km/h). The nidifugous chicks of the gallinaceous birds are able to fly shortly after hatching. The chicks of the phasianids first attempt to fly at the age of ten to sixteen days, and the cracid chicks start to fly three to four days after hatching. Megapode chicks, which are not tended by their parents, are able to fly short distances just after hatching.[28]

Locomotor System

The furcula (wishbone) of the domestic fowl is V-shaped and has a ventral process (see Figure 12.32). In the Crested and Plumed Guineafowl, an indentation exists at the junction of the two clavicles. This indentation holds the U-shaped loop of the elongated trachea. The medial notch of the sternum extends far cranially, and the lateral and medial notches are connected by fibrous membranes. In this region, the liver is not protected by the sternum, and injections, abdominocentesis or handling procedures must be carefully performed.[35]

The ground-dwelling phasianids generally have a long femur, tibiotarsus and tarsometatarsus to facilitate ambulation, while the tree-dwelling cracids have shorter tarsometatarsi. The legs of all gallinaceous birds are well muscled.[35] Cracids are active climbers, and other gallinaceous birds need strong feet and legs to scratch the ground in search of food. The toes of cracids and megapodes are on the same plane, whereas the first toe of the phasianids originates more proximally than the other digits. The first digit of the gallinaceous birds is oriented mediocaudally and the three other digits are directed cranially.[28] Some breeds of the domestic fowl have five digits (Houdans, Faverolles, Dorkins, Chinese Silk Fowl), with the additional digit being located medial to the first.[33]

Respiratory System

Desert-dwelling gallinaceous birds such as sand partridges, possess well developed salt glands situated in an osseous indentation above the eyes. This extrarenal excretory organ for salt empties through a duct into the nasal cavity.[36]

TABLE 45.2 Respiratory Rate, Heart Rate and Rectal Temperatures of Selected Gallinaceous Birds[37,36]

Species	Respiratory Rate (per min)	Heart Rate (per min)	Temperature (°C)
Domestic Fowl	12-37	220-360	41.2
Domestic Turkey	28-49	93-163	40.7
Pheasant	12-37	–	–
Bobwhite Quail	–	–	44.0
Common Quail	40-85	249-494	42.2

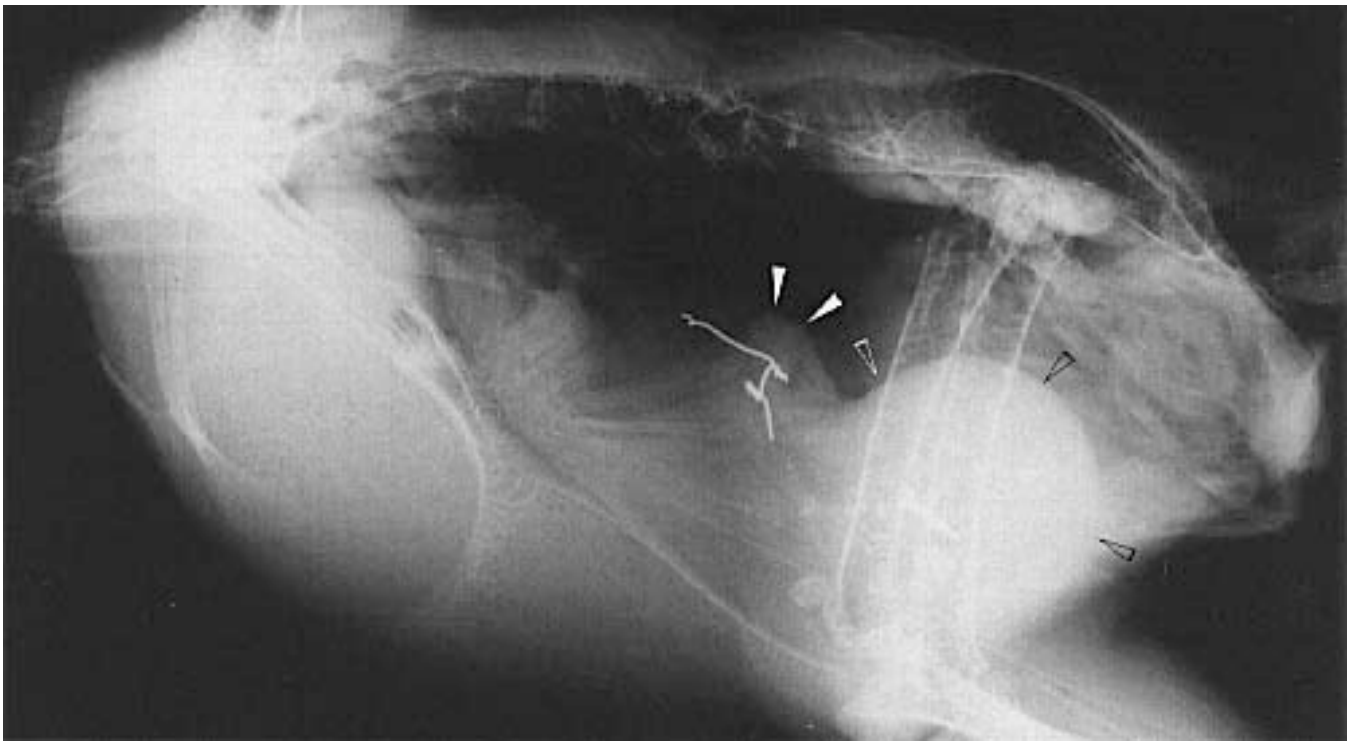
The cocks or both genders of some gallinaceous birds have elongated tracheas. The additional length produces a U-shaped or circular loop in the trachea that lies between the skin and the muscle layer in the ventral thoracic or cranial abdominal region. In Helmeted Curassows, the loop extends to the cloaca, and in some other cracids, it extends to the caudal end of the sternum. Crested and Plumed Guineafowl and the Common Capercaillie also have an elongated trachea. Although the function of the loop is not fully understood, it may be involved in generating deep sounds.[28]

The tracheobronchial syrinx of gallinaceous birds is a simple structure. The neopulmo, which is the phylogenetically younger portion of the lung, is well developed in Galliformes. A phylogenetic increase in the size of the neopulmo is accompanied by a decrease in the size of the caudal thoracic air sacs. The Common Turkey has a well developed neopulmo and has no caudal thoracic air sacs. Four clavicular air sacs are recognized in gallinaceous embryos. In the Common Turkey, only two of the four clavicular air sacs merge with the unpaired cervical air sac, and two clavicular air sacs remain distinct. In other birds, all the embryonic clavicular air sacs merge into one. With these adaptations, the Common Turkey has only seven air sacs, while most gallinaceous birds have nine air sacs: the unpaired clavicular air sac, and the paired cervical, cranial thoracic, caudal thoracic and abdominal air sacs.[36]

Alimentary Tract

Most gallinaceous birds have a pointed bill (rostrum) that is used to pick up food.[37] In grouse, the bill is stronger and is used for cutting tough vegetable matter.[5,17] In gallinaceous birds, the cere is usually limited to the base of the upper bill; however, in cracids, two-thirds of the bill is covered by the cere.[28]

The tongue of gallinaceous birds is shaped like an acute triangle, is stabilized by a bone and has no



intrinsic musculature. Most gallinaceous birds have a crop.[37] This esophageal diverticulum is missing in small cracids and snowcocks, and in its place is a slight bulge in the diameter of the esophagus or only an increased stretchability of the esophagus.[28] The Sage Grouse and some other North American grouse use a diverticulum in the middle part of the esophagus for territorial display and not for the storage of food. During display, the "inflatable esophageal air sacs" are inflated to expose featherless, brightly colored skin. The organ may also play a part in amplifying the voice.[5,17]

The ventriculus and its associated musculature is well developed in most gallinaceous birds (Figure 45.2). Grouse and snowcocks, which eat extremely rough food, possess the most heavily muscled ventriculus. The Sage Grouse, which feeds on soft food, has a thin-walled ventriculus.[5,17,28]

The secretory ducts of the liver and the pancreas open into the duodenum. Gallinaceous birds have a

FIG 45.2 Most gallinaceous birds have a well developed ventriculus with its associated musculature. Note the density of the thick ventriculus (open arrows) containing a partially digested screw and grit. In this case, a peafowl hen was presented for weight loss and regurgitation of several days' duration. An ingested wire had penetrated the proventricular mucosa. The formation of a granuloma (arrows) at the end of the foreign body had prevented the wire from penetrating through the proventriculus. A proventriculotomy was used to remove the wire.

gall bladder and two bile ducts. In the domestic fowl, the pancreas extends to the apex of the duodenal loop and generally has three secretory ducts. The largest pancreas is found in gallinaceous birds that feed on grain.[37]

All gallinaceous birds have well developed ceca. Fluid and small food particles are transported into the cecal lumen by peristaltic movements of the small intestine and antiperistaltic movements of the rectum. The contents of the ceca are dark-colored and have a sticky consistency.[10] The size of the ceca will increase or decrease depending on the amount of crude fiber in the diet.[15,27] In some species, bacterial digestion of cellulose occurs in the ceca,[12] and species like grouse and snowcocks that feed on foods with high amounts of crude fiber have particularly well developed ceca.[28]

The cecal flora probably plays an important role in the synthesis of vitamins and the metabolism of nitrogen.[9] Uric acid that enters the cloaca is transported into the ceca by antiperistaltic movements of the rectum and is used for the synthesis of bacterial amino acids.[6] The ceca are usually emptied once a day, typically in the morning.[28]

Urinary and Reproductive System

The testicles are generally yellowish or white, but can be pigmented in some species like the Common Capercaillie or in some breeds of the domestic fowl. The testicles enlarge during the breeding season. Fertile semen is not produced between breeding seasons. The ductus deferens and, in some species, an enlarged area of the caudal ductus deferens, serve as reservoirs for the storage of semen. Gallinaceous cocks have a non-erectile phallus.[38]

Husbandry

Most gallinaceous birds are best maintained in combination indoor and outdoor aviaries and can live to 6 to 20 years depending on the species (Table 45.3) In general, the available space should be as large as possible. In some countries the minimum areas are stipulated by law.

TABLE 45.3 Longevity of Selected Gallinaceous Birds[28,39]

Bird	Years
Peafowl	Approx. 20
Bobwhite Quail	Approx. 6
Grouse	8-10
Common Pheasant	10-18
Cracids	20 and more

A pair of pheasants can be maintained and bred in an aviary with a floor space 4 by 6 meters with an additional 4 square meter shelter. A Common Pheasant cock with 5 to 6 hens needs 30 to 40 square meters. An aviary for peafowl should be at least 3 meters wide, 3 meters deep and 3 meters high. These species are best maintained in open-air enclosures or big gardens. One pair of Bobwhite or California Quail needs a minimum of 1.5 m x 1.5 m floor space.[28] For grouse, small aviaries measuring 4 meters in depth and 8 meters in width are recommended, because these birds may injure themselves if they fly into netting at the high speeds attained in larger flights.[5]

Many Galliformes prefer to roost in elevated positions, making the height of an aviary important. Shelters should be provided to protect birds from sun, wind and rain. Tropical or subtropical species maintained in cold climates require an indoor aviary or, if kept outdoors in winter, a heated shelter. The mesh size of netting should be small enough to prevent a bird from placing its head through the mesh. It should also prevent the smallest predators from entering the aviary. Some gallinaceous birds, especially the Common Pheasant, fly straight up when panicked. For this species, the top netting in an enclosure should be loose to provide some give and reduce the chances of head and neck injuries. An opaque barrier can be placed at the back of the aviary, extending up to one-half of the height, to provide extra visual security for the birds.[28]

Ground-dwellers like some quail, some partridges and some francolins do not need elevated perches. Perches should be placed far enough from walls or wire netting to prevent the tail or wing feathers from contacting these surfaces. Peafowl, Reeve's Pheasant, argus pheasants and Phoenix Fowl require especially high perches, three to four meters above the ground, to accommodate their long tail feathers. Sharp corners should be avoided in designing the aviary. Curved corners or dense bushes planted in the corners reduce the possibility of trauma.[1,28]

Shrubs also help to landscape an aviary and provide shelter for the birds; however, the aviary should not

be overplanted. Too many plants will make an aviary difficult to clean. Natural turfs are attractive, but are not recommended when keeping birds that are highly susceptible to infectious diseases. An aviary with a concrete floor that is covered with an exchangeable layer of sand meets the needs of sensitive species (like grouse or the Cheer Pheasant) and is better than natural soil. Plants may be grown in containers that are removed when the aviary needs cleaning.

Snowcocks need large rocks for perching and shaping their bills. Some species like monals, eared pheasants and the Cheer Pheasant use their upper bill to search the soil for roots and insects. If these birds are maintained on artificial substrate, natural abrasion of the bill will not occur and manual trimming will be necessary. Gallinaceous birds do not bathe in water. Most gallinaceous birds like to take dust or sand baths. The placement of abrasive materials on the plumage may function to lightly abraid and polish the edges of the feathers, and may help reduce the number of external parasites as long as the sand itself is not contaminated. Insect powders should be used only if they are known to be nontoxic for the species concerned and only if the birds in fact have parasites. In the winter, Willow Ptarmigan bathe in the snow.[28]

Various bird species should generally not be mixed in one aviary because of possible interspecific aggression and the potential transmission of infectious agents. If species are combined, it is best to mix birds that do not compete for the same food or biotope. Ground-dwelling gallinaceous birds can be combined with bush- or tree-living species like thrushes, babblers, starlings, bulbuls and doves (with the exception of the Ground Pigeon); however, mixing of species is not recommended. Predatory species, including birds that feed on eggs, should not be combined with gallinaceous birds.

Silver Pheasant, eared pheasants, Golden Pheasant, Lady Amherst's Pheasant, Elliot's Pheasant, Swinhoe's Pheasant and Indian peafowl can be maintained in open-air enclosures that are fenced but not covered. Birds in open-air enclosures must have sufficient hedges, bushes or trees for cover. Higher trees should be available for roosting. Fruit trees or oaks (some are poisonous) provide a food source as well as cover. The flight capacity of a bird should be reduced by clipping the wings before introducing it to new surroundings.

Losses to predators can occur in open-topped facilities, particularly with respect to chicks. Rare species should not be maintained in an open-topped enclosure. A breeder who uses open-topped enclosures should expect that the loss of a bird to a predator is the responsibility of the breeder and not the fault of the predator. Some gallinaceous birds are noisy, especially the Indian peafowl and guineafowl during the breeding season, and should be maintained in secluded areas to avoid complaints from neighbors.

Nutrition

Many diseases and problems in captive Galliformes are directly or indirectly related to malnutrition. Breeders of gallinaceous birds should be aware of the natural foods consumed by any species maintained in captivity. Conclusive data on the nutritional demands (with respect to maximal egg or meat production and not for longevity and appearance) is available only for the domestic fowl, domestic turkey and the Japanese Quail. Some information is available for the domestic guineafowl, and less has been determined for the Common Pheasant. All nutritional guidelines for other gallinaceous birds are based on experience.

Generally, the protein requirement increases at the beginning of the mating season because of egg and semen production. After the breeding season, the amount of protein in the feed should be gradually reduced. With any change in the diet, the new feed should be mixed slowly into the daily diet until the conversion is complete.

"Easy" Birds

Many gallinaceous birds are omnivorous. The nutritional requirements of Common Pheasant, Golden Pheasant, Lady Amherst's Pheasant, Silver Pheasant, peafowl, guineafowl, turkeys, partridges and New World quail are relatively easy to provide. Commercial diets for domestic fowl, domestic turkey, Common Pheasant and Japanese Quail are available in many countries. Pellets designed for turkeys can be used in species without special requirements. Adding fresh green plants to the diet provides the birds with nutritional diversity. Grass or corn silage can also be offered in small quantities. During the breed-

ing season, the diet should contain 20 to 25% crude protein. Outside the breeding season, a maintenance diet containing less than 20% crude protein is best. Commercial diets for domestic turkey are usually better suited for pheasants than diets developed for domestic fowl. Feeding is best accomplished by providing small portions of the diet several times a day in the non-breeding season and offering food ad libitum during the breeding season.[28,31]

Most New World quail are primarily seed-eaters and are easy to feed. Forest-adapted species may be largely insectivorous and have higher and more specific protein requirements in comparison to other gallinaceous birds.[28] Cracids are mainly, but not exclusively, vegetarians. They can be sustained on pellets containing 21% crude protein supplemented with fruits but no grains. During the breeding season, they are fed soybean paste, chopped hard-cooked eggs, chopped meat or mealworms (larvae of the meal beetle).[25] Megapodes can be fed a commercial poultry diet.[28]

Birds with a High Protein Requirement

Some gallinaceous birds like peacock pheasants, argus pheasants and the Roulroul (Crested Wood Partridge) do best with high-protein diets. In addition to high-protein turkey or pheasant diets, adult peacock pheasants should be fed mealworms, chopped meat, fruits and a small quantity of grain. Green plants are rarely consumed by these species. The Roulroul is fed a commercial soft feed for insectivorous birds mixed with live insects, chopped hard-cooked eggs and chopped meat. The primarily meat diet of these birds results in an odoriferous feces.[28]

"Difficult" Birds

Some gallinaceous birds consume almost exclusively vegetable material. The Koklass, the Blood Pheasant, snowcocks, tragopans and grouse are examples. Feeding these species with game bird pellets or, even worse, with commercial diets for domestic fowl and turkeys, results in obesity, reduced fertility and imbalances in the intestinal microflora. These species should be maintained only where natural-type foods are available year round. These gallinaceous birds should be fed large amounts of fresh vegetables. Pellets should be provided only in small quantities, if at all. Koklass naturally feed on ferns, grasses, leaves, mosses, buds and berries. In captivity they should be provided soft green plants, fruits and berries and no grains. In the summer, grasses and lucerne can be provided. Spinach, romaine lettuce and fresh, frozen vegetables can be substituted in the winter months. Free-ranging Blood Pheasants feed on mosses, lichen, ferns, grass tips and conifer needle-buds. They browse constantly in planted aviaries. Snowcocks eat mostly grasses and leguminous plants. Their chicks feed on these plants immediately after hatching.

Tragopans consume oak trees, bamboo sprouts, grasses, mosses, oaknuts, berries and a few insects. In captivity, tragopans can be fed lucerne, grasses, cucumbers, apples and different kinds of berries.[28] In the spring, summer and autumn, grouse feed on a variety of plants. In the winter, most grouse species are restricted to consuming one or a few plant species. During the winter season, the Spruce Grouse, capercaillies and other grouse species feed almost exclusively on conifer needles, the Black Grouse on birch buds, and ptarmigans on buds from different deciduous trees (birch, alder, willow).

Captive grouse should receive natural foods or at least large amounts of leaves, grass and berries supplemented with a limited quantity of pellets and grain. Capercaillies and ptarmigans require a diet high in crude fiber.[5,17] Even with strict attention to the diet, the bacterial fecal flora in capercaillies in captivity is similar to the fecal flora of the domestic fowl, and differs substantially from the fecal flora of free-ranging capercaillies.[30] The tannin and essential oil content of natural food plants may support the growth of autochthonous intestinal flora in free-ranging grouse.[29] In the Sage Grouse, leaves and sprouts of the North American Big Sagebrush are the sole winter food and the main portion of food in the summer.[5,17]

Some commercial poultry diets contain coccidiostatic agents. Halofuginone is toxic for the Common Pheasant, guineafowl and the Common Partridge. Monensin is toxic for guineafowl.[14] Commercial diets for the Common Turkey contain antiflagellates. The presence of antimicrobial agents can be life-threatening in species that depend on a functional cecal flora and fauna (eg, grouse) for proper digestion. In general, the effects of coccidiostats and other medical feed supplements on gallinaceous birds have not been sufficiently studied. It is safer to provide food without these potentially toxic supplements.

All gallinaceous birds should have access to grit. The grit container should be emptied and refilled regularly because birds select only stones that are suitable for their body mass. Pellets or complete rations have an adequate supply of calcium and should not

be supplemented with lime or crushed shell. Fresh, clean water must be available at all times for all species.

Chicks

During their first few weeks of life, free-ranging gallinaceous chicks feed mainly on live invertebrates like insects, larvae of insects, worms and snails in order to obtain the protein levels needed to sustain rapid growth. Starting at five to six weeks of age, the protein requirements begin to decrease, and the intake of carbohydrates increases to meet energy requirements. By six months of age, most young gallinaceous birds have reached a mass equivalent to that of adults. The quantity of carbohydrates in the diet must then be reduced to prevent obesity.

Feed should be provided to newly hatched chicks on a large flat plate on which they can move around and practice picking. By five to seven days of age, food can be offered in larger containers. The change from the plate to larger containers should occur by offering feed in both containers at the same time. Small chicks may drown in large water containers. Placing stones or glass marbles in the container will reduce losses.

Chicks of unpretentious species (Common Pheasant, peafowl, guineafowl) are initially fed a starter diet like turkey starter (28% crude protein) and are transferred to a lower protein diet (18% to 20% crude protein) from the eighth to eighteenth week of age.[31]

Chicks of the vegetarian species are difficult to feed. It is best to provide these birds with foods that are similar to those eaten by their free-ranging conspecifics. A diet composed of turkey starter mixed with mealworms, ant cocoons, chopped hard-cooked eggs, diced romaine lettuce, spinach, dandelion and other green plants is a viable substitute. In several species (some grouse), chicks obtain food by picking at the ground and by cutting off parts of plants with the bill. In these species, it is important that chicks be provided intact plants that are placed in the ground or tied in bundles to facilitate natural food-gathering behavior.[5] Chicks that are to be released into the wild must be introduced to their natural foods to prevent starvation. Perhaps chicks are imprinted with food shapes and colors, or at the least, they learn what foods to consume from the hen.

The chicks of some gallinaceous birds will not pick downwards in the first days of life. This is because peacock pheasants, Crested Argus, Great Argus and some other gallinaceous hens feed their chicks for several days after hatching. Argus pheasant chicks can be enticed to pick by offering live food (mealworms). Monal chicks fed mealworms will pick at their siblings' toes.[28]

Reproduction

Some gallinaceous birds breed readily in captivity while others rarely reproduce. Breeding failures are an indication that the birds are not happy or healthy, and that the natural conditions of the bird are not being sufficiently simulated. Some pheasant and quail species are approaching a level of domestication that is advantageous for both the captive animal and the breeder. Comparatively, "semi-domesticated" animals are of no value if offspring are to be released to the wild with the intent of reintroducing genetic diversity into dwindling populations. Genetic selection and breeding to achieve color variants increase the expression of genetic abnormalities, semilethal factors and susceptibility to disease. The clutch size and incubation times for commonly maintained gallinaceous birds are listed in Table 45.4. Parameters for artificial incubation are listed in Table 45.5.

General Considerations

Gallinaceous birds to be used for breeding purposes should be introduced to each other before the breeding season in surroundings that are novel to all the candidates concerned. The female should be introduced to the enclosure a few hours prior to the male. In some species, it is possible to keep several males together if there are no females present. If females are present, only one male should be housed in an aviary or in one compartment. In monogamous species, only a single pair should be housed together.

Males of some species are very aggressive, and during the breeding season may attack other males, other bird species or even the keeper. Pursuit by the male and mock escape by the female is normal behavior in some species like eared pheasants and francolins. If there is insufficient space for the hen to escape, she may be injured or killed by the cock. Debeaking or restricting the flight capabilities of the male can prevent injuries to the hen, but are inferior

Black Grouse	37.4	55-60	-	85-90
Ruffed Grouse	37.5	60-65	-	70-75
Chukar Partridge	37.5	65	37.0	85

procedures to providing adequate space for a pair of birds to behave normally. Densely planted aviaries that provide a hen with areas to hide may still have inherent problems. Fiberglass panels leaned against the wall or concrete tubes provide similar protection and are easy to clean.[28]

For species in which there are substantial differences in body size between the genders, aviaries can be designed to allow the hens to visit the cock when she wishes. Small holes, just big enough for the hen, are used to connect adjacent enclosures. This allows the hen to enter the cock's enclosure, while preventing the cock from entering the hen's area. This is an effective method for breeding birds like the Common Capercaillie.[5] In some species, the hen chooses the most attractive of several cocks and if only one cock is available, breeding may not occur if the hen does not like the cock. In some species, the visual or acoustic presence of other males is necessary to stimulate display and mating behavior.

Most gallinaceous birds incubate eggs on the ground and should be provided with flat trays containing moss, foliage or hay for nesting material. Tragopans, the Congo Peafowl, the Bronze-tailed Peacock Pheasant, the Crested Argus Pheasant, the Mikado Pheasant, the Salvadori's Pheasant and the cracids nest in trees. A box placed approximately 150 cm from the ground and filled with hay and foliage can be used as an artificial nest. A slanted limb should be provided for easy access to the nest. Nests of ground- and tree-nesting birds should be inconspicuous to provide the pair with visual security but should be placed such that the birds can easily look out.[28]

Most gallinaceous birds are nondeterminant layers, and if the first clutch of eggs is removed, the hen will lay a second and sometimes a third clutch. Hatching is genetically determined and should not be assisted. Because gallinaceous chicks are nidifuguous, the family can stay together only if all the chicks hatch at the same time. Synchronization of the hatch dates can occur by two mechanisms: 1) The hen does not incubate the clutch until the last egg has been laid, allowing the eggs to cool (which slows the process of embryogenesis); or 2) The chicks in a clutch synchronize hatching through audible signals. This latter process occurs in species like the Japanese Quail. When sounds are heard from other eggs, the chicks increase the speed of hatching. When no sounds are heard from other eggs, the most developed chicks reduce their speed of hatching. Most gallinaceous chicks are independent by three months of age. The exception is the megapode chick, which is independent immediately after hatching.[28]

Foster Breeding

The hens of some gallinaceous birds are unreliable brooders in captivity. Cracid, Common Pheasant and nearly all species of New World quail hens are unamenable brooders in captivity.[28] These hens can be encouraged to produce two or three clutches per year instead of one by using foster parents or an incubator for hatching eggs. Chinese Silk Fowl and Bantams make excellent foster parents. Domestic turkey hens can be used to incubate the eggs of larger gallinaceous birds. Small and fragile eggs should be placed under Golden Pheasant hens, which are cautious brooders and excellent care-providers. During the last week of incubation, the eggs of tropical birds being raised in dry climates should be moistened with a clean mister once a day. After hatching, the hen and chicks can be placed in a small enclosure that is movable, and can be placed on fresh grassy areas on a daily basis. Chicks are prone to chilling the first few days post-hatching and must have supplemental body heat from the attending hen.[28]

The disadvantages of foster parenting are:

- crushing of small fragile eggs by heavy or clumsy adults;
- premature cessation of brooding if the natural incubation period of the foster hen is shorter than the fostered eggs;
- trauma or death of the chicks if the hen recognizes them to be strange (this is a particular problem when behavioral incompatibilities exist between the hen and chicks);

- transmission of infectious agents between hen and chicks.

Infanticide and disease transmission can be reduced by placing the eggs in an incubator for the last third of the incubation period (this method is often used for grouse). Generally, chicks that are to be released into the wild should be reared by a hen of the same species.[5,17]

For many pheasants, the percentage of carbon dioxide in the incubator must be increased up to approximately 1%, verified with a gas detector, during the last two days of incubation. This is achieved by reducing the intake of fresh air. Chicks should be taken out of the incubator immediately after hatching.

Specific Reproductive Characteristics

Megapodes

Megapode eggs differ from those of other gallinaceous birds, owing to the uncommon brooding biology of these birds. The eggs are not incubated by the parents but by solar heat, fermentation heat or geothermal energy. One egg can reach a size of up to 17% of the hen's body mass. The eggs are thin-shelled and contain a large yolk that is rich in lipids. Cocks or both sexes begin constructing an induction mound out of foliage and earth when the air temperature and atmospheric humidity reach a certain level. The hens lay their eggs every two to three days in previously prepared holes, which are quickly covered after oviposition. Eggs are deposited in a mound with the pointed pole downwards, and they are not turned during incubation. They do not have a fixed air chamber or chalaza.

The birds may determine the temperature of the mound, and perhaps other parameters, with the bill or tongue. The mean temperature in the incubation mound is around 34°C. The incubation mound is cooled when needed by scratching holes. This allows carbon dioxide to escape and oxygen to enter. The incubation period varies from 45 to 90 days, depending on the temperature in the mound. Brush Turkey chicks leave the mound 24 to 30 hours after hatching.[28] Normally, megapode chicks do not come into contact with their parents, who function only to care for the incubation mound. The chicks join their brothers and sisters who have hatched at around the same time. Megapodes are sexually mature by one year of age.[28]

The Australian Brush Turkey is easy to maintain and breed in captivity, and is the most common captive representative of the megapodes. This species is monogamous. In one breeding season, an Australian Brush Turkey hen lays about 25 to 30 eggs.

Cracids

Cracids are Central and South American species that are considered monogamous. The breeding season lasts from March until July. Most nests are well hidden in a fork or branch of a tree, but some species are ground-nesters. Only the hen incubates the eggs. A clutch consists of two to three eggs, which are rough-shelled with wide pores and a uniform white color. Newly hatched chicks are immediately able to climb trees. The family stays together until the next breeding season. Sexual maturity occurs by two years of age.[28]

Turkeys

The Common Turkey is polygamous. Behavior of free-ranging birds is dramatically different from that of domesticated breeds. The brain volume of domesticated turkeys is 35% smaller than that of their wild-type conspecifics. The nest is formed of a flat depression in the soil and may be padded with leaves, grass or twigs. The chicks are able to fly at two weeks of age. Several hens, together with their offspring, typically associate in a flock in winter. The young birds leave their mother before the next breeding season. Young turkeys of both species are sexually mature at two years of age.[28]

New World Quail

New World quail are monogamous. Both parents participate in building the nest and brooding the chicks. Young birds are sexually mature by one year of age, in some species even earlier. Outside the breeding season, the gregarious New World quail live together in large family groups (coveys). At the beginning of the breeding season, the older cocks become very aggressive toward young cocks. Captive Bobwhite Quail have become polygamous and it is possible to keep one cock with two hens, indicating the effects of domestication.[18,28]

Grouse

Some grouse species like ptarmigan, Ruffed Grouse, Hazelhen, Spruce Grouse and Blue Grouse are monogamous. In these species, cocks should not be allowed to see or hear other cocks. Hazelhen males may attack the female if a rival can be heard but not seen. Other grouse species are polygamous. In these species, the hen chooses one cock from a group of display-

ing males. One cock may be chosen to mate with several hens. Hens in captivity breed best when allowed to choose between two or more cocks. The cocks, which are housed in different compartments of an aviary, may see and hear each other if there are enough hiding places for the hens. In most grouse only the hen provides chick care. The chicks of different species can be distinguished by the varying color patterns on the head and back plumage. Most grouse are sexually mature at one year of age. Crossbreeding between different genera and species occurs in free-ranging birds. Similarities in the appearance and display behavior of hens seem to induce cocks to crossbreed. Hens will choose cocks of another species if a representative of their own species is not available.[5,17,28]

Peafowl

The Congo Peafowl is monogamous. The nest is always built in a tree. Both parents care for the chicks. The Indian and the Green Peafowl are polygamous. In captivity, it is possible to keep one cock with four to five hens. The hens care for the clutch and the chicks, which mature slowly. Hens reach sexual maturity in the second year and cocks in the third year of life. The Green Peafowl is more aggressive than the Indian Peafowl, but has a more pleasant call.[28]

Pheasant

Most pheasant species are polygamous. One Common Pheasant cock can be kept with five to six hens. The hens make poor care-providers in captivity. They tend to be indiscriminant in the placement of eggs and will not incubate the eggs. Young Common Pheasants are sexually mature at one year of age. Free-ranging Golden Pheasants are monogamous, but in captivity one cock can be kept with three to four hens. The hens are exceptional care-providers and de-

TABLE 45.6 Gender Determination of Selected Species of Gallinaceous Birds Without Marked Sexual Dimorphism[28]

Genus	Plumage Identical	Plumage Similar	Differences
Megapodiidae:			
Alectura	*		Cocks have neck appendages
Cracidae:			
Ortalis	*		Voice of cock is deeper
Penelope	*		In some species iris colors differ
Nothocrax	*		In cocks the tracheal loop is palpable
Pauxi	*		In hens, plumage is sometimes a red phase
Phasianidae:			
Numidinae:			
(all genera)	*		Cock's call has 3 syllables; hen's call has 2 syllables
Argusianinae:			
Polyplectron		*	Hen's plumage is dull; cocks have spurs
Phasianinae:			
Crossoptilon	*		In general, cocks have spurs
Catreus		*	Cocks have long, sharp spurs
Ptilopachinae:			
Ptilopachus		*	
Perdicinae:			
Tetraogallus	*	**	In some species, cocks have short spurs.
Arborophila	*	**	In some species, cocks have short spurs.
Bambusicola	*	**	
Frankolinus	*		
Pternistis	*		In some species, cocks have spurs.
Scleroptila	*		Cocks have spurs.
Ortygornis	*		Cocks have spurs.
Coturnix		*	
Odontophorinae:			
Odontophorus	*	**	
Tetraoninae:			
Tympanuchus		*	
Bonasa		*	
Tetrastes		*	
Lagopus	*		(only in winter)

** Some species of the genus are identically colored and some are similar.

fend their chicks. Young Golden Pheasant hens are sexually mature within one year, cocks within two years. Lady Amherst's Pheasant cocks and hens can be aggressive during the breeding season. Only a few of the birds found in captivity are purebred. Both male and female argus pheasants, peacock pheasants and the Copper Pheasant establish and defend their own territories. Males should be introduced to females only for a short time during the breeding season to prevent aggressive behavior and traumatic injuries from both genders.[28]

Junglefowl and Domestic Fowl

Junglefowl can be either monogamous or polygamous. The hens can breed year-round, but the main breeding season is from February to May in the northern hemisphere. A Red Junglefowl cock can be maintained with three to four hens. The young birds are independent at an age of four months, and sexually mature after the first year. Many domestic fowl breeds have lost their brooding behavior, and eggs must be artificially incubated.[28]

Gender Determination

Many gallinaceous birds show a marked sexual dimorphism. The size (height and width), the body mass (weight), the color of the plumage, the shape of certain feathers, the presence of spurs and the length and color of the tail feathers assist in gender determination between adults of some species (Table 45.6). In some breeds of domestic fowl, fertile cocks may have plumage that resembles that of hens.

CLINICAL APPLICATIONS

In rare and endangered species, the production of offspring by artificial insemination might be useful in several situations:

- The semen of one cock can be used to inseminate numerous hens; however, spread of genetic defects is increased, while the genetic diversity is decreased.
- In many species, the captive production of offspring is still difficult. Cocks may not mate with the hen, or if they do, insemination may not occur. (As an example, Brown-eared Pheasants will rarely produce fertile eggs in captivity. It has been assumed that the cocks were not producing fertile semen. Artificial insemination has proven that the semen is usually fertile, suggesting that breeding problems are primarily behavioral.)[40]
- Different aviculturists can exchange semen from their cocks; however, this procedure can result in the spread of venereal diseases, like leukosis.
- Semen can be used from cocks that are genetically and organically healthy but have been handicapped by an injury and are no longer able to mate.

Gender can be determined by highly skilled individuals by examining the cloaca in one-day-old chicks or adults. The cloacal examination in newly hatched chicks of small bird species must be done carefully (see Chapter 46). Holding a chick too tightly can cause asphyxiation. Restraint of a chick for gender determination should start by gently pressing on the abdomen from both sides distal to the keel bone to stimulate defecation. The procedure is then similar to that described for Anseriformes (see Chapter 46).

Behavioral clues like dominance and certain mating rituals may suggest a gender, but are not always indicative. Under certain conditions the hens of some gallinaceous birds behave like, and can have plumage like, the males.[19] Only endoscopic examination of the gonads provides definitive determination of gender in species with similar morphologic characteristics (see Chapter 13).

Artificial Insemination

Artificial insemination is of economic importance in the domestic turkey and domestic guineafowl. Domestic turkey cocks, like domestic fowl cocks, are fertile year-round, except during periods of extreme heat or during the molt period. Domestic guineafowl cocks are not fertile all year, and artificial insemination is used to induce year-round production.

The semen is collected by massaging the caudal region of the back or the abdomen, followed by stimulation of the cloaca. Fecal contamination of the semen may occur. It is best to collect the semen directly from the spermatic duct with a syringe and a blunted hypodermic needle. The semen may be diluted with Ringer's or Tyrode's solutions by up to a factor of three.

Avian semen has a short half-life and must be used as quickly as possible. The semen is introduced with a syringe and a blunted hypodermic needle into the hen's oviduct. It is best to inseminate the hen just after she has laid an egg. This ensures that the oviduct is open, providing the semen with unrestricted access to the infundibulum.[14,39]

TABLE 45.7 Checklist of Infectious Diseases in Gallinaceous Birds

Viruses (see Chapter 32)

Poxviridae
- Avian pox

Herpesviridae
- Infectious laryngotracheitis
- Marek's disease

Adenoviridae
- Quail bronchitis
- Inclusion body hepatitis
- Egg drop syndrome = (infectious salpingitis)
- Marble spleen disease
- Hemorrhagic enteritis of turkeys
- Chicken splenomegaly
- Adenovirus infection of the Blue Grouse

Parvoviridae
- Parvovirus infection of chickens
- Parvovirus-like infection of turkeys

Circodnaviridae
- Infectious anemia

Reoviridae
- Viral arthritis
- Other reovirus infections
- Rotavirus infections

Birnaviridae
- Infectious bursal disease

Togaviridae
- Eastern and western encephalitis
- Avian serositis
- Louping-ill
- Israel turkey meningoencephalitis

Coronaviridae
- Coronaviral enteritis of turkeys (bluecomb disease)
- Infectious bronchitis

Rhabdoviridae
- Rabies

Paramyxoviridae
- Newcastle disease
- PMV-2-infection (Yucaipa)
- PMV-3-infection (Wisconsin)
- Turkey rhinotracheitis
- Swollen head syndrome

Orthomyxoviridae
- Avian influenza, fowl plague

Retroviridae
- Leukosis
- Reticuloendotheliosis
- Lymphoproliferative disease of turkeys

Picornaviridae
- Avian encephalomyelitis
- Turkey viral hepatitis
- Infectious nephritis

Bacteria (see Chapter 33)

Staphylococcus spp.
- Staphylococcosis

Streptococcus spp.
- Streptococcosis

Mycobacterium avium
- Tuberculosis

Erysipelothrix rusiopathiae
- Erysipelas

Listeria monocytogenes
- Listeriosis

Clostridium spp.
- Ulcerative and necrotic enteritis (*Cl. colinum* and *Cl. perfringens*)
- Botulism (toxin of *Cl. botulinum*)

Escherichia coli
- Colibacillosis
- Coligranulomatosis

Salmonella spp.
- Salmonellosis

Klebsiella spp.
- Klebsiella infection

Yersinia pseudotuberculosis
- Pseudotuberculosis

Pseudomonas spp.
- Pseudomonas infection

Aeromonas hydrophila
- Aeromonas infection

Bordetella avium
- Bordetellosis (turkey coryza)

Campylobacter spp.
- Avian hepatitis

Borrelia anserina
- Spirochetosis

Treponema spp.
- Infectious typhlitis in chickens

Pasteurella spp.
- Fowl cholera

Actinobacillus salpingitidis
- Actinobacillosis

Haemophilus spp.
- Haemophilus infection

Francisella tularensis
- Tularemia

Mycoplasma (see Chapter 38)

Mycoplasma spp.
Ureaplasma sp.

Chlamydia (see Chapter 34)

Chlamydia psittaci
- Chlamydiosis

Rickettsia (see Chapter 38)

Coxiella burnetii
- Query (Q) fever

Aegyptianella pullorum
- Aegyptianellosis

Mycoses (see Chapter 35)

Aspergillus spp.
- Aspergillosis

Candida albicans
- Candidiasis

Dactylaria gallopavo
- Dactylariosis

Trichophyton spp.
- Favus

Mycotoxicoses (see Chapter 37)

Toxins of *Aspergillus* spp., *Penicillium* spp., *Fusarium* spp. and others

Parasites (see Chapter 36)

Protozoal Parasites:
- *Trypanosoma avium*
- *Spironucleus meleagridis*
- *Histomonas meleagridis* (blackhead disease)
- *Trichomonas* spp.
- *Chilomastix gallinarum*
- *Entamoeba* spp.
- *Endolimax* spp.
- *Eimeria* spp.
- *Toxoplasma gondii*
- *Sarcocystis* spp.
- *Cryptosporidium* spp.
- *Haemoproteus* spp.
- *Leucocytozoon* spp.
- *Plasmodium* spp.

Metazoal Parasites

Trematodes
- *Prosthogonimus* sp.

Cestodes
- *Davainea proglottina*
- *Raillietina* spp.
- *Amoebotaenia cuneata*
- *Choanotaenia infundibulum*
- *Hymenolepis* spp.
- *Metroliasthes lucida*
- *Fimbriaria fasciolaris*

Nematodes (in digestive tract)
- *Capillaria* spp.
- *Trichostrongylus tenuis*
- *Heterakis* spp.
- *Ascaridia* spp.
- *Gangylonema ingluvicola*
- *Cheilospirura* spp.
- *Dispharynx nasuta*
- *Tetrameres* spp.
- *Subulura* spp.

Nematodes (in respiratory tract)
- *Syngamus trachea*

Nematodes (in the eye)
- *Oxyspirura* spp.

Nematodes (in other locations)
- *Aproctella stoddardi*
- *Singhfilaria hayesi*

Acanthocephalans
- *Mediorhynchus papillosus*

Arthropods
- External parasites like lice, fleas, flies, mosquitoes, midges, and ticks occur in most gallinaceous birds. Mites occur above all in intensively reared gallinaceous birds, predacious bugs in some gallinaceous birds.

Restraint

Cocks with spurs can injure handlers, especially when they become increasingly aggressive during the mating season. The beak can also serve as a weapon. Although serious injuries are rare, the face and the eyes of handlers should always be protected from a bird's beak, even in small species. The legs of a gallinaceous bird should be the initial focus for restraint.

Catching gallinaceous birds in an aviary can be done gently with a hooked, long stick. The birds should never be restrained by the feathers alone. The whole body must be secured to prevent a shock molt. Shock molt is most common in tail feathers, but other feathers can be involved. Birds can be nearly "bald" after several failed restraint attempts. In larger species, the base of the wing is fixed with one hand and the legs are controlled with the other hand (see Chapter 44). The abdomen should be supported from below. If assistance is not available, a large bird can be restrained by placing it under one arm and pressing it gently against one's body.[11] Birds can usually be calmed by placing a loose-fitting, lightweight cotton sock over the head to reduce vision.

Disease Considerations[3,8,14,39]

Gallinaceous birds are susceptible to a wide variety of viral, bacterial, mycoplasmal, parasitic, chlamydial, rickettsial and fungal agents (Table 45.7). Information on these diseases may be found in the appropriate chapters.

Nutritional Diseases

Vitamin C deficiency does not occur in most birds; however, it has been reported in Willow Ptarmigan chicks, and may occur in other grouse chicks.[16] Though the chicks are able to produce endogenous vitamin C (as all gallinaceous birds probably can), the internal production is not sufficient in the first weeks of life, and has to be augmented by the intake of vitamin C from natural food plants (eg, blueberries). Clinical signs of vitamin C deficiency are abnormal behavior, enteritis, ruffled plumage, weakness of the wings and legs, bone fractures, retarded growth and death before the age of four weeks. Characteristic necropsy findings include weight loss, pale and edematous skeletal muscles, petechial hemorrhage in the muscles and mild subcutaneous edema. Fractures in the diaphysis of the humerus, radius, ulna, femur and tibiotarsus with massive callus formation and lateral twisting of the tibia may also occur. Feeding the chicks natural food stuffs will prevent vitamin C deficiency.

Integument Concerns

Amputation of the comb or the wattles may be indicated following extensive injury, infection or frostbite. Adequate hemostasis is necessary to prevent fatal hemorrhage. Occasional trimming of the keratinous tip of the bill is necessary if the horny layer grows too fast, or is insufficient abrasive materials are available to facilitate normal wear. The excessive horn is pared off prudently with a sharp knife without cutting into the viable parts of the bill.

Cannibalism may occur in some Galliformes and is characterized by vent-picking, feather-pulling, toe-picking, head-picking and egg-eating. Overcrowding, incorrect feeding, an inappropriate daylight cycle, poor housing conditions (eg, high proportion of toxic gases in the air), genetic predisposition and other factors may all promote cannibalism.

Amputating the comb and wattles and "debeaking" have been used to control cannibalism; however, these control methods should be viewed as cruel and unacceptable procedures. These procedures are painful, cause permanent loss of tissue, may heal improperly or become infected and cause a change in social ranking. The bill is not only important for the uptake of food, but also has sensory functions, and is necessary for preening. Damage to the beak should be considered a substantial handicap. In most cases, cannibalism can be successfully prevented by correcting deficiencies in the birds' environment; however, once feather picking is initiated, some birds never stop. In these cases, affected birds should be separated from the remainder of the flock.

Trimming of the flight feathers in one wing can be used to prevent birds from escaping from open aviaries, or to reduce the mobility of an aggressive cock during the breeding period. Usually all but the outermost two primaries and the innermost three secon-

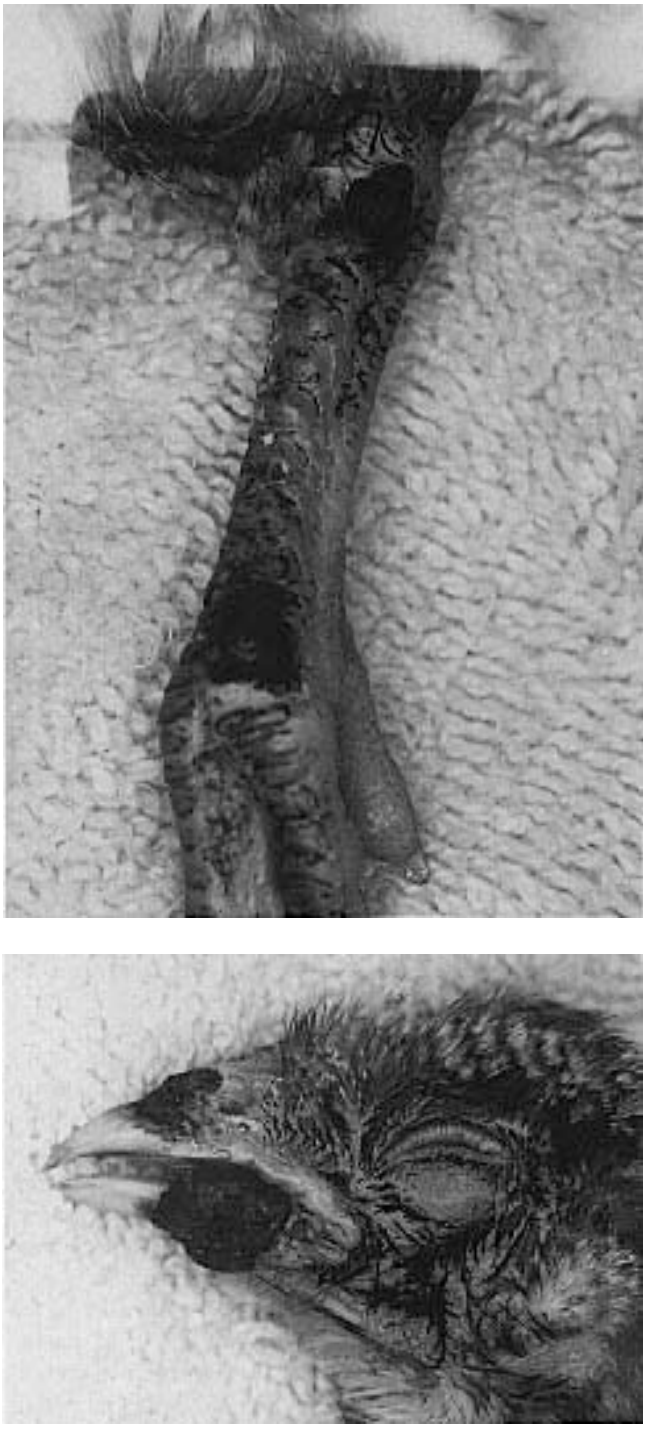

FIG 45.3 Poxvirus lesions on the legs and beak of a gallinaceous bird. The client had placed black shoe polish on the lesions, which is a commonly discussed lay treatment of poxvirus. The shoe polish will delay healing and may cause secondary infections.

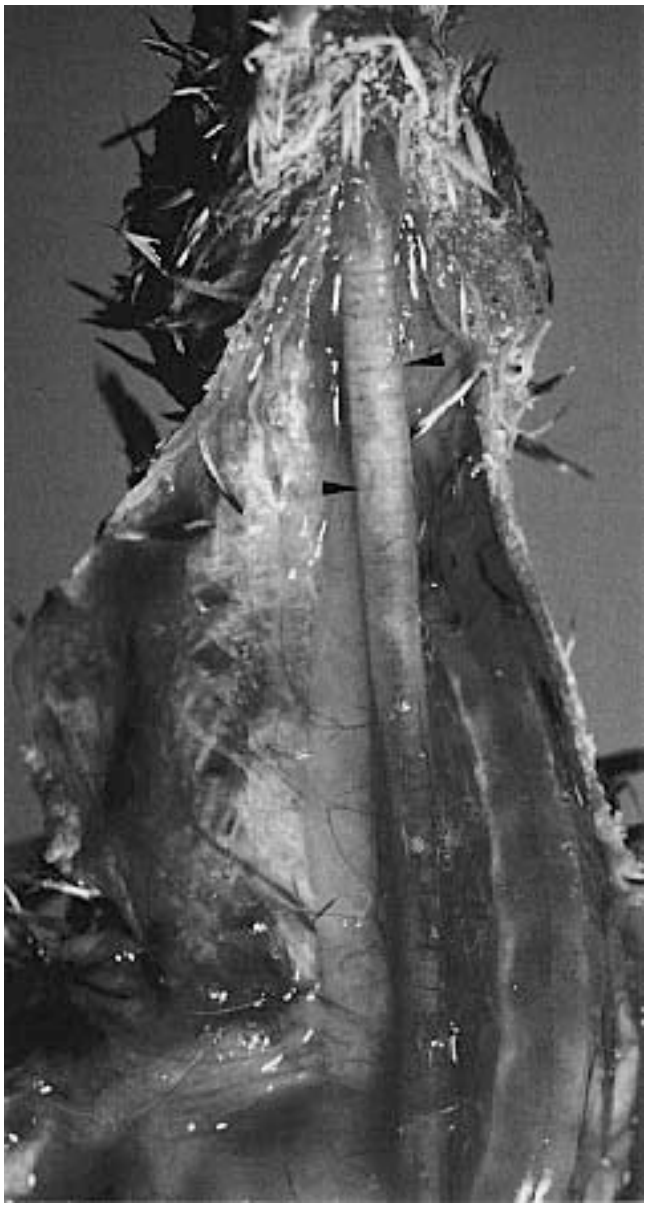

FIG 45.4 Necrotic tracheitis in gallinaceous birds is frequently caused by laryngotracheitis virus. Infected birds may develop sneezing and coughing and have audible tracheal rales. Gross necropsy findings frequently include diphtheritic tracheitis with the accumulation of necrotic debris (arrows) that may cause asphyxiation (courtesy of SW Jack).

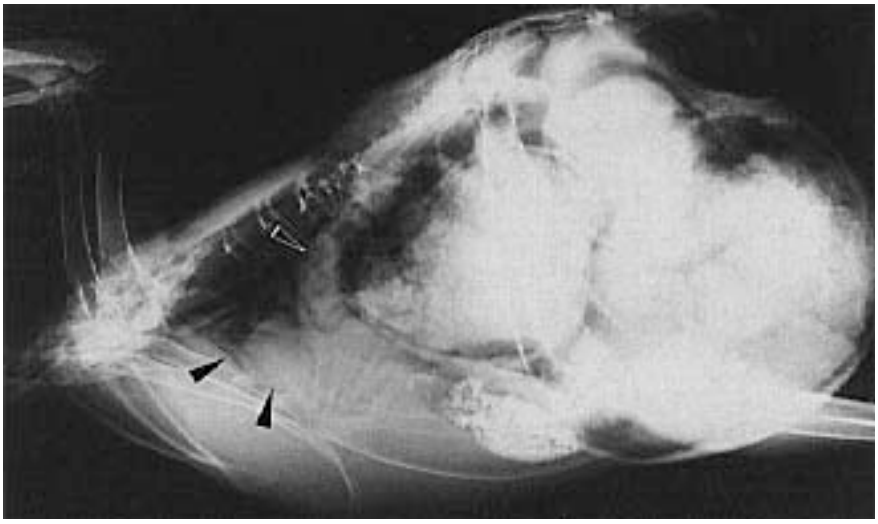

FIG 45.5 An adult Brown-eared Pheasant hen was presented for severe dyspnea and anorexia, which had initially been noted two days earlier when the hen produced a soft-shelled egg. Radiographs indicated gastrointestinal impaction with cranial displacement of the heart (arrows) and intestinal tract (open arrow). At necropsy, fibrous exudate and ingesta were covering the abdominal viscera. The ceca were impacted and had thickened walls. Histopathology indicated *E. coli* peritonitis with severe *Heterakis* sp. typhlitis.

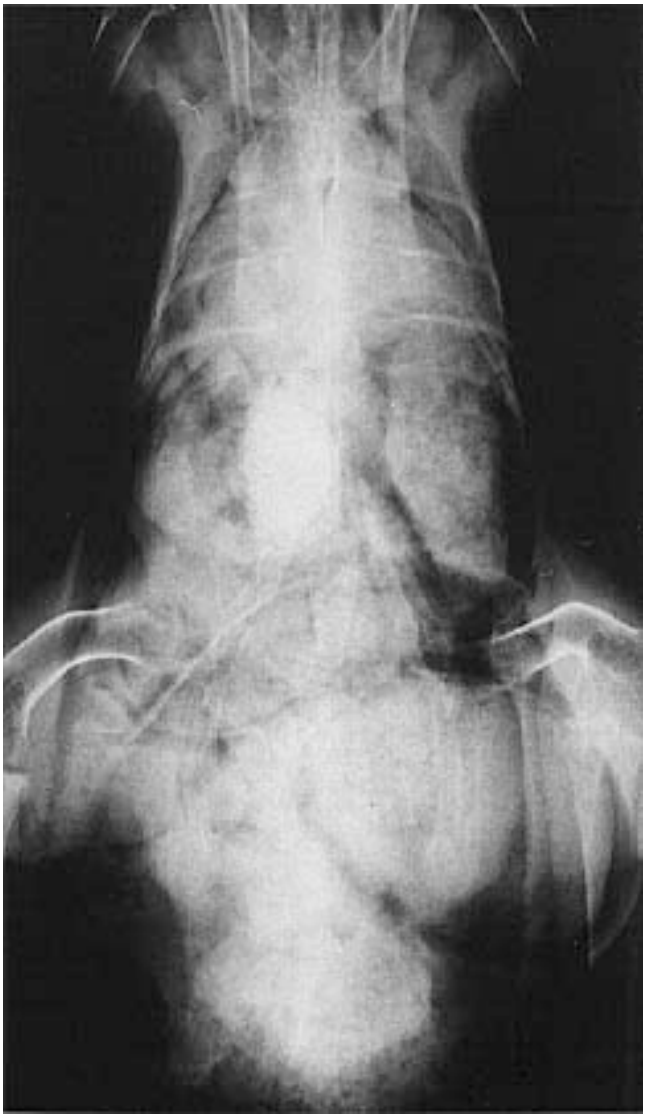

daries are transected, creating an effective and cosmetic wing trim (see Chapter 1). With one wing trimmed, the bird is unbalanced and cannot gain speed during flight. Because the feathers will be replaced during the next molt, trimming must be repeated annually in adults. Under certain circumstances, it may be necessary to trim both wings. Other methods, like pinioning or cutting the short tendon of the extensor carpi radialis, make birds permanently unable to fly. The client should be made aware of the consequences of these procedures.

Heterakis sp.

Heterakis isolonche infections have been described in a number of free-ranging and captive Galliformes. This parasite causes typhlitis with clinical signs of infection including diarrhea, weight loss and depression. Mortality rates in captive pheasants may reach 50%. The parasite invades the wall of the cecum and causes lymphocytic infiltration and granuloma formation. In pheasants, the nodules merge, leading to substantial thickening of the cecal wall. The ceca may dilate and increase in size (volume) by up to ten times (Figure 45.5).

CHAPTER

46

ANSERIFORMES

John H. Olsen

Avian practitioners with a general understanding of Anseriformes are needed to care for valuable private waterfowl breeding facilities as well as backyard waterfowl. Waterfowl have generally been treated on a flock rather than an individual basis; however, a flock approach to rare birds, pets or small collections is usually not accepted by the client. Waterfowl aviaries are frequently plagued by problems associated with overstocking, poor management practices, and pathogen-contaminated ground or water.[37,51,39,108]

Veterinarians who plan to treat free-ranging or captive Anseriformes in the United States should be aware of pertinent federal and state laws. The Migratory Bird Treaty Act involves the US, Mexico, Canada and Japan, and provides federal protection for all free-ranging birds in the US except for resident exotic species such as the English sparrow, starling, feral pigeon and resident game birds such as pheasant, grouse and quail. It is unlawful for anyone to kill, capture, collect, process, buy, sell, trade, ship, import or export any migratory birds, eggs, nests or part thereof without first obtaining an appropriate federal permit. These regulations do not necessarily apply to waterfowl species not indigenous to North America. Most states also have their own regulations.

The state requirements for interstate shipment of Anseriformes vary. Some states require testing for *Salmonella* sp., avian influenza, exotic Newcastle disease virus and duck plague virus before an import permit is issued. The state veterinarian's office in the destination state should be contacted to determine specific requirements.

Biology

Family and Subfamily Characteristics

Anseriformes have nostrils that connect with one another and a lower mandible with a long process at the angle. The sternum has two indentations or foramina at the rear. Two pairs of muscles are located between the sternum and the trachea. The neck is extended in flight. There are 10 to 11 primaries, the fifth secondary is absent and there are 12 to 24 tail feathers. Down feathers are numerous in the fully developed plumage. The unspotted eggs are light in color. The young are nidifugous, have a dense, downy plumage and are tended for a long time by one or both parents (except in parasitic species that lay eggs in the nests of other birds). The flamingos and the Ciconiiformes (herons, bitterns) are the nearest relatives of the Anseriformes (Figure 46.1).[37]

The Anhimidae are goose-sized birds of fowl-like appearance, with thick, long legs and unwebbed feet. They weigh two to three kilograms.[37] The bill is game bird-like with a downward hook and has none of the filtering fringes (lamellae) common in ducks. Flight feathers are molted gradually so that, like the Magpie Goose, but unlike most waterfowl, they do not pass through an annual flightless period.[39]

The family Anatidae has three subfamilies. Subfamily Anseranatinae contains the Magpie Goose. This bird differs from the rest of the family. The feet are slightly webbed with an unusually long hind toe adapted for semiterrestrial life. The trachea is elongated in adults of both sexes, and in adult males may reach 150 cm long. The trachea is not convoluted inside the sternum as it is in some swans (Figure 46.2); in contrast, the trachea penetrates the area between the breast muscles and the skin in a manner comparable to that in certain species of Cracidae. The elongated trachea probably functions as an effective resonator producing low-frequency sounds.[51]

Breeding birds often form trios consisting of a male and two females that lay their eggs in a single nest. All the birds share incubation responsibility. Magpie Geese are the only waterfowl species to provide food

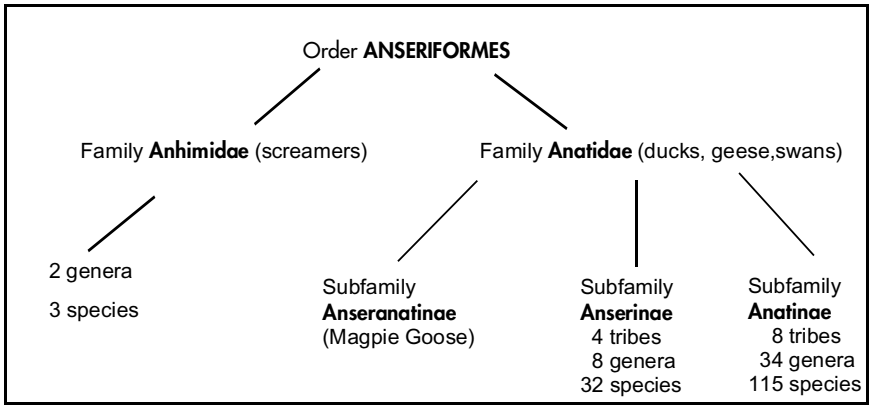

FIG 46.1 The order Anseriformes.

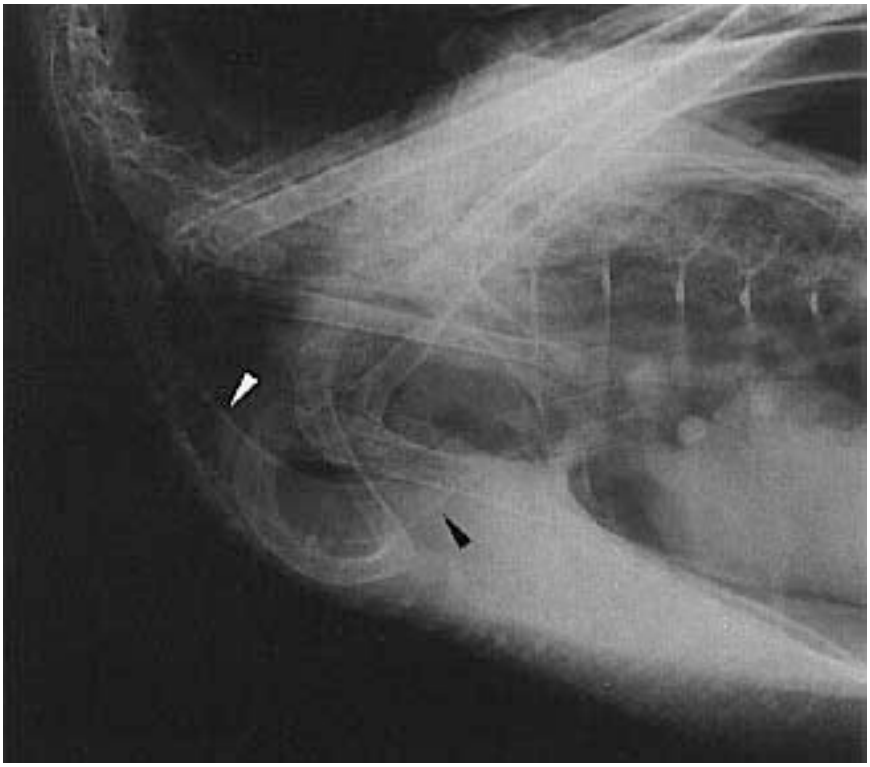

FIG 46.2 The structure of the trachea and syrinx varies among Anseriformes. A syringeal bulla may be present on the left side of the syrinx in male ducks (see Figure 12.16). In this goose, the trachea can be seen to be more elongated (arrows) than in companion birds, and the sternum is broad and less convex than in many avian species.

to their young. The adults deposit proper foodstuffs in front of their downy chicks.[51]

The subfamily Anserinae includes Whistling Ducks, swans, true geese, Cape Barren Geese and Freckled Ducks. These species undergo a complete annual molt following the breeding season. The flight feathers are shed almost simultaneously so the birds are unable to fly for a period of about three to six weeks. The front toes are fully webbed except in two semiterrestrial species of geese. In all species, the plumage is monomorphic and all species lack iridescent coloration, even on the wings.[51]

Subfamily Anatinae includes Sheldgeese, Shelducks and all the typical ducks. Most of the members of this subfamily molt the body feathers twice each year. Consequently, the breeding (nuptial) and non-breeding (winter or eclipse) plumage are distinct. In some species the breeding plumage of the male closely resembles that of the female, but more often, the genders have dimorphic plumage. There is frequently a gender difference in calls as a result of a difference in the structure of the syrinx and sometimes the trachea. The front surface of the lower tarsus has a linearly arranged (scutellated) scale pattern not seen in the other subfamilies. Iridescent coloration is frequently present in the plumage, particularly among males. The male of sexually dimorphic species is typically larger, more brilliantly patterned and more aggressive. The plumage of juveniles and the non-breeding males generally resembles that of the adult female. The patterns of the downy young are often quite contrasting and distinctive, and usually include spotting and striping on the head and back. Males of this subfamily do not assist in incubation but, depending on the tribe, participate in brooding the chicks.[51]

Diversity of Anseriformes

Waterfowl species range in size from the diminutive Pygmy Goose (300 g) to the Trumpeter Swan (13.6 kg), which has a wing spread approaching 2.5 m (Table 46.1). Normal body weight can vary tremendously with the season.

Although Anseriformes generally surface feed, they may also graze or feed by diving. Some species are omnivorous while others are strictly herbivorous. For example, the Ruddy Shelduck has been observed eating carrion, whereas the algae-eating Pink-eared Duck of Australia has a highly specialized bill for filter feeding.[108]

A few species are widely distributed, such as the Northern Pintail, which is found over nearly the entire northern hemisphere. The Madagascar White-eye, on the other hand, occurs on only a few island lakes. Ducks are usually sexually dimorphic (exceptions: Pekin, Muscovy, American Black and Mexican). Swans and geese are usually sexually monomorphic (exceptions: Magellan and Kelp geese).[56]

Most waterfowl are excellent swimmers, with webbed front toes and short legs. The short femurs, long tibiotarsal bones and extremely short tarsometatarsus bones are adapted for powerful swimming and account for the poor ambulatory abilities and characteristic waddling gait when Anseriformes attempt to walk. The normal speed of swimming for waterfowl is about two to three miles per hour.[108] Most diving ducks stay within 10 to 20 feet of the surface. The Oldsquaw and King Eider are reported to dive at least 180 feet.[108]

Waterfowl are thickly feathered and have compact waterproof plumage and a dense coat of insulating down. A Whistling Swan may have 25,000 feathers, a Green Wing Teal, about 11,500. They have a highly developed uropygial (oil) gland. Frequent preening and oiling is imperative to keep feathers in prime condition so that chilling and sinking do not occur. Waterfowl are generally powerful fliers that cruise with their necks and legs extended. The wing beat of swans is approximately 160 per minute, while some ducks may exceed 300 wing beats per minute. The Canvasback Duck, one of the fastest waterfowl, has been clocked at 70 mph in flight, but normally cruises at 25 to 35 mph. During migration, waterfowl often cruise at 1000- to 3000-foot elevations, but may go as high as 20,000 feet or more.[108]

Ducks have anatomic variations in the syrinx that should not be misinterpreted as pathologic lesions. In most ducks, only the male has a left-sided enlargement of the syrinx (syringeal bulla) (see Figure 12.16). This structure may be responsible for courtship vocalizations. Vocalizations are also used as communication for defense, warning, recognition and flocking signals.[84,108] A syringeal bulla is not present in geese and swans. In swans the trachea is elongated and in the Trumpeter Swan it extends into the sternum, turns on itself and reenters the syrinx (see Figure 12.17).

Many waterfowl species roost on shore where they typically sleep while standing on one leg with the head turned back and the bill inserted into the scapu-

TABLE 46.1 Anseriformes: Body Weight, Eggs/Nest and Incubation Data[8,41,108]

Common Name	Body Weight (grams)		Average Eggs/Nest	Average Incubation in Days

lar feathers. Other species seldom come ashore, preferring to sleep on the water.[108]

Young Anseriformes easily imprint on humans or other species of birds. Pair formation may be difficult in imprinted birds. Homosexual and interspecific pairs are common under captive conditions. Some geese (Cereopsis and Egyptian) may be very aggressive and should not be maintained where they can injure animals or children. Imprinted geese and swans of all species can be dangerous to children.

Physiology

Pulse and respiration rates differ so widely in normal Anseriformes that they have limited value as indicators of disease. In the domestic Pekin Duck the heart rate (HR) varies from 180 to 230 bpm and the respiration rate (RR) from 30 to 95 bpm. Daytime body temperature (BT) is 41°C.[44] In the goose, RR is 13 to 40 bpm and BT is 40.5°C.[111] The values in Table 46.2 illustrate some consistency within these species.

The heart rate slows dramatically when a bird dives and there is an increased use of oxygen in the blood. Heat loss occurs through panting or through the webs of the feet. Anseriformes will try to prevent heat loss through the feet by squatting down on them in cold weather.[44]

Anseriformes from tropical countries (eg, Whistling Ducks) are prone to frostbite and subsequent gangrene of the toes. These species should be housed indoors during freezing conditions. Otherwise, waterfowl are remarkably tolerant of adverse climatic conditions, especially if open water is available for swimming. They can be maintained successfully in most regions of the world.[44]

The growth rate in Anseriformes is usually faster than that of gallinaceous birds. Species from extreme latitudes grow faster than those from low latitudes. Growth rate and egg production appear to be related to day length during the breeding period.[56]

Anseriformes are often long-lived. In captivity, ducks often live 10 to 12 years, and geese and swans commonly live for 25 years or more.[44] Mortality rates in free-ranging birds are high. Smaller duck species survive two to three or possibly up to six breeding seasons. In the first year of life 60 to 70% of the annual hatch die, and 90 to 95% die before three years of age. Some free-ranging ducks are known to survive 16 years and geese, 18 years (Table 46.3).[108,111]

Evaluating blood parameters is a useful diagnostic tool in Anseriformes. Limited data are available on many species, but there is considerable data on Mallard Ducks. Selected serum constituents and hematologic parameters were analyzed[a] from Mallard Ducks of both sexes during several stages of reproduction: pre-egg laying, egg laying, incubating, molting and post-reproductive (see Appendix).[22,23] Similar assays were also conducted on ducklings, 5 to 58 days of age. These findings indicated that clinical chemistry values must be evaluated with respect to sex, age and reproductive status of the birds. Lactate dehydrogenase (LDH), cholinesterase (CHE), alanine aminotransferase (ALT), aspartate aminotrans-

TABLE 46.2 Compilation of Normal Parameters in Pekin and Muscovy Ducks

Parameter	Pekin Duck[35,67,90]	Muscovy Duck[55]
Cloacal Temperature (°C)	40.5 - 41.6	39.1 - 41.1
Heart Rate (bpm)	150 - 250	
Respiratory Rate (bpm)	13 - 23	
Mean Arterial Blood Pressure (mmHg)	111 - 142.5	
PaO_2 (mmHg)	73 - 109.1	80 - 83
$PaCO_2$ (mmHg)	28.9 - 43	32 - 39
HCO_3 (mEq/l)	19.6 - 24.8	
Blood pH	7.36 - 7.48	7.48 - 7.53
Tidal volume (ml)	40 - 58	
Minute ventilation (l/min)	0.67 - 0.97	

ferase (AST), creatinine (CRN) and direct bilirubin (BIDI) were the only parameters that did not vary with the reproductive status of the bird. All assays except albumin (ALB), glucose (GLU), calcium (CA) and magnesium (MG) showed age-related changes (see Appendix).[23]

For nonreproductive birds, GLU was the only assay where values differed between males and females. Hens and drakes in pre-egg laying condition had significantly different concentrations of ALB, gamma-glutamyl transferase (GGT), CA, phosphorus (PHOS) and MG. Laying hens differed from drakes in the ALB, amylase (AMY), GGT, CA, PHOS, MG, uric acid (UA) and total bilirubin (BITO) assays. Incubating birds had sex-related differences in ALB, AMY and PHOS concentrations. In molting birds, only AMY differed between the genders.

Egg-laying activity significantly influenced serum enzyme activity and chemistry concentrations, causing increased values in 12 of the 17 assays. Egg-laying hens had a ten-fold increase in GGT during the reproductive periods. AMY doubled during egg laying while other constituents increased by a statistically significant, although lesser, amount. Values of 12 of the assays in samples from the drakes also differed by reproductive condition. GGT activity in molting males was twice their nonreproductive values (see Appendix).[23]

Differential white blood cell counts were also recorded in these test birds. Gender or reproductive state of the adult birds did not significantly change (P) the cell ratio. Non-laying and laying birds had a similar number of thrombocytes, which were significantly greater than thrombocyte counts of incubating, molting or post-reproductive birds. Young birds had a decrease of the percent lymphocytes from 50 to greater than 60 days of age and a concomitant, compensating increase in percent heterophils. Thrombocyte numbers increased from 5 days of age to a peak at 18 days of age, after which they did not vary significantly.[22]

TABLE 46.3 Longevity of Selected Waterfowl[37,39,51,52,108]

Species	Years

Egyptian Goose	25
Greylag Goose	26
Magpie Goose	26
Trumpeter Swan	32.5
Canada Goose	33

Husbandry Practices

Hospitalization

Anseriformes are relatively easy to restrain. Their primary defenses include scratching with sharp toenails, pinching with their bills, striking with their wings or poking at eyes. A dry, warm enclosure with good footing is suitable for brief hospitalization. When confined, waterfowl sometimes stress, so a quiet, dimly lighted enclosure may be preferable. If longer hospitalization is necessary, an enclosure with an accessible pool and padded flooring[b] is necessary to prevent leg and foot problems. Hard surfaces (concrete) may damage the plantar foot surfaces, eventually promoting bumblefoot. Chain-link enclosures should be protected with burlap or other similar materials to prevent birds from abrading their wings, heads or eyes.

Housing

Waterfowl are commonly kept as pairs in small, planted, open pens with a small pool or stream, or in large, open, mixed-species groups with a large pond. Most Anseriformes should have an area for swimming to maintain long-term overall health. Open enclosures allow various free-ranging birds to com-

pete for feed and nesting sites and potentially to introduce infectious diseases (Figure 46.3). Pests and predators (rats, snakes, otters, raccoons, bobcats, opossums, hawks, owls and eagles) may also complicate waterfowl maintenance in large open exhibits. Burying the fence line will discourage some predators from digging under the fence, and electric fencing will discourage terrestrial predators. Some aviculturists use small aviary mesh to cover pens to reduce access by free-ranging birds, pests and predators.

FIG 46.3 While aesthetically pleasing, open enclosures create management problems with respect to free-ranging birds, rodents and predators. A portion of the pond should be protected from the sun, which was accomplished in this enclosure using shade cloth. The pool has gently sloping sides and can be easily drained for cleaning (1994 Busch Gardens Tampa. All rights reserved.).

Covered enclosures allow birds to be full-flighted (most are typically pinioned or wing-clipped to prevent escape from open enclosures). Wing clipping is accomplished by cutting the flight feathers from one wing with a pair of scissors or shears. This procedure impedes flight until the next molt. The feathers should be trimmed at the level of the rachis, not at the level of the hollow calamus. This will reduce the chances of water entering the feather shaft, resulting in algae growth and folliculitis. Pinioning is the amputation of the distal portion of the wing, permanently handicapping a bird's flight abilities.

Large ponds should have islands to provide nesting areas and privacy for the birds. Some birds will nest on small floating platforms. Grazing species, such as geese, require more land area than do diving ducks. Small ducks can be maintained in small planted pens with an elevated cement water container that holds three to five gallons.

A high water flow rate or filtration is important for maintaining clean water and reducing the incidence of disease. Cold water is better for ponds than warm water. Generally, a depth of two feet is adequate for most Anseriformes, although swans and some diving ducks require three to four feet of water.[108] Many waterfowl species require standing water to breed. Anseriformes typically dig or nibble at the pond bank. Lining the banks with concrete blocks, stone or other solid materials will help maintain pond continuity.[44]

The nasal secretions of some marine and semi-marine waterfowl are believed to inhibit the growth of mycotic spores. If these species are maintained in fresh water, the salt glands producing these secretions may atrophy, affecting the bird's ability to resist infections.[44] These birds may die from hypernatremia if they are returned to salt water.

Multiple-species aviaries are frequently constructed with pens arranged in rows and a common stream flowing from pen to pen. This arrangement creates disease control and maintenance problems. Preferably, each enclosure should have an individual pool draining into a common drainage ditch that does not contain animals (Figure 46.4).

Planted aviaries provide nesting materials, shade and privacy for sensitive species. Large, destructive waterfowl, such as swans and geese, require hardy plants. Safe plants that are partially bird-proof include juniper, palm, pine, bird of paradise, coral tree, cycad and natal plum. Geese and other grazing birds do well on golf course fairway grasses (eg, hybrid bermuda) (Figure 46.5). In warm climates, Korean grass (Zosia or Zoysia) provides a relatively durable, lush ground cover that birds tend not to consume.[108]

Housing is not usually necessary for Anseriformes if they have access to open water. Some very sensitive tropical species may require protection during the winter. Water circulation systems should be used to keep ponds from freezing in the winter. If housing units are necessary, they should contain soft flooring or mats to prevent calluses and abrasions that are common with unprotected concrete floors.

FIG 46.4 Facilities that are designed with individual enclosures, but a common pool, increase the risk of disease transmission. Preferably, each enclosure should have its own pool that can be drained into a common ditch outside the enclosure (1994 Busch Gardens Tampa. All rights reserved.).

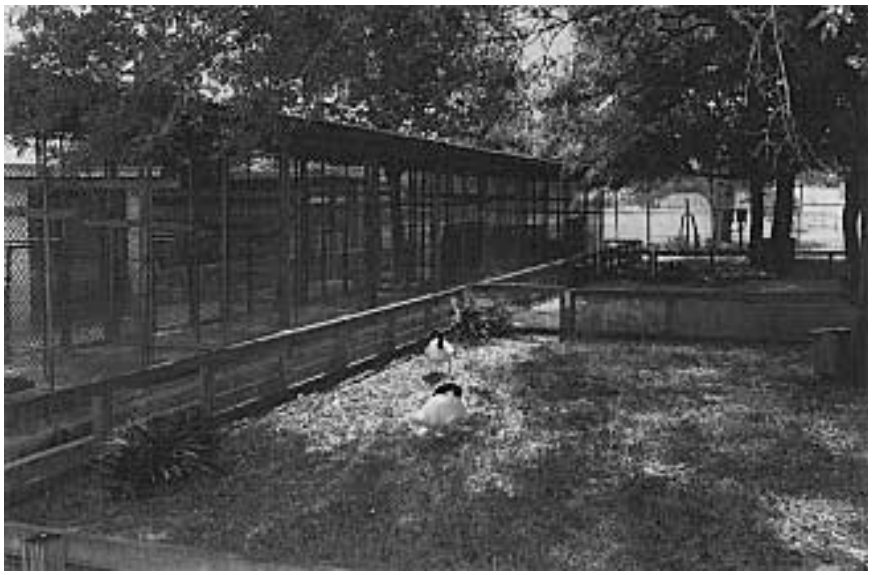

FIG 46.5 Geese and swans should be provided ample areas for grazing (1994 Busch Gardens Tampa. All rights reserved.).

Nutrition

Considerable nutritional information is available for commercially produced waterfowl; however, very little information is available for nondomesticated species. Because of a lack of extensive research, nutritional recommendations for nondomesticated Anseriformes are often based on observation and opinion.

The types of food consumed, and thus their nutritional components, vary widely between surface-feeding ducks and divers. High protein (28%) gamebird rations are frequently recommended for feeding ducklings; however, it has been found that a ration of 19% protein supplemented with scratch grains on a free-choice basis produced better growth and feed efficiency than higher protein diets (Table 46.4). Diets with 8% animal protein (19% total protein) promoted the best growth. Redhead, Pintail and Canvasback chicks grew best when fed a starting diet containing 2,970 kcal/kg and 19% protein until three weeks of age.[43] After three weeks of age, this pelleted diet was offered free choice with a mixture of cracked corn, wheat and oats or barley (the grain mixture used should depend upon the grains that free-ranging ducks are likely to consume).[97] Amino acid quality of the diet was maintained by the inclusion of 8% fish meal. This diet produced similar results with both dabbling and diving ducks, even though their natural feeding habits differ widely. This did not include species such as the sea ducks and mergansers that feed exclusively on fish.

Rations designed for feeding commercial ducks are not generally recommended for the long-term maintenance of other waterfowl. These diets are designed to produce a carcass to be processed for food and usually contain growth additives and compounds to stimulate feather loss. The fat content in dog foods is much higher than waterfowl can tolerate, particularly when mixed grains are fed as part of the diet. Most ducks have a tendency to deposit excessive fat in the abdomen and around the heart and ventriculus, and overweight birds frequently die from fatty liver degeneration (see Color 20). Adequate levels of choline chloride have been found to help protect Anseriformes from fatty infiltration of the liver.[45,81]

FIG 46.6 A 1.5-year-old female duck was presented with a three-week history of anorexia, ataxia and inability to fly. Abnormal clinical pathology findings included WBC=24,000, LDH=479, PCV=36.5. The bird was offered free-choice grit and, for an undetermined reason, engorged on grit, causing an impaction. The bird was given corn oil by gavage tube to facilitate passage of the grit.

Many experienced Anseriforme breeders are convinced that all waterfowl need a high-protein diet, and one pelleted ration is fed to all species. This is an inaccurate and dangerous assumption. Many geese are grazers, and most lush grasses seldom exceed 17% protein. Feeding high-protein diets to these birds can cause terminal renal failure. In addition, excessive water consumption is necessary to remove the extra protein, and a relatively short period of water deprivation can be fatal.[45,81] High-protein diets may also cause developmental abnormalities in the wings and legs.

Diets designed for the long-term health and breeding of Anseriformes are listed in Table 46.4. Chicken, broiler and commercial duck diets are not acceptable for commonly maintained Anseriformes. A turkey ration (20% protein) can be used as an adequate diet for recently hatched ducklings. This should be supplemented with scratch grains when birds are two to three weeks of age. After the birds mature, they can be fed a maintenance diet of 10% turkey grower pellets and 90% mixed grains until laying season begins. If grains are fed to ducklings, their diet should be supplemented with a hard, insoluble granite grit. Various-sized particles should be sprinkled on top of the feed when the ducklings are eating well (about three days of age). Later it can be provided in a separate dish. Some breeders add four percent grit to their pellets (Figure 46.6).[45,81]

Feeding Habits of Free-ranging Ducks

The fall and winter diets of non-breeding, free-ranging waterfowl depend largely on the kinds of foods available in each particular locality. Gadwalls wintering in Louisiana were found to consume 95.3% vegetable foods and only 4.2% animal matter. White-faced Tree Ducks of Senegal were found to consume primarily seeds, rice, grass, water lilies and tubers. Studies with free-ranging Mallard Ducks have shown that, when given a choice, these birds consumed those foods that were most readily available in volume. When a choice was given between barley, soft wheat, or two varieties of hard wheat, the ducks preferred the barley.

Post-breeding feeding studies of Redhead Ducks at Long Island Sound showed that plant material accounted for over 90% of the total food intake in both males and females. Muskgrass and fennel leaf pond weed were the most important foods. In the breeding season, the females appeared to prefer the tubers and root stalks of this pond weed.

In New South Wales, Black Ducks were found to eat a varied diet including seeds of grasses, swamp plants, legume plants, water snails, water beetles (adults and larvae), water spiders and ostracods, as well as terrestrial invertebrates. In one study, Canvasback hens were found to enter the breeding season with heavy fat reserves and appeared to consume decreased quantities of food throughout the laying

period. Redhead hens were found to forage continuously on the most abundant foods in the marsh. During the laying and incubation periods, the Canvasback hens lost about 68% and the redhead hens, about 76% of their lipid stores.

Female free-ranging ducks seem to instinctively consume more animal materials during the laying period than they do during other times of the year. In male and non-laying female Mallard Ducks, it was found that animal foods represented about 38% of the total food intake. In comparison, animal foods represented about 72% of the diet of laying females. It is possible that ducks increase animal food consumption during breeding for reasons other than an instinctive desire for additional protein.

Studies in chickens have shown that they consume food to satisfy an inner craving for energy. They will increase their consumption of low-energy diets in order to grow and perform normally, but will not increase their consumption of low-protein diets, even when these diets are too low in protein to support normal body requirements. Breeding hens also appear to have an inner instinct that calls for extra consumption of calcium during egg production. When offered graded levels of calcium during the egg-laying period, hens will increase the total food intake when the calcium content of the diet is low. The increase in consumption of animal materials during the breeding season may relate to calcium needs rather than protein.[97]

Free-ranging ducks and geese consume large quantities of energy-rich foods to establish the fat reserves necessary for migration. The same diet fed to captive birds will predispose them to obesity and fat metabolism problems when they are provided excessive quantities of food.

TABLE 46.4 Diet for Wild Ducklings

	WILD DUCK STARTER RATION	WILD DUCK GROWER RATION
Ingredient	**Pounds per Ton**	
Corn meal, No. 2 yellow	933.0	753.0
Oats, heavy, pulverized	200.0	400.0
Wheat standard middlings	300.0	300.0
Soybean oil meal, 50% protein, low fiber	250.0	280.0
Fish meal, 60% protein	160.0	100.0
Fish solubles, dried basis	10.0	10.0
Dried brewer's yeast, 40% protein	20.0	20.0
Whey, dried product, 55% lactose	20.0	20.0
Alfalfa meal, dehydrated, 17% protein (100,000 A/lb)	60.0	80.0
Dicalcium phosphate	10.0	10.0
Calcium carbonate, ground	30.0	20.0
Salt, iodized	5.0	5.0
Manganese sulfate, feed grade	0.5	0.5
Copper sulfate	0.5	0.5
Zinc carbonate	0.25	0.25
DL-methionine (hydroxyanalog)	1.0	1.0
Santoquin		0.25
Vitamin, Unit of Measure	**Amount per Ton**	
Stabilized vitamin A, USP units	10,000,000	12,000,000
Vitamin D_3 ICU	1,500,000	1,500,000
Vitamin E, IU	5,000	5,000
Riboflavin, grams	3	4
Choline chloride, grams	112	250
Niacin, grams	40	40
Calcium pantothenate, pure D-isomer, grams	6	10
Vitamin K (menadione sodium bisulfite), grams	4	4
Vitamin B_{12}, milligrams	6	6
Calculated Analysis (%)		
Protein	20.0	19.0
Fat	6.5	5.0
Fiber	4.0	4.5
Calcium	1.2	1.0
Phosphorus	0.7	0.7

Starter ration to be fed for first three weeks with insoluble grit available at all times. Grower ration to be fed from 21 days of age to maturity with scratch grains free choice. Grit to be available at all times. This diet plus scratch grain free choice can be used as a maintenance ration and for nonlaying breeders (adapted from Hyde[45]).

Geese appeared to have a better ability to utilize dietary fiber than ducks.[97] Captive geese did best when provided alfalfa hay in addition to a pelleted ration. Geese do well when fed the same diets recom-

mended for ducks (Table 46.4). A duck starter diet should be provided for four weeks, followed by the duck grower/finisher diet until maturity. Scratch grains should be added to the grower/finisher diet, approximately 50:50, after eight weeks of age.[97]

A duck's ability to gather food from flooded or muddy areas is assisted by cutaneous mechanoreceptors on the bill and tongue, which allow them to quickly differentiate edible from non-edible matter. Taste buds may also assist in this process.[97] A duck's bill is designed to allow efficient straining of submerged food particles (Figure 46.7) as well as the intake of most dry foods of appropriate size. They are not equipped for the consumption of mixed feeds in a dry mash form. Mashes tend to form a sticky paste when mixed with saliva and adhere to the lamellae and other structures bordering the outer margin of the tongue and upper and lower bill. The adhered material interferes with food passing to the tongue, where it is usually rotated and coated with saliva before being propelled back to the esophagus and swallowed. This results in a reduced food intake and increased feed wastage because the duck tries to shake or wash off the mash sticking to its mouth parts.[97]

When given a choice, ducks prefer pellets to mash.[97] The maximum diameter pellet a duckling can swallow easily dictates acceptable size. In North America, the two most common sizes used for ducklings are 1/8 inch (3.18 mm) and 5/32 inch (3.97 mm), with the latter being the maximum size for newly hatched Pekin ducklings. Starter pellets should not exceed a length of 5/16 inch (7.94 mm). Pekin ducklings can eat pellets 3/16 inch (4.76 mm) in diameter and about 1/2 inch (12.7 mm) in length by two weeks of age.[97]

Feeding containers for ducks should be several inches deep and at least one foot square to facilitate their normal forward "shoveling" prehension motion for food collection.[97] Anseriformes should always have access to fresh, uncontaminated water. The daily water requirement of ducks (by weight) is approximately four to five times the weight of the daily feed intake. Water and food containers should be positioned near each other. Poultry water units and nipple drinkers can be used for waterfowl (Figure 46.8).

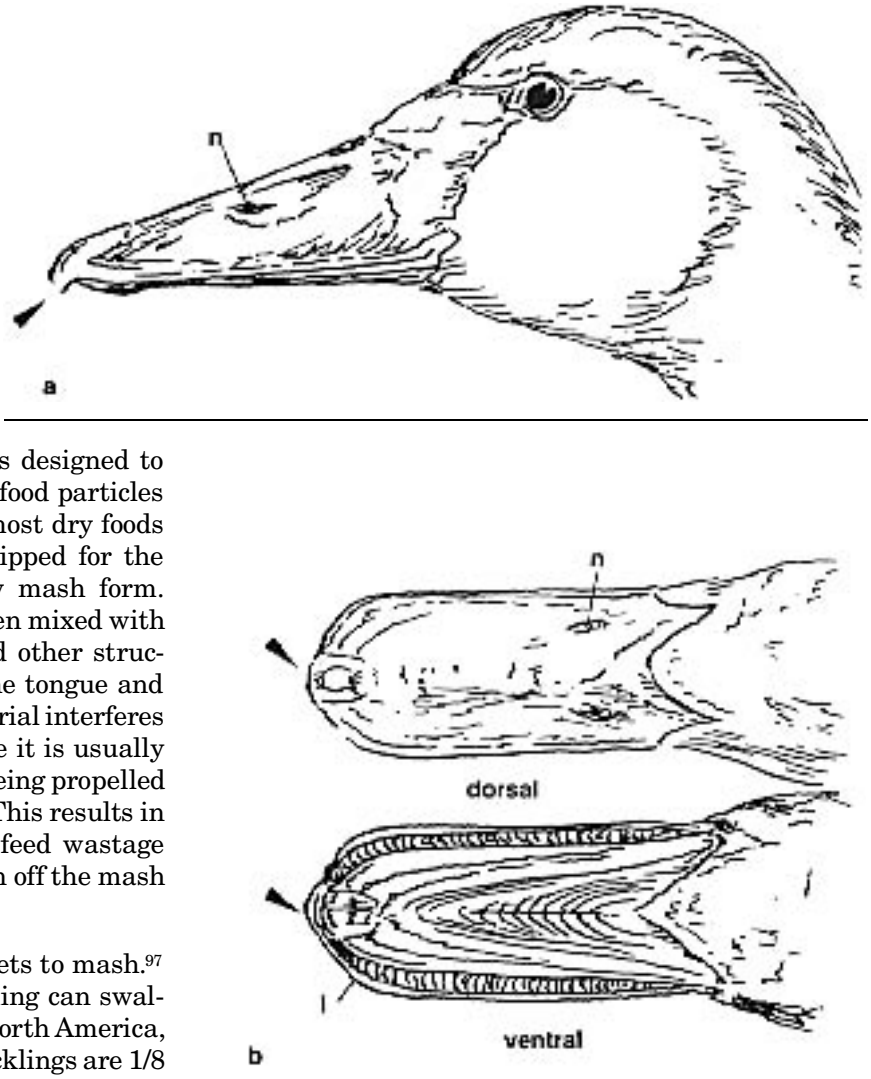

FIG 46.7 The bill of a duck is designed to gather food from flooded and muddy areas and has highly developed cutaneous mechanoreceptors. **a)** The nares (n) are located in the mid-portion of the upper beak. **b)** The epidermis is thickened at the tip of the upper beak (ducks, geese and swans) and lower beak (ducks) to form a "nail" (arrows). These nails are designed to grasp small slippery objects and have well-developed nerve endings (Herbst's corpuscles). The lamellae (l) vary in form among species and serve either to cut or to filter food (modified from Lucas and Stettenheim, 1972).

Energy Requirements

Metabolizable energy levels commonly used for poultry are similar to those required by ducks. The Pekin Duck has been shown to thrive with pelleted diets varying from 2200-3300 kcal ME/kg of diet, provided the proper ratio of energy to protein and necessary nutrients is maintained.[97]

FIG 46.8 Waterfowl should always have access to clean, fresh water of sufficient depth. The food should be kept in a flat, large container to facilitate the scooping motion of the head and neck (1994 Busch Gardens, Tampa. All rights reserved.).

Protein Requirements

Varying reports on the protein requirement of ducks may be a result of these animals' exceptional capacity for compensatory growth. Diets formulated using milo, corn, barley, wheat or other cereal grains mixed with fish meal, soybean meal, bone meal and meat have been shown to contain adequate amounts of essential amino acids except for methionine, and possibly cystine and lysine.[97]

Nutrient Requirements of Laying Ducks

Theoretical ME requirements of laying Pekin Ducks: The energy requirement for maintenance of a moderately active Pekin Duck at an environmental temperature of 21°C is about 472 kcal/day.[98] A duck egg contains 185 kcal energy/100 g egg.[109] A large Pekin Duck has an egg that weighs about 90 grams. The energy put into the egg is 0.9 x 185 = 167 kcal. The efficiency of converting feed energy into duck egg energy is about 73.6%.[24] To produce a 90 g duck egg, the feed energy needed is approximately 167 divided by 0.736 = 227 kcal. For 100% egg production, the total ME requirement of the Pekin Duck is approximately 472 + 227 = 699 kcal/day. A Pekin Duck would need to consume 252 g (0.55 lb) of a diet containing 2,772 kcal/kg to obtain this amount of ME.[97]

Theoretical protein requirements of laying Pekin Ducks: A duck egg contains 12.81% protein.[109] A 90 g egg contains 0.1281 x 90 or approximately 11.5 g of protein. The protein maintenance requirement of the Pekin Duck has been calculated to be approximately 10 g/day.[98] To produce an egg, assuming the duck is 55% efficient in conversion of feed protein to egg and tissue proteins, a duck must eat 11.5/0.55 = 20.9 g of feed protein. When this is added to the 10 g of feed protein required for body maintenance, the total feed protein needed per day is 30.9 g. When a duck consumes the 252 g of feed needed to provide its energy requirements, the feed should have 12.5% protein, balanced in all amino acids needed for maintenance and egg production. Protein requirements for feather replacement is not included in this calculation. A diet for breeding ducks with 16% protein provides a reasonable quantity of the essential amino acids. [97]

Vitamins

Recommended vitamin levels for practical commercial duck rations are in Table 46.5.[97]

- ***Vitamin A:*** Vitamin A is important in maximizing the efficiency of feed utilization. It has also been shown that young ducklings do not utilize the provitamin A found in alfalfa meal as well as they utilize preformed vitamin A.[97] This is caused by a reduced digestion of plant matter in the undeveloped cecum. The vitamin A content of the livers of ducklings remains high up to 14 days of age as a result of the vitamin A fed to the hen. After 14 days of age, the ducklings acquire vitamin A from their food.

  Hypovitaminosis A is associated with poor growth, muscular weakness, retardation of endochondral bone growth and ataxia, paralysis and death. Chronic hypovitaminosis A in ducks has not been verified but has been suggested as a precipitating factor in the high incidence of bumblefoot described in Anseriformes (see Color 8).[97]

- ***Vitamin D_3:*** Deficiencies of calcium or phosphorus result in rickets. Vitamin D_3 deficiency may occur in birds on proper diets if an animal lacks the enzymes needed to convert dietary vitamin to the metabolically active metabolite, 1,25-dihydroxycholecalciferol.[97]

- ***Vitamin E:*** Hypovitaminosis E has not been associated with encephalomalacia in ducks. The muscular dystrophy caused by hypovitaminosis E in ducklings is not prevented by dietary cystine as it is in gallinaceous chicks.[97] Prevention of vitamin E-related muscular dystrophy in ducks is mostly associated with

their requirement for dietary selenium. With low-selenium diets, 27 mg vitamin E/kg is needed to prevent myopathies. Vitamin E-deficient diets may cause neurocalcinosis in the heart, ventriculus and intestinal muscles, while skeletal muscles may have typical hyaline degeneration. Ducklings on deficient diets often will die by three weeks of age. Muscular dystrophy is prevented with diets containing 1.2 mg vitamin E/kg of food when selenium is added at a level of 0.1 ppm.[46,47]

- ***Thiamine (Vitamin B_1):*** Ducklings begin to lose weight four days after being placed on thiamine-deficient diets. "Star-gazing" is a characteristic clinical sign. If deficiencies occur, thiamine should be added to the drinking water at 100 μg/l.[97]

- ***Riboflavin (Vitamin B_2):*** Riboflavin deficiencies in ducklings cause poor growth and high mortality. The "curled toe" syndrome common in riboflavin-deficient chicks has not been reported in ducklings (see Color 48). Deficiencies in breeding ducks cause late embryonic mortality.[97]

- ***Niacin (Nicotinic Acid):*** Ducklings have a relatively high requirement for niacin, which is required for growth and prevents severe leg weaknesses. Ducks have high levels of picolinic acid carboxylase, an enzyme that converts tryptophan to carbon dioxide and water instead of allowing it to be converted to niacin. Ducklings receiving a diet deficient in niacin showed a 100% incidence of bowed legs. Severity of the leg deformities increased, and growth was depressed when 2% cod liver oil was added to the diet. The growth rate was returned to normal when 5% brewer's yeast was added to the diet. Bowed legs were completely prevented when 7.5% brewer's yeast was added. Niacin has been shown to be poorly available from natural feedstuffs, and supplementation with pure niacin may be necessary.[97]

- ***Biotin:*** The dermatitis associated with biotin deficiency in chickens has not been described in ducks. A poor growth rate appears to be the only sign of deficiency.

- ***Folic Acid:*** Deficiencies result in severe anemia as well as reduced growth and poor feathering.

- ***Choline:*** Unlike young mammals, ducklings, chicks and poults are unable to synthesize choline until later in life. Choline deficiency in Pekin ducklings causes perosis and fatty liver degeneration. Ducklings on choline-deficient diets grow poorly, have weak legs, develop perosis and may die. Most diets for ducklings contain adequate levels of choline. After eight weeks of age, it is recommended that choline supplementation be added to diets so that maximum choline biosynthesis will occur before the onset of egg production.[97]

TABLE 46.5 Vitamin Requirements for Pekin Ducks

Vitamin	A	B	C
Vitamin A, IU	8000	5000	10,000
Vitamin D_3, IU	1000	500	1000
Vitamin E, IU	25	20	40
Vitamin K, IU	2	1	2
Thiamine, mg	2.0	2.0	2.0
Riboflavin, mg	4.5	4.5	4.5
Niacin, mg	70.0	70.0	50.0
Pantothenic acid, mg	12.0	11.0	15.0
Pyridoxine, mg	3.0	3.0	3.0
Folacin, mg	0.5	0.25	0.5
Biotin, mg	0.15	0.1	0.15
Vitamin B_{12}, mg	0.01	0.005	0.01
Choline, mg	1300.0	1000.0**	1000.0**

* Must be increased to 8 mg/kg if sulfaquinoxaline or other vitamin K antagonist is present in the diet.
** growing ducks may be able to synthesize choline
Adapted from Scott.[97]

A = Recommended vitamin allowances for **starting** ducks
B = Recommended vitamin allowances for **growing-finishing** ducks
C = Recommended vitamin allowances for **breeding** ducks

- ***Vitamin B_{12}:*** Ducks appear to have minimal requirements for dietary B_{12} and newly hatched ducklings have sufficient levels of this vitamin derived from the hen.[97]

- ***Ascorbic Acid (Vitamin C):*** Ducks readily synthesize vitamin C; however, birds receiving supplemental vitamin C have superior erythrocyte and hemoglobin values as well as greater bacteriocidal and lysozyme activity than unsupplemented ducks.

Mineral Requirements

Only eight of the thirteen minerals required by animals have been studied in ducks. Of the other five, all (potassium, iron, copper, molybdenum) except iodine are found in adequate amounts in most commercial feedstuffs.[97] Recommended allowances for minerals in starting ducks, growing Pekin Ducks and breeding Pekin Ducks are found in Table 46.6.

- ***Calcium:*** Calcium levels for ducklings are recommended at 0.6 to 0.8%. Levels up to 1 or 1.5% may cause progressive-to-severe decreases in weight gain. Ducklings receiving a diet with 0.17% will develop

rickets. For laying Tsaiya Ducks, the calcium allowance is 3%. For Pekin Ducks, it is 2.75% and for Khaki Campbell Ducks, 3.25%.[97]

- ***Phosphorus:*** Adequate levels for maximum growth and percentage of bone ash is 0.6% total phosphorus, of which 0.35% is available. When phosphorus was increased to 1%, there was neither a beneficial nor negative effect on weight gain or bone ash.[97]

- ***Sodium:*** Ducklings are considerably more susceptible to low sodium levels than gallinaceous chicks. All ducklings receiving a diet without sodium chloride or sodium bicarbonate died by the 19th day on this diet. In order to maximize weight gain, sodium chloride was supplemented to 0.3% (0.135% total sodium). Mortality was prevented, but inferior growth rates occurred when sodium bicarbonate was added to the diet. Chloride at a level of 0.072% provided by the basal diet was not adequate for normal growth. Supplementation with potassium chloride (KCl) to bring chloride level to 0.122% produced normal weight gains. There is a range from 0.4 to 0.8% total dietary salt (0.15 to 0.32% sodium) that is tolerated. When more than 1% salt is added, weight gain is significantly depressed. The sodium requirement of ducks is suggested to be 0.15% throughout all stages of life.[97]

TABLE 46.6 Mineral Requirements for Pekin Ducks

Mineral	A	B	C
Calcium, %	0.7	0.6	2.75
Available phosphorus, %	0.5	0.4	0.4
Sodium, %	0.18	0.18	0.18

Reproduction

Breeding Factors

Most ducks become sexually mature at about one year of age. A few exceptions, such as the Bufflehead and Scaup, require longer. Geese often take two years to mature, while swans may take five years to reach sexual maturity.[44] Waterfowl maintained in captivity are prone to hybridize, and related species should not be housed together.

A bird's behavior may change drastically during the breeding season, and aggressive species such as Cape Barren Geese, Sheldgeese, swans and Bronze-winged Ducks must be carefully monitored. Mixed aviaries must be large enough to allow birds involved in territorial aggression to escape.[108]

Male Anseriformes have an erectile phallus covered with keratinized papillae. This anatomic feature allows the gender of ducks or geese to be accurately determined at a very early age (Figure 46.9). Exposure and identification of structures is easier in mature breeding birds. The cloaca is manually everted to visualize the phallus by holding the bird vertically with its head down and abdomen toward the examiner. Gentle, firm pressure with the thumbs on each side of the cloaca will tend to evert the phallus. It may take some time to overcome the resistance of the cloacal sphincter but continued downward and outward pressure of the thumbs will help achieve exposure. Two small labia-like structures are found in the female. The phallus can be palpated in its retractile state and needs to be everted only for confirmation; the female requires little effort as a palpable mass cannot be detected.[44]

Male ducks frequently leave after the eggs are laid and the pair may or may not re-mate the following season. Swans and geese form a lasting pair bond that is broken only by the death of one of the birds. The surviving bird may have difficulty forming another pair bond, or may not breed again.[44]

Waterfowl nest in a variety of ways. Some prefer cavities, some thick vegetation and others, open areas. Waterfowl generally lay their eggs in the early morning. Smaller species usually lay one egg a day, while larger species lay an egg every other day. Information on average number of eggs per clutch, incubation time and incubation responsibility can be found in Table 46.1. Once incubation begins, the hen is reluctant to leave the nest, except for brief periods in the early morning or late afternoon to feed, drink and bathe.[108] During incubation, it is not uncommon for some free-ranging migratory waterfowl to lose up to 40% of their peak weight.

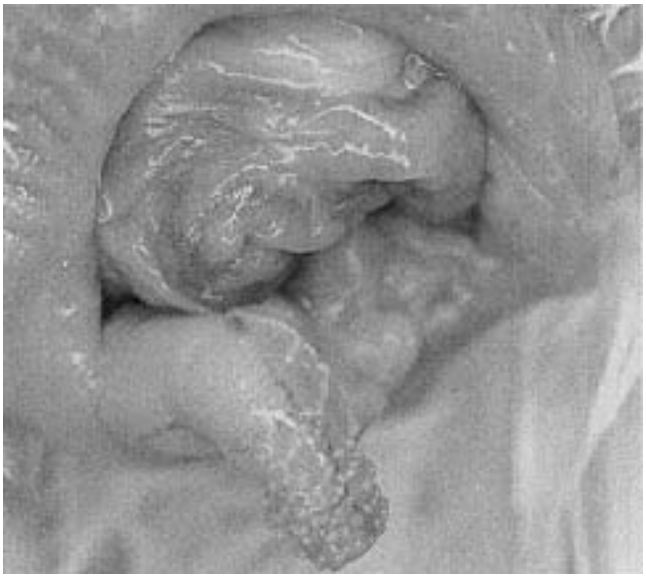

FIG 46.9 The phallus of a male Anseriformes can be visualized or palpated in the ventral wall of the cloaca and is covered with keratinized papillae.

Because incubation of the clutch usually begins at the same time, most eggs in a clutch will hatch within a day or two of each other.[108] Once an egg pips, there is usually an interval of 16 to 24 hours before hatching is complete.

In some species, both parents protect the young (swans and geese), while in other species only the hen cares for the brood. There are also parasitic species (such as the Redhead) in which no parental care occurs, and the hen lays her eggs in the host nest.[44]

Anseriformes have nidifugous young that are covered in down and can eat, swim and dive almost from hatching. The young begin to forage within a day or so of hatching. Normal chicks have sufficient fat and yolk stores to survive for several days without eating. Some of the smaller species will fledge and can fly at about 40 days of age. Larger birds may take two to three months to fledge. An exception is the Ross's Goose chick that may fledge by four weeks of age.[108]

Preservation of semen and artificial insemination have been successful in free-ranging as well as captive waterfowl. Successful cryogenic preservation of semen has been reported for the Aleutian Canada Goose. Semen was diluted with Beltsville poultry semen extender, adjusted to 270 ± 30 mOs and 7.5 ± 0.4 pH. DMSO was added to seven percent concentration. With frozen-thawed semen, 19 of 31 eggs were fertile. About half of the live spermatozoa from the fresh semen (87.3 to 92.9% live sperm) survived the freeze-thaw process.[33] Information on naturally occurring and artificial breeding programs for various waterfowl can be found in a variety of sources.[37,39,51,108]

Embryo and Neonatal Management and Pathology

Incubation

Artificial incubation and brooding of waterfowl is a common practice. A pair of birds may be stimulated to produce another clutch of eggs by removing the first clutch. In some aviaries, eggs and babies are susceptible to predators or environmental injury, and artificial incubation is necessary to ensure survival. Small enclosures may alter normal behavior so that a pair will not properly incubate or brood.

Typically, an incubator temperature of 99.3°F and 85% humidity is appropriate for most waterfowl. Improper egg storage, egg contamination, low humidity, air flow problems and inadequate turning of the eggs can all cause reduced hatchability (see Chapter 29).

Nutrition, infectious diseases and genetics can also reduce hatchability and survivability. Genetic factors have not been adequately explored as a cause of poor hatchability in birds. Inbreeding in domestic birds correlates with a significant increase in infant mortality, which may reach 100% after three to four generations of breeding.[25]

In a study at the New York Zoological Park, attempts to determine the cause of early embryonic death in birds were inconclusive due to rapid degeneration of the embryo at high incubation temperatures.[20] A study at the Regent's Park Zoo from 1973 to 1975 on 442 birds was unable to document bacterial infections as a cause of poor hatchability.[96]

Brooder Room Management

The requirements of Anseriforme chicks are the same whether they are reared by their parents, a surrogate hen or artificially. Ducklings seem to thrive best if they are provided a thermal gradient and allowed to choose their own temperature. The temperature on the heated side of the enclosure should be about 95 to 99°F initially and then gradually decreased to about 70°F over a three-week period. It is important that chicks never become chilled. Although they may appear to recover when warmed, many affected chicks develop gastrointestinal problems or liver or kidney failure and die several days later. The chicks are the best guide to determine if a proper temperature is available. If chicks are huddled under the heat, they are too cold; if they are panting, appear stressed and

are staying away from the heat, then they are too hot (Figure 46.10).[81]

Housing enclosures for ducklings should be easy to clean and sanitize. With any brooding method, it is important to maintain a clean, dry, warm enclosure with an easily available supply of clean food and water. Drafts should be avoided. Many chicks seem suicidal, and pebbles or marbles must be added to the water container to prevent drowning. Chicks have been known to get stuck between the food container and a wall, and they may also jump out of the brooder and become chilled.[81]

An effective brooder room has a sloping concrete floor with a drain in one corner. The room has a control system that allows heating, cooling and adequate ventilation. A metal rack is attached to the wall to suspend individual containers off the floor for easy cleaning. Individual brooder boxes can be removed for intensive cleaning and disinfecting. Each box is 19 inches wide by 36 inches long. The back is 16 inches deep and the front is 10 inches deep. The bottom is made of one-fourth inch by one-half inch vinylized wire[c] and the removable top is made of one-fourth inch by one-fourth inch hardware cloth in a wood frame that is hinged in the middle for access to both the front and back of the brooder. Enclosures for older birds have higher walls and lack a sloping top. A small stainless steel pool is inserted into the front bottom of the enclosure (Figure 46.11). This pool has a sloping bottom so the birds can get in and out easily, and a maximum depth of three to four inches. Shallow pools, three-fourths inch deep, are used initially to acclimate young ducklings to the water.[81]

A 150-watt infrared heat lamp is placed over each box on an extendable cord so that the heat can vary from directly over the enclosure to 32 inches above the enclosure (Figure 46.12). Room temperature is maintained at 76 to 82°F while the box temperatures are increased by the lights. A poultry water bottle is used in each box with pebbles in the troughs so that young birds do not drown. The water bottle and food pan are positioned away from the wall at the opposite end of the heat source.

For younger birds, it is advisable to use a vinyl turf-type mat[b] or towel under the heat source to make the flooring more comfortable as well as to retain heat. Hay, straw, shavings, newspaper or other absorbent materials used for bedding may be consumed by some ducklings and cause impactions. The room should have a treatment area with a counter, scale and record keeping materials. Daily records are maintained on each group of birds. A double sink is effective for cleaning pans and a hose is used for cleaning the wall-mounted brooder boxes. Various disinfectants can be used. Water bottles may be changed several times a day as needed, and enclosures are cleaned once a day.[81] Further information on brooder room set-ups may be found in Brown[3] and Hyde.[45]

FIG 46.10 Behavior of a neonate is the best indication of a proper temperature gradient. These chicks are standing together for security but are not huddled, which would indicate chilling. Note that the back half of the brood box is heated (Figure 46.12) and the front half is unheated, creating a natural thermogradient (1994 Busch Gardens Tampa. All rights reserved.).

The ducklings are ready for outside pens at two to four weeks of age. It is preferable to use an intermediate facility to acclimate the ducklings to the difference between the very controlled environment of the brooder room and the limited control of outside pens. Providing birds free choice to indoor or outdoor environment is optimal. Outside enclosures approximately eight feet square with concrete floors and a gently sloping pool covering about half of the floor space are ideal. The slope of the pools should be

FIG 46.11 As waterfowl mature, they should be provided a shallow pool with gently slopping edges. Neonates are best raised in groups of similarly sized individuals. This lone neonate was provided a stuffed toy for company (1994 Busch Gardens Tampa. All rights reserved.).

gradual, and vinyl mats should be placed on the edge of the pool and on some of the dry areas to prevent leg and foot problems. A heat lamp should be available for each pen. All pools should have overflows and good drainage for easy cleaning. Once acclimatized to the outdoors, the birds can be moved to larger growing pens. They can then be moved to other areas such as breeding pens or large mixed species aviaries.

Neonatal Problems

The majority of losses during the first two weeks of life are associated with the poorly understood diagnosis of starveout. Starveout is a term coined by poultry pathologists to describe a condition of turkey poults wherein birds never start to eat; they starve after their yolk stores are depleted. Characteristically, deaths occur in waterfowl at 7 to 14 days of age; the birds have an empty, contracted gastrointestinal tract, a small yellow liver, a distended gall bladder and no fat stores. It has been shown that many species, especially in captive situations, require specific stimuli and encouragement to begin self-feeding,[64] and a lack of these stimuli may contribute to the problem.

Young waterfowl generally do not require food for the first 24 to 48 hours while the yolk sac is being absorbed. Scoters, Harlequins, Oldsquaw ducklings and other specialized species may be particularly difficult to get started eating and must be fed by hand and pampered for considerable lengths of time. Mallard ducklings may be used to stimulate feeding in reluctant eaters. It is easier to raise a brood of young rather than a single bird.

Simulating the natural conditions that a free-ranging hatchling would encounter may stimulate feeding behavior. Newly hatched Mandarin Ducks and Wood Ducks tend to calm down in the brooder and begin to eat after they have been tossed in the air and allowed to drop to the ground. As strange as this may seem, it works because these species are cavity nesters and young often fall 60 feet or more to the ground when they leave the nest.[108] Wood Duck chicks feed best if a cotton floor mop is hung in the brooder.

Ducklings may become wet and chilled in a brooder or when moved to an outdoor area and exposed to heavy rains. Their undeveloped feathers lack the natural oils and proper structure to repel water. Weaker ducklings that are not competing effectively with other chicks for food may become hypoglycemic, weak and chilled. A hair dryer can be used to dry the feathers and warm the body. Once the birds are dry, tube feeding with 0.25 to 3 cc of a prepared formula[d] provides a quick energy source. Steroids, subcutaneous fluids and antibiotics may prevent secondary problems. Large doses of rapidly metabolized ster-

FIG 46.12 An ideal brooder room designed for Anseriformes and Galliformes. Tile floors and walls are easy to clean, and the brooder boxes can be removed for cleaning and disinfecting. Heat lamps are placed on retractable extension cords to allow changes in the amount of heat provided to an individual brood box. (1994 Busch Gardens Tampa. All rights reserved.).

oids (prednisolone sodium succinate 2 mg/60 g chick) should be repeated every 15 minutes (some chicks may require four or five doses) until the chick is warm and stabilized (Harrison G, unpublished).

Gastrointestinal disorders seem to be particularly common in neonatal birds. A high energy requirement and the need to establish a resident flora in what is a sterile environment at hatching probably account for many of these problems. Impaction of the crop and ventriculus, and less commonly the colon, may be the only lesions seen at necropsy. A precise etiology is rarely identified although inappropriate or excessive food intake is often implicated. Impactions lead to putrefaction of the gastrointestinal contents causing inflammation of the gastrointestinal mucosa and frequently systemic intoxication.[64]

- ***Yolk Sac Disorders*** can be divided into three overlapping syndromes. The first is retention of the yolk sac. At necropsy, affected birds have a moderate-to-large unabsorbed yolk sac in the abdominal cavity that is recognized clinically as a distended abdomen. No other abnormalities are noted. In domestic fowl, the yolk sac is completely absorbed by ten days of age. Similar data are not available for most aviary species, but, in general, persistence of the yolk past two weeks of age is abnormal and detrimental. Causes for nonabsorption are unknown, as are the events that lead from retention to death of the bird. Neonates depend on the yolk sac for the first two to three days of life and if the yolk is not absorbed, the birds will be malnourished. Maternal immunoglobulins, specifically IgG, are absorbed with the yolk. Improper absorption of the yolk could result in the same immunosuppression seen in mammals that do not ingest colostrum.[64]

Temperature and humidity during incubation affect yolk sac development. High humidity or low temperature may cause a failure to retract the yolk sac into the abdomen prior to hatching. Low humidity during incubation has been associated with infection of the yolk sac. Infected yolk appears as a thick brownish or yellow coagulated mass compared to normal yolk, which is a greenish-yellow liquid (see Color 48). Compared to other birds, precocial birds such as waterfowl have a large yolk sac. One study showed that yolk sacs in precocial species ranged from 12 to 25% of the body weight. The majority of the yolk sac should be absorbed within a week.

The yolk sac should be surgically removed if clinical signs, palpation and radiography indicate nonabsorption. Surgery usually is successful if performed before a bird becomes dyspneic. Clinical signs suggesting that surgery is necessary include swollen abdomen, dyspnea, exercise intolerance, inability to stand or walk, inappetence, weight loss or failure to grow. For surgery, birds are anesthetized with isoflurane and placed in dorsal recumbency with the legs pulled caudally. Feathers on the abdomen are plucked from flank to flank and from the keel to the cloaca, and the skin is surgically prepped (see Figure 48.13). Birds should be given 0.016 ml/g body weight of a 50:50 mixture of 5% dextrose in lactated Ringer's solution and 0.9% sodium chloride to compensate for any blood loss during surgery. Birds should be given broad-spectrum antibiotics postoperatively pending results of a yolk sac culture. Some chicks will require tube-feeding for several days before they will resume feeding, whereas others will begin to eat and gain weight one to two days postoperatively.[58]

A second syndrome, rupture of the yolk sac, can occur as a sequela to yolk sac retention or yolk sacculitis (the third yolk sac-related syndrome). Rupture can also occur following traumatic events in two- to three-day-old birds with normal yolk sacs. Death results from yolk-related peritonitis and shock. Yolk sacculitis and omphalitis can occur separately or concurrently in a bird and are most frequently associated with gram-negative organisms, especially *Salmonella* sp. and *E. coli* (see Color 48). Omphalitis is characterized by edema and inflammation of the abdominal wall surrounding the umbilicus. Yolk sacculitis is characterized by enlargement, hyperemia and petechiation of the wall and greenish discoloration and coagulation of the yolk sac. In most cases, omphalitis and yolk sacculitis arise from contamination of the umbilicus. Incubator and brooder sanitation are crucial for prevention of yolk sacculitis.[64]

- ***Miscellaneous Microbial Infections:*** Bacterial infections in neonates usually cause a multisystemic, fatal septicemia. Bacteriemia occurs so quickly that the entry point for the bacteria cannot be determined. The gross and microscopic lesions of septicemia are often subtle: splenomegaly, hyperemia and petechiation of the lung and gastrointestinal serosa, and congestion or focal necrosis of the liver. *Salmonella*, *E. coli*, *Pseudomonas*, *Streptococcus* and *Erysipelas* spp. are usually implicated. The incidence of bacterial septicemia can be reduced through sound brooder hygiene and by identifying and controlling infections in subclinical parents. *Salmonella* sp. have been implicated in necrotizing colitis in Anseriforme neonates. Infections may be localized or occur as part of a systemic infection including yolk sacculitis and air

sacculitis.[64] Aspergillosis is uncommon in healthy birds; however, neonates with immature defense mechanisms that are compromised by malnutrition or environmental stress are more susceptible to inhaled spores (see Color 23).

Nutritional Diseases

- ***Angel Wing:*** This condition is also referred to as healed-over, slipped, crooked, rotating, tilt, sword, spear, reversed, airplane and dropped wing. Angel wing is apparently caused by the weight of the growing flight feathers placing excess stress on the weak muscles of the carpal joint. Gravity encourages the developing wing to hang and finally to twist outward. If untreated, the wing may remain in that position and the ligaments and bones will be permanently deformed (Figure 46.13). Simply taping the wing on itself (not to the body) in a normal position for three to five days is usually sufficient to correct the problem. Manganese deficiency and hypovitaminosis D_3 have been suggested as etiologies. Genetic factors, environmental influences or management practices have also been implicated. [56,111]

FIG 46.13 Angel wing is characterized by droop and outward twist of the wing. In this Black Swan cygnet, the carpus is ventrally displaced (arrows) (1994 Busch Gardens Tampa. All rights reserved.).

Angel wing has been suggested to be a problem associated with captivity; however, it has been described also in free-flying populations of Cereopsis in South Australia, Canada Geese in Sweden, Mute Swans in Switzerland and semi-wild Mallard Ducks in England. Most affected birds have slow natural growth rates and are from temperate or tropical areas.[57] Interesting differences in the susceptibility of different waterfowl species to angel wing are being recognized.

Several fast-growing species originating from the Arctic have not yet shown slipped wing. These include the Greater Snow Goose, which can grow to nearly 14 times its hatching weight by three weeks of age, and the Barnacle Goose that can grow to thirteen times. The Swan Goose and Hawaiian Goose, in similar conditions of light, heat, food and water, increase their weight by only a factor of eight. Similar slow growth rates occur for most low-latitude ducks, geese and swans.

Differences in food intake are also apparent among Anseriformes from different geographic regions. For instance, Cereopsis goslings spend a large part of each 24 hours sitting or sleeping. Snow Geese, on the other hand, are restless even in the dark and will feed steadily if given the chance, with frequent pauses for brief periods of sleep. The result of these differences is that the Arctic species fledge much faster than temperate or tropical species. In nature, this quick maturation is vital so that the birds are ready for migration before winter storms occur.[57]

These findings would suggest that angel wing is associated with overfeeding tropical and temperate species, causing an excessively rapid growth. Deformities are more common in the heavier members of a brood and are more frequent in males, which grow more rapidly. Angel wing is also more common during warmer weather when young birds are able to use more dietary energy for growth and less to maintain body temperatures. Angel wing seems to occur more commonly in birds fed ad libitum and provided inadequate areas for exercise. In one flock, four out of six New Zealand Gray ducklings developed angel wing, apparently after the accidental feeding of turkey starter diet (28% protein) instead of chick diet (18.5% protein).[57]

Excessive energy, excessive protein or a deficiency of vitamin E have all been suggested as dietary factors in the occurrence of angel wing. Clearly, a balanced diet formulated for tropical and temperate waterfowl species is required. A study with Mallard, Pintail and Redhead ducklings (slow growth-rate species) indicated that the protein requirement during the first three weeks of life is below 19%. Optimum growth curves occurred when the animal protein content of the diet was 8%.

Factors that may reduce the incidence of angel wing include exercise (swimming, diving) and plenty of grass and other green foods. Birds originating from low latitudes should not be fed high-energy, high-protein foods. It is clear that waterfowl chicks from different species must be treated differently. Birds originating north of the Arctic Circle should be provided constant light, plenty of water and a constant supply of food that is relatively high in protein. Those originating from equatorial regions should be provided 11 hours of darkness per 24 hours; these birds can consume comparatively less food of a lower quality.[57]

- ***Perosis:*** Also known as slipped tendon, perosis is characterized by enlargement of the hock, bending deformities of the mediotarsal and tarsal metatarsal bones and medial luxation of the Achilles tendon, which prevents the bird from bearing weight on the affected limb (Figure 46.14). One suggested etiology is a manganese deficiency caused by excessive calcium supplementation (calcium binds manganese). If the problem occurs before two weeks of age, it is likely that the hen's diet is deficient in manganese. Ducklings and goslings fed a manganese-deficient diet will develop perosis in two to ten weeks.[111] Angel wing and perosis may have a similar etiology.

  A leg undergoes rapid pathologic changes once it begins to deviate (see Color 8). Bandaging or splinting the leg is usually unsuccessful. Trochlear grooving or transplantation of the insertion of the Achilles tendon laterally have been attempted. Open reduction and stabilization of the luxated tendon are successful in some cases. An incision is made through the skin and over the posterolateral aspect of the joint midway between the displaced tendon and lateral condyle of the tibiotarsal bone (Figure 46.15). The tendon is dissected free of its trochlear and medial adhesions and reduced to its normal position in the trochlear groove. The tendon sheath is sutured to the lateral periosteum and retinaculum with simple interrupted 3-0 absorbable suture. The skin incision is closed with simple interrupted 4-0 nonabsorbable suture. A tongue depressor can be used as a splint for a week. The patient should be using its leg normally by the second postoperative week.[118]

- ***Nutritional Secondary Hyperparathyroidism:*** Ducklings whose diets are poor in calcium or contain excessive phosphorus may develop fibrous osteodystrophy or osteomalacia. The birds may appear reluctant to move. Abscesses or blisters of the keel often develop in birds that are non-ambulatory. Soft bones and enlarged parathyroids are common postmortem findings (see Color 14).[45]

- ***Rickets:*** Rickets results from a lack of vitamin D. The first clinical signs are lameness, retarded growth and bent or twisted breast bones. Providing a proper diet will reverse the symptoms in two to four weeks unless advanced changes have occurred.[45]

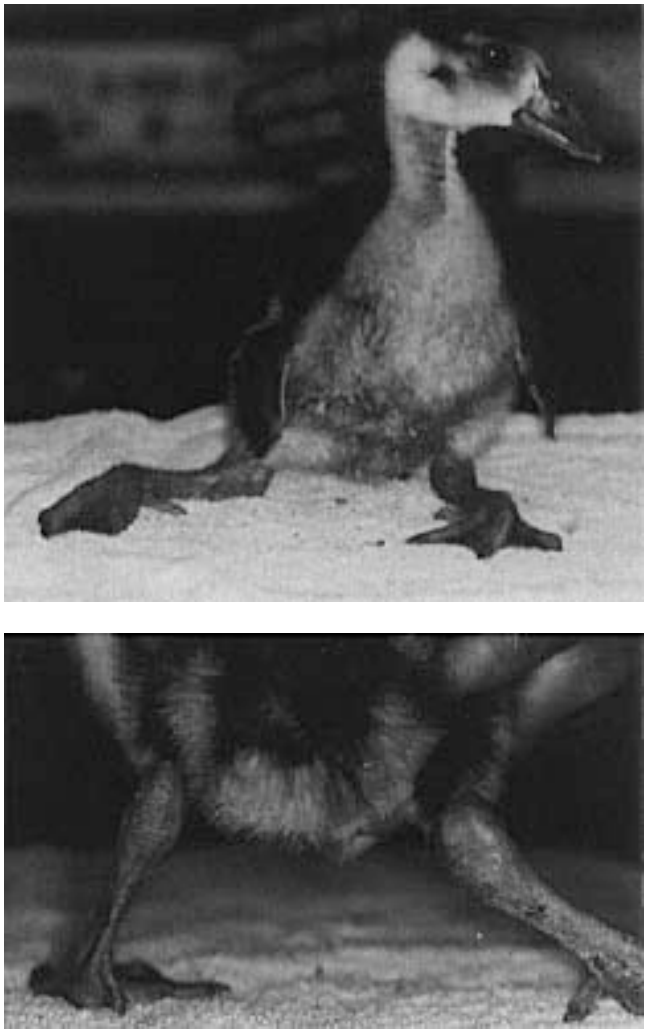

FIG 46.14 Cranial and caudal view of a duckling showing the clinical appearance of a medially luxated Achilles tendon of the right hock joint. Manganese deficiencies (possibly exacerbated by over-supplementation of calcium) have been suggested as a cause (courtesy of John Olsen).

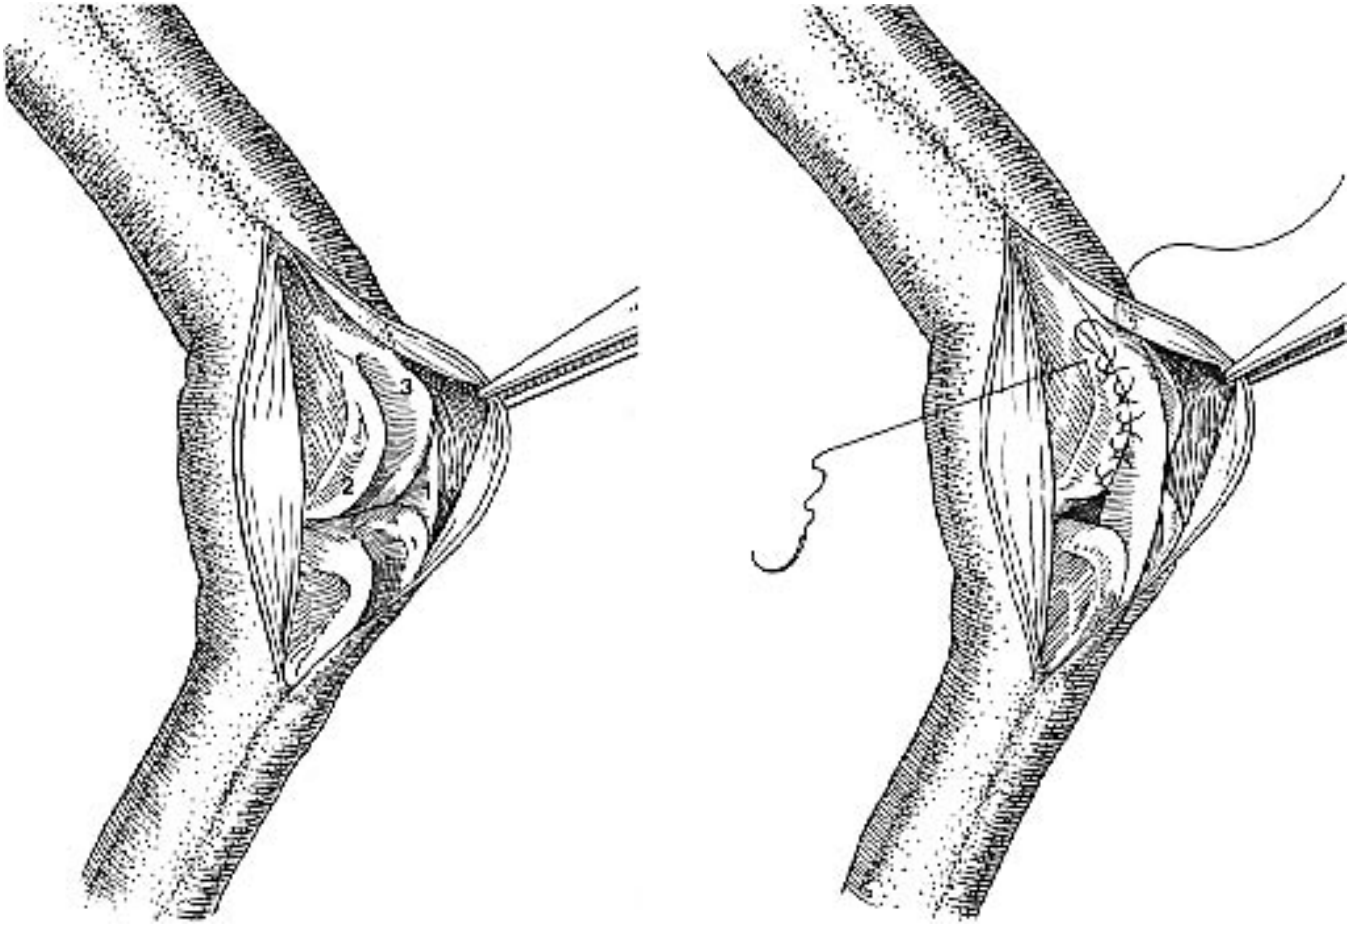

FIG 46.15 An incision is made through the skin and over the caudolateral aspect of the joint midway between the 1) displaced tendon and 2) lateral condyle of the tibiotarsal bone. The tendon is dissected free of its trochlear and medial adhesions and reduced to its normal position in the 3) trochlear groove. The tendon sheath (right) is sutured to the lateral periosteum and retinaculum with simple interrupted 3-0 absorbable suture. The skin incision is closed with simple interrupted 4-0 nonabsorbable suture. A tongue depressor can be used as a splint for a week. The patient should be using its leg normally by the second post operative week (modified from Wolfe [118]).

Restraint, Handling and Anesthesia

Capture and Handling

Various nets can be used to catch waterfowl in the confines of an aviary. In some cases, a group of birds can be herded to a corner of the enclosure and captured together or individually. On large ponds, a boat or several people wading in the water may be needed to capture waterfowl. A bright spotlight can be used at night to "freeze" a bird, allowing it to be quietly approached.

Heavy-bodied species should not be carried by using the wings or feet alone, although smaller species can be restrained by their wings. Smaller ducks can also be held by grasping the back and wings and using the thumb and fingers to restrain the feet (Figure 46.16). For larger birds, the base of both wings should be grasped with one hand while the other hand and arm supports the body. These birds should be carried under one arm, with their head facing to the back. The arm is wrapped around the wings and a hand is used to support the body and control the legs (Figure 46.17). A wrap using Velcro adhesive straps or a pillowcase-type bag with a hole in the end for the head and neck can be used for restraining waterfowl during certain examinations, blood collection and radiographic procedures.

Field Immobilization and Capture

Occasionally, a practitioner may be asked to catch waterfowl from a pond. Attempts to capture these free-ranging birds can be frustrating. Capture nets, mist nets, spring-loaded nets, funnel nets and rocket or cannon nets are useful but are not typically available to private practitioners.[c,e]

Several agents have been used to immobilize free-ranging ducks or geese, with sodium amobarbital being the most frequently used. In test studies, an oral dose of 100 mg/kg was found to produce muscle incoordination approximately 20 minutes after ingestion. The test ducks never reached a plane of anesthesia but were immobilized sufficiently to allow easy capture. For field immobilization, one cup of hen scratch was mixed with 900 mg of dissolved amobarbital and allowed to dry in shallow pans (50 pounds of scratch will dry in about four hours with the aid of fans). Animals should not be approached for 60 minutes after feeding to ensure that they are adequately immobilized and will not fly to another location and die. Recovery may take up to eight hours.[36]

The drug has a low therapeutic index and should be used only in a field setting when restraint is critical and all other methods of capture have failed. There must be a fast method of retrieving birds from the water before they drown. Some birds may consume excessive concentrations of the drug and die. There was an eight percent mortality rate in one study of ducks. Half of these losses may have been prevented with post-capture gastrolavage or tubing with fresh water to dilute and accelerate passage of the drug.[36]

Another study evaluated seven agents as possible immobilizing drugs for field use on ducks. The only compound to satisfy the study criteria was tribromoethanol. Alpha-chloralose, methoxymol, metomidate, pentobarbital sodium, secobarbital sodium and thiopental sodium were all inferior to tribromoethanol. At the median effective dosage (ED_{50}) for immobilization (100 mg/kg of body weight), the duration of induction was 2.4 minutes, immobilization was 8.7 minutes, and recovery was 1.3 hours. The median lethal dosage (LD_{50}) was 400 mg/kg of body weight. None of these drugs was given in feed in field situations.[6] The study refers to other work indicating that a drug-to-bait ratio of three grams tribromoethanol per cup of whole corn was effective.[10]

Anesthesia

Waterfowl, like other birds, have a highly variable regional response to pain. The most sensitive areas are the beak, head, feet and feather follicles. Removing one or two feathers may elicit a more violent reaction than suturing a cutaneous wound or cutting skin. It is frequently possible to handle viscera without evoking any sign of pain from a conscious bird.

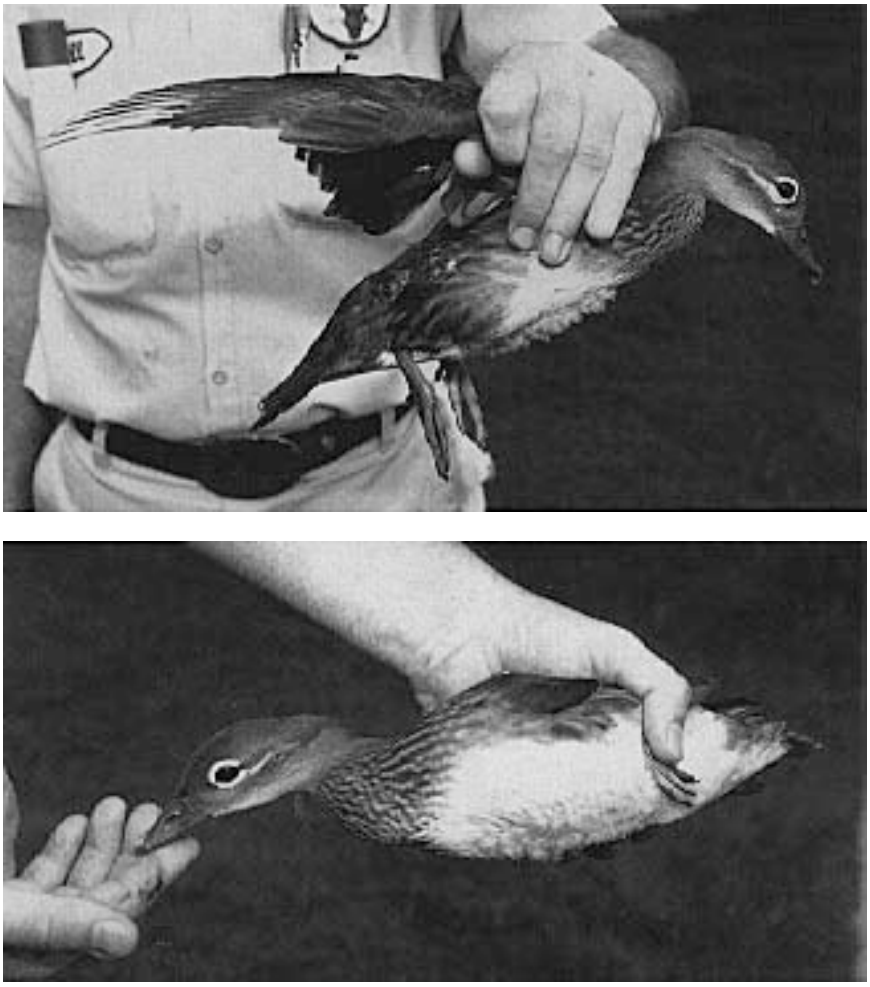

FIG 46.16 Restraint technique used for small waterfowl. This technique should not be used for larger Anseriformes. Some small duck species can be restrained (bottom) by folding the legs caudally and holding the wings and legs in one hand (1994 Busch Gardens Tampa. All rights reserved.).

FIG 46.17 Larger waterfowl should be restrained by holding the legs against the bird's body and tucking the bird, with head facing backward, under the arm of the handler (1994 Busch Gardens Tampa. All rights reserved.).

Local anesthesia is often sufficient for performing superficial procedures. Lidocaine hydrochloride (2%) is one of the safest local anesthetics for waterfowl; however, general depression can occur with high doses.[4] Reasonable amounts relative to weight are usually safe and effective. Using 1 ml of 2% procaine in ducks and 3 ml in swans was found to provide good local anesthesia with few problems.

Isoflurane anesthesia is convenient for performing minor procedures, positioning for radiographs or major surgery. Mask induction and maintenance for short procedures (< 15 minutes), or mask induction followed by intubation for longer procedures are common. The neck must be extended in intubated, long-necked birds to prevent the trachea from folding over the end of the tube, causing partial or complete airway obstruction. Halothane and methoxyflurane have also been used in waterfowl but are inferior to isoflurane. Many waterfowl species have profuse salivary secretions under anesthesia and may benefit from the use of an antisialogogue such as glycopyrrolate.[42]

Induction times for gas anesthetics in waterfowl are frequently prolonged when compared to psittacines, probably due to the substantial subcutaneous fat deposits in the former. Recovery periods are also prolonged.[54] Breathing amplitude (an indicator of tidal volume) has been shown to decrease by 40 to 50% and the frequency of respiration increases 20 to 50% when birds are in dorsal recumbency. This causes a 10 to 60% decrease in minute ventilation, probably due to visceral compression of the air sacs.[90] Positive pressure ventilation can be used to decrease these effects. A peak positive pressure of 15 to 20 cm of water is adequate.[54]

With both isoflurane and halothane, waterfowl tend to change planes of anesthesia rapidly and unexpectedly. Cardiac monitoring of anesthetized waterfowl can be done with a doppler flow probe placed under the tongue, against the carotid artery or on the ventral surface of the elbow on the recurrent ulnar artery. An esophageal stethoscope or ECG can also be used. A rectal or esophageal thermometer is useful to monitor body temperature. Time of recovery from anesthesia is directly proportional to the amount of heat loss. The lower the body temperature, the longer the anesthetic recovery period.[54]

In one study evaluating isoflurane and halothane, 2.2 to 2.7 kg Pekin Ducks were masked with a concentration of 3.5% anesthetic gas with an oxygen flow of 3 l/min. They were intubated with 5 mm cuffed endotracheal tubes (uncuffed tubes are preferred in birds) and maintained with 2 to 3% isoflurane or 2 to 2.5% halothane. When anesthesia was discontinued, ducks received oxygen for two minutes prior to breathing room air. The ducks showed no distress from the mask or vapors.[35]

Palpable reflexes were lost during induction with both agents. Isoflurane induction was significantly shorter than halothane induction. Slow to absent pedal and wing reflex characterized a surgical plane of anesthesia. Both anesthetics had a smooth recovery pattern of similar length. Respiration was regular and deep with halothane and isoflurane. Both anesthetics significantly depressed respiratory rate,

TABLE 46.7 Gas Anesthetic Parameters in Pekin Ducks

	Induction Time	Respiratory Rate - (bpm)	Heart Rate - (bpm)	Blood Pressure - (mmHg)
Baseline	—	15 - 23	173 - 207	114 - 142
Halothane	5 - 9 minutes	4 - 6	230 - 388	96 - 128
Isoflurane	3 - 5 minutes	7 - 11	176 - 310	107 - 131

Values at 30 minutes post-induction
Adapted from Goetz.[35]

increased heart rate (HR) and decreased blood pressure (Table 46.7).[35]

Cardiac rhythm was not affected by isoflurane. With halothane, four of eight ducks showed abnormal rhythms. Three ducks developed abnormal ECGs with ventricular bigeminy and multifocal ventricular rhythms (perhaps due to increased $paCO_2$). One duck developed ventricular fibrillation and died. Mean arterial blood pressure decreased with both anesthetics.[35]

Isoflurane is superior to halothane because induction and recovery times are shorter, there is less preoperative stress and less postoperative hypoglycemia and hypothermia. Isoflurane also causes fewer cardiac arrhythmias and is less of a cardiopulmonary depressant. The editors believe that injectable anesthetics are a poor choice in Anseriformes and should be avoided (see Chapter 39).

Diseases

The most prominent problems in a group of Anseriformes presented over a six-year period to the Canadian Disease Research Institute were improper management, nephritis and reproductive disorders.[103] At the National Zoological Park, 1,500 Anseriformes that died during a ten-year period were found to have many diseases similar to those described in free-ranging Anseriformes. Diseases identified included botulism, erysipelas, tuberculosis, pasteurellosis (avian cholera), salmonellosis, other bacterial septicemias, aspergillosis, candidiasis, amyloidosis, gout, hematozoan infections, schistosomiasis, echinuriasis and others (Table 46.8).[73,74] Several diagnostic facilities may be helpful in resolving problems associated with Anseriformes.

Non-infectious Diseases

Bumblefoot

Bumblefoot (pododermatitis) occurs frequently in captive waterfowl, especially swans. It is believed to be caused by rough, hard surfaces such as concrete pools or pens that cause trauma to the bottom of the birds' feet (see Chapter 16). Large, lumpy protuberances or eroded or scabbed lesions can develop (see Color 46). A bird may naturally recover from mild lesions if it is placed in a pen with adequate pool space and easy access in and out of the pool (Figure 46.18).

Treatment of bumblefoot is difficult and often unrewarding. If a bird is not lame, it may be best to forego treatment that frequently increases the severity of the problem. Suggested therapies that include surgical debulking of the lesion and medical management frequently fail. The bird must be maintained on soft footing during the recovery period.[b] One common treatment is a topically applied combination of dimethylsulfoxide (DMSO) (30 ml), dexamethasone (2 mg) and chloromycetin succinate (200 mg) (or other appropriate antibiotics based on sensitivity). This is applied to the lesion every eight hours. Recovery may take three to six weeks.[104] Another treatment includes daily cleaning of the lesion with iodine scrub followed by the application of camphor spirits (drying agent) and benzoin (toughens the tissues).[91] Supplemental vitamin A and an improved diet may also be helpful (see Chapter 16).

U.S. Diagnostic Facilities for Resolving Problems in Anseriformes

The federal diagnostic facility is the U.S. Fish and Wildlife Service, National Wildlife Health Center, Madison, Wisconsin. Several states have active wildlife disease programs located at: Fairbanks, Alaska; Sacramento, California; Fort Collins, Colorado; Rose Lake, Michigan; Hampton, New Jersey; Delmar, New York; Fargo, North Dakota; Madison, Wisconsin; and Laramie, Wyoming.[28]

There are three regional wildlife disease programs affiliated with universities. These include the Southeastern Cooperative Wildlife Disease Study, University of Georgia, Athens; Northeastern Center for Wildlife Disease, University of Connecticut, Storrs; and Colorado Wild Animal Disease Center, Colorado State University, Fort Collins. The University of Florida-Gainesville and Virginia Polytechnic Institute and State University-Blacksburg also have active wildlife disease programs. Cornell University has the Duck Research Laboratory located at Box 217, Eastport, New York 11941, telephone (516) 325-0600. The primary focus of the Duck Research Laboratory is on production duck management, nutrition and disease, but it also has involvement with wild fowl. The staff has considerable expertise and diagnostic capability available. The U.S. Department of Agriculture, Veterinary Services Laboratory, Ames, Iowa can also accept diagnostic specimens that have been submitted through appropriate channels.

Oil-contaminated Birds

Anseriformes are often affected by oil spills. The oil destroys the insulating and waterproofing properties of the plumage. Oil may also be associated with reproductive disorders; alteration of neural, endocrine and osmoregulatory functions; toxic changes in the gastrointestinal tract, pancreas and liver; aspiration pneumonia; renal damage; and Heinz-body anemia. Mortality of birds affected by oil spills often exceeds 80% but can be reduced to 15% with proper teatment (see Chapter 15).[16,65]

Amyloidosis

Amyloidosis is a common finding in captive and domestic waterfowl, but is rarely diagnosed in free-ranging birds. Gross lesions include pallor and enlargement of the liver, spleen or adrenal glands. Less commonly affected organs include the pancreas, kidney, intestine, lung and heart. Affected organs are firm and usually yellow-brown in color. Histologically (with hematoxylin-eosin stain), amyloid is amorphous, eosinophilic, acellular material that separates, compresses and displaces normal cells. With Congo red stain, amyloid is orange-red and slightly fibrillar, and under ultraviolet light it fluoresces when treated with thioflavine S or T.[116]

The pathogenesis of amyloidosis appears to be complex and is poorly understood.[18] Amyloidosis is found in association with a number of chronic primary diseases and can be induced by some types of immunization. Amyloidosis in domestic ducks has been associated with crowding and social stress.[116] Although there is no treatment for amyloidosis, maintenance of environments with minimal stress and low exposure to infectious diseases should decrease its occurrence.[73]

Capture Myopathy

Capture myopathy has been reported in Lesser Snow Geese and Ross's Geese that were captured with rocket nets and restrained for several hours. Some birds (18 hours post-capture) were stiff and unable to fly but could walk. Others were unwilling to walk and appeared depressed. The only gross necropsy lesions were pallor of the skeletal muscles and pulmonary and hepatic congestion. Histologically, there was lysis and fragmentation of skeletal muscle fibers.

FIG 46.18 Severe foot infections can progress to osteomyelitis. In this case, osteomyelitis secondary to bumblefoot was resolved, but resulted in ankylosis of the tarsometatarsal phalangeal joint.

The prevalence and importance of this condition in captured free-ranging waterfowl are unknown, but a small number of restrained birds are stiff and reluctant or unable to fly when released (see Chapter 48).

Botulism

Botulism (limberneck, western duck sickness, duck disease, alkali poisoning) occurs from the ingestion of toxins produced by the bacterium *Clostridium botulinum*. It is a paralytic, often fatal disease. Waterfowl die-offs are usually caused by type C toxin. *C. botulinum* is commonly found in wetlands (especially those overlying limestone and alkaline water). It is resistant to heat and drying and remains viable for years in a spore form. The vegetative form produces the toxin and requires dead organic matter and an anaerobic environment. The presence of carcasses of invertebrates and vertebrates, rotting vegetation, poor water quality and high temperatures promote growth of C. *botulinum*. High temperature and vertebrate carcasses also promote maggot infestations. Birds that eat maggots may consume the toxin at the same time.[28]

The botulism toxin affects peripheral nerves and results in paralysis of voluntary muscles and an inability to sustain flight. Once paralysis of leg muscles has occurred, ducks may attempt to swim using their wings. By comparison, birds with lead poison-

ing retain their ability to walk and run. As the disease progresses, paralysis of the neck muscles results in an inability to hold the head erect. Death from drowning is common. Many affected waterfowl (75 to 90%) can be saved by being provided fluids, a cool environment and antitoxin.[28] Removing toxins and maggots from the stomach by gavage may increase the recovery rate.

Disease prevention requires control of fluctuating water levels during hot summer months and a prompt removal of animal protein to decrease the source of toxin production and maggot infestations. A single waterfowl carcass can produce several thousand toxic maggots. A duck can become intoxicated by eating only two to four maggots. Carcasses should be buried or burned. The toxin is quite stable in the environment. Botulism outbreaks have occurred worldwide. U.S. outbreaks usually occur west of the Mississippi River. In the United States and Canada, most outbreaks occur from July to September, although cases are seen in south Florida on a year round basis.[28] A commercial type C toxoid is available for mink and has proven to be effective in birds. One-half of the dose recommended for mink should be used in birds (Harrison GJ, unpublished).

Lead Poisoning

Lead poisoning is a common problem in waterfowl because of the ingestion of lead shot. Less common causes are ingestion of lead fishing sinkers, mine wastes, paint pigments, bullets and other lead objects. Lead shot has been banned in many states for hunting, but is still used in skeet shooting.[82] Within the United States, annual waterfowl losses from lead poisoning are between 1.6 to 2.4 million birds. Lead poisoning in Trumpeter Swans occurred when drought conditions caused water levels to drop, allowing birds to reach previously unattainable shot.[15]

Clinical signs of lead intoxication include weight loss, weakness and depression, bright green diarrhea, anorexia and variable neurologic disorders such as leg paresis, wing droop and abnormal head tremors.[15] Blood (2 to 5 ml) should be collected in lead-free tubes containing sodium citrate. Treatment includes use of chelating agents such as Ca+ disodium EDTA, DMSA, PA and DTPA (see Chapter 37).[28]

Gastric lavage and endoscopy can be used to remove lead shot from the ventriculus. Birds are fasted for 8 to 12 hours, masked down with isoflurane and intubated. A flexible polyvinyl chloride tube (1.5 cm in diameter) is lubricated and passed (approximately 110 cm in a Trumpeter Swan) to the cranial aspect of the ventriculus. The bird is tilted, head down, at a 45° angle on the table. Large quantities of warm water are pumped into the ventriculus using a 140 ml gastric lavage syringe. Water pressure and gravity will force most of the food, grit and lead pellets out of the intestinal tract. Radiographs can be used to confirm that the lead pellets have been removed. A colonoscope can be used to visualize and remove remaining lead particles (see Chapter 37).[15]

TABLE 46.8 Typical Disease Prevalence in Captive Anseriformes

Type	Condition*	Number Affected
Viral	Duck Virus Enteritis	30
Bacterial	Pasteurellosis	2
	Tuberculosis	33
	Erysipelas	3
	Salmonellosis	1
Fungal	Aspergillosis	99
	Candidiasis	62
Parasitism	Haemoproteus	1
	Capillariasis	6
	Echinuriasis	1
	Amidostomiasis	2
	Tetrameriasis	4
	Cestodiasis, intestinal	16
	Schistosomiasis, intestinal	19
	Trematodiasis	6
Toxicity	Botulism	28
	Talon	6
Noninfectious	Amyloidosis	122
	Gout	52
	Bumblefoot	3
	Predator	106
	Foreign Body, GI	3
	Vandalism	5

Important pathologic conditions in 1528 captive Anseriformes necropsied at the National Zoological Park, 1975 - 1984. Adapted from Montali.[73]

*An individual bird may have had more than one condition.

Zinc Poisoning

Zinc toxicity has been reported in captive Anseriformes following the ingestion of pennies minted after 1983 (containing 98% zinc) or metal fence clips (96% zinc). Clinical signs include weight loss, depression, anorexia and posterior paresis. Normal serum levels of zinc are 1.84 to 4.65 μg/g; normal liver levels are 34.9 μg/g. Abnormal levels seen in an affected group of ducks were 12.6 to 16.6 μg/g (serum) and 242 to 548 μg/g (liver). Pathologic findings include necrotizing ventriculitis and degenerative pancreatic lesions re-

sulting in acinar atrophy and ductular proliferation. Exposure to a penny for two months in the ventriculus is sufficient to cause toxicity.[121] Treatment consists of endoscopic removal of the foreign bodies and chelation therapy (see Chapter 37).

Mycotoxicity

Mycotoxins are toxic metabolites produced by molds. Mold-contaminated foods are frequently unpalatable and avoided by free-ranging waterfowl, while captive birds may be forced to consume the moldy food. Diagnosis in field cases is difficult, because some toxins have subtle or nonspecific effects. Clinical changes may be delayed and animals may have changed food by the time symptoms occur, making it difficult to find the source of the toxin. Moldy food may contain more than one toxin, and analytical procedures for identification of toxins are not readily available. Aflatoxicosis, fusariotoxicosis and ergotism have been described in free-ranging waterfowl.

Aflatoxin poisoning is caused by the metabolic byproduct of *Aspergillus flavis*, which can be found in feed (especially peanut products and corn). Aflatoxin has been associated with liver cirrhosis in older ducks. Nodular hypoplasia or hepatoma may occur in chronic cases. Young ducks exposed to aflatoxin die at one to two weeks of age, showing signs of inappetence, depressed growth, cyanosis of the feet and legs (caused by subcutaneous hemorrhages), ataxia, convulsions and opisthotonos.[111] Gross lesions include a slightly enlarged, putty-colored liver, pale and slightly swollen kidneys, and petechiae on the kidneys and pancreas. In birds over three weeks of age, the liver is firm and slightly shrunken and has a reticulated pattern; ascites and hydropericardium and petechiation may also be noted. The LD_{50} for day-old ducklings is approximately 0.3 to 0.4 mg/kg.[111, 116]

Immunosuppression with chronic aflatoxicosis may be a problem with waterfowl as it is with some other species. The significance of aflatoxicosis in free-ranging waterfowl is unknown. The disease has occurred among Mallards consuming waste peanuts in the southern United States. Birds recover quickly from short-term sublethal exposure to aflatoxin once the source of toxin is removed from the diet.[116]

Fusariotoxicosis is caused by *Fusarium* spp., which are common saprophytes and parasites on plants. Their presence on cereal grains is important because of the variety of toxins they produce, including zearalenone (F_2) and tricothecene toxins (including T_2). Zearalenone was found to interfere with sperm production in ganders but not with egg production in geese (it causes hyperestrogenism in domestic mammals). Clinical signs of T_2 intoxication include vomition, thirst and depression. Geese force-fed 60 to 90 grams of contaminated grain developed head and leg tremors and died within 19 hours. Gross lesions were restricted to mucosal necrosis in the esophagus, proventriculus and ventriculus.[116]

Ergotism is caused by toxic alkaloids formed by the fungus *Claviceps purpurea*, which parasitizes and forms sclerotia in place of the seed in certain cereal grains. Heavy mortality was seen in two- to four-month-old Muscovy Ducks fed wheat containing 1.7% ergot sclerotia. The birds died 48 hours after developing lethargy and diarrhea. Older birds were not affected. Necrosis and gangrene of the extremities, which occur in mammals, have not been reported in waterfowl. Ergotism is unlikely in free-ranging waterfowl that have a choice of food.[116]

Algal Toxins

Algae blooms usually occur in eutrophic waters in warm, sunny weather. The algae must accumulate in shallow water so that the liberated toxin will not be diluted. Algae often concentrate on the downwind shore of lakes. Some of the common genera of blue-green algae implicated in animal intoxication include *Nodularia, Rivularia, Aphanizomenom, Oscillaria, Anabaena, Microcystis, Collosphaerium, Nostoc* and *Gloeotrichia*. An *Anabaena* bloom on Storm Lake in Iowa was associated with the deaths of 5,000 to 7,000 Franklin's Gulls, 560 ducks, 400 coots and 200 pheasants. Death occurred two to ten minutes after ingestion of a minimal lethal dose. The very fast death factor of this *Anabaena* was found to be a depolarizing neuromuscular blocking agent that was rapidly absorbed following ingestion.

Clinical signs may be peracute prostration and death, restlessness, blinking of the eyes, repeated swallowing, salivation and regurgitation. There is no specific treatment, but oral administration of charcoal and mineral oil has been suggested. Access to clean water and food should be provided. There are no specific histologic lesions and there are no tests to detect these toxins. Diagnosis is subjective and is based on identifying toxic algae in an affected bird's environment and ruling out other etiologies of similar clinical signs.[116] Control in the wild is not practical. Algae blooms may be controlled in ponds with copper sulfate, or by increasing water flow to remove nutri-

ents and dilute the algae; however, copper sulfate can also be toxic.

Marine Dinoflagellates

Waterfowl may be poisoned by mollusks living in areas affected by "red tides." Several thousand Lesser Scaup died in Florida as a result of "red tide" caused by *Gymnodinium breve*. *Gonyaulax catenella* and *G. tamarensis* are other dinoflagellates that can be a problem. Clinical signs include weakness, reluctance to fly, dehydration, nasal and oral discharge, lacrimation, edema of the nictitating membrane, bilateral mydriasis, chalky yellow diarrhea, tachypnea, tachycardia and depressed blood pressure.[44] No specific gross or histologic lesions have been described. Recovery occurred rapidly when affected birds were placed in fresh water.[116]

Plant Toxicities

Some plants may be toxic to waterfowl. A seven-week-old goose was treated for sudden onset of ataxia, progressive paresis, recumbency and prolific salivation. Its pen mate died with similar clinical signs. Microscopic lesions included occasional hemosiderin-containing macrophages in the proximal lamina propria of the small intestine. Multifocal loss of cardiac muscle striation was consistent with oleander toxicity. Oleander leaves were found in the proventriculus and ventriculus.[60]

Chemicals

Fertilizers or pesticides should not be used around birds or where runoff may enter animal enclosures. In one case, several ducks died with evidence of coagulopathy while others in the same enclosure were bleeding and had prolonged prothrombin times. The poisoning was attributed to the ingestion of insects that had consumed brodifacoum (Talon). Diagnosis was confirmed by finding 43 ppm brodifacoum in the liver.[73]

Tumors

Spontaneously occurring tumors are infrequently described in waterfowl. The tumors that do occur are histologically similar to those seen in mammals. At the Philadelphia Zoo, between 1901 and 1963, there were only 19 primary neoplasias in the 19,000 birds examined. The largest number of spontaneous tumors was reported in 1949 when 148 hepatomas were found in 1,113 ducks. The youngest ducklings died when they were 143 days old, 14.5% died between three months to one year of age, 23.7% died between 1 and 1.5 years of age and 3.5% died between 1.5 and 2 years of age. Periportal inflammation and degeneration, bile duct proliferation, regeneration and nodular hyperplasia of liver cells with adenomatous formation were common.

This report of spontaneously occurring hepatomas is important today in view of tumors resulting from the feeding of Brazilian ground nut meal. Young ducks are most susceptible to aflatoxin toxicity (see Color 20). Hepatic tumors developed in 5 of 37 one-week-old Khaki Campbell ducklings when fed aflatoxin. Similar lesions developed in 11 ducks that were fed a ration containing 0.5% Brazilian ground nut meal for 14 months.[87]

Egg-related Peritonitis

Egg-related peritonitis is life-threatening and requires intense and aggressive care.[117] It is not uncommon to find old remnants of egg adhered to the abdominal wall or viscera of waterfowl hens at necropsy. These findings are incidental and are usually not related to the cause of death. It is assumed these are eggs that were laid intra-abdominally and were partially reabsorbed (see Chapter 29).

Infectious Diseases

A compilation of data on a variety of bacterial, fungal, parasitic and viral diseases seen in waterfowl can be found in Table 46.9. The reader is also referred to the appropriate etiology chapters elsewhere in this book. Few investigations have been performed on the pharmacokinetics of antibiotics and other therapeutics in free-ranging and captive waterfowl. Antibiotics and other therapeutics used in other aspects of avian medicine can often be used in waterfowl at similar dosages.

Aspergillosis

Aspergillosis is commonly seen at necropsy in Anseriformes. Diagnosis and treatment can be difficult (see Chapter 35 and Color 22).[48,80,86,120]

Parasites

Schistosomes in the genera *Trichobilharzia* and *Dendritobilharzia* were considered the cause of high mortality rates (90%) in a group of geese. The principal pathologic changes included thrombosis of the caudal mesenteric vein, fibrinohemorrhagic colitis and hepatomegaly. This parasite is frequently found in waterfowl but is rarely associated with disease. Weight loss and lameness were the principal clinical findings. Parasites were identified in the lumen of the thrombosed vessels. In general, lesions associated with schistosomes are secondary to reactions to the

TABLE 46.9 Bacterial, Fungal, Viral and Parasitic Diseases of Anseriformes*

DISEASE/AGENT	HOST RANGE	TRANSMISSION	CLINICAL SIGNS	TREATMENT/CONTROL
Aspergillosis *Aspergillus fumigatus*[8,28,44,93,111,116]	All species varying susceptibility	Airborne spores; moldy litter or feed	Respiratory signs; chronic debility	Prevent exposure; surgical excision of affected tissue.
Avian cholera *Pasturella multocida*[8,14,28,50,93,111,116]	Most species highly susceptible; epidemics in wild waterfowl and aviaries, mortality up to 50%	In excrement and respiratory secretions; recovered birds are carriers	Peracute death; acute form - anorexia, dyspnea, diarrhea, mucoid oral discharge; chronic form - dyspnea, diarrhea	Isolate affected birds; burn/bury corpses; autogenous bacterin every three months[g]; A, B, E, F, H*
Avian diphtheria, contagious epithelioma, avian pox, Poxvirus[8,28,111,116]	Undefined, most Anseriformes; seen in Greenwing Teal, Canada and Hawaiian Geese, Mute and Tundra Swans, Mallard Duck	Mosquitoes, direct contact, skin wounds	Wart-like growths on unfeathered skin, dysphagia, dyspnea if lesions in pharynx	Self-limiting, course long; supportive care; control vectors; efficacy/safety fowl pox vaccine undetermined
Avian encephalomyelitis, epidemic tremors Picornavirus[8,111]	All species; affects chicks 1-2 weeks old	Egg transmission possible	CNS signs in chicks, decreased egg production	No treatment, vaccinate
Avian influenza, fowl plague Orthomyxovirus[8,44,93,111]	Ducks and other anseriformes; rare; not reported in wild waterfowl	Inhalation, direct contact, excrement	Sinusitis - mild to severe, mucopurulent or casseous	Reduce stress and crowding, supportive care
Chlamydiosis, ornithosis *Chlamydia psittaci*[8,28,44,93,111]	All species, young mainly; 20-70% mortality in ducklings possible	Excrement; inhalation; asymptomatic carriers	Conjunctivitis, rhinitis, sinusitis, diarrhea, weakness	Chlortetracycline 0.044% in feed 3-6 weeks; doxycycline
Colibacillosis *Escherichia coli* [8,44,93,111]	All species; common	Excrement; ingestion	Septicemia, death, diarrhea, decreased hatchability, omphalitis, salpingitis, bumblefoot	Sanitation, antibiotics based on sensitivity; A, B, G*
Duck plague, duck viral enteritis Herpesvirus[8,11,28,50,93,111,116]	Ducks, geese, swans; susceptibility varies; sporadic outbreaks, see in spring; mortality up to 100%	Excrement - ingestion or inhalation, free-ranging waterfowl carriers	Peracute death, hematochezia, depression, photophobia, epiphora	No therapy, live-virus vaccine,[g] prevent access to carriers and outside water
Duck virus hepatitis Picornavirus[8,92,93,111,116]	Seen in domestics; not reported in free-living waterfowl; ducklings 2-6 weeks old ≤ 90% mortality	Excrement; ingestion or parenteral	Peracute death within hours; sluggishness, paddling of feet, CNS signs	Hyperimmune serum, vaccinate breeders MLV vaccine before laying; vaccinate day old chicks[g]
Eastern and western encephalomyelitis virus, Alpha Virus/Togavirus[8,111,116]	All species; clinical disease rare; not reported in free-living waterfowl	Insect vectors	Asymptomatic or CNS signs; morbidity and mortality highest in chicks	None; vaccine for horses used in ratites and pheasants
Erysipelas *Erysipelothrix insidiosa*[8,44,93,111]	All, 30% mortality in ducklings	Wound infection or ingestion	Depression, diarrhea, inappetance	D;* Bacterin for turkeys may be effective by SC or aerosol (ducklings)
Goose gonorrhea, Neisseria-like organism[106,116]	Geese, captive birds only	Direct cloacal contact; egg transmission	Cloacitis, inflamed/ulcerated phallus; 10% ganders die	Reference 106
Goose virus hepatitis, goose influenza, goose plague Parvovirus[8,93,111,116]	Common in Europe; not seen in US; domestic goslings < 30 days of age; mortality ≤ 80%	Highly contagious	Coryza, diarrhea, ataxia; survivors stunted, loss feathers neck and back	Hyperimmune serum; attenuated virus vaccine in Hungary
Leukosis/sarcoma virus[8]	All species; rare		Tumors of the parenchymous organs	
Necrotizing enteritis agent unknown, possible flagellate, enteric bacteria, *Clostridium* sp.[116]	Seen in free-living waterfowl, captive geese, mallards; common in breeder ducks, mortality ≤ 40%	Stress predisposes	Depression, subcutaneous and pulmonary hemorrhages, mucoid necrotic enteritis	Neomycin sulfate 0.02% in food for 2-3 weeks; reduce stress
New duck disease, infectious serositis *Cytophaga* sp.[8,14,44,93,111,116]	Ducks, geese, swans; sporadic outbreaks in wild; more common domestic flocks; ducklings = acute; older birds = chronic	Probably egg-transmitted	Lethargy, ocular discharge, diarrhea, ataxia, torticollis, often on back paddling legs, acute death	Reduce crowding; bacterin at 2-3 weeks of age; live vaccine experimental[g]; A, C, D, H*
Newcastle disease Paramyxovirus NDV (serotype group 1)[111]	All species; uncommon; few reports clinical disease	Fecal spread likely	Respiratory, conjunctivitis, gastrointestinal, CNS signs	Vaccination for poultry may effective if legal; depopulate
Pseudotuberculosis *Yersinia* sp.[8,44,111]	All species; not uncommon at end of severe winter	Contaminated food supply (rodents and wild birds)	Non-specific clinical signs	
Reticuloendotheliosis Retroviruses[116]	Unknown; rare; high mortality in 2 week old domestic ducks	Unknown	Tumors of RE cells and organs	
Salmonellosis *Salmonella* spp.[8,28,44,93,111,116]	All; rare in free-ranging; common in captivity, domestic ducklings disease < 2 weeks of age	Excrement; ingestion; carried by rodents, insects, water, wild birds	Depression, sudden death; acute septicemia, enteritis	Sanitation; remove carriers; antibiotics may reduce disease but not stop carriers; B, F, I*
Tuberculosis, Mycobacterium avian, spp.[8,44,111,116]	All; rare in free-ranging; common in captivity	Excrement	Emaciation, diarrhea, debility; often dead, no symptoms	Depopulate infected birds, flame environment; potential treat rare birds

table continued on next page

* see Chapters 18, 32, 33, 35 and 36 for further information; treatments: A — sulfaquinoxaline 0.025-0.05% in feed, or penicillin-streptomycin 50,000 U/kg IM; B — sulfadimethoxine-ormetoprim 0.02-0.08% in feed; C — sulfamethazine 0.2-0.25% in drinking water or feed; D — penicillin 50,000 U/kg IM; E — tetracycline IM; F — chlorotetracycline 300-400 g/ton feed; G — lincomycin-spectinomycin IM; H — novobiocin 350 g/ton feed; I — furazolidone 0.022-0.044% in feed.

DISEASE/AGENT	HOST RANGE/TRANSMISSION	CLINICAL SIGNS	DIAGNOSIS	TREATMENT/CONTROL
Acuaria *Echinuria uncinata australis*[5]	Unknown. Daphnia is intermediate host	Proventricular ulceration, anorexia, weight loss, anemia, death		Increase water flow to decrease daphnia; J, L, M, N, O*
Air sac mites *Cytodites nudus*[111]	Anseriformes are aberrant hosts		Seen in respiratory passages and air sacs	Difficult
Avioeserpens taiwana[44]	Ducks in Taiwan, Indochina and North America; cyclops is intermediate host	Parasite-induced masses, submandibular, thigh, shoulder		Remove masses
Capillariasis *Capillaria contorta*[8,44,111]	All; rare	Occasionally, anorexia, dysphagia, diarrhea, necrotizing enteritis	Fecal flotation; barrel-shaped eggs, bipolar plugs; parasites in esophagus, crop, small intestine	J, K, L, N, O*
Cecal worms *Heterakis* sp.[8,44,111]	All; rare	Common at postmortem; rarely clinical signs	Fecal flotation; ellipsoidal, thick shelled eggs, 60x40μ	
Coccidiosis *Eimeria* sp., *Tyzzeria* sp., *Wenyonella* sp.[8,22,93,111]	All; common; mortality ≤ 10% in ducklings; direct transmission	Enteritis, emaciation, anemia, death, renal disease in geese	Fecal flotation; intestinal lesions with merozoites	Amprolium; B, C, Q*
Conjunctival worms *Oxyspirura mansoni*[111]	All; rare	Conjunctivitis, blepharitis, epiphora	Direct visualization; slender, thread-like worms	Manual removal, dilute ivermectin topically
Gape worms of geese *Cyathostoma bronchalis*[31,44,111]	Geese; mortality highest in goslings. Carrier adults	Depression, anemia, coughing, blood-tinged tracheal mucus	Parasite or eggs in tracheal mucus or feces; worms in bronchi and trachea	L, O, P*
Gizzard worms (several nematode species)[8,28,111]	Ducks, geese, swans; mortality highest in young; direct life cycle	Unthriftiness, ventricular dysfunction	Eggs in feces; hairlike worms under horny gizzard lining	K, L, N, O*
Heartworms *Sarcoma eurycerca*[111]	Whistling Swan, White-faced Goose; rare	Depression, death, myocardial necrosis	Microfilaria in blood smear; 2-3 adults/host	Unknown
Leeches *Hirudinea* sp., Theromyzon[12,21]	Many species; occasional	Anemia, conjunctivitis, asphyxiation, bloody nasal discharge		Drain and disinfect pond
Lice - shaftlice, wetfeather *Holomenopen leucocytozoon*	Unknown	Moist-appearing feathers; louse feeds on quill; severe irritation		Malathion powder
Lice - chewing *Mallophaga* spp.[8,44,111]	All; common; life cycle 2-3 weeks	Mainly nonpathogenic; feed on feather debris may cause local irritation	Adults or eggs on feathers	5% carbaryl powder
Ocular trematodes *Philophthelmus gralli*[111]	Ducks, geese	Conjunctivitis, epiphora	Direct visualization 5 x 1.2 mm	Manual removal
Sarcocystis *Sarcocystis ridleyi*[9]	Ducks, especially dabblers; more common in adults	Asymptomatic	Small white rice grain masses in muscles	Nonpathogenic
Schistosomiasis *Dendritobilhargia pulverulenta*[115]	Diving ducks, geese	In arteries, not veins; multisystemic signs; granulomatous encephalitis	Flukes in aorta and cranial branches	
Simulian black fly[111]	Many species	Anemia, toxicity; transmit leukocytozoon and microfilaria		4% malathion inside buildings
Spirurids *Streptocara* spp.[105]	Ducks; common	Proliferative gastritis, vomiting, weight loss	Parasites in gizzard or under mucus lining gizzard and proventriculus	Unknown
Tapeworms[8,23,111]	All; not uncommon; invertebrate or fish = intermediate host	Asymptomatic; catarrhal enteritis, diarrhea, emaciation	Fecal flotation; onchosphere proglottids in feces	R*
Tetrameres[44]	Rare; grasshopper or anthropod is intermediate host	Poor growth; proventricular dystrophy; anemia	Parasite in mucus glands proventriculus	J, K*
Toxoplasmosis *Toxoplasma gondii*[111]	Geese	Anorexia, anemia, emaciation, diarrhea, CNS signs	Complement fixation; Sabin-Fellman Dye test	C, D*
Trematodes/flukes (numerous species)[8,23,111]	Ducks, geese; not uncommon; mollusk is intermediate host	Unthriftiness, enteritis or hepatitis depending on location	Fluke eggs in feces	Difficult; O*

* see Chapters 18, 32, 33, 35 and 36 for further information; treatments: A — sulfaquinoxaline 0.025-0.05% in feed, or penicillin-streptomycin 50,000 U/kg IM; B — sulfadimethoxine-ormetoprim 0.02-0.08% in feed; C — sulfamethazine 0.2-0.25% in drinking water or feed; D — penicillin 50,000 U/kg IM; E — tetracycline IM; F — chlorotetracycline 300-400 g/ton feed; G — lincomycin-spectinomycin IM; H — novobiocin 350 g/ton feed; I — furazolidone 0.022-0.044% in feed; J — piprazine 200-1000 mg/kg PO, 6-10 g/gal drinking water for four days; K — piprazine 45-200 mg/kg PO single dose or 6-10 g in 4 liters of drinking water; L — mebendazole 5-15 mg/kg PO for two days; M — thibendazole 100 mg/kg PO; N — thibendazole 200-500 mg/kg PO; O — levamisole 25-50 mg/kg PO; P — ivermectin 1% (200μg/kg SC); Q — furazolidone in the feed at 0.033% for 14-21 days; R — niclosamide (toxic to geese) 250 mg/kg PO, droncit, Bunamadine PO.

eggs. Lesions associated with adult schistosomes have been reported in the liver, intestines and lung, and reactions to eggs have been reported to cause encephalitis. The high mortality in this group of birds was believed to have been potentiated by placing a group of birds that normally spend the summer in an Arctic marine environment into a fresh water pond.

Proventricular Dilatation

A syndrome similar to that described with neuropathic gastric dilatation in Psittaciformes was documented in two free-ranging Canada Geese. The birds were found in an emaciated state. Postmortem findings included pectoral muscle atrophy and a dilated, thin-walled proventriculus. Nonsuppurative encephalitis with lymphoplasmacytic perivascular cuffing was the principal histologic lesion (see Chapter 32).

Common Surgical Procedures

Most surgical techniques used in psittacines can be applied to waterfowl. Anseriformes normally have a high concentration of subcutaneous and intra-abdominal fat, making the delineation of anatomic structures (particularly vessels) difficult. The transection of large vessels coursing through the fat is common. Blood that may be present on feathers following a surgical procedure should be carefully removed from goslings, ducklings or cygnets to prevent the parents from traumatizing the area through excessive grooming.[44] Most waterfowl can be easily managed in a hospital situation although some do better when their mate or a companion is with them. Birds that are stressed do well in a quiet, darkened enclosure.

Pinioning

There are various surgical means of deflighting birds including patagiectomy,[68,89] joint ankylosis,[111] tendonectomy[71,94] and pinioning.[44,68,71,89,94,111,114] The most common procedure is pinioning. When waterfowl are one to four days of age, they can be quickly and easily pinioned without anesthesia. This procedure causes very little hemorrhage or stress to young chicks. Early pinioning obviates the need for a more complicated procedure at a later date. Toe nail clippers, scissors or other cutting device (suture scissors and wire cutting scissors work well) are used for the procedure. The chick is held upside down, preferably with one wing outstretched, and the alula (second digit) is held out from the carpus (Figure 46.19). The third and fourth metacarpals are then cut as close to the alular and carpus as possible. This will remove all of the primary flight feathers. Although no further treatment is usually necessary, bleeding can be controlled with silver nitrate, Monsel's solution or radiosurgery. The stump can be sprayed with an antibiotic powder.

In older birds, pinioning can be performed at the level of the carpus, but is usually performed at the proximal end of metacarpals III and IV. The procedure can be performed using a local anesthetic in a bird that is manually restrained or the bird may be anesthetized with isoflurane (Figure 46.20). Feathers are removed from the carpus to midway on metacarpals III and IV. A tourniquet is placed on the wing at the level of the humerus. The skin is prepped with povidone iodine and alcohol. A ligature of absorbable suture of approximately 2-0 size is placed around the proximal end of metacarpal IV, incorporating as much interosseus tissue as possible. A similar ligature is placed around metacarpal III, also incorporating as much interosseus tissue as possible. These sutures are designed to ligate the interosseus metacarpal artery, which passes between these bones. A figure-of-eight suture placed around and between the metacarpal bones has been suggested, but in the author's opinion it is inferior to the described technique.

The skin is then incised between mid-shaft and the proximal one-third of metacarpals III and IV. Muscle and fascia are cut deep to the bone. The skin and muscle are bluntly dissected and pushed proximally using a gauze pad to expose the metacarpal bones. The bone should be exposed as close to the base of the alula as possible. Metacarpal bones III and IV are cut as proximal as possible with a bone saw. Rongeur's or nail trimmers tend to splinter the bone. Vessels are ligated if necessary. The skin and muscle are pulled back over the bone end and excess tissue is removed. Muscle and fascia should be sutured over the bone to help pad the ends. Two or three overlapping horizontal mattress sutures are generally sufficient for closure, and the end of the incision can be sealed with tissue adhesive. Skin should be sutured loosely over the bone ends to prevent pressure necrosis.

Although bandaging is not usually required, a pressure wrap may be placed over the stump for several

FIG 46.19 Pinioning is easiest in two- to three-day-old birds. A pair of sterile scissors (top) is used to remove metacarpals III and IV, while leaving the alula intact. Bleeding is minimal (bottom) and can be controlled with a silver nitrate stick, if necessary (1994 Busch Gardens Tampa. All rights reserved.).

days to control mild hemorrhage and protect the incision. Birds should be restricted from the pool for three to seven days to prevent water and bacteria from contaminating the incision. If tissue glue is used to seal the skin, the wound may be sufficiently protected to allow immediate release to water.[111] The comparison of a pinioned and non-pinioned wing is shown in Figure 46.21. A modification of this procedure utilizes elastic castration bands at the base of the metacarpal and excision of bone and tissue distal with a double action bone cutter.[66] However, several weeks may be necessary for the stump to necrose, slough and heal. The editors do not recommended this procedure, for humane reasons.

Tendonectomy

Pinioning results in an aesthetically altered bird, particularly if the wings are extended during preening or courtship behavior. Some bird keepers believe that a pinioned male will have difficulties in maintaining the necessary balance to properly mount and mate with a hen. Suggested alternatives to pinioning include removal of the extensor carpi radialis tendon (tendonectomy) or a wedge resection of the propatagium (patagiectomy). Both techniques are cosmetically and functionally unacceptable. In addition, scar tissue may form that allows the carpus to be sufficiently extended to sustain flight. This is more likely to occur in large-winged birds on windy days when the birds are able to run, jump and glide for variable distances.

Another form of tendonectomy involves removing the insertion point of the superficial pectoralis muscle. This will result in a bird that cannot fly but is cosmetically normal (Figure 46.22). To perform this procedure, the bird is anesthetized with isoflurane and placed in lateral recumbency. The feathers are removed from the ventral side of the humerus directly over the pectoral crest, distal to the level of the scapulohumeral joint. The area is aseptically prepared and the skin is incised with a bipolar radiosurgical unit in a curvilinear manner beginning just distal to the pectoral crest. The incision ends at a point proximal to the scapulohumeral joint. In most birds, the pectoral crest can be visualized through the skin. The dorsomedial aspect of the pectoral crest is the insertion point for the supracoracoideus muscle, which originates deep to the pectoralis and is the primary muscle responsible for elevation of the wing. The wing is then extended fully over the bird's back and should approach the mid-line of the body. This

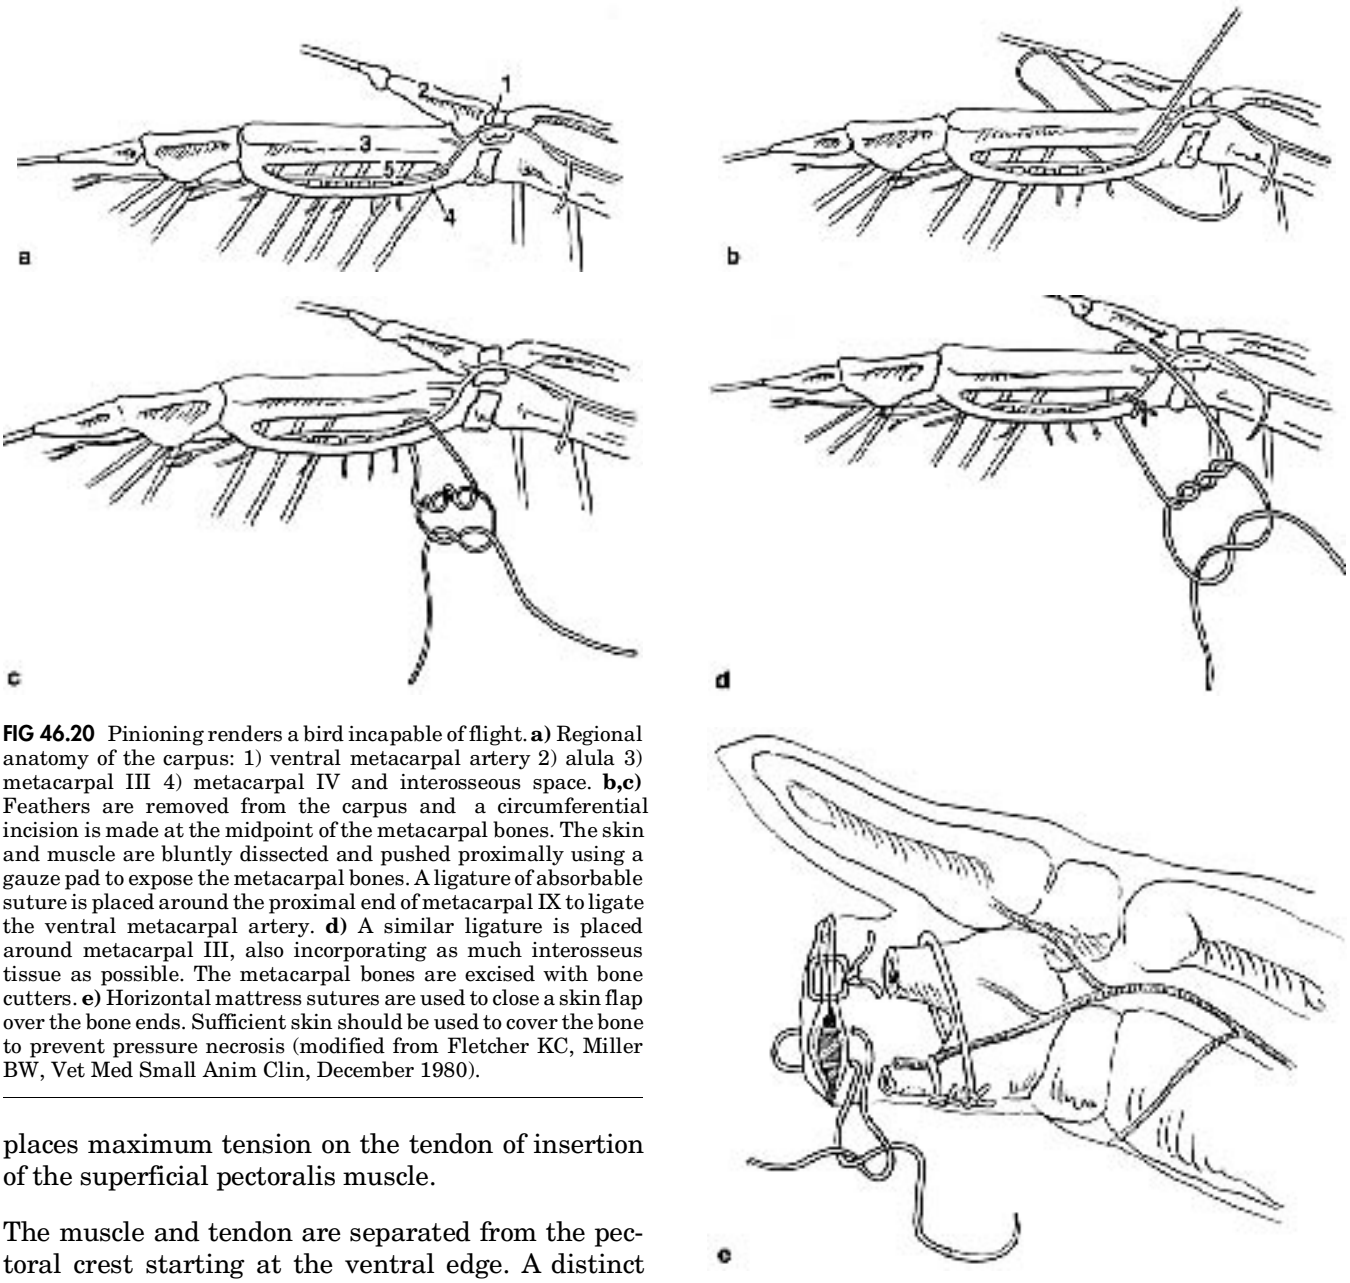

FIG 46.20 Pinioning renders a bird incapable of flight. **a)** Regional anatomy of the carpus: 1) ventral metacarpal artery 2) alula 3) metacarpal III 4) metacarpal IV and interosseous space. **b,c)** Feathers are removed from the carpus and a circumferential incision is made at the midpoint of the metacarpal bones. The skin and muscle are bluntly dissected and pushed proximally using a gauze pad to expose the metacarpal bones. A ligature of absorbable suture is placed around the proximal end of metacarpal IX to ligate the ventral metacarpal artery. **d)** A similar ligature is placed around metacarpal III, also incorporating as much interosseus tissue as possible. The metacarpal bones are excised with bone cutters. **e)** Horizontal mattress sutures are used to close a skin flap over the bone ends. Sufficient skin should be used to cover the bone to prevent pressure necrosis (modified from Fletcher KC, Miller BW, Vet Med Small Anim Clin, December 1980).

places maximum tension on the tendon of insertion of the superficial pectoralis muscle.

The muscle and tendon are separated from the pectoral crest starting at the ventral edge. A distinct popping sound is audible when the final strands of muscle and tendon are separated from the crest. All of the fibrous connective tissues (tendon and periosteum) are radiosurgically removed and the site is fulgurated. The complete radiosurgical destruction of the area of insertion of the superficial pectoralis will prevent the muscle from partially reattaching, which could allow flight. Tissue fragments are debrided from the humerus by scraping with a scalpel blade. The wound should be flushed with sterile LRS. The insertion of the supracoracoideus muscle on the dorso-medial aspect of the pectoral crest should be avoided. This muscle elevates the wing and must be intact to provide the bird with proper balance.

A second branch of the pectoralis muscle, the tensor propatagialis, crosses the shoulder cranial to the superficial pectoralis muscle. The tensor propatagialis is easily identified by grasping and pulling on the leading edge of the wing (propatagial membrane). A 2 or 3 cm section of the tensor propatagialis is removed. The incision should be carefully examined to ensure that the transection is complete. The skin is closed in a continuous or simple interrupted suture pattern. This procedure prevents a bird from flying,

FIG 46.21 A pinioned bird. Note that the alula (arrows) remains to cover and protect the transected end of metacarpals III and IV (1994 Busch Gardens Tampa. All rights reserved.).

but allows normal flexion and extension of the wing. The wing can be moved in a relatively normal fashion for breeding or display, but there is no strength to the down stroke of the wing or control to the leading edge of the wing and thus, no lift. Aesthetically, the bird is normal. The procedure has been successful in deflighting Anseriformes, Ciconiiformes, Pelecaniformes, Galliformes, Gruiformes, Charadriiformes and Columbiformes (see Figure 46.22) (Fletcher K, unpublished).

Beak Repair

Beak injuries that result in an inability to eat, drink and preen will occur in waterfowl. Various attempts at applying prosthetic bills have been described.[7,30,117] One report described the placement of a fully threaded 0.045 Kirschner wire into each tomial margin of the maxilla. The pins were threaded until the tapping end was palpated exiting the caudal aspect of the maxilla at the rectus. The distal tips of the Kirschner wire were bent approximately 90° medially, slightly shorter than the planned rostral prosthetic edge. Prior to surgery, a two-piece template (dorsal and ventral halves) of the upper bill from a Canada Goose model was formed using fast, self-curing dental repair acrylic[f] at a 1.5:1 ratio of powder to liquid. The templates were then waxed to help prevent adherence to the prosthesis.

The nares and the oral cavity were plugged with cotton to prevent possible influx of dental acrylic. The dorsal half of the template was fitted into position over the maxillary stump and the Kirschner wires. The mold was manually held in position while dental acrylic was poured onto it using a 3 ml syringe. The ventral half of the template was positioned over the semi-solid acrylic and pushed down in apposition with the dorsal half of the template. Holding the mold in position, the acrylic was allowed to harden (approximately ten minutes) and the mold was removed.

Additional acrylic was applied with a fine brush to strengthen thin areas of the prosthesis and to feather out the caudal edges of the prosthesis, both on the dorsal surface and the ventral surface where the prosthetic overlapped the bill. This feathering was carried caudally approximately 6 mm with care being taken to exclude external nasal openings. At this point, a high-speed hand-held drill with a fine grinding stone was used to do final shaping and smoothing. A grinding disk was used to create lamellae on the prosthesis. Postoperative care was uneventful, and the bird immediately started to utilize the new bill and was able to eat, drink and preen normally. This bird was monitored for six months, and there were no signs of loosening or instability of the prosthesis.[117] This procedure would be considered a temporary repair and would need replacement in 6 to 12 months (see Chapter 42).

Air Sac Cannulation

Installation of an air sac cannula as emergency care for airway obstruction is described in Chapter 15. In Psittaciformes, this procedure is usually performed in the abdominal air sac. Successful cannulation of the clavicular air sac has been reported in Pekin Ducks.[90] The clavicular air sac is located just under the skin in the area of the thoracic inlet and can be visualized with minimal dissection (see Anatomy Overlay). Chest tubing (6.5 cm long) of the same internal diameter as the endotracheal tube was placed 2 cm into the air sac and fixed in place with a purse-string skin suture. The study showed that the heart rate, mean arterial blood pressure, PaO_2, and $PaCO_2$ of cannulated birds remained unchanged from control values. There were significant increases in tidal and minute volume.[90]

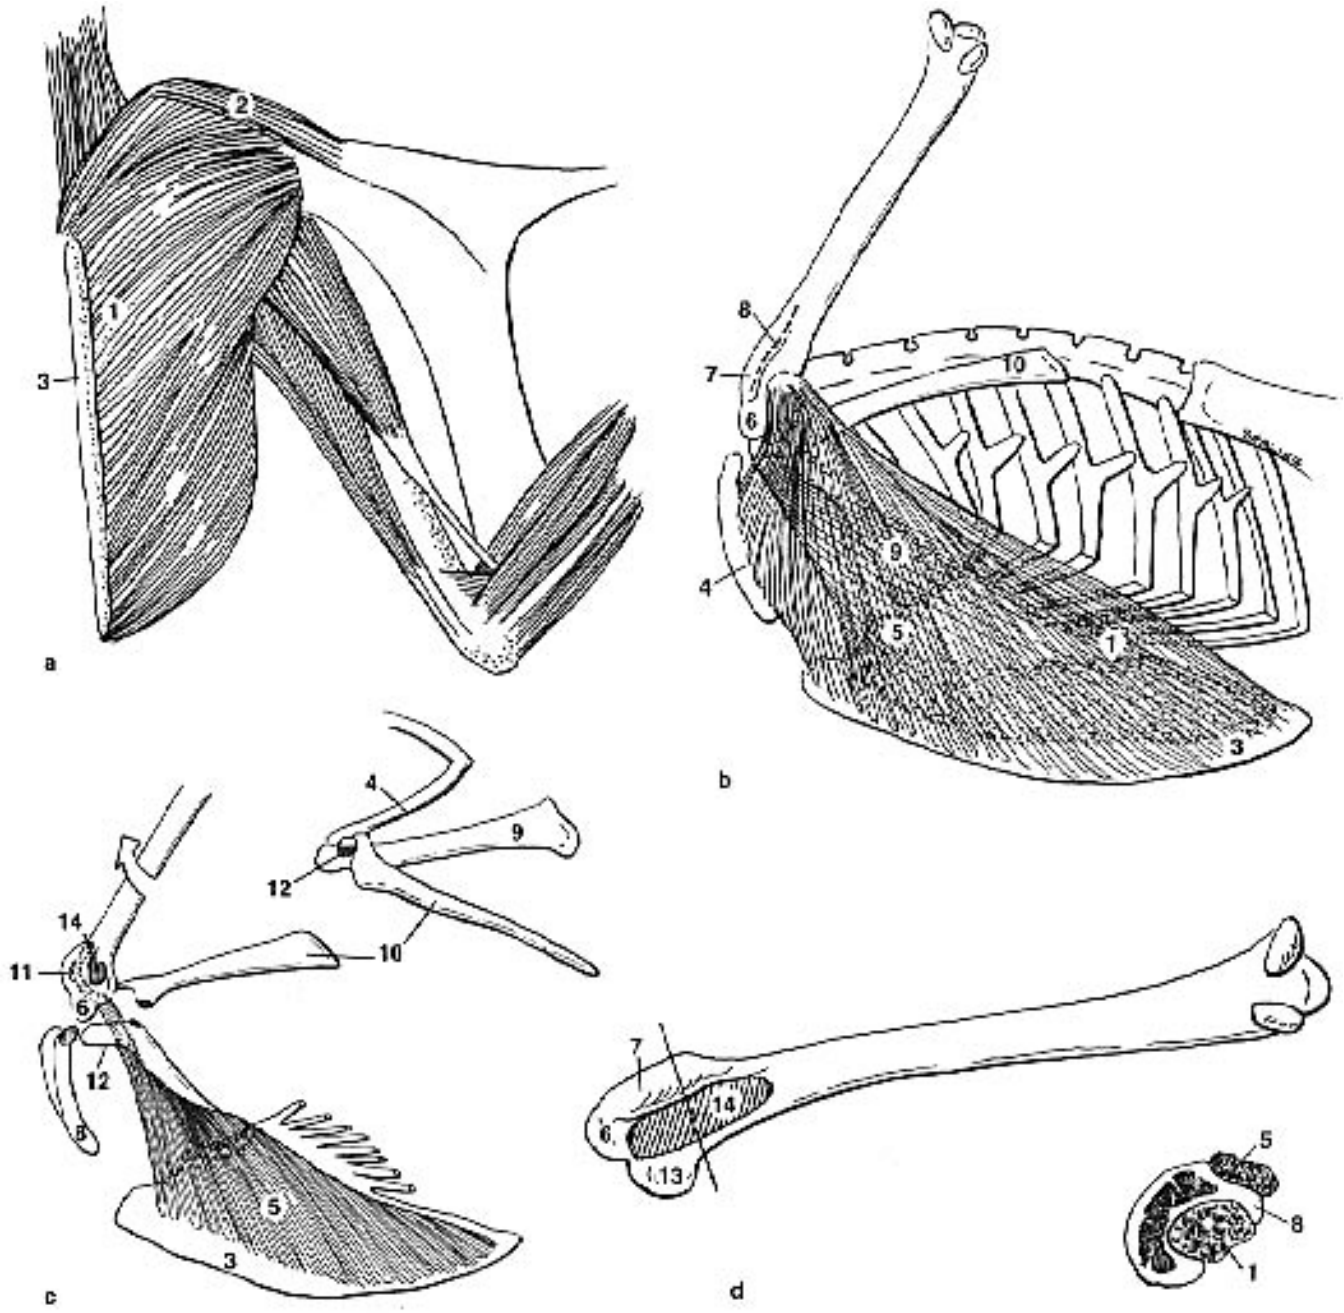

FIG 46.22 Superficial pectoralis tendonectomy for cosmetic deflighting: **a)** The insertion point of the 1) superficial pectoralis muscle and the 2) tensor propotagalis can be excised. **b)** A curvilinear incision (dotted line) is made from a point distal to the pectoral crest extending to a point proximal to the scapulohumeral joint. The wing is then extended fully over the bird's back and should approach the mid-line of the body. This places maximum tension on the tendon of insertion of the superficial pectoralis muscle. **c)** The superficial pectoralis muscle is removed at its insertion on the humerus. The insertion of the supracoracoideus muscle on the dorsomedial aspect of the coracoid must be avoided. A two- to three-cm section of the tensor propatagialis is removed. **d)** Anatomy of the head of the proximal humerus including a cross section showing the relationship of the superficial pectoralis and supracoracoideus muscles to the pectoral crest. 3) sternum 4) clavicle 5) supracoracoideus muscle 6) head of the humerus 7) dorsal tubercle 8) pectoral crest 9) coracoid 10) scapula 11) attachment of supracoracoideus muscle 12) triosseal canal 13) ventral tubercle and 14) insertion of the superficial pectoralis muscle.

Castration and Caponizing

Ganders may become very aggressive during the breeding season. As an alternative to removing an aggressive bird, some clients will choose to have the animal castrated to prevent inter-male fighting, reduce aggression toward people and prevent additional offspring. The procedure is performed on an anesthetized bird placed in lateral recumbency. The wings are extended and taped above the body. Geese are very muscular, so full caudal extension of the up leg is necessary to expose the surgery site. The area of the last two ribs cranial to the femur is plucked and prepped for surgery.

The lungs extend almost to the last intercostal space, so care is necessary when making a one-half-inch vertical incision between the last two ribs. Retractors are necessary to keep the ribs separated. Blunt dissection through the air sac reveals the testicle. Two curved hemostats are clamped between the testicle and body wall and left in place for two minutes. The outer hemostat is then pulled up and away from the other hemostat, tearing the testicle free. Minimal bleeding can be expected. Alternatively, two hemostatic clips may be applied between the testicle and the body wall, taking care not to occlude the aorta or vena cava. The ribs are closed in a simple interrupted pattern with an absorbable suture material. The skin is then closed. The opposite testicle is removed in a similar manner. Several affected birds have been reported to maintain their original personality, but their bellicose nature associated with previous breeding seasons did not develop.[83] This procedure can be most safely performed in young birds.

RAMPHASTIDAE

Hans Cornelissen
Branson W. Ritchie

The family Ramphastidae, included in the order Piciformes, consists of six genera divided into 43 species or subspecies (Table 47.1).[15]

These birds are indigenous to South America, ranging from southern Mexico to northern Argentina.[15] Of the 43 species of toucans, toucanets and aracaris, only a few are frequently seen in captivity, including the Toco, Keel-billed, Red-billed and Channel-billed Toucans, and the Green Aracari (rare). These birds have been maintained in captivity since the Spanish Conquistadors first landed in the Americas, but active breeding programs have occurred only during the past 30 years. The average longevity in captivity is 20 years.

The *Ramphastos* spp. most commonly encountered as companion birds are the Toco and Keel-billed Toucans. If hand-raised, these birds are tame, easily handled and highly inquisitive. These large, active birds require plenty of space for exercise and produce a voluminous, moist excrement, which may account for the low numbers of these birds that are maintained as pets.

Anatomy

Toucans have a large, lightweight, highly vascular bill composed of spongy bone (Figure 47.1). Several branches of the fifth cranial nerve innervate the bill (Figure 47.2), which is extremely sensitive. Toucans have a long keratinous tongue with lateral horn fringes. These birds have no crop and have an intestinal tract that is shorter and wider than that found in Psittaciformes of similar size. There is no cecum. The gall bladder is elongated. Nestlings have a keratinous thickening on the caudal side of the intertarsal joints (heel pad), which falls off shortly after they leave the nest.[31] Ramphastids have a zygodactyl foot. The trachea deviates ventrally at the level of the thoracic inlet and should not be misinterpreted as pathology radiographically (Figure 47.3). A detailed description of the biomechanics of the skull and beak is available in the literature.[18,19]

Gender Determination

Sexual dimorphism occurs in some Ramphastidae, while others are monomorphic and gender must be determined by endoscopy (Table 47.2).[35] Spot-billed Toucans have individually distinct beak patterns that can be photographed and used for identification.

In general, male Ramphastids have a larger beak than females. To determine the beak's length, the lower margin of the upper mandible is measured from the edge of the facial skin outward toward the tip. In Toco Toucans, the beak of the male is generally greater than 16 cm in length, while in the female the measurement is less than 15.5 cm.[35]

TABLE 47.1 The Family Ramphastidae

Genera	Characteristics
Ramphastos	Large, black toucans
Andigena	Mountain-ranging toucans
Aulacorhynchus	Green mountain toucanets
Selenider	Lowland toucanets
Ballonius	Lowland toucanets
Pteroglossus	Aracaris

TABLE 47.2 Gender Dimorphism

Genera	Male	Female
Selenidera sp.	Black head feathers	Brown head feathers
S. culik	Black neck and underparts	Chestnut neck, grey underparts
Pteroglossus viridis	Black head feathers	Brown head feathers
P. inscriptus	Black head feathers	Brown head feathers

Behavior

Toucans can be loud and aggressive, particularly if untamed. Tame birds that are not given sufficient attention may also become very aggressive toward their keepers. Ramphastids are best restrained by initially removing them from the enclosure with a net or large towel. The bird can then be controlled by holding the beak in one hand and using a towel loosely wrapped around the body to control the wings and feet. Toucans should never be handled by the head and neck alone, as is commonly done with psittacine birds.

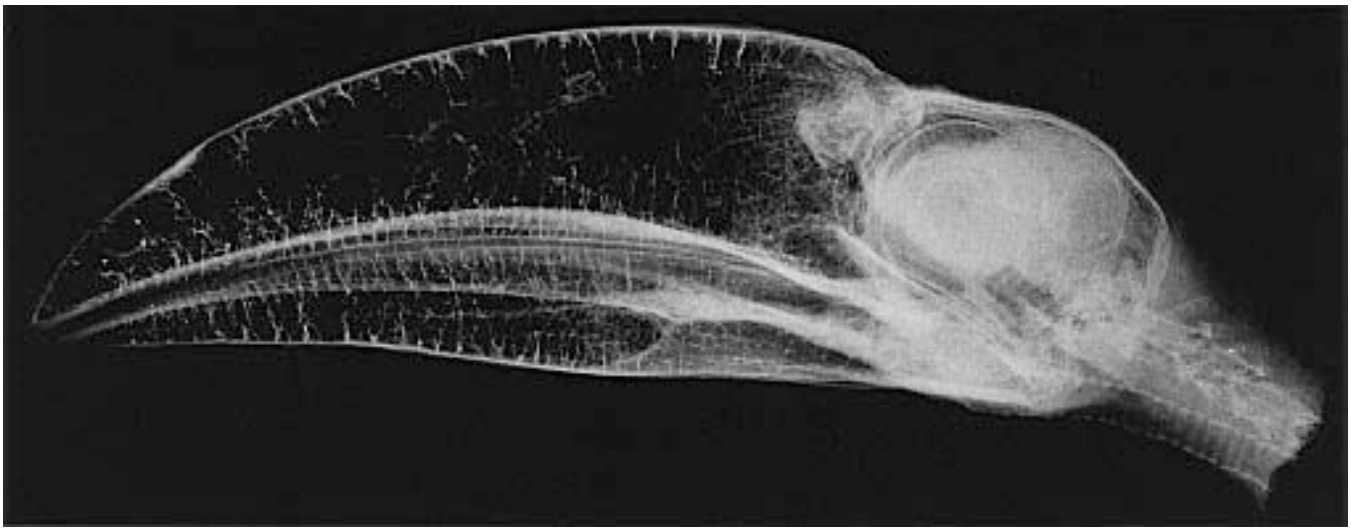

FIG 47.1 Radiograph of the head of a Channel-billed Toucan showing the massive bill composed of spongy bone. Note the large scleral ossicles that support the eyes (courtesy of Hans Cornelissen).

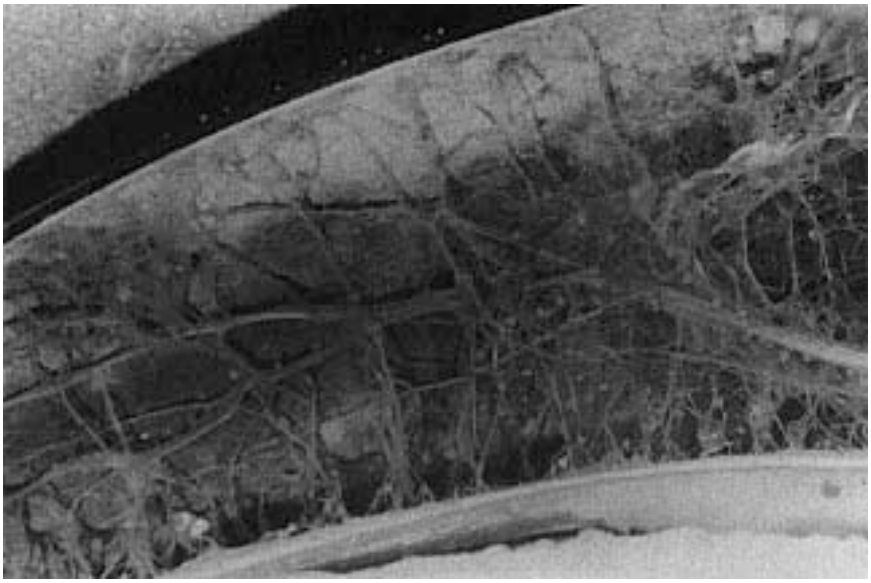

FIG 47.2 Cross-section of the bill of a Channel-billed Toucan showing the extensive nerve supply to the extremely sensitive bill (courtesy of Hans Cornelissen).

The active, curious nature of these birds often leads them to pick up and consume nonedible foreign bodies found in the enclosure (eg, rocks, pieces of wood, screws, string, coins). Resulting impactions can cause perforation or stasis of the gastrointestinal tract, which may lead to death. These birds are capable of being extremely destructive and can injure their beaks when biting on solid objects.

Ramphastids are known to sunbathe. This activity involves spreading the wings with their back to the sun. The mouth is usually open. However, these birds are extremely sensitive to heat prostration and must have access to shade at all times. When sleeping, these birds frequently place their bills into the feathers on the back and raise their tails to form a roof over the back and beak.

Toucans are active, inquisitive birds that are best housed as pairs in large flights with numerous, variably-sized perches. These birds are carnivorous, and if housed in mixed-species aviaries may consume smaller aviary inhabitants. If these birds must be mixed with other birds in the same flight, there should be sufficient room and adequate hiding places to ensure the safety of all inhabitants. Emerald Toucanets are particularly aggressive and should always be housed alone. Most male toucans are aggressively territorial and should not be housed with other males.

The aracaris are the most secretive of the Ramphastidae and require a nest box for security and privacy. This group can thrive if raised in species-specific

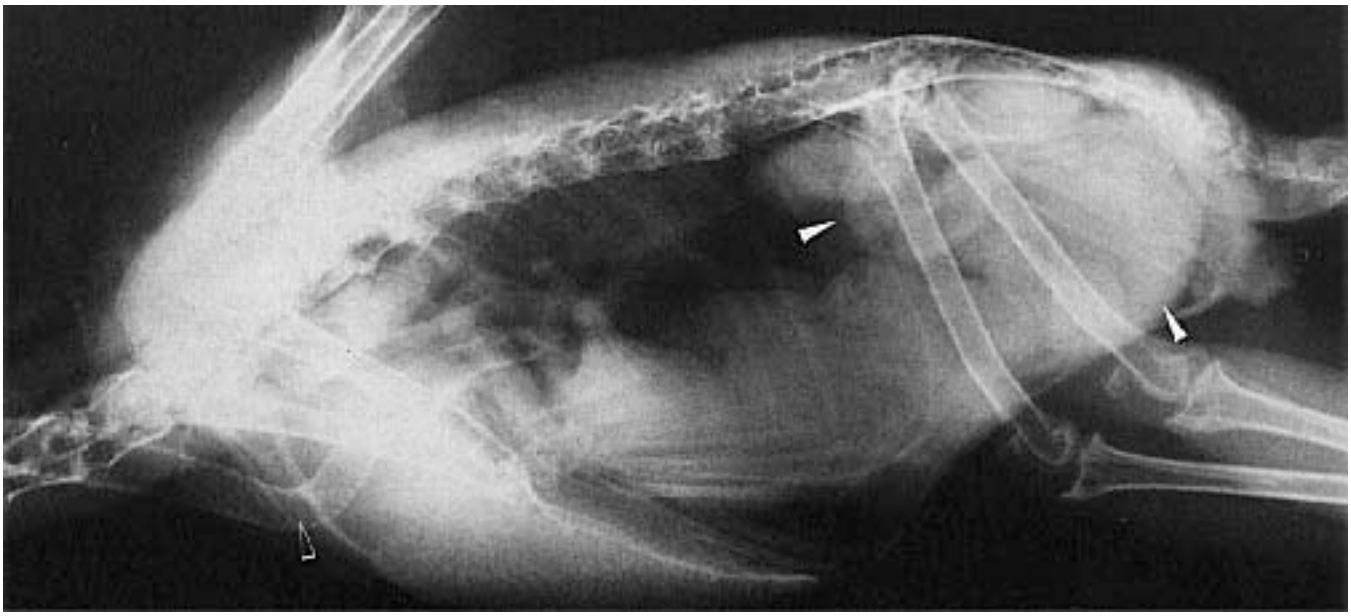

FIG 47.3 A three-year-old Toco Toucan was presented with a progressive posterior paresis of four months' duration. Clinical pathology findings were unremarkable. Radiographs indicated enlarged kidneys. Necropsy findings included renal tubular necrosis and multifocal nonsuppurative neuritis. Note the normal ventral deviation of the trachea (open arrow) in the thoracic inlet. The normal bowel loops (arrows) of toucans appear distended when compared to those of similarly sized Psittaciformes.

colonies where the young from one clutch may assist the parents in caring for subsequent chicks.[35]

Husbandry

Free-ranging Ramphastids eat a variety of fruits, insects, spiders, bird eggs and small vertebrates.[35] They grasp the food with the tip of the bill, toss it into the air, catch the food in the open bill and swallow. Large food items are compressed with a foot and segmented into smaller pieces with the bill. An adequate maintenance diet for toucans would consist of fresh fruits (eg, melons, papaya, berries, tomatoes) supplemented with a low-iron, formulated diet.[a-d] Paprika may be added to the diet to maintain the bright coloration of the beak. During the breeding season, the diet should be supplemented with crickets (up to 800 per day when a pair is raising chicks), small mice and crushed hard-boiled eggs.[34] Fresh water for drinking and bathing should always be available. Toucans like to bathe and should be provided with large, easy-to-clean water containers.

The diet recommended for toucans is low in iron, which may reduce the chances of iron storage disease. The recommended level of iron for poultry is 40 to 60 ppm and the suggested diets for toucans approximate these levels. Many dog foods contain high levels of iron (up to 1500 ppm) and these high-iron foods should be avoided in a diet designed for Ramphastids. Grapes and raisins are also high in iron and should be avoided. Vitamin C enhances the absorption of iron, and citrus fruits should be offered on a limited basis.

The floor of a toucan enclosure should be well drained and easy to clean.[4] The large amount of moist foods that these birds consume results in the production of voluminous, malodorous excrement. These birds may normally pass some undigested food. Birds that are losing weight and consistently excreting undigested food should be evaluated.

Reproductive Characteristics

Toucans are best bred in large, planted flight enclosures with plenty of privacy. The walls of the enclosure should be covered with a cloth or plastic barrier to protect young chicks from collision injuries while they are learning to fly or, more appropriately, stop.

Toucans are cavity nesters. The larger species make an entrance hole in decayed portions of large trees. The smaller species take over the nests of woodpeckers and remodel them for their own use. Most birds will readily accept natural palm logs as nesting cavities. Some toucans can be adapted to plywood boxes six feet long and one foot square with a concave bottom. The front can be covered with bark to simulate a natural nest. The nests of free-ranging birds can be found from a few inches to several feet below the entrance hole.

Courtship behavior is characterized by the males feeding the females, and both adults share incubation and rearing responsibilities. Sexual maturity generally occurs by three years of age.

Toco Toucans usually lay three to four eggs per clutch with an 18-day incubation period. Red-breasted Toucans usually have two to three eggs with a 16- to 17-day incubation period. Some of the toucans will use nesting material while others will empty the nesting cavity and lay the eggs directly on the bottom of the container.[3a] Frequently, the addition of nesting material will stimulate a pair to clean out the nest box and induce breeding.

Toucan chicks may leave the nest within 45 days of hatch and are generally weaned from two to four months of age.[22] Cannibalism of young chicks by the parents is common if the diet is not supplemented with crickets, mice or mealworms.

Toucan chicks have been successfully hand-raised from the egg. Initially, the diet consisted of small diced pieces of grape, banana, and pinkie mice soaked in water and offered by forceps. By three days of age, soaked monkey biscuit was added to the diet. The neonates were fed every two hours for the first twelve hours and then every three hours for 16 days, when the feeding frequency was reduced to four times per day. The eyes were open at three to four weeks of age. It is important to remember that these birds do not have a crop and should be fed smaller quantities and more frequently than psittacine neonates. Weaning may occur from two to four months of age.[3a] A neonate should be expected to gain weight daily and any weight loss is an indication of a problem. The weight should double each week.

Toucans can be anesthetized using isoflurane delivered through a modified face mask (Figure 47.4). Blood collection techniques are similar to those described for other avian species. Normal blood parameters are listed in the Appendix.[33,34]

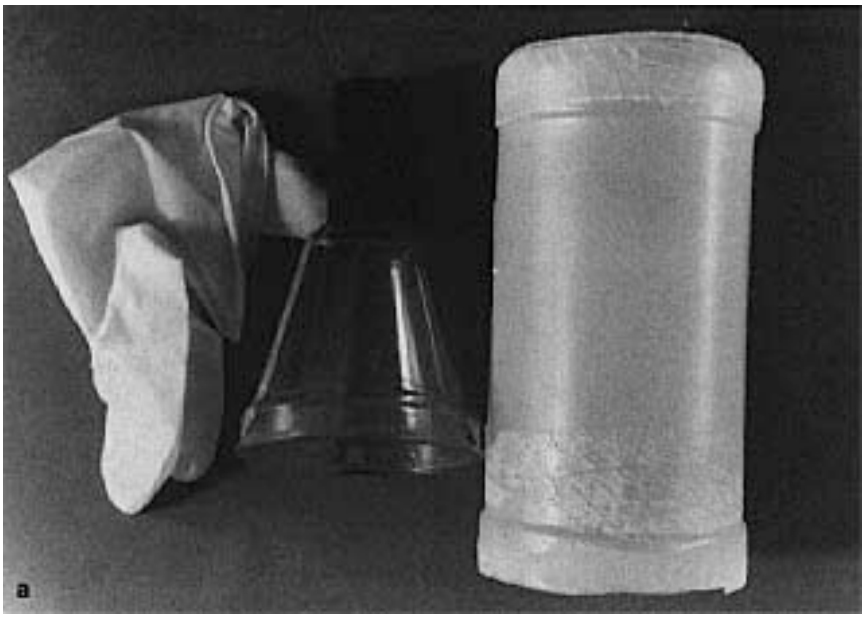

FIG 47.4 **a)** A face mask for delivering isoflurane can be constructed using a small animal mask, a rubber glove and a one-quart cylindrical plastic bottle. **b)** The ends are removed from the bottle, leaving a flange on one end to prevent the small animal mask from slipping through. The small animal mask is passed into the bottle and taped in place. A rubber glove is stretched over the opposite end of the bottle and taped in place. An appropriate-sized slit is placed in the glove to allow insertion of the beak and nostrils. The mask components should be sterilized between patients.

Diseases

Liver Disease

Toucans are frequently diagnosed with iron storage disease, liver cirrhosis and chronic acute hepatitis (Figure 47.5). They are among the species of birds most susceptible to iron storage disease.[14,21,30,33,34,35] Primary iron storage disease is generally considered to be of hereditary origin, while secondary disease occurs from exposure to toxic levels of iron, anemia or other factors (see Color 20).[23] It remains unclear whether hemochromatosis in toucans is caused by hereditary factors, excess dietary iron or a defect in iron metabolism. There does seem to be some species predisposition, with Toco Toucans being particularly susceptible.

Studies have shown that birds of paradise absorb 90% of their dietary iron intake, while humans absorb only 10% of their dietary iron.[10] Studies on the efficiency of dietary iron absorption in toucans have not been performed. Based on the frequency of iron storage disease in a presumably genetically diverse group of birds, it is likely that an efficient iron absorption process plays some role in the development of iron storage disease.

Toucans with hemochromatosis may die acutely with no premonitory signs or can develop clinical signs, including emaciation, dyspnea and abdominal enlargement (ascites). Affected birds typically have an enlarged, yellow liver with ascites (see Color 20). Histologically, iron deposits are most frequently identified in hepatocytes and Kupffer cells, but may also be demonstrated in the spleen, renal tubular epithelium, lung, pancreas and intestines.[35] Definitive diagnosis requires the confirmation, with a Prussian blue stain, of excess iron in affected tissues or toxicologic analysis of liver tissue.[39]

Previously, an antemortem diagnosis of iron storage disease was made by measuring total serum iron, the total iron binding capacity (TIBC) and by taking a liver biopsy for histologic evaluation.[33,35] More recently, the same author surveyed 24 clinically normal birds and found bile acids, serum chemistries and hematology values within the normal reference in-

tervals. Liver biopsies from these birds showed histologic evidence of hemochromatosis, and toxic levels of iron were above the reported normal of 100-300 ppm.[37]

A low iron diet (< 150 mg/kg) and weekly phlebotomies to remove a blood volume equivalent to one percent of body weight have been suggested as methods to prevent hemochromatosis in Ramphastids with high serum iron levels.[34] Iron chelating agents have also been suggested as a method of treatment.[33,35]

Toucans do not frequently breed in captivity.[2,4,17,22] Because the liver is critical in the formation of yolk, it is possible that the frequency of hepatic-related problems in toucans directly affects their ability to reproduce.

FIG 47.5 Ascites secondary to iron storage disease, liver cirrhosis and chronic active hepatitis is one of the most common clinical presentations in toucans. In this case, a toucanet from a breeding aviary was found dead in its enclosure. The bird had a severely distended abdomen. Fluid collected by abdominocentesis at necropsy was characterized as a transudate and there was no bacterial growth. The liver was enlarged and pale-orange. The histologic diagnosis was hemachromatosis.

Infectious Diseases

The normal aerobic and microaerophilic microflora of clinically normal toucans include *Escherichia coli*, *Staphylococcus* spp. and *Streptococcus* serotype D. These organisms were detected in the cloaca of 90% of 53 asymptomatic toucans representing five different species.[6] *Klebsiella pneumonia* was recovered from 50% of the clinically normal Red-billed and Plated-billed Mountain Toucans examined in one study. Birds from aviaries with good hygiene had fewer gram-negative bacteria than birds from less well maintained facilities. However, the fact that pathogenic gram-negative bacteria were commonly recovered from normal birds suggests that toucans are able to withstand colonization of the gastrointestinal tract by these bacteria better than are psittacine birds. Because gram-negative pathogens are frequently recovered from clinically normal Ramphastids, antimicrobial therapy should be considered only in patients with high concentrations of these bacteria, especially when they are demonstrating clinical signs of disease.

Avian pseudotuberculosis (*Yersinia pseudotuberculosis*) has been documented as a cause of acute death following a brief period of lethargy in toucans.[3,4,7,8,16] Infections are most frequently associated with a rapid bacteremia and peracute death. Postmortem findings include pneumonia, hepatomegaly and splenomegaly. The enlarged liver and spleen are generally covered with numerous raised, white-to-yellow-orange foci (see Color 20).[7] Chronic debilitating infections have also been defined with *Y. pseudotuberculosis*. In these cases, bacteremia results in formation of granulomas in numerous parenchymatous organs.

It has been suggested that *Y. pseudotuberculosis* may cause dark-green or black discoloration of the orange portion of a toucan's bill, but the involvement of this bacteria in causing these lesions has not been confirmed.[35] In one study, *Y. pseudotuberculosis* was not isolated from the cloacal contents of 53 clinically normal toucans representing five species.[6] Small rodents, such as mice and rats, which normally are part of the toucan diet, are known to carry *Y. pseudotuberculosis* and may serve as a reservoir for infection.[11] The aviary should be rodent-proof, and only laboratory-raised mice and rats should be offered as food items.

An experimental *Y. pseudotuberculosis* vaccine appears to be clinically effective in reducing the prevalence of infections. All newly arriving toucans, turacos and hornbills in a bird facility that normally experienced loss from *Y. pseudotuberculosis* were vaccinated with the experimental vaccine. A reduction in the morbidity and mortality in this group was evident.

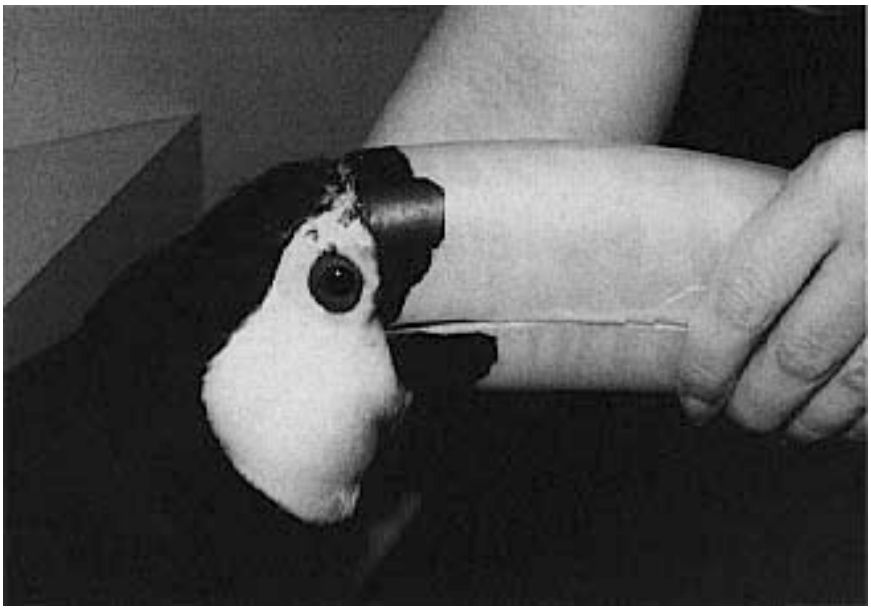

FIG 47.6 Toco Toucan with a chronic dermatitis. Cytology of skin scrapings from the wounds indicated a mixture of bacteria and fungi.

A pet male Toco Toucan that was housed indoors died following a one-day history of anorexia. The bird had acute nephrosis, and *Aeromonas hydrophilia* was recovered from the heart and liver. The source of bacterial infection was undetermined.[27] A three-year-old female Toco Toucan was diagnosed with *Mycobacterium* sp. Clinical abnormalities were limited to lethargy, poor feather formation and an enlarged abdomen. Necropsy findings included a swollen and congested liver, spleen and kidney. The intestinal wall was thickened, and the lumen was dilated and filled with fluid. In most species, mycobacterium infections tend to induce localized infections that result in the formation of discrete granulomas. In contrast, mycobacterium infections in psittacine birds and toucans are usually diffuse.[32]

Mycotic Diseases

A group of Toco Toucan neonates was diagnosed with corneal ulcers caused by *Candida* sp. Some of the affected birds had secondary bacterial infections. A combination of IV and topical amphotericin B as well as topical gentamicin ophthalmic solution resolved the ulcers. Scar formation was common (Figure 47.6).[20]

Acute deaths caused by *Penicillium griseofulum* were reported in a group of toucanets. Affected birds had a pale-green mold that was visible in the trachea, abdominal air sacs and lungs.[1]

Ergotism was suspected in a group of Keel-billed Toucan neonates being fed a kitten chow diet. Constrictive lesions occurred to multiple digits in the neonates. The most severely affected chick died. Changing the diet and initiating antifungal therapy prevented any further problems in the other neonates.

Viral Diseases

Newcastle disease virus was isolated from 3 of 48 toucans tested in a quarantine station.[28] A herpesvirus was recovered from a mature female toucan that died following a brief episode of depression and inappetence. Severe necrotizing hepatitis with intranuclear inclusion bodies in the spleen and liver were the principal histologic lesions. The toucan had been exposed to several macaws that died from herpesvirus five days before clinical signs developed in the toucan. The herpesvirus isolated from the toucan did not react with Pacheco's disease virus-specific antibodies, suggesting that the isolate from the toucan was a serologically distinct herpesvirus. The bird was also diagnosed with chlamydiosis using the direct fluorescent antibody test of impression smears from the liver and spleen.[5]

Parasites

Three species of *Plasmodium* (*P. huffi*, *P. nucleophilum tucani* and *P. rouxi*) have been documented in toucans. High levels of *P. huffi* usually result in death. The other species have been associated with mild to subclinical infections in Swanson's Toucans, Sulphur-crested Toucans, Collared Aracaris, White-throated Toucans and Plate-billed Mountain Toucans.[24,25]

Fluke eggs and numerous giardia were found in the feces of a Red-bellied Toucan with loose droppings that contained undigested food. Metronidazole resolved the giardia infection in four days but had no effect on the flukes. Treatment with praziquantel (10 mg/kg) IM daily for three days followed by the same dose orally daily for 11 days was effective in stopping the passage of fluke eggs.[12]

Giardia is frequently identified in fecal samples collected from asymptomatic toucans. Currently, no clinical disease has been associated with these infections. However, toucans could serve as a reservoir for

this parasite and expose other avian species housed in the same facility. Ascarids, coccidia and capillaria are other parasites frequently encountered in toucans. These infections are treated in a manner similar to those described for psittacine birds (see Chapter 36).[35]

Subclinical infections with ventricular nematodes have been documented in toucans that were housed in enclosures once occupied by finches (the nematodes' natural host).[35] A subclinical infection with a diurnal microfilaria of an undetermined genera was documented in a Swanson's Toucan.[24]

Metabolic Diseases

Idiopathic diabetes mellitus is frequently diagnosed in toucans. Weight loss, glucosuria (1 mg/dl), hyperglycemia (700 mg/dl often occur), polyuria and polydipsia are frequent clinical findings. The frequency with which this disease occurs suggests that the etiology is related to management or diet rather than genetic defects. Pancreatic islet cell tumors and hypothyroidism have also been suggested as causes for diabetes mellitus in toucans.[35]

Protamine zinc insulin (0.1 to 0.5 units BID) has been suggested as a possible treatment.[35] However, maintaining proper blood glucose in toucans with insulin is difficult. Long-term therapy is generally associated with pancreatic atrophy, which causes pancreatic exocrine insufficiency, eventually leading to death. Toucans also develop rapid tolerance to insulin, making proper administration difficult. In a study involving three normal adult Toco Toucans, it was determined that glucagon suppression did not occur following glucose challenge, suggesting that toucans metabolize glucose differently than do other birds.[26]

A toucan being fed a fruit and dog food kibble diet was found to have diabetes mellitus with a blood glucose level of 1587 mg/dl. Changing the diet to a 100% formulated diet[d] supplemented with prozyme reduced the blood glucose level to 365 mg/dl, suggesting this bird's diabetes was dietary related.[26]

Products Mentioned in the Text

a. Bird of Paradise Diet, Ziegler Bros. Inc., Gardners, PA (iron content 77 ppm)
b. Harrison's Bird Diets, Pawnee City, NE (iron content 65 ppm)

CHAPTER

48

RATITES

James Stewart

Ratites are a group of large, ground-dwelling birds that share the common characteristic of flightlessness. The term ratite is derived from the Latin *ratitus*, meaning raft, and refers to the shape of the sternum that lacks a keel. There is no scientific classification "ratite," but the term is used to collectively describe the ostrich (from Africa), rhea (from South America), emu (from Australia), cassowary (from Australia and the New Guinea archipelago) and the kiwi (from New Zealand).[1] Once considered to be a single category of related primitive birds, the ratites are now considered to be derived from unrelated groups of flighted birds that have adapted to a highly specialized terrestrial lifestyle.

In the 1980's, it was estimated that between 90,000 to 120,000 ostriches existed on approximately 400 farms as part of a multi-crop rotation system in South Africa. During the same time period, a fledgling industry arose in the United States and by the end of the decade, it was estimated that there were close to 10,000 ostriches and about 3,000 emus in the US.[55]

This growing interest in breeding ostriches and emus has occurred due to the birds' potential as producers of meat, feathers and skin. Ostrich skin is characterized by prominent feather follicles and is a high status product of the leather industry. Ostriches yield a red meat that has the flavor and texture of beef, yet has the cholesterol and nutritional value of poultry. Ostrich feathers, still used for dusters, are also used in the manufacture of fashion and theatrical attire.

Characteristics

Ostrich

The ostrich is the largest living bird, reaching over 200 kg in weight and 2.7 m in height. The ostrich that was first described (nominate race) was put in the family Struthionidae and the genus *Struthio*. The bird's dome-backed profile, desert living conditions and odd-shaped feet are reminiscent of the camel, thus the species name, *camelus*. Four subspecies are currently recognized; their range is through the northern, eastern and southern savannahs of the African continent. The Syrian ostrich of the Arabian peninsula became extinct in 1941.

Struthio camelus camelus (North African ostrich) ranges from Morocco to Ethiopia and Uganda. A male *S. c. camelus* has a red coloration of the skin of the neck and thighs and a bald crown of the head. The hens of all races are indistinguishable. The eggs can be differentiated among subspecies, and those of the nominate species are characterized by fine stellate pores.

S. c. massaicus (East African or Masai ostrich) inhabits Kenya and Tanzania. The male has a red neck and thigh and the crown of the head is feathered.

S. c. molybdophanes (Somali ostrich) is found in Ethiopia and Somalia. The male has a blue-gray neck and thighs and the crown of the head is bald.

S. c. australis (South African ostrich) ranges throughout southern Africa. The neck and thighs of the male are gray and the head is feathered.[5] The large pores in the shells of this subspecies leave the egg with a pitted appearance.

A hybridized ostrich that is a combination of *S. c. australis, S. c. massaicus* and *S. c. syriacus* is referred to as a "domestic" or "African black" ostrich. The careful breeding of this bird since the 1870's has resulted in a smaller, calmer bird that has higher quality feathers than its free-ranging relatives.[55]

Ostriches can run up to 40 mph for several miles and can kick forward with powerful and accurate blows. Ostriches have large eyes with substantial visual acuity, and large ear canals with a keen sense of hearing. These birds have been known to breed for up to 42 years, and may live over 80 years. The male has black and white plumage at maturity, while the females and juveniles have dull brown plumage.

Rhea

Rheas are frequently referred to as South American ostriches, but are related only in superficial appearance. Weighing 25 kg and standing 1.5 m in height, the rhea is the largest bird of the western hemisphere. Two distinct species are recognized. The Common Rhea ranges throughout the central continent, and as many as five subspecies have been described. Darwin's Rhea, including three subspecies, is a smaller bird residing in the eastern foothills of the Andes. Free-ranging rheas eat grass, leaves and insects.

Cassowary

Cassowaries are stout, heavy-bodied birds reaching 85 kg in weight and 1.5 m in height. They are distinguished by a large bony casque on the forehead that is used to deflect brush as they dart through their dense rain forest habitat. Three species are found on New Guinea; one also ranges in northern Australia. Cassowaries are solitary, the males are highly aggressive and these birds adapt poorly to most captive settings.

Emu

Emus are closely related to cassowaries and share the same type of feather. The shaft and aftershaft are equally well developed, giving each feather the appearance of being doubled. The single existing species is found throughout Australia, while the Tasmanian and Kangaroo Island emus became extinct only in the past century. Adult emus may weigh 55 kg and stand 1.7 m in height. Emus may live 30 years and have strong eyesight and hearing. Like ostriches, emus are good swimmers. Free-ranging emus consume grasses, herbs, fruits and insects.

Other Ratites

Included among the ratites is the kiwi, and frequently the tinamous. Both groups are specialized ground-dwelling birds that bear little resemblance and no relationship to the larger species. This chapter will focus primarily on the ostrich as the model ratite, with only occasional comment on the emu, rhea and cassowary.

Clinical Anatomy and Physiology

Despite their impressive size, ratites are, nonetheless, birds, and their anatomy and physiology are fundamentally similar to a psittacine model. The deviations from this model, including their size, are all adaptations to a terrestrial lifestyle. The similarities and differences are clinically relevant and should be familiar to the ratite veterinarian.[2,11,19]

Integument

The skin of ratites is thick along the legs and body, but relatively thin along the neck where it is subject to tears (Figure 48.1). The ostrich, emu and rhea have sternal callosities. In addition, the ostrich has a callosity distal to the pubic bone and another distal to the hock joint; both anatomic areas contact the ground in a recumbent bird. Apteria are present along the lateral body wall and provide convenient access sites for surgery and diagnostic procedures such as ultrasound. In contrast to other birds, the feathers of the ostrich function to shade the body, rather than insulate it, and an ostrich will erect the feathers when hot and flatten them when cold. Ostriches have no feathers on the thigh, while in other ratites feathers extend to the tarsometatarsus. Ostrich, emu and rhea feathers lack barbiceli, making their feathers less water-resistant than those of other birds (Color 48.14).

Musculoskeletal System

The rhea, emu and cassowary have three toes (digits 2, 3 and 4), each with four phalanges. The ostrich is the most specialized runner and has only two toes (digits 3 and 4); the metatarsal-phalangeal joint is suspended so that the standing weight is born entirely by the digits (Figure 48.2). The pubic bones of the ostrich form a solid ventral symphysis to support the weight of the abdomen (Figure 48.3).

Corresponding with flightlessness, the pectoral musculature is greatly reduced and the sternum lacks a keel. Because there is no need for flight, the thoracic girdle is modified, and the fused scapula, coracoid and clavicle are attached to the cranial sternum (Figure 48.3). The patella is absent in ratites. In the

FIG 48.1 Ratite skin is thin and easily torn by sharp projections on fences and transporting vehicles. The trachea and jugular vein are visible through the tear in the skin (courtesy of James Stewart).

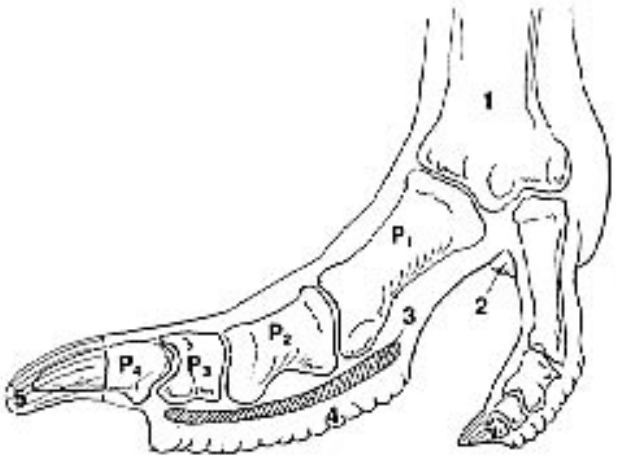

FIG 48.2 The ostrich foot is composed of two toes. 1) tarsometatarsus 2) metatarsal phalangeal pad 3) digital cushion 4) phalangeal pad 5) toenail (modified with permission from Murray Fowler[19]).

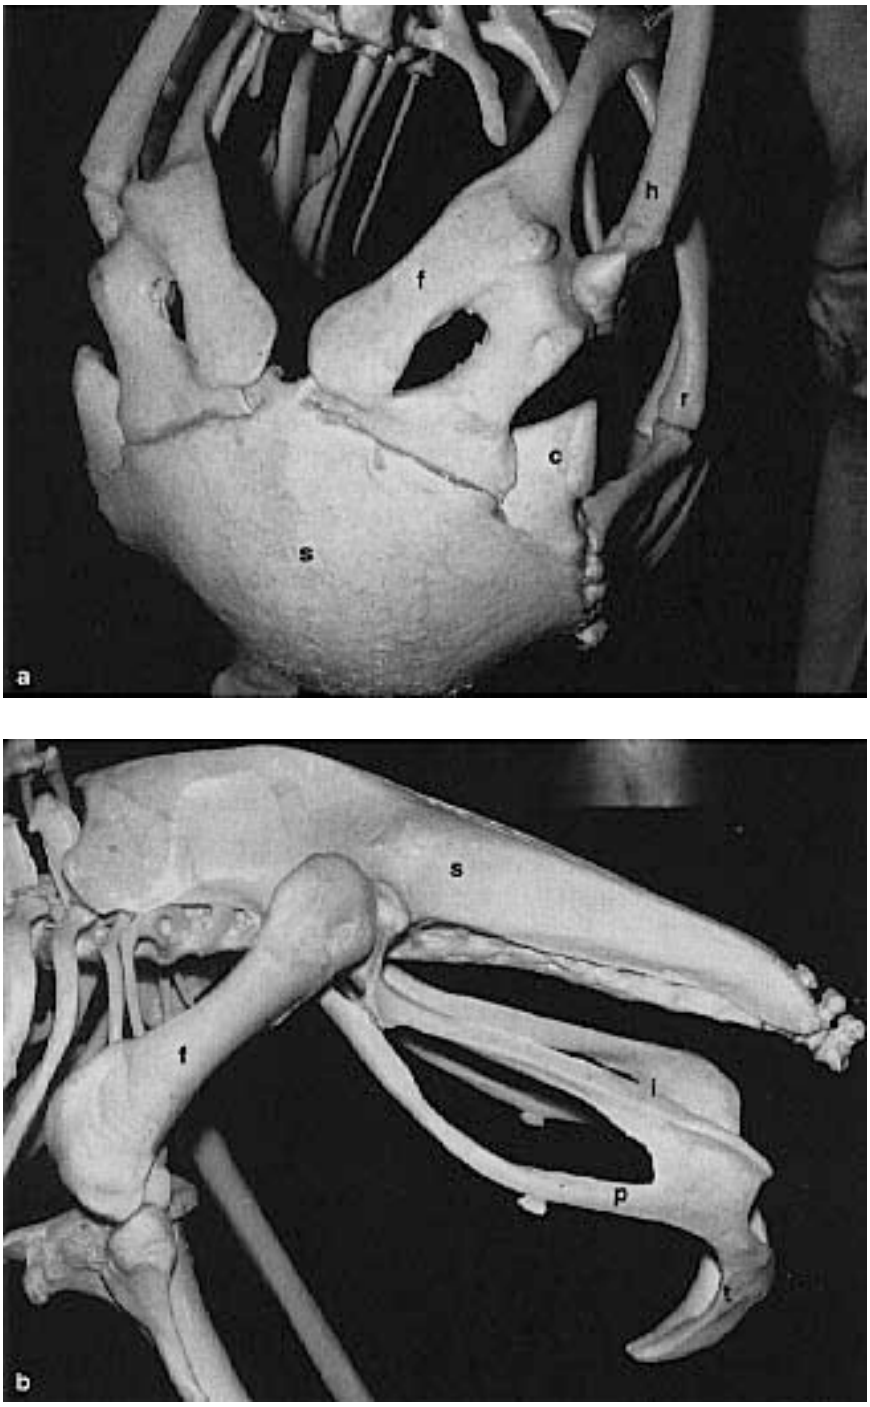

FIG 48.3 **a)** The sternum (s) of ratites lacks a keel, and the coracoid and scapula are fused to form the scapulocoracoid (f). Other structures of interest include the first rib (r), cartilaginous extension of the sternum (c) and the humerus (h). **b)** The pubic bones (p) of the ostrich are fused to form a solid ventral symphysis that supports the weight of the bird. Other structures include the femur (f), ilium (s), ischium (i) and pubic symphysis (t) (courtesy of Murray Fowler,[19] reprinted with permission).

ostrich there may be a small bone in the tendon of insertion of the muscle on the cnemial crest of the tibiotarsus. The crest is projected craniodorsally providing extra leverage for quick, sure forward movement of the leg when the bird is running, swimming or kicking. In the ostrich and emu, one of the tarsal bones remains unfused to the contiguous bones, which should not be misinterpreted as the knee radiographically.[19]

The ventral midline area of the abdominal wall consists only of the aponeuroses of the abdominal muscles. A surgical incision made along the midline penetrates the skin, subcutaneous fat (minimal) and a dense fibrous abdominal tunic. The next layer is retroperitoneal fat, which may be two to eight centimeters thick, especially in the emu. When a laparotomy is performed, the bulk of this adipose tissue should be peeled away prior to closing the body wall (Color 48.26).[19,20]

Respiratory System

Unlike other birds, the sternum is fixed and bears the weight of the resting ratite. Respiration occurs by lateral excursions of the chest wall, which must be considered during anesthesia and recovery. The normal respiratory rate in adult ostriches is 6 to 12 bpm, which may increase to 40 to 60 bpm during periods of stress, exercise or with high temperatures.[19] The syrinx is poorly developed in these relatively avocal birds. The lungs and air sacs are similar to those of other avian species, but the air sac capacity is greatly reduced. The distinct visceral outlines created by the air sacs in the radiographs of psittacines are not present in ratites. The femur is the only pneumatized long bone in ratites.

Emus have a longitudinal cleft in the trachea 10 to 15 cm cranial to the thoracic inlet that opens into a resonation chamber for vocalization (Color 48.16). This area is particularly well developed in the female. In the chick, a thin membrane covers the cleft. Air di-

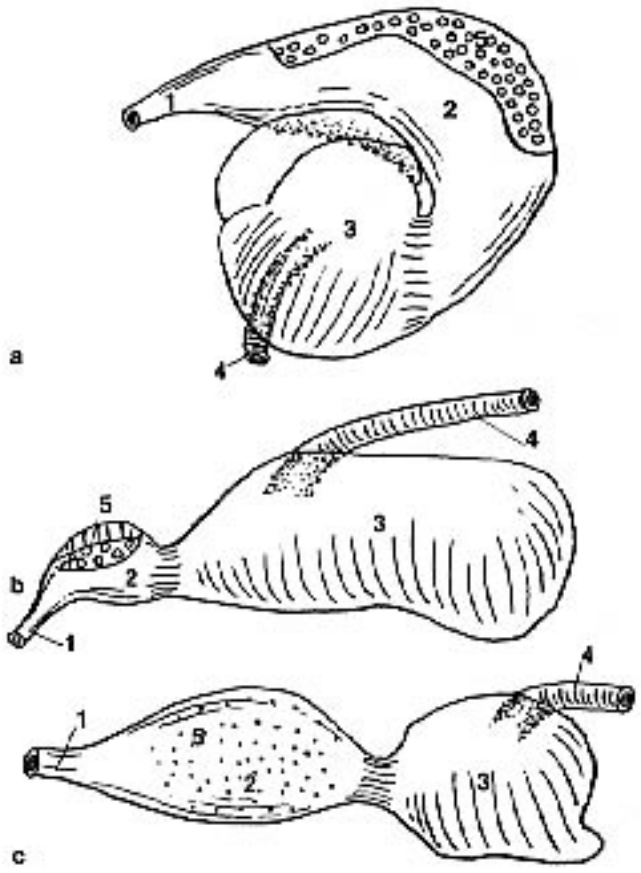

FIG 48.4 Anatomic arrangement of the 2) proventriculus and 3) ventriculus in the **a)** ostrich, **b)** rhea and **c)** emu. 1) esophagus 4) duodenum and 5) glandular area of the proventriculus (modified with permission from Murray Fowler[19]).

rected into the pouch causes a drumming sound in the female and a growling sound in the male. The skin of the neck enlarges laterally when the pouch is inflated.

The presence of this expandable pouch may complicate inhalation anesthesia in mature emus. If positive pressure ventilation is used to inflate the air sacs and ventilate the lungs, air may be directed into and thus inflate the pouch. Inflation of the pouch can be prevented by wrapping the lower neck with a self-adhesive bandage, taking care not to place excessive pressure on the major vessels of the neck. Ostriches may inflate the neck by gulping air into the esophagus.[19]

Digestive System

The digestive system of ratites reflects the ecological niche of these large grazing ungulates. Ratites have no crop, and the large proventriculus serves the feed storage function. Material deposited into the esophagus during tube-feeding is routinely regurgitated, creating a risk for aspiration. Consequently, gavage feeding requires that a tube extend into the proventriculus.

The proventriculus of the ostrich is a large, dilated, thin-walled structure that is easy to access surgically because it extends caudal to the ventriculus (Figure 48.4). In most avian species, the entire inner surface of the proventriculus secretes digestive enzymes. In contrast, the secretory region of the ostrich proventriculus is restricted to an area of glandular tissue on the greater curvature. The distal extremity of the ostrich proventriculus passes dorsal to the ventriculus and empties into this organ through a large opening on its caudal aspect. Ventricular foreign bodies can be easily removed through an incision made into the proventriculus.[19,20]

The ostrich ventriculus is a thick-walled structure similar to that in seed-eating birds. The ventriculus is situated slightly to the left of the midline at the caudal border of the sternum. Though the proventriculus and ventriculus can normally contain small stones, gastric impaction from the consumption of foreign bodies is a common problem in ratites, particularly in juvenile birds (Color 48.30).

Rheas have a small proventriculus and an elongated ventriculus. The stomach is slightly to the left of midline, dorsal to the sternal notch and more caudal to the sternum than is found with ostriches. In emus

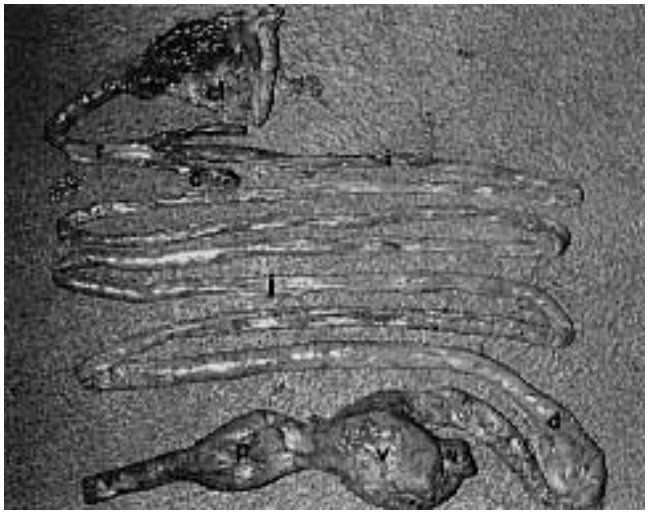

FIG 48.5 Digestive tract of an emu. Proventriculus (p), ventriculus (v), duodenum (d), jejunum (j), ileum (i), ceca (c), rectum (r) and cloaca (cl) (courtesy of Murray Fowler, reprinted with permission[19]).

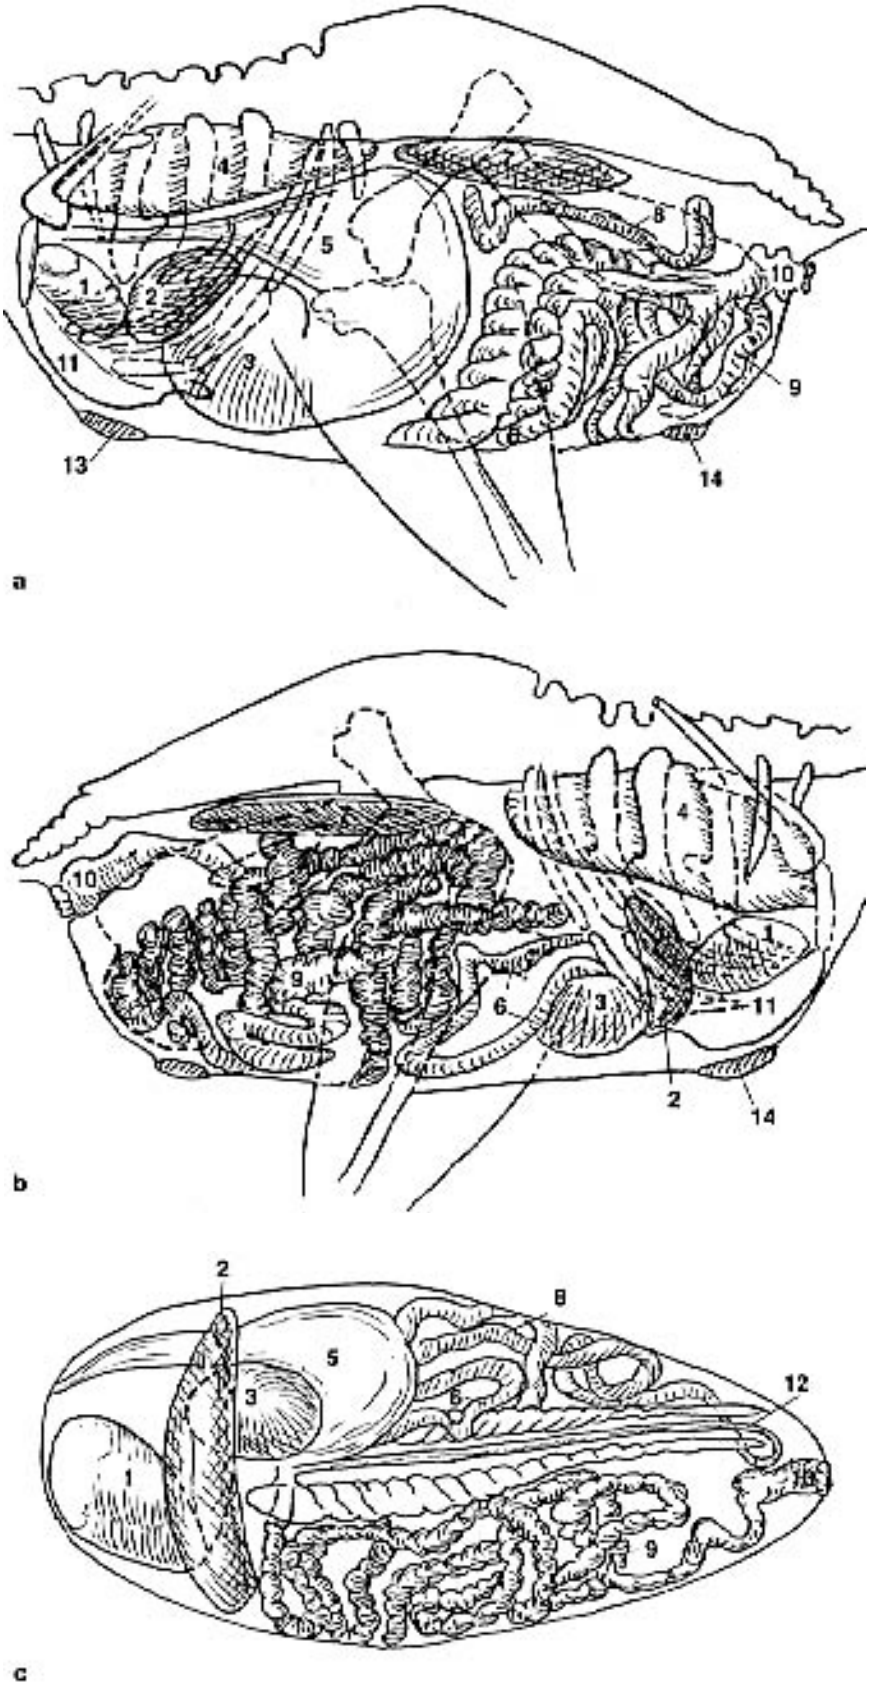

and cassowaries, the proventriculus is large and spindle-shaped, and the ventriculus is slightly larger and less heavily muscled than the proventriculus (Figure 48.4). Cassowaries have no koilin membrane.

The opening from the ventriculus to the duodenum is on the right side in all ratites.[19,20] Intestinal length and morphology are highly variable. The small intestine is most important in the emu, in which it occupies most of the abdomen caudal to the ventriculus.

The cecae are paired in ratites (Figure 48.5). In the ostrich and rhea, the elongated, well developed ceca, visible immediately after entering the midline abdominal wall, course diagonally from right to left in a caudal direction. The lumen of the ceca appears sacculated as a result of spiral folds that increase the surface area in the organ and facilitate the fermentive digestion of fiber (Color 48.27). The cecae of the emu and cassowary are short.

The large intestine of the ostrich is voluminous and occupies the caudal right abdomen (Figure 48.6). The long, large intestine is considered necessary to digest high-fiber food items. The large intestine of the emu is short (10 to 15 cm). The gastrointestinal transit time is slow in ostrich and rheas (36 hours) and much faster in emus (5 to 6 hours). Interestingly, emus produce a large portion of their energy through fermentation even though they have poorly developed ceca, a short colon and a rapid gastrointestinal transit time.[26] These differences in gastrointestinal morphol-

FIG 48.6 Thoracoabdominal anatomy of an ostrich: **a)** left lateral view **b)** right lateral view and **c)** ventrodorsal view. 1) heart 2) liver 3) ventriculus 4) lung 5) proventriculus 6) duodenum 7) kidney 8) jejunum 9) rectum 10) cloaca 11) sternum 12) ileum 13) sternal callosity and 14) pelvic callosity (modified with permission from Murray Fowler[19]).

ogy and function would suggest that free-ranging ostriches and emus ingest different feeds and may require different diets in captivity; however, these differences are rarely considered when formulating diets for these birds.

In the ostrich, the urodeum and coprodeum are separated by a muscular sphincter, making the ostrich the only bird that can urinate independent of defecation. The coprodeum is a large sac that may be covered by a dark tough membrane similar to koilin. The cloacal bursa begins to involute by 18 months of age in ostriches and rheas and is complete by two to three years in the male rhea, and three to four years in the female rhea (Figure 48.7).[60]

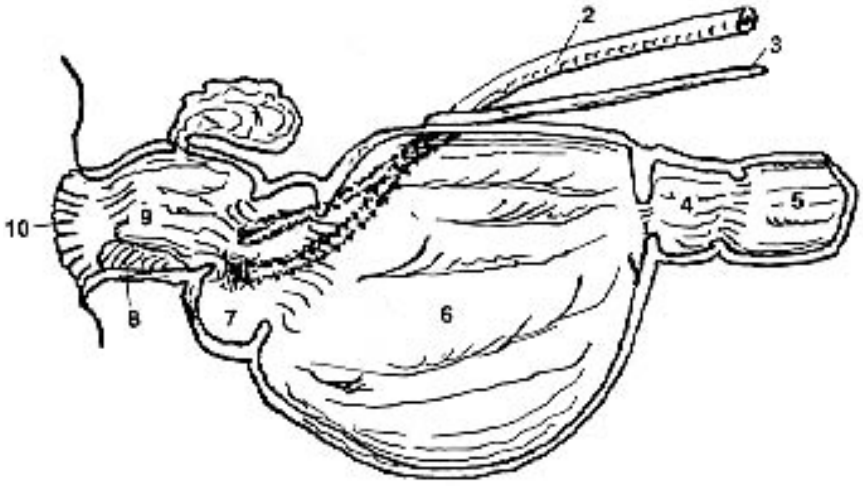

FIG 48.7 Right lateral view of the cloaca of an ostrich. 1) bursa 2) ureter 3) genital tract 4) rectal pouch 5) rectum 6) coprodeum 7) urodeum 8) genital eminence 9) proctodeum and 10) vent (modified with permission from Murray Fowler[19]).

The liver is cranial to the ventriculus and caudal to the transverse membrane (avian equivalent of a diaphragm). There is no gallbladder in the ostrich, but this organ is present in the emu and rhea.[19,20]

Reproductive System

All female ratites have a single left ovary and oviduct similar in form and function to other birds. All of the follicles ("eggs") that the female will have are present at birth. As a hen reaches sexual maturity, the follicles begin to develop, so the ovary has many visible follicles of different sizes at any one time (see Color 29).

FIG 48.8 Testicle size and location in a mature rhea. Cranial division of the left kidney (k), left testicle (t) and left adrenal gland (a) (courtesy of Murray Fowler, reprinted with permission[19]).

The male ratite has two intra-abdominal testicles that are located near the kidney. During the breeding season, the testicles increase 200 to 300 percent in size (Figure 48.8). The cock does not produce sperm during the non-breeding season.[19] Testicles are tan in all ratites except emus, in which they are black. Male ratites have a phallus that serves to transport semen from the ejaculatory ducts in the cloaca of the male to the cloaca of the female. The phallus is shaped differently in ostrich, emu and rhea; however, the function is the same, and the phallus contains a dorsal groove through which the semen travels (Figure 48.9).[19] The avian phallus serves no function within the urinary system and does not contain a urethra.[19]

Ratites of both genders possess a genital prominence that extends from the ventral aspect of the cloaca. This prominence may be visualized or palpated to determine the gender of any aged individual.[25] Gender determination is easiest in chicks between one

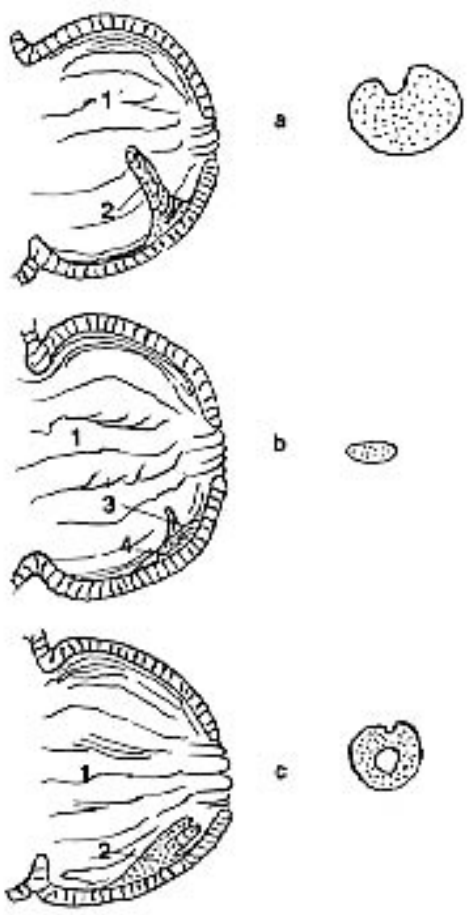

FIG 48.9 Left lateral view of the cloaca of juvenile ratites. and three months of age. A lubricated gloved finger is used to expose the cranio-ventral aspect of the cloaca.

The male ostrich chick has a phallus that is conical in cross section, contains a palpable core of fibroelastic tissue and is characterized by the presence of a seminal groove. By comparison, the clitoris in the hen is laterally compressed, soft and lacks the seminal groove. The clitoris of the adult female remains approximately one to two centimeters in length (Figure 48.10). By six months of age the phallus of the male is approximately three to five centimeters in length and is readily detected on the ventral wall of the cloaca by palpation. The phallus of the adult male ostrich is "J"-shaped and when everted curves to the left (Figure 48.11). The phallus of the emu and rhea are considerably smaller, and the males are usually distinguished from females by the spiral conformation of the phallus.

Anatomic Considerations for Sample Collection and Supportive Care

Blood samples can be collected by routine venipuncture techniques used in most other avian species. Venipuncture can be performed using the jugular, brachial and medial metatarsal veins. The right jugular vein is larger than the left as in other avian species and is a convenient site for venipuncture or placement of intravenous catheters (Figure 48.12). The brachial vein is inaccessible in the reduced wings of the cassowary and emu, but is well developed in the large wings of the ostrich and can be easily accessed. The medial metatarsal vein is readily accessible in sedated or immobilized adult ratites and in unsedated chicks. The medial metatarsal vein generally is not used in standing adults due to the potential for being kicked.[4] Reference hematologic and biochemical values for the ostrich, emu and cassowary are listed in the Appendix.[36,37,41,58]

Intravenous catheters can be placed in any of the vessels used for venipuncture. The medial metatarsal vein is a common preference for intravenous catheterization of chicks (Figure 48.13). Catheterization of the brachial vein (18 ga) is preferred in adults. A 14 ga catheter can be placed in the jugular vein of an adult ostrich. Catheters should be secured in place using tissue adhesive followed by a light bandage.[4]

Samples for cytology and for culture and sensitivity can be collected from the oviduct of adult hens (see Chapter 29). Abdominocentesis can be performed on birds with clinical signs suggestive of intestinal torsions, penetrating foreign objects, egg yolk peritonitis or retained eggs. A teat cannula is the safest device for use for abdominocentesis in ratites (see Chapter 10).

Oral medications are relatively simple to administer by orogastric tube to chicks or tractable adults. Occasional feedings can be provided by placing an equine stomach tube directly into the proventriculus; however, to perform gastric lavage or supply sustained enteral nutrition, an equine stomach tube is passed through an esophagostomy incision and is sutured into place. The tube is most easily placed by introducing it orally into the esophagus, making an incision over the cranial end of the tube and retracting it back through the incision. Blended canine maintenance kibble administered TID has been suggested as an effective enteral nutrition product.[22]

Parenteral medications are often administered to ratites. Subcutaneous administration of medications

The clitoris is soft, small and laterally compressed (courtesy of James Stewart).

is difficult because the skin adheres to the underlying tissues. Subcutaneous medications can be given in the knee web cranial to the thigh.[4]

The pectoral musculature of ratites is greatly reduced, and the large thigh muscles are frequently selected as a site for intramuscular injections. It has been suggested that this site may be inappropriate for the administration of nephrotoxic or renally excreted drugs because of the renal portal system. However, in one study involving the clearance of aminoglycoside, there was no difference in plasma levels when the drug was given in the posterior or anterior portions of the body.[30] This finding suggests that the renal portal system may not be of importance when considering drug administration in ratites. The epaxial musculature along either side of the spine serves as an alternative site to the thigh muscles for IM injections.

Adult Bird Management

Identification

It is suggested that all ratites be permanently identified. The importance of properly identifying birds is dramatically illustrated by a case in which an ostrich was identified on a health certificate as an "African black" and was insured for twenty thousand dollars. The bird died, and at necropsy the veterinarian identified the bird as a "blue-necked" ostrich, and the animal was cremated. The insurance company declared that the dead bird was not insured.

The implantation of a microchip provides one fail-safe method of identification. Sterilized microchips can be implanted immediately after hatching in the left side of the pipping muscle approximately two to three centimeters below the ear (Color 48.9). These chips help in the recovery of stolen birds, satisfy most insurance company requirements for identification and provide unmistakable identification for record keeping purposes.

Nutrition

Numerous pelleted rations are commercially available for ratites. Most of these are locally produced and are highly variable in content and quality. Information on the specific nutritional requirements of ratites is lacking. In South Africa, range-raised ostriches are fed on alfalfa pastures supplemented with maize. Captive ratites seem to maintain a good state of health and reproduction when fed a diet that contains 16 to 20% protein, 10% fat and 10% fiber. Diets with 18% protein produced the best weight gains in one small nutritional study that compared only the effects of varying levels of protein.[23] The calcium to phosphorus ratio should be about two to one.

Several commercial ratite foods are available with 18 to 23% protein and greater than 10% fiber. The feed-

ing of higher protein diets (27%) to young birds would be expected to induce an accelerated rate of growth and may predispose them to leg deformities. Nutritional deficiencies are unlikely in birds that are fed a pelleted ration supplemented with good quality grazing areas.[31]

The adequacy of the breeder diet is reflected in the eggs produced. Generally speaking, hens deficient in carbohydrates, proteins and fats produce fewer, smaller eggs. Vitamin and trace mineral deficiencies can result in nutrient-deficient eggs. The effects may be graded with the level of the deficiency. Characteristic lesions may be noted at various stages of incubation or several days post-hatch. Gastrointestinal or other systemic disease may affect nutritional uptake and metabolism, resulting in nutrient-deficient eggs.

Hypovitaminosis A has been described in rhea chicks with clinical signs of epiphora, oral abscesses and decreased growth. A goose-stepping gait was thought to have been corrected with supplemental vitamin B_6.[16]

Thiamine deficiencies are thought to cause star-gazing (Color 48.5), and riboflavin deficiencies may be a cause of curled toe deformities in ratite embryos (Color 48.4) (Hopkins B, unpublished). Pantothenic acid and biotin have been associated with curling of the feathers and hyperkeratosis of the skin, particularly around the mouth, beak, feet and neck (Color 48.25).[44]

In a group of ostrich chicks fed crushed corn, hypovitaminosis E was suspected to have been the cause of muscle degeneration, which was characterized by paresis, poor weight gains and high AST (up to 1600 U/l) and CPK (up to 69,600 U/l) activities.[4] Vitamin E and selenium deficiencies also may occur in birds fed locally produced foods from regions with low levels of selenium in the soil.

Manganese deficiencies have been associated with slipped tendons in gallinaceous birds, but a deficiency of this mineral has not been associated with porosis in ratite chicks. Angular limb deformities are probably multifactorial, with decreased exercise, genetics and diets of high fat and protein all being involved.[44]

Restraint and Transportation

Ratites are large fractious birds that can easily injure themselves or attendants. Clients and veterinarians should be aware of the dangers associated with handling ratites and should be well versed in restraint techniques. Male ostriches are particularly aggressive during the breeding season and must be handled with caution. Any handling procedure is best performed in an area with solid walls in which the lights can be dimmed. Many basic procedures can be performed in these confined areas without the need for excessive physical restraint.

The natural defense of ratites is the kick, enhanced by the well developed toenails. Ostriches kick straight forward at chest level to the bird, followed by a downward sweep of the foot. Emus and cassowaries may kick either forward or backward and may incorporate wide lateral swings into the range of motion. All ratites jump with great agility, and when restrained, cassowaries roll onto their backs with their legs flailing.

When physical restraint is necessary, it is best to make slow, methodical movements. Working with untrained birds is an exercise in patience. It is important when handling chicks to use gentle restraint because rough handling can cause fractures, tendon damage and severe bruising. Whenever possible, larger chicks are usually herded rather than carried, but they may also be guided by placing one hand across the sternum and the other below the pelvis.

Most adult ostriches will become tractable when the head is covered with a dark, tight-fitting cloth hood, such as a sweatshirt sleeve (Figure 48.14). The sleeve is placed over the arm, the bird is grasped by the beak and the sleeve is then inverted over the head of the ostrich. The natural curiosity of a captive ostrich is usually sufficient to tempt the bird close enough to the handler to grasp the beak. A long smooth shepherd's hook can also be used to grasp the ostrich around the neck and lower the head, but the handler must be prudent of potential injuries to himself or the bird (Color 48.17).

Ostriches may also be restrained without a hood if one person holds the head and neck horizontal to the ground while a second person provides upward and forward pressure to the pelvis. Grasping ostriches by the wings is a common cause of fractures and paralysis. Emus can be crowded into a corner and restrained by standing straddled over the bird's hips while holding the bird across the sternum with the hands (Figure 48.15).

FIG 48.14 A sweatshirt sleeve or similar cloth tube can be placed over the head of a ratite to keep it quiet and to facilitate examination or recovery from anesthesia (courtesy of James Stewart).

Mechanical Restraint

Enclosures designed with catch pens, alley systems and stanchions facilitate the restraint of ratites. Facilities designed for cattle and horses usually include fencing inappropriate for use with ostriches. One side of the standard horse trailer is suitable to accomplish most procedures on an adult ostrich. A stanchion is used in the commercial feather industry to restrain ostriches for the clipping and plucking of feathers and is excellent for veterinary procedures. The stanchion consists of two thigh-high side-bars in the formation of a "V," with a strap to be placed over the shoulders and a bar to be positioned behind the legs and below the pelvis, thus restricting the bird's motion in all directions.

Chemical Restraint

Anesthetic protocols for the different ratite species are basically similar when adjusted to body size.[31,54] The author's preference for smaller birds (under 20 kg) is face mask induction with four per cent isoflurane, followed by intubation and maintenance at two to three percent levels. The success of any anesthetic episode can be improved by performing the procedure in a small, quiet, dark room. Injectable agents are adequate for short procedures such as wound repair or casting in large birds. The author's agent of choice is tiletamine-zolazepam administered intravenously at 2-8 mg/kg depending upon the desired duration of anesthesia. Induction time is less than 15 seconds, and cardiac and respiratory functions are well maintained. The duration of anesthesia for a single dose is approximately 20 to 40 minutes, and supplemental doses may be administered as needed.

FIG 48.15 Emus can be restrained by straddling the hips of the bird and wrapping the hands around the sternum (courtesy of James Stewart).

Alternatively, ketamine hydrochloride may be administered IV at 2-5 mg/kg when used in conjunction with either xylazine at 0.2-0.3 mg/kg or diazepam at 0.2-0.3 mg/kg. Ketamine alone gives unacceptable results. A smoother recovery from injectable agents may be facilitated by the administration of aza-

FIG 48.16 Isoflurane is the anesthetic of choice for use in ratites. Anesthetized birds can be intubated with standard, cuffed endotracheal tubes that are available for small animals (courtesy of Tom Tully).

paerone IM at 1 to 2 mg/kg following induction, or the administration of diazepam IV at 0.2 to 0.3 mg/kg during recovery. In one study of ostriches, induction with tiletamine/zolazepam at a dose of 4.4 mg/kg IM was found to provide the best induction and recovery.[12]

For surgical anesthesia, large ratites are generally induced with low doses of tiletamine-zolazepam by intravenous administration and maintained on either 2 to 4% halothane or 2 to 4% isoflurane. Mature ostriches can be intubated using 14 to 18 mm cuffed endotracheal tubes (Figure 48.16). Intermittent positive pressure ventilation can be performed with a peak pressure of 15 to 20 cm of H_2O. The tidal volume of ratites is considered to be 10 to 15 ml/kg. Birds may become apneic immediately after or commonly at 15 to 20 minutes into anesthesia. These birds should be provided IPPV at 6 to 30 breaths per minute until $paCO_2$ levels have stabilized.

Bradycardia, apnea, hypercapnia, hypocapnia and movement are complications of anesthesia in ratites. Glycopyrrolate (0.011 mg/kg) was effective in reversing bradycardia (<30 bpm) in one bird. Heart rates in young ostriches at rest are normally 100 to 150 bpm and in the adults, 80 bpm.[24] The respiratory rate in a group of anesthetized ostriches was 25 to 40 bpm and the heart rate was 65 to 70 bpm. Mean blood pressure varied from 165 to 220 mm HG. In another group of anesthetized ostriches, the mean blood pressure was 60 to 137 mm Hg.[39]

Ratites can easily injure themselves during the ataxic phase of anesthetic recovery, particularly following injectable agents. Extubation should occur in recovery when the bird is swallowing. Large, shaded areas, padded with mats or straw and clear of objects or walls within reach of the flailing legs can be used for recovery. Alternatively, a bird may be packed in a crate that is heavily padded with straw to restrict extension and flailing of the legs. Because ratites respire with lateral excursions of the chest, the sternal position for recovery is preferred. Small ratites can be recovered by wrapping them in a towel and using manual restraint. Adults should remain hooded with minimal disturbances. When the bird sits sternally with the head held upright, the hood should then be removed.

Transportation

When considering the transportation of ratites, it should be remembered that these birds are bipedal and have difficulty balancing when provided unstable footing. Excessively large trailers with slippery surfaces have been a leading cause of injury and mortality. Chicks and juveniles may be transported by land or air most safely if confined to small individual crates. Specifications for air shipment of ratites are outlined in the International Air Transportation Association live animal regulations and container requirements. The individual compartment of a standard horse trailer is well suited for the routine transport of one adult ostrich. The compartment should be modified to have solid smooth walls to the floor, and adequate traction can be provided by covering the floor with wet wood shavings or sand. Hauling birds at night tends to keep them calm and reduces the possibility of overheating. Food and water should be offered two to three times per day, but should be removed from the compartment while traveling.

Ostrich Management

Housing

Adult ostriches are maintained in outdoor paddocks.[53] They are tolerant of extremes in weather conditions, faring well even in snow. Birds in southern climates can be maintained outdoors in the win-

FIG 48.17 Wire (smooth or barbed) should never be used for fencing ratites. This breeding bird became entangled in the wire and died (courtesy of James Stewart).

ter with adequate protection from the wind, but birds in northern areas may require completely enclosed areas to survive long periods of sub-zero temperatures. Ostriches are gregarious in nature, with one male breeding several hens; however, they do have preferences, and incompatible pairs are common when birds are not allowed to select their mates. The breeding group in intensive operations consists of one male and one to three females. Semi-intensive farms utilize large paddocks containing many birds with an excess of hens. Visually separating breeding groups and allowing a hen to select a male may improve reproductive success. Housing trios adjacent to each other may cause males to spend time soliciting attention from females in adjacent enclosures, while neglecting the hens in his pen.

Breeding paddocks in intensive systems are typically one-quarter to one-half acre in size. A paddock with 5,000 square feet would be considered minimum for a pair of adult ostriches. Fencing should be approximately two meters tall, clearly visible to a running bird and designed so that the feet or neck cannot become entangled within the fence. The bottom of the fence can be raised 40 cm from the ground to prevent the bird's legs and feet from becoming entangled.

Stranded wire fence (barbed or smooth) should never be used for ratites (Figure 48.17). Wood corrals, 2 x 4" field fencing, chain-link fence or pipe fencing are all effective. Electric fencing may be necessary to prevent terrestrial predators from entering the compound.

Birds should have a supply of fresh water and dry food at all times. Placing the food and water station in the fence line with a flap to allow access without entering the paddock is the easiest way to maintain ostriches. Ratites readily adapt to the use of automatic water supplies and bin-type feeders. These devices reduce labor and minimize disturbances in the breeding group.

Breeding Behavior

In general, ostriches reach puberty around two years of age, but are not at full reproductive maturity until four years of age.

Ostriches are long-day breeders, are photoperiod dependent and primarily breed in the summer (Table 48.1). Free-ranging ostrich cocks do not produce sperm in the non-breeding season. With increasing day length, testosterone production increases and secondary sexual characteristics such as reddening of the beak and legs, vocalization and territorial displays (kanteling) begin (Figure 48.18). Sperm production, which is controlled by follicle stimulating hormone, starts at the same time.

CLINICAL APPLICATIONS

Specific factors that might affect the onset of maturity in ostriches include:

- The "breed" - The smaller African black ostrich matures earlier than the larger North African subspecies ("red-necked").
- The season of hatch - Birds that hatch during a period of increasing day length mature faster than those that hatch during a period of decreasing day length. Throughout its lifetime, a bird hatched early in the year will produce better than a bird hatched late in the year.
- The plane of nutrition
- The environment - The specific effect of temperature on reproductive activity is unknown; however, extremes in temperature may stop production or reduce egg fertility.[27]

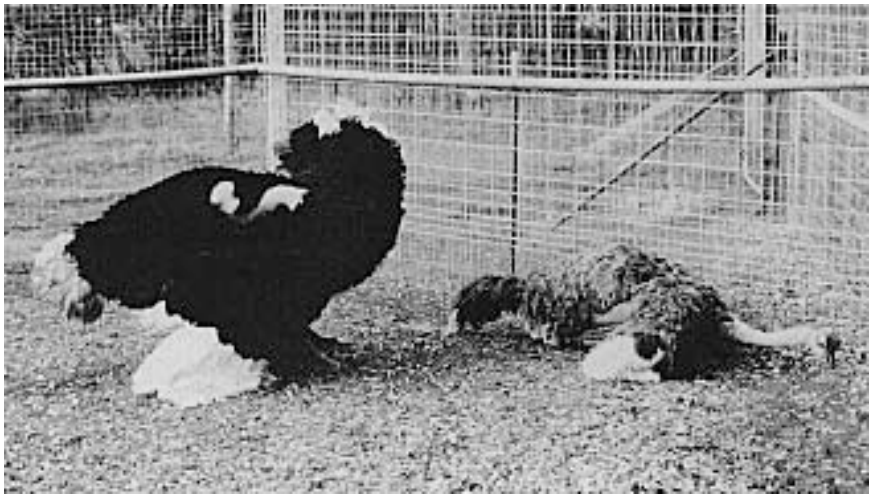

FIG 48.18 Courtship behavior in ostriches. The male (left) drops to his hocks, fans his wings and slaps his head on his back (kanteling). The female (right) is on the ground with the neck extended in a receptive position (courtesy of James Stewart).

The cock displays to the hen during breeding season by dropping to his hocks, fanning his wings and striking the back of his head on either side of his back. In captivity, males frequently display and make a booming noise to any visitor that approaches the enclosure. The hen flutters her wings, drops her head and makes a snapping motion with her beak. She will drop to the ground with her head extended. The male mounts from the left placing his right foot on the hen's back (Figure 48.18). He drops to his hocks and intromission occurs. During copulation, the male will strike his back with his head. When ejaculation occurs, the male makes a guttural sound.[27]

In the United States, the breeding season varies from north to south. Birds in the northern US have a laying season from May to September, while birds in the southern US may produce all year. The nest consists of a shallow depression in the ground that is formed and protected by the male. Ostriches and rheas usually lay eggs in the afternoon or evening while emus generally lay at night. If left to parental care, the eggs are incubated by the male at night and the female during the day. In free-ranging groups, the dominant hen will incubate the eggs during the day. The dominant hen recognizes her eggs, and if the nest is overcrowded (20 to 25 eggs), the hen will remove the eggs laid by rival females. Nondominant hens may lay in several nests and be bred by several males. Both adults brood the chicks.[27]

Ostrich hens are indeterminate layers and if the eggs are removed, a hen may lay an egg every other day throughout the breeding season. Free-ranging hens may have a normal clutch size of 15 to 25 eggs. Forty is the average for hens in captivity; however, some birds may produce 70 to 100 eggs per year.

Both sexes may have periods of reproductive quiescence within the breeding season, each lasting three or four weeks. During this time the female stops laying and the male "goes out of color" (ie, the bright red coloration of the face and tarsal scutes fades).

Breeding males may become territorial and aggressive, and stressful social interactions within and between breeding groups can decrease reproductive behavior and egg fertility. These problems can best be prevented by having visual barriers between breeding groups. Fertility in the male may decrease with prolonged breeding periods, and separating the breeding adults for several weeks may improve egg fertility.[31]

Emu

Breeding Behavior

Emus are managed in a manner similar to ostriches, but with proportionately smaller facilities. During

TABLE 48.1 Factors Affecting Ostrich Reproduction[27]

Behavior:	Most of the breeding birds available in the US are from free-ranging stock and have not been genetically selected to adapt to captive conditions. Some individual birds adapt well to enclosed spaces and varying terrain while others do not.
Genetics:	Highly productive hens are more likely to produce daughters that also are extremely productive.
Environment:	Severe weather fluctuations, looming predators and objects overhead have been shown to decrease productivity.
Age:	Ostriches sexually mature two to three years after hatch, and production improves as the bird ages. The most productive age for ostriches has not been established.
Nutrition:	Obesity is one of the biggest causes of decreased production in birds. Although nutritional deficiencies can decrease productivity, nutritional excesses are just as detrimental (Color 48.26).
Season:	Production is best in the early and middle portion of the breeding season.

breeding, the female sits on the ground with her cloaca everted. The male drops to his hocks behind her and intromission occurs. The male pecks the hen's back and makes guttural noises during ejaculation. Breeding occurs most often in the morning and evening hours.[27] Adults are typically maintained as pairs, but colony breeding is effective. Eggs are laid in grass or straw and are partially hidden. The male conducts the incubation and chick-raising. The male may not leave the nest during the entire incubation period, leading to a substantial degree of weight loss.

Emus are short-day breeders, with a breeding season that lasts from October to March in the United States. Free-ranging emus are gregarious during the non-breeding season, but these birds tend to form pairs or trios during the breeding season. Free-ranging birds may begin egg laying at two to three years of age. Captive females may require one to two extra years to reach sexual maturity.

Rhea

Breeding Behavior

The male rhea performs the courtship displays, builds the nest, incubates the eggs and rears the young. The male attracts the apparently disinterested females with wing-spreading and head-swaying displays. Several females will lay eggs near a nest established by the male. The male collects these eggs for about one week and then initiates incubation of all the eggs at one time so that the hatch is synchronized.[27]

Medical Disorders and Therapies

Among the ratites, ostrich diseases are best documented because of the development of a breeder industry (Table 48.2). When viewed from the perspective of disease, ostriches are little more than giant chickens. Most medical disorders of ratites have models within the commercial poultry industry. The important differences lie with the susceptibilities and relative prevalence of these diseases. Many of the infectious diseases are also shared by psittacines, waterfowl and other common companion and aviary birds. Sound management dictates that ratites should not be reared in close proximity to other types of birds.

TABLE 48.2 Infectious Diseases Reported in Ratites

Due to the lack of research targeted at accurate identification of organisms that affect ratites, the list provided in Table 48.2 will certainly prove to be incomplete. There are many disease syndromes that epidemiologically suggest an infectious etiology for which a specific pathogen has not been described. Waste management, sanitation and human movement patterns within the flock are essential in preventing the transmission of infectious agents from paddock to paddock or from farm to farm. Ratite clinicians must be acutely aware of the role they can play in the transmission of disease through improper

hygienic practices. New birds should be quarantined in an area separated from the remainder of the group for at least one month. During this period, the birds should receive a thorough physical examination and should be treated for parasites.

Reproductive Abnormalities

On the average, 50% of the ratite eggs produced annually in the United States are infertile. This represents a considerable economic loss given current market values for fertile eggs. Fertilization of the egg must occur during the first 15 minutes after ovulation while the egg is in the infundibulum.[27] Ratite hens are subject to all the reproductive disorders seen in other birds including oviduct infections, egg retention, uterine prolapse, internal ovulation and egg-related peritonitis. The anatomy, physiology and pathogenesis of disease are comparable to the psittacine model (see Chapter 29). In contrast to the smaller avian species, ratites may be afflicted with severe reproductive disorders for months or even years, but remain otherwise healthy and exhibit no outward signs of disease. Excessive ventrodorsal movement of the cloaca when a hen is jogging may be an early sign of egg-related problems.

A diagnosis of reproductive tract disease is based upon the reproductive history, physical examination (including cloacal palpation and eversion of the phallus), and diagnostic tests including hematology and serum biochemistry, oviduct cultures, abdominocentesis, radiology and ultrasonography.

Prolapse of the phallus has been described in male ostriches. A partial prolapse may occur in reproductively active males with no adverse effects. The precise etiology is unknown, but debilitation toward the end of the breeding season and extreme weather fluctuations have been suggested as causes. Frostbite or necrotizing dermatitis are frequent sequela to a prolapse. Full prolapse requires replacement of the phallus into the cloaca, with or without a purse-string suture, and administration of nonsteroidal anti-inflammatory agents. If the phallus is traumatized, daily washes with a disinfectant solution and administration of systemic antibiotics may be indicated. The prognosis is good if the damage is not too extreme.

Intersex appears to be common in the ostrich. The black pigment of the male's feathers is due to a lack of estrogen. A mature black bird that sexes cloacally as a hen will not reproduce and may have inactive ovaries, testes or both. Many young hens may be very dark brown or even have a few black feathers, but become gray with maturity.

Prolapse of the vagina can occur without egg laying and may be seen in hens less than one year of age. These prolapses are thought to be caused by unseasonably cold temperatures. Replacement and application of a retention suture are usually corrective.[27]

Peritoneal hernias occur in the caudal abdominal cavity, allowing the intestines and uterus to prolapse into the pericloacal region. Affected hens appear to have a large pericloacal swelling. Ultrasound is diagnostic. Surgical repair is required.

E. coli, *Pseudomonas* spp., *Acinetobacter* spp. and other gram-negative bacteria are common causes of oviduct infections in ostriches. Affected hens generally present with a history of erratic egg production, cessation of egg production or malformed or odoriferous eggs. On physical examination, the temperature and respiration are variable. The hen may have a discharge below the cloaca and may have a peculiar odor. Affected hens often have white blood counts ranging from 20,000 to 100,000 (pronounced heterophilia in acute cases or lymphocytosis in chronic cases); however, the severity of the infection varies with the etiologic agent. In mild cases, only the uterus or shell gland (metritis) may be affected, and in these hens clinical signs range from the formation of abnormal shells to the cessation of breeding.

Salpingitis or peritonitis may also occur with chronic infections or those that occur secondary to septicemia.[27] Therapy for metritis should include appropriate antimicrobial therapy, multiple vitamin and calcium injections. Surgical (laparotomy) or nonsurgical (vaginal) flushing of the oviduct can be used to remove accumulated debris.

Mycoplasma spp. and paramyxovirus have been isolated from the reproductive tracts of ratites but their clinical importance is unknown.[27] Papillomas have been described in the reproductive tract of both cocks and hens.

Egg binding may occur in ratite hens and is thought to be caused by genetic factors, malnutrition, cold weather or lack of exercise. Many affected hens are asymptomatic, while others may present with a history of tenesmus or with a vaginal prolapse. An impacted egg may be palpable in the caudal abdomen. Radiology or ultrasound may be required for diagnosis. Medical treatment consists of increasing the

bird's ambient temperature along with the injection of multivitamins, calcium and oxytocin (prostaglandin may be superior, see Chapter 29). Ovocentesis procedures that have been described for correcting egg binding in other avian species are dangerous in the ostrich because of the likelihood of fractured egg shell damaging the oviduct. Impacted eggs should be removed surgically.

None of the methods traditionally used to artificially collect semen from birds is effective in ostriches because of their physical size, demeanor and lack of sexual imprinting response. Ostrich semen has been collected by means of forced massage and voluntary response; however, the semen collected is usually contaminated with urine, making assessment of concentration, volume and pH unreliable.[27]

Emu semen can be easily collected by voluntary ejaculation because the birds do sexually imprint on humans. Emu ejaculation volume averages 1.2 milliliters with 4.4 billion sperm per milliliter. Average pH is 7.32. Beltsville chicken semen extender in a 1:1 dilution has been found to be an appropriate diluent in some birds.[27]

Gastrointestinal Abnormalities

Ingestion of foreign bodies is a common problem in ratites. These birds are likely to swallow anything that fits into their mouths, and their keen eyesight and curiosity all but ensure that they will find many unusual items in their pen. Stones, sand, hardware and long-stemmed grasses are common offenders (Figure 48.19). The consumption of materials that induce impactions may be caused by primary enteric disease, inadequate feed availability, nutritional inadequacies and movement to a new environment with a different substrate. Ingestion of foreign bodies can be reduced by making certain that pastures and paddocks are covered with grass and do not contain abundant or clearly visible rocks or sand (Color 48.30). Decreasing stress by slowly introducing birds to a new area also may reduce the consumption of foreign bodies.

Impactions may be acute or chronic, primary or secondary. The most common clinical presentation includes lethargy accompanied by small, firm, fecal balls and a distended abdomen. Occasionally, affected birds may appear lame or be unwilling to rise due to weakness or pain. A cloacal prolapse may occur in chicks with proventricular impaction. Eighty-five percent of impactions occur in birds under six or seven months of age, with 10 to 12% occurring in birds six to twelve months of age and 3 to 5% occurring in adults.[61]

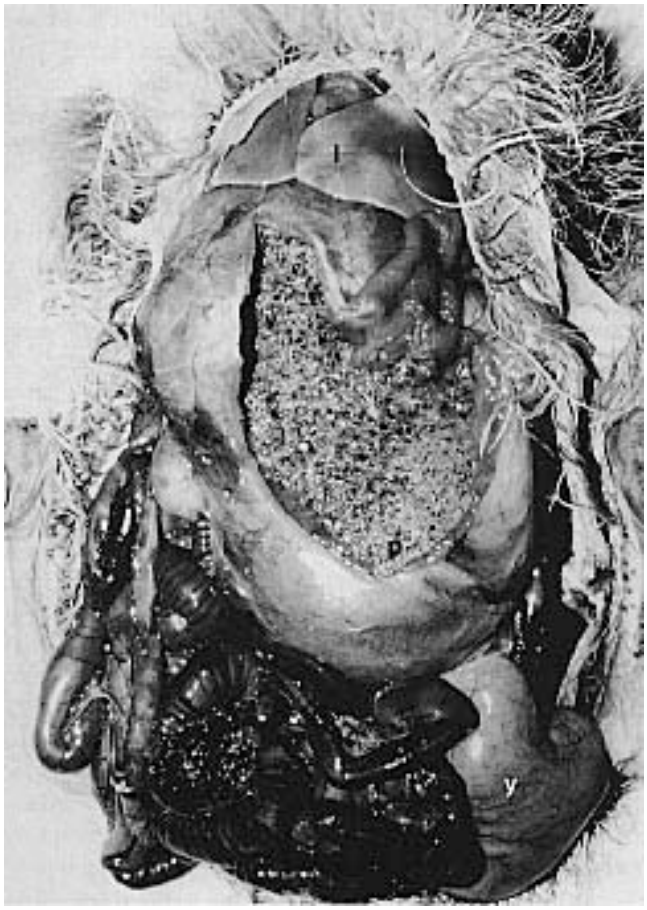

FIG 48.19 Sand impaction of the proventriculus (p) and ventriculus (v) in an ostrich chick. Note that the proventriculus in ostriches extends caudal to the ventriculus. Also visible are the liver (l) and yolk sac (y) (courtesy of James Stewart).

Ingested foreign objects initially settle in the well developed proventriculus and obstruct the flow of ingesta or act as valves by blocking outflow into the ventriculus. In chronic cases, the blockage may also involve the ventriculus. Ventricular ulcers often develop from the trauma of constant grinding against an immobile mass.[22] Chronic and severe distension of the proventriculus may cause a permanent loss of muscle tone. These irreparable changes can be prevented through the early diagnosis and surgical correction of gastric impactions.

An impacted proventriculus can frequently be palpated on the left side of the abdomen by identifying the caudal and dorsal extremities of this organ. Impactions with rocks or sand can best be detected by

palpating caudal to the sternum. Impactions caused by grasses and leaves may be more difficult to palpate.[22] Radiography can be used to document the presence of foreign bodies and an enlarged stomach. Ultrasound and gastroscopy may be other effective diagnostic techniques.

Psyllium administered by stomach tube may be effective in resolving mild cases of gastric distension, but true impactions can be resolved only by surgical removal of the foreign material. The proventriculus of the ostrich lies caudal and to the left of the ventriculus, and the surgical procedure is a slight variation of that used in psittacines (see Chapter 41). The proventriculus may be approached via either a midline or left paramedian incision that extends caudally from the caudal margin of the ventriculus.[28,52] A 15 cm skin incision is made caudal to the end of the sternum just to the left of midline, and the peritoneum is incised to expose the proventriculus. Allis tissue forceps or stay sutures can be used to manipulate the proventriculus. The proventriculus is temporarily sutured to the abdominal wall to minimize contamination of the coelomic cavity with ingesta. The proventriculus is then incised and the contents are removed. Closure is in two layers with a simple continuous primary closure that is oversown with a continuous inverting suture pattern.

Recovery from proventriculotomy is usually uneventful when the impaction is detected early. Chronic impactions may be accompanied by gastric atony, ulcers and candidiasis that require additional therapy. Birds can be offered alfalfa pellets and corn as soon as they are fully recovered from anesthesia.[28]

Many ingested objects will penetrate the wall of the ventriculus or proventriculus causing peritonitis (Color 48.29). The diagnostic procedures are the same as those used for gastric impaction. A proventriculotomy to remove the foreign body and surgical removal of necrotic peritoneum is indicated. Other common digestive disorders include cloacal prolapse and intussusception. Cloacal prolapse may be associated with diarrhea, or more frequently, with tenesmus due to constipation. Treatment of the prolapse is similar to methods used in other birds, but the initiating cause must be addressed to prevent recurrence (see Chapter 41). Intussusception is caused by hypermotility and gastrointestinal tract irritation and is often the result of an abrupt dietary change, especially when the new diet is higher in fiber.

Any number of ingested toxins can cause enteritis. Cantharidin, for example, is a toxin produced by the Three-striped Beetle, which swarms to feed on Mesquite trees and alfalfa hay. Mortality levels of 25% were reported in a group of emus that consumed these beetles that were attracted to a barn light.[61]

Torsion of the large bowel occurs sporadically. The etiology is unknown, but it is speculated that an abrupt change in feed may be an inciting factor. Clinically, these birds are dehydrated, depressed and produce a scant diarrhea. Diagnosis is confirmed through an exploratory laparotomy. Intestinal anastomosis may be effective in resolving mild cases that do not involve an extensive amount of the gastrointestinal tract.[61]

Porphyrins, a breakdown product of chlorophyll, are sometimes seen in the urates, giving them a red or orange coloration. Clients often mistake this substance for blood. This porphyruria is routinely noted following the ingestion of fresh green vegetation, and becomes more prominent during colder weather when water intake reduction makes the urine more concentrated.

Fractures

Leg fractures are common in ratites, and successful repair is difficult in these large, fractious, easily stressed, bipedal birds that must be able to ambulate postoperatively.[18,35] Femoral and proximal tibiotarsal fractures in ostriches frequently result in internal exsanguination. Tarsometatarsal fractures are usually open and infected. Prolonged recumbency results in muscle necrosis and tendon contraction.

The long-term use of slings is unsuccessful with ostriches, but emus tolerate them well. Tibiotarsal fractures in small birds under 15 kg are best repaired with a through-and-through, six-pin, modified external fixation device (see Chapter 42). Plates may be used in larger birds if bone quality is normal (Figure 48.20). Fractures of the phalanges, fractures of the distal metaphysis of the tarsometatarsus and luxations of the metatarsal-phalangeal or interphalangeal joints can be stabilized with fiberglass casts, to which most ratites readily adapt.

Wing fractures in ostriches frequently occur secondary to improper restraint. These may be resolved by placing the wing in a normal anatomic position and taping it to the body for six weeks; however, intramedullary pinning usually produces more satisfactory

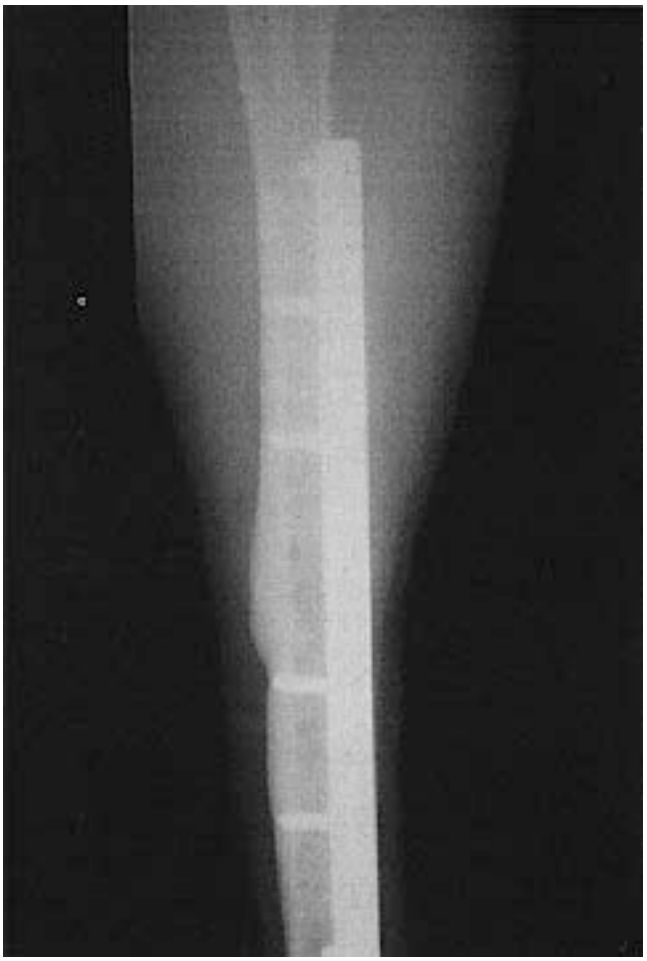

FIG 48.20 A bone plate was used to stabilize a dome osteotomy site in an emu with a valgus deformity of the tibiotarsal bone. Fractures of the leg are relatively easy to repair surgically, but are rarely successful long-term because of problems in managing these large, fractious, bipedal patients (courtesy of Louise Bauck).

results. The author prefers a closed reduction and fixation technique. A small diameter pin may enter the distal caudal surface of the humeral shaft and be advanced through the fracture site into the proximal fragment. Alternatively, the pin may enter the proximal fragment at the fracture site, be advanced proximally out the deltoid crest and then retrograded into the distal fragment. The wing is then taped to the body for a period of six weeks to provide rotational stability to the fracture site.

Ruptured Aorta

Ostriches are prone to spontaneous rupture of the aorta (Color 48.15). These are most often located at the aortic arch, but ruptures in the caudal aorta have also been described. Surprisingly, this condition is seen with some frequency but the cause is unknown. Copper deficiencies have been implicated in other species. Overweight yearlings that are subjected to physical stress are most commonly affected.

Degenerative Myopathy

A large percentage of the young ostriches, rheas and emus submitted for necropsy have evidence of degenerative myopathy, with the majority of affected birds being less than six months of age.[47] It should be noted that myocyte degeneration appears the same histologically, regardless of the cause. In birds, several etiologies for degenerative myopathy have been reported, including capture myopathy, selenium or vitamin E deficiency, furazolidone and ionophore toxicity.[33] Clinical signs of degenerative myopathy that have been described in ratites include depression, reluctance to rise or move, and a rapid progression to death (two to five days). White foci and streaks in the myocardium and muscles of the hind limbs and myocyte degeneration with infiltration of macrophages and early calcification may be noted in birds that die several days after transport.[47]

Furazolidone is a nitrofuran antibiotic commonly used in the poultry industry. This compound is premixed in some chick starter feeds. Young turkey poults appear particularly susceptible to intoxication. Ionophore coccidiostats, such as monensin, lasalocid and salinomycin, are frequently added to chick starter feeds. These compounds may be contributing factors in the development of degenerative myopathy, and ratite producers should avoid the use of turkey or chick starter feeds that contain furazolidone and ionophores.

In the southern United States, pastures may contain the shrubs or trees of coffee senna (*Cassia occidentalis* or *Cassia obtusifolia*). In ruminants, ingestion of these beans may cause diarrhea, weakness, gait abnormalities, recumbency and muscular lesions consistent with degenerative myopathy. *Cassia* spp. intoxication has not been reported in ratites, but exposure to this toxic plant should be considered in cases of acute myocyte degeneration.[47]

Some authors believe that capture myopathy, which has been described in ratites with some frequency, is simply the acute manifestation of a chronic subclinical deficiency of selenium or vitamin E.[13] Degenerative myopathy appears to be primarily a disease of young ratites and higher levels of vitamin E may be required for growth. Two rheas with limb abnormali-

ties had a mean plasma vitamin E level of 1.34 mcg/ml, compared with a level of 11.5 mcg/ml in apparently healthy rheas.[13] The mean serum levels of vitamin E in 23 ostriches was 2.1 mcg/ml, and in 23 emus was found to be 2.39 mcg/ml.[32] Circulating vitamin E levels in five rheas with no suspected deficiency ranged from 9.0 to 14.5 mcg/ml (mean of 11.60 mcg/ml).[13] Additional work is required to determine whether there is an age-related difference in serum vitamin E levels.

Normal liver selenium levels are not available for ratites but levels below 0.25 ppm are considered deficient in poultry, and levels below 0.35 ppm are considered marginally deficient. Adequate liver selenium levels in poultry range from 0.35 to 1.00 ppm wet weight.[46] Liver selenium levels ranged from 0.176 ppm to 0.986 ppm and liver vitamin E levels ranged from 0.69 mcg/gm to 9.10 mcg/gm in a group of ratite neonates with clinical or histologic lesions suggestive of degenerative myopathy.[47]

Additional investigations to determine the normal serum and organ levels of selenium and vitamin E and their correlation with degenerative myopathy, diet and health are necessary. Studies in horses with degenerative myopathy suggest that skeletal muscle and adipose tissue may be a better sample for determining vitamin E levels than liver.[47]

Therapy and Prevention

Treatment with vitamin E followed by immediate correction of the diet is the recommended therapy and is generally effective in early cases.[62] One author has suggested the parenteral administration of 3.0 mg of vitamin E and 0.06 mg of selenium/kg of body weight at two days of age, then weekly thereafter for a total of three injections.[43]

It is probably safer to supplement a bird with vitamin E rather than selenium. The latter has a low therapeutic index and can readily reach a toxic level. A chick with clinical signs suggestive of degenerative myopathy that was treated with this regime died despite therapy and had histologic lesions suggestive of the syndrome. Liver selenium levels in this bird were 3.738 ppm. The toxic liver selenium level in poultry is considered 4.00 ppm wet weight.[46]

A safer treatment regimen may be to use injectable vitamin E at a dose of 5.0 mg/kg IM every other day until clinical signs resolve. Adding oral formulations of vitamin E to the drinking water or the feed (100 IU/kg of feed) can be used for maintenance therapy. This treatment regime was successful in stopping morbidity and mortality in a flock of emu chicks experiencing degenerative myopathy.[47]

Neoplasms

Neoplasias have been reported in all ratites with none of particular prevalence. Lymphoid tumors have been described in ratites, and their similarity to tumors caused by leukosis virus in poultry warrants further investigation.

Lymphoma was diagnosed in a three-year-old female red-necked ostrich with a history of weight loss, mild bilateral conjunctivitis and a bright green mucoid diarrhea. On palpation, the liver was enlarged with rounded edges, and a bilobed mass was detected in the thoracic inlet. Abdominocentesis revealed a small amount of straw-colored, cloudy fluid with changes suggestive of chronic active hepatitis. Ultrasonography of the abdomen revealed an enlarged oviduct and multiple nodules within the liver. Abnormal clinical pathology results included a marked leukocytosis (160,000), lymphocytosis (95%), hyperproteinemia (6.9 g/dl), anemia (26%), hypoglycemia (102 g/dl), hypergammaglobulinemia and elevated AST (450 U/l) and CPK (6286 U/l) activities.[59]

Viral Disease

There has been little definitive work completed on viral diseases in ratites; consequently, specific diagnostic tests as well as vaccines are currently unavailable. The transmission of viruses from paddock to paddock or from farm to farm should be prevented through good sanitation practices and by not allowing visitors on the farm. Optimum nutrition, environmental conditions and reduced stress will ensure that a bird has an adequate immune system to resist disease.

Newcastle disease was the only disease of viral etiology reported in the ostrich prior to 1987. Recent international interest in ostrich production, particularly in the United States and Israel, has prompted further viral investigations. Numerous viruses have been detected in ratites by virus isolation or electron microscopy, but the clinical relevance of most of these findings is uncertain. Newcastle disease virus,[49] coronavirus, reovirus, influenzavirus and togavirus have been associated with specific diseases.[21]

Coronavial particles were reported in the small intestines of an 18-day-old ostrich chick that died following a one-week history of anorexia, lethargy, weak-

ness and diarrhea. Lesions included dilation of the proventriculus, nutritional osteodystrophy and degenerative myopathy.[21]

Avian influenza was associated with high levels of mortality among ostriches in South Africa. Clinical signs in affected birds included respiratory signs, conjunctivitis, green discoloration of the urine and death. Although ostriches up to 14 months of age have been shown to be affected, morbidity is greatest in chicks under six months of age. Mortality may reach 80% in hatchlings and is complicated by secondary bacterial and nutritional problems. Characteristic postmortem findings include fibrinous air sacculitis, mucoid sinusitis, multifocal hepatic necrosis, splenomegaly and nephritis.

Fowlpox infections are well documented in ostriches.[45] This disease presents primarily as the dry form, although diphtheritic lesions may also occur. Vesicles that turn to encrustations form along the eyelids, ear openings, beak, neck and legs. Morbidity may be high but mortality is low. A commercial fowlpox vaccine administered at 10 to 14 days of age appears to provide some protection.

Eastern equine encephalomyelitis virus has been associated with high mortality (14 of 23 birds in one outbreak) among flocks of emus in the southeastern United States.[57] Clinical signs include profuse hemorrhagic diarrhea, depression, ataxia and death. Terminally, affected birds may become recumbent and develop hemorrhagic hyperemesis. Paired serum samples can be used to document an increase in antibodies indicating an active infection. Some infected birds will respond to supportive care.[57]

An inactivated equine vaccine is apparently effective in preventing the disease in emus. The initial vaccination is given at three months of age followed by boosters at six-month intervals. Written consent from the client and clearance from the insurance carrier should be obtained before the extra-label use of this vaccine is initiated.[57]

Bacterial Disease

Bacterial infections in ratites are similar to those described in other birds and may be associated with conjunctivitis, sinusitis, pneumonia and air sacculitis, gastroenteritis, omphalitis and septicemia. Young chicks are most susceptible, and the diagnostic techniques and treatments are comparable to those of other avian species. Although the normal intestinal flora for ratites has not been established, the birds are terrestrial; thus, ample gram-negative bacteria would be expected in the healthiest of individuals.

Common pathogens include *Pseudomonas, Klebsiella, Proteus, Salmonella* and *Campylobacter* spp. (see Color 24). *E. coli* can be a pathogen, but it is also a normal component of the ratite intestinal flora, and is frequently misrepresented as the cause of mortality in ostrich chicks (Color 48.21). Clostridial enteritis is a common disorder in ratites of all ages and is often associated with the excessive consumption of wet soil (Colors 48.18, 48.19). Botulism, clinically characterized by paralysis and death, has historically been a significant industry problem in adult ostriches in South Africa.

Tuberculosis is a common finding in adult ostriches. Affected birds develop a chronic wasting syndrome with visceral tubercles that can be detected by exploratory laparotomy. Salmonella outbreaks have been described in three- to six-week-old birds presented with acute weight loss, lethargy and bilaterally symmetrical distal limb edema. The total serum protein in affected chicks was less than 1 g/dl. Diarrhea was present in chronic cases but did not occur in peracute infections that resulted in rapid death.[61] *Staphylococcus* sp. is frequently associated with omphalitis and septic arthritis.

Ostriches are the only birds susceptible to anthrax, and the symptoms and diagnostic methods are identical to those for mammalian hoof-stock. Commercial anthrax vaccines are safe and effective in ostriches, following standard recommendations for hoof-stock. The client and insurance company should provide written consent before the extra-label use of this vaccine.

Mycotic Disease

In South Africa, aspergillosis causes the condemnation of up to ten per cent of inspected ostrich carcasses. Granulomatous nodules are most frequently distributed through the parenchyma of the lung, and only occasionally in the air sacs (see Chapter 22). Infections in older birds are enhanced by the inhalation of dust from dry feeds and soil. Outbreaks in chicks are associated with prolonged antibiotic therapy or inadequate hatcher and brooder hygiene.

If they occur, clinical signs include dyspnea, outstretched wings, exercise intolerance, anorexia and weight loss. Heterophilia is a common clinico-

Ratites

pathologic finding. Clinical changes usually indicate an advanced disease and recovery is unlikely. Endoscopy can be used to document air sac lesions and to perform biopsies or obtain cultures from diseased tissues. Serologic tests for *Aspergillus* sp. may prove to be useful in ratites but have not been adequately investigated.[61]

Flock management should be carefully evaluated to prevent other cases. Appropriate antibiotics to treat secondary bacterial pathogens and aerosolized and oral antifungals are suggested therapies, but are rarely effective. Aspergillosis is best prevented by reducing a bird's access to organic debris, reducing stress, minimizing the use of antibiotics and providing adequate ventilation.

Candidiasis of the proventriculus, esophagus and mouth may occur in ostrich chicks. Infections are most common in birds maintained in damp environments or secondary to proventricular impaction or the long-term use of antibiotics. Chlorhexidine, ketoconazole or nystatin have been discussed as effective therapies. Candidiasis may be prevented with good hygiene and a dry environment.

Mycoplasma and Chlamydia

Mycoplasma spp. infections in ostriches are an enigma. Serologic tests designed for poultry occasionally yield positive results, but the interpretation of these results is speculative. Mycoplasma have been identified on culture as well, but there is no firm evidence to implicate these microbes as the cause of clinical disease in ratites. Ostriches in the United States are gradually falling under stricter guidelines for interstate transport including screening for mycoplasma, and the need for an accurate diagnostic test is imminent.

A pigeon-like isolate of chlamydia has been diagnosed in rheas and ostriches.[25a] Birds raised on an open range may be at risk. Treatment of chlamydial infections in ratites with chlortetracycline (CTC) at the rate of 400 g per ton of feed for 45 days may be expected to be effective (see Chapter 34).

Parasites

Ratites are susceptible to a number of parasitic infections. The most important parasites are listed in Table 48.3.

Protozoa

Intestinal protozoa including *Cryptosporidium, Toxoplasma, Histomonas, Giardia* and *Trichomonas* spp. have been discussed as causes of severe and transient diarrhea in ratites (see Chapter 36). It is unclear the extent to which these organisms cause disease in ratites, but they should be treated when identified. Coccidiosis is a common finding in emu chicks, but is not confirmed as a clinically important problem in ostriches. Asymptomatic leukocytozoon infections are common in ostriches in Africa.

Cestodes

The tapeworm *Houttuynia struthionis* is abundant on South African ostrich farms and has been seen sporadically in the United States. Chicks are particularly susceptible, becoming unthrifty with high mortality rates. Adults are unaffected. A diagnosis is made by identification of parasite segments passed in the feces. The intermediate host is unknown, but infestations can be controlled with regular use of fenbendazole at 15 mg/kg orally.[17]

Nematodes

The wireworm *Libyostrongylus douglassi* is an economically important parasite of ostriches. The adult worms and third and fourth stage larvae reside in the glandular crypts of the proventriculus. The resultant inflammation obstructs gastric secretions and inhibits digestion. Food decays within the stomach, and the disorder is referred to as "vrotmaag" or rotten stomach. Eggs may survive in dried feces for over a year, and the infective third stage larvae develop to maturity in 29 days. Diagnosis is made by identification of the trichostrongyloid-type egg in the feces. The eggs can be confused with those of the harmless cecal worm, *Codiostomum struthionis*. Levamisole hydrochloride dosed at 30 mg/kg is routinely administered monthly to chicks and four times per year to adults. Fenbendazole (15 mg/kg)[17] and ivermectin (0.2 mg/kg) are also considered to be effective.

Tracheal worms *Syngamus trachea* have been associated with hemorrhagic tracheitis in emus (Color 48.13). The ostrich guinea worm, *Dicheilonema spicularum,* is a large filarial worm found in the subperitoneal connective tissue. Females may exceed 2.1 m in length and 2.5 cm in diameter. They are frequently found in free-ranging ostriches where they induce no clinically detectable problems.

Filariid nematodes *Chandlerella quiscali* were removed from the spinal cord and lateral ventricles of the brain of emus with clinical signs that included

torticollis, ataxia and abnormal gait followed by recumbency and death.[3] Only two- to five-month-old emus were affected, with adult and yearling emus apparently resistant. The cause of apparent resistance in these older birds is unclear. It is possible that older birds were immune to the parasite or that the neural tissues were less severely damaged. Emu chicks that were affected by the parasite were repeatedly tested for circulating microfilaria, but all birds were negative during a three-month period of sampling. Several birds with mild neurologic signs were followed for a six-month period and never developed a microfilaremia.

Grackles are the normal host for *C. quiscali*, which is transmitted by *Culicoides* sp. Following a migration of unknown duration, the larvae enter the brain and spinal cord and migrate toward the lateral ventricles of the brain where the adults mature and produce microfilaria. When the microfilaria are ingested by gnats, the life cycle of the nematode is completed. Infected Great-tailed Grackles and *Culicoides* sp. were collected from farms with affected emus.

Prevention of this cerebrospinal nematode may be possible by control of the vector, elimination of the environmental conditions conducive to transmission of the parasite and prevention of larval migration. Treatment would be expected to be ineffective once the larvae enter the CNS because anthelmintics normally do not pass the blood-brain barrier. Several emu farms use anthelmintics in an attempt to arrest larval migration, but it is unclear if this preventative is effective. Although this parasite has not been reported in the ostrich, it should be considered a threat until proven otherwise.[3] *Baylisascaris* sp. has also been shown to cause neurologic signs in ratites (see Chapter 36).

Arthropods

Ostriches are subject to infestation by a variety of external parasites, both host-specific and indiscriminate. The ostrich louse, *Struthiolipeurus struthionis,* is commonly found on ostriches worldwide. These

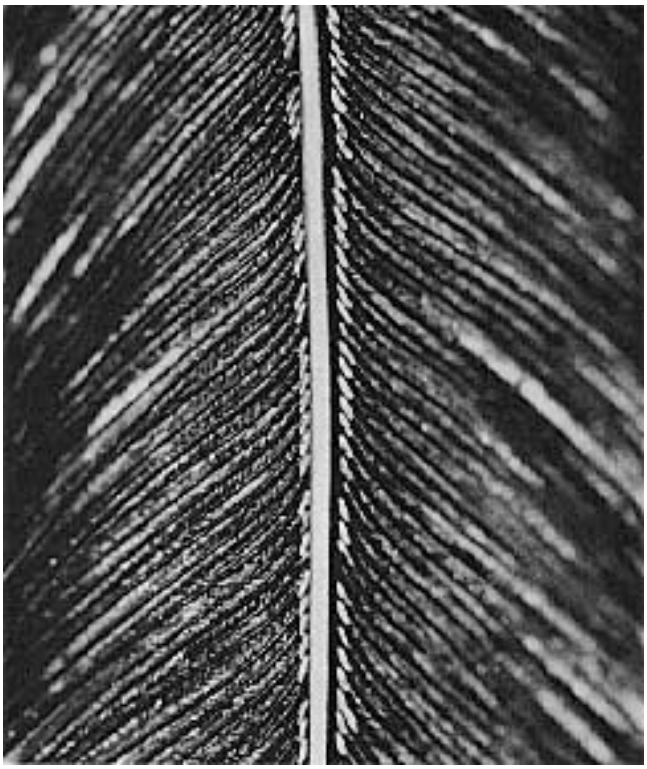

FIG 48.21 Nits of the ostrich feather louse (*Struthiolipeums struthionis*) can be seen along both sides of the rachis (courtesy of James Stewart).

chewing lice feed on skin scale and feathers and by removing the barbules, make the feather coat appear thin and tattered. Infestation is easily diagnosed by identification of the nits glued to the barbs along the shaft of feathers, particularly under the wing (Figure 48.21). The ostrich louse fly, *Struthiobosca struthionis*, is a minor annoyance to African birds but may also bite the human caretakers. Quill mites may be found within the feather shaft or along the external groove of the shaft.

Ticks from a variety of mammalian, avian and reptile hosts have been reported to infest ostriches. They may cause blemishes on the skin that reduce its commercial value. More importantly, many of these tick species are potential vectors of livestock diseases. The discovery of ticks on imported ostriches released from private quarantine in 1989 caused the United States Department of Agriculture to impose an immediate ban on the importation of ratites.[40] Following considerable study and public debate, the importation of ratites was reapproved in 1992 with modified quarantine restrictions and guidelines.

External parasites may be treated with monthly applications of five percent carbaryl or two to four percent malathion in either powder or liquid form. Benzene hexachloride is highly toxic to ostriches and should be avoided. Quill mites are responsive to monthly treatments with ivermectin at standard doses.[29]

Respiratory Problems

Upper respiratory tract infections may be caused by bacteria, mycoplasma, fungi (*Aspergillus* spp.) or possibly viruses (see Color 22). Clinical signs are characterized by ocular or nasal discharge, and birds may be dyspneic and appear unkempt. Treatment is based on the etiology. Affected birds should be isolated immediately and flockmates should be carefully observed. Adequate ventilation and reduced airborne debris are necessary to prevent the spread of infections in the flock. Air sacculitis and pneumonia are most commonly caused by bacteria or *Aspergillus* spp.[61] A sunken sinus syndrome has been described in emus secondary to sinusitis (see Figure 26.8).

Ocular Problems[53,54]

Cataracts are frequently seen in ostriches. They are more common in older birds, but may occur also in chicks only a few months of age (Color 48.10). Unilateral cataracts are of little clinical importance. Bilateral cataracts must be removed, and surgery has been successful.

Lacerations, abrasions or ulcerations to the eye may cause epiphora or blepharospasms. Foreign bodies may or may not be found. The discharge in these cases is usually clear and often is present in only one eye. Diagnosis is made via physical examination and fluorescein-staining of the eye. Standard ocular therapies used in other birds are effective in ratites (see Chapter 26). Subpalpebral flukes may cause chronic epiphora in birds raised in moist areas.

Eye infections generally cause the production of a purulent discharge and will usually be bilateral (Color 48.11). Cytology and cultures are necessary to determine the etiologic agent. Ocular discharges are common with upper respiratory infections. A blocked nasolacrimal duct is recognized clinically by epiphora and swelling within the lower lid. The lacrimal duct can be cannulated and flushed to determine if a blockage has occurred and to correct the problem.

FIG 48.22 Feather picking in ratites may be caused by malnutrition or overcrowded, small or barren enclosures (courtesy of James Stewart).

Feather Loss (With or Without Skin Involvement)

Bacterial folliculitis has been described in ratites and is most commonly caused by *Staphylococcus* spp. The ingestion of parsley was associated with a photosensitization reaction in an ostrich (see Chapter 37). Poxvirus may cause crusty proliferative lesions on the head, periocular area and legs. Lice or mites can damage the skin and feathers of ratites. Adult lice and their eggs can be visualized along the shaft of the feather (Figure 48.21). Five percent Sevin dust is an effective treatment.

Feather picking can be caused by overcrowding, excessive exposure to light at night and a lack of available food. Feather picking is common in adult ostriches maintained in small, barren paddocks and may be a reflection of malnutrition or environmental stresses (Figure 48.22). Large deplumed areas of skin are subject to sunburn. These birds will usually respond to an enriched environment, especially green pasture. In one case, a large, reflective, chrome plate (mirror) was used to distract a male and prevent him from feather picking a hen.

Neural Diseases

Toxins that can cause neurologic lesions in ratites may include plants, oil, grease and insecticides. Endotoxins produced by bacteria can lead to severe ataxia. Infectious causes of neurologic problems include viruses, bacteria, fungi or parasites. Paramyxovirus, EEE virus and Newcastle disease virus have all been associated with neurologic signs in ratites. Overheating may cause ataxia or seizures. The normal body temperature of ratites is approximately 103°F. Birds, particularly chicks, that are panting with extended wings are overheated. Treatment should include cold water baths. Hypoglycemia can cause ataxia and tremors in anorectic neonates. Oral or IV dextrose as well as tube feeding with high-carbohydrate diets three to four times daily is usually curative.[62]

Hatchery Management

The Egg

The general principles of egg management for ratites are no different than those for other avian species.[52,56] Hatchability exceeding 90% of fertile eggs should be expected with well managed commercial ostrich operations. The maintenance of accurate records, including the analysis of unhatched eggs, is an absolute necessity for the elucidation of incubation and hatchery problems.

There is an optimum size for all eggs. Unusually small eggs lose excessive moisture during incubation and produce small dehydrated chicks that rarely survive. Conversely, large eggs produce weak, edematous chicks that frequently fail to hatch (Color 48.2).

The shell of an egg balances two opposing functions: the egg shell must allow the free exchange of oxygen, carbon dioxide and water vapor, yet inhibit the penetration of infectious agents. Thick shells and shells with low porosity inhibit gas and water vapor exchange, while thin, highly porous or defective shells may lose excessive water vapor and readily allow bacterial penetration (Color 48.1). Shell quality is influenced by nutrition, disease and genetics, as well as by the conditions of the nest site and the egg handling methods.[27] Porosity of the shell is a heritable trait, and each hen will have unique eggs.[27] Strict sanitation is essential to maintain hatchability.

The physical health of the hen can also affect egg quality. Pathogens colonizing the reproductive tract may result in a thin or absent shell, or may be a source of infection for eggs that appear otherwise normal. Eggs with rough-textured surfaces, ridges, a lack of a mucin coat or soft shells may indicate metri-

tis. Soft shells may also occur as a result of dietary deficiencies. Yolkless eggs may be caused by metritis, deposition of yolk into the peritoneal cavity or abnormalities of the ovary. Double yolks are postulated to occur with abnormal egg passage through the oviduct.

The physical characteristics of an egg have a strong genetic basis. Commercial poultry have been selected to produce a nearly uniform egg that results in uniform incubation and hatching characteristics. Ostrich breeding stock from free-ranging linage will retain their full natural variability in egg quality and specific incubation requirements.

Ratites lay their eggs on the ground, creating a potential for egg contamination by infectious agents. Management practices require that a clean nest such as sand or straw be available for egg laying and that eggs to be artificially incubated are collected and disinfected promptly. Ostriches typically lay in the evening hours, while emus frequently lay shortly after dark. Eggs should be gently collected from the nest and transported by hand to the preparation area. Excessive jarring of the egg contents or damage to the shell can be fatal to the developing embryo.

Cold storage of eggs allows the use of efficient batch incubation and brooding systems and is a routine practice on large farms. Disinfected eggs are maintained up to seven days between 12.8°C (55.0°F) and 18.3°C (65.0°F) and near 75% relative humidity. Eggturning is not necessary for storage periods of less than one week. Ideally, eggs are stored directly in the incubation trays and the entire tray may then be loaded into the incubator racks.

Egg washing is a controversial issue in ratite production. It is better to provide the breeding pair with a clean, dry area in which to lay eggs rather than attempting to clean or disinfect dirty moist eggs. Wet washing of eggs involves the use of warm dilute solutions of commercial quaternary ammonia or phenolic disinfectants, chlorhexidine or sodium hypochlorite. Dry washing is performed by using a soft bristle brush to remove gross organic debris and misting the egg with a disinfectant. The dried mucinous cuticle of ratite eggs is particularly well developed and serves as a significant barrier to bacterial penetration. It has been suggested that the wet washing of clean eggs removes this cuticle and increases the incidence of infection over that of a dry cleaning method.

Incubation

The incubation temperatures and humidities required for ratite eggs are lower than those used for other avian species (Table 48.4).[52,56] The incubators currently available for ratite production vary in quality. Many of them are inadequate in several aspects, and faulty incubators are a common cause of hatchery problems. Incubators should generate a uniform temperature throughout the cabinet and maintain the temperature within narrow limits, preferably one- or two-tenths of a degree. Late-term embryos are particularly sensitive to decreasing temperatures, and it is imperative that backup electrical power be available for incubation equipment so that eggs are not chilled if a power outage occurs.

Ventilation is the amount of fresh air brought into the incubator. Circulation is the amount of air movement within the incubator. The minimum ventilation requirement for the incubation of ostrich eggs is calculated at 50 cubic feet of fresh air per hour per 100 eggs. Inadequate ventilation causes an accumulation of carbon dioxide and severely reduces hatchability. Ventilation also controls the humidity in most incubators. Circulation functions to maintain uniformity of temperature, humidity and gas levels throughout the incubator cabinet. Rapid air circulation is critical with the large ratite eggs to effectively dissipate the high temperature and humidity that develops at the egg surface.

Ratite eggs should be incubated in the vertical position with the air cell end upward. Embryonic malposition 2 (head at opposite end from air cell, see

TABLE 48.4 Breeding and Hatchery Parameters for Ratites

Species	Eggs/year	Egg wt. (g)	Temperature	Humidity (%)	Period (days)
Ostrich	40-60	1300-1700	36.0-36.4°C (96.8-97.5°F)	20-40	41-43
Rhea	40-60	400-700	36.0-37.2°C (96.8-99.0°F)	55-70	36-41
Emu	20-40	500-700	36.0-36.7°C (96.8-98.0°F)	25-40	50-57
Cassowary	3-10	500-700	36.0-36.7°C (96.8-98.0°F)	55-70	47-53

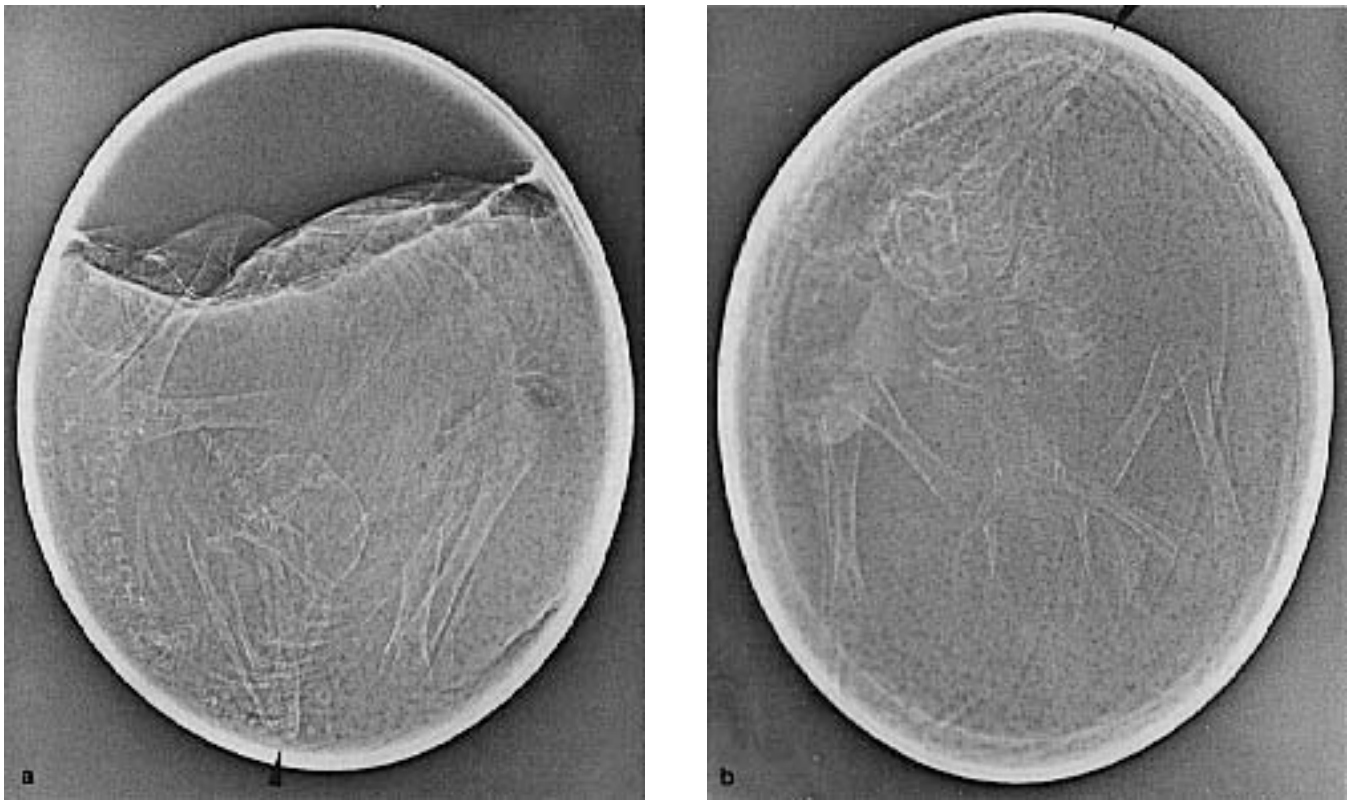

FIG 48.23 Xeroradiographs of ostrich eggs. **a)** Notice the dead embryo skeleton positioned with its head and the tip of its beak (arrow) oriented opposite the air cell end of the egg. The embryo died late in development. The air cell at the top of the egg has not been penetrated. **b)** Notice the dead embryo skeleton in a normal position after penetration of the air cell with the tip of the beak (arrow). The embryo did not pip the shell, and the air cell has been displaced by the embryo (courtesy of David Ley, reprinted with permission[38]).

Chapter 29) is especially common in ostrich eggs incubated in the horizontal position and results in poor hatchability. The incidence of malposition 2 increases from 3% among eggs incubated vertically to 16 to 20% among eggs incubated horizontally (Figure 48.23).

Eggs are rotated during incubation in order to stir the liquid layers of nutrients and waste products around the developing embryo. Inadequate turning increases both embryonic and post-hatch mortality. Following poultry protocol, the egg rotation angle should be 45° from vertical, shifting a minimum of six times per day.

Incubator humidity settings vary with the type of incubator as well as the size and shell characteristics of the eggs. Humidity is generally set at 20 to 40% to achieve the desired evaporative water loss during the course of incubation (13 to 14% for ostrich eggs and 10 to 11% for emu eggs). Egg monitoring during the course of incubation should include determination of weight loss and candling for embryonic development. The weight loss of eggs is fairly linear throughout incubation, and weighing an egg weekly can be used to monitor an embryo's development and guide adjustments in humidity.

It is important to determine when mortality occurred in a dead embryo. Losing ten per cent of fertile eggs during incubation is considered normal, with peaks of loss at 3 to 4 days (organogenesis) and 40 days (respiration change) of incubation. Embryonic death at other times may be caused by incorrect incubation parameters, nutritional deficiencies in the egg, infectious agents, genetic abnormalities, improper egg storage or toxins. If candling indicates that an egg is not developing after ten days of incubation, the egg should be opened to determine if the egg was infertile if early embryonic death occurred (see Chapter 29). The embryonic disc floats up and can be examined for any development. This is best done early in the incubation cycle rather than at day 43, because embryos that die early in incubation decompose rapidly.[27]

Fluctuating incubation temperatures result in unthrifty chicks. High temperatures result in an early hatch, small dry chicks, increased embryonic mortal-

ity and malformations (Color 48.2). Low temperatures result in soft, large, weak chicks with a delayed hatch. Excessive humidity (inadequate moisture loss from the egg) may cause a delayed hatch, small air cells, wet edematous chicks and mild degeneration of the leg muscles (Color 48.4). Humidity that is too low (excess moisture loss from the egg) results in large air cells, increased malpositions due to sticky chicks (dry albumen), albumen plugs in the non-air cell end of the egg and weak, dehydrated chicks with poor survivability.

Hatching

Ratite eggs are transferred to a hatcher with the same temperature and humidity settings as the incubator three to five days prior to the anticipated date of hatch. Hatching should be a gradual process that gives the chick time to switch from chorioallantoic to pulmonary respiration. The yolk sac with the blood from the chorioallantois is absorbed, and the navel closes during the last 24 hours of incubation.

The social facilitation of pipping and hatching is strongly developed in ratite chicks, and light, sound and motion help stimulate a hatch. Daily candling of ostrich and rhea eggs allows for careful monitoring of the chicks' progress, and assisted hatches are a common management procedure. The pigmented shells of cassowary and emu eggs prohibit effective candling, and various techniques of percussion and auscultation have been used to evaluate embryo development in these species. Many clients are anxious to help a chick out of the shell and begin to assist with the hatching process prematurely. This procedure results in chicks with a high incidence of yolk sac infections (see Chapter 29).

Chick Management

Ratite chicks are precocial, hatching with a full coat of natal feathers, open eyes and the ability to stand within hours.[53] They should be removed from the hatcher at one to two days of age and placed in brooder pens with other neonates that do not vary more than three weeks in age. Eating and drinking are behaviors that must be learned from older birds, and dehydration or starvation are common in chicks that are housed alone. Bin feeders and automatic water units designed for poultry and gamebirds can be effectively used in recently hatched young. Numerous commercial starter and grower rations are available for ratites. Chicks should be expected to lose weight for three to five days following hatch and then to begin a steady increase in weight gain.

Young chicks should have access to supplemental heat that can be provided by infrared lamps, heated floors or space heaters. Chicks should be maintained at decreasing temperatures with age (90°F one to two weeks, 85°F to 12 weeks).[31] Indoor flooring should be inedible, provide good traction and be easily cleaned. Brushed concrete, with or without perforated plastic or rubber matting, is commonly used. In order to prevent gastric impactions, hay or wood chips should not be used. Adequate ventilation is essential in the brooding area. The general consideration for air circulation is 0.012 cubic feet per minute/per pound of bird for each degree F. For example, if the temperature is 70° and ten birds weighing 50 lbs each are in the space (500 lbs total), then the air exchange requirement is 0.012 x 500 x 70 or 420 cubic feet per minute.[61]

As soon after hatching as ambient temperatures permit, chicks should be moved to outdoor grazing areas with fencing that is low to the ground and with holes no larger than 2.5 cm. Chicks should be considered cold-intolerant and provided supplemental heat in cold weather until they are six months of age. Chicks should be housed with birds of similar age to prevent injuries. Young chicks require constant attention to keep them tame and to quickly detect any developmental problems.

To reduce the chances of foreign body ingestion, chicks should be carefully monitored during their initial introduction to a pasture. Using a grassy area that has been well groomed (cut to three inches) and placing chicks with slightly older birds to serve as feeding models are the best techniques to introduce chicks to pasture. Initial introduction periods should be 10 to 15 minutes in length with daily doubling of the time in the paddocks.

Chick Problems

"Wet" is the term applied to chicks that have not lost sufficient weight during incubation and are consequently edematous at hatching (Color 48.2). These birds may or may not be capable of an unassisted hatch. Diuretics have been suggested to reduce the edema but they are rarely necessary. Most birds will

lose the excess water several days after hatch.[61] This condition can be caused by several factors including: 1) Large ostrich eggs (greater than 1700 to 1800 g) that do not have sufficient surface area to allow adequate water loss; 2) Poor egg shell quality, such as low pore density or excessive thickness; 3) High incubation humidity. Relative humidity in the incubator should be 20 to 25% as a starting point. Adjustments must be made to achieve a 13 to 15% egg weight loss throughout incubation.

"Sticky" Chicks

This condition occurs when the inner shell membrane is excessively dry, causing the chick to stick to the membrane. Assisted hatching is mandatory in these chicks or they will not survive. To correct this problem, the humidity in the hatcher must be increased (perhaps as high as 80 to 90% relative humidity) to a point that allows the membrane and its underlying chorioallantois to remain pliable and easy for the chick to tear. This problem can occur if the humidity in the incubator is too low.[61]

External Yolk Sac

If the umbilicus does not close properly, the yolk will protrude from the abdomen to varying degrees (Color 48.2). High incubation temperatures (early hatch), poor gas exchange (may occur with high altitude or high humidity) and egg infections are thought to be the principal causes of improperly absorbed yolk sacs. The cause can best be determined by carefully evaluating the incubation and hatching parameters and culturing affected embryos. In mild cases, the yolk can be placed in the abdomen, the umbilicus covered with antibiotic ointment and gauze, and the abdomen wrapped with self-adherent bandage. Systemic antibiotic therapy should be initiated immediately. If a large quantity of the yolk sac is externalized or the umbilicus has sealed (Color 48.2), the yolk sac should be surgically removed. The prognosis for chicks with externalized yolk sac is poor.[61]

Retained Yolk Sac

Chicks that fail to absorb the yolk sac are generally weak, depressed and may peck erratically at the air with or without their eyes closed. A distended abdomen in a depressed chick less than two weeks old is a characteristic finding (Figure 48.24). Additionally, they may display a characteristic "S"-curve in the neck and feign eating without ingesting any food. These birds will continue to lose weight beyond the normal weight loss seen the first four to five days after hatch.

Retained yolk sacs are thought to be caused by improper incubation parameters, malnourished hens or infected eggs (Color 48.7). Improper incubation temperature as well as inappropriate gas exchange (poor circulation or ventilation) between the embryo and the air surrounding the shell can cause retention of the yolk sac. Ventilation defects are thought to have their most profound effects late in the incubation process and may be most common when an incubator is filled to near capacity, which causes an accumulation of CO_2 if the ventilation is inadequate. Incubation problems are suspected if infectious agents cannot be cultured from the yolk sac of affected chicks.

Inflammation of the umbilicus shortly after hatching can be an early warning sign of an impending yolk sac infection (Color 48.6). Affected chicks have subnormal weight gains over a two- to three-week period and intermittently appear depressed or chilled. These chicks may absorb a portion of their yolk sac and may not have a severely distended abdomen until late in the disease process. Applying an antibiotic ointment to the umbilicus of recently hatched chicks may help prevent infections.

Retained or infected yolk sacs may represent 15 to 40% of a chick's total body weight and should be surgically removed in conjunction with the administration of broad-spectrum antibiotics. *E. coli* is frequently cultured from retained yolk sacs (Color 48.7). To remove the yolk sac, the chick is placed in dorsal recumbency and the abdomen is prepared for surgery. The skin is incised circumferentially around the umbilicus and the incision is extended transversely at the three and nine o'clock positions to the lateral distance required to allow easy removal of the intact yolk sac. The body wall is then incised in a corresponding pattern being careful to not damage the underlying yolk sac. The yolk sac is exteriorized by placing gentle traction on the umbilical stump. The

CLINICAL APPLICATIONS

Management Tips for Chicks[61]

- Feed pellets with 19 to 21% protein content supplemented with fresh grazing as soon as possible.
- Weigh chicks daily for the first two to three weeks after hatching. Weight gain is a good indicator of a healthy chick, and weight loss often precedes clinical signs of disease.
- The single most important requirement for growing ratites is ample exercise.
- Exposure of chicks to infectious agents can be reduced by restricting access of all visitors, utilizing sound hygiene procedures and caring for neonates in a youngest to oldest pattern.

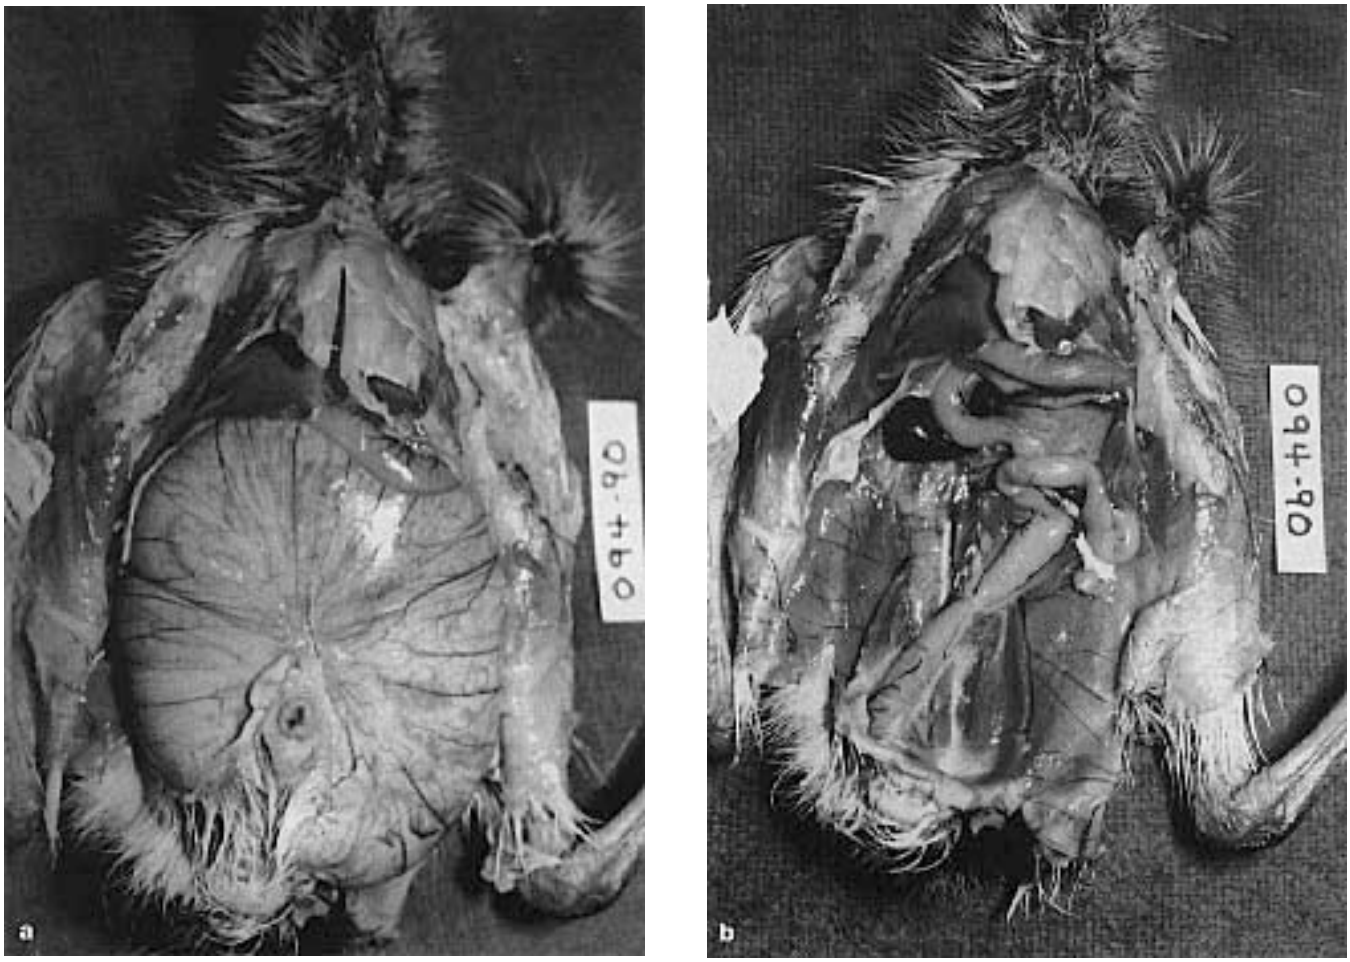

FIG 48.24 **a)** Retained egg yolk in a six-day-old cassowary chick that developed dyspnea and an inability to walk. **b)** The yolk sac has been removed showing cranial displacement of the abdominal viscera (courtesy of Richard Cambre, reprinted with permission J Zoo Wildl Med 23:1992).

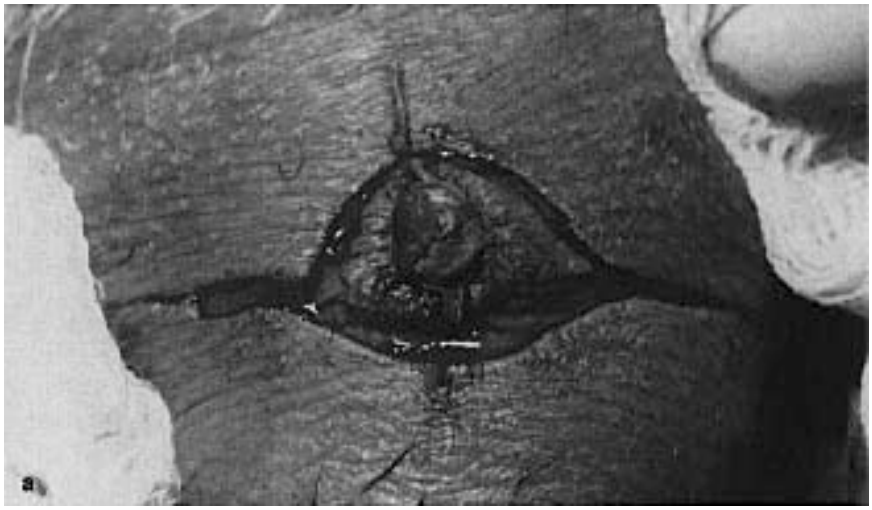
yolk stalk is clamped, clipped or ligated just distal to the intestine to allow the stalk to be transected and the yolk sac to be removed. The body wall is closed with a monofilament, absorbable material in a simple continuous pattern. Broad-spectrum antibiotic therapy is indicated pending culture results. Trimethoprim-based antibiotics can be administered until the results of yolk sac culture and sensitivities are available. Some chicks begin to eat and gain weight within a day or two of surgery while others require nutritional support by tube-feeding for several days before they resume normal growth.[10]

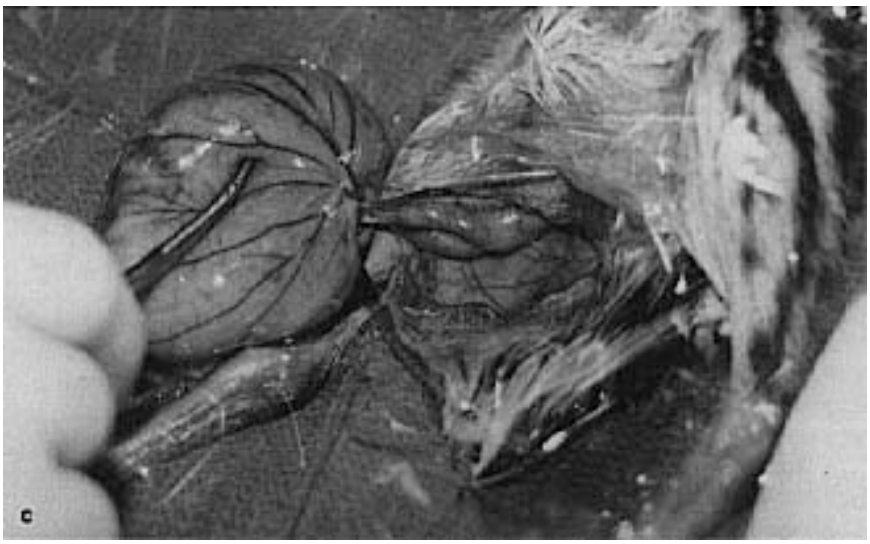
Congenital Disorders

Congenital anomalies described in ostrich chicks include albinism, leucism, melanism, pied, prognathism, crossed beak, choanal atresia, microphthalmia, blindness, meningocele, crooked neck, hernia, schistomus reflexus, polydactyly, third leg, micromelia and hermaphroditism. Congenital defects in chicks may be attributable to genetics, the effects of nutritional deficiencies or teratogens in the laying hen, or may be caused by inadequate egg handling and incubation procedures. The incidence of these problems is usually sporadic and the specific etiology obscure.

Cloacal Prolapse

Prolapse of the cloaca may occur in neonates. This condition is most common in birds less than four weeks of age and has been associated with distension of the abdomen (ie, excessive water-drinking on hot days, proventricular impactions, retention of the yolk sac) and tenesmus. Mild cases can be resolved by simply replacing the cloaca through the vent. More severe cases require retention sutures for one to three days (see Chapter 41).





Stress

Stress is an extremely important consideration in ostrich management and is generally under-rated or ignored. It is the most frequent primary cause of chick mortality. Ostriches are highly social animals that do not readily adapt to change. Young chicks require a stable social group that might include a parental figure in the form of a natural parent, older counselor chick or a human substitute. Complete social isolation of young chicks is tantamount to death.

Management systems in which chicks are transferred through a series of pens are disturbing to the birds. Relocating or mixing chicks from different groups may alter the social structure causing some chicks to be harassed or rejected by dominant birds. These abandoned chicks may exhibit neurotic pacing, inadequate or inappropriate ingestion behavior, intermittent diarrhea and stunting. Chicks shielded from constant human activity become flighty, adjust poorly to captivity and may mature to become substandard producers. Environmental and social stability, combined with the taming of young chicks through continuous human presence, are among the most important components of a successful ostrich management program. Gradually introducing chicks to a new area or situation will help maintain the group stability and reduce stress.

FIG 48.25 **a)** To remove a retained yolk sac, a circumferential incision is made around the umbilicus extending laterally at the three and nine o'clock positions. **b)** The yolk is exteriorized by placing gentle traction on the umbilical stump. **c)** The exteriorized yolk sac showing the vascular and yolk sac connection to the small intestines. These structures are ligated close to the small intestines (courtesy of Richard Cambre, reprinted with permission J Zoo Wildl Med 23:1992).

Musculoskeletal Disorders of Chicks

Rolled toe in ostrich chicks is a problem frequently seen in backyard operations the first few day after hatching (Color 48.22). The distal portion of the main toe is rotated off of the centerline (Figure 48.25).

In poultry, riboflavin deficiencies cause damage of the peripheral nerve trunks and paralysis resulting in curling of the toes and leg weakness; however, in ostriches, rolled toe syndrome seems to be caused by genetic abnormalities, incubation problems or inappropriate substrates during the first week of life while the phalanges are mineralizing. Brooder pens with soft surfaces or wire mesh allow the toe to flex and roll medially. A firm flat surface such as packed dirt or concrete induces proper toe formation.

Rolled toe deformities may be corrected with a variety of simple splints, but become more difficult to resolve as the chick matures. A splint can be applied by wrapping tape around the toe in a direction opposite to the deflection (Figure 48.26). A tongue depressor can be incorporated into the plantar surface of the toe on the final wrap to provide extra stability. Correction of this problem in older chicks requires surgical intervention.

Rotational and angular deformities of the legs are a common problem in the rearing of all ratite chicks and should be viewed primarily as a management problem (Figure 48.27). This condition occurs when one or both legs rotate laterally at the distal tibiotarsus causing the toe to point laterally (Color 48.23). Chicks from a particular breeding pair may have a high incidence of deformities under conditions in which other chicks are raised satisfactorily, implicating genetics as a contributing factor. Chicks raised on slick and slippery surfaces have severe leg deformities. Classical rickets is often seen, with elongated metaphyses of the long bones and ricketic rosaries along the ribs. These chicks respond favorably to adjusted dietary levels of calcium, phosphorus and vitamin D_3. Leg problems associated with inadequate or imbalanced levels of these compounds are exacerbated by high levels of dietary protein.

Leg deformities are more common in birds that are pushed to grow too fast (high-protein, high-fat diets) combined with reduced exercise, and are maintained in areas with poor footing (sand, straw, Astroturf). An injury of the growth plate (nutritional, traumatic) will result in a rapid bending or twisting of the bone due to the rapid growth rates. In long-legged altricial species, bone growth in the tarsometatarsus may be six millimeters/day. In precocial young, the growth rate may be two millimeters/day.[34]

An excessive growth rate induced by high-energy diets may cause an unacceptable level of stress on the cartilage in the developing bones, causing deviations in the growth patterns. Weight gains should be linear, and several days of excess weight gain may induce bone deformities.[6] Chicks are best raised on moderate protein diets (20%) in large pastures with plenty of room for exercise. Empirical observation suggests that the incidence of leg deformities is reduced with increased exercise. Bone strength responds to usage, and it is hypothesized that exercise increases circulation to the developing bone and enhances the mineralization process.

Leg deformities in poultry are associated with deficiencies in manganese, zinc, choline, biotin, folic acid, niacin and pyridoxine, and the involvement of these nutrients in certain leg deformities of ratites is likely. Infectious disease, gastric impaction and dehydration often inhibit the appropriate absorption and utilization of feeds and induce secondary skeletal deformities.

Treatment of afflicted individuals can be attempted with a variety of external splints and slings or by derotational osteotomy and fracture repair, but the prognosis is exceptionally poor. Re-rotation following surgery commonly occurs. Proper positioning with external bracing coupled with an immediate decrease in protein content of the feed may be helpful in arresting the process. It is best to apply bracing at night during roost time and to release the chick with the flockmates during the day. It is stressful for chicks to be alone and, with a rotational problem especially, they need extensive exercise. In commercial ratite production, such techniques are economically unfeasible and individuals with marked deformities should be condemned.

Spraddle Leg

Spraddle leg is caused by a deformity in the coxofemoral joint that prevents the legs from being adducted. This condition, usually associated with edematous chicks, is manifested by the legs being directed laterally resulting in the inability to stand. Hobbling the legs with a self-adherent bandage or placing the chick in a restrictive box that forces the legs together is usually effective if initiated immediately after the problem is noted. The problem can be prevented by ensuring proper weight loss of the egg during incubation.[61]

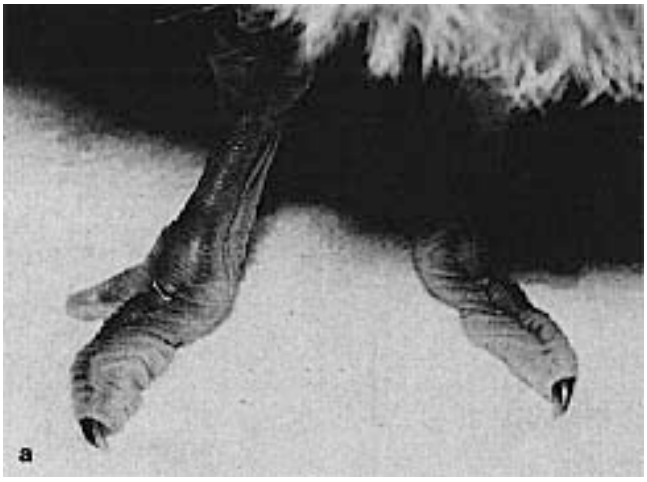


FIG 48.26 Rolled toe deformity **a)** before and **b)** after applying a splint (courtesy of James Stewart).

Ruptured or Slipped Achilles Tendon

Rupture or slippage of the Achilles tendon may occur secondary to valgus or varus deformities of the leg. Manganese deficiency has been suggested as a possible predisposing factor. Management practices must be scrutinized if multiple cases occur in a flock. Feed analysis, feeding frequency, exercise programs, concurrent rotations or angular deformities are areas to evaluate. Surgical repair can be attempted (see Chapter 46).

Septic arthritis is frequently seen in ratites. Numerous gram-negative bacteria, *Mycoplasma* spp., *Staphylococcus* spp. and some fungi have been recovered from affected joints (Color 48.21). These infections may originate from traumatic injuries or can be secondary to septicemia.

With the increasing exchange of knowledge between the United States, Europe and other parts of the world with regard to avian clinical chemistry, it is imperative that a uniform system of units be used to avoid confusion. The World Health Assembly recommended the International System of Units (SI, Systeme International d'Unites) for the health professions in 1977. The SI is the result of many decades of international efforts to develop a universally acceptable system. In many countries and many scientific journals, the use of the SI system is mandatory. It seems that the SI has gained more acceptance in European countries than in the USA. Many American veterinary journals still use conventional units (Journal of the Association of Avian Veterinarians) or a mixture of conventional and SI units (Avian Diseases) while European journals use the SI system (Avian Pathology). Until the SI system is used in all scientific papers and handbooks conversion factors are indispensable.

This table is not complete and further information may be obtained from: Units, Symbols and Abbreviations. London, Royal Society of Medicine Services, 1988, ISBN 0905958780.

In the American veterinary literature the units of weight, temperature and pressure used are often different from SI (derived) units and therefore conversion factors for these quantities will also be given.

Serum Biochemical Methods (37°C) Used in Determining Reference Values in Psittaciformes

Parameter	Method
Albumin	Modified Doumas Method (Bovine Standard)
ALP	Mod. Bowers and McComb
ALT	Mod. IFCC
AST	Mod. IFCC
T. Bili	Mod. Walters and Gerarde
BUN	Mod. Talke and Schubert
Calcium	Mod. Connerty and Briggs
Chloride	Mod. Schoenfeld and Lewellen
Cholesterol	Enzymatic Method
CK	Mod. Oliver and Rosalki
Creatinine	Kinetic Jaffe
GGT	Mod. Szasz
Glucose	Trinder Glucose (Gilford Reagent)
LDH	Mod. Wacker
Phosphorus	Mod. Daly and Ertingshausen
Total CO_2	Enzymatic PEPC
Total Protein	Mod. Biuret
Triglyceride	Mod. Fossati and Prencipe
Uric Acid	Mod. Fossati
Sodium	Ion Selective Electrode
Potassium	Ion Selective Electrode

ANSERIFORMES

All tables in this section compiled by Olsen J.

Leukocyte Percentages in Adult Mallards during Different Reproductive States (Mean ± SD)*

Reproductive State	Lymphoctyes	Heterophils	Basophils	Monocytes	Eosinophils
Females					
PE	60 ± 1.4	35 ± 1.5	2.2 ± 0.2	2.2 ± 0.3	0.7 ± 0.15
EL	58 ± 3.0	37 ± 3.0	3.2 ± 0.5	1.8 ± 0.2	0.8 ± 0.30
INC	62 ± 1.5	33 ± 1.7	3.0 ± 0.4	1.9 ± 0.2	0.2 ± 0.07
MOLT	68 ± 2.1	28 ± 2.4	2.1 ± 0.5	1.8 ± 0.5	0.1 ± 0.08
PR	57 ± 1.6	37 ± 1.4	3.2 ± 0.3	3.2 ± 0.3	0.2 ± 0.06
Males					
PE	58 ± 1.8	36 ± 1.9	3.4 ± 0.4	1.9 ± 0.2	0.9 ± 0.18
EL	59 ± 3.0	36 ± 3.1	2.6 ± 0.4	1.9 ± 0.2	0.6 ± 0.18
INC	66 ± 1.4	29 ± 1.4	2.2 ± 0.3	2.5 ± 0.3	0.2 ± 0.17
MOLT	67 ± 1.9	27 ± 2.0	2.9 ± 0.4	2.9 ± 0.4	0.3 ± 0.10
PR	54 ± 1.6	38 ± 1.5	3.6 ± 0.3	3.6 ± 0.3	0.4 ± 0.10

* PE (Pre-egg laying); EL (Laying); INC (Incubating); MOLT (Molting); PR (Postreproductive). Males were classified in the same reproductive state as the female with whom they were paired until they began the post-reproductive molt.

III

Class Aves: A List of Orders, Common and Scientific Names

APTERYGIFORMES
Kiwi *Apteryx* sp.

STRUTHIONIFORMES
Cassowary *Casuarius* spp.
Emu *Dromiceius novaehollandiae*
Greater Rhea *Rhea americana*
Lesser Rhea *Pterocnemia pennata*
Ostrich *Struthio camelus*

TINAMINIFORMES
Tinamou *Eudromia* spp.
Bustard (Houbara) *Chlamydotis undulata*

GRUIFORMES
Blue Crane *Tetrapteryx paradisea*
Brolga *Grus rubicunda*
Crowned Crane *Balearica pavonina*
Demoiselle Crane *Anthropoides virgo*
Hooded Crane *Grus monacha*
Manchurian Crane *Grus japonensis*
Sandhill Crane *Grus canadensis*
Sarus Crane *Grus antigone*
White-naped Crane *Grus vipio*

RALLIFORMES
Coot (European) *Fulica atra*

CHARADRIIFORMES
Sanderling (eroliinae) *Crocetha ulba*
Turnstone *Arenaria interpres*

LARIFORMES
Black-headed Gull *Chroicocephalus ridibundus*
Herring Gull *Larus argentatus*
Kittiwake (Black -legged) *Rissa tridactyla*

ALCIFORMES
Black Guillemot *Cepphus grylle*

SPHENISCIFORMES
Fairy Blue (Little) Penguins *Eudyptula minor*
Humboldt penguin *Spheniscus humboldti*
Jackass Penguin *Spheniscus demersus*

PELECANIFORMES
Brandt's Cormorant *Phalacrocorax penicillatus*
White Pelican *Pelecanus onocrotalus*

COLUMBIFORMES

Pigeons
Crowned (Blue) Pigeon *Goura cristata*
Nicobar Pigeon *Caloenas nicobarica*
Pheasant Pigeon *Otidiphabs noblis*
Rock-Pigeon (Racing, King) *Columba livia*
Tooth-billed Pigeon *Didunculus strigirostris*
Wood-Pigeon *Palumbus palumbus*

Doves
African Collared Dove *Streptopelia roseogrisea*
Collard (African) Dove *Streptopelia roseogrisea*
Emerald Dove *Chalcophabs indica*
Galapagos Dove *Nesopelia galapagoensis*
Luzon Bleeding-heart *Galliculomba luzonica*
Mourning Dove *Zenaida macroura Zenaidura*
Namaqua Dove *Oena capensis*
Plain-breasted Ground Dove *Columbigallina minuta*
Turtle-Dove *Streptopelia turtur*

PSITTACIFORMES

Lovebirds
Black-cheeked Lovebird *Agapornis nigrigenis*
Black-collared Lovebird *Agapornis swindernianus*
Black-winged Lovebird *Agapornis taranta*
Fischer's Lovebird *Agapornis fischeri*
Grey-headed Lovebird *Agapornis canus*
Lilian's (Nyassa) Lovebird *Agapornis lilianae*
Masked Lovebird *Agapornis personatus*
Red-faced Lovebird *Agapornis pullarius*
Rosy-faced Lovebird *Agapornis roseicollis*

Macaws
Blue and Yellow (Gold) Macaw *Ara ararauna*
Buffon's Macaw *Ara ambigua*
Green-winged Macaw *Ara chloroptera*
Hyacinth Macaw *Anodrohynchus hyacinthinus*
Illiger's Macaw *Ara maracana*
Military Macaw *Ara militaris*
Red-shouldered Macaw *Diopsittaca noblis*
Scarlet Macaw *Ara macao*
Yellow-collared Macaw *Ara auricollis*

Conures
Australian Conure *Enicognathus ferrugineus*
Blue-crowned Conure *Thectocercus acuticaudatus*
Brown-throated Conure *Eupsittula pertinax*
Cactus Conure *Eupsittula cactorum*
Dusky-headed Conure *Eupsittula weddellii*
Finsch's Conure *Psittacara finschi*
Golden Conure *Guaruba guarouba*
Green-cheeked Conure *Pyrrhura molinae*
Green Conure *Psittacara holochlora*
Maroon-bellied Conure *Pyrrhura frontalis*
Mitred Conure *Psittacara mitrata*
Nanday Conure *Nandayus nenday*
Painted Conure *Pyrrhura picta*
Patagonian Conure *Cyanoliseus patagonus*
Peach-fronted Conure *Eupsittula aurea*
Pearly Conure *Pyrrhura perlata*
Slender-billed Conure *Enicognathus leptorhynchus*
Sun Conure *Aratinga solstitialis*
White-eyed Conure *Psittacara leucophthalma*

Parakeets
Alexandrine Parakeet *Psittacula eupatria*
Blossom-headed Parakeet *Psittacula roseata Biswas*
Blyth's Parakeet *Psittacula caniceps*
Derbyan Parakeet *Psittacula derbiana*
Grey-cheeked Parakeet *Brotogeris pyrrhoptera*
Monk (Quaker) Parakeet *Myiopsitta monachus*
Moustached Parakeet *Psittacula alexandria*
Orange-chinned Parakeet *Brotogeris jugularis*
Red-fronted (Kakariki) Parakeet *Cyanoramphus novaezelandiae*
Rose-ringed Parakeet *Psittacula krameri*
Yellow-fronted (Kakariki) Parakeet *Cyanoramphus auriceps*
Black-headed Caique *Pionites melanocephalus*
White-bellied Caique *Pionites leucogaster*

Parrots
African Grey Parrot *Psittacus erithacus*
Amboina King Parrot *Alisterus amboinensis*
Australian King Parrot *Alisterus scapularis*
Barraband's Parrot *Gypopsitta barrabandi*
Black Parrot *Coracopsis nigra*
Blue-bonnet *Psephotus haematogaster*
Blue-winged Parrot *Neophema chrysostoma*
Bourke's Parrot *Neopsephotus bourkii*
Budgerigar *Melopsittacus undulatus*
Eastern Rosella *Platycercus eximius*
Eclectus Parrot *Eclectus roratus*
Elegant Parrot *Neophema elegans*
Golden-shouldered Parrot *Psephotus chrysopterygius*
Great-billed Parrot *Tanygnathus megalorhynchos*
Green Rosella *Platycercus caledonicus*
Green-winged King Parrot *Alisterus chloropterus*
Ground Parrot *Pezoporus wallicus*
Hawk-headed Parrot *Deroptyus accipitrinus*
Kakapo *Strigops habroptilus*
Mulga Parrot *Psephotus varius*
Night Parrot *Geopsittacus occidentalis*
Northern Rosella *Platycercus venustus*
Orange-bellied Parrot *Neophema chrysogaster*
Paradise Parrot *Psephotus pulcherrimus*
Pennant's Rosella *Platycercus elegans*
Pileated Parrot *Pionopsitta pileata*
Princess Parrot *Spacthopterus alexandrae*
Red-capped Parrot *Purpureicephalus spurius*
Red-rumped Parrot *Psephotus haematonotus*
Red-winged Parrot *Aprosmictus erythropterus*
Regent Parrot *Spathopterus anthopeplus*
Ringneck Parrot *Barnardius zonarius*
Scarlet-chested Parrot *Neophema splendida*
Short-tailed Parrot *Graydidascalus brachyurus*
Superb Parrot *Polytelis swainsonii*
Thick-billed Parrot *Rhynchopsitta pachyrhyncha*
Timor Red-winged Parrot *Aprosmictus jonquillaceus*
Turquoise-Parrot *Neophema pulchella*
Vasa Parrot *Coracopsis vasa greater*
Western Rosella *Platycercus icterotis*

Amazon parrots
Blue-fronted Amazon *Amazona aestiva*
Cuban Amazon *Amazona leucocephala*
Festive Amazon *Amazona festiva*
Green-cheeked Amazon *Amazona viridigenalis*
Hispaniolan Amazon *Amazona ventralis*
Lilac-crowned Amazon *Amazona finschi*
Mealy Amazon *Amazona farinosa*
Orange-winged Amazon *Amazona amazonica*
Puerto Rican Amazon *Amazona vittata*
Red-spectacled Amazon *Amazona pretrei*
Red-lored Amazon *Amazona autumnalis*
Tucuman Amazon *Amazona tucumana*
Vinaceous Amazon *Amazona vinacea*
White-fronted Amazon *Amazona albifrons*
Yellow-lored Amazon *Amazona xantholora*
Yellow-crowned Amazon *Amazona ochrocephala*
Yellow-billed (Jamacian) Amazon *Amazona collaria*
Yellow-shouldered Amazon *Amazona barbadenis*
Yellow-faced Amazon *Amazona xanthops*

Fig parrots
Desmarest's Fig Parrot *Psittaculirostris desmarestii*
Double-eyed Fig Parrot *Opopsitta diophthalma*
Edward's Fig Parrot *Psittaculirostris edwardsii*
Salvadori's Fig Parrot *Psittaculirostris salvadorii*

Pionus parrots
Blue-headed Parrot *Pionus menstuus*
Bronze-winged Parrot *Pionus chalcopterus*
Dusky Parrot *Pionus fuscus*
Plum-crowned Parrot *Pionus tumultuosus*
Red-billed Parrot *Pionus sordidus*
Scaly-headed Parrot *Pionus maximiliani*
White-capped Parrot *Pionus senilis*
White-headed Parrot *Pionus seniloides*

Poicephalus parrots
Brown-headed Parrot *Poicephalus cryptoxanthus*
Cape Parrot *Poicephalus robustus*
Jardine's Parrot *Poicephalus guilielmi*
Meyer's Parrot *Poicephalus meyeri*
Niamnian Parrot *Poicephalus crassus*
Red-bellied Parrot *Poicephalus rufiventris*
Ruppell's Parrot *Poicephalus rueppellii*
Senegal Parrot *Poicephalus senegalus*
Yellow-faced Parrot *Poicephalus flavifrons*

Lories
Black-capped Lory *Lorius lory*
Black Lory *Chalcopsitta atra*
Blue-streaked Lory *Eos reticulata*
Cardinal-Lory *Chalcopsitta cardinalis*
Chattering Lory *Lorius garrulus*
Dusky Lory *Pseudeos fuscata*
Duyvenbode's Lory *Chalcopsitta duivenbodei*
Ornate Lory *Trichoglossus ornatus*
Purple-bellied Lory *Lorius hypoinochrous*
Purple-naped Lory *Lorius domicella*
Rainbow-Lory *Trichoglossus haematodus*
Red Lory *Eos bornea*
Violet-necked Lory *Eos squamata*
Yellow-streaked Lory *Chalcopsitta sintillata*

Lorikeets
Goldie's Lorikeet *Psitteuteles goldiei*
Little Lorikeet *Glossopsitta pusilla*
Scaly-breasted Lorikeet *Trichoglossus chlorolepidotus*
Varied Lorikeet *Psitteuteles versicolor*

Cockatoos
Black Cockatoo *Calyptorhynchus funereus*
Blue-eyed Cockatoo *Cacatua ophthalmica*
Ducorps's Cockatoo *Cacatua ducorps*
Galah *Eolophus roseicapillus*
Gang-gang Cockatoo *Callocephalon fimbriatum*
Glossy Cockatoo *Calyptorhynchus lathami*
Goffin's Cockatoo *Cacatua goffini*
Lesser Sulfur-crested Cockatoo *Cacatua sulphurea*
Little (Slender-bill) Corella *Cacatua sanguinea*
Long-billed Corella *Cacatua tenuirostris*
Mitchell's Cockatoo *Cacatua leadbeateri*
Palm Cockatoo *Probosciger aterrimus*
Red-vented Cockatoo *Cacatua haematuropygia*
Red-tailed Cockatoo *Calyptorhynchus magnificus*

Salmon-crested Moluccan Cockatoo *Cacatua moluccensis*
Sulfur-crested Cockatoo *Cacatua galerita*
White Umbrella Cockatoo *Cacatua alba*
Cockatiel *Nymphicus hollandicus*
Kaka *Nestor meridionalis*
Kea *Nestor notabilis*

ANSERIFORMES

Subfamily Anseranatinae

Tribe Anseranatini

Cuban (Black-billed) Whistling (tree) Duck *Dendrocygna arborea*
Eyton's (Plumed) (Grass) Whistling Duck *Dendrocygna eytoni*
Fulvous Whistling Duck *Dendrocygna bicolor*
Javan (Lesser) Whistling Duck *Dendrocygna javanica*
Magpie Goose *Anseranas semipalmata*
Northern Black-bellied (Red-billed) Whistling Duck *Dendrocygna autumnalis*
Spotted Whistling Duck *Dendrocygna guttata*
Wandering (East Indian) Whistling Duck *Dendrocygna arcuata*
White-Backed(African) Whistling Duck *Thalassornis*
White-faced Whistling Duck *Dendrocygna viduata*

Leuconotus

Tribe Anserini (Swans and True Geese)

Bar-headed Goose *Eulabeia indica*
Barnacle Goose *Branta leucopis*
Bewick's Swan *Olor bewickii*
Black-necked Swan *Sthenelides melancoryphus*
Black Swan *Chenopis atrata*
Brent (Russian) (Dark-Bellied) *Brant bernicla*
Canada (Atlantic) Goose *Branta canadensis*
Coscoroba Swan *Coscoroba coscoroba*
Emperor Goose *Philacte canagica*
Freckled (Monkey) Duck *Stictonetta naevosa*
Graylag (Domestic) Goose (Western) *Anser anser*
Lesser White-fronted Goose *Anser erythropus*
Mute Swan *Cygnus olor*
Nene (Hawaiian) Goose *Branta sandvicensis*
Pink-footed Goose *Ansewr brachyrhynchus*
Red-breasted Goose *Rufibrenta ruficollis*
Ross's Goose *Chen rossii*
Snow (Lesser) (Blue) Goose *Chen caerulescens*
Swan Goose *Anser cynoides*
Trumpeter Swan *Olor buccinator*
Western (Yellow-billed) Bean Goose *Anser fabalis*
Whistling Swan *Olor columbianus*
White-fronted (European) Goose *Anser albifrons*
Whooper Swan *Olor cygnus*

Sub-Family Antinae

Tribe Tadornini (Shelducks and Sheldgeese)

Abyssinian Blue-winged Goose *Cyanochen cyanopterus*
Andean Goose *Chloephaga melanoptera*
Ashy-headed Goose *Chloephaga poliocephala*
Australian Shelduck *Casarca tadornoides*
Cape Barren (Cereopsis) Goose *Cereopsis novaehollandiae*
Common (European) Shelduck *Tadorna tadorna*
Crested Shelduck *Pseudotadorna cristata*
Egyptian Goose *Alopochen aegyptiacus*
Kelp (Patagonian) (Lesser) Goose *Chloephaga hybrida*
Magellan (Lesser) (Upland) Goose *Chloephaga picta*
Orinoco Goose *Neochen jubatus*
Paradise (New Zealand) Shelduck *Casarca variegata*
Radjah Shelduck (Moluccan) (Black-Backed) *Radjah radjah*
Ruddy-headed Goose *Chloephaga rubidiceps*
Ruddy Shelduck *Casarca ferrugina*
South African (Cape) Shelduck *Casarca cana*
Spur-winged (Gambian) Goose *Plectropterus gambensis*

Tribe Cairinini (Perching Ducks)

African (South) Black Duck *Melananas sparsa*
African Pygmy Goose *Nettapus auritus*
American (Baldpate) Wigeon *Mareca americana*
Australian Shoveler *Spatula rhynochotis*
Australian Wood Duck (Maned Goose) *Chenonetta jubata*
Bahama (Lesser) (Northern White-Cheeked) Pintail *Paecilonetta bahamensis*
Baikal Teal *Nettion formosum*
Blue-winged (Prairie) Teal *Spatula discors*
Brazilian (Lesser) Teal *Amazonetta brasiliensis*
Brown (Chillian) Pintail *Dafila georgica*
Brown (New Zealand) Teal *Nettion aucklandicum*
Cape (South African) Shoveler *Spatula capensis*
Cape Teal *Nettion capense*
Chestnut Teal *Nettion castaneum*
Chiloe Wigeon *Mareca sibilatrix*
Cinnamon (Northern) Teal *Spatula cyanoptera*
Common (European Green-Winged) Teal *Nettion crecca*
Common (Northern) Shoveler *Spatula clypeata*
Common (Northern) Pintail *Dafila acuta*
Cotton (Indian) Pygmy Goose (Cotton Teal) *Nettapus coromandelianus (albipennis)*
European (Eurasian) Wigeon *Mareca penelope*
Falcated Duck *Eunetta falcata*
Gadwall (Gray Duck) *Chaulelasmus streperus*
Garganey *Querquedula querquedula*
Green Pygmy Goose *Nettapus pulchellus*
Grey Teal (East Indian) *Nettion gibberifrons*
Hartlaub's Duck *Pteronetta hartlaubii*
Hottentot Teal *Punanetta hottentota*
Knob-billed (Old World Comb) Duck *Sarkidiornis melanotos*
Madagascan (Bernier's) Teal *Nettion bernieri*
Mandarin Duck *Dendronessa galericulata*
Muscovy Duck *Cairina moschata*
Red (Argentine) Shoveler *Spatula platalea*
Red-billed Pintail *Paecilonetta erythrorhyncha*
Ringed Teal *Callonetta leucophrys*
Silver (Northern) (Versicolor) Teal *Punanetta versicolor*
South American (Chilean Speckled) Teal *Nettion flavirostre*
White-winged Wood Duck *Asarcornis scutulatus*
Wood Duck (North American) (Carolina Duck) *Aix sponsa*

Tribe Anatini (Dabbling Ducks)

American (North) Black Duck *Anas fulvigula*
Blue (Mountain) Duck *Hymenolaimus malacorhynchos*
Bronze-winged (Spectacled) Duck *Speculanas specularis*
Crested (Patagonian) Duck *Lophonetta specularioides*
Falkland Flightless Steamer-Duck *Tachyeres brachypterus*
Flying Steamer Duck *Tachyeres patachonicus*
Grey Duck (New Zealand) *Anas superciliosa*
Hawaiian Duck (Koloa) *Anas wyvilliana*
Laysan Teal *Anas laysanenis*
Magellanic Flightless Steamer-Duck *Tachyeres pteneres*
Mallard (Northern) (Domestic) Duck (*Anas platyrhynchos*)
Marbled Teal *Marmaronetta angustirostris*
Meller's Duck *Anas melleri*
Philippine Duck *Anas luzonica*
Pink-eared (Zebra) Duck *Malacorhynchus membranaceus*
Salvadori's Duck *Salvadorina waigiuensis*
Spot-billed (Indian) Duck *Anas poecilorhyncha*
Torrent (Chilean) Duck *Merganetta armata*
Yellow-billed (South African) Duck *Anas undulata*

Tribe Aythya (Pochards)

Australasian (White-Eye) (Hardhead) Pochard *Aythya australis*
Baer's Pochard (Siberian White-Eye) *Aythya baeri*
Canvasback *Aythya valisineria*
Common (Ferruginous)(White-Eyed) Pochard *Aythya nyroca*
European (Eurasian) Pochard *Aythya ferina*
Greater (European) Scaup *Aythya marila*
Lesser Scaup *Aythya affinis*
Madagascan (White-Eye) Pochard *Aythya innotata*
New Zealand Scaup (Black Teal) *Aythya novaeseelandiae*
Pink-headed Duck *Rhodonessa caryophyllace*
Red-Crested Pochard *Netta rufina*
Redhead Duck *Aythya americana*
Ring-necked Duck *Aythya collaris*
Rosy-bill (Rosybilled) Pochard *Metopiana peposaca*
Southern (South American) Pochard *Phaeoaythia erythrophtalma*
Tufted Duck *Aythya fuligula*

Tribe Somteria (Eiders)

Common (European) Eider *Somateria mollissima*
King Eider *Somateria spectabilis*
Spectacled (Fischer's) Eider *Somateria fischeri*
Steller's Eider *Polysticta stelleri*

Tribe Merginia (Sea Ducks)

Auckland Island Merganser *Mergus australis*
Barrow's Goldeneye *Glaucionetta islandica*
Black (European) Scoter *Melanitta nigra*
Brazilian Merganser *Mergus octosetaceus*
Bufflehead *Bucephala albeola*
Common (European) Goldeneye *Glaucionetta clangula*
Goosander (Curasian) *Mergus merganser*
Harlequin (Atlantic) Duck *Histrionicus histrionicus*
Hooded Merganser *Lophodytes cucullatus*
Labrador Duck *Camptorhynchus labradorius*
Long-tailed (Oldsquaw) Duck *Clangula hyemalis*
Red-breasted (Common) Merganser *Mergus serrator*
Scaley-sided (Chinese) Merganser *Mergus squamatus*
Smew *Mergellus albellus*
Surf Scoter *Melanitta perspicillata*
White-winged (European) (Velvet) Scoter *Melanitti fusca*

Tribe Oxyurini (Stiff-Tailed Ducks)

Black-headed Duck *Heteronetta atricapilla*
Blue-billed (Australian) Duck *Oxyura australis*
Lake (Argentine) (Ruddy) (Blue-billed) Duck *Oxyura vittata*
Maccoa Duck *Oxyura maccoa*
Masked Duck *Oxyura dominica*
Musk Duck *Biziura lobata*
Ruddy Duck (North American) *Oxyura jamaicensis*
White headed Duck *Oxyura leucocephala*

RAPTORS

American Kestrel (Sparrow Hawk) *Tinnunculus sparverius*
Bald Eagle *Haliaeetus leucocephalus*
Barn Owl *Tyto alba*
Common (European) (Rock) Kestrel *Tinnunculus tinnunculus*
Common Buzzard *Buteo buteo*
Eagle Owl *Bubo bubo*
Eastern Turkey Vulture *Cathartes aura*
European Sparrow Hawk *Accipiter nisus*
Forest Eagle Owl *Bubo nipalensis*
Golden Eagle *Aquila chrysaetos*
Goshawk *Accipiter gentilis*
Great Horned Owl *Bubo virginianus*
Grey Eagle Buzzard *Geranoaetus melanoleucus*
Griffon Vulture *Gyps fulvus*
Little Owl *Athene noctua*
Long-eared Owl *Asio otus*
Merlin (Pigeon) Hawk *Aesalon columbarius*
Peregrine Falcon *Hierofalco peregrinus*
Prairie Falcon *Hierofalco mexicanus*
Red Kite *Milvus milvus*
Red-necked Falcon *Chiquera chiquera*
Rough-legged Buzzard *Buteo lagopus*
Saker Falcon *Hierofalco cherrug*
Screech Owl *Megascops asio*
Short-eared Owl *Asio flammeus*
Snowy Owl *Nyctea scandiaca*
South American Black-collared Hawk (Fishing Buzzard) *Busarellus nigricollis*
Striped Owl *Asio clamator*
Tengmalm's Owl *Aegolius funereus*
Ural Owl *Strix uralensis*

CICONIIFORMES

Black Stork *Ciconia nigra*
Cattle Egret *Bubulcus ibis*
Greater Adjutant Stork *Leptoptilos dubius*
Grey Heron *Ardea cinerea*
Hermit Ibis *Geronticus eremita*
Marabou Stork *Leptoptilos crumeniferus*
Night Heron (Black-Crowned) *Nycticorax nicticorax*
Striated Heron *Butorides striatus*
White Stork *Ciconia ciconia*
Yellow-crowned Night Heron *Nyctanassa violacea*

GALLIFORMES

Brush-Turkey *Alectura lathami*

Numidinae

Crested Guineafowl *Guttera pucherani*
Domestic Guineafowl *Numida meleagris forma domestica*
Helmeted Guineafowl *Numida meleagris*
Plumed Guineafowl *Guttera plumifera*
Vulturine Guineafowl *Acryllium vulturinum*

Pavoninae

Congo Peafowl *Afropavo congensis*
Green Peafowl *Pavo muticus*
Indian Peafowl *Pavo cristatus*

Meleagridinae

Common Turkey *Meleagris gallopavo*
Domestic Turkey *Meleagris gallopavo forma domestica*
Oscillated Turkey *Meleagris ocellata*

Argusianinae
Bronze-tailed Peacock-Pheasant *Polyplectron chalcurom*
Crested Argus *Rheinardia ocellata*
Great Argus *Argusianus argus*
Grey Peacock-Pheasant *Polyplectron bicalcaratum*
Palawan Peacock-Pheasant *Polyplectron emphanum*

Phasianinae
Bar-tailed Pheasant *Calophasis humiae*
Blue-eared Pheasant *Crossoptilon auritum*
Brown-eared Pheasant *Crossoptilon mantchuricum*
Bulwer's Wattled Pheasant *Lophura Bulweri*
Cheer Pheasant *Catreus wallichii*
Common (Ring-necked) Pheasant *Phasianus colchicus*
Copper Pheasant *Graphephasianus soemmeringii*
Elliot's Pheasant *Calophasis ellioti*
Golden Pheasant *Chrysolophus pictus*
Lady Amherst's Pheasant *Chrysolophus amherstiae*
Mikado Pheasant *Calophasis mikado*
Reeve's Pheasant *Syrmaticus reevesii*
Salvadori's Pheasant *Lophura inornata*
Siamese Fireback *Lophura diardi*
Silver Pheasant *Lophura nycthemera*
Swinhoe's Pheasant *Lophura swinhoii*

Lophophorinae
Himalayan Monal *Lophophorus impejanus*

Pucrasiinae
Koklass *Pucrasia macrolopha*

Ithagininae
Blood Pheasant *Ithaginis cruentus*

Gallinae
Domestic Fowl *Gallus gallus formadomestica*
Red Junglefowl *Gallus gallus*

Tragopaninae
Satyr Tragopan *Tragopan satyra*

Ptilopachinae
Stone Partridge *Ptilopachus petrosus*

Perdicinae
Black Francolin *Francolinus francolinus*
Chinese Bamboo Partridge *Bambusicola thoracica*
Chukar Partridge *Alectoris chukar*
Common Partridge *Perdix perdix*
Common Quail *Coturnix coturnix*
Himalayan Snowcock *Tetraogallus himalayensis*
Japanese Quail *Coturnix japonica*
Jungle Bush Quail *Perdicula asiatica*
Painted Quail *Coturnix chinensis*
Redlegged Partridge *Alectoris rufa*
Rock Partridge *Alectoris graeca*
Roulroul (Crested Wood Partridge) *Rollulus roulroul*

Odontophorinae
Bobwhite Quail *Colinus virginianus*
California Quail *Callipepla californica*
Gambel's Quail *Callipepla gambelii*
Scaled Quail *Callipepla squamata*

Tetraoninae
Black Grouse *Lyrurus tetrix*
Blue Grouse *Dendragapus obscurus*
Common Capercaillie *Tetrao urogallus*
Hazelhen (Common) *Tetrastes bonasia*
Prairie Chicken *Tympanuchus cupido*
Red Grouse *Lagopus lagopus scoticus*
Ruffed Grouse *Bonasa umbellus*
Sage Grouse *Centrocercus urophasianus*
Sharp-tailed Grouse *Tympanuchus phasianellus*
Spruce Grouse *Falcipennis canadensis*
Willow Ptarmigan (-Grouse) *Lagopus lagopus*

Cracidae
Black-billed Turaco *Tauraco schuetti*
Common Piping Guan *Aburria pipile*
Great Curassow *Crax rubra*
Guinea Turaco *Tauraco persa*
Helmeted (Northern) Curassow *Pauxi pauxi*
Lady Ross's Turaco *Musophaga rossae*
Purple-crested Turaco *Tauraco porphyreolophus*
Razor-billed Curassow *Mitu mitu*
Wattled Curassow *Crax globulosa*
White-crested Turaco *Tauraco leucolophus*

UPUPIFORMES
Hoopoe *Upupa epops*

CAPRIMULGIFORMES
Indian Edible-nest Swiftlet *Collocalia unicolor*
Quetzal *Pharomachrus mocinno*
Tawny Frogmouth *Podargus strigoides*

PASSERIFORMES
African Silverbill *Euodice cantans*
American Bare-eyed Thrush *Planesticus nudigenis*
American Goldfinch *Spinus tristis*
American Tree-Sparrow *Spizella arborea*
Antbirds and gnateaters *Formicariidae*
Apostle-bird *Struthidea cinerea*
Ashey (Brown-eared) Bulbul *Hemixos flavala*
Australian Magpie *Gymnorhina tibicen*
Avadavat (Strawberry-Finch, Red Munia) *Amandava amandava*
Barn-Swallow *Hirundo rustica*
Bearded Manakin *Manacus manacus*
Bengalese (Society) Finch *Lonchura domestic)*
Birds of Paradise *Paradisaeidae*
Black (Pied) (Pied Bell-Magpie) Currawong *Strepera graculina*
Black-eared Wheatear *Oenanthe hispanica*
Black-faced Cuckoo-Shrike *Coracina novaehollandiae*
Black-faced Babbler *Turdoides melanops*
Black-throated Grass-(Parson-)Finch *Poephila cincta*
Blackbird (Common) *Merula merula*
Blue jay *Cyanocitta cristata*
Blue Tit *Cyanistes caeruleus*
Blue Waxbill (Angola Cordon-bleu) *Uraeginthus angolensis*
Broad-tailed (Long-tailed) Paradise Whydah *Steganura interjecta*
Brown-headed Cowbird *Molothrus ater*
Brown Tree-Creeper *Climacteris picumnus*
Bushlark (Horsfield's, Cinnamon) *Mirafra javanica*
Canary *Serinus canaria*
Cape May Warbler *Dendroica tigrina*
Cardinal (Creasted) *Paroaria coronata*
Catbird *Dumetella carolinensis*
Cedar Waxwing *Bombycilla cedrorum*
Chaffinch *Fringilla coelebs*
Chatham Islands Robin (-Flycatcher) *Miro traversi*
Common Bullfinch *Pyrrhula pyrrhula*
Common Cardinal *Cardinalis cardinalis*
Common Raven *Corvus corax*
Cowbird *Molothrus aeneus*
Crested Lark *Galerida cristata*
Crested Oropendola *Psaracolius decumanus*
Crimson Finch *Neochmia phaeton*
Cuban (Grassquit) Finch *Tiaris canora*
Cutthroat Finch *Amadina fasciata*
Diamond Firetail (Diamond Sparrow) *Stagonopleura guttata*
Double-barred Finch *Stizoptera bichenovii*
Eastern Bluebird *Sialia sialis*
European Goldfinch *Carduelis carduelis*
European Robin *Erithacus rubecula*
Fox Sparrow *Passerella iliaca*
Glossy (Superb) Starling *Lamprospreo superbus*
Golden-collared Manakin *Manacus mvitellinus*
Golden-headed Manakin *Pipra erythrocephal*
Goldfinch *Carduelis carduelis*
Gouldian Finch *Chloebia gouldiae*
Great Tit *Parus major*
Green Avadavat *Stictospiza formosa*
Green Catbird *Ailuroedus crassirostris*
Greenfinch *Carduelis chloris*
Greenfinch *Chloris chloris*
Grey-headed Wheatear *Oenanthe moesta*
Hawaiian Crow *Corvus tropicus*
Hawfinch *Coccothraustes coccothraustes*
Hooded Siskin *Spinus magellanicus*
House Sparrow *Passer domesticus*
Jackdaw *Coleus monedula*
Java Sparrow (Rice Bird) *Padda oryzivora*
Large-billed Seed Finch (Suriname Finch, Twa twa's) *Oryzoborus crassirostris*
Long-tailed (Shaft-tailed) Grass-Finch *Poephila acuticauda*
Magpie *Pica pica*
Melba Finch (Grey-naped Pytilia) *Pytilia melba*
Mockingbird *Mimus polyglottos*
Mynah (Hill) birds *Gracula religiosa*
Nutmeg Mannikin (Spice-Finch) (Spotted Munia) (Rice-bird) *Lonchura punctulata*
Orange-cheeked Waxbill *Estrilda melpoda*
Painted Firetail *Emblema picta*
Pekin Robin *Leiothrix lutea*
Pied wagtail *Motacilla alba*
Pin-tailed Parrot-Finch *Erythrura prasina*
Purple Grackle *Quiscalus quiscula*
Red (hooded) Siskin *Spinus cucullatus*
Red-breasted Flycatcher *Erythrosterna parva*
Red-capped Manakin *Pipra mentalis*
Red-cheeked (Cordon-blue) Blue Waxbill *Uraeginthus bengalus*
Red-headed Barbet *Eubucco bourcierii*
Red Wattlebird *Anthochaera carunculata*
Red-winged Pytilia (American Aurora finch,Crimson-winged Waxbill) *Pytilia phoenicotera*
Rock Robin *Petroica archboldi*
Rook (European) *Corvus frugilegus*
Rothschild's (Bali) Myna *Leucospar rothschildi*
Rufous-sided Towhee *Pipilo erythrophthalmus*
Rufous-tailed Weaver *Histurgops ruficauda*
Siberian Rubythroat *Calliope calliope*
Silvereye *Zosterops lateralis*
Siskin (Euroasian) *Spinus spinus*
Sky-lark *Alauda arvensis*
Spotted Pardalote *Pardalotus punctatus*
Starling (Common) *Sturnus vulgaris*
Superb Lyrebird *Menura novaehollandiae*
Swainson's (Olive-backed) Thrush *Catharus ustulatus*
Tree Sparrow (Eurasian) *Passer montanus*
Ultramarine Grosbeak *Cyanoloxia cyanea*
Vesper Sparrow *Pooecetes gramineus*
Violaceous Euphonia *Euphonia violacea*
Waxwing (Bohemian) *Bombycilla garrulus*
Weebill *Smicrornis brevirostris*
Welcome Swallow *Hirundo neoxena*
White-rumpted Canary *Ochrospiza leucopygia*
White-throated Sparrow *Zonotrichia albicollis*
Wood Thrush *Hylocichla mustelina*
Yellow-backed (Orange-winged) Pytilia (Red-faced Waxbill) *Pytilie afra*
Yellow-tufted (Helmeted) honeyeater *Lichenostomus melanops race cassidex*
Zebra Finch *Taeniopygia guttata*

II

Determination of Metabolic Scaling

Step-by-step Technique for Determining Metabolic Scaling

Harrison G.

One may determine the quantity of an enteral nutritional product for a bird from information supplied in Chapter 15. This mathematical calculation requires a scientific calculator. The following is offered to assist one not familiar with such calculations.

Required Data and Formulas

$BMR = K(W_{kg}^{0.75})$ = Basic Metabolic Rate.

K = a theoretical constant for kcal required per 24 hours and varies with the species of bird. K is 129 for passerines and 78 for non-passerines.

MER = 1.5 X BMR = Metabolizable Energy Requirement.

W_{kg} is the weight of the bird in kg.

To determine the BMR:

1. Divide the bird's weight in grams by 1000 to determine the W_{kg}.
2. With this number entered in the calculator, press the y^x function key.
3. Input 0.75. Then push =.
4. Multiply the number determined in step 3 by the K value for the bird (78 if it is a psittacine bird).
5. This number is the BMR for the patient in kcal/day.

To determine the quantity of enteral nutrient required:

1. Multiply the calculated BMR by 1.5.
2. This number is the MER in kcal per day.
3. Determine the total kcal/day of nutrients required, by multiplying the MER by the stress factor (see Table 15.4).
4. Determine the mls/day of enteral nutrient to use (see Table 15.5) by dividing the value determined in line 3 by the Calories (kcal)/ml in the enteral formula selected.
   a. Example: ISO cal contains 1 kcal/ml. The value determined in line 3 would be divided by 1 and the resulting number would be the ml/day of this product that the patient should receive.
   b. Example: ISO cal HCN contains 2 kcal/ml. The value determined in line 3 would be divided by 2 and the resulting number would be the ml/day of this product that the patient should receive.
5. The volume of enteral formula/feeding is determined by dividing the total number of mls required (answer from line 4) by the number of feedings per day (generally four to six).
