Cardiac dysfunction due to primary myocarditis is presumed to be caused by either an acute viral infection or a postviral immune response. Secondary myocarditis is the result of inflammation caused by nonviral pathogens, drugs, chemicals, physical agents, or inflammatory diseases such as systemic lupus erythematosus. The list of infectious causes of myocarditis is extensive and includes viruses with DNA and RNA cores. The coxsackie virus is the predominant agent, but many others have been implicated. Rickettsial myocarditis occurs with scrub typhus, Rocky Mountain spotted fever, and Q fever. Diphtheritic myocarditis is caused by the exotoxin and is often manifested by conduction abnormalities as well as heart failure.

Chagas disease, caused by the insect-borne protozoan *Trypanosoma cruzi*, is a common form of myocarditis in Central and South America; the major clinical manifestations appear after a latent period of more than a decade. At this stage, patients present with cardiomyopathy, conduction disturbances, and sudden death. Associated gastrointestinal involvement (megaesophagus and megacolon) is the rule. Toxoplasmosis causes myocarditis that is usually asymptomatic but can lead to heart failure. Among parasitic infections, trichinosis is the most common cause of cardiac involvement. HIV virus can cause myocarditis, though the prevalence of this complication is not known and it appears related to the level of viral load and CD4 count. In addition, other infectious causes of myocarditis are more common in patients with AIDS. A list of infectious causes of myocarditis is shown in Table 10–11.

Giant cell myocarditis is a rare idiopathic disorder characterized by giant cell and lymphocyte infiltration of the heart muscle. Patients usually die of ventricular arrhythmias or heart failure but occasionally respond to immunosuppressive therapy or early transplantation.

▶ Clinical Findings

A. Symptoms and Signs

Patients may present several days to a few weeks after the onset of an acute febrile illness or a respiratory infection or with heart failure without antecedent symptoms. The onset of heart failure may be gradual or may be abrupt and fulminant. Emboli may occur. Pleural-pericardial chest pain is common. Examination reveals tachycardia, gallop rhythm, and other evidence of heart failure or conduction defect. Many acute infections are subclinical, though they may present later as idiopathic cardiomyopathy or with ventricular arrhythmias. At times, the presentation may mimic an acute myocardial infarction with ST changes, positive cardiac markers, and regional wall motion abnormal-

MYOCARDITIS & THE CARDIOMYOPATHIES

INFECTIOUS MYOCARDITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Often follows an upper respiratory infection.

Modified, with permission, from Pisani B et al. Inflammatory myocardial disease and cardiomyopathies. *Am J Med.* 1997 May;102(5):459–69.

malities despite normal coronaries. Microaneurysms may also occur and may be associated with serious ventricular arrhythmias. Patients may present in a variety of ways with fulminant, subacute, or chronic myocarditis.

B. ECG and Chest Radiography

ECG may show sinus tachycardia, other arrhythmias, non-specific repolarization changes, and intraventricular conduction abnormalities. Ventricular ectopy may be the initial and only clinical finding. Chest radiograph is non-specific, but cardiomegaly is frequent, though not universal. Evidence for pulmonary venous hypertension is common and frank pulmonary edema may be present.

C. Diagnostic Studies

There is no specific laboratory study that is consistently present, though the white blood cell count is usually elevated and the sedimentation rate may increase. Troponin I levels are elevated in about one-third of patients, but CK-MB is elevated in only 10%. Echocardiography provides the most convenient way of evaluating cardiac function and can exclude many other processes. Gallium-67 scintigraphy may reveal increased cardiac uptake in acute or subacute myocarditis, but it is not very sensitive. MRI with gadolinium enhancement reveals spotty areas of injury throughout the myocardium. Paired serum viral titers and serologic tests for other agents may indicate the cause.

D. Endomyocardial Biopsy

Pathologic examinations may reveal a lymphocytic inflammatory response with necrosis, but the patchy distribution of abnormalities makes this relatively insensitive. By biopsy, the diagnosis of myocarditis has been established by the 1986 “Dallas” criteria. The diagnosis is dependent on describing the severity of an inflammatory infiltrate with necrosis and degeneration of adjacent myocytes. The type of infiltrate is dependent on the causal agent; usually this is lymphocytic in viral disease, but it may be neutrophilic, eosinophilic, giant cell, granulomatous, or mixed.

▶ Treatment & Prognosis

Patients with fulminant myocarditis may present with acute cardiogenic shock. Their ventricles are usually not dilated, but thickened (possibly due to myoedema). There is a high death rate, but if the patients recover, they are usually left with no residual cardiomyopathy. Patients who present with subacute disease have a dilated cardiomyopathy and generally make an incomplete recovery. Those who present with chronic disease tend to have only mild dilation of the LV and eventually present with a more restrictive cardiomyopathy.

Specific antimicrobial therapy is indicated when an infecting agent is identified. All patients should receive standard heart failure therapy and have arrhythmias suppressed. Exercise should be limited during the recovery phase. Some believe digoxin should be avoided. Immunosuppressive therapy with corticosteroids and intravenous immunoglobulins may improve the outcome when the process is acute (< 6 months) and if the biopsy suggests ongoing inflammation. However, controlled trials have not been positive, so the value of routine myocardial biopsies in patients presenting with an acute myocarditic picture is uncertain; immunosuppressive therapy without histologic confirmation is clearly unwise, and there are few data to support its use. Patients with fulminant myocarditis require aggressive short-term support including an IABP or an LV assist device. Ongoing studies are addressing whether patients with giant cell myocarditis may be responsive to immunosuppressive agents, as a special case. Overall, if improvement does not occur, many patients may be eventual candidates for cardiac transplantation.

DRUG-INDUCED & TOXIC MYOCARDITIS

A variety of medications, illicit drugs, and toxic substances can produce acute or chronic myocardial injury; the clinical presentation varies widely. Doxorubicin and other cytotoxic agents, emetine, and catecholamines (especially with pheochromocytoma) can produce a pathologic picture of inflammation and necrosis together with clinical heart failure and arrhythmias; toxicity of the first two is dose related. The phenothiazines, lithium, chloroquine, disopyramide, antimony-containing compounds, and

arsenicals can also cause ECG changes, arrhythmias, or heart failure. Hypersensitivity reactions to sulfonamides, penicillins, and aminosalicic acid as well as other drugs can result in cardiac dysfunction. Radiation can cause an acute inflammatory reaction as well as a chronic fibrosis of heart muscle, usually in conjunction with pericarditis.

The incidence of cocaine cardiotoxicity has increased markedly. Cocaine can cause coronary artery spasm, myocardial infarction, arrhythmias, and myocarditis. Because many of these processes are believed to be mediated by cocaine's inhibitory effect on norepinephrine reuptake by sympathetic nerves, β -blockers have been used therapeutically. In documented coronary spasm, calcium channel blockers and nitrates may be effective.

DILATED CARDIOMYOPATHY

ESSENTIALS OF DIAGNOSIS

- ▶ Symptoms and signs of heart failure.
- ▶ Echocardiogram confirms LV dilation, thinning, and global dysfunction.

General Considerations

The cardiomyopathies are a heterogeneous group of entities affecting the myocardium primarily and not associated with the major causes of cardiac disease, ie, ischemic heart disease, hypertension, pericardial disease, valvular disease, or congenital defects. More recently, two additional entities have been added to the list: a transient cardiomyopathy due to high catecholamine discharge (Tako-Tsubo cardiomyopathy, see below) and an embryologic defect resulting in massive trabeculation in the LV (ventricular noncompaction). Although some have specific causes, many cases are idiopathic. The classification of cardiomyopathies is based on features of presentation and pathophysiology (Table 10–12).

Dilated cardiomyopathies cause about 25% of all cases of CHF. It usually presents with symptoms and signs of CHF (most commonly dyspnea). Occasionally, symptomatic ventricular arrhythmias are the presenting event. LV dilation and systolic dysfunction (EF < 50%) are essential for diagnosis. Dilated cardiomyopathy occurs more often in blacks than whites and in men more than women. A growing number of cardiomyopathies due to genetic abnormalities are being recognized, and these may represent up to 25–30% of cases. Often no cause can be identified, but chronic alcohol abuse and unrecognized myocarditis are probably frequent causes. There is increasing recognition that chronic tachycardia may also precipitate a dilated cardiomyopathy that may improve over time if rate control can be achieved. Amyloidosis, sarcoidosis, hemochromatosis, and diabetes may rarely present as dilated cardiomyopathies, as well as the more classic restrictive picture. The RV may be primarily involved in arrhythmogenic RV dysplasia, an unusual cardiomyopathy with displacement of myocar-

Table 10–12. Classification of the cardiomyopathies.

| | Dilated | Hypertrophic | Restrictive |
|--------------------------------------|--|--|---|
| Frequent causes | Idiopathic, alcoholic, major catecholamine discharge, myocarditis, postpartum, doxorubicin, endocrinopathies, genetic diseases | Hereditary syndrome, possibly chronic hypertension | Amyloidosis, post-radiation, post-open heart surgery, diabetes, endomyocardial fibrosis |
| Symptoms | Left or biventricular congestive heart failure | Dyspnea, chest pain, syncope | Dyspnea, fatigue, right-sided congestive heart failure |
| Physical examination | Cardiomegaly, S_3 , elevated jugular venous pressure, rales | Sustained point of maximal impulse, S_4 , variable systolic murmur, bisferiens carotid pulse | Elevated jugular venous pressure, Kussmaul sign |
| Electrocardiogram | ST-T changes, conduction abnormalities, ventricular ectopy | Left ventricular hypertrophy, exaggerated septal Q waves | ST-T changes, conduction abnormalities, low voltage |
| Chest radiograph | Enlarged heart, pulmonary congestion | Mild cardiomegaly | Mild to moderate cardiomegaly |
| Echocardiogram, nuclear studies, MRI | Left ventricular dilation and dysfunction | Left ventricular hypertrophy, asymmetric septal hypertrophy, small left ventricular size, normal or supranormal function, systolic anterior mitral motion, diastolic dysfunction | Small or normal left ventricular size, normal or mildly reduced left ventricular function |
| Cardiac catheterization | Left ventricular dilation and dysfunction, high diastolic pressures, low cardiac output | Small, hypercontractile left ventricle, dynamic outflow gradient, diastolic dysfunction | High diastolic pressure, "square root" sign, normal or mildly reduced left ventricular function |

dial cells by adipose tissue, or in Uhl disease, in which there is extreme thinning of the RV walls.

Dilated cardiomyopathy can now be considered a disease that results from more varied perturbations, including, but not limited to, defects of the cytoskeleton. Positional cloning and candidate gene approaches have been successful in identifying greater than 40 disease loci, many of which have led to disease genes in hypertrophic cardiomyopathy, restrictive cardiomyopathy, dilated cardiomyopathy, and arrhythmogenic right ventricular dysplasia. This exciting area is only now being explored. Since most dilated cardiomyopathies are considered “idiopathic,” the potential for discovery of a genetic predisposition seems very promising.

Intraventricular thrombus is not uncommon in dilated cardiomyopathy. Histologically, the picture is one of extensive fibrosis unless a specific diagnosis is established. Myocardial biopsy is rarely useful in establishing the diagnosis, though occasionally the underlying cause (eg, sarcoidosis, hemochromatosis) can be discerned. Biopsy is most useful in transplant rejection.

► Clinical Findings

A. Symptoms and Signs

In most patients, symptoms of heart failure develop gradually. The physical examination reveals rales, an elevated JVP, cardiomegaly, S₃ gallop rhythm, often the murmurs of functional mitral or tricuspid regurgitation, peripheral edema, or ascites. In severe CHF, Cheyne-Stokes breathing, pulsus alternans, pallor, and cyanosis may be present.

B. ECG and Chest Radiography

The major findings are listed in Table 10–12. Sinus tachycardia is common. Other common abnormalities include left bundle branch block and ventricular or atrial arrhythmias. The chest radiograph reveals cardiomegaly, evidence for left and/or right heart failure, and pleural effusions (right > left).

C. Diagnostic Studies

An echocardiogram is indicated to exclude unsuspected valvular or other lesions and confirm the presence of dilated cardiomyopathy and reduced systolic function (as opposed to pure diastolic heart failure). Mitral Doppler inflow patterns also help in the diagnosis of associated diastolic dysfunction. Color flow Doppler can reveal tricuspid or mitral regurgitation, and continuous Doppler can help define PA pressures. Exercise or pharmacologic stress myocardial perfusion imaging may suggest the possibility of underlying coronary disease. Radionuclide ventriculography provides a noninvasive measure of the EF and both RV and LV wall motion. Cardiac MRI is particularly helpful in infiltrative processes, such as sarcoidosis or hemochromatosis, and is the diagnostic study of choice for RV dysplasia. MRI can also help define an ischemic etiology by noting gadolinium enhancement consistent with myocardial scar. Cardiac catheterization is seldom of specific value unless myocardial ischemia or LV aneurysm is

suspected. The serum ferritin is an adequate screening study for hemochromatosis. The erythrocyte sedimentation rate may be low due to liver congestion if right heart failure is present. The serum level of BNP or pro-BNP can be used to help quantitate the severity of CHF.

► Treatment

Standard therapy for heart failure should include ACE inhibitor, β -blockers, diuretics, and an aldosterone antagonist. Digoxin is a second-line drug but remains favored as an adjunct by some clinicians. Calcium channel blockers should generally be avoided unless absolutely necessary for rate control in atrial fibrillation. Sodium restriction is helpful, especially in acute CHF. When atrial fibrillation is present, heart rate control is important if sinus rhythm cannot be established or maintained. Many patients may be candidates for cardiac synchronization therapy with biventricular pacing and an implantable defibrillator. Few cases of cardiomyopathy are amenable to specific therapy for the underlying cause. Alcohol use should be discontinued, since there is often marked recovery of cardiac function following a period of abstinence in alcoholic cardiomyopathy. Endocrine causes (thyroid dysfunction, acromegaly, and pheochromocytoma) should be treated. Immunosuppressive therapy is not indicated in chronic dilated cardiomyopathy. The management of CHF is outlined in the section on heart failure.

► Prognosis

The prognosis of dilated cardiomyopathy without clinical heart failure is variable, with some patients remaining stable, some deteriorating gradually, and others declining rapidly. Once heart failure is manifest, the natural history is similar to that of other causes of heart failure, with an annual mortality around 11–13%. Arterial and pulmonary emboli are more common in dilated cardiomyopathy than in ischemic cardiomyopathy. Suitable candidates may benefit from long-term anticoagulation, and all patients with atrial fibrillation should be so treated. Some patients may be candidates for cardiac transplantation.

► When to Refer

- Referral to a cardiologist is warranted when there is any question about the etiology of the reduced systolic function.
- Essentially all patients with a dilated cardiomyopathy need to have a coronary evaluation to exclude an underlying ischemic cause that might be treatable.
- Referral should also be considered when heart failure symptoms emerge, especially if there is a possibility the patient may eventually be a cardiac transplant candidate.

TAKO-TSUBO CARDIOMYOPATHY

ESSENTIALS OF DIAGNOSIS

- ▶ Occurs after a major catecholamine discharge.
- ▶ Acute chest pain or shortness of breath.
- ▶ Predominately affects postmenopausal women.
- ▶ Presents as an acute anterior myocardial infarction, but coronaries normal at cardiac catheterization.
- ▶ Imaging reveals apical left ventricular ballooning due to anteroapical stunning of the myocardium.

▶ General Considerations

LV apical ballooning can follow a high catecholamine stress. The resulting shape of the LV suggests a rounded ampulla form similar to a Japanese octopus pot (takotsubo pot). Mid-ventricular ballooning is also seen on occasion. The acute myocardial injury is more common in postmenopausal women. It has been described following some stressful event, such as hypoglycemia, lightning strikes, earthquakes, postventricular tachycardia, during alcohol withdrawal, following surgery, during hyperthyroidism, and following emotional stress.

▶ Clinical Findings

A. Symptoms and Signs

The symptoms are similar to any acute coronary syndrome. Typical angina and dyspnea is usually present. Syncope is rare.

B. ECG and Chest Radiography

The ECG reveals ST segment elevation as well as deep anterior T wave inversion. The chest radiograph is either normal or reveals pulmonary congestion. The dramatic T wave inversions gradually resolve over time.

C. Diagnostic Studies

The echocardiogram reveals LV apical dyskinesia. The urgent cardiac catheterization reveals the LV apical ballooning in association with normal coronaries. Initial cardiac enzymes are positive but often taper quickly.

▶ Treatment

Immediate therapy is similar to any acute myocardial infarction. Initiation of long-term therapy depends on whether LV

dysfunction persists. Most patients receive aspirin, β -blockers, and ACE-inhibitors until the LV fully recovers.

▶ Prognosis

Prognosis is good unless there is a serious complication (such as mitral regurgitation, ventricular rupture, ventricular tachycardia). Recovery is expected in most cases after a period of weeks to months. At times, the LV function recovers in days.

HYPERTROPHIC CARDIOMYOPATHY

ESSENTIALS OF DIAGNOSIS

- ▶ May present with dyspnea, chest pain, syncope.
- ▶ Though LV outflow gradient is classic, symptoms are primarily related to diastolic dysfunction.
- ▶ Echocardiogram shows septal hypertrophy, which is usually asymmetric, and enhanced contractility. Systolic anterior motion of the anterior mitral valve is present if there is outflow tract obstruction.
- ▶ The highest risk group for sudden death includes those with a marked LVH, with a family history for sudden death, with ventricular ectopy, and with an abnormal BP response to exercise.

▶ General Considerations

Myocardial hypertrophy unrelated to any pressure or volume overload reduces LV systolic stress, increases the EF, and can result in an “empty ventricle” at end-systole. The interventricular septum may be disproportionately involved (asymmetric septal hypertrophy), but in some cases the hypertrophy is localized to mid ventricle or to the apex. The LV outflow tract is often narrowed during systole between the bulging septum and an anteriorly displaced anterior mitral valve leaflet, causing a dynamic obstruction. The obstruction is worsened by factors that increase myocardial contractility (sympathetic stimulation, digoxin, postextrasystolic beat) or that decrease LV filling (Valsalva maneuver, peripheral vasodilators). The amount of obstruction is preload and afterload dependent and can vary from day to day. The consequence of the hypertrophy is elevated diastolic pressures rather than systolic dysfunction. Rarely, systolic dysfunction develops late in the disease. The LV is usually more involved than the RV and the atria are frequently significantly enlarged. It has been increasingly appreciated that hypertrophic obstructive cardiomyopathy (HOCM) is inherited as an autosomal dominant trait with variable penetrance and is caused by mutations of one of a large

number of genes, most of which code for myosin heavy chains or proteins regulating calcium handling. The prognosis is related to the specific gene mutation. These patients usually present in early adulthood. Elite athletes may demonstrate considerable hypertrophy that can be confused with HOCM, but generally diastolic dysfunction is not present. The apical variety is particularly common in those of Asian descent. A mid-ventricular obstructive form is also known. A hypertrophic cardiomyopathy in the elderly (usually in association with hypertension) has also been defined as a distinct entity. Mitral annular calcification is often present.

► Clinical Findings

A. Symptoms and Signs

The most frequent symptoms are dyspnea and chest pain (Table 10–12). Syncope is also common and is typically postexertional, when diastolic filling diminishes and outflow obstruction increases. Arrhythmias are an important problem. Atrial fibrillation is a long-term consequence of chronically elevated LA pressures and is a poor prognostic sign. Ventricular arrhythmias are also common, and sudden death may occur, often in athletes after extraordinary exertion.

Features on physical examination are a bisferiens carotid pulse, triple apical impulse (due to the prominent atrial filling wave and early and late systolic impulses), and a loud S_4 . The JVP may reveal a prominent a wave due to reduced RV compliance. In cases with outflow obstruction, a loud systolic murmur is present along the left sternal border that increases with upright posture or Valsalva maneuver and decreases with squatting. These maneuvers help differentiate the murmur of HOCM from that of aortic stenosis. Mitral regurgitation is frequently present as well.

B. ECG and Chest Radiography

LVH is nearly universal in symptomatic patients, though entirely normal ECGs are present in up to 25%, usually in those with localized hypertrophy. Exaggerated septal Q waves inferolaterally may suggest myocardial infarction. The chest radiograph is often unimpressive. Unlike aortic stenosis, the ascending aorta is not dilated.

C. Diagnostic Studies

The echocardiogram is diagnostic, revealing asymmetric LVH, systolic anterior motion of the mitral valve, early closing followed by reopening of the aortic valve, a small and hypercontractile LV, and delayed relaxation and filling of the LV during diastole. The septum is usually 1.3–1.5 times the thickness of the posterior wall. Septal motion tends to be reduced. Doppler ultrasound reveals turbulent flow and a dynamic gradient in the LV outflow tract and, commonly, mitral regurgitation. Abnormalities in the diastolic filling pattern are present in 80% of patients. Myocardial perfusion imaging may suggest septal ischemia in the presence of normal coronary arteries. Cardiac MRI confirms the hypertrophy and contrast enhancement frequently reveals evidence for scar at the junction of the RV attachment to the septum. Cardiac catheterization confirms the diagnosis and assesses

the presence of CAD. Frequently, coronary arterial bridging (squeezing in systole) occurs, especially of the septal arteries.

► Treatment

β -Blockers should be the initial drug in symptomatic individuals, especially when dynamic outflow obstruction is noted on the echocardiogram. The resulting slower heart rates assist with diastolic filling of the stiff LV. Dyspnea, angina, and arrhythmias respond in about 50% of patients. Calcium channel blockers, especially verapamil, have also been effective in symptomatic patients. Their effect is due primarily to improved diastolic function, but their vasodilating actions can also increase outflow obstruction and cause hypotension. Disopyramide (Norpace) is also used because of its negative inotropic effects; it is usually used in addition to the other therapies. Diuretics are frequently necessary due to the high diastolic pressure and PCWP. Patients do best in sinus rhythm, and atrial fibrillation should be aggressively treated with antiarrhythmics. Dual-chamber pacing may prevent the progression of hypertrophy and obstruction. Nonsurgical septal ablation has been performed by injection of alcohol into septal branches of the left coronary artery with good results in small series of patients. Patients with malignant ventricular arrhythmias and unexplained syncope in the presence of a positive family history for sudden death are probably best managed with an implantable defibrillator. Excision of part of the outflow myocardial septum (myotomy–myomectomy) by surgeons experienced with the procedure has been successful in patients with severe symptoms. A few surgeons advocate mitral valve replacement, as this results in resolution of the gradient as well, and prevents associated mitral regurgitation.

► Prognosis

The natural history of HOCM is highly variable. Several specific mutations are associated with a higher incidence of early malignant arrhythmias and sudden death, and definition of the genetic abnormality provides the best estimate of prognosis. Some patients remain asymptomatic for many years or for life. Sudden death, especially during exercise, may be the initial event. The **highest risk patients** are those with a family history of sudden death, those with marked hypertrophy, and those that do not increase their systemic BP with exercise. HOCM is the pathologic feature most frequently associated with sudden death in athletes. Pregnancy is generally well tolerated. Endocarditis prophylaxis is no longer indicated. A final stage may be a transition into dilated cardiomyopathy in 5–10% of patients due to the long-term effects of LV remodeling.

► When to Refer

Patients should be referred to a cardiologist when symptoms are difficult to control, syncope has occurred, or there are any of the high-risk features present as noted above.

RESTRICTIVE CARDIOMYOPATHY

ESSENTIALS OF DIAGNOSIS

- ▶ Right heart failure tends to dominate over left heart failure.
- ▶ Pulmonary hypertension present.
- ▶ Amyloidosis is the most common cause.
- ▶ Echocardiography is key to diagnosis. Rapid early filling is present with diastolic dysfunction. Normal or near normal EF.
- ▶ MRI and cardiac catheterization are helpful. Myocardial biopsy can confirm.

▶ General Considerations

Restrictive cardiomyopathy is characterized by impaired diastolic filling with reasonably preserved contractile function. The condition is relatively uncommon, with the most frequent cause being amyloidosis. In Africa, endomyocardial fibrosis, a specific entity in which there is severe fibrosis of the endocardium, often with eosinophilia (Löffler syndrome), is seen. Other causes of restrictive cardiomyopathy are infiltrative cardiomyopathies (eg, hemochromatosis, sarcoidosis) and connective tissue diseases (eg, scleroderma).

▶ Clinical Findings

A. Symptoms and Signs

Restrictive cardiomyopathy must be distinguished from constrictive pericarditis (Table 10–12). The key feature is that ventricular interaction is accentuated with respiration in constrictive pericarditis, and that interaction is absent in restrictive cardiomyopathy. Pulmonary pressure is invariably elevated in restrictive cardiomyopathy due to the high pulmonary capillary wedge pressure and is normal in uncomplicated constrictive pericarditis.

B. Diagnostic Studies

Conduction disturbances are frequently present. Low voltage on the ECG combined with ventricular hypertrophy on the echocardiogram is suggestive of disease. Cardiac MRI presents a distinctive pattern of hyper-enhancement of the gadolinium image in amyloidosis and is a useful screening test. The echocardiogram reveals a small

thickened LV with bright myocardium, rapid early diastolic filling revealed by the mitral inflow Doppler, and biatrial enlargement. Atrial septal thickening may be evident. Rectal, abdominal fat, or gingival biopsies can confirm systemic involvement, but myocardial involvement may still be present if these are negative, and requires endomyocardial biopsy for the confirmation of cardiac amyloid. Demonstration of tissue infiltration on biopsy specimens using special stains followed by immunohistochemical studies and genetic testing is essential to define which specific protein is involved.

▶ Treatment

Unfortunately, little useful therapy is available for either the causative conditions or the restrictive cardiomyopathy itself. Diuretics can help, but excessive diuresis can produce worsening kidney dysfunction. As with most patients with severe right heart failure, loop diuretics, thiazides, and aldosterone antagonists are all useful. Recently, the use of ultrafiltration devices have allowed for improved diuresis. Digoxin may precipitate arrhythmias and generally should not be used. β -Blockers help slow heart rates and improve filling. Corticosteroids may be helpful in sarcoidosis but they are more effective for the conduction abnormalities than heart failure. In amyloidosis, the therapeutic strategy depends on the characterization of the type of amyloid protein and extent of disease and may include chemotherapy or bone marrow transplantation. In familial amyloidosis liver transplantation may be an option. Cardiac transplantation has also been used in patients with primary cardiac amyloidosis.

▶ When to Refer

All patients with the diagnosis of a restrictive cardiomyopathy should be referred to a cardiologist to decide etiology and plan appropriate treatment. This is especially true if amyloidosis is suspected.

ACUTE RHEUMATIC FEVER & RHEUMATIC HEART DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Uncommon in the United States (approximately 2 cases/100,000 population); more common (100 cases/100,000 population) in developing countries.
- ▶ Peak incidence ages 5–15 years.

- ▶ **Diagnosis based on Jones criteria and confirmation of streptococcal infection.**
- ▶ **May involve mitral and other valves acutely, rarely leading to heart failure.**

▶ General Considerations

Rheumatic fever is a systemic immune process that is a sequela to β -hemolytic streptococcal infection of the pharynx. Pyodermic infections are not associated with rheumatic fever. Signs of rheumatic fever usually commence 2–3 weeks after infection but may appear as early as 1 week or as late as 5 weeks. In recent years, the disease has become quite uncommon in the United States, except in immigrants; however, there have been reports of new outbreaks in several regions of the United States. The peak incidence is between ages 5 and 15 years; rheumatic fever is rare before age 4 years or after age 40 years. Rheumatic carditis and valvulitis may be self-limited or may lead to slowly progressive valvular deformity. The characteristic lesion is a perivascular granulomatous reaction with vasculitis. The mitral valve is attacked in 75–80% of cases, the aortic valve in 30% (but rarely as the sole valve), and the tricuspid and pulmonary valves in under 5% of cases.

Chronic rheumatic heart disease results from single or repeated attacks of rheumatic fever that produce rigidity and deformity of valve cusps, fusion of the commissures, or shortening and fusion of the chordae tendineae. Stenosis or insufficiency results, and the two often coexist. The mitral valve alone is affected in 50–60% of cases; combined lesions of the aortic and mitral valves occur in 20%; pure aortic lesions are less common. Tricuspid involvement occurs in about 10% of cases but only in association with mitral or aortic disease and is thought to be more common when recurrent infections have occurred. The pulmonary valve is rarely affected. A history of rheumatic fever is obtainable in only 60% of patients with rheumatic heart disease.

▶ Clinical Findings

The diagnostic criteria first described by Jones were updated in 1992. The presence of two major criteria—or one major and two minor criteria—establishes the diagnosis. Echocardiographic studies revealing valvular abnormalities have suggested that subclinical cardiac involvement may be missed using the strict Jones criteria. India, New Zealand, and Australia have all published revised guidelines.

A. Major Criteria

1. Carditis—Carditis is most likely to be evident in children and adolescents. Any of the following suggests the presence of carditis: (1) pericarditis; (2) cardiomegaly, detected by physical signs, radiography, or echocardiography; (3) CHF, right- or left-sided—the former perhaps more prominent in children, with painful liver engorgement due to tricuspid regurgitation; and (4) mitral or aortic regurgitation murmurs, indicative of dilation of a valve ring with or without associated valvulitis. The Carey–Coombs short mid-diastolic mitral murmur may be present.

In the absence of any of the above definitive signs, the diagnosis of carditis depends on the following less specific abnormalities: (1) ECG changes, including changing contour of P waves or inversion of T waves; (2) changing quality of heart sounds; and (3) sinus tachycardia, arrhythmia, or ectopic beats.

2. Erythema marginatum and subcutaneous nodules—Erythema marginatum begins as rapidly enlarging macules that assume the shape of rings or crescents with clear centers. They may be raised, confluent, and either transient or persistent.

Subcutaneous nodules are uncommon except in children. They are small (≤ 2 cm in diameter), firm, and nontender and are attached to fascia or tendon sheaths over bony prominences. They persist for days or weeks, are recurrent, and are indistinguishable from rheumatoid nodules.

3. Sydenham chorea—Sydenham chorea—involuntary choreoathetoid movements primarily of the face, tongue, and upper extremities—may be the sole manifestation; only 50% of cases have other overt signs of rheumatic fever. Girls are more frequently affected, and occurrence in adults is rare. This is the least common (3% of cases) but most diagnostic of the manifestations of rheumatic fever.

4. Polyarthritides—This is a migratory polyarthritides that involves the large joints sequentially. In adults, only a single joint may be affected. The arthritis lasts 1–5 weeks and subsides without residual deformity. Prompt response of arthritis to therapeutic doses of salicylates or nonsteroidal agents is characteristic.

B. Minor Criteria

These include fever, polyarthralgias, reversible prolongation of the PR interval, and an elevated erythrocyte sedimentation rate or CRP. Supporting evidence includes positive throat culture or rapid streptococcal antigen test and elevated or rising streptococcal antibody titer.

C. Laboratory Findings

There is nonspecific evidence of inflammatory disease, as shown by a rapid sedimentation rate. High or increasing titers of antistreptococcal antibodies (antistreptolysin O and anti-DNase B) are used to confirm recent infection; 10% of cases lack this serologic evidence.

▶ Differential Diagnosis

Rheumatic fever may be confused with the following: rheumatoid arthritis, osteomyelitis, endocarditis, chronic meningococcemia, systemic lupus erythematosus, Lyme disease, sickle cell anemia, “surgical abdomen,” and many other diseases.

▶ Complications

CHF occurs in severe cases. In the longer term, the development of rheumatic heart disease is the major problem. Other complications include arrhythmias, pericarditis with effusion, and rheumatic pneumonitis.

▶ Treatment

A. General Measures

The patient should be kept at strict bed rest until the temperature returns to normal (without the use of antipyretic medications) and the sedimentation rate, plus the resting pulse rate, and the ECG have all returned to baseline.

B. Medical Measures

1. Salicylates—The salicylates markedly reduce fever and relieve joint pain and swelling. They have no effect on the natural course of the disease. Adults may require large doses of aspirin, 0.6–0.9 g every 4 hours; children are treated with lower doses.

2. Penicillin—Penicillin (benzathine penicillin, 1.2 million units intramuscularly once, or procaine penicillin, 600,000 units intramuscularly daily for 10 days) is used to eradicate streptococcal infection if present. Erythromycin may be substituted (40 mg/kg/d).

3. Corticosteroids—There is no proof that cardiac damage is prevented or minimized by corticosteroids. A short course of corticosteroids (prednisone, 40–60 mg orally daily, with tapering over 2 weeks) usually causes rapid improvement of the joint symptoms and is indicated when response to salicylates has been inadequate.

▶ Prevention of Recurrent Rheumatic Fever

The initial episode of rheumatic fever can usually be prevented by early treatment of streptococcal pharyngitis. (See Chapter 33.) Prevention of recurrent episodes of rheumatic fever is critical. Recurrences of rheumatic fever are most common in patients who have had carditis during their initial episode and in children, 20% of whom will have a second episode within 5 years. The preferred method of prophylaxis is with benzathine penicillin G, 1.2 million units intramuscularly every 4 weeks. Oral penicillin (200,000–250,000 units twice daily) is less reliable.

If the patient is allergic to penicillin, sulfadiazine (or sulfisoxazole), 1 g daily, or erythromycin, 250 mg orally twice daily, may be substituted. The macrolide azithromycin is similarly effective against group A streptococcal infection. If the patient has not had an immediate hypersensitivity (anaphylactic-type) reaction to penicillin, then cephalosporin may also be used.

Recurrences are uncommon after 5 years following the first episode, and in patients over 25 years of age. Prophylaxis is usually discontinued after these times except in groups with a high risk of streptococcal infection—parents or teachers of young children, nurses, military recruits, etc. Secondary prevention of rheumatic fever depends on whether carditis has occurred. If there is no evidence for carditis, preventive therapy can be stopped at age 21 years. If carditis has occurred but there is no residual valvular disease, it can be stopped at 10 years after the episode. If carditis has occurred with residual valvular involvement, it should be continued for 10 years after the last episode or until age 40 years if the patient is in a situation in which reexposure would be expected.

▶ Prognosis

Initial episodes of rheumatic fever may last months in children and weeks in adults. The immediate mortality rate is 1–2%. Persistent rheumatic carditis with cardiomegaly, heart failure, and pericarditis implies a poor prognosis; 30% of children thus affected die within 10 years after the initial attack. After 10 years, two-thirds of patients will have detectable valvular abnormalities (usually thickened valves with limited mobility), but significant symptomatic valvular heart disease or persistent cardiomyopathy occurs in less than 10% of patients with a single episode. In developing countries, acute rheumatic fever occurs earlier in life, recurs more frequently, and the evolution to chronic valvular disease is both accelerated and more severe.

DISEASES OF THE PERICARDIUM

ACUTE INFLAMMATORY PERICARDITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Anterior pleuritic chest pain that is worse supine than upright.
- ▶ Pericardial rub.
- ▶ Fever common.
- ▶ Erythrocyte sedimentation rate usually elevated.
- ▶ ECG reveals diffuse ST segment elevation with associated PR depression.

▶ General Considerations

Acute (< 2 weeks) inflammation of the pericardium may be infectious in origin or may be due to systemic diseases (autoimmune syndromes, uremia), neoplasm, radiation, drug toxicity, hemopericardium, postcardiac surgery, or contiguous inflammatory processes in the myocardium or lung. In many of these conditions, the pathologic process involves both the pericardium and the myocardium.

Viral infections (especially infections with coxsackieviruses and echoviruses but also influenza, Epstein–Barr, varicella, hepatitis, mumps, and HIV viruses) are the most common cause of acute pericarditis and probably are

responsible for many cases classified as idiopathic. Males—usually under age 50 years—are most commonly affected. The differential diagnosis is primarily with myocardial infarction. **Tuberculous pericarditis** has become rare in developed countries but remains common in other areas. It results from direct lymphatic or hematogenous spread; clinical pulmonary involvement may be absent or minor, although associated pleural effusions are common. **Bacterial pericarditis** has become rare and usually results from direct extension from pulmonary infections. Pneumococci can cause a primary pericardial infection. *Borrelia burgdorferi*, the organism responsible for Lyme disease, can also cause myopericarditis. **Uremic pericarditis** is a common complication of chronic kidney disease. The pathogenesis is uncertain; it occurs both with untreated uremia and in otherwise stable dialysis patients. Spread of adjacent lung cancer as well as invasion by breast cancer, renal cell carcinoma, Hodgkin disease, and lymphomas are the most common **neoplastic processes** involving the pericardium and have become the most frequent causes of pericardial tamponade in many countries. Pericarditis may occur 2–5 days after infarction due to an inflammatory reaction to transmural myocardial necrosis (**postmyocardial infarction or postcardiotomy pericarditis (Dressler syndrome)**). **Radiation** can initiate a fibrinous and fibrotic process in the pericardium, presenting as subacute pericarditis or constriction. Radiation pericarditis usually follows treatments of more than 4000 cGy delivered to ports including more than 30% of the heart.

Other causes of pericarditis include connective tissue diseases, such as lupus erythematosus and rheumatoid arthritis, drug-induced pericarditis (minoxidil, penicillins, clozapine), and myxedema.

► Clinical Findings

A. Symptoms and Signs

The presentation and course of inflammatory pericarditis depend on its cause, but most syndromes have associated chest pain, which is usually pleuritic and postural (relieved by sitting). The pain is substernal but may radiate to the neck, shoulders, back, or epigastrium. Dyspnea may also be present and the patient is often febrile. A pericardial friction rub is characteristic, with or without evidence of fluid accumulation or constriction (see below). The presentation of **tuberculous pericarditis** tends to be subacute, but nonspecific symptoms (fever, night sweats, fatigue) may be present for days to months. Pericardial involvement develops in 1–8% of patients with pulmonary tuberculosis. Symptoms and signs of **bacterial pericarditis** are similar to those of other types of inflammatory pericarditides, but patients appear toxic and are often critically ill. **Uremic pericarditis** can present with or without symptoms; fever is absent. Often **neoplastic pericarditis** is painless, and the presenting symptoms relate to hemodynamic compromise or the primary disease. **Postmyocardial infarction or postcardiotomy pericarditis (Dressler syndrome)** usually presents as a recurrence of pain with pleural-pericardial features. A rub is often audible, and repolarization changes on the ECG may be confused with

ischemia. Large effusions are uncommon, and spontaneous resolution usually occurs in a few days. Dressler syndrome occurs weeks to several months after myocardial infarction or open heart surgery, may be recurrent, and probably represents an autoimmune syndrome. Patients present with typical pain, fever, malaise, and leukocytosis. Occasionally, the syndrome will occur within days of surgery. Rarely, other symptoms of an autoimmune disorder, such as joint pain and fever, may occur. Tamponade is rare with Dressler syndrome after myocardial infarction but not when it occurs postoperatively. The clinical onset of **radiation pericarditis** is usually within the first year but may be delayed for many years; often a full decade may pass before constriction becomes evident.

B. Laboratory Findings and Diagnostic Studies

The diagnosis of **viral pericarditis** is usually clinical, and leukocytosis is often present. Rising viral titers in paired sera may be obtained for confirmation but are rarely done. Cardiac enzymes may be slightly elevated, reflecting an epicardial myocarditis component. The echocardiogram is often normal or reveals only a trivial amount of fluid during the acute inflammatory process. The diagnosis of **tuberculous pericarditis** can be inferred if acid-fast bacilli are found elsewhere. The tuberculous pericardial effusions are usually small or moderate but may be large. The yield of organisms by pericardiocentesis is low; pericardial biopsy has a higher yield but may also be negative, and pericardiectomy may be required. If **bacterial pericarditis** is suspected on clinical grounds, diagnostic pericardiocentesis may be of value. In **uremic patients** not on dialysis, the incidence of pericarditis correlates roughly with the level of blood urea nitrogen (BUN) and creatinine. The pericardium is characteristically “shaggy” in uremic pericarditis, and the effusion is hemorrhagic and exudative. The diagnosis of **neoplastic pericarditis** can occasionally be made by cytologic examination of the effusion or by pericardial biopsy, but it may be difficult to establish clinically if the patient has received mediastinal radiation within the previous year. Neoplastic pericardial effusions develop over a long period of time and may become quite huge (> 2 L). The sedimentation rate is high in **postmyocardial infarction or postcardiotomy pericarditis**. Large pericardial effusions and accompanying pleural effusions are frequent. Myxedema pericardial effusions due to hypothyroidism usually are characterized by the presence of cholesterol crystals.

C. Other Studies

The ECG usually shows generalized ST and T wave changes and may manifest a characteristic progression beginning with diffuse ST elevation, followed by a return to baseline and then to T wave inversion. Atrial injury is often present and manifested by PR depression especially in the limb leads. The chest radiograph is frequently normal, but may show cardiac enlargement if pericardial fluid is present, as well as signs of related pulmonary disease. Mass lesions and enlarged lymph nodes may suggest a neoplastic process. MRI and CT scan can visualize neighboring tumor in neoplastic pericarditis. A screening chest CT or MRI is

often recommended to ensure there are no extracardiac diseases contiguous to the pericardium.

► Treatment

Treatment of **viral pericarditis** is generally symptomatic. Aspirin (650 mg every 3–4 hours) or other nonsteroidal agents (eg, indomethacin, 100–150 mg daily in divided doses) are usually effective. Corticosteroids may be beneficial in unresponsive cases. In general, symptoms subside in several days to weeks. The major early complication is tamponade, which occurs in less than 5% of patients. There may be recurrences in the first few weeks or months. Rare patients will continue to experience recurrences chronically. These patients may require long-term anti-inflammatory medications, either corticosteroids or colchicine. Rarely, acute pericarditis may lead to constrictive pericarditis, which may necessitate pericardial resection (see below). Standard antituberculous drug therapy is usually successful for **tuberculous pericarditis** (see Chapter 9), but constrictive pericarditis can occur. **Uremic pericarditis** usually resolves with the institution of—or with more aggressive—dialysis. Tamponade is fairly common, and partial pericardiectomy (pericardial window) may be necessary. Whereas anti-inflammatory agents may relieve the pain and fever associated with uremic pericarditis, indomethacin and systemic corticosteroids do not affect its natural history. The prognosis with **neoplastic effusion** is dismal, with only a small minority surviving 1 year. If it is compromising the clinical comfort of the patient, the effusion is initially drained percutaneously. Early attempts at ballooning the pericardium from a subxiphoid approach have been mostly abandoned in favor of surgical approaches. A pericardial window, either by a subxiphoid approach or via video-assisted thoracic surgery, allows for partial pericardiectomy. Instillation of chemotherapeutic agents or tetracycline may occasionally be used to reduce the recurrence rate. Aspirin or other nonsteroidal anti-inflammatory agents in dosages given for viral pericarditis above for 2–4 weeks are usually effective for the treatment of **postmyocardial infarction or postcardiotomy pericarditis (Dressler syndrome)**. In more severe cases, corticosteroids should be given in rapidly tapering doses. Relapses do occur and may require slow withdrawal of anti-inflammatory therapy over several months. Colchicine may be required for months to help prevent recurrences. Symptomatic therapy is the initial approach to **radiation pericarditis**, but recurrent effusions and constriction often require surgery.

PERICARDIAL EFFUSION

Pericardial effusion can develop during any of the processes previously discussed. The speed of accumulation determines

the physiologic importance of the effusion. Because the pericardium stretches, large effusions (> 1000 mL) that develop slowly may produce no hemodynamic effects. Conversely, smaller effusions that appear rapidly can cause tamponade. Tamponade is characterized by elevated intrapericardial pressure (> 15 mm Hg), which restricts venous return and ventricular filling. As a result, the stroke volume and pulse pressure fall, and the heart rate and venous pressure rise. Shock and death may result.

► Clinical Findings

A. Symptoms and Signs

Pericardial effusions may be associated with pain if they occur as part of an acute inflammatory process or may be painless, as is often the case with neoplastic or uremic effusion. Dyspnea and cough are common, especially with tamponade. Other symptoms may result from the primary disease.

A pericardial friction rub may be present even with large effusions. In cardiac tamponade, tachycardia, tachypnea, a narrow pulse pressure, and a relatively preserved systolic pressure are characteristic. Pulsus paradoxus—a greater than 10 mm Hg decline in systolic pressure during inspiration due to further impairment of LV filling—is the classic finding, but it may also occur with obstructive lung disease. Central venous pressure is elevated and there is no evident γ descent in the RA, RV, or LV hemodynamic tracings. Edema or ascites are rarely present; these signs favor a more chronic process.

B. Laboratory Findings

Laboratory tests tend to reflect the underlying processes (see causes of pericarditis above).

C. Diagnostic Studies

Chest radiograph can suggest chronic effusion by an enlarged cardiac silhouette with a globular configuration but may appear normal in acute situations. The ECG often reveals nonspecific T wave changes and low QRS voltage. Electrical alternans is present uncommonly but is pathognomonic. It is due to the heart swinging within the large effusion. Echocardiography is the primary method for demonstrating pericardial effusion and is quite sensitive. If tamponade is present, the high intrapericardial pressure may collapse lower pressure cardiac structures, such as the RA and RV. In tamponade, the normal inspiratory reduction in LV filling is accentuated due to RV/LV interaction and there is a > 25% reduction in maximal mitral inflow velocities. Cardiac CT and MRI also demonstrate pericardial fluid and any associated contiguous lesions. Diagnostic pericardiocentesis or biopsy is often indicated for microbiologic and cytologic studies; a pericardial biopsy may be performed relatively simply through a small subxiphoid incision. Unfortunately, the quality of the pericardial fluid rarely leads to a diagnosis, and any type of fluid (serous, serosanguinous, bloody, etc) can be seen in most diseases.

► Treatment

Small effusions can be followed clinically by careful observations of the JVP and by testing for a paradoxical pulse.

Serial echocardiograms are indicated if no intervention is immediately contemplated. When tamponade is present, urgent pericardiocentesis is required. Because the pressure–volume relationship in the pericardial fluid is curvilinear and upsloping, removal of a small amount of fluid often produces a dramatic fall in the intrapericardial pressure and immediate hemodynamic benefit; but complete drainage with a catheter is preferable. Continued or repeat drainage may be indicated, especially in malignant effusions. Pericardial windows via video-assisted thoracoscopy have been particularly effective in preventing recurrences.

Additional therapy is determined by the nature of the primary process. Recurrent effusion in neoplastic disease and uremia, in particular, may require partial pericardiectomy as noted earlier.

▶ When to Refer

- Any unexplained pericardial effusion should be referred to a cardiologist for a complete evaluation and treatment.
- Trivial pericardial effusions are common, especially in CHF, and need not be referred.
- Hypotension or a paradoxical pulse suggesting the pericardial effusion is hemodynamically compromising the patient should prompt an immediate referral.

CONSTRICTIVE PERICARDITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Evidence of right heart failure with an elevated JVP, edema, hepatomegaly, and ascites.
- ▶ No fall or an elevation of the JVP with inspiration (Kussmaul sign).
- ▶ Echocardiographic evidence for septal bounce and reduced mitral inflow velocities with inspiration.
- ▶ Catheterization evidence for RV-LV interaction, a “square root” sign, equalization of diastolic pressures, normal pulmonary artery pressure, and narrow RV pressure tracing that increases with inspiration.

▶ General Considerations

Inflammation can lead to a thickened, fibrotic, adherent pericardium that restricts diastolic filling and produces chronically elevated venous pressures. In the past, tuberculosis was the most common cause of constrictive pericarditis, but the process now more often occurs after radiation

therapy, cardiac surgery, or viral pericarditis; histoplasmosis is another uncommon cause.

▶ Clinical Findings

A. Symptoms and Signs

The principal symptoms are slowly progressive dyspnea, fatigue, and weakness. Chronic edema, hepatic congestion, and ascites are usually present. Ascites often seems out of proportion to the degree of peripheral edema. The examination reveals these signs and a characteristically elevated jugular venous pressure with a rapid y descent. This can be detected at bedside by careful observation of the jugular pulse and noting an apparent increased pulse wave at the end of systole (due to accentuation of the v wave by the rapid y descent). Kussmaul sign—a failure of the JVP to fall with inspiration—is also a frequent finding. The apex may actually retract with systole and a pericardial “knock” may be heard in early diastole. Pulsus paradoxus is unusual. Atrial fibrillation is common.

B. Diagnostic Studies

At times constrictive pericarditis is extremely difficult to differentiate from restrictive cardiomyopathy. When unclear, the use of noninvasive testing and cardiac catheterization is required to sort out the difference.

1. Radiographic findings—The chest radiograph may show normal heart size or cardiomegaly. Pericardial calcification is best seen on the lateral view and is uncommon. It rarely involves the LV apex, and finding of calcification at the LV apex is more consistent with LV aneurysm. Cardiac CT and MRI are only occasionally helpful. Pericardial thickening of > 4 mm must be present to establish the diagnosis, yet no pericardial thickening is demonstrated in 20–25% of patients with constrictive pericarditis.

2. Echocardiography—Echocardiography rarely demonstrates a thickened pericardium. A septal “bounce” reflecting the rapid early filling is common, though. RV/LV interaction may be demonstrated by a reduction in the mitral inflow pattern of $> 25\%$, much as in tamponade.

3. Cardiac catheterization—As a generality, the pulmonary pressure is low in constriction and there must be signs of RV/LV interaction (reduced LV filling pattern with inspiration) on echocardiography/Doppler. In constrictive pericarditis, because of the need to demonstrate RV/LV interaction, cardiac catheterization should include simultaneous measurement of both the LV and RV. Hemodynamically, patients with constriction have equalization of end-diastolic pressures throughout their cardiac chambers, there is rapid early filling then an abrupt increase in diastolic pressure (“square-root” sign), the RV end-diastolic pressure is more than one-third the systolic pressure, simultaneous measurements of RV and LV systolic pressure reveal a discordance with inspiration (the RV rises as the LV falls), and there is usually a Kussmaul sign (failure of the RA pressure to fall with inspiration). The width (or area) of the RV pressure tracing may also be less in expiration and greater during inspiration, reflecting the variability in filling of the RV with respiration.

In restrictive cardiomyopathy, the LV diastolic pressure is usually greater than the RV diastolic pressure by 5 mm Hg, there is pulmonary hypertension, and simultaneous measurements of the RV and LV systolic pressure reveal a concordant drop in the peak systolic pressure in both with inspiration.

► Treatment

Initial treatment consists of diuresis. As in other disorders of right heart failure, the diuresis should be aggressive, using loop diuretics (torsemide if bowel edema is suspected), thiazides, and aldosterone antagonists (especially if ascites is present). At times, aquaphoresis may be of value. Surgical pericardiectomy should be done when diuretics are unable to control symptoms. Pericardiectomy removes the pericardium between the phrenic nerve pathways only, however, and most patients still require diuretics after the procedure, though symptoms are usually dramatically improved. Morbidity and mortality after pericardiectomy are high (up to 15%) and are greatest in those with the most disability prior to the procedure. For that reason, most experts recommend earlier rather than later pericardiectomy if symptoms are present.

► When to Refer

If the diagnosis of constrictive pericarditis is unclear or the symptoms resist medical therapy, then referral to a cardiologist is warranted to both establish the diagnosis and recommend therapy.

PULMONARY HYPERTENSION & PULMONARY HEART DISEASE

IDIOPATHIC PULMONARY HYPERTENSION

ESSENTIALS OF DIAGNOSIS

- Most frequently seen in younger women.
- Dyspnea, and often cyanosis, with no evidence of left heart disease.
- Enlarged pulmonary arteries on chest radiograph.
- Elevated JVP and RV heave.
- Echocardiography is often diagnostic.

► General Considerations

The normal pulmonary bed offers about one-tenth as much resistance to blood flow as the systemic arterial system.

Pulmonary hypertension is classified as mild if the mean PA pressure is > 20 mm Hg, moderate if > 30 mm Hg, and severe if > 45 mm Hg. As opposed to the systemic circulation, the pulmonary resistance is influenced by local vascular mediators much more than the adrenergic nervous system, even though both α - and β -receptors are present on pulmonary vascular smooth muscle. The normal pulmonary endothelial cell maintains the vascular smooth muscle in a state of relaxation. Pulmonary vasoconstriction is mediated by hypoxia and by endothelin and angiotensin II. Vasodilation can be affected by certain prostaglandins, endothelin receptor blockers, smooth muscle relaxants, and by nitric oxide. Formally called “**primary**” pulmonary hypertension, the preferred term now is “idiopathic pulmonary hypertension” and is defined as pulmonary hypertension and elevated PVR in the absence of other disease of the lungs or heart. Its cause is unknown, though there are clear genetic patterns that have been identified, and it likely represents a derangement in one or more of the biologic pathways described above. Pathologically, it is characterized by diffuse narrowing of the pulmonary arterioles. Circumstantial evidence suggests that unrecognized recurrent pulmonary emboli or in situ thrombosis may play a role in some cases. However, the latter may well be an exacerbating factor (precipitated by local endothelial injury) rather than a cause of the syndrome. Idiopathic pulmonary hypertension must be distinguished from other causes of severe secondary pulmonary hypertension, such as systemic sclerosis, HIV-related pulmonary hypertension, cirrhosis, and congenital heart defects (primarily those with a shunt distal to the level of the tricuspid valve). Rarely, pulmonary venous disease (pulmonary veno-occlusive disease) or peripheral PA stenosis may be present. Left heart disease, in particular mitral stenosis, or any reason for an elevated LA pressure must be excluded as well. Table 10–13 includes clinical disorders causing pulmonary hypertension.

► Clinical Findings

A. Symptoms and Signs

The clinical picture is similar to that of pulmonary hypertension from other causes. Chronic lung disease, especially sleep apnea, can be overlooked as a cause for pulmonary hypertension. Patients are characteristically young women who have evidence of right heart failure that is usually progressive, leading to death in 2–8 years. This is a decidedly different prognosis than patients with Eisenmenger physiology due to a left-to-right shunt; 40% of patients with Eisenmenger physiology are alive 25 years after the diagnosis has been made. Patients have manifestations of low cardiac output, with weakness and fatigue, as well as edema and ascites as right heart failure advances. Peripheral cyanosis is present, and syncope on effort may occur.

B. Diagnostic Studies

The laboratory evaluation of idiopathic pulmonary hypertension must exclude a secondary cause. A hypercoagulable state should be sought and chronic pulmonary emboli excluded (usually by lung scan or contrast spiral CT). The chest radiograph helps exclude a primary pulmonary etiol-

Modified from Rich S (editor). Primary pulmonary hypertension: Executive summary from the World Symposium—Primary Pulmonary Hypertension, 1998.

ogy—evidence for patchy edema may raise the suspicion of pulmonary veno-occlusive disease. A sleep study may be warranted. The ECG is generally consistent with RVH and RA enlargement. Echocardiography/Doppler demonstrates an enlarged RV and RA—at times they may be huge and hypocontractile. Severe pulmonic or tricuspid regurgitation may be present. Septal flattening is consistent with pulmonary hypertension. Doppler interrogation of the tricuspid regurgitation jet helps provide an estimate of RV systolic pressure. Pulmonary function tests help exclude other disorders, though primary pulmonary hypertension may present with a reduced carbon monoxide diffusing capacity of the lung (DL_{CO}) and severe desaturation (particularly if a PFO has been stretched open and a right-to-left shunt is present). Chest CT demonstrates enlarged pulmonary arteries and excludes other causes (such as emphysema or interstitial lung disease). Pulmonary angiography (or MR angiography or CT angiography) reveals loss of the smaller acinar pulmonary vessels and tapering of the larger ones. Catheterization allows measurement of pulmonary pressures and testing for vasoreactivity using a variety of agents, including 100% oxygen, adenosine, epoprostenol, and nitric oxide. A positive response is one that decreases the pulmonary mean pressure by > 20%, and the mean pulmonary pressure is reduced to \leq 45 mm Hg.

▶ Treatment

Until recently, the only therapy for idiopathic pulmonary hypertension has been trials of calcium channel blockers, oxygen, and eventually lung transplantation. Currently, a variety of therapeutic options are now available and approved. Many authorities advocate long-term oral anticoagulation and this is given to most patients with idiopathic pulmonary hypertension. Supplemental oxygen, particularly at night, appears to improve symptoms and helps reduce pulmonary pressures. Diuretics help with right heart edema. Calcium channel blockers, at times in large doses, have been used with mixed results. Some patients respond well, especially if the patient has responded to acute vasodilator testing. However, calcium channel blockers can worsen RV function by their negative inotropic effects. Responders should also be considered for phosphodiesterase-5 inhibitors, such as sildenafil.

Other agents are available for treatment of patients who do not respond to vasodilator challenge. Epoprostenol is administered by continuous infusion and has been shown to improve functional capacity and survival. Analogs of epoprostenol are also available, including treprostinil, beraprost, and iloprost. Treprostinil is given by subcutaneous injection, beraprost by mouth, and iloprost by inhalation. Endothelin antagonists are also available orally, such as bosentan and sitaxentan. Pulmonary transplantation is a viable option in selected centers, though the operative mortality is high (around 20–25%) and 2-year survival only about 55%. Women with significant pulmonary hypertension should not get pregnant, and permanent birth control measures should be considered.

▶ When to Refer

All patients with suspected idiopathic pulmonary hypertension should be referred to either a cardiologist or pulmonologist who specializes in the evaluation and treatment of patients with unexplained pulmonary hypertension (RV systolic > 35 mm Hg as measured by an echocardiogram).

PULMONARY HEART DISEASE (Cor Pulmonale)

ESSENTIALS OF DIAGNOSIS

- ▶ Symptoms and signs of chronic bronchitis and pulmonary emphysema.
- ▶ Elevated jugular venous pressure, parasternal lift, edema, hepatomegaly, ascites.
- ▶ ECG shows tall, peaked P waves (P pulmonale), right axis deviation, and RVH.

- ▶ Chest radiograph: Enlarged RV and PA.
- ▶ Echocardiogram or radionuclide angiography excludes primary LV dysfunction.

▶ General Considerations

The term “cor pulmonale” denotes RV hypertrophy and eventual failure resulting from pulmonary disease and the attendant hypoxia or from pulmonary vascular disease (pulmonary hypertension). Its clinical features depend on both the primary underlying disease and its effects on the heart.

Cor pulmonale is most commonly caused by COPD. Less frequent causes include pneumoconiosis, pulmonary fibrosis, kyphoscoliosis, idiopathic pulmonary hypertension, repeated episodes of subclinical or clinical pulmonary embolization, Pickwickian syndrome, schistosomiasis, and obliterative pulmonary capillary or lymphangitic infiltration from metastatic carcinoma.

▶ Clinical Findings

A. Symptoms and Signs

The predominant symptoms of compensated cor pulmonale are related to the pulmonary disorder and include chronic productive cough, exertional dyspnea, wheezing respirations, easy fatigability, and weakness. When the pulmonary disease causes RV failure, these symptoms may be intensified. Dependent edema and right upper quadrant pain may also appear. The signs of cor pulmonale include cyanosis, clubbing, distended neck veins, RV heave or gallop (or both), prominent lower sternal or epigastric pulsations, an enlarged and tender liver, and dependent edema.

B. Laboratory Findings

Polycythemia is often present in cor pulmonale secondary to COPD. The arterial oxygen saturation is often below 85%; PCO_2 may or may not be elevated.

C. ECG and Chest Radiography

The ECG may show right axis deviation and peaked P waves. Deep S waves are present in lead V_6 . Right axis deviation and low voltage may be noted in patients with pulmonary emphysema. Frank RVH is uncommon except in idiopathic pulmonary hypertension. The ECG often mimics myocardial infarction; Q waves may be present in leads II, III, and aVF because of the vertically placed heart, but they are rarely deep or wide, as in inferior myocardial infarction. Supraventricular arrhythmias are frequent and nonspecific.

The chest radiograph discloses the presence or absence of parenchymal disease and a prominent or enlarged RV and PA.

D. Diagnostic Studies

Pulmonary function tests usually confirm the underlying lung disease. The echocardiogram should show normal LV size and function but RV and RA dilation. Perfusion lung scans are rarely of value, but, if negative, they help to

exclude chronic pulmonary emboli, an occasional cause of cor pulmonale. Multislice CT has replaced pulmonary angiography as the most specific method of diagnosis for the pulmonary emboli.

▶ Differential Diagnosis

In its early stages, cor pulmonale can be diagnosed on the basis of radiologic, echocardiographic, or ECG evidence. Catheterization of the right heart will establish a definitive diagnosis but is more often performed to exclude left-sided heart failure, which can be an unrecognized cause of right-sided failure in some patients. Differential diagnostic considerations relate primarily to the specific pulmonary disease that has produced RV failure (see above).

▶ Treatment

The details of the treatment of chronic pulmonary disease (chronic respiratory failure) are discussed in Chapter 9. Otherwise, therapy is directed at the pulmonary process responsible for right heart failure. Oxygen, salt and fluid restriction, and diuretics are mainstays, with combination diuretic therapy (loop diuretics, thiazides and spironolactone) often useful, as described above for other causes of right heart failure.

▶ Prognosis

Compensated cor pulmonale has the same prognosis as the underlying pulmonary disease. Once congestive signs appear, the average life expectancy is 2–5 years, but survival is significantly longer when uncomplicated emphysema is the cause.

▶ When to Refer

Patients with unexplained or difficult to manage right heart failure should be referred to a cardiologist or a pulmonologist.

NEOPLASTIC DISEASES OF THE HEART

Primary cardiac tumors are rare and constitute only a small fraction of all tumors that involve the heart or pericardium. The most common primary tumor is atrial myxoma; it comprises about 50% of all tumors in adult case series. It is generally attached to the atrial septum and is more likely to affect the LA than the RA. Familial myxomas occur as part of the **Carney complex**—that consists of myxomas, pigmented skin lesions, and endocrine neoplasia. Patients with myxoma can present with the characteristics of a systemic illness, with obstruction of blood flow through the heart, or with signs of

peripheral embolization. The characteristics include fever, malaise, weight loss, leukocytosis, elevated sedimentation rate, and emboli (peripheral or pulmonary, depending on the location of the tumor). This is often confused with infective endocarditis, lymphoma, other cancers, or autoimmune diseases. In other cases, the tumor may grow to considerable size and produce symptoms by obstructing mitral flow. Episodic pulmonary edema (classically occurring when an upright posture is assumed) and signs of low output may result. Physical examination may reveal a diastolic sound related to motion of the tumor (“tumor plop”) or a diastolic murmur similar to that of mitral stenosis. Right-sided myxomas may cause symptoms of right-sided failure. The diagnosis is established by echocardiography or by pathologic study of embolic material. Cardiac MRI is useful as an adjunct only. Contrast angiography is frequently not necessary. Surgical excision is usually curative, though recurrences do occur and serial echocardiographic follow-up, on at least a yearly basis, is recommended.

The second most common cardiac tumors are valvular papillary fibroelastomas and atrial septal lipomas. These tend to be benign and usually require no therapy. Other primary cardiac tumors include rhabdomyomas (that often appear multiple in both the RV and LV), fibrous histiocytomas, hemangiomas, and a variety of unusual sarcomas. The diagnosis may be supported by an abnormal cardiac contour on radiograph. Echocardiography is usually helpful but may miss tumors infiltrating the ventricular wall. Cardiac MRI is emerging as the diagnostic procedure of choice.

Metastases from malignant tumors can also affect the heart. Most often this occurs in malignant melanoma, but other tumors involving the heart include bronchogenic carcinoma, carcinoma of the breast, the lymphomas, renal cell carcinoma, and, in patients with AIDS, Kaposi sarcoma. These are often clinically silent but may lead to pericardial tamponade, arrhythmias and conduction disturbances, heart failure, and peripheral emboli. The diagnosis is often made by echocardiography, but cardiac MRI and CT scanning are also helpful. ECG may reveal regional Q waves. The prognosis is dismal; effective treatment is not available. On rare occasions, surgical resection or chemotherapy is warranted.

CARDIAC INVOLVEMENT IN MISCELLANEOUS SYSTEMIC DISEASES

The heart may be involved in a number of systemic syndromes. Many of these have been mentioned briefly in

this chapter. The pericardium, myocardium, heart valves, and coronary arteries may be involved either singly or in various combinations. In most cases the cardiac manifestations are not the dominant feature, but in some it is the primary cause of symptoms and may be fatal.

The most common type of myocardial involvement is an infiltrative cardiomyopathy, such as systemic amyloidosis, sarcoidosis, hemochromatosis, Fabry or glycogen storage disease. These result in a restrictive cardiomyopathy (see above). Cardiac calcinosis can occur in hyperparathyroidism (usually the secondary form) and in primary oxalosis. A number of muscular dystrophies can cause a cardiomyopathic picture (particularly Duchenne, less frequently myotonic dystrophy, and several rarer forms). Involvement of the heart in Duchenne dystrophy results in a focal cardiomyopathy of the posterior wall; the classic ECG has prominent anterior precordial forces. In addition to LV dysfunction and heart failure, all of these conditions frequently cause conduction abnormalities, which may be the presenting or only feature. The myocardium may also be involved in inflammatory and autoimmune diseases. It is commonly affected in polymyositis and dermatomyositis, but usually this is subclinical. Systemic lupus erythematosus, scleroderma, and mixed connective tissue disease may cause myocarditis, but these more commonly involve the pericardium, coronary arteries, or valves. Several endocrinopathies, including acromegaly, thyrotoxicosis, myxedema, and pheochromocytoma, can produce dilated cardiomyopathies that resolve when the underlying disease is appropriately treated.

Pericardial involvement is quite common in many of the connective tissue diseases. Systemic lupus erythematosus may present with pericarditis, and pericardial involvement is not uncommon (but is less frequently symptomatic) in active rheumatoid arthritis, systemic sclerosis, and mixed connective tissue disease. Endocardial involvement takes the form of patchy fibrous—predominantly on the right side—or inflammatory or sclerotic changes of the heart valves. Carcinoid heart disease results from the layering of plaque-like material over the tricuspid valve, RV endocardium, and pulmonic valve and presents with right heart failure due to tricuspid and pulmonic regurgitation. The hypereosinophilic syndromes involve the endocardium, leading to restrictive cardiomyopathy. A variety of arthritic syndromes are associated with aortic valvulitis or aortitis with resulting aortic regurgitation. These include ankylosing spondylitis, rheumatoid arthritis, and Reiter syndrome. Disorders of collagen (Marfan syndrome is the most frequent, followed by Ehlers–Danlos syndrome) often affect the ascending aorta, with resulting aneurysmal dilation and aortic regurgitation. Mitral valve prolapse is also a common finding in these disorders.

Almost any vasculitic syndrome can involve the coronary arteries, leading to myocardial infarction. This is most common with polyarteritis nodosa and systemic lupus erythematosus. Two vasculitic syndromes have a particular predilection for the coronary arteries—Kawasaki disease and Takayasu disease. Kawasaki disease can result in coronary aneurysms, occasionally of huge size. Takayasu disease affects the great vessels more than the coronaries and

smooth, tapering lesions are usually seen, particularly at the vessel ostia. In these, myocardial infarction may be the presenting symptom.

TRAUMATIC HEART DISEASE

Penetrating wounds to the heart are, of course, usually lethal unless surgically repaired. Stab wounds to the RV occasionally lead to hemopericardium without progressing to tamponade.

Blunt trauma is a more frequent cause of cardiac injuries, particularly outside of the emergency department setting. This type of injury is quite frequent in motor vehicle accidents and may occur with any form of chest trauma, including CPR efforts. The most common injuries are myocardial contusions or hematomas. Other forms of nonischemic cardiac injury include metabolic injury due to burns, electrical current, or sepsis. These may be asymptomatic (particularly in the setting of more severe injuries) or may present with chest pain of a nonspecific nature or, not uncommonly, with a pericardial component. Elevations of cardiac enzymes are frequent but the levels do not correlate with prognosis. Echocardiography may reveal an akinetic segment or pericardial effusion. Pericardiocentesis is warranted if tamponade is evident. Heart failure is uncommon if there are no associated cardiac or pericardial injuries, and conservative management is usually sufficient.

Severe trauma may also cause cardiac or valvular rupture. Cardiac rupture may involve any chamber, but survival is most likely if injury is to one of the atria or the RV. Hemopericardium or pericardial tamponade is the usual clinical presentation, and surgery is almost always necessary. Mitral and aortic valve rupture may occur during severe blunt trauma—the former presumably if the impact occurs during systole and the latter if during diastole. Patients reach the hospital in shock or severe heart failure. Immediate surgical repair is essential. The same types of injuries may result in transection of the aorta, either at the level of the arch or distal to the takeoff of the left subclavian artery. Transthoracic echocardiography and TEE are the most helpful and immediately available diagnostic techniques.

Blunt trauma may also result in damage to the coronary arteries. Acute or subacute coronary thrombosis is the most common presentation. The clinical syndrome is one of acute myocardial infarction with attendant ECG, enzymatic, and contractile abnormalities. Emergent revascularization is sometimes feasible, either by the percutaneous route or by coronary artery bypass surgery. LV aneurysms are common outcomes of traumatic coronary occlusions. Coronary artery dissection or rupture may also occur in the setting of blunt cardiac trauma.

THE CARDIAC PATIENT & SURGERY

There are now guidelines to help the physician and patient better define the risk of both cardiac and noncardiac surgery in heart patients. The easiest to use algorithms for cardiac surgery can be found on either of two websites: one includes the euroSCORE (euroSCORE.org/calc.html) and the other the STS (Society of Thoracic Surgeons) database that provides a longitudinal look at the risk of cardiac surgery (www.ctsnet.org/section/stsdatabase).

To assess the risk of noncardiac surgery, the guidelines from the ACC/AHA Task Force provide useful algorithms to help determine risk (www.acc.org or <http://content.onlinejacc.org/cgi/content/full/50/17/e59>).

THE CARDIAC PATIENT & PREGNANCY

The management of cardiac disease in pregnancy is discussed in detail in the references listed below. Only a few major points can be covered in this brief section.

A comprehensive review of the safety of drugs in pregnancy and during breast-feeding can be found at www.perinatology.com/exposures/druglist.htm.

Elkayam U et al. Valvular heart disease and pregnancy: part I: native valves. *J Am Coll Cardiol*. 2005 Jul 19;46(2):223–30. [PMID: 16022946]

Warnes CA et al. ACC/AHA 2008 Guidelines for the Management of Adults With Congenital Heart Disease. A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2008 Dec 2;118(23):e714–833. [PMID: 18997169]

CARDIOVASCULAR COMPLICATIONS OF PREGNANCY

Pregnancy-related hypertension (eclampsia and pre-eclampsia) is discussed in Chapter 19.

1. Cardiomyopathy of Pregnancy (Peripartum Cardiomyopathy)

In approximately one of 4000–15,000 patients, dilated cardiomyopathy develops in the final month of pregnancy or within 6 months after delivery. The cause is unclear, but immune and viral causes have been postulated. More recently, it has been noted that the disease may be related to a cathepsin-D cleavage product of the hormone prolactin—suggesting blockage of prolactin may be a potential therapeutic strategy if proven in clinical trials using bromocriptine. The disease occurs more frequently in women over age 30 years, is generally related to the first or second pregnancy, and is associated with gestational hypertension and drugs used to stop uterine contractions. The course of the disease is variable; many cases improve or resolve completely over several months, but others progress to refractory heart failure. About 60% of patients make a complete recovery. Immunosuppressive therapy has been advocated, but few supportive data are available. Recently, β -blockers have been administered judiciously to these patients, with at least anecdotal success. Some advocate anticoagulation because of an increased risk for thrombotic events. Recurrence in subsequent pregnancies is common, particularly if cardiac function has not recovered.

Leinwand LA. Molecular events underlying pregnancy-induced cardiomyopathy. *Cell.* 2007 Feb 9;128(3):437–8. [PMID: 17289564]

2. Coronary Artery & Other Vascular Abnormalities

There have been a number of reports of myocardial infarction during pregnancy. It is known that pregnancy predisposes to dissection of the aorta and other arteries, perhaps because of the accompanying connective tissue changes. The risk may be particularly high in patients with Marfan or Ehlers-Danlos syndromes. However, coronary artery dissection is responsible for only a minority of the infarctions; most are caused by atherosclerotic CAD or coronary emboli. Most of the events occur near term or shortly following delivery, and paradoxical emboli through a PFO has been implicated in some cases. Clinical management is essentially similar to that of other patients with acute infarction, unless there is a connective tissue disorder. If nonatherosclerotic dissection is present, coronary intervention is risky as further dissection can be aggravated. In most instances, conservative management is warranted.

James AH et al. Acute myocardial infarction in pregnancy: a United States population-based study. *Circulation.* 2006 Mar 28;113(12):1564–71. [PMID: 16534011]

SPECIAL PROBLEMS

► Prophylaxis for Infective Endocarditis

The ACC/AHA Task Force addressing adults with congenital heart disease has formulated new guidelines outlining

recommendations for pregnant women during labor and delivery.

There are no class 1 indications nor class 3 contraindications. The patients who should be considered for coverage with antibiotics during delivery include those who fall into the class 2A category (level of evidence: B).

In select patients with the highest risk of adverse outcomes, it is reasonable to consider antibiotic prophylaxis against infective endocarditis before vaginal delivery at the time of membrane rupture. This includes patients with the following indications: (1) prosthetic cardiac valve or prosthetic material used for cardiac valve repair, and (2) unrepaired and palliated cyanotic congenital heart disease, including surgically constructed palliative shunts conduits.

Warnes CA et al. ACC/AHA 2008 Guidelines for the Management of Adults With Congenital Heart Disease. A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2008 Dec 2;118(23):e714–833. [PMID: 18997169]

Wilson W et al. Prevention of infective endocarditis: guidelines from the American Heart Association: a guideline from the American Heart Association Rheumatic Fever, Endocarditis and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *J Am Dent Assoc.* 2007 Jun;138(6):739–45, 747–60. [PMID: 17545263]

► Management of Labor

Although vaginal delivery is usually well tolerated, unstable patients (including patients with severe hypertension and worsening heart failure) should have planned cesarean section. An increased risk of aortic rupture has been noted during delivery in patients with coarctation of the aorta and severe aortic root dilation with Marfan syndrome, and vaginal delivery should be avoided in these conditions. For most patients, even those with congenital heart disease, vaginal delivery is preferred.

CARDIOVASCULAR SCREENING OF ATHLETES

The sudden death of a competitive athlete inevitably becomes an occasion for local if not national publicity. On each occasion, the public and the medical community ask whether such events could be prevented by more careful or complete screening. Although each event is tragic, it must be appreciated that there are approximately 5 million competitive athletes at the high school level or above in any given year. The number of cardiac deaths occurring during athletic participation is unknown, but estimates at the high school level range from one in 300,000 to one in 100,000 participants. Death rates among more mature athletes increase as the prevalence of CAD rises. These numbers highlight the problem of how to screen individual participants. Even an inexpensive test such as an ECG would generate an enormous cost if required of all athletes, and it is likely that few at-risk individuals would be detected. Echocardiography, either

as a routine test or as a follow-up examination for abnormal ECGs, would be prohibitively expensive except for the elite professional athlete. Thus, the most feasible approach is that of a careful medical history and cardiac examination performed by personnel aware of the conditions responsible for most sudden deaths in competitive athletes. In a series of 158 athletic deaths in the United States between 1985 and 1995, hypertrophic cardiomyopathy (36%) and coronary anomalies (19%) were by far the most frequent underlying conditions. LV hypertrophy was present in another 10%, ruptured aorta (presumably due to Marfan syndrome or cystic medial necrosis) in 6%, myocarditis or dilated cardiomyopathy in 6%, aortic stenosis in 4%, and arrhythmogenic RV dysplasia in 3%. In addition, commotio cordis, or sudden death due to direct myocardial injury, may occur. More common in children, it may occur even after a minor direct blow to the heart; it is thought to be due to the precipitation of a premature ventricular contraction just prior to the peak of the T wave on ECG.

It is likely that a careful family and medical history and cardiovascular examination will identify some individuals at risk. A family history of premature sudden death or cardiovascular disease or of any of these predisposing conditions should mandate further workup, including an ECG and echocardiogram. Symptoms of chest pain, syncope, or near-syncope also warrant further evaluation. A Marfan-like appearance, significant elevation of BP or abnormalities of heart rate or rhythm, and pathologic heart murmurs or heart sounds should also be investigated before clearance for athletic participation is given. Such an evaluation is recommended before participation at the high school and college levels and every 2 years during athletic competition.

Stress-induced syncope or chest pressure may be the first clue to an anomalous origin of a coronary artery. Anatomically, this lesion occurs most often when the left anterior descending artery arises from the right coronary cusp and traverses between the aorta and pulmonary trunks. The “slit-like” orifice that results from the angulation at the vessel origin is thought to cause ischemia when the aorta and pulmonary arteries enlarge during rigorous exercise.

The toughest distinction may be in sorting out the healthy athlete with LVH from the athlete with hypertrophic cardiomyopathy. In general, the healthy athlete’s heart is *less* likely to have an unusual pattern of LVH, LA enlargement, an abnormal ECG, an LV cavity < 45 mm in diameter at end-diastole, an abnormal diastolic filling pattern, a family history of hypertrophic cardiomyopathy, and the athlete is more likely to be male than the individual with hypertrophic cardiomyopathy.

Selective use of routine ECG and stress testing is recommended in men above age 40 years and women above age 50 years who continue to participate in vigorous exercise and at earlier ages when there is a positive family history for premature CAD, hypertrophic cardiomyopathy, or multiple risk factors.

Systemic Hypertension

Michael Sutters, MD, MRCP (UK)

Sixty-six million Americans have elevated blood pressure (systolic blood pressure ≥ 140 mm Hg or diastolic blood pressure ≥ 90 mm Hg); of these, 63% are aware of their diagnosis, but only 45% are receiving treatment and only 34% are under control using a threshold criterion of 140/90 mm Hg. The prevalence of hypertension increases with age and is more common in blacks than in whites. The mortality rates for stroke and coronary heart disease, two of the major complications of hypertension, have declined by 50–60% over the past three decades but have recently leveled off. The numbers of patients with end-stage kidney disease and heart failure—two other conditions in which hypertension plays a major causative role—continue to rise.

Cardiovascular morbidity and mortality increase as both systolic and diastolic blood pressures rise, but in individuals over age 50 years, the systolic pressure and pulse pressure are better predictors of complications than diastolic pressure. Table 11–1 provides a summary of the classification and management of blood pressure in adults from the 7th Report of the U.S. Joint National Commission on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7).

HOW IS BLOOD PRESSURE MEASURED AND HYPERTENSION DIAGNOSED?

Blood pressure should be measured with a well-calibrated sphygmomanometer. The bladder width within the cuff should encircle at least 80% of the arm circumference. Readings should be taken after the patient has been resting comfortably, back supported in the sitting or supine position, for at least 5 minutes and at least 30 minutes after smoking or coffee ingestion. A video demonstrating the correct technique can be found at <http://content.nejm.org/cgi/video/360/5/e6/>. Hypertension is diagnosed when systolic blood pressure is consistently elevated above 140 mm Hg, or diastolic blood pressure is above 90 mm Hg; a single elevated blood pressure reading is not sufficient to establish the diagnosis of hypertension. The major exceptions to this rule are hypertensive presentations with unequivocal evidence of life-threatening end-organ damage, as seen in hypertensive emergency, or in hypertensive urgency where blood pressure is $> 220/125$ mm Hg but life-threatening

end-organ damage is absent. In less severe cases, the diagnosis of hypertension depends on a series of measurements of blood pressure, since readings can vary and tend to regress toward the mean with time. Patients whose initial blood pressure is in the hypertensive range exhibit the greatest fall toward the normal range between the first and second encounters. Although blood pressure readings may still show variability after the third visit, these later changes are mostly random. However, the concern for diagnostic precision needs to be balanced by an appreciation of the importance of establishing the diagnosis of hypertension as quickly as possible, since a 3-month delay in treatment of hypertension in high-risk patients is associated with a twofold increase in cardiovascular morbidity and mortality. The guidelines of the 2005 Canadian Hypertension Education Program provide an algorithm designed to expedite the diagnosis of hypertension (Figure 11–1). To this end, these guidelines recommend short intervals between the initial office visits and stress the importance of early identification of target organ damage which, if present, obviates the need for protracted confirmation of blood pressure elevation prior to pharmacologic intervention. The Canadian guidelines exploit the less volatile ambulatory and home blood pressure measurements as complements to office-based evaluations. Hypertension is diagnosed at lower levels when based on measurements taken outside the office environment. In addition to avoiding office-induced artifacts, ambulatory blood pressure measurements provide a more integrated view of blood pressure and the response to treatment. There is now evidence that ambulatory measurements are more reliable predictors of cardiovascular risk than measurements taken in the office. Blood pressure is normally lowest at night and the loss of this nocturnal dip is strongly associated with cardiovascular risk, particularly thrombotic stroke. An accentuation of the normal morning increase in blood pressure is associated with increased likelihood of cerebral hemorrhage.

PREHYPERTENSION

Data from the Framingham cohort indicate that blood pressure bears a linear relationship with cardiovascular risk down to a systolic blood pressure of 115 mm Hg; based on

Table 11-1. Classification and management of blood pressure for adults aged 18 years or older.

| BP Classification | Systolic BP, mm Hg ¹ | and | Diastolic BP, mm Hg ¹ | Lifestyle Modification | Management | |
|----------------------|---------------------------------|-----|----------------------------------|------------------------|---|---|
| | | | | | Initial Drug Therapy | |
| | | | | | Without Compelling Indication | With Compelling Indications ² |
| Normal | < 120 | and | < 80 | Encourage | | |
| Prehypertension | 120-139 | or | 80-89 | Yes | No antihypertensive drug indicated | Drug(s) for the compelling indications ³ |
| Stage 1 hypertension | 140-159 | or | 90-99 | Yes | Thiazide-type diuretics for most; may consider ACE inhibitor, ARB, β -blocker, CCB, or combination | Drug(s) for the compelling indications Other antihypertensive drugs (diuretics, ACE inhibitor, ARB, β -blocker, CCB) as needed |
| Stage 2 hypertension | \geq 160 | or | \geq 100 | Yes | Two-drug combination for most (usually thiazide-type diuretic and ACE inhibitor or ARB or β -blocker or CCB) ⁴ | Drug(s) for the compelling indications Other antihypertensive drugs (diuretics, ACE inhibitor, ARB, β -blocker, CCB) as needed |

¹Treatment determined by highest BP category.

²See Table 11-4.

³Treat patients with chronic kidney disease or diabetes to BP goal of < 130/80 mm Hg.

⁴Initial combined therapy should be used cautiously in those at risk for orthostatic hypotension.

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP, blood pressure; CCB, calcium channel blocker.

Source: Chobanian AV et al. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure: the JNC 7 report. *JAMA*. 2003 May 21;289(19):2560-72.

these data, it is recommended that individuals with blood pressures in the gray area of 120–139/80–89 mm Hg be categorized as having prehypertension (Table 11-1). This demonstrates a trend away from defining hypertension as a simple numerical threshold and toward a more subtle appreciation of blood pressure as a component of overall cardiovascular risk. This trend gains support from increasing evidence for a relationship between blood pressure and disruption of cardiovascular function at levels below the hypertensive threshold. Because prehypertension often develops into hypertension (50% of people within 4 years), even low-risk prehypertensive patients should be monitored annually. Circumspection about labeling patients as hypertensive is warranted since there is evidence that simply telling someone that he or she has hypertension has unintended consequences, transforming a perception of general health into one of general ill-health.

APPROACH TO HYPERTENSION

▶ Etiology & Classification

A. Primary (Essential) Hypertension

Primary (essential) hypertension is the term applied to the 95% of cases in which no cause for hypertension can be identified. When there is no identifiable cause of hypertension, it is most often the result of complex interactions between multiple genetic and environmental factors, but the proportion regarded as “primary/essential” will diminish with improved detection of clearly defined secondary causes and with better understanding of pathophysiology. Primary or essential hypertension occurs in 10–15% of white adults and 20–30% of black adults in the United States. The onset is usually between ages 25 and 55 years; it is uncommon before age 20 years. The best understood endogenous and environmental determinants of blood pressure are discussed below.

1. Sympathetic nervous system hyperactivity—This is most apparent in younger persons with hypertension, who

▲ **Figure 11-1.** The 2005 Canadian Hypertension Education Program recommendations for the assessment and diagnosis of hypertension. Patients with an elevated blood pressure measured during visits 4–5 may still have white-coat (office-induced) hypertension. (Applying the 2005 Canadian Hypertension Education Program recommendations: 1. Diagnosis of hypertension—Reprinted, with permission from CMAJ 30-Aug-05; 173(5), Page(s) 480–483. © 2005 CMA Media Inc.)

may exhibit tachycardia and an elevated cardiac output. However, correlations between plasma catecholamines and blood pressure are poor. Insensitivity of the baroreflexes may play a role in the genesis of adrenergic hyperactivity.

2. Abnormal cardiovascular or renal development—

The normal cardiovascular system develops so that elasticity of the great arteries is matched to the resistance in the periphery to optimize large vessel pressure waves. In this way, myocardial oxygen consumption is minimized and coronary flow maximized. Elevated blood pressure later in life could arise from abnormal development of aortic elasticity or reduced development of the microvascular network. This has been postulated as the sequence of events in

low birth weight infants, who have an increased risk of hypertension developing in adulthood. Another hypothesis proposes that the association between low birth weight and hypertension arises from reduced nephron number.

3. Renin-angiotensin system activity—

Renin, a proteolytic enzyme, is secreted by cells surrounding glomerular afferent arterioles in response to a number of stimuli, including reduced renal perfusion pressure, diminished intravascular volume, circulating catecholamines, increased sympathetic nervous system activity, increased arteriolar stretch, and hypokalemia. Plasma renin levels are classified in relation to dietary sodium intake or urinary sodium excretion. Renin acts on angiotensinogen to cleave off the

ten-amino-acid peptide angiotensin I. This peptide is then acted upon by angiotensin-converting enzyme (ACE) to create the eight-amino-acid peptide angiotensin II, a potent vasoconstrictor and a major stimulant of aldosterone release from the adrenal glands. The incidence of hypertension and its complications may be increased in individuals with the DD genotype of the allele coding for ACE. Despite the role of this system in the regulation of blood pressure, it probably does not play a central role in the pathogenesis of most primary (essential) hypertension; only 10% of patients have high renin activity, whereas 60% have normal levels, and 30% have low levels. Black persons with hypertension and older patients tend to have lower plasma renin activity, which may be associated with expanded intravascular volume.

4. Defect in natriuresis—Normal individuals increase their renal sodium excretion in response to elevations in arterial pressure. In hypertensive patients, this pressure-natriuresis relationship is reset so that maintenance of sodium homeostasis requires increased extracellular fluid volume and higher arterial pressure.

5. Intracellular sodium and calcium—Intracellular Na^+ is elevated in blood cells and other tissues in primary (essential) hypertension. This may result from abnormalities in Na^+/K^+ exchange and other Na^+ transport mechanisms. An increase in intracellular Na^+ may lead to increased intracellular Ca^{2+} concentration as a result of facilitated exchange and might explain the increase in vascular smooth muscle tone that is characteristic of established hypertension.

6. Exacerbating factors—A number of conditions elevate blood pressure, especially in predisposed individuals. **Obesity** is associated with an increase in intravascular volume, elevated cardiac output, activation of the renin-angiotensin system and, probably, increased sympathetic outflow. Weight reduction lowers blood pressure modestly. The relationship between **sodium intake** and hypertension remains controversial, but dietary salt restriction is recommended in patients with elevated blood pressure (see below).

Excessive use of **alcohol** also raises blood pressure, perhaps by increasing plasma catecholamines. Hypertension can be difficult to control in patients who consume more than 40 g of ethanol (two drinks) daily or drink in “binges.” **Cigarette smoking** raises blood pressure, again by increasing plasma norepinephrine. Although the long-term effect of smoking on blood pressure is less clear, the synergistic effects of smoking and high blood pressure on cardiovascular risk are well documented. The relationship of **exercise** to hypertension is variable. Aerobic exercise lowers blood pressure in previously sedentary individuals, but increasingly strenuous exercise in already active subjects has less effect. The relationship between stress and hypertension is not established. **Polycythemia**, whether primary or due to diminished plasma volume, increases blood viscosity and may raise blood pressure. **Nonsteroidal anti-inflammatory drugs (NSAIDs)** produce increases in blood pressure averaging 5 mm Hg and are best avoided in patients with borderline or elevated blood pressures. Low **potassium intake** is associated

with higher blood pressure in some patients; an intake of 90 mmol/d is recommended.

There is a growing recognition that the complex of abnormalities termed the “metabolic syndrome” is associated with both the development of hypertension and an increased risk of adverse cardiovascular outcomes. The metabolic syndrome (sometimes also called syndrome X or the “deadly quartet”) consists of upper body obesity, hyperinsulinemia and insulin resistance, hypertriglyceridemia, and hypertension. Affected patients usually also have low high-density lipoprotein (HDL) cholesterol levels and have been found to have elevated catecholamines and inflammatory markers such as C-reactive protein.

B. Secondary Hypertension

Approximately 5% of patients with hypertension have identifiable specific causes (Table 11–2) revealed by the history, physical examination, and routine laboratory tests. In particular, secondary hypertension should be suspected in patients in whom hypertension develops at an early age, those who first exhibit hypertension when over age 50 years, or those previously well controlled who become refractory to treatment. Causes include genetic syndromes, kidney disease, renal vascular hypertension, primary hyperaldosteronism, Cushing syndrome, pheochromocytoma, coarctation of the aorta, hypertension associated with pregnancy, estrogen use, hypercalcemia and medications.

1. Genetic causes—Hypertension can be caused by mutations in single genes, inherited on a mendelian basis. Although rare, these conditions provide important insight into blood pressure regulation and possibly the genetic basis of essential hypertension. **Glucocorticoid remediable aldosteronism** is an autosomal dominant cause of early-onset hypertension with normal or high aldosterone and low renin levels. It is caused by the formation of a chimeric gene encoding both the enzyme responsible for the synthesis of aldosterone (transcriptionally regulated by angiotensin II) and an enzyme responsible for synthesis of cortisol (transcriptionally regulated by ACTH). As a consequence, aldosterone synthesis becomes driven by ACTH, which can

be suppressed by exogenous cortisol. In the **syndrome of apparent mineralocorticoid excess**, early-onset hypertension with hypokalemic metabolic alkalosis is inherited on an autosomal recessive basis. Although plasma renin is low and plasma aldosterone level is very low in these patients, aldosterone antagonists are effective in controlling hypertension. This disease is caused by loss of the enzyme, 11 β -hydroxysteroid dehydrogenase, which normally metabolizes cortisol and thus protects the otherwise “promiscuous” mineralocorticoid receptor in the distal nephron from inappropriate glucocorticoid activation. Similarly, glycyrrhetic acid, found in licorice, causes increased blood pressure through inhibition of 11 β -hydroxysteroid dehydrogenase. The syndrome of **hypertension exacerbated in pregnancy** is inherited as an autosomal dominant trait. In these patients, a mutation in the mineralocorticoid receptor makes it abnormally responsive to progesterone and, paradoxically, to spironolactone. **Liddle syndrome** is an autosomal dominant condition characterized by early-onset hypertension, hypokalemic alkalosis, low renin and low aldosterone levels. This is caused by a mutation that results in constitutive activation of the epithelial sodium channel of the distal nephron, with resultant unregulated sodium reabsorption and volume expansion.

2. Renal disease—Renal parenchymal disease is the most common cause of secondary hypertension. Hypertension may result from diabetic and inflammatory glomerular diseases, tubular interstitial disease, and polycystic kidneys. Most cases are related to increased intravascular volume or increased activity of the renin–angiotensin–aldosterone system.

3. Renal vascular hypertension—Renal artery stenosis is present in 1–2% of hypertensive patients. Its cause in most younger individuals is fibromuscular hyperplasia, particularly in women under 50 years of age. The remainder of renal vascular disease is due to atherosclerotic stenoses of the proximal renal arteries. The mechanism of hypertension is excessive renin release due to reduction in renal blood flow and perfusion pressure.

Renal vascular hypertension should be suspected in the following circumstances: (1) if the documented onset is before age 20 or after age 50 years, (2) hypertension is resistant to three or more drugs, (3) if there are epigastric or renal artery bruits, (4) if there is atherosclerotic disease of the aorta or peripheral arteries (15–25% of patients with symptomatic lower limb atherosclerotic vascular disease have renal artery stenosis), (5) if there is abrupt deterioration in kidney function after administration of ACE inhibitors, or (6) if episodes of pulmonary edema are associated with abrupt surges in blood pressure. There is no ideal screening test for renal vascular hypertension. If suspicion is sufficiently high and endovascular intervention is a viable option, renal arteriography, the definitive diagnostic test, is the best approach. Renal arteriography is not recommended as a routine adjunct to coronary studies. Where suspicion is moderate to low, noninvasive angiography using magnetic resonance (MR) or CT are reasonable approaches. With improvements in technology, Doppler

sonography may play an increasing role in detection of RAS, providing physiologic indices of stenosis severity and ease of repeated examination to detect progression. However, results of all these modalities vary greatly between institutions. In 2006, a public health advisory was issued regarding the use of gadolinium (a contrast agent used in MRA), warning that it might precipitate nephrogenic systemic fibrosis in patients with advanced kidney disease. Clearly, no diagnostic study should be undertaken without a careful consideration of the risk-benefit ratio. In young patients with fibromuscular disease, angioplasty is very effective, but there is controversy regarding the best approach to the treatment of atheromatous renal artery stenosis. Correction of the stenosis in selected patients might reduce the number of medications required to control blood pressure and could protect kidney function, but the extent of preexisting parenchymal damage to the affected and contralateral kidney has a significant influence on both blood pressure and kidney function outcomes following revascularization. A reasonable approach advocates medical therapy as long as hypertension can be well controlled and there is no progression of kidney disease. The addition of a statin should be considered. Endovascular intervention might be considered in patients with uncontrollable hypertension, progressive kidney disease, or episodic pulmonary edema attributable to the lesion. Angioplasty might also be warranted when progression of stenosis is either demonstrated or is predicted by a constellation of risk factors, including systolic blood pressure > 160 mm Hg, advanced age, diabetes mellitus, and high-grade stenosis (> 60%) at the time of diagnosis. However, conclusive outcomes data to guide management are still awaited. Although ACE inhibitors have improved the success rate of medical therapy of hypertension due to renal artery stenosis, they have been associated with marked hypotension and (usually reversible) kidney dysfunction in individuals with bilateral disease. Thus, kidney function and blood pressure should be closely monitored during the first weeks of therapy in patients in whom this is a consideration.

4. Primary hyperaldosteronism—Over the past decade, studies have suggested that primary hyperaldosteronism might account for some 10% of essential hypertension. However, this could be an overestimate due to sampling bias and problems with the specificity of a screening test based on the measurement of plasma aldosterone concentration (normal: 1–16 ng/dL) and plasma renin activity (normal: 1–2.5 ng/mL/h) and calculation of the plasma aldosterone/renin ratio (normal < 30). This is because “bottoming out” of renin assays leads to exponential increases in the plasma aldosterone/renin ratio even when aldosterone levels are normal. Hence, an elevated plasma aldosterone/renin ratio should probably not be taken as evidence of hyperaldosteronism unless the aldosterone level is actually elevated. The primacy of aldosterone in driving hypertension in low-renin patients has been questioned because spironolactone, which is uniquely potent in hyperaldosteronism, seems to be no more effective at lowering blood pressure than thiazide diuretics in low renin hypertensive patients. The lesion responsible for

hyperaldosteronism is an adrenal adenoma or bilateral adrenal hyperplasia and can be demonstrated by CT or MRI scanning. Screening is appropriate in patients with resistant hypertension, (needing more than three drugs for control) and those with spontaneous or thiazide-induced hypokalemia, incidentaloma, or family history of primary hyperaldosteronism.

Medications that alter renin and aldosterone levels, including ACE inhibitors, angiotensin receptor blockers (ARBs), diuretics (especially spironolactone), β -blockers, and clonidine, should be discontinued at least a week before sampling. Calcium channel and α -receptor blockers can be used to control blood pressure during this drug washout period. Based on this approach, patients with aldosterone/renin ratios of ≥ 30 with a plasma aldosterone level > 15 ng/dL might require further evaluation for primary hyperaldosteronism.

5. Cushing syndrome—Among those with spontaneous Cushing syndrome, hypertension occurs in about 75–85% of patients. The exact pathogenesis of the hypertension is unclear. It may be related to salt and water retention from the mineralocorticoid effects of the excess glucocorticoid. Alternatively, it may be due to increased secretion of angiotensinogen. In addition, glucocorticoids exert permissive effects on vascular tone by a variety of mechanisms.

Diagnosis and treatment of Cushing syndrome are discussed in Chapter 26.

6. Pheochromocytoma—Pheochromocytomas are uncommon; they are probably found in less than 0.1% of all patients with hypertension and in approximately two individuals per million population. However, autopsy studies indicate that pheochromocytomas are very often undiagnosed in life. The blood pressure elevation caused by the catecholamine excess results from two mechanisms: α -receptor-mediated vasoconstriction of arterioles, leading to an increase in peripheral resistance, and β_1 -receptor-mediated increases in cardiac output and in renin release, leading to increased circulating levels of angiotensin II. The increased total peripheral vascular resistance is probably primarily responsible for the maintenance of high arterial pressures. Chronic vasoconstriction of the arterial and venous beds leads to a reduction in plasma volume and predisposes to postural hypotension. Glucose intolerance develops in some patients. Hypertensive crisis in pheochromocytoma may be precipitated by a variety of drugs, including tricyclic antidepressants, antidopaminergic agents, metoclopramide, and naloxone. The diagnosis and treatment of pheochromocytoma are discussed in Chapter 26.

7. Coarctation of the aorta—This uncommon cause of hypertension is discussed in Chapter 10.

8. Hypertension associated with pregnancy—Hypertension occurring de novo or worsening during pregnancy, including preeclampsia and eclampsia, is one of the most common causes of maternal and fetal morbidity and mortality (see Chapter 19).

9. Estrogen use—A small increase in blood pressure occurs in most women taking oral contraceptives, but

considerable increases are noted occasionally. This is caused by volume expansion due to increased hepatic synthesis of renin substrate and consequent activation of the renin-angiotensin-aldosterone system. Five percent of women taking long-term oral contraceptives exhibit a rise in blood pressure above 140/90 mm Hg, twice the expected prevalence. Contraceptive-related hypertension is more common in women over 35 years of age, in those who have taken contraceptives for more than 5 years, and in obese individuals. It is less common in those taking low-dose estrogen tablets. In most, hypertension is reversible by discontinuing the contraceptive, but it may take several weeks. Postmenopausal estrogen does not generally cause hypertension, but rather maintains endothelium-mediated vasodilation.

10. Other causes of secondary hypertension—Hypertension has also been associated with hypercalcemia due to any cause: acromegaly, hyperthyroidism, hypothyroidism, baroreceptor denervation, compression of the rostral ventrolateral medulla, and increased intracranial pressure. A number of medications may cause or exacerbate hypertension—most importantly cyclosporine, tacrolimus, angiogenesis inhibitors, decongestants, and NSAIDs; cocaine and alcohol should also be considered.

▶ When to Refer

Referral to a hypertension specialist should be considered in cases of severe, resistant or early/late onset hypertension or when secondary hypertension is suggested by screening.

▶ Complications of Untreated Hypertension

Complications of hypertension are related either to sustained elevations of blood pressure, with consequent changes in the vasculature and heart, or to atherosclerosis that accompanies and is accelerated by long-standing hypertension. Most of the adverse outcomes in hypertension are associated with thrombosis rather than bleeding, possibly because increased vascular shear stress converts the normally anticoagulant endothelium to a prothrom-

botic state. The excess morbidity and mortality related to hypertension are progressive over the whole range of systolic and diastolic blood pressures; the risk approximately doubles for each 6 mm Hg increase in diastolic blood pressure. However, target-organ damage varies markedly between individuals with similar levels of office hypertension; ambulatory pressures are superior to office readings in the prediction of end-organ damage.

A. Hypertensive Cardiovascular Disease

Cardiac complications are the major causes of morbidity and mortality in primary (essential) hypertension, and preventing them is a major goal of therapy. Electrocardiographic evidence of left ventricular hypertrophy is found in up to 15% of persons with chronic hypertension. For any level of blood pressure, its presence is associated with incremental cardiovascular risk. Echocardiographic left ventricular hypertrophy is a powerful predictor of prognosis. Left ventricular hypertrophy may cause or facilitate many cardiac complications of hypertension, including congestive heart failure, ventricular arrhythmias, myocardial ischemia, and sudden death.

Left ventricular diastolic dysfunction, which may present with all of the symptoms and signs of congestive heart failure, is common in patients with long-standing hypertension. The occurrence of heart failure is reduced by 50% with antihypertensive therapy. Hypertensive left ventricular hypertrophy regresses with therapy and is most closely related to the degree of systolic blood pressure reduction. Diuretics have produced equal or greater reductions of left ventricular mass when compared with other drug classes. β -Blockers are less effective in reducing left ventricular hypertrophy but play a specific role in patients with established coronary artery disease or impaired left ventricular function.

B. Hypertensive Cerebrovascular Disease and Dementia

Hypertension is the major predisposing cause of hemorrhagic and ischemic stroke. Cerebrovascular complications are more closely correlated with systolic than diastolic blood pressure. The incidence of these complications is markedly reduced by antihypertensive therapy. Preceding hypertension is associated with a higher incidence of subsequent dementia of both vascular and Alzheimer types. Effective blood pressure control may reduce the risk of development of cognitive dysfunction later in life, but once cerebral small vessel disease is established, low blood pressure might exacerbate this problem.

C. Hypertensive Kidney Disease

Chronic hypertension leads to nephrosclerosis, a common cause of chronic kidney disease; aggressive blood pressure control attenuates the process. In patients with hypertensive nephropathy, the blood pressure should be 130/80 mm Hg or lower, especially when proteinuria is present. Secondary kidney disease is more common in blacks, particularly when accompanied by diabetes mellitus. Hypertension also plays an important role in accelerating the progression of all forms of kidney disease.

D. Aortic Dissection

Hypertension is a contributing factor in many patients with dissection of the aorta. Its diagnosis and treatment are discussed in Chapter 12.

E. Atherosclerotic Complications

Most Americans with hypertension die of complications of atherosclerosis, but the link between hypertension and atherosclerotic cardiovascular disease is not as clear as that with the previously discussed complications. Effective antihypertensive therapy is thus less successful in preventing complications of coronary heart disease.

Clinical Findings

The clinical and laboratory findings are mainly referable to involvement of the target organs: heart, brain, kidneys, eyes, and peripheral arteries.

A. Symptoms

Mild to moderate primary (essential) hypertension is largely asymptomatic for many years. The most frequent symptom, headache, is also very nonspecific. Accelerated hypertension is associated with somnolence, confusion, visual disturbances, and nausea and vomiting (hypertensive encephalopathy).

Hypertension in patients with pheochromocytomas that secrete predominantly norepinephrine is usually sustained but may be episodic. The typical attack lasts from minutes to hours and is associated with headache, anxiety, palpitation, profuse perspiration, pallor, tremor, and nausea and vomiting. Blood pressure is markedly elevated, and angina or acute pulmonary edema may occur. In primary aldosteronism, patients may have muscular weakness, polyuria, and nocturia due to hypokalemia; malignant hypertension is rare. Chronic hypertension often leads to left ventricular hypertrophy, which can present with exertional and paroxysmal nocturnal dyspnea. Cerebral involvement causes stroke due to thrombosis or hemorrhage from microaneurysms of small penetrating intracranial arteries. Hypertensive encephalopathy is probably caused by acute capillary congestion and exudation with cerebral edema, which is reversible.

B. Signs

Like symptoms, physical findings depend on the cause of hypertension, its duration and severity, and the degree of effect on target organs.

1. Blood pressure—Blood pressure is taken in both arms and, if lower extremity pulses are diminished or delayed, in the legs to exclude coarctation of the aorta. An orthostatic drop is present in pheochromocytoma. Older patients may have falsely elevated readings by sphygmomanometry because of noncompressible vessels. This may be suspected in the presence of Osler sign—a palpable brachial or radial artery when the cuff is inflated above systolic pressure. Occasionally, it may be necessary to make direct measurements of intra-arterial pressure, especially in patients with apparent severe hypertension who do not tolerate therapy.

2. Retinas—Narrowing of arterial diameter to less than 50% of venous diameter, copper or silver wire appearance, exudates, hemorrhages, or papilledema are associated with a worse prognosis.

3. Heart—A left ventricular heave indicates severe or long-standing hypertrophy. Aortic insufficiency may be auscultated in up to 5% of patients, and hemodynamically insignificant aortic insufficiency can be detected by Doppler echocardiography in 10–20%. A presystolic (S4) gallop due to decreased compliance of the left ventricle is quite common in patients in sinus rhythm.

4. Pulses—Radial-femoral delay suggests coarctation of the aorta; loss of peripheral pulses occurs due to atherosclerosis, less commonly aortic dissection, and rarely Takayasu arteritis, all of which can involve the renal arteries.

C. Laboratory Findings

Recommended testing includes the following: hemoglobin; urinalysis and renal function studies, to detect hematuria, proteinuria, and casts, signifying primary kidney disease or nephrosclerosis; fasting blood sugar level, since hypertension is a risk factor for the development of diabetes and hyperglycemia can be a presenting feature of pheochromocytoma; plasma lipids, as an indicator of atherosclerosis risk and an additional target for therapy; serum uric acid which, if elevated, is a relative contraindication to diuretic therapy; and serum electrolytes. Measurement of the plasma aldosterone/renin ratio is indicated to screen for mineralocorticoid excess in hypertensive patients with hypokalemic alkalosis (even if they are taking diuretics), resistant hypertension, or an adrenal incidentaloma (see Primary Hyperaldosteronism, above).

D. Electrocardiography and Chest Radiographs

Electrocardiographic criteria are highly specific but not very sensitive for left ventricular hypertrophy. The “strain” pattern of ST–T wave changes is a sign of more advanced disease and is associated with a poor prognosis. A chest radiograph is not necessary in the workup for uncomplicated hypertension.

E. Echocardiography

The primary role of echocardiography should be to evaluate patients with clinical symptoms or signs of cardiac disease.

F. Diagnostic Studies

Additional diagnostic studies are indicated only if the clinical presentation or routine tests suggest secondary or complicated hypertension. These may include tests such as 24-hour urine free cortisol, plasma metanephrines and the plasma aldosterone/renin ratio for endocrine causes of hypertension, renal ultrasound to diagnose primary kidney disease (polycystic kidneys, obstructive uropathy), and testing for renal artery stenosis. Further evaluation may include abdominal imaging studies (ultrasound, CT scan, or MRI) or renal arteriography.

G. Summary

Since most hypertension is “primary,” few studies are necessary beyond those listed above. If conventional therapy is unsuccessful or if symptoms suggest a secondary cause, further studies are indicated.

▶ Nonpharmacologic Therapy

Lifestyle modification may have an impact on morbidity and mortality. A diet rich in fruits, vegetables, and low-fat dairy foods and low in saturated and total fats (DASH diet) has been shown to lower blood pressure. Additional measures, listed in Table 11–3, can prevent or mitigate hypertension or its cardiovascular consequences.

All patients with high-normal or elevated blood pressures, those who have a family history of cardiovascular complications of hypertension, and those who have multiple coronary risk factors should be counseled about nonpharmacologic approaches to lowering blood pressure. Approaches of proved but modest value include weight reduction, reduced alcohol consumption and, in some patients, reduced salt intake. Gradually increasing activity levels should be encouraged in previously sedentary patients, but strenuous exercise training programs in already active individuals may have less benefit. Calcium and potassium supplements have been advocated, but their ability to lower blood pressure is limited. Smoking cessation will reduce overall cardiovascular risk. Overall, the effects of lifestyle modification on blood pressure are modest. Although all patients should be urged to modify risk factors, medication is likely to be required for optimal blood pressure control in stage 1 hypertension.

Table 11-3. Lifestyle modifications to manage hypertension.¹

| Modification | Recommendation | Approximate Systolic BP Reduction, Range |
|-----------------------------------|--|--|
| Weight reduction | Maintain normal body weight (BMI, 18.5-24.9) | 5-20 mm Hg/10-kg weight loss |
| Adopt DASH eating plan | Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated fat and total fat | 8-14 mm Hg |
| Dietary sodium reduction | Reduce dietary sodium intake to no more than 100 mEq/d (2.4 g sodium or 6 g sodium chloride) | 2-8 mm Hg |
| Physical activity | Engage in regular aerobic physical activity such as brisk walking (at least 30 minutes per day, most days of the week) | 4-9 mm Hg |
| Moderation of alcohol consumption | Limit consumption to no more than two drinks per day (1 oz or 30 mL ethanol [eg, 24 oz beer, 10 oz wine, or 3 oz 80-proof whiskey]) in most men and no more than one drink per day in women and lighter-weight persons | 2-4 mm Hg |

¹For overall cardiovascular risk reduction, stop smoking. The effects of implementing these modifications are dose and time dependent and could be higher for some individuals. BMI, body mass index calculated as weight in kilograms divided by the square of height in meters; BP, blood pressure; DASH, Dietary Approaches to Stop Hypertension. Source: Chobanian AV et al. ► Who Should Be Treated with Medications?

The decision to initiate drug therapy is relatively straightforward once hypertension has been unequivocally diagnosed (Table 11-1 and Figure 11-1), but less clear in persons with prehypertension (blood pressure of 120-139/80-89 mm Hg). Some experts have suggested that early blood pressure elevation, and perhaps antecedent metabolic abnormalities, lead to vascular damage that propels further

blood pressure elevation in an ever accelerating spiral of progression. If so, then interception early in the course might modify the natural history of the disease, leading to diminished requirements for multiple antihypertensive agents and, perhaps, a much more dramatic effect on cardiovascular risk than can be attained with initiation of treatment once hypertension is established. In beginning to address this question, the TROPHY study showed that treatment of prehypertension in a population at no particular risk for cardiovascular events only seemed to delay the onset of hypertension, since blood pressure in the treated group increased toward the placebo group when treatment was discontinued. The situation is a little clearer in nonhypertensive patients at elevated cardiovascular risk, in whom the HOPE and PROGRESS trials indicated improved outcomes with antihypertensive medication (ACE inhibitor and ACE inhibitor plus diuretic, respectively). These observations have prompted some to think in terms of “optimizing” blood pressure to a suggested 120/80 mm Hg. However, the public health consequences of recommendations to treat prehypertension would be enormous. Forty-eight percent of all Americans have hypertension or prehypertension, and much higher proportions fit these categories in a typical family medicine population. The JNC 7 guidelines suggest that antihypertensive medications be offered to persons with prehypertension with compelling indications for treatment such as chronic kidney disease or diabetes mellitus (Table 11-4). According to the British Hypertension Society (BHS) recommendations, risk analysis should be used to target treatment to patients with borderline hypertension who are most likely to benefit, particularly individuals at high combined risk of coronary heart or stroke event (> 20-30% within 10 years) (Figure 11-2). Risk is calculated according to Framingham study criteria (calculated from several of the risk factors listed in Table 11-5). A low-risk patient with blood pressure between 120-139/80-89 mm Hg may be advised to make lifestyle modifications (Table 11-3) and be monitored without receiving an absolute diagnosis of prehypertension. A risk calculation tool can be downloaded from http://www.bhsoc.org/Cardiovascular_Risk_Charts_and_Calculators.stm (in using this tool, convert serum cholesterol from mg/dL to mmol/L by dividing by 38.7). A free PDA-based coronary heart disease risk calculator is available at <http://www.statcoder.com/cholesterol.htm>. In general, 20% total cardiovascular risk (which includes stroke) is equivalent to 15% coronary heart disease risk.

► Goals of Treatment

Treatment should ideally be offered to all persons in whom blood pressure reduction, irrespective of initial blood pressure levels, will reduce overall cardiovascular risk (see above). Blood pressure targets for hypertensive patients at the greatest risk for cardiovascular events, particularly patients with diabetes and those with chronic kidney disease, should be lower (< 130/80 mm Hg) than for individuals at lower total cardiovascular risk (< 140/90 mm Hg). However, since there does not seem to be a blood pressure level below which risk plateaus, these recommendations should be taken

Table 11–4. Clinical trial and guideline basis for compelling indications for individual drug classes.¹

| High-Risk Conditions with Compelling Indication ² | Recommended Drugs | | | | | | Clinical Trial Basis |
|--|-------------------|------------|----------------|-----|-----|------------------------|--|
| | Diuretic | β-Blockers | ACE Inhibitors | ARB | CCB | Aldosterone Antagonist | |
| Heart failure | • | • | • | • | | • | ACC/AHA Heart Failure Guideline, MERIT-HF, COPERNICUS, CIBIS, SOLVD, AIRE, TRACE, ValHEFT, RALES |
| Post-myocardial infarction | | • | • | | | • | ACC/AHA Post-MI Guideline, BHAT, SAVE, Capricorn, EPHEBUS |
| High coronary disease risk | • | • | • | | • | | ALLHAT, HOPE, ANBP2, LIFE, CONVINCENCE |

Source: Chobanian AV et al. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure: the JNC 7 report. *JAMA*. 2003 May 21;289(19):2560–72.

as reasonable goals pending further information on optimal targets, which may be even lower. On the other hand, lower may not always be better. The association between cognitive decline and lower blood pressure in the elderly has led to the proposal that hypertension in mid-life gives rise to cerebrovascular small vessel disease that predisposes to hypoperfusion of subcortical white matter and cognitive decline later in life. Similarly, excessive lowering of diastolic pressure, perhaps below 70 mm Hg, should be avoided in patients with coronary artery disease. Overall, however, several studies in older persons with predominantly systolic hypertension have confirmed that antihypertensive therapy prevents fatal and nonfatal myocardial infarction and overall cardiovascular mortality. These trials have also placed the focus on control of systolic blood pressure—in contrast to the historical emphasis on diastolic blood pressures.

There is no clear consensus on blood pressure goals in the management of prehypertension, but pressure should still be treated until it is < 130/80 mm Hg in prehypertensive patients with diabetes or chronic kidney disease and perhaps also in those at high risk for a cardiovascular event.

Large-scale trials in hypertension have focused on discrete end points occurring over relatively short intervals, thereby placing the emphasis on the prevention of cata-

strophic events in advanced disease. More recently, in parallel with a new emphasis on hypertension in the context of overall cardiovascular risk, attention is turning to the importance of the long view. Accordingly, treatment of persons with hypertension should focus on comprehensive risk reduction with more careful consideration of the possible long-term adverse consequences of the metabolic derangements linked to some antihypertensives (particularly conventional β-blockers and thiazide diuretics).

Statins should be more widely used. In this respect, there is evidence from the Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT) that statins can significantly improve outcomes in persons with hypertension (with modest background cardiovascular risk) whose total cholesterol is < 250 mg/dL. Furthermore, this effect appeared to be synergistic with calcium channel blocker/ACE inhibitor regimens but not β-blocker/diuretic regimens. The BHS guidelines recommend that statins be offered as secondary prevention to patients whose total cholesterol exceeds 135 mg/dL if they have documented coronary artery disease or a history of ischemic stroke. In addition, statins should be considered as primary prevention in patients with long-standing type 2 diabetes mellitus or in those with type 2 diabetes mellitus who are older than age 50 years, and perhaps in all persons

¹Assessed with CVD risk chart.

with type 2 diabetes mellitus. Ideally, total and low-density lipoprotein (LDL) cholesterol should be reduced by 30% and 40% respectively, or to approximately < 155 mg/dL and < 77 mg/dL, whichever is the greatest reduction. However, total and LDL cholesterol levels of < 194 mg/dL and < 116 mg/dL respectively, or reductions of 25% and 30% are regarded as clinically acceptable objectives. Primary prevention with statins might also be reasonably extended to all patients with total cholesterol > 135 mg/dL and a total cardiovascular risk > 20% (to similar target cholesterol levels), but trial evidence for this is not currently available. Low-dose aspirin (81 mg/day) is likely to be beneficial in patients older than age 50 with either target organ damage or elevated total cardiovascular risk (> 20–30%). Care should be taken to ensure that blood pressure is controlled to the recommended levels before starting aspirin to minimize the risk of bleeding.

DRUG THERAPY: CURRENT ANTIHYPERTENSIVE AGENTS

There are now many classes of potentially antihypertensive drugs of which six (diuretics, β -blockers, renin inhibitors, ACE inhibitors, calcium channel blockers, and ARBs) are suitable for initial therapy based on efficacy and tolerability. A number of considerations enter into the selection of the initial regimen for a given patient. These include the weight of evidence for beneficial effects on clinical outcomes, the safety and tolerability of the drug, its cost, demographic differences in response, concomitant medical conditions, and lifestyle issues. The specific classes of antihypertensive medications are discussed below, and guidelines for the choice of initial medications are offered.

A. Diuretics

Thiazide diuretics (Table 11–6) are the antihypertensives that have been most extensively studied and most consistently effective in clinical trials. They lower blood pressure initially by decreasing plasma volume (by suppressing tubular reabsorption of sodium, thus increasing the excretion of sodium and water) and cardiac output, but during long-term therapy their major hemodynamic effect is reduction of peripheral vascular resistance. Most of the antihypertensive effect of these agents is achieved at lower dosages than used previously (typically, 12.5 or 25 mg of hydrochlorothiazide or equivalent), but their biochemical and metabolic

effects are dose related. Chlorthalidone has the advantage of better 24-hour blood pressure control than hydrochlorothiazide. The loop diuretics (such as furosemide) may lead to electrolyte and volume depletion more readily than the thiazides and have short durations of action; therefore, loop diuretics should not be used in hypertension except in the presence of kidney dysfunction (serum creatinine above 2.5 mg/dL). Relative to the β -blockers and the ACE inhibitors, diuretics are more potent in blacks, older individuals, the obese, and other subgroups with increased plasma volume or low plasma renin activity. Interestingly, they are relatively more effective in smokers than in nonsmokers. Long-term thiazide administration also mitigates the loss of bone mineral content in older women at risk for osteoporosis.

Overall, diuretics administered alone control blood pressure in 50% of patients with mild to moderate hypertension and can be used effectively in combination with all other agents. They are also useful for lowering isolated or predominantly systolic hypertension. The adverse effects of diuretics relate primarily to the metabolic changes listed in Table 11–6. Impotence, skin rashes, and photosensitivity are less frequent. Hypokalemia has been a concern but is uncommon at the recommended dosages (12.5–25 mg hydrochlorothiazide). The risk can be minimized by limiting dietary salt or increasing dietary potassium; potassium replacement is not usually required to maintain serum K^+ at > 3.5 mmol/L. Higher serum K^+ levels are prudent in patients at special risk from intracellular potassium depletion, such as those taking digoxin or with a history of ventricular arrhythmias. If higher doses of diuretic are required, the drug should be used in combination with a potassium-sparing agent or with an ACE inhibitor or ARB. Compared with ACE inhibitors and ARBs, diuretic therapy is associated with a slightly higher incidence of mild new-onset diabetes. Diuretics also increase serum uric acid and may precipitate gout. Increases in blood glucose, triglycerides, LDL cholesterol, and plasma insulin may occur but are relatively minor during long-term low-dose therapy.

B. β -Adrenergic Blocking Agents

These drugs are effective in hypertension because they decrease the heart rate and cardiac output. Even after continued use of β -blockers, cardiac output remains lower and systemic vascular resistance higher with agents that do not have intrinsic sympathomimetic or α -blocking activity. The β -blockers also decrease renin release and are more efficacious in populations with elevated plasma renin activity, such as younger white patients. They neutralize the reflex tachycardia caused by vasodilators and are especially useful in patients with associated conditions that benefit from the cardioprotective effects of these agents. These include individuals with angina pectoris, previous myocardial infarction, and stable congestive heart failure as well as those with migraine headaches and somatic manifestations of anxiety.

Although all β -blockers appear to be similar in antihypertensive potency, controlling approximately 50% of patients, they differ in a number of pharmacologic properties (these differences are summarized in Table 11–7), including specificity to the cardiac β_1 -receptors (cardioselect-

Table 11–6. Antihypertensive drugs: Diuretics.

| Drugs | Proprietary Names | Initial Oral Doses | Dosage Range | Cost per Unit | Cost of 30 Days Treatment ¹ (Average Dosage) | Adverse Effects | Comments |
|--|--|---------------------------|-------------------------------|---------------|---|---|--|
| Thiazides and related diuretics | | | | | | | |
| Hydrochlorothiazide | Esidrix, Hydro-Diuril | 12.5 or 25 mg once daily | 12.5–50 mg once daily | \$0.08/25 mg | \$2.40 | ↓ K ⁺ , ↓ Mg ²⁺ , ↑ Ca ²⁺ , ↓ Na ⁺ , ↑ uric acid, ↑ glucose, ↑ LDL cholesterol, ↑ triglycerides; rash, erectile dysfunction. | Low dosages effective in many patients without associated metabolic abnormalities; metolazone more effective with concurrent kidney disease; indapamide does not alter serum lipid levels. |
| Chlorthalidone | Hygroton, Thaliton | 12.5 or 25 mg once daily | 12.5–50 mg once daily | \$0.23/25 mg | \$6.90 | | |
| Metolazone | Zaroxolyn | 1.25 or 2.5 mg once daily | 1.25–5 mg once daily | \$1.48/5 mg | \$44.40 | | |
| Indapamide | Lozol | 2.5 mg once daily | 2.5–5 mg once daily | \$0.83/2.5 mg | \$24.90 | | |
| Loop diuretics | | | | | | | |
| Furosemide | Lasix | 20 mg twice daily | 40–320 mg in 2 or 3 doses | \$0.16/40 mg | \$9.60 | Same as thiazides, but higher risk of excessive diuresis and electrolyte imbalance. Increases calcium excretion. | Furosemide: Short duration of action a disadvantage; should be reserved for patients with kidney disease or fluid retention. Poor anti-hypertensive. |
| Ethacrynic acid | Edecrin | 50 mg once daily | 50–100 mg once or twice daily | \$1.17/25 mg | \$140.00 | | |
| Bumetanide | Bumex | 0.25 mg twice daily | 0.5–10 mg in 2 or 3 doses | \$0.45/1 mg | \$27.00 | | |
| Torsemide | Demadex | 2.5 mg once daily | 5–10 mg once daily | \$0.70/10 mg | \$21.00 | | Torsemide: Effective blood pressure medication at low dosage. |
| Aldosterone receptor blockers | | | | | | | |
| Spironolactone | Aldactone | 12.5 or 25 mg once daily | 12.5–100 mg once daily | \$0.46/25 mg | \$13.80 | Hyperkalemia, metabolic acidosis, gynecomastia. | Can be useful add-on therapy in patients with refractory hypertension. |
| Amiloride | Midamor | 5 mg once daily | 5–10 mg once daily | \$1.29/5 mg | \$38.70 | | |
| Eplerenone | Inspra | 25 mg once daily | 25–100 mg once daily | \$4.10/25 mg | \$123.07 | | |
| Combination products | | | | | | | |
| Hydrochlorothiazide and triamterene | Dyazide (25/50 mg); Maxzide (25/37.5 mg) | 1 tab once daily | 1 or 2 tabs once daily | \$0.34 | \$10.20 | Same as thiazides plus GI disturbances, hyperkalemia rather than hypokalemia, headache; triamterene can cause kidney stones and kidney dysfunction; spironolactone causes gynecomastia. Hyperkalemia can occur if this combination is used in patients with advanced kidney disease or those taking ACE inhibitors. | Use should be limited to patients with demonstrable need for a potassium-sparing agent. |
| Hydrochlorothiazide and amiloride | Moduretic (50/5 mg) | 1/2 tab once daily | 1 or 2 tabs once daily | \$0.42 | \$12.60 | | |
| Hydrochlorothiazide and spironolactone | Aldactazide (25/25 mg) | 1 tab once daily | 1 or 2 tabs once daily | \$0.50 | \$15.00 | | |

²Agents with β_1 selectivity are less likely to precipitate bronchospasm and decreased peripheral blood flow *in low doses*, but selectivity is only relative.

³Agents with ISA cause less resting bradycardia and lipid changes.

⁴MSA generally occurs at concentrations greater than those necessary for β -adrenergic blockade. The clinical importance of MSA by β -blockers has not been defined.

⁵Adverse effects of all β -blockers: bronchospasm, fatigue, sleep disturbance and nightmares, bradycardia and atrioventricular block, worsening of congestive heart failure, cold extremities, gastrointestinal disturbances, impotence, \uparrow triglycerides, \downarrow HDL cholesterol, rare blood dyscrasias.

ANA, antinuclear antibody; ISA, intrinsic sympathomimetic activity; LE, lupus erythematosus; MI, myocardial infarction; MSA, membrane-stabilizing activity; SR, sustained release; 0, no effect; +, some effect; ++, moderate effect; +++, most effect.

tivity) and whether they also block the β_2 -receptors in the bronchi and vasculature; at higher dosages, however, all agents are nonselective. The β -blockers also differ in their pharmacokinetics and lipid solubility—which determines whether they cross the blood–brain barrier and affect the incidence of central nervous system side effects—and route of metabolism. Labetalol and carvedilol are combined α - and β -blockers and, unlike most β -blockers, decrease peripheral vascular resistance.

The side effects of all β -blockers include inducing or exacerbating bronchospasm in predisposed patients (eg, those with asthma and some patients with chronic obstructive pulmonary disease [COPD]); sinus node dysfunction and atrioventricular (AV) conduction depression (resulting in bradycardia or AV block); nasal congestion; Raynaud phenomenon; and central nervous system symptoms with nightmares, excitement, depression, and confusion. Fatigue, lethargy, and impotence may occur. All β -blockers tend to increase plasma triglycerides. The nonselective and, to a lesser extent, the cardioselective (β_1 -selective) β -blockers tend to depress the protective HDL fraction of plasma cholesterol. As with diuretics, the changes are blunted with time and dietary changes.

β -Blockers have traditionally been considered contraindicated in patients with congestive heart failure. Evolving experience suggests that they have a propitious effect on the natural history of patients with chronic stable heart failure and reduced ejection fraction (see Chapter 10). β -Blockers are used cautiously in patients with type 1 diabetes, since they can mask the symptoms of hypoglycemia and prolong these episodes by inhibiting gluconeogenesis. Although they may increase blood glucose levels in type 2 diabetics, the prognosis of these patients on balance is improved. These drugs should also be used with caution in patients with advanced peripheral vascular disease associated with rest pain or nonhealing ulcers, but they are generally well tolerated in patients with mild claudication. In treatment of pheochromocytoma, β -blockers should not be administered until α -blockade has been established. Otherwise, blockade of vasodilatory β_2 -adrenergic receptors will allow unopposed vasoconstrictor α -adrenergic receptor activation with worsening of hypertension. For the same reason, β -blockers should not be used to treat hypertension arising from cocaine use.

Because of the lack of efficacy in prevention of myocardial infarction and inferiority compared with other drugs in prevention of stroke and left ventricular hypertrophy, there is now increasing doubt whether β -blockers should still be regarded as ideal first-line agents in the treatment of hypertension without specific compelling indications (such as active coronary artery disease). In addition to adverse metabolic changes associated with their use (see below), some experts have suggested that the therapeutic shortcomings of β -blockers are the consequence of the particular hemodynamic profile associated with these drugs. Pressure peaks in the aorta are augmented by reflection of pressure waves from the peripheral circulation. These reflected waves are delayed in patients taking ACE inhibitors and thiazide diuretics, resulting in decreased systolic and pulse pressures. By contrast, β -blockers appear to potentiate

reflection of pressure waves, possibly because peripheral resistance vessels are a reflection point and peripheral resistance is not decreased by β -blockers. This might explain why β -blockers are less effective at controlling systolic and pulse pressure.

Despite these concerns, the compelling indications for β -blockers remain, such as active coronary artery disease and impaired left ventricular function. Great care should be exercised if the decision is made, in the absence of compelling indications, to remove β -blockers from the treatment regimen since abrupt withdrawal can precipitate acute coronary events and severe increases in blood pressure.

C. Renin Inhibitors

Since renin cleavage of angiotensinogen is the rate-limiting step in the renin-angiotensin cascade, the most efficient inactivation of this system would be expected with renin inhibition, but this option has only recently become available. Conventional ACE inhibitors and ARBs probably offer incomplete blockade, even in combination. Aliskiren, a renin inhibitor, was recently approved by the FDA for use as monotherapy or combination therapy of hypertension. This drug binds the proteolytic site of renin, thereby preventing cleavage of angiotensinogen. As a consequence, levels of angiotensins I and II are reduced and renin concentration is increased. Aliskiren is synergistic with diuretics, ACE inhibitors, and ARBs in lowering blood pressure. Whether renin inhibition offers real advantages over conventional drugs remains to be demonstrated. As yet there is no clinical trial data with this new drug, so the effect of aliskiren on outcomes in hypertension, diabetes, or cardiovascular disease remains unknown.

D. Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors are being increasingly used as the initial medication in mild to moderate hypertension (Table 11–8). Their primary mode of action is inhibition of the renin-angiotensin-aldosterone system, but they also inhibit bradykinin degradation, stimulate the synthesis of vasodilating prostaglandins and, sometimes, reduce sympathetic nervous system activity. These latter actions may explain why they exhibit some effect even in patients with low plasma renin activity. ACE inhibitors appear to be more effective in younger white patients. They are relatively less effective in blacks and older persons and in predominantly systolic hypertension. Although as single therapy they achieve adequate antihypertensive control in only about 40–50% of patients, the combination of an ACE inhibitor and a diuretic or calcium channel blocker is potent.

ACE inhibitors are the agents of choice in persons with type 1 diabetes with frank proteinuria or evidence of kidney dysfunction because they delay the progression to end-stage kidney disease. Many authorities have expanded this indication to include persons with type 2 diabetes and those who have type 1 diabetes with microalbuminuria, even when they do not meet the usual criteria for antihypertensive therapy. ACE inhibitors may also delay the progression of nondiabetic kidney disease. The Heart Outcomes Prevention Evaluation (HOPE) trial demonstrated

Table 11–8. Antihypertensive drugs: Renin and ACE inhibitors and angiotensin II receptor blockers.

| Drug | Proprietary Name | Initial Oral Dosage | Dosage Range | Cost per Unit | Cost of 30 Days Treatment (Average Dosage) ¹ | Adverse Effects | Comments |
|---|-------------------|---------------------------|---|-----------------------|---|---|--|
| Renin inhibitors | | | | | | | |
| Aliskiren | Tekturna | 150 mg once daily | 150–300 mg/d | \$2.48/150 mg | \$74.41 | Angioedema, hypotension, hyperkalemia Contraindicated in pregnancy. | Probably metabolized by CYP3A4. Absorption is inhibited by high fat meal. |
| Aliskiren/Hydrochlorothiazide | Tekturna HCT | 150 mg/12.5 mg once daily | 150–300 mg Aliskiren daily | \$2.48/150 mg/12.5 mg | \$74.41 | | |
| ACE inhibitors | | | | | | | |
| Benazepril | Lotensin | 10 mg once daily | 5–40 mg in 1 or 2 doses | \$1.05/20 mg | \$31.50 | Cough, hypotension, dizziness, kidney dysfunction, hyperkalemia, angioedema; taste alteration and rash (may be more frequent with captopril); rarely, proteinuria, blood dyscrasia. Contraindicated in pregnancy. | More fosinopril is excreted by the liver in patients with renal dysfunction (dose reduction may or may not be necessary). Captopril and lisinopril are active without metabolism. Captopril, enalapril, lisinopril, and quinapril are approved for congestive heart failure. |
| Captopril | Capoten | 25 mg twice daily | 50–300 mg in 2 or 3 doses | \$0.76/25 mg | \$45.60 | | |
| Enalapril | Vasotec | 5 mg once daily | 5–40 mg in 1 or 2 doses | \$1.52/20 mg | \$45.60 | | |
| Fosinopril | Monopril | 10 mg once daily | 10–80 mg in 1 or 2 doses | \$1.19/20 mg | \$35.70 | | |
| Lisinopril | Prinivil, Zestril | 5–10 mg once daily | 5–40 mg once daily | \$1.06/20 mg | \$31.80 | | |
| Moexipril | Univasc | 7.5 mg once daily | 7.5–30 mg in 1 or 2 doses | \$1.39/7.5 mg | \$41.70 | | |
| Perindopril | Aceon | 4 mg once daily | 4–16 mg in 1 or 2 doses | \$3.11/8 mg | \$93.30 | | |
| Quinapril | Accupril | 10 mg once daily | 10–80 mg in 1 or 2 doses | \$1.57/20 mg | \$47.10 | | |
| Ramipril | Altace | 2.5 mg once daily | 2.5–20 mg in 1 or 2 doses | \$1.89/5 mg | \$56.70 | | |
| Trandolapril | Mavik | 1 mg once daily | 1–8 mg once daily | \$1.24/4 mg | \$37.20 | | |
| Angiotensin II receptor blockers | | | | | | | |
| Candesartan cilexetil | Atacand | 16 mg once daily | 8–32 mg once daily | \$2.02/16 mg | \$60.68 | Hyperkalemia, kidney dysfunction, rare angioedema. Combinations have additional side effects. Contraindicated in pregnancy. | Losartan has a very flat dose-response curve. Valsartan and irbesartan have wider dose-response ranges and longer durations of action. Addition of low-dose diuretic (separately or as combination pills) increases the response. |
| Candesartan cilexetil/HCTZ | Atacand HCT | 16 mg/12.5 mg once daily | 8–32 mg of candesartan once daily | \$2.74/16 mg/12.5 mg | \$82.20 | | |
| Eprosartan | Teveten | 600 mg once daily | 400–800 mg in 1–2 doses | \$3.11/600 mg | \$93.30 | | |
| Eprosartan/HCTZ | Teveten HCT | 600 mg/12.5 mg once daily | 600 mg/12.5 mg or 600 mg/25 mg once daily | \$3.30/600 mg/12.5 mg | \$99.00 | | |
| Irbesartan | Avapro | 150 mg once daily | 150–300 mg once daily | \$2.27/150 mg | \$68.17 | | |
| Irbesartan and HCTZ | Avalide | 150 mg/12.5 mg once daily | 150–300 mg irbesartan daily | \$2.75/150 mg | \$82.48 | | |

Table 11-8. Antihypertensive drugs: Renin and ACE inhibitors and angiotensin II receptor blockers. (continued)

| Drug | Proprietary Name | Initial Oral Dosage | Dosage Range | Cost per Unit | Cost of 30 Days Treatment (Average Dosage) ¹ | Adverse Effects | Comments |
|----------------------------------|------------------|--------------------------|-----------------------------|-----------------------------|---|---|---|
| Losartan | Cozaar | 50 mg once daily | 25–100 mg in 1 or 2 doses | \$2.28/50 mg | \$68.47 | Hyperkalemia, kidney dysfunction, rare angioedema. Combinations have additional side effects. Contraindicated in pregnancy. | Losartan has a very flat dose-response curve. Valsartan and irbesartan have wider dose-response ranges and longer durations of action. Addition of low-dose diuretic (separately or as combination pills) increases the response. |
| Losartan and hydrochlorothiazide | Hyzaar | 50 mg/12.5 mg once daily | One or 2 tablets once daily | \$2.50/50 mg/12.5 mg/tablet | \$75.07 | | |
| Olmesartan | Benicar | 20 mg once daily | 20–40 mg daily | \$2.10/20 mg | \$63.00 | | |
| Olmesartan and HCTZ | Benicar HCT | 20 mg/12.5 mg daily | 20–40 mg olmesartan daily | \$2.54/20 mg/12.5 mg | \$76.32 | | |
| Telmisartan | Micardis | 40 mg once daily | 20–80 mg once daily | \$2.30/40 mg | \$69.02 | | |
| Telmisartan and HCTZ | Micardis HCT | 40 mg/12.5 mg once daily | 20–80 mg telmisartan daily | \$2.46/40 mg/12.5 mg | \$73.93 | | |
| Valsartan | Diovan | 80 mg once daily | 80–320 mg once daily | \$2.68/160 mg | \$80.53 | | |
| Valsartan and HCTZ | Diovan HCT | 80 mg/12.5 mg once daily | 80–320 mg valsartan daily | \$3.31/160 mg/12.5 mg | \$99.40 | | |

¹Average wholesale price (AWP, for AB-rated generic when available) for quantity listed. Source: *Red Book Update*, Vol. 28, No. 3, March 2009. AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions. ACE, angiotensin-converting enzyme; HCTZ, hydrochlorothiazide.

that the ACE inhibitor ramipril reduced the number of cardiovascular deaths, nonfatal myocardial infarctions, and nonfatal strokes and also reduced the incidence of new-onset heart failure, kidney dysfunction, and new-onset diabetes in a population of patients at high risk for vascular events. Although this was not specifically a hypertensive population, the benefits were associated with a modest reduction in blood pressure, and the results inferentially support the use of ACE inhibitors in similar hypertensive patients. ACE inhibitors are a drug of choice (usually in conjunction with a diuretic and a β -blocker) in patients with congestive heart failure and are indicated also in asymptomatic patients with reduced ejection fraction. An advantage of the ACE inhibitors is their relative freedom from troublesome side effects. Severe hypotension can occur in patients with bilateral renal artery stenosis; acute renal failure may ensue but is usually reversible with discontinuation of ACE inhibition. Hyperkalemia may develop in patients with intrinsic kidney disease and type IV renal tubular acidosis (commonly seen in diabetics) and in the elderly. A chronic dry cough is common, seen in 10% of patients or more, and may require stopping the drug. Skin rashes are observed with any ACE inhibitor. Angioedema is an uncommon but potentially dangerous side effect of all agents of this class because of their inhibition of kininase. Exposure of the fetus to ACE inhibitors during the second and third trimesters of pregnancy has been associated with a variety of defects due to hypotension and reduced renal blood flow.

E. Angiotensin II Receptor Blockers

A growing body of data indicates that ARBs can improve cardiovascular outcomes in patients with hypertension as well as in patients with related conditions such as heart failure and type 2 diabetes with nephropathy. ARBs have not been compared with ACE inhibitors in randomized controlled trials in patients with hypertension, but two trials comparing losartan with captopril in heart failure and post-myocardial infarction left ventricular dysfunction showed trends toward worse outcomes in the losartan group. Whether this suggestion of reduced efficacy is specific to losartan or may also be true for other ARBs is as yet unknown. However, the Losartan Intervention for Endpoints (LIFE) trial in nearly 9000 hypertensive patients with electrocardiographic evidence of left ventricular hypertrophy—comparing losartan with the β -blocker atenolol as initial therapy—demonstrated a significant reduction in stroke with losartan. Of note is that in diabetic patients, death and myocardial infarction were also reduced, and there was a lower occurrence of new-onset diabetes. In this trial, as in the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) with an ACE inhibitor, blacks exhibited less blood pressure reduction and less benefit with regard to clinical end points. ARBs may synergize with ACE inhibitors in protection of heart and kidney, and ARB/ACE inhibitor combinations may also improve control of hypertension.

Unlike ACE inhibitors, the ARBs do not cause cough and are less likely to be associated with skin rashes or

angioedema. However, as seen with ACE inhibitors, hyperkalemia can be a problem, and patients with bilateral renal artery stenosis may exhibit hypotension and worsened kidney function.

F. Aldosterone Receptor Antagonists

Spironolactone and eplerenone are natriuretic in sodium-retaining states, such as heart failure and cirrhosis, but only very weakly so in hypertension. These drugs have reemerged in the treatment of hypertension, particularly in resistant patients and are helpful additions to most other antihypertensive medications. Consistent with the increasingly appreciated importance of aldosterone in essential hypertension, the aldosterone receptor blockers are effective at lowering blood pressure in all hypertensive patients regardless of renin level, and are also effective in blacks. Aldosterone plays a central role in target organ damage, including the development of ventricular and vascular hypertrophy and renal fibrosis. Aldosterone receptor antagonists ameliorate these consequences of hypertension, to some extent independently of effects on blood pressure. Spironolactone can cause breast pain and gynecomastia in men through activity at the progesterone receptor, an effect not seen with the more specific eplerenone. Hyperkalemia is a problem with both drugs, chiefly in patients with chronic kidney disease.

G. Calcium Channel Blocking Agents

These agents act by causing peripheral vasodilation but with less reflex tachycardia and fluid retention than other vasodilators. They are effective as single-drug therapy in approximately 60% of patients in all demographic groups and all grades of hypertension (Table 11–9). For these reasons, they may be preferable to β -blockers and ACE inhibitors in blacks and older persons. Verapamil and diltiazem should be combined cautiously with β -blockers because of their potential for depressing AV conduction and sinus node automaticity as well as contractility.

Initial concerns about possible adverse cardiac effects of calcium channel blockers have been convincingly allayed by several subsequent large studies which have demonstrated that calcium channel blockers are equivalent to ACE inhibitors and thiazide diuretics in prevention of coronary heart disease, major cardiovascular events, cardiovascular death, and total mortality. A protective effect against stroke with calcium channel blockers is well established, and in two trials (ALLHAT and the Systolic Hypertension in Europe trial), these agents appeared to be more effective than diuretic-based therapy.

The most common side effects of calcium channel blockers are headache, peripheral edema, bradycardia, and constipation (especially with verapamil in the elderly). The dihydropyridine agents—nifedipine, nicardipine, isradipine, felodipine, nisoldipine, and amlodipine—are more likely to produce symptoms of vasodilation, such as headache, flushing, palpitations, and peripheral edema. Calcium channel blockers have negative inotropic effects and should be used cautiously in patients with cardiac dysfunction.

Table 11-9. Antihypertensive drugs: Calcium channel blocking agents.

| Drug | Proprietary Name | Initial Oral Dosage | Dosage Range | Cost of 30 Days Treatment (Average Dosage) ¹ | Special Properties | | | Adverse Effects | Comments |
|----------------------------------|------------------------|-------------------------|----------------------------|---|-------------------------|-------------------------------------|---------------|---|--|
| | | | | | Peripheral Vasodilation | Cardiac Automaticity and Conduction | Contractility | | |
| Nondihydropyridine agents | | | | | | | | | |
| Diltiazem | Cardizem SR | 90 mg twice daily | 180–360 mg in 2 doses | \$74.25 (120 mg twice daily) | ++ | ↓↓ | ↓↓ | Edema, headache, bradycardia, GI disturbances, dizziness, AV block, congestive heart failure, urinary frequency. | Also approved for angina. |
| | Cardizem CD; Cartia XT | 180 mg daily | 180–360 mg daily | \$61.50 (240 mg daily) | | | | | |
| | Dilacor XR | 180 or 240 mg daily | 180–480 mg daily | \$34.50 (240 mg daily) | | | | | |
| | Tiazac SA | 240 mg daily | 180–540 mg daily | \$73.40 (240 mg daily) | | | | | |
| Verapamil | Calan SR | 180 mg daily | 180–480 mg in 1 or 2 doses | \$46.80 (240 mg daily) | ++ | ↓↓↓ | ↓↓↓ | Same as diltiazem but more likely to cause constipation and congestive heart failure. | Also approved for angina and arrhythmias. |
| | Isoptin SR | | | | | | | | |
| | Verelan | | | | | | | | |
| | Covera HS | | | | | | | | |
| Dihydropyridines | | | | | | | | | |
| Amlodipine | Norvasc | 2.5 mg daily | 2.5–10 mg daily | \$71.20 (10 mg daily) | +++ | ↓/0 | ↓/0 | Edema, dizziness, palpitations, flushing, headache, hypotension, tachycardia, GI disturbances, urinary frequency, worsening of congestive heart failure (may be less common with felodipine, amlodipine). | Amlodipine, nifedipine, and nifedipine also approved for angina. |
| Felodipine | Plendil | 5 mg daily | 5–20 mg daily | \$81.60 (10 mg daily) | +++ | ↓/0 | ↓/0 | | |
| Isradipine | DynaCirc | 2.5 mg twice daily | 2.5–5 mg twice daily | \$120.00 (5 mg twice daily) | +++ | ↓/0 | ↓ | | |
| | DynaCirc CR | 5 mg daily | 5–10 mg daily | \$126.12 (10 mg daily) | | | | | |
| Nifedipine | Cardene | 20 mg three times daily | 20–40 mg three times daily | \$36.90 (20 mg three times daily) | +++ | ↓/0 | ↓ | | |
| | Cardene SR | 30 mg twice daily | 30–60 mg twice daily | \$72.31 (30 mg twice daily) | | | | | |
| Nifedipine | Adalat CC | 30 mg daily | 30–120 mg daily | \$65.10 (60 mg daily) | +++ | ↓ | ↓↓ | | |
| | Procardia XL | 30 mg daily | 30–120 mg daily | \$70.80 (60 mg daily) | | | | | |
| Nisoldipine | Sular | 20 mg/d | 20–60 mg/d | \$93.00 (40 mg daily) | +++ | ↓/0 | ↓ | | |

AV, atrioventricular; GI, gastrointestinal.

Amlodipine is the only calcium channel blocker with established safety in patients with severe heart failure. Most calcium channel blockers are now available in preparations that can be administered once daily.

H. α -Adrenoceptor Antagonists

Prazosin, terazosin, and doxazosin (Table 11–10) block postsynaptic α -receptors, relax smooth muscle, and reduce blood pressure by lowering peripheral vascular resistance. These agents are effective as single-drug therapy in some individuals, but tachyphylaxis may appear during long-term therapy and side effects are relatively common. These include marked hypotension and syncope after the first dose which, therefore, should be small and given at bedtime. Post-dosing palpitations, headache, and nervousness may continue to occur during long-term therapy; these symptoms may be less frequent or severe with doxazosin because of its more gradual onset of action. Cataractectomy in patients exposed to α -blockers can be complicated by the floppy iris syndrome, even after discontinuation of the drug, so the ophthalmologist should be alerted that the patient has been taking the drug prior to surgery.

Unlike the β -blockers and diuretics, the α -blockers have no adverse effect on serum lipid levels—in fact, they increase HDL cholesterol while reducing total cholesterol. Whether this is beneficial in the long term has not been established. In ALLHAT, persons receiving doxazosin as initial therapy had a significant increase in heart failure hospitalizations and a higher incidence of stroke relative to the persons receiving diuretics, prompting discontinuation of this arm of the study. To summarize, α -blockers should generally not be used as initial agents to treat hypertension—except perhaps in men with symptomatic prostatism.

I. Drugs with Central Sympatholytic Action

Methyldopa, clonidine, guanabenz, and guanfacine (Table 11–10) lower blood pressure by stimulating α -adrenergic receptors in the central nervous system, thus reducing efferent peripheral sympathetic outflow. These agents are effective as single therapy in some patients, but they are usually used as second- or third-line agents because of the high frequency of drug intolerance, including sedation, fatigue, dry mouth, postural hypotension, and impotence. An important concern is rebound hypertension following withdrawal. Methyldopa also causes hepatitis and hemolytic anemia and is avoided except in individuals who have already tolerated long-term therapy. There is considerable experience with methyldopa in pregnant women, and it is still used for this population. Clonidine is available in patches and may have particular value in patients in whom compliance is a troublesome issue.

J. Arteriolar Dilators

Hydralazine and minoxidil (Table 11–10) relax vascular smooth muscle and produce peripheral vasodilation. When given alone, they stimulate reflex tachycardia, increase myocardial contractility, and cause headache, palpitations, and fluid retention. They are usually given in combination

with diuretics and β -blockers in resistant patients. Hydralazine produces frequent gastrointestinal disturbances and may induce a lupus-like syndrome. Minoxidil causes hirsutism and marked fluid retention; this agent is reserved for the most refractory of cases.

K. Peripheral Sympathetic Inhibitors

These agents are now used infrequently and usually in refractory hypertension. Reserpine remains a cost-effective antihypertensive agent (Table 11–10). Its reputation for inducing mental depression and its other side effects—sedation, nasal stuffiness, sleep disturbances, and peptic ulcers—has made it unpopular, though these problems are uncommon at low dosages. Guanethidine and guanadrel inhibit catecholamine release from peripheral neurons but frequently cause orthostatic hypotension (especially in the morning or after exercise), diarrhea, and fluid retention.

▶ Developing an Antihypertensive Regimen

Historically, data from a number of large trials support the overall conclusion that antihypertensive therapy with diuretics and β -blockers has a major beneficial effect on a broad spectrum of cardiovascular outcomes, reducing the incidence of stroke by 30–50% and of congestive heart failure by 40–50%, and halting progression to accelerated hypertension syndromes. The decreases in fatal and nonfatal coronary heart disease and cardiovascular and total mortality have been less dramatic, ranging from 10% to 15%. Similar placebo-controlled data pertaining to the newer agents are generally lacking, except for stroke reduction with the calcium channel blocker nitrendipine in the Systolic Hypertension in Europe trial. However, there is substantial evidence that ACE inhibitors, and to a lesser extent ARBs, reduce adverse cardiovascular outcomes in other related populations (eg, patients with diabetic nephropathy, heart failure, or postmyocardial infarction and individuals at high risk for cardiovascular events). Most large clinical trials that have compared outcomes in relatively unselected patients have failed to show a difference between newer agents—such as ACE inhibitors, calcium channel blockers, and ARBs—and the older diuretic-based regimens with regard to survival, myocardial infarction, and stroke. Where differences have been observed, they have mostly been attributable to subtle asymmetries in blood pressure control rather than to any inherent advantages of one agent over another. Therefore, experts recommend thiazide diuretics as the first-line treatment of older and perhaps all patients with hypertension because these agents are very effective and less expensive than the newer drugs. Exceptions are appropriate for individuals who have specific indications for another class of agent, such as postmyocardial infarction patients (β -blockers, ACE inhibitors), patients with diabetic nephropathy (ACE inhibitors, ARBs), or other comorbid conditions. Table 11–4 provides suggestions for individualizing first-line treatment based on compelling indications.

As discussed above, many experts would suggest that β -blockers no longer be considered ideal first-line drugs in the

Table 11-10. α -Adrenoceptor blocking agents, sympatholytics, and vasodilators.

| Drug | Proprietary Names | Initial Dosage | Dosage Range | Cost per Unit | Cost of 30 Days Treatment (Average Dosage) ¹ | Adverse Effects | Comments |
|--|-------------------|-----------------------|---------------------------|-----------------------|---|---|--|
| α-Adrenoceptor blockers | | | | | | | |
| Prazosin | Minipress | 1 mg hs | 2-20 mg in 2 or 3 doses | \$0.78/5 mg | \$46.80 (5 mg twice daily) | Syncope with first dose; postural hypotension, dizziness, palpitations, headache, weakness, drowsiness, sexual dysfunction, anticholinergic effects, urinary incontinence; first-dose effects may be less with doxazosin. | May ↑ HDL and ↓ LDL cholesterol. May provide short-term relief of obstructive prostatic symptoms. Less effective in preventing cardiovascular events than diuretics. |
| Terazosin | Hytrin | 1 mg hs | 1-20 mg in 1 or 2 doses | \$1.60/1, 2, 5, 10 mg | \$48.00 (5 mg daily) | | |
| Doxazosin | Cardura | 1 mg hs | 1-16 mg daily | \$0.97/4 mg | \$29.10 (4 mg daily) | | |
| Central sympatholytics | | | | | | | |
| Clonidine | Catapres | 0.1 mg twice daily | 0.2-0.6 mg in 2 doses | \$0.22/0.1 mg | \$13.20 (0.1 mg twice daily) | Sedation, dry mouth, sexual dysfunction, headache, bradyarrhythmias; side effects may be less with guanfacine. Contact dermatitis with clonidine patch. Methyl-dopa also causes hepatitis, hemolytic anemia, fever. | "Rebound" hypertension may occur even after gradual withdrawal. Methyl-dopa should be avoided in favor of safer agents. |
| | Catapres TTS | 0.1 mg/d patch weekly | 0.1-0.3 mg/d patch weekly | \$39.23/0.2 mg | \$156.90 (0.2 mg weekly) | | |
| Guanabenz | Wytensin | 4 mg twice daily | 8-64 mg in 2 doses | \$0.98/4 mg | \$58.80 (4 mg twice daily) | | |
| Guanfacine | Tenex | 1 mg once daily | 1-3 mg daily | \$0.87/1 mg | \$26.10 (1 mg daily) | | |
| Methyl-dopa | Aldomet | 250 mg twice daily | 500-2000 mg in 2 doses | \$0.63/500 mg | \$37.80 (500 mg twice daily) | | |
| Peripheral neuronal antagonists | | | | | | | |
| Reserpine | Serpasil | 0.05 mg once daily | 0.05-0.25 mg daily | \$0.48/0.1 mg | \$14.40 (0.1 mg daily) | Depression (less likely at low dosages, ie, < 0.25 mg), night terrors, nasal stuffiness, drowsiness, peptic disease, gastrointestinal disturbances, bradycardia. | |
| Direct vasodilators | | | | | | | |
| Hydralazine | Apresoline | 25 mg twice daily | 50-300 mg in 2-4 doses | \$0.51/25 mg | \$30.60 (25 mg twice daily) | GI disturbances, tachycardia, headache, nasal congestion, rash, LE-like syndrome. | May worsen or precipitate angina. |
| Minoxidil | Loniten | 5 mg once daily | 5-40 mg once daily | \$1.29/10 mg | \$38.70 (10 mg once daily) | Tachycardia, fluid retention, headache, hirsutism, pericardial effusion, thrombocytopenia. | Should be used in combination with β -blocker and diuretic. |

¹Average wholesale price (AWP, for AB-rated generic when available) for quantity listed. Source: *Red Book Update*, Vol. 28, No. 3, March 2009. AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions. GI, gastrointestinal; LE, lupus erythematosus.

treatment of hypertension without compelling indications for their use. Although theoretical considerations suggest that the newer vasodilator β -blockers may be superior to the older drugs, this possibility remains to be tested.

For the purpose of devising an optimal treatment regimen, drugs can be divided into two complementary groups easily remembered as AB and CD. A and B refer to drugs that interrupt the renin-angiotensin system (ACE/ARB and β -blockers) and C and D refer to those that do not (calcium channel blockers and thiazide diuretics). Combinations of drugs between these groups are likely to be more potent in lowering blood pressure than combinations within a group. Drugs A/B are more effective in young, white persons, in whom renins tend to be higher, and drugs C/D are more effective in old or black persons, in whom renin levels are generally lower. It is also important to note that antihypertensive treatment is effective at reducing cardiovascular risk at all ages, including the very elderly.

Figure 11–3 illustrates guidelines established by the BHS for developing a rational antihypertensive regimen. In the BHS guidelines, “B” is placed in parentheses to reflect the increasingly prevalent view that β -blockers should no longer be considered an ideal first-line agent. In trials that include patients with systolic hypertension, most patients require two or more medications and even then a substantial proportion fail to achieve the goal systolic blood pressure of < 140 mm Hg (< 130 mm Hg in high-risk persons).

▲ **Figure 11–3.** The British Hypertension Society’s recommendations for combining blood pressure lowering drugs. The “ABCD” rule. A, Angiotensin-converting enzyme inhibitor or angiotensin receptor blocker; B, β -blocker (the parentheses indicate that β -blockers should no longer be considered ideal first-line agents); C, calcium channel blockers; D, diuretic (thiazide). (Reprinted, with permission, from Williams B; British Hypertension Society. Guidelines for management of hypertension: report of the Fourth Working Party of the British Hypertension Society, 2004-BHS IV. *J Hum Hypertens.* 2004 Mar;18(3):139–185.)

In diabetic patients, three or four drugs are usually required to reduce systolic blood pressure to < 140 mm Hg. In many patients, blood pressure cannot be maintained at the recommended goal of < 130 mm Hg with any combination. As a result, debating the appropriate first-line agent is less relevant than determining the most appropriate combinations of agents. This has led many experts and practitioners to reconsider the use of fixed-dose combination antihypertensive agents as first-line therapy in patients with substantially elevated systolic pressures (> 160/100 mm Hg) or difficult-to-control hypertension (which is often associated with diabetes or kidney dysfunction). Based both on antihypertensive efficacy and complementarity, combinations of a diuretic and an ACE inhibitor (or an ARB if patient is intolerant of ACE inhibitor) are recommended. In younger white patients, the best choice is probably a combination of an ACE inhibitor and calcium channel blocker or thiazide. In light of side effect profiles, some experts have expressed the view that calcium channel blockers might be preferable to thiazides in the younger hypertensive patient. Furthermore, based on the results from the ACCOMPLISH trial, a combination of ACE inhibitor and calcium channel blocker may also prove optimal for patients at high risk for cardiovascular events. The initial use of low-dose combinations allows faster blood pressure reduction without substantially higher intolerance rates and is likely to be better accepted by patients. Improved blood pressure control can also be achieved by combining an ACE with an ARB. A suggested approach to treatment, tailored to patient demographics, is outlined in Table 11–11.

When an initial agent is selected, the patient should be informed of common side effects and the need for diligent compliance. Treatment should start at a low dose, and unless the initial blood pressure is very high (> 160/100 mm Hg), follow-up visits should usually be at 4- to 6-week intervals to allow for full medication effects to be established (especially with diuretics) before further titration or adjustment. If, after titration to usual doses, the patient has shown a discernible but incomplete response and a good tolerance of the initial drug, a second medication should be added. As a rule of thumb, a blood pressure reduction of 10 mm Hg can be expected for each antihypertensive agent added to the regimen.

Patients who are compliant with their medications and who do not respond to the combination regimens should usually be evaluated for secondary hypertension before proceeding to more complex regimens.

► Special Considerations in the Treatment of Diabetic Hypertensive Patients

Hypertensive patients with diabetes are at particularly high risk for cardiovascular events. More aggressive treatment of hypertension in these patients prevents progressive nephropathy, and a meta-analysis supports the notion that lower treatment goals (perhaps to lowest tolerated levels), are especially effective at reducing cardiovascular risk in diabetics compared with nondiabetics. Because of their beneficial effects in diabetic nephropathy, ACE inhibitors (and ARBs or perhaps renin inhibitors in intolerant

Table 11–11. Choice of antihypertensive agent based on demographic considerations.^{1,2}

| | Black, All Ages | All Others, Age < 55 Years | All Others, Age > 55 Years |

¹Compelling indications may alter the selection of an antihypertensive drug.

²Start with full dose of one agent, or lower doses of combination therapy.

³ACE and ARB can be synergistic in combination.

⁴Women of childbearing age should avoid ACE and ARB or discontinue as soon as pregnancy is diagnosed.

⁵The adverse metabolic effects of thiazide diuretics and β -blockers should be considered in younger patients but may be less important in the older patient.

⁶For patients with significant renal impairment, use loop diuretic instead of thiazide.

⁷ α -Antagonists may precipitate or exacerbate orthostatic hypotension in the elderly.

ACE, angiotensin-converting enzyme inhibitor; ARB, angiotensin II receptor blocker; CCB, calcium channel blocker.

patients) should be part of the initial treatment regimen. However, most diabetics require combinations of three to five agents to achieve target blood pressure, usually including a diuretic and a calcium channel blocker or β -blocker. In addition to rigorous blood pressure control, treatment of persons with diabetes should include aggressive treatment of other risk factors and early intervention for coronary disease and left ventricular dysfunction.

► Treatment of Hypertension in Chronic Kidney Disease

Hypertension is present in 40% of patients with a glomerular filtration rate (GFR) of 60–90 mL/min, and 75% of patients with a GFR < 30 mL/min. ACE inhibitors and ARBs have been shown to delay progression of kidney disease in persons with type 1 and type 2 diabetes, respectively. It is also likely that inhibition of the renin-angiotensin system protects kidney function in nondiabetic kidney disease associated with significant proteinuria.

As discussed above, hypertension should be treated until blood pressure reaches < 130/80 mm Hg in patients with chronic kidney disease. There is a lack of definitive data to show that this level of blood pressure control slows the decline of GFR in persons with hypertensive chronic kidney disease without high-grade proteinuria. However, since all patients with chronic kidney disease are at high risk for cardiovascular damage, treatment of blood pressure to the < 130/80 mm Hg target is appropriate, and interruption of the renin-angiotensin system would seem a reasonable approach. Transition from thiazide to loop diuretic is often necessary to control volume expansion as kidney function worsens. Evidence has demonstrated that ACE inhibitors remain protective and safe in kidney disease associated with significant proteinuria and serum creatinine as high as 5 mg/dL. Note that such treatment would likely result in acute worsening of kidney function in patients with significant renal artery stenosis, so kidney function and electrolytes should be monitored carefully after introduction of ACE inhibitors. In any event, persis-

tence with ACE inhibitor/ARB therapy in the face of hyperkalemia is probably not warranted, since other antihypertensive medications are renoprotective as long as goal blood pressures are maintained.

► Hypertension Management in Blacks

Substantial evidence indicates that blacks are not only more likely to become hypertensive and more susceptible to the cardiovascular complications of hypertension—they also respond differently to many antihypertensive medications. This may reflect genetic differences in the cause of hypertension or the subsequent responses to it, differences in occurrence of comorbid conditions such as diabetes or obesity, or environmental factors such as diet, activity, stress, or access to health care services. In any case, as in all persons with hypertension, a multifaceted program of education and lifestyle modification is warranted. Early introduction of combination therapy has been advocated. Because it appears that ACE inhibitors and ARBs—in the absence of concomitant diuretics—are less effective in blacks than in whites, initial therapy should generally be a diuretic or a diuretic combination with a calcium channel blocker.

► Follow-Up of Patients Receiving Hypertension Therapy

Once blood pressure is controlled on a well-tolerated regimen, follow-up visits can be infrequent and laboratory testing limited to tests appropriate for the patient and the medications used. Yearly monitoring of blood lipids is recommended, and an electrocardiogram should be repeated at 2- to 4-year intervals depending on whether initial abnormalities are present, the presence of coronary risk factors, and age. Pharmacy care programs have been shown to improve compliance with medications. Patients who have had excellent blood pressure control for several years, especially if they have lost weight and initiated favorable lifestyle modifications, should be considered for

“step-down” of therapy to determine whether lower doses or discontinuation of medications are feasible.

RESISTANT HYPERTENSION

Resistant hypertension is defined in JNC 7 as the failure to reach blood pressure control in patients who are adherent to full doses of an appropriate three-drug regimen (including a diuretic). In this situation, the clinician should first exclude identifiable causes of hypertension (Table 11–2), and then carefully explore reasons why the patient might not be at goal blood pressure (Table 11–12). The clinician should pay particular attention to the type of diuretic being used in relation to the patient's kidney function. Aldosterone may play an important role in resistant hypertension and aldosterone receptor blockers can be very useful. If goal blood pressure cannot be achieved by these measures, consultation with a hypertension specialist should be considered.

HYPERTENSIVE URGENCIES & EMERGENCIES

Hypertensive emergencies have become less frequent in recent years but still require prompt recognition and aggressive but careful management. A spectrum of urgent presentations exists, and the appropriate therapeutic approach varies accordingly.

Hypertensive urgencies are situations in which blood pressure must be reduced within a few hours. These include patients with asymptomatic severe hypertension

Table 11–2. Causes of resistant hypertension.

(systolic blood pressure > 220 mm Hg or diastolic pressure > 125 mm Hg that persists after a period of observation) and those with optic disk edema, progressive target organ complications, and severe perioperative hypertension. Elevated blood pressure levels alone—in the absence of symptoms or new or progressive target organ damage—rarely require emergency therapy. Parenteral drug therapy is not usually required, and partial reduction of blood pressure with relief of symptoms is the goal.

Hypertensive emergencies require substantial reduction of blood pressure within 1 hour to avoid the risk of serious morbidity or death. Although blood pressure is usually strikingly elevated (diastolic pressure > 130 mm Hg), the correlation between pressure and end-organ damage is often poor. It is the latter that determines the seriousness of the emergency and the approach to treatment. Emergencies include hypertensive encephalopathy (headache, irritability, confusion, and altered mental status due to cerebrovascular spasm), hypertensive nephropathy (hematuria, proteinuria, and progressive kidney dysfunction due to arteriolar necrosis and intimal hyperplasia of the interlobular arteries), intracranial hemorrhage, aortic dissection, preeclampsia-eclampsia, pulmonary edema, unstable angina, or myocardial infarction. **Malignant hypertension** is by historical definition characterized by encephalopathy or nephropathy with accompanying papilledema. Progressive kidney disease usually ensues if treatment is not provided. The therapeutic approach is identical to that used with other antihypertensive emergencies.

Parenteral therapy is indicated in most hypertensive emergencies, especially if encephalopathy is present. The

initial goal in hypertensive emergencies is to reduce the pressure by no more than 25% (within minutes to 1 or 2 hours) and then toward a level of 160/100 mm Hg within 2–6 hours. Excessive reductions in pressure may precipitate coronary, cerebral, or renal ischemia. To avoid such declines, the use of agents that have a predictable, dose-dependent, transient, and not precipitous antihypertensive effect is preferable. In that regard, the use of sublingual or oral fast-acting nifedipine preparations is best avoided.

Acute ischemic stroke is often associated with marked elevation of blood pressure, which will usually fall spontaneously. In such cases, antihypertensives should only be used if the blood pressure exceeds 220/120 mm Hg, and blood pressure should be reduced cautiously by 10–15%. If thrombolytics are to be given, blood pressure should be maintained at < 185/110 mm Hg during treatment and for 24 hours following treatment.

In hemorrhagic stroke, the aim is to minimize bleeding with a target mean arterial pressure of < 130 mm Hg. In acute subarachnoid hemorrhage, as long as the bleeding source remains uncorrected, a compromise must be struck between preventing further bleeding and maintaining cerebral perfusion in the face of cerebral vasospasm. In this situation, blood pressure goals depend on the patient's usual blood pressure. In normotensive patients, the target should be a systolic blood pressure of 110–120 mm Hg; in hypertensive patients, blood pressure should be treated to 20% below baseline pressure. In the treatment of hypertensive emergencies complicated by (or precipitated by) central nervous system injury, labetalol or nicardipine are good choices, since they are nonsedating and do not appear to cause significant increases in cerebral blood flow or intracranial pressure in this setting. In hypertensive emergencies arising from catecholaminergic mechanisms, such as pheochromocytoma or cocaine use, β -blockers can worsen the hypertension because of unopposed peripheral vasoconstriction; phentolamine is a better choice. Labetalol is useful in these patients if the heart rate must be controlled.

► Pharmacologic Management

A. Parenteral Agents

A growing number of agents are available for management of acute hypertensive problems. (Table 11–13 lists drugs, dosages, and adverse effects.) Sodium nitroprusside is the agent of choice for the most serious emergencies because of its rapid and easily controllable action, but continuous monitoring is essential when this agent is used. In the presence of myocardial ischemia, intravenous nitroglycerin or an intravenous β -blocker, such as labetalol or esmolol, is preferable.

1. Nitroprusside sodium—This agent is given by controlled intravenous infusion gradually titrated to the desired effect. It lowers the blood pressure within seconds by direct arteriolar and venous dilation. Monitoring with an intra-arterial line avoids hypotension. Nitroprusside—in combination with a β -blocker—is especially useful in patients with aortic dissection.

2. Nitroglycerin, intravenous—This agent is a less potent antihypertensive than nitroprusside and should be reserved for patients with accompanying acute ischemic syndromes.

3. Labetalol—This combined β - and α -blocking agent is the most potent adrenergic blocker for rapid blood pressure reduction. Other β -blockers are far less potent. Excessive blood pressure drops are unusual. Experience with this agent in hypertensive syndromes associated with pregnancy has been favorable.

4. Esmolol—This rapidly acting β -blocker is approved only for treatment of supraventricular tachycardia but is often used for lowering blood pressure. It is less potent than labetalol and should be reserved for patients in whom there is particular concern about serious adverse events related to β -blockers.

5. Fenoldopam—Fenoldopam is a peripheral dopamine-1 (DA_1) receptor agonist that causes a dose-dependent reduction in arterial pressure without evidence of tolerance, rebound, or withdrawal or deterioration of kidney function. In higher dosage ranges, tachycardia may occur.

6. Nicardipine—Intravenous nicardipine is the most potent and the longest acting of the parenteral calcium channel blockers. As a primarily arterial vasodilator, it has the potential to precipitate reflex tachycardia, and for that reason it should not be used without a β -blocker in patients with coronary artery disease.

7. Enalaprilat—This is the active form of the oral ACE inhibitor enalapril. The onset of action is usually within 15 minutes, but the peak effect may be delayed for up to 6 hours. Thus, enalaprilat is used primarily as an adjunctive agent.

8. Diuretics—Intravenous loop diuretics can be very helpful when the patient has signs of heart failure or fluid retention, but the onset of their hypotensive response is slow, making them an adjunct rather than a primary agent for hypertensive emergencies. Low dosages should be used initially (furosemide, 20 mg, or bumetanide, 0.5 mg). They facilitate the response to vasodilators, which often stimulate fluid retention.

9. Diazoxide—Diazoxide acts promptly as a vasodilator without decreasing renal blood flow. To avoid hypotension, it should be given in small boluses or as an infusion rather than as the previously recommended large bolus. One use of diazoxide has been in preeclampsia-eclampsia. Hyperglycemia and sodium and water retention may occur. The drug should be used only for short periods and is best combined with a loop diuretic.

10. Hydralazine—Hydralazine can be given intravenously or intramuscularly, but its effect is less predictable than that of other drugs in this group. It produces reflex tachycardia and should not be given without β -blockers in patients with possible coronary disease or aortic dissection. Hydralazine is now used primarily in pregnancy and in children, but even in these situations, newer agents are supplanting it.

11. Trimethaphan—The ganglionic blocking agent trimethaphan is titrated with the patient sitting; its activity

Table 11-13. Drugs for hypertensive emergencies and urgencies.

| Agent | Action | Dosage | Onset | Duration | Adverse Effects | Comments |
|---|---------------------------------|---|---------------|-----------------|--|---|
| Parenteral agents (intravenous unless noted) | | | | | | |
| Nitroprusside (Nipride) | Vasodilator | 0.25-10 mcg/kg/min | Seconds | 3-5 minutes | GI, CNS; thiocyanate and cyanide toxicity, especially with renal and hepatic insufficiency; hypotension. | Most effective and easily titratable treatment. Use with β -blocker in aortic dissection. |
| Nitroglycerin | Vasodilator | 0.25-5 mcg/kg/min | 2-5 minutes | 3-5 minutes | Headache, nausea, hypotension, bradycardia. | Tolerance may develop. Useful primarily with myocardial ischemia. |
| Labetalol (Normodyne, Trandate) | β - and α -blocker | 20-40 mg every 10 minutes to 300 mg; 2 mg/min infusion | 5-10 minutes | 3-6 hours | GI, hypotension, bronchospasm, bradycardia, heart block. | Avoid in congestive heart failure, asthma. May be continued orally. |
| Esmolol (Brevibloc) | β -Blocker | Loading dose 500 mcg/kg over 1 minute; maintenance, 25-200 mcg/kg/min | 1-2 minutes | 10-30 minutes | Bradycardia, nausea. | Avoid in congestive heart failure, asthma. Weak antihypertensive. |
| Fenoldopam (Corlopan) | Dopamine receptor agonist | 0.1-1.6 mcg/kg/min | 4-5 minutes | < 10 minutes | Reflex tachycardia, hypotension, \uparrow intraocular pressure. | May protect kidney function. |
| Nicardipine (Cardene) | Calcium channel blocker | 5 mg/h; may increase by 1-2.5 mg/h every 15 minutes to 15 mg/h | 1-5 minutes | 3-6 hours | Hypotension, tachycardia, headache. | May precipitate myocardial ischemia. |
| Enalaprilat (Vasotec) | ACE inhibitor | 1.25 mg every 6 hours | 15 minutes | 6 hours or more | Excessive hypotension. | Additive with diuretics; may be continued orally. |
| Furosemide (Lasix) | Diuretic | 10-80 mg | 15 minutes | 4 hours | Hypokalemia, hypotension. | Adjunct to vasodilator. |
| Hydralazine (Apressoline) | Vasodilator | 5-20 mg intravenously or intramuscularly (less desirable); may repeat after 20 minutes | 10-30 minutes | 2-6 hours | Tachycardia, headache, GI. | Avoid in coronary artery disease, dissection. Rarely used except in pregnancy. |
| Diazoxide (Hyperstat) | Vasodilator | 50-150 mg repeated at intervals of 5-15 minutes, or 15-30 mg/min by intravenous infusion to a maximum of 600 mg | 1-2 minutes | 4-24 hours | Excessive hypotension, tachycardia, myocardial ischemia, headache, nausea, vomiting, hyperglycemia. Necrosis with extravasation. | Avoid in coronary artery disease and dissection. Use with β -blocker and diuretic. Mostly obsolete. |
| Trimethaphan (Arfonad) | Ganglionic blocker | 0.5-5 mg/min | 1-3 minutes | 10 minutes | Hypotension, ileus, urinary retention, respiratory arrest. Liberates histamine; use caution in allergic individuals. | Useful in aortic dissection. Otherwise rarely used. |
| Oral agents | | | | | | |
| Nifedipine (Adalat, Procardia) | Calcium channel blocker | 10 mg initially; may be repeated after 30 minutes | 15 minutes | 2-6 hours | Excessive hypotension, tachycardia, headache, angina, myocardial infarction, stroke. | Response unpredictable. |
| Clonidine (Catapres) | Central sympatholytic | 0.1-0.2 mg initially; then 0.1 mg every hour to 0.8 mg | 30-60 minutes | 6-8 hours | Sedation. | Rebound may occur. |
| Captopril (Capoten) | ACE inhibitor | 12.5-25 mg | 15-30 minutes | 4-6 hours | Excessive hypotension. | |

ACE, angiotensin-converting enzyme; CNS, central nervous system; GI, gastrointestinal.

depends on this. The patient can be placed supine if the hypotensive effect is excessive. The effect occurs within a few minutes and persists for the duration of the infusion. This agent has largely been replaced by nitroprusside and newer medications.

B. Oral Agents

Patients with less severe acute hypertensive syndromes can often be treated with oral therapy. Abrupt blood pressure lowering is not usually necessary in asymptomatic individuals, and the use of agents such as rapid-acting nifedipine probably causes more adverse effects than benefits.

1. Nifedipine—The effect of fast-acting nifedipine capsules is unpredictable and may be excessive, resulting in hypotension and reflex tachycardia. Because myocardial infarction and stroke have been reported in this setting, the use of sublingual nifedipine is not advised.

2. Clonidine—Clonidine, 0.2 mg orally initially, followed by 0.1 mg every hour to a total of 0.8 mg, will usually lower

blood pressure over a period of several hours. Sedation is frequent, and rebound hypertension may occur if the drug is stopped.

3. Captopril—Captopril, 12.5–25 mg orally, will also lower blood pressure in 15–30 minutes. The response is variable and may be excessive.

C. Subsequent Therapy

When the blood pressure has been brought under control, combinations of oral antihypertensive agents can be added as parenteral drugs are tapered off over a period of 2–3 days. Most subsequent regimens should include a diuretic.

ATHEROSCLEROTIC PERIPHERAL VASCULAR DISEASE

OCCLUSIVE DISEASE: AORTA & ILIAC ARTERIES

ESSENTIALS OF DIAGNOSIS

- ▶ Cramping pain or tiredness in the calf, thigh, or hip while walking (claudication).
- ▶ Diminished femoral pulses.
- ▶ Tissue loss (ulceration, gangrene) or rest pain.

▶ General Considerations

Occlusive atherosclerotic lesions can develop in the distal aorta and proximal common iliac arteries, often in relatively young men, age 50–60 years. The patient with aortoiliac disease is usually a smoker in whom this is the initial manifestation of systemic atherosclerosis. Disease progression may lead to complete occlusion of one or both common iliac arteries, which can precipitate occlusion of the entire abdominal aorta to the level of the renal arteries. Lesions affecting the external iliac arteries are less common as are lesions isolated to the aorta. Pathologic changes of atherosclerosis may be diffuse, but flow-limiting stenoses occur segmentally. This is particularly true of the aortoiliac segment where patients may have limited or no narrowing of the vessels in the more distal vessels of the lower extremities.

▶ Clinical Findings

A. Symptoms and Signs

Intermittent claudication occurs because blood flow cannot keep up with demand. The pain is severe, cramping, and usually located in the calf muscles. The pain may extend into the thigh and buttocks with continued exercise. It may be unilateral or bilateral if there is bilateral disease. Rarely, patients complain only of weakness in the legs when walking, or simply extreme limb fatigue. The symptoms are relieved with rest. With bilateral common

iliac disease, impotence is a common complaint. Femoral pulses are absent or very weak as are the distal pulses. A bruit may be heard over the aorta, iliac, or femoral arteries or over all three arteries.

B. Doppler Findings

The ratio of systolic blood pressure detected by Doppler examination at the ankle compared with the brachial artery is reduced to below 0.9 (normal ratio is 1.0–1.2); this difference is exaggerated by exercise. Segmental waveforms or pulse volume recordings obtained by strain gauge technology through blood pressure cuffs demonstrate blunting of the arterial inflow throughout the lower extremity.

C. Imaging

CT angiography (CTA) and magnetic resonance angiography (MRA) have largely replaced invasive angiography to determine the anatomic location of disease. Imaging is only required when symptoms require intervention, since a history and physical examination with segmental waveform analysis should appropriately identify the involved levels of the arterial tree.

▶ Treatment

A. Conservative Care

A program that includes smoking cessation, risk factor reduction, weight loss, and walking will substantially improve exercise tolerance. A trial of phosphodiesterase inhibitors, such as cilostazol 100 mg orally twice a day, may be beneficial in approximately two-thirds of patients. Antiplatelet agents reduce overall cardiovascular morbidity but do not ameliorate symptoms. Several large trials have failed to show a benefit from warfarin therapy. In the initial stages of a rehabilitation program, simply slowing the cadence of walking will allow patients to walk further without pain.

B. Endovascular Techniques

If the atherosclerotic lesions are truly segmental, they can be effectively treated with angioplasty and stenting. This approach matches the results of surgery for single stenoses

but both effectiveness and durability decreases with multiple stenoses.

C. Surgical Intervention

A prosthetic aorto-femoral bypass graft that bypasses the diseased segments of the aortoiliac system is a highly effective and durable treatment for this disease. High-risk patients may be treated with a graft from the axillary artery to the femoral arteries (axillo-femoral bypass graft) or, in the unusual case of iliac disease limited to one side, a graft from the contralateral femoral artery (fem-fem bypass). The axillo-femoral and femoral to femoral grafts have lower operative risk; however, they are less durable.

► Complications

The complications of the aorto-femoral bypass are those of any major abdominal reconstruction in a patient population that has a high prevalence of cardiovascular disease. Mortality should be low, in the range of 2–3%, but morbidity is higher with a 5–10% rate of myocardial infarction. The total complication rate may be over 10%. Complications of endovascular repair include embolization and vessel dissection. These are relatively uncommon and the total complication rate should be below 3% with this technique.

► Prognosis

Without intervention patients with aorto-iliac disease may have a further reduction in walking distance but symptoms rarely progress to rest pain or threatened limb loss. Life expectancy is limited by their attendant cardiac disease with a mortality rate of 25–40% at 5 years.

Symptomatic relief is generally excellent after intervention. After aorto-femoral bypass, a patency rate of 90% at 5 years is common. Patency rates and symptom relief for less extensive procedures are also good with 20–30% symptom return at 3 years.

► When to Refer

Patients with progressive reduction in walking distance and those with limitations in ambulation that interfere with their activities of daily living should be referred for consultation to a vascular surgeon.

[PMID: 16368284]

OCCLUSIVE DISEASE: FEMORAL & POPLITEAL ARTERIES

ESSENTIALS OF DIAGNOSIS

- Cramping pain or tiredness in the calf with exercise.
- Reduced popliteal or pedal pulses.
- Foot pain at rest, relieved by dependency.
- Foot gangrene or ulceration.

► General Considerations

The superficial femoral artery (SFA) is the artery most commonly occluded by atherosclerosis. The disease frequently occurs where the SFA passes through the abductor magnis tendon in the distal thigh. The profunda femoris artery and the popliteal artery are relatively spared occlusive lesions except in patients with diabetes. As with atherosclerosis of the aorto-iliac segment, these lesions are closely associated with a history of smoking.

► Clinical Findings

A. Symptoms and Signs

Symptoms of intermittent claudication are confined to the calf. Occlusion or stenosis of the SFA at the abductor canal when the patient has good collaterals from the profunda femoris will cause claudication at approximately 2–4 blocks. However, with concomitant disease of the profunda femoris or the popliteal artery, much shorter distances may trigger symptoms. With short-distance claudication, dependent rubor of the foot with blanching on elevation may be present. Chronic low blood flow states will also cause atrophic changes in the lower leg and foot with loss of hair, thinning of the skin and subcutaneous tissues, and disuse atrophy of the muscles. With segmental occlusive disease of the SFA, the common femoral pulsation is normal, but the popliteal and pedal pulses are reduced.

B. Laboratory Findings

The ankle-brachial index (ABI) is reduced; levels below 0.5 suggest severe reduction in flow. ABI readings depend on arterial compression. Since the vessels may be calcified in diabetic patients and the elderly, ABIs can be misleading and must be accompanied by a waveform analysis. Pulse volume recordings with cuffs placed at the high thigh, mid thigh, calf, and ankle will delineate the levels of obstruction with reduced pressures and blunted waveforms. Angiogra-

phy, CTA, or MRA all adequately show the anatomic location of the obstructive lesions. Generally, these studies are only done if revascularization is planned.

► Treatment

A. Conservative Care

As with aorto-iliac disease, conservative management has an important role for some patients, particularly those individuals with SFA occlusion and good profunda femoris collaterals. For these patients conservative management as noted above can result in excellent outcomes with no intervention required.

B. Surgical Intervention

1. Bypass surgery—Intervention is indicated if intermittent claudication is progressive, incapacitating or interferes significantly with essential daily activities. Intervention is mandatory if there is rest pain or threatened tissue loss of the foot. The most effective and durable treatment for lesions of the SFA is a femoral-popliteal bypass with autogenous saphenous vein. Synthetic material, usually polytetrafluoroethylene (PTFE), can be used, but these grafts do not have the durability of vein bypass.

2. Endovascular surgery—Endovascular techniques are effective for lesions of the SFA. There are several options. Angioplasty may be combined with stenting either with a bare metal stent or a PTFE-covered stent to form an endoluminal bypass. Cryoplasty, angioplasty with balloon cooled to -20°C , and endoluminal atherectomy also have their proponents. These techniques have lower morbidity than bypass surgery but also have a lower rate of success and durability.

Endovascular therapy is most effective when the lesions are less than 10 cm long and in patients who are undergoing aggressive risk factor modification.

3. Thromboendarterectomy—Removal of the atherosclerotic plaque is limited to the lesions of the common femoral and profunda femoris artery where bypass grafts and endovascular techniques have a more limited role.

► Complications

Open surgical procedures of the lower extremity, particularly long bypasses with vein harvest, have a risk of wound infection that is higher than in other areas of the body. Wound infection or seroma can occur in as many as 15–20% of cases. Myocardial infarction rates after open surgery are 5–10%, with a 1–4% mortality rate. Complication rates of endovascular therapy are 1–5%, making these therapies attractive despite their lower durability.

► Prognosis

The prognosis for motivated patients with isolated SFA disease is excellent, and surgery is not recommended for mild or moderate claudication in these patients. However, when claudication significantly limits daily activity and undermines quality of life as well as overall cardiovascular

health, intervention may be warranted. All interventions require close postprocedure follow-up with ultrasound surveillance so that any recurrent narrowing can be treated promptly to prevent complete occlusion. The patency rate of bypass grafts of the femoral artery, SFA, and popliteal artery may be as high as 70% at 3 years with patency for endovascular procedures somewhat lower.

Because of the extensive atherosclerotic disease, including associated coronary lesions, 5-year survival among patients with lower extremity disease can be as high as 50%, particularly with involvement of the infrapopliteal vessels (see below). However, with aggressive risk factor modification, substantial improvement in longevity has been reported.

► When to Refer

Patients with progressive symptoms, short distance claudication, rest pain, or any ulceration should be referred to a peripheral vascular specialist.

OCCLUSIVE DISEASE: LOWER LEG & FOOT ARTERIES

ESSENTIALS OF DIAGNOSIS

- Rest pain of the forefoot that is severe and relieved by dependency.
- Pain or numbness of the foot with walking.
- Ulceration or gangrene of the foot or toes.
- Pallor when the foot is elevated.

► General Considerations

Occlusive processes of the lower leg and foot primarily involve the tibial vessels with rare involvement the arteries of the foot. There often is extensive calcification of the artery wall. This distribution of atherosclerosis is primarily seen in patients with diabetes mellitus.

► Clinical Findings

A. Symptoms and Signs

Unless there are associated lesions in the aorto-iliac or femoral/SFA segments, claudication may not be evident. The gastrocnemius and soleus muscles may receive adequate blood supply from collateral vessels from the popliteal artery; therefore, when disease is isolated to the tibial vessels, there may be foot ischemia without atten-

dant claudication, and rest pain or ulceration may be the first sign of severe vascular insufficiency. Classically, rest pain is confined to the dorsum of the foot at the area of the metatarsal heads and is relieved with dependency. The pain is severe, usually burning in character and will awaken the patient from sleep. Because of the high incidence of neuropathy in these patients, it is important to differentiate rest pain from neuropathic dysesthesia. If the pain is relieved by simply dangling the foot over the edge of the bed, which increases blood flow to the foot, then the rest pain is due to vascular insufficiency. On examination, depending on whether associated proximal disease is present, there may or may not be femoral and popliteal pulses, but the pedal pulses will be absent. Dependent rubor may be prominent with pallor on elevation. The skin of the foot is generally cool, atrophic, and hairless.

B. Laboratory Findings

The ABI may be quite low (in the range of 0.3 or lower), but ABIs may be falsely elevated because of the noncompressibility of the calcified tibial vessels. Waveform analysis is important in these patients; a monophasic flow pattern denotes critically low flow. Segmental pulse volume recordings will show a fall-off in blood pressure between the calf and ankle, although pulse volume recordings also may be affected by tibial vessel calcification.

C. Imaging

CTA, MRA, or angiography, is often needed to delineate the anatomy of the tibial-popliteal segment.

► Treatment

Good foot care may avoid ulceration, and most diabetic patients will do well with a conservative regimen. However, if ulcerations appear and there is no significant healing within 2–3 weeks, revascularization will be required. Infrequent rest pain is not an absolute indication for revascularization. However, rest pain occurring nightly with monophasic waveforms requires revascularization to prevent threatened tissue loss.

A. Bypass and Endovascular Techniques

Bypass with vein to the distal tibial or pedal arteries has been shown to be an effective mechanism to treat rest pain and heal gangrene or ischemic ulcerations of the foot. Because the foot often has relative sparing of vascular disease, these bypasses have had adequate patency rates (70% at 3 years). Fortunately, in nearly all series, limb salvage rates are much higher than patency rates.

Endovascular techniques are beginning to be used in the tibial vessels with modest results, but bypass grafting remains the primary technique of revascularization.

B. Amputation

Patients with rest pain and tissue loss are at high risk for amputation, particularly if revascularization cannot be

done. It may be necessary to debride necrotic or severely infected tissue. Toe amputations have little or no effect on the mechanics of walking. Removal of the first toe or a transmetatarsal amputation, removing all toes and the heads of the metatarsals, are durable but increase the energy required of walking by 5–10%. Unfortunately, the next level that can be successfully used for a prosthesis is at the below-knee level. The energy expenditure of walking is then increased by 50%. With an above-knee amputation, the energy required to ambulate may be increased as much as 100%. While there are good prosthetic alternatives for these patients, activity levels are limited after amputation, and there are issues relating to self-image. These factors combine to demand revascularization whenever possible to preserve the limb.

► Complications

The complications of intervention are similar to those listed for SFA disease with evidence that the overall cardiovascular risk increases with decreasing ABI. The patients with critical limb ischemia require aggressive risk factor modification. Wound infection rates after bypass are higher if there is an open wound in the foot.

► Prognosis

Patients with tibial atherosclerosis have extensive atherosclerotic burden and a high prevalence of diabetes. Their prognosis without intervention is poor and complicated by the risk of amputation.

► When to Refer

Patients with diabetes should be referred to a vascular specialist for evaluation if there is a reduction in the pedal pulses, even if small. Intervention may not be necessary but the severity of the disease will be quantified, which has implications for future symptom development.

ACUTE ARTERIAL OCCLUSION OF A LIMB

ESSENTIALS OF DIAGNOSIS

- Sudden pain in an extremity.
- Generally associated with some element of neurologic dysfunction with numbness, weakness, or complete paralysis.
- Absent extremity pulses.

► General Considerations

Acute occlusion may be due to an embolus or to thrombosis of a diseased atherosclerotic segment. Arterial to arterial emboli such as in the cerebrovascular tree can occur, but emboli large enough to occlude proximal arteries in the lower extremities are almost always from the heart. Over 50% of the emboli from cardiac sources go to the lower extremities, 20% to the cerebrovascular circulation, and the remainder to the upper extremities and mesenteric and renal circulation. Atrial fibrillation is the usual cause of cardiac thrombus formation; other causes are valvular disease or ischemic heart disease where thrombus has formed on the ventricular surface of a transmural myocardial infarct.

Emboli from arterial sources such as arterial ulcerations or calcified excrescences are usually small and go to the distal arterial tree (toes).

The typical patient with **primary** thrombosis has had a history of claudication and now has an acute occlusion. If the stenosis has developed over time, collateral blood vessels will develop, and the resulting occlusion may only cause a minimal increase in symptoms.

► Clinical Findings

A. Symptoms and Signs

The sudden onset of extremity pain, with loss or reduction in pulses, is diagnostic of acute arterial occlusion. This often will be accompanied by neurologic dysfunction, such as numbness or paralysis in extreme cases. With popliteal occlusion, symptoms may only affect the foot. With proximal occlusions, the whole leg may be affected. Signs of severe arterial ischemia, such as pallor on elevation, coolness of the extremity, mottling, and impaired neurologic function with hyperesthesia progressing to anesthesia accompanied with paralysis will also occur.

B. Laboratory Findings

There will be little or no flow found with Doppler examination of the distal vessels. Imaging, if done, shows an abrupt cutoff of the vessel involved. Blood work may indicate systemic acidosis.

C. Imaging

Whenever possible, imaging should be done in the operating room because obtaining angiography, MRA, or CTA may delay revascularization and jeopardize the viability of the extremity. However, in cases with only modest symptoms and light touch of the extremity is maintained, imaging may be helpful in planning the revascularization procedure.

► Treatment

Immediate revascularization is required in all cases of symptomatic acute arterial thrombosis. Evidence of neurologic injury, including loss of light touch sensation, indicates that collateral flow is inadequate to maintain limb viability and revascularization should be accom-

plished within 3 hours. Longer delays carry a significant risk of irreversible tissue damage. This risk approaches 100% at 6 hours.

A. Heparin

As soon as the diagnosis is made, unfractionated heparin should be administered (5000–10,000 units) intravenously. This helps prevent clot propagation and may also help relieve associated vessel spasm. There may be some reduction in symptoms with aggressive anticoagulation, but revascularization will still be required. Patients in atrial fibrillation need to continue taking anticoagulants until cardioversion can be attempted.

B. Endovascular Techniques

Chemical thrombolysis with TPA may be done but often requires 24 hours or longer to fully lyse the thrombus. This approach can be taken only in patients with an intact neurologic exam. An echocardiogram should be done first to identify additional clot in the atrium. If an additional clot is found, thrombolysis may be ill advised because of the risk of subsequent emboli from the cardiac clot. Catheter-based mechanical thrombolysis may be an excellent alternative.

C. Surgical Intervention

General anesthesia is usually indicated in these patients; local anesthesia may be used in extremely high-risk patients if the exploration is to be limited to the common femoral artery. In extreme cases, it may be necessary to perform embolectomy from the femoral, popliteal and even the pedal vessels to revascularize the limb. Devices to pulverize and aspirate clot and intraoperative thrombolysis with tissue plasminogen activator (TPA) are being used to improve outcomes.

► Complications

Complications of revascularization of an acutely ischemic limb can include severe acidosis and myocardial arrest. In cases where several hours have elapsed but recovery of viable tissue may still be possible, significant levels of lactic acid, potassium, and other harmful agents may be released into the circulation during revascularization. Pretreatment of the patient with sodium bicarbonate prior to reestablishing arterial flow is required. Surgery in the presence of thrombolytic agents and heparin carries a high risk of postoperative wound hematoma.

► Prognosis

There is a 10–25% risk of amputation with acute arterial occlusion, and a 25% or higher in-hospital mortality rate. Prognosis for acute occlusion of an atherosclerotic segment is generally much better because the collateral flow can maintain extremity viability. The longer term survival reflects the overall condition of the patient. In high-risk patients, an acute arterial occlusion suggests a dismal prognosis.

OCCLUSIVE CEREBROVASCULAR DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden onset of weakness and numbness of an extremity, aphasia, dysarthria, or unilateral blindness (amaurosis fugax).
- ▶ Bruit heard loudest in the mid neck.

▶ General Considerations

Unlike the other vascular territories, symptoms of occlusive cerebrovascular disease are predominantly due to emboli. Transient ischemic attacks (TIAs) are the result of small emboli, and the risk of additional emboli causing permanent deficits is high. One-third of all strokes may be due to emboli. In the absence of atrial fibrillation, approximately 90% of these emboli originate from the proximal internal carotid artery, an area uniquely prone to the development of atherosclerosis. Lesions in the proximal great vessels, the common carotid and the carotid siphon, are far less common.

▶ Clinical Findings

A. Symptoms and Signs

Generally, the symptoms of a TIA last only a few minutes but may continue up to 24 hours. The most common lesions develop in the cortex, and there is usually both motor and sensory involvement. Emboli to the retinal artery cause unilateral blindness which, when transient, is termed “amaurosis fugax.” Posterior circulation symptoms referable to the brainstem, cerebellum, and visual regions of the brain are due to atherosclerosis of the vertebral basilar systems and are much less common.

Signs of cerebrovascular disease include bruits in the mid-cervical area with reduced or absent arm pulses. While bruits in the neck in older patients and generalized atherosclerosis are important signs of cerebrovascular disease, they are not specific for narrowing within the vessel. There is poor correlation between the degree of stenosis and the presence of the bruit. Furthermore, absence of a bruit does not exclude the possibility of carotid stenosis. Nonfocal symptoms, such as dizziness and unsteadiness, seldom are related to cerebrovascular atherosclerosis.

B. Imaging

Duplex ultrasonography is the imaging modality of choice with a high specificity and sensitivity for detecting and grading the degree of stenosis at the carotid bifurcation: 50% stenosis in a symptomatic patient and 80% in an asymptomatic patient require intervention. Mild to moderate disease (30–50% stenosis) indicates the need for ongoing surveillance and aggressive risk factor modification.

Excellent depiction of the full anatomy of the cerebrovascular circulation from arch to cranium can be obtained with either MRA or CTA. Each of these modalities may have

false-positive or false-negative findings. Since the decision to intervene in cases of carotid stenosis depends on an accurate assessment of the degree of stenosis, it is recommended that at least two modalities be used to confirm the degree of stenosis. Cerebral angiography is reserved for cases that cannot be resolved by these less invasive imaging modalities.

▶ Treatment

A. Asymptomatic Patients

Patients with no neurologic symptoms but with carotid stenosis on imaging will benefit from carotid intervention if they are considered to be at low risk for intervention and their expected survival is greater than 5 years. Recommendation for intervention also presumes that the treating institution has a stroke rate in asymptomatic patients that is acceptable (< 3%). Large studies indicate a reduction in stroke from 11.5% to 5.0% over 5 years with surgical treatment of asymptomatic carotid stenoses of greater than 60%. However, the usual practice is to only treat those patients who have greater than 80% stenosis. Patients with carotid stenosis that suddenly worsens are thought to have an unstable plaque and are at particularly high risk for embolic stroke.

B. Symptomatic Patients

Large randomized trials have shown that patients with TIAs or strokes from which they have completely or nearly completely recovered will benefit from carotid intervention if the ipsilateral carotid stenosis has a stenosis of $\geq 70\%$, and they are likely to derive benefit with a stenosis of 50–69%. In these situations, carotid endarterectomy has been shown to have a durable effect in preventing further events.

▶ Complications

The primary complication of carotid intervention is stroke due to embolization of plaque material during the procedure. The American Heart Association has recommended upper limits of acceptable combined morbidity and mortality for these interventions: 3% for asymptomatic, 5% for those with TIAs, and 7% for patients with previous stroke. Results that do not match these guidelines will jeopardize the therapeutic benefit of carotid intervention.

A. Carotid Endarterectomy

In addition to stroke risk, carotid endarterectomy carries an 8% risk of transient cranial nerve injury (usually the vagus or hypoglossal nerve) and 1–2% risk of permanent deficits. There is also the risk of postoperative neck hematoma, which can cause acute compromise of the airway. Coronary artery disease exists as a comorbidity in most of these patients. Myocardial infarction rates after carotid endarterectomy are approximately 5%.

B. Angioplasty and Stenting

Carotid angioplasty and stenting has been advocated as an alternative to carotid endarterectomy. Angioplasty and stenting offers the advantage of avoidance of both cranial nerve injury and neck hematoma. However, emboli are

more common during angioplasty in spite of the use of embolic protection devices during the procedure. The Carotid Revascularization Endarterectomy versus Stent Trial (CREST), sponsored by the National Institutes of Health, is a randomized trial comparing outcomes of carotid endarterectomy and angioplasty and should determine the role of stenting in carotid disease.

C. Recurrent Carotid Stenosis

Scarring of the arterial wall at the site of the intervention after both angioplasty and endarterectomy may create recurrent stenosis. These lesions tend to be less embologenic, and treatment need not be as aggressive as for primary disease. The cranial nerve risk for these patients may be higher with repeat endarterectomy than with angioplasty of the narrowed segment.

► Prognosis

Prognosis for patients with carotid stenosis who have had a TIA or small stroke is poor without treatment; 25% of these patients will have a stroke with most of the events occurring in the first year of follow-up. Patients with carotid stenosis without symptoms have an annual stroke rate of just over 2% even with risk factor modification and antiplatelet agents. Symptomatic patients most likely have unstable plaques with ulceration or they have had a recent progression of the stenosis; prospective ultrasound screening is recommended in asymptomatic patients. Approximately 10% of asymptomatic patients have evidence of plaque progression in a given year. Concomitant coronary artery disease is common and is an important factor in these patients both for perioperative risk and long-term prognosis. Aggressive risk factor modification should be prescribed for patients with cerebrovascular disease regardless of planned intervention.

► When to Refer

Patients in whom an intervention is indicated should be referred to a vascular specialist.

VISCERAL ARTERY INSUFFICIENCY (Intestinal Angina)

ESSENTIALS OF DIAGNOSIS

- Severe postprandial abdominal pain.
- Weight loss with a “fear of eating.”
- Acute mesenteric ischemia: severe abdominal pain yet minimal findings on physical examination.

► General Considerations

Acute visceral artery insufficiency results from either embolic occlusion or primary thrombosis of at least one major mesenteric vessel. Ischemia can also result from non-occlusive mesenteric vascular insufficiency, which is generally seen in patients with low flow states, such as congestive heart failure, or who are in shock. A **chronic syndrome** occurs when there is adequate perfusion for the viscera at rest but ischemia occurs with severe abdominal pain when flow demands increase with feeding. Because of the rich collateral network in the mesentery, generally at least two of the three major visceral vessels (celiac, superior mesenteric, inferior mesenteric arteries) are affected before symptoms develop. **Ischemic colitis**, a variant of mesenteric ischemia, usually occurs in the distribution of the inferior mesenteric artery. The intestinal mucosa is the most sensitive to ischemia and will slough if underperfused. The clinical presentation is similar to inflammatory bowel disease. Ischemic colitis can occur after aortic surgery, particularly aortic aneurysm resection or aorto-femoral bypass for occlusive disease, when there is sudden reduction in blood flow to the inferior mesenteric artery.

► Clinical Findings

A. Symptoms and Signs

1. Acute intestinal ischemia—Patients with primary visceral thrombosis often give an antecedent history consistent with chronic intestinal ischemia. The key finding with acute mesenteric ischemia is severe, steady epigastric and periumbilical pain with minimal or no findings on physical examination of the abdomen because the visceral peritoneum is severely ischemic or infarcted and the parietal peritoneum is not involved. A high white cell count, lactic acidosis, hypotension, and abdominal distention may aid in the diagnosis.

2. Chronic intestinal ischemia—Patients are generally over 45 years of age and may have evidence of atherosclerosis in other vascular beds. Symptoms consist of epigastric or periumbilical postprandial pain lasting 1–3 hours. To avoid the pain, patients limit food intake and may develop a fear of eating. Weight loss is universal.

3. Ischemic colitis—Characteristic symptoms are left lower quadrant pain and tenderness, abdominal cramping, and mild diarrhea, which is often bloody.

B. Imaging and Colonoscopy

In patients with **acute** or **chronic mesenteric ischemia**, a CTA or MRA can demonstrate narrowing of the proximal visceral vessels. In acute mesenteric ischemia from a non-occlusive low flow state, angiography is needed to display the typical “pruned tree” appearance of the distal visceral vascular bed. Ultrasound scanning of the mesenteric vessels may show proximal obstructing lesions in laboratories that have experience with this technique.

In patients with **ischemic colitis**, colonoscopy may reveal segmental ischemic changes, most often in the rectal sigmoid and splenic flexure where collateral circulation may be poor.

▶ Treatment

A high suspicion of **acute mesenteric ischemia** dictates immediate exploration to determine bowel viability. If the bowel remains viable, bypass can be done from the aorta to the celiac and the superior mesenteric artery. In cases where bowel viability is questionable or bowel resection will be required, the bypass can be done with autologous vein, or with PTFE. There is a surprisingly low incidence of graft infection in these cases. For the treatment of **nonocclusive mesenteric disease**, vasodilators can be delivered through a catheter in the mesenteric arteries.

In **chronic visceral ischemia**, angioplasty and stenting of the proximal vessel may be beneficial depending on the anatomy of the stenosis. Should an endovascular solution not be available, an aorto-visceral artery bypass is the preferred management. The long-term results are highly durable. Visceral artery endarterectomy is reserved for cases with multiple lesions where bypass would be difficult.

The mainstay of treatment of **ischemic colitis** is maintenance of blood pressure and perfusion until collateral circulation becomes well established.

▶ Prognosis

The combined morbidity and mortality rates are 10–15% from surgical intervention in these debilitated patients. However, without intervention both acute and chronic visceral ischemia are uniformly fatal. Adequate collateral circulation usually develops in those who have ischemic colitis; the prognosis for this entity is better than chronic mesenteric insufficiency.

▶ When to Refer

Any patient in whom there is a suspicion of visceral ischemia should be referred for imaging and possible intervention.

Acosta S et al. Clinical implications for the management of acute thromboembolic occlusion of the superior mesenteric artery: autopsy findings in 213 patients. *Ann Surg.* 2005 Mar;241(3):516–22. [PMID: 15729076]

Wilson DB et al. Clinical course of mesenteric artery stenosis in elderly Americans. *Arch Intern Med.* 2006 Oct 23;166(19):2095–100. [PMID: 17060539]

ACUTE MESENTERIC VEIN OCCLUSION

The hallmarks of acute mesenteric vein occlusion are postprandial pain and evidence of a hypercoagulable state. Acute mesenteric vein occlusion presents similarly to the arterial occlusive syndromes but is much less common. Patients at risk include those with a systemic hypercoagulable state, such as that observed with paroxysmal nocturnal hemoglobinuria or protein C, protein S, or antithrombin deficiencies. These lesions are difficult to treat surgically, and thrombolysis is the mainstay of therapy. Aggressive long-term anticoagulation is required for these patients.

NONATHEROSCLEROTIC VASCULAR DISEASE

THROMBOANGIITIS OBLITERANS (Buerger Disease)

ESSENTIALS OF DIAGNOSIS

- ▶ Typically occurs in young male cigarette smokers.
- ▶ Distal extremities involved with severe circulatory insufficiency.
- ▶ Thrombosis of the superficial veins may occur.
- ▶ Amputation will be necessary unless the patient stops smoking.

▶ General Considerations

Buerger disease is a segmental, inflammatory, and thrombotic process of the distal most arteries and occasionally veins of the extremities. Pathologic examination reveals arteritis in the affected vessels. The cause is not known but it is rarely seen in nonsmokers. Arteries most commonly affected are the plantar and digital vessels of the foot and lower leg. In advanced stages, the fingers and hands may become involved. Fortunately, the incidence of Buerger disease seems to have decreased in the past decade.

▶ Clinical Findings

A. Symptoms and Signs

Buerger disease may be initially difficult to differentiate from routine peripheral vascular disease, but in most cases, the lesions are on the toes and the patient is younger than 40 years old. The observation of superficial thrombophlebitis may aid the diagnosis. Because the distal vessels are usually affected, intermittent claudication is not common with Buerger disease, but rest pain, particularly pain in the distal most extremity (ie, toes), is frequent. This pain often progresses to tissue loss and amputation, unless the patient stops smoking. The progression of the disease seems to be intermittent with acute and dramatic episodes followed by some periods of remission.

B. Imaging

MRA or invasive angiography can demonstrate the obliteration of the distal arterial tree typical of Buerger disease.

▶ Differential Diagnosis

In atherosclerotic peripheral vascular disease, the onset of tissue ischemia tends to be less dramatic than in Buerger disease, and symptoms of proximal arterial involvement, such as claudication, predominate.

Symptoms of Raynaud disease may be difficult to differentiate from Buerger disease. Repetitive atheroemboli may also mimic Buerger disease and may be difficult to differentiate. It may be necessary to image the proximal arterial tree to rule out sources of arterial emboli.

▶ Treatment

Smoking cessation is the mainstay of therapy and will halt the disease in most cases. As the distal arterial tree is occluded, revascularization is not possible. Sympathectomy is rarely effective.

▶ Prognosis

If smoking cessation can be achieved, the outlook for Buerger disease may be better than in patients with premature peripheral vascular disease. If smoking cessation is not achieved, then the prognosis is generally poor, with amputation of both lower and upper extremities the eventual outcome.

Olin JW. Thromboangiitis obliterans (Buerger's disease). *N Engl J Med*. 2000 Sep 21;343(12):864–9. [PMID: 10995867]

ARTERIAL ANEURYSMS

ABDOMINAL AORTIC ANEURYSMS

ESSENTIALS OF DIAGNOSIS

- ▶ Most aortic aneurysms are asymptomatic until rupture.
- ▶ Abdominal aortic aneurysms measuring 5 cm are palpable in 80% of patients.
- ▶ Back or abdominal pain with aneurysmal tenderness may precede rupture.
- ▶ Rupture is catastrophic; hypotension; excruciating abdominal pain that radiates to the back.

▶ General Considerations

Dilatation of the infrarenal aorta is a normal part of aging. The aorta of a healthy young man measures approximately 2 cm. An aneurysm is considered present when the aortic diameter exceeds 3 cm, but aneurysms rarely rupture until their diameter exceeds 5 cm. Abdominal aortic aneurysms are found in 2% of men over 55 years of age; the male to female ratio is 8:1. Ninety percent of abdominal atherosclerotic aneurysms originate below the renal arteries. The aneurysms usually involve the aortic bifurcation and often involve the common iliac arteries.

Inflammatory aneurysms are an unusual variant. These have an inflammatory peel, similar to the inflammation seen with retroperitoneal fibrosis that surrounds the aneurysm and encases adjacent retroperitoneal structures, such as the duodenum and, occasionally, the ureters.

▶ Clinical Findings

A. Symptoms and Signs

1. Asymptomatic—Although 80% of 5-cm infrarenal aneurysms are palpable on routine physical examination, most aneurysms are discovered as incidental findings on ultrasound or CT imaging during the evaluation of unrelated abdominal symptoms.

2. Symptomatic

A. PAIN—Aneurysmal expansion may be accompanied by pain that is mild to severe midabdominal discomfort often radiating to the lower back. The pain may be constant or intermittent and is exacerbated by even gentle pressure on the aneurysm sack. Pain may also accompany inflammatory aneurysms.

B. RUPTURE—The sudden escape of blood into the retroperitoneal space causes severe pain, a palpable abdominal mass, and hypotension. Free rupture into the peritoneal cavity is a lethal event. Most aneurysms have a thick lining of blood clot, which can embolize to a peripheral artery and occlude blood flow. This phenomenon is surprisingly rare.

B. Laboratory Findings

Even with a contained rupture, there may be little change in routine laboratory findings. The hematocrit will be normal, since there has been no opportunity for hemodilution.

Aneurysms are associated with the cardiopulmonary diseases of elderly male smokers, which include coronary artery disease, carotid disease, renal impairment, and emphysema. Preoperative testing may indicate the presence of these comorbid conditions, which may increase the risk of intervention.

C. Imaging

Abdominal ultrasonography is the diagnostic study of choice for initial diagnosis. In approximately three-quarters of patients with aneurysms, curvilinear calcifications outlining portions of the aneurysm wall may be visible on plain films of the abdomen or back. CT scans provide a more reliable assessment of aneurysm diameter and should be done when the aneurysm nears the diameter threshold (5.5 cm) for treatment. Contrast-enhanced CT scans show the arteries above and below the aneurysm. The visualization of this vasculature is essential for planning repair.

▶ Screening

Data support the use of abdominal ultrasound to screen 65- to 74-year-old men, but not women, who have a history of smoking. Repeated screening does not appear to be needed if the aorta shows no enlargement.

▶ Treatment

A. Elective Repair

In general, elective repair is indicated for aortic aneurysms > 5.5 cm in diameter or aneurysms that have undergone rapid expansion (> 5 mm in 6 months). Symptoms such as

pain or tenderness may indicate impending rupture. These patients need to undergo aneurysm repair regardless of the aneurysm's diameter. Improving outcomes with endovascular techniques have caused some experts to recommend treatment of smaller aneurysms. Current studies are ongoing to determine whether this may be appropriate with initial findings suggesting that it is not.

B. Aneurysmal Rupture

In approximately one-half of patients, aortic rupture is lethal. In the others, the bleeding is contained in the retroperitoneum, which may arrest the blood loss long enough for the patient to undergo urgent operation. Endovascular repair is available for urgent aneurysm repair in most major vascular centers, although the results offer only slight improvement over open repair for these critically ill patients.

C. Inflammatory Aneurysm

The presence of peri-aortic inflammation (inflammatory aneurysm) is not an indication for surgical treatment, unless there is associated compression of retroperitoneal structures, such as the ureter. Interestingly, the inflammation that encases an inflammatory aneurysm recedes after either endovascular or surgical aneurysm repair.

D. Assessment of Operative Risk

Aneurysms appear to be a variant of systemic atherosclerosis. Patients with aneurysms have a high rate of coronary disease. A 2004 trial demonstrated minimal value in addressing stable coronary artery disease prior to aneurysm resection. However, in patients with significant symptoms of coronary disease, the coronary disease should be treated first. Aneurysm resection should follow shortly thereafter because there is a significant increased risk in aneurysm rupture after the coronary procedures. In patients with concomitant carotid stenosis, there is no benefit in repairing asymptomatic carotid disease prior to aneurysm resection unless it is symptomatic or involves bilateral critical stenoses.

E. Open Surgical Resection versus Endovascular Repair

In open surgical aneurysm repair, a graft is sutured to the non-dilated vessels above and below the aneurysm. This involves an abdominal incision, extensive dissection, and interruption of aortic blood flow. The mortality rate is low in centers that have a high volume for this procedure and when it is performed in good risk patients. Older, sicker patients may not tolerate the cardiopulmonary stresses of the operation. With endovascular repair, a stent-graft is used to line the aorta and exclude the aneurysm. The anatomic requirements to securely achieve aneurysm exclusion vary according to the performance characteristics of the specific stent-graft device. In general, successful attachment requires a segment of non-dilated aorta (neck) between the renal arteries and the aneurysm that is at least 15 mm in length, and device insertion requires the lumen of the iliac arteries to be at least 7 mm in diameter.

► Complications

Myocardial infarction, the most common complication, occurs in up to 10% of patients who undergo open aneurysm repair. The incidence of myocardial infarction is substantially lower with endovascular repair. For routine infrarenal aneurysms, renal injury is unusual; however, when it does occur, or if the baseline creatinine is elevated, it is a significant complicating factor in the postoperative period. Respiratory complications are similar to those seen in most major abdominal surgery. Gastrointestinal hemorrhage, even years after aortic surgeries, suggests the possibility of graft enteric fistula; the incidence of this complication is higher when the initial surgery is performed on an emergency basis.

► Prognosis

The mortality rate for an open elective surgical resection is 1–5%. Of those who survive surgery, approximately 60% are alive at 5 years; myocardial infarction is the leading cause of death. The decision to repair aneurysms in high-risk patients has been made easier with the reduced perioperative morbidity and mortality of the endovascular approach. In long-term follow up, there is no survival advantage for endovascular repair.

Mortality rates of untreated aneurysms vary with aneurysm diameter. The mortality rate among patients with large aneurysms who have not undergone surgery, has been defined as follows: 12% annual risk of rupture with an aneurysm ≥ 6 cm in diameter and a 25% annual risk of rupture in aneurysms of ≥ 7 cm diameter. In general, a patient with an aortic aneurysm has a threefold greater chance of dying of a consequence of rupture of the aneurysm than of dying of the surgical resection.

At present, endovascular aneurysm repair may be less definitive than open surgical repair and requires close follow up. With complete exclusion of blood from the aneurysm sac, the pressure is lowered, which causes the aneurysm to shrink. An "endoleak" from the top or bottom of the graft (type 1) or through a graft defect (type 3) is associated with a persistent risk of rupture. Indirect leakage of blood through persistent lumbar and inferior mesenteric branches of the aneurysm (endoleak, type 2) produces an intermediate picture with somewhat reduced pressure in the sac, slow shrinkage, and low rupture risk. However, type 2 endoleak warrants close observation because aneurysm dilatation and rupture can occur.

► When to Refer

- Any patient with a 4 cm aortic aneurysm or larger should be referred for imaging and assessment by a vascular specialist.
- Urgent referrals should be made if the patient complains of pain and gentle palpation of the aneurysm confirms that it is the source.

► When to Admit

Patients with signs of aortic rupture require hospital admission.

THORACIC AORTIC ANEURYSMS

ESSENTIALS OF DIAGNOSIS

- ▶ Widened mediastinum on chest radiograph.
- ▶ With rupture, sudden onset chest pain radiating to the back.

▶ General Considerations

Most thoracic aortic aneurysms are due to atherosclerosis; syphilis is now a rare cause. Disorders of connective tissue and Ehlers-Danlos and Marfan syndromes also are rare causes but have important therapeutic implications. Traumatic, false aneurysms, caused by partial tearing of the aortic wall with deceleration injuries, may occur just beyond the origin of the left subclavian artery. Less than 10% of aortic aneurysms occur in the thoracic aorta.

▶ Clinical Findings

A. Symptoms and Signs

Most thoracic aneurysms are asymptomatic. When symptoms occur, they depend largely on the size and the position of the aneurysm and its rate of growth. Substernal back or neck pain may occur. Pressure on the trachea, esophagus, or superior vena cava can result in the following symptoms and signs: dyspnea, stridor, or brassy cough; dysphagia; and edema in the neck and arms as well as distended neck veins. Stretching of the left recurrent laryngeal nerve causes hoarseness. With aneurysms of the ascending aorta, aortic regurgitation may be present due to dilation of the aortic valve annulus. Rupture of a thoracic aneurysm is catastrophic because bleeding is

rarely contained, so there is not enough time for emergent repair.

B. Imaging

The aneurysm may be diagnosed on chest radiograph by the calcified outline of the dilated aorta. CT scanning is the modality of choice to demonstrate the anatomy and size of the aneurysm and to exclude lesions that can mimic aneurysms, such as neoplasms or substernal goiter. MRI can also be useful. Cardiac catheterization and echocardiography may be required to describe the relationship of the coronary vessels to an aneurysm of the ascending aorta.

▶ Treatment

Indications for repair depend on the location of dilation, rate of growth, associated symptoms, and overall condition of the patient. Aneurysms measuring 6 cm or larger may be considered for repair. Aneurysms of the **descending thoracic aorta** are treated routinely by endovascular grafting. Repair of **arch aneurysms** should be undertaken only if there is a skilled surgical team with an acceptable record of outcomes for these complex procedures. The availability of endografting for descending thoracic aneurysms or experimental branched endovascular reconstructions for arch aneurysms (custom made grafts with branches to the vessels involved in the aneurysm) does not change the indications for aneurysm repair. Aneurysms that involve the proximal aortic arch or ascending aorta represent particularly challenging problems. Open surgery is usually required, which carries substantial risk of morbidity, including stroke, diffuse neurologic injury, and intellectual impairment.

▶ Complications

With the exception of endovascular repair for discrete saccular aneurysms of the descending thoracic aorta, the morbidity and mortality of thoracic repair is considerably higher than that for infra-renal abdominal aortic aneurysm repair. Paraplegia remains a rare, but devastating, complication. Most large series report approximately 4% rate of paraplegia following endovascular repair of thoracic aortic aneurysms. The spinal arterial supply is segmental through intercostal branches of the aorta with variable degrees of intersegmental connection. Therefore, the more extensive the aneurysm, the greater is the risk of paraplegia with resection. Prior to abdominal aortic surgery, compromise of the subclavian or internal iliac arteries and hypotension all increase the paraplegia risk. Involvement of the aortic arch also increases the risk of stroke, even when the aneurysm does not directly affect the carotid artery.

▶ Prognosis

Generally, degenerative aneurysms of the thoracic aorta will enlarge and require repair to prevent death from rupture. However, stable aneurysms can be followed with CT scanning. Saccular aneurysms, particularly those distal to the left subclavian artery and the descending thoracic aorta, have had good results with endovascular repair.

Resection of large complex aneurysms of the aortic arch involves major technical issues and requires a skilled surgical team and should only be attempted in low-risk patients. Experimental branched technology for endovascular grafting holds promise for reduced morbidity and mortality.

► When to Refer

Patients who are deemed to have a reasonable surgical risk with a 5–6 cm aneurysm should be considered for repair, particularly if the aneurysm involves the descending thoracic aorta.

► When to Admit

Any patient with chest or back pain with a known or suspected thoracic aorta aneurysm must be admitted to the hospital and undergo appropriate imaging studies to rule out the aneurysm as a cause of the pain.

Chuter TA. Branched and fenestrated stent grafts for endovascular repair of thoracic aortic aneurysms. *J Vasc Surg.* 2006 Feb;43(Suppl A):111A–115A. [PMID: 16473163]

AORTIC DISSECTION

ESSENTIALS OF DIAGNOSIS

- Sudden searing chest pain with radiation to the back, abdomen, or neck in a hypertensive patient.
- Widened mediastinum on chest radiograph.
- Pulse discrepancy in the extremities.
- Acute aortic regurgitation may develop.

► General Considerations

Aortic dissection occurs when a spontaneous intimal tear develops and blood dissects into the media of the aorta. The tear probably results from the repetitive torque applied to the ascending and proximal descending aorta during the cardiac cycle; hypertension is an important component of this disease process. **Type A dissection** involves the arch proximal to the left subclavian artery, and **type B dissection** occurs in the proximal descending thoracic aorta typically just beyond the left subclavian artery. Dissections may occur in the absence of hypertension but abnormalities of smooth muscle, elastic tissue, or collagen are more common in these patients. Pregnancy, bicuspid aortic valve, and coarctation also are associated with increased risk of dissection.

Blood entering the intimal tear may extend the dissection into the abdominal aorta, the lower extremities, the carotid arteries or, less commonly, the subclavian arteries. Both absolute pressure levels and the pulse pressure are important

in propagation of dissection. The aortic dissection is a true emergency and requires immediate control of blood pressure to limit the extent of the dissection. With type A dissection, which has the worse prognosis, death may occur within hours, usually due to rupture of the dissection into the pericardial sac. Rupture into the plural cavity is also possible. The intimal/medial flap of the aortic wall created by the dissection may occlude major aortic branches, resulting in ischemia of the brain, intestines, kidney, or lower extremities. Patients whose blood pressure is controlled and who survive the acute episode without complications may have long-term survival without surgical treatment.

► Clinical Findings

A. Symptoms and Signs

Severe persistent chest pain of sudden onset radiating down the back or possibly into the anterior chest is characteristic. Radiation of the pain into the neck may also occur. The patient is usually hypertensive. Syncope, hemiplegia, or paralysis of the lower extremities may occur. Intestinal ischemia or renal insufficiency may develop. Peripheral pulses may be diminished or unequal. A diastolic murmur may develop as a result of a dissection in the ascending aorta close to the aortic valve, causing valvular regurgitation, heart failure, and cardiac tamponade.

B. Electrocardiographic Findings

Left ventricular hypertrophy from long-standing hypertension is often present. Acute changes suggesting myocardial ischemia do not develop unless dissection involves the coronary artery ostium. Classically, inferior wall abnormalities predominate since dissection leads to compromise of the right rather than the left coronary artery. In some patients, the ECG may be completely normal.

C. Imaging

A multiplanar CT scan is the immediate diagnostic imaging modality of choice; clinicians should have a low threshold for obtaining a CT scan in any hypertensive patient with chest pain and equivocal findings on ECG.

The CT scan should include both the chest and abdomen to fully delineate the extent of the dissected aorta. MRI is an excellent imaging modality for chronic dissections, but in the acute situation, the longer imaging time and the difficulty of monitoring patients in the MRI scanner make the CT scan preferable. Chest radiographs may reveal an abnormal aortic contour or widened superior mediastinum. Although transesophageal echocardiography (TEE) is an excellent diagnostic imaging method, it is generally not readily available in the acute setting.

► Differential Diagnosis

Aortic dissection is most commonly misdiagnosed as myocardial infarction or other causes of chest pain such as pulmonary embolization. Dissections may occur with minimal pain; branch vessel occlusion of the lower extremity can mimic arterial embolus.

► Treatment

A. Medical

Aggressive measures to lower blood pressure should occur when an aortic dissection is suspected, even before the diagnostic studies have been completed. Treatment requires a simultaneous reduction of the systolic blood pressure to 100–120 mm Hg and pulse pressure. β -Blockers have the most desirable effect of reducing the left ventricular ejection force that continues to weaken the arterial wall and should be first-line therapy. Labetalol, both an α - and β -blocker, lowers pulse pressure and achieve rapid blood pressure control. Give 20 mg over 2 minutes by intravenous injection. Additional doses of 40–80 mg intravenously can be given every 10 minutes (maximum dose 300 mg) until the desired blood pressure has been reached. Alternatively, 2 mg/min may be given by intravenous infusion, titrated to desired effect. In patients who have asthma, bradycardia, or other conditions that necessitate the patient's reaction to β -blockers be tested, esmolol is a reasonable choice because of its short half-life. Give a loading dose of esmolol, 0.5 mg/kg over 1 minute followed by an infusion of .0025–.02 mg/kg/min. Titrate the infusion to a goal heart rate of 60–70 beats/min. If β -blockade alone does not control the hypertension, nitroprusside may be added as follows: 50 mg of nitroprusside in 1000 mL of 5% dextrose and water, infused at a rate of 0.5 mL/min; the infusion rate is increased by 0.5 mL every 5 minutes until adequate control of the pressure has been achieved. In patients with bronchial asthma, while there are no data supporting the use of the calcium-channel antagonists, diltiazem and verapamil are potential alternatives to treatment with β -blocking drugs. Morphine sulfate is the appropriate drug to use for pain relief. Long-term medical care of patients should include β -blockers in their antihypertensive regimen.

B. Surgical Intervention

Urgent surgical intervention is required for all **type A aneurysms**. If a skilled cardiovascular team is not available, the patient should be transferred to an appropriate facility. The procedure involves grafting and replacing the diseased portion of the arch and brachiocephalic vessels as necessary. Replacement of the aortic valve may be required with reattachment of the coronary arteries.

Urgent surgery is required for **type B aneurysms** if the dissection is continuing or there is aortic branch compromise. Endovascular repair of type B dissections is the treatment of choice if it is anatomically feasible.

► Prognosis & Follow-up

The mortality rate for untreated type A dissections is approximately 1% per hour for 72 hours and over 90% at 3 months. Mortality is also extremely high for untreated complicated type B dissections. The surgical and endovascular options for these patients also have significant morbidity and mortality. They are technically demanding and require an experienced team to achieve perioperative mortalities of less than 10%. Patients with uncomplicated type B dissections whose blood pressure is controlled and who

survive the acute episode without complications may have long-term survival without surgical treatment. Aneurysmal enlargement of the false lumen may develop in these patients despite adequate antihypertensive therapy. Yearly CT scans are required to monitor the size of the dissecting aneurysm. Indications for repair are similar to undissected thoracic aneurysms. Endovascular covering of the intimal tear in the acute setting may prevent this complication, but initial trials on the routine endovascular treatment of type B dissections have not shown an advantage for early intervention and therefore cannot be widely endorsed at this time. Indications for repair remain similar to those of undissected thoracic aneurysms.

► When to Admit

Any dissection involving the aortic arch (type A) should be immediately repaired. Acute type B dissections require repair only when there is evidence of rupture or major branch occlusion.

VENOUS DISEASES

VARICOSE VEINS

ESSENTIALS OF DIAGNOSIS

- Dilated, tortuous superficial veins in the lower extremities.
- May be asymptomatic or associated with aching discomfort or pain.
- Edema, pigmentation, and stasis ulcers of the skin may develop.
- Usually hereditary, with most patients reporting a family member with similar lesions.
- Increased frequency after pregnancy.

► General Considerations

Varicose veins develop in the lower extremities. Periods of high venous pressure related to prolonged standing or heavy lifting are contributing factors, but the highest incidence occurs in women after pregnancy. Varicosities develop in 15% of all adults.

The greater saphenous vein and its tributaries are most commonly involved, but the short saphenous vein (posterior lower leg) may also be affected. Distention of the vein prevents the valve leaflets from coapting, creating incompetence. Thus, dilation at any point along the vein leads to

increased pressure and distention of the vein segment below that valve, which in turn causes progressive failure of the next lower valve and progressive venous reflux. Perforating veins that connect the deep and superficial systems may become incompetent, allowing blood to reflux into the superficial veins from the deep system through the incompetent perforators and increasing venous pressure and distention.

Secondary varicosities can develop as a result of obstructive changes and valve damage in the deep venous system following thrombophlebitis, or rarely as a result of proximal venous occlusion due to neoplasm or fibrosis. Congenital or acquired arteriovenous fistulas or venous malformations are also associated with varicosities.

► Clinical Findings

A. Symptoms and Signs

Symptom severity is not correlated with the number and size of the varicosities; extensive varicose veins may produce no subjective symptoms, whereas minimal varicosities may produce many symptoms. Dull, aching heaviness or a feeling of fatigue of the legs brought on by periods of standing is the most common complaint.

Clinicians must be careful to identify symptoms of arteriosclerotic peripheral vascular disease, such as intermittent claudication and coldness of the feet, since occlusive arterial disease is usually a contraindication to the operative treatment of varicosities distal to the knee. Itching from a venous stasis dermatitis may occur either above the ankle or directly overlying large varicosities.

Dilated, tortuous veins beneath the skin in the thigh and leg are generally visible upon standing, although in very obese patients palpation may be necessary to detect their presence and location. Some swelling is common but secondary tissue changes may be absent even in extensive varicosities. However, if the varicosities are of long duration, brownish pigmentation and thinning of the skin above the ankle may be present. The presence of a bruit or a thrill is useful in making the diagnosis of an associated arteriovenous fistula.

B. Imaging

The identification of the source of venous reflux that feeds the symptomatic veins is necessary for effective surgical treatment. Duplex ultrasonography by a technician experienced in the diagnosis and localization of venous reflux is the test of choice for planning therapy. In most cases, reflux will arise from the greater saphenous vein.

► Differential Diagnosis

Primary varicose veins should be differentiated from those secondary to chronic venous insufficiency of the deep system of veins with extensive swelling, fibrosis, pigmentation, and ulceration of the distal lower leg (the postphlebotic syndrome). Pain or discomfort secondary to arthritis, radiculopathy, or arterial insufficiency should be distinguished from symptoms associated with coexistent varicose veins. In adolescent patients with varicose veins,

imaging of the deep venous system is important to exclude a congenital malformation or atresia of the deep veins. Surgical treatment of varicose veins in these patients is contraindicated because the varicosities may play a significant role in venous drainage of the limb.

► Complications

Thrombophlebitis within a varicose vein is uncommon. This presents as subacute to acute localized pain and palpable hardness at the site of the phlebitis. The process is self-limiting, has a low risk of embolization, and usually resolves within weeks. Rarely, the phlebitis extends to involve the greater saphenous vein.

In older patients, superficial varicosities may bleed with even minor trauma. The amount of bleeding can be alarming as the pressure in the varicosity is high.

Predisposing conditions for thrombophlebitis include pregnancy, local trauma, or prolonged periods of sitting.

► Treatment

A. Nonsurgical Measures

Nonsurgical treatment is effective. Elastic graduated compression stockings (medium or heavy weight) give external support to the veins. These stockings may be useful in early varicosities to prevent progression of disease. When elastic stockings worn during standing are combined with elevation of the legs when possible, good control can be maintained and the development of complications can often be avoided. This approach may be used in elderly patients, in those who refuse or wish to defer surgery, and in those with mild asymptomatic varicosities.

B. Surgical Measures

Treatment with endovenous ablation (with either radiofrequency or laser) or, less commonly, with greater saphenous vein stripping is very effective for reflux arising from the greater saphenous vein. Less common sources of reflux include the lesser saphenous vein (for varicosities in the posterior calf), and nonsaphenous incompetent perforator veins arising directly from the deep venous system in the thigh. Correction of reflux is performed at the same time as excision of the symptomatic varicose veins. Phlebectomy without correction of reflux results in a high rate of recurrent varicosities, as the uncorrected reflux progressively dilates adjacent veins. Concurrent reflux detected by ultrasonography in the deep system is not a contraindication to treatment of superficial reflux because the majority of deep vein dilatation is secondary to volume overload in this setting, which will resolve with correction of the superficial reflux.

C. Compression Sclerotherapy

Sclerotherapy to obliterate and produce permanent fibrosis of the involved veins is generally reserved for the treatment of small varicose veins less than 4 mm in diameter. Use of foam sclerotherapy can allow treatment of larger veins, although systemic embolization of the foam

sclerosant may be a concern. The injection of the sclerosing solution into the varicosed vein is followed by a period of compression of the segment, resulting in obliteration of the vein. Complications such as phlebitis, tissue necrosis, or infection may occur, and vary in incidence with the skill of the clinician.

► Prognosis

Correction of the venous insufficiency and excision of varicose veins provide excellent results. The 5-year success rate (as defined as lack of pain and recurrent varicosities) is 85–90%. Simple excision (phlebectomy) or injection sclerotherapy without correction of reflux is associated with higher rates of recurrence. Even after adequate treatment, secondary tissue changes, such as lipodermosclerosis, may persist.

► When to Refer

- Absolute indications for referral for saphenous ablation include phlebitis and bleeding.
- Pain and cosmetic concerns are responsible for the majority of referrals for ablation.

SUPERFICIAL VENOUS THROMBOPHLEBITIS

ESSENTIALS OF DIAGNOSIS

- Induration, redness, and tenderness along a superficial vein, usually the saphenous vein.
- Induration at the site of a recent intravenous line or trauma.
- Significant swelling of the extremity may not be seen.

► General Considerations

Short-term venous catheterization of superficial arm veins as well as the use of longer term peripherally inserted central catheter (PICC) lines are the most common cause of superficial thrombophlebitis. Intravenous catheter sites should be observed daily for signs of local inflammation and should be removed if a local reaction develops in the vein. Serious thrombotic or septic complications can occur if this policy is not followed.

Superficial thrombophlebitis may occur spontaneously, as in pregnant or postpartum women or in individuals with varicose veins or thromboangiitis obliterans; or it may be associated with trauma, as in the case of a blow to the leg or following intravenous therapy with irritating solutions. It also may be a manifestation of systemic hypercoagulability secondary to abdominal cancer such as carcinoma of the pancreas and may be the earliest sign of these

conditions. Superficial thrombophlebitis may be associated with occult deep venous thrombosis (DVT) in about 20% of cases. Pulmonary emboli are exceedingly rare and occur from an associated DVT. (See Chapter 9 for discussion on Deep Venous Thrombosis.)

► Clinical Findings

In spontaneous superficial thrombophlebitis, the long saphenous vein is most often involved. The patient usually experiences a dull pain in the region of the involved vein. Local findings consist of induration, redness, and tenderness along the course of a vein. The process may be localized, or it may involve most of the long saphenous vein and its tributaries. The inflammatory reaction generally subsides in 1–2 weeks; a firm cord may remain for a much longer period. Edema of the extremity is uncommon.

Localized redness and induration at the site of a recent intravenous line requires urgent attention. Chills and high fever suggest septic phlebitis and indicate that aggressive debridement of the area is warranted.

► Differential Diagnosis

The linear rather than circular nature of the lesion and the distribution along the course of a superficial vein serve to differentiate superficial phlebitis from cellulitis, erythema nodosum, erythema induratum, panniculitis, and fibrositis. Lymphangitis and deep thrombophlebitis must also be considered.

► Treatment

If the process is well localized and not near the saphenofemoral junction, local heat, and nonsteroidal anti-inflammatory medications are usually effective in limiting the process. If the induration is extensive or is progressing toward the saphenofemoral junction (leg) or cephaloaxillary junction (arm), ligation and division of the vein at the junction of the deep and superficial veins is indicated.

Anticoagulation therapy is usually not indicated unless the disease is rapidly progressing or there is extension into the deep system.

Septic superficial thrombophlebitis is an intravascular abscess and may require excision of the involved vein in order to control the infection. *Staphylococcus aureus* is the most common pathogen. Because of the lethal nature of this complication, broad-spectrum antibiotics and systemic anticoagulation with heparin should be instituted immediately. If cultures are positive, therapy should be continued for 7–10 days or for 4–6 weeks if complicating endocarditis cannot be excluded. Other organisms, including fungi, may also be responsible.

► Prognosis

With spontaneous thrombophlebitis, the course is generally benign and brief. The prognosis depends on the underlying pathologic process. In patients with phlebitis secondary to varicose veins, recurrent episodes are likely unless correction of the underlying venous reflux and excision of varicosities is done. The mortality from septic thrombophlebi-

tis is 20% or higher and requires aggressive treatment. However, if the involvement is localized, the mortality is low and prognosis is excellent with early treatment.

 van Weert H et al. Spontaneous superficial venous thrombophlebitis: does it increase risk for thromboembolism? A historic follow-up study in primary care. *J Fam Pract*. 2006 Jan;55(1):52–7. [PMID: 16388768]

CHRONIC VENOUS INSUFFICIENCY

ESSENTIALS OF DIAGNOSIS

- ▶ History of prior DVT or leg injury.
- ▶ Edema, stasis (brawny) skin pigmentation, subcutaneous liposclerosis in the lower leg.
- ▶ Large ulcerations at or above the ankle are common (stasis ulcers).

▶ General Considerations

Chronic venous insufficiency can result from changes secondary to deep venous thrombophlebitis, although a definite history of phlebitis is not obtainable in about 25% of these patients. There may be a history of leg trauma. Obesity is often a complicating factor. Chronic venous insufficiency also may occur in association with superficial venous reflux and varicose veins or as a result of neoplastic obstruction of the pelvic veins or congenital or acquired arteriovenous fistula.

The basic pathology is caused by valve leaflets that do not coapt because they are either thickened and scarred (the post-thrombotic syndrome) or in a dilated vein and are therefore functionally inadequate. This results in an abnormally high hydrostatic force transmitted to the subcutaneous veins and tissues of the lower leg. The resulting edema results in dramatic and deleterious secondary changes. The stigmata of chronic venous insufficiency include fibrosis of the subcutaneous tissue and skin, pigmentation of skin (hemosiderin taken up by the dermal macrophages) and, later, ulceration which is extremely slow to heal. Itching may precipitate the formation of ulceration or local wound cellulitis. Dilation of the superficial veins may occur, leading to varicosities. Whereas primary varicose veins with no abnormality of the deep venous system may be associated with some similar changes, the edema is more pronounced in the post-thrombotic extremities, and the secondary changes are more extensive and debilitating.

▶ Clinical Findings

A. Symptoms and Signs

Progressive edema of the leg (particularly the lower leg) is the usual initial symptom. Secondary changes in the skin and subcutaneous tissues develop. The usual symptoms are itching, a dull discomfort made worse by periods of stand-

ing, and pain if an ulceration is present. The skin at the ankle is usually thin, shiny, and a brownish pigmentation often develops. If the condition is long-standing, the subcutaneous tissues become thick and fibrous. Ulcerations may occur, usually just above the ankle, on the medial or anterior aspect of the leg. Healing results in a thin scar on a fibrotic base that often breaks down with minor trauma or another bout of leg swelling. Varicosities frequently appear that are associated with incompetent perforating veins. Cellulitis, which is often difficult to distinguish from the hemosiderin pigmentation, may be diagnosed by blanching erythema.

B. Imaging

Patients with post-thrombotic syndrome or signs of chronic venous insufficiency should undergo duplex ultrasonography to determine whether superficial reflux is present and to evaluate the degree of deep reflux and obstruction.

▶ Differential Diagnosis

Patients with congestive heart failure, chronic renal disease, or decompensated liver disease may have bilateral edema of the lower extremities. Swelling from lymphedema may be unilateral, and varicosities are absent. Edema from these causes pits easily and brawny discoloration is rare. Lipedema is a disorder of adipose tissue that occurs almost exclusively in women, is bilateral and symmetric, and is characterized by stopping at a distinct line just above the ankles.

Primary varicose veins may be difficult to differentiate from the secondary varicosities that often develop in this condition, as discussed above.

Other conditions associated with chronic ulcers of the leg include autoimmune diseases (eg, Felty syndrome), arterial insufficiency (often very painful with absent pulses), sickle cell anemia, erythema induratum (bilateral and usually on the posterior aspect of the lower part of the leg), and fungal infections (cultures specific: no chronic swelling or varicosities).

▶ Prevention

Irreversible tissue changes and associated complications in the lower legs can be minimized through early and aggressive anticoagulation of acute DVT to minimize the valve damage and by prescribing stockings if chronic edema develops in subsequent years. Catheter-directed thrombolysis or mechanical thrombectomy of acute DVT may be of greater value than simple anticoagulants in preventing post-thrombotic syndrome and chronic venous insufficiency.

▶ Treatment

A. General Measures

Well-fitting, graduated compression stockings worn from the mid foot to just below the knee during the day and evening are the mainstays of treatment. Long periods of sitting or standing should be avoided. During the day, the patient's legs should be elevated intermittently, and at

night, the legs should be kept above the level of the heart with pillows under the mattress. Pneumatic compression of the leg, which can pump the fluid out of the leg, is used in cases refractory to the above measures.

B. Ulceration

As the primary pathology is edema, healing of the ulcer will not occur until the edema is controlled. A lesion can often be treated on an ambulatory basis by means of a semi-rigid gauze boot made with Unna paste (Gelocast, Medicopaste) or a multi-layer compression (such as Profore) and applied to the leg after much of the swelling has been reduced by a period of elevation. The pumping action of the calf muscles on the blood flow out of the lower extremity is enhanced by a circumferential nonelastic bandage on the ankle and lower leg. The boot must be changed every 2–3 days, depending on the amount of drainage from the ulcer. The ulcer, tendons, and bony prominences must be adequately padded. As an alternative and after the ulcer has healed, elastic stockings with graduated compression below the knee are used in an effort to prevent recurrent edema and ulceration. If compression stockings are used with ulcers, an absorbent dressing must be applied under the stocking as the wounds can leak large volumes of fluid. Home compression therapy with a pneumatic compression device is also effective at reducing edema but many patients have severe pain with the “milking” action of the pump device. Some patients will require admission for complete bed rest and leg elevation to achieve ulcer healing.

C. Correction of Superficial Reflux

Incompetent (refluxing) perforator veins that feed the area of ulceration can be treated with percutaneous means (radiofrequency ablation or endovenous laser treatment) to help decrease the venous pressure in the area of ulceration and promote healing. Venous valvular reconstructive surgery is under investigation. Where there is substantial obstruction of the deep venous system, superficial varicosities supply the venous return and they should not be removed.

► Prognosis

Individuals with chronic venous insufficiency often have recurrent problems, particularly if they do not consistently wear support stockings that have at least 30 mm Hg compression.

► When to Refer

- Patients with significant saphenous reflux should be evaluated for ablation as this may reduce the recirculation of blood and return the deep system to competence.
- Patients with ulcers should be monitored in a wound center where these challenging wounds can receive aggressive care.

SUPERIOR VENA CAVAL OBSTRUCTION

ESSENTIALS OF DIAGNOSIS

- Swelling of the neck, face and upper extremities.
- Dilated veins over the upper chest and neck.

► General Considerations

Partial or complete obstruction of the superior vena cava is a relatively rare condition that is usually secondary to neoplastic or inflammatory processes in the superior mediastinum. The most frequent causes are (1) neoplasms, such as lymphomas, primary malignant mediastinal tumors, or carcinoma of the lung with direct extension (over 80%); (2) chronic fibrotic mediastinitis, either of unknown origin or secondary to tuberculosis, histoplasmosis, pyogenic infections, or drugs, especially methysergide; (3) DVT, often by extension of the process from the axillary or subclavian vein into the innominate vein and vena cava associated with catheterization of these veins for dialysis or for hyperalimentation; (4) aneurysm of the aortic arch; and (5) constrictive pericarditis.

► Clinical Findings

A. Symptoms and Signs

The onset of symptoms is acute or subacute. Symptoms include swelling of the neck and face, and upper extremities. Symptoms are often perceived as congestion and present as headache, dizziness, visual disturbances, stupor, syncope, or cough. Symptoms are particularly exacerbated when the patient is supine or bends over. There is progressive obstruction of the venous drainage of the head, neck, and upper extremities. The cutaneous veins of the upper chest and lower neck become dilated, and flushing of the face and neck develops. Brawny edema of the face, neck, and arms occurs later, and cyanosis of these areas then appears. Cerebral and laryngeal edema ultimately results in impaired function of the brain as well as respiratory insufficiency. Bending over or lying down accentuates the symptoms; sitting quietly is generally preferred. The manifestations are more severe if the obstruction develops rapidly and if the azygos junction or the vena cava between that vein and the heart is obstructed.

B. Laboratory Findings

The venous pressure is elevated (often > 20 cm of water) in the arm and is normal in the leg. Since lung cancer is a common cause, bronchoscopy is often performed; transbronchial biopsy, however, is relatively contraindicated because of venous hypertension and the risk of bleeding.

C. Imaging

Chest radiographs and a CT scan will define the location and often the nature of the obstructive process, and contrast venography or magnetic resonance venography (MRV) will map out the extent and degree of the venous obstruction and the collateral circulation. Brachial venography or radionuclide scanning following intravenous injection of technetium Tc-99m pertechnetate demonstrates a block to the flow of contrast material into the right heart and enlarged collateral veins. These techniques also allow estimation of blood flow around the occlusion as well as serial evaluation of the response to therapy.

► Treatment

Urgent treatment for neoplasm consists of (1) cautious use of intravenous diuretics and (2) mediastinal irradiation, starting within 24 hours, with a treatment plan designed to give a high daily dose but a short total course of therapy to rapidly shrink the local tumor even further. Intensive combined therapy will palliate the process in up to 90% of patients. In patients with a subacute presentation, radiation therapy alone usually suffices. Chemotherapy is added if lymphoma or small-cell carcinoma is diagnosed.

Conservative measures, such as elevation of the head of the bed and lifestyle modification to avoid bending over, are useful. Occasionally, anticoagulation is needed, while thrombolysis is rarely needed. Balloon angioplasty of the obstructed caval segment combined with stent placement provides prompt relief of symptoms and is the procedure of choice. Long-term outcome is complicated by risk of re-occlusion from either thrombosis or further growth of neoplasm. Surgical procedures to bypass the obstruction are complicated by bleeding relating to high venous pressure. In cases where the thrombosis is secondary to an indwelling catheter, thrombolysis may be attempted. Clinical judgment is required since a long-standing clot may be fibrotic and the risk of bleeding will outweigh the potential benefit.

► Prognosis

The prognosis depends on the nature and degree of obstruction and its speed of onset. Slowly developing forms secondary to fibrosis may be tolerated for years. A high degree of obstruction of rapid onset secondary to cancer is often fatal in a few days or weeks because of increased intracranial pressure and cerebral hemorrhage, but treatment of the tumor with radiation and chemotherapeutic drugs may result in significant palliation. Balloon angioplasty and stenting provides good relief but may require re-treatment for recurrent symptoms secondary to thrombosis or restenosis.

► When to Refer

Referral should occur with any patient with progressive head and neck swelling to rule out superior vena cava syndrome.

► When to Admit

Any patient with acute edema of the head and neck or any patient in whom signs and symptoms of airway compromise, such as hoarseness or stridor, develop should be admitted.

DISEASES OF THE LYMPHATIC CHANNELS

LYMPHANGITIS & LYMPHADENITIS

ESSENTIALS OF DIAGNOSIS

- Red streak from wound or area of cellulitis toward regional lymph nodes, which are usually enlarged and tender.
- Chills, fever, and malaise may be present.

► General Considerations

Lymphangitis and lymphadenitis are common manifestations of a bacterial infection that is usually caused by hemolytic streptococci or *S aureus* (or by both organisms) and usually arises from the site of an infected wound. The wound may be very small or superficial, or an established abscess may be present, feeding bacteria into the lymphatics. The involvement of the lymphatics is often manifested by a red streak in the skin extending in the direction of the regional lymph nodes, which are, in turn, generally tender and engorged. Systemic manifestations include fever, chills, and malaise. The infection may progress rapidly, often in a matter of hours, and may lead to septicemia and even death.

► Clinical Findings

A. Symptoms and Signs

Throbbing pain is usually present in the area of cellulitis at the site of bacterial invasion. Malaise, anorexia, sweating, chills, and fever of 38–40 °C develop rapidly. The red streak, when present may be definite or may be very faint and easily missed, especially in dark-skinned patients. It is usually tender or indurated in the area of cellulitis. The involved regional lymph nodes may be significantly enlarged and are usually quite tender. The pulse is often rapid.

B. Laboratory Findings

Leukocytosis with a left shift is usually present. Blood cultures may be positive, most often for staphylococcal or streptococcal species. Culture and sensitivity studies of the wound exudate or pus may be helpful in treatment of the more severe or refractory infections but are often difficult to interpret because of skin contaminants.

▶ Differential Diagnosis

Lymphangitis may be confused with superficial thrombophlebitis, but the erythema and induration of thrombophlebitis is localized in and around the thrombosed vein. Venous thrombosis is not associated with lymphadenitis, and a wound of entrance with secondary cellulitis is generally absent.

Cat-scratch fever should be considered when lymphadenitis is present; the nodes, though often very large, are relatively nontender. Exposure to cats is common, but the patient may have forgotten about the scratch.

It is extremely important to differentiate cellulitis from acute streptococcal hemolytic gangrene or necrotizing fasciitis. These are deeper infections that may be extensive and are potentially lethal. Patients appear more seriously ill; there may be redness due to leakage of red cells, creating a non-blanching erythema; and subcutaneous crepitus may be palpated or auscultated using the diaphragm with light pressure over the involved area. Immediate wide debridement of all involved deep tissues should be done if these signs are present.

▶ Treatment

A. General Measures

Prompt treatment should include heat (hot, moist compresses or heating pad), elevation when feasible, and immobilization of the infected area. Analgesics may be prescribed for pain.

B. Specific Measures

Antibiotic therapy should always be instituted when local infection becomes invasive, as manifested by cellulitis and lymphangitis. Because such infections are so frequently caused by streptococci, cephalosporins or extended-spectrum penicillins are commonly used. Given the increasing incidence of methicillin-resistant *S aureus* (MRSA) in the community, coverage of this pathogen with appropriate antibiotic therapy should be considered (see Table 30–4).

C. Wound Care

Any wound that is the initiating site of lymphangitis should be treated aggressively. Any necrotic tissue must be debrided and loculated pus drained.

▶ Prognosis

With proper therapy including an antibiotic effective against the invading bacteria, control of the infection can usually be achieved in a few days. Delayed or inadequate therapy can lead to overwhelming infection with septicemia.

LYMPHEDEMA

ESSENTIALS OF DIAGNOSIS

- ▶ Painless persistent edema of one or both lower extremities, primarily in young women.

- ▶ Pitting edema without ulceration, varicosities, or stasis pigmentation.
- ▶ There may be episodes of lymphangitis and cellulitis.

▶ General Considerations

When lymphedema is due to congenital developmental abnormalities consisting of hypoplastic or hyperplastic involvement of the proximal or distal lymphatics, it is referred to as the **primary** form. The obstruction may be in the pelvic or lumbar lymph channels and nodes when the disease is extensive and progressive. The **secondary** form of lymphedema involves inflammatory or mechanical lymphatic obstruction from trauma, regional lymph node resection or irradiation, or extensive involvement of regional nodes by malignant disease or filariasis. Secondary dilation of the lymphatics that occurs in both forms leads to incompetence of the valve system, disrupting the orderly flow along the lymph vessels, and results in progressive stasis of a protein-rich fluid. Episodes of acute and chronic inflammation may be superimposed, with further stasis and may create secondary fibrosis. Hypertrophy of the limb results, with markedly thickened and fibrotic skin and subcutaneous tissue in very advanced cases.

Lymphangiography and radioactive isotope studies may identify focal defects in lymph flow but are of little value in planning therapy.

▶ Treatment

Since there is no effective cure for lymphedema, the treatment strategies are designed to control the problem and allow normal activity and function. Most patients can be treated with some of the following measures: (1) The flow of lymph out of the extremity can be aided through intermittent elevation of the extremity, especially during the sleeping hours (foot of bed elevated 15–20 degrees, achieved by placing pillows beneath the mattress); the constant use of graduated elastic compression stockings; and massage toward the trunk—either by hand or by means of pneumatic pressure devices designed to milk edema out of an extremity. (2) Secondary cellulitis in the extremity should be avoided by means of good hygiene and treatment of any trichophytosis of the toes. Once an infection starts, it should be treated by periods of elevation and antibiotic therapy that covers *Staphylococcus* and *Streptococcus* organisms. Infections can be a serious and recurring problem and are often difficult to control. Prophylactic antibiotics have not been shown to be of benefit. (3) Intermittent courses of diuretic therapy, especially in those with premenstrual or seasonal exacerbations, are rarely helpful. (4) Amputation is used only for the rare complication of lymphangiosarcoma in the extremity.

▶ Prognosis

With aggressive treatment, including pneumatic compression devices, good relief of symptoms can be achieved. The long-term outlook is dictated by the associated conditions and avoidance of recurrent cellulitis.

Rockson SG. Diagnosis and management of lymphatic vascular disease. *J Am Coll Cardiol.* 2008 Sep 2;52(10):799–806. [PMID: 18755341]

SHOCK

ESSENTIALS OF DIAGNOSIS

- ▶ Hypotension, tachycardia, oliguria, altered mental status.
- ▶ Peripheral hypoperfusion and impaired oxygen delivery.

General Considerations

Shock occurs when the rate of arterial blood flow is inadequate to meet tissue metabolic needs. This results in regional hypoxia and subsequent lactic acidosis from anaerobic metabolism in peripheral tissues as well as eventual end-organ damage and failure.

Classification (Table 12-1)

A. Hypovolemic Shock

Hypovolemic shock results from decreased intravascular volume secondary to loss of blood or fluids and electrolytes. The etiology may be suggested by the clinical setting (eg, trauma) or by signs and symptoms of blood loss (eg, gastrointestinal bleeding) or dehydration (eg, vomiting or diarrhea). Compensatory vasoconstriction may transiently maintain the blood pressure but unreplaced losses of over 15% of the intravascular volume can result in hypotension and progressive tissue hypoxia.

B. Cardiogenic Shock

Cardiogenic shock results from pump failure. This may be related to myocardial infarction, cardiomyopathy, myocardial contusion, valvular incompetence or stenosis, or arrhythmias. See Chapter 10.

C. Obstructive Shock

Cardiac tamponade, tension pneumothorax, and massive pulmonary embolism can cause an acute decrease in cardiac output resulting in shock. These are medical emergencies requiring prompt diagnosis and treatment.

D. Distributive Shock

Distributive or vasodilatory shock has many causes including sepsis, anaphylaxis, systemic inflammatory response syndrome (SIRS) produced by severe pancreatitis or burns, or acute adrenal insufficiency. The reduction in systemic vascular resistance results in inadequate cardiac output and tissue hypoperfusion despite normal circulatory volume.

1. Septic shock—Sepsis is the most common cause of distributive shock and carries a high mortality rate of 30–87%. Sepsis is typically secondary to gram-negative bacte-

Table 12-1. Classification of shock by mechanism and common causes.

Hypovolemic shock

- Loss of blood (hemorrhagic shock)
 - External hemorrhage
 - Trauma
 - Gastrointestinal tract bleeding
 - Internal hemorrhage
 - Hematoma
 - Hemothorax or hemoperitoneum
- Loss of plasma
 - Burns
 - Exfoliative dermatitis
- Loss of fluid and electrolytes
 - External
 - Vomiting
 - Diarrhea
 - Excessive sweating
 - Hyperosmolar states (diabetic ketoacidosis, hyperosmolar nonketotic coma)
 - Internal (“third spacing”)
 - Pancreatitis
 - Ascites
 - Bowel obstruction

Cardiogenic shock

- Dysrhythmia
 - Tachyarrhythmia
 - Bradyarrhythmia
- “Pump failure” (secondary to myocardial infarction or other cardiomyopathy)
- Acute valvular dysfunction (especially regurgitant lesions)
- Rupture of ventricular septum or free ventricular wall

Obstructive shock

- Tension pneumothorax
- Pericardial disease (tamponade, constriction)
- Disease of pulmonary vasculature (massive pulmonary emboli, pulmonary hypertension)
- Cardiac tumor (atrial myxoma)
- Left atrial mural thrombus
- Obstructive valvular disease (aortic or mitral stenosis)

Distributive shock

- Septic shock
- Anaphylactic shock
- Neurogenic shock
- Vasodilator drugs
- Acute adrenal insufficiency

Reproduced, with permission, from Stone CK, Humphries RL (editors). *Current Emergency Diagnosis & Treatment*, 5th ed. p. 193. McGraw-Hill, 2004.

remia (such as *Escherichia coli*, *Klebsiella*, *Proteus*, and *Pseudomonas*) and less often due to gram-positive cocci and gram-negative anaerobes (*Bacteroides*). Risk factors include extremes of age, diabetes, immunosuppression, and history of a recent invasive procedure.

2. Neurogenic shock—Neurogenic shock is caused by traumatic spinal cord injury or effects of an epidural or spinal anesthetic. This results in loss of sympathetic tone with a reduction in systemic vascular resistance and hypotension without a compensatory tachycardia. Reflex vagal parasympathetic stimulation evoked by pain, gastric

dilation, or fright may simulate neurogenic shock, producing hypotension, bradycardia, and syncope.

► Clinical Findings

Hypotension is traditionally defined as a systolic blood pressure of 90 mm Hg or less or a mean arterial pressure of less than 60–65 mm Hg but must be evaluated relative to the patient's normal blood pressure. A drop in systolic pressure of more than 10–20 mm Hg and an increase in pulse of more than 15 beats per minute with positional change suggests depleted intravascular volume. However, blood pressure is often not the best indicator of organ perfusion because compensatory mechanisms, such as increased heart rate, contractility, and vasoconstriction can occur to prevent hypotension. Patients often have cool or mottled extremities and weak or thready peripheral pulses. Splanchnic vasoconstriction may lead to oliguria, bowel ischemia, and hepatic dysfunction, which can ultimately result in multiorgan failure. Mentation may be normal or patients may become restless, agitated, confused, lethargic, or comatose as a result of inadequate perfusion of the brain. Consequently, intubation and mechanical ventilation may be required to protect the patient's airway.

Hypovolemic shock is evident when signs of hypoperfusion, such as oliguria, altered mental status, and cool extremities, are present. Jugular venous pressure is low, and there is a narrow pulse pressure indicative of reduced stroke volume. Rapid replacement of fluids restores tissue perfusion. In **cardiogenic shock**, there are also signs of global hypoperfusion with oliguria, altered mental status, and cool extremities. Jugular venous pressure is elevated. There may be evidence of pulmonary edema in the setting of left-sided heart failure. A transthoracic echocardiogram (TTE) or a TEE is an effective diagnostic tool to differentiate hypovolemic shock from cardiogenic shock. In hypovolemic shock, the left ventricle will be small because of decreased filling, but contractility is often preserved. Cardiogenic shock results from pump failure and therefore there will be evidence of a decrease in left ventricular contractility. In some cases, the left ventricle may appear dilated and full because of its inability to eject.

In **obstructive shock**, the central venous pressure may be elevated but the TEE or TTE may show reduced left ventricular filling, a layer of fluid between the pericardium as in the case of tamponade, or thickened pericardium as in the case of pericarditis. Pericardiocentesis or pericardial window, chest tube placement, or catheter-directed thrombolytic therapy can be lifesaving in the case of tamponade.

In **distributive shock**, signs include hyperdynamic heart sounds, warm extremities, and a wide pulse pressure indicative of large stroke volume. The echocardiogram may show hyperdynamic left ventricle. Fluid resuscitation may have little effect on blood pressure, urinary output, or mentation.

Septic shock is diagnosed when there is clinical evidence of infection in the setting of persistent hypotension and evidence of organ hypoperfusion, such as lactic acidosis, decreased urinary output, or altered mental status despite volume resuscitation. Neurogenic shock is diagnosed when

there is evidence of central nervous system injury and persistent hypotension despite volume resuscitation.

► Treatment

A. General Measures

Treatment depends on prompt diagnosis and an accurate appraisal of inciting conditions. Initial management consists of basic life support with an assessment of the patient's airway, breathing, and circulation. This may entail airway intubation and mechanical ventilation. Ventilatory failure should be anticipated in patients with a severe metabolic acidosis in association with shock. Mechanical ventilation along with sedation and paralysis can decrease the oxygen demand of the respiratory muscles and allow improved oxygen delivery to other hypoperfused tissues. Intravenous access and fluid resuscitation should be instituted along with cardiac monitoring and assessment of hemodynamic parameters such as blood pressure and heart rate. Cardiac monitoring can detect myocardial ischemia requiring cardiac catheterization or malignant arrhythmias, which can be treated by standard advanced cardiac life support (ACLS) protocols.

Unresponsive or minimally responsive patients should immediately be given 1 ampule of **50% dextrose** intravenously and 2 mg of **naloxone** intravenously or intramuscularly. An **arterial line** should be placed for continuous blood pressure measurement, and a **Foley catheter** should be inserted to monitor urinary output. **Blood specimens** should be evaluated for complete blood count, electrolytes, glucose, arterial blood gas determinations, coagulation parameters, typing and cross-matching, and bacterial cultures.

B. Central Venous Pressure or Pulmonary Capillary Wedge Pressure

Early consideration is given to placement of a central line or pulmonary artery catheter for hemodynamic pressure measurements. A pulmonary artery catheter can be helpful in distinguishing cardiogenic and septic shock and in monitoring the effects of volume resuscitation or pressor medications. Pulmonary artery catheter allows measurement of the pulmonary artery pressure, left-sided filling pressure or the pulmonary capillary wedge pressure (PCWP), and cardiac output. Because of the attendant risks associated with pulmonary artery catheters (such as infection, arrhythmias, vein thrombosis, and pulmonary artery rupture), the value of the information they might provide must be carefully weighed in each patient. TTE is a noninvasive alternative to pulmonary artery catheter and can provide information about the pulmonary artery pressure, PCWP, and cardiac output. In addition, TTE can provide information about the function of the heart.

A **central venous pressure (CVP)** under 5 mm Hg suggests hypovolemia, and a CVP over 18 mm Hg suggests volume overload, cardiac failure, tamponade, or pulmonary hypertension. A cardiac index < 2 L/min/m² indicates a need for inotropic support. A high cardiac index > 4 L/min/m² in a hypotensive patient is consistent with early

septic shock. The systemic vascular resistance is low (< 800 dynes.s/cm⁻⁵) in sepsis and neurogenic shock and high (> 1500 dynes.s/cm⁻⁵) in hypovolemic and cardiogenic shock. Treatment is directed at maintaining a CVP of 8–12 mm Hg, and mean arterial pressure of 65–90 mm Hg, a cardiac index of 2–4 L/min/m², and a central venous oxygen saturation of greater than 70%.

C. Volume Replacement

Volume replacement is critical in the initial management of shock. **Hemorrhagic shock** is treated with immediate efforts to achieve hemostasis and rapid infusions of blood substitutes, such as type-specific or type O negative packed red blood cells (PRBC) or whole blood, which also provides extra volume and clotting factors. Each unit of PRBC or whole blood is expected to raise the hematocrit by 3%. **Hypovolemic shock** secondary to dehydration is managed with rapid boluses of isotonic crystalloid, usually in 1 liter increments. **Cardiogenic shock** in the absence of fluid overload requires smaller fluid challenges, usually in increments of 250 mL. **Septic shock** usually requires large volumes of fluid for resuscitation as the associated capillary leak releases fluid to the extravascular space.

Meta-analyses of studies of critically ill heterogeneous populations comparing crystalloid and colloid resuscitation (with albumin) indicate no benefit of colloid over crystalloid solutions, and some have suggested a trend toward increased mortality with albumin. Clinical trials and meta-analyses have also found no difference in mortality between trauma patients receiving hypertonic saline (7.5%) and those receiving isotonic crystalloid. More positive results were found with hypertonic saline plus dextran with an increase in survival over patients managed with isotonic saline, particularly in patients with traumatic brain injury.

Large-volume resuscitation with unwarmed fluids produces hypothermia, which must be treated to avoid hypothermia-induced coagulopathy.

D. Early Goal-Directed Therapy

Early goal-directed therapy within the first 6 hours in the treatment of septic shock provides significant benefits. In a randomized, controlled trial, patients were assigned to early goal-directed therapy or usual care. Patients who were assigned to early goal-directed care received fluid resuscitation to achieve a CVP of 8–12 mm Hg; PRBCs to reach a hematocrit of 30%; vasopressors to reach a mean arterial blood pressure of 65 mm Hg; and dobutamine, if necessary, to achieve a central venous oxygen saturation of $> 70\%$. These patients had a significantly lower in-hospital and 60-day mortality rate compared with control patients. A meta-analysis of hemodynamic optimization trials has also suggested that early treatment before the development of organ failure results in improved survival.

Compensated shock can occur in the setting of normalized hemodynamic parameters with ongoing global tissue hypoxia. Traditional endpoints of resuscitation such as blood pressure, heart rate, urinary output, mental status, and skin perfusion can therefore be misleading. Additional endpoints such as lactate levels and base deficit can help

guide further resuscitative therapy. Patients who respond well to initial efforts demonstrate a survival advantage over nonresponders.

E. Medications

1. Vasoactive therapy—Vasopressors and inotropic agents are administered only after adequate fluid resuscitation. Choice of vasoactive therapy depends on cardiac output. If there is evidence of low cardiac output with high filling pressures, inotropic support is needed to improve contractility. If there is continued hypotension with evidence of high cardiac output after adequate volume resuscitation, then vasopressor support is needed to improve vasomotor tone.

Dobutamine, a β -adrenergic agonist, is the first-line drug for **cardiogenic shock**, increasing contractility and decreasing afterload. The initial dose is 0.5–1 mcg/kg/min as a continuous intravenous infusion, then titrated every few minutes. The usual dosage range is 2–20 mcg/kg/min intravenously. Tachyphylaxis can occur after 48 hours secondary to the down-regulation of β -adrenergic receptors. Amrinone or milrinone are phosphodiesterase inhibitors that can be substituted for dobutamine. These drugs increase cyclic AMP levels and increase cardiac contractility, bypassing the β -adrenergic receptor. However, vasodilation is a side effect of amrinone and milrinone.

For **vasodilatory shock** when increased vasoconstriction is required to maintain an adequate perfusion pressure, α -adrenergic agonists such as phenylephrine and norepinephrine are generally used. Although **norepinephrine** is both an α -adrenergic and β -adrenergic agonist, it preferentially increases mean arterial pressure over cardiac output. The initial dose is 0.5–1 mcg/min as an intravenous infusion, titrated to maintain the systolic blood pressure to at least 80 mm Hg. The usual maintenance dose is 2–4 mcg/min (maximum dose is 30 mcg/min). Patients with refractory shock may require dosages of 8–30 mcg/min. **Epinephrine**, also with both α -adrenergic and β -adrenergic effects, may be used in severe shock and during acute resuscitation. Initially, give 1 mcg/min as a continuous intravenous infusion; the usual dosage range is 2–10 mcg/min IV.

Dopamine has variable effects according to dosage. At low doses (2–3 mcg/kg/min) stimulation of dopaminergic and β -agonist receptors produces increased glomerular filtration, heart rate, and contractility. At higher doses (> 5 mcg/kg/min), α -adrenergic effects predominate, resulting in peripheral vasoconstriction. Recent studies have suggested some advantages to norepinephrine over dopamine at high doses.

Vasopressin (antidiuretic hormone or ADH) is gaining widespread acceptance in the treatment of **distributive** or **vasodilatory shock**. Vasopressin causes peripheral vasoconstriction via V1 receptors located on smooth muscle cells and attenuation of nitric oxide (NO) synthesis and cGMP, the second messenger of NO. The rationale for using low-dose vasopressin in the management of septic shock include the relative deficiency of vasopressin in late shock and the increased sensitivity of the systemic circulation to the vasopressor effects of vasopressin. Vasopressin

also potentiates the effects of catecholamines on the vasculature and stimulates cortisol production. Several small clinical trials have demonstrated improvement in hemodynamic parameters and urinary output with vasopressin use but no clinical study has yet demonstrated improved survival. In addition, some studies have reported reduced catecholamine requirements with vasopressin administration. Infusion of vasopressin at a low dose (0.01–0.04 units/min) may be safe and beneficial in septic patients with hypotension that is refractory to fluid resuscitation and conventional catecholamine vasopressors. Higher doses of vasopressin decrease cardiac output and may put patients at greater risk for splanchnic and coronary artery ischemia. Further recommendations regarding vasopressin use will likely follow the publication of the results from the recent Vasopressin in Septic Shock Trial. Terlipressin is a synthetic long-acting analog of vasopressin that increases blood pressure at the expense of cardiac index and oxygen consumption but may be an effective rescue therapy in patients with catecholamine resistant septic shock.

NO plays an important role in the vasodilatation associated with septic shock. Endotoxin and inflammatory cytokines induce a calcium independent NO synthase that results in a sustained production of NO. The NO pathway is inhibited by methylene blue which, when given to patients with septic shock, has been shown to increase mean arterial pressure and systemic vascular resistance while decreasing vasopressor requirements. However, no improvement in survival has been demonstrated. A large randomized study showed an increased mortality rate in patients with septic shock who received another NO inhibitor N^G-methyl-L-arginine hydrochloride.

2. Corticosteroids—The observation that severe sepsis may be associated with relative adrenal insufficiency or glucocorticoid receptor resistance has led to several trials to evaluate the role of treatment with corticosteroids in septic shock. Early trials where high doses of corticosteroids were administered to patients in septic shock did not show improved survival; rather, some worse outcomes were observed from increased rates of secondary infections. Subsequent trials have studied the use of low-dose corticosteroids in patients who were in septic shock and had relative adrenal insufficiency, defined by a cortisol response of 9 mcg/dL or less after one injection of 250 mcg of corticotropin. Low-dose corticosteroid regimens included hydrocortisone 50 mg every 6 hours and 50 mcg of 9- α -fludrocortisone once a day, both for 7 days, or hydrocortisone 50 mg by intravenous bolus, followed by a continuous infusion of 0.18 mg/kg of body weight/hr until cessation of vasopressor support. These trials demonstrated a shorter duration of use of vasopressors, significantly reduced 28-day mortality rates, and no increased adverse effects. There was no benefit from low-dose corticosteroid use in patients who did not have adrenal insufficiency. In 2008, however, the Corticosteroid Therapy of Septic Shock (CORTICUS) study has shown that low-dose hydrocortisone (50 mg every 6 hours for 5 days and then tapered over a 6 day period) did not improve survival in patients with septic shock, either overall or in patients who did not respond to corticotropin. This study

was a randomized, double-blinded, placebo-controlled trial that is the largest to date of corticosteroids in septic patients. One limitation of the CORTICUS trial was it was not adequately powered to detect a clinically important difference in mortality. Thus, there is still uncertainty over the role of corticosteroids and corticotropin stimulation testing in patients with septic shock.

3. Activated Protein C (Drotrecogin alpha)—Activated protein C is an endogenous protein that has antithrombotic, profibrinolytic, and anti-inflammatory properties. A large randomized trial demonstrated an improved 28-day mortality rate (from 31% to 25%) in patients with severe sepsis and organ failure when treated with recombinant human activated protein C as a continuous infusion of 24 mcg/kg/h for 96 hours. A retrospective follow up of the persons enrolled in the trial demonstrated that the survival benefit observed in patients with severe sepsis persisted only to hospital discharge. Post hoc analysis, however, suggested that the benefit of activated protein C on long-term survival was greater in patients with APACHE (acute physiology and chronic health evaluation) II scores \geq 25. A randomized, placebo-controlled study evaluating patients with severe sepsis and a low risk of death, as defined by an APACHE II score of < 25 or single organ failure, confirmed the finding of no mortality benefit at 28 days. However, the rate of serious bleeding was greater in the group treated with activated protein C.

4. Antibiotics—Definitive therapy for septic shock includes an early initiation of empiric broad-spectrum antibiotics after appropriate cultures have been obtained. Surgical management may also be necessary if necrotic tissue or loculated infections are present (see Table 30–9).

5. Sodium bicarbonate—For patients with sepsis of any etiology and lactic acidosis, clinical studies have failed to show any hemodynamic benefit from bicarbonate therapy, either in increasing cardiac output or in decreasing the vasopressor requirement even in patients with severe acidemia.

F. Other Treatment Modalities

Cardiac failure may require use of transcutaneous or transvenous pacing or placement of an intra-arterial balloon pump. Emergent revascularization by percutaneous angioplasty or coronary artery bypass surgery appears to improve long-term outcome with increased survival compared with initial medical stabilization. Urgent hemodialysis or continuous venovenous hemofiltration may be indicated for maintenance of fluid and electrolyte balance during acute renal insufficiency resulting in shock.

ANEMIAS

▶ General Approach to Anemias

Anemia is present in adults if the hematocrit is less than 41% (hemoglobin < 13.5 g/dL) in males or less than 37% (hemoglobin < 12 g/dL) in females. Congenital anemia is suggested by the patient's personal and family history. Poor diet may result in folic acid deficiency and contribute to iron deficiency, but bleeding is much more commonly the cause of iron deficiency in adults. Physical examination includes attention to signs of primary hematologic diseases (lymphadenopathy, hepatosplenomegaly, or bone tenderness). Mucosal changes such as a smooth tongue suggest megaloblastic anemia.

Anemias are classified according to their pathophysiologic basis, ie, whether related to diminished production or accelerated loss of red blood cells (Table 13–1), or according to cell size (Table 13–2). The diagnostic possibilities in microcytic anemia are iron deficiency, thalassemia, and anemia of chronic disease. A severely microcytic anemia (mean cell volume [MCV] < 70 fL) is due either to iron deficiency or thalassemia. Macrocytic anemia may be due to megaloblastic (folate or vitamin B₁₂ deficiency) or nonmegaloblastic causes, in particular myelodysplasia and the use of antiretroviral drugs. A severely macrocytic anemia (MCV > 125 fL) is almost always due to either megaloblastic anemia or myelodysplasia.

IRON DEFICIENCY ANEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Serum ferritin < 12 mcg/L.
- ▶ Caused by bleeding unless proved otherwise.
- ▶ Responds to iron therapy.

▶ General Considerations

Iron deficiency is the most common cause of anemia worldwide. The causes are listed in Table 13–3. Aside from

circulating red blood cells, the major location of iron in the body is the storage pool as ferritin or as hemosiderin and in macrophages.

The average American diet contains 10–15 mg of iron per day. About 10% of this amount is absorbed. Absorption occurs in the stomach, duodenum, and upper jejunum. Dietary iron present as heme is efficiently absorbed (10–20%) but nonheme iron less so (1–5%), largely because of interference by phosphates, tannins, and other food constituents. Small amounts of iron—approximately 1 mg/d—are normally lost through exfoliation of skin and mucosal cells. There is no physiologic mechanism for increasing normal body iron losses.

Menstrual blood loss plays a major role in iron metabolism. The average monthly menstrual blood loss is approximately 50 mL, or about 0.7 mg/d. However, menstrual blood loss may be five times the average. To maintain adequate iron stores, women with heavy menstrual losses must absorb 3–4 mg of iron from the diet each day. This strains the upper limit of what may reasonably be absorbed, and women with menorrhagia of this degree will almost always become iron deficient without iron supplementation.

In general, iron metabolism is balanced between absorption of 1 mg/d and loss of 1 mg/d. Pregnancy may also upset the iron balance, since requirements increase to 2–5 mg of iron per day during pregnancy and lactation. Normal dietary iron cannot supply these requirements, and medicinal iron is needed during pregnancy and lactation. Repeated pregnancy (especially with breast-feeding) may cause iron deficiency if increased requirements are not met with supplemental medicinal iron. Decreased iron absorption can on very rare occasions cause iron deficiency and usually occurs after gastric surgery, though concomitant bleeding is frequent.

By far the most important cause of iron deficiency anemia is blood loss, especially gastrointestinal blood loss. Prolonged aspirin use, or the use of other anti-inflammatory drugs, may cause it even without a documented structural lesion. Iron deficiency demands a search for a source of gastrointestinal bleeding if other sites of blood loss (menorrhagia, other uterine bleeding, and repeated blood donations) are excluded.

Table 13-1. Classification of anemias by pathophysiology.

| |
|---|
| Decreased production |
| Hemoglobin synthesis lesion: iron deficiency, thalassemia, anemia of chronic disease |
| DNA synthesis lesion: megaloblastic anemia |
| Stem cell lesion: aplastic anemia, myeloproliferative leukemia |
| Bone marrow infiltration: carcinoma, lymphoma |
| Pure red cell aplasia |
| Increased destruction |
| Blood loss |
| Hemolysis (intrinsic) |
| Membrane lesion: hereditary spherocytosis, elliptocytosis |
| Hemoglobin lesion: sickle cell, unstable hemoglobin |
| Glycolysis: pyruvate kinase deficiency, etc |
| Oxidation lesion: glucose-6-phosphate dehydrogenase deficiency |
| Hemolysis (extrinsic) |
| Immune: warm antibody, cold antibody |
| Microangiopathic: thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, mechanical cardiac valve, paravalvular leak |
| Infection: clostridial |
| Hypersplenism |

Chronic hemoglobinuria may lead to iron deficiency since iron is lost in the urine, but this is uncommon; traumatic hemolysis due to a prosthetic cardiac valve and other causes of intravascular hemolysis (eg, paroxysmal nocturnal hemoglobinuria) should also be considered. Frequent blood donors may also be at risk for iron deficiency.

► Clinical Findings

A. Symptoms and Signs

As a rule, the only symptoms of iron deficiency anemia are those of the anemia itself (easy fatigability, tachycardia, palpitations and tachypnea on exertion). Severe deficiency causes skin and mucosal changes, including a smooth tongue, brittle nails, and cheilosis. Dysphagia because of the formation of esophageal webs (Plummer-Vinson syndrome) also occurs.

Table 13-2. Classification of anemias by mean cell volume.

| |
|------------------------------------|
| Microcytic |
| Iron deficiency |
| Thalassemia |
| Anemia of chronic disease |
| Macrocytic |
| Megaloblastic |
| Vitamin B ₁₂ deficiency |
| Folate deficiency |
| Nonmegaloblastic |
| Myelodysplasia, chemotherapy |
| Liver disease |
| Increased reticulocytosis |
| Myxedema |
| Normocytic |
| Many causes |

Table 13-3. Causes of iron deficiency.

| |
|-------------------------|
| Deficient diet |
| Decreased absorption |
| Increased requirements |
| Pregnancy |
| Lactation |
| Blood loss |
| Gastrointestinal |
| Menstrual |
| Blood donation |
| Hemoglobinuria |
| Iron sequestration |
| Pulmonary hemosiderosis |

Many iron-deficient patients develop pica, craving for specific foods (ice chips, etc) often not rich in iron.

B. Laboratory Findings

Iron deficiency develops in stages. The first is depletion of iron stores. At this point, there is anemia and no change in red blood cell size. The serum ferritin will become abnormally low. A ferritin value less than 12 mcg/L is a highly reliable indicator of iron deficiency. Bone marrow biopsy for evaluation of iron stores is now rarely performed because of intraobserver variation in its interpretation.

After iron stores have been depleted, red blood cell formation will continue with deficient supplies of iron. Serum iron values decline to less than 30 mcg/dL and transferrin levels rise, leading to transferrin saturation of less than 15%.

In the early stages, the MCV remains normal. Subsequently, the MCV falls and the blood smear shows hypochromic microcytic cells. With further progression, anisocytosis (variations in red blood cell size) and poikilocytosis (variation in shape of red cells) develop. Severe iron deficiency will produce a bizarre peripheral blood smear, with severely hypochromic cells, target cells, hypochromic pencil-shaped cells, and occasionally small numbers of nucleated red blood cells. The platelet count is commonly increased.

► Differential Diagnosis

Other causes of microcytic anemia include anemia of chronic disease, thalassemia, and sideroblastic anemia. Anemia of chronic disease is characterized by normal or increased iron stores in the bone marrow and a normal or elevated ferritin level; the serum iron is low, often drastically so, and the total iron-binding capacity (TIBC) is either normal or low. Thalassemia produces a greater degree of microcytosis for any given level of anemia than does iron deficiency. Red blood cell morphology on the peripheral smear is abnormal earlier in the course of thalassemia.

► Treatment

The diagnosis of iron deficiency anemia can be made either by the laboratory demonstration of an iron-deficient state

or by evaluating the response to a therapeutic trial of iron replacement.

Since the anemia itself is rarely life-threatening, the most important part of treatment is identification of the cause—especially a source of occult blood loss.

A. Oral Iron

Ferrous sulfate, 325 mg three times daily, which provides 180 mg of iron daily of which up to 10 mg is absorbed (though absorption may exceed this amount in cases of severe deficiency), is the preferred therapy. Compliance is improved by introducing the medicine more slowly in a gradually escalating dose with food. Alternatively, in cases of poor tolerance, one pill of ferrous sulfate can be taken at bedtime on an empty stomach. It is preferable to prescribe a lower dose of iron or to allow ingestion concurrent with food than to insist on a more rigorous schedule that will not be followed. An appropriate response is a return of the hematocrit level halfway toward normal within 3 weeks with full return to baseline after 2 months. Iron therapy should continue for 3–6 months after restoration of normal hematologic values to replenish iron stores. Failure of response to iron therapy is usually due to noncompliance, although occasional patients may absorb iron poorly, particularly if the stomach is achlorhydric. Such patients may benefit from concomitant administration of ascorbic acid (250 mg daily). Other reasons for failure to respond include incorrect diagnosis (anemia of chronic disease, thalassemia) and ongoing gastrointestinal blood loss that exceeds the rate of new erythropoiesis.

B. Parenteral Iron

The indications are intolerance to oral iron, refractoriness to oral iron, gastrointestinal disease (usually inflammatory bowel disease) precluding the use of oral iron, and continued blood loss that cannot be corrected. Because of the possibility of anaphylactic reactions, parenteral iron therapy has been advocated only for use in cases of persistent anemia after a reasonable course of oral therapy. Sodium ferric gluconate is available and has been shown to result in a lower incidence of severe anaphylaxis, allowing wider use of parenteral therapy.

The dose (total 1.5–2 g) may be calculated by estimating the decrease in volume of red blood cell mass and then supplying 1 mg of iron for each milliliter of volume of red blood cells below normal. Approximately 1 g should then be added for storage iron. Total body iron ranges between 2 g and 4 g; approximately 50 mg/kg in men and 35 mg/kg in women. Most (70–95%) of the iron is present in hemoglobin in circulating red blood cells. One milliliter of packed red blood cells (not whole blood) contains approximately 1 mg of iron. In men, red blood cell volume is approximately 30 mL/kg. A 70-kg man will therefore have approximately 2100 mL of packed red blood cells and consequently 2100 mg of iron in his circulating blood. In women, the red cell volume is about 27 mL/kg; a 50-kg woman will thus have 1350 mg of iron circulating in her red blood cells. Thus, a woman whose hemoglobin is 9 g/dL would be treated with a total of 1315

mg of parenteral iron, 315 mg for the increased red blood cell mass and 1000 mg to provide iron stores. The entire dose may be given as an intravenous infusion over 4–6 hours. A test dose of a dilute solution is given first, and the patient should be observed during the entire infusion for anaphylaxis.

▶ When to Refer

Referral to a hematologist should not generally be necessary. Refer the patient if he or she is not responsive to iron therapy.

ANEMIA OF CHRONIC DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Anemia, normocytic, or microcytic.
- ▶ Normal or increased iron stores.
- ▶ Underlying chronic disease.

▶ General Considerations

Many chronic systemic diseases are associated with mild or moderate anemia. Common causes include chronic infection or inflammation, cancer, and liver disease. The anemia of chronic kidney failure is somewhat different in pathophysiology, involving reduced production of erythropoietin, and is usually more severe. Hepcidin has been identified as an important mediator of sequestration of iron within macrophages, and upregulation of hepcidin in response to mediators of inflammation, such as IL-6, is an important cause of anemia of chronic disease.

▶ Clinical Findings

A. Symptoms and Signs

The clinical features are those of the causative condition. The diagnosis should be suspected in patients with known chronic diseases. In cases of significant anemia, coexistent iron deficiency or folic acid deficiency should be suspected. Decreased dietary intake of folate or iron is common in these ill patients, and many will also have ongoing gastrointestinal blood losses. Patients undergoing hemodialysis regularly lose both iron and folate during dialysis.

B. Laboratory Findings

The hematocrit rarely falls below 60% of baseline (except in kidney failure). The MCV is usually normal or slightly reduced. Red blood cell morphology is nondiagnostic, and the reticulocyte count is neither strikingly reduced nor increased. Serum iron values may be low or unmeasurable, and transferrin saturation may be extremely low, leading to an erroneous diagnosis of iron deficiency. In contrast to iron deficiency, serum ferritin values should be normal or increased. A serum ferritin value of less than 30 mcg/L should suggest coexistent iron deficiency.

► Treatment

In most cases no treatment is necessary. Purified recombinant erythropoietin (epoetin alfa) is effective for treatment of the anemia of kidney failure and other secondary anemias such as anemia related to cancer or inflammatory disorders (eg, rheumatoid arthritis). In kidney failure, optimal response to epoetin alfa requires adequate intensity of dialysis. Epoetin alfa must be injected subcutaneously and is very expensive. One effective schedule is 30,000 units once weekly, or darbepoetin 300 mcg every 2 to 3 weeks. Because of its cost, erythropoietin should be used only when the patient is transfusion-dependent or when the quality of life is improved by the hematologic response.

► When to Refer

Referral to a hematologist is not necessary.

THE THALASSEMIAS

ESSENTIALS OF DIAGNOSIS

- Microcytosis disproportionate to the degree of anemia.
- Positive family history or lifelong personal history of microcytic anemia.
- Abnormal red blood cell morphology with microcytes, acanthocytes, and target cells.
- In β -thalassemia, elevated levels of hemoglobin A₂ or F.

► General Considerations

The thalassemias are hereditary disorders characterized by reduction in the synthesis of globin chains (α or β). Reduced globin chain synthesis causes reduced hemoglobin synthesis and eventually produces a hypochromic microcytic anemia because of defective hemoglobinization of red blood cells. Thalassemias can be considered among the hypoproliferative anemias, the hemolytic anemias, and the anemias related to abnormal hemoglobin, since all of these factors play a role in pathogenesis.

Normal adult hemoglobin is primarily hemoglobin A, which represents approximately 98% of circulating hemoglobin. Hemoglobin A is formed from a tetramer—two α chains and two β chains—and can be designated $\alpha_2\beta_2$. Two copies of the α -globin gene are located on chromosome 16, and there is no substitute for α -globin in the formation of hemoglobin. The β -globin gene resides on chromosome 11 adjacent to genes encoding the β -like globin chains, δ and γ . The tetramer of $\alpha_2\delta_2$ forms hemoglobin A₂, which normally comprises 1–2% of adult hemoglobin. The tetramer $\alpha_2\gamma_2$ forms hemoglobin F, which is the major hemoglobin of fetal life but which comprises less than 1% of normal adult hemoglobin.

The thalassemias are described as “**trait**” when there are laboratory features without significant clinical impact, “**intermedia**” when there is a red blood cell transfusion requirement or other moderate clinical impact, and “**major**” when the disorder is life-threatening.

α -Thalassemia is due primarily to gene deletion causing reduced α -globin chain synthesis (Table 13–4). Since all adult hemoglobins are α containing, α -thalassemia produces no change in the percentage distribution of hemoglobins A, A₂, and F. In severe forms of α -thalassemia, excess β chains may form a β_4 tetramer called hemoglobin H.

β -Thalassemias are usually caused by point mutations rather than deletions (Table 13–5). These mutations result in premature chain termination or in problems with transcription of RNA and ultimately result in reduced or absent β -globin chain synthesis. The molecular defects leading to β -thalassemia are numerous and heterogeneous. Defects that result in absent globin chain expression are termed β^0 , whereas those causing reduced synthesis are termed β^+ . The reduced β -globin chain synthesis in β -thalassemia results in a relative increase in the percentages of hemoglobins A₂ and F compared to hemoglobin A, as the β -like globins (γ and δ) substitute for the missing β chains. In the presence of reduced β chains, the excess α chains are unstable and precipitate, leading to damage of red blood cell membranes. This leads to intramedullary and peripheral hemolysis. The bone marrow becomes hyperplastic under the drive of anemia and ineffective erythropoiesis resulting from the intramedullary destruction of the developing erythroid cells. In cases of severe thalassemia, the marked expansion of the erythroid element in the bone marrow may cause severe bony deformities, osteopenia, and pathologic fractures.

► Clinical Findings

A. Symptoms and Signs

The α -thalassemia syndromes are seen primarily in persons from southeast Asia and China, and, less commonly, in blacks.

Table 13-4. α -Thalassemia syndromes.

| α -Globin Genes | Syndrome | Hematocrit | MCV |
|------------------------|----------------------|------------|----------|
| 4 | Normal | Normal | |
| 3 | Silent carrier | Normal | |
| 2 | Thalassemia minor | 28–40% | 60–75 fL |
| 1 | Hemoglobin H disease | 22–32% | 60–70 fL |
| 0 | Hydrops fetalis | | |

MCV, mean cell volume.

Normally, adults have four copies of the α -globin chain. When three α -globin genes are present, the patient is hematologically normal (silent carrier). When two α -globin genes are present, the patient is said to have α -thalassemia trait, one form of thalassemia minor. These patients are clinically normal and have a normal life expectancy and performance status, with a mild microcytic anemia. When only one α -globin chain is present, the patient has hemoglobin H disease. This is a chronic hemolytic anemia of variable severity (thalassemia minor or intermedia). Physical examination will reveal pallor and splenomegaly. Although affected individuals do not usually require transfusions, they may do so during periods of hemolytic exacerbation caused by infection or other stresses. When all four α -globin genes are deleted, the affected fetus is stillborn as a result of hydrops fetalis.

β -Thalassemia primarily affects persons of Mediterranean origin (Italian, Greek) and to a lesser extent Chinese, other Asians, and blacks. Patients homozygous for β -thalassemia have thalassemia major. Affected children are normal at birth but after 6 months, when hemoglobin synthesis switches from hemoglobin F to hemoglobin A, develop severe anemia requiring transfusion. Numerous clinical problems ensue, including growth failure, bony deformities (abnormal facial structure, pathologic fractures), hepatosplenomegaly, and jaundice. The clinical course is modified significantly by transfusion therapy, but the transfusional iron overload (hemosiderosis) results in a clinical picture similar to hemochromatosis, with heart failure, cirrhosis, and endocrinopathies, usually after more than 100 units of red blood cells. These problems develop because of the body's inability to excrete the iron (see above) from transfused red

cells. Before the application of allogeneic stem cell transplantation and the development of more effective forms of iron chelation, death from cardiac failure usually occurred between the ages of 20 and 30 years. This has been profoundly changed.

Patients homozygous for a milder form of β -thalassemia (allowing a higher rate of globin gene synthesis) have thalassemia intermedia. These patients have chronic hemolytic anemia but do not require transfusions except under periods of stress. They also may develop iron overload because of periodic transfusion. They survive into adult life but with hepatosplenomegaly and bony deformities. Patients heterozygous for β -thalassemia have thalassemia minor and a clinically insignificant microcytic anemia.

Prenatal diagnosis is available, and genetic counseling should be offered and the opportunity for prenatal diagnosis discussed.

B. Laboratory Findings

1. α -Thalassemia trait—Patients with two α -globin genes have mild anemia, with hematocrits between 28% and 40%. The MCV is strikingly low (60–75 fL) despite the modest anemia, and the red blood count is normal or increased. The peripheral blood smear shows microcytes, hypochromia, occasional target cells, and acanthocytes (cells with irregularly spaced bulbous projections). The reticulocyte count and iron parameters are normal. Hemoglobin electrophoresis will show no increase in the percentage of hemoglobins A₂ or F and no hemoglobin H. α -Thalassemia trait is thus usually diagnosed by exclusion.

Table 13-5. β -Thalassemia syndromes.

| | β -Globin Genes | Hb A | Hb A ₂ | Hb F |
|------------------------|-----------------------------|--------|-------------------|--------|
| Normal | Homozygous β | 97–99% | 1–3% | < 1% |
| Thalassemia major | Homozygous β^0 | 0% | 4–10% | 90–96% |
| Thalassemia major | Homozygous β^+ | 0–10% | 4–10% | 90–96% |
| Thalassemia intermedia | Homozygous β^+ (mild) | 0–30% | 0–10% | 6–100% |
| Thalassemia minor | Heterozygous β^0 | 80–95% | 4–8% | 1–5% |
| | Heterozygous β^+ | 80–95% | 4–8% | 1–5% |

Hb, hemoglobin.

Genetic testing to demonstrate α -globin gene deletion is available in research laboratories.

2. Hemoglobin H disease—These patients have a more marked hemolytic anemia, with hematocrits between 22% and 32%. The MCV is remarkably low (60–70 fL) and the peripheral blood smear is markedly abnormal, with hypochromia, microcytosis, target cells, and poikilocytosis. The reticulocyte count is elevated. Hemoglobin electrophoresis will show the presence of a fast migrating hemoglobin (hemoglobin H), which comprises 10–40% of the hemoglobin. A peripheral blood smear can be stained with supravital dyes to demonstrate the presence of hemoglobin H.

3. β -Thalassemia minor—As in α -thalassemia trait, these patients have a modest anemia with hematocrit between 28% and 40%. The MCV ranges from 55 to 75 fL, and the red blood cell count is normal or increased. The peripheral blood smear is mildly abnormal, with hypochromia, microcytosis, and target cells. In contrast to α -thalassemia, basophilic stippling may be present. The reticulocyte count is normal or slightly elevated. Hemoglobin electrophoresis (using quantitative techniques) may show an elevation of hemoglobin A₂ to 4–8% and occasional elevations of hemoglobin F to 1–5%.

4. β -Thalassemia major— β -Thalassemia major produces severe anemia, and without transfusion the hematocrit may fall to less than 10%. The peripheral blood smear is bizarre, showing severe poikilocytosis, hypochromia, microcytosis, target cells, basophilic stippling, and nucleated red blood cells. Little or no hemoglobin A is present. Variable amounts of hemoglobin A₂ are seen, and the major hemoglobin present is hemoglobin F.

► Differential Diagnosis

Mild forms of thalassemia must be differentiated from iron deficiency. Compared to iron deficiency anemia, patients with thalassemia have a lower MCV, a more normal red blood count, and a more abnormal peripheral blood smear at modest levels of anemia. Iron studies are normal. Severe forms of thalassemia may be confused with other hemoglobinopathies. The diagnosis is made by hemoglobin electrophoresis.

► Treatment

Patients with mild thalassemia (α -thalassemia trait or β -thalassemia minor) require no treatment and should be identified so that they will not be subjected to repeated evaluations and treatment for iron deficiency. Patients with hemoglobin H disease should take folate supplementation and avoid medicinal iron and oxidative drugs such as sulfonamides. Patients with severe thalassemia are maintained on a regular transfusion schedule and receive folate supplementation. Splenectomy is performed if hypersplenism causes a marked increase in the transfusion requirement. Patients with regular transfusion requirements should be treated with iron chelation in order to prevent life-limiting organ damage from iron overload. Subcutaneous infusion of deferoxamine has largely been replaced by the oral agent deferasirox.

Allogeneic bone marrow transplantation is the treatment of choice for β -thalassemia major. Children who have not yet experienced iron overload and chronic organ toxicity do well, with long-term survival in more than 80% of cases.

SIDEROBLASTIC ANEMIA

ESSENTIALS OF DIAGNOSIS

- Presence of ringed sideroblasts in the bone marrow.
- Elevated serum iron levels and transferrin saturation.

► General Considerations

The sideroblastic anemias are a heterogeneous group of disorders in which hemoglobin synthesis is reduced because of failure to incorporate heme into protoporphyrin to form hemoglobin. Iron accumulates, particularly in the mitochondria. The disorder is usually acquired. Sometimes it represents a stage in evolution of a generalized bone marrow disorder (myelodysplasia) that may ultimately terminate in acute leukemia. Other causes include chronic alcoholism and lead poisoning.

► Clinical Findings

Patients have no specific clinical features other than those related to anemia. The anemia is usually moderate, with hematocrits of 20–30%, but transfusions may occasionally be required. Although the MCV is usually normal or slightly increased, it may occasionally be low, leading to confusion with iron deficiency. However, serum iron level is elevated and transferrin saturation is high. The peripheral blood smear characteristically shows a dimorphic population of red blood cells, one normal and one hypochromic. In cases of lead poisoning, coarse basophilic stippling of the red cells is seen and the serum lead levels will be elevated.

The diagnosis is made by examination of the bone marrow. Characteristically, there is marked erythroid hyperplasia, a sign of ineffective erythropoiesis (expansion of the erythroid compartment of the bone marrow that does not result in the production of reticulocytes in the peripheral blood). The Prussian blue iron stain of the bone marrow shows a generalized increase in iron stores and the presence of ringed sideroblasts, which are cells with iron deposits

encircling the red cell nucleus. Occasionally, the anemia is so severe that support with transfusion is required. These patients usually do not respond to erythropoietin therapy.

▶ When to Refer

Refer to a hematologist if transfusion support is needed.

VITAMIN B₁₂ DEFICIENCY

ESSENTIALS OF DIAGNOSIS

- ▶ Macrocytic anemia.
- ▶ Macro-ovalocytes and hypersegmented neutrophils on peripheral blood smear.
- ▶ Serum vitamin B₁₂ level less than 100 pg/mL.

▶ General Considerations

Vitamin B₁₂ belongs to the family of cobalamins and serves as a cofactor for two important reactions in humans. As methylcobalamin, it is a cofactor for methionine synthetase in the conversion of homocysteine to methionine, and as adenosylcobalamin for the conversion of methylmalonyl-coenzyme A (CoA) to succinyl-CoA. All vitamin B₁₂ comes from the diet and is present in all foods of animal origin. The daily absorption of vitamin B₁₂ is 5 mcg.

The liver contains 2000–5000 mcg of stored vitamin B₁₂. Since daily losses are 3–5 mcg/d, the body usually has sufficient stores of vitamin B₁₂ so that vitamin B₁₂ deficiency develops more than 3 years after vitamin B₁₂ absorption ceases.

Since vitamin B₁₂ is present in all foods of animal origin, dietary vitamin B₁₂ deficiency is extremely rare and is seen only in vegans—strict vegetarians who avoid all dairy products as well as meat and fish (Table 13–6). Abdominal surgery may lead to vitamin B₁₂ deficiency in several ways. Gastrectomy will eliminate that site of intrinsic factor production; blind loop syndrome will cause competition for vitamin B₁₂ by bacterial overgrowth in the lumen of the intestine; and surgical resection of the ileum will eliminate the site of vitamin B₁₂ absorption. Rare causes of vitamin B₁₂ deficiency include fish tapeworm (*Diphyllobothrium latum*) infection, in which the parasite uses luminal vitamin B₁₂, pancreatic insufficiency (with failure to inactivate competing cobalamin-binding proteins), and severe Crohn disease, causing sufficient destruction of the ileum to impair vitamin B₁₂ absorption.

▶ Clinical Findings

A. Symptoms and Signs

The hallmark of symptomatic vitamin B₁₂ deficiency is megaloblastic anemia. However, subclinical cobalamin defi-

ciency is an increasingly recognized condition, especially in those with predisposing conditions such as ileal disease or gastric surgery. In advanced cases, the anemia may be severe, with hematocrits as low as 10–15%, and may be accompanied by leukopenia and thrombocytopenia. The megaloblastic state also produces changes in mucosal cells, leading to glossitis, as well as other vague gastrointestinal disturbances such as anorexia and diarrhea. Vitamin B₁₂ deficiency also leads to a complex neurologic syndrome. Peripheral nerves are usually affected first, and patients complain initially of paresthesias. The posterior columns next become impaired, and patients complain of difficulty with balance. In more advanced cases, cerebral function may be altered as well, and on occasion dementia and other neuropsychiatric changes may precede hematologic changes.

Patients are usually pale and may be mildly icteric. Neurologic examination may reveal decreased vibration and position sense but is more commonly normal in early stages of the disease.

B. Laboratory Findings

The megaloblastic state produces an anemia of variable severity that on occasion may be very severe. The MCV is usually strikingly elevated, between 110 and 140 fL. However, it is possible to have vitamin B₁₂ deficiency with a normal MCV. Occasionally, the normal MCV may be explained by coexistent thalassemia or iron deficiency, but in other cases the reason is obscure. Patients with neurologic symptoms and signs that suggest possible vitamin B₁₂ deficiency should be evaluated for that deficiency despite a normal MCV and the absence of anemia. The peripheral blood smear is usually strikingly abnormal, with anisocytosis and poikilocytosis. A characteristic finding is the macro-ovalocyte, but numerous other abnormal shapes are usually seen. The neutrophils are hypersegmented. Typical features include a mean lobe count greater than four or the finding of six-lobed neutrophils. The reticulocyte count is reduced. Because vitamin B₁₂ deficiency affects all hematopoietic cell lines, in severe cases the white blood cell count and the platelet count are reduced, and pancytopenia is present.

Bone marrow morphology is characteristically abnormal. Marked erythroid hyperplasia is present as a response

to defective red blood cell production (ineffective erythropoiesis). Megaloblastic changes in the erythroid series include abnormally large cell size and asynchronous maturation of the nucleus and cytoplasm—ie, cytoplasmic maturation continues while impaired DNA synthesis causes retarded nuclear development. In the myeloid series, giant metamyelocytes are characteristically seen.

Other laboratory abnormalities include elevated serum lactate dehydrogenase (LDH) and a modest increase in indirect bilirubin. These two findings are a reflection of intramedullary destruction of developing abnormal erythroid cells and are similar to those observed in peripheral hemolytic anemias.

The diagnosis of vitamin B₁₂ deficiency is made by finding an abnormally low vitamin B₁₂ (cobalamin) serum level. Whereas the normal vitamin B₁₂ level is > 240 pg/mL, most patients with overt vitamin B₁₂ deficiency will have serum levels < 170 pg/mL, with symptomatic patients usually having levels < 100 pg/mL. A level of 170–240 pg/mL is borderline. When the serum level of vitamin B₁₂ is borderline, the diagnosis is best confirmed by finding an elevated level of serum methylmalonic acid (> 1000 nmol/L). However, elevated levels of serum methylmalonic acid can be due to kidney insufficiency.

► Differential Diagnosis

Vitamin B₁₂ deficiency should be differentiated from folic acid deficiency, the other common cause of megaloblastic anemia, in which red blood cell folate is low while vitamin B₁₂ levels are normal. The distinction between vitamin B₁₂ deficiency and myelodysplasia (the other common cause of macrocytic anemia with abnormal morphology) is based on the characteristic morphology and the low vitamin B₁₂ and elevated methylmalonic acid levels.

► Treatment

Patients with pernicious anemia have historically been treated with parenteral therapy. Intramuscular injections of 100 mcg of vitamin B₁₂ are adequate for each dose. Replacement is usually given daily for the first week, weekly for the first month, and then monthly for life. It is a lifelong disorder, and if patients discontinue their monthly therapy the vitamin deficiency will recur. Oral cobalamin may be used instead of parenteral therapy and can provide equivalent results. The dose is 1000 mcg/d and must be continued indefinitely.

Patients respond to therapy with an immediate improvement in their sense of well-being. Hypokalemia may complicate the first several days of therapy, particularly if the anemia is severe. A brisk reticulocytosis occurs in 5–7 days, and the hematologic picture normalizes in 2 months. Central nervous system symptoms and signs are reversible if they are of relatively short duration (less than 6 months) but become permanent if treatment is not initiated promptly.

► When to Refer

Referral to a hematologist is not usually necessary.

FOLIC ACID DEFICIENCY

ESSENTIALS OF DIAGNOSIS

- Macrocytic anemia.
- Macro-ovalocytes and hypersegmented neutrophils on peripheral blood smear.
- Normal serum vitamin B₁₂ levels.
- Reduced folate levels in red blood cells or serum.

► General Considerations

Folic acid is the term commonly used for pteroylmonoglutamic acid. Folic acid is present in most fruits and vegetables (especially citrus fruits and green leafy vegetables) and daily requirements of 50–100 mcg/d are usually met in the diet. Total body stores of folate are approximately 5000 mcg, enough to supply requirements for 2–3 months.

By far the most common cause of folate deficiency is inadequate dietary intake (Table 13–7). Alcoholic or anorectic patients, persons who do not eat fresh fruits and vegetables, and those who overcook their food are candidates for folate deficiency. Reduced folate absorption is rarely seen, since absorption occurs from the entire gastrointestinal tract. However, drugs such as phenytoin, trimethoprim-sulfamethoxazole, or sulfasalazine may interfere with folate absorption. Folic acid requirements are increased in pregnancy, hemolytic anemia, and exfoliative skin disease, and in these cases the increased requirements (five to ten times normal) may not be met by a normal diet. Patients with increased folate requirements should receive supplementation with 1 mg/d of folic acid.

Table 13–7. Causes of folate deficiency.

| Dietary deficiency |
| Decreased absorption |
| Tropical sprue |
| Drugs: phenytoin, sulfasalazine, trimethoprim-sulfamethoxazole |
| Increased requirement |
| Chronic hemolytic anemia |
| Pregnancy |
| Exfoliative skin disease |
| Loss: dialysis |
| Inhibition of reduction to active form |
| Methotrexate |

► Clinical Findings

A. Symptoms and Signs

The features are similar to those of vitamin B₁₂ deficiency, with megaloblastic anemia and megaloblastic changes in mucosa. However, there are none of the neurologic abnormalities associated with vitamin B₁₂ deficiency.

B. Laboratory Findings

Megaloblastic anemia is identical to anemia resulting from vitamin B₁₂ deficiency (see above). However, the serum vitamin B₁₂ level is normal. A red blood cell folate level of less than 150 ng/mL is diagnostic of folate deficiency.

► Differential Diagnosis

The megaloblastic anemia of folate deficiency should be differentiated from vitamin B₁₂ deficiency by the finding of a normal vitamin B₁₂ level and a reduced red blood cell folate or serum folate level. Alcoholic patients, who often have folate deficiency, may also have anemia of liver disease. This latter macrocytic anemia does not cause megaloblastic morphologic changes but rather produces target cells in the peripheral blood. Hypothyroidism is associated with mild macrocytosis but also with pernicious anemia.

► Treatment

Folic acid deficiency is treated with folic acid, 1 mg/d orally. The response is similar to that seen in the treatment of vitamin B₁₂ deficiency, with rapid improvement and a sense of well-being, reticulocytosis in 5–7 days, and total correction of hematologic abnormalities within 2 months. Large doses of folic acid may produce hematologic responses in cases of vitamin B₁₂ deficiency but will allow neurologic damage to progress.

► When to Refer

Referral to a hematologist is not usually necessary.

PURE RED CELL APLASIA

Adult acquired pure red cell aplasia is rare. It appears to be an autoimmune disease mediated either by T lymphocytes or (rarely) by an IgG antibody against erythroid precursors. In adults, the disease is usually idiopathic. However, cases have been seen in association with systemic lupus erythematosus, chronic lymphocytic leukemia, lymphomas, or thymoma. Some drugs (phenytoin, chloramphenicol) may cause red cell aplasia. Transient episodes of red cell aplasia are probably common in response to viral infections, especially parvovirus infections. However, these acute episodes will go unrecognized unless the patient has a chronic hemolytic disorder, in which case the hematocrit may fall precipitously.

The only signs are those of anemia unless the patient has an associated autoimmune or lymphoproliferative disorder. The anemia is often severe and normochromic, with low or absent reticulocytes. Red blood cell morphology is normal, and the myeloid and platelet lines are unaffected. The bone marrow is normocellular. All elements present are normal, but erythroid precursors are markedly reduced or absent. In some cases, chest imaging studies will reveal a thymoma.

The disorder is distinguished from aplastic anemia (in which the marrow is hypocellular and all cell lines are affected) and from myelodysplasia. This latter disorder is recognized by the presence of morphologic abnormalities that should not be present in pure red cell aplasia.

Possible offending drugs should be stopped. With thymoma, resection results in amelioration of anemia in some instances. High-dose intravenous immune globulin has produced excellent responses in a small number of cases, especially in parvovirus-related cases. For most cases, the treatment of choice is immunosuppressive therapy with a combination of antithymocyte globulin and cyclosporine (or tacrolimus)—similar to therapy of aplastic anemia. Anti-CD20 monoclonal antibody (rituximab) has also enjoyed some success.

► When to Refer

All patients should be referred to a hematologist.

HEMOLYTIC ANEMIAS

Hemolytic disorders are generally classified according to whether the defect is intrinsic to the red cell or due to some external factor (Table 13–8). Intrinsic defects have been described in all components of the red blood cell, including the membrane, enzyme systems, and hemoglobin; most of these disorders are hereditary. Hemolytic anemias due to external factors are the immune and microangiopathic hemolytic anemias.

Certain laboratory features are common to all the hemolytic anemias. Haptoglobin, a normal plasma protein that binds and clears hemoglobin released into plasma, may be depressed in hemolytic disorders. However, haptoglobin levels are influenced by many factors and, by themselves, are not a reliable indicator of hemolysis. When intravascular hemolysis occurs, transient hemoglobinemia occurs. Hemoglobin is filtered through the glomerulus and is usually reabsorbed by tubular cells. Hemoglobinuria will be present only when the capacity for reabsorption of hemoglobin by these cells is exceeded. In its absence, evidence for prior intravascular hemolysis is the presence of hemosiderin in shed renal tubular cells (positive urine hemosiderin). With severe intravascular hemolysis, hemo-

Table 13–8. Classification of hemolytic anemias.

| |

| Intrinsic |
| Membrane defects: hereditary spherocytosis, hereditary elliptocytosis, paroxysmal nocturnal hemoglobinuria |
| Glycolytic defects: pyruvate kinase deficiency, severe hypophosphatemia |
| Oxidation vulnerability: glucose-6-phosphate dehydrogenase deficiency, methemoglobinemia |
| Hemoglobinopathies: sickle cell syndromes, unstable hemoglobins, methemoglobinemia |
| Extrinsic |
| Immune: autoimmune, lymphoproliferative disease, drug toxicity |
| Microangiopathic: thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, disseminated intravascular coagulation, valve hemolysis, metastatic adenocarcinoma, vasculitis |
| Infection: <i>Plasmodium</i> , <i>Clostridium</i> , <i>Borrelia</i> |
| Hypersplenism |
| Burns |

globinemia and methemalbuminemia may be present. Hemolysis increases the indirect bilirubin, and the total bilirubin may rise to 4 mg/dL. Bilirubin levels higher than this may indicate some degree of hepatic dysfunction. Serum LDH levels are strikingly elevated in cases of microangiopathic hemolysis (thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome) and may be elevated in other hemolytic anemias.

HEREDITARY SPHEROCYTOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Positive family history.
- ▶ Splenomegaly.
- ▶ Spherocytes and increased reticulocytes on peripheral blood smear.
- ▶ Microcytic, hyperchromic indices.

▶ General Considerations

Hereditary spherocytosis is a disorder of the red blood cell membrane, leading to chronic hemolytic anemia.

The membrane defect is an abnormality in spectrin or actin, the proteins providing most of the scaffolding for the red blood cell membranes. The result is a decrease in surface-to-volume ratio that results in a spherical shape of the cell. These spherical cells are less deformable and unable to pass through 2-mcm fenestrations in the splenic red pulp. Hemolysis takes place because of trapping of red blood cells within the spleen.

▶ Clinical Findings

A. Symptoms and Signs

Hereditary spherocytosis is an autosomal dominant disease of variable severity. It is often diagnosed during childhood, but milder cases may be discovered incidentally late in adult

life. Anemia may or may not be present, since the bone marrow may be able to compensate for shortened red cell survival. Severe anemia (aplastic crisis) may occur in folic acid deficiency or when bone marrow compensation is temporarily impaired by infection. Chronic hemolysis causes jaundice and pigment (calcium bilirubinate) gallstones, leading to attacks of cholecystitis. Examination may reveal icterus and a palpable spleen.

B. Laboratory Findings

The anemia is of variable severity, and the hematocrit may be normal. Reticulocytosis is always present. The peripheral blood smear shows the presence of spherocytes, small cells that have lost their central pallor. Spherocytes usually make up only a small percentage of red blood cells on the peripheral smear. Hereditary spherocytosis is the only important disorder associated with microcytosis and an increased mean corpuscular hemoglobin concentration (MCHC), often greater than 36 g/dL. As with other hemolytic disorders, there may be an increase in indirect bilirubin. The Coombs test is negative.

Because spherocytes are red cells that have lost some membrane surface, they are abnormally vulnerable to swelling induced by hypotonic media. Increased osmotic fragility merely reflects the presence of spherocytes and does not distinguish hereditary spherocytosis from other spherocytic hemolytic disorders such as autoimmune hemolytic anemia. In some laboratories, the osmotic fragility test has been supplanted by ektacytometry, which has the advantages of better reliability and the ability to distinguish spherocytes from other red blood cell abnormalities such as elliptocytosis.

▶ Treatment

These patients should receive uninterrupted supplementation with folic acid, 1 mg/d. The treatment of choice is splenectomy, which will correct neither the membrane defect nor the spherocytosis but will eliminate the site of hemolysis. In very mild cases discovered late in adult life, splenectomy may not be necessary.

▶ When to Refer

Patients in whom hereditary spherocytosis is suspected should have the diagnosis confirmed by a hematologist, and decisions regarding splenectomy should be made in consultation with a hematologist.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

ESSENTIALS OF DIAGNOSIS

- ▶ Episodic hemoglobinuria.

- ▶ Thrombosis is common.
- ▶ Suspect in confusing cases of hemolytic anemia or pancytopenia.
- ▶ Flow cytometry is best screening test.

▶ General Considerations

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired clonal stem cell disorder that results in abnormal sensitivity of the red blood cell membrane to lysis by complement. The underlying cause is a defect in the gene for phosphatidylinositol class A (PIG-A), which results in a deficiency of the glycosylphosphatidylinositol (GPI) anchor for cellular membrane proteins. In particular, the complement-regulating proteins CD55 and CD59 are deficient.

▶ Clinical Findings

A. Symptoms and Signs

Classically, patients report episodic hemoglobinuria resulting in reddish brown urine. Hemoglobinuria is most often noticed in the first morning urine, probably because of its increased concentration. In addition to being prone to anemia, these patients are prone to thrombosis, especially mesenteric and hepatic vein thromboses. Other common sites of thrombosis include the central nervous system (sagittal vein) and the skin, with formation of painful nodules. This hypercoagulopathy may be related to platelet activation by complement. As this is a stem cell disorder, PNH may progress either to aplastic anemia, to myelodysplasia, or to acute myeloid leukemia.

B. Laboratory Findings

Anemia is of variable severity, and reticulocytosis may or may not be present. Abnormalities on the blood smear are nondiagnostic and may include macro-ovalocytes. Since the episodic hemolysis in PNH is intravascular, the finding of urine hemosiderin is a useful test. Serum LDH is characteristically elevated. Iron deficiency is commonly present and is related to chronic iron loss from hemoglobinuria, since hemolysis is primarily intravascular.

The white blood cell count and platelet count may be decreased. The best screening test is flow cytometry to demonstrate deficiency of CD59 and CD55 on red blood cells. Bone marrow morphology is variable and may show either generalized hypoplasia or erythroid hyperplasia. Flow cytometric assays may confirm the diagnosis by demonstrating the absence of CD59.

▶ Treatment

Iron replacement is often indicated for treatment of iron deficiency. This may improve the anemia but may also cause a transient increase in hemolysis. For unclear reasons, prednisone is effective in decreasing hemolysis, and some patients can be managed effectively with alternate-day steroids. In severe cases and cases of transformation to myelodysplasia, allogeneic bone marrow transplantation has been used to treat the disorder. The anti-complement C5 anti-

body eculizumab has been shown to be effective in reducing hemolysis and transfusion requirements.

▶ When to Refer

Most patients with PNH should be under the care of a hematologist.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

ESSENTIALS OF DIAGNOSIS

- ▶ X-linked recessive disorder seen commonly in American black men.
- ▶ Episodic hemolysis in response to oxidant drugs or infection.
- ▶ Minimally abnormal peripheral blood smear.
- ▶ Reduced levels of glucose-6-phosphate dehydrogenase between hemolytic episodes.

▶ General Considerations

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is a hereditary enzyme defect that causes episodic hemolytic anemia because of the decreased ability of red blood cells to deal with oxidative stresses. Oxidized hemoglobin denatures and forms precipitants called Heinz bodies. These Heinz bodies cause membrane damage, which leads to removal of these cells by the spleen.

Numerous types of glucose-6-phosphate dehydrogenase deficiency (G6PD) enzymes have been described. The normal type found in whites is designated G6PD-B. Most American blacks have G6PD-A, which is normal in function. Ten to 15 percent of American blacks have the variant G6PD designated A-, in which there is only 15% of normal enzyme activity, and enzyme activity declines rapidly as the red blood cell ages past 40 days, a fact that explains many of the clinical findings in this disorder. Many other G6PD variants have been described, including some Mediterranean variants with extremely low enzyme activity.

▶ Clinical Findings

G6PD deficiency is an X-linked recessive disorder affecting 10–15% of American black males. Female carriers are

rarely affected—only when an unusually high percentage of cells producing the normal enzyme is inactivated.

A. Symptoms and Signs

Patients are usually healthy, without chronic hemolytic anemia or splenomegaly. Hemolysis occurs as a result of oxidative stress on the red blood cells, generated either by infection or exposure to certain drugs. Common drugs initiating hemolysis include dapsone, primaquine, quinidine, quinine, sulfonamides, and nitrofurantoin. Even with continuous use of the offending drug, the hemolytic episode is self-limited because older red blood cells (with low enzyme activity) are removed and replaced with a population of young red blood cells with adequate functional levels of G6PD. Severe G6PD deficiency (as in Mediterranean variants) may produce a chronic hemolytic anemia.

B. Laboratory Findings

Between hemolytic episodes, the blood is normal. During episodes of hemolysis, there is reticulocytosis and increased serum indirect bilirubin. The red blood cell smear is not diagnostic but may reveal a small number of “bite” cells—cells that appear to have had a bite taken out of their periphery. This indicates pitting of hemoglobin aggregates by the spleen. Heinz bodies may be demonstrated by staining a peripheral blood smear with cresyl violet; they are not visible on the usual Wright-Giemsa-stained blood smear. Specific enzyme assays for G6PD may reveal a low level but may be misleading if they are performed shortly after a hemolytic episode when the enzyme-deficient cohort of cells has been removed. In these cases, the enzyme assays should be repeated weeks after hemolysis has resolved. In severe cases of G6PD deficiency, enzyme levels are always low.

▶ Treatment

No treatment is necessary except to avoid known oxidant drugs.

SICKLE CELL ANEMIA & RELATED SYNDROMES

ESSENTIALS OF DIAGNOSIS

- ▶ Recurrent painful episodes.
- ▶ Positive family history and lifelong history of hemolytic anemia.
- ▶ Irreversibly sickled cells on peripheral blood smear.
- ▶ Hemoglobin S is the major hemoglobin seen on electrophoresis.

▶ General Considerations

Sickle cell anemia is an autosomal recessive disorder in which an abnormal hemoglobin leads to chronic hemolytic anemia with numerous clinical consequences. A single DNA base change leads to an amino acid substitution of valine for glutamine in the sixth position on the β -globin chain. The abnormal β chain is designated β^s and the tetramer of $\alpha_2\beta_2^s$ is designated hemoglobin S.

The rate of sickling is influenced by the concentration of hemoglobin S and by the presence of other hemoglobins within the cell. Hemoglobin F cannot participate in polymer formation, and its presence markedly retards sickling. Other factors that increase sickling are red cell dehydration and factors that lead to formation of deoxyhemoglobin S, eg, acidosis and hypoxemia, either systemic or locally in tissues. Hemolytic crises may be related to splenic sequestration of sickled cells (primarily in childhood before the spleen has been infarcted as a result of repeated sickling) or with coexistent disorders such as G6PD deficiency.

The hemoglobin S gene is carried in 8% of American blacks, and 1 of 400 American black children will be born with sickle cell anemia. Prenatal diagnosis is available for couples at risk for producing a child with sickle cell anemia. Genetic counseling should be made available to such couples.

▶ Clinical Findings

A. Symptoms and Signs

The disorder has its onset during the first year of life, when hemoglobin F levels fall as a signal is sent to switch from production of γ -globin to β -globin.

Chronic hemolytic anemia produces jaundice, pigment (calcium bilirubinate) gallstones, splenomegaly, and poorly healing ulcers over the lower tibia. Life-threatening severe anemia can occur during hemolytic or aplastic crises, generally associated with viral or other infection or by folate deficiency.

Acute painful episodes due to acute vaso-occlusion from clusters of sickled red cells may occur spontaneously or be provoked by infection, dehydration, or hypoxia. Common sites of acute painful episodes include the bones (especially the back and long bones) and the chest. These episodes last hours to days and may produce low-grade fever. Acute vaso-occlusion may also cause strokes due to sinus thrombosis and priapism. Vaso-occlusive episodes are not associated with increased hemolysis.

Repeated episodes of vascular occlusion especially affect the heart, lungs, and liver. Ischemic necrosis of bone occurs, rendering the bone susceptible to osteomyelitis due to staphylococci or (less commonly) salmonellae. Infarction of the papillae of the renal medulla causes renal tubular concentrating defects and gross hematuria, more often encountered in sickle cell trait than in sickle cell anemia. Retinopathy similar to that noted in diabetes is often present and may lead to blindness. Pulmonary hypertension may develop and is associated with a poor prognosis.

These patients are prone to delayed puberty. An increased incidence of infection is related to hyposplenism as well as to defects in the alternative pathway of complement.

On examination, patients are often chronically ill and jaundiced. There is hepatomegaly, but the spleen is not palpable in adult life. The heart is enlarged, with a hyperdynamic precordium and systolic murmurs. Nonhealing ulcers of the lower leg and retinopathy may be present.

Sickle cell anemia becomes a chronic multisystem disease, with death from organ failure. With improved supportive care, average life expectancy is now between 40 and 50 years of age.

B. Laboratory Findings

Chronic hemolytic anemia is present. The hematocrit is usually 20–30%. The peripheral blood smear is characteristically abnormal, with irreversibly sickled cells comprising 5–50% of red cells. Other findings include reticulocytosis (10–25%), nucleated red blood cells, and hallmarks of hyposplenism such as Howell–Jolly bodies and target cells. The white blood cell count is characteristically elevated to 12,000–15,000/mcL, and thrombocytosis may occur. Indirect bilirubin levels are high.

After a screening test for sickle cell hemoglobin, the diagnosis of sickle cell anemia is confirmed by hemoglobin electrophoresis (Table 13–9). Hemoglobin S will usually comprise 85–98% of hemoglobin. In homozygous S disease, no hemoglobin A will be present. Hemoglobin F levels are variably increased, and high hemoglobin F levels are associated with a more benign clinical course.

▶ Treatment

No specific treatment is available for the primary disease. Patients are maintained on folic acid supplementation and given transfusions for aplastic or hemolytic crises. Pneumococcal vaccination reduces the incidence of infections with this pathogen.

When acute painful episodes occur, precipitating factors should be identified and infections treated if present. The patient should be kept well hydrated, and oxygen should be given if the patient is hypoxic.

Acute vaso-occlusive crises can be treated with exchange transfusion. These are primarily indicated for the treatment of intractable pain crises, priapism, and stroke. Long-term transfusion therapy has been shown to be effective in reducing the risk of recurrent stroke in children.

Cytotoxic agents increase hemoglobin F levels by stimulating erythropoiesis in more primitive erythroid precursors. Hydroxyurea (500–750 mg/d) reduces the frequency of painful crises in patients whose quality of life is disrupted by frequent pain crises. Although there remains some level of concern about the possibility of secondary malignancies from this type of treatment, substantial data suggest that it is safe. Allogeneic bone marrow transplantation is being studied as a possible curative option for severely affected young patients.

▶ When to Refer

Patients with sickle cell anemia should have their care coordinated with a hematologist and should be referred to a Comprehensive Sickle Cell Center if one is available.

▶ When to Admit

Patients should be admitted for management of chest crises or for painful episodes that do not respond to outpatient care.

SICKLE CELL TRAIT

Patients with the heterozygous genotype (AS) have sickle cell trait. These persons are clinically normal and have acute painful episodes only under extreme conditions such as vigorous exertion at high altitudes (or in unpressurized

Table 13–9. Hemoglobin distribution in sickle cell syndromes.

| Genotype | Clinical Diagnosis | Hb A | Hb S | Hb A ₂ | Hb F |
|-------------------------------|----------------------|--------|--------|-------------------|--------|
| AA | Normal | 97–99% | 0 | 1–2% | < 1% |
| AS | Sickle trait | 60% | 40% | 1–2% | < 1% |
| SS | Sickle cell anemia | 0 | 86–98% | 1–3% | 5–15% |
| S β ⁰ -thalassemia | Sickle β-thalassemia | 0 | 70–80% | 3–5% | 10–20% |
| S β ⁺ -thalassemia | Sickle β-thalassemia | 10–20% | 60–75% | 3–5% | 10–20% |
| AS, α-thalassemia | Sickle trait | 70–75% | 25–30% | 1–2% | < 1% |

Hb, hemoglobin.

aircraft). The patients are hematologically normal, with no anemia and normal red blood cells on peripheral blood smear. They may, however, have a defect in renal tubular function, causing an inability to concentrate the urine, and experience episodes of gross hematuria. This appears to be caused by many years of sickling in the sluggish circulation of the renal medulla. A screening test for sickle hemoglobin will be positive, and hemoglobin electrophoresis will reveal that approximately 40% of hemoglobin is hemoglobin S (Table 13–9).

No treatment is necessary. Genetic counseling is a reasonable strategy.

SICKLE THALASSEMIA

Patients with homozygous sickle cell anemia and α -thalassemia have a somewhat milder form of hemolysis because of a slower rate of sickling related to reduced hemoglobin concentration within the red blood cell.

Patients who are double heterozygotes for sickle cell anemia and β -thalassemia are clinically affected with sickle cell syndromes. Sickle β^0 -thalassemia is clinically very similar to homozygous SS disease. Vaso-occlusive crises may be somewhat less severe, and the spleen is usually not infarcted. Hematologically, the MCV is usually low, in contrast to the normal MCV of sickle cell anemia. Hemoglobin electrophoresis (Table 13–9) reveals no hemoglobin A but will show an increase in hemoglobin A₂, which is not present in sickle cell anemia.

Sickle β^+ -thalassemia is a milder disorder than homozygous SS disease, with fewer crises. The spleen is usually palpable. The hemolytic anemia is less severe, and the hematocrit is usually 30–38%, with reticulocytes of 5–10%. Hemoglobin electrophoresis shows the presence of some hemoglobin A.

HEMOGLOBIN C DISORDERS

Hemoglobin C is formed by a single amino acid substitution at the same site of substitution as in sickle hemoglobin but with lysine instead of valine substituted for glutamine at the β_6 position. Hemoglobin C is nonsickling but may participate in polymer formation in association with hemoglobin S. Homozygous hemoglobin C disease produces a mild hemolytic anemia with splenomegaly, mild jaundice, and pigment (calcium bilirubinate) gallstones. The peripheral blood smear shows generalized red cell targeting and occasional cells with rectangular crystals of hemoglobin C. Persons heterozygous for hemoglobin C are clinically normal.

Patients with hemoglobin SC disease are double heterozygotes for β S and β C. These patients, like those with sickle β^+ -thalassemia, have a milder hemolytic anemia and milder clinical course than those with homozygous SS disease. There are fewer vaso-occlusive events, and the spleen remains palpable in adult life. However, persons with hemoglobin SC disease have more retinopathy and more ischemic necrosis of bone than those with SS disease. The hematocrit is usually 30–38%, with 5–10% reticulocytes and few irreversibly sickled cells on the blood smear. Target cells are more numerous than in SS disease. Hemoglobin electro-

phoresis will show approximately 50% hemoglobin C, 50% hemoglobin S, and no increase in hemoglobin F levels.

Nagel RL et al. The paradox of hemoglobin SC disease. *Blood Rev.* 2003 Sep;17(3):167–78. [PMID: 12818227]

UNSTABLE HEMOGLOBINS

Unstable hemoglobins are prone to oxidative denaturation even in the presence of a normal G6PD system. The disorder is autosomal dominant and of variable severity. Most patients have a mild chronic hemolytic anemia with splenomegaly, mild jaundice, and pigment (calcium bilirubinate) gallstones. Less severely affected patients are not anemic except under conditions of oxidative stress.

The diagnosis is made by the finding of Heinz bodies and a normal G6PD level. Hemoglobin electrophoresis is usually normal, since these hemoglobins characteristically do not have a change in their migration pattern. These hemoglobins precipitate in isopropanol. Usually no treatment is necessary. Patients with chronic hemolytic anemia should receive folate supplementation and avoid known oxidative drugs. In rare cases, splenectomy may be required.

AUTOIMMUNE HEMOLYTIC ANEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Acquired anemia caused by IgG autoantibody.
- ▶ Spherocytes and reticulocytosis on peripheral blood smear.
- ▶ Positive Coombs test.

▶ General Considerations

Autoimmune hemolytic anemia is an acquired disorder in which an IgG autoantibody is formed that binds to the red blood cell membrane. The antibody is most commonly directed against a basic component of the Rh system present on most human red blood cells. When IgG antibodies coat the red blood cell, the Fc portion of the antibody is recognized by macrophages present in the spleen and other portions of the reticuloendothelial system. The interaction between splenic macrophage and the antibody-coated red blood cell results in removal of red blood cell membrane and the formation of a spherocyte because of the decrease in surface-to-volume ratio of the red blood cell. These spherocytic cells have decreased deformability and become trapped in the red pulp of the spleen because of their inability to squeeze through the 2- μ m fenestrations. When large amounts of IgG are present on red blood cells, complement may be fixed. Direct lysis of cells is rare, but the presence of C3b on the surface of red blood cells allows Kupffer cells in the liver to participate in the hemolytic process because of the presence of C3b receptors on Kupffer cells.

Approximately 50% of all cases of autoimmune hemolytic anemia are idiopathic. The disorder may also be seen in association with systemic lupus erythematosus, chronic lym-

phocytic leukemia, or lymphomas. It must be distinguished from drug-induced hemolytic anemia. Penicillin (and other drugs) coats the red blood cell membrane, and the antibody is directed against the membrane–drug complex.

► Clinical Findings

A. Symptoms and Signs

Autoimmune hemolytic anemia typically produces an anemia of rapid onset that may be life-threatening in severity. Patients complain of fatigue and may present with angina or congestive heart failure. On examination, jaundice and splenomegaly are usually present.

B. Laboratory Findings

The anemia is of variable severity but may be severe, with hematocrit of less than 10%. Reticulocytosis is usually present, and spherocytes are seen on the peripheral blood smear. In cases of severe hemolysis, the stressed bone marrow may also release nucleated red blood cells. As with other hemolytic disorders, indirect bilirubin is increased. Approximately 10% of patients with autoimmune hemolytic anemia have coincident immune thrombocytopenia (Evans syndrome).

The Coombs antiglobulin test forms the basis for diagnosis. The Coombs reagent is a rabbit IgM antibody raised against human IgG or human complement. The direct Coombs test is performed by mixing the patient's red blood cells with the Coombs reagent and looking for agglutination, which indicates the presence of antibody on the red blood cell surface. The indirect Coombs test is performed by mixing the patient's serum with a panel of type O red blood cells. After incubation of the test serum and panel red blood cells, the Coombs reagent is added. Agglutination in this system indicates the presence of free antibody in the patient's serum.

The direct Coombs test is positive in autoimmune hemolytic anemia, and the indirect Coombs test may or may not be positive. A positive indirect Coombs test indicates the presence of a large amount of autoantibody that has saturated binding sites in the red blood cell and consequently appears in the serum. Because the patient's serum usually contains the autoantibody, it may be difficult to obtain a compatible cross-match with donor's cells.

► Treatment

Initial treatment consists of prednisone, 1–2 mg/kg/d in divided doses. Most transfused blood will survive similarly to the patient's own red blood cells. Because of difficulty in performing the cross-match, incompatible blood may be given. Decisions regarding transfusions should be made in consultation with a hematologist. If prednisone is ineffective or if the disease recurs on tapering the dose, splenectomy should be performed. Patients with autoimmune hemolytic anemia refractory to prednisone and splenectomy may be treated with a variety of agents. Treatment with rituximab, a monoclonal antibody against the B cell antigen CD20, is effective in some cases. The suggested dose is 375 mg/m² intravenously weekly for 4 weeks. Danazol,

600–800 mg/d, is less often effective than in immune thrombocytopenia but is well suited for long-term use because of its low toxicity. Immunosuppressive agents, including cyclophosphamide, azathioprine, mycophenolate mofetil, or cyclosporine, may also be used. High-dose intravenous immune globulin (1 g daily for 1 or 2 days) may be highly effective in controlling hemolysis. The benefit is short-lived (1–3 weeks), and the drug is very expensive. The long-term prognosis for patients with this disorder is good, especially if there is no underlying autoimmune disorder or lymphoma. Splenectomy is often successful in controlling the disorder.

► When to Refer

Patients with autoimmune hemolytic anemia should be referred to a hematologist for confirmation of the diagnosis and subsequent care.

► When to Admit

Patients should be hospitalized for symptomatic anemia or rapidly falling hematocrit levels.

COLD AGGLUTININ DISEASE

ESSENTIALS OF DIAGNOSIS

- Increased reticulocytes and spherocytes on peripheral blood smear.
- Coombs test positive only for complement.
- Positive cold agglutinin test.

► General Considerations

Cold agglutinin disease is an acquired hemolytic anemia due to an IgM autoantibody usually directed against the I antigen on red blood cells. These IgM autoantibodies characteristically will not react with cells at 37 °C but only at lower temperatures. Since the blood temperature (even in the most peripheral parts of the body) rarely goes lower than 20 °C, only antibodies active at higher temperatures will produce clinical effects. Hemolysis results indirectly from attachment of IgM, which in the cooler parts of the circulation (fingers, nose, ears) binds and fixes complement. When the red blood cell returns to a warmer temperature, the IgM antibody dissociates, leaving complement on the cell. Lysis of cells rarely occurs. Rather, C3b present on

the red cells is recognized by Kupffer cells (which have receptors for C3b), and red blood cell sequestration ensues.

Most cases of chronic cold agglutinin disease are idiopathic. Others occur in association with Waldenström macroglobulinemia, in which a monoclonal IgM paraprotein is produced. Acute postinfectious cold agglutinin disease occurs following mycoplasmal pneumonia or infectious mononucleosis (with antibody directed against antigen i rather than I).

► Clinical Findings

A. Symptoms and Signs

In chronic cold agglutinin disease, symptoms related to red blood cell agglutination occur on exposure to cold, and patients may complain of mottled or numb fingers or toes. Hemolytic anemia is rarely severe, but episodic hemoglobinuria may occur on exposure to cold. The hemolytic anemia in acute postinfectious syndromes is rarely severe.

B. Laboratory Findings

Mild anemia is present with reticulocytosis and spherocytes. The direct Coombs test will be positive for complement only. Occasionally, a micro-Coombs test is necessary to reveal bound complement (low-titer cold agglutinin disease). A bedside cold agglutinin test may be performed by placing a glass slide in ice and then putting a few drops of heparinized blood on it. Inspection may reveal small clumps of agglutinated blood.

► Treatment

Treatment is largely symptomatic, based on avoiding exposure to cold. Splenectomy and prednisone are usually ineffective since hemolysis takes place in the liver. Rituximab, a monoclonal antibody directed against the CD20 antigen on B lymphocytes, is the treatment of choice. The dose is 375 mg/m² intravenously weekly for 4 weeks. Relapses may be effectively re-treated. High-dose intravenous immunoglobulin (2 g/kg) may be effective temporarily, but it is rarely used because of the extreme cost and short duration of benefit. Patients with severe involvement may be treated with alkylating agents, such as cyclophosphamide, or with immunosuppressive agents, such as cyclosporine.

MICROANGIOPATHIC HEMOLYTIC ANEMIAS

The microangiopathic hemolytic anemias are a group of disorders in which red blood cell fragmentation takes place. The anemia is intravascular, producing hemoglobinemia, hemoglobinuria and, in severe cases, methemalbuminemia. The hallmark of the disorder is the finding of fragmented red blood cells (schistocytes, helmet cells) on the peripheral blood smear.

These fragmentation syndromes can be caused by a variety of disorders (Table 13–8). Thrombotic thrombocytopenic purpura is the most important of these and is

discussed below. Clinical features are variable and depend on the underlying disorder. Coagulopathy and thrombocytopenia are variably present.

Chronic microangiopathic hemolytic anemia (such as is present with a malfunctioning cardiac valve prosthesis) may cause iron deficiency anemia because of continuous low-grade hemoglobinuria.

APLASTIC ANEMIA

ESSENTIALS OF DIAGNOSIS

- Pancytopenia.
- No abnormal cells seen.
- Hypocellular bone marrow.

► General Considerations

Aplastic anemia is a condition of bone marrow failure that arises from injury to or abnormal expression of the stem cell. The bone marrow becomes hypoplastic, and pancytopenia develops.

There are a number of causes of aplastic anemia (Table 13–10). Direct stem cell injury may be caused by radiation, chemotherapy, toxins, or pharmacologic agents. Systemic lupus erythematosus may rarely cause suppression of the hematopoietic stem cell by an IgG autoantibody directed against the stem cell. However, the most common pathogenesis of aplastic anemia appears to be autoimmune suppression of hematopoiesis by a T cell-mediated cellular mechanism.

► Clinical Findings

A. Symptoms and Signs

Patients come to medical attention because of the consequences of bone marrow failure. Anemia leads to symptoms of weakness and fatigue, neutropenia causes vulnerability to bacterial infections, and thrombocytopenia results in mucosal and skin bleeding. Physical examination may reveal signs of pallor, purpura, and petechiae. Other abnormalities such as hepatosplenomegaly, lymphadenopathy, or bone tenderness should *not* be present, and their presence should lead to questioning the diagnosis.

Table 13–10. Causes of aplastic anemia.

| |
|---|
| Congenital (rare) |
| “Idiopathic” (probably autoimmune) |
| Systemic lupus erythematosus |
| Chemotherapy, radiotherapy |
| Toxins: benzene, toluene, insecticides |
| Drugs: chloramphenicol, phenylbutazone, gold salts, sulfonamides, phenytoin, carbamazepine, quinacrine, tolbutamide |
| Posthepatitis |
| Pregnancy |
| Paroxysmal nocturnal hemoglobinuria |

B. Laboratory Findings

The hallmark of aplastic anemia is pancytopenia. However, early in the evolution of aplastic anemia, only one or two cell lines may be reduced.

Anemia may be severe and is always associated with decreased reticulocytes. Red blood cell morphology is unremarkable, but there may be macrocytosis. Neutrophils and platelets are reduced in number, and no immature or abnormal forms are seen. The bone marrow aspirate and the bone marrow biopsy appear hypocellular, with only scant amounts of normal hematopoietic progenitors. No abnormal cells are seen.

► Differential Diagnosis

Aplastic anemia must be differentiated from other causes of pancytopenia (Table 13–11). Myelodysplastic disorders, especially hypocellular forms of myelodysplasia, or acute leukemia may occasionally be confused with aplastic anemia. These are differentiated by the presence of morphologic abnormalities or increased blasts, or by the presence of abnormal cytogenetics in bone marrow cells. Hairy cell leukemia has been misdiagnosed as aplastic anemia and should be recognized by the presence of splenomegaly and by abnormal lymphoid cells on the bone marrow biopsy. Pancytopenia with a normocellular bone marrow may be due to systemic lupus erythematosus, disseminated infection, or hypersplenism. Isolated thrombocytopenia may occur early as aplastic anemia develops and be confused with immune thrombocytopenia.

► Treatment

Mild cases of aplastic anemia may be treated with supportive care. Red blood cell transfusions and platelet transfusions are given as necessary, and antibiotics are used to treat infections.

Severe aplastic anemia is defined by a neutrophil count of less than 500/mcL, platelets less than 20,000/mcL, reticulocytes less than 1%, and bone marrow cellularity less than 20%. When this constellation of features is present (or three of the four), the median survival without treatment is approximately 3 months, and only 20% of patients survive for 1 year. The treatment of choice for young adults (under

age 50 years) who have HLA-matched siblings is allogeneic bone marrow transplantation. Children or young adults may also benefit from allogeneic transplantation using an unrelated donor. The use of reduced-intensity preparative regimens for allogeneic transplantation has reduced the toxicity of transplantation. Because of the increased risks associated with unrelated-donor transplantation, this treatment is usually reserved for patients who have not benefited from immunosuppressive therapy.

For adults over age 50 years or those without HLA-matched donors, the treatment of choice for severe aplastic anemia is immunosuppression with antithymocyte globulin (ATG) plus cyclosporine (or tacrolimus). ATG is given in the hospital in conjunction with transfusion and antibiotic support. A useful regimen is equine ATG 40 mg/kg/d for 4 days in combination with cyclosporine, 6 mg/kg orally twice daily. Rabbit ATG is more immunosuppressive than equine ATG and may also be used in a dose of 3.5 mg/kg for 4 days. ATG must be used in combination with corticosteroids (prednisone 1–2 mg/kg/d initially, followed by a rapid taper) to avoid complications of serum sickness. Responses usually occur in 4–12 weeks and are usually only partial, but the blood counts rise high enough to give patients a safe and transfusion-free life.

High-dose immunosuppression with cyclophosphamide, 200 mg/kg, has produced remissions in refractory cases and should be considered for patients without suitable bone marrow donors. Androgens have been widely used in the past, with a low response rate. However, a few patients can be maintained successfully with this form of treatment. One regimen is oxymetholone, 2–3 mg/kg orally daily.

► Course & Prognosis

Patients with severe aplastic anemia have a rapidly fatal illness if left untreated. Allogeneic bone marrow transplantation is highly successful in children and young adults, especially with HLA-matched siblings. For this group of patients, the durable complete response rate exceeds 80%. Advances in the field of unrelated donor transplantation have made this a more attractive option than in the past, with durable responses in more than 50% of cases. ATG treatment leads to partial response in approximately 60% of adults, and the long-term prognosis of responders appears to be good. There is increasing evidence that clonal hematologic disorders, such as PNH or myelodysplasia, may develop in some fraction (as many as 25%) of these non-transplanted patients after many years of follow-up.

► When to Refer

All patients should be referred to a hematologist.

► When to Admit

Admission is necessary only for treatment of neutropenic infection.

NEUTROPENIA

ESSENTIALS OF DIAGNOSIS

- ▶ Severe neutropenia if neutrophils < 500/mcL.
- ▶ Sharp rise in risk of infection in severe neutropenia.

▶ General Considerations

Neutropenia is present when the neutrophil count is below 1500/mcL, although blacks and other specific population groups may normally have neutrophil counts as low as 1200/mcL. The neutropenic patient is increasingly vulnerable to infection by gram-positive and gram-negative bacteria and by fungi. The risk of infection is related to the severity of neutropenia. The risk of serious infection rises sharply with neutrophil counts below 500/mcL, and neutrophil counts less than 100/mcL (“profound neutropenia”) are associated with a high risk of infection within days. Patients with “chronic benign neutropenia” are free of infection for years despite very low stable neutrophil levels. In contrast, the neutrophil count of patients with cyclic neutropenia alternates between normal and low, and the period during which there is a risk of infection is during the nadirs.

A variety of bone marrow disorders and nonmarrow conditions may cause neutropenia (Table 13–12). All the causes of aplastic anemia (Table 13–10) and pancytopenia (Table 13–11) may cause neutropenia. Isolated neutropenia is

often due to an idiosyncratic reaction to a drug, and agranulocytosis (complete absence of neutrophils in the peripheral blood) is almost always due to a drug reaction. In these cases, examination of the bone marrow shows an almost complete absence of myeloid precursors, with other cell lines undisturbed. **Felty syndrome**—immune neutropenia associated with seropositive nodular rheumatoid arthritis and splenomegaly—is another cause. Neutropenia in the presence of a normal bone marrow may be due to immunologic peripheral destruction, sepsis, or hypersplenism. Severe neutropenia may be associated with clonal disorders of T lymphocytes, often with the morphology of large granular lymphocytes.

▶ Clinical Findings

Neutropenia results in stomatitis and in infections due to gram-positive or gram-negative aerobic bacteria or to fungi such as *Candida* or *Aspergillus*. The most common infections are septicemia, cellulitis, and pneumonia. In the presence of severe neutropenia, the usual signs of inflammatory response to infection may be absent. Nevertheless, fever in the neutropenic patient should always be assumed to be of infectious origin.

▶ Treatment

Potential causative drugs are discontinued. Infections are treated with broad-spectrum antibiotics, but particular attention should be paid to enteric gram-negative bacteria. Effective antibiotics include the quinolones such as levofloxacin, 500 mg orally or intravenously daily, or new cephalosporins such as cefepime, 2 g intravenously every 8 hours. The antifungal agent voriconazole provides both better efficacy and reduced toxicity compared with amphotericin.

Many cases of idiopathic or autoimmune neutropenia respond to myeloid growth factors such as granulocyte colony-stimulating factor (G-CSF). Once-weekly or twice-weekly dosage will often be sufficient to produce a protective neutrophil count.

When Felty syndrome leads to repeated bacterial infections, splenectomy has been the treatment of choice, but it now appears that sustained use of G-CSF is effective and provides a nonsurgical alternative. The prognosis of patients with neutropenia depends on the underlying cause. Most patients with drug-induced agranulocytosis can be supported with broad-spectrum antibiotics and will recover completely. The myeloid growth factor G-CSF (filgrastim) may be useful in shortening the duration of neutropenia associated with chemotherapy. The neutropenia associated with large granular lymphocytes may respond to therapy with either cyclosporine or low-dose methotrexate.

▶ When to Refer

Refer to a hematologist if neutrophils are less than 1000/mcL.

▶ When to Admit

Neutropenia by itself is not an indication for hospitalization. However, most patients with severe neutropenia have a serious underlying disease that may require inpatient treatment.

LEUKEMIAS & OTHER MYELOPROLIFERATIVE DISORDERS

Myeloproliferative disorders are due to acquired clonal abnormalities of the hematopoietic stem cell. Since the stem cell gives rise to myeloid, erythroid, and platelet cells, qualitative and quantitative changes are seen in all these cell lines. In some disorders (chronic myeloid leukemia), specific characteristic chromosomal changes are seen. In others, no characteristic cytogenetic abnormalities are seen.

Classically, the myeloproliferative disorders produce characteristic syndromes with well-defined clinical and laboratory features (Tables 13–13 and 13–14). However, these disorders are grouped together because the disease may evolve from one form into another and because hybrid disorders are commonly seen. All of the myeloproliferative disorders may progress to acute myeloid leukemia.

POLYCYTHEMIA VERA

ESSENTIALS OF DIAGNOSIS

- ▶ JAK2 mutation.
- ▶ Increased red blood cell mass.
- ▶ Splenomegaly.
- ▶ Normal arterial oxygen saturation.
- ▶ Usually elevated white blood count and platelet count.

▶ General Considerations

Polycythemia vera is an acquired myeloproliferative disorder that causes overproduction of all three hematopoietic cell lines, most prominently the red blood cells. The hematocrit is elevated (at sea level) when values exceed 54% in males or 51% in females (Table 13–15). True

Table 13–13. Classification of myeloproliferative disorders.

| |
|------------------------------|
| Myeloproliferative syndromes |
| Polycythemia vera |
| Myelofibrosis |
| Essential thrombocytosis |
| Chronic myeloid leukemia |
| Myelodysplastic syndromes |
| Acute myeloid leukemia |

erythrocytosis, with an elevated red blood cell mass, is distinguished from spurious erythrocytosis caused by a constricted plasma volume.

Primary polycythemia (polycythemia vera) is a bone marrow disorder characterized by autonomous overproduction of erythroid cells. Erythroid production is independent of erythropoietin, and the serum erythropoietin level is low. A mutation in JAK2, a signaling molecule, has been demonstrated in 95% of cases, and is almost certainly involved in the pathogenesis.

▶ Clinical Findings

A. Symptoms and Signs

Common complaints related to expanded blood volume and increased blood viscosity are headache, dizziness, tinnitus, blurred vision, and fatigue. Generalized pruritus, especially following a warm shower or bath, is related to histamine release from the basophilia. Epistaxis is probably related to engorgement of mucosal blood vessels in combination with abnormal hemostasis due to qualitative abnormalities in platelet function. Sixty percent of patients are men, and the median age at presentation is 60 years. Polycythemia rarely occurs in persons under age 40 years.

Physical examination reveals plethora and engorged retinal veins. The spleen is palpable in 75% of cases but is nearly always enlarged when imaged.

Thrombosis is the most common complication of polycythemia vera and the major cause of morbidity and death in this disorder. Thrombosis appears to be related both to increased blood viscosity and abnormal platelet function. Uncontrolled polycythemia leads to a very high incidence of thrombotic complications of surgery, and elective surgery should be deferred until the condition has been treated. Paradoxically, in addition to thrombosis, increased bleeding also occurs. There is a high incidence of peptic ulcer disease.

Table 13–14. Laboratory features of myeloproliferative disorders.

| | White Count | Hematocrit | Platelet Count | Red Cell Morphology |
|--------------------------|-------------|------------|----------------|---------------------|
| Chronic myeloid leukemia | ↑↑ | N | N or ↑ | N |
| Myelofibrosis | N or ↓ or ↑ | N or ↓ | ↓ or N or ↑ | Abn |
| Polycythemia vera | N or ↑ | ↑ | N or ↑ | N |
| Essential thrombocytosis | N or ↑ | N | ↑↑ | N |

Table 13–15. Causes of polycythemia.

| |
|--|
| Spurious polycythemia |
| Secondary polycythemia |
| Hypoxia: cardiac disease, pulmonary disease, high altitude |
| Carboxyhemoglobin: smoking |
| Kidney lesions |
| Erythropoietin-secreting tumors (rare) |
| Abnormal hemoglobins (rare) |
| Polycythemia vera |

B. Laboratory Findings

The hallmark of polycythemia vera is a hematocrit above normal, at times greater than 60%. Red blood cell morphology is normal (Table 13–14). By definition, the red blood cell mass is elevated, but this is rarely measured. The white blood count is elevated to 10,000–20,000/mcL and the platelet count is variably increased, sometimes to counts exceeding 1,000,000/mcL. Platelet morphology is usually normal. White blood cells are usually normal, but basophilia and eosinophilia are frequently present. Erythropoietin levels are suppressed and are usually low. The diagnosis should be confirmed with the finding of the JAK2 mutation (JAK2V617F), and the absence of this finding should lead the clinician to question the diagnosis.

The bone marrow is hypercellular, with panhyperplasia of all hematopoietic elements, but bone marrow examination is usually not necessary to establish the diagnosis. Iron stores are usually absent from the bone marrow, having been transferred to the increased circulating red blood cell mass. Iron deficiency may also result from chronic gastrointestinal blood loss. Bleeding may lower the hematocrit to the normal range (or lower), creating diagnostic confusion.

Vitamin B₁₂ levels are strikingly elevated because of increased levels of transcobalamin III (secreted by white blood cells). Overproduction of uric acid may lead to hyperuricemia.

Although red blood cell morphology is usually normal at presentation, microcytosis, hypochromia, and poikilocytosis may result from iron deficiency following treatment by phlebotomy (see below). Progressive hypersplenism may also lead to elliptocytosis.

► Differential Diagnosis

Spurious polycythemia, in which an elevated hematocrit is due to contracted plasma volume rather than increased red cell mass, may be related to diuretic use or may occur without obvious cause.

A secondary cause of polycythemia should be suspected if splenomegaly is absent and the high hematocrit is not accompanied by increases in other cell lines. Secondary causes of polycythemia include hypoxia and smoking; carboxyhemoglobin levels may be elevated in smokers. A renal CT scan or sonogram may be considered to look for an erythropoietin-secreting cyst or tumor. A positive family history should lead to investigation for congenital high-oxygen-affinity hemoglobin. An absence of a mutation in JAK2 suggests a different diagnosis. However, JAK2 muta-

tions are also commonly found in the myeloproliferative disorders essential thrombocytosis and myelofibrosis.

Polycythemia vera should be differentiated from other myeloproliferative disorders (Table 13–14). Marked elevation of the white blood count (above 30,000/mcL) suggests chronic myeloid leukemia. Abnormal red blood cell morphology and nucleated red blood cells in the peripheral blood are seen in myelofibrosis. Essential thrombocytosis is suggested when the platelet count is strikingly elevated.

► Treatment

The treatment of choice is phlebotomy. One unit of blood (approximately 500 mL) is removed weekly until the hematocrit is less than 45%; the hematocrit is maintained at less than 45% by repeated phlebotomy as necessary. Patients for whom phlebotomy is problematic (because of poor venous access or logistical reasons) may be managed primarily with hydroxyurea (see below). Because repeated phlebotomy intentionally produces iron deficiency, the requirement for phlebotomy should gradually decrease. It is important to avoid medicinal iron supplementation, as this can thwart the goals of a phlebotomy program. Maintaining the hematocrit at normal levels has been shown to decrease the incidence of thrombotic complications. A diet low in iron may also increase the intervals between phlebotomies.

Occasionally, myelosuppressive therapy is indicated. Indications include a high phlebotomy requirement, thrombocytosis, and intractable pruritus. There is evidence that reduction of the platelet count to less than 600,000/mcL will reduce the risk of thrombotic complications. Alkylating agents have been shown to increase the risk of conversion of this disease to acute leukemia and should be avoided. Hydroxyurea is now being widely used when myelosuppressive therapy is indicated. The usual dose is 500–1500 mg/d orally, adjusted to keep platelets < 500,000/mcL without reducing the neutrophil count to < 2000/mcL. Anagrelide may be substituted or added when hydroxyurea is not well tolerated, but it is not the preferred initial agent. Low-dose aspirin (75–81 mg daily) has been shown to reduce the risk of thrombosis without excessive bleeding, and should be part of therapy for all patients without contraindications to aspirin.

Allopurinol 300 mg orally daily may be indicated for hyperuricemia. Antihistamine therapy with diphenhydramine or other H₁-blockers may be helpful for control of pruritus, and some reports suggest the efficacy of selective serotonin reuptake inhibitors in refractory cases.

► Prognosis

Polycythemia is an indolent disease with median survival of 11–15 years. The major cause of morbidity and mortality is arterial thrombosis. Over time, polycythemia vera may convert to myelofibrosis or to chronic myeloid leukemia. In approximately 5% of cases, the disorder progresses to acute myeloid leukemia, which is usually refractory to therapy.

► When to Refer

Patients with polycythemia vera should be referred to a hematologist.

▶ When to Admit

Inpatient care is not required.

Tefferi A. Classification, diagnosis, and management of myeloproliferative disorders in the JAK2V617F era. Hematology Am Soc Hematol Educ Program. 2006:240–5. [PMID: 17124067]

ESSENTIAL THROMBOCYTOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Elevated platelet count in absence of other causes.
- ▶ Normal red blood cell mass.
- ▶ Absence of Philadelphia chromosome.

▶ General Considerations

Essential thrombocytosis is an uncommon myeloproliferative disorder of unknown cause in which marked proliferation of the megakaryocytes in the bone marrow leads to elevation of the platelet count. As with polycythemia vera, the recent finding of a high frequency of mutations of JAK2 in these patients promises to advance the understanding of this disorder.

▶ Clinical Findings

A. Symptoms and Signs

The median age at presentation is 50–60 years, and there is a slightly increased incidence in women. The disorder is often suspected when an elevated platelet count is found. Less frequently, the first sign is thrombosis, which is the most common clinical problem. The risk of thrombosis rises with age. Venous thromboses may occur in unusual sites such as the mesenteric, hepatic, or portal vein. Some patients experience erythromelalgia, painful burning of the hands accompanied by erythema; this symptom is reliably relieved by aspirin. Bleeding, typically mucosal, is less common and is related to a concomitant qualitative platelet defect. Splenomegaly is present in at least 25% of patients.

B. Laboratory Findings

An elevated platelet count is the hallmark of this disorder, and may be over 2,000,000/mcL (Table 13–14). The white blood cell count is often mildly elevated, usually not above 30,000/mcL, but with some immature myeloid forms. The hematocrit is normal. The peripheral blood smear reveals large platelets, but giant degranulated forms seen in myelofibrosis are not observed. Red blood cell morphology is normal.

The bone marrow shows increased numbers of megakaryocytes but no other morphologic abnormalities. The Philadelphia chromosome is absent but should be assayed by molecular testing of peripheral blood for the *bcr/abl* fusion gene in all suspected cases to differentiate the disorder from chronic myeloid leukemia.

▶ Differential Diagnosis

Essential thrombocytosis must be distinguished from secondary causes of an elevated platelet count. In reactive thrombocytosis, the platelet count seldom exceeds 1,000,000/mcL. Inflammatory disorders such as rheumatoid arthritis and ulcerative colitis cause significant elevations of the platelet count, as may chronic infection. The thrombocytosis of iron deficiency is observed only when anemia is significant. The platelet count is temporarily elevated after splenectomy. JAK2 mutations are found in 50% of cases.

Regarding other myeloproliferative disorders, the lack of erythrocytosis distinguishes it from polycythemia vera. Unlike myelofibrosis, red blood cell morphology is normal, nucleated red blood cells are absent, and giant degranulated platelets are not seen. In chronic myeloid leukemia, the Philadelphia chromosome (or *bcr/abl* by molecular testing) establishes the diagnosis.

▶ Treatment

The risk of thrombosis can be reduced by control of the platelet count, which should be kept at less than 500,000/mcL. The treatment of choice is hydroxyurea in a dose of 0.5–2 g/d. Hydroxyurea has been shown to be more effective than anagrelide in preventing thrombotic events, with no increase in toxicity. In cases in which hydroxyurea is not well tolerated because of anemia, low doses of anagrelide, 1–2 mg/d, may be added. Higher doses of anagrelide are often complicated by headache, peripheral edema, and congestive heart failure.

Vasomotor symptoms such as erythromelalgia and paresthesias respond rapidly to aspirin, and long-term low-dose (81 mg/d) aspirin may reduce the risk of thrombotic complications. In the unusual event of severe bleeding, the platelet count can be lowered rapidly with plateletpheresis.

▶ Course & Prognosis

Essential thrombocytosis is an indolent disorder and allows long-term survival. Average survival is longer than 15 years from diagnosis, and the survival of patients younger than 50 years does not appear different from matched controls. The major source of morbidity—thrombosis—can be reduced by appropriate platelet control. Late in the course of the disease, the bone marrow may become fibrotic, and massive splenomegaly may occur, sometimes with splenic infarction. There is a 10–15% risk of progression to myelofibrosis after 15 years, and a 1–5% risk of transformation to acute leukemia over 20 years.

▶ When to Refer

Patients with essential thrombocytosis should be referred to a hematologist.

MYELOFIBROSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Striking splenomegaly.
- ▶ Teardrop poikilocytosis on peripheral smear.
- ▶ Leukoerythroblastic blood picture; giant abnormal platelets.
- ▶ Hypercellular bone marrow with reticulin or collagen fibrosis.

▶ General Considerations

Myelofibrosis (myelofibrosis with myeloid metaplasia, agnogenic myeloid metaplasia) is a myeloproliferative disorder characterized by fibrosis of the bone marrow, splenomegaly, and a leukoerythroblastic peripheral blood picture with teardrop poikilocytosis. It is believed that fibrosis occurs in response to increased secretion of platelet-derived growth factor (PDGF) and possibly other cytokines. In response to bone marrow fibrosis, extramedullary hematopoiesis takes place in the liver, spleen, and lymph nodes. In these sites, mesenchymal cells responsible for fetal hematopoiesis can be reactivated. As with other myeloproliferative diseases, abnormalities of JAK2 signaling pathways may be involved in the pathogenesis.

▶ Clinical Findings

A. Symptoms and Signs

Myelofibrosis develops in adults over age 50 years and is usually insidious in onset. Patients most commonly present with fatigue due to anemia or abdominal fullness related to splenomegaly. Uncommon presentations include bleeding and bone pain. On examination, splenomegaly is almost invariably present and is commonly massive. The liver is enlarged in more than 50% of cases.

Later in the course of the disease, progressive bone marrow failure takes place as it becomes increasingly more fibrotic. Progressive thrombocytopenia leads to bleeding. The spleen continues to enlarge, which leads to early satiety. Painful episodes of splenic infarction may occur. The patient becomes cachectic and may experience severe bone pain, especially in the upper legs. Hematopoiesis in the liver leads to portal hypertension with ascites, esophageal varices, and occasionally transverse myelitis caused by myelopoiesis in the epidural space.

B. Laboratory Findings

Patients are almost invariably anemic at presentation. The white blood count is variable—either low, normal, or elevated—and may be increased to 50,000/mcL. The platelet count is variable. The peripheral blood smear is dramatic, with significant poikilocytosis and numerous teardrop forms in the red cell line. Nucleated red blood cells are present and the myeloid series is shifted, with immature forms including a small percentage of promyelocytes or myeloblasts. Platelet morphology may be bizarre, and giant degranulated platelet forms (megakaryocyte fragments) may be seen. The triad of teardrop poikilocytosis, leukoerythroblastic blood, and giant abnormal platelets is highly suggestive of myelofibrosis.

The bone marrow usually cannot be aspirated (dry tap), though early in the course of the disease it is hypercellular, with a marked increase in megakaryocytes. Fibrosis at this stage is detected by a silver stain demonstrating increased reticulin fibers. Later, biopsy reveals more severe fibrosis, with eventual replacement of hematopoietic precursors by collagen. There is no characteristic chromosomal abnormality.

▶ Differential Diagnosis

A leukoerythroblastic blood picture from other causes may be seen in response to severe infection, inflammation, or infiltrative bone marrow processes. However, teardrop poikilocytosis and giant abnormal platelet forms will not be present. Bone marrow fibrosis may be seen in metastatic carcinoma, Hodgkin disease, and hairy cell leukemia. These disorders are diagnosed by characteristic morphology of involved tissues.

Of the other myeloproliferative disorders, chronic myeloid leukemia is diagnosed when there is marked leukocytosis, normal red blood cell morphology, and the presence of the *bcr/abl* fusion gene. Polycythemia vera is characterized by an elevated hematocrit. Essential thrombocytosis shows predominant platelet count elevations.

▶ Treatment

Patients with mild forms of the disease may require no therapy or occasional transfusion support. Biologic agents have shown some benefit. Thalidomide has produced definite responses with acceptable toxicity, and lenalidomide has at least the same efficacy with less toxicity. Clinical trials testing the effect of JAK2 inhibitors are currently being performed, but it is too early to know the results. Allogeneic bone marrow transplantation has been performed successfully with 50% long-term survival and should be considered in younger patients. The use of less toxic, nonmyeloablative regimens for allogeneic transplantation has produced encouraging results. Anemic patients are supported with transfusion. Erythropoietin may increase red blood cell production and decrease transfusion requirements. Splenectomy is not routinely performed but is indicated for splenic enlargement causing recurrent painful episodes, severe thrombocytopenia, or an unacceptable transfusion requirement.

▶ Course & Prognosis

The median survival from time of diagnosis is approximately 5 years. Therapies with biologic agents, such as thalidomide and lenalidomide, and the application of reduced-intensity allogeneic stem cell transplantation appear to offer the possibility of improving the outcome for many patients. End-stage myelofibrosis is characterized by generalized asthenia liver failure, and bleeding from thrombocytopenia, with some cases terminating in acute myeloid leukemia.

▶ When to Refer

Patients in whom myelofibrosis is suspected should be referred to a hematologist.

▶ When to Admit

Admission is not usually necessary.

CHRONIC MYELOID LEUKEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Elevated white blood count.
- ▶ Markedly left-shifted myeloid series but with a low percentage of promyelocytes and blasts.
- ▶ Presence of Philadelphia chromosome or *bcr/abl* gene.

▶ General Considerations

Chronic myeloid leukemia (CML) is a myeloproliferative disorder characterized by overproduction of myeloid cells. These myeloid cells retain the capacity for differentiation, and normal bone marrow function is retained during the early phases.

CML is characterized by a specific chromosomal abnormality and specific molecular abnormality. The Philadelphia chromosome is a reciprocal translocation between the long arms of chromosomes 9 and 22. A large portion of 22q is translocated to 9q, and a smaller piece of 9q is moved to 22q. The portion of 9q that is translocated contains *abl*, a protooncogene that is the cellular homolog of the Ableson murine leukemia virus. The *abl* gene is received at a specific site on 22q, the break point cluster (*bcr*). The fusion gene *bcr/abl* produces a novel protein that differs from the normal transcript of the *abl* gene in that it possesses tyrosine kinase activity (a characteristic activity of transforming genes). Evidence that the *bcr/abl* fusion gene is pathogenic is provided by transgenic mouse models in

which introduction of the gene almost invariably leads to leukemia.

Early CML (“chronic phase”) does not behave like a malignant disease. Normal bone marrow function is retained, white blood cells differentiate and, despite some qualitative abnormalities, the neutrophils combat infection normally. However, untreated CML is inherently unstable, and without treatment the disease progresses to an accelerated and then acute blast phase, which is morphologically indistinguishable from acute leukemia. In recent years, remarkable advances in therapy have changed the natural history of the disease, and the relentless progression to more advanced stages of disease is at least greatly delayed, if not eliminated.

▶ Clinical Findings

A. Symptoms and Signs

CML is a disorder of middle age (median age at presentation is 55 years). Patients usually complain of fatigue, night sweats, and low-grade fever related to the hypermetabolic state caused by overproduction of white blood cells. Patients may also complain of abdominal fullness related to splenomegaly. In some cases, an elevated white blood count is discovered incidentally. Rarely, the patient will present with a clinical syndrome related to leukostasis with blurred vision, respiratory distress, or priapism. The white blood count in these cases is usually greater than 500,000/mcL.

On examination, the spleen is enlarged (often markedly so), and sternal tenderness may be present as a sign of marrow overexpansion. In cases discovered during routine laboratory monitoring, these findings are often absent.

Acceleration of the disease is often associated with fever in the absence of infection, bone pain, and splenomegaly.

B. Laboratory Findings

CML is characterized by an elevated white blood count; the median white blood count at diagnosis is 150,000/mcL, although in some cases the white blood cell count is only modestly increased (Table 13–14). The peripheral blood is characteristic. The myeloid series is left shifted, with mature forms dominating and with cells usually present in proportion to their degree of maturation. Blasts are usually less than 5%. Basophilia and eosinophilia of granulocytes may be present. At presentation, the patient is usually not anemic. Red blood cell morphology is normal, and nucleated red blood cells are rarely seen. The platelet count may be normal or elevated (sometimes to strikingly high levels).

The bone marrow is hypercellular, with left-shifted myelopoiesis. Myeloblasts comprise less than 5% of marrow cells.

The hallmark of the disease is that the *bcr/abl* gene is detected by the polymerase chain reaction (PCR) test in the peripheral blood. A bone marrow examination is not necessary for diagnosis, although it is useful for prognosis and for detecting additional chromosomal abnormalities in addition to the Philadelphia chromosome.

With progression to the accelerated and blast phases, progressive anemia and thrombocytopenia occur, and the

percentage of blasts in the blood and bone marrow increases. Blast phase CML is diagnosed when blasts comprise more than 20% of bone marrow cells.

► Differential Diagnosis

Early CML must be differentiated from the reactive leukocytosis associated with infection. In such cases, the white blood count is usually less than 50,000/mcL, splenomegaly is absent, and the *bcr/abl* gene is not present.

CML must be distinguished from other myeloproliferative disease (Table 13–14). The hematocrit should not be elevated, the red blood cell morphology is normal, and nucleated red blood cells are rare or absent. Definitive diagnosis is made by finding the *bcr/abl* gene.

► Treatment

Treatment is usually not emergent even with white blood counts over 200,000/mcL, since the majority of circulating cells are mature myeloid cells that are smaller and more deformable than primitive leukemic blasts. In the rare instances in which symptoms result from extreme hyperleukocytosis (priapism, respiratory distress, visual blurring, altered mental status), emergent leukapheresis is performed in conjunction with myelosuppressive therapy.

Imatinib mesylate specifically inhibits the tyrosine kinase activity of the *bcr/abl* oncogene. It is well tolerated and results in nearly universal (98%) hematologic control of chronic phase disease. For patients with the chronic phase of CML, the standard dose is 400 mg orally daily. Higher doses such as 600–800 mg daily may overcome some degree of resistance and may produce more rapid initial responses, but side effects are more prominent with these doses. The most common toxicities are nausea, periorbital swelling, edema, rash, and myalgia, but most of these are modest. Less than 5% of patients discontinue the drug due to unacceptable side effects.

Response is assessed in several ways. First, the patient should enter hematologic complete remission, with normalization of blood counts and splenomegaly. This usually occurs within several weeks, but should occur within 3 months. Second, cytogenetic responses should be achieved, ideally within 6 months but certainly within 12 months. A “major cytogenetic response” is identified when < 35% of metaphases contain the Philadelphia chromosome, and a “complete cytogenetic response” indicates the absence of the abnormal chromosome by standard cytogenetic testing. Quantitative assessment of the *bcr/abl* gene using PCR assays is the standard method of assessment. The current goal of therapy is to achieve a “good molecular response,” with at least a 3-log reduction in *bcr/abl* level. This roughly corresponds to a *bcr/abl* ratio (compared to *abl*) of less than 0.03. Patients who achieve this level of molecular response have an excellent prognosis, with 100% of such patients remaining free of progression at 7 years. Furthermore, in this favorable group, the depth of molecular remission appears to increase over time, leading to the hope that this can actually be a curative treatment. Patients with suboptimal molecular responses are best treated by switching from imatinib to an alternative tyrosine kinase inhibitor such as dasatinib (or nilotinib). Dasatinib appears to be a more potent agent and can over-

come approximately 90% of the mutations that can form in *bcr/abl* and limit the effectiveness of imatinib. Dasatinib can be given in a dose of 100 mg/d but is dependent on an acid environment for absorption and cannot be used concurrently with drugs that decrease stomach acidity. Patients who cannot achieve a good molecular response to any of these agents are at increased risk for disease progression and should be considered for treatment with allogeneic transplantation.

Patients with an accelerated phase of CML should initially be treated with imatinib, 600 mg/d, or dasatinib, 100 mg/d, but should be considered for allogeneic transplantation.

The only proven curative therapy for CML is allogeneic bone marrow transplantation. The best results (80% cure rate) are obtained in patients who are under 40 years of age and transplanted within 1 year after diagnosis from HLA-matched siblings. The introduction of imatinib has changed the approach to allogeneic transplant for CML. Allogeneic transplantation is reserved for patients in whom disease is not well controlled, in whom disease progresses after initial control, or for those who have accelerated phase disease. It is too early to judge whether the curative potential from transplantation in patients who are initially treated with imatinib will be compromised compared to using transplantation as initial therapy.

► Course & Prognosis

In the era of imatinib therapy (since 2001), and with the development of molecular targeted agents, more than 80% of patients remain alive and without disease progression at 7 years. While allogeneic stem cell transplantation is the only proven curative option, some patients may be cured by well-tolerated oral agents.

► When to Refer

All patients with CML should be referred to a hematologist.

► When to Admit

Hospitalization is rarely necessary and should be reserved for symptoms of leukostasis at diagnosis or for transformation to acute leukemia.

MYELODYSPLASTIC SYNDROMES

ESSENTIALS OF DIAGNOSIS

- Cytopenias with a hypercellular bone marrow.
- Morphologic abnormalities in two or more hematopoietic cell lines.

► General Considerations

The myelodysplastic syndromes are a group of acquired clonal disorders of the hematopoietic stem cell. They are characterized by the constellation of cytopenias, a usually hypercellular marrow, and a number of morphologic and cytogenetic abnormalities. The disorders are usually idiopathic but may be seen after cytotoxic chemotherapy. Ultimately, the disorder may evolve into acute myeloid leukemia, and the term “preleukemia” has been used in the past to describe these disorders. Although no single specific chromosomal abnormality is seen in myelodysplasia, there are frequently abnormalities involving the long arm of chromosome 5 (which contains a number of genes encoding both growth factors and receptors involved in myelopoiesis) as well as deletions of chromosomes 5 and 7.

Myelodysplasia encompasses several heterogeneous syndromes. Those without excess bone marrow blasts are termed “refractory anemia,” with or without ringed sideroblasts. One important subgroup of the refractory anemia patients are those with the 5q- syndrome, characterized by the cytogenetic finding of loss of part of the long arm of chromosome 5. Those with excess blasts are diagnosed as “refractory anemia with excess blasts” (RAEB 5–19% blasts). Those with a proliferative syndrome including peripheral blood monocytes greater than 1000/mcL are termed “chronic myelomonocytic leukemia” (CMML). An International Prognostic Scoring System (IPSS) has been developed that classifies patients by risk status based on the percentage of bone marrow blasts, cytogenetics, and the severity of cytopenias.

► Clinical Findings

A. Symptoms and Signs

Patients are usually over age 60 years. Many are diagnosed while asymptomatic because of the finding of abnormal blood counts. Patients usually present with fatigue, infection, or bleeding related to bone marrow failure. The course may be indolent, and the disease may present as a wasting illness with fever, weight loss, and general debility. On examination, splenomegaly may be present in combination with pallor, bleeding, and various signs of infection.

B. Laboratory Findings

Anemia may be marked and may require transfusion support. The MCV is normal or increased, and macroovalocytes may be seen on the peripheral blood smear. The white blood cell count is usually normal or reduced, and neutropenia is common. The neutrophils may exhibit morphologic abnormalities, including deficient numbers of granules or deficient segmentation of the nucleus, especially a bilobed nucleus (Pelger-Huet). The myeloid series may be left shifted, and small numbers of promyelocytes or blasts may be seen. The platelet count is normal or reduced, and hypogranular platelets may be present.

The bone marrow is characteristically hypercellular, but may be hypocellular. Erythroid hyperplasia is common, and signs of abnormal erythropoiesis include megaloblastic features, nuclear budding, or multinucleated erythroid

precursors. The Prussian blue stain may demonstrate ringed sideroblasts. The myeloid series is often left shifted, with variable increases in blasts. Deficient or abnormal granules may be seen. A characteristic abnormality is the presence of dwarf megakaryocytes with a unilobed nucleus. A variety of cytogenetic abnormalities in the bone marrow are characteristic of myelodysplasia. Some patients with an indolent form of the disease have an isolated partial deletion of chromosome 5 (5q- syndrome). The presence of other abnormalities such as monosomy 7 or complex abnormalities is associated with more aggressive disease.

► Differential Diagnosis

In subtle cases, cytogenetic evaluation of the bone marrow may help distinguish this clonal disorder from other causes of cytopenias. As the number of blasts increases in the bone marrow, myelodysplasia is arbitrarily separated from acute myeloid leukemia by the presence of less than 20% blasts.

► Treatment

Erythropoietin (epoetin alfa), 30,000 units subcutaneously weekly, reduces the red cell transfusion requirement in some patients. The response rate is 20%, but a 4-week trial of epoetin alfa is reasonable since it will be cost-effective for the subgroup of responders. Patients with low serum erythropoietin (< 100 mU/mL) levels are the most likely to respond to erythropoietin treatment, whereas those with levels > 500 mU/mL almost never respond. Unfortunately, the patients with the highest transfusion requirements are the least likely to respond. Lenalidomide is approved for the treatment of transfusion-dependent anemia due to myelodysplasia. It is the treatment of choice in patients with the 5q- cytogenetic abnormality, with significant responses and freedom from transfusion in 70% of patients, and with responses typically lasting longer than 2 years. In addition, nearly half of these patients enter a cytogenetic remission with clearing of the abnormal 5q- clone, leading to the hope that lenalidomide may change the natural history of the disease. The response rate in patients with transfusion-dependent myelodysplasia lacking 5q- is only 25% and responses usually last less than 1 year, but it is still worth trying. The recommended initial dose is 10 mg orally daily. The most common side effects are neutropenia and thrombocytopenia, but venous thrombosis is also seen and warrants prophylaxis with aspirin. The cost of lenalidomide is extremely high, and it is not usually effective either for cell lines other than red blood cells or for patients with increased blasts. Patients who remain dependent on red blood cell transfusion and who do not have immediately life-threatening disease should receive iron chelation in order to prevent serious iron overload; the dose of oral agent deferasirox is 20 mg/kg/d. Patients affected primarily with severe neutropenia may benefit from the use of myeloid growth factors such as G-CSF. Experimental oral agents (AMG 531) that stimulate platelet production by mimicking the effect of thrombopoietin on the thrombopoietin receptor have shown some effectiveness in raising the platelet count in myelodysplasia.

Azacitidine is approved as an effective treatment based on its ability to improve both symptoms and blood counts and to prolong both overall survival and the time to conversion to acute leukemia. It is the treatment of choice for many patients, especially those with higher risk disease based on increased blasts in the bone marrow. A related agent, decitabine, can produce similar responses. Occasional patients can benefit from immunosuppressive therapy including antithymocyte globulin (ATG). Predictors of response to ATG include age less than 60 years, absence of 5q-, and presence of HLA DR15. Allogeneic stem cell transplantation is the only curative therapy for myelodysplasia, but its role is limited by the advanced age of many patients and the indolent course of disease in some subsets of patients. The optimal use and timing of allogeneic transplantation are controversial, but the use of reduced-intensity preparative regimens for transplantation has expanded the role of this therapy, using both family and matched unrelated donors.

► Course & Prognosis

Myelodysplasia is an ultimately fatal disease, and allogeneic transplantation is the only curative therapy, with cure rates of 30–60% depending primarily on the risk status of the disease. Patients most commonly succumb to infections or bleeding. The risk of transformation to acute myeloid leukemia depends on the percentage of blasts in the bone marrow. Patients with refractory anemia may survive many years, and the risk of leukemia is low (< 10%). Those with excess blasts or CMML have short survivals (usually < 2 years) and have a higher (20–50%) risk of developing acute leukemia. The finding of full deletions of chromosomes 5 and 7 is associated with a poor prognosis.

► When to Refer

All patients with myelodysplasia should be referred to a hematologist.

► When to Admit

Hospitalization is needed only for specific complications, such as severe infection.

ACUTE LEUKEMIA

ESSENTIALS OF DIAGNOSIS

- Short duration of symptoms, including fatigue, fever, and bleeding.
- Cytopenias or pancytopenia.
- More than 20% blasts in the bone marrow.
- Blasts in peripheral blood in 90% of patients.
- Classify as acute myeloid leukemia (AML) or acute lymphoblastic leukemia (ALL).

► General Considerations

Acute leukemia is a malignancy of the hematopoietic progenitor cell. These cells proliferate in an uncontrolled fashion and replace normal bone marrow elements. Most cases arise with no clear cause. However, radiation and some toxins (benzene) are leukemogenic. In addition, a number of chemotherapeutic agents (especially cyclophosphamide, melphalan, other alkylating agents, and etoposide) may cause leukemia. The leukemias seen after toxin or chemotherapy exposure often develop from a myelodysplastic prodrome and are often associated with abnormalities in chromosomes 5 and 7, and those related to etoposide may have abnormalities in chromosome 11q23.

Much has been learned about the molecular biology of the leukemias. One subtype, acute promyelocytic leukemia (APL), is characterized by chromosomal translocation t(15;17), which produces the fusion gene *PML-RAR α* , which interacts with the retinoic acid receptor to produce a block in differentiation that can be overcome with pharmacologic doses of retinoic acid (see below).

Most of the clinical findings in acute leukemia are due to replacement of normal bone marrow elements by the malignant cell. Less common manifestations result from organ infiltration (skin, gastrointestinal tract, meninges). Acute leukemia is potentially curable with combination chemotherapy.

Acute lymphoblastic leukemia (ALL) comprises 80% of the acute leukemias of childhood. The peak incidence is between 3 and 7 years of age. It is also seen in adults, causing approximately 20% of adult acute leukemias. Acute myeloid leukemia (AML) is primarily an adult disease with a median age at presentation of 60 years and an increasing incidence with advanced age.

► Clinical Findings

A. Symptoms and Signs

Most patients have been ill only for days or weeks. Bleeding (usually due to thrombocytopenia) occurs in the skin and

mucosal surfaces, with gingival bleeding, epistaxis, or menorrhagia. Less commonly, widespread bleeding is seen in patients with disseminated intravascular coagulation (DIC) (in APL and monocytic leukemia). Infection is due to neutropenia, with the risk of infection rising as the neutrophil count falls below 500/mcL; with neutrophil counts less than 100/mcL, infection within days is the rule. The most common pathogens are gram-negative bacteria (*Escherichia coli*, *Klebsiella*, *Pseudomonas*) or fungi (*Candida*, *Aspergillus*). Common presentations include cellulitis, pneumonia, and perirectal infections; death within a few hours may occur if treatment with appropriate antibiotics is delayed.

Patients may also seek medical attention because of gum hypertrophy and bone and joint pain. The most dramatic presentation is hyperleukocytosis, in which a markedly elevated circulating blast count (usually > 200,000/mcL) leads to impaired circulation, presenting as headache, confusion, and dyspnea. Such patients require emergent leukapheresis and chemotherapy.

On examination, patients appear pale and have purpura and petechiae; signs of infection may not be present. Stomatitis and gum hypertrophy may be seen in patients with monocytic leukemia, as may rectal fissures. There is variable enlargement of the liver, spleen, and lymph nodes. Bone tenderness may be present, particularly in the sternum, tibia, and femur.

B. Laboratory Findings

The hallmark of acute leukemia is the combination of pancytopenia with circulating blasts. However, blasts may be absent from the peripheral smear in as many as 10% of cases (“aleukemic leukemia”). The bone marrow is usually hypercellular and dominated by blasts. More than 20% blasts are required to make a diagnosis of acute leukemia.

Hyperuricemia may be seen. If DIC is present, the fibrinogen level will be reduced, the prothrombin time prolonged, and fibrin degradation products or fibrin D-dimers present. Patients with ALL (especially T cell) may have a mediastinal mass visible on chest radiograph. Meningeal leukemia will have blasts present in the spinal fluid, seen in approximately 5% of cases at diagnosis; it is more common in monocytic types of AML.

The Auer rod, an eosinophilic needle-like inclusion in the cytoplasm, is pathognomonic of AML and, if seen, secures the diagnosis. Leukemia cells retain properties of the lineages from which they are derived. Thus, histochemistry will demonstrate peroxidase in myeloid cells and butyrate esterase in monocytic cells, whereas ALL cells will not contain either of these enzymes. The phenotype of leukemia cells is usually demonstrated by flow cytometry. AML cells usually express myeloid antigens such as CD 13 or CD 33. ALL cells of B lineage will express CD19, common to all B cells, and most cases will express CD10, formerly known as the “common ALL antigen.” ALL cells of T lineage will usually not express mature T-cell markers, such as CD 3, 4, or 8, but will express some combination of CD 2, 5, and 7 and do not express surface immunoglobulin. Almost all ALL cells express terminal deoxynucleotidyl transferase (TdT). The uncommon Burkitt type of ALL has a “lymphoma”

phenotype, expressing CD19, CD20 and surface immunoglobulin but not TdT.

AML has been characterized in several ways. The “FAB,” (French, American, British) classification was based on morphology and histochemistry as follows: acute undifferentiated leukemia (M0), acute myeloblastic leukemia (M1), acute myeloblastic leukemia with differentiation (M2), acute promyelocytic leukemia (APL) (M3), acute myelomonocytic leukemia (M4), acute monoblastic leukemia (M5), erythroleukemia (M6), and megakaryoblastic leukemia (M7). The World Health Organization (WHO) has sponsored a classification of the leukemias and other hematologic malignancies that incorporates cytogenetic, molecular, and immunophenotype information.

ALL is most usefully classified by immunologic phenotype as follows: common, early B lineage, and T cell.

In considering the various types of AML, APL is now considered separately because of its unique biologic features and unique response to non-chemotherapy treatments. APL is characterized by the cytogenetic finding of t(15;17) and the fusion gene *PML-RAR alpha*. Among the other types of AML, cytogenetic studies are the most powerful prognostic factors. Favorable cytogenetics such as t(8;21) and inv(16)(p13;q22) are seen in 15% of cases and are termed the “core-binding factor” leukemias because of common genetic lesions affecting DNA-binding elements. These patients have a higher chance of achieving both short- and long-term disease control. The majority of cases of AML are of intermediate risk and have either normal cytogenetics or abnormalities that do not confer strong prognostic significance. Within this large subgroup, a relatively favorable group of patients has been defined based on a molecular signature that includes mutations of nucleophosmin 1 (NPM1) and lacks the internal tandem duplication of the *FLT3* gene. A poor prognosis is conferred by the cytogenetics finding of monosomy 5 or 7, or complex cytogenetics with more than three separate abnormalities.

In ALL, the hyperdiploidy (with more than 50 chromosomes) is associated with a better prognosis, but is seldom seen in adults. Unfavorable cytogenetics in ALL are the Philadelphia chromosome t(9;22) and t(4;11), which has fusion genes involving the *MLL* gene at 11q23.

► Differential Diagnosis

AML must be distinguished from other myeloproliferative disorders, chronic myeloid leukemia, and myelodysplastic syndromes. Acute leukemia may also resemble a left-shifted bone marrow recovering from a previous toxic insult. If the question is in doubt, a bone marrow study should be repeated in several days to see if maturation has taken place. ALL must be separated from other lymphoproliferative disease such as chronic lymphocytic leukemia, lymphomas, and hairy cell leukemia. It may also be confused with the atypical lymphocytosis of mononucleosis and pertussis.

► Treatment

Most young patients with acute leukemia are treated with the objective of effecting a cure. The first step in treatment

is to obtain complete remission, defined as normal peripheral blood with resolution of cytopenias, normal bone marrow with no excess blasts, and normal clinical status. The type of initial chemotherapy depends on the subtype of leukemia.

1. AML—Most patients with AML are treated with a combination of an anthracycline (daunorubicin or idarubicin) plus cytarabine, either alone or in combination with other agents. This therapy will produce complete remissions in 80% of patients under age 60 years and in 50–60% of older patients (see Tables 39–3 and 39–4). APL is treated differently from other forms of AML. Induction therapy should include an anthracycline plus all-*trans*-retinoic acid. With this approach 90–95% of patients will achieve complete remission. For patients with high-risk APL based on an initial white blood cell count > 10,000/mcL, the addition of arsenic trioxide may be beneficial, and the addition of this biologic agent may be helpful in other cases as well.

Once a patient has entered remission, postremission therapy should be given with curative intent whenever possible. Options include standard chemotherapy and autologous and allogeneic transplantation. The optimal treatment strategy depends on the patient's age and clinical status, and the risk factor profile of the leukemia. Significant advances have been made in the treatment of APL. With the use of all-*trans* retinoic acid, arsenic trioxide, and chemotherapy, 90% of patients remain in long-term remission. Only the uncommon group of high-risk patients (based on initial white blood cell count > 10,000/mcL) have not shared in this favorable outcome, but studies of the potentially synergistic combination of retinoic acid and arsenic trioxide may improve results here. For intermediate-risk patients with AML, cure rates for postremission therapy are 35–40% for chemotherapy, 40–50% for autologous transplantation, and 50–60% for allogeneic transplantation. Some types of AML whose cytogenetics involved core-binding factors have a more favorable prognosis, with cure rates of 50–60% with chemotherapy and 70–80% with autologous transplantation. Patients who do not enter remission or who have high-risk cytogenetics (such as monosomy 7 and complex cytogenetics) do far more poorly and are rarely cured with chemotherapy. Allogeneic transplantation is the treatment of choice, but cure rates are only 20–30%.

Once leukemia has recurred after initial chemotherapy, the prognosis is much more guarded. For patients in second remission, transplantation (autologous or allogeneic) offers a 20–40% chance of cure. For those patients with APL who relapse, arsenic trioxide can produce second remissions in 90% of cases, and autologous transplant in second remission produces cure rates of 60–70%.

2. ALL—Adults with ALL are treated with combination chemotherapy, including daunorubicin, vincristine, prednisone, and asparaginase. This treatment produces complete remissions in 90% of patients. Those patients with Philadelphia chromosome-positive ALL (or *bcr-abl* plus ALL) should have imatinib (or dasatinib) added to their initial chemotherapy.

Remission induction therapy for ALL is less myelosuppressive than treatment for AML and does not necessarily produce marrow aplasia. After achieving complete remission, patients receive central nervous system prophylaxis so that meningeal sequestration of leukemic cells does not develop. As with AML, patients may be treated with either chemotherapy or high-dose chemotherapy plus bone marrow transplantation. Treatment decisions are made based on patient age and risk factors of the disease. Low-risk patients with ALL may be treated with chemotherapy with a 70% chance of cure. Intermediate-risk patients have a 30–50% chance of cure with chemotherapy, and high-risk patients are rarely cured with chemotherapy alone. High-risk patients with adverse cytogenetics or poor responses to chemotherapy are best treated with allogeneic transplantation. Autologous transplantation is a possibility in high-risk patients who lack a suitable donor.

► Prognosis

Approximately 70–80% of adults with AML under age 60 years achieve complete remission. High-dose postremission chemotherapy leads to cure in 35–40% of these patients, and high-dose cytarabine has been shown to be superior to therapy with lower doses. Allogeneic bone marrow transplantation (for younger adults with HLA-matched siblings) is curative in 50–60% of cases. Autologous bone marrow transplantation may be superior to nonablative chemotherapy. Older adults with AML achieve complete remission in up to 50% of instances. The cure rates for older patients with AML have been very low (approximately 10–15%) even if they achieve remission and are able to receive postremission chemotherapy. The use of reduced-intensity allogeneic transplantation is being explored in order to improve on these outcomes.

► When to Refer

All patients should be referred to a hematologist.

► When to Admit

Most patients with acute leukemia will be admitted for treatment.

CHRONIC LYMPHOCYTIC LEUKEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Lymphocytosis > 5000/mcL.
- ▶ Coexpression of CD19, CD5 on lymphocytes.

▶ General Considerations

Chronic lymphocytic leukemia (CLL) is a clonal malignancy of B lymphocytes. The disease is usually indolent, with slowly progressive accumulation of long-lived small lymphocytes. These cells are immunoincompetent and respond poorly to antigenic stimulation.

CLL is manifested clinically by immunosuppression, bone marrow failure, and organ infiltration with lymphocytes. Immunodeficiency is also related to inadequate antibody production by the abnormal B cells. With advanced disease, CLL may cause damage by direct tissue infiltration.

Information about CLL is now evolving rapidly, with new findings in biology and new treatment options.

▶ Clinical Findings

A. Symptoms and Signs

CLL is a disease of older patients, with 90% of cases occurring after age 50 years and a median age at presentation of 70 years. Many patients will be incidentally discovered to have lymphocytosis. Others present with fatigue or lymphadenopathy. On examination, 80% of patients will have lymphadenopathy and 50% will have enlargement of the liver or spleen.

The long-standing Rai classification system remains prognostically useful today: stage 0, lymphocytosis only; stage I, lymphocytosis plus lymphadenopathy; stage II, organomegaly; stage III, anemia; stage IV, thrombocytopenia. These stages can be collapsed in to low-risk (stages 0–I), intermediate risk (stage II) and high-risk (stages III–IV).

CLL usually pursues an indolent course, but some subtypes behave more aggressively; a variant, prolymphocytic leukemia, is more aggressive. The morphology of the latter is different, characterized by larger and more immature cells. In 5–10% of cases, CLL may be complicated by autoimmune hemolytic anemia or autoimmune thrombocytopenia. In approximately 5% of cases, while the systemic disease remains stable, an isolated lymph node transforms into an aggressive large cell lymphoma (**Richter syndrome**).

B. Laboratory Findings

The hallmark of CLL is isolated lymphocytosis. The white blood count is usually greater than 20,000/mcL and may be markedly elevated to several hundred thousand. Usually 75–98% of the circulating cells are lymphocytes. Lymphocytes appear small and mature, with condensed nuclear chromatin, and are morphologically indistinguishable from normal small lymphocytes, but smaller numbers of larger and activated lymphocytes may be seen. The hemat-

ocrit and platelet count are usually normal at presentation. The bone marrow is variably infiltrated with small lymphocytes. The immunophenotype of CLL demonstrates coexpression of the B lymphocyte lineage marker CD19 with the T lymphocyte marker CD5; this finding is commonly observed only in CLL and mantle cell lymphoma. CLL is distinguished from mantle cell lymphoma by the expression of CD23, low expression of surface immunoglobulin and CD20, and the absence of overexpression of cyclin D1. Patients whose CLL cells have mutated forms of the immunoglobulin gene (which can currently be tested only in research laboratories) have a more indolent form of disease; these cells typically express low levels of the surface antigen CD38 and do not express the zeta-associated protein (ZAP-70). Conversely, patients whose cells have unmutated IgV genes and high levels of ZAP-70 expression do less well and require treatment sooner. The assessment of genomic changes by fluorescence in-situ hybridization (FISH) provides important prognostic information. The finding of deletions of chromosome 17p or 11q confers a poor prognosis, whereas those whose only genomic change is deletion of 13q have a very favorable outcome.

Hypogammaglobulinemia is present in 50% of patients and becomes more common with advanced disease. In some, a small amount of IgM paraprotein is present in the serum.

▶ Differential Diagnosis

Few syndromes can be confused with CLL. Viral infections producing lymphocytosis should be obvious from the presence of fever and other clinical findings; however, fever may occur in CLL from concomitant bacterial infection. Pertussis may cause a particularly high total lymphocyte count. Other lymphoproliferative diseases such as Waldenström macroglobulinemia, hairy cell leukemia, or lymphoma (especially mantle cell) in the leukemic phase are distinguished on the basis of the morphology and immunophenotype of circulating lymphocytes and bone marrow.

▶ Treatment

Most cases of early indolent CLL require no specific therapy, and the standard of care for early stage disease has been observation. Indications for treatment include progressive fatigue, symptomatic lymphadenopathy, or anemia or thrombocytopenia. These patients have either symptomatic and progressive Rai stage II disease or stage III/IV disease. The initial treatment of choice is the combination of the chemotherapeutic agent fludarabine plus the antibody rituximab, with or without the addition of the chemotherapeutic drug cyclophosphamide. The addition of cyclophosphamide appears to have greater anti-leukemic effectiveness but also increases the risk of treatment-related infection. The question of whether this increase in toxicity is warranted by improved anti-leukemic effectiveness is currently being studied. Chlorambucil, 0.6–1 mg/kg orally every 3 weeks for approximately 6 months, was the standard treatment prior to the development of fludarabine. This treatment is convenient, well tolerated, and remains a reasonable first choice for elderly patients for whom fre-

quent trips to the clinician's office is a hardship. The monoclonal antibody alemtuzumab is approved for treatment of refractory CLL and can be especially useful in clearing the blood and bone marrow of disease. However, it produces significant immunosuppression, and its role in primary therapy has been limited due to the risk of severe and fatal infections. Lenalidomide has been shown to have effectiveness in refractory cases of CLL, and its role in primary therapy is being studied. The investigational agent flavopiridol has produced encouraging results in types of CLL (such as those with deletions of 17p) that have not responded to other treatments.

Associated autoimmune hemolytic anemia or immune thrombocytopenia may require treatment with rituximab, prednisone, or splenectomy. Fludarabine should be avoided in patients with autoimmune hemolytic anemia since it may exacerbate this condition. Patients with recurrent bacterial infections and hypogammaglobulinemia benefit from prophylactic infusions of gamma globulin 0.4 g/kg/month), but this treatment is very expensive and can be justified only when these infections are severe.

Allogeneic transplantation offers potentially curative treatment for patients with CLL, but it should be used only in patients whose disease cannot be controlled by standard therapies. Nonmyeloablative allogeneic transplant has produced encouraging results and may expand the role of transplant in CLL. Some subtypes of CLL with genomic abnormalities such as 17p deletions have a sufficiently poor prognosis with standard therapies that early intervention with allogeneic transplant is being studied to assess whether it can improve outcomes.

► Prognosis

New therapies are changing the prognosis of CLL. In the past, median survival was approximately 6 years, and only 25% of patients lived more than 10 years. Patients with stage 0 or stage I disease have a median survival of 10–15 years, and these patients may be reassured that they can live a normal life for many years. Patients with stage III or stage IV disease had a median survival of less than 2 years in the past, but with fludarabine-based combination therapies, 2-year survival is now greater than 90% and the long-term outlook appears to be substantially changed. For patients with high-risk and resistant forms of CLL, there is evidence that allogeneic transplantation can overcome risk factors and lead to long-term disease control.

► When to Refer

All patients with CLL should be referred to a hematologist.

► When to Admit

Hospitalization is rarely needed.

HAIRY CELL LEUKEMIA

ESSENTIALS OF DIAGNOSIS

- Pancytopenia.
- Splenomegaly, often massive.
- Hairy cells present on blood smear and especially in bone marrow biopsy.

► General Considerations

Hairy cell leukemia, an uncommon form of leukemia, is an indolent cancer of B lymphocytes.

► Clinical Findings

A. Symptoms and Signs

The disease characteristically presents in middle-aged men. The median age at presentation is 55 years, and there is a striking 5:1 male predominance. Most patients present with gradual onset of fatigue, others complain of symptoms related to markedly enlarged spleen, and some come to attention because of infection.

Splenomegaly is almost invariably present and may be massive. The liver is enlarged in 50% of cases; lymphadenopathy is uncommon.

Hairy cell leukemia is usually an indolent disorder whose course is dominated by pancytopenia and recurrent infections, including mycobacterial infections.

B. Laboratory Findings

The hallmark of hairy cell leukemia is pancytopenia. Anemia is nearly universal, and 75% of patients have thrombocytopenia and neutropenia. Nearly all patients have striking monocytopenia, which is encountered in almost no other condition. The “hairy cells” are usually present in small numbers on the peripheral blood smear and have a characteristic appearance with numerous cytoplasmic projections. The bone marrow is usually inaspirable (dry tap), and the diagnosis is made by characteristic morphology on bone marrow biopsy. The hairy cells have a characteristic histochemical staining pattern, with tartrate-resistant acid phosphatase (TRAP). On immunophenotyping, the cells coexpress the antigens CD11c and CD22. Pathologic examination of the spleen shows marked infiltration of the red pulp with hairy cells. This is in contrast to the usual predilection of lymphomas to involve the white pulp of the spleen.

► Differential Diagnosis

Hairy cell leukemia should be distinguished from other lymphoproliferative diseases such as Waldenström macroglobulinemia and non-Hodgkin lymphomas. It also may be confused with other causes of pancytopenia, including hypersplenism due to any cause, aplastic anemia, and paroxysmal nocturnal hemoglobinuria.

► Treatment

The treatment of choice is intravenous cladribine (2-chlorodeoxyadenosine; CdA), 0.14 mg/kg daily for 7 days. This is a relatively nontoxic drug that produces benefit in 95% of cases and complete remission in more than 80%. Responses are long-lasting, with few patients relapsing in the first few years. Treatment with pentostatin produces similar results, but that drug is more cumbersome to administer.

► Course & Prognosis

The development of new therapies has changed the prognosis of this disease. Formerly, median survival was 6 years, and only one-third of patients survived longer than 10 years. More than 95% of patients with hairy cell leukemia will live longer than 10 years.

Swords R et al. Hairy cell leukemia. *Med Oncol*. 2007;24(1):7–15. [PMID: 17673807]

LYMPHOMAS

NON-HODGKIN LYMPHOMAS

ESSENTIALS OF DIAGNOSIS

- Often presents with painless lymphadenopathy.
- Pathologic diagnosis of lymphoma is made by pathologic examination of tissue.

► General Considerations

The non-Hodgkin lymphomas are a heterogeneous group of cancers of lymphocytes. The disorders vary in clinical presentation and course from indolent to rapidly progressive.

Molecular biology has provided clues to the pathogenesis of these disorders. The best-studied example is Burkitt lymphoma, in which a characteristic cytogenetic abnormality of translocation between the long arms of chromosomes 8 and 14 has been identified. The protooncogene *c-myc* is

translocated from its normal position on chromosome 8 to the heavy chain locus on chromosome 14. Cells committed to B cell differentiation are likely to have enhanced expression of this heavy chain locus, and it is likely that overexpression of *c-myc* (in its new anomalous position) is related to malignant transformation. In the follicular lymphomas, the t(14,18) translocation is characteristic and results in overexpression of *bcl-2*, resulting in protection against apoptosis, the usual mechanism of cell death.

Classification of the lymphomas is a controversial area still undergoing evolution. The most recent grouping (Table 13–16) separates diseases based on both clinical and pathologic features.

► Clinical Findings

A. Symptoms and Signs

Patients with indolent lymphomas usually present with painless lymphadenopathy, which may be isolated or widespread. Involved lymph nodes may be present in the retroperitoneum, mesentery, and pelvis. The indolent lymphomas are usually disseminated at the time of diagnosis, and bone marrow involvement is frequent. Patients with intermediate and high-grade lymphomas may have constitutional symptoms such as fever, drenching night sweats, or weight loss.

On examination, lymphadenopathy may be isolated, or extranodal sites of disease (skin, gastrointestinal tract) may be found. Patients with Burkitt lymphoma are noted to have abdominal pain or abdominal fullness because of the predilection of the disease for the abdomen.

Once a pathologic diagnosis is established, the patient is staged. Chest radiograph and CT scan of the abdomen and pelvis, bone marrow biopsy, and—in selected cases with high-risk morphology—a lumbar puncture are performed.

Table 13–16. World Health Organization proposed classification of non-Hodgkin lymphomas.

| |
|-----------------------------------|
| Precursor B |
| B cell lymphoblastic lymphoma |
| Mature B |
| Diffuse large B cell lymphoma |
| Mediastinal large B cell lymphoma |
| Follicular lymphoma |
| Small lymphocytic lymphoma |
| Lymphoplasmacytic lymphoma |
| Mantle cell lymphoma |
| Burkitt lymphoma |
| Marginal zone lymphoma |
| MALT type |
| Nodal |
| Splenic |
| Mucosal tissue associated |
| Precursor T |
| T cell lymphoblastic lymphoma |
| Mature T (and NK cell) |
| Anaplastic T cell lymphoma |
| Peripheral T cell lymphoma |

B. Laboratory Findings

The peripheral blood is usually normal, but a number of lymphomas may present in a leukemic phase.

Bone marrow involvement is manifested as paratrabecular lymphoid aggregates. In some high-grade lymphomas, the meninges are involved and malignant cells are found with cerebrospinal fluid cytology. The chest radiograph may show a mediastinal mass in lymphoblastic lymphoma. The serum LDH has been shown to be a useful prognostic marker and is now incorporated in risk stratification of treatment.

The diagnosis of lymphoma is made by tissue biopsy. Needle aspiration may yield suspicious results, but a lymph node biopsy (or biopsy of involved extranodal tissue) is required for diagnosis and staging.

Molecular profiling based on the examination of gene expression may lead to a new classification of the lymphomas.

► Treatment

The treatment of indolent lymphoma depends on the stage of disease and the clinical status of the patient. A small number of patients have limited disease with only one abnormal lymph node and may be treated with localized irradiation with curative intent. Most patients with indolent lymphoma have disseminated disease at the time of diagnosis. If the disease is not bulky and the patient not symptomatic, no initial therapy may be required. Some patients will have spontaneous remissions and may defer treatment for 1–3 years. There are an increasing number of reasonable treatment options for low-grade lymphomas, but no clear consensus has emerged on the best strategy. Treatment with the anti-CD20 antibody rituximab is a commonly used treatment because of its very low toxicity and avoidance of chemotherapy. Combinations of rituximab with chemotherapy may also be used. Common chemotherapy regimens include fludarabine; the combination of cyclophosphamide, vincristine, and prednisone (R-CVP); and cyclophosphamide, doxorubicin, vincristine, prednisone (R-CHOP). Radioimmunoconjugates that fuse anti-B cell antibodies with radiation may produce improved results with modest increases in toxicity compared with antibody alone, and one such agent (yttrium-90 ibritumomab tiuxetan) is in use. Some patients with clinically aggressive low-grade lymphomas may be appropriate candidates for allogeneic transplantation. As in other hematologic malignancies, the use of less toxic nonmyeloablative regimens for allogeneic transplant may expand the role of transplant in this disease. The role of autologous transplantation for follicular lymphoma remains uncertain, but some patients with recurrent disease appear to have prolonged remissions.

Patients with diffuse large B-cell lymphoma are treated with curative intent. Those with localized disease receive either short-course chemo-immunotherapy (such as three courses of R-CHOP) plus localized radiation or six courses of chemotherapy without radiation. Most patients who have more advanced disease are treated with six to eight cycles of chemotherapy such as R-CHOP. Individuals with very **high-**

risk lymphoma may benefit from autologous stem cell transplantation early in the course. Patients with diffuse large B-cell lymphoma who relapse after initial chemotherapy may still be cured by autologous stem cell transplantation if their disease remains responsive to chemotherapy.

Persons with **special forms of lymphoma** require individualized therapy. Burkitt lymphoma is treated with intensive regimens specifically tailored for this histologic type. Those with lymphoblastic lymphoma receive regimens similar to those used for T cell ALL. Mantle cell lymphoma is not effectively treated with standard chemotherapy regimens. Intensive initial therapy including autologous stem cell transplantation has been shown to improve outcomes and is now the standard of care. Reduced-intensity allogeneic stem cell transplantation offers curative potential. Patients with mucosal associated lymphoid tumors (MALT lymphomas) of the stomach may be appropriately treated with combination antibiotics directed against *Helicobacter pylori* but require frequent endoscopic monitoring.

► Prognosis

The median survival of patients with indolent lymphomas has been 6–8 years, but this appears to be improving. These diseases ultimately become refractory to chemotherapy. This often occurs at the time of histologic progression of the disease to a more aggressive form of lymphoma.

The International Prognostic Index is widely used to categorize patients with intermediate-grade lymphoma into risk groups. Factors that confer adverse prognosis are age over 60 years, elevated serum LDH, stage III or stage IV disease, and poor performance status. Patients with no risk factors or one risk factor have high complete response rates (80%) to standard chemotherapy, and most responses (80%) are durable. Patients with two risk factors have a 70% complete response rate, 70% being long-lasting. Patients with higher-risk disease have lower response rates and poor survival with standard regimens, and alternative treatments are needed. Early treatment with high-dose therapy and autologous stem cell transplantation improves the outcome.

For patients who relapse after initial chemotherapy, the prognosis depends on whether the lymphoma is still partially sensitive to chemotherapy. If it is, autologous transplantation offers a 50% chance of long-term salvage.

The treatment of older patients with lymphoma has been difficult because of poorer tolerance of aggressive chemotherapy. The use of myeloid growth factors and prophylactic antibiotics to reduce neutropenic complications may improve outcomes.

Molecular profiling techniques using gene array technology are being studied to better define subsets of lymphomas with different biologic features and prognoses.

► When to Refer

All patients with lymphoma should be referred to a hematologist or an oncologist.

► When to Admit

Admission is necessary only for specific complications.

HODGKIN DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Painless lymphadenopathy.
- ▶ Constitutional symptoms may or may not be present.
- ▶ Pathologic diagnosis by lymph node biopsy.

▶ General Considerations

Hodgkin disease is a group of cancers characterized by Reed–Sternberg cells in an appropriate reactive cellular background. The malignant cell is derived from B lymphocytes of germinal center origin.

▶ Clinical Findings

There is a bimodal age distribution, with one peak in the 20s and a second over age 50 years. Most patients seek medical attention because of a painless mass, commonly in the neck. Others may seek medical attention because of constitutional symptoms such as fever, weight loss, or drenching night sweats, or because of generalized pruritus. An unusual symptom of Hodgkin disease is pain in an involved lymph node following alcohol ingestion.

An important feature of Hodgkin disease is its tendency to arise within single lymph node areas and spread in an orderly fashion to contiguous areas of lymph nodes. Only late in the course of the disease will vascular invasion lead to widespread hematogenous dissemination.

Hodgkin disease is divided into several subtypes: lymphocyte predominance, nodular sclerosis, mixed cellularity, and lymphocyte depletion. Hodgkin disease should be distinguished pathologically from other malignant lymphomas and may occasionally be confused with reactive lymph nodes seen in infectious mononucleosis, cat-scratch disease, or drug reactions (eg, phenytoin).

Patients undergo a staging evaluation to determine the extent of disease. The staging nomenclature (Ann Arbor) is as follows: stage I, one lymph node region involved; stage II, involvement of two lymph node areas on one side of the diaphragm; stage III, lymph node regions involved on both sides of the diaphragm; and stage IV, disseminated disease with bone marrow or liver involvement. In addition, patients are designated stage A if they lack constitutional symptoms and stage B if 10% weight loss over 6 months, fever, or night sweats are present. If symptoms indicate careful evaluation for higher numerical stage, clinical stage IB (for example) is highly likely to emerge as stage II or stage IIIB.

▶ Treatment

The treatment of Hodgkin disease has evolved, with radiation therapy used as initial treatment only for patients with low-risk stage IA and IIA disease. The addition of limited chemotherapy for some patients treated with radiation appears promising.

Most patients with Hodgkin disease (including all with stage IIIB and IV disease) are best treated with combination chemotherapy using doxorubicin (Adriamycin), bleomycin, vincristine, and dacarbazine (ABVD). New shorter and more intensive regimens are being studied, but have not yet proved superior to ABVD.

▶ Prognosis

All patients with both localized and disseminated disease should be treated with curative intent. The prognosis of patients with stage IA or IIA disease treated by radiotherapy is excellent, with 10-year survival rates in excess of 80%. Patients with disseminated disease (IIIB, IV) have 5-year survival rates of 50–60%. Poorer results are seen in patients who are older, those who have bulky disease, and those with lymphocyte depletion or mixed cellularity on histologic examination. The prognosis of those with the lymphocyte-predominant form of the disease is better than in other subtypes, with cure seen in > 70% of those with disseminated disease and with limited treatment needed for those with early-stage disease. Others whose disease recurs after initial radiotherapy treatment may still be curable with chemotherapy. The treatment of choice for patients who relapse after initial chemotherapy is high-dose chemotherapy with autologous stem cell transplantation. This offers a 35–50% chance of cure when disease is still chemotherapy sensitive.

MULTIPLE MYELOMA

ESSENTIALS OF DIAGNOSIS

- ▶ Bone pain, often in the lower back.
- ▶ Monoclonal paraprotein by serum or urine protein electrophoresis or immunofixation.
- ▶ Abnormal plasma cells ≥ 20% of bone marrow.

► General Considerations

Multiple myeloma is a malignancy of plasma cells characterized by replacement of the bone marrow, bone destruction, and paraprotein formation.

Malignant plasma cells can form tumors (plasmacytomas) that may cause spinal cord compression. The pathogenesis of osteoclast activation in myeloma appears to involve osteoprotegerin ligand, and the decoy receptor osteoprotegerin may be able to interfere with this pathway.

The paraproteins secreted by the malignant plasma cells may cause problems in their own right. Very high paraprotein levels (either IgG or IgA) may cause hyperviscosity, though this is more often caused by IgM in Waldenström macroglobulinemia. The light chain component of the immunoglobulin often leads to kidney failure (often aggravated by hypercalcemia). Light chain components may be deposited in tissues as amyloid, worsening kidney failure with albuminuria and causing a vast array of systemic symptoms.

Myeloma patients are prone to recurrent infections for a number of reasons, including neutropenia and the immunosuppressive effects of chemotherapy. More often, there is a failure of antibody production in response to antigen challenge, and myeloma patients are especially prone to infections with encapsulated organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae*.

► Clinical Findings

A. Symptoms and Signs

Myeloma is a disease of older adults (median age at presentation, 65 years). The most common presenting complaints are those related to anemia, bone pain, and infection. Bone pain is most common in the back or ribs or may present as a pathologic fracture, especially of the femoral neck. Patients may also come to medical attention because of kidney failure, spinal cord compression, or the hyperviscosity syndrome (mucosal bleeding, vertigo, nausea, visual disturbances, alterations in mental status). Equally as often, patients are diagnosed because of laboratory findings of hypercalcemia, proteinuria, elevated sedimentation rate, or abnormalities on serum protein electrophoresis obtained for symptoms or in routine screening studies. A few patients come to medical attention because of amyloidosis.

Examination may reveal pallor, bone tenderness, and soft tissue masses. Patients may have neurologic signs related to neuropathy and spinal cord compression. Patients with amyloidosis may have an enlarged tongue, neuropathy, congestive heart failure, or hepatomegaly. Splenomegaly is absent unless amyloidosis is present. Fever occurs only with infection.

B. Laboratory Findings

Anemia is nearly universal. Red blood cell morphology is normal, but rouleau formation is common and may be marked. The neutrophil and platelet counts are usually normal at presentation. Only rarely will plasma cells be visible on peripheral smear (plasma cell leukemia).

The hallmark of myeloma is the finding of a paraprotein on serum protein electrophoresis (SPEP). The majority of patients will have a monoclonal spike visible in the β - or γ -globulin region. Immunofixation (IF) will reveal this to be a monoclonal protein. Approximately 15% of patients will have no demonstrable paraprotein in the serum because their myeloma cells produce only light chains and not intact immunoglobulin, and the light chains pass through the glomerulus into the urine. The paraprotein will be demonstrated by electrophoresis and immunofixation of the urine. A recently developed assay for serum free light chains will similarly demonstrate the abnormality. Overall, approximately 60% of patients with myeloma will have an IgG paraprotein, 25% an IgA, and 15% light chains only. In sporadic cases, no paraprotein is present (“nonsecretory myeloma”); these patients have particularly aggressive disease.

The bone marrow will be infiltrated by variable numbers of plasma cells ranging from 20% to 100%. The plasma cells will occasionally appear normal but more commonly are morphologically abnormal. The plasma cells will display marked skewing of the ratio of kappa to lambda light chain, which will indicate their clonality. Many benign processes can result in plasmacytosis, but the presence of atypical plasma cells, light chain skewing, or effacement of normal bone marrow elements helps distinguish myeloma. Bone radiographs are important in establishing the diagnosis of myeloma. Lytic lesions are most commonly seen in the axial skeleton: skull, spine, proximal long bones, and ribs. At other times, only generalized osteoporosis is seen. The radionuclide bone scan is not useful in detecting bone lesions in myeloma, as there is usually no osteoblastic component. Positron emission tomography (PET) scans will demonstrate significantly more disease than is shown in plain radiographs, but their use has not yet become standard. The International Staging System for myeloma relies on two factors, β_2 -microglobulin and albumin. Stage 1 patients have both β_2 -microglobulin < 3.5 mg/L and albumin ≥ 3.5 ; Stage 3 is diagnosed when β_2 -microglobulin > 5.5 mg/L, and stage 2 is diagnosed with values in between. The other laboratory finding of important prognostic significance is genetic abnormalities diagnosed by FISH involving the immunoglobulin heavy chain locus at chromosome 14q32. The translocations involved are usually t(4;14) and less commonly t(14;16). The previous finding of the adverse prognostic effect of deletions of chromosome 13 now appear to be due to the linkage between 13q deletions and 14q32 abnormalities. Abnormalities of chromosome 17p also appear to confer a poor prognosis. Hypercalcemia is an important laboratory finding in myeloma and is associated with kidney failure.

► Differential Diagnosis

When a patient is discovered to have a monoclonal paraprotein, the distinction between myeloma and monoclonal gammopathy of unknown significance (MGUS) must be made. MGUS is present in 1% of all adults and 3% of adults over age 70 years. Thus, among all patients with paraproteins, MGUS is far more common than myeloma.

Most commonly, patients with MGUS will have a monoclonal IgG spike less than 2.5 g/dL, and the height of the spike remains stable. In approximately 25% of cases, MGUS progresses to overt malignant disease, but this may take many years.

Myeloma is distinguished from MGUS by findings of replacement of the bone marrow, bone destruction, and progression. Although the height of the paraprotein spike should not be used by itself to distinguish benign from malignant disease, nearly all patients with IgG spikes greater than 3.5 g/dL prove to have myeloma; an IgA spike of > 2 g/dL is similarly suggestive. If there is doubt about whether paraproteinemia is benign or malignant, the patient should be observed without therapy, since there is no advantage to early treatment of asymptomatic multiple myeloma.

Myeloma must be distinguished from reactive polyclonal hypergammaglobulinemia. Myeloma may also be similar to other malignant lymphoproliferative diseases such as Waldenström macroglobulinemia, lymphomas, and primary amyloidosis (with which it is commonly associated).

▶ Treatment

Patients with minimal disease or in whom the diagnosis of malignancy is in doubt should be observed without treatment. Most commonly, patients require treatment at diagnosis because of bone pain or other symptoms related to the disease. The initial step in treatment, referred to as “**induction**,” has changed from being based on cytotoxic chemotherapy to being based on other biologic agents. The immunomodulatory agents (IMiDs) have significant activity in myeloma; the second-generation agent lenalidomide is both more active and less toxic than thalidomide and has replaced the older drug in treatment. It is given orally and is generally well tolerated. The major side effect of lenalidomide is cumulative myelosuppression, and some type of prophylaxis is needed to prevent deep venous thrombosis. Bortezomib, a proteasome inhibitor, is also highly active and has the advantages of producing rapid responses and of being effective in poor-prognosis myeloma. The major side effect of bortezomib is neuropathy (both peripheral and autonomic), and it has the disadvantage of requiring frequent intravenous administration. At the present time, induction therapy should include dexamethasone and either lenalidomide or bortezomib or both. The combination of bortezomib, dexamethasone, and the chemotherapeutic agent doxorubicin liposomal is also highly successful.

After induction therapy, the optimal **consolidation therapy** for patients under age 70 years with myeloma is autologous stem cell transplantation. Early aggressive treatment prolongs both duration of remission and overall survival, and has the advantage of providing long treatment-free intervals. Clinical trials are evaluating the role of posttransplant maintenance therapy with agents such as lenalidomide. For young patients with aggressive disease, autologous transplant followed by a reduced-intensity allogeneic transplant is under active investigation.

Allogeneic transplantation is potentially curative in myeloma, but its role has been limited because of the unusually high mortality rate (40–50%) in myeloma patients.

Newer and less toxic forms of allogeneic transplantation using nonmyeloablative regimens have produced encouraging results, especially when performed early in the course of disease, such as the minimal disease state following autologous stem cell transplantation.

Localized radiotherapy may be useful for palliation of bone pain or for eradicating tumor at the site of pathologic fracture. Hypercalcemia should be treated aggressively and immobilization and dehydration avoided. The bisphosphonates (pamidronate 90 mg or zoledronic acid 4 mg intravenously monthly) reduce pathologic fractures in patients with significant bony disease and are an important adjunct in this subset of patients. However, long-term zoledronate has been associated with a risk of osteonecrosis of the jaw, and patients must be monitored for this complication.

▶ Prognosis

The outlook for patients with myeloma has been steadily improving for the past decade. The median survival of patients is now between 4 and 6 years, and it is possible that the use of newly approved agents will result in further survival gains. Patients with low-stage disease (low β_2 -microglobulin and normal albumin) who lack the high-risk genomic changes involving chromosome 14q32 respond very well to treatment and derive significant benefit from autologous stem cell transplantation as part of initial therapy. With modern treatment, expected survivals for such patients are in excess of 6 years. Novel approaches, possibly involving allogeneic stem cell transplantation, are being studied to try to improve the outlook for patients with high-risk disease.

▶ When to Refer

All patients with myeloma should be referred to a hematologist or an oncologist.

▶ When to Admit

Hospitalization is indicated for treatment of acute kidney failure, hypercalcemia, or suspicion of spinal cord compression.

WALDENSTRÖM MACROGLOBULINEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Monoclonal IgM paraprotein.
- ▶ Infiltration of bone marrow by plasmacytic lymphocytes.
- ▶ Absence of lytic bone disease.

▶ General Considerations

Waldenström macroglobulinemia is a malignant disease of B cells that appear to be a hybrid of lymphocytes and plasma cells. These cells characteristically secrete an IgM paraprotein, and many clinical manifestations of the disease are related to this macroglobulin.

▶ Clinical Findings

A. Symptoms and Signs

This disease characteristically develops insidiously in patients in their 60s or 70s. Patients usually present with fatigue related to anemia. Hyperviscosity of serum may be manifested in a number of ways. Mucosal and gastrointestinal bleeding are related to engorged blood vessels and platelet dysfunction. Other complaints include nausea, vertigo, and visual disturbances. Alterations in consciousness vary from mild lethargy to stupor and coma. The IgM paraprotein may also cause symptoms of cold agglutinin disease or peripheral neuropathy.

On examination, there may be hepatosplenomegaly or lymphadenopathy. The retinal veins are engorged. Purpura may be present. There should be no bone tenderness.

B. Laboratory Findings

Anemia is nearly universal, and rouleau formation is common. The anemia is related in part to expansion of the plasma volume by 50–100% due to the presence of the paraprotein. Other blood counts are usually normal. The abnormal plasmacytic lymphocytes usually appear in small numbers on the peripheral blood smear. The bone marrow is characteristically infiltrated by the plasmacytic lymphocytes.

The hallmark of macroglobulinemia is the presence of a monoclonal IgM spike seen on SPEP in the β - or γ -globulin region. The serum viscosity is usually increased above the normal of 1.4–1.8 times that of water. Symptoms of hyperviscosity usually develop when the serum viscosity is over four times that of water, and marked symptoms usually arise when the viscosity is over six times that of water. Because paraproteins vary in their physicochemical properties, there is no strict correlation between the concentration of paraprotein and serum viscosity.

The IgM paraprotein may cause a positive Coombs test or have cold agglutinin or cryoglobulin properties. If macroglobulinemia is suspected but the SPEP shows only hypogammaglobulinemia, the test should be repeated while taking special measures to maintain the blood at 37 °C,

since the paraprotein may precipitate out at room temperature if it is cryoprecipitable.

Bone radiographs are normal, and there is no evidence of kidney failure.

▶ Differential Diagnosis

Waldenström macroglobulinemia is differentiated from monoclonal gammopathy of unknown significance by the finding of bone marrow infiltration. It is distinguished from chronic lymphocytic leukemia and multiple myeloma by bone marrow morphology and the finding of the characteristic IgM spike, and also on clinical grounds.

▶ Treatment

Patients with marked hyperviscosity syndrome (stupor or coma) should be treated on an emergency basis with plasmapheresis. On a chronic basis, some patients can be managed with periodic plasmapheresis alone. As with other indolent lymphoid diseases, fludarabine and rituximab have replaced alkylator-based chemotherapy for initial therapy.

As with multiple myeloma, autologous stem cell transplantation is playing a more important role in management and is considered in younger patients with more aggressive disease.

▶ Prognosis

Waldenström macroglobulinemia is an indolent disease with a median survival rate of 3–5 years. However, patients may survive 10 years or longer.

▶ When to Refer

All patients should be referred to a hematologist or an oncologist.

▶ When to Admit

Patients should be admitted for treatment of hyperviscosity syndrome.

STEM CELL TRANSPLANTATION

Stem cell transplantation using hematopoietic stem cells is an extremely valuable treatment for a variety of hematologic malignancies and is also used in a few non-hematologic cancers and some nonmalignant conditions. In many cases, stem cell transplantation offers the only curative option for some types of cancer and can be a life-saving procedure.

The basis of treatment with stem cell transplantation is the ability of the hematopoietic stem cell to completely restore bone marrow function and formation of all blood

components, as well as the ability to re-form the immune system. These hematopoietic stem cells were formerly collected from the bone marrow but are now more commonly collected from the peripheral blood after maneuvers to mobilize them from the bone marrow into the blood.

In the field of cancer chemotherapy, the dose-limiting toxicity of almost all chemotherapy has been myelosuppression, that is, damage to the bone marrow. It is typical during the administration of chemotherapy for blood counts to be transiently suppressed and to have to wait for recovery of the blood in order to safely give the next treatment. However, if too high a dose of chemotherapy is given, it is possible to damage the bone marrow beyond recovery, and for the blood counts to never return to within normal ranges. For cancers for which there is a dose-response relationship, that is, a relationship between the dose of chemotherapy administered and the number of cancer cells killed, the limits placed on the allowable dose of chemotherapy can make the difference between cure and failure to cure. In stem cell transplantation, the limit placed on the allowable dose of chemotherapy by the risks of permanent bone marrow damage is eliminated and much higher doses of chemotherapy can be given, since re-infusion of hematopoietic stem cells can completely restore the bone marrow.

AUTOLOGOUS STEM CELL TRANSPLANTATION

Autologous stem cell transplantation is a treatment in which hematopoietic stem cells are collected from the patient and then re-infused after chemotherapy. Therefore, autologous stem cell transplantation relies solely for its effectiveness on the ability to give much higher doses of chemotherapy than would otherwise be possible. In this procedure, the hematopoietic stem cells are usually collected from the patient's peripheral blood. First, the hematopoietic stem cells are mobilized from the bone marrow into the blood. This can be accomplished by a variety of techniques, most commonly the use of myeloid growth factors such as filgrastim (granulocyte-colony stimulating factor, G-CSF) either alone or in combination with chemotherapy. The investigational agent plerixafor can also mobilize these cells into the blood. During the process of leukopheresis the patient's blood is centrifuged into layers of different densities; the hematopoietic stem cells are collected from the appropriate layer while the remainder of the blood elements are returned unchanged to the patient. After collection, these autologous hematopoietic stem cells are frozen and cryopreserved for later use. Treatment with autologous stem cell transplantation involves administration of high-dose chemotherapy (referred to as the "preparative regimen") followed, after clearance of the chemotherapy out of the patient's system, by intravenous re-infusion of the thawed autologous hematopoietic stem cells. The hematopoietic stem cells home to the bone marrow and grow into new bone marrow cells.

With the autologous stem cell transplantation treatment, there is a period of severe pancytopenia during the gap between myelosuppression caused by the chemotherapy and the recovery produced from the new bone marrow derived from the infused hematopoietic stem cells. This

period of pancytopenia typically lasts 7–10 days and requires support with transfusions of red blood cells and platelets as well as antibiotics. Hospitalization to receive such treatment usually lasts 2–3 weeks. The morbidity of such a treatment varies according to the type of chemotherapy used, and the chance of fatal treatment-related complications is between 1% and 4%.

Autologous stem cell transplantation has the potential to cure cancers that would otherwise be fatal. Autologous stem cell transplantation is the treatment of choice for lymphomas such as diffuse large B-cell lymphomas that have recurred after initial chemotherapy but are still responsive to chemotherapy. It is similarly also the treatment of choice for relapsed Hodgkin lymphoma that still responds to chemotherapy, and for testicular germ cell cancers that have recurred. Autologous stem cell transplantation is also the treatment of choice for mantle cell lymphomas in first remission. Autologous stem cell transplantation also plays an important role in the treatment of AML in both first and second remission and is potentially curative in these settings. Autologous stem cell transplantation is currently part of the standard of care for the treatment of multiple myeloma, based not on curative potential, but the prolongation of remission.

ALLOGENEIC STEM CELL TRANSPLANTATION

Allogeneic stem cell transplantation is a treatment in which the source of hematopoietic stem cells to restore bone marrow and immune function are derived, not from the patient, but from a different donor. Initially allogeneic stem cell transplantation was thought to derive its effectiveness from the high-dose chemotherapy (or radiation plus chemotherapy) that forms the "preparative regimen" in a manner similar to autologous stem cell transplantation. However, it is now known that there is a second type of effector mechanism in allogeneic stem cell transplantation, the allo-immune graft-versus-malignancy (GVM) effect derived from the donor immune system. In some cases, this GVM effect can be more important than the chemotherapy in producing a cure of disease.

In order to perform an allogeneic stem cell transplantation, an appropriate donor of hematopoietic stem cells must be located. At the present time, it is important that the donor be matched with the patient (recipient) at the HLA loci (HLA A, B, C, DR) that specify major histocompatibility antigens. These donors may be full siblings or unrelated donors recruited from a large panel of anonymous volunteer donors through the National Marrow Donor Program (NMDP). Cells derived from umbilical cord blood units may also be used. The hematopoietic stem cells are collected from the donor either from the bone marrow, or, more commonly through leukopheresis of the blood after mobilizing hematopoietic stem cells from the bone marrow with filgrastim (G-CSF). They are infused intravenously into the recipient and may be given either fresh or after cryopreservation and thawing. The hematopoietic stem cells home to the bone marrow and start to grow.

In the allogeneic stem cell transplantation procedure, the patient is treated with the "preparative regimen" with two

purposes: to treat the underlying cancer and to sufficiently suppress the patient's immune system so that the hematopoietic stem cells from the donor will not be rejected. As with autologous stem cell transplantation, the hematopoietic stem cells are infused after the preparative chemotherapy has been given and has had a chance to clear from the body. There is a period of pancytopenia in the gap between the effect of the chemotherapy given to the patient and the time it takes the infused hematopoietic stem cells to grow into bone marrow, usually 10–14 days.

A major difference between autologous and allogeneic SCT is that in the allogeneic setting, the patient becomes a “chimera”, that is, a mixture of self and non-self. In allogeneic stem cell transplantation, the infused cells contain mature cells of the donor immune system, and the infused hematopoietic stem cells will grow into bone marrow and blood cells as well as cells of the new immune system. Unless the donor is an identical twin (called a “syngeneic transplant”), the donor's immune system will recognize the patient's tissues as foreign and initiate the “graft-versus-host” (GVH) reaction, the graft from the donor reacting against the patient (host). This GVH is the major cause of morbidity and mortality during an allogeneic SCT. Immunosuppression must be given during allogeneic stem cell transplantation to reduce the incidence and severity of GVH reaction. The most common regimen used for GVH prophylaxis is a combination of a calcineurin inhibitor (cyclosporine or tacrolimus) plus methotrexate. In contrast to the experience with solid organ transplant in which life-long immunosuppression is required to prevent rejection of the transplanted organ, in most cases of allogeneic stem cell transplantation, the immunosuppression can be tapered and discontinued 6 or more months after transplantation.

However, there is an important and positive side to the allo-immune reaction of the donor against the host. If there are residual cancer cells present in the patient that have survived the high-dose chemoradiotherapy of the preparative regimen, these residual cancer cells can be recognized as foreign by the donor immune system and killed in the GVM effect. Even cells that are resistant to chemotherapy may not be resistant to killing through the immune system. Depending on the type of cancer cell, this can be a highly effective mechanism of long-term cancer control. Based on the understanding of how important GVM can be, the allogeneic stem cell transplantation procedure can be modified by reducing the intensity of the preparative regimen, relying for cure more on the GVM effect and less on the high-dose chemotherapy. In these “reduced-intensity” allogeneic stem cell transplantation procedures, the preparative regimen still has to suppress the patient's immune system enough to avoid rejection of the donor hematopoietic stem cells, but these types of transplants can be far less toxic than full-dose transplants. Based on this greatly reduced short-term toxicity, the potential benefits of allogeneic stem cell transplantation have been extended to older adults (age 60–75) and to those with comorbid conditions that would have been a contraindication to standard full-dose stem cell transplantation.

Allogeneic stem cell transplantation is the treatment of choice for high-risk acute leukemias, and in many cases will be the only potentially curative treatment. Allogeneic

stem cell transplantation is the only curative treatment for myelodysplasia and for CML, although its use in CML has been greatly curtailed based on the effectiveness of imatinib and related tyrosine kinase inhibitors. Allogeneic stem cell transplantation is also the only definitive treatment for most cases of severe aplastic anemia. The use of reduced-intensity allogeneic stem cell transplantation has led to its exploration in the management of difficult cases of CLL and follicular lymphoma, and it will likely play a major role in these diseases. Given the age of many patients with AML and myelodysplasia, this procedure will likely play an important role in these diseases as well.

BLOOD TRANSFUSIONS

RED BLOOD CELL TRANSFUSIONS

Red blood cell transfusions are given to raise the hematocrit levels in patients with anemia or to replace losses after acute bleeding episodes.

▶ Preparations of Red Cells for Transfusion

Several types of preparations containing red blood cells are available.

A. Fresh Whole Blood

The advantage of whole blood for transfusion is the simultaneous presence of red blood cells, plasma, and fresh platelets. Fresh whole blood is never absolutely necessary, since all the above components are available separately. The major indications for use of whole blood are cardiac surgery or massive hemorrhage when more than 10 units of blood is required in a 24-hour period.

B. Packed Red Blood Cells

Packed red cells are the component most commonly used to raise the hematocrit. Each unit has a volume of about 300 mL, of which approximately 200 mL consists of red blood cells. One unit of packed red cells will usually raise the hematocrit by approximately 4%. The expected rise in hematocrit can be calculated using an estimated red blood cell volume of 200 mL/unit and a total blood volume of about 70 mL/kg. For example, a 70-kg man will have a total blood volume of 4900 mL, and each unit of packed red blood cells will raise the hematocrit by $200 \div 4900$, or 4%.

C. Leukocyte-Poor Blood

Patients with severe leukoagglutinin reactions to packed red blood cells may require depletion of white blood cells

and platelets from transfused units. White blood cells can be removed either by centrifugation or by washing. Preparation of leukocyte-poor blood is expensive and leads to some loss of red cells.

D. Frozen Blood

Red blood cells can be frozen and stored for up to 3 years, but the technique is cumbersome and expensive, and frozen blood should be used sparingly. The major application is for the purpose of maintaining a supply of rare blood types. Patients with such types may donate units for autologous transfusion should the need arise. Frozen red cells are also occasionally needed for patients with severe leukoagglutinin reactions or anaphylactic reactions to plasma proteins, since frozen blood has essentially all white blood cells and plasma components removed.

E. Autologous Packed Red Blood Cells

Patients scheduled for elective surgery may donate blood for autologous transfusion. These units may be stored for up to 35 days.

▶ Compatibility Testing

Before transfusion, the recipient's and the donor's blood are cross-matched to avoid hemolytic transfusion reactions. Although many antigen systems are present on red blood cells, only the ABO and Rh systems are specifically tested prior to all transfusions. The A and B antigens are the most important, because everyone who lacks one or both red cell antigens has isoantibodies against the missing antigen or antigens in his or her plasma. These antibodies activate complement and can cause rapid intravascular lysis of the incompatible red cells. In emergencies, type O blood can be given to any recipient, but only packed cells should be given to avoid transfusion of donor plasma containing anti-A or anti-B antibodies.

The other important antigen routinely tested for is the D antigen of the Rh system. Approximately 15% of the population lack this antigen. In patients lacking the antigen, anti-D antibodies are not naturally present, but the antigen is highly immunogenic. A recipient whose red cells lack D and who receives D-positive blood may develop anti-D antibodies that can cause severe lysis of subsequent transfusions of D-positive red cells.

Blood typing includes assay of recipient serum for unusual antibodies by mixing the serum with panels of red cells representing commonly occurring weak antigens. The screening is particularly important if the recipient has had previous transfusions.

▶ Hemolytic Transfusion Reactions

The most severe reactions are those involving mismatches in the ABO system. Most of these cases are due to clerical errors and mislabeled specimens. Hemolysis is rapid and intravascular, releasing free hemoglobin into the plasma. The severity of these reactions depends on the dose of red blood cells given. The most severe reactions are those seen in surgical patients under anesthesia.

Hemolytic transfusion reactions caused by minor antigen systems are typically less severe. The hemolysis usually takes place at a slower rate and is extravascular. Sometimes these transfusion reactions may be delayed for 5–10 days after transfusion. In such cases, the recipient has received blood containing an immunogenic action, and in the time since transfusion, a new alloantibody has been formed. The most common antigens involved in such reactions are Duffy, Kidd, Kell, and C and E loci of the Rh system.

A. Symptoms and Signs

Major hemolytic transfusion reactions cause fever and chills, with backache and headache. In severe cases, there may be apprehension, dyspnea, hypotension, and vascular collapse. *The transfusion must be stopped immediately.* In severe cases, DIC, acute kidney failure from tubular necrosis, or both can occur.

Patients under general anesthesia will not manifest such signs, and the first indication may be generalized bleeding and oliguria.

B. Laboratory Findings

Identification of the recipient and of the blood should be checked. The donor transfusion bag with its pilot tube must be returned to the blood bank, and a fresh sample of the recipient's blood must accompany the donor bag for retyping of donor and recipient blood samples and for repeat of the cross-match.

The hematocrit will fail to rise by the expected amount. Coagulation studies may reveal evidence of kidney failure and DIC. Hemoglobinemia will turn the plasma pink and eventually result in hemoglobinuria. In cases of delayed hemolytic reactions, the hematocrit will fall and the indirect bilirubin will rise. In these cases, the new offending alloantibody is easily detected in the patient's serum.

C. Treatment

If a hemolytic transfusion reaction is suspected, the transfusion should be stopped at once. A sample of anticoagulated blood from the recipient should be centrifuged to detect free hemoglobin in the plasma. If hemoglobinemia is present, the patient should be vigorously hydrated to prevent acute tubular necrosis. Forced diuresis with mannitol may help prevent kidney damage.

▶ Leukoagglutinin Reactions

Most transfusion reactions are not hemolytic but represent reactions to antigens present on white blood cells in patients who have been sensitized to the antigens through previous transfusions or pregnancy. Most commonly, patients will develop fever and chills within 12 hours after transfusion. In severe cases, cough and dyspnea may occur and the chest radiograph may show transient pulmonary infiltrates. Because no hemolysis is involved, the hematocrit rises by the expected amount despite the reaction.

Leukoagglutinin reactions may respond to acetaminophen and diphenhydramine; corticosteroids are also of

value. Removal of leukocytes by filtration before blood storage will reduce the incidence of these reactions.

▶ Anaphylactic Reactions

Rarely, patients will develop urticaria or bronchospasm during a transfusion. These reactions are almost always due to plasma proteins rather than white blood cells. Patients who are IgA deficient may develop these reactions because of antibodies to IgA. Patients with such reactions may require transfusion of washed or even frozen red blood cells to avoid future severe reactions.

▶ Contaminated Blood

Rarely, blood is contaminated with gram-negative bacteria. Transfusion can lead to septicemia and shock from endotoxin. If this is suspected, the offending unit should be cultured and the patient treated with antibiotics as indicated.

▶ Diseases Transmitted Through Transfusion

Despite the use of only volunteer blood donors and the routine screening of blood, transfusion-associated viral diseases remain a problem. All blood products (red blood cells, platelets, plasma, cryoprecipitate) can transmit viral diseases. All blood donors are screened with questionnaires designed to detect donors at high risk of transmitting diseases. All blood is now screened for hepatitis B surface antigen, antibody to hepatitis B core antigen, syphilis, p24 antigen and antibody to HIV, antibody to hepatitis C virus (HCV), antibody to human T cell lymphotropic/leukemia virus (HTLV), and antibody to West Nile virus.

With improved screening, the risk of posttransfusion hepatitis has steadily decreased. The risk of hepatitis B is 1:200,000 per unit and of HIV 1:250,000 per unit. The risk of seroconversion to HTLV is 1:70,000, but clinical sequelae when this occurs are rare. The major infectious risk of blood products is hepatitis C, with a seroconversion rate of 1:3300 per unit transfused. Most of these cases are clinically silent, but there is a high incidence of chronic hepatitis.

PLATELET TRANSFUSION

Platelet transfusions are indicated in cases of thrombocytopenia due to decreased platelet production. They are not useful in immune thrombocytopenia, since transfused platelets will last no longer than the patient's endogenous platelets. The risk of spontaneous bleeding rises when the platelet count falls to less than 10,000/mcL, and the risk of life-threatening bleeding increases when the platelet count is less than 5000/mcL. Because of this, prophylactic platelet transfusions are often given at these very low levels. Platelet transfusions are also given prior to invasive procedures or surgery, and the goal should be to raise the platelet count to over 50,000/mcL.

Platelets are most commonly derived from donated blood units. One unit of platelets (derived from 1 unit of blood) usually contains $5-7 \times 10^{10}$ platelets suspended in

35 mL of plasma. Ideally, 1 platelet unit will raise the recipient's platelet count by 10,000/mcL, and transfused platelets will last for 2 or 3 days. However, responses are often suboptimal, with poor platelet increments and short survival times. This may be due to sepsis, splenomegaly, or alloimmunization. Most alloantibodies causing platelet destruction are directed at HLA antigens. Patients requiring long periods of platelet transfusion support should be monitored to document adequate responses to transfusions so that the most appropriate product can be used. Patients may benefit from HLA-matched platelets derived from either volunteer donors or family members, with platelets obtained by plateletpheresis. Techniques of cross-matching platelets have been developed and appear to identify suitable platelet donors (nonreactive with the patient's serum) without the need for HLA typing. Such single-donor platelets usually contain the equivalent of six units of random platelets, or $30-50 \times 10^{10}$ platelets suspended in 200 mL of plasma. Ideally, these platelet concentrates will raise the recipient's platelet count by 60,000/mcL. Leukocyte depletion of platelets has been shown to delay the onset of alloimmunization.

GRANULOCYTE TRANSFUSIONS

Granulocyte transfusions are seldom indicated and have largely been replaced by the use of myeloid growth factors (G-CSF and GM-CSF) that speed neutrophil recovery. However, they may be beneficial in patients with profound neutropenia ($< 100/\text{mcL}$) who have gram-negative sepsis or progressive soft tissue infection despite optimal antibiotic therapy. In these cases, it is clear that progressive infection is due to failure of host defenses. In such situations, daily granulocyte transfusions should be given and continued until the neutrophil count rises to above 500/mcL. Such granulocytes must be derived from ABO-matched donors. Although HLA matching is not necessary, it is preferred, since patients with alloantibodies to donor white blood cells will have severe reactions and no benefit.

The donor cells usually contain some immunocompetent lymphocytes capable of producing graft-versus-host disease in HLA-incompatible hosts whose immunocompetence may be impaired. Irradiation of the units of cells with 1500 cGy will destroy the lymphocytes without harm to the granulocytes or platelets.

TRANSFUSION OF PLASMA COMPONENTS

Fresh-frozen plasma is available in units of approximately 200 mL. Fresh plasma contains normal levels of all coagulation factors (about 1 unit/mL). Fresh frozen plasma is

used to correct coagulation factor deficiencies and to treat TTP. The risk of transmitting viral disease is comparable to that associated with transfusion of red blood cells.

Cryoprecipitate is made from fresh plasma. One unit has a volume of approximately 20 mL and contains approxi-

mately 250 mg of fibrinogen and between 80 and 100 units of factor VIII and vWF. Cryoprecipitate is used to supplement fibrinogen in cases of congenital deficiency of fibrinogen or DIC. One unit of cryoprecipitate will raise the fibrinogen level by about 8 mg/dL.

Disorders of Hemostasis, Thrombosis, & Antithrombotic Therapy

Patrick F. Fogarty, MD
Tracy Minichiello, MD

In assessing patients for defects of hemostasis, the clinical context must be considered carefully (Table 14–1). Heritable defects are suggested by bleeding that begins in infancy or childhood, is recurrent, and occurs at multiple anatomic sites, although many other patterns of presentation are possible. Acquired disorders of hemostasis more typically are associated with bleeding that begins later in life and may be relatable to introduction of medications (eg, agents that affect platelet activity) or to onset of underlying medical conditions (such as renal failure or myelodysplasia), or may be idiopathic. Importantly, however, a sufficient hemostatic challenge (such as major trauma) may produce excessive bleeding even in individuals with completely normal hemostasis.

Fogarty PF et al. Disorders of Hemostasis I: Coagulation. In: *The Bethesda Handbook of Clinical Hematology*. Rodgers GP, Young NS (editors). Philadelphia: Lippincott Williams and Wilkins; 2005.

PLATELET DISORDERS

THROMBOCYTOPENIA

The causes of thrombocytopenia are shown in Table 14–2. The age of the patient and presence of any comorbid conditions may help direct the diagnostic work-up.

The risk of spontaneous bleeding (including petechial hemorrhage and bruising) does not typically increase appreciably until the platelet count falls below 10,000–20,000/mcL, although patients with dysfunctional platelets may bleed with higher platelet counts. Suggested platelet counts to prevent spontaneous bleeding or to provide adequate hemostasis around the time of invasive procedures are found in Table 14–3.

DECREASED PLATELET PRODUCTION

1. Bone Marrow Failure

ESSENTIALS OF DIAGNOSIS

- ▶ Bone marrow failure states may be congenital or acquired.
- ▶ Most congenital marrow failure disorders present in childhood.

▶ General Considerations

Congenital conditions that cause thrombocytopenia include amegakaryocytic thrombocytopenia, the thrombocytopenia-absent radius (TAR) syndrome, and Wiskott-Aldrich syndrome; these disorders usually feature isolated thrombocytopenia, whereas patients with Fanconi anemia and dyskeratosis congenita typically have depressions in other blood cell counts as well.

Acquired causes of bone marrow failure leading to thrombocytopenia include acquired aplastic anemia, myelodysplastic syndrome (MDS), and acquired amegakaryocytic thrombocytopenia. Unlike aplastic anemia, MDS is more common among older patients.

▶ Clinical Findings

Acquired **aplastic anemia** typically presents with reductions in multiple blood cell lines; a bone marrow biopsy subsequently reveals hypocellularity. **Myelodysplasia** may also present as cytopenias with variable marrow cellularity, at times mimicking aplastic anemia; however, the presence of macrocytosis, ringed sideroblasts on iron staining of the bone marrow aspirate, dysplasia of hematopoietic ele-

Table 14-1. Evaluation of the bleeding patient.

| Necessary Component of Evaluation | Diagnostic Correlate |
|--|--|
| Location | |
| Mucocutaneous (bruises, petechiae, gingival, nosebleeds) | Likely qualitative/quantitative platelet defects |
| Joints, soft tissue | Likely disorders of coagulation factors |
| Onset | |
| Infancy/childhood | Suggests heritable condition |
| Adulthood | Suggests milder heritable condition or acquired defect of hemostasis (eg, ITP, medication-related) |
| Clinical context | |
| Postsurgical | Anatomic/surgical defect must be ruled out |
| Pregnancy | vWD, HELLP syndrome, ITP, acquired factor VIII inhibitor |
| Sepsis | May indicate DIC |
| Patient taking anticoagulants | Rule out excessive anticoagulation |
| Personal history¹ | |
| Absent | Suggests acquired rather than congenital defect, or anatomic/surgical defect (if applicable) |
| Present | Suggests established acquired defect or congenital disorder |
| Family history | |
| Absent | Suggests acquired defect or no defect of hemostasis |
| Present | May signify hemophilia A or B, vWD, other heritable bleeding disorders |

¹Includes evaluation of prior spontaneous bleeding, as well as excessive bleeding with circumcision, menses, dental extractions, trauma, minor procedures (eg, endoscopy, biopsies) and major procedures (surgery).

DIC, disseminated intravascular coagulation; HELLP, hemolysis, elevated liver enzymes, low platelets; ITP, immune thrombocytopenic purpura; vWD, von Willebrand disease.

ments, or cytogenetic abnormalities (especially monosomy 5 or 7, and trisomy 8) are more suggestive of MDS. Thrombocytopenia in patients with MDS is usually mild to moderate, rather than severe.

► Differential Diagnosis

Adult patients with acquired amegakaryocytic thrombocytopenia have isolated thrombocytopenia and reduced or absent megakaryocytes in the bone marrow, which (along with failure to respond to immunomodulatory regimens typically administered in immune thrombocytopenic purpura [ITP]) distinguishes them from patients with ITP.

Table 14-2. Causes of thrombocytopenia.

| |
|---|
| Decreased production of platelets |
| Congenital bone marrow failure (eg, Fanconi anemia, Wiskott-Aldrich syndrome) |
| Acquired bone marrow failure (eg, aplastic anemia, myelodysplasia) |
| Exposure to chemotherapy, irradiation |
| Marrow infiltration (neoplastic, infectious) |
| Nutritional (deficiency of vitamin B ₁₂ , folate, iron; alcohol) |
| Increased destruction of platelets |
| Immune thrombocytopenic purpura (including hepatitis C virus- and HIV-related, ¹ and drug-induced) |
| Heparin-induced thrombocytopenia |
| Thrombotic microangiopathy |
| Disseminated intravascular coagulation |
| Posttransfusion purpura |
| Neonatal alloimmune thrombocytopenia |
| Mechanical (aortic valvular dysfunction; extracorporeal bypass) |
| von Willebrand disease, type 2B |
| Hemophagocytosis |
| Increased sequestration of platelets |
| Hypersplenism (eg, related to cirrhosis, myeloproliferative disorders, lymphoma) |
| Other conditions causing thrombocytopenia |
| Gestational thrombocytopenia |
| Bernard-Soulier syndrome, gray platelet syndrome, May-Hegglin anomaly |
| Pseudothrombocytopenia |

¹HIV-related thrombocytopenia as well as disorders such as some cases of immune thrombocytopenia and cyclic thrombocytopenia may feature both decreased production and increased clearance of platelets.

► Treatment

A. Congenital Conditions

Treatment is varied but may include blood product support, blood cell growth factors, androgens, and (some cases) allogeneic hematopoietic progenitor cell transplantation.

B. Acquired Conditions

Patients with severe aplastic anemia are treated with allogeneic hematopoietic progenitor cell transplantation,

Table 14-3. Desired platelet count ranges.

| Clinical Scenario | Platelet count (/mcl) |
|---|------------------------------|
| Prevention of spontaneous mucocutaneous bleeding | > 10,000–20,000 |
| Insertion of central venous catheters | > 20,000–50,000 ¹ |
| Administration of therapeutic anticoagulation | > 30,000–50,000 |
| Minor surgery and selected invasive procedures ² | > 50,000–80,000 |
| Major surgery | > 80,000–100,000 |

¹A platelet target within the higher range of the reference is required for tunneled catheters.

²Such as endoscopy with biopsy.

which is the preferred therapy for patients younger than age 40 who have an HLA-matched sibling donor (see Chapter 13), or with immunosuppression, which is the preferred therapy for older patients and those who lack an HLA-matched sibling donor.

Treatments of thrombocytopenia due to MDS, if clinically significant bleeding is present or if the risk of bleeding is high, is limited to chronic transfusion of platelets in most instances (Table 14–3). Newer immunomodulatory agents such as lenalidomide do not produce increases in the platelet count in most patients.

Kantarjian H et al. The incidence and impact of thrombocytopenia in myelodysplastic syndromes. *Cancer*. 2007 May 1;109(9):1705–14. [PMID: 17366593]

2. Bone Marrow Infiltration

Massive replacement of the bone marrow by leukemic cells, myeloma, lymphoma, or other tumors may cause thrombocytopenia; however, abnormalities in other blood cell lines are also usually present. The same is true for infectious causes leading to marrow infiltration (mycobacterial disease, ehrlichiosis). These entities are easily diagnosed after examining the bone marrow biopsy and aspirate or determining the infecting organism from an aspirate specimen. Treatment of thrombocytopenia is directed at eradication of the underlying infiltrative disorder, but platelet transfusion may be required if clinically significant bleeding is present.

3. Chemotherapy & Irradiation

Chemotherapeutic agents and irradiation may lead to thrombocytopenia by direct toxicity to megakaryocytes, hematopoietic progenitor cells, or both. The severity and duration of chemotherapy-induced depressions in the platelet count are determined by the specific regimen used, although the platelet count typically resolves more slowly following a chemotherapeutic insult than does neutropenia or anemia, especially if multiple cycles of treatment have been given. Until recovery occurs, patients may be supported with transfused platelets if bleeding is present or the risk of bleeding is high (Table 14–3). Drug applications of novel platelet growth factors (eltrombopag, romiplostim) are underway for the treatment of chemotherapy-induced thrombocytopenia, whereas use of an existing recombinant IL-11-like cytokine (oprelvekin) has been limited by significant drug-related toxicities.

4. Nutritional Deficiencies

Thrombocytopenia, typically in concert with anemia, may be observed when a deficiency of folate (that may accompany alcoholism) or vitamin B₁₂ is present (concomitant neurologic findings are common). In addition, thrombocytopenia rarely can occur in very severe iron deficiency. Replacing the deficient vitamin or mineral results in improvement in the platelet count.

5. Cyclic Thrombocytopenia

Cyclic thrombocytopenia is a very rare disorder that produces cyclic oscillations of the platelet count, usually with a

periodicity of 3–6 weeks. The exact pathophysiologic mechanisms responsible for the condition may vary from patient to patient. Severe thrombocytopenia and bleeding typically occur at the platelet nadir. Identification of the endogenous cyclic phenomenon may be difficult because of the usual practice of providing treatment (platelet transfusion or otherwise) at times of very low platelet counts. Oral contraceptive medications, androgens, azathioprine, and thrombopoietic growth factors have been used successfully in the management of cyclic thrombocytopenia.

Bussell JB et al. Eltrombopag for the treatment of chronic idiopathic thrombocytopenic purpura. *N Engl J Med*. 2007 Nov 29;357(22):2237–47. [PMID: 18046028]

Fogarty PF et al. Large granular lymphocytic proliferation-associated cyclic thrombocytopenia. *Am J Hematol*. 2005 Aug;79(4):334–6. [PMID: 16044437]

INCREASED PLATELET DESTRUCTION

1. Immune Thrombocytopenic Purpura

ESSENTIALS OF DIAGNOSIS

- ▶ Isolated thrombocytopenia.
- ▶ Assess for any new causative medications and HIV and hepatitis C infections.
- ▶ ITP is a diagnosis of exclusion.

▶ General Considerations

ITP is an autoimmune condition in which pathogenic antibodies bind platelets, resulting in accelerated platelet clearance. The disorder is primary and idiopathic in most adult patients, although it can be associated with connective tissue disease (such as lupus), lymphoproliferative disease (such as lymphoma), medications, and infections (such as hepatitis C virus and HIV infections). Targets of antiplatelet antibodies include glycoproteins IIb/IIIa and Ib/IX on the platelet membrane, although antibodies are demonstrable in only two-thirds of patients. The mechanisms underlying drug-induced thrombocytopenia are thought in most cases to be immune, although exceptions exist (such as chemotherapy). Table 14–4 lists medications associated with thrombocytopenia. HIV and hepatitis C virus both are associated with thrombocytopenia that has immune-mediated underpinnings and can respond to immunomodulation, although both also may lead to thrombocytopenia through additional mechanisms (for instance, by direct suppression of platelet production [HIV] and cirrhosis-related splenomegaly [hepatitis C virus]).

▶ Clinical Findings

A. Symptoms and Signs

Mucocutaneous bleeding manifestations may be present, depending on the platelet count. The typical presentation of **drug-induced thrombocytopenia** is severe thrombocytopenia and mucocutaneous bleeding 7–14 days after

Table 14-4. Medications causing drug-associated thrombocytopenia.

| Class | Examples |
|--------------------------|---|
| Chemotherapy | Most agents |
| Antiplatelet agents | Anagrelide Abciximab Eptifibatid Tirofiban Ticlopidine |
| Antimicrobial agents | Penicillins Isoniazid Rifampin Sulfa drugs Vancomycin Adefovir Indinavir Ritonavir Fluconazole Linezolid |
| Cardiovascular agents | Digoxin Amiodarone Captopril Hydrochlorothiazide Procainamide Atorvastatin Simvastatin |
| Gastrointestinal agents | Cimetidine Ranitidine Famotidine |
| Neuropsychiatric agents | Haloperidol Carbamazepine Methyldopa Phenytoin |
| Analgesic agents | Acetaminophen Ibuprofen Sulindac Diclofenac Naproxen |
| Anticoagulant agents | Heparin Low-molecular-weight heparin |
| Immunomodulator agents | Interferon- α Gold Rituximab |
| Immunosuppressant agents | Mycophenolate mofetil Tacrolimus |
| Other agents | Iodinated contrast dye Immunizations |

exposure to a new drug, although a range of presentations is possible.

B. Laboratory Findings

Typically, patients have isolated thrombocytopenia. If bleeding has occurred, anemia may also be present. Hepa-

titis virus B and C and HIV infections should be excluded by serologic testing.

Bone marrow should be examined in patients with unexplained cytopenias, in patients older than 60 years, or in those who did not respond to primary ITP-specific therapy. Megakaryocyte abnormalities and hypocellularity or hypercellularity are not characteristic of ITP. If there are clinical findings suggestive of a lymphoproliferative malignancy, a CT scan should be performed. In the absence of such findings, otherwise asymptomatic patients with unexplained isolated thrombocytopenia of recent onset may be considered to have ITP.

▶ Treatment

Discontinuation of the offending agent leads to resolution of drug-induced thrombocytopenia within 7–10 days in most cases, but patients with severe hemorrhage should be given platelet transfusions or intravenous immunoglobulin (IVIG), or both. For other etiologies of ITP, only individuals with platelet counts < 20,000–30,000/mcL or those with significant bleeding should be treated; the remainder may be monitored serially for progression. The mainstay of initial treatment is a short course of corticosteroids with or without IVIG or anti-D (WinRho) (Figure 14-1). Responses are generally seen within 3–5 days of initiating treatment. Platelet transfusions may be given concomitantly if active bleeding is present.

Although over two-thirds of patients with ITP respond to initial treatment, most relapse following reduction of the corticosteroid dose. Patients with a persistent platelet count < 30,000/mcL or clinically significant bleeding are appropriate candidates for treatment. To bring the platelet count into a safe range quickly, an increased dose of corticosteroids can be administered initially, with the goal of rapid taper once the response has been regained. Then, anti-D (WinRho) or IVIG may be administered once every 2–3 weeks as directed by platelet counts < 30,000/mcL; serial anti-D treatment may allow adult patients to delay or avoid splenectomy. The monoclonal anti-B cell antibody **rituximab** leads to initial responses in about 50% of adults with corticosteroid-refractory chronic ITP.

In clinical trials, the novel thrombopoietin receptor agonists romiplostim (administered subcutaneously weekly) and eltrombopag (taken orally daily) led to improvement in platelet counts in most patients with prednisone-refractory ITP; furthermore, these agents were well-tolerated and, importantly, did not show evidence of suppressing the immune system, distinguishing them from other agents. Romiplostim and eltrombopag are indicated in adult patients with chronic ITP who have not responded durably to corticosteroids, IVIG, or splenectomy.

Splenectomy has a durable response rate of over 60%, but usually is reserved for cases of severe thrombocytopenia that is refractory to second-line agents; patients should receive pneumococcal, *Haemophilus influenzae* type b, and meningococcal vaccination at least 2 weeks before the procedure. If available, laparoscopic splenectomy is preferred, in light of decreased morbidity and shorter hospi-

¹ Use in non-splenectomized, Rh blood type-positive, non-anemic patients only.

² Both lymphoma-type chemotherapy and single-agent vincristine have been used successfully in refractory cases of ITP.

▲ **Figure 14-1.** Management of immune thrombocytopenia (ITP).

talizations when compared with the traditional approach. Additional treatments for ITP are found in Figure 14-1.

The goal of management of **pregnancy-associated ITP** is a platelet count > 10,000/mcL in the first trimester, > 30,000/mcL during the second or third trimester, or > 50,000/mcL prior to cesarean section or vaginal delivery. Moderate-dose oral prednisone or intermittent infusions of IVIG are standard. Splenectomy is reserved for failure to respond to these therapies and may be performed in the first or second trimester.

For thrombocytopenia associated with HIV or hepatitis C virus, treatment of either infection leads to an amelioration in the platelet count in most cases, whereas refractory thrombocytopenia may be treated with infusion of IVIG or anti-D (HIV and hepatitis C virus), splenectomy (HIV), or interferon-alpha (hepatitis C virus). Clinical trials of eltrombopag in treatment of HCV-associated thrombocytopenia have shown promising results. Treatment with corticosteroids is not recommended in hepatitis C virus infection.

► When to Refer

Chronic thrombocytopenia will develop in most patients with newly diagnosed ITP; therefore, all patients with ITP

should be referred to a subspecialist for evaluation at the time of diagnosis.

2. Thrombotic Microangiopathy

ESSENTIALS OF DIAGNOSIS

- Microangiopathic hemolytic anemia and thrombocytopenia, in the absence of another plausible explanation, are sufficient for the diagnosis of TMA.

- ▶ Fever, neurologic abnormalities, and renal insufficiency may occur concurrently but are not required for diagnosis.
- ▶ Renal insufficiency occurs in hemolytic-uremic syndrome.

▶ General Considerations

The thrombotic microangiopathies (TMAs) include thrombotic thrombocytopenic purpura (TTP) and the hemolytic-uremic syndrome (HUS). These disorders are characterized by thrombocytopenia, due to the incorporation of platelets into thrombi in the microvasculature, and microangiopathic hemolytic anemia, which results from shearing of erythrocytes in the microcirculation.

In idiopathic TTP, autoantibodies against the ADAMTS-13 (A disintegrin and metalloproteinase with thrombospondin type 1 repeat, member 13) molecule, also known as the von Willebrand factor cleaving protease (vWFCP), leads to accumulation of ultra-large von Willebrand factor (vWF) multimers that bridge platelets and facilitate excessive platelet aggregation, leading to TTP. In some cases of pregnancy-associated TMA, an antibody to vWFCP is present. In contrast, the activity of the vWFCP in congenital TTP is decreased due to a mutation in the gene encoding for the molecule. Damage to endothelial cells—such as the damage that occurs in endemic HUS due to presence of toxins from *Escherichia coli* (especially type O157:H7) or in the setting of cancer, hematopoietic stem cell transplantation, or HIV infection—may also lead to TMA. Certain drugs (eg, cyclosporine, quinine, ticlopidine, clopidogrel, mitomycin C, and bleomycin) have been associated with the development of TMA, possibly by promoting injury to endothelial cells, although inhibitory antibodies to ADAMTS-13 also have been demonstrated in some cases.

▶ Clinical Findings

A. Symptoms and Signs

Microangiopathic hemolytic anemia and thrombocytopenia are presenting signs in all patients with TTP and most

patients with HUS; in a subset of patients with HUS, the platelet count remains in the normal range. Only approximately 25% of patients with TMA manifest all components of the so-called pentad of findings (microangiopathic hemolytic anemia, thrombocytopenia, fever, renal insufficiency, and neurologic system abnormalities) (Table 14–5). Most patients (especially children) with HUS have a recent or current diarrheal illness. Neurologic manifestations, including headache, somnolence, delirium, seizures, paresis, and coma, may result from deposition of microthrombi in the cerebral vasculature.

B. Laboratory Findings

Laboratory features of TMA include those associated with microangiopathic hemolytic anemia (anemia, elevated lactate dehydrogenase (LD), elevated indirect bilirubin, decreased haptoglobin, reticulocytosis, negative direct antiglobulin test, and schistocytes on the blood smear); thrombocytopenia; elevated creatinine; positive stool culture for *E coli* O157:H7 or assays for Shiga-like toxins (cases of HUS only); and reductions in vWFCP activity. Notably, routine coagulation studies are within the normal range in most patients with TMA.

▶ Treatment

Immediate administration of plasma exchange is essential in most cases due to the mortality rate of > 95% without treatment. With the exception of children or adults with endemic diarrhea-associated HUS, who generally recover with supportive care only, plasma exchange must be initiated as soon as the diagnosis of TMA is suspected. Plasma exchange usually is administered once daily until the platelet count and LD have returned to normal for at least 2 days, after which the frequency of treatments may be tapered slowly while the platelet count and LD are monitored for relapse. In cases of insufficient response to once-daily plasma exchange, twice-daily treatments should be given. Fresh frozen plasma may be administered if immediate access to plasma exchange is not available or in cases of familial TMA. *Platelet transfusions are contraindicated* in the

Table 14–5. Clinical features of thrombotic microangiopathy.

| Parameter | Thrombotic Thrombocytopenic Purpura | Hemolytic-Uremic Syndrome |
|-----------------------------------|--|---|
| Microangiopathic hemolytic anemia | All patients | All patients |
| Thrombocytopenia | All patients | Most patients (may be mild/absent in a subset of patients) |
| Fever | 75% of patients | Usually absent |
| Renal insufficiency | Mild/absent in some patients | All patients |
| Neurologic defects | Most patients | Present in less than half |
| Epidemiologic | Most cases in adults | Most cases in children |
| Historical | Idiopathic (minority of cases: antecedent viral illness or familial) | Antecedent hemorrhagic enteritis in most patients |
| Laboratory findings | Decreased activity of ADAMTS-13 | Positive stool culture for <i>Escherichia coli</i> O157:H7; ADAMTS-13 activity usually normal |

ADAMTS-13, a disintegrin and metalloproteinase with a thrombospondin type 1 repeat, member 13 (von Willebrand factor cleaving protease).

treatment of TMAs due to reports of worsening thrombotic microangiopathy, possibly due to propagation of platelet-rich microthrombi. In cases of documented life-threatening bleeding, however, platelet transfusions may be given slowly and after plasma exchange is underway. Red blood cell transfusions may be administered in cases of clinically significant anemia. Hemodialysis should be considered for patients with significant renal impairment.

In cases of relapse following initial treatment, plasma exchange should be reinstated. If ineffective, or in cases of primary refractoriness, second-line treatments may be considered including rituximab, corticosteroids, IVIG, vincristine, cyclophosphamide, and splenectomy.

► When to Refer

Consultation by a hematologist or transfusion medicine specialist familiar with plasma exchange is required at the time of presentation. Patients with refractory or relapsing TMA require ongoing care by a subspecialist.

► When to Admit

All patients with newly suspected or diagnosed TMA should be hospitalized initially.

Moake JL. Thrombotic thrombocytopenic purpura and the hemolytic uremic syndrome. *Arch Pathol Lab Med.* 2002 Nov;126(11):1430–3. [PMID: 12421153]

3. Heparin-Induced Thrombocytopenia

ESSENTIALS OF DIAGNOSIS

- Thrombocytopenia within 5–10 days of exposure to heparin.
- Decline in baseline platelet count of 50% or greater.
- Thrombosis occurs in 50% of cases; bleeding is uncommon.

► General Considerations

Heparin-induced thrombocytopenia (HIT) is an acquired disorder that affects approximately 3% of patients who are exposed to unfractionated heparin and 0.6% of patients who are exposed to low molecular-weight heparin (LMWH). The condition results from formation of IgG antibodies to heparin-platelet factor 4 (PF4) complexes; the antibodies then bind platelets, which activates them. Platelet activation leads to both thrombocytopenia and a pro-thrombotic state.

► Clinical Findings

A. Symptoms and Signs

Due to the paradoxical pro-thrombotic nature of HIT, bleeding usually does not occur. Thrombosis subsequently is detected in about 50% of patients, which may include thromboses at any venous or arterial site.

B. Laboratory Findings

A presumptive diagnosis of HIT is made when new-onset thrombocytopenia is detected in a patient (frequently a hospitalized patient) within 5–10 days of exposure to heparin. A decline of 50% or more from the baseline platelet count is regarded as compatible with the diagnosis. Occasionally, rapid-onset HIT occurs in a patient with preexisting heparin-PF4 antibodies, due to exposure within the past 100 days; in these cases, the platelet count decline occurs within 1–4 days of reexposure. Confirmation of the diagnosis can be obtained through a positive PF4-heparin antibody enzyme-linked immunosorbent assay (ELISA) or functional assay (such as serotonin release assay), or both.

► Treatment

Treatment should be initiated as soon as the diagnosis of HIT is suspected, before results of laboratory testing is available.

Management of HIT (Table 14–6) involves the immediate discontinuation of all forms of heparin.

If thrombosis has not already been detected, duplex Doppler ultrasound of the lower extremities should be per-

Table 14–6. Management of suspected or proven HIT.

| I. Discontinue all forms of heparin. Send PF4-heparin ELISA (if indicated). | | |
|---|---|--|
| II. Begin treatment with direct thrombin inhibitor. | | |
| Agent | Indication | Dosing |
| Argatroban | Prophylaxis or treatment of HIT | Continuous IV infusion of 0.5 – 1.2 mcg/kg/min, titrate to aPTT = 1.5 to 3 × the baseline value. ¹ Max infusion rate ≤ 10 mcg/kg/min. |
| Lepirudin | Treatment of HIT | Bolus of 0.4 mg/kg ² slowly IV followed by continuous IV infusion of 0.15 mg/kg/h. Titrate to aPTT = 1.5 – 2.5 × baseline value. |
| Bivalirudin | Percutaneous coronary intervention ³ | Bolus of 0.75 mg/kg IV followed by initial continuous IV infusion of 1.75 mg/kg/h. Manufacturer indicates monitoring should be by ACT. |
| III. Perform Doppler ultrasound of lower extremities to rule out subclinical thrombosis (if indicated). | | |
| IV. Follow platelet counts daily until recovery occurs. | | |
| V. When platelet count has recovered, transition anticoagulation to warfarin; treat for 30 days (HIT) or 3–6 months (HITT). | | |
| VI. Document heparin allergy in medical record (confirmed cases). | | |

¹Hepatic insufficiency: initial infusion rate = 0.5 mcg/kg/min.

²Renal insufficiency: initial bolus = 0.2 mg/kg.

³Not approved for HIT/HITT.

ACT, activated clotting time; aPTT, activated partial thromboplastin time; ELISA, enzyme-linked immunosorbent assay; HIT, heparin-induced thrombocytopenia; HITT, heparin-induced thrombocytopenia and thrombosis; PF4, platelet factor 4.

formed to rule out subclinical deep venous thrombosis. Despite thrombocytopenia, platelet transfusions are rarely necessary. Due to the substantial frequency of thrombosis among HIT patients, an alternative anticoagulant, typically a direct thrombin inhibitor (DTI) such as argatroban or lepirudin should be administered immediately. The DTI should be continued until the platelet count has recovered to at least 100,000/mcL, at which point treatment with a vitamin K antagonist (warfarin) may be initiated. The DTI should be continued until therapeutic anticoagulation with the vitamin K antagonist has been achieved (international normalized ratio [INR] of 2.0–3.0) due to the warfarin effect; the infusion of argatroban must be temporarily discontinued for 2 hours before the INR is obtained so that it reflects the anticoagulant effect of warfarin alone. Warfarin is contraindicated as initial treatment of HIT because of its potential to transiently worsen hypercoagulability. In all patients with HIT, warfarin subsequently should be continued for at least 30 days, due to a persistent risk of thrombosis even after the platelet count has recovered, whereas in patients in whom thrombosis has been documented, anticoagulation with warfarin should continue for at least 3 months.

Bivalirudin, another DTI, is not approved for the treatment of HIT but may be considered when hepatic or renal failure prevents use of argatroban or lepirudin.

Subsequent exposure to heparin should be avoided in all patients with a prior history of HIT, if possible. If its use is regarded as necessary for a procedure, it should not be given until PF4-heparin antibodies are no longer detectable by ELISA (usually as of 100 days following an episode of HIT), and exposure should be limited to the shortest time period possible.

▶ When to Refer

Due to the tremendous thrombotic potential of the disorder and the complexity of use of the DTI, all patients with HIT should be evaluated by a hematologist as soon as the thrombocytopenia is detected.

▶ When to Admit

Most patients with HIT are hospitalized at the time of detection of thrombocytopenia. Any outpatient in whom HIT is suspected should be admitted because the DTIs must be administered by continuous intravenous infusion.

4. Disseminated Intravascular Coagulation

ESSENTIALS OF DIAGNOSIS

- ▶ A frequent cause of thrombocytopenia in hospitalized patients.

- ▶ Prolonged activated partial thromboplastin time and prothrombin time.
- ▶ Thrombocytopenia and decreased fibrinogen levels.

▶ General Considerations

Disseminated intravascular coagulation (DIC) results from uncontrolled local or systemic activation of coagulation, which leads to depletion of coagulation factors and fibrinogen and to thrombocytopenia as platelets are activated and consumed.

The numerous disorders that are associated with DIC include sepsis (in which coagulation is activated by presence of lipopolysaccharide) as well as cancer, trauma, burns, or pregnancy-associated morbidity (in which tissue factor is released). Aortic aneurysm and cavernous hemangiomas may promote DIC by leading to vascular stasis, and snake bites may result in DIC due to the introduction of exogenous toxins.

▶ Clinical Findings

A. Symptoms and Signs

Bleeding in DIC usually occurs at multiple sites, such as intravenous catheters or incisions, and may be widespread (**purpura fulminans**). Malignancy-related DIC may manifest principally as thrombosis (Trousseau syndrome).

B. Laboratory Findings

Frequently, there are acute and progressive prolongations in coagulation studies or thrombocytopenia is found in a patient who is being treated for a separate disorder. In early DIC, the platelet count and fibrinogen levels may remain within the normal range, albeit reduced from baseline levels. There is progressive thrombocytopenia (rarely severe), prolongation of the activated partial thromboplastin time (aPTT) and prothrombin time (PT), and low levels of fibrinogen. D-dimer levels typically are elevated due to the activation of coagulation and diffuse cross-linking of fibrin. Schistocytes on the blood smear, due to shearing of red cells through the microvasculature, are present in 10–20% of patients. Laboratory abnormalities in the HELLP syndrome (hemolysis, elevated liver enzymes, low platelets), a severe form of DIC with a particularly high mortality rate that occurs in peripartum women, include elevated liver transaminases and (many cases) renal dysfunction due to gross hemoglobinuria and pigment nephropathy. Malignancy-related DIC may feature normal platelet counts and coagulation studies.

▶ Treatment

The underlying causative disorder must be treated (eg, antimicrobials, chemotherapy, surgery, or delivery of conceptus [see below]). If clinically significant bleeding is present, hemostasis must be achieved (Table 14–7).

Blood products should be administered only if clinically significant hemorrhage has occurred or is thought likely to occur without intervention (Table 14–7). The goal

Table 14-7. Management of DIC.

| | |
|---|---|
| I. Assess for underlying cause of DIC and treat. | |
| II. Establish baseline platelet count, PT, aPTT, D-dimer, fibrinogen. | |
| III. Transfuse blood products only if ongoing bleeding or high risk of bleeding: | Platelets: goal > 20,000/mcL (most patients) or > 50,000/mcL (severe bleeding, eg, intracranial hemorrhage) Cryoprecipitate: goal fibrinogen level > 80–100 mg/dL Fresh frozen plasma: goal PT and aPTT < 1.5 × normal Packed red blood cells: goal hemoglobin > 8 g/dL or improvement in symptomatic anemia |
| IV. Follow platelets, aPTT/PT, fibrinogen every 4–6 hours or as clinically indicated. | |
| V. If persistent bleeding, consider use of heparin ¹ (initial infusion, 5–10 units/kg/h); do not administer bolus. | |
| VI. Follow laboratory parameters every 4–6 hours until DIC resolved and underlying condition successfully treated | |

¹Contraindicated if platelets cannot be maintained at > 50,000/mcL, in cases of gastrointestinal or central nervous system bleeding, in conditions that may require surgical management, or placental abruption.

aPTT, activated partial thromboplastin time; DIC, disseminated intravascular coagulation; PT, prothrombin time.

of platelet therapy for most cases is > 20,000–30,000/mcL or > 50,000/mcL for serious bleeding, such as intracranial bleeding. Fresh frozen plasma should be given only to patients with a prolonged aPTT and PT and significant bleeding; 4 units typically are administered at a time, and the posttransfusion platelet count should be documented. Cryoprecipitate may be given for bleeding and fibrinogen levels < 80–100 mg/dL. The PT, aPTT, fibrinogen, and platelet count should be monitored at least every 6 hours in acutely ill patients with DIC.

In some cases of **refractory bleeding** despite replacement of blood products, administration of low doses of heparin can be considered; it may help interfere with thrombin generation, which then could lead to a lessened consumption of coagulation proteins and platelets. An infusion of 6–10 units/kg/h (no bolus) may be used. Heparin, however, is contraindicated if the platelet count cannot be maintained at ≥ 50,000/mcL and in cases of central nervous system/gastrointestinal bleeding, placental abruption, and any other condition that is likely to require imminent surgery. Fibrinolysis inhibitors may be considered in some patients with refractory DIC.

The treatment of **HELLP syndrome** must include evacuation of the uterus (eg, delivery of a term or near-term infant or removal of retained placental or fetal fragments). Patients with **Trousseau syndrome** require treatment of the underlying malignancy or administration of unfractionated heparin or subcutaneous therapeutic-dose LMWH as treatment of thrombosis, since warfarin typically is ineffective at secondary prevention of thromboembolism in the disorder. Immediate initiation of chemotherapy (usually within 24 hours of diagnosis) is required for patients with **acute**

promyelocytic leukemia (APL)–associated DIC, along with administration of blood products as clinically indicated.

▶ When to Refer

Patients with diffuse bleeding that is unresponsive to administration of blood products should be evaluated by a hematologist.

▶ When to Admit

Most patients with DIC are hospitalized when DIC is detected.

OTHER CONDITIONS CAUSING THROMBOCYTOPENIA

1. Posttransfusion Purpura (PTP)

Posttransfusion purpura (PTP) is a rare disorder that features sudden-onset thrombocytopenia in an individual who recently has received transfusion of red cells, platelets, or plasma within 1 week prior to detection of thrombocytopenia. Antibodies against the human platelet antigen Pl^{A1} are detected in most individuals with PTP. Patients with PTP almost universally are either multiparous women or persons who have received transfusions previously. Severe thrombocytopenia and bleeding is typical. Initial treatment consists of administration of IVIG (1 g/kg/d for 2 days) should be administered as soon as the diagnosis is suspected. Platelets are not indicated unless severe bleeding is present, but if they are to be administered, HLA-matched platelets are preferred. A second course or IVIG, plasma exchange, corticosteroids, or splenectomy may be used in case of refractoriness. Pl^{A1} -negative or washed blood products are preferred for subsequent transfusions.

2. von Willebrand Disease Type 2B

von Willebrand disease (vWD) type 2B leads to chronic, characteristically mild to moderate thrombocytopenia via an abnormal vWF molecule that binds platelets with increased affinity, resulting in aggregation and clearance. Passage of the blood for prolonged periods outside the body in an artificial circuit (such as occurs with extracorporeal circulation) also can result in platelet clearance; thrombocytopenia typically resolves within several days.

3. Platelet Sequestration

At any given time, one-third of the platelet mass is sequestered in the spleen. Splenomegaly, due to a variety of

| Niemann-Pick disease |

conditions (Table 14–8), may lead to thrombocytopenia of variable severity. Whenever possible, treatment of the underlying disorder should be pursued, but splenectomy, splenic embolization, or splenic irradiation may be considered in selected cases.

4. Pregnancy

Gestational thrombocytopenia results from progressive expansion of the blood volume that typically occurs during pregnancy, leading to hemodilution. Cytopenias result, although production of blood cells is normal or increased. Platelet counts < 100,000/mcL, however, are observed in less than 10% of pregnant women in the third trimester; decreases to less than 70,000/mcL should prompt consideration of pregnancy-related ITP (see above) as well as preeclampsia or a pregnancy-related thrombotic microangiopathy.

5. Infection or Sepsis

Both immune- and platelet production–mediated defects are possible, and there may be significant overlap with concomitant DIC (see above). In either case, the platelet count typically improves with effective antimicrobial treatment or after the infection has resolved. In some critically ill patients, a defect in immunomodulation may lead to bone marrow macrophages (histiocytes) engulfing cellular components of the marrow in a process also called hemophagocytosis. The phenomenon typically resolves with resolution of the infection, but with certain infections (Epstein Barr virus) immunosuppression may be required. Hemophagocytosis also may arise in the setting of malignancy, in which case the disorder is usually unresponsive to treatment with immunosuppression.

6. Pseudothrombocytopenia

Pseudothrombocytopenia results from EDTA anticoagulant-induced platelet clumping; the phenomenon typically disappears when blood is collected in a tube containing citrate anticoagulant.

QUALITATIVE PLATELET DISORDERS

CONGENITAL DISORDERS OF PLATELET FUNCTION

ESSENTIALS OF DIAGNOSIS

- ▶ Usually diagnosed in childhood.
- ▶ May be diagnosed in adulthood when there is excessive bleeding.

▶ General Considerations

Heritable qualitative platelet disorders are far less common than acquired disorders of platelet function (see below) and lead to variably severe bleeding, often beginning in childhood. Occasionally, however, disorders of platelet function may go undetected until later in life when excessive bleeding occurs following a sufficient hemostatic insult. Thus, the true incidence of hereditary qualitative platelet disorders is unknown.

Bernard-Soulier syndrome (BSS) is a rare, autosomal recessive bleeding disorder that is due to reduced or abnormal platelet membrane expression of glycoprotein Ib/IX (vWF receptor).

Glanzmann thrombasthenia results from a qualitative or quantitative abnormality in glycoprotein IIb/IIIa receptors on the platelet membrane, which are required to bind fibrinogen and vWF, both of which bridge platelets during aggregation. Inheritance is autosomal recessive.

Under normal circumstances, activated platelets release the contents of platelet granules to reinforce the aggregatory response. **Storage pool disease** is caused by defects in release of alpha or dense (delta) platelet granules, or both (alpha-delta storage pool disease).

▶ Clinical Findings

A. Symptoms and Signs

In patients with **Glanzmann thrombasthenia**, the onset of bleeding is usually in infancy or childhood. The degree of deficiency in IIb/IIIa may not correlate well with bleeding symptoms. Patients with **storage pool disease** are affected by variable bleeding, ranging from mild and trauma-related to spontaneous.

B. Laboratory Findings

In **Bernard-Soulier syndrome**, there are abnormally large platelets (approaching the size of red cells), moderate

Table 14–9. Causes of acquired platelet dysfunction.

| Cause | Mechanism(s) | Treatment of Bleeding |
|--|--|--|
| Drug-induced | | |
| Salicylates (eg, aspirin) | Irreversible inhibition of platelet cyclooxygenase | Discontinuation of drug; platelet transfusion |

ADP, adenosine diphosphate; cAMP, cyclic adenosine monophosphate; DDAVP, desmopressin acetate; DHA, docosahexaenoic acid; EHA, eicosahexaenoic acid; NSAIDs, nonsteroidal anti-inflammatory drugs; PM, platelet membrane; SSRIs, selective serotonin release inhibitors; TXA₂, thromboxane A₂.

thrombocytopenia, and a prolonged bleeding time. Platelet aggregation studies show a marked defect in response to ristocetin, whereas aggregation in response to other agonists is normal; the addition of normal platelets corrects the abnormal aggregation. The diagnosis can be confirmed by platelet flow cytometry.

In **Glanzmann thrombasthenia**, platelet aggregation studies show marked impairment of aggregation in response to stimulation with typical agonists.

There are several presentations of **storage pool disease**. Patients have a prolonged bleeding time. Platelet aggregation studies characteristically show platelet dissociation following an initial aggregatory response, and electron microscopy confirms the diagnosis.

▶ Treatment

The mainstay of treatment (including periprocedural prophylaxis) is transfusion of normal platelets, although desmopressin acetate (DDAVP), antifibrinolytic agents, and recombinant human activated factor VII also have been used successfully.

Roberts HR et al. The use of recombinant factor VIIa in the treatment of bleeding disorders. *Blood*. 2004 Dec 15; 104(13):3858–64. [PMID: 15328151]

Toogeh G et al. Presentation and pattern of symptoms in 382 patients with Glanzmann thrombasthenia in Iran. *Am J Hematol*. 2004 Oct;77(2):198–9. [PMID: 15389911]

ACQUIRED DISORDERS OF PLATELET FUNCTION

Platelet dysfunction is more commonly acquired than inherited; the widespread use of platelet-active medications accounts for most of the cases of qualitative defects (Table 14–9). In these cases, platelet inhibition typically declines within 5–10 days following discontinuation of the drug, and transfusion of platelets may be required if clinically significant bleeding is present.

Laboratory manifestations of aspirin toxicity include a prolonged epinephrine cartridge closure time in the platelet function analyzer (PFA)-100 system, or a decreased aggregation to low-dose collagen and thrombin (and preserved aggregation in response to high-dose collagen and thrombin) on platelet aggregation studies.

DISORDERS OF COAGULATION

CONGENITAL DISORDERS OF COAGULATION

1. Hemophilia A & B

ESSENTIALS OF DIAGNOSIS

- ▶ Hemophilia A: congenital deficiency of coagulation factor VIII.

- ▶ Hemophilia B: congenital deficiency of coagulation factor IX.
- ▶ Symptomatic in males.
- ▶ Recurrent hemarthroses and arthropathy.
- ▶ Infection with HIV or hepatitis C virus from receipt of contaminated blood products.

▶ General Considerations

The frequency of hemophilia A is 1 per 5000 live male births, whereas hemophilia B occurs in approximately 1 in 25,000 live male births. Inheritance is X-linked recessive, leading to affected males and carrier females. There is no race predilection. Testing is indicated for asymptomatic male infants with a hemophilic pedigree, for male infants with a family history of hemophilia who experience excessive bleeding, or for an otherwise asymptomatic adolescent or adult who experiences unexpected excessive bleeding with trauma or invasion.

Inhibitors to factor VIII will develop in approximately 25% of patients with hemophilia A, and inhibitors to factor IX will develop in less than 5% of patients with hemophilia B.

The prevalence of hepatitis C virus infection is highest among individuals with severe disease who received plasma-derived clotting factor concentrates or blood products in the pre-mid-1980s, and approaches a 100% exposure rate in this population. New infection is now rare, given current methodology for screening of blood products, viral inactivation of plasma-derived factor, and use of recombinant products. Many patients infected with hepatitis C virus have undergone eradication treatment successfully. New HIV infection related to the treatment of hemophilia, too, is rare in the modern era, although a large number of patients with hemophilia were exposed to HIV through contaminated blood products of factor concentrates in the 1980s.

▶ Clinical Findings

A. Symptoms and Signs

Severe hemophilia presents in infant males or in early childhood with spontaneous bleeding into joints, soft tissues, or other locations. Spontaneous bleeding is rare in patients with mild hemophilia, but bleeding may occur with a significant hemostatic challenge (eg, surgery, trauma). Intermediate clinical symptoms are seen in patients with moderate hemophilia. Female carriers of hemophilia are usually asymptomatic.

Significant hemophilic arthropathy is usually avoided in patients who have received long-term prophylaxis with factor concentrate in childhood, whereas severe arthritis and limited range of motion in affected joints are common in adults who received episodic or little treatment during childhood and experienced recurrent hemarthroses.

Inhibitor development to factor VIII or factor IX is characterized by bleeding episodes that are resistant to treatment and new or unusual bleeding.

B. Laboratory Findings

Hemophilia is diagnosed by demonstration of an isolated reproducibly low factor VIII or factor IX activity level, in the absence of other conditions. If the aPTT is prolonged, it typically corrects upon mixing with normal plasma. A variety of mutations, including inversions, large and small deletions, insertions, missense mutations, and nonsense mutations may be causative. Depending on the level of residual factor VIII or factor IX activity and the sensitivity of the thromboplastin used in the aPTT coagulation reaction, the aPTT may or may not be prolonged (although it typically is markedly prolonged in severe hemophilia). Hemophilia is classified according to the level of factor activity in the plasma. Severe hemophilia is characterized by less than 1% factor activity, mild hemophilia features greater than 5% factor activity, and moderate hemophilia features 1–5% factor activity. Female carriers may become symptomatic if significant lyonization has occurred favoring the defective factor VIII or factor IX gene, leading to factor VIII or factor IX activity level markedly less than 50%.

In the presence of an inhibitor to factor VIII or factor IX, there is accelerated clearance of and suboptimal or absent rise in measured activity of infused factor, and the aPTT does not correct on mixing. The Bethesda assay measures the potency of the inhibitor.

▶ Treatment

Plasma-derived or recombinant factor concentrates are the mainstay of treatment. By the age of 4 years, children with severe hemophilia typically receive long-term, prophylactic, twice- or thrice-weekly infusions of factor to prevent the recurrent joint bleeding that otherwise would characterize the disorder, leading to severe morbidity. Adults generally do not use intensive, long-term prophylaxis, and instead treat with factor concentrate as needed for bleeding episodes or prior to high-risk activities (Table 14–10). Patients with mild hemophilia A may respond to as-needed intravenous or intranasal treatment with DDAVP. Antifibrinolytic agents may be useful in cases of mucosal bleeding and are commonly used adjunctively, such as following dental procedures. Thus far, early trials of gene therapy (delivery of normal factor VIII or factor IX genes via viral vectors) have not shown increases in factor activity levels of both adequate magnitude and duration.

The cyclooxygenase (COX)-2 selective nonsteroidal anti-inflammatory drug celecoxib may be used to treat arthritis symptoms; generally, other NSAIDs and aspirin should be avoided due to the increased risk of bleeding from inhibition of platelet function. Oral opioid medications are commonly used to control pain, and surgery, including total joint replacement, is often required.

It may be possible to overcome low-titer inhibitors (< 5 Bethesda units, BU) by giving larger doses of factor, whereas treatment of bleeding in the presence of a high-titer inhibitor (> 5 BU) requires infusion of an activated prothrombin complex concentrate or recombinant activated factor VII. Inhibitor tolerance induction, achieved by giving large doses (50–300 units/kg intravenously of

Table 14-10. Treatment of selected inherited bleeding disorders.

| Disorder | Subtype | Treatment for Minor Bleeding | Treatment for Major Bleeding | Comment |
|----------------------|---------------------------|------------------------------|---|--|
| Hemophilia A | Mild | DDAVP ¹ | DDAVP ¹ or factor VIII concentrate | Treat for 3–10 days for major bleeding or following surgery, keeping factor activity level ≥ 50–80% initially. Adjunctive aminocaproic acid may be useful for mucosal bleeding or procedures |
| | Moderate or severe | Factor VIII concentrate | Factor VIII concentrate | |
| Hemophilia B | Mild, moderate, or severe | Factor IX concentrate | Factor IX concentrate | |
| | von Willebrand disease | DDAVP | DDAVP, vWF concentrate | |
| Factor XI deficiency | Type 1 | DDAVP, vWF concentrate | vWF concentrate | |
| | Type 2 | vWF concentrate | vWF concentrate | |
| | Type 3 | FFP or aminocaproic acid | FFP | |

¹Mild hemophilia A and type 2A or 2B vWD patients: therapeutic trial must have previously confirmed an adequate response (i.e., elevation of factor VIII or vWF activity level into the normal range) and (for type 2B) no exacerbation of thrombocytopenia. DDAVP is not typically effective for type 2M vWD. A vWF-containing factor VIII concentrate is preferred for treatment of type 2N vWD.

Notes:

DDAVP dose is 0.3 mcg/kg IV in 50 mL saline over 20 minutes, or nasal spray 300 mcg for weight > 50 kg or 150 mcg for < 50 kg, every 12–24 hours, maximum of three doses in a 48-hour period. If more than two doses are used in a 12–24 hour period, free water restriction and/or monitoring for hyponatremia is essential.

EACA dose is 50 mg/kg PO four times daily for 3–5 d; maximum 24 g/d, useful for mucosal bleeding/dental procedures.

Factor VIII concentrate dose is 50 units/kg IV initially followed by 25 units/kg every 8 hours followed by lesser doses at longer intervals once hemostasis has been established.

Factor IX concentrate dose is 100 units/kg (120 units/kg if using Benefix) IV initially followed by 50 units/kg (60 units/kg if using Benefix) every 8 hours followed by lesser doses at longer intervals once hemostasis has been established.

vWF-containing factor VIII concentrate dose is 60–80 RCoF units/kg IV every 12 hours initially followed by lesser doses at longer intervals once hemostasis has been established.

FFP is typically administered in 4-unit boluses and may not need to be re-bolused after the initial administration due to the long half-life of factor XI.

DDAVP, desmopressin acetate; FFP, fresh frozen plasma; vWF, von Willebrand factor.

factor VIII daily) for 6–18 months, succeeds in eradicating the inhibitor in 70% of patients with hemophilia A and in 30% of patients with hemophilia B; hemophilia B patients who receive inhibitor tolerance induction, however, are at risk for development of nephrotic syndrome and anaphylactic reactions, making eradication of their inhibitors less feasible.

Highly active antiretroviral treatment is almost universally administered to individuals with HIV infection.

▶ When to Refer

All patients with hemophilia should be seen regularly in a comprehensive hemophilia treatment center staffed by a hematologist.

▶ When to Admit

- Most bleeding events can be treated as an outpatient.
- Some invasive procedures that could otherwise be performed as an outpatient require admission in a patient with hemophilia due to the need for serial infusions of clotting factor concentrate.
- Patients with hemophilia and inhibitors who experience bleeding that is unresponsive to bypassing agents typically require admission.

Hay CR et al. The diagnosis and management of factor VIII and IX inhibitors: a guideline from the United Kingdom Haemophilia Centre Doctors Organisation. *Br J Haematol.* 2006 Jun;133(6):591–605. [PMID: 16704433]

Mannucci PM et al. The hemophiliac—from royal genes to gene therapy. *N Engl J Med.* 2001 Jun 7;344(23):1773–9. [PMID: 11396445]

2. von Willebrand Disease**ESSENTIALS OF DIAGNOSIS**

- ▶ The most common inherited bleeding disorder.
- ▶ von Willebrand factor aggregates platelets and prolongs the half-life of factor VIII.

▶ General Considerations

Up to 1% of the population have depressed vWF levels. vWF is an unusually large multimeric glycoprotein that binds to its receptor, platelet glycoprotein Ib, bridging platelets together and tethering them to the subendothelial matrix at the site of vascular injury. vWF also has a

binding site for factor VIII, prolonging its half-life in the circulation.

Between 75% and 80% of patients with vWD have type 1. It is a quantitative abnormality of the vWF molecule that usually does not feature an identifiable causal mutation in the vWF gene.

Type 2 vWD is seen in 15–20% of patients with vWD. In type 2A or 2B vWD, a qualitative defect in the vWF molecule is causative. Type 2N and 2M vWD are due to defects in vWF that decrease binding to factor VIII or to platelets, respectively. Importantly, type 2N vWD clinically resembles hemophilia A, with the exception of a family history that shows affected females. Factor VIII activity levels are markedly decreased, and vWF activity and antigen (Ag) are normal. Type 2M vWD features a normal multimer pattern. Type 3 vWD is rare, and mutational homozygosity or double heterozygosity leads to undetectable levels of vWF and severe bleeding in infancy or childhood.

► Clinical Findings

A. Symptoms and Signs

Patients with type 1 vWD usually have mild or moderate platelet-type bleeding (especially involving the integument and mucous membranes). Patients with type 2 vWD usually have moderate to severe bleeding that presents in childhood or adolescence.

B. Laboratory Findings

In type 1 vWD, the vWF activity (by ristocetin co-factor assay) and Ag are mildly depressed, whereas the vWF multimer pattern is normal (Table 14–11). Laboratory testing of type 2A or 2B vWD typically shows a ratio of vWF Ag:vWF activity of approximately 2:1 and a multimer pattern that lacks the highest molecular weight multimers. Thrombocytopenia is common in type 2B vWD due to a gain-of-function mutation of the vWF molecule, which leads to increased binding to its receptor on platelets, resulting in clearance; a ristocetin-induced platelet aggregation (RIPA) study shows an increase in platelet aggregation in response to low concentrations of ristocetin. Except in the more severe forms of vWD that feature

a significantly decreased factor VIII activity, the aPTT and PT in vWD are usually normal.

► Treatment

The treatment of vWD is summarized in Table 14–10. DDAVP is useful in the treatment of mild bleeding in most cases of type 1 and some cases of type 2 vWD. DDAVP causes release of vWF and factor VIII from storage sites, leading to increases in vWF and factor VIII twofold to sevenfold that of baseline levels. A therapeutic trial to document sufficient vWF levels posttreatment is recommended. Due to tachyphylaxis and the risk of significant hyponatremia secondary to fluid retention, more than two doses should not be given in a 48-hour period. Intermediate-purity vWF-containing factor VIII concentrates are used in all other clinical scenarios, and when bleeding is not controlled with DDAVP. Cryoprecipitate should not be given due to lack of viral inactivation. Antifibrinolytic agents (eg, aminocaproic acid) may be used adjunctively for mucosal bleeding or procedures. Pregnant patients with vWD usually do not require treatment because of the natural physiologic increase in vWF levels (up to threefold that of baseline) that are observed by the time of delivery; however, if excessive bleeding is encountered, DDAVP may be given to patients with mild disease or vWF-containing factor VIII concentrates may be given to patients with more severe disease.

3. Factor XI Deficiency

Factor XI deficiency (sometimes referred to as **hemophilia C**) is inherited in an autosomal recessive manner, leading to heterozygous or homozygous defects. It is most prevalent among individuals of Ashkenazi Jewish descent. Levels of factor XI, while variably reduced, do not correlate well with bleeding symptoms. Mild bleeding is most common,

Table 14–11. Laboratory diagnosis of von Willebrand disease.

| Type | vWF Activity | vWF Antigen | FVIII | RIPA | Multimer Analysis |
|------|--------------|-------------|---------|------|---|
| 1 | ↓ | ↓ | NI or ↓ | ↓ | Uniform ↓ in intensity |
| 2 | A | ↓↓ | ↓ | ↓ | Large and intermediate multimers decreased or absent. |
| | B | ↓↓ | ↓ | ↑ | Large multimers decreased or absent |

| | N | NI | NI | ↓↓ | NI |
| 3 | ↓↓↓ | ↓↓↓ | ↓↓↓ | ↓↓↓ | Absent |

NI, normal; RIPA, ristocetin-induced platelet aggregation; vWF, von Willebrand factor.

and surgery or trauma may expose or worsen the bleeding tendency. Fresh frozen plasma (FFP) is the mainstay of treatment, since no factor XI concentrate is available in the United States. Administration of adjunctive aminocaproic acid is regarded as mandatory for procedures or bleeding episodes involving the mucosa (Table 14–10).

4. Less Common Heritable Disorders of Coagulation

Congenital deficiencies of clotting factors II, V, VII, and X are rare and typically are inherited in an autosomal recessive pattern. A prolongation in the PT (and aPTT for factor X and factor II deficiency) that corrects upon mixing with normal plasma is typical.

Deficiency of factor XIII, a transglutaminase that cross-links fibrin, characteristically leads to delayed bleeding that occurs hours to days after a hemostatic challenge (such as surgery or trauma). Cryoprecipitate or infusion of a plasma-derived factor XIII concentrate (available through a research study; appropriate for patients with A-subunit deficiency only) is the treatment of choice for bleeding or surgical prophylaxis.

Congenital deficiencies of factor XII, prekallikrein, high molecular-weight kininogen may lead to a prolonged aPTT that corrects with extended incubation but do not lead to bleeding.

ACQUIRED DISORDERS OF COAGULATION

1. Acquired Antibodies to Factor VIII

Spontaneous antibodies to factor VIII occasionally occur in adults without a prior history of hemophilia; the elderly and patients with lymphoproliferative malignancy or connective tissue disease, who are postpartum, or postsurgical are at highest risk. The clinical presentation typically includes extensive soft-tissue ecchymoses, hematomas, and mucosal bleeding, as opposed to hemarthrosis in congenital hemophilia A. The aPTT is typically prolonged and does not correct upon mixing; factor VIII activity is found to be low and a Bethesda assay reveals the titer of the inhibitor. Inhibitors of low titer (< 5 BU) may often be overcome by infusion of high doses of factor VIII concentrates, whereas high-titer inhibitors (> 5 BU) must be treated with serial infusions of activated prothrombin complex concentrates or recombinant human activated factor VII. Along with establishment of hemostasis by one of these measures, immunosuppressive treatment with corticosteroids and oral cyclophosphamide should be instituted; treatment with IVIG, rituximab, or plasmapheresis can be considered in refractory cases.

Stasi R et al. Selective B-cell depletion with rituximab for the treatment of patients with acquired hemophilia. *Blood*. 2004 Jun 15;103(12):4424–8. [PMID: 14996701]

2. Acquired Antibodies to Factor II

Patients with antiphospholipid antibodies occasionally manifest specificity to coagulation factor II (prothrombin),

leading typically to a severe hypoprothrombinemia and bleeding. Mixing studies may or may not reveal presence of an inhibitor, as the antibody typically binds a non-enzymatically active portion of the molecule that leads to accelerated clearance, but characteristically the PT is prolonged and levels of factor II are low. FFP should be administered for treatment of bleeding. Treatment is immunosuppressive.

3. Acquired Antibodies to Factor V

Products containing bovine factor V (such as topical thrombin or fibrin glue, frequently used in surgical procedures) can lead to formation of an anti-factor V antibody that has specificity for human factor V. Clinicopathologic manifestations range from a prolonged PT in an otherwise asymptomatic individual to severe bleeding. Mixing studies suggest the presence of an inhibitor, and the factor V activity level is low. In cases of serious or life-threatening bleeding, IVIG or platelet transfusions, or both, should be administered, and immunosuppression (as for acquired inhibitors to factor VIII) may be offered.

4. Vitamin K Deficiency

Vitamin K deficiency may occur as a result of deficient dietary intake of vitamin K (from green leafy vegetables, soybeans, and other sources), malabsorption, or decreased production by intestinal bacteria (due to treatment with chemotherapy or antibiotics). Vitamin K normally participates in activity of the vitamin K epoxide reductase that assists in posttranslational gamma-carboxylation of the coagulation factors II, VII, IX, and X that is necessary for their activity. Thus, vitamin K deficiency typically features a prolonged PT (in which the activity of the vitamin K-dependent factors is more reflected than in the aPTT) that corrects upon mixing; levels of individual clotting factors II, VII, IX, and X typically are low. Importantly, a concomitantly low factor V activity level is not indicative of isolated vitamin K deficiency, and may indicate an underlying defect in liver synthetic function (see below).

For treatment, vitamin K₁ (phytonadione) may be administered via intravenous or oral routes; the subcutaneous route is not recommended due to erratic absorption. Oral absorption is typically excellent and at least partial improvement in the PT should be observed within 1 day of administration. Intravenous administration (1 mg/d) results in even faster normalization of a prolonged PT than oral administration (5–10 mg/d); due to descriptions of anaphylaxis, parenteral doses should be administered at lower doses and slowly (eg, over 30 minutes) with concomitant monitoring.

5. Coagulopathy of Liver Disease

Impaired hepatic function due to cirrhosis or other causes leads to decreased synthesis of clotting factors, including factors II, VII, V, VIII, and fibrinogen, whereas factor VIII levels may be elevated in spite of depressed levels of other coagulation factors. The PT (and with advanced disease, the aPTT) is typically prolonged and corrects on mixing with normal plasma. A normal factor V level, in spite of decreases in the

activity of factors II, VII, IX, and X, however, suggests vitamin K deficiency rather than liver disease (see above). Qualitative and quantitative deficiencies of fibrinogen also are prevalent among patients with advanced liver disease, typically leading to a prolonged PT, thrombin time, and reptilase time.

The coagulopathy of liver disease usually does not require hemostatic treatment until bleeding complications occur. Infusion of FFP may be considered if active bleeding is present and the aPTT and PT are markedly prolonged; however, the effect is transient and concern for volume overload may limit infusions. Patients with bleeding and a fibrinogen level consistently below 80 mg/dL should receive cryoprecipitate. Liver transplantation, if feasible, results in production of coagulation factors at normal levels. The appropriateness of use of recombinant human activated factor VII in patients with bleeding varices is controversial, although some patient subgroups may experience benefit.

Thabut D et al. Efficacy of activated recombinant factor VII in cirrhotic patients with upper gastrointestinal bleeding: a randomized placebo-controlled double-blind multicenter trial. *Critical Care*. 2004;8(Suppl 1):P136.

Youssef WI et al. Role of fresh frozen plasma infusion in correction of coagulopathy of chronic liver disease: a dual phase study. *Am J Gastroenterol*. 2003 Jun;98(6):1391–4. [PMID: 12818286]

6. Warfarin Ingestion

See Antithrombotic Therapy section below.

7. Heparin Use or Contamination

The presence of heparin in the coagulation reaction system (whether by contamination or intentional administration to the patient) may prolong the aPTT. The thrombin time is dramatically prolonged in the presence of heparin. If contamination is suspected, use of a heparin neutralizing agent on the sample will result in normalization of the aPTT; alternatively, a fresh sample from a peripheral site can be obtained and tested. Patients who are receiving heparin and who have bleeding should be managed by discontinuation of the heparin and (some cases) administration of protamine sulfate; 1 mg of protamine neutralizes approximately 100 units of heparin sulfate, and the maximum dose is 50 mg intravenously. LMWHs typically do not prolong clotting times and are poorly reversible with protamine.

8. Disseminated Intravascular Coagulation

The consumptive coagulopathy of DIC results in decreases in the activity of clotting factors, leading to bleeding in most patients (see above). The aPTT and PT are characteristically prolonged, and platelets and fibrinogen levels are reduced from baseline.

9. Lupus Anticoagulants

Lupus anticoagulants prolong clotting times by binding proteins associated with phospholipid, which is a necessary component of coagulation reactions. Lupus anticoagulants were so named because of their increased prevalence among

patients with connective tissue disease, although they may occur with increased frequency in individuals with underlying infection, inflammation, or malignancy, and they also can occur in asymptomatic individuals in the general population. Importantly, lupus anticoagulants do not cause bleeding.

A prolongation in the aPTT is observed that does not correct completely on mixing. Specialized testing such as the hexagonal phase phospholipid neutralization assay, the dilute Russel viper venom time, and platelet neutralization assays can confirm the presence of a lupus anticoagulant.

CONDITIONS CAUSING BLEEDING DESPITE NORMAL HEMOSTASIS

Occasionally, abnormalities of the vasculature and integument may lead to bleeding despite normal hemostasis; congenital or acquired disorders may be causative. These abnormalities include Ehlers-Danlos syndrome, osteogenesis imperfecta, Osler-Weber-Rendu disease, and Marfan syndrome (heritable defects) and integumentary thinning due to prolonged corticosteroid administration or normal aging, amyloidosis, vasculitis, and scurvy (acquired defects). The bleeding time often is prolonged. If possible, treatment of the underlying condition should be pursued, but if this is not possible or feasible (ie, congenital syndromes), globally hemostatic agents such as DDAVP can be considered for treatment of bleeding.

Yasui H et al. Combination therapy of DDAVP and conjugated estrogens for a recurrent large subcutaneous hematoma in Ehlers-Danlos syndrome. *Am J Hematol*. 2003 Jan;72(1):71–2. [PMID: 12508273]

ANTITHROMBOTIC THERAPY

▶ Prevention of Venous Thromboembolic Disease

The frequency of venous thromboembolic disease (VTE) among hospitalized patients ranges widely; up to 20% of low-risk medical patients and 80% of critical care patients and high-risk surgical patients have been reported to experience this complication, which includes deep venous thrombosis (DVT) and pulmonary embolism (PE).

Avoidance of fatal PE, which occurs in up to 5% of high-risk inpatients, as a consequence of hospitalization or surgery is a major goal of pharmacologic prophylaxis. Standard regimens are listed in Table 14–12. In medical patients, 5000 units of subcutaneous unfractionated heparin three times daily resulted in a trend toward decreased proximal DVT and PE but increased risk of major bleeding when compared with 5000 units of unfractionated heparin twice daily. Compared with unfractionated heparin taken three times daily, LMWH appears more effective at preventing DVT without increased bleeding risk.

If bleeding is present or the risk of bleeding is high, some measure of thromboprophylaxis may be provided through use of graduated compression stockings or intermittent pneumatic compression devices, which have been

Table 14–12. Pharmacologic prophylaxis of VTE in selected clinical scenarios.¹

| Anticoagulant | Dose | Frequency | Clinical Scenario | Comment |
|------------------------|------------|--------------------------|---|--|
| Enoxaparin | 40 mg | Once daily | Most medical inpatients and critical care patients | — |
| | | Twice daily | Surgical patients (moderate risk for VTE) | — |
| | 30 mg | Twice daily | Abdominal/pelvic cancer surgery | Continue for 4 weeks total duration |
| | | Twice daily | Bariatric surgery | Higher doses may be required |
| | | Twice daily | Orthopedic surgery ² | Give for at least 10 days. For THR, TKA, or HFS, continue up to 35 days after surgery |
| | | Major trauma | Not applicable to patients with isolated lower extremity trauma | |
| | | Acute spinal cord injury | — | |
| Dalteparin | 2500 units | Once daily | Most medical inpatients | — |
| | 5000 units | Once daily | Abdominal surgery (moderate risk for VTE) | Give for 5–10 days |
| | | | Orthopedic surgery ² | First dose = 2500 units. Give for at least 10 days. For THR, TKA, or HFS, continue up to 35 days after surgery |
| | | | | Abdominal surgery (higher-risk for VTE) |
| | | Medical inpatients | — | |
| Fondaparinux | 2.5mg | Once daily | Orthopedic surgery ² | Give for at least 10 days. For THR, TKA or HFS, continue up to 35 days after surgery |
| Unfractionated heparin | 5000 units | Three times daily | Patients with severe renal insufficiency ³ | LMWHs contraindicated |
| | | | Patients with epidural catheters | LMWHs contraindicated |
| | | | Surgical patients (higher risk for VTE) | Includes gynecologic surgery for malignancy and urologic surgery, neurosurgery in high-risk patients |
| | 5000 units | Twice daily | Surgical patients (moderate risk) | Includes gynecologic surgery (moderate risk) |
| Warfarin | (variable) | Once daily | Orthopedic surgery ² | Titrate to goal INR = 2.5. Give for at least 10 days. For THR, TKA, or HFS, continue up to 35 days after surgery |

¹All regimens administered subcutaneously, except for warfarin.

²Includes TKA, THR, and HFS.

³Defined as creatinine clearance < 30 mL/min.

HFS, hip fracture surgery; LMWH, low-molecular-weight heparin; THR, total hip replacement; TKA, total knee arthroplasty; VTE, venous thromboembolic disease.

shown to reduce the incidence of VTE among select patient groups and can be a valuable adjunctive measure in patients who already are receiving pharmacologic prophylaxis and are at particularly high risk for VTE.

► Treatment of Venous Thromboembolic Disease

A. Anticoagulant Therapy

Treatment for VTE should be offered to patients with objectively confirmed DVT or PE, or to those in whom the clinical suspicion is high for the disorder yet have not yet undergone diagnostic testing (see Chapter 9). The management of VTE primarily involves administration of anticoagulants, which initially are given parenterally followed by long-term oral therapy; the goal is the secondary prevention of additional thrombi. Suggested anticoagulation regimens are found in Table 14–13. Table 14–14 outlines the selection criteria for outpatient treatment of DVT. Most patients with DVT alone may be treated as outpatients, provided that their risk of bleeding is low, they are candi-

Table 14-13. Initial anticoagulation for VTE.¹

| Anticoagulant | Dose/Frequency | Clinical Scenario | | | | | Comment |
|-------------------------|---|----------------------|----------------------|----|--|---------------------|---|
| | | DVT, Lower Extremity | DVT, Upper Extremity | PE | VTE, with Concomitant Severe Renal Impairment ² | VTE, Cancer-Related | |
| Unfractionated heparin | 80 units/kg IV bolus then continuous IV infusion of 18 units/kg/h | × | × | × | × | | Bolus may be omitted if risk of bleeding is perceived to be elevated. Maximum bolus, 10,000 units. Requires aPTT monitoring. Most patients: begin warfarin at time of initiation of heparin aPTT monitoring required with dose adjustment Fixed-dose; no aPTT monitoring required |
| | 17,500 units SC q12h (initial dose) | × | | | | | |
| | 330 units/kg SC × 1 then 250 units/kg SC q12h | × | | | | | |
| Enoxaparin ³ | 1 mg/kg SC q12h | × | × | × | | | Most patients: begin warfarin at time of initiation of LMWH |
| | 1.5 mg/kg SC once daily | | × | | | | |
| Tinzaparin ³ | 175 units/kg SC once daily | × | × | × | | × | Cancer: administer LMWH for ≥ 3-6 months |
| Dalteparin ³ | 200 units/kg SC once daily | × | × | × | | × | Cancer: administer LMWH for ≥ 3-6 months; reduce dose to 150 units/kg after first month of treatment |
| Fondaparinux | 5-10 mg SC once daily (see Comment) | × | × | × | | | Use 7.5 mg for body weight 50-100 kg. 10 mg for body weight > 100 kg |

Note: An “×” denotes appropriate use of the anticoagulant.

¹Obtain baseline hemoglobin, platelet count, aPTT/PT/INR, creatinine, urinalysis, and hemocult prior to initiation of anticoagulation. Anticoagulation is contraindicated in the setting of active bleeding.

²Defined as creatinine clearance < 30 mL/min.

³Body weight < 50 kg: reduce dose and monitor anti-Xa levels.

DVT, deep venous thrombosis; IV, intravenously; PE, pulmonary embolism; SC, subcutaneously; VTE, venous thromboembolic disease (includes DVT and PE).

dates for injectable anticoagulants, and they have good follow-up. Risk stratification in patients with PE should be done at time of diagnosis to identify patients at higher risk for mortality and complications. These patients may benefit from a higher level of care, prolonged hospitalization, or treatment with thrombolysis.

1. Heparin—Selection of a parenteral anticoagulant should be determined by patient characteristics (renal function, immediate bleeding risk, weight) and clinical scenario (if thrombolysis is being considered). LMWHs are as efficacious as unfractionated heparin in the immediate treatment of DVT and PE. LMWHs are preferred over unfractionated heparin as initial treatment because of predictable pharmacokinetics, which allow for subcutaneous, once- or twice-daily dosing with no requirement for monitoring in most patients. Monitoring of the therapeutic effect of LMWH may be indicated in pregnancy, compromised renal func-

tion, and extremes of weight. Accumulation of the LMWH and increased rates of bleeding have been observed among patients with severe renal insufficiency (creatinine clearance < 30 mL/min), leading to a recommendation to use intravenous unfractionated heparin in the place of LMWH in these higher-risk patients. If concomitant thrombolysis is being considered, unfractionated heparin is indicated. In addition, patients with VTE and a perceived higher risk of bleeding (ie, post-surgery) may be better candidates for treatment with unfractionated heparin than LMWH given its shorter half-life and reversibility.

Weight-based, fixed-dose daily subcutaneous fondaparinux (a synthetic factor Xa inhibitor) may also be used for the initial treatment of DVT and PE, with no increase in bleeding over that observed with LMWH. Its lack of reversibility, long half-life, and primarily renal clearance limits its use in patients with an increased risk of bleeding or renal failure.

Table 14-14. Patient selection for outpatient treatment of DVT.

| Patients considered appropriate for outpatient treatment |
|--|
| No clinical signs or symptoms of PE and pain controlled |
| Motivated and capable of self-administration of injections |
| Confirmed prescription insurance that covers injectable medication or patient can pay out-of-pocket for injectable agents |
| Capable and willing to comply with frequent follow-up |
| Initially, patients may need to be seen daily to weekly |
| Potential contraindications for outpatient treatment |
| DVT involving inferior vena cava, iliac, common femoral, or upper extremity vein (these patients might benefit from vascular intervention) |
| Comorbid conditions |
| Active peptic ulcer disease, GI bleeding in past 14 days, liver synthetic dysfunction: |
| Brain metastases, current or recent CNS or spinal cord injury/surgery in the last 10 days, CVA \leq 4-6 weeks |
| Familial bleeding diathesis |
| Active bleeding from source other than GI |
| Thrombocytopenia |
| Creatinine clearance $<$ 30 mL/min |
| Patient weighs $<$ 55 kg (male) or 45 kg (female) |
| Recent surgery, spinal or epidural anesthesia in the past 3 days |
| History of heparin-induced thrombocytopenia |
| Inability to inject medication at home, reliably follow medication schedule, recognize changes in health status, understand or follow directions |

2. Warfarin—Patients with DVT with or without PE require a minimum of 3 months of anticoagulation in order to reduce the risk of recurrence of thrombosis. An oral vitamin K antagonist, such as warfarin, is usually initiated along with the parenteral anticoagulant, although patients with cancer-related thrombosis may benefit from ongoing treatment with LMWH alone. Most patients require 5 mg of warfarin daily for initial treatment, but lower doses (2.5 mg daily) should be considered for patients of Asian descent, the elderly, and those with hyperthyroidism, congestive heart failure, liver disease, recent major surgery, malnutrition, certain polymorphisms for the CYP2C9 or the VKORC1 genes or who are receiving concurrent medications that increase sensitivity to warfarin (Table 14-15). Conversely, individuals of African descent, those with larger body mass index or hypothyroidism, and those who are receiving medications that increase warfarin metabolism may require higher initial doses (7.5 mg daily). Daily INR results should guide dosing adjustments (Table 14-16). Web-based warfarin dosing calculators that consider these clinical and genetic factors are available to help clinicians choose the appropriate starting dose (www.warfarindosing.org and <http://warfdocs.ucdavis.edu/>). Because an average of 5 days is required to achieve a steady-state reduction in the activity of vitamin K-dependent coagulation factors, the parenteral anticoagulant should be continued for at least 5 days and until the INR is $>$ 2.0 on 2 consecutive days. Meticulous follow-up should be arranged for all patients taking warfarin because of the bleeding risk that is associated with initiation of therapy (Table 14-17). INR monitoring should occur at

Table 14-15. Commonly used agents and their potential effect on the INR.

| Tendency to Increase INR | Tendency to Decrease INR |
|---------------------------------|---------------------------------|
| Phenytoin | Phenytoin |
| Erythromycin | Rifampin/rifabutin |
| Metronidazole | Carbamazepine |
| Ketoconazole | Vitamin K |
| Trimethoprim-sulfamethoxazole | Phenobarbital |

INR, international normalized ratio.

least twice weekly during initiation. Once stabilized, the INR should be checked at an interval no longer than every 4 weeks. Supratherapeutic INRs should be managed according to evidence-based guidelines (Table 14-18).

3. New investigational oral anticoagulants—The vitamin K antagonists have been the only oral anticoagulants available for nearly 7 decades. Now, a number of novel oral anticoagulant agents that promise more predictable dose effect and ease of administration than warfarin are under investigation. Rivaroxaban, a direct factor Xa inhibitor, has a

Table 14-16. Warfarin adjustment guidelines for patients newly starting therapy.

| | INR | Action |
|-------------------------|---------------------------------|--|

¹Adapted from Guidelines used at the VA Medical Center, Reno NV.

predictable dose effect, minimal drug interactions, and does not require laboratory monitoring. It has been found to be effective in prevention of VTE in orthopedic surgery in phase III trials. Dabigatran, a DTI, was recently approved for use in Europe for prevention of VTE in orthopedic surgery. It requires an acid environment for absorption and cannot be used in renal failure; however, it can be taken once daily and does not require monitoring. Phase III trials for treatment of VTE and stroke prevention in atrial fibrillation are ongoing.

4. Duration of anticoagulation therapy—The clinical scenario in which the thrombosis occurred is the strongest

predictor of recurrence and, in most cases, guides duration of anticoagulation (Table 14-19). In the first year after discontinuation of anticoagulation therapy, the frequency of recurrence of VTE among individuals whose thrombosis occurred in the setting of a transient, major, reversible risk factor (such as surgery) is approximately 3%, compared with 8% for individuals whose thrombosis was unprovoked, and > 20% in patients with cancer. Patients with provoked VTE are generally treated with a 3-month course of anticoagulation, whereas unprovoked VTE should prompt consideration of indefinite anticoagulation. Both normal D-dimer levels and lack of residual vein thrombosis

Table 14-18. American College of Chest Physicians' evidence-based clinical practice guidelines for the management of supratherapeutic INR.

| Clinical Situation | INR | Recommendations |
|--------------------------------|-----------------------------------|---|
| No significant bleed | Above therapeutic range but < 5.0 | <ul style="list-style-type: none"> Lower dose or omit dose Monitor more frequently and resume at lower dose when INR falls within therapeutic range (if INR slightly above range, may not be necessary to decrease dose) |
| | ≥ 5.0 but < 9.0 | <ul style="list-style-type: none"> Hold next 1-2 doses Monitor more frequently and resume therapy at lower dose when INR falls within therapeutic range <i>Patients at high risk for bleeding</i>¹: Hold warfarin PLUS give vitamin K₁ ≤ 2.5 mg PO, check INR in 24-48 h to ensure response to therapy |
| | ≥ 9.0 | <ul style="list-style-type: none"> Hold warfarin Vitamin K₁ 2.5-5 mg PO × 1; may repeat Monitor frequently and resume therapy at lower dose when INR within therapeutic range |
| Serious/life-threatening bleed | | <ul style="list-style-type: none"> Hold warfarin and give 10 mg vitamin K by slow IV infusion supplemented by FFP, PCC, or recombinant factor VIIa |

¹Patients at higher risk for bleeding include the elderly; conditions that increase the risk of bleeding include renal failure, hypertension, falls, liver disease, and history of gastrointestinal or genitourinary bleeding.

FFP, fresh frozen plasma; PCC, prothrombin complex concentrate.

(Ansell J et al. Pharmacology and management of the vitamin K antagonists: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th Edition) Chest. 2008 Jun;133(6 Suppl):160S-198S.)

Table 14-19. Long-term treatment of VTE.

| Scenario | Suggested Duration of Therapy | Comments |
|--|--|---|
| Major transient risk factor (eg, immobilization, major surgery, major trauma, major hospitalization) | 3 months | VTE prophylaxis required upon future exposure to transient risk factors |
| Minor transient risk factor (eg, exposure to exogenous estrogens/progestins, pregnancy, airline travel lasting more than 6 hours) | 3 months | VTE prophylaxis required upon future exposure to transient risk factors |
| Cancer-related VTE | ≥ 3-6 months or as long as cancer active, whichever is longer | LMWH recommended for initial treatment (see Table 14-13) |
| Unprovoked thrombosis | Minimum of 3 months, consider indefinite if bleeding risk allows | May risk-stratify for recurrence based on presence of residual venous occlusion, D-dimer levels |
| Underlying significant thrombophilia (eg, antiphospholipid antibody syndrome, antithrombin deficiency, protein C deficiency, protein S deficiency, ≥ two concomitant thrombophilic conditions) | Indefinite | Delay investigation for laboratory thrombophilia until 3 months after event to avoid false positivity |

LMWH, low-molecular-weight heparin; VTE, venous thromboembolic disease.

3-6 months after cessation of warfarin therapy are associated with lower recurrence risk, potentially identifying a cohort of patients with unprovoked VTE in whom anticoagulation does not need to be continued indefinitely. Risk-stratification schemas have not been standardized and remain an area of active research. The benefit of anticoagulation must be weighed against the bleeding risks posed by this therapy and should be assessed at the initiation of therapy and then at least annually in any patient receiving prolonged therapy. Bleeding risk scores have been developed to help clinicians in this process.

B. Thrombolytic Therapy

Anticoagulation alone is appropriate treatment for most patients with PE; however, those with massive PE, defined as PE with persistent hemodynamic instability, have an in-hospital mortality rate that approaches 30% and require immediate thrombolysis in combination with anticoagulation (Table 14-20). Thrombolytic therapy also has been used in selected patients with submassive PE, defined as PE with hemodynamic stability and evidence of right ventricular compromise. A single, randomized, controlled trial comparing thrombolytics plus heparin with heparin alone in this population showed a statistically significant decrease in the combined end point of mortality and escalation of care in patients who underwent thrombolysis. However, selection of patients with submassive PE remains controversial, and clinical investigation into this issue is in progress.

Limited data suggest that patients with large proximal iliofemoral DVT may also benefit from catheter-directed thrombolysis in addition to treatment with anticoagulation. However, standardized guidelines are lacking, and use of the intervention may be limited by institutional availability and provider experience. Importantly, thrombolytics should be considered only in patients who have a low risk of bleeding, as rates of bleeding are increased in patients who receive these products compared with rates of hemorrhage in those who are treated with anticoagulation alone.

C. Nonpharmacologic Therapy

1. Graduated compression stockings—In order to reduce the likelihood of the post-thrombotic syndrome, which is characterized by swelling, pain, and skin ulceration, all patients with DVT should wear a graduated compression stocking with 30–40 mm Hg pressure at the ankle on the affected lower extremity for 1–2 years. Stockings should be provided immediately to have the most impact on post-thrombotic syndrome; however, they are contraindicated in patients with peripheral vascular disease.

Kolbach DN et al. Non-pharmacologic measures for prevention of post-thrombotic syndrome. *Cochrane Database Syst Rev.* 2004;(1):CD004174. [PMID: 14974060]

2. Inferior vena caval (IVC) filters—There is a paucity of data to support the use of IVC filters for the prevention of PE in any clinical scenario. A single, randomized, controlled trial of IVC filter placement and PE prevention in patients with documented DVT involved concurrent administration of anticoagulation and showed mixed results of a reduction in the rate of nonfatal PE and an increase in the rate of DVT (20% at 2 years) in patients who had received permanent filters. Most experts agree with placing a device in patients with acute proximal DVT and an absolute contraindication to anticoagulation. The remainder of the indications (submassive PE, free-floating iliofemoral DVT, perioperative risk

reduction) are controversial. If the contraindication to anticoagulation is temporary (eg, perisurgical patients), placement of a retrievable IVC filter should be considered so that the device can be removed once anticoagulation has been started and has been shown to be tolerated.

Complications of IVC filters include local thrombosis, tilting, migration, and inability to retrieve the device. When considering placement of an IVC filter, it is best to consider both short- and long-term complications, since even devices intended for removal may become permanent.

▶ When to Refer

- Presence of large iliofemoral VTE, IVC thrombosis, or Budd-Chiari syndrome for consideration of catheter-directed thrombolysis.
- Massive PE for urgent embolectomy.
- History of HIT or prolonged PTT plus renal failure for alternative anticoagulation regimens.
- Need for IVC filter placement.

▶ When to Admit

- Documented or suspected PE.
- DVT with poorly controlled pain, high bleeding risk, contraindications to LMWH or fondaparinux.
- Large iliofemoral DVT for consideration of thrombolysis.
- Acute DVT and absolute contraindication to anticoagulation for IVC filter placement.

15

Gastrointestinal Disorders

Kenneth R. McQuaid, MD

SYMPTOMS & SIGNS OF GASTROINTESTINAL DISEASE

DYSPEPSIA

ESSENTIALS OF DIAGNOSIS

- ▶ Epigastric pain or burning, early satiety, or postprandial fullness.
- ▶ Endoscopy is warranted in patients with alarm features or in those older than 55 years.
- ▶ All other patients should first undergo testing for *Helicobacter pylori* or a trial of empiric proton pump inhibitor.

▶ General Considerations

Dyspepsia refers to acute, chronic, or recurrent pain or discomfort centered in the upper abdomen. An international committee of clinical investigators (Rome III Committee) has defined dyspepsia as epigastric pain or burning, early satiety, or postprandial fullness. Heartburn (retrosteral burning) should be distinguished from dyspepsia. When heartburn is the dominant complaint, gastroesophageal reflux is nearly always present. Dyspepsia occurs in 25% of the adult population and accounts for 3% of general medical office visits.

▶ Etiology

A. Food or Drug Intolerance

Acute, self-limited “indigestion” may be caused by overeating, eating too quickly, eating high-fat foods, eating during stressful situations, or drinking too much alcohol or coffee. Many medications cause dyspepsia, including aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), antibiotics (metronidazole, macrolides), diabetes drugs (metformin, α -glucosidase inhibitors, amylin analogs, GLP-1 receptor antagonists), anti-hypertensive medications (angiotensin-converting enzyme [ACE] inhibitors, angiotensin-receptor blockers), cholesterol-

lowering agents (niacin, fibrates), neuropsychiatric medications (cholinesterase inhibitors [donepezil, rivastigmine]), SSRIs (fluoxetine, sertraline), serotonin-norepinephrine-reuptake inhibitors (venlafaxine, duloxetine), Parkinson’s drugs (dopamine agonists, monoamine oxidase [MAO]-B inhibitors), corticosteroids, estrogens, digoxin, iron, and opioids.

B. Luminal Gastrointestinal Tract Dysfunction

Peptic ulcer disease is present in 5–15% of patients with dyspepsia. Gastroesophageal reflux disease (GERD) is present in up to 20% of patients with dyspepsia, even without significant heartburn. Gastric cancer is identified in 1% but is extremely rare in persons under age 55 years with uncomplicated dyspepsia. Other causes include gastroparesis (especially in diabetes mellitus), lactose intolerance or malabsorptive conditions, and parasitic infection (*Giardia*, *Strongyloides*).

C. *Helicobacter pylori* Infection

Although chronic gastric infection with *H pylori* is an important cause of peptic ulcer disease, it is an uncommon cause of dyspepsia in the absence of peptic ulcer disease. The prevalence of *H pylori*-associated chronic gastritis in patients with dyspepsia without peptic ulcer disease is 20–50%, the same as in the general population.

D. Pancreatic Disease

Pancreatic carcinoma and chronic pancreatitis may present with dyspepsia.

E. Biliary Tract Disease

The abrupt onset of epigastric or right upper quadrant pain due to cholelithiasis or choledocholithiasis should be readily distinguished from dyspepsia.

F. Other Conditions

Diabetes mellitus, thyroid disease, chronic kidney disease, myocardial ischemia, intra-abdominal malignancy, gastric volvulus or paraesophageal hernia, and pregnancy are sometimes accompanied by dyspepsia.

G. Functional Dyspepsia

This is the most common cause of chronic dyspepsia. Up to two-thirds of patients have no obvious organic cause for their symptoms after evaluation. Symptoms may arise from a complex interaction of increased visceral afferent sensitivity, gastric delayed emptying or impaired accommodation to food, or psychosocial stressors. Although benign, these symptoms may be chronic and difficult to treat.

► Clinical Findings

A. Symptoms and Signs

Given the nonspecific nature of dyspeptic symptoms, the history has limited diagnostic utility. It should clarify the chronicity, location, and quality of the discomfort, and its relationship to meals. The discomfort may be characterized by one or more upper abdominal symptoms including epigastric pain or burning, early satiety, postprandial fullness, bloating, nausea, or vomiting. Concomitant weight loss, persistent vomiting, constant or severe pain, dysphagia, hematemesis, or melena warrants endoscopy or abdominal imaging. Potentially offending medications and excessive alcohol use should be identified and discontinued if possible. The patient's reason for seeking care should be determined. Recent changes in employment, marital discord, physical and sexual abuse, anxiety, depression, and fear of serious disease may all contribute to the development and reporting of symptoms. Patients with functional dyspepsia often are younger, report a variety of abdominal and extragastrointestinal complaints, show signs of anxiety or depression, or have a history of use of psychotropic medications.

The symptom profile alone does not differentiate between functional dyspepsia and organic gastrointestinal disorders. Based on the clinical history alone, primary care physicians misdiagnose nearly half of patients with peptic ulcers or gastroesophageal reflux and have < 25% accuracy in diagnosing functional dyspepsia.

The physical examination is rarely helpful. Signs of serious organic disease such as weight loss, organomegaly, abdominal mass, or fecal occult blood are further evaluated. In patients older than age of 50 years, initial laboratory work should include a blood count, electrolytes, liver enzymes, calcium, and thyroid function tests.

B. Laboratory Findings

In patients younger than 55 years with uncomplicated dyspepsia (in whom gastric cancer is rare), initial noninvasive management strategies should be pursued (see below). In most clinical settings, a noninvasive test for *H pylori* (urea breath test, fecal antigen test, or IgG serology) should be performed first. Although serologic tests are inexpensive, performance characteristics are poor in low-prevalence populations. If breath test or fecal antigen test results are negative in a patient not taking NSAIDs, peptic ulcer disease is virtually excluded.

C. Upper Endoscopy

Upper endoscopy is indicated to look for gastric cancer or other serious organic disease in all patients over age 55 years

with new-onset dyspepsia and in all patients with "alarm" features, such as weight loss, dysphagia, recurrent vomiting, evidence of bleeding, or anemia. Upper endoscopy is the study of choice to diagnose gastroduodenal ulcers, erosive esophagitis, and upper gastrointestinal malignancy. It is also helpful for patients who are concerned about serious underlying disease. For patients born in regions in which there is a higher incidence of gastric cancer, an age threshold of 45 years may be appropriate.

Endoscopic evaluation is also warranted when symptoms fail to respond to initial empiric management strategies or when frequent symptom relapse occurs after discontinuation of antisecretory therapy.

D. Other Tests

Abdominal imaging (ultrasonography or CT scanning) is performed only when pancreatic or biliary tract disease is suspected. Gastric emptying studies are valuable only in patients with recurrent vomiting. Ambulatory esophageal pH testing may be of value when atypical gastroesophageal reflux is suspected.

► Treatment

Initial empiric treatment is warranted for patients who are less than 55 years and who have no alarm features (defined above). All other patients as well as patients whose symptoms fail to respond or relapse after empiric treatment should undergo upper endoscopy with subsequent treatment directed at the specific disorder (eg, peptic ulcer, gastroesophageal reflux, cancer). Most patients will have no significant findings on endoscopy and will be given a diagnosis of functional dyspepsia.

A. Empiric Therapy

H pylori-negative patients most likely have functional dyspepsia or atypical GERD and can be treated with an anti-secretory agent (proton pump inhibitor) for 4 weeks. For patients who have symptom relapse after discontinuation of the proton pump inhibitor, intermittent or long-term proton pump inhibitor therapy may be considered.

For patients in whom test results are positive for *H pylori*, antibiotic therapy proves definitive for over 90% of peptic ulcers and may improve symptoms in a small subset (< 10%) of infected patients with functional dyspepsia. Patients with persistent dyspepsia after *H pylori* eradication can be given a trial of proton pump inhibitor therapy. In clinical settings in which the prevalence of *H pylori* infection in the population is low (< 10%), it may be more cost-effective to initially treat all young patients with uncomplicated dyspepsia with a 4-week trial of a proton pump inhibitor. Patients who have symptom relapse after discontinuation of the proton pump inhibitor should be tested for *H pylori* and treated if positive.

B. Treatment of Functional Dyspepsia

1. General measures—Most patients have mild, intermittent symptoms that respond to reassurance and lifestyle changes. Alcohol, caffeine, and fatty foods should be

reduced or discontinued. A food diary, in which patients record their food intake, symptoms, and daily events, may reveal dietary or psychosocial precipitants of pain.

2. Pharmacologic agents—Drugs have demonstrated limited efficacy in the treatment of functional dyspepsia. One-third of patients derive relief from placebo. Antisecretory therapy for 4–8 weeks with proton pump inhibitors (omeprazole, esomeprazole, or rabeprazole 20 mg, lansoprazole 30 mg, or pantoprazole 40 mg) may benefit 10–15% of patients, particularly those with dyspepsia characterized as epigastric pain (“ulcer-like dyspepsia”) or dyspepsia and heartburn (“reflux-like dyspepsia”). Low doses of antidepressants (eg, desipramine or nortriptyline, 10–50 mg at bedtime) are believed to benefit some patients, possibly by moderating visceral afferent sensitivity. However, side effects are common and response is patient-specific. Doses should be increased slowly. The prokinetic agent metoclopramide (5–10 mg three times daily) may improve symptoms, but improvement does not correlate with the presence or absence of gastric emptying delay. In 2009, the FDA issued a black box warning that metoclopramide use for more than 3 months is associated with a high incidence of tardive dyskinesia and should be avoided. The elderly, particularly elderly women, are most at risk. Recently, a randomized, placebo-controlled study has demonstrated efficacy of the novel prokinetic agent itopride in the treatment of functional dyspepsia. This agent enhances the release of gastric acetylcholine through dual inhibition of D₂ receptors and acetylcholinesterase. This agent is not yet available in the United States.

3. Anti-*H pylori* treatment—Meta-analyses have suggested that a small number of patients with functional dyspepsia (< 10%) derive benefit from *H pylori* eradication therapy. Therefore, patients with functional dyspepsia should be tested and treated for *H pylori*.

4. Alternative therapies—Psychotherapy and hypnotherapy may be of benefit in selected motivated patients with functional dyspepsia. Herbal therapies (peppermint, caraway) may offer benefit with little risk of adverse effects.

NAUSEA & VOMITING

Nausea is a vague, intensely disagreeable sensation of sickness or “queasiness” and is distinguished from anorexia. Vomiting often follows, as does retching (spasmodic respiratory and abdominal movements). Vomiting should be distinguished from regurgitation, the effortless reflux of liquid or food stomach contents; and from rumination, the chewing and swallowing of food that is regurgitated voluntarily after meals.

The brainstem vomiting center is composed of a group of neuronal areas (area postrema, nucleus tractus solitarius, and central pattern generator) within the medulla that coordinate emesis. It may be stimulated by four different sources of afferent input: (1) Afferent vagal fibers from the gastrointestinal viscera are rich in serotonin 5-HT₃ receptors; these may be stimulated by biliary or gastrointestinal distention, mucosal or peritoneal irritation, or infections. (2) Fibers of the vestibular system, which have high concentrations of histamine H₁ and muscarinic cholinergic receptors. (3) Higher central nervous system centers (amygdala); here, certain sights, smells, or emotional experiences may induce vomiting. For example, patients receiving chemotherapy may start vomiting in anticipation of its administration. (4) The chemoreceptor trigger zone, located outside the blood-brain barrier in the area postrema of the medulla, which is rich in opioid, serotonin 5-HT₃, neurokinin 1 (NK₁) and dopamine D₂ receptors. This region may be stimulated by drugs and chemotherapeutic agents, toxins, hypoxia, uremia, acidosis, and radiation therapy. Although the causes of vomiting are many, a simplified list is provided in Table 15–1.

► Clinical Findings

A. Symptoms and Signs

Acute symptoms without abdominal pain are typically caused by food poisoning, infectious gastroenteritis, drugs, or systemic illness. Inquiry should be made into recent changes in medications, diet, other intestinal symptoms, or similar illnesses in family members. The acute onset of severe pain and vomiting suggests peritoneal irritation, acute gastric or intestinal obstruction, or pancreaticobiliary disease. Persistent vomiting suggests pregnancy, gastric outlet obstruction, gastroparesis, intestinal dysmotility, psychogenic disorders, and central nervous system or systemic disorders. Vomiting that occurs in the morning before breakfast is common with pregnancy, uremia, alcohol intake, and increased intracranial pressure. Vomiting immediately after meals strongly suggests bulimia or psychogenic causes. Vomiting of undigested food one to several hours after meals is characteristic of gastroparesis or a gastric outlet obstruction; physical examination may reveal a succussion splash. Patients with acute or chronic symptoms should be asked about neurologic symptoms that

Table 15–1. Causes of nausea and vomiting.

CNS, central nervous system; NSAIDs, nonsteroidal anti-inflammatory drugs.

suggest a central nervous system cause such as headache, stiff neck, vertigo, and focal paresthesias or weakness.

B. Special Examinations

With vomiting that is severe or protracted, serum electrolytes should be obtained to look for hypokalemia, azotemia, or metabolic alkalosis resulting from loss of gastric contents. Flat and upright abdominal radiographs or abdominal CT are obtained in patients with severe pain or suspicion of mechanical obstruction to look for free intraperitoneal air or

dilated loops of small bowel. If mechanical small intestinal or gastric obstruction is thought likely, a nasogastric tube is placed for relief of symptoms. The cause of gastric outlet obstruction is best demonstrated by upper endoscopy, and the cause of small intestinal obstruction is best demonstrated with abdominal CT imaging. Gastroparesis is confirmed by nuclear scintigraphic studies or ^{13}C -octanoic acid breath tests, which show delayed gastric emptying and either upper endoscopy or barium upper gastrointestinal series showing no evidence of mechanical gastric outlet obstruction.

tion. Abnormal liver function tests or elevated amylase or lipase suggest pancreaticobiliary disease, which may be investigated with an abdominal sonogram or CT scan. Central nervous system causes are best evaluated with either head CT or MRI.

► Complications

Complications include dehydration, hypokalemia, metabolic alkalosis, aspiration, rupture of the esophagus (Boerhaave syndrome), and bleeding secondary to a mucosal tear at the gastroesophageal junction (Mallory-Weiss syndrome).

► Treatment

A. General Measures

Most causes of acute vomiting are mild, self-limited, and require no specific treatment. Patients should ingest clear liquids (broths, tea, soups, carbonated beverages) and small quantities of dry foods (soda crackers). For more severe acute vomiting, hospitalization may be required. Patients unable to eat and losing gastric fluids may become dehydrated, resulting in hypokalemia with metabolic alkalosis. Intravenous 0.45% saline solution with 20 mEq/L of potassium chloride is given in most cases to maintain hydration. A nasogastric suction tube for gastric decompression improves patient comfort and permits monitoring of fluid loss.

B. Antiemetic Medications

Medications may be given either to prevent or to control vomiting (see above). Combinations of drugs from different classes may provide better control of symptoms with less toxicity in some patients. All of these medications should be avoided in pregnancy. (For dosages, see Table 15–2.)

1. Serotonin 5-HT₃-receptor antagonists—Ondansetron, granisetron, dolasetron, and palonosetron are effective in preventing chemotherapy- and radiation-induced emesis when initiated prior to treatment. Single-dose administration schedules are as effective as multiple-dose regimens. Although serotonin antagonists are effective for the prevention of postoperative nausea and vomiting, less expensive alternatives (eg, dexamethasone or droperidol) are equally effective.

2. Corticosteroids—Corticosteroids (eg, dexamethasone) have antiemetic properties, but the basis for these effects is unknown. These agents enhance the efficacy of serotonin receptor antagonists for preventing acute and delayed nausea and vomiting in patients receiving moderately to highly emetogenic chemotherapy regimens. For the prevention of postoperative nausea and vomiting, corticosteroids, serotonin antagonists, and droperidol have efficacy; however, combinations of these agents have additive benefit.

3. Neurokinin receptor antagonists—Aprepitant (125 mg orally) and fosaprepitant (115 mg intravenously) are highly selective antagonists for NK₁-receptors in the area postrema. They are used in combination with corticosteroids and serotonin antagonists for the prevention of acute and

Table 15–2. Common antiemetic dosing regimens.

| | Dosage | Route |
|---|---|----------------|
| Serotonin 5-HT₃ antagonists | | |
| Ondansetron | Doses vary: 8 mg once or twice daily to 24–32 mg once daily | IV |
| | 8 mg twice daily | PO |
| Granisetron | 1 mg or 0.01 mg/kg once daily | IV |

| Lorazepam | 1–2 mg every 4–6 hours | PO, IV |

IM, intramuscularly; IV, intravenously; PO, orally; PR, per rectum.

delayed nausea and vomiting with highly emetogenic chemotherapy regimens. Combined therapy with a neurokinin1 receptor antagonist prevents acute emesis in 80–90% and delayed emesis in > 70% of patients treated with highly emetogenic regimens.

4. Dopamine antagonists—The phenothiazines, butyrophenones, and substituted benzamides have antiemetic properties that are due to dopaminergic blockade as well as to their sedative effects. High doses of these agents are associated with antidopaminergic side effects, including extrapyramidal reactions and depression. These agents are used in a variety of situations. Cases of QT prolongation leading to ventricular tachycardia (torsades de pointes) have been reported in several patients receiving droperidol, hence electrocardiographic monitoring is recommended before and after administration.

5. Antihistamines and anticholinergics—These drugs (eg, meclizine, dimenhydrinate, transdermal scopolamine) may be valuable in the prevention of vomiting arising from stimulation of the labyrinth, ie, motion sickness, vertigo, and migraines. They may induce drowsiness.

6. Sedatives—Benzodiazepines are used in psychogenic and anticipatory vomiting.

7. Cannabinoids—Marijuana has been used widely as an appetite stimulant and antiemetic. Pure Δ^9 -tetrahydrocannabinol (THC) is the major active ingredient in marijuana and is available by prescription as dronabinol. In doses of 5–15 mg/m², oral dronabinol is effective in treating nausea associated with chemotherapy, but it is associated with central nervous system side effects in most patients.

HICCUPS (Singultus)

Though usually a benign and self-limited annoyance, hiccups may be persistent and a sign of serious underlying illness. In patients on mechanical ventilation, hiccups can trigger a full respiratory cycle and result in respiratory alkalosis.

Causes of benign, self-limited hiccups include gastric distention (carbonated beverages, air swallowing, overeating), sudden temperature changes (hot then cold liquids, hot then cold shower), alcohol ingestion, and states of heightened emotion (excitement, stress, laughing). There are over 100 causes of recurrent or persistent hiccups, grouped into the following categories:

Central nervous system: Neoplasms, infections, cerebrovascular accident, trauma.

Metabolic: Uremia, hypocapnia (hyperventilation).

Irritation of the vagus or phrenic nerve: (1) Head, neck: Foreign body in ear, goiter, neoplasms. (2) Thorax: Pneumonia, empyema, neoplasms, myocardial infarction, pericarditis, aneurysm, esophageal obstruction, reflux esophagitis. (3) Abdomen: Subphrenic abscess, hepatomegaly, hepatitis, cholecystitis, gastric distention, gastric neoplasm, pancreatitis, or pancreatic malignancy.

Surgical: General anesthesia, postoperative.

Psychogenic and idiopathic.

► Clinical Findings

Evaluation of the patient with persistent hiccups should include a detailed neurologic examination, serum creatinine, liver chemistry tests, and a chest radiograph. When the cause remains unclear, CT of the head, chest, and abdomen, echocardiography, bronchoscopy, and upper endoscopy may help. On occasion, hiccups may be unilateral; chest fluoroscopy will make the diagnosis.

► Treatment

A number of simple remedies may be helpful in patients with acute benign hiccups. (1) Irritation of the nasopharynx

by tongue traction, lifting the uvula with a spoon, catheter stimulation of the nasopharynx, or eating 1 tsp of dry granulated sugar. (2) Interruption of the respiratory cycle by breath holding, Valsalva maneuver, sneezing, gasping (fright stimulus), or rebreathing into a bag. (3) Stimulation of the vagus, carotid massage. (4) Irritation of the diaphragm by holding knees to chest or by continuous positive airway pressure during mechanical ventilation. (5) Relief of gastric distention by belching or insertion of a nasogastric tube.

A number of drugs have been promoted as being useful in the treatment of hiccups. Chlorpromazine, 25–50 mg orally or intramuscularly, is most commonly used. Other agents reported to be effective include anticonvulsants (phenytoin, carbamazepine), benzodiazepines (lorazepam, diazepam), metoclopramide, baclofen, gabapentin, and occasionally general anesthesia.

CONSTIPATION

Constipation occurs in 10–15% of adults and is a common reason for seeking medical attention. It is more common in women. The elderly are predisposed due to comorbid medical conditions, medications, poor eating habits, decreased mobility and, in some cases, inability to sit on a toilet (bed-bound patients). The first step in evaluating the patient is to determine what is meant by “constipation.” Patients may define constipation as infrequent stools (fewer than three in a week), hard stools, excessive straining, or a sense of incomplete evacuation. Table 15–3 summarizes the many causes of constipation, which are discussed below.

► Etiology

A. Primary Constipation

Most patients have constipation that cannot be attributed to any structural abnormalities or systemic disease. Some of these patients have normal colonic transit time; however, a subset have slow colonic transit or anorectal dysfunction. Normal colonic transit time is approximately 35 hours; more than 72 hours is significantly abnormal. Slow colonic transit is commonly idiopathic but may be part of a generalized gastrointestinal dysmotility syndrome. Patients may complain of infrequent bowel movements and abdominal bloating. Slow transit is more common in women, some of whom have a history of psychosocial problems (depression, anxiety, eating disorder, childhood trauma) or sexual abuse. Normal defecation requires coordination between relaxation of the anal sphincter and pelvic floor musculature while abdominal pressure is increased. Patients with dyssynergic defecation (also known as anismus or pelvic floor dyssynergia)—women more often than men—have impaired relaxation or paradoxical contraction of the anal sphincter and/or pelvic floor muscles during attempted

Table 15–3. Causes of constipation in adults.

| |
|--|
| Most common |
| Inadequate fiber or fluid intake |
| Poor bowel habits |
| Systemic disease |
| Endocrine: hypothyroidism, hyperparathyroidism, diabetes mellitus |
| Metabolic: hypokalemia, hypercalcemia, uremia, porphyria |
| Neurologic: Parkinson disease, multiple sclerosis, sacral nerve damage (prior pelvic surgery, tumor), paraplegia, autonomic neuropathy |
| Medications |
| Opioids |
| Diuretics |
| Calcium channel blockers |
| Anticholinergics |
| Psychotropics |
| Calcium and iron supplements |
| NSAIDs |
| Clonidine |
| Cholestyramine |
| Structural abnormalities |
| Anorectal: rectal prolapse, rectocele, rectal intussusception, anorectal stricture, anal fissure, solitary rectal ulcer syndrome |
| Perineal descent |
| Colonic mass with obstruction: adenocarcinoma |
| Colonic stricture: radiation, ischemia, diverticulosis |
| Hirschsprung disease |
| Idiopathic megarectum |
| Slow colonic transit |
| Idiopathic: isolated to colon |
| Psychogenic |
| Eating disorders |
| Chronic intestinal pseudo-obstruction |
| Pelvic floor dyssynergia |
| Irritable bowel syndrome |

NSAIDs, nonsteroidal anti-inflammatory drugs.

defecation that impedes the bowel movement. This problem may be acquired during childhood or adulthood. Patients may complain of excessive straining, sense of incomplete evacuation, or need for digital manipulation. Patients with primary complaints of abdominal pain or bloating with alterations in bowel habits (constipation, or alternating constipation and diarrhea) may have irritable bowel syndrome (see below).

B. Secondary Constipation

Constipation may be caused by systemic disorders, medications, or obstructing colonic lesions. Systemic disorders can cause constipation because of neurologic gut dysfunction, myopathies, endocrine disorders, or electrolyte abnormalities (eg, hypercalcemia or hypokalemia); medication side effects are sometimes responsible (eg, anticholinergics or opioids). Colonic lesions that obstruct fecal passage, such as neoplasms and strictures, are an uncommon cause but important in new-onset constipation. Such lesions should be excluded in patients older than 45–50 years, in patients with “alarm” symptoms or signs (hematochezia, weight loss, anemia, or positive fecal occult blood tests [FOBT] or fecal immunochemical tests [FIT]), and in

patients with a family history of colon cancer or inflammatory bowel disease. Defecatory difficulties also can be due to a variety of anorectal problems that impede or obstruct flow (perineal descent, rectal prolapse, rectocele), some of which may require surgery, and Hirschsprung disease (usually suggested by lifelong constipation).

► Clinical Findings

A. Symptoms and Signs

All patients should undergo a history and physical examination to distinguish primary from secondary causes of constipation. Physical examination should include digital rectal examination with assessment for anatomic abnormalities, such as anal stricture, rectocele, rectal prolapse, or perineal descent during straining. Further diagnostic tests should be performed in patients with any of the following: age 50 years or older, severe constipation, signs of an organic disorder, alarm symptoms (hematochezia, weight loss, positive FOBT or FIT), or a family history of colon cancer or inflammatory bowel disease. These tests should include laboratory studies (complete blood count; serum electrolytes, calcium, glucose, and thyroid-stimulating hormone); and a colonoscopy or flexible sigmoidoscopy.

B. Special Examinations

Patients with refractory constipation not responding to routine medical management warrant further diagnostic studies, including colonic transit and pelvic floor function studies, in order to distinguish slow colonic transit from anorectal dysfunction. Colon transit time is most commonly measured by performing an abdominal radiograph 120 hours after ingestion of 24 radiopaque markers. Retention of greater than 20% of the markers indicates prolonged transit. Dyssynergic defecation is assessed with balloon expulsion testing, anal manometry, and defecography.

► Treatment

A. Chronic Constipation

1. Dietary and lifestyle measures—Adverse psychosocial issues should be identified and addressed. Patients should be instructed on normal defecatory function and optimal toileting habits, including regular timing, proper positioning, and abdominal pressure. Proper dietary fiber intake should be emphasized. A trial of fiber supplements is recommended (Table 15–4). Increased dietary fiber may cause distention or flatulence, which often diminishes over several days. Response to fiber therapy is not immediate, and increases in dosage should be made gradually over 7–10 days. Fiber is most likely to benefit patients with normal colonic transit, but it may not benefit patients with colonic inertia, anorectal dysfunction, or irritable bowel syndrome; it may even exacerbate symptoms in these patients. Regular exercise is associated with a decreased risk of constipation. When possible, discontinue medications that may be causing constipation.

2. Laxatives—Laxatives may be given on an intermittent or chronic basis for constipation that does not respond to

Table 15–4. Pharmacologic management of constipation.

| Agent | Dosage | Onset of Action | Comments |
|--|--|-----------------|--|
| Fiber laxatives | | | |
| Bran powder | 1–4 tbsp orally twice daily | Days | Inexpensive; may cause gas, flatulence |
| Psyllium | 1 tsp once or twice daily | Days | (Metamucil; Perdiem) |
| Methylcellulose | 1 tsp once or twice daily | Days | (Citrucel) Less gas, flatulence |
| Calcium polycarboxylate | 1 or 2 tablets once or twice daily | 12–24 hours | (FiberCon) Does not cause gas; pill form |
| Guargum | 1 tbsp once or twice daily | Days | (Benefiber) Non-gritty, tasteless, less gas |
| Stool surfactants | | | |
| Docusate sodium | 100 mg once or twice daily | 12–72 hours | (Colace) Marginal benefit |
| Mineral oil | 15–45 mL once or twice daily | 6–8 hours | May cause lipid pneumonia if aspirated |
| Osmotic laxatives | | | |
| Magnesium hydroxide | 15–30 mL orally once or twice daily | 6–24 hours | (Milk of magnesia; Epsom salts) |
| Lactulose or 70% sorbitol | 15–60 mL orally once daily to three times daily | 6–48 hours | Cramps, bloating, flatulence |
| Polyethylene glycol (PEG 3350) | 17 g in 8 oz liquid once or twice daily | 6–24 hours | (Miralax) Less bloating than lactulose, sorbitol |
| Stimulant laxatives | | | |
| Bisacodyl | 5–20 mg orally as needed | 6–8 hours | May cause cramps; avoid daily use if possible |
| Bisacodyl | 10 mg per rectum as needed | 1 hour | |
| Cascara | 4–8 mL or 2 tablets as needed | 8–12 hours | (Nature’s Remedy) May cause cramps; avoid daily use if possible |
| Senna | 8.6–17.2 mg orally as needed | 8–12 hours | (ExLax; Senekot) May cause cramps; avoid daily use if possible |
| Lubiprostone | 24 mcg orally twice daily | 12–48 hours | Expensive; may cause nausea. Contraindicated in pregnancy |
| Enemas | | | |
| Tap water | 500 mL per rectum | 5–15 minutes | |
| Sodium phosphate enema | 120 mL per rectum | 5–15 minutes | Commonly used for acute constipation or to induce movement prior to medical procedures |
| Soapsuds enema | Up to 1500 mL per rectum | 5–15 minutes | Impaction |
| Mineral oil enema | 100–250 mL per rectum | | To soften and lubricate fecal impaction |
| Agents used for acute purgative or to clean bowel prior to medical procedures | | | |
| Polyethylene glycol (PEG 3350) | 4 L orally administered over 2–4 hours | < 4 hours | (GoLYTELY; CoLYTE; NuLYTE, MoviPrep) Used to cleanse bowel before colonoscopy |
| Sodium phosphate | As directed with total of 2–4 L of clear liquids | 1–6 hours | (OsmoPrep, Visicol, Fleets) Used before colonoscopy |
| Magnesium citrate | 10 oz orally | 3–6 hours | Lemon-flavored |

dietary and lifestyle changes (Table 15–4). There is no evidence that long-term use of these agents is harmful.

A. OSMOTIC LAXATIVES—Nonabsorbable osmotic agents increase secretion of water into the intestinal lumen, thereby softening stools and promoting defecation. Magnesium hydroxide, non-digestible carbohydrates (sorbitol, lactulose), and polyethylene glycol are all efficacious and safe for treating acute and chronic cases. The dosages are adjusted to achieve soft to semi-liquid movements. Magnesium-con-

taining saline laxatives should not be given to patients with chronic renal insufficiency. Non-digestible carbohydrates may induce bloating, cramps, and flatulence. Polyethylene glycol 3350 (Miralax) is a component of solutions traditionally used for colonic lavage prior to colonoscopy and does not cause flatulence. When used in conventional doses, the onset of action of these osmotic agents is generally within 24 hours. For more rapid treatment of acute constipation or as a purgative prior to surgical, endoscopic, or radiographic procedures, polyethylene glycol solutions (GoLYTELY,

CoLYTE, NuLYTE, MoviPrep) may be used. Polyethylene glycol solutions (2–4 L administered over 2–4 hours) are balanced osmotic and electrolyte solutions that do not cause any significant fluid or electrolyte shifts and may be used safely in almost all patients. Alternatively, potent, hyperosmolar saline purgatives may administered. These hyperosmolar agents draw significant fluid into the intestine and must be given with substantial oral fluids (2–4 L) to minimize fluid shifts that can result in dehydration or acute kidney injury. They should be avoided in patients with chronic kidney disease or congestive heart failure. Magnesium citrate may cause hypermagnesemia. Oral sodium phosphate preparations (Visicol, OsmoPrep, and Fleets Phospho-soda) can cause hypocalcemia, hyperphosphatemia, hypokalemia and, rarely, acute kidney injury due to acute phosphate nephropathy. The FDA has issued a warning that sodium phosphate should be avoided in people over age 55, people with known kidney disease, or people taking medications that affect kidney function (diuretics, NSAIDs, ACE inhibitors, angiotensin-receptor blockers). Patients taking sodium phosphate should be advised to ingest sufficient oral fluids (2–4 L).

B. STIMULANT LAXATIVES—These agents stimulate fluid secretion and colonic contraction, resulting in a bowel movement within 6–12 hours after oral ingestion or 15–60 minutes after rectal administration. Oral agents are usually administered once daily at bedtime. Common preparations include bisacodyl, senna, and cascara (Table 15–4).

Lubiprostone is an oral cyclic fatty acid that activates intestinal chloride channels, increasing fluid secretion and secondarily increasing peristalsis. In large, multicenter controlled trials, patients treated with lubiprostone 24 mcg orally twice daily increased the number of bowel movements to approximately four to five per week, compared with two to three per week in patients treated with placebo. Lubiprostone is associated with nausea in up to one-third of patients and should not be given to women who may be pregnant (category C). Because lubiprostone is expensive, it should be reserved for patients who have suboptimal response or side effects with less expensive agents.

C. OPIOID-RECEPTOR ANTAGONISTS—Long-term use of opioids can cause constipation by inhibiting peristalsis and increasing intestinal fluid absorption. Methylnaltrexone is mu-opioid receptor antagonist that blocks peripheral opioid receptors (including the gastrointestinal tract) without affecting central analgesia. In 2008, it was approved for the treatment of opioid-induced constipation in patients receiving palliative care for advanced illness who had not responded to conventional laxative regimens. In controlled trials, methylnaltrexone subcutaneously (8 mg [38–62 kg], 12 mg [62–114 kg], or 0.15 mg/kg [less 38 kg] every other day) achieves laxation in 50% of patients compared with 15% of patients who received placebo. Its role for other patients with opioid-induced constipation is under investigation.

B. Fecal Impaction

Severe impaction of stool in the rectal vault may result in obstruction to further fecal flow, leading to partial or com-

plete large bowel obstruction. Predisposing factors include medications (eg, opioids), severe psychiatric disease, prolonged bed rest, neurogenic disorders of the colon, and spinal cord disorders. Clinical presentation includes decreased appetite, nausea, and vomiting, and abdominal pain and distention. There may be paradoxical “diarrhea” as liquid stool leaks around the impacted feces. Firm feces are palpable on digital examination of the rectal vault. Initial treatment is directed at relieving the impaction with enemas (saline, mineral oil, or diatrizoate) or digital disruption of the impacted fecal material. Long-term care is directed at maintaining soft stools and regular bowel movements (as above).

► When to Refer

- Patients with refractory constipation for anorectal testing.
- Patients with dyssynergic defecation may benefit from biofeedback therapy.
- Patients with alarm symptoms or who are over age 50 should be referred for colonoscopy.
- Rarely, surgery (subtotal colectomy) is required for patients with severe colonic inertia.

GASTROINTESTINAL GAS

► Belching

Belching (eructation) is the involuntary or voluntary release of gas from the stomach or esophagus. It occurs most frequently after meals, when gastric distention results in transient lower esophageal sphincter (LES) relaxation. Belching is a normal reflex and does not itself denote gastrointestinal dysfunction. Virtually all stomach gas comes from swallowed air. With each swallow, 2–5 mL of air is ingested, and excessive amounts may result in distention, flatulence, and abdominal pain. This may occur with rapid eating, gum chewing, smoking, and the ingestion of carbonated beverages. Chronic excessive belching is almost always caused by aerophagia, common in anxious individuals and institutionalized patients. Evaluation should be restricted to

patients with other complaints such as dysphagia, heartburn, early satiety, or vomiting.

Once patients understand the relationship between aerophagia and belching, most can deal with the problem by behavioral modification. Physical defects that hamper normal swallowing (ill-fitting dentures, nasal obstruction) should be corrected. Antacids and simethicone are of no value.

▶ Flatus

The rate and volume of expulsion of flatus is highly variable. Flatus is derived from two sources: swallowed air and bacterial fermentation of undigested carbohydrate. The majority of swallowed air not belched passes through the gut and leaves as flatus. Swallowed air may contribute up to 500 mL of flatus per day (primarily nitrogen). Bacterial fermentation of undigested carbohydrates leads to the additional production of gas, particularly H₂, CO₂, and methane. The majority of this fermentation takes place in the colon. Under normal circumstances, a small substrate of fermentable substances reaches the colon. These substances include fructose, lactose, sorbitol, trehalose (mushrooms), raffinose, and stachyose (legumes, cruciferous vegetables). Complex starches and fiber may also cause gas. Gas production may be increased with ingestion of these carbohydrates or with malabsorption.

Determining abnormal from normal amounts of flatus is difficult. An initial trial of a lactose-free diet is recommended. Common gas-producing foods should be reviewed and the patient given an elimination trial. These include beans of all kinds, peas, lentils, brussels sprouts, cabbage, parsnips, leeks, onions, beer, and coffee. Fructose intolerance is common. Fructose is present not only in many fruits but is also used commonly as a sweetener or as fructose corn syrup in candy, fruit juices, and soda. Foul odor may be caused by garlic, onion, eggplant, mushrooms, and certain herbs and spices. For patients with persistent complaints, complex starches, and fiber may be eliminated, but such restrictive diets are unacceptable to most patients. Of refined flours, only rice flour is gas-free.

The nonprescription agent Beano (α -d-galactosidase enzyme) reduces gas caused by foods containing raffinose and stachyose, ie, cruciferous vegetables, legumes, nuts, and some cereals. Activated charcoal may afford relief. Simethicone is of no proved benefit.

Complaints of chronic abdominal distention or bloating are common. Some of these patients may produce excess gas. However, many patients have impaired small bowel gas propulsion or enhanced visceral sensitivity to gas distention. Many of these patients have an underlying functional gastrointestinal disorder such as irritable bowel syndrome or functional dyspepsia. Reduction of dietary fat, which delays intestinal gas clearance, may be helpful. Rifaximin, 400 mg twice daily, a nonabsorbable oral antibiotic with high activity against enteric bacteria, has been shown to reduce abdominal bloating and flatulence in approximately 40% of treated patients compared with 20% of controls. Symptom improvement may be attributable to

suppression of gas-producing colonic bacteria; however, relapse occurs within days after stopping the antibiotic. Further trials are needed to clarify the role of nonabsorbable antibiotics in symptom management.

DIARRHEA

Diarrhea can range in severity from an acute self-limited episode to a severe, life-threatening illness. To properly evaluate the complaint, the physician must determine the patient's normal bowel pattern and the nature of the current symptoms.

Approximately 10 L of fluid enter the duodenum daily, of which all but 1.5 L are absorbed by the small intestine. The colon absorbs most of the remaining fluid, with < 200 mL lost in the stool. Although diarrhea sometimes is defined as a stool weight of more than 200–300 g/24 h, quantification of stool weight is necessary only in some patients with chronic diarrhea. In most cases, the physician's working definition of diarrhea is increased stool frequency (more than three bowel movements per day) or liquidity of feces.

The causes of diarrhea are myriad. In clinical practice, it is helpful to distinguish acute from chronic diarrhea, as the evaluation and treatment are entirely different (Tables 15–5 and 15–6).

1. Acute Diarrhea

▶ Etiology & Clinical Findings

Diarrhea acute in onset and persisting for less than 2 weeks is most commonly caused by infectious agents, bacterial toxins (either preformed or produced in the gut), or drugs. Community outbreaks (including nursing homes, schools, cruise ships) suggest a viral etiology or a common food source. Similar recent illnesses in family members suggest an infectious origin. Ingestion of improperly stored or prepared food implicates food poisoning. Day care attendance or exposure to unpurified water (camping, swimming) may result in infection with *Giardia* or *Cryptosporidium*. Large *Cyclospora* outbreaks have been traced to contaminated produce. Recent travel abroad suggests “traveler's diarrhea” (see Chapter 30). Antibiotic administration within the preceding several weeks increases the likelihood of *Clostridium difficile* colitis. Finally, risk factors for HIV infection or sexually transmitted diseases should be determined. (AIDS-associated diarrhea is discussed in Chapter 31; infectious proctitis is discussed in this chapter under Anorectal Disorders.) Persons engaging in anal intercourse or oral-anal sexual activities are at risk

Table 15–5. Causes of acute infectious diarrhea.

| Noninflammatory Diarrhea | Inflammatory Diarrhea |
|--|---|
| Viral Noroviruses Rotavirus | Viral Cytomegalovirus |
| Protozoal <i>Giardia lamblia</i> <i>Cryptosporidium</i> <i>Cyclospora</i> | Protozoal <i>Entamoeba histolytica</i> |
| Bacterial 1. Preformed enterotoxin production <i>Staphylococcus aureus</i> <i>Bacillus cereus</i> <i>Clostridium perfringens</i> 2. Enterotoxin production Enterotoxigenic <i>Escherichia coli</i> (ETEC) <i>Vibrio cholerae</i> | Bacterial 1. Cytotoxin production Enterohemorrhagic <i>E coli</i> O157:H5 (EHEC) <i>Vibrio parahaemolyticus</i> <i>Clostridium difficile</i> 2. Mucosal invasion <i>Shigella</i> <i>Campylobacter jejuni</i> <i>Salmonella</i> Enteroinvasive <i>E coli</i> (EIEC) <i>Aeromonas</i> <i>Plesiomonas</i> <i>Yersinia enterocolitica</i> <i>Chlamydia</i> <i>Neisseria gonorrhoeae</i> <i>Listeria monocytogenes</i> |

for a variety of infections that cause proctitis, including gonorrhea, syphilis, lymphogranuloma venereum, and herpes simplex.

The nature of the diarrhea helps distinguish among different infectious causes (Table 15–5).

A. Noninflammatory Diarrhea

Watery, nonbloody diarrhea associated with periumbilical cramps, bloating, nausea, or vomiting suggests a small bowel source caused by either a toxin-producing bacterium (enterotoxigenic *Escherichia coli* [ETEC], *Staphylococcus aureus*, *Bacillus cereus*, *Clostridium perfringens*) or other agents (viruses, *Giardia*) that disrupt normal absorption and secretory process in the small intestine. Prominent vomiting suggests viral enteritis or *S aureus* food poisoning. Although typically mild, the diarrhea (which originates in the small intestine) can be voluminous and result in dehydration with hypokalemia and metabolic acidosis (eg, cholera). Because tissue invasion does not occur, fecal leukocytes are not present.

B. Inflammatory Diarrhea

The presence of fever and bloody diarrhea (dysentery) indicates colonic tissue damage caused by invasion (shigellosis, salmonellosis, *Campylobacter* or *Yersinia* infection, amebiasis) or a toxin (*C difficile*, *E coli* O157:H7). Because these organisms involve predominantly the colon,

MAI, *Mycobacterium avium-intracellulare*.

the diarrhea is small in volume (< 1 L/d) and associated with left lower quadrant cramps, urgency, and tenesmus. Fecal leukocytes or lactoferrin usually are present in infections with invasive organisms. *E coli* O157:H7 is a Shiga toxin-producing noninvasive organism most commonly acquired from contaminated meat that has resulted in several outbreaks of an acute, often severe hemorrhagic colitis. In immunocompromised and HIV-infected patients, cytomegalovirus (CMV) can cause intestinal ulceration with watery or bloody diarrhea.

Infectious dysentery must be distinguished from acute ulcerative colitis, which may also present acutely with fever, abdominal pain, and bloody diarrhea. Diarrhea that persists for more than 14 days is not attributable to bacterial pathogens (except for *C difficile*) and should be evaluated as chronic diarrhea.

► Evaluation

In over 90% of patients with acute noninflammatory diarrhea, the illness is mild and self-limited, responding within 5 days to simple rehydration therapy or antidiarrheal agents; diagnostic investigation is unnecessary.

The isolation rate of bacterial pathogens from stool cultures in patients with acute noninflammatory diarrhea is under 3%. Thus, the goal of initial evaluation is to distinguish patients with mild disease from those with

more serious illness. If diarrhea worsens or persists for more than 7 days, stool should be sent for fecal leukocyte or lactoferrin determination, ovum and parasite evaluation, and bacterial culture.

Prompt medical evaluation is indicated in the following situations (Figure 15–1): (1) Signs of inflammatory diarrhea manifested by any of the following: fever (> 38.5 °C), bloody diarrhea, or abdominal pain. (2) The passage of six or more unformed stools in 24 hours. (3) Profuse watery diarrhea and dehydration. (4) Frail older patients. (5) Immunocompromised patients (AIDS, posttransplantation). (6) Hospital-acquired diarrhea (onset > 3 days after hospitalization).

Physical examination pays note to the patient's level of hydration, mental status, and the presence of abdominal tenderness or peritonitis. Peritoneal findings may be present in infection with *C difficile* or enterohemorrhagic *E coli*. Hospitalization is required in patients with severe dehydration, toxicity, or marked abdominal pain. Stool specimens should be sent for examination for bacterial cultures.

The rate of positive bacterial cultures in such patients is 60–75%. For bloody stools, the laboratory should be directed to perform serotyping for Shiga-producing *E coli* O157:H7. Special culture media are required for *Yersinia*, *Vibrio*, and *Aeromonas*. In patients who are hospitalized or who have a history of antibiotic exposure, a stool sample should be tested for *C difficile* toxin. In patients with diar-

▲ **Figure 15–1.** Evaluation of acute diarrhea.

rehea that persists for more than 10 days, who have a history of travel to areas where amebiasis is endemic, or who engage in oral-anal sexual practices, three stool examinations for ova and parasites should also be performed. The stool antigen detection tests for both *Giardia* and *Entamoeba histolytica* are more sensitive than stool microscopy for detection of these organisms. A serum antigen detection test for *E histolytica* is also available. *Cyclospora* and *Cryptosporidium* are detected by fecal acid-fast staining.

► Treatment

A. Diet

Most mild diarrhea will not lead to dehydration provided the patient takes adequate oral fluids containing carbohydrates and electrolytes. Patients find it more comfortable to rest the bowel by avoiding high-fiber foods, fats, milk products, caffeine, and alcohol. Frequent feedings of tea, “flat” carbonated beverages, and soft, easily digested foods (eg, soups, crackers, bananas, applesauce, rice, toast) are encouraged.

B. Rehydration

In more severe diarrhea, dehydration can occur quickly, especially in children, the frail, and the elderly. Oral rehydration with fluids containing glucose, Na⁺, K⁺, Cl⁻, and bicarbonate or citrate is preferred when feasible. A convenient mixture is ½ tsp salt (3.5 g), 1 tsp baking soda (2.5 g NaHCO₃), 8 tsp sugar (40 g), and 8 oz orange juice (1.5 g KCl), diluted to 1 L with water. Alternatively, oral electrolyte solutions (eg, Pedialyte, Gatorade) are readily available. Fluids should be given at rates of 50–200 mL/kg/24 h depending on the hydration status. Intravenous fluids (lactated Ringer injection) are preferred in patients with severe dehydration.

C. Antidiarrheal Agents

Antidiarrheal agents may be used safely in patients with mild to moderate diarrheal illnesses to improve patient comfort. Opioid agents help decrease the stool number and liquidity and control fecal urgency. However, they should not be used in patients with bloody diarrhea, high fever, or systemic toxicity and should be discontinued in patients whose diarrhea is worsening despite therapy. With these provisos, such drugs provide excellent symptomatic relief. Loperamide is preferred, in a dosage of 4 mg initially, followed by 2 mg after each loose stool (maximum: 16 mg/24 h).

Bismuth subsalicylate (Pepto-Bismol), two tablets or 30 mL four times daily, reduces symptoms in patients with traveler’s diarrhea by virtue of its anti-inflammatory and antibacterial properties. It also reduces vomiting associated with viral enteritis. Anticholinergic agents (eg, diphenoxylate with atropine) are contraindicated in acute diarrhea because of the rare precipitation of toxic megacolon.

D. Antibiotic Therapy

1. Empiric treatment—Empiric antibiotic treatment of all patients with acute diarrhea is not indicated. Even patients with inflammatory diarrhea caused by invasive

pathogens usually have symptoms that will resolve within several days without antimicrobials. Empiric treatment may be considered in patients with non-hospital-acquired diarrhea with moderate to severe fever, tenesmus, or bloody stools or the presence of fecal lactoferrin while the stool bacterial culture is incubating, provided that infection with *E coli* O157:H7 is not suspected. The drugs of choice for empiric treatment are the fluoroquinolones (eg, ciprofloxacin 500 mg, ofloxacin 400 mg, or norfloxacin 400 mg, twice daily, or levofloxacin 500 mg once daily) for 5–7 days. Alternatives include trimethoprim-sulfamethoxazole, 160/800 mg twice daily; or doxycycline, 100 mg twice daily. Macrolides and penicillins are no longer recommended because of widespread microbial resistance to these agents. Rifaximin, a nonabsorbed oral antibiotic, 200 mg three times daily for 3 days, is approved for empiric treatment of noninflammatory traveler’s diarrhea (see Chapter 30).

2. Specific antimicrobial treatment—Antibiotics are not recommended in patients with nontyphoid *Salmonella*, *Campylobacter*, *E coli* O157:H7, *Aeromonas*, or *Yersinia*, except in severe disease, because they do not hasten recovery or reduce the period of fecal bacterial excretion. The infectious diarrheas for which treatment is recommended are shigellosis, cholera, extraintestinal salmonellosis, traveler’s diarrhea, *C difficile* infection, giardiasis, and amebiasis. Therapy for traveler’s diarrhea, infectious (sexually transmitted) proctitis, and AIDS-related diarrhea is presented in other chapters of this book.

2. Chronic Diarrhea

► Etiology

The causes of chronic diarrhea may be grouped into the following major pathophysiologic categories: medications, osmotic diarrheas, secretory conditions, inflammatory conditions, malabsorptive conditions, motility disorders, chronic infections, and factitious diarrhea (Table 15–6).

A. Medications

Numerous medications can cause diarrhea. Common offenders include cholinesterase inhibitors, SSRIs, angiotensin II-receptor blockers, proton pump inhibitors, NSAIDs, metformin, and allopurinol. All medications should be carefully reviewed, and discontinuation of potential culprits should be considered.

B. Osmotic Diarrheas

As stool leaves the colon, fecal osmolality is equal to the serum osmolality, ie, approximately 290 mosm/kg. Under

normal circumstances, the major osmoles are Na^+ , K^+ , Cl^- , and HCO_3^- . The stool osmolality may be estimated by multiplying the stool $(\text{Na}^+ + \text{K}^+) \times 2$. The **osmotic gap** is the difference between the *measured* osmolality of the stool (or serum) and the *estimated* stool osmolality and is normally less than 50 mosm/kg. An increased osmotic gap (> 125 mosm/kg) implies that the diarrhea is caused by ingestion or malabsorption of an osmotically active substance. The most common causes are carbohydrate malabsorption (lactose, fructose, sorbitol), laxative abuse, and malabsorption syndromes (see below). Osmotic diarrheas resolve during fasting. Those caused by malabsorbed carbohydrates are characterized by abdominal distention, bloating, and flatulence due to increased colonic gas production.

Carbohydrate malabsorption is common and should be considered in all patients with chronic diarrhea. Lactase deficiency occurs in 75% of nonwhite adults and up to 25% of whites. It may also be acquired after an episode of viral gastroenteritis, medical illness, or gastrointestinal surgery. Fructose and sorbitol are present in many fruits, and are commonly used as a sweetener in gums, candies, and some medications. The diagnosis of carbohydrate malabsorption may be established by an elimination trial for 2–3 weeks or by hydrogen breath tests.

Ingestion of magnesium- or phosphate-containing compounds (laxatives, antacids) should be considered in enigmatic chronic diarrhea. The fat substitute olestra also causes diarrhea and cramps in occasional patients.

C. Secretory Conditions

Increased intestinal secretion or decreased absorption results in a high-volume watery diarrhea with a normal osmotic gap. There is little change in stool output during the fasting state, and dehydration and electrolyte imbalance may develop. Causes include endocrine tumors (stimulating intestinal or pancreatic secretion) and bile salt malabsorption (stimulating colonic secretion).

D. Inflammatory Conditions

Diarrhea is present in most patients with inflammatory bowel disease (ulcerative colitis, Crohn disease, microscopic colitis). A variety of other symptoms may be present, including abdominal pain, fever, weight loss, and hematochezia. (See Inflammatory Bowel Disease, below.)

E. Malabsorptive Conditions

The major causes of malabsorption are small mucosal intestinal diseases, intestinal resections, lymphatic obstruction, small intestinal bacterial overgrowth, and pancreatic insufficiency. Its characteristics are weight loss, osmotic diarrhea, steatorrhea, and nutritional deficiencies. Significant diarrhea in the absence of weight loss is not likely to be due to malabsorption. The physical and laboratory abnormalities related to deficiencies of vitamins or minerals are discussed in Chapter 29.

F. Motility Disorders

Abnormal intestinal motility secondary to systemic disorders or surgery may result in diarrhea due to rapid transit or

to stasis of intestinal contents with bacterial overgrowth, resulting in malabsorption. Probably the most common cause of chronic diarrhea is irritable bowel syndrome (see Irritable Bowel Syndrome, below).

G. Chronic Infections

Chronic parasitic infections may cause diarrhea through a number of mechanisms. Pathogens most commonly associated with diarrhea include the protozoans *Giardia*, *E histolytica*, and *Cyclospora* as well as the intestinal nematodes. Strongyloidiasis and capillariasis should be excluded in patients from endemic regions, especially in the presence of eosinophilia. Bacterial infections with *Aeromonas* and *Plesiomonas* may uncommonly be a cause of chronic diarrhea.

Immunocompromised patients are susceptible to infectious organisms that can cause acute or chronic diarrhea (see Chapter 31), including Microsporidia, *Cryptosporidium*, CMV, *Isoospora belli*, *Cyclospora*, and *Mycobacterium avium* complex.

H. Factitious Diarrhea

Fifteen percent of patients have factitious diarrhea caused by surreptitious laxative abuse or dilution of stool. This should especially be considered in patients with a long history of undiagnosed medical ailments or employment in the medical field.

► Clinical Findings

The history and physical examination commonly suggest the underlying pathophysiology that guides the subsequent diagnostic workup (Figure 15–2). Important tests are described here. AIDS-associated diarrhea is discussed in Chapter 31.

A. Stool Analysis

1. Twenty-four-hour stool collection for weight and quantitative fecal fat—A stool weight of more than 200 g/24 h confirms diarrhea. A weight > 500 g excludes irritable bowel syndrome, whereas a weight > 1000 – 1500 g suggests a secretory process. A fecal fat determination in excess of 10 g/24 h indicates a malabsorptive disorder. (See Celiac Sprue and specific tests for malabsorption, below.)

2. Stool osmolality—Stool osmolality less than serum osmolality implies that water or urine has been added to the specimen (factitious diarrhea). A stool pH < 5.6 is consistent with carbohydrate malabsorption.

3. Stool laxative screen—In cases of suspected laxative abuse, stool magnesium, phosphate, and sulfate levels may be measured. Phenolphthalein and bisacodyl can be analyzed in stool water, using chromatographic techniques. Anthraquinones and bisacodyl are sought for in the urine.

4. Fecal leukocytes—The presence of fecal leukocytes or lactoferrin implies inflammatory diarrhea.

5. Stool for ova and parasites—The presence of *Giardia* and *E histolytica* may be detected in wet mounts. However, fecal antigen detection tests for *Giardia* and *E histolytica* may be a more sensitive and specific method of

▲ **Figure 15-2.** Decision diagram for diagnosis of causes of chronic diarrhea.

detection. *Cryptosporidium* and *Cyclospora* are found with modified acid-fast staining.

B. Diagnostic Tests

1. Routine laboratory tests—Complete blood count, serum electrolytes, liver function tests, calcium, phosphorus, albumin, TSH, vitamin A and D levels, and prothrombin time may be of value. Anemia occurs in malabsorption syndromes (folate, iron deficiency, or vitamin B₁₂) as well as inflammatory conditions. Hypoalbuminemia is present in malabsorption, protein-losing enteropathies, and inflammatory diseases. Hyponatremia and nonanion gap metabolic acidosis occur in secretory diarrheas.

2. Other laboratory tests—In patients with suspected malabsorption, serologic testing for celiac sprue includes IgA tissue transglutaminase (tTG) antibody tests. Secretory diarrheas due to neuroendocrine tumors are rare. When this is suspected, serum chromogranin A, vasoactive intestinal peptide (VIP) (VIPoma), calcitonin (medullary thy-

roid carcinoma), gastrin (Zollinger-Ellison syndrome), and glucagon determinations may be diagnostic, and urine should be sent for 5-hydroxyindoleacetic acid (5-HIAA) (carcinoid).

3. Endoscopic examination and mucosal biopsy—Colonoscopy with terminal ileum inspection mucosal biopsy is helpful in the detection of inflammatory bowel disease (including Crohn disease, ulcerative colitis, and microscopic colitis) and melanosis coli (indicative of chronic anthraquinone laxative use). Upper endoscopy with small bowel biopsy is performed when a small intestinal malabsorptive disorder is suspected (celiac sprue, Whipple disease) and less commonly to diagnose severe helminthic infections (strongyloidiasis, capillariasis); it may also be done in patients with advanced AIDS to document *Cryptosporidium*, Microsporidia, and *M avium-intracellulare* infection. If bacterial overgrowth is suspected, the diagnosis is confirmed with noninvasive breath tests (d-[¹⁴C]xylose, glucose, or lactulose) or by obtaining an aspirate of small intestinal contents for quantitative aerobic and anaerobic bacterial culture.

4. Other imaging studies—Calcification on a plain abdominal radiograph confirms a diagnosis of chronic pancreatitis, although abdominal CT and endoscopic ultrasonography are more sensitive for the diagnosis of chronic pancreatitis as well as pancreatic cancer. Small intestinal imaging with barium, CT, or MRI is helpful in the diagnosis of Crohn disease, small bowel lymphoma, carcinoid, and jejunal diverticula. Neuroendocrine tumors may be localized using somatostatin receptor scintigraphy. Retention of < 11% at 7 days of intravenous ⁷⁵Se-homotaurocholate on scintigraphy suggests bile salt malabsorption.

▶ Treatment

A number of antidiarrheal agents may be used in certain patients with chronic diarrheal conditions and are listed below. Opioids are safe in most patients with chronic, stable symptoms.

Loperamide: 4 mg initially, then 2 mg after each loose stool (maximum: 16 mg/d).

Diphenoxylate with atropine: One tablet three or four times daily as needed.

Codeine and deodorized tincture of opium: Because of potential habituation, these drugs are avoided except in cases of chronic, intractable diarrhea. Codeine may be given in a dosage of 15–60 mg every 4 hours; tincture of opium, 0.3–1.2 mL every 6 hours as needed.

Clonidine: α_2 -Adrenergic agonists inhibit intestinal electrolyte secretion. Clonidine, 0.1–0.6 mg twice daily, or a clonidine patch, 0.1–0.2 mg/d, may help in some patients with secretory diarrheas, diabetic diarrhea, or cryptosporidiosis.

Octreotide: This somatostatin analog stimulates intestinal fluid and electrolyte absorption and inhibits intestinal fluid secretion and the release of gastrointestinal peptides. It is given for secretory diarrheas due to neuroendocrine tumors (VIPomas, carcinoid) and in some cases of AIDS-related diarrhea. Effective doses range from 50 to 250 mcg subcutaneously three times daily.

Cholestyramine: This bile salt-binding resin may be useful in patients with bile salt-induced diarrhea, which may be idiopathic or secondary to intestinal resection or ileal disease. A dosage of 4 g once to three times daily is recommended.

GASTROINTESTINAL BLEEDING

1. Acute Upper Gastrointestinal Bleeding

ESSENTIALS OF DIAGNOSIS

- ▶ Hematemesis (bright red blood or “coffee grounds”).
- ▶ Melena in most cases; hematochezia in massive upper gastrointestinal bleeds.
- ▶ Volume status to determine severity of blood loss; hematocrit is a poor early indicator of blood loss.
- ▶ Endoscopy diagnostic and may be therapeutic.

▶ General Considerations

There are over 250,000 hospitalizations a year in the United States for acute upper gastrointestinal bleeding, with a mortality rate of 4–10%. Approximately half of patients are over 60 years of age, and in this age group the mortality rate is even higher. Patients seldom die of exsanguination but rather from complications of an underlying disease.

The most common presentation of upper gastrointestinal bleeding is hematemesis or melena. Hematemesis may be either bright red blood or brown “coffee grounds” material. Melena develops after as little as 50–100 mL of blood loss in the upper gastrointestinal tract, whereas hematochezia requires a loss of more than 1000 mL. Although hematochezia generally suggests a lower bleeding source (eg, colonic), upper gastrointestinal bleeding may present with hematochezia in 10% of cases.

Upper gastrointestinal bleeding is self-limited in 80% of patients; urgent medical therapy and endoscopic evaluation are obligatory in the rest. Patients with bleeding more than 48 hours prior to presentation have a low risk of recurrent bleeding.

▶ Etiology

Acute upper gastrointestinal bleeding may originate from a number of sources. These are listed in order of the frequency and discussed in detail below.

A. Peptic Ulcer Disease

Peptic ulcers account for half of major upper gastrointestinal bleeding with an overall mortality rate of 4%. However, in North America the incidence of bleeding from ulcers is declining, perhaps due to eradication of *H pylori*, use of safer NSAIDs, and prophylaxis with proton pump inhibitors in high-risk patients.

B. Portal Hypertension

Portal hypertension accounts for 10–20% of upper gastrointestinal bleeding. Bleeding usually arises from esophageal varices and less commonly gastric or duodenal varices or portal hypertensive gastropathy. Approximately 25% of patients with cirrhosis have medium to large

esophageal varices, of whom 30% experience acute variceal bleeding within a 2-year period. Due to improved care, the hospital mortality rate has declined over the past 20 years from 40% to 15%. Nevertheless, a mortality rate of 60–80% is expected at 1–4 years due to recurrent bleeding or other complications of chronic liver disease.

C. Mallory-Weiss Tears

Lacerations of the gastroesophageal junction cause 5–10% of cases of upper gastrointestinal bleeding. Many patients report a history of heavy alcohol use or retching. Less than 10% have continued or recurrent bleeding.

D. Vascular Anomalies

Vascular anomalies are found throughout the gastrointestinal tract and may be the source of chronic or acute gastrointestinal bleeding. They account for 7% of cases of acute upper tract bleeding. **Vascular ectasias** (angiodyplasias) have a bright red stellate appearance. They may be part of systemic conditions (hereditary hemorrhagic telangiectasia, CREST syndrome) or may occur sporadically. There is an increased incidence in patients with chronic renal failure. The Dieulafoy lesion is an aberrant, large-caliber submucosal artery, most commonly in the proximal stomach that causes recurrent, intermittent bleeding.

E. Gastric Neoplasms

Gastric neoplasms result in 1% of upper gastrointestinal hemorrhages.

F. Erosive Gastritis

Because this process is superficial, it is a relatively unusual cause of severe gastrointestinal bleeding (< 5% of cases) and more commonly results in chronic blood loss. Gastric mucosal erosions are due to NSAIDs, alcohol, or severe medical or surgical illness (stress-related mucosal disease).

G. Erosive Esophagitis

Severe erosive esophagitis due to chronic gastroesophageal reflux may rarely cause significant upper gastrointestinal bleeding, especially in patients who are bed bound long-term.

H. Others

An aortoenteric fistula complicates 2% of abdominal aortic grafts or can occur as the initial presentation of a previously untreated aneurysm. Usually located between the graft or aneurysm and the third portion of the duodenum, these fistulas characteristically present with a herald nonexsanguinating initial hemorrhage, with melena and hematemesis, or with chronic intermittent bleeding. The diagnosis may be suspected by upper endoscopy or abdominal CT. Surgery is mandatory to prevent exsanguinating hemorrhage. Unusual causes of upper gastrointestinal bleeding include hemobilia (from hepatic tumor, angioma, penetrating trauma), pancreatic malignancy, and pseudoaneurysm (hemorrhage from pancreaticus).

► Initial Evaluation & Treatment

A. Stabilization

The initial step is assessment of the hemodynamic status. A systolic blood pressure less than 100 mm Hg identifies a high-risk patient with severe acute bleeding. A heart rate over 100 beats/min with a systolic blood pressure over 100 mm Hg signifies moderate acute blood loss. A normal systolic blood pressure and heart rate suggest relatively minor hemorrhage. Postural hypotension and tachycardia are useful when present but may be due to causes other than blood loss. Because the hematocrit may take 24–72 hours to equilibrate with the extravascular fluid, it is not a reliable indicator of the severity of acute bleeding.

In patients with significant bleeding, two 18-gauge or larger intravenous lines should be started prior to further diagnostic tests. Blood is sent for complete blood count, prothrombin time with international normalized ratio (INR), serum creatinine, liver enzymes, and blood typing and screening (in anticipation of need for possible transfusion). In patients without hemodynamic compromise or overt active bleeding, aggressive fluid repletion can be delayed until the extent of the bleeding is further clarified. Patients with evidence of hemodynamic compromise are given 0.9% saline or lactated Ringer injection and cross-matched for 2–4 units of packed red blood cells. It is rarely necessary to administer type-specific or O-negative blood. Central venous pressure monitoring is desirable in some cases, but line placement should not interfere with rapid volume resuscitation.

A nasogastric tube should be placed in all patients with suspected active upper tract bleeding. The aspiration of red blood or “coffee grounds” confirms an upper gastrointestinal source of bleeding, though 10% of patients with confirmed upper tract sources of bleeding have nonbloody aspirates—especially when bleeding originates in the duodenum. An aspirate of bright red blood indicates active bleeding and is associated with the highest risk of further bleeding, and complications, while a clear aspirate identifies patients at lower initial risk. Erythromycin (250 mg) administered intravenously 30 minutes prior to upper endoscopy promotes gastric emptying of clots and improves quality of endoscopic examination. Efforts to stop or slow bleeding by gastric lavage with large volumes of fluid are of no benefit and expose the patient to an increased risk of aspiration. Periodic reaspiration of the nasogastric tube serves as an indicator of ongoing bleeding or rebleeding.

B. Blood Replacement

The amount of fluid and blood products required is based on assessment of vital signs, evidence of active bleeding from nasogastric aspirate, and laboratory tests. Sufficient packed red blood cells should be given to maintain a hematocrit of 25–30%. In the absence of continued bleeding, the hematocrit should rise 4% for each unit of transfused packed red cells. Transfusion of blood should not be withheld from patients with brisk active bleeding regardless of the hematocrit. It is desirable to transfuse blood in

anticipation of the nadir hematocrit. In actively bleeding patients, platelets are transfused if the platelet count is under 50,000/mcL and considered if there is impaired platelet function due to aspirin or clopidogrel use (regardless of the platelet count). Uremic patients (who also have dysfunctional platelets) with active bleeding are given three doses of desmopressin (DDAVP), 0.3 mcg/kg intravenously, at 12-hour intervals. Fresh frozen plasma is administered for actively bleeding patients with a coagulopathy and an INR > 1.5. In the face of massive bleeding, 1 unit of fresh frozen plasma should be given for each 5 units of packed red blood cells transfused.

C. Initial Triage

A preliminary assessment of risk based on several clinical factors aids in the resuscitation as well as the rational triage of the patient. Clinical predictors of increased risk of rebleeding and death include age > 60 years, comorbid illnesses, systolic blood pressure < 100 mm Hg, pulse > 100 beats/min, and bright red blood in the nasogastric aspirate or on rectal examination.

1. High risk—Patients with active bleeding manifested by hematemesis or bright red blood on nasogastric aspirate, shock, persistent hemodynamic derangement despite fluid resuscitation, serious comorbid medical illness, or evidence of advanced liver disease require admission to an intensive care unit (ICU). Emergent endoscopy should be performed after adequate resuscitation, usually within 12 hours.

2. Low to moderate risk—All other patients are admitted to a step-down unit or medical ward after appropriate stabilization for further evaluation and treatment. Patients without evidence of active bleeding undergo nonemergent endoscopy usually within 12–24 hours.

► Subsequent Evaluation & Treatment

Specific treatment of the various causes of upper gastrointestinal bleeding is discussed elsewhere in this chapter. The following general comments apply to most patients with bleeding.

The physician's impression of the bleeding source is correct in only 40% of cases. Signs of chronic liver disease implicate bleeding due to portal hypertension, but a different lesion is identified in 25% of patients with cirrhosis. A history of dyspepsia, NSAID use, or peptic ulcer disease suggests peptic ulcer. Acute bleeding preceded by heavy alcohol ingestion or retching suggests a Mallory-Weiss tear, though most of these patients have neither.

A. Upper Endoscopy

Virtually all patients with upper tract bleeding should undergo upper endoscopy within 6–24 hours of arriving in the emergency department. The benefits of endoscopy in this setting are threefold.

1. To identify the source of bleeding—The appropriate acute and long-term medical therapy is determined by the cause of bleeding. Patients with portal hypertension will be treated differently from those with ulcer disease. If

surgery is required for uncontrolled bleeding, the source of bleeding as determined at endoscopy will determine the approach.

2. To determine the risk of rebleeding and guide triage—Patients with a nonbleeding Mallory-Weiss tear, esophagitis, gastritis, and ulcers that have a clean, white base have a very low risk (< 5%) of rebleeding. Patients with one of these findings who are < age 60 years, without hemodynamic instability or transfusion requirement, without serious coexisting illness, and who have stable social support may be discharged from the emergency department or medical ward after endoscopy with outpatient follow-up. All others with one of these low-risk lesions should be observed on a medical ward for 24–48 hours. Patients with ulcers that are actively bleeding or have a visible vessel or adherent clot, or who have variceal bleeding usually require at least a 3-day hospitalization with closer initial observation in an ICU or step down unit.

3. To render endoscopic therapy—Hemostasis can be achieved in actively bleeding lesions with endoscopic modalities such as cautery, injection, or endoclips. About 90% of bleeding or nonbleeding varices can be effectively treated immediately with injection of a sclerosant or application of rubber bands to the varices. Similarly, 90% of bleeding ulcers, angiomas, or Mallory-Weiss tears can be controlled with either injection of epinephrine, direct cauterization of the vessel by a heater probe or multipolar electrocautery probe, or application of an endoclip. Certain nonbleeding lesions such as ulcers with visible blood vessels, and angiomas are also treated with these therapies. Specific endoscopic therapy of varices, peptic ulcers, and Mallory-Weiss tears is dealt with elsewhere in this chapter.

B. Acute Pharmacologic Therapies

1. Acid inhibitory therapy—**Intravenous proton pump inhibitors** (esomeprazole or pantoprazole, 80 mg bolus, followed by 8 mg/h continuous infusion for 72 hours) reduce the risk of rebleeding in patients with peptic ulcers with high-risk features (active bleeding, visible vessel, or adherent clot) after endoscopic treatment. High doses of **oral proton pump inhibitors** (esomeprazole 40 mg or lansoprazole 60 mg, twice daily for 5 days) may also be effective.

A randomized, placebo-controlled clinical trial demonstrated that a continuous intravenous infusion of omeprazole *before* endoscopy resulted in an increased number of clean-based peptic ulcers (which do not require endoscopic therapy) and a decreased number of ulcers that were actively bleeding or had a visible vessel (resulting in a decreased need for endoscopic therapy) *during* endoscopy. It has become standard clinical practice at many institutions to administer either an intravenous or a high-dose oral proton pump inhibitor prior to endoscopy in patients with significant upper gastrointestinal bleeding. Based on the findings during endoscopy, the proton pump inhibitor may be continued or discontinued.

2. Octreotide—Continuous intravenous infusion of octreotide (100 mcg bolus, followed by 50–100 mcg/h) reduces splanchnic blood flow and portal blood pressures and is

effective in the initial control of bleeding related to portal hypertension. It is administered promptly to all patients with active upper gastrointestinal bleeding and evidence of liver disease or portal hypertension until the source of bleeding can be determined by endoscopy.

3. Vasoactive agents—Intravenous vasopressin is no longer used in the treatment of upper gastrointestinal bleeding. In countries where it is available, terlipressin may be preferred to octreotide for the treatment of bleeding related to portal hypertension because of its sustained reduction of portal and variceal pressures and its proven reduction in mortality.

C. Other Treatment

1. Intra-arterial embolization—Angiographic treatment is used rarely in patients with persistent bleeding from ulcers, angiomas, or Mallory-Weiss tears who have failed endoscopic therapy and are poor operative risks.

2. Transvenous intrahepatic portosystemic shunts (TIPS)—Placement of a wire stent from the hepatic vein through the liver to the portal vein provides effective decompression of the portal venous system and control of acute variceal bleeding. It is indicated in patients in whom endoscopic modalities have failed to control acute variceal bleeding.

2. Acute Lower Gastrointestinal Bleeding

ESSENTIALS OF DIAGNOSIS

- ▶ Hematochezia usually present.
- ▶ Ten percent of cases of hematochezia due to upper gastrointestinal source.
- ▶ Evaluation with colonoscopy in stable patients.
- ▶ Massive active bleeding calls for evaluation with sigmoidoscopy, upper endoscopy, angiography, or nuclear bleeding scan.

▶ General Considerations

Lower gastrointestinal bleeding is defined as that arising below the ligament of Treitz, ie, the small intestine or colon; however, up to 95% of cases arise from the colon.

The severity of lower gastrointestinal bleeding ranges from mild anorectal bleeding to massive, large-volume hematochezia. Bright red blood that drips into the bowl after a bowel movement or is mixed with solid brown stool signifies mild bleeding, usually from an anorectosigmoid source, and can be evaluated in the outpatient setting. Serious lower gastrointestinal bleeding is more common in older men. In patients hospitalized with gastrointestinal bleeding, lower tract bleeding is one-fourth as common as upper gastrointestinal hemorrhage and tends to have a more benign course. Patients hospitalized with lower gastrointestinal tract bleeding are less likely to present with shock or orthostasis (< 20%) or to require transfusions (< 40%). Spontaneous cessation of bleeding occurs in over 85% of cases, and hospital mortality is less than 4%.

▶ Etiology

The cause of these lesions depends on both the age of the patient and the severity of the bleeding. In patients under 50 years of age, the most common causes are infectious colitis, anorectal disease, and inflammatory bowel disease. In older patients, significant hematochezia is most often seen with diverticulosis, vascular ectasias, malignancy, or ischemia. In 20% of acute bleeding episodes, no source of bleeding can be identified.

A. Diverticulosis

Hemorrhage occurs in 3–5% of all patients with diverticulosis and is the most common cause of major lower tract bleeding, accounting for 50% of cases. A significant percentage of cases are associated with the use of nonsteroidal anti-inflammatory agents. Although diverticula are more prevalent on the left side of the colon, bleeding more commonly originates on the right side. Diverticular bleeding usually presents as acute, painless, large-volume maroon or bright red hematochezia in patients over age 50 years. More than 95% of cases require less than 4 units of blood transfusion. Bleeding subsides spontaneously in 80% but may recur in up to 25% of patients.

B. Vascular Ectasias

Vascular ectasias (or angiodysplasias) occur throughout the upper and lower intestinal tracts and cause painless bleeding ranging from melena or hematochezia to occult blood loss. They are responsible for 3% of cases of lower gastrointestinal bleeding, where they are most often seen in the cecum and ascending colon. They are flat, red lesions (2–10 mm) with ectatic peripheral vessels radiating from a central vessel, and are most common in patients over 70 years and in those with chronic renal failure. Bleeding in younger patients more commonly arises from the small intestine.

Most colonic ectasias are degenerative lesions that are believed to arise from chronic colonic mucosal contraction obstructing venous mucosal drainage. The cause of gastric and small intestinal ectasias is unknown. Some are congenital, part of an inherited syndrome such as hereditary hemorrhagic telangiectasia, or related to autoimmune disorders, typically scleroderma. Ectasias can be identified in

up to 6% of subjects over age 60 years, so their mere presence does not prove that the lesion is the source of bleeding, as active bleeding is seldom seen.

C. Neoplasms

Benign polyps and carcinoma are associated with chronic occult blood loss or intermittent anorectal hematochezia. Furthermore, they may cause up to 7% of acute lower gastrointestinal hemorrhage. After endoscopic removal of colonic polyps, important bleeding may occur up to 2 weeks later in 0.3% of patients. In general, prompt colonoscopy is recommended to treat postpolypectomy hemorrhage and minimize the need for transfusions.

D. Inflammatory Bowel Disease

Patients with inflammatory bowel disease (especially ulcerative colitis) often have diarrhea with variable amounts of hematochezia. Bleeding varies from occult blood loss to recurrent hematochezia usually mixed with stool. Symptoms of abdominal pain, tenesmus, and urgency are often present.

E. Anorectal Disease

Anorectal disease (hemorrhoids, fissures) usually results in small amounts of bright red blood noted on the toilet paper, streaking of the stool, or dripping into the toilet bowl; clinically significant blood loss can sometimes occur. Hemorrhoids are the source in 10% of patients admitted with lower bleeding. Rectal ulcers may account for up to 9% of lower bleeding, usually in elderly or debilitated patients with constipation.

F. Ischemic Colitis

This condition is seen commonly in older patients, most of whom have atherosclerotic disease. Most cases occur spontaneously due to transient episodes of nonocclusive ischemia. Ischemic colitis may also occur in 5% of patients after surgery for ileo-aortic or abdominal aortic aneurysm. In young patients, colonic ischemia may develop due to vasculitis, coagulation disorders, estrogen therapy, and long distance running. Ischemic colitis results in hematochezia or bloody diarrhea associated with mild cramps. In most patients, the bleeding is mild and self-limited.

G. Others

Radiation-induced proctitis causes anorectal bleeding that may develop months to years after pelvic radiation. Endoscopy reveals multiple rectal telangiectasias. Acute infectious colitis (see Acute Diarrhea, above) commonly causes bloody diarrhea. Rare causes of lower tract bleeding include vasculitic ischemia, solitary rectal ulcer, NSAID-induced ulcers in the small bowel or right colon, small bowel diverticula, and colonic varices.

► Clinical Findings

A. Symptoms and Signs

The color of the stool helps distinguish upper from lower gastrointestinal bleeding, especially when observed by the

clinician. Brown stools mixed or streaked with blood predict a source in the rectosigmoid or anus. Large volumes of bright red blood suggest a colonic source; maroon stools imply a lesion in the right colon or small intestine; and black stools (melena) predict a source proximal to the ligament of Treitz. Although 10% of patients admitted with self-reported hematochezia have an upper gastrointestinal source of bleeding (eg, peptic ulcer), this almost always occurs in the setting of massive hemorrhage with hemodynamic instability. Painless large-volume bleeding usually suggests diverticular bleeding. Bloody diarrhea associated with cramping abdominal pain, urgency, or tenesmus is characteristic of inflammatory bowel disease, infectious colitis, or ischemic colitis.

B. Diagnostic Tests

Important considerations in management include exclusion of an upper tract source, anoscopy and sigmoidoscopy, colonoscopy, nuclear bleeding scans and angiography, and small intestine push enteroscopy or capsule imaging.

1. Exclusion of an upper tract source—A nasogastric tube with aspiration should be considered, especially in patients with hemodynamic compromise. Aspiration of red blood or dark brown (“coffee grounds”) guaiac-positive material strongly implicates an upper gastrointestinal source of bleeding. If blood is not seen and bile is aspirated, an upper source is found in only 1% of patients.

2. Anoscopy and sigmoidoscopy—In otherwise healthy patients without anemia under age 45 years with small-volume bleeding, anoscopy and sigmoidoscopy are performed to look for evidence of anorectal disease, inflammatory bowel disease, or infectious colitis. If a lesion is found, no further evaluation is needed immediately unless the bleeding persists or is recurrent. In patients over age 45 years with small-volume hematochezia, the entire colon must be evaluated with colonoscopy to exclude tumor.

3. Colonoscopy—In patients with acute, large-volume bleeding requiring hospitalization, colonoscopy is the preferred initial study in most cases. The bowel first is purged rapidly by administration of a high-volume colonic lavage solution, given until the effluent is clear of blood and clots (4–10 L of GoLYTELY, CoLYTE, NuLYTE given orally or 1 L every 30 minutes over 2–5 hours by nasogastric tube). For patients with stable vital signs and whose lower gastrointestinal bleeding appears to have stopped, colonoscopy can be performed electively within 24 hours of admission. For patients with signs of hemodynamically significant bleeding (unstable vital signs) or who have signs of continued active bleeding during bowel preparation, urgent colonoscopy should be performed within 1–2 hours of completing the bowel purgative, when the bowel discharge is without clots. The probable site of bleeding can be identified in 70–85% of patients, and a high-risk lesion can be identified and treated in up to 20%.

4. Nuclear bleeding scans and angiography—Technetium-labeled red blood cell scanning can detect significant active bleeding and, in some cases, can localize the

source to the small intestine, right colon, or left colon. Thus, some physicians obtain a nuclear bleeding scan to guide initial decision-making. If no bleeding is detected on scintigraphy, an “elective” colonoscopy is performed within 24 hours after conventional bowel preparation. If bleeding is detected on scintigraphy, urgent angiography is performed instead of colonoscopy. Nuclear studies are more apt to be positive in patients who are passing bright red or maroon stools at the time of the scan. Because most bleeding is slow or intermittent, less than half of nuclear studies are diagnostic and the accuracy of localization is poor. Thus, the main utility of scintigraphy is to determine whether bleeding is ongoing in order to determine whether angiography should be pursued. Less than half of patients with a positive nuclear study have positive angiography. Accordingly, angiograms are performed only in patients with positive technetium scans believed to have significant, ongoing bleeding.

In patients with massive lower gastrointestinal bleeding manifested by continued hemodynamic instability and hematochezia, urgent angiography should be performed without attempt at colonoscopy or scintigraphy.

5. Small intestine push enteroscopy or capsule imaging—Up to 5% of acute episodes of lower gastrointestinal bleeding arise from the small intestine, eluding diagnostic evaluation with upper endoscopy and colonoscopy. Because of the difficulty of examining the small intestine and its relative rarity as a source of acute bleeding, evaluation of the small bowel is not usually pursued in patients during the initial episode of acute lower gastrointestinal bleeding. However, the small intestine is investigated in patients with unexplained recurrent hemorrhage of obscure origin. (See *Obscure Gastrointestinal Bleeding* below.)

► Treatment

Initial stabilization, blood replacement, and triage are managed in the same manner as described above for *Acute Upper Gastrointestinal Bleeding*.

A. Therapeutic Colonoscopy

High-risk lesions (eg, angioectasias or diverticulum, rectal ulcer with active bleeding, or a visible vessel) may be treated endoscopically with epinephrine injection, cautery (bipolar or heater probe), or application of metallic endoclips or bands. In diverticular hemorrhage with high-risk lesions identified at colonoscopy, rebleeding occurs in half of untreated patients compared with virtually no rebleeding in patients treated endoscopically. Radiation proctitis is effectively treated with applications of cautery therapy to the rectal telangiectasias, preferably with an argon plasma coagulator.

B. Intra-arterial Embolization

When a bleeding lesion is identified, angiography with selective embolization achieves immediate hemostasis in more than 95% of patients. Major complications occur in 5% (mainly ischemic colitis) and rebleeding occurs in up to 25%.

C. Surgical Treatment

Emergency surgery is required in less than 5% of patients with acute lower gastrointestinal bleeding due to the efficacy of colonoscopic and angiographic therapies. It is indicated in patients with ongoing bleeding that requires more than 4–6 units of blood within 24 hours or more than 10 total units in whom attempts at endoscopic or angiographic therapy failed. Most such hemorrhages are caused by a bleeding diverticulum or vascular ectasia. Preoperative localization of the bleeding site by nuclear scan or angiography allows limited resection of the bleeding segment of small intestine or colon. When accurate localization is not possible or when emergency surgery is required for massive hemorrhage, total abdominal colectomy with ileorectal anastomosis is required—with significantly higher morbidity and mortality than limited resections.

Surgery may also be indicated in patients with two or more hospitalizations for diverticular hemorrhage depending on the severity of bleeding and the patient’s other comorbid conditions.

3. Occult Gastrointestinal Bleeding

Occult gastrointestinal bleeding refers to bleeding that is not apparent to the patient. Chronic gastrointestinal blood loss of less than 100 mL/d may cause no appreciable change in stool appearance. Thus, occult bleeding in an adult is identified by a positive FOBT, FIT, or iron deficiency anemia in the absence of visible blood loss. FOBT or FIT may be performed in patients with gastrointestinal symptoms or as a screening test for colorectal neoplasia (see Chapter 39). From 2% to 6% of patients in screening programs have a positive FOBT or FIT.

In the United States, 2% of men and 5% of women have iron deficiency anemia (serum ferritin < 30–45 mcg/L). In premenopausal women, iron deficiency anemia is most commonly attributable to menstrual and pregnancy-associated iron loss; however, a gastrointestinal source of chronic blood loss is present in 10%. Occult blood loss may arise from anywhere in the gastrointestinal tract. Among men and postmenopausal women, a potential gastrointestinal cause of blood loss can be identified in the colon in 15–30% and in the upper gastrointestinal tract in 35–55%; a malignancy is present in 10%. Iron deficiency on rare occasions is caused by malabsorption (especially celiac disease) or malnutrition. The most common causes are: (1) neoplasms; (2) vascular abnormalities (vascular ectasias); (3) acid-peptic lesions (esophagitis, peptic ulcer disease, erosions in hiatal hernia); (4) infections (nematodes, especially hookworm; tuberculosis); (5) medications (especially NSAIDs or aspirin); and (6) other causes such as inflammatory bowel disease.

► Evaluation of Occult Bleeding

Asymptomatic adults with positive FOBTs or FITs that are performed for routine colorectal cancer screening should undergo colonoscopy (see Chapter 39). All symptomatic adults with positive FOBTs or FITs or iron deficiency anemia should undergo evaluation of the upper and lower gastrointestinal tract with colonoscopy and upper endoscopy, unless the anemia can be definitively ascribed to a nongastrointestinal source (eg, menstruation, blood donation, or recent surgery). The presence and nature of gastrointestinal symptoms help guide the choice of initial study. After evaluation of the upper and lower gastrointestinal tract with upper endoscopy and colonoscopy, the origin of occult bleeding remains unexplained in 30–50% of patients. Patients with occult bleeding who have a negative initial endoscopic evaluation may be given a trial of iron supplementation and closely observed. Although many older patients require no further evaluation, it is reasonable in younger patients with unexplained iron deficiency anemia to pursue further evaluation of the small intestine for a source of bleeding (as described below). When possible, antiplatelet agents (aspirin, NSAIDs, clopidogrel) should be discontinued. For recurrent or persistent chronic gastrointestinal blood loss or anemia that responds poorly to iron supplementation, further evaluation is pursued for a source of obscure bleeding (as described below).

4. Obscure Gastrointestinal Bleeding

Obscure gastrointestinal bleeding refers to bleeding of unknown origin that persists or recurs after initial endoscopic evaluation with upper endoscopy and colonoscopy. *Obscure-occult* bleeding refers to bleeding that is not apparent to the patient. It is manifested by recurrent positive FOBTs or FITs or recurrent iron deficiency anemia, or both in the absence of visible blood loss. *Obscure-overt* bleeding is manifested by persistent or recurrent visible evidence of gastrointestinal bleeding (hematemesis, hematochezia, or melena). Up to 5% of patients admitted to hospitals with clinically overt gastrointestinal bleeding do not have a cause identified on upper endoscopy or colonoscopy (and therefore have obscure-overt bleeding).

Obscure bleeding (either occult or overt) most commonly arises from lesions in the small intestine. In up to one-third of cases, however, a source of bleeding has been overlooked in the upper or lower tract on prior endoscopic studies. Hematemesis or melena suggests an overlooked source proximal to the ligament of Treitz (ie, within the esophagus, stomach, or duodenum): erosions in a hiatal hernia (“Cameron erosions”), peptic ulcer, vascular ectasias, Dieulafoy vascular malformation, portal hypertensive gastropathy, gastroduodenal varices, duodenal neoplasms, aortoenteric fistula, or hepatic and pancreatic lesions. In the colon, the most commonly overlooked lesions are vascular ectasias and neoplasms. The etiology of obscure bleeding that arises from the small intestine depends on the age of the patient. The most common causes of small intestinal bleeding in patients younger than 40 years are neoplasms (stromal tumors, lymphomas, adenocarcinomas, carcinoids), Crohn disease, celiac disease, and Meckel

diverticulum. These disorders also occur in patients over age 40; however, vascular ectasias and NSAID-induced ulcers are far more common.

Evaluation of Obscure Bleeding

The evaluation of obscure bleeding depends on the age and overall health status of the patient, associated symptoms, and severity of the bleeding. In an older patient with significant comorbid illnesses, no gastrointestinal symptoms, and occult or obscure bleeding in whom the suspected source of bleeding is vascular ectasias, it may be reasonable to limit diagnostic evaluations, provided the anemia can be managed with long-term iron therapy or occasional transfusions. On the other hand, aggressive diagnostic evaluation is warranted in younger patients with obscure bleeding (in whom small bowel tumors are the most common cause) and symptomatic older patients with overt or obscure bleeding. Upper endoscopy and colonoscopy should be repeated to ascertain that a lesion in these regions has not been overlooked. If these studies are unrevealing, capsule endoscopy should be performed to evaluate the small intestine. Capsule endoscopy is superior to radiographic studies (standard small bowel follow through, enteroclysis, or CT enterography) and standard push enteroscopy for the detection of small bowel abnormalities, demonstrating possible sources of occult bleeding in 60–70% of patients, most commonly vascular abnormalities (25–35%), ulcers (25%), and neoplasms (10%). Further management depends on the capsule endoscopic findings. Laparotomy is warranted if a small bowel tumor is identified by capsule endoscopy or radiographic studies. Most other lesions identified by capsule imaging can be further evaluated with one of several new enteroscopes that use balloons or spiral overtubes to advance the scope through most of the small intestine in a forward and retrograde direction. Neoplasms can be biopsied or resected, and vascular ectasias may be cauterized. For patients with overt obscure bleeding, it may be more cost-effective to proceed directly with deep enteroscopy rather than capsule endoscopy. For hemodynamically significant acute bleeding, angiography may be superior to enteroscopy for localization and embolization of a bleeding vascular abnormality. Abdominal CT may be considered to exclude a hepatic or pancreatic source of bleeding. With the advent of capsule imaging and advanced endoscopic technologies for evaluating and treating bleeding lesions in the small intestine, intraoperative enteroscopy of the small bowel is seldom required.

DISEASES OF THE PERITONEUM

ASSESSMENT OF THE PATIENT WITH ASCITES

▶ Etiology of Ascites

The term “ascites” denotes the pathologic accumulation of fluid in the peritoneal cavity. Healthy men have little or no intraperitoneal fluid, but women normally may have up to 20 mL depending on the phase of the menstrual cycle. The causes of ascites may be classified into two broad pathophysiologic categories: that which is associated with a normal peritoneum and that which occurs due to a diseased peritoneum (Table 15–7). The most common cause of ascites is portal hypertension secondary to chronic liver disease, which accounts for over 80% of patients with ascites. The management of portal hypertensive ascites is discussed in Chapter 16. The most common causes of nonportal hypertensive ascites include infections (tuberculous peritonitis), intra-abdominal malignancy, inflammatory disorders of the peritoneum, and ductal disruptions (chylous, pancreatic, biliary).

▶ Clinical Findings

A. Symptoms and Signs

The history usually is one of increasing abdominal girth, with the presence of abdominal pain depending on the cause. Because most ascites is secondary to chronic liver disease with portal hypertension, patients should be asked about risk factors for liver disease, especially alcohol consumption, transfusions, tattoos, injection drug use, a history of viral hepatitis or jaundice, and birth in an area endemic for hepatitis. A history of cancer or marked weight loss arouses suspicion of malignant ascites. Fevers may suggest infected peritoneal fluid, including bacterial peritonitis (spontaneous or secondary). Patients with chronic liver disease and ascites are at greatest risk for developing spontaneous bacterial peritonitis. In immigrants, immunocompromised hosts, or severely malnourished alcoholics, tuberculous peritonitis should be considered.

Physical examination should emphasize signs of portal hypertension and chronic liver disease. Elevated jugular

¹Hepatic congestion usually associated with SAAG \geq 1.1 g/dL and ascitic fluid total protein > 2.5 g/dL.

²There may be cases of “mixed ascites” in which portal hypertensive ascites is complicated by a secondary process such as infection. In these cases, the SAAG is \geq 1.1 g/dL.

SAAG, serum-ascites albumin gradient.

venous pressure may suggest right-sided congestive heart failure or constrictive pericarditis. A large tender liver is characteristic of acute alcoholic hepatitis or Budd-Chiari syndrome. The presence of large abdominal wall veins with cephalad flow also suggests portal hypertension; inferiorly directed flow implies hepatic vein obstruction. Signs of chronic liver disease include palmar erythema, cutaneous spider angiomas, gynecomastia, and Dupuytren contracture. Asterixis secondary to hepatic encephalopathy may be present. Anasarca results from cardiac failure or

nephrotic syndrome with hypoalbuminemia. Finally, firm lymph nodes in the left supraclavicular region or umbilicus may suggest intra-abdominal malignancy.

The physical examination is relatively insensitive for detecting ascitic fluid. In general, patients must have at least 1500 mL of fluid to be detected reliably by this method. Even the experienced clinician may find it difficult to distinguish between obesity and small-volume ascites. Abdominal ultrasound establishes the presence of fluid.

B. Laboratory Testing

1. Abdominal paracentesis—Abdominal paracentesis is performed as part of the diagnostic evaluation in all patients with new onset of ascites to help determine the cause. It should also be performed to diagnose bacterial peritonitis in all patients admitted to the hospital with cirrhosis and ascites (in whom the prevalence of bacterial peritonitis is 10–30%) and when patients with known ascites develop clinical deterioration (fever, abdominal pain, rapid worsening of renal function, or worsened hepatic encephalopathy).

A. INSPECTION—Cloudy fluid suggests infection. Milky fluid is seen with chylous ascites due to high triglyceride levels. Bloody fluid is most commonly attributable to a traumatic paracentesis, but up to 20% of cases of malignant ascites are bloody.

B. ROUTINE STUDIES

(1) Cell count—A white blood cell count with differential is the most important test. Normal ascitic fluid contains < 500 leukocytes/mL and < 250 polymorphonuclear neutrophils (PMNs)/mL. Any inflammatory condition can cause an elevated ascitic white count. A PMN count of > 250/mL (neutrocytic ascites) with a percentage of > 75% of all white cells is highly suggestive of bacterial peritonitis, either spontaneous primary peritonitis or secondary peritonitis (ie, caused by an intra-abdominal source of infection, such as a perforated viscus or appendicitis). An elevated white count with a predominance of lymphocytes arouses suspicion of tuberculosis or peritoneal carcinomatosis.

(2) Albumin and total protein—The serum-ascites albumin gradient (SAAG) is the best single test for the classification of ascites into portal hypertensive and nonportal hypertensive causes (Table 15–7). Calculated by subtracting the ascitic fluid albumin from the serum albumin, the gradient correlates directly with the portal pressure. An SAAG \geq 1.1 g/dL suggests underlying portal hypertension, while gradients < 1.1 g/dL implicate nonportal hypertensive causes.

The accuracy of the SAAG exceeds 95% in classifying ascites. It should be recognized, however, that approximately 4% of patients have “mixed ascites,” ie, underlying cirrhosis with portal hypertension complicated by a second cause for ascites formation (such as malignancy or tuberculosis). Thus, a high SAAG is indicative of portal hypertension but does not exclude concomitant malignancy.

The ascitic fluid total protein provides some additional clues to the cause. An elevated SAAG and a high protein level (> 2.5 g/dL) are seen in most cases of hepatic congestion secondary to cardiac disease or Budd-Chiari

syndrome. However, an increased ascitic fluid protein is also found in up to 20% of cases of uncomplicated cirrhosis. Two-thirds of patients with malignant ascites have a total protein level > 2.5 g/dL.

(3) Culture and Gram stain—The best technique consists of the inoculation of aerobic and anaerobic blood culture bottles with 5–10 mL of ascitic fluid at the patient’s bedside, which increases the sensitivity for detecting bacterial peritonitis to over 85% in patients with neutrocytic ascites (> 250 PMNs/mL), compared with approximately 50% sensitivity by conventional agar plate or broth cultures.

C. OPTIONAL STUDIES—Other laboratory tests are of utility in some specific clinical situations. Glucose and lactate dehydrogenase (LDH) may be helpful in distinguishing spontaneous from secondary bacterial peritonitis (see below). An elevated amylase may suggest pancreatic ascites or a perforation of the gastrointestinal tract with leakage of pancreatic secretions into the ascitic fluid. Perforation of the biliary tree is suspected with an ascitic bilirubin concentration that is greater than the serum bilirubin. An elevated ascitic creatinine suggests leakage of urine from the bladder or ureters. Ascitic fluid cytologic examination is ordered if peritoneal carcinomatosis is suspected. Adenosine deaminase may be useful for the diagnosis of tuberculous peritonitis.

C. Imaging

Abdominal ultrasound is useful in confirming the presence of ascites and in the guidance of paracentesis. Both ultrasound and CT imaging are useful in distinguishing between causes of portal and nonportal hypertensive ascites. Doppler ultrasound and CT can detect thrombosis of the hepatic veins (Budd-Chiari syndrome) or portal veins. In patients with nonportal hypertensive ascites, these studies are useful in detecting lymphadenopathy and masses of the mesentery and of solid organs such as the liver, ovaries, and pancreas. Furthermore, they permit directed percutaneous needle biopsies of these lesions. Ultrasound and CT are poor procedures for the detection of peritoneal carcinomatosis; the role of positron emission tomography (PET) imaging is unclear.

D. Laparoscopy

Laparoscopy is an important test in the evaluation of some patients with nonportal hypertensive ascites (low SAAG) or mixed ascites. It permits direct visualization and biopsy of the peritoneum, liver, and some intra-abdominal lymph nodes. Cases of suspected peritoneal tuberculosis or suspected malignancy with nondiagnostic CT imaging and ascitic fluid cytology are best evaluated by this method.

Kuiper JJ et al. Management of ascites and associated complications in patients with cirrhosis. *Aliment Pharmacol Ther.* 2007 Dec;26(Suppl 2):183–93. [PMID: 18081661]

SPONTANEOUS BACTERIAL PERITONITIS

ESSENTIALS OF DIAGNOSIS

- ▶ A history of chronic liver disease and ascites.
- ▶ Fever and abdominal pain.
- ▶ Peritoneal signs uncommonly encountered on examination.
- ▶ Neutrocytic ascites (> 250 white blood cells/mcL) with neutrophilic predominance.

▶ General Considerations

“Spontaneous” bacterial infection of ascitic fluid occurs in the absence of an apparent intra-abdominal source of infection. It is seen with few exceptions in patients with ascites caused by chronic liver disease. Translocation of enteric bacteria across the gut wall or mesenteric lymphatics leads to seeding of the ascitic fluid, as may bacteremia from other sites. Approximately 20–30% of cirrhotic patients with ascites develop spontaneous peritonitis; however, the incidence is greater than 40% in patients with ascitic fluid total protein < 1 g/dL, probably due to decreased ascitic fluid opsonic activity.

Virtually all cases of spontaneous bacterial peritonitis are caused by a monomicrobial infection. The most common pathogens are enteric gram-negative bacteria (*E coli*, *Klebsiella pneumoniae*) or gram-positive bacteria (*Streptococcus pneumoniae*, viridans streptococci, *Enterococcus* species). Anaerobic bacteria are not associated with spontaneous bacterial peritonitis.

▶ Clinical Findings

A. Symptoms and Signs

Eighty to 90 percent of patients with spontaneous bacterial peritonitis are symptomatic; in many cases the presentation is subtle. Spontaneous bacterial peritonitis may be present in 20% of patients hospitalized with chronic liver disease in the absence of any suggestive symptoms or signs.

The most common symptoms are fever and abdominal pain, present in two-thirds of patients. Spontaneous bacterial peritonitis may also present with a change in mental status due to exacerbation or precipitation of hepatic encephalopathy, or sudden worsening of renal function. Physical examination typically demonstrates signs of chronic liver disease with ascites. Abdominal tenderness is present in less than 50% of patients, and its presence suggests other processes.

B. Laboratory Findings

The most important diagnostic test is abdominal paracentesis. Ascitic fluid should be sent for cell count with differential, and blood culture bottles should be inoculated at the bedside; Gram stain is insensitive.

In the proper clinical setting, an ascitic fluid PMN count of > 250 cells/mcL (neutrocytic ascites) is presumptive

evidence of bacterial peritonitis. The percentage of PMNs is greater than 50–70% of the ascitic fluid white blood cells and commonly approximates 100%. Patients with neutrocytic ascites are presumed to be infected and should be started—regardless of symptoms—on antibiotics. Although 10–30% of patients with neutrocytic ascites have negative ascitic bacterial cultures (“culture-negative neutrocytic ascites”), it is presumed that these patients have bacterial peritonitis and should be treated empirically. Occasionally, a positive blood culture identifies the organism when ascitic fluid is sterile.

▶ Differential Diagnosis

Spontaneous bacterial peritonitis must be distinguished from secondary bacterial peritonitis, in which ascitic fluid has become secondarily infected by an intra-abdominal infection. Even in the presence of perforation, clinical symptoms and signs of peritonitis may be lacking owing to the separation of the visceral and parietal peritoneum by the ascitic fluid. Causes of secondary bacterial peritonitis include appendicitis, diverticulitis, perforated peptic ulcer, and perforated gallbladder. Secondary bacterial infection accounts for 3% of cases of infected ascitic fluid.

Ascitic fluid total protein, LDH, and glucose are useful in distinguishing spontaneous bacterial peritonitis from secondary infection. Up to two-thirds of patients with secondary bacterial peritonitis have at least two of the following: decreased glucose level (< 50 mg/dL), an elevated LDH level (greater than serum), and total protein > 1 g/dL. Ascitic neutrophil counts $> 10,000$ /mcL also are suspicious; however, most patients with secondary peritonitis have neutrophil counts within the range of spontaneous peritonitis. The presence of multiple organisms on ascitic fluid Gram stain or culture is diagnostic of secondary peritonitis.

If secondary bacterial peritonitis is suspected, abdominal CT imaging of the upper and lower gastrointestinal tracts should be obtained to look for evidence of an intra-abdominal source of infection. If these studies are negative and secondary peritonitis still is suspected, repeat paracentesis should be performed after 48 hours of antibiotic therapy to confirm that the PMN count is decreasing. Secondary bacterial peritonitis should be suspected in patients in whom the PMN count is not below the pre-treatment value at 48 hours.

Neutrocytic ascites may also be seen in some patients with peritoneal carcinomatosis, pancreatic ascites, or tuberculous ascites. In these circumstances, however, PMNs account for less than 50% of the ascitic white blood cells.

▶ Prevention

Up to 70% of patients who survive an episode of spontaneous bacterial peritonitis will have another episode within 1 year. Prophylactic therapy—with norfloxacin, 400 mg/d; ciprofloxacin, 750 mg weekly; or trimethoprim-sulfamethoxazole, one double-strength tablet daily—has been shown to reduce the rate of recurrent infections to less than 20% and is recommended. Prophylaxis should be considered also in patients who have not had prior bacterial peritonitis but are at increased risk of infection due to low-protein

ascites (total ascitic protein < 1 g/dL). Although improvement in survival in cirrhotic patients with ascites treated with prophylactic antibiotics has not been shown, decision analytic modeling suggests that in patients with prior bacterial peritonitis or low ascitic fluid protein, the use of prophylactic antibiotics is a cost-effective strategy.

► Treatment

Empiric therapy for spontaneous bacterial peritonitis should be initiated with a third-generation cephalosporin such as cefotaxime (dosage: 2 g intravenously every 8–12 hours depending on renal function), which covers 98% of causative agents of this disorder. If enterococcus infection is suspected, ampicillin may be added. Because of a high risk of nephrotoxicity in patients with chronic liver disease, aminoglycosides should not be used. Although the optimal duration of therapy is unknown, a course of 5–10 days is sufficient in most patients, or until the ascites fluid PMN count decreases to < 250 cells/mcL. Renal failure develops in up to 40% of patients and is a major cause of death. In patients given intravenous albumin, 1.5 g/kg on day 1 and 1 g/kg on day 3, the incidence of renal failure and mortality are reduced both during hospitalization and at follow-up. Patients with suspected secondary bacterial peritonitis should be given broad-spectrum coverage for enteric aerobic and anaerobic flora with a third-generation cephalosporin and metronidazole pending identification and definitive (usually surgical) treatment of the cause. In fact, the most effective treatment for spontaneous bacterial peritonitis is liver transplant.

► Prognosis

The mortality rate of spontaneous bacterial peritonitis exceeds 30%. However, if the disease is recognized and treated early, the rate is less than 10%. As the majority of patients have underlying severe liver disease, many may die of liver failure, hepatorenal syndrome, or bleeding complications from portal hypertension.

TUBERCULOUS PERITONITIS

Tuberculosis occurs in extrapulmonary sites in 20% of non-HIV-infected people and up to 70% of those infected

with HIV. Although tuberculous involvement of the peritoneum accounts for less than 2% of all causes of ascites in the United States, it remains a significant problem in the developing world. In Western countries, its incidence is higher among those with uncontrolled HIV disease, immigrants from underdeveloped countries, the urban poor, patients with cirrhosis, and nursing home residents.

The presenting symptoms include low-grade fever, abdominal pain, anorexia, and weight loss. Most patients have symptoms for months before the diagnosis is established. On physical examination, patients may have generalized abdominal tenderness and distention. There may be clinically evident ascites or suggestion of an abdominal mass. Ultrasonography or CT imaging of the abdomen reveals free or loculated ascites in > 80% of patients and also may demonstrate lymphadenopathy or peritoneal, mesenteric, or omental thickening.

The diagnosis thus can be difficult to establish, particularly in patients with underlying cirrhosis with ascites and in patients without ascites (in whom the diagnosis may not be suspected). Chest radiographs are abnormal in over 70%, but active tuberculous pulmonary disease is evident in less than 20% of patients. Skin tests are positive in 50%. Smears of ascitic fluid for acid-fast bacilli are usually negative, and cultures are positive in only 35%. Other findings are an ascitic fluid total protein > 3.0 g/dL, LDH > 90 units/L, or mononuclear cell-predominant leukocytosis > 500/mcL—each has a sensitivity of 70–80% but limited specificity. Meta-analysis of four international studies reports that ascites adenosine deaminase activity ≥ 36 –40 international unit/L has a sensitivity of 100% and a specificity of 97% for the diagnosis of tuberculous peritonitis; however, the accuracy of this method may be lower in patients in the United States who have cirrhotic ascites or HIV disease.

In patients with suspected tuberculous peritonitis, laparoscopy establishes the diagnosis. In over 90% of patients, characteristic peritoneal nodules are visible, and granulomas are seen on peritoneal biopsy. Peritoneal cultures require at least 4–6 weeks and are positive in less than two-thirds of patients.

Treatment of tuberculosis is discussed in Chapter 9.

MALIGNANT ASCITES

Two-thirds of cases of malignant ascites are caused by peritoneal carcinomatosis. The most common tumors causing carcinomatosis are primary adenocarcinomas of the ovary, uterus, pancreas, stomach, colon, lung, or breast. The remaining one-third is due to lymphatic obstruction or portal hypertension due to hepatocellular carcinoma or diffuse hepatic metastases. Patients present with nonspecific abdominal discomfort and weight loss associated with increased abdominal girth. Nausea or vomiting may be caused by partial or complete intestinal obstruction.

Abdominal CT may be useful to demonstrate the primary malignancy or hepatic metastases but seldom confirms the diagnosis of peritoneal carcinomatosis. In patients with carcinomatosis, paracentesis demonstrates a low serum ascites-albumin gradient (< 1.1 mg/dL), an increased total protein (> 2.5 g/dL), and an elevated white cell count (often both neutrophils and mononuclear cells) but with a lymphocyte predominance. Cytology is positive in over 95%, but laparoscopy may be required in patients with negative cytology to confirm the diagnosis and to exclude tuberculous peritonitis, with which it may be confused. Malignant ascites attributable to portal hypertension usually is associated with an increased serum ascites-albumin gradient (> 1.1 g/dL), a variable total protein, and negative ascitic cytology. Ascites caused by peritoneal carcinomatosis does not respond to diuretics.

Patients may be treated with periodic large-volume paracentesis for symptomatic relief. Intraperitoneal chemotherapy is sometimes used to shrink the tumor, but the overall prognosis is extremely poor, with only 10% survival at 6 months. Ovarian cancers represent an exception to this rule. With newer treatments consisting of surgical debulking and intraperitoneal chemotherapy, long-term survival from ovarian cancer is possible.

FAMILIAL MEDITERRANEAN FEVER

This is a rare autosomal recessive disorder of unknown pathogenesis that almost exclusively affects people of Mediterranean ancestry, especially Sephardic Jews, Armenians, Turks, and Arabs. Patients lack a protease in serosal fluids that normally inactivates interleukin-8 and the chemotactic complement factor 5A. Symptoms present in most patients before the age of 20 years. It is characterized by episodic bouts of acute peritonitis that may be associated with serositis involving the joints and pleura. Peritoneal attacks are marked by the sudden onset of fever, severe abdominal pain, and abdominal tenderness with guarding or rebound tenderness. If left untreated, attacks resolve within 24–48 hours. Because symptoms resemble those of surgical peritonitis, patients may undergo unnecessary exploratory laparotomy. Colchicine, 0.6 mg two or three times daily, has been shown to decrease the frequency and severity of attacks. Secondary amyloidosis (AA protein) with renal or hepatic involvement may occur in 25% of cases and is the main cause of death. Colchicine prevents or arrests further progression of amyloidosis development. In the absence of amyloidosis, the prognosis is excellent. The diagnosis of familial Mediterranean fever still is based on clinical criteria. Although the gene responsible for familial Mediterranean fever (*MEFV*) has been identified, commercial genetic tests fail to identify one of the known gene mutations in up to one-third of patients. Genetic testing is most useful to confirm the diagnosis in patients with atypical symptoms.

MESOTHELIOMA

Primary malignant mesothelioma is a rare tumor. Over 70% of cases have a history of asbestos exposure. Presenting symptoms and signs include abdominal pain or bowel obstruction, increased abdominal girth, and small to moderate ascites. The chest radiograph reveals pulmonary asbestosis in over 50%. The ascitic fluid is hemorrhagic, with a low serum-ascites albumin gradient. Cytology is often negative. Abdominal CT or PET-CT may reveal sheet-like masses involving the mesentery and omentum. Diagnosis is made at laparotomy or laparoscopy. The prognosis is extremely poor, but long-term survivors have been described with a combination of surgical debulking of tumor followed by heated intraoperative intraperitoneal chemotherapy and early postoperative intraperitoneal chemotherapy. Postoperative radiotherapy or combination chemotherapy may be helpful. Multicystic and well-differentiated papillary mesotheliomas are associated with a long survival with surgical treatment alone. (See Chapter 39 for Mesothelioma.)

MISCELLANEOUS PERITONEAL DISEASES

Chylous ascites is the accumulation of lipid-rich lymph in the peritoneal cavity. The ascitic fluid is characterized by a milky appearance with a triglyceride level > 1000 mg/dL. The usual cause in adults is lymphatic obstruction or leakage caused by malignancy, especially lymphoma. Nonmalignant causes include postoperative trauma, cirrhosis, tuberculosis, pancreatitis, and filariasis.

Pancreatic ascites is the intraperitoneal accumulation of massive amounts of pancreatic secretions due either to disruption of the pancreatic duct or to a pancreatic pseudocyst. It is most commonly seen in patients with chronic pancreatitis and complicates up to 3% of cases of acute pancreatitis. Because the pancreatic enzymes are not activated, pain often is absent. The ascitic fluid is characterized by a high protein level (> 2.5 g/dL) but a low SAAG. Ascitic fluid amylase levels are in excess of 1000 units/L. In nonsurgical cases, initial treatment consists of bowel rest, total parenteral nutrition (TPN), and octreotide to decrease pancreatic secretion. Persistent leakage requires treatment with either endoscopic placement of stents into the pancreatic duct or surgical drainage.

Bile ascites is caused most commonly by complications of biliary tract surgery, percutaneous liver biopsy, or abdominal trauma. Unless the bile is infected, bile ascites usually does not cause abdominal pain, fever, or leukocytosis. Paracentesis reveals yellow fluid with a ratio of ascites bilirubin to serum bilirubin greater than 1.0. Treatment

depends on the location and rate of bile leakage. Postcholecystectomy cystic duct leaks may be treated with endoscopic sphincterotomy or biliary stent placement to facilitate bile flow across the sphincter of Oddi. Other leaks may be treated with percutaneous drainage by interventional radiologists or with surgical closure.

DISEASES OF THE ESOPHAGUS

Symptoms

Heartburn, dysphagia, and odynophagia almost always indicate a primary esophageal disorder.

A. Heartburn

Heartburn (pyrosis) is the feeling of substernal burning, often radiating to the neck. Caused by the reflux of acidic (or, rarely, alkaline) material into the esophagus, it is highly specific for GERD.

B. Dysphagia

Difficulties in swallowing may arise from problems in transferring the food bolus from the oropharynx to the upper esophagus (oropharyngeal dysphagia) or from impaired transport of the bolus through the body of the esophagus (esophageal dysphagia). The history usually leads to the correct diagnosis.

1. Oropharyngeal dysphagia—The oropharyngeal phase of swallowing is a complex process requiring elevation of the tongue, closure of the nasopharynx, relaxation of the upper esophageal sphincter, closure of the airway, and pharyngeal peristalsis. A variety of mechanical and neuromuscular conditions can disrupt this process (Table 15–8). Problems with the oral phase of swallowing cause drooling or spillage of food from the mouth, inability to chew or initiate swallowing, or dry mouth. Pharyngeal dysphagia is characterized by an immediate sense of the bolus catching in the neck, the need to swallow repeatedly to clear food from the pharynx, or coughing or choking during meals. There may be associated dysphonia, dysarthria, or other neurologic symptoms.

2. Esophageal dysphagia—Esophageal dysphagia may be caused by **mechanical lesions** obstructing the esophagus or by **motility disorders** (Table 15–9). Patients with mechanical obstruction experience dysphagia, primarily for solids. This is recurrent, predictable, and, if the lesion progresses, will worsen as the lumen narrows. Patients with **motility disorders** have dysphagia for both solids and liquids. It is episodic, unpredictable, and can be progressive.

Table 15–8. Causes of oropharyngeal dysphagia.

Neurologic disorders

Brainstem cerebrovascular accident, mass lesion
Amyotrophic lateral sclerosis, multiple sclerosis, pseudobulbar palsy, post-polio syndrome, Guillain-Barré syndrome
Parkinson disease, Huntington disease, dementia
Tardive dyskinesia

Muscular and rheumatologic disorders

Myopathies, polymyositis
Oculopharyngeal dystrophy
Sjögren syndrome

Metabolic disorders

Thyrotoxicosis, amyloidosis, Cushing disease, Wilson disease
Medication side effects: anticholinergics, phenothiazines

Infectious disease

Polio, diphtheria, botulism, Lyme disease, syphilis, mucositis (*Candida*, herpes)

Structural disorders

Zenker diverticulum
Cervical osteophytes, cricopharyngeal bar, proximal esophageal webs
Oropharyngeal tumors
Postsurgical or radiation changes
Pill-induced injury

Motility disorders

Upper esophageal sphincter dysfunction

C. Odynophagia

Odynophagia is sharp substernal pain on swallowing that may limit oral intake. It usually reflects severe erosive disease. It is most commonly associated with infectious esophagitis due to *Candida*, herpesviruses, or CMV, especially in immunocompromised patients. It may also be caused by corrosive injury due to caustic ingestions and by pill-induced ulcers.

Table 15–9. Causes of esophageal dysphagia.

| Cause | Clues |
|-------------------------------|---|
| Mechanical obstruction | Solid foods worse than liquids |
| Schatzki ring | Intermittent dysphagia; not progressive |
| Peptic stricture | Chronic heartburn; progressive dysphagia |
| Esophageal cancer | Progressive dysphagia; age over 50 years |
| Eosinophilic esophagitis | Young adults; small-caliber lumen, proximal stricture, corrugated rings, or white papules |
| Motility disorder | Solid and liquid foods |
| Achalasia | Progressive dysphagia |
| Diffuse esophageal spasm | Intermittent; not progressive; may have chest pain |
| Scleroderma | Chronic heartburn; Raynaud phenomenon |

▶ Diagnostic Studies

A. Upper Endoscopy

Endoscopy is the study of choice for evaluating persistent heartburn, dysphagia, odynophagia, and structural abnormalities detected on barium esophagography. In addition to direct visualization, it allows biopsy of mucosal abnormalities and of normal mucosa (to evaluate for eosinophilic esophagitis) as well as dilation of strictures.

B. Videoesophagography

Oropharyngeal dysphagia is best evaluated with rapid-sequence videoesophagography.

C. Barium Esophagography

Patients with esophageal dysphagia often are evaluated first with a radiographic barium study to differentiate between mechanical lesions and motility disorders, providing important information about the latter in particular. In patients with esophageal dysphagia and a suspected motility disorder, barium esophagoscopy should be obtained first. In patients in whom there is a high suspicion of a mechanical lesion, many clinicians will proceed first to endoscopic evaluation because it better identifies mucosal lesions (eg, erosions) and permits mucosal biopsy and dilation. However, barium study is more sensitive for detecting subtle esophageal narrowing due to rings, achalasia, and proximal esophageal lesions.

D. Esophageal Manometry

Esophageal motility may be assessed using manometric techniques. They are indicated: (1) to determine the location of the LES to allow precise placement of a conventional electrode pH probe; (2) to establish the etiology of dysphagia in patients in whom a mechanical obstruction cannot be found, especially if a diagnosis of achalasia is suspected by endoscopy or barium study; (3) for the preoperative assessment of patients being considered for antireflux surgery to exclude an alternative diagnosis (eg, achalasia) or possibly to assess peristaltic function in the esophageal body. High-resolution manometry may be superior to conventional manometry for distinguishing motility disorders.

E. Esophageal pH Recording and Impedance Testing

The pH within the esophageal lumen may be monitored continuously for 24–48 hours. There are two kinds of systems in use: catheter-based and wireless. Traditional systems use a long transnasal catheter that is connected directly to the recording device. Wireless systems are increasingly used; in these systems, a capsule is attached directly to the esophageal mucosa under endoscopic visualization and data are transmitted by radiotelemetry to the recording device. The recording provides information about the amount of esophageal acid reflux and the temporal correlations between symptoms and reflux.

Esophageal pH monitoring devices provide information about the amount of esophageal acid reflux but not nonacid

reflux. New techniques using multichannel intraluminal impedance allow assessment of gas and nonacid liquid reflux. Although not yet widely available, they may be useful in evaluation of patients with atypical reflux symptoms or persistent symptoms despite therapy with proton pump inhibitors to diagnose hypersensitivity, functional symptoms, and symptoms caused by non-acid reflux.

GASTROESOPHAGEAL REFLUX DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Heartburn; may be exacerbated by meals, bending, or recumbency.
- ▶ Typical uncomplicated cases do not require diagnostic studies.
- ▶ Endoscopy demonstrates abnormalities in one-third of patients.

▶ General Considerations

GERD is defined by a recent consensus as a condition that develops when the reflux of stomach contents causes troublesome symptoms or complications. GERD affects 20% of adults, who report at least weekly episodes of heartburn, and up to 10% complain of daily symptoms. Although most patients have mild disease, esophageal mucosal damage (reflux esophagitis) develops in up to one-third and more serious complications develop in a few others. Several factors may contribute to GERD.

A. Impaired Lower Esophageal Sphincter Function

The antireflux barrier at the gastroesophageal junction depends on LES pressure, the intra-abdominal location of the sphincter, and the extrinsic compression of the sphincter by the crural diaphragm. In most patients with GERD, baseline LES pressures are normal (10–30 mm Hg). In these patients, most reflux episodes occur during transient relaxations of the LES that are triggered by gastric distention by a vagovagal reflex. A subset of patients with GERD have an incompetent (< 10 mm Hg) LES that results in increased acid reflux, especially when supine or when intra-abdominal pressures are increased by lifting or bending. A hypotensive sphincter is present in up to 50% of patients with severe erosive GERD.

B. Hiatal Hernia

Hiatal hernias are common and usually cause no symptoms. In patients with gastroesophageal reflux, however, they are associated with higher amounts of acid reflux and delayed esophageal acid clearance leading to more severe esophagitis, especially Barrett esophagus. Increased reflux episodes occur during normal swallowing-induced relaxation, transient LES relaxations, and straining due to reflux of acid from the hiatal hernia sac into the esophagus. Hiatal hernias are found in one-fourth of patients with nonerosive GERD, three-fourths of patients with severe erosive esophagitis, and over 90% of patients with Barrett esophagus.

C. Irritant Effects of Refluxate

Esophageal mucosal damage is related to the potency of the refluxate and the amount of time it is in contact with the mucosa. Acidic gastric fluid (pH < 4.0) is extremely caustic to the esophageal mucosa and is the major injurious agent in the majority of cases. In some patients, reflux of bile or alkaline pancreatic secretions may be contributory.

D. Abnormal Esophageal Clearance

Acid refluxate normally is cleared and neutralized by esophageal peristalsis and salivary bicarbonate. During sleep, swallowing-induced peristalsis is infrequent, prolonging acid exposure to the esophagus. One-half of patients with severe GERD also have diminished peristaltic clearance. Certain medical conditions such as scleroderma are associated with diminished peristalsis. Sjögren syndrome, anticholinergic medications, and oral radiation therapy may exacerbate GERD due to impaired salivation.

E. Delayed Gastric Emptying

Impaired gastric emptying due to gastroparesis or partial gastric outlet obstruction potentiates GERD.

► Clinical Findings

A. Symptoms and Signs

The typical symptom is heartburn. This most often occurs 30–60 minutes after meals and upon reclining. Patients often report relief from taking antacids or baking soda. When this symptom is dominant, the diagnosis is established with a high degree of reliability. Many patients, however, have less specific dyspeptic symptoms with or without heartburn. Overall, a clinical diagnosis of gastroesophageal reflux has a sensitivity of 80% but a specificity of only 70%. Severity is not correlated with the degree of tissue damage. In fact, some patients with severe esophagitis are only mildly symptomatic. Patients may complain of regurgitation—the spontaneous reflux of sour or bitter gastric contents into the mouth. Dysphagia occurs in one-third of patients and may be due to erosive esophagitis, abnormal esophageal peristalsis, or the development of an esophageal stricture.

“Atypical” or “extraesophageal” manifestations of gastroesophageal disease may occur, including asthma, chronic

cough, chronic laryngitis, sore throat, and noncardiac chest pain. Gastroesophageal reflux may be either a causative or an exacerbating factor in up to 50% of these patients, especially those with refractory symptoms. In the absence of heartburn or regurgitation, atypical symptoms are unlikely to be related to gastroesophageal reflux.

Physical examination and laboratory data are normal in uncomplicated disease.

B. Special Examinations

Initial diagnostic studies are not warranted for patients with typical GERD symptoms suggesting uncomplicated reflux disease. Patients with typical symptoms of heartburn and regurgitation should be treated empirically with a once- or twice-daily proton pump inhibitor for 4–8 weeks. Further investigation is required in patients with “alarm features” (troublesome dysphagia, odynophagia, weight loss, iron deficiency anemia) and in patients with troublesome symptoms that persist despite empiric proton pump inhibitor therapy in order to identify complications of reflux disease and to diagnose other conditions with similar symptoms.

1. Upper endoscopy—Upper endoscopy with biopsy is excellent for documenting the type and extent of tissue damage in gastroesophageal reflux; for detecting other gastroesophageal lesions that may mimic GERD; and for detecting GERD complications, including esophageal stricture, Barrett metaplasia, and esophageal adenocarcinoma. In the absence of prior antisecretory therapy, up to one-third of patients with GERD have visible mucosal damage (known as reflux esophagitis), characterized by single or multiple erosions or ulcers in the distal esophagus at the squamocolumnar junction. In patients treated with a proton pump inhibitor prior to endoscopy, preexisting reflux esophagitis may be partially or completely healed. The Los Angeles classification grades reflux esophagitis on a scale of A (one or more isolated mucosal breaks ≤ 5 mm that do not extend between the tops of two mucosal folds) to D (one or more mucosal breaks that involve at least 75% of the esophageal circumference).

2. Barium esophagography—This study plays a limited role. In patients with severe dysphagia, it is sometimes obtained prior to endoscopy to identify a stricture.

3. Manometry and esophageal pH monitoring—Esophageal manometry and pH monitoring are unnecessary in most patients but may be indicated in a small percentage who have persistent troublesome symptoms despite empiric twice-daily proton pump inhibitor therapy and who have normal findings on endoscopy. Esophageal manometry may be useful to diagnose motility disorders presenting with atypical GERD-like symptoms such as achalasia or diffuse esophageal spasm. Ambulatory or impedance pH monitoring may be indicated under the following circumstances: (1) to document abnormal esophageal acid exposure in a patient being considered for antireflux surgery who has a normal endoscopy (ie, no evidence of reflux esophagitis); and (2) to determine the correlation between symptoms and acid and non-acid reflux episodes.

► Differential Diagnosis

Symptoms of GERD may be similar to those of other diseases such as esophageal motility disorders, peptic ulcer, functional dyspepsia, and angina pectoris. Reflux erosive esophagitis may be confused with pill-induced damage, eosinophilic esophagitis, or infections (CMV, herpes, *Candida*).

► Complications

A. Barrett Esophagus

This is a condition in which the squamous epithelium of the esophagus is replaced by metaplastic columnar epithelium containing goblet and columnar cells (specialized intestinal metaplasia). Present in up to 10% of patients with chronic reflux, it arises from chronic reflux-induced injury to the esophageal squamous epithelium. Barrett esophagus is suspected at endoscopy from the presence of orange, gastric type epithelium that extends upward from the stomach into the distal tubular esophagus in a tongue-like or circumferential fashion. Biopsies obtained at endoscopy confirm the diagnosis. Three types of columnar epithelium may be identified: gastric cardiac, gastric fundic, and specialized intestinal metaplasia. Only the latter is believed to carry an increased risk of neoplasia.

Barrett esophagus does not provoke specific symptoms but gastroesophageal reflux does. Most patients have a long history of reflux symptoms, such as heartburn and regurgitation. Paradoxically, one-third of patients report minimal or no symptoms of GERD, suggesting decreased acid sensitivity of Barrett epithelium. Indeed, over 90% of individuals with Barrett esophagus in the general population do not seek medical attention.

Barrett esophagus should be treated with long-term proton pump inhibitors. Medical therapy may prevent progression, but there is no convincing evidence that regression occurs in most patients.

The most serious complication of Barrett esophagus is esophageal adenocarcinoma. It is believed that most adenocarcinomas of the esophagus and many such tumors of the gastric cardia arise from dysplastic epithelium in Barrett esophagus. The incidence of adenocarcinoma in patients with Barrett esophagus is 0.5%/year. Although this is a 40-fold increased risk compared with patients without Barrett esophagus, adenocarcinoma of the esophagus remains a relatively uncommon malignancy in the United States (7000 cases/year). Some clinical guidelines recommend endoscopic screening for Barrett esophagus and dysplasia in adults 50 years or older with more than 5–10 years of heartburn. However, given the large number of adults with chronic GERD relative to the small number in whom adenocarcinoma develops, it is unclear whether screening for Barrett esophagus is cost-effective.

A number of endoscopic therapies (multipolar electrocoagulation, argon plasma coagulation, and photodynamic therapy using photosensitizers and laser energy) have been used to ablate the Barrett columnar epithelium in an effort to reduce the risk of progression to neoplasia. When high-dose proton pump inhibitors are administered to normalize intraesophageal pH, ablation of Barrett columnar epi-

thelium may be followed by healing with normal squamous epithelium. These techniques are often incompletely effective, have a significant risk of complications (bleeding, perforation, strictures), and may result in mucosal healing in which residual metaplastic tissue is buried beneath reconstituted squamous epithelium. The FDA has recently approved a bipolar probe (HALO) that uses radiofrequency wave energy for thermal ablative therapy. Preliminary studies with this probe demonstrate complete eradication of Barrett epithelium in up to 70% of patients without significant complications. Further long-term studies are needed to establish the role of ablative therapy in patients with Barrett esophagus without dysplasia.

In patients known to have Barrett esophagus, surveillance endoscopy every 3 years to look for dysplasia or adenocarcinoma generally is recommended. Patients with low-grade dysplasia require repeat endoscopic surveillance in 6 months to screen for coexisting high-grade dysplasia or cancer. If low-grade dysplasia persists (which occurs in < 25% of patients), endoscopic surveillance should be repeated yearly. The treatment of patients with high-grade dysplasia or superficial mucosal cancers is controversial and evolving rapidly. Approximately 40% of patients may progress to (or already have) adenocarcinoma, of which 28% are intramucosal but 12% have tumor that invades the submucosal or lymph nodes. Until recently, esophagectomy has been recommended for all patients deemed to have a low operative risk. However, esophagectomy is associated with high morbidity and mortality rates (40% and 2–9%, respectively). Therefore, other options should be considered for patients with high-grade dysplasia, especially those who are deemed to be at high risk for esophagectomy.

Patients with a visible esophageal nodule containing high-grade dysplasia or intramucosal cancer should undergo endoscopic ultrasound evaluation to look for invasive cancer. For patients with disease that appears to be limited to the mucosa, endoscopic mucosal snare resection may be performed. If pathologic assessment of the tissue specimen demonstrates submucosal invasion, esophagectomy should be recommended; however, if the cancer is intramucosal, the risk of esophagectomy may exceed the risk of developing metastatic disease (< 5%). Photodynamic therapy or radiofrequency wave electrocautery (HALO) may be used to ablate Barrett tissue in patients with high-grade dysplasia without a visible esophageal nodule and to ablate Barrett tissue after endoscopic mucosal resection of a nodule with high-grade dysplasia or intramucosal cancer. An uncontrolled prospective US endoscopic study of radiofrequency wave ablation of Barrett tissue with high-grade dysplasia has shown complete resolution of dysplasia in 80% of patients. Alternatively, patients with high-grade dysplasia without visible lesions may undergo close endoscopic surveillance with biopsy every 3–6 months, reserving surgery or photodynamic therapies for approximately 7% of patients per year during follow-up in whom adenocarcinoma develops.

B. Peptic Stricture

Stricture formation occurs in about 5% of patients with esophagitis. It is manifested by the gradual development of

solid food dysphagia progressive over months to years. Often there is a reduction in heartburn because the stricture acts as a barrier to reflux. Most strictures are located at the gastroesophageal junction. Endoscopy with biopsy is mandatory in all cases to differentiate peptic stricture from malignant causes of esophageal stricture (esophageal carcinoma). Active erosive esophagitis is often present. Up to 90% of symptomatic patients are effectively treated with dilation with graduated polyvinyl catheters passed over a wire placed at the time of endoscopy or fluoroscopically, or balloons passed fluoroscopically or through an endoscope. Dilation is continued over one to several sessions. A luminal diameter of 13–17 mm is usually sufficient to relieve dysphagia. Long-term therapy with a proton pump inhibitor is required to decrease the likelihood of stricture recurrence. Some patients require intermittent dilation to maintain luminal patency, but operative management for strictures that do not respond to dilation is seldom required. Refractory strictures may benefit from endoscopic injection of triamcinolone into the stricture.

► Treatment

A. Medical Treatment

The goal of treatment is to provide symptomatic relief, to heal esophagitis (if present), and to prevent complications. In the majority of patients with uncomplicated disease, empiric treatment is initiated based on a compatible history without the need for further confirmatory studies. Patients not responding and those with suspected complications undergo further evaluation with upper endoscopy or esophageal manometry and pH recording (see above).

1. Mild, intermittent symptoms—Patients with mild or intermittent symptoms that do not impact adversely on quality of life may benefit from lifestyle modifications with medical interventions taken as needed. Patients may find that eating smaller meals and elimination of acidic foods (citrus, tomatoes, coffee, spicy foods) and foods that precipitate reflux (fatty foods, chocolate, peppermint, alcohol, cigarettes) may reduce symptoms. Weight loss should be recommended for overweight patients. Patients with nocturnal symptoms should be advised to avoid lying down within 3 hours after meals, the period of greatest reflux, and to elevate the head of the bed on 6-inch blocks or a foam wedge to reduce reflux and enhance esophageal clearance.

Antacids are the mainstay for rapid relief of occasional heartburn; however, their duration of action is less than 2 hours. Many are available over the counter. Those containing magnesium should not be used in renal failure, and patients with this condition should be cautioned appropriately.

All H₂-receptor antagonists are available in over-the-counter formulations: cimetidine 200 mg, ranitidine and nizatidine 75 mg, famotidine 10 mg—all of which are half of the typical prescription strength. When taken for active heartburn, these agents have a delay in onset of at least 30 minutes; antacids provide more immediate relief. However, once these agents take effect, they provide heartburn relief for up to 8 hours. When taken before meals known to provoke heartburn, these agents reduce the symptom. A

combination agent containing famotidine 10 mg and antacid (calcium carbonate and magnesium hydroxide) is available.

2. Troublesome symptoms

A. INITIAL THERAPY—Patients with troublesome reflux symptoms and patients with known complications of GERD should be treated with a once-daily oral proton pump inhibitor (omeprazole or rabeprazole, 20 mg; omeprazole with sodium bicarbonate, 40 mg; lansoprazole, 30 mg; esomeprazole or pantoprazole, 40 mg) taken 30 minutes before breakfast for 4–8 weeks. Because there appears to be little difference between these agents in efficacy or side effect profiles, the choice of agent is determined by cost. Omeprazole, 20 mg, is now available both as an over-the-counter formulation and as a generic formulation available by prescription. Once-daily proton pump inhibitors achieve adequate control of heartburn in 80–90% of patients, complete heartburn resolution in over 50%, and healing of erosive esophagitis (when present) in over 80%. Because of their superior efficacy and ease of use, proton pump inhibitors are preferred to H₂-receptor antagonists for the treatment of acute and chronic GERD. Approximately 10–20% of patients do not achieve symptom relief with a once-daily dose within 2–4 weeks and require a twice-daily proton pump inhibitor (taken 30 minutes before breakfast and dinner). Patients with inadequate symptom relief with empiric twice-daily proton pump inhibitor therapy should undergo evaluation with upper endoscopy. Many providers prefer to prescribe initial twice-daily proton pump inhibitor therapy for patients who have documented severe erosive esophagitis (LA Grade C or D), Barrett esophagus, or peptic stricture.

B. LONG-TERM THERAPY—In those who achieve good symptomatic relief with a course of empiric once-daily proton pump inhibitor, therapy may be discontinued after 8–12 weeks. Most patients (over 80%) will experience relapse of GERD symptoms, usually within 3 months. Patients whose symptoms relapse may be treated with either continuous proton pump inhibitor therapy, intermittent 2–4 week courses, or “on demand” therapy (ie, drug taken until symptoms abate) depending on symptom frequency and patient preference. Patients who required twice-daily proton pump inhibitor therapy for initial symptom control and patients with complications of GERD, including severe erosive esophagitis, Barrett esophagus, or peptic stricture, should be maintained on long-term therapy with a once- or twice-daily proton pump inhibitor titrated to the lowest effective dose to achieve satisfactory symptom control.

Side effects of proton pump inhibitors are uncommon. Headache, diarrhea, and abdominal pain may occur with any of the agents but generally resolve when another formulation is tried. Potential risks of long-term use of proton pump inhibitors include an increased risk of infectious gastroenteritis (including *C difficile*), hip fractures (possibly due to impaired calcium absorption), and fundic gland polyps (which appear to be of no clinical significance).

3. Extraesophageal reflux manifestations—Establishing a causal relationship between gastroesophageal reflux and extraesophageal symptoms (eg, asthma, hoarseness,

cough) is difficult. Gastroesophageal reflux seldom is the sole cause of extraesophageal disorders but may be a contributory factor. Although ambulatory esophageal pH testing can document the presence of increased acid esophageal reflux, it does not prove a causative connection. Current guidelines recommend that a trial of a twice-daily proton pump inhibitor be administered for 3 months in patients with suspected extraesophageal GERD syndromes who also have typical GERD symptoms. Improvement of extraesophageal symptoms suggests but does not prove that acid reflux is the causative factor. Esophageal pH testing should be performed in patients whose symptoms persist after 3 months of twice-daily proton pump inhibitor therapy. The pH study is performed on therapy if the suspicion for GERD is high (to determine whether therapy has adequately suppressed acid esophageal reflux) and off therapy if the suspicion for GERD is low (to determine whether the patient has reflux disease). Combined esophageal pH monitoring with impedance monitoring may be considered to look for nonacid reflux events in patients with persistent reflux symptoms who are receiving prolonged proton pump inhibitor therapy.

4. Unresponsive disease—Approximately 5% do not respond to twice-daily proton pump inhibitors or a change to a different proton pump inhibitor. These patients undergo endoscopy prior for detection of severe, inadequately treated reflux esophagitis and for other gastroesophageal lesions that may mimic GERD. The presence of active erosive esophagitis usually is indicative of inadequate acid suppression and can almost always be treated successfully with higher proton pump inhibitor doses (eg, omeprazole 40 mg twice daily). Truly refractory esophagitis may be caused by gastrinoma with gastric acid hypersecretion (Zollinger-Ellison syndrome), pill-induced esophagitis, resistance to proton pump inhibitors, and medical noncompliance. Patients without endoscopically visible esophagitis should undergo esophageal manometry followed by ambulatory pH or impedance pH and to determine the correlation between symptoms and acid and nonacid reflux episodes. If the pH study shows a normal amount of acid reflux, treatment with a low-dose tricyclic antidepressant (eg, imipramine or nortriptyline 25 mg at bedtime) may be beneficial.

B. Surgical Treatment

Surgical fundoplication affords good to excellent relief of symptoms and healing of esophagitis in over 85% of properly selected patients and can be performed laparoscopically with low complication rates in most instances. Cost-effectiveness studies suggest that aggregate medical costs exceed surgical costs after 10 years. Although patient satisfaction is high, over 50% of patients require intermittent or continuous acid-suppression medication after fundoplication. Furthermore, new symptoms of dysphagia, bloating, increased flatulence, dyspepsia, or diarrhea develop in over 30% of patients. Within 5–10 years after surgery, typical reflux symptoms occur in 10–30% of patients. Surgical treatment is not recommended for patients who are well controlled with medical therapies but should be consid-

ered for: (1) otherwise healthy, carefully selected patients with extraesophageal manifestations of reflux, as these symptoms often require high doses of proton pump inhibitors and may be more effectively controlled with antireflux surgery; (2) those with severe reflux disease who are unwilling to accept lifelong medical therapy due to its expense, inconvenience, or theoretical risks; and (3) patients with large hiatal hernias and persistent regurgitation despite proton pump inhibitor therapy.

▶ When to Refer

- Patients with typical GERD whose symptoms do not resolve with empiric management with a twice-daily proton pump inhibitor.
- Patients with suspected extraesophageal GERD symptoms that do not resolve with 3 months of twice-daily proton pump inhibitor therapy.
- Patients with significant dysphagia or other alarm symptoms for upper endoscopy.
- Patients with Barrett esophagus for endoscopic surveillance.
- Patients who have Barrett esophagus with dysplasia or early mucosal cancer.
- Surgical fundoplication is considered.

INFECTIOUS ESOPHAGITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Immunosuppressed patient.
- ▶ Odynophagia, dysphagia, and chest pain.
- ▶ Endoscopy with biopsy establishes diagnosis.

▶ General Considerations

Infectious esophagitis occurs most commonly in immunosuppressed patients. Patients with AIDS, solid organ transplants, leukemia, lymphoma, and those receiving immunosuppressive drugs are at particular risk for opportunistic infections. *Candida albicans*, herpes simplex, and CMV are the most common pathogens. *Candida* infection may occur also in patients who have uncontrolled diabetes and those being treated with systemic corticosteroids, radiation therapy, or systemic antibiotic therapy. Herpes simplex can affect normal hosts, in which case the infection is generally self-limited.

▶ Clinical Findings

A. Symptoms and Signs

The most common symptoms are odynophagia and dysphagia. Substernal chest pain occurs in some patients. Patients with candidal esophagitis are sometimes asymptomatic. Oral thrush is present in only 75% of patients with candidal esophagitis and 25–50% of patients with viral esophagitis and is therefore an unreliable indicator of the cause of esophageal infection. Patients with esophageal CMV infection may have infection at other sites such as the colon and retina. Oral ulcers (herpes labialis) are often associated with herpes simplex esophagitis.

B. Special Examinations

Treatment may be empiric. For diagnostic certainty, endoscopy with biopsy and brushings (for microbiologic

and histopathologic analysis) is preferred because of its high diagnostic accuracy. The endoscopic signs of candidal esophagitis are diffuse, linear, yellow-white plaques adherent to the mucosa. CMV esophagitis is characterized by one to several large, shallow, superficial ulcerations. Herpes esophagitis results in multiple small, deep ulcerations.

▶ Treatment

A. Candidal Esophagitis

Initial episodes of oropharyngeal candidiasis may be treated with clotrimazole troches (10 mg dissolved in mouth five times daily) or nystatin suspension (500,000 units five times daily), but systemic therapy is required for esophageal candidiasis. An empiric trial of antifungal therapy is often administered without performing diagnostic endoscopy. Initial therapy is generally with fluconazole, 100 mg/d orally for 14–21 days. Patients not responding to empiric therapy within 7–14 days should undergo endoscopy with brushings, biopsy, and culture to distinguish resistant fungal infection from other infections (eg, CMV, herpes). Esophageal candidiasis not responding to fluconazole therapy may be treated with itraconazole suspension (not capsules), 200 mg/d orally, or voriconazole, 200 mg twice daily. Refractory infection may be treated intravenously with caspofungin, 50 mg daily or amphotericin B, 0.3–0.7 mg/kg/d.

B. Cytomegalovirus Esophagitis

In patients with HIV infection, immune restoration with highly active antiretroviral therapy (HAART) is the most effective means of controlling CMV disease. Initial therapy is with ganciclovir, 5 mg/kg intravenously every 12 hours for 3–6 weeks. Neutropenia is a frequent dose-limiting side effect. Once resolution of symptoms occurs, it may be possible to complete the course of therapy with oral valganciclovir, 900 mg once daily. Patients who either do not respond to or cannot tolerate ganciclovir are treated acutely with foscarnet, 90 mg/kg intravenously every 12 hours for 3–6 weeks. The principal toxicity is renal failure, hypocalcemia, and hypomagnesemia.

C. Herpetic Esophagitis

Immunocompetent patients may be treated symptomatically and generally do not require specific antiviral therapy. Immunosuppressed patients may be treated with oral acyclovir, 400 mg orally five times daily, or 250 mg/m² intravenously every 8–12 hours, usually for 7–10 days. Famciclovir, 250 mg three times daily, and valacyclovir, 1 g twice daily, are effective but significantly more expensive than generic acyclovir. Nonresponders require therapy with foscarnet, 40 mg/kg intravenously every 8 hours for 21 days.

▶ Prognosis

Most patients with infectious esophagitis can be effectively treated with complete symptom resolution. Depending on the patient's underlying immunodeficiency, relapse of symptoms off therapy can raise difficulties. Long-term suppressive therapy is sometimes required.

- Weerasuriya N et al. Oesophageal candidiasis in elderly patients: risk factors, prevention and management. *Drugs Aging.* 2008;25(2):119–30. [PMID: 18257599]

PILL-INDUCED ESOPHAGITIS

A number of different medications may injure the esophagus, presumably through direct, prolonged mucosal contact. The most commonly implicated are the NSAIDs, potassium chloride pills, quinidine, zalcitabine, zidovudine, alendronate and risedronate, emepronium bromide, iron, vitamin C, and antibiotics (doxycycline, tetracycline, clindamycin, trimethoprim-sulfamethoxazole). Because injury is most likely to occur if pills are swallowed without water or while supine, hospitalized or bed-bound patients are at greater risk. Symptoms include severe retrosternal chest pain, odynophagia, and dysphagia, often beginning several hours after taking a pill. These may occur suddenly and persist for days. Some patients (especially the elderly) have relatively little pain, presenting with dysphagia. Endoscopy may reveal one to several discrete ulcers that may be shallow or deep. Chronic injury may result in severe esophagitis with stricture, hemorrhage, or perforation. Healing occurs rapidly when the offending agent is eliminated. To prevent pill-induced damage, patients should take pills with 4 oz of water and remain upright for 30 minutes after ingestion. Known offending agents should not be given to patients with esophageal dysmotility, dysphagia, or strictures.

- Abid S et al. Pill-induced esophageal injury: endoscopic features and clinical outcomes. *Endoscopy.* 2005 Aug;37(8):740–4. [PMID: 16032493]

CAUSTIC ESOPHAGEAL INJURY

Caustic esophageal injury occurs from accidental (usually children) or deliberate (suicidal) ingestion of liquid or crystalline alkali (drain cleaners, etc) or acid. Ingestion is followed almost immediately by severe burning and varying degrees of chest pain, gagging, dysphagia, and drooling. Aspiration results in stridor and wheezing. Initial examination should be directed to circulatory status as well as assessment of airway patency and the oropharyngeal mucosa, including laryngoscopy. Patients without major symptoms (dyspnea, dysphagia, drooling, hematemesis) or oropharyngeal lesions have a very low likelihood of having severe gastroesophageal injury. Subsequently, chest and abdominal radiographs are obtained looking for pneumonitis or free perforation. Initial treatment is supportive, with intravenous fluids and analgesics. Nasogastric lavage and oral antidotes may be dangerous and should generally not be administered. Most patients may be managed medically. Endoscopy is usually performed within the first 12–24 hours to assess the extent of injury, especially in patients with

significant symptoms or oropharyngeal lesions. Many patients are discovered to have no mucosal injury to the esophagus or stomach, allowing prompt discharge and psychiatric referral. Patients with evidence of mild damage (edema, erythema, exudates or superficial ulcers) recover quickly, have low risk of developing stricture, and may be advanced from liquids to a regular diet over 24–48 hours. Patients with signs of severe injury—deep or circumferential ulcers or necrosis (black discoloration) have a high risk (up to 65%) of acute complications, including perforation with mediastinitis or peritonitis, bleeding, stricture, or esophageal-tracheal fistulas. These patients must be kept fasting and monitored closely for signs of deterioration that warrant emergency surgery with possible esophagectomy and colonic or jejunal interposition. A nasogastric feeding tube is placed after 24 hours. Oral feedings of liquids may be initiated after 2–3 days if the patient is able to tolerate secretions. Neither corticosteroids nor antibiotics are recommended. Esophageal strictures develop in up to 70% of patients with serious esophageal injury weeks to months after the initial injury, requiring recurrent dilations. Endoscopic injection of intralésional corticosteroids (triamcinolone 40 mg) increases the interval between dilations. The risk of esophageal squamous carcinoma is 2–3%, warranting endoscopic surveillance 15–20 years after the caustic ingestion.

- Betalli P et al. Caustic ingestion in children: is endoscopy always indicated? The results of an Italian multicenter observational study. *Gastrointest Endosc.* 2008 Sept;68(3):434–9. [PMID: 18448103]

BENIGN ESOPHAGEAL LESIONS

1. Mallory-Weiss Syndrome (Mucosal Laceration of Gastroesophageal Junction)

ESSENTIALS OF DIAGNOSIS

- ▶ Hematemesis; usually self-limited.
- ▶ Prior history of vomiting, retching in 50%.
- ▶ Endoscopy establishes diagnosis.

▶ General Considerations

Mallory-Weiss syndrome is characterized by a nonpenetrating mucosal tear at the gastroesophageal junction that is hypothesized to arise from events that suddenly raise transabdominal pressure, such as lifting, retching, or vomiting. Alcoholism is a strong predisposing factor. Mallory-Weiss tears are responsible for approximately 5% of cases of upper gastrointestinal bleeding.

▶ Clinical Findings

A. Symptoms and Signs

Patients usually present with hematemesis with or without melena. A history of retching, vomiting, or straining is obtained in about 50% of cases.

B. Special Examinations

As with other causes of upper gastrointestinal hemorrhage, upper endoscopy should be performed after the patient has been appropriately resuscitated. The diagnosis is established by identification of a 0.5- to 4-cm linear mucosal tear usually located either at the gastroesophageal junction or, more commonly, just below the junction in the gastric mucosa.

► Differential Diagnosis

At endoscopy, other potential causes of upper gastrointestinal hemorrhage are found in over 35% of patients with Mallory-Weiss tears, including peptic ulcer disease, erosive gastritis, arteriovenous malformations, and esophageal varices. Patients with underlying portal hypertension are at higher risk of continued or recurrent bleeding.

► Treatment

Patients are initially treated as needed with fluid resuscitation and blood transfusions. Most patients stop bleeding spontaneously and require no therapy. Endoscopic hemostatic therapy is employed in patients who have continuing active bleeding. Injection with epinephrine (1:10,000), cautery with a bipolar or heater probe coagulation device, or mechanical compression of the artery by application of an endoclip or band is effective in 90–95% of cases. Angiographic arterial embolization or operative intervention is required in patients who fail endoscopic therapy.

Cho YS et al. Endoscopic band ligation and endoscopic hemoclip placement for patients with Mallory-Weiss syndrome and active bleeding. *World J Gastroenterol.* 2008 Apr 7;14(13):2080–4. [PMID: 18395910]

2. Eosinophilic Esophagitis

► General Considerations

Eosinophilic esophagitis is an entity that previously was recognized in children but is increasingly identified in young or middle-aged adults, predominantly men (75%). A history of allergies or atopic conditions (asthma, eczema, hayfever) is present in over half of patients.

► Clinical Findings

Most adults have a long history of dysphagia for solid foods or with an episode of food impaction. Heartburn may be present. Children may have abdominal pain, vomiting, chest pain, or failure to thrive. On laboratory tests, a few have eosinophilia or elevated IgE levels. Barium swallow studies may demonstrate a small-caliber esophagus, long and tapered strictures, or multiple concentric rings. However, endoscopy with esophageal biopsy and histologic evaluation is required to establish the diagnosis. Endoscopic appearances include multiple fine concentric rings, vertical furrowing or shearing, and whitish papules or exudates; however, the esophagus is grossly normal in one-third of patients. Multiple biopsies (at least 5) from

the proximal and distal esophagus should be obtained to demonstrate multiple (> 15/high-powered field) eosinophils in the mucosa. GERD may cause increased eosinophils in the distal esophageal mucosa and must be excluded. Most children have other coexisting atopic disorders. Skin testing for food allergies may be helpful to identify causative factors, especially in children.

► Treatment

The optimal treatment of eosinophilic esophagitis is uncertain. Referral to an allergist for evaluation of coexisting atopic disorders and for skin prick testing for food and environmental allergens is recommended. In children, food elimination or elemental diets lead to clinical and histologic improvement in 75%; however, the effectiveness of dietary therapy in adults is not established. The most common allergenic foods are dairy, eggs, wheat, soy, peanuts, and shellfish. To exclude GERD, all patients should be given an empiric trial of a proton pump inhibitor (eg, omeprazole, lansoprazole, pantoprazole, esomeprazole, rabeprazole) orally twice daily or undergo esophageal pH testing. Topical corticosteroids (eg, use of fluticasone 220 mcg/puff inhaler without a spacer, swallowing two to four puffs after inspiration, twice daily after meals) led to symptom resolution in 75% of adults in uncontrolled trials. Symptomatic relapse is common after discontinuation of therapy. Graduated dilation of strictures should be conducted cautiously because there is an increased risk of perforation and postprocedural chest pain.

Furuta G et al. Eosinophilic esophagitis in children and adults: a systematic review and consensus recommendations for diagnosis and treatment. *Gastroenterology.* 2007 Oct;133(4):1342–63. [PMID: 17919504]

3. Esophageal Webs & Rings

Esophageal webs are thin, diaphragm-like membranes of squamous mucosa that typically occur in the mid or upper esophagus and may be multiple. They may be congenital but also occur with graft-versus-host disease, pemphigoid, epidermolysis bullosa, pemphigus vulgaris, and, rarely, in association with iron deficiency anemia (Plummer-Vinson syndrome). Esophageal “Schatzki” rings are smooth, circumferential, thin (< 4 mm in thickness) mucosal structures located in the distal esophagus at the squamocolumnar junction. Their pathogenesis is controversial. They are associated in nearly all cases with a hiatal hernia, and reflux symptoms are common, suggesting that acid gastroesophageal reflux may be contributory in many cases. Most webs and rings are over 20 mm in diameter and are asymptomatic. Solid food dysphagia most often occurs with rings less than 13 mm in diameter. Characteristically, dysphagia is intermittent and not progressive. Large poorly chewed food boluses such as beefsteak are most likely to cause symptoms. Obstructing boluses may pass by drinking extra liquids or after regurgitation. In some cases, an impacted bolus must be extracted endoscopically. Esophageal webs

and rings are best visualized using a barium esophagogram with full esophageal distention. Endoscopy is less sensitive than barium esophagography.

The majority of symptomatic patients with a single ring or web can be effectively treated with the passage of a large (> 16-mm-diameter) bougie dilator to disrupt the lesion or endoscopic electrocautery incision of the ring. A single dilation may suffice, but repeat dilations are required in many patients. Patients who have heartburn or who require repeated dilation should receive long-term acid suppressive therapy with a proton pump inhibitor.

Sgouros SN et al. Long-term acid suppressive therapy may prevent the relapse of esophageal (Schatzki's) rings: a prospective, randomized, placebo-controlled study. *Am J Gastroenterol.* 2005 Sep;100(9):1929–34. [PMID: 16128935]

4. Esophageal Diverticula

Diverticula may occur in the proximal, mid, or distal esophagus. These may arise secondary to motility disorders (diffuse esophageal spasm, achalasia) or may develop above esophageal strictures. Diverticula are seldom symptomatic. For patients with severe symptoms or pulmonary complications, surgical myotomy with or without diverticulectomy is the optimal treatment.

► Zenker Diverticulum

Zenker diverticulum is a protrusion of pharyngeal mucosa that develops at the pharyngoesophageal junction between the inferior pharyngeal constrictor and the cricopharynx. The cause is believed to be loss of elasticity of the upper esophageal sphincter, resulting in restricted opening during swallowing. Symptoms of dysphagia and regurgitation tend to develop insidiously over years in older patients. Initial symptoms include vague oropharyngeal dysphagia with coughing or throat discomfort. As the diverticulum enlarges and retains food, patients may note halitosis, spontaneous regurgitation of undigested food, nocturnal choking, gurgling in the throat, or a protrusion in the neck. Complications include aspiration pneumonia, bronchiectasis, and lung abscess. The diagnosis is best established by a barium esophagogram.

Symptomatic patients require upper esophageal myotomy and, in most cases, surgical diverticulectomy. An intraluminal approach has been developed in which the septum between the esophagus and diverticulum is incised using a rigid or flexible endoscope. Significant improvement occurs in over 90% of patients treated surgically. Small asymptomatic diverticula may be observed.

Seaman DL et al. A new device to simplify flexible endoscopic treatment of Zenker's diverticulum. *Gastrointest Endosc.* 2008 Jan;67(1):112–5. [PMID: 18155432]

5. Benign Esophageal Neoplasms

Benign tumors of the esophagus are quite rare. They are submucosal, the most common being leiomyoma. Most are asymptomatic and picked up incidentally on endoscopy or barium esophagography. Larger lesions can cause dysphagia, pain, and rarely ulceration with bleeding. The risk of malignant transformation is low. Therefore, the major clinical importance of these lesions is to distinguish them from malignant neoplasms. At endoscopy, a smooth, sessile nodule is observed with normal overlying mucosa. Because the lesion is submucosal, endoscopic biopsies are generally nonrevealing. Endoscopic ultrasonography is extremely helpful to confirm the submucosal origin of the tumor and to help distinguish benign leiomyomas from malignant leiomyosarcomas. Surgical (or in selected cases endoscopic) resection is indicated for lesions that are symptomatic, ulcerated, or increasing in size. (See **Chapter 39 for Esophageal Cancer.**)

Jiang G et al. Thoroscopic enucleation of esophageal leiomyoma: a retrospective study on 40 cases. *Dis Esophagus.* 2009;22(3):279–83. [PMID: 19021682]

6. Esophageal Varices

ESSENTIALS OF DIAGNOSIS

- Develop secondary to portal hypertension.
- Found in 50% of patients with cirrhosis.
- One-third of patients with varices develop upper gastrointestinal bleeding.
- Diagnosis established by upper endoscopy.

► General Considerations

Esophageal varices are dilated submucosal veins that develop in patients with underlying portal hypertension and may result in serious upper gastrointestinal bleeding. The causes of portal hypertension are discussed in Chapter 16. Under normal circumstances, there is a 2–6 mm Hg pressure gradient between the portal vein and the inferior vena cava. When the gradient exceeds 10–12 mm Hg, significant portal hypertension exists. Esophageal varices are the most common cause of important gastrointestinal bleeding due to portal hypertension, though gastric varices and, rarely, intestinal varices may also bleed. Bleeding from esophageal varices most commonly occurs in the distal 5 cm of the esophagus.

The most common cause of portal hypertension is cirrhosis. Approximately 50% of patients with cirrhosis have esophageal varices. Bleeding from varices occurs in 30% of patients with esophageal varices. In the absence of any treatment, variceal bleeding spontaneously stops in

about 50% of patients. Patients surviving this bleeding episode have a 60% chance of recurrent variceal bleeding, usually within the first 6 weeks. With current therapies, the in-hospital mortality rate associated with bleeding esophageal varices is 15%.

A number of factors have been identified that may portend an increased risk of bleeding from esophageal varices. The most important are: (1) the size of the varices; (2) the presence at endoscopy of red wale markings on the varix; (3) the severity of liver disease (as assessed by Child scoring); and (4) active alcohol abuse—alcoholic cirrhotics who continue to drink have an extremely high risk of bleeding.

► Clinical Findings

A. Symptoms and Signs

Patients with bleeding esophageal varices present with symptoms and signs of acute gastrointestinal hemorrhage. (See Acute Upper Gastrointestinal Bleeding, above.) In some cases, there may be preceding retching or dyspepsia attributable to alcoholic gastritis or withdrawal. Varices per se do not cause symptoms of dyspepsia, dysphagia, or retching. Variceal bleeding usually is severe, resulting in hypovolemia manifested by postural vital signs or shock. Twenty percent of patients with chronic liver disease in whom bleeding develops have a nonvariceal source of bleeding.

B. Laboratory Findings

These are identical to those listed above in the section on acute upper gastrointestinal tract bleeding.

► Initial Management

A. Acute Resuscitation

The initial management of patients with acute upper gastrointestinal bleeding is also discussed in the section on acute upper gastrointestinal bleeding (see above). Variceal hemorrhage is life-threatening; rapid assessment and resuscitation with fluids or blood products are essential. Overtransfusion should be avoided as it leads to increased central and portal venous pressures, increasing the risk of rebleeding. Many patients with bleeding esophageal varices have coagulopathy due to underlying cirrhosis; fresh frozen plasma (20 mL/kg loading dose, then 10 mg/kg every 6 hours) or platelets should be administered to patients with INRs > 1.8–2.0 or with platelet counts < 50,000/mcL in the presence of active bleeding. Patients with advanced liver disease are at high risk for poor outcome regardless of the bleeding source and should be transferred to an ICU.

B. Pharmacologic Therapy

1. Antibiotic prophylaxis—Cirrhotic patients admitted with upper gastrointestinal bleeding have a greater than 50% chance of developing a severe bacterial infection during hospitalization—such as bacterial peritonitis, pneumonia, or urinary tract infection. Most infections are caused by gram-negative organisms of gut origin. Prophylactic administration of antibiotics reduces the risk of

serious infection to 10–20% as well as hospital mortality. Antibiotic treatment with an oral poorly absorbed quinolone antibiotic (norfloxacin 400 mg twice daily) for 5–7 days has been recommended; however, a controlled trial found that patients who had decompensated cirrhosis with gastrointestinal bleeding had a significantly higher probability of developing infections when treated with norfloxacin 400 mg orally twice daily (26%) than those who were treated with ceftriaxone 1 g/d intravenously for 7 days (11%). Because of a rising incidence of infections caused by gram-positive organisms as well as fluoroquinolone-resistant organisms, intravenous third-generation cephalosporins may be preferred.

2. Vasoactive drugs—Somatostatin and octreotide infusions reduce portal pressures in ways that are poorly understood. Somatostatin (250 mcg/h)—not available in the United States—or octreotide (50 mcg intravenous bolus followed by 50 mcg/h) reduces splanchnic and hepatic blood flow and portal pressures in cirrhotic patients. Both agents appear to provide acute control of variceal bleeding in up to 80% of patients although neither has been shown to reduce mortality. Data about the absolute efficacy of both are conflicting, but they may be comparable in efficacy to endoscopic therapy. Combined treatment with octreotide or somatostatin infusion and endoscopic therapy (band ligation or sclerotherapy) is superior to either modality alone in controlling acute bleeding and early rebleeding, and it may improve survival. In patients with advanced liver disease and upper gastrointestinal hemorrhage, it is reasonable to initiate therapy with octreotide or somatostatin on admission and continue for 3–5 days. If bleeding is determined by endoscopy not to be secondary to portal hypertension, the infusion can be discontinued.

Terlipressin, 1–2 mg intravenous every 4 hours, (not available in the United States) is a synthetic vasopressin analog that causes a significant and sustained reduction in portal and variceal pressures while preserving renal perfusion. It is superior to placebo in the control of acute variceal hemorrhage and reduces mortality by 34%. Where available, terlipressin may be preferred to somatostatin or octreotide. Terlipressin is contraindicated in patients with significant coronary, cerebral, or peripheral vascular disease.

3. Vitamin K—In cirrhotic patients with an abnormal prothrombin time, vitamin K (10 mg) should be administered subcutaneously.

4. Lactulose—Encephalopathy may complicate an episode of gastrointestinal bleeding in patients with severe liver disease. In patients with encephalopathy, lactulose should be administered in a dosage of 30–45 mL/h orally until evacuation occurs, then reduced to 15–45 mL/h every 8–12 hours as needed to promote two or three bowel movements daily. (See Chapter 16.)

C. Emergent Endoscopy

Emergent endoscopy is performed after the patient's hemodynamic status has been appropriately stabilized (usually within 2–12 hours). In patients with active bleeding, endotracheal intubation is commonly performed to protect

against aspiration during endoscopy. An endoscopic examination is performed to exclude other or associated causes of upper gastrointestinal bleeding such as Mallory-Weiss tears, peptic ulcer disease, and portal hypertensive gastropathy. In many patients, variceal bleeding has stopped spontaneously by the time of endoscopy, and the diagnosis of variceal bleeding is made presumptively. Acute endoscopic treatment of the varices is performed with either banding or sclerotherapy. These techniques arrest active bleeding in 80–90% of patients and reduce the chance of in-hospital recurrent bleeding to about 20%.

If banding is chosen, repeat sessions are scheduled at intervals of 1–3 weeks until the varices are obliterated or reduced to a small size. Banding achieves lower rates of rebleeding, complications, and death than sclerotherapy and should be considered the endoscopic treatment of choice.

Sclerotherapy is still preferred by some endoscopists in the actively bleeding patient (in whom visualization for banding may be difficult). Sclerotherapy is performed by injecting the variceal trunks with a sclerosing agent (eg, ethanolamine, tetradecyl sulfate). Complications occur in 20–30% of patients and include chest pain, fever, bacteremia, esophageal ulceration, stricture, and perforation. After initial treatment, band ligation therapy should be performed.

D. Balloon Tube Tamponade

Mechanical tamponade with specially designed nasogastric tubes containing large gastric and esophageal balloons (Minnesota or Sengstaken-Blakemore tubes) provides initial control of active variceal hemorrhage in 60–90% of patients; rebleeding occurs in 50%. The gastric balloon is inflated first, followed by the esophageal balloon if bleeding continues. After balloon inflation, tension is applied to the tube to directly tamponade the varices. Complications of prolonged balloon inflation include esophageal and oral ulcerations, perforation, aspiration, and airway obstruction (due to a misplaced balloon). Endotracheal intubation is recommended before placement. Given its high rate of complications, mechanical tamponade is used as a temporizing measure only in patients with bleeding that cannot be controlled with pharmacologic or endoscopic techniques until more definitive decompressive therapy (eg, TIPS; see below) can be provided.

E. Portal Decompressive Procedures

In patients with variceal bleeding that cannot be controlled with pharmacologic or endoscopic therapy, emergency portal decompression may be considered.

1. Transvenous intrahepatic portosystemic shunts (TIPS)—Over a wire that is passed through a catheter inserted in the jugular vein, an expandable wire mesh stent (8–12 mm in diameter) is passed through the liver parenchyma, creating a portosystemic shunt from the portal vein to the hepatic vein. TIPS can control acute hemorrhage in over 90% of patients actively bleeding from gastric or esophageal varices. However, when TIPS is performed in the actively bleeding patient, the mortality approaches

40%, especially in patients requiring ventilatory support or blood pressure support and patients with renal insufficiency, bilirubin > 3.0 mg/dL, or encephalopathy. Therefore, TIPS should be considered in the 10–20% of patients with acute variceal bleeding that cannot be controlled with pharmacologic and endoscopic therapy, but it may not be warranted in patients with a poor prognosis.

2. Emergency portosystemic shunt surgery—Emergency portosystemic shunt surgery is associated with a 40–60% mortality rate. At centers where TIPS is available, that procedure has become the preferred means of providing emergency portal decompression.

► Prevention of Rebleeding

Once the initial bleeding episode has been controlled, therapy is warranted to reduce the high risk (60%) of rebleeding.

A. β -Blockers and Variceal Band Ligation

Long-term treatment with band ligation reduces the incidence of rebleeding to about 30%; the mortality rate may also be reduced. In most patients, two to six treatment sessions (performed at 7–14 day intervals) are needed to eradicate the varices.

Nonselective β -adrenergic blockers (propranolol, nadolol) reduce the risk of rebleeding from esophageal varices to about 40%. Some—but not all—studies demonstrate a lower incidence of rebleeding with band ligation than with β -adrenergic blockers. However, a combination of band ligation plus β -blockers is superior to either variceal band ligation or β -blockers alone. In randomized clinical trials, combination therapy markedly reduced the rate of recurrent bleeding (25%) compared with endoscopic therapy alone (37%). Therefore, combination therapy is recommended for patients without contraindications to β -blockers. Propranolol, 20–60 mg twice daily, long-acting propranolol, 60–80 mg once daily, or nadolol, 40 mg once daily may be used, with gradual increases in the dosage every 1–2 weeks until the heart rate falls by 25% or reaches 55 beats/min, provided the systolic blood pressure remains above 90 mm Hg and the patient has no side effects. The average dosage of long-acting propranolol is 120 mg once daily and for nadolol, 80 mg once daily. One-third of patients with cirrhosis are intolerant of β -blockers, experiencing fatigue or hypotension. Drug administration at bedtime may reduce the frequency and severity of side effects.

B. Transvenous Intrahepatic Portosystemic Shunt

TIPS has resulted in a significant reduction in recurrent bleeding compared with endoscopic sclerotherapy or band ligation—either alone or in combination with β -blocker therapy. At 1 year, rebleeding rates in patients treated with TIPS versus various endoscopic therapies average 20% and 40%, respectively. However, TIPS was also associated with a higher incidence of encephalopathy (35% versus 15%) and did not result in a decrease in mortality. Another

limitation of TIPS is that stenosis and thrombosis of the stents occur in the majority of patients over time with a consequent risk of rebleeding. Therefore, periodic monitoring with Doppler ultrasonography or hepatic venography is required. Stent patency usually can be maintained by balloon angioplasty or additional stent placement. Given these problems, TIPS should be reserved for patients who have recurrent (two or more) episodes of variceal bleeding that have failed endoscopic or pharmacologic therapies. TIPS is also useful in patients with recurrent bleeding from gastric varices or portal hypertensive gastropathy (for which endoscopic therapies cannot be used). TIPS is likewise considered in patients who are noncompliant with other therapies or who live in remote locations (without access to emergency care).

C. Surgical Portosystemic Shunts

Shunt surgery has a significantly lower rate of rebleeding compared with endoscopic therapy but also a higher incidence of encephalopathy. With the advent and widespread adoption of TIPS, surgical shunts are seldom performed.

D. Liver Transplantation

Candidacy for orthotopic liver transplantation should be assessed in all patients with chronic liver disease and bleeding due to portal hypertension. Transplant candidates should be treated with band ligation or TIPS to control bleeding pretransplant.

▶ Prevention of First Episodes of Variceal Bleeding

Because of the high mortality rate associated with variceal hemorrhage, prevention of the initial bleeding episode is desirable. Therefore, patients with cirrhosis should undergo diagnostic endoscopy or capsule endoscopy to determine whether varices are present as well as their size and whether they have red wale markings. Varices are present in 40% of patients with Child-Turcotte-Pugh class A cirrhosis and in 85% with Child-Turcotte-Pugh class C cirrhosis. Approximately 25% of patients have large varices (> 5 mm in size). Patients with varices have a higher risk of bleeding if they have Childs-Turcotte-Pugh class B or C cirrhosis or varices with red wale markings, or both. The risk of bleeding in patients with small varices (< 5 mm) is 5% per year and with large varices is 15–20% per year. Nonselective β -adrenergic blockers are recommended to reduce the risk of first variceal hemorrhage in patients with large varices and patients with small varices who either have variceal red wale marks or advanced cirrhosis (Child-Turcotte-Pugh class B or C). For patients with contraindications to or intolerance of β -blockers and for higher risk patients with large varices (Childs-Turcotte-Pugh class B or C or red wale markings), prophylactic treatment with band ligation should be considered. For patients with small varices (without red wale marks) and compensated (Child-Turcotte-Pugh class A) cirrhosis, no prophylaxis is necessary, but endoscopy should be

repeated in 1–2 years. In patients without varices on screening endoscopy, a repeat endoscopy is recommended in 3 years, since varices develop in 8% of patients per year.

▶ When to Refer

- All patients with upper gastrointestinal bleeding and suspected varices should be evaluated by a physician skilled in therapeutic endoscopy.
- Patients being considered for TIPS procedures or liver transplantation.

▶ When to Admit

All patients with acute upper gastrointestinal bleeding and suspected cirrhosis should be admitted to an ICU.

ESOPHAGEAL MOTILITY DISORDERS

1. Achalasia

ESSENTIALS OF DIAGNOSIS

- ▶ Gradual, progressive dysphagia for solids and liquids.
- ▶ Regurgitation of undigested food.
- ▶ Barium esophagogram with “bird’s beak” distal esophagus.
- ▶ Esophageal manometry confirms diagnosis.

▶ General Considerations

Achalasia is an idiopathic motility disorder characterized by loss of peristalsis in the distal two-thirds (smooth muscle) of the esophagus and impaired relaxation of the LES. There appears to be denervation of the esophagus resulting primarily from loss of nitric oxide-producing inhibitory neurons in the myenteric plexus. The cause of the neuronal degeneration is unknown.

► Clinical Findings

A. Symptoms and Signs

There is a steady increase in the incidence of achalasia with age; however, it can be seen in individuals as young as 25 years. Patients complain of the gradual onset of dysphagia for solid foods and, in the majority, of liquids also. Symptoms at presentation may have persisted for months to years. Substernal discomfort or fullness may be noted after eating. Many patients eat more slowly and adopt specific maneuvers such as lifting the neck or throwing the shoulders back to enhance esophageal emptying. Regurgitation of undigested food is common and may occur during meals or up to several hours later. Nocturnal regurgitation can provoke coughing or aspiration. Up to 50% of patients report substernal chest pain that is unrelated to meals or exercise and may last up to hours. Weight loss is common. Physical examination is unhelpful.

B. Imaging

Chest radiographs may show an air-fluid level in the enlarged, fluid-filled esophagus. Barium esophagography discloses characteristic findings, including esophageal dilation, loss of esophageal peristalsis, poor esophageal emptying, and a smooth, symmetric “bird’s beak” tapering of the distal esophagus. Without treatment, the esophagus may become markedly dilated (“sigmoid esophagus”).

C. Special Examinations

After esophagography, endoscopy is always performed to evaluate the distal esophagus and gastroesophageal junction to exclude a distal stricture or a submucosal infiltrating carcinoma. The diagnosis is confirmed by esophageal manometry. The typical manometric features are as follows: (1) Complete absence of peristalsis; swallowing results in simultaneous waves that are usually of low amplitude. (2) Incomplete lower esophageal sphincteric relaxation with swallowing. Whereas the normal sphincter relaxes by over 90%, relaxation with most swallows in patients with achalasia is less than 50%. In many patients, the baseline lower esophageal sphincteric pressure is quite elevated. (3) Intraesophageal pressures are greater than gastric pressures due to a fluid- and food-filled esophagus.

► Differential Diagnosis

Chagas disease is associated with esophageal dysfunction that is indistinguishable from idiopathic achalasia and should be considered in patients from endemic regions (Central and South America); it is becoming more common in the southern United States. Primary or metastatic tumors can invade the gastroesophageal junction, resulting in a picture resembling that of achalasia, called “pseudoachalasia.” Endoscopic ultrasonography and chest CT may be required to examine the distal esophagus in suspicious cases. Tumors such as small cell lung cancer can cause a paraneoplastic syndrome resembling achalasia due to secretion of antineuronal nuclear antibodies (ANNA-1 or Anti-Hu) that affect the myenteric plexus. Achalasia must

be distinguished from other motility disorders such as diffuse esophageal spasm and scleroderma esophagus with a peptic stricture.

► Treatment

A. Botulinum Toxin Injection

Endoscopically guided injection of botulinum toxin directly into the LES results in a marked reduction in LES pressure with initial improvement in symptoms in 65–85% of patients. However, symptom relapse occurs in over 50% of patients within 6–9 months and in all patients within 2 years. Three-fourths of initial responders who relapse have improvement with repeated injections. Because it is inferior to pneumatic dilation therapy and surgery in producing sustained symptomatic relief, this therapy is most appropriate for patients with comorbidities who are poor candidates for more invasive procedures. Botulinum injection may cause submucosal scarring that may make subsequent surgical myotomy more difficult.

B. Pneumatic Dilation

Between 75% and 85% of patients derive good to excellent relief of dysphagia after one to three sessions of pneumatic dilation of the LES. Approximately 15% of patients respond poorly to dilation and require surgical myotomy. Dilation is less effective in patients who are younger than age 50 or have spastic esophageal contractions (“vigorous achalasia”). Symptoms recur in up to 60% within 10 years but usually respond to repeated dilation. Perforations occur in less than 3% of dilations and may require operative repair. The success of laparoscopic myotomy is not compromised by prior pneumatic dilation.

C. Surgical Myotomy

A modified Heller cardiomyotomy of the LES and cardia results in good to excellent symptomatic improvement in over 85% of patients. Because gastroesophageal reflux develops in up to 20% of patients after myotomy, most surgeons also perform an antireflux procedure (fundoplication), and all patients are prescribed a once-daily proton pump inhibitor. Myotomy is now performed with a laparoscopic approach and is preferred to the open surgical approach. The low morbidity of laparoscopic surgery has led some experts to recommend it for initial treatment, especially for young patients. In experienced hands, however, the initial efficacies of pneumatic dilation and laparoscopic myotomy are nearly equivalent.

Ferulano GP et al. Short and long term results of the laparoscopic Heller-Dor myotomy. The influence of age and previous conservative therapies. *Surg Endosc.* 2007 Nov;21(11):2017–23. [PMID: 17705085]

Richter JE. A young man with new diagnosis of achalasia. *Clin Gastroenterol Hepatol.* 2008 Aug;6(8):859–63. [PMID: 18456570]

2. Other Primary Esophageal Motility Disorders

Abnormalities in esophageal motility may cause dysphagia or chest pain. Dysphagia for liquids as well as solids tends to be intermittent and nonprogressive. Periods of normal swallowing may alternate with periods of dysphagia, which usually is mild though bothersome—rarely severe enough to result in significant alterations in lifestyle or weight loss. Dysphagia may be provoked by stress, large boluses of food, or hot or cold liquids. Some patients may experience anterior chest pain that may be confused with angina pectoris but usually is nonexertional. The pain generally is unrelated to eating. (See Chest Pain of Undetermined Origin, below.)

The evaluation of suspected esophageal motility disorders includes barium esophagography, upper endoscopy, and, in some cases, esophageal manometry. Barium esophagography is useful to exclude mechanical obstruction and to evaluate esophageal motility. The presence of simultaneous contractions (spasm), disordered peristalsis, or failed peristalsis supports a diagnosis of esophageal dysmotility. Upper endoscopy also is performed to exclude a mechanical obstruction (as a cause of dysphagia) and to look for evidence of erosive reflux esophagitis (a common cause of chest pain) or eosinophilic esophagitis (confirmed by esophageal biopsy).

The further evaluation of noncardiac chest pain is discussed in a subsequent section. For patients with mild symptoms of dysphagia, therapy is directed at symptom reduction and reassurance. Patients should be instructed to eat more slowly and take smaller bites of food. In some cases, a warm liquid at the start of a meal may facilitate swallowing. Because unrecognized gastroesophageal reflux may cause dysphagia, a trial of a proton pump inhibitor (esomeprazole 40 mg, lansoprazole 30 mg) orally twice daily should be administered for 4–8 weeks. Manometry is not routinely used for mild to moderate symptoms because the findings seldom influence further medical management, but it may be useful in patients with persistent, disabling dysphagia to exclude achalasia and to look for other disorders of esophageal motility. These include spastic disorders (diffuse esophageal spasm, nutcracker esophagus, and hypertensive LES) and findings of ineffective esophageal peristalsis (failed or low-amplitude esophageal contractions).

Treatment of patients with severe dysphagia is empiric. Suspected spastic disorders may be treated with nitrates (isosorbide, 10–20 mg four times daily) or nitroglycerin (0.4 mg sublingually as needed) and calcium channel blockers (nifedipine 10 mg or diltiazem 60–90 mg, 30–45 minutes before meals) may be tried; their efficacy is unproved. Phosphodiesterase type 5 inhibitors (eg, sildenafil) promote smooth muscle relaxation and improve esophageal motility in small numbers of patients with spastic disorders but require further clinical study before they can be recommended. Injection of botulinum toxin into the lower esophagus may improve chest pain and dysphagia in some patients for a limited time. For unclear reasons, esophageal dilation provides symptomatic relief in

some cases. Debilitated patients with severe dysphagia and proven esophageal spasm may be treated with a long surgical myotomy.

Lacy BE et al. Esophageal motility disorders: medical Therapy. *J Clin Gastroenterol*. 2008 May–Jun;42(5):652–8. [PMID: 18364589]

CHEST PAIN OF UNDETERMINED ORIGIN

One-third of patients with chest pain undergo negative cardiac evaluation. Patients with recurrent noncardiac chest pain thus pose a difficult clinical problem. Because coronary artery disease is common and can present atypically, it must be excluded prior to evaluation for other causes.

Causes of noncardiac chest pain may include the following.

A. Chest Wall and Thoracic Spine Disease

These are easily diagnosed by history and physical examination.

B. Gastroesophageal Reflux

Up to 50% of patients have increased amounts of gastroesophageal acid reflux or a correlation between acid reflux episodes and chest pain demonstrated on esophageal pH testing. An empiric 4-week trial of acid-suppressive therapy with a high-dose proton pump inhibitor is recommended (eg, omeprazole or rabeprazole, 40 mg orally twice daily; lansoprazole, 30–60 mg orally twice daily; or esomeprazole or pantoprazole, 40 mg orally twice daily), especially in patients with reflux symptoms. In patients with persistent symptoms, ambulatory esophageal pH or impedance and pH study may be useful to exclude definitively a relationship between acid and nonacid reflux episodes and chest pain events.

C. Esophageal Dysmotility

Esophageal motility abnormalities such as diffuse esophageal spasm or nutcracker esophagus are uncommon causes of noncardiac chest pain. In patients with chest pain and dysphagia, a barium swallow radiograph should be obtained to look for evidence of achalasia or diffuse esophageal spasm. Esophageal manometry is not routinely performed because of low specificity and the unlikelihood of finding a clinically significant disorder, but it may be recommended in patients with frequent symptoms.

D. Heightened Visceral Sensitivity

Some patients with noncardiac chest pain report pain in response to a variety of minor noxious stimuli such as physiologically normal amounts of acid reflux, inflation of

balloons within the esophageal lumen, injection of intravenous edrophonium (a cholinergic stimulus), or intracardiac catheter manipulation. Low doses of antidepressants such as trazodone 50 mg or imipramine 50 mg reduce chest pain symptoms and are thought to reduce visceral afferent awareness.

E. Psychological Disorders

A significant number of patients have underlying depression, anxiety, and panic disorder. Patients reporting dyspnea, sweating, tachycardia, suffocation, or fear of dying should be evaluated for panic disorder.

Fass R et al. Noncardiac chest pain. *J Clin Gastroenterol.* 2008 May-Jun;42(5):636–46. [PMID: 18364579]

DISEASES OF THE STOMACH & DUODENUM

GASTRITIS & GASTROPATHY

The term “gastropathy” should be used to denote conditions in which there is epithelial or endothelial damage without inflammation, and “gastritis” should be used to denote conditions in which there is histologic evidence of inflammation. In clinical practice, the term “gastritis” is commonly applied to three categories: (1) erosive and hemorrhagic “gastritis” (gastropathy); (2) nonerosive, nonspecific (histologic) gastritis; and (3) specific types of gastritis, characterized by distinctive histologic and endoscopic features diagnostic of specific disorders.

1. Erosive & Hemorrhagic “Gastritis” (Gastropathy)

ESSENTIALS OF DIAGNOSIS

- ▶ Most commonly seen in alcoholics, critically ill patients, or patients taking NSAIDs.
- ▶ Often asymptomatic; may cause epigastric pain, nausea, and vomiting.
- ▶ May cause hematemesis; usually not significant bleeding.

▶ General Considerations

The most common causes of erosive gastropathy are drugs (especially NSAIDs), alcohol, stress due to severe medical or surgical illness, and portal hypertension (“portal gastropathy”). Uncommon causes include caustic ingestion and radiation. Erosive and hemorrhagic gastropathy typically are diagnosed at endoscopy, often being performed because of dyspepsia or upper gastrointestinal bleeding. Endoscopic findings include subepithelial hemorrhages, petechiae, and erosions. These lesions are superficial, vary in size and number, and may be focal or diffuse. There usually is no significant inflammation on histologic examination.

Major risk factors for stress gastritis include mechanical ventilation, coagulopathy, trauma, burns, shock, sepsis, central nervous system injury, liver failure, kidney disease, and multiorgan failure. The use of enteral nutrition reduces the risk of stress-related bleeding.

▶ Clinical Findings

A. Symptoms and Signs

Erosive gastropathy is usually asymptomatic. Symptoms, when they occur, include anorexia, epigastric pain, nausea, and vomiting. There is poor correlation between symptoms and the number or severity of endoscopic abnormalities. The most common clinical manifestation of erosive gastritis is upper gastrointestinal bleeding, which presents as hematemesis, “coffee grounds” emesis, or bloody aspirate in a patient receiving nasogastric suction, or as melena. Because erosive gastritis is superficial, hemodynamically significant bleeding is rare.

B. Laboratory Findings

The laboratory findings are nonspecific. The hematocrit is low if significant bleeding has occurred; iron deficiency may be found.

C. Special Examinations

Upper endoscopy is the most sensitive method of diagnosis. Although bleeding from gastritis is usually insignificant, it cannot be distinguished on clinical grounds from more serious lesions such as peptic ulcers or esophageal varices. Hence, endoscopy is generally performed within 24 hours in patients with upper gastrointestinal bleeding to identify the source. An upper gastrointestinal series is sometimes obtained in lieu of endoscopy in patients with hemodynamically insignificant upper gastrointestinal bleeds to exclude serious lesions but is insensitive for the detection of gastritis.

▶ Differential Diagnosis

Epigastric pain may be due to peptic ulcer, gastroesophageal reflux, gastric cancer, biliary tract disease, food poisoning, viral gastroenteritis, and functional dyspepsia. With severe pain, one should consider a perforated or penetrating ulcer, pancreatic disease, esophageal rupture, ruptured aortic aneurysm, gastric volvulus, and myocardial colic. Causes of upper gastrointestinal bleeding include peptic ulcer disease, esophageal varices, Mallory-Weiss tear, and arteriovenous malformations.

▶ Specific Causes & Treatment

A. Stress Gastritis

1. Prophylaxis—Stress-related mucosal erosions and subepithelial hemorrhages develop within 72 hours in the majority of critically ill patients. Clinically overt bleeding occurs in 6%, but clinically important bleeding in less than 3%. Bleeding is associated with a higher mortality rate but is seldom the cause of death.

In critically ill patients, pharmacologic prophylaxis with intravenous H₂-receptor antagonists, sucralfate, and an oral, rapid-release suspension of omeprazole plus sodium bicarbonate (Zegerid) has been shown to reduce the incidence of clinically overt and significant bleeding by 50%. At this time, the optimal, cost-effective regimen for the reduction of stress-related mucosal bleeding is uncertain. Prophylaxis should be routinely administered upon admission to critically ill patients with risk factors for significant bleeding. Two of the most important risk factors are coagulopathy (platelets < 50,000/mcL or INR greater than 1.5) and respiratory failure with the need for mechanical ventilation for over 48 hours. When these two risk factors are absent, the risk of significant bleeding is only 0.1%.

Although most critically ill patients have normal or decreased acid secretion, numerous studies have shown that maintaining intragastric pH > 4 reduces the incidence of clinically significant stress-related bleeding. Continuous infusions of H₂-receptor antagonists provide adequate control of intragastric pH in most patients in the following doses over 24 hours: cimetidine (900–1200 mg), ranitidine (150 mg), or famotidine (20 mg). After 4 hours of infusion, the pH should be checked by nasogastric aspirate and the dose doubled if the pH is under 4.0. For patients with nasoenteric tubes, immediate-release omeprazole (40 mg at 1 and 6 hours on day 1; then 40 mg once daily beginning on day 2) may be preferred to intravenous H₂-receptor antagonists because of lower cost, ease of administration, and comparable efficacy. Although intravenous proton pump inhibitors also are widely used for this indication, their efficacy and optimal dosing have not been established in controlled trials.

Sucralfate suspension (1 g orally every 4–6 hours) is effective also for the prevention of stress-related bleeding, and a reduction of nosocomial pneumonia had been observed compared with H₂-receptor antagonists. However, there is a higher incidence of clinically important upper gastrointestinal bleeding with sucralfate (4%) versus H₂-receptor antagonists (2%) with no difference in nosocomial pneumonia in more recent studies. In most ICUs, intravenous H₂-receptor antagonists or proton pump inhibitors are preferred because of their ease of administration.

2. Treatment—Once bleeding occurs, patients should receive continuous infusions of a proton pump inhibitor (esomeprazole or pantoprazole, 80 mg intravenous bolus, followed by 8 mg/h continuous infusion) as well as sucralfate suspension. Endoscopy should be performed in patients with clinically significant bleeding to look for treatable causes, especially stress-related peptic ulcers with active bleeding or visible vessels. When bleeding arises from diffuse gastritis, endoscopic hemostasis techniques are not helpful.

B. NSAID Gastritis

Of patients receiving NSAIDs in clinical trials, 25–50% have gastritis and 10–20% have ulcers at endoscopy; however, symptoms of significant dyspepsia develop in about 5%. In population surveys, the rate of dyspepsia is increased 1.5- to 2-fold with NSAID use. However, dys-

peptic symptoms correlate poorly with significant mucosal abnormalities or the development of adverse clinical events (ulcer bleeding or perforation). Given the frequency of dyspeptic symptoms in patients taking NSAIDs, it is neither feasible nor desirable to investigate all such cases. Patients with alarm symptoms or signs, such as severe pain, weight loss, vomiting, gastrointestinal bleeding, or anemia, should undergo diagnostic upper endoscopy. For other patients, symptoms may improve with discontinuation of the agent, reduction to the lowest effective dose, or administration with meals. Proton pump inhibitors have demonstrated efficacy in controlled trials for the treatment of NSAID-related dyspepsia. Although superiority to H₂-receptor antagonists for relief of NSAID-related dyspepsia has not been established, proton pump inhibitors have demonstrated superiority for healing of NSAID-related ulcers in the setting of continued NSAID use. Therefore, an empiric 2–4 week trial of an oral proton pump inhibitor (omeprazole, rabeprazole, or esomeprazole 20–40 mg/d; lansoprazole, 30 mg/d; pantoprazole, 40 mg/d) is recommended for patients with NSAID-related dyspepsia, especially those in whom continued NSAID treatment is required. If symptoms do not improve, diagnostic upper endoscopy should be conducted.

C. Alcoholic Gastritis

Excessive alcohol consumption may lead to dyspepsia, nausea, emesis, and minor hematemesis—a condition sometimes labeled “alcoholic gastritis.” However, it is not proven that alcohol alone actually causes significant erosive gastritis. Therapy with H₂-receptor antagonists, proton pump inhibitors, or sucralfate for 2–4 weeks often is empirically prescribed.

D. Portal Hypertensive Gastropathy

Portal hypertension commonly results in gastric mucosal and submucosal congestion of capillaries and venules, which is correlated with the severity of the portal hypertension and underlying liver disease. Usually asymptomatic, it may cause chronic gastrointestinal bleeding in 10% of patients and, less commonly, clinically significant bleeding with hematemesis. Treatment with propranolol or nadolol reduces the incidence of recurrent acute bleeding by lowering portal pressures. Patients who fail propranolol therapy may be successfully treated with portal decompressive procedures (see section on treatment of esophageal varices).

2. Nonerosive, Nonspecific Gastritis

The diagnosis of nonerosive gastritis is based on histologic assessment of mucosal biopsies. Endoscopic findings are normal in many cases and do not reliably predict the presence of histologic inflammation. The main types of nonerosive gastritis are those due to *H pylori* infection, those associated with pernicious anemia, and lymphocytic gastritis. (See Specific Types of Gastritis below.)

Helicobacter pylori Gastritis

H pylori is a spiral gram-negative rod that resides beneath the gastric mucous layer adjacent to gastric epithelial cells. Although not invasive, it causes gastric mucosal inflammation with PMNs and lymphocytes. The mechanisms of injury and inflammation may in part be related to the products of two genes, *vacA* and *cagA*.

In developed countries the prevalence of *H pylori* is rapidly declining. In the United States, the prevalence rises from less than 10% in non-immigrants under age 30 years to over 50% in those over age 60 years. The prevalence is higher in non-whites and immigrants from developing countries and is correlated inversely with socioeconomic status. Transmission is from person to person, mainly during infancy and childhood; however, the mode of transmission is unknown.

Acute infection with *H pylori* may cause a transient clinical illness characterized by nausea and abdominal pain that may last for several days and is associated with acute histologic gastritis with PMNs. After these symptoms resolve, the majority progress to chronic infection with chronic, diffuse mucosal inflammation (gastritis) characterized by PMNs and lymphocytes. Although chronic *H pylori* infection with gastritis is present in 30–50% of the population, most persons are asymptomatic and suffer no sequelae. Three gastritis phenotypes occur which determine clinical outcomes. Most infected people have a mild, diffuse gastritis that does not disrupt acid secretion and seldom causes clinically important outcomes. About 15% of infected people have inflammation that predominates in the gastric antrum but spares the gastric body (where acid is secreted). People with this phenotype tend to have increased gastrin; increased acid production; and increased risk of developing peptic ulcers, especially duodenal ulcers. About 1% of infected adults have inflammation that predominates in the gastric body. Over time, this may lead to destruction of acid-secreting glands with resultant mucosal atrophy, decreased acid secretion, and intestinal metaplasia. This phenotype is associated with an increased risk of gastric ulcers and gastric cancer. Chronic *H pylori* gastritis is associated with a 3.5- to 20-fold increased risk of gastric adenocarcinoma and low-grade B cell gastric lymphoma (mucosa-associated lymphoid tissue lymphoma; MALToma).

Eradication of *H pylori* may be achieved with antibiotics in over 85% of patients and leads to resolution of the chronic gastritis (see section on Peptic Ulcer Disease). Testing for *H pylori* is indicated for patients with either active or a past history of documented peptic ulcer disease or gastric MALToma and for patients with a family history of gastric carcinoma. Testing and empiric treatment is cost-effective in young patients (< 55 years of age) with uncomplicated

dyspepsia prior to further medical evaluation. The role of testing and treating *H pylori* in patients with functional dyspepsia remains controversial (see Dyspepsia, above). Some groups recommend population-based screening of all asymptomatic persons in regions in which there is a high prevalence of *H pylori* and gastric cancer (such as Japan, Korea, and China) to reduce the incidence of gastric cancer. Population-based screening of asymptomatic individuals is not recommended in western countries, in which the incidence of gastric cancer is low, but should be performed in immigrants from high-prevalence regions.

1. Noninvasive Testing for *H pylori*—Although serologic tests are easily obtained and widely available, most clinical guidelines no longer endorse their use for testing for *H pylori* infection because they are less accurate than other noninvasive tests that measure active infection. Laboratory-based quantitative serologic ELISA tests have an overall accuracy of only 80%. In comparison, the fecal antigen immunoassay and [¹³C] urea breath test have excellent sensitivity and specificity (> 95%) at a cost of less than \$60. Although more expensive and cumbersome to perform, these tests of active infection are more cost-effective in most clinical settings because they reduce unnecessary treatment for patients without active infection.

Recent proton pump inhibitors or antibiotics significantly reduce the sensitivity of urea breath tests and fecal antigen assays (but not serologic tests). Prior to testing, proton pump inhibitors should be discontinued 7–14 days and antibiotics for at least 28 days.

2. Endoscopic Testing for *H pylori*—Endoscopy is not indicated to diagnose *H pylori* infection in most circumstances. However, when it is performed for another reason, gastric biopsy specimens can be obtained for detection of *H pylori* and tested for active infection by urease production. This simple, inexpensive (\$10) test has excellent sensitivity and specificity (90%). In patients with active upper gastrointestinal bleeding or patients recently taking proton pump inhibitors or antibiotics, histologic assessment for *H pylori* is preferred. Histologic assessment of biopsies from the gastric antrum and body is more definitive but more expensive (\$150–\$250) than a rapid urease test. Histologic assessment is also indicated in patients with suspected MALTomas and, possibly, in patients with suspected infection whose rapid urease test is negative. However, serologic testing is the most cost-effective means of confirming *H pylori* infection in patients with a negative rapid urease test.

Pernicious Anemia Gastritis

Pernicious anemia gastritis is an autoimmune disorder involving the fundic glands with resultant achlorhydria and vitamin B₁₂ malabsorption. Of patients with B₁₂ deficiency, less than half have pernicious anemia. Most patients have malabsorption secondary to aging or chronic *H pylori* infection that results in atrophic gastritis, hypochlorhydria, and impaired release of B₁₂ from food. Fundic histology in pernicious anemia is characterized by severe gland atrophy and intestinal metaplasia caused by autoimmune destruction of the gastric fundic mucosa. Parietal cell antibodies directed against the H⁺-K⁺-ATPase pump are present in 90% of patients. Inflammation and autoimmune destruction of the acid-secreting parietal cells leads to secondary loss of fundic zymogen cells, which secrete intrinsic factor. Achlorhydria leads to pronounced hypergastrinemia (> 1000 pg/mL) due to loss of acid inhibition of gastrin G cells. Hypergastrinemia may induce hyperplasia of gastric enterochromaffin-like cells that may lead to the development of small, multicentric carcinoid tumors in 5% of patients. Metastatic spread is uncommon in lesions smaller than 2 cm. The risk of gastric adenocarcinoma is increased threefold, with a prevalence of 1–3%. Endoscopy with biopsy is indicated in patients with pernicious anemia at the time of diagnosis. Patients with dysplasia or small carcinoids require periodic endoscopic surveillance. Pernicious anemia is discussed in detail in Chapter 13.

Malizia RW et al. Ambulatory dysfunction due to unrecognized pernicious anemia. *J Emerg Med.* 2007 Nov 30; [Epub ahead of print]. [PMID: 18061389]

3. Specific Types of Gastritis

A number of disorders are associated with specific mucosal histologic features.

Infections

Acute bacterial infection of the gastric submucosa and muscularis with a variety of aerobic or anaerobic organisms produces a rare, rapidly progressive, life-threatening condition known as phlegmonous or necrotizing gastritis, which requires broad-spectrum antibiotic therapy and, in many cases, emergency gastric resection. Viral infection with CMV is commonly seen in patients with AIDS and after bone marrow or solid organ transplantation. Endoscopic findings include thickened gastric folds and ulcerations. Fungal infection with mucormycosis and *Candida* may occur in immunocompromised and diabetic patients. Larvae of *Anisakis marina* ingested in raw fish or sushi may become embedded in the gastric mucosa, producing severe abdominal pain. Pain persists for several days until the larvae die. Endoscopic removal of the larvae provides rapid symptomatic relief.

Ugenti I et al. Acute gastric anisakiasis: an Italian experience. *Minerva Chir.* 2007 Feb;62(1):51–60. [PMID: 17287696]

Eosinophilic Gastritis

This is a rare disorder in which eosinophils infiltrate the antrum and sometimes the proximal intestine. Infiltration may involve the mucosa, muscularis, or serosa. Peripheral eosinophilia is prominent. Symptoms include anemia from mucosal blood loss, abdominal pain, early satiety, and postprandial vomiting. Treatment with corticosteroids is beneficial in the majority of patients.

Ménétrier Disease (Hypertrophic Gastropathy)

This is an idiopathic entity characterized by giant thickened gastric folds involving predominantly the body of the stomach. Patients complain of nausea, epigastric pain, weight loss, and diarrhea. Because of chronic protein loss, patients may develop severe hypoproteinemia and anasarca. The cause is unknown. There are case reports of resolution of symptoms and improvement in histologic appearance after *H pylori* eradication. Dramatic improvement has been reported in a small number of patients with cetuximab, an antibody that binds epidermal growth factor receptor (EGFR). Gastric resection is required in severe cases.

Coffey RJ et al. Ménétrier disease and gastrointestinal stromal tumors: hyperproliferative disorders of the stomach. *J Clin Invest.* 2007 Jan;117(1):70–80. [PMID: 17200708]

PEPTIC ULCER DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ History of dyspepsia present in 80–90% of patients with variable relationship to meals.
- ▶ Ulcer symptoms characterized by rhythmicity and periodicity.
- ▶ Ten to 20 percent of patients present with ulcer complications without antecedent symptoms.
- ▶ Most NSAID-induced ulcers are asymptomatic.
- ▶ Upper endoscopy with gastric biopsy for *H pylori* is the diagnostic procedure of choice in most patients.
- ▶ Gastric ulcer biopsy or documentation of complete healing necessary to exclude gastric malignancy.

▶ General Considerations

Peptic ulcer is a break in the gastric or duodenal mucosa that arises when the normal mucosal defensive factors are impaired or are overwhelmed by aggressive luminal factors such as acid and pepsin. By definition, ulcers extend through the muscularis mucosae and are usually over 5 mm in diameter. In the United States, there are about 500,000 new cases per year of peptic ulcer and 4 million ulcer recurrences; the lifetime prevalence of ulcers in the adult population is approximately 10%. Ulcers occur five times more commonly in the duodenum, where over 95% are in the bulb or pyloric channel. In the stomach, benign

ulcers are located most commonly in the antrum (60%) and at the junction of the antrum and body on the lesser curvature (25%).

Ulcers occur slightly more commonly in men than in women (1.3:1). Although ulcers can occur in any age group, duodenal ulcers most commonly occur in patients between the ages of 30 and 55 years, whereas gastric ulcers are more common in patients between the ages of 55 and 70 years. Ulcers are more common in smokers and in patients taking NSAIDs on a long-term basis (see below). Alcohol, dietary factors, and stress do not appear to cause ulcer disease. The incidence of duodenal ulcer disease has been declining dramatically for the past 30 years, but the incidence of gastric ulcers appears to be increasing as a result of the widespread use of NSAIDs and low-dose aspirin.

► Etiology

There are three major causes of peptic ulcer disease: NSAIDs, chronic *H pylori* infection, and acid hypersecretory states such as Zollinger-Ellison syndrome. Evidence of *H pylori* infection or NSAID ingestion should be sought in all patients with peptic ulcer. NSAID- and *H pylori*-associated ulcers will be considered in the present section; Zollinger-Ellison syndrome will be discussed subsequently. Uncommon causes of ulcer disease include CMV (especially in transplant recipients), systemic mastocytosis, Crohn disease, lymphoma, and medications (eg, alendronate). Up to 10% of ulcers are idiopathic.

A. *H pylori*-Associated Ulcers

H pylori appears to be a necessary cofactor for the majority of duodenal and gastric ulcers not associated with NSAIDs. Overall, it is estimated that one in six infected patients will develop ulcer disease. The prevalence of *H pylori* infection in duodenal ulcer patients is 75–90%. Most *H pylori*-infected duodenal ulcer patients have infection predominantly in the gastric antrum, which is associated with increased gastric acid secretion. It is hypothesized that increased acid exposure can give rise to small islands of gastric metaplasia in the duodenal bulb. Colonization of these islands by *H pylori* may lead to duodenitis or duodenal ulcer. The association with gastric ulcers is lower, but *H pylori* is found in the majority of patients in whom NSAIDs cannot be implicated. *H pylori*-associated gastric ulcers tend to form at the junction of the gastric body and antrum—the site of transition from oxyntic to pyloric epithelium. Most *H pylori*-infected gastric ulcer patients have infection that predominates in the gastric body and is associated with decreased acid secretion. It is hypothesized that chronic inflammation overwhelms the gastric mucosal defense mechanisms.

The natural history of *H pylori*-associated peptic ulcer disease is well defined. In the absence of specific antibiotic treatment to eradicate the organism, 85% of patients will have an endoscopically visible recurrence within 1 year. Half of these will be symptomatic. After successful eradication of *H pylori* with antibiotics, ulcer recurrence rates are reduced dramatically to 5–20% at 1 year. Some of these ulcer recurrences may be due to NSAID use or reinfection with *H pylori*.

B. NSAID-Induced Ulcers

There is a 10–20% prevalence of gastric ulcers and a 2–5% prevalence of duodenal ulcers in long-term NSAID users. Approximately 2–5%/year of long-term NSAID users will have an ulcer that causes clinically significant dyspepsia or a serious complication. The incidence of serious gastrointestinal complications (hospitalization, bleeding, perforation) is 0.2–1.9%/year. The risk of NSAID complications is greater within the first 3 months of therapy and in patients who are older than 60 years; who have a prior history of ulcer disease; or who take NSAIDs in combination with aspirin, corticosteroids, or anticoagulants.

Traditional nonselective NSAIDs (nsNSAIDs) inhibit prostaglandins through reversible inhibition of both cyclooxygenase (COX)-1 and COX-2 enzymes. Aspirin causes irreversible inhibition of COX-1 and COX-2 as well as of platelet aggregation. Coxibs (or selective NSAIDs) preferentially inhibit COX-2—the principal enzyme involved in prostaglandin production at sites of inflammation—while providing relative sparing of COX-1, the principal enzyme involved with mucosal cytoprotection in the stomach and duodenum. Celecoxib is the only coxib currently available in the United States, although other older NSAIDs (etodolac, meloxicam) may have similar COX-2/COX-1 selectivity.

Coxibs decrease the incidence of endoscopically visible ulcers by approximately 75% compared with nsNSAIDs. Of greater clinical importance, the risk of significant clinical events (obstruction, perforation, bleeding) is reduced by up to 50% in patients taking coxibs versus nsNSAIDs. However, a twofold increase in the incidence in cardiovascular complications (myocardial infarction, cerebrovascular infarction, and death) has been detected in patients taking coxibs compared with placebo, prompting the voluntary withdrawal of two coxibs (rofecoxib and valdecoxib) from the market by the manufacturers. It is hypothesized that selective inhibition of COX-2 leads to decreased vascular prostacyclin, reduced arterial vasodilation, hypertension, enhanced atherogenesis, and enhanced platelet adhesion. In two large, prospective, randomized controlled trials testing the efficacy of coxibs on polyp prevention, celecoxib was associated with a 1.3- to 3.4-fold increased risk of cardiovascular complications versus placebo; the risk was greatest in patients taking higher doses of celecoxib. A review by an FDA panel suggested that all NSAIDs (other than aspirin and, possibly, naproxen) may be associated with an increased risk of cardiovascular complications, but concluded that celecoxib, which has less COX-2 selectivity than rofecoxib and valdecoxib, does not have higher risk than other nsNSAIDs when used in currently recommended doses (200 mg/day).

Use of even low-dose aspirin (81–325 mg/d) leads to a twofold increased risk of gastrointestinal bleeding complications. In randomized controlled trials, the absolute annual increase of gastrointestinal bleeding attributable to low-dose aspirin is only 0.12% higher than with placebo therapy. However, in population studies, gastrointestinal bleeding occurs in 1.2% of patients each year. Patients with a prior history of peptic ulcers or gastrointestinal bleeding have a markedly increased risk of complications on low-

dose aspirin. It should be noted that low-dose aspirin in combination with NSAIDs or coxibs increases the risk of ulcer complications by up to 10-fold compared with NSAIDs or low-dose aspirin alone.

H pylori infection increases the risk of ulcer disease and complications over 3-fold in patients taking NSAIDs or low-dose aspirin. It is hypothesized that NSAID initiation may potentiate or aggravate ulcer disease in susceptible infected individuals.

► Clinical Findings

A. Symptoms and Signs

Epigastric pain (dyspepsia), the hallmark of peptic ulcer disease, is present in 80–90% of patients. However, this complaint is not sensitive or specific enough to serve as a reliable diagnostic criterion for peptic ulcer disease. The clinical history cannot accurately distinguish duodenal from gastric ulcers. Less than 25% of patients with dyspepsia have ulcer disease at endoscopy. Twenty percent of patients with ulcer complications such as bleeding have no antecedent symptoms (“silent ulcers”). Nearly 60% of patients with NSAID-related ulcer complications do not have prior symptoms.

Pain is typically well localized to the epigastrium and not severe. It is described as gnawing, dull, aching, or “hunger-like.” Approximately 50% of patients report relief of pain with food or antacids (especially duodenal ulcers) and a recurrence of pain 2–4 hours later. However, many patients deny any relationship to meals or report worsening of pain. Two-thirds of duodenal ulcers and one-third of gastric ulcers cause nocturnal pain that awakens the patient. A change from a patient’s typical rhythmic discomfort to constant or radiating pain may reflect ulcer penetration or perforation. Most patients have symptomatic periods lasting up to several weeks with intervals of months to years in which they are pain free (periodicity).

Nausea and anorexia may occur with gastric ulcers. Significant vomiting and weight loss are unusual with uncomplicated ulcer disease and suggest gastric outlet obstruction or gastric malignancy.

The physical examination is often normal in uncomplicated peptic ulcer disease. Mild, localized epigastric tenderness to deep palpation may be present. FOBT or FIT is positive in one-third of patients.

B. Laboratory Findings

Laboratory tests are normal in uncomplicated peptic ulcer disease but are ordered to exclude ulcer complications or confounding disease entities. Anemia may occur with acute blood loss from a bleeding ulcer or less commonly from chronic blood loss. Leukocytosis suggests ulcer penetration or perforation. An elevated serum amylase in a patient with severe epigastric pain suggests ulcer penetration into the pancreas. A fasting serum gastrin level to screen for Zollinger-Ellison syndrome is obtained in some patients (see below).

C. Endoscopy

Upper endoscopy is the procedure of choice for the diagnosis of duodenal and gastric ulcers. Duodenal ulcers are virtually

never malignant and do not require biopsy. Three to 5 percent of benign-appearing gastric ulcers prove to be malignant. Hence, biopsies of the ulcer margin are almost always performed. Provided that the gastric ulcer appears benign to the endoscopist and adequate biopsy specimens reveal no evidence of cancer, dysplasia, or atypia, the patient may be monitored without further endoscopy. If these conditions are not fulfilled, follow-up endoscopy should be performed 12 weeks after the start of therapy to document complete healing; nonhealing ulcers are suspicious for malignancy.

D. Imaging

Because barium upper gastrointestinal series is less sensitive for detection of ulcers and less accurate for distinguishing benign from malignant ulcers, it has been supplanted by upper endoscopy in most settings. Abdominal CT imaging is obtained in patients with suspected complications of peptic ulcer disease (perforation, penetration, or obstruction).

E. Testing for *H pylori*

In patients in whom an ulcer is diagnosed by endoscopy, gastric mucosal biopsies should be obtained both for a rapid urease test and for histologic examination. The specimens for histology are discarded if the urease test is positive.

In patients with a history of peptic ulcer or when an ulcer is diagnosed by upper gastrointestinal series, noninvasive assessment for *H pylori* with fecal antigen assay or urea breath testing should be done. Proton pump inhibitors may cause false-negative urea breath tests and fecal antigen tests and should be withheld for at least 7 days before testing. Because of its lower sensitivity and specificity, serologic testing should not be performed unless fecal antigen testing or urea breath testing is unavailable.

► Differential Diagnosis

Peptic ulcer disease must be distinguished from other causes of epigastric distress (dyspepsia). Over 50% of patients with dyspepsia have no obvious organic explanation for their symptoms and are classified as having functional dyspepsia (see sections above on Dyspepsia and Functional Dyspepsia). Atypical gastroesophageal reflux may be manifested by epigastric symptoms. Biliary tract disease is characterized by discrete, intermittent episodes of pain that should not be confused with other causes of dyspepsia. Severe epigastric pain is atypical for peptic ulcer disease unless complicated by a perforation or penetration. Other causes include acute pancreatitis, acute cholecystitis or choledocholithiasis, esophageal rupture, gastric volvulus, and ruptured aortic aneurysm.

► Pharmacologic Agents

The pharmacology of several agents that enhance the healing of peptic ulcers is briefly discussed here. They may be divided into three categories: (1) acid-antisecretory agents, (2) mucosal protective agents, and (3) agents that promote healing through eradication of *H pylori*. Recommendations for their use are provided in subsequent sections.

A. Acid-Antisecretory Agents

1. Proton pump inhibitors—Proton pump inhibitors covalently bind the acid-secreting enzyme $H^+-K^+-ATPase$, or “proton pump,” permanently inactivating it. Restoration of acid secretion requires synthesis of new pumps, which have a half-life of 18 hours. Thus, although these agents have a serum half-life of less than 60 minutes, their duration of action exceeds 24 hours. The available oral agents—omeprazole or rabeprazole 20 mg, lansoprazole 30 mg, esomeprazole or pantoprazole 40 mg—suppress over 90% of 24-hour acid secretion, compared with under 65% for H_2 -receptor antagonists in standard dosages. Proton pump inhibitors should be administered 30 minutes before meals (usually breakfast).

Each of the proton pump inhibitors results in over 90% healing of duodenal ulcers after 4 weeks and 90% of gastric ulcers after 8 weeks when given once daily. Compared with H_2 -receptor antagonists, proton pump inhibitors provide faster pain relief and more rapid ulcer healing. However, nearly equivalent overall healing rates may be achieved with longer courses of H_2 -receptor antagonists.

The proton pump inhibitors are remarkably safe in short- and long-term therapy. Serum gastrin levels rise significantly (> 500 pg/mL) in 3% of patients receiving long-term therapy. Clinical experience with these agents for over 15 years has not detected any significant toxicity in humans. Long-term use may lead to mild decreases in vitamin B_{12} , iron, and calcium absorption of unclear significance. Observational studies suggest a twofold increased risk of enteric infections including *C difficile* and bacterial gastroenteritis. A case-control study reported a 1.4-fold higher risk of hip fracture among patients taking long-term proton pump inhibitors.

2. H_2 -receptor antagonists—Although H_2 -receptor antagonists are effective in the treatment of peptic ulcer disease, proton pump inhibitors are now the preferred agents because of their ease of use and superior efficacy. Four H_2 -receptor antagonists are available: cimetidine, ranitidine, famotidine, and nizatidine. All four agents effectively inhibit nocturnal acid output, but they are less effective at inhibiting meal-stimulated acid secretion. For uncomplicated peptic ulcers, H_2 -receptor antagonists may be administered once daily at bedtime as follows: ranitidine and nizatidine 300 mg, famotidine 40 mg, and cimetidine 800 mg. Duodenal and gastric ulcer healing rates of 85–90% are obtained within 6 weeks and 8 weeks, respectively. All four agents are well tolerated, and serious adverse effects are rare. Cimetidine is rarely used because it inhibits hepatic cytochrome P450 metabolism (raising the serum concentration of theophylline, warfarin, lidocaine, and phenytoin) and may cause gynecomastia or impotence.

B. Agents Enhancing Mucosal Defenses

Bismuth, misoprostol, and antacids all have been shown to promote ulcer healing through the enhancement of mucosal defensive mechanisms. Given the greater efficacy and safety of antisecretory agents and better compliance of patients, these other agents are no longer used as first-line therapy for

active ulcers in most clinical settings. Because of the rapid relief of ulcer symptoms they provide, antacids are commonly used as needed to supplement antisecretory agents during the first few days of treatment. Bismuth has direct antibacterial action against *H pylori* and may be used in combination with antibiotics for eradication (see below). Misoprostol is a prostaglandin analog that stimulates gastroduodenal mucus and bicarbonate secretion. It is effective as a prophylactic agent in reducing the incidence of gastroduodenal ulcers in patients taking nsNSAIDs but must be given four times daily and causes diarrhea in 10–20% of patients.

C. *H pylori* Eradication Therapy

Eradication of *H pylori* has proved difficult. Combination regimens that use two antibiotics with a proton pump inhibitor or bismuth are required to achieve adequate rates of eradication and to reduce the number of failures due to antibiotic resistance. In the United States, up to 50% of strains are resistant to metronidazole and 13% are resistant to clarithromycin. It is advisable to include amoxicillin in first-line therapy in most patients, reserving metronidazole for penicillin-allergic patients. Recommended regimens are listed in Table 15–10. All currently recommended regimens achieve rates of eradication greater than 80% after 10–14 days of treatment. In most centers in the United States, the preferred regimen is with a 14-day course of treatment with an oral proton pump inhibitor—omeprazole or rabeprazole 20 mg twice daily, lansoprazole 30 mg twice daily, pantoprazole 40 mg twice daily, or esomeprazole 40 mg once daily—plus amoxicillin 1 g twice daily and clarithromycin 500 mg twice daily. In patients who are allergic to penicillin, who have previously been treated with a macrolide antibiotic, or whose infection persists after an initial course of antibiotic therapy, the optimal regimen may be quadruple therapy with a proton pump inhibitor, bismuth subsalicylate, tetracycline, and metronidazole for 14 days (Table 15–10). Several international studies report eradication rates of $> 90\%$ using a novel 10-day sequential regimen consisting of a proton pump inhibitor and amoxicillin for 5 days, followed by a proton pump inhibitor, clarithromycin, and tinidazole for 5 days; however, corroboration by studies in North America are needed before this can be accepted as first-line therapy.

▶ Medical Treatment

Patients should be encouraged to eat balanced meals at regular intervals. There is no justification for bland or restrictive diets. Moderate alcohol intake is not harmful. Smoking retards the rate of ulcer healing and increases the frequency of recurrences and should be discouraged.

A. Treatment of *H pylori*-Associated Ulcers

1. Treatment of active ulcer—The goals of treatment of active *H pylori*-associated ulcers are to relieve dyspeptic symptoms, to promote ulcer healing, and to eradicate *H pylori* infection. Uncomplicated *H pylori*-associated ulcers should be treated for 10–14 days with one of the proton

Table 15–10. Treatment options for peptic ulcer disease.**Active *Helicobacter pylori*-associated ulcer**

1. Treat with anti-*H pylori* regimen for 10–14 days. Treatment options:

- Proton pump inhibitor orally twice daily¹
Clarithromycin 500 mg orally twice daily²
Amoxicillin 1 g orally twice daily (OR metronidazole 500 mg orally twice daily, if penicillin allergic³)
- Proton pump inhibitor orally twice daily^{1,4}
Bismuth subsalicylate two tablets orally four times daily
Tetracycline 500 mg orally four times daily
Metronidazole 250 mg orally four times daily
(OR bismuth subcitrate potassium 140 mg/metronidazole 125 mg/tetracycline 125 mg [Pylera] three capsules orally four times daily)⁵
- Proton pump inhibitor orally twice daily^{1,6}
Days 1–5: amoxicillin 1 g orally twice daily
Days 6–10: clarithromycin 500 mg and metronidazole 500 mg, both orally twice daily

2. After completion of course of *H pylori* eradication therapy, continue treatment with proton pump inhibitor¹ once daily for 4–6 weeks if ulcer is large (> 1 cm) or complicated.

3. Confirm successful eradication of *H pylori* with urea breath test, fecal antigen test, or endoscopy with biopsy at least 4 weeks after completion of antibiotic treatment and 1–2 weeks after proton pump inhibitor treatment.

Active ulcer not attributable to *H pylori*

1. Consider other causes: NSAIDs, Zollinger-Ellison syndrome, gastric malignancy. Treatment options:

- Proton pump inhibitors¹:
Uncomplicated duodenal ulcer: treat for 4 weeks
Uncomplicated gastric ulcer: treat for 8 weeks
- H₂-receptor antagonists:
Uncomplicated duodenal ulcer: cimetidine 800 mg, ranitidine or nizatidine 300 mg, famotidine 40 mg, orally once daily at bedtime for 6 weeks
Uncomplicated gastric ulcer: cimetidine 400 mg, ranitidine or nizatidine 150 mg, famotidine 20 mg, orally twice daily for 8 weeks
Complicated ulcers: proton pump inhibitors are the preferred drugs

Prevention of ulcer relapse

1. NSAID-induced ulcer: prophylactic therapy for high-risk patients (prior ulcer disease or ulcer complications, use of corticosteroids or anticoagulants, age > 60 years, serious comorbid illnesses).

Treatment options:

- Proton pump inhibitor once daily¹
- COX-2 selective NSAID (celecoxib) (contraindicated in patients with increased risk of cardiovascular disease)
- Misoprostol 200 mcg orally 4 times daily

2. Long-term “maintenance” therapy indicated in patients with recurrent ulcers who either are *H pylori*-negative or who have failed attempts at eradication therapy: once-daily oral proton pump inhibitor¹ or oral H₂-receptor antagonist at bedtime (cimetidine 400–800 mg, nizatidine or ranitidine 150–300 mg, famotidine 20–40 mg)

¹Oral proton pump inhibitors: omeprazole 20 mg, rabeprazole 20 mg, lansoprazole 30 mg, pantoprazole 40 mg, esomeprazole 40 mg. Proton pump inhibitors are administered before meals. Esomeprazole may be given as 40 mg orally once daily.

²If patient has previously been treated with macrolide antibiotic, choose another regimen.

³Avoid in areas of known high metronidazole resistance or in patients who have failed a course of treatment that included metronidazole.

⁴Preferred regimen in patients who have previously received a macrolide antibiotic or are penicillin allergic. Effective against metronidazole-resistant organisms.

⁵Pylera is an FDA-approved formulation containing: bismuth subcitrate 140 mg/tetracycline 125 mg/metronidazole 125 mg per capsule.

⁶Regimen requires validation in US studies. Appears effective against clarithromycin-resistant organisms.

COX-2, cyclooxygenase-2; NSAIDs, nonsteroidal anti-inflammatory drugs.

pump inhibitor-based *H pylori* eradication regimens listed in Table 15–10. At that point, no further antisecretory therapy is needed, provided the ulcer was small (< 1 cm) and dyspeptic symptoms have resolved. For patients with large or complicated ulcers, an antisecretory agent should be continued for an additional 2–4 weeks (duodenal ulcer) or 4–6 weeks (gastric ulcer) after completion of the antibiotic

regimen to ensure complete ulcer healing. A once-daily oral proton pump inhibitor (omeprazole or rabeprazole 20 mg, lansoprazole 30 mg, pantoprazole or esomeprazole 40 mg) is recommended. Confirmation of *H pylori* eradication is recommended for all patients > 4 weeks after completion of therapy either with noninvasive tests (urea breath test, fecal antigen test) or endoscopy with biopsy for histology.

2. Therapy to prevent recurrence—Successful eradication reduces ulcer recurrences to less than 20% after 1–2 years. The most common cause of recurrence after antibiotic therapy is failure to achieve successful eradication. Once cure has been achieved, reinfection rates are less than 0.5% per year. Although *H pylori* eradication has reduced the need for long-term maintenance antisecretory therapy to prevent ulcer recurrences, there remains a subset of patients who require long-term therapy with either a proton pump inhibitor once daily or an H₂-receptor antagonist at bedtime. This subset includes patients with *H pylori*-positive ulcers who have not responded to repeated attempts at eradication therapy, patients with a history of *H pylori*-positive ulcers who have recurrent ulcers despite successful eradication, and patients with idiopathic ulcers (ie, *H pylori*-negative and not taking NSAIDs). In all patients with recurrent ulcers, NSAID usage (unintentional or surreptitious) and hypersecretory states (including gastrinoma) should be excluded.

B. Treatment of NSAID-Associated Ulcers

1. Treatment of active ulcers—In patients with NSAID-induced ulcers, the offending agent should be discontinued whenever possible. Both gastric and duodenal ulcers respond rapidly to therapy with H₂-receptor antagonists or proton pump inhibitors (Table 15–10) once NSAIDs are eliminated. In some patients with severe inflammatory diseases, it may not be feasible to discontinue NSAIDs. These patients should be treated with proton pump inhibitors once daily, which results in ulcer healing rates of approximately 80% at 8 weeks in patients continuing to take NSAIDs. All patients with NSAID-associated ulcers should undergo testing for *H pylori* infection. Antibiotic eradication therapy should be given if *H pylori* tests are positive.

2. Prevention of NSAID-induced ulcers—Clinicians should carefully weigh the benefits of NSAID therapy with the risks of cardiovascular and gastrointestinal complications. For all patients, NSAIDs should be prescribed at the lowest effective dose and for the shortest period possible. Both COX-2 selective NSAIDs (“coxibs”) and nonselective NSAIDs (nsNSAIDs) with the possible exception of naproxen increase the risk of cardiovascular complications. Ulcer complications occur in up to 2% of all nsNSAID-treated patients per year but in up to 10–20% per year of patients with multiple risk factors. These include age over 60 years, history of ulcer disease or complications, concurrent use of antiplatelet therapy (low-dose aspirin or clopidogrel, or both), concurrent therapy with anticoagulants or corticosteroids, and serious underlying medical illness. After considering the patient’s risk of cardiovascular and gastrointestinal complications due to NSAID use, the clinician can decide what type of NSAID (nsNSAID vs coxib) is appropriate and what strategies should be used to reduce the risk of such complications.

A. TEST FOR AND TREAT *H PYLORI* INFECTION—All patients with a known history of peptic ulcer disease who are treated with NSAIDs or antiplatelet agents (aspirin, clopidogrel) should be tested for *H pylori* infection and treated, if

positive. Although *H pylori* eradication may decrease the risk of NSAID-related complications, cotherapy with a proton pump inhibitor or misoprostol therapy is still required in high-risk patients.

B. PROTON PUMP INHIBITOR—Treatment with an oral proton pump inhibitor given once daily (omeprazole or rabeprazole 20 mg, lansoprazole 30 mg, or pantoprazole or esomeprazole 20–40 mg) is effective in the prevention of NSAID-induced gastric and duodenal ulcers and is approved by the FDA for this indication. Among high-risk patients taking nsNSAIDs or coxibs, the incidence of endoscopically visible gastric and duodenal ulcers after 6 months of therapy in patients treated with esomeprazole 20–40 mg/d was 5%, compared with 17% who were given placebo. Nonetheless, proton pump inhibitors are not fully protective in high-risk patients in preventing NSAID-related complications. In prospective, controlled trials of patients with a prior history of NSAID-related ulcer complications, the incidence of recurrent bleeding was almost 5% after 6 months in patients taking nsNSAIDs and a proton pump inhibitor. In prospective, controlled trials of patients with a prior history of ulcer complications related to low-dose aspirin, the incidence of recurrent ulcer bleeding in patients taking low-dose aspirin alone is approximately 15% per year, compared with 0–2% per year in patients taking low-dose aspirin and proton pump inhibitor and 9–14% per year in patients taking clopidogrel. Thus, proton pump inhibitors are highly effective in preventing complications related to low-dose aspirin, even in high-risk patients.

C. MISOPROSTOL—The prostaglandin analog misoprostol reduces the incidence of NSAID-induced gastric and duodenal ulcers by 50–75% when given at a dosage of 100–200 mcg four times daily. In a large, prospective study, misoprostol reduced the incidence of NSAID-associated complications by 40% compared with placebo. However, misoprostol is less commonly used as a prophylactic agent against NSAID-induced complications than either concurrent therapy with a proton pump inhibitor or COX-2 selective agent because of its high side-effect profile and the need for dosing four times daily.

3. Recommendations for use of nsNSAIDs and coxibs—For patients with a low-risk of cardiovascular disease who have no risk factors for gastrointestinal complications, an nsNSAID alone may be given. For patients with 1–2 gastrointestinal risk factors, a coxib alone or an nsNSAID should be given with a proton pump inhibitor once daily (omeprazole or rabeprazole 20 mg, lansoprazole 30 mg, or pantoprazole or esomeprazole 20–40 mg) or misoprostol to reduce the risk of gastrointestinal complications. NSAIDs should be avoided if possible in patients with multiple risk factors. If required, combination therapy with a coxib or one of the “safer” nsNSAIDs (etodolac, meloxicam) and a proton pump inhibitor once daily is recommended.

For patients with an increased risk of cardiovascular complications, it is preferable to avoid NSAIDs, if possible. If an NSAID is required, naproxen is preferred because it appears to have reduced risk of cardiovascular complica-

tions compared with other nsNSAIDs. Coxibs should not be prescribed in patients with increased cardiovascular risk. Almost all patients with increased cardiovascular risk also will be taking antiplatelet therapy with low-dose aspirin or clopidogrel, or both. Because combination therapy with an nsNSAID and antiplatelet therapy increases the risks of gastrointestinal complications, these patients should all receive cotherapy with a proton pump inhibitor once daily or misoprostol.

4. Recommendations for use of antiplatelet agents—

The risk of significant gastrointestinal complications in persons taking Low-dose aspirin (81–325 mg/d) or clopidogrel, or both, for cardiovascular prophylaxis is 0.5%/year. Aspirin, 81 mg/d, is recommended in most patients because it has a lower risk of gastrointestinal complications but equivalent cardiovascular protection compared with higher aspirin doses. Complications are increased with combinations of aspirin and clopidogrel or aspirin and anticoagulants. Patients with dyspepsia or prior ulcer disease should be tested for *H pylori* infection and treated, if positive. Patients younger than age 60 who have no other risk factors for gastrointestinal complications may be treated with low-dose aspirin alone without a proton pump inhibitor or misoprostol. Virtually all other patients who require low-dose aspirin, dual antiplatelet therapy (aspirin and clopidogrel), or aspirin and anticoagulant therapy should receive a proton pump inhibitor once daily. Recent studies suggest that proton pump inhibitors that are metabolized by CYP2C19 may inhibit activation of clopidogrel, reducing its antiplatelet effects.

C. Refractory Ulcers

Ulcers that are truly refractory to medical therapy are now uncommon. Less than 5% of ulcers are unhealed after 8 weeks of therapy with proton pump inhibitors. Noncompliance is the most common cause of ulcer nonhealing. Cigarettes retard ulcer healing and should be proscribed. NSAID and aspirin use, sometimes surreptitious, are commonly implicated in refractory ulcers and must be stopped. *H pylori* infection should be sought and the infection treated, if present, in all refractory ulcer patients. Fasting serum gastrin levels should be obtained to exclude gastrinoma with acid hypersecretion (Zollinger-Ellison syndrome). Nonhealing gastric ulcers raise concerns that an undiagnosed gastric malignancy may be masquerading as a benign gastric ulcer. Repeat ulcer biopsies are mandatory after 2–3 months of therapy in all nonhealed gastric ulcers, and they should be followed with serial endoscopies to verify complete healing. Almost all benign refractory ulcers heal within 8 weeks with an oral proton pump inhibitor twice daily (omeprazole or rabeprazole 20 mg, lansoprazole 30 mg). Patients with persistent nonhealing ulcers are referred for surgical therapy after exclusion of NSAID use and persistent *H pylori* infection.

COMPLICATIONS OF PEPTIC ULCER DISEASE

1. Gastrointestinal Hemorrhage

ESSENTIALS OF DIAGNOSIS

- ▶ “Coffee grounds” emesis, hematemesis, melena, or hematochezia.
- ▶ Emergent upper endoscopy is diagnostic and therapeutic.

▶ General Considerations

Approximately 50% of all episodes of upper gastrointestinal bleeding are due to peptic ulcer. Clinically significant bleeding occurs in 10% of ulcer patients. About 80% of patients stop bleeding spontaneously and generally have an uneventful recovery; the remaining 20% have more severe bleeding. The overall mortality rate for ulcer bleeding is 4%, but it is higher in the elderly, in patients with comorbid medical problems, and in patients with hospital-associated bleeding. Mortality is also higher in patients who present with persistent hypotension or shock, bright red blood in the vomitus or nasogastric lavage fluid, or severe coagulopathy.

► Clinical Findings

A. Symptoms and Signs

Up to 20% of patients have no antecedent symptoms of pain; this is particularly true of patients receiving NSAIDs. Common presenting signs include melena and hematemesis. Massive upper gastrointestinal bleeding or rapid gastrointestinal transit may result in hematochezia rather than melena; this may be misinterpreted as signifying a lower tract bleeding source. Nasogastric lavage that demonstrates “coffee grounds” or bright red blood confirms an upper tract source. Recovered nasogastric lavage fluid that is negative for blood does not exclude active bleeding from a duodenal ulcer.

B. Laboratory Findings

The hematocrit may fall as a result of bleeding or expansion of the intravascular volume with intravenous fluids. The blood urea nitrogen (BUN) may rise as a result of absorption of blood nitrogen from the small intestine and prerenal azotemia.

► Treatment

The assessment and initial management of upper gastrointestinal tract bleeding are discussed elsewhere in this chapter. Specific issues pertaining to peptic ulcer bleeding are described below.

A. Medical Therapy

1. Antisecretory agents—Intravenous proton pump inhibitors or high-dose oral proton pump inhibitors should be administered for 3 days in patients with ulcers whose endoscopic appearance suggests a high risk of rebleeding after endoscopic therapy. Intravenous or high-dose oral proton pump inhibitors have been associated with a reduction in rebleeding, transfusions, the need for further endoscopic therapy, and surgery in the subset of patients with high-risk ulcers, ie, an ulcer with active bleeding, visible vessel, or adherent clot (see below). After initial successful endoscopic treatment of ulcer hemorrhage, intravenous omeprazole (80 mg bolus injection, followed by 8 mg/h continuous infusion for 72 hours) reduces the rebleeding rate from approximately 20% to < 10%; however, intravenous omeprazole is not available in the United States. In the United States, intravenous esomeprazole and pantoprazole are available and commonly used at comparable dosing (80 mg bolus injection, followed by 8 mg/h) for this indication, although published data confirming their efficacy are unavailable.

High-dose oral proton pump inhibitors (omeprazole 40 mg twice daily) also appear to be effective in reducing rebleeding but have not been compared with the intravenous regimen. Many physicians choose to administer a high-dose proton pump inhibitor prior to endoscopy in all patients admitted to the hospital with gastrointestinal bleeding suspected to be due to peptic ulcer, discontinuing therapy after endoscopy in patients with ulcers deemed to be at low risk of rebleeding. Intravenous H₂-receptor antagonists have not been demonstrated to be of any benefit in the treatment of acute ulcer bleeding.

2. Long-term prevention of rebleeding—Recurrent ulcer bleeding develops within 3 years in one-third of patients if no specific therapy is given. In patients with bleeding ulcers who are *H pylori*-positive, successful eradication effectively prevents recurrent ulcer bleeding in almost all cases. It is therefore recommended that all patients with bleeding ulcers be tested for *H pylori* infection and treated if positive. Four to 8 weeks after completion of antibiotic therapy, a urea breath or fecal antigen test for *H pylori* should be administered or endoscopy performed with biopsy for histologic confirmation of successful eradication. In patients in whom *H pylori* persists or the small subset of patients whose ulcers are not associated with NSAIDs or *H pylori*, long-term acid suppression with a once-daily proton pump inhibitor should be prescribed to reduce the likelihood of recurrence of bleeding.

B. Endoscopy

Endoscopy is the preferred diagnostic procedure in almost all cases of upper gastrointestinal bleeding because of its high diagnostic accuracy, its ability to predict the likelihood of recurrent bleeding, and its availability for therapeutic intervention in high-risk lesions. Endoscopy should be performed within 12–24 hours in most cases. In cases of severe active bleeding, endoscopy is performed as soon as patients have been appropriately resuscitated and are hemodynamically stable.

On the basis of clinical and endoscopic criteria, it is possible to predict which patients are at a higher risk of rebleeding and therefore to make more rational use of hospital resources. Nonbleeding ulcers under 2 cm in size with a base that is clean have a less than 5% chance of rebleeding. Most young (under age 60 years), otherwise healthy patients with clean-based ulcers may be safely discharged from the emergency department or hospital after endoscopy. Ulcers that have a flat red or black spot have a less than 10% chance of significant rebleeding. Patients who are hemodynamically stable with these findings should be admitted to a hospital ward for 24–72 hours and may begin immediate oral feedings and antiulcer (or anti-*H pylori*) medication.

By contrast, the risk of rebleeding or continued bleeding in ulcers with a firmly adherent clot is 12–33%, with a nonbleeding visible vessel is 50%, and with active bleeding it is 80–90%. Endoscopic therapy with thermocoagulation (bipolar or heater probes) or application of endoscopic clips (akin to a staple) is the standard of care for such lesions because it reduces the risk of rebleeding, the number of transfusions, and the need for subsequent surgery. For actively bleeding ulcers, a combination of epinephrine injection followed by thermocoagulation or clip application commonly is used. These techniques achieve successful hemostasis of actively bleeding lesions in 90% of patients. Significant rebleeding occurs in 10–20% of cases, of which over 70% can be managed successfully with repeat endoscopic treatment. After endoscopic treatment, high-risk patients should be monitored in an ICU setting for at least 24 hours and should remain hospitalized for at least 72 hours, when the risk of rebleeding is less than 3%.

C. Surgical Treatment

Patients with recurrent bleeding or bleeding that cannot be controlled by endoscopic techniques should be evaluated by a surgeon. However, less than 5% of patients treated with hemostatic therapy require surgery for continued or recurrent bleeding. Overall surgical mortality for emergency ulcer bleeding is less than 6%. The prognosis is poorer for patients over age 60 years, those with serious underlying medical illnesses or chronic renal failure, and those who require more than 10 units of blood transfusion.

2. Ulcer Perforation

Perforations develop in less than 5% of ulcer patients, usually from ulcers on the anterior wall of the stomach or duodenum. The incidence of perforations may be increasing, perhaps as a consequence of using NSAIDs or crack cocaine. Perforation results in a chemical peritonitis that causes sudden, severe generalized abdominal pain that prompts most patients to seek immediate attention. Elderly or debilitated patients and those receiving long-term corticosteroid therapy may experience minimal initial symptoms, presenting late with bacterial peritonitis, sepsis, and shock. On physical examination, patients appear ill, with a rigid, quiet abdomen and rebound tenderness. Hypotension develops later after bacterial peritonitis has developed. If hypotension is present early with the onset of pain, other abdominal emergencies should be considered such as a ruptured aortic aneurysm, mesenteric infarction, or acute pancreatitis. Leukocytosis is almost always present. A mildly elevated serum amylase (less than twice normal) is sometimes seen. Abdominal CT usually establishes the diagnosis without need for further studies. The absence of free air may lead to a misdiagnosis of pancreatitis, cholecystitis, or appendicitis.

Traditional surgical dogma held that the majority of patients with perforated ulcers should undergo emergency laparotomy. Closure of the perforation was performed with an omental ("Graham") patch and, in stable patients, a proximal gastric vagotomy was performed to decrease the chance of ulcer recurrence. This approach has changed for two reasons. The first is minimally invasive surgical technique. Laparoscopic perforation closure can be performed in many centers, significantly reducing operative morbidity. Second is the recognition that *H pylori* infection is associated with most ulcers and ulcer perforations. Postoperative treatment of *H pylori* reduces the risk of ulcer recurrence, obviating the need for intraoperative vagotomy. The overall mortality rate in patients treated surgically is 5%.

Up to 40% of ulcer perforations seal spontaneously by the adherence of omentum or adjacent organs to the lesion and do not have significant intraperitoneal spillage. Thus, initial nonoperative management may be suitable for patients whose onset of symptoms is less than 12 hours and whose upper gastrointestinal series with water-soluble contrast medium does not demonstrate leakage. Such conservative therapy is most appropriate for patients who are poor operative candidates. Patients should be monitored closely while receiving fluids, nasogastric suction, intravenous proton pump inhibitors, and broad-spectrum

antibiotics. If their condition deteriorates over the first 12 hours (as evidenced by increasing pain, rising pulse or temperature, or worsening peritonitis), they should be taken to the operating room.

3. Ulcer Penetration

An ulcer located along the posterior wall of the duodenum or stomach may perforate into contiguous structures such as the pancreas, liver, or biliary tree. Patients complain of a change in the intensity and rhythmicity of their ulcer symptoms. The pain becomes more severe and constant, may radiate to the back, and is unresponsive to antacids or food. Physical examination and laboratory tests are nonspecific. Mild amylase elevations may sometimes occur. Endoscopy and barium x-ray studies confirm the ulceration but are not diagnostic of an actual penetration. Patients should be given intravenous proton pump inhibitors and monitored closely. Those who do not improve should be considered for surgery.

4. Gastric Outlet Obstruction

Gastric outlet obstruction occurs in < 2% of patients with ulcer disease and is due to edema or cicatricial narrowing of the pylorus or duodenal bulb. With the advent of potent antisecretory therapy with proton pump inhibitors and the eradication of *H pylori*, obstruction now is less commonly caused by peptic ulcers than by gastric neoplasms or extrinsic duodenal obstruction by intra-abdominal neoplasms. The most common symptoms are early satiety, vomiting, and weight loss. Early symptoms are epigastric fullness or heaviness after meals. Later, vomiting may develop that typically occurs one to several hours after eating and consists of partially digested food contents. Chronic obstruction may result in a grossly dilated, atonic stomach, severe weight loss, and malnutrition. Patients may develop dehydration, metabolic alkalosis, and hypokalemia. On physical examination, a succussion splash may be heard in the epigastrium. In most cases, nasogastric aspiration will result in evacuation of a large amount (> 200 mL) of foul-smelling fluid, which establishes the diagnosis. Patients are treated initially with intravenous isotonic saline and KCl to correct fluid and electrolyte disorders, an intravenous proton pump inhibitor, and nasogastric decompression of the stomach. Upper endoscopy is performed after 24–72 hours to define the nature of the obstruction and to exclude gastric neoplasm. In patients with gastric outlet obstruction caused by peptic ulcer disease, dilation of the gastric obstruction by hydrostatic balloons passed through the endoscope improves symptoms in up to two-thirds of patients; repeat dilations may be necessary. Surgical treatment with vagotomy and either pyloroplasty or antrectomy is required in patients with inadequate response or symptom relapse after endoscopic dilation.

ZOLLINGER-ELLISON SYNDROME (Gastrinoma)

ESSENTIALS OF DIAGNOSIS

- ▶ Peptic ulcer disease; may be severe and atypical.
- ▶ Gastric acid hypersecretion.
- ▶ Diarrhea common, relieved by nasogastric suction.
- ▶ Most cases are sporadic; 25% with multiple endocrine neoplasia type 1 (MEN 1).

▶ General Considerations

Zollinger-Ellison syndrome is caused by gastrin-secreting gut neuroendocrine tumors (gastrinomas), which result in hypergastrinemia and acid hypersecretion. Less than 1% of peptic ulcer disease is caused by gastrinomas. Primary gastrinomas may arise in the pancreas (25%), duodenal wall (45%), or lymph nodes (5–15%), and in other locations or of unknown primary in 20%. Approximately 80% arise within the “gastrinoma triangle” bounded by the porta hepatis, the neck of the pancreas, and the third portion of the duodenum. Most gastrinomas are solitary or multifocal nodules that are potentially resectable. Over two-thirds of gastrinomas are malignant, and one-third have already metastasized to the liver at initial presentation. Approximately 25% of patients have small multicentric gastrinomas associated with MEN 1 that are more difficult to resect.

▶ Clinical Findings

A. Symptoms and Signs

Over 90% of patients with Zollinger-Ellison syndrome develop peptic ulcers. In most cases, the symptoms are indistinguishable from other causes of peptic ulcer disease and therefore may go undetected for years. Ulcers usually

are solitary and located in the duodenal bulb, but they may be multiple or occur more distally in the duodenum. Isolated gastric ulcers do not occur. Gastroesophageal reflux symptoms occur often. Diarrhea occurs in one-third of patients, in some cases in the absence of peptic symptoms. Gastric acid hypersecretion can cause direct intestinal mucosal injury and pancreatic enzyme inactivation, resulting in diarrhea, steatorrhea, and weight loss; nasogastric aspiration of stomach acid stops the diarrhea. Screening for Zollinger-Ellison syndrome with fasting gastrin levels should be obtained in patients with ulcers that are refractory to standard therapies, giant ulcers (> 2 cm), ulcers located distal to the duodenal bulb, multiple duodenal ulcers, frequent ulcer recurrences, ulcers associated with diarrhea, ulcers occurring after ulcer surgery, and patients with ulcer complications. Ulcer patients with hypercalcemia or family histories of ulcers (suggesting MEN 1) should also be screened. Finally, patients with peptic ulcers who are *H pylori* negative and who are not taking NSAIDs should be screened.

B. Laboratory Findings

The most sensitive and specific method for identifying Zollinger-Ellison syndrome is demonstration of an increased fasting serum gastrin concentration (> 150 pg/mL). Levels should be obtained with patients not taking H₂-receptor antagonists for 24 hours or proton pump inhibitors for 6 days. The median gastrin level is 500–700 pg/mL, and 60% of patients have levels less than 1000 pg/mL. Hypochlorhydria with increased gastric pH is a much more common cause of hypergastrinemia than is gastrinoma. Therefore, a measurement of gastric pH (and, where available, gastric secretory studies) is performed in patients with fasting hypergastrinemia. Most patients have a basal acid output of over 15 mEq/h. A gastric pH of > 3.0 implies hypochlorhydria and excludes gastrinoma. In a patient with a serum gastrin level of > 1000 pg/mL and acid hypersecretion, the diagnosis of Zollinger-Ellison syndrome is established. With lower gastrin levels (150–1000 pg/mL) and acid secretion, a secretin stimulation test is performed to distinguish Zollinger-Ellison syndrome from other causes of hypergastrinemia. Intravenous secretin (2 units/kg) produces a rise in serum gastrin of over 200 pg/mL within 2–30 minutes in 85% of patients with gastrinoma. An elevated serum calcium suggests hyperparathyroidism and MEN 1 syndrome. In all patients with Zollinger-Ellison syndrome, a serum parathyroid hormone (PTH), prolactin, luteinizing hormone-follicle-stimulating hormone (LH-FSH), and growth hormone (GH) level should be obtained to exclude MEN 1.

C. Imaging

Imaging studies are obtained in an attempt to determine whether there is metastatic disease and, if not, to identify the site of the primary tumor. Gastrinomas express somatostatin receptors that bind radiolabeled octreotide. Somatostatin receptor scintigraphy (SRS) with single photon emission computed tomography (SPECT) allows total body imaging for detection of primary gastrinomas in the pancreas and lymph nodes, primary gastrinomas in unusual

locations, and metastatic gastrinomas (liver and bone). SRS has a sensitivity (> 80%) for tumor detection that exceeds all other imaging studies combined. If SRS is positive for tumor localization, further imaging studies are not necessary. In patients with negative SRS, endoscopic ultrasonography (EUS) may be useful to detect small gastrinomas in the duodenal wall, pancreas, or peripancreatic lymph nodes. CT and MRI scans are commonly obtained to look for large hepatic metastases and primary lesions, but they have low sensitivity for small lesions. With a combination of SRS and EUS, more than 90% of primary gastrinomas can be localized preoperatively.

► Differential Diagnosis

Gastrinomas are one of several gut neuroendocrine tumors that have similar histopathologic features and arise either from the gut or pancreas. These include carcinoid, insulinoma, VIPoma, glucagonoma, and somatostatinoma. These tumors usually are differentiated by the gut peptides that they secrete; however, poorly differentiated neuroendocrine tumors may not secrete any hormones. Patients may present with symptoms caused by tumor metastases (jaundice, hepatomegaly) rather than functional symptoms. Once a diagnosis of a neuroendocrine tumor is established from the liver biopsy, the specific type of tumor can subsequently be determined. Both carcinoids and gastrinomas may be detected incidentally during endoscopy after biopsy of a submucosal nodule and must be distinguished by subsequent studies.

Hypergastrinemia due to gastrinoma must be distinguished from other causes of hypergastrinemia. Atrophic gastritis with decreased acid secretion is detected by gastric secretory analysis. Other conditions associated with hypergastrinemia (eg, gastric outlet obstruction, vagotomy, chronic renal failure) are associated with a negative secretin stimulation test.

► Treatment

A. Metastatic Disease

The most important predictor of survival is the presence of hepatic metastases. In patients with multiple hepatic metastases, initial therapy should be directed at controlling hypersecretion. Oral proton pump inhibitors (omeprazole, esomeprazole, rabeprazole, pantoprazole, or lansoprazole) are given at a dose of 40–120 mg/d, titrated to achieve a basal acid output of < 10 mEq/h. At this level, there is complete symptomatic relief and ulcer healing. In patients with isolated hepatic metastases, surgical resection or cryoablation may decrease the need for antisecretory medications and may prolong survival. Owing to the slow growth of these tumors, 30% of patients with hepatic metastases have a survival of 10 years.

B. Localized Disease

Cure can be achieved only if the gastrinoma can be resected before hepatic metastatic spread has occurred. Lymph node metastases do not adversely affect prognosis. Laparotomy should be considered in all patients in whom preoperative

studies fail to demonstrate hepatic or other distant metastases. A combination of preoperative studies, duodenotomy with careful duodenal inspection, and intraoperative palpation and sonography allows successful localization and resection in the majority of cases. The 15-year survival of patients who do not have liver metastases at initial presentation is over 95%. The role of surgery in patients with MEN 1 is controversial. Surgical cure in patients with MEN 1 rarely occurs, and long-term survival is common in the absence of surgery. Some experts recommend surgery only in patients with MEN 1 whose tumors are larger than 2 cm, in whom the risk of hepatic metastases is increased.

Ellison EC et al. The Zollinger-Ellison syndrome: a comprehensive review of historical, scientific, and clinical considerations. *Curr Probl Surg.* 2009 Jan;46(1):13–106. [PMID: 19059523]

BENIGN TUMORS OF THE STOMACH

Gastric epithelial polyps are usually detected incidentally at endoscopy. The majority are fundic gland polyps or hyperplastic polyps, which are small, single or multiple, have no malignant potential, and do not require removal or endoscopic surveillance. Adenomatous polyps account for 10–20% of gastric polyps. They are usually solitary lesions. In rare instances they ulcerate, causing chronic blood loss. Because of their premalignant potential, endoscopic removal is indicated. Annual endoscopic surveillance is recommended to screen for further polyp development. Submucosal gastric polypoid lesions include benign gastric stromal tumors (commonly misclassified as leiomyomas) and pancreatic rests. (See **Chapter 39 for Gastric Adenocarcinoma, Lymphoma, Carcinoid Tumors, and Mesenchymal Tumors.**)

DISEASES OF THE SMALL INTESTINE

MALABSORPTION

The term “malabsorption” denotes disorders in which there is a disruption of digestion and nutrient absorption. The clinical and laboratory manifestations of malabsorption are summarized in Table 15–11.

► Pathogenesis

Normal digestion and absorption may be divided into three phases: intraluminal, mucosal, and absorptive.

A. Intraluminal Phase

Dietary fats, proteins, and carbohydrates are hydrolyzed and solubilized by pancreatic and biliary secretions. Fats

Table 15–11. Clinical manifestations and laboratory findings in malabsorption of various nutrients.

| Manifestations | Laboratory Findings | Malabsorbed Nutrients |
|--|--|--|
| Steatorrhea (bulky, light-colored stools) | Increased fecal fat; decreased serum cholesterol; decreased serum carotene, vitamin A, vitamin D | Triglycerides, fatty acids, phospholipids, cholesterol. Fat soluble vitamins: A, D, E, K |
| Diarrhea (increased fecal water) | Increased stool volume and weight; increased fecal fat; increased stool osmolality gap | Fats; carbohydrates |
| Weight loss; muscle wasting | Increased fecal fat; decreased carbohydrate (D-xylose) absorption | Fat, protein, carbohydrates |
| Microcytic anemia | Low serum iron | Iron |
| Macrocytic anemia | Decreased serum vitamin B ₁₂ or red blood cell folate | Vitamin B ₁₂ or folic acid |
| Paresthesia; tetany; positive Trousseau and Chvostek signs | Decreased serum calcium or magnesium | Calcium, vitamin D, magnesium |
| Bone pain; pathologic fractures; skeletal deformities | Osteopenia on radiograph; osteoporosis (adults); osteomalacia (children) | Calcium, vitamin D |
| Bleeding tendency (ecchymoses, epistaxis) | Prolonged prothrombin time or INR | Vitamin K |
| Edema | Decreased serum total protein and albumin; increased fecal loss of α_1 -antitrypsin | Protein |
| Milk intolerance (cramps, bloating, diarrhea) | Abnormal lactose tolerance test | Lactose |

INR, international normalized ratio.

are broken down by pancreatic lipase to monoglycerides and fatty acids that form micelles with bile salts. Micelles are important for the solubilization and absorption of fat-soluble vitamins (A, D, E, K). Proteins are hydrolyzed by pancreatic proteases to di- and tripeptides and amino acids. Impaired intraluminal digestion may be caused by insufficient intraluminal concentrations of pancreatic enzymes or bile salts. These conditions will not be covered in detail here (see Chapter 16).

Pancreatic insufficiency may be caused by chronic pancreatitis, cystic fibrosis, or pancreatic cancer. Pancreatic enzymes may also be inactivated within the intestinal lumen by acid hypersecretion (Zollinger-Ellison syndrome). Significant pancreatic enzyme insufficiency generally results in significant steatorrhea (due to malabsorption of triglycerides)—often more than 20–40 g/24 h—resulting in weight loss, gaseous distention and flatulence, and large, greasy, foul-smelling stools. The digestion of proteins and carbohydrates is affected to a far lesser degree and is generally not clinically significant. Because micellar function and intestinal absorption are normal, signs of other nutrient or vitamin deficiencies are rare.

Decreased bile salt concentrations may be due to biliary obstruction or cholestatic liver diseases. Because bile salts are resorbed in the terminal ileum, resection or disease of this area (eg, Crohn disease) can lead to insufficient intraluminal bile salts. Finally, destruction or loss of bile salts may be caused by bacterial overgrowth, massive acid hypersecretion, or medications that bind bile salts (eg, cholestyramine). (Bacterial overgrowth is discussed below.)

Insufficient concentrations of intraluminal bile salts lead to mild steatorrhea (due to malabsorption of fatty acids and monoglycerides), though generally less than 20 g/d. Weight

loss is minimal. Impaired absorption of fat-soluble vitamins (A, D, E, K) is common, resulting in bleeding tendencies, osteoporosis, and hypocalcemia (Table 15–11). Other nutrient absorption is intact. Intestinal loss of bile salts into the colon may cause a watery secretory diarrhea.

B. Mucosal Phase

The mucosal phase requires a sufficient surface area of intact small intestinal epithelium. Brush border enzymes are important in the hydrolysis of disaccharides and di- and tripeptides. Malabsorption of specific nutrients may occur as a result of deficiency in an isolated brush border enzyme. With the exception of lactase deficiency, these are rare congenital disorders that are evident in childhood. Malabsorption due to primary mucosal diseases, extensive intestinal resections (short bowel syndrome), or lymphoma is discussed below. These disorders result in malabsorption of all nutrients: fats, proteins, and amino acids. Depending on the severity of malabsorption, patients may manifest a number of symptoms and signs, as outlined in Table 15–11.

C. Absorptive Phase

Obstruction of the lymphatic system results in impaired absorption of chylomicrons and lipoproteins. This may lead to steatorrhea and significant enteric protein losses or “protein-losing enteropathy,” discussed below.

1. Celiac Disease

ESSENTIALS OF DIAGNOSIS

- ▶ Typical symptoms: weight loss, chronic diarrhea, abdominal distention, growth retardation.
- ▶ Atypical symptoms: dermatitis herpetiformis, iron deficiency anemia, osteoporosis.
- ▶ Abnormal serologic test results.
- ▶ Abnormal small bowel biopsy.
- ▶ Clinical improvement on gluten-free diet.

▶ General Considerations

Celiac disease is a permanent dietary disorder caused by an immunologic response to gluten, a storage protein found in certain grains, that results in diffuse damage to the proximal small intestinal mucosa with malabsorption of nutrients. Although symptoms may manifest between 6 months and 24 months of age after the introduction of weaning foods, the majority of cases present in childhood or adulthood. Population screening with serologic tests suggests that the disease is present in 1:100 whites of Northern European ancestry, in whom a clinical diagnosis of celiac disease is made in only 10%, suggesting that most cases are undiagnosed or asymptomatic. Celiac disease only develops in people with the HLA-DQ2 (95%) or -DQ8 (5%) class II molecules, which are present in 40% of the population. Although the precise pathogenesis is unclear, celiac disease arises in a small subset of genetically susceptible (-DQ2 or -DQ8) individuals when dietary gluten stimulates an inappropriate immunologic response. Glutens are partially digested in the intestinal lumen into glutamine-rich peptides. Some of the glutamines are deamidated by the enzyme tTG, generating negatively charged glutamic acid residues. If these peptides are able to bind to HLA-DQ2 or -DQ8 molecules on antigen-presenting cells, they may stimulate an inappropriate T cell–mediated activation in the intestinal submucosa that results in destruction of mucosal enterocytes as well as a humoral immune response that results in antibodies to gluten, tTG, and other autoantigens.

▶ Clinical Findings

The most important step in diagnosing celiac disease is to consider the diagnosis. Symptoms are present for more than 10 years in most adults before the correct diagnosis is established. Because of its protean manifestations, celiac disease is grossly underdiagnosed in the adult population.

A. Symptoms and Signs

The gastrointestinal symptoms and signs of celiac disease depend on the length of small intestine involved and the patient's age when the disease presents. "Classic" symptoms of malabsorption, including diarrhea, steatorrhea, weight loss, abdominal distention, weakness, muscle wasting, or growth retardation, more commonly present in infants

(< 2 years). Older children and adults are less likely to manifest signs of serious malabsorption. They may report chronic diarrhea, dyspepsia, or flatulence due to colonic bacterial digestion of malabsorbed nutrients, but the severity of weight loss is variable. Many adults have minimal or no gastrointestinal symptoms but present with extraintestinal "atypical" manifestations, including fatigue, depression, iron-deficiency anemia, osteoporosis, short stature, delayed puberty, amenorrhea, or reduced fertility. Approximately 40% of patients with positive serologic tests consistent with sprue have no symptoms of disease; the natural history of these patients with "silent" sprue is unclear.

Physical examination may be normal in mild cases or may reveal signs of malabsorption such as loss of muscle mass or subcutaneous fat, pallor due to anemia, easy bruising due to vitamin K deficiency, hyperkeratosis due to vitamin A deficiency, bone pain due to osteomalacia, or neurologic signs (peripheral neuropathy, ataxia) due to vitamin B₁₂ or vitamin E deficiency. Abdominal examination may reveal distention with hyperactive bowel sounds.

Dermatitis herpetiformis is regarded as a cutaneous variant of celiac disease. It is a characteristic skin rash consisting of pruritic papulovesicles over the extensor surfaces of the extremities and over the trunk, scalp, and neck. Dermatitis herpetiformis occurs in less than 10% of patients with celiac disease; however, almost all patients who present with dermatitis herpetiformis have evidence of celiac disease on intestinal mucosal biopsy, though it may not be clinically evident.

B. Laboratory Findings

1. Routine laboratory tests—Depending on the severity of illness and the extent of intestinal involvement, nonspecific laboratory abnormalities may be present that may raise the suspicion of malabsorption and celiac disease. Limited proximal involvement may result only in microcytic anemia due to iron deficiency. Up to 5% of adults with iron deficiency not due to gastrointestinal blood loss have undiagnosed celiac disease. More extensive involvement results in a megaloblastic anemia due to folate or vitamin B₁₂ deficiency. Low serum calcium or elevated alkaline phosphatase may reflect impaired calcium or vitamin D absorption with osteomalacia or osteoporosis. Dual-energy x-ray densitometry scanning is recommended for all patients with sprue to screen for osteoporosis. Elevations of prothrombin time, or decreased vitamin A or D levels reflect impaired fat-soluble vitamin absorption. A low serum albumin may reflect small intestine protein loss or poor nutrition. Severe diarrhea may result in a nonanion gap acidosis and hypokalemia. Mild elevations of aminotransferases are found in up to 40%.

2. Serologic tests—Serologic tests should be performed in all patients in whom there is a suspicion of celiac disease. The two tests with the highest diagnostic accuracy are the IgA endomysial antibody and IgA tTG antibody tests, both of which have a $\geq 90\%$ sensitivity and $\geq 95\%$ specificity for the diagnosis of celiac disease. A negative test reliably excludes the diagnosis of celiac disease. Antigliadin antibodies are no longer recommended because of their lower

sensitivity and specificity. Because up to 3% of patients with celiac disease have IgA deficiency, an IgA level should be obtained in patients with a negative IgA endomysial antibody or tTG antibody when celiac disease is strongly suspected. For the subset of patients with IgA deficiency, IgG tTG or endomysial antibodies can be obtained. Levels of all antibodies become undetectable after 6–12 months of dietary gluten withdrawal and may be used to monitor dietary compliance, especially in patients whose symptoms fail to resolve after institution of a gluten-free diet.

C. Mucosal Biopsy

Endoscopic mucosal biopsy of the distal duodenum or proximal jejunum is the standard method for confirmation of the diagnosis in patients with a positive serologic test for celiac disease. Rarely, mucosal biopsy may be pursued in patients with negative serologies when symptoms and laboratory studies are suggestive of celiac disease. At endoscopy, atrophy or scalloping of the duodenal folds may be observed. Histology reveals loss or blunting of intestinal villi, hypertrophy of the intestinal crypts, and extensive infiltration of the lamina propria with lymphocytes and plasma cells. An adequate normal biopsy excludes the diagnosis. Partial or complete reversion of these abnormalities on repeat biopsy after a patient is placed on a gluten-free diet establishes the diagnosis. However, if a patient with a compatible biopsy demonstrates prompt clinical improvement on a gluten-free diet and a decrease in antigliadin antibodies, a repeat biopsy is unnecessary.

► Differential Diagnosis

Many patients with chronic diarrhea or flatulence are erroneously diagnosed as having irritable bowel syndrome. Celiac sprue must be distinguished from other causes of malabsorption, as outlined above. Severe panmalabsorption of multiple nutrients is almost always caused by mucosal disease. The histologic appearance of celiac sprue may resemble other mucosal diseases such as tropical sprue, bacterial overgrowth, cow's milk intolerance, viral gastroenteritis, eosinophilic gastroenteritis, and mucosal damage caused by acid hypersecretion associated with gastrinoma. Documentation of clinical response to gluten withdrawal therefore is essential to the diagnosis.

► Treatment

Removal of all gluten from the diet is essential to therapy—all wheat, rye, and barley must be eliminated. Although oats appear to be safe, commercial products may be contaminated with wheat or barley during processing. Because of the pervasive use of gluten products in manufactured foods and additives, in medications, and by restaurants, it is imperative that patients and their families confer with a knowledgeable dietitian to comply satisfactorily with this lifelong diet. Several excellent dietary guides and patient support groups are available. Most patients with celiac disease also have lactose intolerance either temporarily or permanently and should avoid dairy products until the intestinal symptoms have improved on the gluten-free diet.

Dietary supplements (folate, iron, calcium, and vitamins A, B₁₂, D, and E) should be provided in the initial stages of therapy but usually are not required long-term with a gluten-free diet. Patients with confirmed osteoporosis may require long-term calcium, vitamin D, and bisphosphonate therapy.

Improvement in symptoms should be evident within a few weeks on the gluten-free diet. The most common reason for treatment failure is incomplete removal of gluten.

► Prognosis & Complications

If appropriately diagnosed and treated, patients with celiac disease have an excellent prognosis. Celiac disease may be associated with other autoimmune disorders, including Addison disease, Graves disease, type 1 diabetes mellitus, myasthenia gravis, scleroderma, Sjögren syndrome, atrophic gastritis, and pancreatic insufficiency. In some patients, celiac disease may evolve and become refractory to the gluten-free diet. The most common cause is intentional or unintentional dietary noncompliance, which may be suggested by positive serologic tests. Celiac disease that is truly refractory to gluten withdrawal generally carries a poor prognosis. It may be caused by the development of enteropathy-associated T cell lymphoma. This diagnosis should be considered in patients previously responsive to the gluten-free diet in whom new weight loss, abdominal pain, and malabsorption develop. Many other patients with refractory symptoms have a “cryptic” intestinal lymphoma, ie, a monoclonal expansion of the intraepithelial T lymphocyte that may or may not progress. Patients with refractory sprue who do not have intestinal T cell lymphoma may respond to corticosteroids or immunosuppression with azathioprine or cyclosporine.

2. Whipple Disease

ESSENTIALS OF DIAGNOSIS

- Multisystemic disease.
- Fever, lymphadenopathy, arthralgias.
- Weight loss, malabsorption, chronic diarrhea.
- Duodenal biopsy with periodic acid-Schiff (PAS)-positive macrophages with characteristic bacillus.

▶ General Considerations

Whipple disease is a rare multisystemic illness caused by infection with the bacillus *Tropheryma whippelii*. It may occur at any age but most commonly affects white men in the fourth to sixth decades. The source of infection is unknown, but no cases of human-to-human spread have been documented.

▶ Clinical Findings

A. Symptoms and Signs

The clinical manifestations are protean. Arthralgias or a migratory, nondeforming arthritis occurs in 80% and is typically the first symptom experienced. Gastrointestinal symptoms occur in approximately 75% of cases. They include abdominal pain, diarrhea, and some degree of malabsorption with distention, flatulence, and steatorrhea. Weight loss is the most common presenting symptom—seen in almost all patients. Loss of protein due to intestinal or lymphatic involvement may result in protein-losing enteropathy with hypoalbuminemia and edema. In the absence of gastrointestinal symptoms, the diagnosis often is delayed for several years. Intermittent low-grade fever occurs in over 50% of cases. Chronic cough is common. There may be generalized lymphadenopathy that resembles sarcoidosis. Myocardial or valvular involvement may lead to congestive failure or valvular regurgitation. Ocular findings include uveitis, vitreitis, keratitis, retinitis, and retinal hemorrhages. Central nervous system involvement is manifested by a variety of findings such as dementia, lethargy, coma, seizures, myoclonus, or hypothalamic signs. Cranial nerve findings include ophthalmoplegia or nystagmus.

Physical examination may reveal hypotension (a late finding), low-grade fever, and evidence of malabsorption (see Table 15–11). Lymphadenopathy is present in 50%. Heart murmurs due to valvular involvement may be evident. Peripheral joints may be enlarged or warm, and peripheral edema may be present. Neurologic findings are cited above. Hyperpigmentation on sun-exposed areas is evident in up to 40%.

B. Laboratory Findings

If significant malabsorption is present, patients may have laboratory abnormalities as outlined in Table 15–11. There may be steatorrhea.

C. Histologic Evaluation

In most cases, the diagnosis of Whipple disease is established by endoscopic biopsy of the duodenum with histologic evaluation, which demonstrates infiltration of the lamina propria with PAS-positive macrophages that contain gram-positive bacilli (which are not acid-fast) and dilation of the lacteals. The Whipple bacillus has a characteristic trimellar wall appearance on electron microscopy. In some patients who present with nongastrointestinal symptoms, the duodenal biopsy may be normal, and biopsy of other involved organs or lymph nodes may be necessary. Because the PAS stain is less sensitive and specific for extraintestinal Whipple

disease, polymerase chain reaction (PCR) is used to confirm the diagnosis by demonstrating the presence of 16S ribosomal RNA of *T whippelii* in blood, cerebrospinal fluid, vitreous fluid, synovial fluid, or cardiac valves. The sensitivity of PCR is 97% and the specificity 100%.

▶ Differential Diagnosis

Whipple disease should be considered in patients who present with signs of malabsorption, fever of unknown origin, lymphadenopathy, seronegative arthritis, culture-negative endocarditis, or multisystemic disease. Small bowel biopsy readily distinguishes Whipple disease from other mucosal malabsorptive disorders, such as celiac sprue. Patients with AIDS and infection of the small intestine with *Mycobacterium avium* complex (MAC) may have a similar clinical and histologic picture; although both conditions are characterized by PAS-positive macrophages, they may be distinguished by the acid-fast stain, which is positive for MAC and negative for the Whipple bacillus. Other conditions that may be confused with Whipple disease include sarcoidosis, Reiter syndrome, familial Mediterranean fever, systemic vasculitides, Behçet disease, intestinal lymphoma, and subacute infective endocarditis.

▶ Treatment

Antibiotic therapy results in a dramatic clinical improvement within several weeks, even in some patients with neurologic involvement. The optimal regimen is unknown. Complete clinical response usually is evident within 1–3 months; however, relapse may occur in up to one-third of patients after discontinuation of treatment. Therefore, prolonged treatment for at least 1 year is required. Drugs that cross the blood-brain barrier are preferred. In severely ill patients, treatment should be initiated with intravenous ceftriaxone (2 g daily) for 2 weeks. Thereafter, trimethoprim-sulfamethoxazole (one double-strength tablet twice daily for 1 year) is recommended as first-line therapy. In patients allergic to sulfonamides or resistant to therapy, long-term treatment with doxycycline and hydroxychloroquine has been proposed. After treatment, repeat duodenal biopsies may be obtained at 6 and 12 months for histologic evaluation. The absence of PAS-positive material predicts a low likelihood of clinical relapse.

▶ Prognosis

If untreated, the disease is fatal. Because some neurologic signs may be permanent, the goal of treatment is to prevent this progression. Patients must be followed closely after treatment for signs of symptom recurrence.

Schneider T et al. Whipple's disease: new aspects of pathogenesis and treatment. *Lancet Infect Dis*. 2008 Mar;8(3):179–90. [PMID: 18291339]

3. Bacterial Overgrowth

The small intestine normally contains a small number of bacteria. Bacterial overgrowth in the small intestine of whatever cause may result in malabsorption via a number

of mechanisms. Bacterial deconjugation of bile salts may lead to inadequate micelle formation, resulting in decreased fat absorption with steatorrhea. Microbial uptake of specific nutrients reduces absorption of vitamin B₁₂ and carbohydrates. Bacterial proliferation also causes direct damage to intestinal epithelial cells and the brush border, further impairing absorption of proteins and carbohydrates. Passage of the malabsorbed bile acids and carbohydrates into the colon leads to an osmotic and secretory diarrhea.

Causes of bacterial overgrowth include: (1) gastric achlorhydria (including proton pump inhibitor therapy); (2) anatomic abnormalities of the small intestine with stagnation (afferent limb of Billroth II gastrojejunostomy, resection of ileocecal valve, small intestine diverticula, obstruction, blind loop); (3) small intestine motility disorders (scleroderma, diabetic enteropathy, chronic intestinal pseudo-obstruction); (4) gastrocolic or coloenteric fistula (Crohn disease, malignancy, surgical resection); and (5) miscellaneous disorders. Bacterial overgrowth is an important cause of malabsorption in the elderly, perhaps because of decreased gastric acidity or impaired intestinal motility.

► Clinical Findings

Many patients with bacterial overgrowth are asymptomatic. Patients with severe overgrowth have symptoms and signs of malabsorption, including distention, weight loss, and steatorrhea (Table 15–11). Watery diarrhea is common. Megaloblastic anemia or neurologic signs due to vitamin B₁₂ deficiency are common findings and may be manifest at presentation. Qualitative or quantitative fecal fat assessment typically is abnormal. D-Xylose absorption is also abnormal due to bacterial uptake of the carbohydrate.

Bacterial overgrowth should be considered in any patient with diarrhea, steatorrhea, weight loss, or macrocytic anemia, especially if the patient has a predisposing cause (such as prior gastrointestinal surgery). A stool collection should be obtained to corroborate the presence of steatorrhea. A small bowel barium radiography or CT enterography study should be obtained to look for mechanical factors predisposing to intestinal stasis. A small intestinal biopsy may be necessary to exclude other mucosal malabsorptive conditions and to detect intestinal inflammation, commonly present with symptomatic bacterial overgrowth. A specific diagnosis can be established firmly only by an aspirate and culture of proximal jejunal secretion that demonstrates over 10⁵ organisms/mL. However, this is an invasive and laborious test that requires careful collection and culturing techniques and therefore is not available in many clinical settings. Noninvasive breath tests have been developed that are easier to perform and have a sensitivity of 60–90% and specificity of 85% compared with jejunal cultures. Breath hydrogen tests with glucose or lactulose as substrate are commonly done because of their ease of use.

Owing to the lack of an optimal test for bacterial overgrowth, many clinicians use an empiric antibiotic trial as a diagnostic and therapeutic maneuver in patients with predisposing conditions for bacterial overgrowth in whom unexplained diarrhea or steatorrhea develops.

► Treatment

Where possible, the anatomic defect that has potentiated bacterial overgrowth should be corrected. Otherwise, treatment as follows for 1–2 weeks with broad-spectrum antibiotics effective against enteric aerobes and anaerobes usually leads to dramatic improvement: twice daily ciprofloxacin 500 mg, norfloxacin 400 mg, or amoxicillin clavulanate 875 mg, or a combination of metronidazole 250 mg three times daily plus either trimethoprim-sulfamethoxazole (one double-strength tablet) twice daily or cephalexin 250 mg four times daily. Rifaximin 400 mg three times daily is a nonabsorbable antibiotic that also appears to be effective but has fewer side effects than the other systemically absorbed antibiotics.

In patients in whom symptoms recur off antibiotics, cyclic therapy (eg, 1 week out of 4) may be sufficient. Continuous antibiotics should be avoided, if possible, to avoid development of bacterial antibiotic resistance.

In patients with severe intestinal dysmotility, treatment with small doses of octreotide may prove to be of benefit.

 Scarpellini E et al. High dosage rifaximin for the treatment of small intestinal bacterial overgrowth. *Aliment Pharmacol Ther.* 2007 Apr 1;25(7):781–6. [PMID: 17373916]

4. Short Bowel Syndrome

Short bowel syndrome is the malabsorptive condition that arises secondary to removal of significant segments of the small intestine. The most common causes in adults are Crohn disease, mesenteric infarction, radiation enteritis, volvulus, tumor resection, and trauma. The type and degree of malabsorption depend on the length and site of the resection and the degree of adaptation of the remaining bowel.

► Terminal Ileal Resection

Resection of the terminal ileum results in malabsorption of bile salts and vitamin B₁₂, which are normally absorbed in this region. Patients with low serum vitamin B₁₂ levels, an abnormal Schilling test, or resection of over 50 cm of ileum require monthly intramuscular vitamin B₁₂ injections. In patients with less than 100 cm of ileal resection, bile salt malabsorption stimulates fluid secretion from the colon, resulting in watery diarrhea. This may be treated with bile salt binding resins (cholestyramine, 2–4 g three times daily with meals). Resection of over 100 cm of ileum leads to a reduction in the bile salt pool that results in steatorrhea and malabsorption of fat-soluble vitamins. Treatment is with a low-fat diet and vitamins supplemented with medium-chain triglycerides, which do not require micellar solubilization. Unabsorbed fatty acids bind with calcium, reducing its absorption and enhancing the absorption of oxalate. Oxalate kidney stones may develop. Calcium supplements should be administered to bind oxalate and increase serum calcium. Cholesterol gallstones due to

decreased bile salts are common also. In patients with resection of the ileocolonic valve, bacterial overgrowth may occur in the small intestine, further complicating malabsorption (as outlined above).

► Extensive Small Bowel Resection

Resection of 40–50% of the total length of small intestine usually is well tolerated. A more massive resection may result in “short-bowel syndrome,” characterized by weight loss and diarrhea due to nutrient, water, and electrolyte malabsorption. After resection, the remaining small intestine has a remarkable ability to adapt, gradually increasing its absorptive capacity up to fourfold over 1 year. The colon also plays an important role in absorption of fluids, electrolytes, and digestion of complex carbohydrates (through bacterial fermentation to short-chain fatty acids) after small bowel resection. If the colon is preserved, 100 cm of proximal jejunum may be sufficient to maintain adequate oral nutrition with a low-fat, high complex-carbohydrate diet, though fluid and electrolyte losses may still be significant. In patients in whom the colon has been removed, at least 200 cm of proximal jejunum is typically required to maintain oral nutrition. Duodenal resection may result in folate, iron, or calcium malabsorption. Levels of other minerals such as zinc, selenium, and magnesium should be monitored. Parenteral vitamin supplementation may be necessary. Antidiarrheal agents (loperamide, 2–4 mg three times daily) slow transit and reduce diarrheal volume. Octreotide reduces intestinal transit time and fluid and electrolyte secretion. Gastric hypersecretion initially complicates intestinal resection and should be treated with proton pump inhibitors.

Patients with less than 100–200 cm of proximal jejunum remaining almost always require parenteral nutrition. Of patients who do, the estimated annual mortality rate is 2–5% per year. Death is most commonly due to TPN-induced liver disease, sepsis, or loss of venous access. Small intestine transplantation is now being performed with reported 5-year graft survival rates of 40%. Currently, it is performed chiefly in patients who develop serious problems due to parenteral nutrition.

Misiakos EP et al. Short bowel syndrome: current medical and surgical trends. *J Clin Gastroenterol.* 2007 Jan;41(1):5–18. [PMID: 17198059]

5. Lactase Deficiency

Lactase is a brush border enzyme that hydrolyzes the disaccharide lactose into glucose and galactose. The concentration of lactase enzyme levels is high at birth but declines steadily in most people of non-European ancestry during childhood and adolescence and into adulthood. Thus, approximately 50 million people in the United States have partial to complete lactose intolerance. As many as 90% of Asian-Americans, 70% of African-Americans, 95% of Native Americans, 50% of Mexican-Americans, and

60% of Jewish Americans are lactose intolerant compared with less than 25% of white adults. Lactase deficiency may also arise secondary to other gastrointestinal disorders that affect the proximal small intestinal mucosa. These include Crohn disease, sprue, viral gastroenteritis, giardiasis, short bowel syndrome, and malnutrition. Malabsorbed lactose is fermented by intestinal bacteria, producing gas and organic acids. The nonmetabolized lactose and organic acids result in an increased stool osmotic load with an obligatory fluid loss.

► Clinical Findings

A. Symptoms and Signs

Patients have great variability in clinical symptoms, depending both on the severity of lactase deficiency and the amount of lactose ingested. Because of the nonspecific nature of these symptoms, there is a tendency for both lactose-intolerant and lactose-tolerant individuals to mistakenly attribute a variety of abdominal symptoms to lactose intolerance. Most patients with lactose intolerance can drink one or two 8 oz glasses of milk daily without symptoms if taken with food at wide intervals, though rare patients have almost complete intolerance. With mild to moderate amounts of lactose malabsorption, patients may experience bloating, abdominal cramps, and flatulence. With higher lactose ingestions, an osmotic diarrhea will result. Isolated lactase deficiency does not result in other signs of malabsorption or weight loss. If these findings are present, other gastrointestinal disorders should be pursued. Diarrheal specimens reveal an increased osmotic gap and a pH of less than 6.0.

B. Laboratory Findings

The most widely available test for the diagnosis of lactase deficiency is the hydrogen breath test. After ingestion of 50 g of lactose, a rise in breath hydrogen of greater than 20 ppm within 90 minutes is a positive test, indicative of bacterial carbohydrate metabolism. In clinical practice, many physicians prescribe an empiric trial of a lactose-free diet for 2 weeks. Resolution of symptoms (bloating, flatulence, diarrhea) is highly suggestive of lactase deficiency (though a placebo response cannot be excluded) and may be confirmed, if necessary, with a breath hydrogen study.

► Differential Diagnosis

The symptoms of late-onset lactose intolerance are nonspecific and may mimic a number of gastrointestinal disorders, such as inflammatory bowel disease, mucosal malabsorptive disorders, irritable bowel syndrome, and pancreatic insufficiency. Furthermore, lactase deficiency frequently develops secondary to other gastrointestinal disorders (as listed above). Concomitant lactase deficiency should always be considered in these gastrointestinal disorders.

► Treatment

The goal of treatment in patients with isolated lactase deficiency is achieving patient comfort. Patients usually

find their “threshold” of intake at which symptoms will occur. Foods that are high in lactose include milk (12 g/cup), ice cream (9 g/cup), and cottage cheese (8 g/cup). Aged cheeses have a lower lactose content (0.5 g/oz). Unpasteurized yogurt contains bacteria that produce lactase and is generally well tolerated.

Many patients will choose simply to restrict or eliminate milk products. By spreading dairy product intake throughout the day in quantities of less than 12 g of lactose (one cup of milk), most patients can take dairy products without symptoms and do not require lactase supplements. Calcium supplementation should be considered in susceptible patients to prevent osteoporosis. Most food markets provide milk that has been pretreated with lactase, rendering it 70–100% lactose free. Lactase enzyme replacement is commercially available as a nonprescription formulation (Lactaid). Caplets of lactase may be taken with milk products, improving lactose absorption and eliminating symptoms. The number of caplets ingested depends on the degree of lactose intolerance.

Montalto M et al. Management and treatment of lactose malabsorption. *World J Gastroenterol.* 2006 Jan 14;12(2):187–91. [PMID: 16482616]

INTESTINAL MOTILITY DISORDERS

1. Acute Paralytic Ileus

ESSENTIALS OF DIAGNOSIS

- ▶ Precipitating factors: surgery, peritonitis, electrolyte abnormalities, medications, severe medical illness.
- ▶ Nausea, vomiting, obstipation, distention.
- ▶ Minimal abdominal tenderness; decreased bowel sounds.
- ▶ Plain abdominal radiography with gas and fluid distention in small and large bowel.

▶ General Considerations

Ileus is a condition in which there is neurogenic failure or loss of peristalsis in the intestine in the absence of any mechanical obstruction. It is commonly seen in hospitalized patients as a result of: (1) intra-abdominal processes such as recent gastrointestinal or abdominal surgery or peritoneal irritation (peritonitis, pancreatitis, ruptured viscus, hemorrhage); (2) severe medical illness such as pneumonia, respiratory failure requiring intubation, sepsis or severe infections, uremia, diabetic ketoacidosis, and electrolyte abnormalities (hypokalemia, hypercalcemia, hypomagnesemia, hypophosphatemia); and (3) medications that affect intestinal motility (opioids, anticholinergics, phenothiazines). Following surgery, small intestinal motility usually normalizes first (often within hours), followed by the stomach (24–48 hours), and the colon (48–72 hours).

▶ Clinical Findings

A. Symptoms and Signs

Patients who are conscious report mild diffuse, continuous abdominal discomfort with nausea and vomiting. Generalized abdominal distention is present with minimal abdominal tenderness but no signs of peritoneal irritation (unless due to the primary disease). Bowel sounds are diminished to absent.

B. Laboratory Findings

The laboratory abnormalities are attributable to the underlying condition. Serum electrolytes, including potassium, magnesium, phosphorus, and calcium, should be obtained to exclude abnormalities as contributing factors.

C. Imaging

Plain film radiography of the abdomen demonstrates distended gas-filled loops of small and large intestine. Air-fluid levels may be seen. Under some circumstances, it may be difficult to distinguish ileus from partial small bowel obstruction. A CT scan may be useful in such instances to exclude mechanical obstruction, especially in postoperative patients.

▶ Differential Diagnosis

Ileus must be distinguished from mechanical obstruction of the small bowel or proximal colon. Pain from small bowel mechanical obstruction is usually intermittent, cramping, and associated initially with profuse vomiting. Acute gastroenteritis, acute appendicitis, and acute pancreatitis may all present with ileus.

▶ Treatment

The primary medical or surgical illness that has precipitated adynamic ileus should be treated. Most cases of ileus respond to restriction of oral intake with gradual liberalization of diet as bowel function returns. Severe or prolonged ileus requires nasogastric suction and parenteral administration of fluids and electrolytes. Alvimopan is a new peripherally acting mu-opioid receptor antagonist with limited absorption or systemic activity that reverses opioid-induced inhibition of intestinal motility. In five randomized controlled trials, it reduced the time to first flatus, bowel movement, solid meal, and hospital discharge compared with placebo in postoperative patients. Alvimopan may be considered in patients undergoing partial large or small bowel resection when postoperative opioid therapy is anticipated.

Batke M et al. Adynamic ileus and acute colonic pseudoobstruction. *Med Clin North Am.* 2008 May;92(3):649–70. [PMID: 18387380]

Tan EK et al. Meta-analysis: alvimopan vs. placebo in the treatment of post-operative ileus. *Aliment Pharmacol Ther.* 2007 Jan 1;25(1):47–57. [PMID: 17042776]

2. Acute Colonic Pseudo-obstruction (Ogilvie Syndrome)

ESSENTIALS OF DIAGNOSIS

- ▶ Severe abdominal distention.
- ▶ Arises in postoperative state or with severe medical illness.
- ▶ May be precipitated by electrolyte imbalances, medications.
- ▶ Absent to mild abdominal pain; minimal tenderness.
- ▶ Massive dilation of cecum or right colon.

▶ General Considerations

Spontaneous massive dilation of the cecum and proximal colon may occur in a number of different settings in hospitalized patients. Progressive cecal dilation may lead to spontaneous perforation with dire consequences. The risk of perforation correlates poorly with absolute cecal size and duration of colonic distention. Early detection and management are important to reduce morbidity and mortality. Colonic pseudo-obstruction is most commonly detected in postsurgical patients (mean 3–5 days), after trauma, and in medical patients with respiratory failure, metabolic imbalance, malignancy, myocardial infarction, congestive heart failure, pancreatitis, or a recent neurologic event (stroke, subarachnoid hemorrhage, trauma). Liberal use of opioids or anticholinergic agents may precipitate colonic pseudo-obstruction in susceptible patients. It may also occur as a manifestation of colonic ischemia. The etiology of colonic pseudo-obstruction is unknown, but either an increase in gut sympathetic activity or a decrease in sacral parasympathetic activity of the distal colon, or both, is hypothesized to impair colonic motility.

▶ Clinical Findings

A. Symptoms and Signs

Many patients are on ventilatory support or are unable to report symptoms due to altered mental status. Abdominal distention is frequently noted by the clinician as the first sign, often leading to a plain film radiograph that demonstrates colonic dilation. Some patients are asymptomatic, although most report constant but mild abdominal pain. Nausea and vomiting may be present. Bowel movements may be absent, but up to 40% of patients continue to pass flatus or stool. Abdominal tenderness with some degree of guarding or rebound tenderness may be detected; however, signs of peritonitis are absent unless perforation has occurred. Bowel sounds may be normal or decreased.

B. Laboratory Findings

Laboratory findings reflect the underlying medical or surgical problems. Serum sodium, potassium, magnesium, phosphorus, and calcium should be obtained. Significant

fever or leukocytosis raises concern for colonic ischemia or perforation.

C. Imaging

Radiographs demonstrate colonic dilation, usually confined to the cecum and proximal colon. The upper limits of normal for cecal size is 9 cm. A cecal diameter greater than 10–12 cm is associated with an increased risk of colonic perforation. Varying amounts of small intestinal dilation and air-fluid levels due to adynamic ileus may be seen. Because the dilated appearance of the colon may raise concern that there is a distal colonic mechanical obstruction due to malignancy, volvulus, or fecal impaction, a CT scan or water-soluble (diatrizoate meglumine) enema may sometimes be performed.

▶ Differential Diagnosis

Colonic pseudo-obstruction should be distinguished from distal colonic mechanical obstruction (as above) and toxic megacolon, which is acute dilation of the colon due to inflammation (inflammatory bowel disease) or infection (*C difficile*-associated colitis, CMV). Patients with toxic megacolon manifest fever; dehydration; significant abdominal pain; leukocytosis; and diarrhea, which is often bloody.

▶ Treatment

Conservative treatment is the appropriate first step for patients with no or minimal abdominal tenderness, no fever, no leukocytosis, and a cecal diameter less than 12 cm. The underlying illness is treated appropriately. A nasogastric tube and a rectal tube should be placed. Patients should be ambulated or periodically rolled from side to side and to the knee-chest position in an effort to promote expulsion of colonic gas. All drugs that reduce intestinal motility, such as opioids, anticholinergics, and calcium channel blockers, are discontinued if possible. Enemas may be administered judiciously if large amounts of stool are evident on radiography. Oral laxatives are not helpful and may cause perforation, pain, or electrolyte abnormalities.

Conservative treatment is successful in over 80% of cases within 1–2 days. Patients must be watched for signs of worsening distention or abdominal tenderness. Cecal size should be assessed by abdominal radiographs every 12 hours. Intervention should be considered in patients with any of the following: (1) no improvement or clinical deterioration after 24–48 hours of conservative therapy; (2) cecal dilation > 10 cm for a prolonged period (> 3–4 days); (3) patients with cecal dilation > 12 cm. Neostigmine injection should be given unless contraindicated. A single dose (2 mg intravenously) results in rapid (within 30 minutes) colonic decompression in 75–90% of patients. Cardiac monitoring during neostigmine infusion is indicated for possible bradycardia that may require atropine administration. Colonoscopic decompression is indicated in patients who fail to respond to neostigmine. Colonic decompression with aspiration of air or placement of a decompression tube is successful in 70% of patients. However, the procedure is technically difficult in an unprepared

bowel and has been associated with perforations in the distended colon. Dilation recurs in up to 50% of patients. In patients in whom colonoscopy is unsuccessful, a tube cecostomy can be created through a small laparotomy or with percutaneous radiologically guided placement.

► Prognosis

In most cases, the prognosis is related to the underlying illness. The risk of perforation or ischemia is increased with cecal diameter > 12 cm and when distention has been present for more than 6 days. With aggressive therapy, the development of perforation is unusual.

Saunders MD. Acute colonic pseudo-obstruction. *Gastrointest Endosc Clin N Am.* 2007 Apr;17(2):341–60. [PMID: 17556152]

3. Chronic Intestinal Pseudo-obstruction & Gastroparesis

Gastroparesis and chronic intestinal pseudo-obstruction are chronic conditions characterized by intermittent, waxing and waning symptoms and signs of gastric or intestinal obstruction in the absence of any mechanical lesions to account for the findings. They are caused by a heterogeneous group of endocrine disorders (diabetes mellitus, hypothyroidism, cortisol deficiency), postsurgical conditions (vagotomy, partial gastric resection, fundoplication, gastric bypass, Whipple procedure), neurologic conditions (Parkinson disease, muscular and myotonic dystrophy, autonomic dysfunction, multiple sclerosis, postpolio syndrome, porphyria), rheumatologic syndromes (progressive systemic sclerosis), infections (postviral, Chagas disease), amyloidosis, paraneoplastic syndromes, medications, and eating disorders (anorexia); a cause may not always be identified.

Gastric involvement leads to chronic or intermittent symptoms of gastroparesis with postprandial fullness (early satiety), nausea, and vomiting (1–3 hours after meals). Patients with predominantly small bowel involvement may have abdominal distention, vomiting, diarrhea, and varying degrees of malnutrition. Abdominal pain is not common and should prompt investigation for structural causes of obstruction. Bacterial overgrowth in the stagnant intestine may result in malabsorption. Colonic involvement may result in constipation or alternating diarrhea and constipation.

Plain film radiography may demonstrate dilation of the esophagus, stomach, small intestine, or colon resembling ileus or mechanical obstruction. Mechanical obstruction of the stomach, small intestine, or colon is much more common than gastroparesis or intestinal pseudo-obstruction and must be excluded with endoscopy, barium radiography (upper gastrointestinal series with small bowel follow-through), or CT enterography, especially in patients with prior surgery, recent onset of symptoms, or abdominal pain. In cases of unclear origin, studies based on the clinical picture are obtained to exclude underlying systemic disease. Gastric scintigraphy with a low-fat solid meal is the optimal means for assessing gastric emptying. Gastric retention of 60% after 2 hours or more than 10%

after 4 hours is abnormal. Small bowel manometry is useful for distinguishing visceral from myopathic disorders and for excluding cases of mechanical obstruction that are otherwise difficult to diagnose by endoscopy or radiographic studies.

There is no specific therapy for gastroparesis or pseudo-obstruction. Acute exacerbations are treated with nasogastric suction and intravenous fluids. Long-term treatment is directed at maintaining nutrition. Patients should eat small, frequent meals that are low in fiber, milk, gas-forming foods, and fat. Some patients may require liquid enteral supplements. Agents that reduce gastrointestinal motility (opioids, anticholinergics, calcium channel blockers) should be avoided. In diabetics, glucose levels should be maintained below 200 mg/dL, as hyperglycemia may slow gastric emptying even in the absence of diabetic neuropathy, and amylin analogs (exenatide or pramlintide) should be discontinued. Metoclopramide (5–20 mg orally or 5–10 mg intravenously or subcutaneously four times daily) and erythromycin (50–125 mg orally three times daily) before meals is of benefit in treatment of gastroparesis but not small bowel dysmotility. The FDA issued a black box warning in 2009 that use of metoclopramide for more than 3 months is associated with an increased risk of tardive dyskinesia and should be avoided. The elderly are at greatest risk. Unblinded studies in small numbers of patients with diabetic or idiopathic gastroparesis report improvement in symptoms and gastric emptying after injection of botulinum toxin into the pylorus, which is hypothesized to reduce pyloric spasm; however, a controlled trial showed no efficacy. Gastric electrical stimulation with internally implanted neurostimulators has shown reduction in vomiting in small studies of patients with severe gastroparesis; however, no randomized studies have been conducted and the mechanism of action is uncertain. Bacterial overgrowth should be treated with intermittent antibiotics (see above). Patients with predominant small bowel distention may require a venting gastrostomy to relieve distress. Some patients may require placement of a jejunostomy for long-term enteral nutrition. Patients unable to maintain adequate enteral nutrition require TPN or small bowel transplantation. Difficult cases should be referred to centers with expertise in this area.

BENIGN TUMORS OF THE SMALL INTESTINE

Benign and malignant tumors (see Chapter 39 for Malignant Tumors) of the small intestine are rare. They often cause no symptoms or signs. However, they may cause acute

gastrointestinal bleeding with hematochezia or melena or chronic gastrointestinal blood loss resulting in fatigue and iron deficiency anemia. Small bowel tumors may cause obstruction due to luminal narrowing or intussusception of a polypoid mass. Small bowel tumors usually are identified by barium radiographic studies, either enteroclysis or a small bowel series. Visualization and biopsy of duodenal and proximal jejunal mass lesions are performed with a long upper endoscope known as an enteroscope.

Benign polyps may be symptomatic or may be incidental findings detected on endoscopy or radiographic study. Most occur singly, and the presence of multiple polyps is suggestive of hereditary polyposis syndrome (discussed under Diseases of the Colon and Rectum). With the exception of lipomas, surgical or endoscopic excision usually is recommended.

Adenomatous polyps are the most common benign mucosal tumor. The majority are asymptomatic, though acute or chronic bleeding may occur. Because malignant transformation does occur, endoscopic or surgical resection is warranted. Villous adenomas occur most commonly in the periampullary region of the duodenum (especially in patients with familial adenomatous polyposis) and carry a high risk for development of invasive cancer. Periodic endoscopic surveillance to detect early ampullary neoplasms is recommended in patients with familial adenomatous polyposis. Evaluation with endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic ultrasound is required to exclude invasive carcinoma. Ampullary adenomas may be removed by endoscopic or surgical techniques. Lipomas occur commonly in the ileum. Most are asymptomatic and identified incidentally at endoscopy or radiography; however, they rarely may cause obstruction with intussusception.

Benign stromal tumors (formerly called leiomyomas) are found at all levels of the intestine. These submucosal mesenchymal lesions may be intraluminal, intramural, or extraluminal. Although most are asymptomatic, they may ulcerate and cause acute or chronic bleeding or obstruction. It is difficult to distinguish benign from malignant stromal tumors (leiomyosarcomas) except by excision.

APPENDICITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Early: periumbilical pain; later: right lower quadrant pain and tenderness.
- ▶ Anorexia, nausea and vomiting, obstipation.
- ▶ Tenderness or localized rigidity at McBurney point.
- ▶ Low-grade fever and leukocytosis.

General Considerations

Appendicitis is the most common abdominal surgical emergency, affecting approximately 10% of the population. It occurs most commonly between the ages of 10 and 30 years. It is initiated by obstruction of the appendix by a fecalith, inflammation, foreign body, or neoplasm. Obstruction leads to increased intraluminal pressure, venous congestion, infection, and thrombosis of intramural vessels. If untreated, gangrene and perforation develop within 36 hours.

Clinical Findings

A. Symptoms and Signs

Appendicitis usually begins with vague, often colicky periumbilical or epigastric pain. Within 12 hours the pain shifts to the right lower quadrant, manifested as a steady ache that is worsened by walking or coughing. Almost all patients have nausea with one or two episodes of vomiting. Protracted vomiting or vomiting that begins before the onset of pain suggests another diagnosis. A sense of constipation is typical, and some patients administer cathartics in an effort to relieve their symptoms—though some report diarrhea. Low-grade fever (< 38 °C) is typical; high fever or rigors suggest another diagnosis or appendiceal perforation.

On physical examination, localized tenderness with guarding in the right lower quadrant can be elicited with gentle palpation with one finger. When asked to cough, patients may be able to precisely localize the painful area, a sign of peritoneal irritation. Light percussion may also elicit pain. Although rebound tenderness is also present, it is unnecessary to elicit this finding if the above signs are present. The psoas sign (pain on passive extension of the right hip) and the obturator sign (pain with passive flexion and internal rotation of the right hip) are indicative of adjacent inflammation and strongly suggestive of appendicitis.

B. Laboratory Findings

Moderate leukocytosis (10,000–20,000/mcL) with neutrophilia is common. Microscopic hematuria and pyuria are present in 25% of patients.

C. Imaging

Both abdominal ultrasound and CT scanning are useful in diagnosing appendicitis as well as excluding other diseases presenting with similar symptoms, including adnexal disease in younger women. However, CT scanning appears to be more accurate (sensitivity 94%, specificity 95%, positive likelihood ratio 13.3, negative likelihood ratio 0.09). Abdominal CT scanning is also useful in cases of suspected appendiceal perforation to diagnose a periappendiceal abscess. In patients in whom there is a clinically high suspicion of appendicitis, some surgeons feel that preoperative diagnostic imaging is unnecessary. However, studies suggest that even in this group, imaging studies suggest an alternative diagnosis in up to 15%.

1. Atypical Presentations of Appendicitis

Owing to the variable location of the appendix, there are a number of “atypical” presentations. Because the retrocecal appendix does not touch the anterior abdominal wall, the pain remains less intense and poorly localized; abdominal tenderness is minimal and may be elicited in the right flank. The psoas sign may be positive. With pelvic appendicitis there is pain in the lower abdomen, often on the left, with an urge to urinate or defecate. Abdominal tenderness is absent, but tenderness is evident on pelvic or rectal examination; the obturator sign may be present. In the elderly, the diagnosis of appendicitis is often delayed because patients present with minimal, vague symptoms and mild abdominal tenderness. Appendicitis in pregnancy may present with pain in the right lower quadrant, periumbilical area, or right subcostal area owing to displacement of the appendix by the uterus.

► Differential Diagnosis

Given its frequency and myriad presentations, appendicitis should be considered in the differential diagnosis of all patients with abdominal pain. It is difficult to reliably diagnose the disease in some cases. A several-hour period of close observation with reassessment usually clarifies the diagnosis. Absence of the classic migration of pain (from the epigastrium to the right lower abdomen), right lower quadrant pain, fever, or guarding makes appendicitis less likely. Ten to 20 percent of patients with suspected appendicitis have either a negative examination at laparotomy or an alternative surgical diagnosis. The widespread use of ultrasonography and CT has reduced the number of incorrect diagnoses. Still, in some cases diagnostic laparotomy or laparoscopy is required. The most common causes of diagnostic confusion are gastroenteritis and gynecologic disorders. Viral gastroenteritis presents with nausea, vomiting, low-grade fever, and diarrhea and can be difficult to distinguish from appendicitis. The onset of vomiting before pain makes appendicitis less likely. As a rule, the pain of gastroenteritis is more generalized and the tenderness less well localized. Acute salpingitis or tubo-ovarian abscess should be considered in young, sexually active women with fever and bilateral abdominal or pelvic tenderness. A twisted ovarian cyst may also cause sudden severe pain. The sudden onset of lower abdominal pain in the middle of the menstrual cycle suggests mittelschmerz. Sudden severe abdominal pain with diffuse pelvic tenderness and shock suggests a ruptured ectopic pregnancy. A positive pregnancy test and pelvic ultrasonography are diagnostic. Retrocecal or retroileal appendicitis (often associated with pyuria or hematuria) may be confused with ureteral colic or pyelonephritis. Other conditions that may resemble appendicitis are diverticulitis, Meckel diverticulitis, carcinoid of the appendix, perforated colonic cancer, Crohn ileitis, perforated peptic ulcer, cholecystitis, and mesenteric adenitis. It is virtually impossible to distinguish appendicitis from Meckel diverticulitis, but both require surgical treatment.

► Complications

Perforation occurs in 20% of patients and should be suspected in patients with pain persisting for over 36

hours, high fever, diffuse abdominal tenderness or peritoneal findings, a palpable abdominal mass, or marked leukocytosis. Localized perforation results in a contained abscess, usually in the pelvis. A free perforation leads to suppurative peritonitis with toxicity. Septic thrombophlebitis (pylephlebitis) of the portal venous system is rare and suggested by high fever, chills, bacteremia, and jaundice.

► Treatment

The treatment of uncomplicated appendicitis is surgical appendectomy. This may be performed through a laparotomy or by laparoscopy. Prior to surgery, patients should be given systemic antibiotics, which reduce the incidence of postoperative wound infections. Emergency appendectomy is also required in patients with perforated appendicitis with generalized peritonitis.

The optimal treatment of stable patients with perforated appendicitis and a contained abscess is controversial. Surgery in this setting can be difficult. Many recommend percutaneous CT-guided drainage of the abscess with intravenous fluids and antibiotics to allow the inflammation to subside. An interval appendectomy may be performed after 6 weeks to prevent recurrent appendicitis.

► Prognosis

The mortality rate from uncomplicated appendicitis is extremely low. Even with perforated appendicitis, the mortality rate in most groups is only 0.2%, though it approaches 15% in the elderly.

Van Randen A et al. Acute appendicitis: meta-analysis of diagnostic performance of CT and graded compression US related to prevalence of disease. *Radiology*. 2008 Oct;249(1):97–106. [PMID: 18682583]

INTESTINAL TUBERCULOSIS

Intestinal tuberculosis is common in underdeveloped countries. Previously rare in the United States, its incidence has been rising in immigrant groups and patients with AIDS. It is caused by both *Mycobacterium tuberculosis* and *M bovis*. Active pulmonary disease is present in less than 50% of patients. The most frequent site of involvement is the ileocecal region; however, any region of the gastrointestinal tract may be involved. Intestinal tuberculosis may cause mucosal ulcerations or scarring and fibrosis with narrowing of the lumen. Patients may be without symptoms or complain of chronic abdominal pain, obstructive symptoms, weight loss, and diarrhea. An abdominal mass may be palpable. Complications include intestinal obstruction, hemorrhage, and fistula formation. The purified protein derivative (PPD) skin test may be negative, especially in patients with weight loss or AIDS. Barium radiography may demonstrate mucosal ulcerations, thickening, or stricture formation. Colonoscopy may demonstrate an ulcerated mass, multiple ulcers with steep edges and adjacent small sessile polyps, small ulcers or erosions, or small diverticula, most commonly in the ileocecal region. The differential diagnosis includes Crohn disease, carcinoma, and intestinal amebiasis. The diagnosis is estab-

lished by either endoscopic or surgical biopsy revealing acid-fast bacilli, caseating granuloma, or positive cultures from the organism. Detection of tubercle bacilli in biopsy specimens by PCR is now the most sensitive means of diagnosis.

Treatment with standard antituberculous regimens is effective.

Rasheed S et al. Intra-abdominal and gastrointestinal tuberculosis. *Colorectal Dis.* 2007 Nov;9(9):773–83. [PMID: 17868413]

PROTEIN-LOSING ENTEROPATHY

Protein-losing enteropathy comprises a number of conditions that result in excessive loss of serum proteins into the gastrointestinal tract. The essential diagnostic features are hypoalbuminemia and an elevated fecal α_1 -antitrypsin level.

The normal intact gut epithelium prevents the loss of serum proteins. Proteins may be lost through one of three mechanisms: (1) mucosal disease with ulceration, resulting in the loss of proteins across the disrupted mucosal surface, such as in chronic gastric ulcer, gastric carcinoma, or inflammatory bowel disease; (2) lymphatic obstruction, resulting in the loss of protein-rich chylous fluid from mucosal lacteals, such as in primary intestinal lymphangiectasia, constrictive pericarditis or congestive heart failure, Whipple disease or tuberculosis, Kaposi sarcoma or lymphoma, retroperitoneal fibrosis, or sarcoidosis; and (3) idiopathic change in permeability of mucosal capillaries and conductance of interstitium, resulting in “weeping” of protein-rich fluid from the mucosal surface, such as in Ménétrier disease, Zollinger-Ellison syndrome, viral or eosinophilic gastroenteritis, celiac disease, giardiasis or hookworm, common variable immunodeficiency, systemic lupus erythematosus, amyloidosis, or allergic protein-losing enteropathy.

Hypoalbuminemia is the sine qua non of protein-losing enteropathy. However, a number of other serum proteins such as α_1 -antitrypsin also are lost from the gut epithelium. In protein-losing enteropathy caused by lymphatic obstruction, loss of lymphatic fluid commonly results in lymphocytopenia ($< 1000/\text{mcL}$), hypoglobulinemia, and hypocholesterolemia.

In most cases, protein-losing enteropathy is recognized as a sequela of a known gastrointestinal disorder. In patients in whom the cause is unclear, evaluation is indicated and is guided by the clinical suspicion. Protein-losing enteropathy must be distinguished from other causes of hypoalbuminemia, which include liver disease and nephrotic syndrome; and from congestive heart failure. Protein-losing enteropathy is confirmed by determining the gut α_1 -antitrypsin clearance (24-hour volume of feces \times stool concentration of α_1 -antitrypsin \div serum α_1 -antitrypsin concentration). A clearance of more than 13 mL/24 h is abnormal.

Laboratory evaluation of protein-losing enteropathy includes serum protein electrophoresis, lymphocyte count, and serum cholesterol to look for evidence of lymphatic obstruction. Serum ANA and C3 levels are useful to screen for autoimmune disorders. Stool samples should be examined for ova and parasites. Evidence of malabsorption is evaluated by means of a stool qualitative fecal fat determi-

nation. Intestinal imaging is performed with small bowel enteroscopy biopsy, CT enterography, or wireless capsule endoscopy of the small intestine. Colonic diseases are excluded with colonoscopy. A CT scan of the abdomen is performed to look for evidence of neoplasms or lymphatic obstruction. Rarely, lymphangiography is helpful. In some situations, laparotomy with full-thickness intestinal biopsy is required to establish a diagnosis.

Treatment is directed at the underlying cause. Patients with lymphatic obstruction benefit from low-fat diets supplemented with medium-chain triglycerides. Case reports suggest that octreotide may lead to symptomatic and nutritional improvement in some patients.

Pungpapong S et al. Protein-losing enteropathy from eosinophilic enteritis diagnosed by wireless capsule endoscopy and double-balloon enteroscopy. *Gastrointest Endosc.* 2007 May;65(6):917–8. [PMID: 17208236]

DISEASES OF THE COLON & RECTUM

IRRITABLE BOWEL SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Chronic functional disorder characterized by abdominal pain or discomfort with alterations in bowel habits.
- ▶ Symptoms usually begin in late teens to early twenties.
- ▶ Limited evaluation to exclude organic causes of symptoms.

▶ General Considerations

The functional gastrointestinal disorders are characterized by a variable combination of chronic or recurrent gastrointestinal symptoms *not explicable by the presence of structural or biochemical abnormalities*. Several clinical entities are included under this broad rubric, including chest pain of unclear origin (noncardiac chest pain), functional dyspepsia, and biliary dyskinesia (sphincter of Oddi dysfunction). There is a large overlap among these entities. For example, over 50% of patients with noncardiac chest pain and over one-third with functional dyspepsia also have symptoms compatible with irritable bowel syndrome. In none of these disorders is there a definitive diagnostic study. Rather, the diagnosis is a subjective one based on the presence of a compatible profile and the exclusion of similar disorders.

Irritable bowel syndrome can be defined, therefore, as an idiopathic clinical entity characterized by chronic (more than 3 months) abdominal pain or discomfort that occurs in association with altered bowel habits. These symptoms may be continuous or intermittent. Consensus definition of irritable bowel syndrome is abdominal discomfort or pain that has two of the following three features: (1) relieved with defecation, (2) onset associated with a change in

frequency of stool, or (3) onset associated with a change in form (appearance) of stool. Other symptoms supporting the diagnosis include abnormal stool frequency; abnormal stool form (lumpy or hard; loose or watery); abnormal stool passage (straining, urgency, or feeling of incomplete evacuation); passage of mucus; and bloating or a feeling of abdominal distention.

Patients may have other somatic or psychological complaints such as dyspepsia, heartburn, chest pain, headaches, fatigue, myalgias, urologic dysfunction, gynecologic symptoms, anxiety, or depression.

The disorder is a common problem presenting to both gastroenterologists and primary care physicians. Up to 10% of the adult population have symptoms compatible with the diagnosis, but most never seek medical attention. Approximately two-thirds of patients with irritable bowel syndrome are women.

► Pathogenesis

A number of pathophysiologic mechanisms have been identified and may have varying importance in different individuals.

A. Abnormal Motility

A variety of abnormal myoelectrical and motor abnormalities have been identified in the colon and small intestine. In some cases, these are temporally correlated with episodes of abdominal pain or emotional stress. Whether they represent a primary motility disorder or are secondary to psychosocial stress is debated. Differences between patients with constipation-predominant and diarrhea-predominant syndromes are reported.

B. Visceral Hypersensitivity

Patients often have a lower visceral pain threshold, reporting abdominal pain at lower volumes of colonic gas insufflation or colonic balloon inflation than controls. Although many patients complain of bloating and distention, their absolute intestinal gas volume is normal. Many patients report rectal urgency despite small rectal volumes of stool.

C. Enteric Infection

Symptoms compatible with irritable bowel syndrome develop within 1 year in up to 10% of patients after an episode of bacterial gastroenteritis compared with less than 2% of controls. Women and patients with increased life stressors at the onset of gastroenteritis appear to be at increased risk for developing “postinfectious” irritable bowel syndrome. Increased inflammatory cells have been found in the mucosa, submucosa, and muscularis of some patients with irritable bowel syndrome, but their importance is unclear. Chronic inflammation is postulated by some investigators to contribute to alterations in motility or visceral hypersensitivity. Some investigators suggest that alterations in the numbers and distribution of bacterial species (estimated 30,000 different species) may affect bowel transit time, gas production, and sensitivity. An increase in breath hydrogen or methane excretion after lactulose inges-

tion in up to 80% of patients with irritable bowel syndrome has been reported, believed to be suggestive of small intestinal bacterial overgrowth, although several investigators dispute these findings. Small bowel bacterial overgrowth may be more likely in patients with bloating, postprandial discomfort, and loose stools. It is hypothesized that bacterial overgrowth may lead to alterations in immune alterations that affect motility or visceral sensitivity or to degradation of carbohydrates in the small intestine could cause increased postprandial gas, bloating, and distention.

D. Psychosocial Abnormalities

More than 50% of patients with irritable bowel who seek medical attention have underlying depression, anxiety, or somatization. By contrast, those who do not seek medical attention are similar psychologically to normal individuals. Psychological abnormalities may influence how the patient perceives or reacts to illness and minor visceral sensations. Chronic stress may alter intestinal motility or modulate pathways that affect central and spinal processing of visceral afferent sensation.

► Clinical Findings

A. Symptoms and Signs

Irritable bowel is a chronic condition. Symptoms usually begin in the late teens to twenties. Symptoms should be present for at least 3 months before the diagnosis can be considered. The diagnosis is established in the presence of compatible symptoms and the judicious use of tests to exclude organic disease.

Abdominal pain usually is intermittent, crampy, and in the lower abdominal region. As previously stated, the onset of pain typically is associated with a change in stool frequency or form and commonly is relieved by defecation. It does not usually occur at night or interfere with sleep. Patients with irritable bowel syndrome may be classified into one of three categories based on the predominant bowel habit: irritable bowel syndrome with diarrhea; irritable bowel syndrome with constipation; or irritable bowel syndrome with mixed constipation and diarrhea. It is important to clarify what the patient means by these complaints. Patients with irritable bowel and constipation report infrequent bowel movements (less than three per week), hard or lumpy stools, or straining. Patients with irritable bowel syndrome with diarrhea refer to loose or watery stools, frequent stools (more than three per day), urgency, or fecal incontinence. Many patients report that they have a firm stool in the morning followed by progressively looser movements. Complaints of visible distention and bloating are common, though these are not always clinically evident.

The patient should be asked about “alarm symptoms” that suggest a diagnosis other than irritable bowel syndrome and warrant further investigation. The acute onset of symptoms raises the likelihood of organic disease, especially in patients aged > 40–50 years. Nocturnal diarrhea, severe constipation or diarrhea, hematochezia, weight loss, and fever are incompatible with a diagnosis of irritable bowel syndrome and warrant investigation for underlying disease.

Patients who have a family history of cancer, inflammatory bowel disease, or celiac disease should undergo additional evaluation.

A physical examination should be performed to look for evidence of organic disease and to allay the patient's anxieties. The physical examination usually is normal. Abdominal tenderness, especially in the lower abdomen, is common but not pronounced. A new onset of symptoms in a patient over age 40 years warrants further examination.

B. Laboratory Findings and Special Examinations

In patients whose symptoms fulfill the diagnostic criteria for irritable bowel syndrome and who have no other alarm symptoms, evidence-based consensus guidelines do not support further diagnostic testing, as the likelihood of serious organic diseases does not appear to be increased. Although the vague nature of symptoms and patient anxiety may prompt clinicians to consider a variety of diagnostic studies, overtesting should be avoided. The use of routine blood tests (complete blood count, chemistry panel, serum albumin, thyroid function tests, erythrocyte sedimentation rate) is unnecessary in most patients. Stool specimen examinations for ova and parasites should be obtained only in patients with increased likelihood of infection (eg, day care workers, campers, foreign travelers). Routine sigmoidoscopy or colonoscopy also are not recommended in young patients with symptoms of irritable bowel syndrome without alarm symptoms but should be considered in patients who do not improve with conservative management. In all patients age 50 years or older who have not had a previous evaluation, colonoscopy should be obtained to exclude malignancy. When colonoscopy is performed, random mucosal biopsies should be obtained to look for evidence of microscopic colitis (which may have similar symptoms). In patients with irritable bowel syndrome with diarrhea, serologic tests for celiac disease may be performed. Pending further clinical studies, routine testing for bacterial overgrowth with hydrogen breath tests are not recommended.

► Differential Diagnosis

A number of disorders may present with similar symptoms. Examples include colonic neoplasia, inflammatory bowel disease (ulcerative colitis, Crohn disease, microscopic colitis), hyperthyroidism or hypothyroidism, parasites, malabsorption (especially celiac disease, bacterial overgrowth, lactase deficiency), causes of chronic secretory diarrhea (carcinoid), and endometriosis. Psychiatric disorders such as depression, panic disorder, and anxiety must be considered as well. Women with refractory symptoms have an increased incidence of prior sexual and physical abuse. These diagnoses should be excluded in patients with presumed irritable bowel syndrome who do not improve within 2–4 weeks of empiric treatment or in whom subsequent alarm symptoms develop.

► Treatment

A. General Measures

As with other functional disorders, the most important interventions the clinician can offer are reassurance, educa-

tion, and support. This includes identifying and responding to the patient's concerns, careful explanation of the pathophysiology and natural history of the disorder, setting realistic treatment goals, and involving the patient in the treatment process. Because irritable bowel symptoms are chronic, the patient's reasons for seeking consultation at this time should be determined. These may include major life events or recent psychosocial stressors, dietary or medication changes, concerns about serious underlying disease, or reduced quality of life and impairment of daily activities. In discussing with the patient the importance of the mind-gut interaction, it may be helpful to explain that alterations in visceral motility and sensitivity may be exacerbated by environmental, social, or psychological factors such as foods, medications, hormones, and stress. Symptoms such as pain, bloating, and altered bowel habits may lead to anxiety and distress, which in turn may further exacerbate bowel disturbances due to disordered communication between the gut and the central nervous system. A symptom diary in which patients record the time and severity of symptoms, food intake, and life events may help uncover aggravating dietary or psychosocial factors. Fears that the symptoms will progress, require surgery, or degenerate into serious illness should be allayed. The patient should understand that irritable bowel syndrome is a chronic disorder characterized by periods of exacerbation and quiescence. The emphasis should be shifted from finding the cause of the symptoms to finding a way to cope with them. Clinicians must resist the temptation to chase chronic complaints with new or repeated diagnostic studies.

B. Dietary Therapy

Patients commonly report dietary intolerances, although a role for dietary triggers in irritable bowel syndrome has never been convincingly demonstrated. Fatty foods and caffeine are poorly tolerated by many patients with irritable bowel syndrome. In patients with diarrhea, bloating, and flatulence, lactose intolerance should be excluded with a breath hydrogen test or a trial of a lactose-free diet. A host of poorly absorbed, fermentable, short-chain carbohydrates may exacerbate bloating, flatulence, and diarrhea in some patients. These include fructose (corn syrups, apples, pears, watermelon, raisins), fructans (onions, leeks, asparagus, artichokes), wheat-based products (breads, pasta, cereals, cakes) sorbitol (stone fruits), and raffinose (legumes, lentils, brussel sprouts, cabbage).

A high-fiber diet and fiber supplements appears to be of little value in patients with irritable bowel syndrome. Many patients report little change in bowel frequency but increased gas and distention.

C. Pharmacologic Measures

More than two-thirds of patients with irritable bowel syndrome have mild symptoms that respond readily to education, reassurance, and dietary interventions. Drug therapy should be reserved for patients with moderate to severe symptoms that do not respond to conservative measures. These agents should be viewed as being adjunctive rather than curative. Given the wide spectrum of symptoms, no

single agent is expected to provide relief in all or even most patients. Nevertheless, therapy targeted at the specific dominant symptom (pain, constipation, or diarrhea) may be beneficial.

1. Antispasmodic agents—Anticholinergic agents are used by some practitioners for treatment of acute episodes of pain or bloating despite a lack of well-designed trials demonstrating efficacy. Available agents include hyoscyamine, 0.125 mg orally (or sublingually as needed) or sustained-release, 0.037 mg or 0.75 mg orally twice daily; dicyclomine, 10–20 mg orally; or methscopolamine 2.5–5 mg orally before meals and at bedtime. Anticholinergic side effects are common, including urinary retention, constipation, tachycardia, and dry mouth. Hence, these agents should be used with caution in the elderly and in patients with constipation. Peppermint oil formulations (which relax smooth muscle) may be helpful.

2. Antidiarrheal agents—Loperamide (2 mg orally three or four times daily) is effective for the treatment of patients with diarrhea, reducing stool frequency, liquidity, and urgency. It may best be used “prophylactically” in situations in which diarrhea is anticipated (such as stressful situations) or would be inconvenient (social engagements).

3. Anticonstipation agents—Treatment with osmotic laxatives (milk of magnesia or polyethylene glycol) may increase stool frequency, improve stool consistency, and reduce straining. Lactulose or sorbitol produces increased flatus and distention, which are poorly tolerated in patients with irritable bowel syndrome. Lubiprostone is a selective chloride C-2 activator that stimulates increased intestinal chloride secretion, which leads to increased stool frequency. Lubiprostone is approved for the treatment of chronic constipation (24 mcg twice daily) as well as for the treatment of women with irritable bowel with constipation (8 mcg twice daily). In clinical trials of patients with irritable bowel syndrome and constipation, lubiprostone led to global symptom improvement in 18% of patients compared with 10% of patients who received placebo. Patients with intractable constipation should undergo further assessment for slow colonic transit and pelvic floor dysfunction (see Constipation, above).

4. Psychotropic agents—Patients with predominant symptoms of pain or bloating may benefit from low doses of tricyclic antidepressants, which are believed to have effects on motility, visceral sensitivity, and central pain perception that are independent of their psychotropic effects. Because of their anticholinergic effects, these agents may be more useful in patients with diarrhea-predominant than constipation-predominant symptoms. Nortriptyline, desipramine, or imipramine, may be started at a low dosage of 10 mg at bedtime and increased gradually to 50–150 mg as tolerated. Response rates do not correlate with dosage, and many patients respond to doses of ≤ 50 mg daily. Side effects are common, and lack of efficacy with one agent does not preclude benefit from another. Improvement should be evident within 4 weeks. The serotonin reuptake inhibitors (sertraline, 50–150 mg daily; citalopram 5–20 mg; paroxetine 10–20 mg daily; or fluoxetine, 20–40 mg daily) may lead

to improvement in overall sense of well-being but have little impact on abdominal pain or bowel symptoms. Anxiolytics should not be used chronically in irritable bowel syndrome because of their habituation potential. Patients with major depression or anxiety disorders should be identified and treated with therapeutic doses of appropriate agents.

5. Serotonin receptor agonists and antagonists—Serotonin is an important mediator of gastrointestinal motility and sensation. Alosetron and tegaserod modulate serotonin pathways. However, in 2007, tegaserod was withdrawn by the FDA from the US market after an analysis of safety data from over 18,000 patients in 29 clinical trials showed an excessive number of serious cardiovascular side effects.

Alosetron is a 5-HT₃ antagonist that is FDA-approved for the treatment of women with severe irritable bowel syndrome with predominant diarrhea. It appears to alter visceral sensation through blockade of peripheral 5-HT₃-receptors on enteric afferent neurons and inhibits enteric cholinergic motor neurons, resulting in inhibition of colonic motility. Alosetron (0.5–1 mg twice daily) reduces symptoms of pain, cramps, urgency, and diarrhea in 50–60% of women compared with 30–40% treated with placebo. Efficacy in men has not been demonstrated. In contrast to the excellent safety profile of other 5-HT₃ antagonists (eg, ondansetron), alosetron may cause constipation (sometimes severe) in 30% of patients or ischemic colitis in 4:1000 patients. Given the seriousness of these side effects, alosetron is restricted to women with severe irritable bowel syndrome with diarrhea who have not responded to conventional therapies and who have been educated about the relative risks and benefits of the agent. It should not be used in patients with constipation.

6. Nonabsorbable antibiotics—A randomized controlled study reported symptom improvement in 40% of patients treated with the nonabsorbable antibiotic rifaximin, 400 mg three times daily for 10 days, compared with a 25% improvement in placebo-treated patients. Improvement persisted over a 10-week follow-up period. Symptom improvement may be attributable to suppression of bacteria in either the small intestine or colon. At this time, the pathologic importance of small intestinal bacterial overgrowth and the therapeutic role of antibiotics in irritable bowel syndrome are controversial. If bacterial overgrowth is suspected, some clinicians may order a lactulose hydrogen breath test to confirm the diagnosis. Others may administer an empiric trial of rifaximin therapy. Still others may choose to defer evaluation or treatment pending further clinical studies.

7. Probiotics—Small controlled clinical trials report improved symptoms in some patients treated with one probiotic, *Bifidobacterium infantis*, but not with another probiotic, *Lactobacillus salivarius*, or placebo. It is hypothesized that alterations in gut flora may reduce symptoms through suppression of inflammation or reduction of bacterial gas production, resulting in reduced distention, flatus, and visceral sensitivity. Such therapy is attractive because it is safe, well tolerated, and inexpensive. A randomized, controlled trial confirmed global symptom improvement in approximately 60% of patients treated with *B infantis* (10⁸

bacteria/capsule once daily), compared with 40% treated with placebo. Although promising, further study is needed to define the efficacy and optimal formulations of probiotic therapy.

D. Psychological Therapies

Cognitive-behavioral therapies, relaxation techniques, and hypnotherapy appear to be beneficial in some patients. Patients with underlying psychological abnormalities may benefit from evaluation by a psychiatrist or psychologist. Patients with severe disability should be referred to a pain treatment center.

► Prognosis

The majority of patients with irritable bowel syndrome learn to cope with their symptoms and lead productive lives.

ANTIBIOTIC-ASSOCIATED COLITIS

ESSENTIALS OF DIAGNOSIS

- Most cases of antibiotic-associated diarrhea are not attributable to *C difficile* and are usually mild and self-limited.
- Symptoms of antibiotic-associated colitis vary from mild to fulminant; almost all colitis is attributable to *C difficile*.
- Diagnosis in mild to moderate cases established by stool toxin assay.
- Flexible sigmoidoscopy provides most rapid diagnosis in severe cases.

► General Considerations

Antibiotic-associated diarrhea is a common clinical occurrence. Characteristically, the diarrhea occurs during the period of antibiotic exposure, is dose related, and resolves spontaneously after discontinuation of the antibiotic. In most cases, this diarrhea is mild, self-limited, and does not require any specific laboratory evaluation or treatment. Stool examination usually reveals no fecal leukocytes, and

stool cultures reveal no pathogens. Although *C difficile* is identified in the stool of 15–25% of cases of antibiotic-associated diarrhea, it is also identified in 5–10% of patients treated with antibiotics who do not have diarrhea. Most cases of antibiotic-associated diarrhea are due to changes in colonic bacterial fermentation of carbohydrates and are not due to *C difficile*.

Antibiotic-associated colitis is a significant clinical problem almost always caused by *C difficile* infection. Hospitalized patients are most susceptible, especially those who are severely ill or malnourished or who are receiving chemotherapy. *C difficile*-colitis is the major cause of diarrhea in patients hospitalized for more than 3 days, affecting 22 patients of every 1000. This anaerobic bacterium colonizes the colon of 3% of healthy adults. It is acquired by fecal-oral transmission. Found throughout hospitals in patient rooms and bathrooms, it is readily transmitted from patient to patient by hospital personnel. Fastidious hand washing and use of disposable gloves are helpful in minimizing transmission. *C difficile* is acquired in approximately 20% of hospitalized patients, most of whom have received antibiotics that disrupt the normal bowel flora and thus allow the bacterium to flourish. Although almost all antibiotics have been implicated, colitis most commonly develops after use of ampicillin, clindamycin, third-generation cephalosporins, and fluoroquinolones. *C difficile*-colitis will develop in approximately one-third of infected patients. Symptoms usually begin during or shortly after antibiotic therapy but may be delayed for up to 8 weeks. All patients with acute diarrhea should be asked about recent antibiotic exposure. Patients who are elderly, debilitated, immunocompromised, receiving multiple antibiotics or prolonged (> 10 days) antibiotic therapy, receiving enteral tube feedings or proton pump inhibitors, or who have gastrointestinal tract disease or surgery have a higher risk of acquiring *C difficile* and developing *C difficile*-associated diarrhea.

The incidence and severity of *C difficile*-colitis in hospitalized patients appear to be increasing, which is attributable to the emergence of a more virulent strain of *C difficile* (BI/NAP1) that contains an 18-base pair deletion of the *tcdC* gene, resulting in 10-fold higher toxin A and B production. This toxin-gene variant strain has been associated with several hospital outbreaks. The 30-day mortality attributed to infection with this strain is 7% but is 14% in the elderly. A recent placebo-controlled study demonstrated that prophylactic administration of probiotics (containing *Lactobacillus casei*, *Lactobacillus bulgaricus*, and *Streptococcus thermophilus*) to hospitalized patients who are receiving antibiotics reduced the incidence of *C difficile*-associated diarrhea from 34% to 12%.

► Clinical Findings

A. Symptoms and Signs

Most patients report mild to moderate greenish, foul-smelling watery diarrhea with lower abdominal cramps. Physical examination is normal or reveals mild left lower quadrant tenderness. With more serious illness, there is abdominal pain and profuse watery diarrhea with up to 30 stools per day. The stools may have mucus but seldom

gross blood. There may be fever up to 40 °C, abdominal tenderness, and leukocytosis as high as 50,000/mcL. *C difficile*-colitis should be considered in all hospitalized patients with unexplained leukocytosis. In most patients, colitis is most severe in the distal colon and rectum. When colitis is more severe in the right side of the colon, there may be little or no diarrhea. In such cases, fever, abdominal distention, pain and tenderness, and leukocytosis suggest the presence of infection.

B. Special Examinations

1. Stool studies—Pathogenic strains of *C difficile* produce two toxins: toxin A is an enterotoxin and toxin B is a cytotoxin. In most patients, the diagnosis of antibiotic-associated colitis is established by the demonstration of *C difficile* toxins in the stool. A cytotoxicity assay (toxin B) performed in cell cultures has a specificity of 90% and a sensitivity of 95%. This is the definitive test, but it is expensive and results are not available for 24–48 hours. Rapid enzyme immunoassays (EIA) (2–4 hours) for toxins A and B are now widely used and have an 80–90% sensitivity with a single stool specimen but > 90% with two specimens. Some toxic strains of *C difficile* do not produce a functional toxin A (and therefore have a negative EIA); therefore, testing for toxin A and B is preferred. When *C difficile* is suspected but the EIA is negative, a cytotoxicity assay should be performed. Culture for *C difficile* is the most sensitive test, but 25% of isolates are not pathogenic. Because it is slower (2–3 days), more costly, and less specific than toxin assays, it is not used in most clinical settings. Fecal leukocytes are present in only 50% of patients with colitis.

2. Flexible sigmoidoscopy—Flexible sigmoidoscopy is performed in patients with more severe symptomatology when a rapid diagnosis is desired so that therapy can be initiated. In patients with mild to moderate symptoms, there may be no abnormalities or only patchy or diffuse, nonspecific colitis indistinguishable from other causes. In patients with severe illness, true **pseudomembranous colitis** is seen. This has a characteristic appearance, with yellow adherent plaques 2–10 mm in diameter scattered over the colonic mucosa interspersed with hyperemic mucosa. Biopsies reveal epithelial ulceration with a classic “volcano” exudate of fibrin and neutrophils. In 10% of cases, pseudomembranous colitis is confined to the proximal colon and may be missed at sigmoidoscopy.

3. Imaging studies—Abdominal radiographs are obtained in patients with fulminant symptoms to look for evidence of toxic dilation or megacolon but are of no value in mild disease. Mucosal edema or “thumbprinting” may be evident. Abdominal CT scan may be very useful in detecting colonic edema, especially in patients with predominantly right-sided colitis or abdominal pain without significant diarrhea (in whom the diagnosis may be unsuspected). CT scanning is also useful in the evaluation of possible complications.

► Differential Diagnosis

In the hospitalized patient in whom acute diarrhea develops after admission, the differential diagnosis includes

simple antibiotic-associated diarrhea (not related to *C difficile*), enteral feedings, medications, and ischemic colitis. Other infectious causes are unusual in hospitalized patients in whom diarrhea develops more than 72 hours after admission, and it is not cost-effective to obtain stool cultures unless tests for *C difficile* are negative. Rarely, other organisms (staphylococci, *Clostridium perfringens*) have been associated with pseudomembranous colitis. *Klebsiella oxytoca* may cause a distinct form of antibiotic-associated hemorrhagic colitis that is segmental (usually in the right or transverse colon); spares the rectum; and is more common in younger, healthier outpatients.

► Complications

Fulminant disease may result in dehydration, electrolyte imbalance, toxic megacolon, perforation, and death. Chronic untreated colitis may result in weight loss and protein-losing enteropathy.

► Treatment

A. Immediate Treatment

If possible, antibiotic therapy should be discontinued and therapy with metronidazole or vancomycin should be initiated. For patients with mild disease, metronidazole, 500 mg orally three times daily or 250 mg orally four times daily, or vancomycin, 125 mg orally four times daily, are equally effective for initial treatment. Vancomycin is significantly more expensive than metronidazole and promotes the emergence of vancomycin-resistant hospital-associated infections. Therefore, metronidazole remains the preferred first-line therapy in most patients, while vancomycin should be reserved for patients who are intolerant of metronidazole, pregnant women, children, and patients who do not respond to metronidazole. The duration of initial therapy is usually 10–14 days. However, in patients requiring long-term systemic antibiotics, it may be appropriate to continue therapy until the antibiotics can be discontinued. Symptomatic improvement occurs in most patients within 72 hours.

For patients with severe disease, vancomycin, 125 mg orally four times daily, is the preferred agent because it achieves significantly higher response rates (97%) than metronidazole (76%). In patients who are unable to take oral medications due to ileus or who do not respond to oral vancomycin and in severely ill patients (marked leukocytosis, acute kidney injury, hypotension), intravenous metronidazole, 500 mg every 6 hours, should be given—supplemented by oral vancomycin administered per nasogastric tube or enema. Intravenous vancomycin does not penetrate the bowel and should not be used. Total abdominal colectomy may be required in patients with toxic megacolon, perforation, sepsis, or hemorrhage.

B. Treatment of Relapse

Up to 20% of patients have a relapse of diarrhea from *C difficile* within 1 or 2 weeks after stopping initial therapy. This may be due to reinfection or failure to eradicate the organism. Most relapses respond promptly to a second

course of metronidazole therapy. Some patients have recurrent relapses that can be difficult to treat. The optimal treatment regimen for recurrent relapses is unknown. Many authorities recommend a 7-week tapering regimen of vancomycin (125 mg orally four times daily for 14 days; twice daily for 7 days; once daily for 7 days; every other day for 7 days; and every third day for 14 days). Controlled trials show that oral administration of a live yeast, *Saccharomyces boulardii*, 500 mg twice daily, reduces the incidence of relapse by 50%. Probiotic therapy with this agent is recommended as adjunctive therapy in patients with relapsing disease.

INFLAMMATORY BOWEL DISEASE

The term “inflammatory bowel disease” includes ulcerative colitis and Crohn disease. Ulcerative colitis is a chronic, recurrent disease characterized by diffuse mucosal inflammation involving only the colon. Ulcerative colitis invariably involves the rectum and may extend proximally in a continuous fashion to involve part or all of the colon. Crohn disease is a chronic, recurrent disease characterized by patchy transmural inflammation involving any segment of the gastrointestinal tract from the mouth to the anus.

Crohn disease and ulcerative colitis may be associated in 50% of patients with a number of extraintestinal manifestations, including oral ulcers, oligoarticular or polyarticular nondeforming peripheral arthritis, spondylitis or sacroiliitis, episcleritis or uveitis, erythema nodosum, pyoderma gangrenosum, hepatitis and sclerosing cholangitis, and thromboembolic events.

▶ Drug Therapy

Although ulcerative colitis and Crohn disease appear to be distinct entities, the same pharmacologic agents are used to treat both. Despite extensive research, there are still no specific therapies for these diseases. The mainstays of therapy are 5-aminosalicylic acid derivatives, corticosteroids, immunomodulating agents (such as mercaptopurine or azathioprine), methotrexate, and biologic agents.

A. 5-Aminosalicylic Acid (5-ASA)

5-ASA is a topically active agent that has a variety of anti-inflammatory effects. It is used in the active treatment of ulcerative colitis and Crohn disease and during disease inactivity to maintain remission. It is readily absorbed from the small intestine but demonstrates minimal colonic

absorption. A number of oral and topical compounds have been designed to target delivery of 5-ASA to the colon or small intestine while minimizing absorption. Commonly used formulations of 5-ASA are sulfasalazine, mesalamine, and azo compounds. Side effects of these compounds are uncommon but include nausea, rash, diarrhea, pancreatitis, and acute interstitial nephritis.

1. Oral mesalamine agents—These 5-ASA agents are coated in various pH-sensitive resins (Asacol and Lialda) or packaged in timed-release capsules (Pentasa). Pentasa releases 5-ASA slowly throughout the small intestine and colon. Asacol and Lialda tablets dissolve at pH 7.0, releasing 5-ASA in the terminal small bowel and proximal colon. Lialda has a multi-matrix system that gradually releases 5-ASA throughout the colon.

2. Azo compounds—Sulfasalazine, balsalazide and olsalazine contain 5-ASA linked by an azo bond that requires cleavage by colonic bacterial azoreductases to release 5-ASA. Absorption of these drugs from the small intestine is negligible. After release within the colon, the 5-ASA works topically and is largely unabsorbed. Olsalazine contains two 5-ASA molecules connected by the azo bond. Balsalazide contains 5-ASA linked to an inert carrier (4-aminobenzoyl-β-alanine).

Sulfasalazine contains 5-ASA linked to a sulfapyridine moiety. It is unclear whether the sulfapyridine group has any anti-inflammatory effects. One gram of sulfasalazine contains 400 mg of 5-ASA. The sulfapyridine group, however, is absorbed and may cause side effects in 15–30% of patients—much higher than with other 5-ASA compounds. Dose-related side effects include nausea, headaches, leukopenia, oligospermia, and impaired folate metabolism. Allergic and idiosyncratic side effects are fever, rash, hemolytic anemia, neutropenia, worsened colitis, hepatitis, pancreatitis, and pneumonitis. Because of its side effects, sulfasalazine is less frequently used than other 5-ASA agents. It should always be administered in conjunction with folate. Eighty percent of patients intolerant of sulfasalazine can tolerate mesalamine.

3. Topical mesalamine—5-ASA is provided in the form of suppositories (Canasa; 1000 mg) and enemas (Rowasa; 4 g/60 mL). These formulations can deliver much higher concentrations of 5-ASA to the distal colon than oral compounds. Side effects are uncommon.

B. Corticosteroids

A variety of intravenous, oral, and topical corticosteroid formulations have been used in inflammatory bowel disease. They have utility in the short-term treatment of moderate to severe disease. However, long-term use is associated with serious, potentially irreversible side effects and is to be avoided. The agents, route of administration, duration of use, and tapering regimens used are based more on personal bias and experience than on data from rigorous clinical trials. The most commonly used intravenous formulations have been hydrocortisone or methylprednisolone, which are given by continuous infusion or every 6 hours. Oral formulations are prednisone or meth-

yprednisolone. Adverse events commonly occur during short-term systemic corticosteroid therapy, including mood changes, insomnia, dyspepsia, weight gain, edema, elevated serum glucose levels, acne, and moon facies. Side effects of long-term use include osteoporosis, osteonecrosis of the femoral head, myopathy, cataracts, and susceptibility to infections. Calcium and vitamin D supplementation should be administered to all patients receiving long-term corticosteroid therapy. Bone densitometry should be considered in patients with inflammatory bowel disease with other risk factors for osteoporosis and in all patients requiring long-term corticosteroids. Topical preparations are provided as hydrocortisone suppositories (100 mg), foam (90 mg), and enemas (100 mg). Budesonide is an oral glucocorticoid with high topical anti-inflammatory activity but low systemic activity due to high first-pass hepatic metabolism. A controlled-release formulation is available (Entocort) that targets delivery to the terminal ileum and proximal colon. It produces less suppression of the hypothalamic-pituitary-adrenal axis and fewer steroid-related side effects than hydrocortisone or prednisone.

C. Immunomodulating Drugs: Mercaptopurine, Azathioprine, or Methotrexate

Mercaptopurine and azathioprine are thiopurine drugs that are used in many patients with Crohn disease and ulcerative colitis who are corticosteroid-dependent in an attempt to reduce or withdraw the corticosteroids and to maintain patients in remission. Azathioprine is converted *in vivo* to mercaptopurine. It is believed that the active metabolite of mercaptopurine is 6-thioguanine. Monitoring of 6-thioguanine levels is performed in some clinical settings but is of unproven value in the management of most patients. Side effects of mercaptopurine and azathioprine, including allergic reactions (fever, rash, or arthralgias) and nonallergic reactions (nausea, vomiting, pancreatitis, hepatotoxicity, bone marrow suppression, infections, and a higher risk of lymphoma), occur in 15% of patients.

Three competing enzymes are involved in the metabolism of mercaptopurine to its active (6-thioguanine) and inactive metabolites. About 1 person in 300 has a homozygous mutation of one of the enzymes that metabolizes thiopurine methyltransferase (TPMT), placing them at risk for profound immunosuppression; 1 person in 9 is heterozygous for TPMT, resulting in intermediate enzyme activity. Measurement of TPMT functional activity is recommended prior to initiation of therapy. Treatment should be withheld in patients with absent TPMT activity. The most effective dose of mercaptopurine is 1–1.5 mg/kg or of azathioprine is 2–3 mg/kg daily. For patients with normal TPMT activity, both drugs may be initiated at the weight-calculated dose. A complete blood count should be obtained weekly for 4 weeks, biweekly for 4 weeks, and then every 1–3 months for the duration of therapy. Liver function tests should be measured periodically. Some clinicians prefer gradual dose-escalation, especially for patients with intermediate TPMT activity or in whom TPMT measurement is not available; both drugs may be started at 25 mg/d and increased by 25 mg every 1–2 weeks while monitoring

for myelosuppression until the target dose is reached. If the white blood count falls below 3000–4000/mcL or the platelet count falls below 100,000/mcL, the medication should be held for at least 1 week before reducing the daily dose by 25–50 mg.

Methotrexate is used in the treatment of patients with inflammatory bowel disease, especially patients with Crohn disease who are intolerant of mercaptopurine. Methotrexate is an analog of dihydrofolic acid. Although at high doses it interferes with cell proliferation through inhibition of nucleic acid metabolism, at low doses it has anti-inflammatory properties, including inhibition of expression of tumor necrosis factor- α (TNF- α) in monocytes and macrophages. Methotrexate may be given intramuscularly, subcutaneously, or orally. Side effects of methotrexate include nausea, vomiting, stomatitis, infections, bone marrow suppression, hepatic fibrosis, and life-threatening pneumonitis. A complete blood count and liver function tests should be monitored every 1–3 months. Folate supplementation (1 mg/d) should be administered.

D. Biologic Therapies

Although the etiology of inflammatory bowel disorders is uncertain, it appears that an abnormal response of the mucosal innate immune system to luminal bacteria may trigger inflammation, which is perpetuated by dysregulation of cellular immunity. A number of biologic therapies are available or in clinical testing that more narrowly target various components of the immune system. Biologic agents are highly effective for patients with corticosteroid-dependent or refractory disease and potentially may improve the natural history of disease. The potential benefits of these agents, however, must be carefully weighed with their high cost and risk of serious and potentially life-threatening side effects.

1. Anti-TNF therapies—A dysregulation of the T_H1 T cell response is present in some patients with inflammatory bowel disease, especially Crohn disease. TNF is one of the key proinflammatory cytokines in the T_H1 response. TNF exists in two biologically active forms: a soluble form (sTNF), which is enzymatically cleaved from its cell surface, and membrane-bound precursor (tmTNF). When either form binds to the TNF-receptors on effector cells, they initiate a variety of signaling pathways that lead to inflammatory gene activation. Three monoclonal antibodies to TNF currently are available for the treatment of inflammatory bowel disease: infliximab, adalimumab, and certolizumab. All three agents bind and neutralize soluble as well as membrane-bound TNF on macrophages and activated T lymphocytes, thereby preventing TNF stimulation of effector cells. When bound to membrane-associated TNF, infliximab and adalimumab may also cause apoptosis and cell lysis of TNF-producing cells.

Infliximab is a chimeric (75% human/25% mouse) IgG₁ antibody that is administered by intravenous infusion. A three-dose regimen of 5 mg/kg administered at 0, 2, and 6 weeks is recommended for acute induction, followed by infusions every 8 weeks for maintenance therapy. Acute

infusion reactions occur in 5–10% of infusions but occur less commonly in patients receiving regularly scheduled infusions or concomitant immunomodulators (ie, azathioprine or methotrexate). Most reactions are mild or moderate (nausea; headache; dizziness; urticaria; diaphoresis; or mild cardiopulmonary symptoms that include chest tightness, dyspnea, or palpitations) and can be treated by slowing the infusion rate and administering acetaminophen and diphenhydramine. Severe reactions (hypotension, severe shortness of breath, rigors, severe chest discomfort) occur in less than 1% and may require oxygen, diphenhydramine, hydrocortisone, and epinephrine. Delayed serum sickness-like reactions occur in 1%. With repeated, intermittent intravenous injections, antibodies to infliximab develop in up to 40% of patients, which are associated with a shortened duration or loss of response and increased risk of acute or delayed infusion reactions. Giving infliximab in a regularly scheduled maintenance therapy (eg, every 8 weeks), concomitant use of infliximab with other immunomodulating agents (azathioprine, mercaptopurine, or methotrexate), or preinfusion treatment with corticosteroids (intravenous hydrocortisone 200 mg) significantly reduces the development of antibodies to approximately 10%.

Adalimumab is a fully human IgG₁ antibody that is administered by subcutaneous injection. A dose of 160 mg at week 0 and 80 mg at week 2 is recommended for acute induction, followed by maintenance therapy with 40 mg subcutaneously every other week. Certolizumab is a fusion compound in which the Fab1 portion of a chimeric (95% human/5% mouse) TNF-antibody is bound to polyethylene glycol in order to prolong the drug half-life. Because it lacks an Fc portion, it does not induce apoptosis, complement activation, or lysis of macrophages and activated T lymphocytes. A dose of 400 mg at weeks 0, 2, and 4 is recommended for acute induction, followed by maintenance therapy every 4 weeks with 400 mg. Both adalimumab and certolizumab are administered subcutaneously. Injection site reactions (burning, pain, redness, itching) are relatively common but are usually minor and self-limited. Because of their subcutaneous route of injection, acute and delayed hypersensitivity reactions are rare. Antibodies to adalimumab develop in 5% of patients and to certolizumab in 10%, which may lead to shortened duration or loss of response to the drug.

Serious infections with anti-TNF therapies may occur in 2–5% of patients, including sepsis, pneumonia, abscess, and cellulitis; however, controlled studies suggest the increased risk may be attributable to increased severity of disease and concomitant use of corticosteroids. Patients treated with anti-TNF therapies are at increased risk for the development of bacterial infections, tuberculosis, mycoses (candidiasis, histoplasmosis, coccidiomycosis, nocardiosis), reactivation of hepatitis B, and other opportunistic infections. Prior to use of these agents, patients should be screened for latent tuberculosis with PPD testing and a chest radiograph. Antinuclear and anti-DNA antibodies occur in a large percentage of patients; however, the development of drug-induced lupus is rare. All agents may cause severe hepatic reactions leading to acute hepatic failure; liver enzymes should be monitored routinely dur-

ing therapy. Although there are conflicting data, some studies suggest that anti-TNF therapies increase the risk of malignancies, especially non-Hodgkin lymphoma and non-melanoma skin cancer. Rare cases of optic neuritis and demyelinating diseases, including multiple sclerosis have been reported. Anti-TNF therapies may worsen congestive heart failure in patients with cardiac disease.

2. Anti-Integrins—Natalizumab is a humanized monoclonal antibody targeted against α_4 -integrins, heterodimeric glycoproteins on circulating immune cells that are involved with adhesion to and migration through the vascular endothelium into sites of inflammation. By binding to α_4 -integrins, natalizumab may decrease the trafficking of circulating leukocytes through the vasculature and reduce chronic inflammation. In clinical trials, natalizumab was efficacious for the induction and maintenance of response and remission in patients with Crohn disease. Natalizumab was approved in 2008 for the treatment of patients with Crohn disease who had not responded to other therapies. However, due to an increased incidence of progressive multifocal leukoencephalopathy caused by reactivation of the JC virus, it is no longer available from the manufacturer for the treatment of Crohn disease.

▶ Social Support for Patients

Inflammatory bowel disease is a lifelong illness that can have profound emotional and social impacts on the individual. Patients should be encouraged to become involved in the Crohn's and Colitis Foundation of America (CCFA). National headquarters may be contacted at 444 Park Avenue South, 11th Floor, New York, NY 10016-7374; phone 212-685-3440. Internet address: <http://www.cffa.org>.

1. Crohn Disease

ESSENTIALS OF DIAGNOSIS

- ▶ Insidious onset.
- ▶ Intermittent bouts of low-grade fever, diarrhea, and right lower quadrant pain.
- ▶ Right lower quadrant mass and tenderness.
- ▶ Perianal disease with abscess, fistulas.
- ▶ Radiographic evidence of ulceration, stricturing, or fistulas of the small intestine or colon.

▶ General Considerations

One-third of cases of Crohn disease involve the small bowel only, most commonly the terminal ileum (ileitis). Half of all cases involve the small bowel and colon, most often the terminal ileum and adjacent proximal ascending colon (ileocolitis). In 20% of cases, the colon alone is affected. One-third of patients have associated perianal disease (fistulas, fissures, abscesses). Less than 5% of patients have symptomatic involvement of the upper intestinal tract. Unlike ulcerative colitis, Crohn disease is a transmural process that can result in mucosal inflammation and ulceration, stricturing, fistula development, and abscess formation. Cigarette smoking is strongly associated with the development of Crohn disease, resistance to medical therapy, and early disease relapse.

▶ Clinical Findings

A. Symptoms and Signs

Because of the variable location of involvement and severity of inflammation, Crohn disease may present with a variety of symptoms and signs. In eliciting the history, the clinician should take particular note of fevers, the patient's general sense of well-being, weight loss, the presence of abdominal pain, the number of liquid bowel movements per day, and prior surgical resections. Physical examination should focus on the patient's temperature, weight, and nutritional status, the presence of abdominal tenderness or an abdominal mass, rectal examination, and extraintestinal manifestations (described below). Most commonly, there is one or a combination of the following clinical constellations.

1. Chronic inflammatory disease—This is the most common presentation and is often seen in patients with ileitis or ileocolitis. Patients report low-grade fever, malaise, weight loss, and loss of energy. In patients with ileitis or ileocolitis, there may be diarrhea, which is usually nonbloody and often intermittent. In patients with colitis involving the rectum or left colon, there may be bloody diarrhea and fecal urgency, which may mimic the symptoms of ulcerative colitis. Cramping or steady right lower quadrant or periumbilical pain is common. Physical examination reveals focal tenderness, usually in the right lower quadrant. A palpable, tender mass that represents thickened or matted loops of inflamed intestine may be present in the lower abdomen.

2. Intestinal obstruction—Narrowing of the small bowel may occur as a result of inflammation, spasm, or fibrotic stenosis. Patients report postprandial bloating, cramping pains, and loud borborygmi. This may occur in patients with active inflammatory symptoms (as above) or later in the disease from chronic fibrosis without other systemic symptoms or signs of inflammation.

3. Penetrating disease and fistulae—Sinus tracts that penetrate through the bowel, where they may be contained or form fistulas to adjacent structures, develop in a subset of patients. Penetration through the bowel can result in an intra-abdominal or retroperitoneal phlegmon or abscess manifested by fevers, chills, a tender abdominal mass, and leukocytosis. Fistulas between the small intestine and colon

commonly are asymptomatic but can result in diarrhea, weight loss, bacterial overgrowth, and malnutrition. Fistulas to the bladder produce recurrent infections. Fistulas to the vagina result in malodorous drainage and problems with personal hygiene. Fistulas to the skin usually occur at the site of surgical scars.

4. Perianal disease—One-third of patients with either large or small bowel involvement develop perianal disease manifested by large painful skin tags, anal fissures, perianal abscesses, and fistulas.

5. Extraintestinal manifestations—Extraintestinal manifestations may be seen with both Crohn disease and ulcerative colitis. These include arthralgias, arthritis, iritis or uveitis, pyoderma gangrenosum (Plate 68), or erythema nodosum. Oral aphthous lesions are common. There is an increased prevalence of gallstones due to malabsorption of bile salts from the terminal ileum. Nephrolithiasis with urate or calcium oxalate stones may occur.

B. Laboratory Findings

There is a poor correlation between laboratory studies and the patient's clinical picture. Laboratory values may reflect inflammatory activity or nutritional complications of disease. A complete blood count and serum albumin should be obtained in all patients. Anemia may reflect chronic inflammation, mucosal blood loss, iron deficiency, or vitamin B₁₂ malabsorption secondary to terminal ileal inflammation or resection. Leukocytosis may reflect inflammation or abscess formation or may be secondary to corticosteroid therapy. Hypoalbuminemia may be due to intestinal protein loss (protein-losing enteropathy), malabsorption, bacterial overgrowth, or chronic inflammation. The sedimentation rate or C-reactive protein level is elevated in many patients during active inflammation. Fecal lactoferrin or calprotectin levels also are increased in patients with intestinal inflammation. Stool specimens are sent for examination for routine pathogens, ova and parasites, leukocytes, fat, and *C difficile* toxin.

C. Special Diagnostic Studies

In most patients, the initial diagnosis of Crohn disease is based on a compatible clinical picture with supporting endoscopic, pathologic, and radiographic findings. Colonoscopy usually is performed first to evaluate the colon and terminal ileum and to obtain mucosal biopsies. Typical endoscopic findings include aphthoid, linear or stellate ulcers, strictures, and segmental involvement with areas of normal-appearing mucosa adjacent to inflamed mucosa. In 10% of cases, it may be difficult to distinguish ulcerative colitis from Crohn disease. Granulomas on biopsy are present in less than 25% of patients but are highly suggestive of Crohn disease. CT or MR enterography or a barium upper gastrointestinal series with small bowel follow-through often is obtained in patients with suspected small bowel involvement. Suggestive findings include ulcerations, strictures, and fistulas; in addition, CT or MR enterography may identify bowel wall thickening and vascularity, mucosal enhancement, and fat stranding. Capsule imaging may help establish a diagnosis when clinical suspicion for small bowel involvement is high but radio-

graphs are normal or nondiagnostic. When the diagnosis remains uncertain, a panel of seven tests that measure autoantibodies to P-ANCA as well as antibodies to the yeast *Saccharomyces cerevisiae*, to the outer membrane porin C of *E coli*, and to the bacterial flagellin Cbir1 (Prometheus IBD Serology 7) is marketed as being 92% accurate for diagnosing inflammatory bowel disease and for distinguishing between Crohn disease and ulcerative colitis. While intriguing, the data supporting these claims are unpublished and independent confirmation is needed before this panel can be recommended in routine clinical practice.

► Complications

A. Abscess

The presence of a tender abdominal mass with fever and leukocytosis suggests an abscess. Emergent CT of the abdomen is necessary to confirm the diagnosis. Patients should be given broad-spectrum antibiotics. Percutaneous drainage or surgery is usually required.

B. Obstruction

Small bowel obstruction may develop secondary to active inflammation or chronic fibrotic stricturing and is often acutely precipitated by dietary indiscretion. Patients should be given intravenous fluids with nasogastric suction. Systemic corticosteroids are indicated in patients with symptoms or signs of active inflammation but are unhelpful in patients with inactive, fixed disease. Patients unimproved on medical management require surgical resection of the stenotic area or stricturoplasty.

C. Abdominal and Rectovaginal Fistulas

Many fistulas are asymptomatic and require no specific therapy. Most symptomatic fistulas eventually require surgical therapy; however, medical therapy is effective in a subset of patients and is usually tried first in outpatients who otherwise are stable. Large abscesses associated with fistulas require percutaneous or surgical drainage. After percutaneous drainage, long-term antibiotics are administered in order to reduce recurrent infections until the fistula is closed or surgically resected. Fistulas may close temporarily in response to TPN or oral elemental diets but recur when oral feedings are resumed. Immunomodulating agents heal fistulas in one-third of patients within 3–6 months. For fistulas that do not close with immunomodulators, anti-TNF agents may promote closure in up to 60% within 10 weeks; however, relapse occurs in over one-half of patients within 1 year despite continued therapy. Surgical therapy is required for symptomatic fistulas that do not respond to medical therapy. Fistulas that arise above (proximal to) areas of intestinal stricturing commonly require surgical treatment.

D. Perianal Disease

Patients with fissures, fistulas, and skin tags commonly have perianal discomfort. Successful treatment of active intestinal disease also may improve perianal disease. Specific treatment of perianal disease can be difficult and is best

approached jointly with a surgeon with an expertise in colorectal disorders. Pelvic MRI and endoscopic ultrasonography are the best noninvasive studies for evaluating perianal fistulas. Patients should be instructed on proper perianal skin care, including gentle wiping with a premoistened pad (baby wipes) followed by drying with a cool hair dryer, daily cleansing with sitz baths or a water wash, and use of perianal cotton balls or pads to absorb drainage. Oral antibiotics (metronidazole, 250 mg three times daily, or ciprofloxacin, 500 mg twice daily) may promote symptom improvement or healing in patients with fissures or uncomplicated fistulas; however, recurrent symptoms are common. Refractory fissures may benefit from mesalamine suppositories or topical 0.1% tacrolimus ointment. Immunomodulators or anti-TNF agents or both promote short-term symptomatic improvement from anal fistulas in two-thirds of patients and complete closure in up to one-half of patients; however, less than one-third maintain symptomatic remission during long-term maintenance treatment.

Anorectal abscesses should be suspected in patients with severe, constant perianal pain, or perianal pain in association with fever. Superficial abscesses are evident on perianal examination, but deep perirectal abscesses may be detected by digital examination or pelvic CT scan. Depending on the abscess location, surgical drainage may be achieved by incision, or catheter or seton placement. Surgery should be considered for patients with severe, refractory symptoms but is best approached after medical therapy of the Crohn disease has been optimized.

E. Carcinoma

Patients with colonic Crohn disease are at increased risk for developing colon carcinoma; hence, screening colonoscopy to detect dysplasia or cancer is recommended for patients with a history of 8 or more years of Crohn colitis. Patients with Crohn disease have an increased risk of lymphoma and of small bowel adenocarcinoma; however, both are rare.

F. Hemorrhage

Unlike ulcerative colitis, severe hemorrhage is unusual in Crohn disease.

G. Malabsorption

Malabsorption may arise after extensive surgical resections of the small intestine and from bacterial overgrowth in patients with enterocolonic fistulas, strictures, and stasis resulting in bacterial overgrowth.

► Differential Diagnosis

Chronic cramping abdominal pain and diarrhea are typical of both irritable bowel syndrome and Crohn disease, but x-ray examinations are normal in the former. Acute fever and right lower quadrant pain may resemble appendicitis or *Yersinia enterocolitica* enteritis. Intestinal lymphoma causes fever, pain, weight loss, and abnormal small bowel radiographs that may mimic Crohn disease. Patients with undiagnosed AIDS may present with fever and diarrhea. Seg-

mental colitis may be caused by tuberculosis, *E histolytica*, *Chlamydia*, or ischemic colitis. *C difficile* or CMV infection may develop in patients with inflammatory bowel disease, mimicking disease recurrence. Diverticulitis with abscess formation may be difficult to distinguish acutely from Crohn disease. NSAIDs may exacerbate inflammatory bowel disease and may also cause NSAID-induced colitis characterized by small bowel or colonic ulcers, erosion, or strictures that tend to be most severe in the terminal ileum and right colon.

► Treatment of Active Disease

Crohn disease is a chronic lifelong illness characterized by exacerbations and periods of remission. As no specific therapy exists, current treatment is directed toward symptomatic improvement and controlling the disease process. The treatment must address the specific problems of the individual patient. All patients with Crohn disease should be counseled to discontinue cigarettes.

A. Nutrition

1. Diet—Patients should eat a well-balanced diet with as few restrictions as possible. Eating smaller but more frequent meals may be helpful. Patients with diarrhea should be encouraged to drink fluids to avoid dehydration. Many patients report that certain foods worsen symptoms, especially fried or greasy foods. Because lactose intolerance is common, a trial off dairy products is warranted if flatulence or diarrhea is a prominent complaint. Patients with obstructive symptoms should be placed on a low-roughage diet, ie, no raw fruits or vegetables, popcorn, nuts, etc. Resection of more than 100 cm of terminal ileum results in fat malabsorption for which a low-fat diet is recommended. Parenteral vitamin B₁₂ (100 mcg intramuscularly per month) commonly is needed for patients with previous ileal resection or extensive terminal ileal disease.

2. Enteral therapy—Supplemental enteral therapy via nasogastric tube may be required for children and adolescents with poor intake and growth retardation.

3. Total parenteral nutrition—TPN is used short term in patients with active disease and progressive weight loss or those awaiting surgery who have malnutrition but cannot tolerate enteral feedings because of high-grade obstruction, high-output fistulas, severe diarrhea, or abdominal pain. It is required long term in a small subset of patients with extensive intestinal resections resulting in short bowel syndrome with malnutrition.

B. Symptomatic Medications

There are several potential mechanisms by which diarrhea may occur in Crohn disease in addition to active Crohn disease. A rational empiric treatment approach often yields therapeutic improvement that may obviate the need for corticosteroids or immunosuppressive agents. Involvement of the terminal ileum with Crohn disease or prior ileal resection may lead to reduced absorption of bile acids that may induce secretory diarrhea from the colon. This diar-

rhea commonly responds to cholestyramine 2–4 g, colestipol 5 g, or colesevelam 625 mg one to two times daily before meals to bind the malabsorbed bile salts. Patients with extensive ileal disease of more than 100 cm of ileal resection have such severe bile salt malabsorption that steatorrhea may arise. Such patients may benefit from a low-fat diet; bile salt-binding agents will exacerbate the diarrhea and should not be given. Patients with Crohn disease are at risk for the development of small intestinal bacterial overgrowth due to enteral fistulas, ileal resection, and impaired motility and may benefit from a course of broad-spectrum antibiotics (see Bacterial Overgrowth, above). Other causes of diarrhea include lactase deficiency and short bowel syndrome (described in other sections). Use of anti-diarrheals may provide benefit in some patients. Loperamide (2–4 mg), diphenoxylate with atropine (one tablet), or tincture of opium (5–15 drops) may be given as needed up to four times daily. Because of the risk of toxic megacolon, these drugs should not be used in patients with active severe colitis.

C. Specific Drug Therapy

1. 5-Aminosalicylic acid agents—Mesalamine (Asacol 2.4–4.8 g/d; Pentasa 4 g/d) has long been used as initial therapy for the treatment of mild to moderately active colonic and ileocolonic Crohn disease. However, meta-analyses of published and unpublished trial data suggest that mesalamine is of little or no value in either the treatment of active Crohn disease or the maintenance of remission. Notwithstanding these data, many clinicians continue to use mesalamine as first-line therapy for patients with mild disease because of its safety relative to other agents.

2. Antibiotics—Antibiotics also are widely used by clinicians for the treatment of active luminal Crohn disease, although meta-analyses of controlled trials suggest that they have little or no efficacy. It is hypothesized that antibiotics may reduce inflammation through alteration of gut flora, reduction of bacterial overgrowth, or treatment of micro-perforations. Oral metronidazole (10 mg/kg/d) or ciprofloxacin (500 mg twice daily), or rifaximin (400 mg three times daily) are commonly administered for 6–12 weeks.

3. Corticosteroids—Approximately one-half of patients with Crohn disease require corticosteroids at some time in their illness. Corticosteroids dramatically suppress the acute clinical symptoms or signs in most patients with both small and large bowel disease; however, they do not alter the underlying disease. An ileal-release budesonide preparation (Entocort), 9 mg once daily for 8–16 weeks, induces remission in 50–70% of patients with mild to moderate Crohn disease involving the terminal ileum or ascending colon. After initial treatment, budesonide is tapered over 2–4 weeks in 3 mg increments. In some patients, low-dose budesonide (6 mg/d) may be used for up to 1 year to maintain remission. Budesonide is superior to mesalamine but somewhat less effective than prednisone. However, because budesonide has markedly reduced acute and chronic steroid-related adverse effects, including smaller reductions of bone mineral density, it is preferred to other

systemic corticosteroids for the treatment of mild to moderate Crohn disease involving the terminal ileum or ascending colon.

Prednisone or methylprednisolone, 40–60 mg/d, is generally administered to patients with Crohn disease that is severe, that involves the distal colon or proximal small intestine, or that has failed treatment with budesonide. Remission or significant improvement occurs in greater than 80% of patients after 8–16 weeks of therapy. After improvement at 2 weeks, tapering proceeds at 5 mg/wk until a dosage of 20 mg/d is being given. Thereafter, slow tapering by 2.5 mg/wk is recommended. Approximately 20% of patients cannot be completely withdrawn from corticosteroids without experiencing a symptomatic flare-up. Furthermore, more than 50% of patients who achieve initial remission on corticosteroids will experience a relapse within 1 year. Use of long-term low corticosteroid doses (2.5–10 mg/d) should be avoided, because of associated complications (see above). Patients requiring long-term corticosteroid treatment should be given immunomodulatory drugs (as described below) in an effort to wean them from corticosteroids.

Patients with persisting symptoms despite oral corticosteroids or those with high fever, persistent vomiting, evidence of intestinal obstruction, severe weight loss, severe abdominal tenderness, or suspicion of an abscess should be hospitalized. In patients with a tender, palpable inflammatory abdominal mass, CT scan of the abdomen should be obtained prior to administering corticosteroids to rule out an abscess. If no abscess is identified, parenteral corticosteroids should be administered (as described for ulcerative colitis).

4. Immunomodulating drugs: Azathioprine, mercaptopurine, or methotrexate

Immunomodulating agents are used in approximately two-thirds of patients with Crohn disease who have not responded to corticosteroids or who require repeated courses of long-term corticosteroids to control symptoms. These agents permit elimination or reduction of corticosteroids in over 75% and fistula closure in 30% of patients. In the United States, mercaptopurine or azathioprine are more commonly used than methotrexate. The mean time to symptomatic response is 2–4 months, so these agents are not useful for acute exacerbations. Meta-analyses of controlled trials suggest that patients with Crohn disease treated with immunomodulating agents are three times as likely to achieve remission and 2.25 times as likely to maintain remission as those treated with corticosteroids. Once patients achieve remission, immunomodulating drugs reduce the 3-year relapse rate from over 60% to less than 25%. Methotrexate (25 mg intramuscularly or subcutaneously weekly for 12 weeks, followed by 12.5–15 mg once weekly) is used in patients who are unresponsive to or intolerant of mercaptopurine or azathioprine. Because oral absorption may be erratic, parenteral administration is preferred. Other immunosuppressive agents have been investigated in the treatment of Crohn disease, including cyclosporine and thalidomide; however, efficacy has been modest and toxicity greater than with the thiopurines.

5. Anti-TNF therapies—Infliximab, adalimumab, and certolizumab are used for the treatment of patients with

moderate to severe Crohn disease (including fistulizing disease) with an inadequate response to mesalamine, antibiotics, corticosteroids or immunomodulators. These agents are also used to treat severe disease in hospitalized patients and extraintestinal manifestations of Crohn disease (except optic neuritis). The doses for acute induction therapy are described above. Up to two-thirds of patients have significant clinical improvement during acute induction therapy. After initial clinical response, symptom relapse occurs in greater than 80% of patients within 1 year in the absence of further maintenance therapy. Therefore, scheduled maintenance therapy is usually recommended (infliximab, 5 mg/kg infusion every 8 weeks; adalimumab, 40 mg subcutaneous injection every 2 weeks; certolizumab, 400 mg subcutaneous injection every 4 weeks). With long-term maintenance therapy, approximately two-thirds have continued clinical response and up to one-half have complete symptom remission. A gradual or complete loss of efficacy occurs over time in some patients, necessitating increased dosing (infliximab 10 mg/kg; adalimumab 80 mg), decreased dosing intervals (infliximab every 6 weeks; adalimumab every week), changing to the alternative agent, or discontinuation of anti-TNF therapy. In some cases, loss of efficacy is due to the development of antibodies to the anti-TNF agent (ATAs). Scheduled maintenance therapy is associated with a lower likelihood of developing ATA and an increased likelihood of sustained response. Concomitant therapy with anti-TNF agents and immunomodulating agents (azathioprine, mercaptopurine, or methotrexate) reduces the risk of development of ATA but may increase the risk of complications from anti-TNF agents, including the development of hepatosplenic T-cell lymphoma. One 2008 trial comparing infliximab alone to combination infliximab and methotrexate found no difference in disease remission rates after 1 year. However, the 2008 interim 6-month analysis of a trial comparing infliximab alone to combination infliximab and azathioprine found higher disease remission rates with combination therapy. Pending further analysis of the outcomes of these trials (including remission rates, complications, and incidence of ATA), it remains controversial whether anti-TNF agents should be used alone or in combination with immunomodulators.

There is also controversy about to whether anti-TNF agents should continue to be reserved as second-line therapy in patients with moderate to severe Crohn disease who have not responded to prior therapy with corticosteroids and immunomodulators (“step-up” therapy) or whether it should be used early in the course of illness (“step-down” therapy) with the goal of inducing early remission and altering the natural history of the disease. A 2008 study of patients with moderate to severe Crohn disease of less than 4 years duration, compared step-down therapy (infliximab for induction followed by azathioprine for maintenance) with step-up therapy (corticosteroids, followed by azathioprine, followed by infliximab). After 1-year, 61% of patients who received step-down therapy were in clinical remission compared with 42% who received step-up therapy. Further investigation of the role up step-down therapy is needed.

▶ Indications for Surgery

Over 50% of patients will require at least one surgical procedure. The main indications for surgery are intractability to medical therapy, intra-abdominal abscess, massive bleeding, symptomatic refractory internal or perianal fistulas, and intestinal obstruction. Patients with chronic obstructive symptoms due to a short segment of ileal stenosis are best treated with resection or stricturoplasty (rather than long-term medical therapy), which promotes rapid return of well-being and elimination of corticosteroids. After surgery, endoscopic evidence of recurrence occurs in 60% within 1 year. Clinical recurrence occurs in 20% of patients within 1 year and 80% within 10–15 years. Therapy with metronidazole, 250 mg three times daily for 3 months, or long-term therapy with immunomodulators (mercaptopurine or azathioprine), or both, may be modestly effective in preventing clinical and endoscopic recurrence after ileocolic resection and is recommended for high-risk patients.

▶ Prognosis

With proper medical and surgical treatment, the majority of patients are able to cope with this chronic disease and its complications and lead productive lives. Few patients die as a direct consequence of the disease.

▶ When to Refer

- For expertise in endoscopic procedures or capsule endoscopy.
- Any patient requiring hospitalization for follow-up.
- Patients with moderate to severe disease for whom therapy with immunomodulators or biologic agents is being considered.
- When surgery may be necessary.

▶ When to Admit

- An intestinal obstruction is suspected.
- An intra-abdominal or perirectal abscess is suspected.
- A serious infectious complication is suspected, especially in patients who are immunocompromised due to concomitant use of corticosteroids, immunomodulators, or anti-TNF agents.
- Patients with severe symptoms of diarrhea, dehydration, weight loss, or abdominal pain.
- Patients with severe or persisting symptoms despite treatment with corticosteroids.

2. Ulcerative Colitis

ESSENTIALS OF DIAGNOSIS

- ▶ Bloody diarrhea.
- ▶ Lower abdominal cramps and fecal urgency.
- ▶ Anemia, low serum albumin.
- ▶ Negative stool cultures.
- ▶ Sigmoidoscopy is the key to diagnosis.

▶ General Considerations

Ulcerative colitis is an idiopathic inflammatory condition that involves the mucosal surface of the colon, resulting in diffuse friability and erosions with bleeding. Approximately one-third of patients have disease confined to the rectosigmoid region (proctosigmoiditis); one-third have disease that extends to the splenic flexure (left-sided colitis); and one-third have disease that extends more proximally (extensive colitis). There is some correlation between disease extent and symptom severity. In the majority of patients, the extent of colonic involvement does not progress over time. In most patients, the disease is charac-

terized by periods of symptomatic flare-ups and remissions. Ulcerative colitis is more common in nonsmokers and former smokers. Disease severity may be lower in active smokers and may worsen in patients who stop smoking. Appendectomy before the age of 20 years for acute appendicitis is associated with a reduced risk of developing ulcerative colitis.

► Clinical Findings

A. Symptoms and Signs

The clinical profile in ulcerative colitis is highly variable. Bloody diarrhea is the hallmark. On the basis of several clinical and laboratory parameters, it is clinically useful to classify patients as having mild, moderate, or severe disease (Table 15–12). Patients should be asked about stool frequency, the presence and amount of rectal bleeding, cramps, abdominal pain, fecal urgency, and tenesmus. Physical examination should focus on the patient's volume status as determined by orthostatic blood pressure and pulse measurements and by nutritional status. On abdominal examination, the clinician should look for tenderness and evidence of peritoneal inflammation. Red blood may be present on digital rectal examination.

1. Mild to moderate disease—Patients with mild disease have a gradual onset of infrequent diarrhea (less than five movements per day) with intermittent rectal bleeding and mucus. Stools may be formed or loose in consistency. Because of rectal inflammation, there is fecal urgency and tenesmus. Left lower quadrant cramps relieved by defecation are common, but there is no significant abdominal tenderness. Patients with moderate disease have more severe diarrhea with frequent bleeding. Abdominal pain and tenderness may be present but are not severe. There may be mild fever, anemia, and hypoalbuminemia.

2. Severe disease—Patients with severe disease have more than six to ten bloody bowel movements per day, resulting in severe anemia, hypovolemia, and impaired nutrition with hypoalbuminemia. Abdominal pain and tenderness are present. “Fulminant colitis” is a subset of

severe disease characterized by rapidly worsening symptoms with signs of toxicity.

B. Laboratory Findings

The degree of abnormality of the hematocrit, sedimentation rate, and serum albumin reflects disease severity.

C. Endoscopy

In acute colitis, the diagnosis is readily established by sigmoidoscopy. The mucosal appearance is characterized by edema, friability, mucopus, and erosions. Colonoscopy should not be performed in patients with fulminant disease because of the risk of perforation. After patients have demonstrated improvement on therapy, colonoscopy is performed to determine the extent of disease.

D. Imaging

Plain abdominal radiographs are obtained in patients with severe colitis to look for significant colonic dilation. Barium enemas are of little utility in the evaluation of acute ulcerative colitis and may precipitate toxic megacolon in patients with severe disease.

► Differential Diagnosis

The initial presentation of ulcerative colitis is indistinguishable from other causes of colitis, clinically as well as endoscopically. Thus, the diagnosis of idiopathic ulcerative colitis is reached after excluding other known causes of colitis. Infectious colitis should be excluded by sending stool specimens for routine bacterial cultures (to exclude *Salmonella*, *Shigella*, and *Campylobacter*, as well as specific assays for *E coli* O157), ova and parasites (to exclude amebiasis), and stool toxin assay for *C difficile*. Mucosal biopsy can distinguish amebic colitis from ulcerative colitis. CMV colitis occurs in immunocompromised patients and is diagnosed on mucosal biopsy. Gonorrhea, chlamydial infection, herpes, and syphilis are considerations in sexually active patients with proctitis. In elderly patients with cardiovascular disease, ischemic colitis may involve the rectosigmoid. A history of radiation to the pelvic region can result in proctitis months to years later. Crohn disease involving the colon but not the small intestine may be confused with ulcerative colitis. In 10% of patients, a distinction between Crohn disease and ulcerative colitis may not be possible. The possible utility of serologic testing (Prometheus IBD Serology 7 panel) in patients with indeterminate colitis requires further clinical study (see discussion in the section on Crohn disease).

► Treatment

There are two main treatment objectives: (1) to terminate the acute, symptomatic attack and (2) to prevent recurrence of attacks. The treatment of acute ulcerative colitis depends on the extent of colonic involvement and the severity of illness.

Patients with mild to moderate disease should eat a regular diet but limit their intake of caffeine and gas-

Table 15–12. Ulcerative colitis: Assessment of disease activity.

| | Mild | Moderate | Severe |
|---------------------------|--------|----------|---------------------|
| Stool frequency (per day) | < 4 | 4–6 | > 6 (mostly bloody) |
| Pulse (beats/min) | < 90 | 90–100 | > 100 |
| Hematocrit (%) | Normal | 30–40 | < 30 |
| Weight loss (%) | None | 1–10 | > 10 |
| Temperature (°F) | Normal | 99–100 | > 100 |
| ESR (mm/h) | < 20 | 20–30 | > 30 |
| Albumin (g/dL) | Normal | 3–3.5 | < 3 |

ESR, erythrocyte sedimentation rate.

producing vegetables. Antidiarrheal agents should not be given in the acute phase of illness but are safe and helpful in patients with mild chronic symptoms. Loperamide (2 mg) or diphenoxylate with atropine (one tablet) may be given up to four times daily. Such remedies are particularly useful at nighttime and when taken prophylactically for occasions when patients may not have reliable access to toilet facilities.

A. Distal Colitis

Patients with disease confined to the rectum or rectosigmoid region generally have mild but distressing symptoms. Patients may be treated with topical mesalamine, topical corticosteroids, or oral aminosalicylates (5-ASA) according to patient preference and cost considerations. Topical mesalamine is the drug of choice and is superior to topical corticosteroids and 5-ASA. Mesalamine is administered as a suppository, 1000 mg once daily at bedtime for proctitis, and as an enema, 4 g at bedtime for proctosigmoiditis, for 4–12 weeks, with 75% of patients improving (Table 15–13). Topical corticosteroids are a less expensive alternative to mesalamine but are also less effective. Hydrocortisone suppository or foam is prescribed for proctitis and hydrocortisone enema (80–100 mg) for proctosigmoiditis. Systemic effects from short-term use are very slight. Patients who either decline or are unable to manage topical therapy may be treated with oral 5-ASA, as discussed below. For patients with distal disease who do not improve with once daily topical therapy, the following options may be considered: (1) combination topical therapy with a 5-ASA suppository or enema at bedtime and a corticosteroid enema or foam in the morning, or (2) a combination of a topical agent with an oral 5-ASA agent.

Patients whose acute symptoms resolve rapidly with immediate therapy may have prolonged periods of remission that are treated successfully with intermittent courses of therapy. Patients with early or frequent relapse should be treated with maintenance therapy with mesalamine suppositories (1000 mg) or enemas (4 g) nightly or every

other night. For patients who have difficulty complying with topical therapies, oral 5-ASA agents are an acceptable, though possibly less effective, alternative (see below).

B. Mild to Moderate Colitis

1. 5-ASA Agents—Disease extending above the sigmoid colon is best treated with 5-ASA agents (mesalamine, balsalazide, or sulfasalazine), which result in symptomatic improvement in 50–75% of patients. Most patients improve within 3–6 weeks, though some require 2–3 months. Mesalamine (Asacol 0.8–1.6 g three times daily; Lialda 1.2 g once or twice daily; Pentasa 0.5–1 g four times daily) and balsalazide, 2.25 g three times daily, are approved for active disease (Table 15–13). These agents achieve clinical improvement in 50–70% of patients and remission in 20–30%. Total doses of mesalamine above 2.0–2.4 g/d result in marginal increases in remission. Sulfasalazine is comparable in efficacy to mesalamine and because of its low cost is still commonly used as a first-line agent by many providers, though it is associated with greater side effects. To minimize side effects, sulfasalazine is begun at a dosage of 500 mg twice daily and increased gradually over 1–2 weeks to 2 g twice daily (Table 15–13). Total doses of 5–6 g/d may have greater efficacy but are poorly tolerated. Folic acid, 1 mg/d, should be administered to all patients taking sulfasalazine.

2. Corticosteroids—Patients with mild to moderate disease who do not improve after 4–8 weeks of 5-ASA therapy should have the addition of corticosteroid therapy. The addition of topical therapy with 5-ASA enemas (4 g once daily) or hydrocortisone foam or enemas (80–100 mg once or twice daily) may be tried first. Patients who do not improve after 2 more weeks require systemic corticosteroid therapy. Prednisone and methylprednisolone are most commonly used. Depending on the severity of illness, the initial oral dose of prednisone is 40–60 mg daily. Rapid improvement is observed in most cases within 2 weeks. Thereafter, tapering of prednisone should proceed by 5–10 mg/wk. After tapering to 20 mg/d, slower tapering (2.5 mg/week) is sometimes required. Complete tapering without symptomatic flare-ups is possible in the majority of patients.

3. Immunomodulating agents—A subset of patients either does not respond to aminosalicylates or corticosteroids or has symptomatic flares during attempts at corticosteroid tapering. Although surgical resection is traditionally recommended for patients with refractory disease, many patients may wish to avoid surgery and others have moderately severe disease for which surgery might not otherwise be warranted. Immunomodulating agents are used for the treatment of ulcerative colitis; however, the risks of these drugs from chronic immunosuppression must be weighed against the certainty of cure with surgical resection. Limited trials suggest mercaptopurine or azathioprine is of benefit in 60% of patients, allowing tapering of corticosteroids and maintenance of remission. There is less evidence that methotrexate is effective.

Infliximab is approved in the United States for the treatment of patients with moderate to severe ulcerative colitis who have had an inadequate response to conven-

tional therapies (oral corticosteroids, mercaptopurine or azathioprine, and mesalamine). Following a three-dose induction regimen of 5 mg/kg administered at 0, 2, and 6 weeks, clinical response occurs in 65% and clinical remission in 35%. Other anti-TNF agents (ie, adalimumab) have not been approved for treatment of ulcerative colitis.

C. Severe Colitis

About 15% of patients with ulcerative colitis have a more severe course. Because they may progress to fulminant colitis or toxic megacolon, hospitalization is generally required.

1. General measures—Discontinue all oral intake for 24–48 hours or until the patient demonstrates clinical improvement. TPN is indicated only in patients with poor nutritional status or if feedings cannot be reinstated within 7–10 days. All opioid or anticholinergic agents should be discontinued. Restore circulating volume with fluids, correct electrolyte abnormalities, and consider transfusion for significant anemia (hematocrit < 25–28%). Abdominal examinations should be repeated to look for evidence of worsening distention or pain. A plain abdominal radiograph should be ordered on admission to look for evidence of colonic dilation. Send stools for bacterial culture, *C difficile* toxin assay, and examination for ova and parasites. CMV superinfection should be considered in patients receiving long-term immunosuppressive therapy who are unresponsive to corticosteroid therapy. Surgical consultation should be sought for all patients with severe disease.

2. Corticosteroid therapy—Methylprednisolone, 48–64 mg, or hydrocortisone, 300 mg, is administered in four divided doses or by continuous infusion over 24 hours. Higher or “pulse” doses are of no benefit. Hydrocortisone enemas (100 mg) may also be administered twice daily for treatment of urgency or tenesmus. Approximately 50–75% of patients achieve remission with systemic corticosteroids within 7–10 days. Once symptomatic improvement has occurred, oral fluids are reinstated. If fluids are well tolerated, intravenous corticosteroids are discontinued and the patient is started on oral prednisone (as described for moderate disease).

3. Anti-TNF therapies—A single infusion of infliximab, 5 mg/kg, has been shown in recent controlled and uncontrolled studies to be effective in treating severe colitis in patients who did not improve within 4–7 days of intravenous corticosteroid therapy. In a controlled study of patients hospitalized for ulcerative colitis, colectomy was required within 3 months in 69% who received placebo therapy, compared with 47% who received infliximab. Although further studies are needed, infliximab therapy should be considered in patients with severe ulcerative colitis who have not improved with intravenous corticosteroid therapy.

4. Cyclosporine—Intravenous cyclosporine (2–4 mg/kg/d as a continuous infusion) benefits 60–75% of patients with severe colitis who have not improved after 7–10 days of corticosteroids. In patients with severe steroid-resistant colitis who are reluctant to undergo colectomy, intravenous cyclosporine may be considered as a “bridge” therapy

while mercaptopurine or azathioprine therapy (which take 2–4 months for full efficacy) is initiated. Up to two-thirds of responders may be maintained in remission with a combination of oral cyclosporine for 3 months and long-term therapy with mercaptopurine or azathioprine. The relative role of infliximab versus cyclosporine in the treatment of severe colitis requires further clinical study.

5. Surgical therapy—Patients with severe disease who fail to improve after 7–10 days of corticosteroid, infliximab or cyclosporine therapy are unlikely to respond to further medical therapy, and surgery is recommended.

D. Fulminant Colitis and Toxic Megacolon

A subset of patients with severe disease has a more fulminant course with rapid progression of symptoms over 1–2 weeks and signs of severe toxicity. These patients appear quite ill, with fever, prominent hypovolemia, hemorrhage requiring transfusion, and abdominal distention with tenderness. They are at a higher risk of perforation or development of toxic megacolon and must be followed closely. Broad-spectrum antibiotics should be administered to cover anaerobes and gram-negative bacteria.

Toxic megacolon develops in less than 2% of cases of ulcerative colitis. It is characterized by colonic dilation of more than 6 cm on plain films with signs of toxicity. In addition to the therapies outlined above, nasogastric suction should be initiated. Patients should be instructed to roll from side to side and onto the abdomen in an effort to decompress the distended colon. Serial abdominal plain films should be obtained to look for worsening dilation or ischemia. Patients with fulminant disease or toxic megacolon who worsen or fail to improve within 48–72 hours should undergo surgery to prevent perforation. If the operation is performed before perforation, the mortality rate should be low.

► Maintenance of Remission

Without long-term therapy, 75% of patients who initially go into remission on medical therapy will experience a symptomatic relapse within 1 year. Long-term maintenance therapy with sulfasalazine, 1–1.5 g twice daily, and mesalamine, 800 mg 2–3 times daily or 500 mg four times daily, has been shown to reduce relapse rates to less than 35%. Mercaptopurine and azathioprine are useful in patients with frequent disease relapses (more than two per year) or corticosteroid-dependent disease to maintain remission. The role of long-term infliximab therapy in the maintenance of remission is evolving. In two, large, controlled studies of patients with active moderate to severe colitis, initial induction therapy was followed by infliximab maintenance infusions (5 mg/kg) administered every 8 weeks for 30–54 weeks. At the end of the study (30 or 54 weeks), 35% were in clinical remission, (21% in corticosteroid-free remission), a modest but impressive response in patients with more refractory disease. In considering long-term infliximab therapy, patients and clinicians need to weigh the long-term risks of immunosuppression against colectomy.

► Risk of Colon Cancer

In patients with ulcerative colitis with disease proximal to the rectum and in patients with Crohn colitis, there is a markedly increased risk of developing colon carcinoma. A large meta-analysis of observational studies reported a cumulative incidence of 2% at 10 years, 8% at 20 years, and 18% after 30 years of disease. Retrospective studies suggest that the risk of colon cancer may be reduced in patients treated with long-term 5-ASA therapy. Ingestion of folic acid, 1 mg/d, also is associated with a decreased risk of cancer development. Colonoscopies are recommended every 1–2 years in patients with colitis, beginning 8–10 years after diagnosis. At colonoscopy, multiple (at least 32) random mucosal biopsies are taken throughout the colon at 10-cm intervals as well as biopsies of mass lesions to look for dysplasia or carcinoma. Because of the relatively high incidence of concomitant carcinoma in patients with dysplasia (either low or high grade) in flat mucosa or mass lesions, colectomy is recommended. Several prospective studies demonstrate that dye spraying with methylene blue or indigo carmine (“chromoendoscopy”) enhances the detection of subtle mucosal lesions, thereby significantly increasing the detection of dysplasia compared with standard colonoscopy. Although surveillance colonoscopy appears to be effective in reducing the incidence of colon cancer, patients must understand that approximately one-third of detected cancers are advanced, despite compliance with routine colonoscopy surveillance.

► Surgery in Ulcerative Colitis

Surgery is required in 25% of patients. Severe hemorrhage, perforation, and documented carcinoma are absolute indications for surgery. Surgery is indicated also in patients with fulminant colitis or toxic megacolon that does not improve within 48–72 hours, in patients with dysplasia on surveillance colonoscopy, and in patients with refractory disease requiring long-term corticosteroids to control symptoms.

Although total proctocolectomy (with placement of an ileostomy) provides complete cure of the disease, most patients seek to avoid it out of concern for the impact it may have on their bowel function, their self-image, and their social interactions. After complete colectomy, patients may have a standard ileostomy with an external appliance, a continent ileostomy, or an internal ileal pouch that is anastomosed to the anal canal (ileal pouch-anal anastomosis). The latter maintains intestinal continuity, thereby obviating an ostomy. Under optimal circumstances, patients have five to seven loose bowel movements per day without incontinence. Endoscopic or histologic inflammation in the ileal pouch (“pouchitis”) develops in over 40% of patients, resulting in increased stool frequency, fecal urgency, cramping, and bleeding, but usually resolves with a 2-week course of metronidazole (10 mg/kg/d) or ciprofloxacin (500 mg twice daily). Patients with frequently relapsing pouchitis may need continuous antibiotics. Probiotics containing nonpathogenic strains of lactobacilli, bifidobacteria, and streptococci (VSL#3) are effective in the maintenance of remission in patients with recurrent pouchitis. Bismuth subsalicylate (Pepto Bismol, 262 mg, two

tablets four times daily) has demonstrated benefit in some series. Some clinicians report that topical corticosteroids or oral budesonide 9 mg/d are of benefit. Refractory cases of proctitis can be disabling and may require conversion to a standard ileostomy.

► Prognosis

Ulcerative colitis is a lifelong disease characterized by exacerbations and remissions. For most patients, the disease is readily controlled by medical therapy without need for surgery. The majority never require hospitalization. A subset of patients with more severe disease will require surgery, which results in complete cure of the disease. Properly managed, most patients with ulcerative colitis lead close to normal productive lives.

► When to Refer

- Colonoscopy: for evaluation of activity and extent of active disease and for surveillance for neoplasia in patients with quiescent disease for more than 8–10 years.
- When hospitalization is required.
- When surgical colectomy is indicated.

► When to Admit

- Patients with severe disease manifested by frequent bloody stools, anemia, weight loss, and fever.
- Patients with fulminant disease manifested by rapid progression of symptoms, worsening abdominal pain, distention, high fever, tachycardia.
- Patients with moderate to severe symptoms that do not respond to oral corticosteroids and require a trial of bowel rest and intravenous corticosteroids.

3. Microscopic Colitis

Microscopic colitis is an idiopathic condition that is found in up to 15% of patients who have chronic or intermittent watery diarrhea with normal-appearing mucosa at endoscopy. There appear to be two subtypes—lymphocytic colitis and collagenous colitis. In both, histologic evaluation of mucosal biopsies reveals chronic inflammation (lymphocytes, plasma cells) in the lamina propria and increased intraepithelial lymphocytes. Collagenous colitis is further characterized by the presence of a thickened band (> 10 μ m) of subepithelial collagen. Both forms occur more commonly in women, especially in the fifth to sixth decades. Symptoms tend to be chronic or recurrent but may remit in most patients after several years. A more severe illness characterized by abdominal pain, fatigue, dehydration, and weight loss may develop in a subset of patients. The cause of microscopic colitis usually is unknown. Several medications have been implicated as etiologic agents, including NSAIDs, sertraline, paroxetine, lansoprazole, lisinopril, and simvastatin. Diarrhea usually abates within 30 days of stopping the offending medication. Celiac sprue may be present in a small subset of patients and should be excluded with serologic testing (anti-tissue transglutaminase or anti-endomysial antibody). Treatment is largely empiric since there are few well-designed, controlled treatment trials. Mild disease may be treated with antidiarrheal agents (loperamide, cholestyramine). In uncontrolled studies, treatment with 5-ASAs (sulfasalazine, mesalamine) or bile-salt binding agents (cholestyramine, colestipol) is reported to be effective in many patients. A small unpublished controlled trial demonstrated efficacy for bismuth subsalicylate (two tablets four times daily) for 2 months; however, clinical experience has yielded only modest benefit. Delayed release budesonide (Entocort) 9 mg/d for 6–8 weeks has been shown in three prospective controlled studies to induce clinical improvement in 81% of patients compared with 17% treated with placebo; however, clinical relapse is common after cessation of therapy. Patients with refractory or severe symptoms may be treated with systemic corticosteroids or, rarely, azathioprine. After

entering remission, clinical relapse occurs in 20–30% of patients within 3 years.

DIVERTICULAR DISEASE OF THE COLON

Colonic diverticulosis increases with age, ranging from 5% in those under age 40, to 30% at age 60, to more than 50% over age 80 years in Western societies. In contrast, it is very uncommon in developing countries with much lower life expectancies. Most are asymptomatic, discovered incidentally at endoscopy or on barium enema. Complications in one-third include lower gastrointestinal bleeding and diverticulitis.

Colonic diverticula may vary in size from a few millimeters to several centimeters and in number from one to several dozen. Almost all patients with diverticulosis have involvement in the sigmoid and descending colon; however, only 15% have proximal colonic disease.

In most patients, diverticulosis is believed to arise after many years of a diet deficient in fiber. The undistended, contracted segments of colon have higher intraluminal pressures. Over time, the contracted colonic musculature, working against greater pressures to move small, hard stools, develops hypertrophy, thickening, rigidity, and fibrosis. Diverticula may develop more commonly in the sigmoid because intraluminal pressures are highest in this region. The extent to which abnormal motility and hereditary factors contribute to diverticular disease is unknown. Patients with diffuse diverticulosis may have an inherent weakness in the colonic wall. Patients with abnormal connective tissue are also disposed to development of diverticulosis, including Ehlers-Danlos syndrome, Marfan syndrome, and scleroderma.

1. Uncomplicated Diverticulosis

More than two-thirds of patients with diverticulosis have uncomplicated disease and no specific symptoms. In some, diverticulosis may be an incidental finding detected during colonoscopic examination or barium enema examination. Some patients have nonspecific complaints of chronic constipation, abdominal pain, or fluctuating bowel habits. It is unclear whether these symptoms are due to alterations in the colonic musculature or underlying irritable bowel syndrome. Physical examination is usually normal but may reveal mild left lower quadrant tenderness with a thickened, palpable sigmoid and descending colon. Screening laboratory studies should be normal in uncomplicated diverticulosis.

There is no reason to perform imaging studies for the purpose of diagnosing uncomplicated disease. Diverticula are best seen on barium enema. Involved segments of colon may also be narrowed and deformed. Colonoscopy is a less sensitive means of detecting diverticula.

Asymptomatic patients in whom diverticulosis is discovered and patients with a history of complicated disease (see below) should be treated with a high-fiber diet or fiber supplements (bran powder, 1–2 tbsp twice daily; psyllium or methylcellulose) (see section on constipation). Retrospective studies suggest that such treatment may decrease the likelihood of subsequent complications.

2. Diverticulitis

ESSENTIALS OF DIAGNOSIS

- ▶ Acute abdominal pain and fever.
- ▶ Left lower abdominal tenderness and mass.
- ▶ Leukocytosis.

▶ Clinical Findings

A. Symptoms and Signs

Perforation of a colonic diverticulum results in an intra-abdominal infection that may vary from microperforation (most common) with localized paracolic inflammation to macroperforation with either abscess or generalized peritonitis. Thus, there is a range from mild to severe disease. Most patients with localized inflammation or infection report mild to moderate aching abdominal pain, usually in the left lower quadrant. Constipation or loose stools may be present. Nausea and vomiting are frequent. In many cases, symptoms are so mild that the patient may not seek medical attention until several days after onset. Physical findings include a low-grade fever, left lower quadrant tenderness, and a palpable mass. Stool occult blood is common, but hematochezia is rare. Leukocytosis is mild to moderate. Patients with free perforation present with a more dramatic picture of generalized abdominal pain and peritoneal signs.

B. Imaging

In patients with mild symptoms and a presumptive diagnosis of diverticulitis, empiric medical therapy is started without further imaging in the acute phase. Patients who respond to acute medical management should undergo complete colonic evaluation with colonoscopy or barium enema after resolution of clinical symptoms to corroborate the diagnosis or exclude other disorders such as colonic neoplasms. In patients who do not improve rapidly after 2–4 days of empiric therapy and in those with severe disease, CT scan of the abdomen is obtained to look for evidence of diverticulitis and determine its severity, and to exclude other disorders that may cause lower abdominal pain. The presence of colonic diverticula and wall thickening, pericolic fat

infiltration, abscess formation, or extraluminal air or contrast suggest diverticulitis. Endoscopy and barium enema are contraindicated during the initial stages of an acute attack because of the risk of free perforation.

▶ Differential Diagnosis

Diverticulitis must be distinguished from other causes of lower abdominal pain, including perforated colonic carcinoma, Crohn disease, appendicitis, ischemic colitis, *C difficile*-associated colitis, and gynecologic disorders (ectopic pregnancy, ovarian cyst or torsion) by abdominal CT scan, pelvic ultrasonography, or radiographic studies of the distal colon that use water-soluble contrast enemas.

▶ Complications

Fistula formation may involve the bladder, ureter, vagina, uterus, bowel, and abdominal wall. Diverticulitis may result in stricturing of the colon with partial or complete obstruction.

▶ Treatment

A. Medical Management

Most patients can be managed with conservative measures. Patients with mild symptoms and no peritoneal signs may be managed initially as outpatients on a clear liquid diet and broad-spectrum oral antibiotics with anaerobic activity. Reasonable regimens include amoxicillin and clavulanate potassium (875 mg/125 mg) twice daily; or metronidazole, 500 mg three times daily; plus either ciprofloxacin, 500 mg twice daily, or trimethoprim-sulfamethoxazole, 160/800 mg twice daily orally, for 7–10 days or until the patient is afebrile for 3–5 days. Symptomatic improvement usually occurs within 3 days, at which time the diet may be advanced. Patients with increasing pain, fever, or inability to tolerate oral fluids require hospitalization. Patients with severe diverticulitis (high fevers, leukocytosis, or peritoneal signs) and patients who are elderly or immunosuppressed or who have serious comorbid disease require hospitalization acutely. Patients should be given nothing by mouth and should receive intravenous fluids. If ileus is present, a nasogastric tube should be placed. Intravenous antibiotics should be given to cover anaerobic and gram-negative bacteria. Single-agent therapy with either a second-generation cephalosporin (eg, cefoxitin), piperacillin-tazobactam, or ticarcillin clavulanate appears to be as effective as combination therapy (eg, metronidazole or clindamycin plus an aminoglycoside or third-generation cephalosporin [eg, ceftazidime, cefotaxime]). Symptomatic improvement should be evident within 2–3 days. Intravenous antibiotics should be continued for 5–7 days, before changing to oral antibiotics. Colonoscopy or barium enema should be performed approximately 6 weeks after the acute episode has resolved in order to exclude unsuspected colon carcinoma or inflammatory bowel disease.

B. Surgical Management

Surgical consultation and repeat abdominal CT imaging should be obtained on all patients with severe disease or those who do not improve after 72 hours of medical management.

Patients with a localized abdominal abscess greater than or equal to 4 cm in size are usually treated urgently with a percutaneous catheter drain placed by an interventional radiologist. This permits control of the infection and resolution of the immediate infectious inflammatory process. In this manner, a subsequent elective one-stage surgical operation can be performed (if deemed necessary) in which the diseased segment of colon is removed and primary colonic anastomosis performed. Patients with chronic disease resulting in fistulas or colonic obstruction will also require elective surgical resection.

Indications for emergent surgical management include generalized peritonitis, large undrainable abscesses, and clinical deterioration despite medical management and percutaneous drainage. Surgery may be performed in one- or two-stage operations depending on the patient's nutritional status, severity of illness, and extent of intra-abdominal peritonitis and abscess formation. In a two-stage operation, the diseased colon is resected and the proximal colon brought out to form a temporary colostomy. The distal colonic stump is either closed (forming a Hartmann pouch) or exteriorized as a mucous fistula. Weeks later, after inflammation and infection have completely subsided, the colon can be reconnected electively.

► Prognosis

Diverticulitis recurs in 10–30% of patients treated with medical management. Recurrent attacks warrant elective surgical resection, which carries a lower morbidity and mortality risk than emergency surgery.

► When to Refer

- Failure to improve within 72 hours of medical management.
- Presence of significant peridiverticular abscesses (≥ 4 cm) requiring possible percutaneous or surgical drainage.
- Generalized peritonitis or sepsis.
- Recurrent attacks.
- Chronic complications including colonic strictures or fistulas.

► When to Admit

- Severe pain or inability to tolerate oral intake.
- Signs of sepsis or peritonitis.
- CT scan showing signs of complicated disease (abscess, perforation).
- Failure to improve with outpatient management.
- Immunocompromised or frail, elderly patient.

3. Diverticular Bleeding

Half of all cases of acute lower gastrointestinal bleeding are attributable to diverticulosis. For a full discussion, see the section on Acute Lower Gastrointestinal Bleeding.

POLYPS OF THE COLON & SMALL INTESTINE

Polyps are discrete mass lesions that protrude into the intestinal lumen. Although most commonly sporadic, they may be inherited as part of a familial polyposis syndrome. Polyps may be divided into three major pathologic groups: mucosal neoplastic (adenomatous) polyps, mucosal nonneoplastic polyps (hyperplastic, juvenile polyps, hamartomas, inflammatory polyps), and submucosal lesions (lipomas, lymphoid aggregates, carcinoids, pneumatosis cystoides intestinalis). The nonneoplastic mucosal polyps have no malignant potential and usually are discovered incidentally at colonoscopy or barium enema. Only the adenomatous polyps have significant clinical implications and will be considered further here. Of polyps removed at colonoscopy, over 70% are adenomatous; most of the remainder are hyperplastic. Small hyperplastic polyps (< 5 mm) located in the rectosigmoid region are of no consequence, except that they cannot reliably be distinguished from adenomatous lesions other than by biopsy. Large hyperplastic polyps located in the proximal colon may evolve into a unique type of premalignant lesion called a “serrated adenoma.”

NONFAMILIAL ADENOMATOUS POLYPS

Histologically, adenomas are classified as tubular, villous, tubulovillous, or serrated. Adenomas may be flat, sessile or pedunculated (containing a stalk). They are present in 30% of adults over 50 years of age. Their significance is that over 95% of cases of adenocarcinoma of the colon are believed to arise from adenomas. It is proposed that there is an adenoma \rightarrow carcinoma sequence whereby colorectal cancer develops through a continuous process from normal mucosa to adenoma to carcinoma. Most adenomas are small (< 1 cm) and have a low risk of becoming malignant; less than 5% of these enlarge with time. Adenomas are classified as “advanced” if they are ≥ 1 cm, or contain villous features or high-grade dysplasia. Advanced adenomas are believed to have a higher risk of harboring or progressing to malignancy. It has been estimated from longitudinal studies that it takes an average of 5 years for a medium-sized polyp to develop from normal-appearing mucosa and 10 years for a gross cancer to arise. In an asymptomatic population of male veterans over age 50 years undergoing screening with colonoscopy, invasive cancer was detected in 1%, adenomas containing high-grade dysplasia in 1.7%, and other adenomas ≥ 1 cm in size in 7.2%. The role of aspirin and NSAIDs for the chemoprevention of adenomatous polyps is discussed in Chapter 39, in the section on Colorectal Cancer.

► Clinical Findings

A. Symptoms and Signs

Most patients with adenomatous polyps are completely asymptomatic. Chronic occult blood loss may lead to iron deficiency anemia. Large polyps may ulcerate, resulting in intermittent hematochezia.

B. Fecal Occult Blood or Multitarget DNA Tests

FOBT, FIT, and, more recently, fecal DNA tests are available as part of colorectal cancer screening programs (see

Chapter 39). FIT is a new fecal blood test (an immunochemical test for hemoglobin) that is more sensitive than prior guaiac-based tests for the detection of colorectal cancer and advanced adenomas. In two recent prospective studies, the FIT and other new fecal tests detected 40–60% of advanced noncancerous adenomas.

C. Radiologic Tests

Polyps are identified by means of barium enema examinations or CT colonography. Barium enema examinations as currently performed detect < 50% of colorectal polyps \geq 1 cm in size. CT colonography (“virtual colonoscopy”) uses data from helical CT imaging with computer-enabled luminal image reconstruction to generate two-dimensional and three-dimensional images of the colon. Using optimal imaging software with multidetector helical CT scanners, several studies report a sensitivity of \geq 90% for the detection of polyps > 10 mm in size. However, the accuracy for detection of polyps 5–9 mm in size is significantly lower (sensitivity 50%). A small proportion of these small polyps harbor advanced histology (3–7%) or carcinoma (< 1%). Abdominal CT imaging results in a radiation exposure that may lead to a small risk of cancer. CT colonography has been endorsed by US Multisociety Task Force as an acceptable option for screening for colorectal adenomatous polyps and cancer in average risk asymptomatic adults.

D. Endoscopic Tests

Flexible sigmoidoscopy is commonly performed as part of colorectal screening programs. Approximately one-half to two-thirds of colonic adenomas are within the reach of a flexible sigmoidoscope. Polyps are seen in 10–20% of patients undergoing screening sigmoidoscopy, and polyps less than 8 mm in size should be removed by excisional biopsy to assess histology. Patients in whom no adenomas are detected or in whom hyperplastic polyps only are detected on sigmoidoscopy require no further evaluation. In such patients, the prevalence of an undetected advanced proximal adenoma is only 1–3%. Patients with an advanced adenoma (as defined above) or multiple small (< 1 cm) adenomas in the distal colon have an increased risk (12%) of harboring other advanced neoplasms in the proximal colon and should undergo colonoscopy. Opinions are conflicting about whether the presence of one or two small adenomas found on sigmoidoscopy is predictive of finding an increased prevalence of advanced neoplasms at colonoscopy. However, several studies suggest that among patients with a distal adenoma less than 10 mm in size, the prevalence of advanced neoplasia at colonoscopy is 5–7%. Therefore, professional guidelines recommend colonoscopy for all patients with adenomas found in the distal colon at sigmoidoscopy irrespective of size.

Colonoscopy allows evaluation of the entire colon and is the best means of detecting and removing adenomatous polyps (Plate 69). It should be performed in all patients who have positive FOBT, FIT, fecal, or DNA tests or iron deficiency anemia (see Occult Gastrointestinal Bleeding and Obscure Gastrointestinal Bleeding, above), as the prevalence of colonic neoplasms is increased in these

patients. Colonoscopy should also be performed in patients with polyps detected on radiologic imaging studies (barium enema or CT colonography) or adenomas detected on flexible sigmoidoscopy to remove these polyps and to fully evaluate the entire colon.

► Treatment

A. Colonoscopic Polypectomy

Most adenomatous polyps are amenable to colonoscopic removal with biopsy forceps or snare cautery. Large sessile polyps (> 2–3 cm) may be removed in piecemeal fashion or may require surgical resection. Patients with large sessile polyps removed in piecemeal fashion should undergo repeated colonoscopy in 2–6 months to verify complete polyp removal. Complications after colonoscopic polypectomy include perforation in 0.2% and clinically significant bleeding in 0.3–1% of patients.

A malignant polyp is an adenoma that appears grossly benign at endoscopy but on histologic assessment is found to contain cancer that has penetrated through the muscularis mucosae into the submucosa. Malignant polyps may be considered to be adequately treated by polypectomy alone if: (1) the polyp is completely excised and submitted for pathologic examination, (2) it is well differentiated, (3) the margin is not involved, and (4) there is no tumor budding vascular invasion. The risk of residual cancer or nodal metastasis with favorable histologic features is < 1%. The excision site of these “favorable” malignant polyps should be checked in 3 months for residual tissue. In patients with malignant polyps that have unfavorable histologic features, cancer resection is advisable if the patient is a good operative candidate.

B. Postpolypectomy Surveillance

Adenomas can be found in 30–40% of patients when another colonoscopy is performed within 3–5 years after the initial examination. Periodic colonoscopic surveillance is therefore recommended to detect these “metachronous” adenomas, which either may be new or may have been overlooked during the initial examination. Most of these adenomas are small, without high-risk features and of little immediate clinical significance. The probability of detecting advanced neoplasms at surveillance colonoscopy depends on the number, size, and histologic features of the polyps removed on initial (index) colonoscopy. Patients with 1–2 small (< 1 cm) tubular adenomas (without villous features or high-grade dysplasia) should have their next colonoscopy in 5–10 years. Patients with 3–10 adenomas, an adenoma > 1 cm, or an adenoma with villous features or high-grade dysplasia should have their next colonoscopy at 3 years. Patients with more than 10 adenomas should have a repeat colonoscopy at 1–2 years and may be considered for evaluation for a familial polyposis syndrome (see below).

HEREDITARY COLORECTAL CANCER & POLYPOSIS SYNDROMES

Up to 4% of all colorectal cancers are caused by germline genetic mutations that impose on carriers a high lifetime risk of developing colorectal cancer (see Chapter 39). Because the diagnosis of these disorders has important implications for treatment of affected members and for screening of family members, it is important to consider these disorders in patients with a family history of colorectal cancer that has affected more than one family member, those with a personal or family history of colorectal cancer developing at an early age (≥ 50 years), those with a personal or family history of multiple polyps (> 20), and those with a personal or family history of multiple extracolonic malignancies.

1. Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) is a syndrome affecting 1:10,000 people and accounts for approximately 0.5% of colorectal cancer. The classic form of FAP is characterized by the development of hundreds to thousands of colonic adenomatous polyps and a variety of extracolonic manifestations. An attenuated variant of FAP also has been recognized in which an average of only 25 polyps (range of 0–500) develop. FAP is most commonly caused by autosomally dominant inherited mutations in the adenomatous polyposis coli (*APC*) gene on chromosome 5q21. FAP arises de novo in 15% of patients in the absence of genetic mutations in the parents. Recently, mutations in the *MYH* gene, a gene involved with base excision repair, have been identified in patients with the classic and attenuated forms of FAP who do not have mutations of the *APC* gene. FAP due to *MYH* mutation is inherited in an autosomal recessive fashion, hence a family history of colorectal cancer may not be evident. Of patients with classic FAP, approximately 90% have a mutation in the *APC* gene and 8% in the *MYH* gene. In contrast, among patients with 10–100 adenomatous polyps and suspected attenuated FAP, *APC* mutations are identified in 15% but *MYH* mutations in 25%.

Colorectal polyps develop by a mean age of 15 years and cancer at 40 years. Unless prophylactic colectomy is per-

formed, colorectal cancer is inevitable by age 50 years. In attenuated FAP, the mean age for development of cancer is about 56 years.

Adenomatous polyps of the duodenum and periampullary area develop in over 90% of patients, resulting in a 5–8% lifetime risk of adenocarcinoma. Adenomas occur less frequently in the gastric antrum and small bowel and in those locations have a lower risk of malignant transformation. Gastric fundus gland polyps occur in over 50% but have an extremely low (0.6%) malignant potential.

A variety of other benign extraintestinal manifestations, including soft tissue tumors of the skin, desmoid tumors, osteomas, and congenital hypertrophy of the retinal pigment, develop in some patients with FAP. These extraintestinal manifestations vary among families, depending in part on the type or site of mutation in the *APC* gene. Desmoid tumors are locally invasive fibromas, most commonly intra-abdominal, that may cause bowel obstruction, ischemia, or hemorrhage. They occur in 15% of patients and are the second leading cause of death in FAP. Malignancies of the central nervous system (Turcot syndrome) and tumors of the thyroid and liver (hepatoblastomas) may also develop in patients with FAP.

Genetic counseling and testing should be offered to patients with a diagnosis of FAP established by endoscopy and to first-degree family members of patients with the disease; testing should be done also to confirm a diagnosis of attenuated disease in patients with 20 or more adenomas. Genetic testing is best performed by sequencing the *APC* gene to identify disease-associated mutations, which are identified in approximately 90% of cases of typical FAP. Mutational assessment of *MYH* should be considered in patients with negative test results and in patients with suspected attenuated FAP. First-degree relatives of patients with FAP should undergo genetic screening after age 10 years. If the assay cannot be done or is not informative, family members at risk should undergo yearly sigmoidoscopy beginning at 12 years of age. Once the diagnosis has been established, complete proctocolectomy with ileoanal anastomosis or colectomy with ileorectal anastomosis is recommended, usually before age 20 years. Ileorectal anastomosis affords superior bowel function but has a 5% risk of development of rectal cancer, and for that reason frequent sigmoidoscopy with fulguration of polyps is required. Sulindac and COX-2 selective agents (celecoxib) have been shown to decrease the number and size of polyps in the rectal stump but not the duodenum. Upper endoscopic evaluation of the stomach, duodenum, and periampullary area should be performed every 1–3 years to look for adenomas or carcinoma. Large (> 2 cm) periampullary adenomas require surgical resection.

Vasen HF et al. Guidelines for the clinical management of familial adenomatous polyposis (FAP). *Gut.* 2008 May;57(5):704–13. [PMID: 18194984]

2. Hamartomatous Polyposis Syndromes

Hamartomatous polyposis syndromes are rare and account for less than 0.1% of colorectal cancers.

Peutz-Jeghers syndrome is an autosomal dominant condition characterized by hamartomatous polyps throughout the gastrointestinal tract (most notably in the small intestine) as well as mucocutaneous pigmented macules on the lips, buccal mucosa, and skin. The hamartomas may become large, leading to bleeding, intussusception, or obstruction. Although hamartomas are not malignant, gastrointestinal malignancies (stomach, small bowel, and colon) develop in 40%, breast cancer in 50%, as well as a host of other malignancies of nonintestinal organs (gonads, pancreas). The defect has been localized to the serine threonine kinase 11 gene, and genetic testing is available.

Familial juvenile polyposis is also autosomal dominant and is characterized by several (more than ten) juvenile hamartomatous polyps located most commonly in the colon. There is an increased risk (up to 50%) of adenocarcinoma due to synchronous adenomatous polyps or mixed hamartomatous-adenomatous polyps. Genetic defects have been identified to loci on 18q and 10q (*MADH4* and *BMPRIA*). Genetic testing is available.

PTEN multiple hamartoma syndrome (Cowden disease) is characterized by hamartomatous polyps and lipomas throughout the gastrointestinal tract, trichilemmomas, and cerebellar lesions. An increased rate of malignancy is demonstrated in the thyroid, breast, and urogenital tract.

Zbuk KM et al. Hamartomatous polyposis syndromes. *Nat Clin Pract Gastroenterol Hepatol.* 2007 Sep;4(9):492–502. [PMID: 17768394]

3. Hereditary Nonpolyposis Colorectal Cancer (HNPCC)

HNPCC (also known as Lynch syndrome) is an autosomal dominant condition in which there is a markedly increased risk of developing colorectal cancer as well as a host of other cancers, including endometrial, ovarian, renal or vesical, hepatobiliary, gastric, and small intestinal cancers. It is estimated to account for up to 3% of all colorectal cancers. Affected individuals have a 50–80% lifetime risk of developing colorectal carcinoma and a 30–60% lifetime risk of endometrial cancer. Unlike individuals with familial adenomatous polyposis, patients with HNPCC develop only a few adenomas, which may be flat and more often contain villous features or high-grade dysplasia. In contrast to the traditional polyp → cancer progression (which may take over 10 years), these polyps are believed to undergo rapid transformation from normal tissue → adenoma → cancer. HNPCC and endometrial cancer tend to develop at an earlier age than sporadic, nonhereditary cancers (mean age 45–50 years). Compared with patients with sporadic tumors of similar pathologic stage, those with HNPCC tumors have improved survival. Synchronous or metachronous cancers occur within 10 years in up to 45% of patients.

HNPCC is caused by a defect in one of several genes that are important in the detection and repair of DNA base-pair mismatches: *MLH1*, *MSH2*, *MSH6*, and *PMS2*. Germline mutations in *MLH1* and *MSH2* account for

more than 90% of the known mutations in families with HNPCC. Mutations in any of these mismatch repair genes result in a characteristic phenotypic DNA abnormality known as microsatellite instability. In over 90% of cancers in patients with HNPCC, microsatellite instability is readily demonstrated by expansion or contraction of DNA microsatellites (short, repeated DNA sequences). Microsatellite instability also occurs in 15% of sporadic colorectal cancers, usually due to aberrant methylation of the *MLH1* promoter resulting in decreased gene expression.

A thorough family cancer history is essential to identify families that may be affected with HNPCC so that appropriate genetic and colonoscopic screening can be offered. Owing to the limitations of genetic testing for HNPCC and the medical, psychological, and social implications that such testing may have, families with suspected HNPCC should be evaluated first by a genetic counselor and should give informed consent in writing before genetic testing is performed. Patients whose families meet any of the revised “Bethesda criteria” have an increased likelihood of harboring a germline mutation in one of the mismatch repair genes and should be considered for genetic testing: (1) colorectal cancer under age 50; (2) synchronous or metachronous colorectal or HNPCC-associated tumor regardless of age (endometrial, stomach, ovary, pancreas, ureter and renal pelvis, biliary tract, brain); (3) colorectal cancer with one or more first-degree relatives with colorectal or HNPCC-related cancer, with one of the cancers occurring before age 50; (4) colorectal cancer with two or more second-degree relatives with colorectal or HNPCC cancer, regardless of age; (5) tumors with infiltrating lymphocytes, mucinous/signet ring differentiation, or medullary growth pattern in patients younger than 60 years. These criteria will identify greater than 90% of mutation-positive HNPCC families. Tumor tissues of affected individuals or family members meeting the revised Bethesda criteria should undergo immunohistochemical staining for *MLH1*, *MSH2*, *MSH6*, and *PMS2* (using commercially available assays) or testing for microsatellite instability (PCR amplification of a panel of DNA markers) or both. Individuals whose tumors have normal immunohistochemical staining or do not have microsatellite instability are unlikely to have germline mutations in mismatch repair genes, do not require further genetic testing, and do not require intensive cancer surveillance. Germline testing for gene mutations is positive in > 90% of individuals whose tumors show absent histochemical staining of one of the mismatch repair genes and in 50% of those whose tumors have a high level of microsatellite instability. Germline testing is also warranted in families with a strong history consistent with HNPCC when tumors from affected members are unavailable for assessment. If a mutation is detected in a patient with cancer in one of the known mismatch genes, genetic testing of other first-degree family members is indicated.

If genetic testing documents an HNPCC gene mutation, affected relatives should be screened with colonoscopy every 1–2 years beginning at age 25 (or at age 5 years younger than the age at diagnosis of the youngest affected family member). If cancer is found, subtotal colectomy with ileorectal anastomosis (followed by annual surveillance of the rectal

stump) should be performed. Women should undergo screening for endometrial and ovarian cancer beginning at age 25–35 years with pelvic examination, CA-125 assay, endometrial aspiration, and transvaginal ultrasound. Prophylactic hysterectomy and oophorectomy may be considered, especially in women of postchildbearing age. Similarly, consideration should be given for increased cancer surveillance in family members in proven or suspected HNPCC families who do not wish to undergo germline testing. (See **Chapter 39 for Colorectal Cancer.**)

ANORECTAL DISEASES

HEMORRHOIDS

ESSENTIALS OF DIAGNOSIS

- ▶ Bright red blood per rectum.
- ▶ Protrusion, discomfort.
- ▶ Characteristic findings on external anal inspection and anosopic examination.

▶ General Considerations

Internal hemorrhoids are subepithelial vascular cushions consisting of connective tissue, smooth muscle fibers, and arteriovenous communications between terminal branches of the superior rectal artery and rectal veins. They are a normal anatomic entity, occurring in all adults, that contribute to normal anal pressures and ensure a water-tight closure of the anal canal. They commonly occur in three primary locations—right anterior, right posterior, and left lateral. External hemorrhoids arise from the inferior hemorrhoidal veins located below the dentate line and are covered with squamous epithelium of the anal canal or perianal region.

Hemorrhoids may become symptomatic as a result of activities that increase venous pressure, resulting in distention and engorgement. Straining at stool, constipation, prolonged sitting, pregnancy, obesity, and low-fiber diets all may contribute. With time, redundancy and enlargement of the venous cushions may develop and result in bleeding or protrusion.

▶ Clinical Findings

A. Symptoms and Signs

Patients often attribute a variety of perianal complaints to “hemorrhoids.” However, the principal problems attributable to internal hemorrhoids are bleeding, prolapse, and mucoid discharge. Bleeding is manifested by bright red blood that may range from streaks of blood visible on toilet paper or stool to bright red blood that drips into the toilet bowl after a bowel movement. Rarely is bleeding severe enough to result in anemia. Initially, internal hemorrhoids are confined to the anal canal (stage I). Over time, the internal hemorrhoids may gradually enlarge and protrude from the anal opening. At first, this mucosal prolapse occurs during straining and reduces spontaneously (stage II). With progression over time, the prolapsed hemorrhoids may require manual reduction after bowel movements (stage III) or may remain chronically protruding (stage IV). Chronically prolapsed hemorrhoids may result in a sense of fullness or discomfort and mucoid perianal discharge, resulting in irritation and soiling of underclothes. Pain is unusual with internal hemorrhoids, occurring only when there is extensive inflammation and thrombosis of irreducible tissue or with thrombosis of an external hemorrhoid (see below).

B. Examination

External hemorrhoids are readily visible on perianal inspection. Nonprolapsed internal hemorrhoids are not visible but may protrude through the anus with gentle straining while the physician spreads the buttocks. Prolapsed hemorrhoids are visible as protuberant purple nodules covered by mucosa. The perianal region should also be examined for other signs of disease such as fistulas, fissures, skin tags, or dermatitis. On digital examination, uncomplicated internal hemorrhoids are neither palpable nor painful. Anoscopic evaluation, best performed in the prone jackknife position, provides optimal visualization of internal hemorrhoids.

▶ Differential Diagnosis

Small volume rectal bleeding may be caused by anal fissure or fistula, neoplasms of the distal colon or rectum, ulcerative colitis or Crohn colitis, infectious proctitis, or rectal ulcers. Rectal prolapse, in which a full thickness of rectum protrudes concentrically from the anus, is readily distinguished from mucosal hemorrhoidal prolapse. Proctosigmoidoscopy or colonoscopy should be performed in all patients with hematochezia to exclude disease in the rectum or sigmoid colon that could be misinterpreted in the presence of hemorrhoidal bleeding.

▶ Treatment

A. Conservative Measures

Most patients with early (stage I and stage II) disease can be managed with conservative treatment. To decrease straining with defecation, patients should be given instructions for a high-fiber diet and told to increase fluid intake with meals. Dietary fiber may be supplemented with bran powder (1–2 tbsps twice daily added to food or in 8 oz of

liquid) or with commercial bulk laxatives (eg, Benefiber, Metamucil, Citrucel). Suppositories and rectal ointments have no demonstrated utility in the management of mild disease. Mucoid discharge may be treated effectively by the local application of a cotton ball tucked next to the anal opening after bowel movements. For edematous, prolapsed hemorrhoids, gentle manual reduction may be supplemented by suppositories (eg, Anusol with or without hydrocortisone) or topical pads containing witch hazel (eg, Tucks) that have anesthetic and astringent properties and by warm sitz baths.

B. Medical Treatment

Patients with stage I, stage II, and stage III hemorrhoids and recurrent bleeding despite conservative measures may be treated without anesthesia with injection sclerotherapy, rubber band ligation, or application of electrocoagulation (bipolar cautery or infrared photocoagulation). The choice of therapy is dictated by operator preference, but rubber band ligation increasingly is preferred due to its ease of use and high rate of efficacy. Major complications occur in < 2%, including pelvic sepsis, pelvic abscess, urinary retention, and bleeding. Recurrence is common unless patients alter their dietary habits.

C. Surgical Treatment

Surgical excision (hemorrhoidectomy) is reserved for < 5–10% of patients with chronic severe bleeding due to stage III or stage IV hemorrhoids or patients with acute thrombosed stage IV hemorrhoids. Complications of surgical hemorrhoidectomy include postoperative pain (which may persist for 2–4 weeks) and impaired continence.

Thrombosed External Hemorrhoid

Thrombosis of the external hemorrhoidal plexus results in a perianal hematoma. It most commonly occurs in otherwise healthy young adults and may be precipitated by coughing, heavy lifting, or straining at stool. The condition is characterized by the relatively acute onset of an exquisitely painful, tense and bluish perianal nodule covered with skin that may be up to several centimeters in size. Pain is most severe within the first few hours but gradually eases over 2–3 days as edema subsides. Symptoms may be relieved with warm sitz baths, analgesics, and ointments. If the patient is evaluated in the first 24–48 hours, removal of the clot may hasten symptomatic relief. With the patient in the lateral position, the skin around and over the lump is injected subcutaneously with 1% lidocaine using a tuberculin syringe with a 30-gauge needle. An ellipse of skin is then excised and the clot evacuated. A dry gauze dressing is applied for 12–24 hours, and daily sitz baths are then begun.

► When to Refer

- Stage I, II, or III: When conservative measures fail and expertise in medical procedures is needed (injection, banding, thermocoagulation).
- Stage III or IV: When surgical excision is required.

ANORECTAL INFECTIONS

A number of organisms can cause inflammation of the anal and rectal mucosa. Proctitis is characterized by anorectal discomfort, tenesmus, constipation, and mucus or bloody discharge. Most cases of proctitis are sexually transmitted, especially by anal-receptive intercourse. Infectious proctitis must be distinguished from noninfectious causes of anorectal symptoms, including anal fissures or fistulas, perirectal abscesses, anorectal carcinomas, and inflammatory bowel disease (ulcerative colitis or Crohn disease).

► Etiology & Management

Several organisms may cause infectious proctitis.

A. *Neisseria gonorrhoeae*

Gonorrhea may cause itching, burning, tenesmus, and a mucopurulent discharge, although many anorectal infections are asymptomatic. Rectal swab specimens should be taken during anoscopy for culture; Gram staining is unreliable. Cultures should also be taken from the urethra and pharynx in men and from the cervix in women. Complications of untreated infections include strictures, fissures, fistulas, and perirectal abscesses.

B. *Treponema pallidum*

Anal syphilis may be asymptomatic or may lead to perianal pain and discharge. With primary syphilis, the chancre may be at the anal margin or within the anal canal and may mimic a fissure, fistula, or ulcer. Proctitis or inguinal lymphadenopathy may be present. With secondary syphilis, condylomata lata (pale-brown, flat verrucous lesions) may be seen, with secretion of foul-smelling mucus. Although the diagnosis may be established with dark-field microscopy or fluorescent antibody testing of scrapings from the chancre or condylomas, this requires proper equipment and trained personnel. The VDRL or RPR test is positive in 75% of primary cases and in 99% of secondary cases.

C. *Chlamydia trachomatis*

Chlamydial infection may cause proctitis similar to gonorrheal proctitis; however, some infections are asymptomatic. It also may cause lymphogranuloma venereum, characterized by proctocolitis with fever and bloody diarrhea, painful perianal ulcerations, anorectal strictures and fistulas, and inguinal adenopathy (buboes); however, this is rare in developed countries. The diagnosis is established by serology and culture of rectal discharge or rectal biopsy.

D. Herpes Simplex Type 2

Herpes simplex virus is a common cause of anorectal infection. Symptoms occur 4–21 days after exposure and include severe pain, itching, constipation, tenesmus, urinary retention, and radicular pain from involvement of lumbar or

sacral nerve roots. Small vesicles or ulcers may be seen in the perianal area or anal canal. Sigmoidoscopy is not usually necessary but may reveal vesicular or ulcerative lesions in the distal rectum. Diagnosis is established by viral culture, PCR, or antigen detection assays of vesicular fluid. Symptoms resolve within 2 weeks, but viral shedding may continue for several weeks. Patients may remain asymptomatic with or without viral shedding or may have recurrent mild relapses. Treatment of acute infection for 7–10 days with acyclovir, 400 mg or famciclovir 250 mg orally three times daily or valacyclovir 1 g twice daily, has been shown to reduce the duration of symptoms and viral shedding. Patients with AIDS and recurrent relapses may benefit from long-term suppressive therapy (see Chapter 31).

E. Condylomata Acuminata

Condylomata acuminata (warts) are a significant cause of anorectal symptoms. Caused by the human papillomavirus (HPV), they may occur in the perianal area, the anal canal, or the genitals. Perianal or anal warts are seen in up to 25% of men who have sex with men. HIV-positive individuals with condylomas have a higher relapse rate after therapy and a higher rate of progression to high-grade dysplasia or anal cancer. The warts are located on the perianal skin and extend within the anal canal up to 2 cm above the dentate line (Plate 35). Patients may have no symptoms or may report itching, bleeding, and pain. The warts may be small and flat or verrucous, or may form a confluent mass that may obscure the anal opening. Warts must be distinguished from condyloma lata (secondary syphilis) or anal cancer. Biopsies should be obtained from large or suspicious lesions. Treatment can be difficult. Sexual partners should also be examined and treated. The treatment of anogenital warts is discussed in Chapter 30. HPV vaccines have demonstrated efficacy in preventing anogenital warts and routine vaccination is now recommended for all girls and women ages 9–26 years. The role of HPV vaccination in boys and men is under investigation (see Chapters 1 and 30). HIV-positive individuals with condylomas who have detectable serum HIV RNA levels should have anosopic surveillance every 3–6 months.

FECAL INCONTINENCE

There are five general requirements for bowel continence: (1) solid or semisolid stool (even healthy young adults have difficulty maintaining continence with liquid rectal contents); (2) a distensible rectal reservoir (as sigmoid contents

empty into the rectum, the vault must expand to accommodate); (3) a sensation of rectal fullness (if the patient cannot sense this, overflow may occur before the patient can take appropriate action); (4) intact pelvic nerves and muscles; and (5) the ability to reach a toilet in a timely fashion.

▶ Minor Incontinence

Many patients complain of inability to control flatus or slight soilage of undergarments that tends to occur after bowel movements or with straining or coughing. This may be due to local anal problems such as prolapsed hemorrhoids that make it difficult to form a tight anal seal or isolated weakness of the internal anal sphincter, especially if stools are somewhat loose. Patients should be treated with fiber supplements to provide greater stool bulk. Coffee and other caffeinated beverages should be eliminated. The perianal skin should be cleansed with moist, lanolin-coated tissue (baby wipes) to reduce excoriation and infection. After wiping, loose application of a cotton ball near the anal opening may absorb small amounts of fecal leakage. Prolapsing hemorrhoids may be treated with band ligation or surgical hemorrhoidectomy. Control of flatus and seepage may be improved by Kegel perineal exercises. Conditions such as ulcerative proctitis that cause tenesmus and urgency, chronic diarrheal conditions, and irritable bowel syndrome may result in difficulty in maintaining complete continence, especially if a toilet is not readily available. Loperamide may be helpful to reduce urge incontinence in patients with loose stools and may be taken in anticipation of situations in which a toilet may not be readily available. The elderly may require more time or assistance to reach a toilet, which may lead to incontinence. Scheduled toileting and the availability of a bedside commode are helpful. Elderly patients with chronic constipation may develop stool impaction leading to “overflow” incontinence.

▶ Major Incontinence

Complete uncontrolled loss of stool reflects a significant problem with central perception or neuromuscular function. Incontinence that occurs without awareness suggests a loss of central awareness (eg, dementia, cerebrovascular accident, multiple sclerosis) or peripheral nerve injury (eg, spinal cord injury, cauda equina syndrome, pudendal nerve damage due to obstetric trauma or pelvic floor prolapse, aging, or diabetes mellitus). Incontinence that occurs despite awareness and active efforts to retain stool suggests sphincteric damage, which may be caused by traumatic childbirth (especially forceps delivery), episiotomy, prolapse, prior anal surgery, and physical trauma.

Physical examination should include careful inspection of the perianal area for hemorrhoids, rectal prolapse, fissures, fistulas, and either gaping or a keyhole defect of the anal sphincter (indicating severe sphincteric injury or neurologic disorder). The perianal skin should be stimulated to confirm an intact anocutaneous reflex. Digital examination during relaxation gives valuable information about resting tone (due mainly to the internal sphincter) and contraction of the external sphincter and pelvic floor during squeezing. It also excludes fecal impaction. Anos-

copy is required to evaluate for hemorrhoids, fissures, and fistulas. Proctosigmoidoscopy is useful to exclude rectal carcinoma or proctitis. Anal ultrasonography or pelvic MRI is the most reliable test for definition of anatomic defects in the external and internal anal sphincters. Anal manometry may also be useful to define the severity of weakness, to assess sensation, and to predict response to biofeedback training. In special circumstances, surface electromyography is useful to document sphincteric denervation and proctography to document perineal descent or rectal intussusception.

Patients who are incontinent only of loose or liquid stools are treated with bulking agents and antidiarrheal drugs (eg, loperamide, 2 mg before meals and prophylactically before social engagements, shopping trips, etc). Patients with incontinence of solid stool benefit from scheduled toilet use after glycerin suppositories or tap water enemas. Biofeedback training with anal sphincteric strengthening (Kegel) exercises (alternating 5-second squeeze and 10-second rest for 10 minutes twice daily) may be helpful in motivated patients to lower the threshold for awareness of rectal filling—or to improve anal sphincter squeeze function—or both. Operative management is seldom needed but should be considered in patients with major incontinence due to prior injury to the anal sphincter who have not responded to medical therapy.

▶ When to Refer

- Conservative measures fail.
- Anorectal tests are deemed necessary (manometry, ultrasonography, electromyography).
- A surgically correctable lesion is suspected.

OTHER ANAL CONDITIONS

▶ Anal Fissures

Anal fissures are linear or rocket-shaped ulcers that are usually less than 5 mm in length. Most fissures are believed to arise from trauma to the anal canal during defecation, perhaps caused by straining, constipation, or high internal sphincter tone. They occur most commonly in the posterior midline, but 10% occur anteriorly. Fissures that occur off the midline should raise suspicion for Crohn disease, HIV/AIDS, tuberculosis, syphilis, or anal carcinoma. Patients complain of severe, tearing pain during defecation followed by throbbing discomfort that may lead to constipation due to fear of recurrent pain. There may be mild associated hematochezia, with blood on the stool or toilet paper. Anal fissures are confirmed by visual inspection of the anal verge while gently separating the buttocks. Acute fissures look like

cracks in the epithelium. Chronic fissures result in fibrosis and the development of a skin tag at the outermost edge (sentinel pile). Digital and anoscopic examinations may cause severe pain and may not be possible. Medical management is directed at promoting effortless, painless bowel movements. Fiber supplements and sitz baths should be prescribed. Topical anesthetics (EMLA cream) may provide temporary relief. Healing occurs within 2 months in up to 45% of patients with conservative management. Chronic fissures may be treated with topical 0.2–0.4% nitroglycerin or diltiazem 2% ointment (1 cm of ointment) applied twice daily just inside the anus with the tip of a finger for 4–8 weeks or injection of botulinum toxin (20 units) into the anal sphincter. All of these treatments result in healing in 50–80% of patients with chronic anal fissure, but headaches occur in up to 40% of patients treated with nitroglycerin. Fissures recur in up to 40% of patients after treatment. Chronic or recurrent fissures benefit from lateral internal sphincterotomy; however, minor incontinence may complicate this procedure.

Brisinda G et al. Botulinum toxin for recurrent anal fissure following lateral internal sphincterotomy. *Br J Surg.* 2008 Jun;95(6):774–8. [PMID: 18425796]

Dhawan S et al. Nonsurgical approaches for the treatment of anal fissures. *Am J Gastroenterol.* 2007 Jun;102(6):1312–21. [PMID: 17531031]

▶ Perianal Abscess & Fistula

The anal glands located at the base of the anal crypts at the dentate line may become infected, leading to abscess formation. Other causes of abscess include anal fissure and Crohn disease. Abscesses may extend upward or downward through the intersphincteric plane. Symptoms of perianal abscess are throbbing, continuous perianal pain. Erythema, fluctuance, and swelling may be found in the perianal region on external examination or in the ischioanal fossa on digital rectal examination. Perianal abscesses are treated with local incision and drainage, while ischioanal abscesses require drainage in the operating room. After drainage of an abscess, most patients are found to have a fistula in ano.

Fistula in ano most often arises in an anal crypt and is usually preceded by an anal abscess. In patients with fistulas that connect to the rectum, other disorders such as Crohn disease, lymphogranuloma venereum, rectal tuberculosis, and cancer should be considered. Fistulas are associated with purulent discharge that may lead to itching, tenderness, and pain. The treatment of Crohn-related fistula is discussed elsewhere in this chapter. Treatment of idiopathic fistula in ano is by surgical incision or excision under anesthesia. Care must be taken to preserve the anal sphincters.

▶ Perianal Pruritus

Perianal pruritus is characterized by perianal itching and discomfort. It may be caused by poor anal hygiene associated with fistulas, fissures, prolapsed hemorrhoids, skin tags, and minor incontinence. Conversely, overzealous cleansing with soaps may contribute to local irritation or contact dermatitis. Contact dermatitis, atopic dermatitis,

bacterial infections (*Staphylococcus* or *Streptococcus*), parasites (pinworms, scabies), candidal infection (especially in diabetics), sexually transmitted disease (condylomata acuminata, herpes, syphilis, molluscum contagiosum), and other skin conditions (psoriasis, Paget, lichen sclerosis) must be excluded. In patients with idiopathic perianal pruritus, examination may reveal erythema, excoriations, or lichenified, eczematous skin. Education is vital to successful therapy. Spicy foods, coffee, chocolate, and tomatoes may cause irritation and should be eliminated. After bowel movements, the perianal area should be cleansed with nonscented wipes premoistened with lanolin followed

by gentle drying. A piece of cotton ball should be tucked next to the anal opening to absorb perspiration or fecal seepage. Anal ointments and lotions may exacerbate the condition and should be avoided. A short course of high-potency topical corticosteroid may be tried, although efficacy has not been demonstrated. Diluted capsaicin cream (0.006%) led to symptomatic relief in 75% of patients in a double-blind crossover study. (**See Chapter 39 for Carcinoma of the Anus.**)

Liver, Biliary Tract, & Pancreas Disorders

Lawrence S. Friedman, MD

JAUNDICE

ESSENTIALS OF DIAGNOSIS

- ▶ Results from accumulation of bilirubin in the body tissues; cause may be hepatic or nonhepatic.
- ▶ Hyperbilirubinemia may be due to abnormalities in the formation, transport, metabolism, and excretion of bilirubin.
- ▶ Total serum bilirubin is normally 0.2–1.2 mg/dL; jaundice may not be recognizable until levels are about 3 mg/dL.
- ▶ Evaluation of obstructive jaundice begins with ultrasonography and is usually followed by cholangiography.

▶ General Considerations

Jaundice (icterus) results from the accumulation of bilirubin—a product of heme metabolism—in the body tissues. Hyperbilirubinemia may be due to abnormalities in the formation, transport, metabolism, and excretion of bilirubin. Total serum bilirubin is normally 0.2–1.2 mg/dL (mean levels are higher in men than women and higher in whites and Hispanics than blacks and correlate inversely with the risk of stroke, suggesting that bilirubin is somehow neuroprotective). Jaundice may not be recognizable until levels are about 3 mg/dL.

Jaundice is caused by predominantly unconjugated or conjugated bilirubin in the serum (Table 16–1). Unconjugated hyperbilirubinemia may result from overproduction of bilirubin because of hemolysis; impaired hepatic uptake of bilirubin due to certain drugs; or impaired conjugation of bilirubin by glucuronide, as in Gilbert syndrome, due to mild decreases in glucuronyl transferase, or Crigler–Najjar syndrome, caused by moderate decreases or absence of glucuronyl transferase. Hemolysis alone rarely elevates the serum bilirubin level to more than 7 mg/dL. Predominantly conjugated hyperbilirubinemia may result from impaired excretion of bilirubin from the liver due to hepatocellular disease, drugs, sepsis, hereditary hepatocanalicular transport defects

(such as Dubin–Johnson syndrome, progressive familial intrahepatic cholestasis syndromes, and some cases of intrahepatic cholestasis of pregnancy), or extrahepatic biliary obstruction. Features of some hyperbilirubinemic syndromes are summarized in Table 16–2. The term “cholestasis” denotes retention of bile in the liver, and the term “cholestatic jaundice” is often used when conjugated hyperbilirubinemia results from impaired bile flow.

▶ Clinical Findings

A. Unconjugated Hyperbilirubinemia

Stool and urine color are normal, and there is mild jaundice and indirect (unconjugated) hyperbilirubinemia with no bilirubin in the urine. Splenomegaly occurs in hemolytic disorders except in sickle cell anemia.

B. Conjugated Hyperbilirubinemia

1. Hereditary cholestatic syndromes or intrahepatic cholestasis—The patient may be asymptomatic; cholestasis is often accompanied by pruritus, light-colored stools, and jaundice.

2. Hepatocellular disease—Malaise, anorexia, low-grade fever, and right upper quadrant discomfort are frequent. Dark urine, jaundice, and, in women, amenorrhea occur. An enlarged tender liver, vascular spiders, palmar erythema, ascites, gynecomastia, sparse body hair, fetor hepaticus, and asterixis may be present, depending on the cause, severity, and chronicity of liver dysfunction.

C. Biliary Obstruction

There may be right upper quadrant pain, weight loss (suggesting carcinoma), jaundice, dark urine, and light-colored stools. Symptoms and signs may be intermittent if caused by stone, carcinoma of the ampulla, or cholangiocarcinoma. Pain may be absent early in pancreatic cancer. Occult blood in the stools suggests cancer of the ampulla. Hepatomegaly and a palpable gallbladder (Courvoisier sign) are characteristic, but neither specific nor sensitive, of a pancreatic head tumor. Fever and chills are more common in benign obstruction with associated cholangitis.

Table 16–1. Classification of jaundice.

| Type of Hyperbilirubinemia | Location and Cause |
|---|--|
| Unconjugated hyperbilirubinemia (predominant indirect-reacting bilirubin) | Increased bilirubin production (eg, hemolytic anemias, hemolytic reactions, hematoma, pulmonary infarction) Impaired bilirubin uptake and storage (eg, posthepatitis hyperbilirubinemia, Gilbert syndrome, Crigler-Najjar syndrome, drug reactions) |
| Conjugated hyperbilirubinemia (predominant direct-reacting bilirubin) | HEREDITARY CHOLESTATIC SYNDROMES |
| | Faulty excretion of bilirubin conjugates (eg, Dubin-Johnson syndrome, Rotor syndrome) or mutation in genes coding for bile salt transport proteins (eg, progressive familial intrahepatic cholestasis syndromes, benign recurrent intrahepatic cholestasis, and some cases of intrahepatic cholestasis of pregnancy) |
| | HEPATOCELLULAR DYSFUNCTION |
| | Biliary epithelial and hepatocyte damage (eg, hepatitis, hepatic cirrhosis) Intrahepatic cholestasis (eg, certain drugs, biliary cirrhosis, sepsis, postoperative jaundice) Hepatocellular damage or intrahepatic cholestasis resulting from miscellaneous causes (eg, spirochetal infections, infectious mononucleosis, cholangitis, sarcoidosis, lymphomas, industrial toxins) |
| | BILIARY OBSTRUCTION |
| | Cholelithiasis, biliary atresia, carcinoma of biliary duct, sclerosing cholangitis, choledochal cyst, external pressure on common duct, pancreatitis, pancreatic neoplasms |

Table 16–2. Hyperbilirubinemic disorders.

| | Nature of Defect | Type of Hyperbilirubinemia | Clinical and Pathologic Characteristics |
|--|--|--|---|
| Gilbert syndrome | Reduced activity of glucuronyl transferase | Unconjugated (indirect) bilirubin | Benign, asymptomatic hereditary jaundice. Hyperbilirubinemia increased by 24- to 36-hour fast. No treatment required. Prognosis excellent. |
| Dubin-Johnson syndrome ¹ | Faulty excretory function of hepatocytes | Conjugated (direct) bilirubin | Benign, asymptomatic hereditary jaundice. Gallbladder does not visualize on oral cholecystography. Liver darkly pigmented on gross examination. Biopsy shows centrilobular brown pigment. Prognosis excellent. |
| Rotor syndrome | | | Similar to Dubin-Johnson syndrome, but liver is not pigmented and the gallbladder is visualized on oral cholecystography. Prognosis excellent. |
| Recurrent intrahepatic cholestasis ² | Cholestasis, often on a familial basis | Unconjugated plus conjugated (total) bilirubin | Episodic attacks of jaundice, itching, and malaise. Onset in early life and may persist for a lifetime. Alkaline phosphatase increased. Cholestasis found on liver biopsy. (Biopsy may be normal during remission.) Prognosis is generally excellent for “benign” recurrent intrahepatic cholestasis but may not be for familial forms. |
| Intrahepatic cholestasis of pregnancy ³ | | | Benign cholestatic jaundice, usually occurring in the third trimester of pregnancy. Itching, gastrointestinal symptoms, and abnormal liver excretory function tests. Cholestasis noted on liver biopsy. Prognosis excellent, but recurrence with subsequent pregnancies or use of birth control pills is characteristic. |

¹The Dubin-Johnson syndrome is caused by a point mutation in the gene coding for an organic anion transporter in bile canaliculi on chromosome 10q23–24.

²Mutations in genes that control hepatocellular transport systems that are involved in the formation of bile and inherited as autosomal recessive traits are on chromosomes 18q21–22, 2q24, and 7q21 in families with progressive familial intrahepatic cholestasis. Gene mutations on chromosome 18q21–22 alter a P-type ATPase expressed in the small intestine and liver and others on chromosome 2q24 alter the bile acid export pump and cause benign recurrent intrahepatic cholestasis.

³Mutations in the *MDR3* gene on chromosome 7q 21 that are responsible for progressive familial intrahepatic cholestasis type 3 account for some cases of intrahepatic cholestasis of pregnancy.

► Diagnostic Methods for Evaluation of Liver Disease & Jaundice (Tables 16–3, 16–4)

A. Laboratory Studies

Serum alanine and aspartate aminotransferase (ALT and AST) levels vary with age and correlate with body mass index,

coronary artery disease, and mortality from liver disease and inversely with caffeine consumption. Normal reference values for ALT and AST may be lower than generally reported when persons with risk factors for fatty liver are excluded. Early-onset paternal obesity is a risk factor for increased ALT levels. Elevated ALT and AST levels result from hepatocellular

Table 16-3. Liver biochemical tests: Normal values and changes in two types of jaundice.

| Tests | Normal Values | Hepatocellular jaundice | Uncomplicated Obstructive jaundice |
|-----------------------------|---|---|---|
| Bilirubin | | | |
| Direct | 0.1-0.3 mg/dL | Increased | Increased |
| Indirect | 0.2-0.7 mg/dL | Increased | Increased |
| Urine bilirubin | None | Increased | Increased |
| Serum albumin/total protein | Albumin, 3.5-5.5 g/dL | Albumin decreased Total protein, 6.5-8.4 g/dL | Unchanged |
| Alkaline phosphatase | 30-115 units/L | Increased (+) | Increased (++++) |
| Prothrombin time | INR of 1.0-1.4. After vitamin K, 10% increase in 24 hours | Prolonged if damage severe and does not respond to parenteral vitamin K | Prolonged if obstruction marked, but responds to parenteral vitamin K |
| ALT, AST | ALT, 5-35 units/L; AST, 5-40 units/L | Increased in hepatocellular damage, viral hepatitis | Minimally increased |

ALT, alanine aminotransferase; AST, aspartate aminotransferase; INR, international normalized ratio.

necrosis or inflammation. Levels are frequently elevated in persons with untreated celiac disease and often rise transiently in healthy persons who begin taking 4 g of acetaminophen per day or experience rapid weight gain on a fast-food diet. Elevated alkaline phosphatase levels are seen

in cholestasis or infiltrative liver disease (such as tumor or granuloma). Alkaline phosphatase elevations of hepatic rather than bone, intestinal, or placental origin are confirmed by concomitant elevation of γ -glutamyl transpeptidase or 5'-nucleotidase levels. The differential diagnosis of any liver test elevation includes toxicity caused by drugs, herbal remedies, and toxins.

Table 16-4. Causes of serum aminotransferase elevations.¹

| Mild Elevations (< 5 \times normal) | Severe Elevations (> 15 \times normal) |
|--|---|
| Hepatic: ALT-predominant Chronic hepatitis B, C, and D Acute viral hepatitis (A-E, EBV, CMV) Steatosis/steatohepatitis Hemochromatosis Medications/toxins Autoimmune hepatitis α_1 -Antitrypsin (α_1 -antitrypsin) deficiency Wilson disease Celiac disease Hepatic: AST-predominant Alcohol-related liver injury (AST:ALT > 2:1) Cirrhosis Nonhepatic Strenuous exercise Hemolysis Myopathy Thyroid disease Macro-AST | Acute viral hepatitis (A-E, herpes) Medications/toxins Ischemic hepatitis Autoimmune hepatitis Wilson disease Acute bile duct obstruction Acute Budd-Chiari syndrome Hepatic artery ligation |

¹Almost any liver disease can cause moderate aminotransferase elevations (5-15 \times normal)

ALT, alanine aminotransferase; AST, aspartate aminotransferase; CMV, cytomegalovirus; EBV, Epstein-Barr virus.

B. Liver Biopsy

Percutaneous liver biopsy is the definitive study for determining the cause and histologic severity of hepatocellular dysfunction or infiltrative liver disease. In patients with suspected metastatic disease or a hepatic mass, it is performed under ultrasound or CT guidance. A transjugular route can be used in patients with coagulopathy or ascites. Panels of blood tests (eg, FibroSure) and transient or magnetic resonance elastography (ultrasonographic and magnetic resonance techniques, respectively, to measure liver stiffness) are emerging approaches for estimating the degree of liver fibrosis without the need for liver biopsy.

C. Imaging

Demonstration of dilated bile ducts by ultrasonography or CT scan indicates biliary obstruction (90-95% sensitivity). Ultrasonography, CT scan, and MRI may also demonstrate hepatomegaly, intrahepatic tumors, and portal hypertension. Multiphasic helical or multislice CT, CT arterial portography, in which imaging follows intravenous contrast infusion via a catheter placed in the superior mesenteric artery, MRI with use of gadolinium or ferumoxides as contrast agents, and intraoperative ultrasonography are the most sensitive techniques for detection of individual small hepatic lesions in patients eligible for resection of metastases. Use of color Doppler ultrasound or contrast agents that produce microbubbles increases the sensitivity of transcutaneous ultrasound for detecting small neoplasms. MRI is the most accurate technique for identifying isolated liver lesions such as hemangiomas, focal nodular

hyperplasia, or focal fatty infiltration and for detecting hepatic iron overload. Dynamic gadolinium-enhanced MRI and administration of superparamagnetic iron oxide show promise in visualizing hepatic fibrosis. Because of its much lower cost (amount charged), ultrasonography (\$300–\$1000) is preferable to CT (\$1700) or MRI (\$2100) as a screening test. Ultrasonography can detect gallstones with a sensitivity of 95%.

Magnetic resonance cholangiopancreatography (MRCP) is a sensitive, noninvasive method of detecting bile duct stones, strictures, and dilation; however, it is less reliable than endoscopic retrograde cholangiopancreatography (ERCP) for distinguishing malignant from benign strictures. ERCP requires a skilled endoscopist and may be used to demonstrate pancreatic or ampullary causes of jaundice, to carry out papillotomy and stone extraction, or to insert a stent through an obstructing lesion or to facilitate direct cholangiopancreatography. Complications of ERCP include pancreatitis (5%) and, less commonly, cholangitis, bleeding, or duodenal perforation after papillotomy. Risk factors for post-ERCP pancreatitis include female gender, prior post-ERCP pancreatitis, suspected sphincter of Oddi dysfunction, and a difficult or failed cannulation. Percutaneous transhepatic cholangiography (PTC) is an alternative approach to evaluating the anatomy of the biliary tree. Severe complications of PTC occur in 3% and include fever, bacteremia, bile peritonitis, and intraperitoneal hemorrhage. Endoscopic ultrasonography is the most sensitive test for detecting small lesions of the ampulla or pancreatic head and for detecting portal vein invasion by pancreatic cancer. It is also accurate in detecting or excluding bile duct stones.

▶ When to Refer

Patients with jaundice should be referred for diagnostic procedures.

▶ When to Admit

Patients with liver failure should be hospitalized.

DISEASES OF THE LIVER

ACUTE VIRAL HEPATITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Prodrome of anorexia, nausea, vomiting, malaise, aversion to smoking.
- ▶ Fever, enlarged and tender liver, jaundice.
- ▶ Normal to low white cell count; abnormal liver tests, especially markedly elevated aminotransferases early in the course.
- ▶ Liver biopsy shows hepatocellular necrosis and mononuclear infiltrate but is rarely indicated.

▶ General Considerations

Hepatitis can be caused by many drugs and toxic agents as well as by numerous viruses, the clinical manifestations of which may be quite similar. Viruses causing hepatitis are (1) hepatitis A virus (HAV), (2) hepatitis B virus (HBV), (3) hepatitis C virus (HCV), (4) hepatitis D virus (HDV) (delta agent), and (5) hepatitis E virus (HEV) (an enterically transmitted hepatitis seen in epidemic form in Asia, the Middle East, and North Africa). Hepatitis G virus (HGV) rarely, if ever, causes frank hepatitis. A DNA virus designated the TT virus (TTV) has been identified in up to 7.5% of blood donors and found to be transmitted readily by blood transfusions, but an association between this virus and liver disease has not been established. A related virus known as SEN-V has been found in 2% of US blood donors, is transmitted by transfusion, and may account for some cases of transfusion-associated non-ABCDE hepatitis. In immunocompromised and rare immunocompetent persons, cytomegalovirus, Epstein–Barr virus, and herpes simplex virus should be considered in the differential diagnosis of hepatitis. Severe acute respiratory syndrome (SARS) may be associated with marked serum aminotransferase elevations. Unidentified pathogens account for a small percentage of cases of acute viral hepatitis.

A. Hepatitis A

Figure 16–1 shows the typical course of HAV infection. HAV is a 27-nm RNA hepatovirus (in the picornavirus family) that causes epidemics or sporadic cases of hepatitis. The virus is transmitted by the fecal–oral route, and its spread is favored by crowding and poor sanitation. Since introduction of the HAV vaccine in the United States in 1995, the incidence rate of HAV infection has declined by over 76%, with a corresponding decline in the mortality rate of 32%. Common source outbreaks result from contaminated water or food, including inadequately cooked shellfish. A large outbreak among patrons of a restaurant in Monaca, Pennsylvania, in 2003 was traced to contaminated green onions from Mexico. Outbreaks among injection drug users and cases among international adoptees and their contacts have been reported.

▲ **Figure 16-1.** The typical course of acute type A hepatitis. (HAV, hepatitis A virus; anti-HAV, antibody to hepatitis A virus; ALT, alanine aminotransferase.) (Reprinted with permission from Koff RS. Acute viral hepatitis. In: *Handbook of Liver Disease*. Friedman LS, Keeffe EB [editors], 2nd ed. ©Elsevier, 2004.)

The incubation period averages 30 days. HAV is excreted in feces for up to 2 weeks before clinical illness but rarely after the first week of illness. The mortality rate for hepatitis A is low, and fulminant hepatitis A is uncommon except for rare instances in which it occurs in a patient with chronic hepatitis C. There is no chronic carrier state. Clinical illness is more severe in adults than in children, in whom it is typically asymptomatic.

Antibody to hepatitis A (anti-HAV) appears early in the course of the illness. Both IgM and IgG anti-HAV are detectable in serum soon after the onset. Peak titers of IgM anti-HAV occur during the first week of clinical disease and disappear within 3–6 months. Detection of IgM anti-HAV is an excellent test for diagnosing acute hepatitis A but is not recommended for the evaluation of asymptomatic persons with persistently elevated serum aminotransferase levels because false-positive results occur. Titers of IgG anti-HAV rise after 1 month of the disease and may persist for years. IgG anti-HAV indicates previous exposure to HAV, noninfectivity, and immunity. In the United States, about 30% of the population have serologic evidence of previous infection.

B. Hepatitis B

Figure 16-2 shows the typical course of HBV infection. HBV is a 42-nm hepadnavirus with a partially double-stranded DNA genome, inner core protein (hepatitis B core antigen, HBcAg), and outer surface coat (hepatitis B surface antigen, HBsAg). There are eight different genotypes (A–H), which may influence the course of infection and responsiveness to antiviral therapy. HBV is usually transmitted by inoculation of infected blood or blood products or by sexual contact and is present in saliva, semen, and vaginal secretions. HBsAg-positive mothers may transmit HBV at delivery; the risk of chronic infection in the infant is as high as 90%.

▲ **Figure 16-2.** The typical course of acute type B hepatitis. (HBsAg, hepatitis B surface antigen; anti-HBs, antibody to HBsAg; HBeAg, hepatitis Be antigen; anti-HBe, antibody to HBeAg; anti-HBc, antibody to hepatitis B core antigen; ALT, alanine aminotransferase.) (Reprinted with permission from Koff RS. Acute viral hepatitis. In: *Handbook of Liver Disease*. Friedman LS, Keeffe EB [editors], 2nd ed. ©Elsevier, 2004.)

HBV is prevalent in men who have sex with men and in injection drug users (about 7% of HIV-infected persons are coinfecting with HBV), but the greatest number of cases results from heterosexual transmission; the incidence has decreased by over 75% since the 1980s. Groups at risk include patients and staff at hemodialysis centers, physicians, dentists, nurses, and personnel working in clinical and pathology laboratories and blood banks. Half of all patients with acute hepatitis B in the United States have previously been incarcerated or treated for a sexually transmitted disease. The risk of HBV infection from a blood transfusion is less than 1 in 60,000 units transfused in the United States.

The incubation period of hepatitis B is 6 weeks to 6 months (average 12–14 weeks). The onset of hepatitis B is more insidious and the aminotransferase levels are higher than in HAV infection. Fulminant hepatitis occurs in less than 1%, with a mortality rate of up to 60%. Following acute hepatitis B, HBV infection persists in 1–2% of immunocompetent adults but in a higher percentage of immunocompromised adults or children. Persons with chronic hepatitis B, particularly when HBV infection is acquired early in life and viral replication persists, are at substantial risk of cirrhosis and hepatocellular carcinoma (up to 25–40%). Men are at greater risk than women. Infection caused by HBV may be associated with serum sickness, glomerulonephritis, and polyarteritis nodosa.

There are three distinct antigen–antibody systems that relate to HBV infection and circulating markers that are useful in diagnosis. Interpretation of common serologic patterns is shown in Table 16-5.

1. HBsAg—The appearance of HBsAg is the first evidence of infection, appearing before biochemical evidence of

Table 16–5. Common serologic patterns in hepatitis B virus infection and their interpretation.

| HBsAg | Anti-HBs | Anti-HBc | HBeAg | Anti-HBe | Interpretation |
|-------|----------|------------------|--------|----------|--|
| + | – | IgM | + | – | Acute hepatitis B |
| + | – | IgG ¹ | + | – | Chronic hepatitis B with active viral replication |
| + | – | IgG | – | + | Chronic hepatitis B with low viral replication |
| + | + | IgG | + or – | + or – | Chronic hepatitis B with heterotypic anti-HBs (about 10% of cases) |
| – | – | IgM | + or – | – | Acute hepatitis B |
| – | + | IgG | – | + or – | Recovery from hepatitis B (immunity) |
| – | + | – | – | – | Vaccination (immunity) |
| – | – | IgG | – | – | False-positive; less commonly, infection in remote past |

¹Low levels of IgM anti-HBc may also be detected.

liver disease, and persists throughout the clinical illness. Persistence of HBsAg more than 6 months after the acute illness signifies chronic hepatitis B.

2. Anti-HBs—Specific antibody to HBsAg (anti-HBs) appears in most individuals after clearance of HBsAg and after successful vaccination against hepatitis B. Disappearance of HBsAg and the appearance of anti-HBs signal recovery from HBV infection, noninfectivity, and immunity.

3. Anti-HBc—IgM anti-HBc appears shortly after HBsAg is detected. (HBcAg alone does not appear in serum.) Its presence in the setting of acute hepatitis indicates a diagnosis of acute hepatitis B, and it fills the serologic gap in rare patients who have cleared HBsAg but do not yet have detectable anti-HBs. IgM anti-HBc can persist for 3–6 months or longer. IgM anti-HBc may also reappear during flares of previously inactive chronic hepatitis B. IgG anti-HBc also appears during acute hepatitis B but persists indefinitely, whether the patient recovers (with the appearance of anti-HBs in serum) or chronic hepatitis B develops (with persistence of HBsAg). In asymptomatic blood donors, an isolated anti-HBc with no other positive HBV serologic results may represent a falsely positive result or latent infection in which HBV DNA is detectable only by polymerase chain reaction testing.

4. HBeAg—HBeAg is a secretory form of HBcAg that appears in serum during the incubation period shortly after the detection of HBsAg. HBeAg indicates viral replication and infectivity. Persistence of HBeAg beyond 3 months indicates an increased likelihood of chronic hepatitis B. Its disappearance is often followed by the appearance of anti-HBe, generally signifying diminished viral replication and decreased infectivity.

5. HBV DNA—The presence of HBV DNA in serum generally parallels the presence of HBeAg, although HBV DNA is a more sensitive and precise marker of viral replication and infectivity. Very low levels of HBV DNA, detectable only by polymerase chain reaction testing, may persist in serum and liver long after a patient has recovered from acute hepatitis B, but the HBV DNA in serum is bound to IgG and is rarely infectious. In some patients with chronic hepatitis B, HBV

DNA is present at high levels without HBeAg in serum because of development of a mutation in the core promoter or precore region of the gene that codes HBcAg; these mutations prevent synthesis of HBeAg in infected hepatocytes. When additional mutations in the core gene are present, the pre-core mutant enhances the severity of HBV infection and increases the risk of cirrhosis.

C. Hepatitis D (Delta Agent)

HDV is a defective RNA virus that causes hepatitis only in association with hepatitis B infection and specifically only in the presence of HBsAg; it is cleared when the latter is cleared.

HDV may coinfect with HBV or may superinfect a person with chronic hepatitis B, usually by percutaneous exposure. When acute hepatitis D is coincident with acute HBV infection, the infection is generally similar in severity to acute hepatitis B alone. In chronic hepatitis B, superinfection by HDV appears to carry a worse short-term prognosis, often resulting in fulminant hepatitis or severe chronic hepatitis that progresses rapidly to cirrhosis.

In the 1970s and early 1980s, HDV was endemic in some areas, such as the Mediterranean countries (and later in central and Eastern Europe), where up to 80% of HBV carriers were superinfected with it. In the United States, HDV occurred primarily among injection drug users. However, new cases of hepatitis D are now infrequent in the United States, and cases seen today are usually from cohorts infected years ago who survived the initial impact of hepatitis D and now have inactive cirrhosis. These patients have a threefold increased risk of hepatocellular carcinoma. Diagnosis is made by detection of antibody to hepatitis D antigen (anti-HDV) or, where available, hepatitis D antigen (HDAg) or HDV RNA in serum.

D. Hepatitis C

Figure 16–3 shows the typical course of HCV infection. HCV is a single-stranded RNA virus (hepacivirus) with properties similar to those of flavivirus. At least six major genotypes of HCV have been identified. In the past, HCV was responsible for over 90% of cases of posttransfusion

▲ **Figure 16-3.** The typical course of acute and chronic hepatitis C. (ALT, alanine aminotransferase; Anti-HCV, antibody to hepatitis C virus by enzyme immunoassay; HCV RNA [PCR], hepatitis C viral RNA by polymerase chain reaction.)

hepatitis, yet only 4% of cases of hepatitis C were attributable to blood transfusions. Over 50% of cases are transmitted by injection drug use. Body piercing, tattoos, and hemodialysis are risk factors. The risk of sexual and maternal–neonatal transmission is low and may be greatest in a subset of patients with high circulating levels of HCV RNA. Having multiple sexual partners may increase the risk of HCV infection, and HIV coinfection increases the risk of HCV transmission in men who have sex with men. Transmission via breastfeeding has not been documented. An outbreak of hepatitis C in patients with immune deficiencies occurred in some recipients of intravenous immune globulin. Hospital-acquired transmission has occurred via multidose vials of saline used to flush Portacaths; through reuse of disposable syringes; through contamination of shared saline, radiopharmaceutical, and sclerosant vials; and between hospitalized patients on a liver unit. In the developing world, unsafe medical practices lead to a substantial number of cases of HCV infection. Covert transmission during bloody fisticuffs has even been reported. In many patients, the source of infection is unknown. Coinfection with HCV is found in at least 30% of persons infected with HIV; HIV infection leads to an increased risk of acute hepatic failure and more rapid progression of chronic hepatitis C to cirrhosis; in addition, HCV increases the hepatotoxicity of highly active antiretroviral therapy. There are more than 2.7 million HCV carriers in the United States and another 1.3 million previously exposed persons who have cleared the virus.

The incubation period averages 6–7 weeks, and clinical illness is often mild, usually asymptomatic, and characterized by waxing and waning aminotransferase elevations and a high rate (> 80%) of chronic hepatitis. In pregnant patients, serum aminotransferase levels frequently normalize despite persistence of viremia, only to increase again after delivery. HCV is a pathogenetic factor in mixed cryoglobulinemia and

membranoproliferative glomerulonephritis and may be related to lichen planus, autoimmune thyroiditis, lymphocytic sialadenitis, idiopathic pulmonary fibrosis, sporadic porphyria cutanea tarda, and monoclonal gammopathies. HCV infection confers a 20–30% increased risk of non-Hodgkin lymphoma. Hepatitis C may induce insulin resistance (which in turn increases the risk of hepatic fibrosis), and the risk of type 2 diabetes mellitus is increased in persons with chronic hepatitis C. Hepatic steatosis is a particular feature of infection with HCV genotype 3 and may also occur in patients with risk factors for fatty liver (see below).

Diagnosis of hepatitis C is based on an enzyme immunoassay that detects antibodies to HCV. Anti-HCV is not protective, and in patients with acute or chronic hepatitis its presence in serum generally signifies that HCV is the cause. Limitations of the enzyme immunoassay include moderate sensitivity (false-negatives) for the diagnosis of acute hepatitis C early in the course and low specificity (false-positives) in some persons with elevated γ -globulin levels. In these situations, a diagnosis of hepatitis C may be confirmed by using an assay for HCV RNA. Occasional persons are found to have anti-HCV in serum, confirmed by a recombinant immunoblot assay (RIBA), without HCV RNA in serum, suggesting recovery from HCV infection in the past. Testing donated blood for HCV has helped reduce the risk of transfusion-associated hepatitis C from 10% in 1990 to about 1 case per 2 million units today.

E. Hepatitis E

HEV is a 29- to 32-nm RNA hepevirus (in the Hepeviridae family) that is a major cause of acute hepatitis throughout Central and Southeast Asia, the Middle East, and North Africa, where it is responsible for waterborne hepatitis outbreaks. It is rare in the United States but should be considered in patients with acute hepatitis after a trip to an endemic area. In industrialized countries, it may be spread by swine. Illness generally is self-limited (no carrier state), but instances of chronic hepatitis attributed to HEV have been reported in transplant recipients. The mortality rate is high (10–20%) in pregnant women, and the risk of hepatic decompensation is increased in patients with underlying chronic liver disease.

F. Hepatitis G

HGV is a flavivirus that is percutaneously transmitted and associated with chronic viremia lasting at least 10 years. HGV has been detected in 1.5% of blood donors, 50% of injection drug users, 30% of hemodialysis patients, 20% of hemophiliacs, and 15% of patients with chronic hepatitis B or C, but it does not appear to cause important liver disease or affect the response of patients with chronic hepatitis B or C to antiviral therapy. HGV coinfection may improve survival in patients with HIV infection and reduce the degree of fibrosis in patients with HCV-HIV coinfection.

► Clinical Findings

The clinical picture of viral hepatitis is extremely variable, ranging from asymptomatic infection without jaundice to a fulminating disease and death in a few days.

A. Symptoms

The onset may be abrupt or insidious, with general malaise, myalgia, arthralgia, easy fatigability, upper respiratory symptoms, and anorexia. A distaste for smoking, paralleling anorexia, may occur early. Nausea and vomiting are frequent, and diarrhea or constipation may occur. Serum sickness may be seen early in acute hepatitis B. Fever is generally present but is low-grade except in occasional cases of hepatitis A. Defervescence and a fall in pulse rate often coincide with the onset of jaundice.

Abdominal pain is usually mild and constant in the right upper quadrant or epigastrium, often aggravated by jarring or exertion, and rarely may be severe enough to simulate cholecystitis.

Jaundice occurs after 5–10 days but may appear at the same time as the initial symptoms. In many patients, jaundice never develops. With the onset of jaundice, prodromal symptoms often worsen, followed by progressive clinical improvement. Stools may be acholic during this phase.

The acute illness usually subsides over 2–3 weeks with complete clinical and laboratory recovery by 9 weeks in hepatitis A and by 16 weeks in hepatitis B. In 5–10% of cases, the course may be more protracted, but less than 1% will have a fulminant course. In some cases of acute hepatitis A, clinical, biochemical, and serologic recovery may be followed by one or two relapses, but recovery is the rule. A protracted course of hepatitis A has been reported to be associated with HLA *DRB1*1301*. Acute cholecystitis occasionally complicates the course of acute hepatitis A. Hepatitis B, D, and C (and G) may become chronic (see below).

B. Signs

Hepatomegaly—rarely marked—is present in over half of cases. Liver tenderness is usually present. Splenomegaly is reported in 15% of patients, and soft, enlarged lymph nodes—especially in the cervical or epitrochlear areas—may occur. Systemic toxicity is most often encountered in hepatitis A. Slight neurocognitive impairment has been described in patients with chronic hepatitis C.

C. Laboratory Findings

The white blood cell count is normal to low, especially in the preicteric phase. Large atypical lymphocytes may occasionally be seen. Rarely, aplastic anemia follows an episode of acute hepatitis not caused by any of the known hepatitis viruses. Mild proteinuria is common, and bilirubinuria often precedes the appearance of jaundice. Strikingly elevated AST or ALT occurs early, followed by elevations of bilirubin and alkaline phosphatase; in a minority of patients, the latter persist after aminotransferase levels have normalized. Cholestasis is occasionally marked in acute hepatitis A. Marked prolongation of the prothrombin time in severe hepatitis correlates with increased mortality.

► Differential Diagnosis

The differential diagnosis includes other viral diseases such as infectious mononucleosis, cytomegalovirus infection, and herpes simplex virus infection; spirochetal diseases

such as leptospirosis and secondary syphilis; brucellosis; rickettsial diseases such as Q fever; drug-induced liver disease; and shock liver (ischemic hepatitis). Occasionally, autoimmune hepatitis (see below) may have an acute onset mimicking acute viral hepatitis. Rarely, metastatic cancer of the liver may present with a hepatitis-like picture.

The prodromal phase of viral hepatitis must be distinguished from other infectious disease such as influenza, upper respiratory infections, and the prodromal stages of the exanthematous diseases. Cholestasis may mimic obstructive jaundice.

► Prevention

Strict isolation of patients is not necessary, but hand washing after bowel movements is required. Thorough hand washing by medical staff who may contact contaminated utensils, bedding, or clothing is essential. Medical staff should handle disposable needles carefully and not recap them. Screening of donated blood for HBsAg, anti-HBc, and anti-HCV has reduced the risk of transfusion-associated hepatitis markedly. All pregnant women should undergo testing for HBsAg. HBV- and HCV-infected persons should practice safe sex, but there is little evidence that HCV is spread easily by sexual contact, and no precautions are recommended for persons in a monogamous relationship. Vaccination against HAV (after prescreening for prior immunity) and HBV is recommended for patients with chronic hepatitis C, and vaccination against HAV is recommended for patients with chronic hepatitis B. Improved public hygiene reduces the risk of HEV infection in endemic areas. A recombinant vaccine against HEV has shown promise in clinical trials.

A. Hepatitis A

Unvaccinated persons who are exposed to HAV are advised to receive postexposure prophylaxis with a single dose of HAV vaccine or immune globulin (0.02 mL/kg) as soon as possible. The vaccine is preferred in healthy persons ages 1 year to 40 years, whereas immune globulin is preferred in those older than 40 years or younger than 1 year or who are immunocompromised or have chronic liver disease.

Two effective inactivated hepatitis A vaccines are available and recommended for persons living in or traveling to endemic areas (including military personnel), patients with chronic liver disease upon diagnosis, persons with clotting-factor disorders who are treated with concentrates, men who have sex with men, men who have sex with both men and women, animal handlers, illicit drug users, sewage workers, food handlers, and children and caregivers in day care centers and institutions. For healthy travelers, a single dose of vaccine at any time before departure can provide adequate protection. Routine vaccination is advised for all children in states with an incidence of hepatitis A at least twice the national average and has been recommended by the Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention (CDC) for all children between ages 1 and 2 in the United States. HAV vaccine is also effective in the prevention of secondary spread to household contacts of

primary cases. The recommended dose for adults is 1 mL (1440 ELISA units) of Havrix (GlaxoSmithKline) or 1 mL (50 units) of Vaqta (Merck) intramuscularly, followed by a booster dose at 6–18 months. A combined hepatitis A and B vaccine (Twinrix, GlaxoSmithKline) is available. HIV infection impairs the response to the HAV vaccine, especially in persons with a CD4 count less than 200/mcL.

B. Hepatitis B

Hepatitis B immune globulin (HBIG) may be protective—or may attenuate the severity of illness—if given in large doses within 7 days after exposure (adult dose is 0.06 mL/kg body weight) followed by initiation of the HBV vaccine series (see below). This approach is currently recommended for persons exposed to HBsAg-contaminated material via mucous membranes or through breaks in the skin and for individuals who have had sexual contact with a person with HBV infection (irrespective of the presence or absence of HBeAg in the source). HBIG is also indicated for newborn infants of HBsAg-positive mothers followed by initiation of the vaccine series (see below).

The currently used vaccines are recombinant-derived. Initially, the vaccine was targeted to persons at high risk, including renal dialysis patients and attending personnel, patients requiring repeated transfusions, spouses of HBsAg-positive persons, men who have sex with men, injection drug users, newborns of HBsAg-positive mothers, beginning medical and nursing students, and all medical technologists. Because this strategy failed to lower the incidence of hepatitis B, the CDC recommends vaccination of all infants and children in the United States and all adults who are at risk for hepatitis B or request vaccination. Over 90% of recipients of the vaccine mount protective antibody to hepatitis B; immunocompromised persons respond poorly. Reduced response to the vaccine may have a genetic basis in some cases and has also been associated with age over 40 years and celiac disease. The standard regimen for adults is 10–20 mcg initially (depending on the formulation) repeated again at 1 and 6 months, but alternative schedules have been approved, including accelerated schedules of 0, 1, 2, and 12 months and of 0, 7, and 21 days plus 12 months. For greatest reliability of absorption, the deltoid muscle is the preferred site. Vaccine formulations free of the mercury-containing preservative thimerosal are given to infants less than 6 months of age. When documentation of seroconversion is considered desirable, postimmunization anti-HBs titers may be checked. Protection appears to be excellent even if the titer wanes—at least for 20 years—and booster reimmunization is not routinely recommended but is advised for immunocompromised persons in whom anti-HBs titers fall below 10 milli-international units/mL. For vaccine nonresponders, three additional vaccine doses may elicit seroprotective anti-HBs levels in 30–50% of persons. Universal vaccination of neonates in countries endemic for HBV has reduced the incidence of hepatocellular carcinoma.

▶ Treatment

Bed rest is recommended only if symptoms are marked. If nausea and vomiting are pronounced or if oral intake is

substantially decreased, intravenous 10% glucose is indicated. Encephalopathy or severe coagulopathy indicates impending acute hepatic failure, and hospitalization at a liver transplant center is mandatory (see below).

Dietary management consists of palatable meals as tolerated, without overfeeding; breakfast is usually tolerated best. Strenuous physical exertion, alcohol, and hepatotoxic agents are avoided. Small doses of oxazepam are safe, as metabolism is not hepatic; morphine sulfate is avoided.

Corticosteroids have no benefit in patients with viral hepatitis, including those with fulminant disease. Treatment of patients with acute hepatitis C with peginterferon (see later) for 6–24 weeks appreciably decreases the risk of chronic hepatitis. In general, patients infected with HCV genotype 1 require a 24-week course of treatment, but a 12-week course is adequate if HCV RNA is undetectable in serum by 4 weeks. Those infected with genotypes 2, 3, or 4 generally require 8–12 weeks of therapy. Because 20% of patients with acute hepatitis C, particularly those who are symptomatic, clear the virus without such treatment, reserving it for patients in whom serum HCV RNA levels fail to clear after 3 months may be advisable. Ribavirin may be added if HCV RNA fails to clear after 3 months of peginterferon. Antiviral therapy is generally unnecessary in patients with acute hepatitis B.

▶ Prognosis

In most patients, clinical recovery is complete in 3–6 months. Laboratory evidence of liver dysfunction may persist for a longer period, but most patients recover completely. The overall mortality rate is less than 1%, but the rate is reportedly higher in older people.

Hepatitis A does not cause chronic liver disease, although it may persist for up to 1 year, and clinical and biochemical relapses may occur before full recovery. The mortality rate is less than 0.2%. The mortality rate for acute hepatitis B is 0.1–1%, but is higher with superimposed hepatitis D. Fulminant hepatitis C is rare in the United States. For unknown reasons, the mortality rate for hepatitis E is especially high in pregnant women (10–20%).

Chronic hepatitis, characterized by elevated aminotransferase levels for more than 6 months, develops in 1–2% of immunocompetent adults with acute hepatitis B but in as many as 90% of infected neonates and infants and a substantial proportion of immunocompromised adults. Chronic hepatitis, which progresses very slowly in many cases, develops in as many as 80% of all persons with acute hepatitis C. Ultimately, cirrhosis develops in up to 30% of those with chronic hepatitis C and 40% of those with chronic hepatitis B; the risk of cirrhosis is even higher in patients coinfecting with both viruses or with HIV. Patients with cirrhosis are at risk for hepatocellular carcinoma at a rate of 3–5% per year. Even in the absence of cirrhosis, patients with chronic hepatitis B—particularly those with active viral replication—are at increased risk.

▶ When to Refer

Refer patients with acute hepatitis who require liver biopsy for diagnosis.

▶ When to Admit

- Encephalopathy is present.
- INR > 1.6.
- The patient is unable to maintain hydration.

ACUTE HEPATIC FAILURE

ESSENTIALS OF DIAGNOSIS

- ▶ May be fulminant or subfulminant; both forms carry a poor prognosis.
- ▶ Acetaminophen and idiosyncratic drug reactions are the most common causes.

▶ General Considerations

Acute hepatic failure may be fulminant or subfulminant. Fulminant hepatic failure is characterized by the development of hepatic encephalopathy within 8 weeks after the onset of acute liver disease. Coagulopathy (international normalized ratio [INR] ≥ 1.5) is invariably present. Subfulminant hepatic failure occurs when these findings appear between 8 weeks and 6 months after the onset of acute liver disease and carries an equally poor prognosis.

An estimated 1600 cases of acute hepatic failure occur each year in the United States. Acetaminophen toxicity is the most common cause, accounting for at least 45% of cases. Suicide attempts account for 44% of cases of acetaminophen-induced hepatic failure, and unintentional overdoses (“therapeutic misadventures”), which are often a result of a decrease in the threshold toxic dose because of chronic alcohol use or fasting, account for at least 48%. Other causes include idiosyncratic drug reactions (now the second most common cause), viral hepatitis, poisonous mushrooms (*Amanita phalloides*), shock, hyperthermia or

hypothermia, Budd–Chiari syndrome, malignancy (most commonly lymphomas), Wilson disease, Reye syndrome, fatty liver of pregnancy and other disorders of fatty acid oxidation, autoimmune hepatitis, parvovirus B19 infection and, rarely, grand mal seizures. The risk of acute hepatic failure is increased in patients with diabetes mellitus, and outcome is worsened by obesity. Herbal and dietary supplements are thought to be contributory to acute hepatic failure in a substantial portion of cases, regardless of cause.

Viral hepatitis now accounts for only 12% of all cases of acute hepatic failure. The decline of viral hepatitis as the principal cause of acute hepatic failure is due to universal vaccination of infants and children against hepatitis B and the availability of the hepatitis A vaccine. In endemic areas, hepatitis E is an important cause of acute hepatic failure. Hepatitis C is a rare cause of acute hepatic failure in the United States, but acute hepatitis A or B superimposed on chronic hepatitis C may cause fulminant hepatitis.

▶ Clinical Findings

Gastrointestinal symptoms, systemic inflammatory response, and hemorrhagic phenomena are common. Adrenal insufficiency and subclinical myocardial injury manifesting as an elevated serum troponin I level often complicate acute hepatic failure. Jaundice may be absent or minimal early, but laboratory tests show severe hepatocellular damage. In acetaminophen toxicity, serum aminotransferase levels are often towering (> 5000 units/L), and diagnosis is aided by the detection of acetaminophen-protein adducts in serum. In acute hepatic failure due to microvesicular steatosis (eg, fatty liver of pregnancy), serum aminotransferase elevations may be modest (< 300 units/L). The blood ammonia level is typically elevated and correlates (along with the Model for End-Stage Liver Disease [MELD] score) with the development of encephalopathy and intracranial hypertension.

▶ Treatment

The treatment of acute hepatic failure is directed toward correcting metabolic abnormalities. These include coagulation defects, electrolyte and acid-base disturbances, advanced chronic kidney disease, hypoglycemia, and encephalopathy. Cerebral edema and sepsis are the leading causes of death. Prophylactic antibiotic therapy decreases the risk of infection, observed in up to 90%, but has no effect on survival and is not routinely recommended. For suspected sepsis, broad coverage is indicated. Despite a high rate of adrenal insufficiency, corticosteroids are of uncertain value. Stress gastropathy prophylaxis with an H₂-receptor blocker or proton pump inhibitor is recommended. Administration of acetylcysteine (140 mg/kg orally followed by 70 mg/kg orally every 4 hours for an additional 17 doses or 150 mg/kg in 5% dextrose intravenously over 15 minutes followed by 50 mg/kg over 4 hours and then 100 mg/kg over 16 hours) is indicated for acetaminophen toxicity up to 72 hours after ingestion and improves cerebral blood flow and oxygenation as well as survival in patients with stage 1 or 2 encephalopathy due to fulminant hepatic failure of any cause. (Acetylcysteine treatment can prolong the prothrombin time, leading to

the erroneous assumption that liver failure is worsening.) Penicillin G (300,000 to 1 million units/kg/day) or silibinin (silymarin or milk thistle), which is not licensed in the United States, is administered to patients with mushroom poisoning. Nucleoside analogs are recommended for patients with fulminant hepatitis B (see Chronic Hepatitis). Subclinical seizure activity is common in patients with acute liver failure, but the value of prophylactic phenytoin is uncertain.

Early transfer to a liver transplantation center is essential. Extradural sensors may be placed to monitor intracranial pressure for impending cerebral edema. Lactulose is administered for encephalopathy (see Cirrhosis). Mannitol, 100–200 mL of a 20% solution by intravenous infusion over 10 minutes, may decrease cerebral edema but should be used with caution in patients with advanced chronic kidney disease. Preliminary experience suggests that intravenously administered hypertonic saline to induce hypernatremia also may reduce intracranial hypertension. Hypothermia to a temperature of 33.1 °C may reduce intracranial pressure when other measures have failed and may improve survival long enough to permit liver transplantation. The value of hyperventilation and intravenous prostaglandin E₁ is uncertain. Short-acting barbiturates are considered for refractory intracranial hypertension. Nonbiologic liver support (eg, molecular adsorbent recirculating system [MARS], an albumin dialysis system) and hepatic-assist devices using living hepatocytes, extracorporeal whole liver perfusion, hepatocyte transplantation, and liver xenografts have shown promise experimentally but have not been shown conclusively to reduce mortality in patients with acute hepatic failure. They may serve as a “bridge” to liver transplantation.

▶ Prognosis

The mortality rate of fulminant hepatic failure with severe encephalopathy is as high as 80%, except for acetaminophen hepatotoxicity, in which the transplant-free survival is 65% and only 8% of patients undergo liver transplantation. For patients with fulminant hepatic failure of other causes, the outlook is especially poor in patients younger than 10 and older than 40 years of age and in those with an idiosyncratic drug reaction but appears to be improved when acetylcysteine is administered to patients with stage 1 or 2 encephalopathy. Spontaneous recovery is less likely for hepatitis B than for hepatitis A. Other adverse prognostic factors are a serum bilirubin level > 18 mg/dL, INR > 6.5, onset of encephalopathy more than 7 days after the onset of jaundice, and a low factor V level (< 20% of normal). For acetaminophen-induced fulminant hepatic failure, indicators of a poor outcome are acidosis (pH < 7.3), INR > 6.5, and azotemia (serum creatinine ≥ 3.4 mg/dL), whereas a rising serum α -fetoprotein level predicts a favorable outcome. An elevated blood lactate level (> 3.5 mmol/L), blood ammonia level (> 124 μ mol/L), and possibly hyperphosphatemia (> 1.2 mmol/L) also predict poor survival outcomes. A prognostic (“Bile”) score based on the serum bilirubin, serum lactate, and etiology has been proposed. Emergency liver transplantation is considered for patients with stage 2 to stage 3 encephalopathy (see

later) and is associated with a 70% survival rate at 5 years. For mushroom poisoning, liver transplantation should be considered when the interval between ingestion and the onset of diarrhea is < 8 hours or the INR is ≥ 6.0, even in the absence of encephalopathy.

▶ When to Admit

All patients with acute hepatic failure should be hospitalized.

CHRONIC VIRAL HEPATITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Defined by chronic infection (HBV, HCV, HDV) for greater than 6 months.
- ▶ Diagnosis is usually made by antibody tests and viral nucleic acid in serum.

▶ General Considerations

Chronic hepatitis is defined as chronic necroinflammation of the liver of more than 3–6 months' duration, demonstrated by persistently abnormal serum aminotransferase levels or characteristic histologic findings. In many cases, the diagnosis of chronic hepatitis may be made on initial presentation. The causes of chronic hepatitis include HBV, HCV, and HDV as well as autoimmune hepatitis; alcoholic and nonalcoholic steatohepatitis; certain medications, such as isoniazid and nitrofurantoin; Wilson disease; α_1 -antitrypsin deficiency; and, rarely, celiac disease. Chronic hepatitis is categorized on the basis of etiology; the grade of portal, periportal, and lobular inflammation (minimal, mild, moderate, or severe); and the stage of fibrosis (none, mild, moderate, severe, cirrhosis). In the absence of advanced cirrhosis, patients are often asymptomatic or have mild nonspecific symptoms.

▶ Clinical Findings & Diagnosis

A. Chronic Hepatitis B

Chronic hepatitis B afflicts nearly 400 million people worldwide (endemic areas include Asia and sub-Saharan Africa) and 1.25 million (predominantly males) in the United States. It may be noted as a continuum of acute hepatitis B or diagnosed because of persistence of HBsAg in serum, often with elevated aminotransferase levels.

Four phases of HBV infection are recognized. Early in the course, HBeAg and HBV DNA are present in serum, indicative of active viral replication. When HBV infection is acquired in infancy or early childhood, serum aminotransferase levels often are normal and little necroinflammation is present in the liver (*immune tolerant phase*). These persons, like those who acquire HBV infection later in life, may enter an *immune clearance phase*, in which aminotransferase levels are elevated and necroinflammation is present in the liver, with a risk of progression to cirrhosis (at a rate of 2–5.5% per year) and for hepatocellular carcinoma (at a rate of > 2% per year in those with cirrhosis); low-level IgM anti-HBc is present in about 70%. Immune clearance may ultimately be followed by biochemical improvement, which coincides with disappearance of HBeAg and reduced HBV DNA levels (< 10⁵ copies/mL, or < 20,000 international units/mL) in serum, appearance of anti-HBe, and integration of the HBV genome into the host genome in infected hepatocytes. If cirrhosis has not yet developed, such persons enter the *inactive HBsAg carrier state* and are at a low risk for cirrhosis and hepatocellular carcinoma. As noted, infection by a pre-core mutant of HBV or spontaneous mutation of the pre-core or core promoter region of the HBV genome during the course of chronic hepatitis caused by wild-type HBV (HBeAg-negative chronic hepatitis B) may result in *reactivated chronic hepatitis B* with a rise in serum HBV DNA levels and possible progression to cirrhosis (at a rate of 8–10% per year), particularly when additional mutations in the core gene of HBV are present. Risk factors for reactivation include male sex and HBV genotype C. In patients with either HBeAg-positive or HBeAg-negative chronic hepatitis B, the risk of cirrhosis and of hepatocellular carcinoma correlates with the serum HBV DNA level. Other risk factors include male sex, advanced age, alcohol use, cigarette smoking, and coinfection with HCV or HDV. HIV coinfection is also associated with an increased frequency of cirrhosis when the CD4 count is low.

B. Hepatitis D

Acute hepatitis D infection superimposed on chronic HBV infection may result in severe chronic hepatitis, which may progress rapidly to cirrhosis and may be fatal. Patients with long-standing chronic hepatitis D and B often have inactive cirrhosis. The diagnosis is confirmed by detection of anti-HDV or HDAg in serum.

C. Chronic Hepatitis C

Chronic hepatitis C develops in up to 85% of patients with acute hepatitis C. It is clinically indistinguishable from chronic hepatitis due to other causes and may be the most common. Worldwide, 170 million people are infected with HCV, with 1.8% of the US population infected. Peak prevalence in the United States (about 4%) is in persons born between 1945 and 1964. In approximately 40% of cases, serum aminotransferase levels are persistently normal. The diagnosis is confirmed by detection of anti-HCV by enzyme immunoassay (EIA). In rare cases of suspected chronic hepatitis C but a negative EIA, HCV RNA is

detected by polymerase chain reaction testing. Progression to cirrhosis occurs in 20% of affected patients after 20 years, with an increased risk in men, those who drink more than 50 g of alcohol daily, and those who acquire HCV infection after age 40 years. The rate of fibrosis progression accelerates after age 50. African Americans have a higher rate of chronic hepatitis C but lower rates of fibrosis progression and response to therapy than whites. Immunosuppressed persons—including patients with hypogammaglobulinemia, HIV infection with a low CD4 count, or those receiving immunosuppressants—appear to progress more rapidly to cirrhosis than immunocompetent persons with chronic hepatitis C. Tobacco and cannabis smoking and hepatic steatosis also appear to promote progression of fibrosis. Persons with chronic hepatitis C and persistently normal serum aminotransferase levels usually have mild chronic hepatitis with slow or absent progression to cirrhosis; however, cirrhosis is present in 10% of these patients.

► Treatment

A. Chronic Hepatitis B

Patients with active viral replication (HBeAg and HBV DNA [$\geq 10^5$ copies/mL, or $\geq 20,000$ international units/mL] in serum; elevated aminotransferase levels) may be treated with pegylated interferon or a nucleoside or nucleotide analog. For patients who are HBeAg-negative, the threshold for treatment is a serum HBV DNA level $\geq 10^4$ copies/mL, or ≥ 2000 international units/mL. If the threshold HBV DNA level for treatment is met but the serum ALT level is normal, treatment may still be considered in patients over age 35–40 if liver biopsy demonstrates a fibrosis stage of 2 (moderate) or higher. Therapy is aimed at reducing and maintaining the serum HBV DNA level to the lowest possible levels, thereby leading to normalization of the ALT level and histologic improvement. An additional goal in HBeAg-positive patients is seroconversion to anti-HBe, which signifies a high likelihood that the benefit will be sustained after discontinuation of treatment. Nucleoside and nucleotide analogs generally are discontinued 6–12 months after HBeAg-to-anti-HBe seroconversion but must be continued long-term when seroconversion does not occur as well as in HBeAg-negative patients.

Peginterferon alfa-2a, 180 mcg subcutaneously once weekly for 48 weeks, leads to sustained normalization of aminotransferase levels, disappearance of HBeAg and HBV DNA from serum, appearance of anti-HBe, and improved survival in up to 40% of treated patients. A response is most likely in patients with a low baseline HBV DNA level and high aminotransferase levels and is more likely in those infected with HBV genotype A than with other genotypes. Moreover, some responders may eventually clear HBsAg from serum and liver and develop anti-HBs in serum, and are thus cured. Relapses are uncommon in complete responders who seroconvert from HBeAg to anti-HBe. Patients with HBeAg-negative chronic hepatitis B have a response rate of 60% after 48 weeks of therapy with peginterferon, but the response may not be durable. The response to interferon is poor in patients with HIV coinfection.

Nucleoside and nucleotide analogs may be used instead of interferon for the treatment of chronic hepatitis B; they are much better tolerated and are often preferred because they can be taken orally. The available drugs differ in efficiency and rates of resistance. The first available nucleoside analog was lamivudine, 100 mg orally daily, which reliably suppresses HBV DNA in serum, improves liver histology in 60% of patients, and leads to normal ALT levels in over 40% and HBeAg seroconversion in 20% of patients after 1 year of therapy. Rates of complete response increase with longer duration of therapy. However, by the end of 1 year, 15–30% of responders experience a relapse (and occasionally frank decompensation) as a result of a mutation in the polymerase gene (the YMDD motif) of HBV DNA that confers resistance to lamivudine. The rate of resistance reaches 70% by 5 years of therapy, and the drug is no longer considered first-line therapy. In patients with advanced fibrosis or cirrhosis, treatment with lamivudine reduces the risk of hepatic decompensation and hepatocellular carcinoma.

Adefovir dipivoxil, a nucleotide analog, has activity against wild-type and lamivudine-resistant HBV. The standard dose is 10 mg orally once a day for at least 1 year. Adding the drug may be effective in patients who have become resistant to lamivudine. As with lamivudine, only a small number of patients achieve sustained suppression of HBV replication with adefovir, and long-term suppressive therapy is often required. Resistance to adefovir is less frequent than with lamivudine but is seen in up to 29% of patients treated for 5 years. Patients with underlying kidney dysfunction are at risk for nephrotoxicity from adefovir.

Telbivudine, given in a daily dose of 600 mg orally, is more potent than either lamivudine or adefovir. Resistance to this drug may develop, particularly in patients who are resistant to lamivudine, and elevated creatine kinase levels are common in patients treated with telbivudine.

Entecavir, another nucleoside analog, has become a preferred first-line treatment for chronic hepatitis B. It is not nephrotoxic, and it is infrequently associated with resistance unless a patient is already resistant to lamivudine. The daily dose is 0.5 mg orally for patients not resistant to lamivudine and 1 mg for patients who have become resistant to lamivudine. Entecavir is more effective than lamivudine and adefovir, with histologic improvement observed in 70% of treated patients and suppression of HBV DNA in serum in up to 80%.

Tenofovir, a nucleotide analog used for HIV infection approved for HBV infection in 2008, has substantial activity against HBV and is used when resistance to a nucleoside analog has developed. Like entecavir, tenofovir has emerged as a first-line agent because of its potency and low rate of resistance.

Other antiviral agents such as emtricitabine and clevudine are under study but are unlikely to offer advantages over available drugs. Strategies using multiple drugs are being investigated.

Nucleoside and nucleotide analogs are well tolerated even in patients with decompensated cirrhosis (for whom the treatment threshold may be an HBV DNA level $< 10^4$ copies/mL) and may be effective in patients with rapidly

progressive hepatitis B (“fibrosing cholestatic hepatitis”) following organ transplantation. Although therapy with these agents leads to biochemical, virologic, and histologic improvement in patients with HBeAg-negative chronic hepatitis B and baseline HBV DNA levels $\geq 10^4$ copies/mL (≥ 2000 international units/mL), relapse is frequent when therapy is stopped, and long-term treatment is often required. Resistance is most likely to develop to lamivudine and may develop to adefovir and telbivudine. The development of resistance occasionally results in hepatic decompensation. Sequential addition of a second antiviral agent is usually effective after resistance to the first agent has developed. Combined use of peginterferon or interferon and a nucleoside or nucleotide analog has not been shown convincingly to have a substantial advantage over the use of either type of drug alone.

Nucleoside analogs are also recommended for inactive HBV carriers prior to the initiation of immunosuppressive therapy or cancer chemotherapy to prevent reactivation. In patients infected with both HBV and HIV, antiretroviral therapy, including two drugs active against both viruses (eg, tenofovir plus lamivudine or emtricitabine), has been recommended when treatment of HIV infection is indicated. Telbivudine and tenofovir are classified as pregnancy category B drugs, and lamivudine, a category C drug, has been shown to be safe in pregnant women with HIV infection.

B. Chronic Hepatitis C

Treatment of chronic hepatitis C is generally considered in patients under age 70 with more than minimal fibrosis on liver biopsy. Because of high response rates to treatment in patients infected with HCV genotype 2 or 3, treatment may be initiated in these patients without a liver biopsy.

Two formulations of pegylated interferon are approved for HCV infection: peginterferon alfa-2b, with a 12-kDa polyethylene glycol (PEG), 1.5 mcg/kg, and peginterferon alfa-2a, with a 40-kDa PEG, 180 mcg, both given subcutaneously once per week. Whether there are clinically important differences between the two formulations is unclear. Addition of the nucleoside analog ribavirin, 800–1400 mg orally daily in two divided doses, results in higher sustained response rates than peginterferon alone in previously untreated patients with chronic hepatitis C or patients who have had a relapse after an initial response to interferon alfa (no longer available in the United States) and ribavirin.

Sustained response rates with a combination of peginterferon and ribavirin are as high as 55% (and up to 80% for HCV genotypes 2 or 3). Low levels of HCV RNA may persist in the liver, lymphocytes, and macrophages of successfully treated (“cured”) patients, but the significance of this finding is uncertain. Response rates are lower in patients with advanced fibrosis, high levels of viremia, alcohol consumption, HIV coinfection, obesity, insulin resistance, and severe steatosis; they are also lower in blacks and Latinos than in whites, in part because of a higher rate of genotype 1 among infected black patients and in part because of intrinsic resistance to therapy. For prior nonresponders to standard

interferon and ribavirin, sustained response rates to retreatment with peginterferon alfa and ribavirin are only 10–15%. When used with peginterferon alfa-2b, the dose of ribavirin in patients infected with genotype 1 is based on the patient's weight and may range from 800 mg to 1400 mg daily in two divided doses. When used with peginterferon alfa-2a, the daily ribavirin dose is 1000 mg or 1200 mg depending on whether the patient's weight is less than or greater than 75 kg. Patients infected with genotype 1 are generally treated for 48 weeks. If there has been a decrease in the serum HCV RNA level to < 50 international units/mL by 4 weeks (rapid virologic response), treatment for at least 24 weeks results in a sustained virologic response rate of 90%. For those who do not achieve a rapid virologic response but have a serum HCV RNA level < 50 international units/mL by 12 weeks (complete early virologic response), treatment is continued for the full 48 weeks. If serum HCV RNA levels decline by at least 2 logs by 12 weeks (partial early virologic response) and become undetectable by 24 weeks (slow response), treatment may be extended to 72 weeks. If none of the aforementioned targets is reached, treatment is discontinued. Patients infected with genotype 2 or 3 (without cirrhosis and with low levels of viremia) are treated for 24 weeks and require a ribavirin total daily dose of only 800 mg. For patients infected with these genotypes who clear the virus within 4 weeks (rapid virologic response), a total treatment duration of only 16 weeks may be sufficient, if the baseline HCV RNA level is < 400,000 international units/mL; however, such a short course is not routinely recommended. For patients with cirrhosis or a high viral level (> 400,000 international units/mL), 48 weeks of treatment may be preferred. For patients infected with HCV genotype 1 and without any hepatic fibrosis, expectant management and a repeat assessment of hepatic fibrosis (usually by liver biopsy) in 3–5 years are often recommended.

Peginterferon alfa with ribavirin may be beneficial in the treatment of cryoglobulinemia associated with chronic hepatitis C. "Chronic HCV carriers" with normal serum aminotransferase levels respond just as well to treatment as do patients with elevated aminotransferase levels. Patients with both HCV and HIV infections may benefit from treatment of HCV. Moreover, in HCV/HIV-coinfected persons, long-term liver-related mortality increases as mortality from HIV infection is reduced by highly active antiretroviral therapy.

Treatment with peginterferon alfa plus ribavirin is costly (up to \$20,000 for a 24-week supply), and side effects, which include flu-like symptoms, psychiatric symptoms (irritability, depression), thyroid dysfunction, and bone marrow suppression, are common. Discontinuation rates are 15–30% and higher in persons over age 60 years than in younger patients. Sustained response rates decline if less than 60% of the cumulative dose is taken. A blood count is obtained at weeks 1, 2, and 4 after therapy is started and monthly thereafter. Peginterferon alfa is contraindicated in pregnant or breast-feeding patients and those with decompensated cirrhosis, prior solid organ transplants (except liver), profound cytopenias, severe psychiatric disorders, autoimmune diseases, or an inability to self-administer treatment. HCV treatment can be successful in carefully

selected persons who continue to inject illicit drugs if they are managed by a multidisciplinary team. Patients taking ribavirin must be monitored for hemolysis, and men and women taking the drug must practice strict contraception until 6 months after conclusion of therapy because of teratogenic effects in animals. Ribavirin should be avoided in persons over age 65 years and in others in whom hemolysis could pose a risk of angina or stroke. Rash, itching, headache, cough, and shortness of breath also occur with the drug. Lactic acidosis is a concern in patients also taking highly active antiretroviral therapy for HIV infection. Erythropoietin (epoetin alfa) and granulocyte colony-stimulating factor (filgrastim) may be used to treat therapy-induced anemia and leukopenia. Peginterferon alfa is generally contraindicated in heart, lung, and kidney transplant recipients because of an increased risk of organ rejection. Selected liver transplant recipients with recurrent hepatitis C may be treated with peginterferon and ribavirin, but response rates are low.

In patients with advanced fibrosis who are nonresponders to interferon-based therapy, long-term maintenance treatment with peginterferon as a strategy to prevent histologic progression and reduce the risk of cirrhosis and hepatocellular carcinoma has been shown in a 3.5-year randomized, controlled trial to be ineffective. Several approaches have been proposed for the treatment of prior nonresponders, but no interferon-based approach achieves response rates exceeding 10–20% in patients who are truly resistant to peginterferon and ribavirin. New approaches to antiviral therapy for hepatitis C include the development of direct antiviral agents, such as protease and polymerase inhibitors. In early clinical trials, when the protease inhibitors telaprevir (phase III trials) and boceprevir (phase II trials) were used with peginterferon and ribavirin, a sustained virologic response rate of ~60% was achieved after total treatment courses of 24 weeks in patients infected with HCV genotype 1.

C. Chronic Hepatitis D

Peginterferon alfa-2b (1.5 mcg/kg/week for 48 weeks) may lead to normalization of serum aminotransferase levels, histologic improvement, and elimination of HDV RNA from serum in 20–50% of patients with chronic hepatitis D, but patients may relapse and tolerance is poor. Nucleoside and nucleotide analogs are not effective in treating chronic hepatitis D.

► Prognosis

The course of chronic viral hepatitis is variable. The sequelae of chronic hepatitis secondary to hepatitis B include cirrhosis, liver failure, and hepatocellular carcinoma. The 5-year mortality rate is 0–2% in those without cirrhosis, 14–20% in those with compensated cirrhosis, and 70–86% following decompensation. The risk of cirrhosis and hepatocellular carcinoma correlates with serum HBV DNA levels, and a focus of therapy is to suppress HBV DNA levels below 300 copies/mL (60 international units/mL). There is some evidence that HBV genotype C is associated with a higher risk of cirrhosis and hepatocellular carcinoma.

noma than other genotypes. Antiviral treatment improves the prognosis in responders.

Chronic hepatitis C is an indolent, often subclinical disease that may lead to cirrhosis and hepatocellular carcinoma after decades. The overall mortality rate in patients with transfusion-associated hepatitis C may be no different from that of an age-matched control population. Nevertheless, mortality rates clearly rise once cirrhosis develops, and mortality from cirrhosis and hepatocellular carcinoma due to hepatitis C is clearly rising. There is some evidence that HCV genotype 1b is associated with a higher risk of hepatocellular carcinoma than other genotypes. Peginterferon plus ribavirin appears to have a beneficial effect on survival and quality of life, is cost-effective, appears to retard and even reverse fibrosis, and in responders may reduce the risk of hepatocellular carcinoma. The risk of mortality from drug addiction is higher than that for liver disease in patients with chronic hepatitis C.

▶ When to Refer

- For liver biopsy.
- For antiviral therapy.

▶ When to Admit

AUTOIMMUNE HEPATITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Usually young to middle-aged women.
- ▶ Chronic hepatitis with high serum globulins.
- ▶ Positive antinuclear antibody (ANA) and/or smooth muscle antibody in most common type.
- ▶ Responds to corticosteroids.

▶ Clinical Findings

A. Symptoms and Signs

Although autoimmune hepatitis is usually seen in young women, it can occur in either sex at any age. Affected younger persons are often positive for HLA-B8 and HLA-DR3; older patients are often positive for HLA-DR4. The principal susceptibility allele among white Americans and northern Europeans is HLA *DRB1*0301*; HLA *DRB1*0401* is a secondary but independent risk factor. The onset is usually insidious, but up to 40% present with an acute (occasionally fulminant) attack of hepatitis and some cases follow a viral illness such as hepatitis A, Epstein-Barr infection, or measles or exposure to a drug or toxin such as nitrofurantoin. Exacerbations may occur postpartum. Thirty-four percent of patients are asymptomatic. Typically, examination reveals a healthy-appearing young woman with multiple spider nevi, cutaneous striae, acne, hirsutism, and hepatomegaly. Amenorrhea may be a presenting feature. Extrahepatic features include arthritis, Sjögren syndrome, thyroiditis, nephritis, ulcerative colitis, and Coombs-positive hemolytic anemia. Patients with autoimmune hepatitis are at increased risk for cirrhosis which, in turn, increases the risk of hepatocellular carcinoma (at a rate of about 1% per year).

B. Diagnostic Tests

Serum aminotransferase levels may be > 1000 units/L, and the total bilirubin is usually increased. In type I (classic)

autoimmune hepatitis, ANA or smooth muscle antibody (either or both) is detected in serum. Serum γ -globulin levels are typically elevated (up to 5–6 g/dL). In patients with the latter, the EIA for antibody to HCV may be falsely positive. Other antibodies, including atypical perinuclear antineutrophil cytoplasmic antibodies (ANCA) and antibodies to histones, may be found. Antibodies to soluble liver antigen–liver pancreas (anti-SLA/LP) characterize a variant of type I that is marked by severe disease, a high relapse rate after treatment, and absence of the usual antibodies (ANA and smooth muscle antibody). Anti-SLA/LP is directed against a transfer RNA complex responsible for incorporating selenocysteine into peptide chains (Sep tRNA:Sec tRNA synthase). Type II, seen more often in girls under age 14 in Europe, is characterized by circulating antibody to liver-kidney microsomes (anti-LKM1)—directed against cytochrome P450 2D6—without anti-smooth muscle antibody or ANA. In some cases, anti-liver cytosol type 1, directed against formiminotransferase cyclodeaminase, is detected. This type of autoimmune hepatitis can be seen in patients with autoimmune polyglandular syndrome type 1. Concurrent primary biliary cirrhosis or primary sclerosing cholangitis has been recognized in 11% and 5% of patients with autoimmune hepatitis, respectively. Liver biopsy is indicated to help establish the diagnosis, evaluate disease severity, and determine the need for treatment.

Simplified diagnostic criteria based on the detection of autoantibodies (1 or 2 points depending on titers), elevated IgG levels (1 or 2 points depending on levels), and characteristic histologic features (1 or 2 points depending on how typical the features are) and exclusion of viral hepatitis (2 points) can be useful for diagnosis; a score of 6 indicates probable and a score of 7 indicates definite autoimmune hepatitis.

► Treatment

Prednisone with or without azathioprine improves symptoms; decreases the serum bilirubin, aminotransferase, and γ -globulin levels; and reduces hepatic inflammation. Symptomatic patients with aminotransferase levels elevated tenfold (or fivefold if the serum globulins are elevated at least twofold) are optimal candidates for therapy, and asymptomatic patients with modest enzyme elevations may be considered for therapy depending on the clinical circumstances and histologic severity; however, asymptomatic patients usually remain asymptomatic, have either mild hepatitis or inactive cirrhosis on liver biopsy specimens, and have a good long-term prognosis without therapy.

Prednisone is given initially in a dose of 30 mg orally daily with azathioprine, 50 mg orally daily, which is generally well tolerated and permits the use of lower corticosteroid doses than a regimen beginning with prednisone 60 mg orally daily alone. Whether patients should undergo testing for the genotype or level of thiopurine methyltransferase prior to treatment with azathioprine to predict toxicity is still a matter of debate. Blood counts are monitored weekly for the first 2 months of therapy and monthly thereafter because of the small risk of bone marrow suppression. The dose of prednisone is lowered from 30 mg/d after 1 week to

20 mg/d and again after 2 or 3 weeks to 15 mg/d. Ultimately, a maintenance dose of 10 mg/d is achieved. While symptomatic improvement is often prompt, biochemical improvement is more gradual, with normalization of serum aminotransferase levels after several months in many cases. Histologic resolution of inflammation may require 18–24 months, the time at which repeat liver biopsy is recommended. Failure of aminotransferase levels to normalize invariably predicts lack of histologic resolution.

The response rate to therapy with prednisone and azathioprine is 80%. Older patients (and those with HLA genotype *DRB1*04*) are more likely to respond than younger patients and those with HLA *DRB1*03* or hyperbilirubinemia. Fibrosis may reverse with therapy and rarely progresses after apparent biochemical and histologic remission. Once remission is achieved, therapy may be withdrawn, but the subsequent relapse rate is 20–90%. Relapses may again be treated in the same manner as the initial episode, with the same remission rate. After successful treatment of a relapse, the patient may continue taking azathioprine (up to 2 mg/kg) indefinitely or the lowest dose of prednisone needed to maintain aminotransferase levels as close to normal as possible—although another attempt at withdrawing therapy may be considered in patients remaining in remission long term (eg, ≥ 4 years). Budesonide, a corticosteroid with less toxicity than prednisone, does not appear to be effective in maintaining remission. Prednisone can be used to treat rare flares during pregnancy, and maintenance azathioprine does not have to be discontinued.

Nonresponders to prednisone and azathioprine (failure of serum aminotransferase levels to decrease by 50% after 6 months) may be considered for a trial of cyclosporine, tacrolimus, methotrexate, or rituximab. Mycophenolate mofetil is an effective alternative to azathioprine in patients who cannot tolerate or do not respond to it. Bone density should be monitored—particularly in patients receiving maintenance corticosteroid therapy—and measures undertaken to prevent or treat osteoporosis (see Chapter 26). Liver transplantation may be required for treatment failures and patients with a fulminant presentation, but the disease has been recognized to recur in up to 40% of transplanted livers (and rarely to develop *de novo*) as immunosuppression is reduced; sirolimus can be effective in such cases.

► When to Refer

- For liver biopsy.
- For immunosuppressive therapy.

► When to Admit

- Hepatic encephalopathy.
- INR > 1.6 .

ALCOHOLIC LIVER DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Chronic alcohol intake usually exceeds 80 g/d in men and 30–40 g/d in women with alcoholic hepatitis or cirrhosis.
- ▶ Fatty liver is often asymptomatic.
- ▶ Fever, right upper quadrant pain, tender hepatomegaly, and jaundice characterize alcoholic hepatitis, but the patient may be asymptomatic.
- ▶ AST is usually elevated but rarely above 300 units/L; AST is greater than ALT, usually by a factor of 2 or more.
- ▶ Alcoholic hepatitis is often reversible but it is the most common precursor of cirrhosis in the United States.

▶ General Considerations

Excessive alcohol intake can lead to fatty liver, hepatitis, and cirrhosis. Alcoholic hepatitis is characterized by acute or chronic inflammation and parenchymal necrosis of the liver induced by alcohol. Alcoholic hepatitis is often a reversible disease, is the most common precursor of cirrhosis in the United States, and is associated with four to five times the number of hospitalizations and deaths as hepatitis C, which is the second most common cause of cirrhosis.

The frequency of alcoholic cirrhosis is estimated to be 10–15% among persons who consume over 50 g of alcohol (4 oz of 100-proof whiskey, 15 oz of wine, or four 12-oz cans of beer) daily for over 10 years (although the risk of cirrhosis may be lower for wine than for a comparable intake of beer or spirits). The risk of cirrhosis is lower (5%) in the absence of other cofactors such as chronic viral hepatitis and obesity. Genetic factors, including polymorphisms of the genes encoding for tumor necrosis factor- α and cytochrome P450 2E1, may also account for differences in susceptibility. Women appear to be more susceptible than men, in part because of lower gastric mucosal alcohol dehydrogenase levels. Over 80% of patients with alcoholic hepatitis have been drinking 5 years or more before symptoms that can be attributed to liver disease develop; the longer the duration of drinking (10–15 or more years) and the larger the alcoholic consumption, the greater the probability of developing alcoholic hepatitis and cirrhosis. In individuals who drink alcohol excessively, the rate of ethanol metabolism can be sufficiently high to permit the consumption of large quantities without raising the blood alcohol level over 80 mg/dL.

Deficiencies in vitamins and calories probably contribute to the development of alcoholic hepatitis or its progression to cirrhosis. Many adverse effects of alcohol on the

liver are thought to be mediated by tumor necrosis factor- α and by the oxidative metabolite acetaldehyde, which contributes to lipid peroxidation and induction of an immune response following covalent binding to proteins in the liver.

▶ Clinical Findings

A. Symptoms and Signs

The clinical presentation of alcoholic liver disease can vary from an asymptomatic hepatomegaly to a rapidly fatal acute illness or end-stage cirrhosis. A recent period of heavy drinking, complaints of anorexia and nausea, and the demonstration of hepatomegaly and jaundice strongly suggest the diagnosis. Abdominal pain and tenderness, splenomegaly, ascites, fever, and encephalopathy may be present.

B. Laboratory Findings

In patients with steatosis, mild liver enzyme elevations may be the only laboratory abnormality. Anemia (usually macrocytic) may be present. Leukocytosis with shift to the left is common in patients with severe alcoholic hepatitis. Leukopenia is occasionally seen and resolves after cessation of drinking. About 10% of patients have thrombocytopenia related to a direct toxic effect of alcohol on megakaryocyte production or to hypersplenism.

AST is usually elevated but rarely above 300 units/L. AST is greater than ALT, usually by a factor of 2 or more. Serum alkaline phosphatase is generally elevated, but seldom more than three times the normal value. Serum bilirubin is increased in 60–90% of patients with alcoholic hepatitis.

Serum bilirubin levels greater than 10 mg/dL and marked prolongation of the prothrombin time (≥ 6 seconds above control) indicate severe alcoholic hepatitis with a mortality rate as high as 50%. The serum albumin is depressed, and the γ -globulin level is elevated in 50–75% of individuals, even in the absence of cirrhosis. Increased transferrin saturation, hepatic iron stores, and sideroblastic anemia are found in many alcoholic patients. Folic acid deficiency may coexist.

C. Liver Biopsy

Liver biopsy, if done, demonstrates macrovesicular fat and, in patients with alcoholic hepatitis, polymorphonuclear infiltration with hepatic necrosis, Mallory bodies (alcoholic hyaline), and perivenular and perisinusoidal fibrosis. Micronodular cirrhosis may be present as well. The findings are identical to those of nonalcoholic steatohepatitis.

D. Other Studies

Imaging studies are used to exclude other diagnoses; they can detect moderate to severe hepatic steatosis reliably but not inflammation or fibrosis. Ultrasound helps exclude biliary obstruction and identifies subclinical ascites. CT scanning with intravenous contrast or MRI may be indicated in selected cases to evaluate patients for collateral

vessels, space-occupying lesions of the liver, or concomitant disease of the pancreas.

► Differential Diagnosis

Alcoholic hepatitis may be closely mimicked by cholecystitis and cholelithiasis and by drug toxicity. Other causes of hepatitis or chronic liver disease may be excluded by serologic or biochemical testing, by imaging studies, or by liver biopsy. A formula based on the AST/ALT ratio, body mass index, mean corpuscular volume, and gender has been reported to reliably distinguish alcoholic liver disease from nonalcoholic fatty liver disease (NAFLD).

► Treatment

A. General Measures

Abstinence from alcohol is essential. Fatty liver is quickly reversible with abstinence. Every effort should be made to provide sufficient amounts of carbohydrates and calories in anorectic patients to reduce endogenous protein catabolism, promote gluconeogenesis, and prevent hypoglycemia. Nutritional support (40 kcal/kg with 1.5–2 g/kg as protein) improves survival in patients with malnutrition. Use of liquid formulas rich in branched-chain amino acids does not improve survival beyond that achieved with less expensive caloric supplementation. The administration of vitamins, particularly folic acid and thiamine, is indicated, especially when deficiencies are noted; glucose administration increases the vitamin B₁ requirement and can precipitate Wernicke-Korsakoff syndrome if thiamine is not coadministered.

B. Pharmacologic Measures

Methylprednisolone, 32 mg/d orally or the equivalent for 1 month, may reduce short-term mortality in patients with alcoholic hepatitis and either encephalopathy or a discriminant function (defined by the patient's prothrombin time minus the control prothrombin time times 4.6 plus the total bilirubin in mg/dL is > 32). Failure of the serum bilirubin level to decline after 7 days of treatment predicts nonresponse and poor long-term survival, as does a model that includes age, advanced chronic kidney disease, serum albumin, prothrombin time, serum bilirubin on admission, and serum bilirubin on day 7. No benefit has been demonstrated in patients with concomitant gastrointestinal bleeding.

Pentoxifylline—an inhibitor of tumor necrosis factor—400 mg orally three times daily for 4 weeks, may reduce 1-month mortality rates in patients with severe alcoholic hepatitis, primarily by decreasing the risk of hepatorenal syndrome. Other experimental therapies include propylthiouracil, oxandrolone, S-adenosyl-L-methionine, infliximab, antioxidants, and extracorporeal liver support. Colchicine does not reduce mortality in patients with alcoholic cirrhosis, and etanercept may increase mortality after 6 months.

► Prognosis

A. Short-Term

When the prothrombin time is short enough to permit liver biopsy (< 3 seconds above control), the 1-year mor-

tality rate is 7%, rising to 20% if there is progressive prolongation of the prothrombin time during hospitalization. Individuals in whom the prothrombin time prohibits liver biopsy have a 42% mortality rate at 1 year. Other unfavorable prognostic factors are a serum bilirubin greater than 10 mg/dL, hepatic encephalopathy, azotemia, leukocytosis, lack of response to corticosteroid therapy, and possibly little steatosis on a liver biopsy specimen and reversal of portal blood flow by Doppler ultrasound. In addition to the discriminant function discussed above, the MELD score used for cirrhosis (see later) and the Glasgow alcoholic hepatitis score (based on age, white blood cell count, blood urea nitrogen, prothrombin time ratio, and bilirubin level) correlate with mortality from alcoholic hepatitis and have higher specificities. A scoring system based on age, serum bilirubin, INR, and serum creatinine (ABIC) has been proposed.

B. Long-Term

In the United States, the 3-year mortality rate of persons who recover from acute alcoholic hepatitis is ten times greater than that of control individuals of comparable age. Histologically severe disease is associated with continued excessive mortality rates after 3 years, whereas the death rate is not increased after the same period in those whose liver biopsies show only mild alcoholic hepatitis. Complications of portal hypertension (ascites, variceal bleeding, hepatorenal syndrome), coagulopathy, and severe jaundice following recovery from acute alcoholic hepatitis also suggest a poor long-term prognosis. Alcoholic cirrhosis is a risk factor for hepatocellular carcinoma, and the risk is highest in carriers of the C282Y mutation for hemochromatosis or with increased hepatic iron.

The most important prognostic consideration is continued excessive drinking. A 6-month period of abstinence is generally required before liver transplantation is considered, although this requirement has been questioned. Optimal candidates have adequate social support, do not smoke, have no psychosis or personality disorder, are adherent to therapy, and have regular appointments with a psychiatrist or psychologist who specializes in addiction treatment.

► When to Refer

Refer patients with alcoholic hepatitis who require liver biopsy for diagnosis.

► When to Admit

- Hepatic encephalopathy.
- INR > 1.6.
- Total bilirubin ≥ 10 mg/dL.
- Inability to maintain hydration.

DRUG- & TOXIN-INDUCED LIVER DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Drug-induced liver disease can mimic viral hepatitis, biliary tract obstruction, or other types of liver disease.
- ▶ Clinicians must inquire about the use of many widely used therapeutic agents, including over-the-counter “natural” and “herbal” products, in any patient with liver disease.

▶ General Considerations

Many therapeutic agents may cause hepatic injury. The medications most commonly implicated are nonsteroidal anti-inflammatory drugs and antibiotics because of their widespread use. Drug-induced liver disease can mimic viral hepatitis, biliary tract obstruction, or other types of liver disease. In any patient with liver disease, the clinician must inquire carefully about the use of potentially hepatotoxic drugs or exposure to hepatotoxins, including over-the-counter “natural” and herbal products. In some cases, coadministration of a second agent may increase the toxicity of the first (eg, isoniazid and rifampin, acetaminophen and alcohol). Drug toxicity may be categorized on the basis of pathogenesis or histologic appearance.

1. Direct Hepatotoxic Group

The liver lesion caused by this group of drugs is characterized by: (1) dose-related severity, (2) a latent period following exposure, and (3) susceptibility in all individuals. Examples include acetaminophen (toxicity is enhanced by fasting and chronic alcohol use because of depletion of glutathione and induction of cytochrome P450 2E1), alcohol, carbon tetrachloride, chloroform, heavy metals, mercaptopurine, niacin, plant alkaloids, phosphorus, pyrazinamide, tetracyclines, tipranavir, valproic acid, and vitamin A. Statins, like all cholesterol-lowering agents, may cause serum aminotransferase elevations but rarely cause true hepatitis and are no longer considered contraindicated in patients with liver disease.

2. Idiosyncratic Reactions

Except for acetaminophen, most severe hepatotoxicity is idiosyncratic. Reactions of this type are: (1) sporadic, (2) not related to dose, and (3) occasionally associated with features suggesting an allergic reaction, such as fever and eosinophilia, which may be associated with a favorable outcome. In some patients, toxicity results directly from a metabolite that is produced only in certain individuals on a genetic basis. Toxicity may be observed only on post-marketing surveillance and not during preclinical trials. Examples include abacavir, amiodarone, aspirin, carbamazepine, chloramphenicol, diclofenac, disulfiram, duloxetine, ezetimibe, flutamide, halothane, isoniazid, ketoconazole, lamotrigine, methylodopa, nevirapine, oxacillin, phenytoin, pyrazinamide, quinidine, streptomycin, rofecoxib and troglitazone (both withdrawn from the market in the United States), and less commonly other thiazolidinediones, and perhaps tacrine.

3. Cholestatic Reactions

A. Noninflammatory

Drug-induced cholestasis results from inhibition or genetic deficiency of various hepatobiliary transporter systems. The following drugs cause cholestasis: anabolic steroids containing an alkyl or ethinyl group at carbon 17, azathioprine, diclofenac, indinavir (increased risk of indirect hyperbilirubinemia in patients with Gilbert syndrome), cyclosporine, estrogens, mercaptopurine, methylestosterone, and ticlopidine.

B. Inflammatory

The following drugs cause inflammation of portal areas with bile duct injury (cholangitis), often with allergic features such as eosinophilia: amoxicillin-clavulanic acid (among most common causes of drug-induced liver injury), azathioprine, azithromycin, captopril, cephalosporins, chlorothiazide, chlorpromazine, chlorpropamide, erythromycin, mercaptopurine, penicillamine, prochlorperazine, semisynthetic penicillins (eg, cloxacillin), and sulfadiazine. Cholestatic and mixed cholestatic hepatocellular toxicity is more likely than pure hepatocellular toxicity to lead to chronic liver disease.

4. Acute or Chronic Hepatitis

Medications that may result in acute or chronic hepatitis that is histologically—and in some cases clinically—indistinguishable from autoimmune hepatitis include aspirin, isoniazid (increased risk in HBV and HCV carriers), methylodopa, minocycline, nitrofurantoin, nonsteroidal anti-inflammatory drugs, propylthiouracil, and terbinafine. Hepatitis also can occur in patients taking cocaine, diclofenac, methylenedioxymethamphetamine (MDMA; Ecstasy), efavirenz, imatinib mesylate, nevirapine (like other protease inhibitors, increased risk in HBV and HCV carriers), ritonavir (greater rate than other protease inhibitors), saquinavir, sulfonamides, telithromycin, troglitazone (withdrawn from the market in the United States),

and zafirlukast as well as a variety of alternative remedies (eg, black cohosh, chaparral, germander, green tea extracts, Herbalife products, jin bu huan, kava, skullcap). In patients with jaundice due to drug-induced hepatitis, the mortality rate without liver transplantation is at least 10%.

5. Other Reactions

A. Fatty Liver

1. Macrovesicular—This type of liver injury may be produced by alcohol, amiodarone, corticosteroids, methotrexate, irinotecan, tamoxifen, zalcitabine, and possibly oxaliplatin.

2. Microvesicular—Often resulting from mitochondrial injury, this condition is associated with didanosine, stavudine, tetracyclines, valproic acid, and zidovudine.

B. Granulomas

Allopurinol, quinidine, quinine, phenylbutazone, and phenytoin can lead to granulomas.

C. Fibrosis and Cirrhosis

Methotrexate and vitamin A are associated with fibrosis and cirrhosis.

D. Sinusoidal Obstruction Syndrome (Veno-occlusive Disease)

This disorder may result from treatment with antineoplastic agents (eg, pre-bone marrow transplant, oxaliplatin), and pyrrolizidine alkaloids (eg, Comfrey).

E. Peliosis Hepatis (Blood-Filled Cavities)

Peliosis hepatis may be caused by anabolic steroids and oral contraceptive steroids as well as azathioprine and mercaptopurine, which may also cause nodular regenerative hyperplasia.

F. Neoplasms

Neoplasms may result from therapy with oral contraceptive steroids, including estrogens (hepatic adenoma but not focal nodular hyperplasia); and vinyl chloride (angiosarcoma).

► When to Refer

Refer patients with drug- and toxin-induced hepatitis who require liver biopsy for diagnosis.

► When to Admit

Patients with liver failure should be hospitalized.

NONALCOHOLIC FATTY LIVER DISEASE

ESSENTIALS OF DIAGNOSIS

- Often asymptomatic.
- Elevated aminotransferase levels and/or hepatomegaly.
- Macrovesicular and/or microvesicular steatosis with or without inflammation and fibrosis on liver biopsy.

► General Considerations

Nonalcoholic fatty liver disease (NAFLD) is estimated to affect 20–30% of the US population. Causes of NAFLD are obesity (present in $\geq 40\%$), diabetes mellitus (in $\geq 20\%$), hypertriglyceridemia (in $\geq 20\%$), corticosteroids, amiodarone, diltiazem, tamoxifen, irinotecan, oxaliplatin, highly active antiretroviral therapy, poisons (carbon tetrachloride and yellow phosphorus), endocrinopathies such as Cushing syndrome and hypopituitarism, polycystic ovary syndrome, hypobetalipoproteinemia and other metabolic disorders, obstructive sleep apnea, starvation and refeeding syndrome, and total parenteral nutrition. Steatosis is nearly universal in obese alcoholic patients and is a hallmark of insulin resistance (metabolic syndrome), which is characterized by obesity, diabetes, hypertriglyceridemia, and hypertension. The risk of fatty liver in persons with metabolic syndrome is 4 to 11 times higher than that of persons without insulin resistance. Physical activity protects against the development of NAFLD. In addition to macrovesicular steatosis, histologic features may include focal infiltration by polymorphonuclear neutrophils and Mallory hyalin, a picture indistinguishable from that of alcoholic hepatitis and referred to as nonalcoholic steatohepatitis (NASH), which affects 3–5% of the US population. In patients with NAFLD, older age, obesity, and diabetes are risk factors for advanced hepatic fibrosis and cirrhosis. Cirrhosis caused by NASH appears to be uncommon in African Americans.

Microvesicular steatosis is seen with Reye syndrome, valproic acid toxicity, high-dose tetracycline, or acute fatty liver of pregnancy and may result in fulminant hepatic failure. Women in whom fatty liver of pregnancy develops often have a defect in fatty acid oxidation due to reduced long-chain 3-hydroxyacyl-CoA dehydrogenase activity.

► Clinical Findings

A. Symptoms and Signs

Most patients with NAFLD are asymptomatic or have mild right upper quadrant discomfort. Hepatomegaly is present

in up to 75% of patients, but the stigmas of chronic liver disease are uncommon. Rare instances of subacute liver failure caused by previously unrecognized NASH have been described.

B. Laboratory Findings

Laboratory studies may show mildly elevated aminotransferase and alkaline phosphatase levels; however, laboratory values may be normal in up to 80% of persons with hepatic steatosis. In contrast to alcoholic liver disease, the ratio of ALT to AST is almost always greater than 1 in NAFLD, but it decreases to less than 1 as advanced fibrosis and cirrhosis develop. Antinuclear or smooth muscle antibodies and an elevated serum ferritin level may each be detected in one-fourth of patients with NASH.

C. Imaging

Macrovascular steatosis may be demonstrated on ultrasound, CT, or MRI. However, imaging does not distinguish steatosis from steatohepatitis.

D. Liver Biopsy

Percutaneous liver biopsy is diagnostic and is the standard approach to assessing the degree of inflammation and fibrosis. The risks of the procedure must be balanced against the impact of the added information on management decisions and assessment of prognosis. The histologic spectrum includes fatty liver, isolated portal fibrosis, steatohepatitis, and cirrhosis. A risk score for predicting advanced fibrosis, known as BARD for the first letter of the terms defining it, is based on body mass index > 28, AST/ALT ratio \geq 0.8, and diabetes mellitus; it has a 96% negative predictive value (ie, a low score reliably excludes advanced fibrosis). Another risk score for advanced fibrosis based on age, hyperglycemia, body mass index, platelet count, albumin, and AST/ALT ratio has a positive predictive value of over 80%. A clinical scoring system to predict the likelihood of NASH in morbidly obese persons includes six predictive factors: hypertension, type 2 diabetes mellitus, sleep apnea, AST > 27 units/L, ALT > 27 units/L, and non-black race.

Treatment

Treatment consists of removing or modifying the offending factors. Weight loss, dietary fat restriction, and exercise (through reduction of abdominal obesity) often lead to improvement in liver tests and steatosis in obese patients with NAFLD. Various drugs are under study. Thiazolidinediones reverse insulin resistance and improve both serum aminotransferase levels and histologic features of steatohepatitis but lead to weight gain. Vitamin E (to reduce oxidative stress) is of uncertain benefit. Betaine (a methyl donor) may have some benefit and is under study. Metformin, which reduces insulin resistance, improves abnormal liver chemistries but may not reliably improve liver histology. Pentoxifylline, which inhibits tumor necrosis factor- α , improves liver biochemical test levels but is associated with a high rate of side effects, particularly nausea. Ursodeoxycholic acid, 12–15 mg/kg/d, has not consistently

resulted in biochemical and histologic improvement in patients with NASH but may be effective when given in combination with vitamin E. Hepatic steatosis due to total parenteral nutrition may be ameliorated—and perhaps prevented—with supplemental choline. Other agents under study include orlistat, an inhibitor of gastrointestinal lipases; recombinant human leptin; glucagon-like protein-1-receptor agonists, which promote insulin secretion; rimonabant, a selective inhibitor of cannabinoid type 1 receptors that decreases hepatic lipogenesis and increases satiety; and losartan, an angiotensin antagonist. Statins are not contraindicated in persons with NAFLD. Gastric bypass may be considered in patients with a body mass index > 35.

Prognosis

Fatty liver often has a benign course and is readily reversible with discontinuation of alcohol (or no more than one glass of wine per day) or treatment of other underlying conditions; if untreated, cirrhosis develops in 1–3% of patients. In patients with NAFLD, the likelihood of NASH is increased by the following factors: obesity, older age, non-African American ethnicity, female sex, diabetes, hypertension, higher AST level, higher AST/ALT ratio, and low platelet count. NASH may be associated with hepatic fibrosis in 40% of cases; cirrhosis develops in 9–25%; and decompensated cirrhosis occurs in 30–50% of cirrhotic patients over 10 years. The course may be more aggressive in diabetic persons than in nondiabetic persons. Mortality is increased in patients with NAFLD and is more likely to be the result of malignancy and ischemic heart disease than liver disease. Risk factors for mortality are older age, male gender, white race, higher body mass index, hypertension, diabetes, and cirrhosis. Steatosis is a cofactor for the progression of fibrosis in patients with other causes of chronic liver disease, such as hepatitis C. Hepatocellular carcinoma is a complication of cirrhosis caused by NASH as it is for other causes of cirrhosis. NASH accounts for a substantial percentage of cases labeled as cryptogenic cirrhosis and can recur following liver transplantation. Central obesity is an independent risk factor for death from cirrhosis of any cause.

When to Refer

Refer patients with non-alcoholic fatty liver disease who require liver biopsy for diagnosis.

CIRRHOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ End result of injury that leads to both fibrosis and nodular regeneration.
- ▶ May be reversible if cause is removed.
- ▶ The clinical features result from hepatic cell dysfunction, portosystemic shunting, and portal hypertension.

▶ General Considerations

Cirrhosis, the twelfth leading cause of death in the United States, is the end result of hepatocellular injury that leads to both fibrosis and nodular regeneration throughout the liver. Mexican Americans and African Americans have a higher frequency of cirrhosis than whites because of a higher rate of risk factors. Causes include chronic viral hepatitis, alcohol, drug toxicity, autoimmune and metabolic liver diseases, and miscellaneous disorders. Many patients have more than one risk factor (eg, chronic hepatitis and alcohol use). In patients at increased risk for liver injury (eg, heavy alcohol use, obesity, iron overload), higher coffee and tea consumption has been reported to reduce the risk of cirrhosis. Hospitalization rates for cirrhosis and portal hypertension are rising in the United States.

The most common histologic classification divides cirrhosis into micronodular, macronodular, and mixed forms. These are descriptive terms rather than separate diseases, and each form may be seen in the same patient at different stages of the disease. In micronodular cirrhosis—typical of alcoholic liver disease (Laennec cirrhosis)—the regenerating nodules are no larger than the original lobules, ie, approximately 1 mm in diameter or less. Macronodular cirrhosis is characterized by larger nodules, which can measure several centimeters in diameter and may contain central veins. This form corresponds more or less to postnecrotic (posthepatic) cirrhosis but does not necessarily follow episodes of massive necrosis and stromal collapse.

▶ Clinical Findings

A. Symptoms and Signs

The clinical features of cirrhosis result from hepatic cell dysfunction, portosystemic shunting, and portal hypertension. Patients may have no symptoms for long periods. The onset of symptoms may be insidious or, less often, abrupt. Weakness, fatigability, disturbed sleep, muscle cramps, and weight loss are common. In advanced cirrhosis, anorexia is usually present and may be extreme, with associated nausea and occasional vomiting. Abdominal pain may be present and is related either to hepatic enlargement and stretching of Glisson capsule or to the presence of ascites. Menstrual abnormalities (usually amenorrhea), impotence, loss of libido, sterility, and gynecomastia in men may occur. Hematemesis is the presenting symptom in 15–25%.

Skin manifestations consist of spider angioma (invariably on the upper half of the body), palmar erythema (mottled redness of the thenar and hypothenar eminences), and Dupuytren contractures. Evidence of vitamin deficiencies (glossitis and cheilosis) is common. Weight loss, wasting, and the appearance of chronic illness are present. Jaundice—usually not an initial sign—is mild at first, increasing in severity during the later stages of the disease. In 70% of cases, the liver is enlarged, palpable, and firm if not hard and has a sharp or nodular edge; the left lobe may predominate. Splenomegaly is present in 35–50% of cases and is associated with an increased risk of complications of portal hypertension. The superficial veins of the abdomen and thorax are dilated, reflecting the intrahepatic obstruction to portal blood flow, as do rectal varices (hemorrhoids). The abdominal wall veins fill from below when compressed. Ascites, pleural effusions, peripheral edema, and ecchymoses are late findings. Encephalopathy characterized by day–night reversal, asterixis, tremor, dysarthria, delirium, drowsiness, and ultimately coma also occurs late except when precipitated by an acute hepatocellular insult or an episode of gastrointestinal bleeding. Fever may be a presenting symptom in up to 35% of patients and usually reflects associated alcoholic hepatitis, spontaneous bacterial peritonitis, or intercurrent infection.

B. Laboratory Findings

Laboratory abnormalities are either absent or minimal in early or compensated cirrhosis. Anemia, a frequent finding, is often macrocytic; causes include suppression of erythropoiesis by alcohol as well as folate deficiency, hemolysis, hypersplenism, and occult or overt blood loss from the gastrointestinal tract. The white blood cell count may be low, reflecting hypersplenism, or high, suggesting infection; thrombocytopenia is secondary to alcoholic marrow suppression, sepsis, folate deficiency, or splenic sequestration. Prolongation of the prothrombin time may result from reduced levels of clotting factors (except factor VIII). However, bleeding risk correlates poorly with results of conventional coagulation parameters because of concomitant abnormalities of fibrinolysis.

Blood chemistries reflect hepatocellular injury and dysfunction, manifested by modest elevations of AST and alka-

line phosphatase and progressive elevation of the bilirubin. Serum albumin is low; γ -globulin is increased and may be as high as in autoimmune hepatitis. The risk of diabetes mellitus is increased in patients with cirrhosis, particularly when associated with HCV infection, alcoholism, hemochromatosis, and NAFLD. Vitamin D deficiency has been reported in as many as 91% of patients with cirrhosis. Patients with alcoholic cirrhosis may have elevated serum cardiac troponin I and brain natriuretic peptide levels. Blunted cardiac inotropic and chronotropic responses to exercise, stress, and drugs, as well as systolic and diastolic ventricular dysfunction (“cirrhotic cardiomyopathy”) and prolongation of the QT interval in the setting of a hyperkinetic circulation, are common in cirrhosis of all causes, but overt heart failure is rare in the absence of alcoholism. Relative adrenal insufficiency appears to be common in patients with advanced cirrhosis, even in the absence of sepsis.

Liver biopsy may show inactive cirrhosis (fibrosis with regenerative nodules) with no specific features to suggest the underlying cause. Alternatively, there may be additional features of alcoholic liver disease, chronic hepatitis, NASH, or other specific causes of cirrhosis. Combinations of routine blood tests (eg, AST, platelet count), including a commercially available panel of five tests called FibroSure, and serum markers of hepatic fibrosis (eg, hyaluronic acid, amino-terminal propeptide of type III collagen, tissue inhibitor of matrix metalloproteinase 1) are potential alternatives to liver biopsy for the diagnosis or exclusion of cirrhosis. In persons with chronic hepatitis C, for example, a low FibroSure score reliably excludes advanced fibrosis, a high score reliably predicts advanced fibrosis, and intermediate scores are inconclusive.

C. Imaging

Ultrasound is helpful for assessing liver size and detecting ascites or hepatic nodules, including small hepatocellular carcinomas. Together with a Doppler study, it may establish patency of the splenic, portal, and hepatic veins. Hepatic nodules are characterized further by contrast-enhanced CT scan or MRI. Nodules suspicious for malignancy may be biopsied under ultrasound or CT guidance.

D. Special Examinations

Esophagogastroduodenoscopy confirms the presence of varices and detects specific causes of bleeding in the esophagus, stomach, and proximal duodenum. Liver biopsy may be performed by laparoscopy or, in patients with coagulopathy and ascites, by a transjugular approach. In selected cases, wedged hepatic vein pressure measurement may establish the presence and cause of portal hypertension. Transient elastography, which uses ultrasonography to determine liver stiffness, and magnetic resonance elastography are under study as noninvasive tests for cirrhosis and portal hypertension.

► Differential Diagnosis

The most common causes of cirrhosis in the United States are alcohol and chronic hepatitis C. NAFLD and hepatitis

B are also common causes. Hemochromatosis is the most commonly identified genetic disorder that causes cirrhosis. Other metabolic diseases that may lead to cirrhosis include Wilson disease and α_1 -antitrypsin (α_1 -antiprotease) deficiency. Primary biliary cirrhosis occurs more frequently in women than men. Secondary biliary cirrhosis may result from chronic biliary obstruction due to a stone, stricture, or neoplasm. Congestive heart failure and constrictive pericarditis may lead to hepatic fibrosis (“cardiac cirrhosis”) complicated by ascites and may be mistaken for other causes of cirrhosis. Hereditary hemorrhagic telangiectasia can lead to portal hypertension because of portosystemic shunting and nodular transformation of the liver as well as high-output heart failure. Many cases of cirrhosis are “cryptogenic,” in which unrecognized NAFLD may play a role. Mutations in the gene encoding cytokeratin 8 have been associated with some cases of cryptogenic cirrhosis.

► Complications

Upper gastrointestinal tract bleeding may occur from varices, portal hypertensive gastropathy, or gastroduodenal ulcer (see Chapter 15). Varices may also result from portal vein thrombosis, which may complicate cirrhosis. Liver failure may be precipitated by alcoholism, surgery, and infection. The risk of carcinoma of the liver is increased greatly in patients with cirrhosis. Hepatic Kupffer cell (reticuloendothelial) dysfunction and decreased opsonic activity lead to an increased risk of systemic infection. Osteoporosis occurs in 12–55% of patients with cirrhosis.

► Treatment

A. General Measures

The most important principle of treatment is abstinence from alcohol. The diet should be palatable, with adequate calories (25–35 kcal/kg body weight per day in those with compensated cirrhosis and 35–40 kcal/kg/d in those with malnutrition) and protein (1–1.2 g/kg/d in those with compensated cirrhosis and 1.5 g/kg/d in those with malnutrition) and, if there is fluid retention, sodium restriction. In the presence of hepatic encephalopathy, protein intake should be reduced to no less than 60–80 g/d. The benefit of using specialized supplements containing branched-chain amino acids to prevent or treat hepatic encephalopathy or delay progressive liver failure is uncertain. Vitamin supplementation is desirable. Patients with cirrhosis should receive the HAV, HBV, and pneumococcal vaccines and a yearly influenza vaccine. Liver transplantation in appropriate candidates is curative, and pharmacologic treatments to halt progression of or even reverse cirrhosis are being developed.

B. Treatment of Complications

1. Ascites and edema—Diagnostic paracentesis is indicated for new ascites. It is rarely associated with serious complications such as bleeding, infection, or bowel perforation even in patients with severe coagulopathy. In addition to a cell count and culture, the ascitic albumin level should be determined; a serum-ascites albumin gradient (serum albumin minus ascitic albumin) ≥ 1.1 suggests portal

hypertension. An elevated ascitic adenosine deaminase level is suggestive of tuberculous peritonitis, but the sensitivity of the test is reduced in patients with portal hypertension. Occasionally, cirrhotic ascites is chylous (rich in triglycerides); other causes of chylous ascites are malignancy, tuberculosis, and recent abdominal surgery or trauma.

Ascites in patients with cirrhosis results from portal hypertension (increased hydrostatic pressure); hypoalbuminemia (decreased oncotic pressure); peripheral vasodilation, perhaps mediated by endotoxin-induced release of nitric oxide from splanchnic and systemic vasculature, with resulting increases in renin and angiotensin levels and sodium retention by the kidneys; impaired liver inactivation of aldosterone; and increased aldosterone secretion secondary to increased renin production. In individuals with ascites, the urinary excretion of sodium is often less than 10 mEq/L. Free water excretion is also impaired in cirrhosis, and hyponatremia may develop.

In all patients with cirrhotic ascites, dietary sodium intake may initially be restricted to 2000 mg/d; the intake of sodium may be liberalized slightly after diuresis ensues. In some patients, ascites diminishes promptly with bed rest and dietary sodium restriction alone. Fluid intake (800–1000 mL/d) is often restricted in patients with hyponatremia (serum sodium < 125 mEq/L). Treatment of severe hyponatremia with vasopressin receptor antagonists (vaptans) is under study.

A. DIURETICS—Spironolactone, generally in combination with furosemide, should be used in patients who do not respond to salt restriction. An initial trial of furosemide 80 mg intravenously demonstrating a rise in urine sodium to 750 mmol in 8 hours may predict response to diuretic therapy. The dose of spironolactone is initially 100 mg orally daily and may be increased by 100 mg every 3–5 days (up to a maximal conventional daily dose of 400 mg/d, although higher doses have been used) until diuresis is achieved, typically preceded by a rise in the urinary sodium concentration. Monitoring for hyperkalemia is important. In patients who cannot tolerate spironolactone because of side effects, such as painful gynecomastia, amiloride (another potassium-sparing diuretic) may be used in a dose of 5–10 mg orally daily. Diuresis is augmented by the addition of a loop diuretic such as furosemide. This potent diuretic, however, will maintain its effect even with a falling glomerular filtration rate, with resulting prerenal azotemia. The dose of oral furosemide ranges from 40 mg/d to 160 mg/d, and the drug should be administered while blood pressure, urinary output, mental status, and serum electrolytes (especially potassium) are monitored.

The goal of weight loss in the ascitic patient without associated peripheral edema should be no more than 1–1.5 lb/d (0.5–0.7 kg/d).

B. LARGE-VOLUME PARACENTESIS—In patients with massive ascites and respiratory compromise, ascites refractory to diuretics, or intolerable diuretic side effects, large-volume paracentesis (4–6 L) is effective. Intravenous albumin concomitantly at a dosage of 10 g/L of ascites fluid removed protects the intravascular volume and may prevent postparacentesis circulatory dysfunction, although

the usefulness of this practice is debated. Moreover, use of albumin adds considerable expense. Large-volume paracentesis can be repeated daily until ascites is largely resolved and may decrease the need for hospitalization. If possible, diuretics should be continued in the hope of preventing recurrent ascites.

C. TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT (TIPS)—TIPS is an effective treatment of variceal bleeding refractory to standard therapy (eg, endoscopic band ligation or sclerotherapy) and has shown benefit in the treatment of severe refractory ascites. The technique involves insertion of an expandable metal stent between a branch of the hepatic vein and portal vein over a catheter inserted via the internal jugular vein. Increased renal sodium excretion and control of ascites refractory to diuretics can be achieved in about 75% of selected cases. The success rate is lower in patients with underlying chronic kidney disease. TIPS appears to be the treatment of choice for refractory hepatic hydrothorax (translocation of ascites across the diaphragm to the pleural space); video-assisted thoracoscopy with pleurodesis using talc may be effective when TIPS is contraindicated. Complications of TIPS include hepatic encephalopathy in 20–30% of cases, infection, shunt stenosis in up to 60% of cases, and shunt occlusion in up to 30% of cases when bare stents are used but lower rates when covered stents are used. Long-term patency usually requires periodic shunt revisions. In most cases, patency can be maintained by balloon dilation, local thrombolysis, or placement of an additional stent. TIPS is particularly useful in patients who require short-term control of variceal bleeding or ascites until liver transplantation can be performed. In patients with refractory ascites, TIPS results in lower rates of ascites recurrence and hepatorenal syndrome but a higher rate of hepatic encephalopathy than occurs with repeated large-volume paracentesis; a benefit in survival has been demonstrated in one study and a meta-analysis. Chronic kidney disease, refractory encephalopathy, and hyperbilirubinemia are associated with mortality after TIPS.

D. PERITONEOVENOUS SHUNTS—Peritoneovenous shunts are sometimes placed in patients with malignant ascites but are no longer used for refractory cirrhotic ascites because of a considerable complication rate: disseminated intravascular coagulation in 65% of patients (25% symptomatic; 5% severe), bacterial infections in 4–8%, congestive heart failure in 2–4%, and variceal bleeding from sudden expansion of intravascular volume. TIPS is now preferred for refractory ascites.

2. Spontaneous bacterial peritonitis—Spontaneous bacterial peritonitis is heralded by abdominal pain, increasing ascites, fever, and progressive encephalopathy in a patient with cirrhotic ascites; symptoms are typically mild. Paracentesis reveals an ascitic fluid with, most commonly, a total white cell count of up to 500 cells/mcL with a high percentage of polymorphonuclear cells (PMNs) (> 250/mcL) and a protein concentration of 1 g/dL or less, corresponding to decreased ascitic opsonic activity. Rapid diagnosis of bacterial peritonitis can be made with a high degree of specificity

with rapid reagent strips (“dipsticks”) that detect leukocyte esterase in ascitic fluid, but the sensitivity is too low for routine use. Cultures of ascites give the highest yield—80–90% positive—using blood culture bottles inoculated at the bedside. Common isolates are *Escherichia coli* and pneumococci. (Gram-positive cocci are the most common isolates in patients who have undergone invasive procedures such as central venous line placement.) Anaerobes are rare. Pending culture results, if there are 250 or more PMN/mcL, intravenous antibiotic therapy should be initiated with cefotaxime, 2 g every 8–12 hours for at least 5 days. Ceftriaxone and amoxicillin-clavulanic acid are alternatives. Oral ofloxacin, 400 mg twice daily, or a 2-day course of intravenous ciprofloxacin, 200 mg twice daily, followed by oral ciprofloxacin, 500 mg twice daily for 5 days, may be effective in selected patients. Supplemental administration of intravenous albumin appears to reduce mortality. Response to therapy can be documented, if necessary, by a decrease in the PMN count of at least 50% on repeat paracentesis 48 hours after initiation of therapy. The overall mortality rate is high—up to 30% during hospitalization and up to 70% by 1 year. Patients with cirrhosis and septic shock have a high frequency of relative adrenal insufficiency, which if present requires administration of hydrocortisone. In survivors of bacterial peritonitis, the risk of recurrent peritonitis may be decreased by long-term norfloxacin, 400 mg orally daily (although in recurrence the causative organism is often resistant to fluoroquinolones). In high-risk cirrhotic patients (eg, those with ascitic protein < 1.5 g/dL, serum bilirubin > 3.0 mg/dL), the risk of peritonitis, hepatorenal syndrome, and mortality for at least 1 year may be reduced by prophylactic norfloxacin, ciprofloxacin (500 mg orally once or twice a day), or trimethoprim-sulfamethoxazole (one double-strength tablet five times a week). Oral norfloxacin or intravenous ceftriaxone (1 g per day) for 7 days reduces the risk of bacterial peritonitis in patients with acute variceal bleeding).

3. Hepatorenal syndrome—Hepatorenal syndrome occurs in up to 10% of patients with advanced cirrhosis and ascites and is characterized by azotemia (serum creatinine > 1.5 mg/dL) in the absence of parenchymal kidney disease or shock and by failure of kidney function to improve following 2 days of diuretic withdrawal and volume expansion with albumin, 1 g/kg up to a maximum of 100 g/d. Oliguria, hyponatremia, and low urinary sodium are typical features. Hepatorenal syndrome is diagnosed only when other causes of acute kidney injury (including prerenal azotemia and acute tubular necrosis) have been excluded. Type I hepatorenal syndrome is characterized by doubling of the serum creatinine to a level greater than 2.5 mg/dL or by halving of the creatinine clearance to less than 20 mL/min in less than 2 weeks. Type II hepatorenal syndrome is more slowly progressive and chronic. The pathogenesis involves intense renal vasoconstriction, possibly because of impaired synthesis of renal vasodilators such as prostaglandin E₂ and decreased total renal blood flow; histologically, the kidneys are normal. An acute decrease in cardiac output is often the precipitating event. Improvement may follow intravenous infusion of albumin in combination with one of the following vasoconstrictor regimens for 7–14 days: intravenous

vasopressin or ornipressin (but with a high rate of ischemic side effects); intravenous ornipressin plus dopamine; intravenous terlipressin (a long-acting vasopressin analog that is not available in the United States but that may be the preferred agent); intravenous norepinephrine; or oral midodrine, an α -adrenergic drug, plus the somatostatin analog octreotide, subcutaneously or intravenously. Prolongation of survival has been associated with use of MARS, a modified dialysis method that selectively removes albumin-bound substances. Improvement and sometimes normalization of kidney function may also follow placement of a TIPS. Liver transplantation is the treatment of choice, but many patients die before a donor liver can be obtained. Mortality correlates with the MELD score and presence of a systemic inflammatory response.

4. Hepatic encephalopathy—Hepatic encephalopathy is a state of disordered central nervous system function resulting from failure of the liver to detoxify noxious agents of gut origin because of hepatocellular dysfunction and portosystemic shunting. The clinical spectrum ranges from day-night reversal and mild intellectual impairment to coma. Patients with minimal hepatic encephalopathy have no recognizable clinical symptoms but demonstrate mild cognitive and psychomotor deficits and attention deficit on standardized tests and an increased rate of traffic accidents. The stages of overt encephalopathy are: (1) mild confusion, (2) drowsiness, (3) stupor, and (4) coma. Ammonia is the most readily identified and measurable toxin but is not solely responsible for the disturbed mental status. Central to the pathogenesis is low-grade cerebral edema and astrocyte swelling accompanied by increased production of reactive oxygen and nitrogen oxide species that trigger RNA and protein modifications and thereby affect brain function. Factors that contribute to cerebral edema are ammonia, hyponatremia, cytokines, and benzodiazepines. Bleeding into the intestinal tract may significantly increase the amount of protein in the bowel and precipitate encephalopathy. Other precipitants include constipation, alkalosis, and potassium deficiency induced by diuretics, opioids, hypnotics, and sedatives; medications containing ammonium or amino compounds; paracentesis with attendant hypovolemia; hepatic or systemic infection; and portosystemic shunts (including TIPS). The diagnosis is based primarily on detection of characteristic symptoms and signs, including asterixis. The role of neuroimaging studies (eg, cerebral positron emission tomography, magnetic resonance spectroscopy) in the diagnosis of hepatic encephalopathy is evolving.

Dietary protein should be withheld during acute episodes if the patient cannot eat. When the patient resumes oral intake, protein intake should be 60–80 g/d as tolerated; vegetable protein is better tolerated than meat protein. Gastrointestinal bleeding should be controlled and blood purged from the gastrointestinal tract. This can be accomplished with 120 mL of magnesium citrate by mouth or nasogastric tube every 3–4 hours until the stool is free of gross blood, or by administration of lactulose. The value of treating patients with minimal hepatic encephalopathy is uncertain; probiotic agents may have some benefit.

Lactulose, a nonabsorbable synthetic disaccharide syrup, is digested by bacteria in the colon to short-chain fatty acids, resulting in acidification of colon contents. This acidification favors the formation of ammonium ion in the $\text{NH}_4^+ \leftrightarrow \text{NH}_3 + \text{H}^+$ equation; NH_4^+ is not absorbable, whereas NH_3 is absorbable and thought to be neurotoxic. Lactulose also leads to a change in bowel flora so that fewer ammonia-forming organisms are present. When given orally, the initial dose of lactulose for acute hepatic encephalopathy is 30 mL three or four times daily. The dose should then be titrated so that two or three soft stools per day are produced. When rectal use is indicated because of the patient's inability to take medicines orally, the dose is 300 mL of lactulose in 700 mL of saline or sorbitol as a retention enema for 30–60 minutes; it may be repeated every 4–6 hours. Lactilol is a less sweet disaccharide alternative available as a powder in some countries.

The ammonia-producing intestinal flora may also be controlled with an oral antibiotic. Traditionally, neomycin sulfate, 0.5–1 g orally every 6 or 12 hours for 7 days, has been used, but side effects (including diarrhea, malabsorption, superinfection, ototoxicity, and nephrotoxicity) are frequent, especially after prolonged use. The nonabsorbable agent rifaximin, 400 mg orally three times daily, is preferred. Metronidazole, 250 mg orally three times daily, has also shown benefit. Patients who do not respond to lactulose alone may improve with a course of an antibiotic in addition to lactulose.

Opioids and sedatives metabolized or excreted by the liver should be avoided. If agitation is marked, oxazepam, 10–30 mg, which is not metabolized by the liver, may be given cautiously by mouth or by nasogastric tube. Zinc deficiency should be corrected, if present, with oral zinc sulfate, 600 mg/d in divided doses. Sodium benzoate, 5 g orally twice daily, ornithine aspartate, 9 g orally three times daily, and L-acyl-carnitine, 4 g orally daily, may lower blood ammonia levels, but there is less experience with these drugs than with lactulose. The benzodiazepine competitive antagonist flumazenil is effective in about 30% of patients with severe hepatic encephalopathy, but the drug is short-acting and intravenous administration is required. Use of special dietary supplements enriched with branched-chain amino acids is usually unnecessary except in occasional patients who are intolerant of standard protein supplements. Treatment with acarbose (an α -glucosidase inhibitor) and L-carnitine (an essential factor in the mitochondrial transport of long-chain fatty acids) is under study; other therapies being evaluated include modulating the gut flora with prebiotic and probiotic agents and the use of extracorporeal albumin dialysis (MARS).

5. Anemia—For iron deficiency anemia, ferrous sulfate, 0.3-g enteric-coated tablets, one tablet orally three times daily after meals, is effective. Folic acid, 1 mg/d orally, is indicated in the treatment of macrocytic anemia associated with alcoholism. Transfusions with packed red blood cells may be necessary to replace blood loss.

6. Coagulopathy—Severe hypoprothrombinemia may be treated with vitamin K (eg, phytonadione, 5 mg orally or subcutaneously daily). This treatment is ineffective when

synthesis of coagulation factors is impaired because of severe hepatic disease. In such cases, correcting the prolonged prothrombin time requires large volumes of fresh frozen plasma (see Chapter 13). Because the effect is transient, plasma infusions are not indicated except for active bleeding or before an invasive procedure. Use of recombinant activated factor VII may be an alternative, but it is expensive and poses a 1–2% risk of thrombotic complications. Eltrombopag, an oral thrombopoietin-receptor agonist, has shown promise in patients with cirrhosis and severe thrombocytopenia.

7. Hemorrhage from esophageal varices—See Chapter 15.

8. Hepatopulmonary syndrome and portopulmonary hypertension—Shortness of breath in patients with cirrhosis may result from pulmonary restriction and atelectasis caused by massive ascites. The hepatopulmonary syndrome is the triad of chronic liver disease, an increased alveolar-arterial gradient while the patient is breathing room air, and intrapulmonary vascular dilations or arteriovenous communications that result in a right-to-left intrapulmonary shunt and occurs in 5–32% of patients with cirrhosis. The syndrome is presumed to result from enhanced pulmonary production of nitric oxide but does not correlate with the degrees of hepatic dysfunction and portal hypertension. Patients often have greater dyspnea (platypnea) and arterial deoxygenation (orthodeoxia) in the upright than in the recumbent position. The diagnosis should be suspected in a cirrhotic patient with a pulse oximetry level $\leq 96\%$.

Contrast-enhanced echocardiography is a sensitive screening test for detecting pulmonary vascular dilations, whereas macroaggregated albumin lung perfusion scanning is more specific and is used to confirm the diagnosis. High-resolution CT may be useful for detecting dilated pulmonary vessels that may be amenable to embolization in patients with severe hypoxemia ($\text{PO}_2 < 60$ mm Hg) who respond poorly to supplemental oxygen.

Medical therapy has been disappointing; experimentally, intravenous methylene blue, oral garlic powder, and oral norfloxacin may improve oxygenation by inhibiting nitric oxide-induced vasodilation, and pentoxifylline may prevent hepatopulmonary syndrome by inhibiting production of tumor necrosis factor- α . Long-term oxygen therapy is recommended for severely hypoxemic patients. The syndrome may reverse with liver transplantation, although postoperative mortality is increased in patients with a preoperative arterial oxygen tension < 50 mm Hg or with substantial intrapulmonary shunting. TIPS may provide palliation in patients with hepatopulmonary syndrome awaiting transplantation.

Portopulmonary hypertension occurs in 0.7% of patients with cirrhosis and is thought to result from an excess of circulating vasoconstrictors, particularly endothelin-1.

Female gender and autoimmune hepatitis have been reported to be risk factors. In cases confirmed by right-sided heart catheterization, treatment with epoprostenol or bosentan may reduce pulmonary hypertension and

thereby facilitate liver transplantation; β -blockers worsen exercise capacity and are contraindicated. Liver transplantation is contraindicated in patients with moderate to severe pulmonary hypertension (mean pulmonary pressure > 35 mm Hg).

C. Liver Transplantation

Liver transplantation is indicated in selected cases of irreversible, progressive chronic liver disease, acute hepatic failure, and certain metabolic diseases in which the metabolic defect is in the liver. Absolute contraindications include malignancy (except relatively small hepatocellular carcinomas in a cirrhotic liver), advanced cardiopulmonary disease (except hepatopulmonary syndrome), and sepsis. Relative contraindications include age over 70 years, morbid obesity, portal and mesenteric vein thrombosis, active alcohol or drug abuse, severe malnutrition, and lack of patient understanding. With the emergence of effective antiretroviral therapy for HIV disease, a major cause of mortality in these patients has shifted to liver disease caused by HCV and HBV infection; preliminary experience suggests that the outcome of liver transplantation is comparable to that for non-HIV-infected liver transplant recipients. Alcoholics should be abstinent for 6 months. Liver transplantation should be considered in patients with worsening functional status, rising bilirubin, decreasing albumin, worsening coagulopathy, refractory ascites, recurrent variceal bleeding, or worsening encephalopathy. The major impediment to more widespread use of liver transplantation is a shortage of donor organs. Increasingly, adult living donor liver transplantation is an option for some patients. Five-year survival rates as high as 80% are now reported. Hepatocellular carcinoma, hepatitis B and C, and some cases of Budd-Chiari syndrome and autoimmune liver disease may recur in the transplanted liver. The incidence of recurrence of hepatitis B can be reduced by preoperative and postoperative treatment with a nucleoside analog and perioperative administration of HBIG. Immunosuppression is achieved with combinations of cyclosporine, tacrolimus or sirolimus, corticosteroids, azathioprine, and mycophenolate mofetil and may be complicated by infections, advanced chronic kidney disease, neurologic disorders, and drug toxicity as well as graft rejection, vascular occlusion, or bile leaks. Patients are at risk for obesity, diabetes mellitus, and hyperlipidemia.

► Prognosis

Factors determining survival include the patient's ability to stop the intake of alcohol as well as the Child-Turcotte-Pugh class (Table 16-6). The MELD score, which incorporates the serum bilirubin and creatinine levels and the INR, is also a measure of mortality risk in patients with end-stage liver disease and is particularly useful for predicting short- and intermediate-term survival and complications of cirrhosis (eg, bacterial peritonitis) and determining allocation priorities for donor livers. The consistency of the MELD score among different hospitals may be improved when the INR is calibrated based on prothrombin time control samples that include patients with liver disease

Table 16-6. Child-Turcotte-Pugh and Model for End-Stage Liver Disease (MELD) scoring systems for staging cirrhosis.

| Child-Turcotte-Pugh scoring system | | | |
|---|-----------------|--------------------|--------------------|
| Parameter | Numerical Score | | |
| | 1 | 2 | 3 |
| Ascites | None | Slight | Moderate to severe |
| Encephalopathy | None | Slight to moderate | Moderate to severe |
| Bilirubin (mg/dL) | < 2.0 | 2-3 | > 3.0 |
| Albumin (g/dL) | > 3.5 | 2.8-3.5 | < 2.8 |
| Prothrombin time (seconds increased) | 1-3 | 4-6 | > 6.0 |
| Total Numerical Score and Corresponding Child-Turcotte-Pugh Class | | | |
| Score | | | Class |
| 5-6 | | | A |
| 7-9 | | | B |
| 10-15 | | | C |
| MELD scoring system | | | |
| MELD = $11.2 \log_e$ (INR) + $3.78 \log_e$ (bilirubin [mg/dL]) + $9.57 \log_e$ (creatinine [mg/dL]) + 6.43. (Range 6-40). | | | |

INR, international normalized ratio.

rather than those taking oral anticoagulants. In patients with a relatively low MELD score (< 21) and a low priority for liver transplantation, a low serum sodium concentration (< 130 mEq/L), an elevated hepatic venous pressure gradient, and persistent ascites appear to be additional independent predictors of mortality, and a modification of the MELD score that incorporates the serum sodium (MELDNa) is under study. Only 50% of patients with severe hepatic dysfunction (serum albumin < 3 g/dL, bilirubin > 3 mg/dL, ascites, encephalopathy, cachexia, and upper gastrointestinal bleeding) survive 6 months. The risk of death in this subgroup of patients with advanced cirrhosis is associated with chronic kidney disease, cognitive dysfunction, ventilatory insufficiency, age ≥ 65 years, and prothrombin time ≥ 16 seconds. Obesity appears to be a risk factor for cirrhosis-related death or hospitalization in nonalcoholic patients, and diabetes mellitus increases the risk of complications and mortality in patients with cirrhosis. Patients with cirrhosis are at risk for the development of hepatocellular carcinoma, with rates of 3-5% per year for alcoholic and viral hepatitis-related cirrhosis. Liver transplantation has markedly improved the outlook for patients with cirrhosis who are acceptable candidates and are referred for evaluation early. Patients with compensated cirrhosis are given additional priority for liver transplantation if they are found to have a lesion > 2 cm in diameter consistent with hepatocellular carcinoma. In-

hospital mortality from variceal bleeding in patients with cirrhosis has declined from over 40% in 1980 to 15% in 2000. Medical treatments to reverse hepatic fibrosis are under investigation.

▶ When to Refer

- For liver biopsy.
- Child-Turcotte-Pugh score ≥ 7 .
- MELD score ≥ 10 .
- For upper endoscopy to screen for gastroesophageal varices.

▶ When to Admit

- Gastrointestinal bleeding.
- Stage 3–4 hepatic encephalopathy.
- Worsening kidney function.
- Severe hyponatremia.
- Profound hypoxia.

PRIMARY BILIARY CIRRHOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Occurs in middle-aged women.
- ▶ Often asymptomatic.
- ▶ Elevation of alkaline phosphatase, positive antimitochondrial antibody, elevated IgM, increased cholesterol.
- ▶ Characteristic liver biopsy.
- ▶ In later stages, can present with fatigue, jaundice, features of cirrhosis, xanthelasma, xanthoma, steatorrhea.

▶ General Considerations

Primary biliary cirrhosis is a chronic disease of the liver characterized by autoimmune destruction of small intrahepatic bile ducts and cholestasis. It is insidious in onset, occurs usually in women aged 40–60 years, and is often detected by the chance finding of elevated alkaline phosphatase levels. Estimated incidence and prevalence rates in the United States are 4.5 and 65.4 per 100,000, respectively, in women, and 0.7 and 12.1 per 100,000, respectively, in men. The frequency of the disease among first-degree relatives of affected persons is 1.3–6%, and the concordance rate in identical twins is high. The disease is associated with HLA *DRB1*08*. The disease may be associated with Sjögren syndrome, autoimmune thyroid disease, Raynaud syndrome, scleroderma, hypothyroidism, and celiac disease. Infection with *Novosphingobium aromaticivorans* or *Chlamydophila pneumoniae* may be triggering or causative in primary biliary cirrhosis; other triggers, including viruses (such as human betaretrovirus), lactobacillus vaccination to prevent recurrent vaginitis, and xenobiotics, are also suspected. X-chromosome monosomy may be a predisposing factor. A history of urinary tract infections (caused by *E coli*) and smoking and use of hormone replacement therapy are risk factors.

▶ Clinical Findings

A. Symptoms and Signs

Many patients are asymptomatic for years. The onset of clinical illness is insidious and is heralded by fatigue (excessive daytime somnolence) and pruritus. With progression, physical examination reveals hepatosplenomegaly. Xanthomatous lesions may occur in the skin and tendons and around the eyelids. Jaundice, steatorrhea, and signs of portal hypertension are late findings. Autonomic dysfunction, including orthostatic hypotension, and cognitive dysfunction appear to be common. The risk of low bone density, osteoporosis, and fractures is increased in patients with primary biliary cirrhosis (who tend to be older women) possibly due in part to polymorphisms of the vitamin D receptor.

B. Laboratory Findings

Blood counts are normal early in the disease. Liver biochemical tests reflect cholestasis with elevation of alkaline phosphatase, cholesterol (especially high-density lipoproteins), and, in later stages, bilirubin. Antimitochondrial antibodies (directed against the dihydrolipoamide acetyltransferase component of pyruvate dehydrogenase or other 2-oxo-acid enzymes in mitochondria) are present in 95% of patients, and serum IgM levels are elevated. ANAs directed against the nuclear pore complex (eg, against gp210 in the nuclear envelope) may be detected in specialized laboratories.

▶ Diagnosis

The diagnosis of primary biliary cirrhosis is based on the detection of cholestatic liver chemistries (often initially an isolated elevation of the alkaline phosphatase) and anti-

tochondrial antibodies in serum. Liver biopsy is not essential for diagnosis but permits histologic staging: I, portal inflammation with granulomas; II, bile duct proliferation, periportal inflammation; III, interlobular fibrous septa; and IV, cirrhosis. Estimation of histologic stage by an “enhanced liver fibrosis assay” that incorporates serum levels of hyaluronic acid, tissue inhibitor of metalloproteinase-1, and procollagen III aminopeptide has shown promise.

► Differential Diagnosis

The disease must be differentiated from chronic biliary tract obstruction (stone or stricture), carcinoma of the bile ducts, primary sclerosing cholangitis, sarcoidosis, cholestatic drug toxicity (eg, chlorpromazine), and in some cases chronic hepatitis. Patients with a clinical and histologic picture of primary biliary cirrhosis but no antimitochondrial antibodies are said to have antimitochondrial antibody-negative primary biliary cirrhosis (“autoimmune cholangitis”), which has been associated with lower serum IgM levels and a greater frequency of smooth muscle and ANAs. Many such patients are found to have antimitochondrial antibodies by immunoblot against recombinant proteins (rather than standard immunofluorescence). Some patients have overlapping features of primary biliary cirrhosis and autoimmune hepatitis.

► Treatment

Cholestyramine (4 g) or colestipol (5 g) in water or juice three times daily may be beneficial for pruritus. Rifampin, 150–300 mg orally twice daily, is inconsistently beneficial. Opioid antagonists (eg, naloxone, 0.2 mcg/kg/min by intravenous infusion, or naltrexone, 50 mg/d by mouth) show promise in the treatment of pruritus. The 5-hydroxytryptamine (5-HT₃) serotonin receptor antagonist ondansetron, 4 mg orally three times a day as needed, and the selective serotonin uptake inhibitor sertraline, 75–100 mg/d orally, may also provide some benefit. For refractory pruritus, plasmapheresis or extracorporeal albumin dialysis may be needed. Modafinil, 100–200 mg/d orally, may improve daytime somnolence. Deficiencies of vitamins A, K, and D may occur if steatorrhea is present and are aggravated when cholestyramine or colestipol is administered. See Chapter 26 for discussion of prevention and treatment of osteoporosis.

Because of its lack of toxicity, ursodeoxycholic acid (13–15 mg/kg/d in one or two doses) is the preferred medical treatment (and only treatment approved by the US FDA) for primary biliary cirrhosis and has been shown to slow the progression of disease (particularly in early-stage disease), stabilize histology, improve long-term survival, reduce the risk of developing esophageal varices, and delay (and possibly prevent) the need for liver transplantation, although the benefit of the drug has been questioned. Complete normalization of liver tests occurs in 20% of treated patients within 2 years and 40% within 5 years, and survival is similar to that of healthy controls when the drug is given to patients with stage 1 or 2 primary biliary cirrhosis. Ursodeoxycholic acid therapy has also been reported to reduce the risk of recurrent colorectal adenomas in patients with primary

biliary cirrhosis. Side effects include weight gain and rarely loose stools. Colchicine (0.6 mg orally twice daily) and methotrexate (15 mg/wk orally) have had some reported benefit in improving symptoms and serum levels of alkaline phosphatase and bilirubin. Methotrexate may also improve liver histology in some patients, but overall response rates have been disappointing. Penicillamine, prednisone, and azathioprine have proved to be of no benefit. Budesonide may improve liver histology but worsens bone density. Mycophenolate mofetil is under study. For patients with advanced disease, liver transplantation is the treatment of choice.

► Prognosis

Without liver transplantation, survival averages 7–10 years once symptoms develop but has improved for younger women since the introduction of ursodeoxycholic acid. Progression to liver failure and portal hypertension is associated with the presence of anti-gp210 and anticentromere antibodies, respectively, and may be accelerated by smoking. Patients in whom the alkaline phosphatase is less than three times normal, AST is less than two times normal, and bilirubin is less than or equal to 1 mg/dL after 1 year of therapy with ursodeoxycholic acid have a 10-year transplant-free survival rate of 90%. In advanced disease, adverse prognostic markers are a high Mayo risk score that includes older age, high serum bilirubin, edema, low serum albumin, and prolonged prothrombin time as well as variceal hemorrhage. Fatigue is associated with an increased risk of cardiac mortality. Among asymptomatic patients, at least one-third will become symptomatic within 15 years. The risk of hepatobiliary malignancies appears to be increased in patients with primary biliary cirrhosis; risk factors include older age, male sex, prior blood transfusions, and signs of cirrhosis or portal hypertension. Liver transplantation for advanced primary biliary cirrhosis is associated with a 1-year survival rate of 85–90%. The disease recurs in the graft in 20% of patients by 3 years, but this does not seem to affect survival.

► When to Refer

- For liver biopsy.
- For liver transplant evaluation.

► When to Admit

- Gastrointestinal bleeding.
- Stage 3–4 hepatic encephalopathy.
- Worsening kidney function.
- Severe hyponatremia.
- Profound hypoxia.

HEMOCHROMATOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Usually diagnosed because of elevated iron saturation or serum ferritin or a family history.
- ▶ Most patients are asymptomatic; the disease is rarely recognized clinically before the fifth decade.
- ▶ Hepatic abnormalities and cirrhosis, congestive heart failure, hypogonadism, and arthritis.
- ▶ *HFE* gene mutation (usually *C282Y/C282Y*) is found in most cases.

▶ General Considerations

Hemochromatosis is an autosomal recessive disease caused in many cases by a mutation in the *HFE* gene on chromosome 6. The *HFE* protein is thought to play an important role in the process by which duodenal crypt cells sense body iron stores, leading in turn to increased iron absorption from the duodenum. A decrease in the synthesis or expression of hepcidin, the principal iron regulatory hormone, is thought to be a principal pathogenic factor in all forms of hemochromatosis. About 85% of persons with well-established hemochromatosis are homozygous for the *C282Y* mutation. The frequency of the gene mutation averages 7% in Northern European and North American white populations, resulting in a 0.5% frequency of homozygotes (of whom up to 88% will develop biochemical evidence of iron overload but only 28% of men and 1% of women will develop clinical symptoms). By contrast, the gene mutation and hemochromatosis are uncommon in blacks and Asian-American populations. A second genetic mutation (*H63D*) may contribute to the development of hemochromatosis in a small percentage (1.5%) of persons who are compound heterozygotes for *C282Y* and *H63D* and have a comorbidity such as diabetes mellitus and fatty liver. *H63D* homozygotes do not develop hemochromatosis but may be at increased risk for amyotrophic lateral sclerosis. Rare instances of hemochromatosis result from mutations in the genes that encode transferrin receptor 2 and ferroprotein. A juvenile-onset variant that is characterized by severe iron overload, cardiac dysfunction, hypogonadotropic hypogonadism, and a high mortality rate is usually linked to a mutation of a gene on chromosome 1q designated *HJV* that produces a protein called hemojuvelin or, rarely, to a mutation in the

HAMP gene on chromosome 19 that encodes hepcidin but not to the *C282Y* mutation.

Hemochromatosis is characterized by increased accumulation of iron as hemosiderin in the liver, pancreas, heart, adrenals, testes, pituitary, and kidneys. Cirrhosis is more likely to develop in affected persons who drink alcohol excessively or have obesity-related steatosis than in those who do not. Eventually, hepatic and pancreatic insufficiency, congestive heart failure, and hypogonadism may develop. Heterozygotes do not develop cirrhosis in the absence of associated disorders such as viral hepatitis or NAFLD.

▶ Clinical Findings

A. Symptoms and Signs

The onset of clinical disease is usually after age 50 years—earlier in men than in women; however, because of widespread liver biochemical testing and iron screening, the diagnosis is usually made long before symptoms develop. Early symptoms are nonspecific (eg, fatigue, arthralgias). Later clinical manifestations include arthropathy, hepatomegaly and evidence of hepatic insufficiency (late finding), skin pigmentation (combination of slate-gray due to iron and brown due to melanin, sometimes resulting in bronze color), cardiac enlargement with or without heart failure or conduction defects, diabetes mellitus with its complications, and impotence in men. Interestingly, population studies have shown an increased prevalence of liver disease but not of diabetes, arthritis, or heart disease in *C282Y* homozygotes. Bleeding from esophageal varices may occur, and in patients in whom cirrhosis develops, there is a 15–20% frequency of hepatocellular carcinoma. Affected patients are at increased risk of infection with *Vibrio vulnificus*, *Listeria monocytogenes*, *Yersinia enterocolitica*, and other siderophilic organisms. The risk of porphyria cutanea tarda is increased in persons with the *C282Y* or *H63D* mutation.

B. Laboratory Findings

Laboratory findings include mildly abnormal liver tests (AST, alkaline phosphatase), an elevated plasma iron with greater than 50% transferrin saturation in men and 45% in women (after an overnight fast), and an elevated serum ferritin (although a normal iron saturation and a normal ferritin do not exclude the diagnosis). Affected men are more likely than affected women to have an elevated ferritin level.

C. Imaging

MRI and CT may show changes consistent with iron overload of the liver, and MRI can quantitate hepatic iron stores. There is also an emerging role for MRI for assessment of the degree of hepatic fibrosis. Testing for *HFE* mutations is indicated in any patient with evidence of iron overload and in siblings of patients with confirmed hemochromatosis.

D. Liver Biopsy

In patients who are homozygous for *C282Y*, liver biopsy is often indicated to determine whether cirrhosis is present.

Biopsy can be deferred, however, in patients in whom the serum ferritin level is < 1000 mcg/L, serum AST level is normal, and hepatomegaly is absent; the likelihood of cirrhosis is low in these persons. Liver biopsy is also indicated when iron overload is suspected even though the patient is not homozygous for C282Y. In patients with hemochromatosis, the liver biopsy characteristically shows extensive iron deposition in hepatocytes and in bile ducts and the hepatic iron index—hepatic iron content per gram of liver converted to micromoles and divided by the patient's age—is generally greater than 1.9. Only 5% of patients with hereditary hemochromatosis identified by screening in a primary care setting have cirrhosis.

► Screening

Genetic testing is recommended for all first-degree family members of the proband; children of an affected person (C282Y homozygote) need to be screened only if the patient's spouse carries the C282Y or H63D mutation. Screening all men of Northern European ancestry over age 25 years by measurement of the transferrin saturation or the unbound iron-binding capacity has been recommended by some experts, but the value of screening has been questioned because morbidity and mortality from hemochromatosis are low. Patients with otherwise unexplained chronic liver disease, arthritis, impotence, and late-onset type 1 (and possibly type 2) diabetes mellitus should be screened for iron overload.

► Treatment

Affected patients should avoid foods rich in iron (such as red meat), alcohol, vitamin C, raw shellfish, and supplemental iron. Weekly phlebotomies of 1 or 2 units (250–500 mL) of blood (each containing about 250 mg of iron) is indicated in all asymptomatic patients, those with a serum ferritin level of at least 1000 mcg/L, and those with an increased fasting iron saturation and should be continued for up to 2–3 years to achieve depletion of iron stores. The hematocrit and serum iron values should be monitored. When iron store depletion is achieved (iron saturation $< 50\%$ and serum ferritin level < 50 mcg/L), maintenance phlebotomies (every 2–4 months) are continued, although compliance has been reported to decrease with time; administration of a proton pump inhibitor, which reduces intestinal iron absorption, appears to decrease the maintenance phlebotomy blood volume requirement. The chelating agent deferoxamine is indicated for patients with hemochromatosis and anemia or in those with secondary iron overload due to thalassemia who cannot tolerate phlebotomies. The drug is administered intravenously or subcutaneously in a dose of 20–40 mg/kg/d infused over 24 hours and can mobilize 30 mg of iron per day. However, treatment is painful and time-consuming. An oral chelator, deferasirox, 20 mg/kg once daily, has been approved for treatment of iron overload due to blood transfusions. Complications of hemochromatosis—arthropathy, diabetes, heart disease, portal hypertension, and hypopituitarism—also require treatment.

The course of the disease is favorably altered by phlebotomy therapy. Fibrosis may regress, and in precirrhotic

patients, cirrhosis may be prevented. Cardiac conduction defects and insulin requirements improve with treatment. In patients with cirrhosis, varices may reverse, and the risk of variceal bleeding declines, although the risk of hepatocellular carcinoma persists. In the past, liver transplantation for advanced cirrhosis associated with severe iron overload, including hemochromatosis, was reported to lead to survival rates that were lower than those for other types of liver disease because of cardiac complications and an increased risk of infections, but since 1997, posttransplant survival rates have been excellent.

► When to Refer

- For liver biopsy.
- For initiation of therapy.

WILSON DISEASE

ESSENTIALS OF DIAGNOSIS

- Excessive deposition of copper in the liver and brain.
- Rare autosomal recessive disorder that usually occurs in persons under age 40.
- Serum ceruloplasmin, the plasma copper-carrying protein, is low.
- Urinary excretion of copper and hepatic copper concentration are high.

► General Considerations

Wilson disease (hepatolenticular degeneration) is a rare autosomal recessive disorder that usually occurs in persons under age 40. The worldwide prevalence is about 30 per million population. The condition is characterized by excessive deposition of copper in the liver and brain. The genetic defect, localized to chromosome 13, has been shown to affect a copper-transporting adenosine triphosphatase (ATP7B) in the liver and leads to copper accumulation in the liver and oxidative damage of hepatic mito-

chondria. Most patients are compound heterozygotes (ie, carry two different mutations). Approximately 300 different mutations in the Wilson disease gene have been identified, making genetic diagnosis impractical except within families in which the mutation has been identified in the index case. The *H1069Q* mutation accounts for 37–63% of disease alleles in populations of Northern European descent.

The major physiologic aberration in Wilson disease is excessive absorption of copper from the small intestine and decreased excretion of copper by the liver, resulting in increased tissue deposition, especially in the liver, brain, cornea, and kidney.

► Clinical Findings

Wilson disease tends to present as liver disease in adolescents and neuropsychiatric disease in young adults, but there is great variability, and onset of symptoms after age 40 is more common than previously thought. The diagnosis should always be considered in any child or young adult with hepatitis, splenomegaly with hypersplenism, Coombs-negative hemolytic anemia, portal hypertension, and neurologic or psychiatric abnormalities. Wilson disease should also be considered in persons under 40 years of age with chronic or fulminant hepatitis.

Hepatic involvement may range from elevated liver tests (although the alkaline phosphatase may be low) to cirrhosis and portal hypertension. In a patient with acute liver failure, the diagnosis of Wilson disease is suggested by an alkaline phosphatase-to-total bilirubin ratio < 4 and an AST-to-ALT ratio > 2.2 . The neurologic manifestations of Wilson disease are related to basal ganglia dysfunction and include an akinetic-rigid syndrome similar to parkinsonism, pseudosclerosis with tremor, ataxia, and a dystonic syndrome. Dysarthria, dysphagia, incoordination, and spasticity are common. Migraines, insomnia, and seizures have been reported. Psychiatric features include behavioral and personality changes and emotional lability and may precede characteristic neurologic features. The pathognomonic sign of the condition is the brownish or gray-green Kayser-Fleischer ring, which represents fine pigmented granular deposits in Descemet membrane in the cornea (Plate 70). The ring is usually most marked at the superior and inferior poles of the cornea. It is sometimes seen with the naked eye and is readily detected by slit-lamp examination. It may be absent in patients with hepatic manifestations only but is usually present in those with neuropsychiatric disease. Renal calculi, aminoaciduria, renal tubular acidosis, hypoparathyroidism, infertility, and hemolytic anemia may occur in patients with Wilson disease.

► Diagnosis

The diagnosis can be challenging and is generally based on demonstration of increased urinary copper excretion (> 40 mcg/24 h and usually > 100 mcg/24 h) or low serum ceruloplasmin levels (< 20 mg/dL; < 5 mg/dL is diagnostic), and elevated hepatic copper concentration (> 250 mcg/g of dry liver). However, increased urinary copper and low serum ceruloplasmin levels are neither completely

sensitive nor specific for Wilson disease. In equivocal cases (when the serum ceruloplasmin level is normal), the diagnosis may require demonstration of a rise in urinary copper determination after a penicillamine challenge, although the test has been validated only in children. Liver biopsy may show acute or chronic hepatitis or cirrhosis. MRI of the brain may show evidence of increased basal ganglia, brainstem, and cerebellar copper even early in the course of the disease. If available, molecular analysis of *ATP7B* mutations can be diagnostic.

► Treatment

Early treatment to remove excess copper is essential before it can produce hepatic or neurologic damage. Early in the treatment phase, restriction of dietary copper (shellfish, organ foods, nuts, mushrooms, and chocolate) may be of value. Oral penicillamine (0.75–2 g/d in divided doses taken 1 h before or 2 h after food) is the drug of choice and enhances urinary excretion of chelated copper. Oral pyridoxine, 50 mg per week, is added, since penicillamine is an antimetabolite of this vitamin. If penicillamine treatment cannot be tolerated because of gastrointestinal intolerance, hypersensitivity, autoimmune reactions, nephrotoxicity, or bone marrow toxicity, consider the use of another chelating agent—trientine, 250–500 mg three times a day. Oral zinc acetate or zinc gluconate, 50 mg three times a day, interferes with intestinal absorption of copper, promotes fecal copper excretion, and may be used as maintenance therapy after decoppering with a chelating agent or as first-line therapy in presymptomatic or pregnant patients. Ammonium tetrathiomolybdate, which complexes copper in the intestinal tract, has shown promise as initial therapy for neurologic Wilson disease.

Treatment should continue indefinitely. The doses of penicillamine and trientine should be reduced during pregnancy. Supplemental vitamin E, an antioxidant, has been recommended but not rigorously studied. Once the serum nonceruloplasmin copper level is within the normal range (50–150 mcg/L), the dose of chelating agent can be reduced to the minimum necessary for maintaining that level. The prognosis is good in patients who are effectively treated before liver or brain damage has occurred. Liver transplantation is indicated for fulminant hepatitis (often after plasma exchange or dialysis with MARS as a stabilizing measure), end-stage cirrhosis, and, in selected cases, intractable neurologic disease, although survival is lower when liver transplantation is undertaken for neurologic disease than for liver disease. Family members, especially siblings, require screening with serum ceruloplasmin, liver biochemical tests, and slit-lamp examination or, if the causative mutation is known, with mutation analysis.

► When to Refer

All patients with Wilson disease should be referred for diagnosis and treatment.

► When to Admit

- Acute liver failure.

- Gastrointestinal bleeding.
- Stage 3–4 hepatic encephalopathy.
- Worsening kidney function.
- Severe hyponatremia.
- Profound hypoxia.

HEPATIC VEIN OBSTRUCTION (Budd-Chiari Syndrome)

ESSENTIALS OF DIAGNOSIS

- ▶ Right upper quadrant pain and tenderness.
- ▶ Ascites.
- ▶ Imaging studies show occlusion/absence of flow in the hepatic vein(s) or inferior vena cava.
- ▶ Clinical picture is similar in veno-occlusive disease but major hepatic veins are patent.

▶ General Considerations

Factors that predispose patients to hepatic vein obstruction, or Budd-Chiari syndrome, including hereditary and acquired hypercoagulable states, can be identified in 75% of affected patients; multiple disorders are found in 25%. Up to 50% of cases are associated with polycythemia vera or other myeloproliferative disease (which has a risk of Budd-Chiari syndrome of 1%). These cases are often associated with a specific mutation (*V617F*) in the gene that codes for JAK2 tyrosine kinase and may be subclinical. In some cases, an underlying predisposition to thrombosis (eg, activated protein C resistance [factor V Leiden mutation] [25% of cases], protein C or S or antithrombin deficiency, hyperprothrombinemia [factor II G20210A mutation], the methylenetetrahydrofolate reductase *TT677* mutation, antiphospholipid antibodies) can be identified. Hepatic vein obstruction may be associated with caval webs, right-sided heart failure or constrictive pericarditis, neoplasms that cause hepatic vein occlusion, paroxysmal nocturnal hemoglobinuria, Behçet syndrome, blunt abdominal trauma, use of oral contraceptives, and pregnancy. Some cytotoxic agents and pyrrolizidine alkaloids (“bush teas”) may cause sinusoidal obstruction syndrome (previously known as veno-occlusive disease because the terminal venules are often occluded), which mimics Budd-Chiari syndrome clinically. Sinusoidal obstruction syndrome is common in patients who have

undergone bone marrow transplantation, particularly those with pretransplant aminotransferase elevations or fever during cytoreductive therapy with cyclophosphamide, azathioprine, carmustine, busulfan, or etoposide or those receiving high-dose cytoreductive therapy or high-dose total body irradiation. In India, China, and South Africa, Budd-Chiari syndrome is associated with a poor standard of living and often the result of occlusion of the hepatic portion of the inferior vena cava, presumably due to prior thrombosis. The clinical presentation is mild but the course is frequently complicated by hepatocellular carcinoma.

▶ Clinical Findings

A. Symptoms and Signs

The presentation may be fulminant, acute, subacute, or chronic. An insidious (subacute) onset is most common. Clinical manifestations generally include tender, painful hepatic enlargement, jaundice, splenomegaly, and ascites. With chronic disease, bleeding varices and hepatic coma may be evident; hepatopulmonary syndrome may occur.

B. Imaging

Hepatic imaging studies may show a prominent caudate lobe, since its venous drainage may not be occluded. The screening test of choice is contrast-enhanced, color, or pulsed-Doppler ultrasonography, which has a sensitivity of 85% for detecting evidence of hepatic venous or inferior vena caval thrombosis. MRI with spin-echo and gradient-echo sequences and intravenous gadolinium injection allows visualization of the obstructed veins and collateral vessels. Direct venography can delineate caval webs and occluded hepatic veins (“spider-web” pattern) most precisely.

C. Liver Biopsy

Percutaneous or transjugular liver biopsy frequently shows a characteristic centrilobular congestion and fibrosis and often multiple large regenerating nodules. Liver biopsy is often contraindicated in sinusoidal obstruction syndrome because of thrombocytopenia, and the diagnosis is based on clinical findings.

▶ Treatment

Ascites should be treated with fluid and salt restriction and diuretics. Treatable causes of Budd-Chiari syndrome should be sought. Prompt recognition and treatment of an underlying hematologic disorder may avoid the need for surgery, but the optimal anticoagulation regimen is uncertain. Low-molecular weight heparins are preferred over unfractionated heparin because of a high rate of heparin-induced thrombocytopenia with the latter. Infusion of a thrombolytic agent into recently occluded veins has been attempted with success. In patients with sinusoidal obstruction syndrome, defibrotide, an adenosine receptor agonist that increases endogenous tissue plasminogen activator levels, has shown promise. TIPS placement may be attempted in patients with persistent hepatic congestion or failed thrombolytic therapy, although late TIPS dysfunction is common. TIPS is now

preferred over surgical decompression (side-to-side portacaval, mesocaval, or mesoatrial shunt) which, in contrast to TIPS, has not been proven to improve long-term survival. Older age, higher serum bilirubin level, and greater INR predict a poor outcome with TIPS. Balloon angioplasty, in some cases with placement of an intravascular metallic stent, is preferred in patients with an inferior vena caval web and is being performed increasingly in patients with a short segment of thrombosis in the hepatic vein. Liver transplantation is considered in patients with fulminant hepatic failure, cirrhosis and hepatocellular dysfunction, and failure of a portosystemic shunt, and outcomes have improved with the advent of patient selection based on the MELD score. Patients often require lifelong anticoagulation and treatment of the underlying myeloproliferative disease; antiplatelet therapy with aspirin and hydroxyurea has been suggested as an alternative to warfarin in patients with a myeloproliferative disorder. The overall 5-year survival rate is 50–90% with treatment (but < 10% without intervention). Adverse prognostic factors in patients with Budd-Chiari syndrome are older age, high Child-Turcotte-Pugh score, ascites, encephalopathy, elevated total bilirubin, prolonged prothrombin time, elevated serum creatinine, concomitant portal vein thrombosis, and histologic features of acute liver disease superimposed on chronic liver injury.

► When to Admit

All patients with hepatic vein obstruction should be hospitalized.

THE LIVER IN HEART FAILURE

Shock liver, or ischemic hepatopathy, results from an acute fall in cardiac output due, for example, to acute myocardial infarction or arrhythmia, usually in a patient with passive congestion of the liver. Clinical hypotension may be absent (or unwitnessed). In some cases, the precipitating event is arterial hypoxemia due to respiratory failure, sleep apnea, septic shock, severe anemia, heat stroke, carbon monoxide poisoning, cocaine use, or bacterial endocarditis. The hallmark is a rapid and striking elevation of serum aminotransferase levels (often > 5000 units/L); an early rapid rise in the serum lactate dehydrogenase level is also typical, but elevations of serum alkaline phosphatase and bilirubin are usually mild. The prothrombin time may be prolonged, and encephalopathy or hepatopulmonary syndrome may develop. The mortality rate due to the underlying disease is

high, but in patients who recover, the aminotransferase levels return to normal quickly, usually within 1 week—in contrast to viral hepatitis.

In patients with passive congestion of the liver due to right-sided heart failure, the serum bilirubin level may be elevated, occasionally as high as 40 mg/dL, due in part to hypoxia of perivenular hepatocytes. Serum alkaline phosphatase levels are normal or slightly elevated. Hepatojugular reflux is present, and with tricuspid regurgitation the liver may be pulsatile. Ascites may be out of proportion to peripheral edema, with a high serum ascites-albumin gradient (≥ 1.1) and a protein content of more than 2.5 g/dL. In severe cases, signs of encephalopathy may develop.

NONCIRRHOTIC PORTAL HYPERTENSION

Noncirrhotic portal hypertension must be considered in the differential diagnosis of splenomegaly or upper gastrointestinal bleeding due to esophageal or gastric varices in patients with little if any liver dysfunction. This syndrome may be due to extrahepatic portal vein obstruction (portal vein thrombosis often with cavernous transformation [portal cavernoma]), splenic vein obstruction (presenting as gastric varices without esophageal varices), schistosomiasis, noncirrhotic portal fibrosis (hepatoportal sclerosis), nodular regenerative hyperplasia, or arterial-portal vein fistula. Acute portal vein thrombosis usually causes abdominal pain. Aside from splenomegaly, the physical findings are not remarkable, although hepatic decompensation can follow severe gastrointestinal bleeding or a concurrent hepatic disorder, and intestinal infarction may occur when portal vein thrombosis is associated with mesenteric venous thrombosis. Minimal hepatic encephalopathy is reported to be common in patients with noncirrhotic portal vein thrombosis. Endoscopy shows esophageal or gastric varices. The liver tests are usually normal, but there may be findings of hypersplenism. Color Doppler ultrasound and contrast-enhanced CT are usually the initial diagnostic tests for portal vein thrombosis. Magnetic resonance angiography (MRA) of the portal system is generally confirmatory. Endoscopic ultrasound may be helpful in some cases. In patients with jaundice, magnetic resonance cholangiography may demonstrate compression of the bile duct by a large portal cavernoma. Needle biopsy of the liver may be indicated to diagnose schistosomiasis, nodular regenerative hyperplasia, and noncirrhotic intrahepatic portal sclerosis and may demonstrate sinusoidal dilatation. An underlying hypercoagulable state is found in many patients with portal vein thrombosis; this includes myeloproliferative disorders (often associated with a specific mutation [V617F] in the gene coding for JAK2 tyrosine kinase), mutation G20210A of prothrombin, factor V Leiden mutation, protein C and S deficiency, antiphospholipid syndrome, mutation TT677 of methylenetetrahydrofolate reductase, elevated factor VIII

levels, hyperhomocysteinemia, and a mutation in the gene that codes for thrombin-activatable fibrinolysis inhibitor. It is possible, however, that deficiency of protein C and S—as well as of antithrombin—is a secondary phenomenon due to portosystemic shunting and reduced hepatic blood flow. Portal vein thrombosis may occur in up to 15% of patients with cirrhosis and may be associated with hepatocellular carcinoma. Other risk factors are oral contraceptives, pregnancy, chronic inflammatory diseases, and other malignancies. Splenic vein thrombosis may complicate pancreatitis or pancreatic cancer. Pylephlebitis (septic thrombophlebitis of the portal vein) may complicate intra-abdominal inflammatory disorders such as appendicitis or diverticulitis, particularly when anaerobic organisms are involved. Nodular regenerative hyperplasia results from altered hepatic perfusion and can be associated with collagen vascular diseases, myeloproliferative disorders, and drugs, including azathioprine, 5-fluorouracil, and oxaliplatin. In patients infected with HIV, exposure to didanosine has been reported to account for some cases of noncirrhotic portal hypertension due to nodular regenerative hyperplasia.

If splenic vein thrombosis is the cause of variceal bleeding, splenectomy is curative. For other causes of noncirrhotic portal hypertension, band ligation or sclerotherapy followed by β -blockers to reduce portal pressure is initiated for variceal bleeding, and portosystemic shunting (including TIPS) is reserved for failures of endoscopic therapy; rarely progressive liver dysfunction requires liver transplantation. Anticoagulation or thrombolytic therapy may be indicated for isolated acute portal vein and possibly acute splenic vein thrombosis if a hypercoagulable disorder is identified. Long-term anticoagulation may be considered for affected patients with a hypercoagulable state.

► When to Refer

All patients with noncirrhotic portal hypertension should be referred.

terol Hepatol. 2008 Oct;6(10):1167–9. [PMID: 18639498]

PYOGENIC HEPATIC ABSCESS

ESSENTIALS OF DIAGNOSIS

- Fever, right upper quadrant pain, jaundice.
- Often in setting of biliary disease but up to 40% are “cryptogenic” in origin.
- Detected by imaging studies.

► General Considerations

The liver can be invaded by bacteria via (1) the common duct (ascending cholangitis); (2) the portal vein (pylephlebitis); (3) the hepatic artery, secondary to bacteremia; (4) direct extension from an infectious process; and (5) traumatic implantation of bacteria through the abdominal wall. Risk factors for liver abscess include older age and male gender. Predisposing conditions include malignancy, diabetes mellitus, inflammatory bowel disease, cirrhosis, and liver transplantation.

Ascending cholangitis resulting from biliary obstruction due to a stone, stricture, or neoplasm is the most common identifiable cause of hepatic abscess in the United States. In 10% of cases, liver abscess is secondary to appendicitis or diverticulitis. At least 40% of abscesses have no demonstrable cause and are classified as cryptogenic. A dental source is identified in some cases. The most frequently encountered organisms are *E coli*, *Klebsiella pneumoniae*, *Proteus vulgaris*, *Enterobacter aerogenes*, and multiple microaerophilic and anaerobic species (eg, *Streptococcus milleri*). Liver abscess caused by virulent strains of *K pneumoniae* may be associated with septic ocular or central nervous system complications. *Staphylococcus aureus* is usually the causative organism in patients with chronic granulomatous disease. Unusual causative organisms include *Salmonella*, *Haemophilus*, and *Yersinia*. Hepatic candidiasis, tuberculosis, and actinomycosis are seen in immunocompromised patients and those with hematologic malignancies. Rarely, hepatocellular carcinoma can present as a pyogenic abscess because of tumor necrosis, biliary obstruction, and superimposed bacterial infection (see Chapter 39). The possibility of an amebic liver abscess must always be considered (see Chapter 35).

► Clinical Findings

A. Symptoms and Signs

The presentation is often insidious. Fever is almost always present and may antedate other symptoms or signs. Pain may be a prominent complaint and is localized to the right hypochondrium or epigastric area. Jaundice, tenderness in the right upper abdomen, and either steady or swinging fever are the chief physical findings.

B. Laboratory Findings

Laboratory examination reveals leukocytosis with a shift to the left. Liver biochemical tests are nonspecifically abnormal. Blood cultures are positive in 50–100% of cases.

C. Imaging

Chest roentgenograms usually reveal elevation of the diaphragm if the abscess is on the right side. Ultrasound, CT, or MRI may reveal the presence of intrahepatic defects. On MRI, characteristic findings include high signal intensity on T2-weighted images and rim enhancement. The characteristic CT appearance of hepatic candidiasis, usually seen in the setting of systemic candidiasis, is that of multiple “bull’s-eyes,” but imaging studies may be negative in neutropenic patients.

► Treatment

Treatment should consist of antimicrobial agents (generally a third-generation cephalosporin such as cefoperazone 1–2 g intravenously every 12 hours and metronidazole 500 mg intravenously every 6 hours) that are effective against coliform organisms and anaerobes. Antibiotics are administered for 2–3 weeks, and sometimes up to 6 weeks. If the abscess is at least 5 cm in diameter or the response to antibiotic therapy is not rapid, intermittent needle aspiration or catheter or surgical (eg, laparoscopic) drainage should be done. Other suggested indications for abscess drainage are patient age of at least 55 years, symptom duration of at least 7 days, and involvement of both lobes of the liver. The underlying source (eg, biliary disease, dental infection) should be identified and treated. The mortality rate is still substantial ($\geq 8\%$ in most studies) and is highest in patients with underlying biliary malignancy or severe multiorgan dysfunction. Hepatic candidiasis often responds to intravenous amphotericin B (total dose of 2–9 g). Fungal abscesses are associated with mortality rates of up to 50% and are treated with intravenous amphotericin B and drainage.

► When to Admit

Nearly all patients with pyogenic hepatic abscess should be hospitalized.

BENIGN LIVER NEOPLASMS

Benign hepatic neoplasms must be distinguished from hepatocellular carcinoma and metastases (see Chapter 39). The most common benign neoplasm of the liver is the **cavernous hemangioma**, often an incidental finding on ultrasound or CT scan. This lesion may enlarge in women who take hormonal therapy and must be differentiated from other space-occupying intrahepatic lesions, usually by contrast-enhanced MRI, CT, or ultrasound. Rarely, fine-needle biopsy is necessary to differentiate these lesions and does not appear to carry an increased risk of bleeding. Surgical resection of cavernous hemangiomas is rarely necessary but may be required for abdominal pain or rapid enlargement, to exclude malignancy, or to treat Kasabach-Merritt syndrome (consumptive coagulopathy complicating a hemangioma).

In addition to rare instances of sinusoidal dilatation and peliosis hepatis, two distinct benign lesions with characteristic clinical, radiologic, and histopathologic features have been described in women taking oral contraceptives—focal nodular hyperplasia and hepatic adenoma. **Focal nodular hyperplasia** occurs at all ages and is probably not caused by the oral contraceptives. It is often

asymptomatic and appears as a hypervascular mass, often with a central hypodense “stellate” scar on CT scan or MRI. Microscopically, focal nodular hyperplasia consists of hyperplastic units of hepatocytes with a central stellate scar containing proliferating bile ducts. It is not a true neoplasm but a nonspecific reaction to altered blood flow is associated with an elevated angiotensin 1/angiotensin 2 mRNA ratio and may also occur in patients with cirrhosis, with exposure to certain drugs such as azathioprine, and in antiphospholipid syndrome. The prevalence of hepatic hemangiomas is increased in patients with focal nodular hyperplasia.

Hepatic adenoma occurs most commonly in the third and fourth decades of life and is usually caused by oral contraceptives; acute abdominal pain may occur if the tumor undergoes necrosis or hemorrhage. The tumor may be associated with mutations in: (1) the gene coding for hepatocyte nuclear factor α (*HNF1 α*) (characterized by steatosis and a low risk of malignant transformation); (2) the gene coding for β -catenin (characterized by a high rate of malignant transformation); or (3) neither gene (designated inflammatory adenoma [previously termed “telangiectatic focal nodular hyperplasia”]), which is associated with a high body mass index and serum biomarkers of inflammation such as C-reactive protein). Rare instances of multiple hepatic adenomas in association with maturity-onset diabetes of the young occur in families with a germline mutation in *HNF1 α* . Hepatic adenomas also occur in patients with glycogen storage disease and familial adenomatous polyposis. The tumor is hypovascular and reveals a cold defect on liver scan. Grossly, the cut surface appears structureless. As seen microscopically, the hepatic adenoma consists of sheets of hepatocytes without portal tracts or central veins.

The only physical finding in focal nodular hyperplasia or hepatic adenoma is a palpable abdominal mass in a minority of cases. Liver function is usually normal. Arterial phase helical CT and MRI with contrast can distinguish an adenoma from focal nodular hyperplasia in 80–90% of cases and may suggest a specific subtype of adenoma (eg, homogeneous fat pattern in *HNF1 α* -mutated adenomas and marked and persistent arterial enhancement in inflammatory adenomas).

Cystic neoplasms of the liver, such as cystadenoma and cystadenocarcinoma, must be distinguished from simple and echinococcal cysts and von Meyenburg complexes (hamartomas).

Treatment of focal nodular hyperplasia is resection only in the symptomatic patient. The prognosis is excellent. Hepatic adenoma often undergoes necrosis and rupture, and resection is advised if the tumor is > 5 cm in diameter, even in asymptomatic persons, or if symptomatic. In selected cases, laparoscopic resection or percutaneous radiofrequency ablation may be feasible. Regression of benign hepatic tumors may follow cessation of oral contraceptives.

► When to Refer

- Diagnostic uncertainty.
- For surgery.

▶ When to Admit

- Severe pain.
- Rupture.

DISEASES OF THE BILIARY TRACT

See Chapter 39 for Carcinoma of the Biliary Tract.

CHOLELITHIASIS (Gallstones)

ESSENTIALS OF DIAGNOSIS

- ▶ Often asymptomatic.
- ▶ Classic biliary pain characterized by infrequent episodes of steady severe pain in epigastrium or right upper quadrant with radiation to right scapula.
- ▶ Detected on ultrasound.

▶ General Considerations

Gallstones are more common in women than in men and increase in incidence in both sexes and all races with aging. In the United States, the prevalence of gallstones is 5.5% in men and 8.6% in women, with the highest rates in persons over age 60 and higher rates in Mexican-Americans than in non-Hispanic whites and African Americans. Although cholesterol gallstones are less common in black people, cholelithiasis attributable to hemolysis occurs in over a third of individuals with sickle cell anemia. Native Americans of both the Northern and Southern Hemispheres have a high rate of cholesterol cholelithiasis, probably because of a predisposition resulting from “thrifty” (*LITH*) genes that promote efficient calorie utilization and fat storage. As many as 75% of Pima and other American Indian women over the age of 25 years have cholelithiasis. Other genetic mutations that predispose persons to gallstones have been identified. Obesity is a risk factor for gallstones, especially in women. Rapid weight loss, as occurs after bariatric surgery, also increases the risk of symptomatic gallstone formation. There is evidence that glucose intolerance and elevated serum insulin levels (insulin resistance) are risk factors for gallstones, and a high intake of carbohydrate and high dietary glycemic load increase the risk of cholecystectomy in women. The incidence of cholelithiasis is increased in patients with diabetes mellitus, and the prevalence of gallbladder disease is increased in men (but not women) with cirrhosis and hepatitis C virus infection. A low-carbohydrate diet, physical activity, and cardiorespiratory fitness may help prevent gallstones. Consumption of

caffeinated coffee appears to protect against gallstones in women, and a high intake of magnesium and of polyunsaturated and monounsaturated fats reduces the risk of gallstones in men. A diet high in fiber, as well as fruits and vegetables, reduces the risk of cholecystectomy in women. Hypertriglyceridemia may promote gallstone formation by impairing gallbladder motility. The incidence of gallstones is high in individuals with Crohn disease; approximately one-third of those with inflammatory involvement of the terminal ileum have gallstones due to disruption of bile salt resorption that results in decreased solubility of the bile. Drugs such as clofibrate, octreotide, and ceftriaxone can cause gallstones. In contrast, aspirin and other nonsteroidal anti-inflammatory drugs may protect against gallstones. Prolonged fasting (over 5–10 days) can lead to formation of biliary “sludge” (microlithiasis), which usually resolves with refeeding but can lead to gallstones or biliary symptoms. Pregnancy, particularly in obese women and those with insulin resistance, is associated with an increased risk of gallstones and of symptomatic gallbladder disease. Hormone replacement therapy appears to increase the risk of gallbladder disease and need for cholecystectomy; the risk is lower with transdermal than oral therapy.

Gallstones are classified according to their predominant chemical composition as cholesterol or calcium bilirubinate stones. The latter comprise less than 20% of the stones found in Europe or the United States but 30–40% of stones found in Japan.

▶ Clinical Findings

Table 16–7 lists the clinical and laboratory features of several diseases of the biliary tract as well as their treatment. Cholelithiasis is frequently asymptomatic and is discovered in the course of routine radiographic study, operation, or autopsy. There is generally no need for prophylactic cholecystectomy in an asymptomatic person unless the gallbladder is calcified, gallstones are over 3 cm in diameter, or the patient is a Native American or a candidate for bariatric surgery or cardiac transplantation. Symptoms (biliary pain) develop in 10–25% of patients (1–4% annually), and acute cholecystitis develops in 20% of these symptomatic persons over time. Occasionally, small intestinal obstruction due to “gallstone ileus” (known as Bouveret syndrome when the obstructing stone is in pylorus or duodenum) presents as the initial manifestation of cholelithiasis.

▶ Treatment

Laparoscopic cholecystectomy is the treatment of choice for symptomatic gallbladder disease. Patients may go home within 1 day of the procedure and return to work within days (instead of weeks for those undergoing standard open cholecystectomy). The procedure is often performed on an outpatient basis and is suitable for most patients, including those with acute cholecystitis. Conversion to a conventional open cholecystectomy may be necessary in 2–8% of cases (higher for acute cholecystitis than for uncomplicated cholelithiasis). Bile duct injuries occur in 0.1% of cases done by experienced surgeons. Cholecystectomy may increase the risk of esophageal, proximal small intestinal,

Table 16-7. Diseases of the biliary tract.

| | Clinical Features | Laboratory Features | Diagnosis | Treatment |
|------------------------------|---|--|--|---|
| Gallstones | Asymptomatic | Normal | Ultrasound | None |
| Gallstones | Biliary pain | Normal | Ultrasound | Laparoscopic cholecystectomy |
| Cholesterosis of gallbladder | Usually asymptomatic | Normal | Oral cholecystography | None |
| Adenomyomatosis | May cause biliary pain | Normal | Oral cholecystography | Laparoscopic cholecystectomy if symptomatic |
| Porcelain gallbladder | Usually asymptomatic, high risk of gallbladder cancer | Normal | Radiograph or CT | Laparoscopic cholecystectomy |
| Acute cholecystitis | Epigastric or right upper quadrant pain, nausea, vomiting, fever, Murphy sign | Leukocytosis | Ultrasound, HIDA scan | Antibiotics, laparoscopic cholecystectomy |
| Chronic cholecystitis | Biliary pain, constant epigastric or right upper quadrant pain, nausea | Normal | Ultrasound (stones), oral cholecystography (non-functioning gallbladder) | Laparoscopic cholecystectomy |
| Cholelithiasis | Asymptomatic or biliary pain, jaundice, fever; gallstone pancreatitis | Cholestatic liver function tests; leukocytosis and positive blood cultures in cholangitis; elevated amylase and lipase in pancreatitis | Ultrasound (dilated ducts), endoscopic ultrasound, MRCP, ERCP | Endoscopic sphincterotomy and stone extraction; antibiotics for cholangitis |

ERCP, endoscopic retrograde cholangiopancreatography; HIDA, hepatic iminodiacetic acid; MRCP, magnetic resonance cholangiopancreatography.

and colonic adenocarcinomas because of increased duodenogastric reflux and changes in intestinal exposure to bile. In pregnant patients a conservative approach to biliary pain is advised, but for patients with repeated attacks of biliary pain or acute cholecystitis, cholecystectomy can be performed—even by the laparoscopic route—preferably in the second trimester. Enterolithotomy alone is considered adequate treatment in most patients with gallstone ileus.

Cheno- and ursodeoxycholic acids are bile salts that when given orally for up to 2 years dissolve some cholesterol stones and may be considered in occasional, selected patients who refuse cholecystectomy. The dose is 7 mg/kg/d of each or 8–13 mg/kg of ursodeoxycholic acid in divided doses daily. They are most effective in patients with a functioning gallbladder, as determined by gallbladder visualization on oral cholecystography, and multiple small “floating” gallstones (representing not more than 15% of patients with gallstones). In half of patients, gallstones recur within 5 years after treatment is stopped. Ursodeoxycholic acid, 500–600 mg daily, reduces the risk of gallstone formation with rapid weight loss.

Lithotripsy in combination with bile salt therapy for single radiolucent stones less than 20 mm in diameter was an option in the past but is no longer generally used in the United States.

► When to Refer

Patients should be referred when they require surgery.

ACUTE CHOLECYSTITIS

ESSENTIALS OF DIAGNOSIS

- Steady, severe pain and tenderness in the right hypochondrium or epigastrium.
- Nausea and vomiting.
- Fever and leukocytosis.

► General Considerations

Cholecystitis is associated with gallstones in over 90% of cases. It occurs when a stone becomes impacted in the cystic

duct and inflammation develops behind the obstruction. Acalculous cholecystitis should be considered when unexplained fever or right upper quadrant pain occurs within 2–4 weeks of major surgery or in a critically ill patient who has had no oral intake for a prolonged period; multiorgan failure is often present. Acute cholecystitis caused by infectious agents (eg, cytomegalovirus, cryptosporidiosis, or microsporidiosis) may occur in patients with AIDS.

▶ Clinical Findings

A. Symptoms and Signs

The acute attack is often precipitated by a large or fatty meal and is characterized by the sudden appearance of steady pain localized to the epigastrium or right hypochondrium, which may gradually subside over a period of 12–18 hours. Vomiting occurs in about 75% of patients and in half of instances affords variable relief. Right upper quadrant abdominal tenderness (often with Murphy sign, or inhibition of inspiration by pain on palpation of the right upper quadrant) is almost always present and is usually associated with muscle guarding and rebound tenderness. A palpable gallbladder is present in about 15% of cases. Jaundice is present in about 25% of cases and, when persistent or severe, suggests the possibility of choledocholithiasis. Fever is typical.

B. Laboratory Findings

The white blood cell count is usually high (12,000–15,000/mcL). Total serum bilirubin values of 1–4 mg/dL may be seen even in the absence of bile duct obstruction. Serum aminotransferase and alkaline phosphatase are often elevated—the former as high as 300 units/mL, or even higher when associated with ascending cholangitis. Serum amylase may also be moderately elevated.

C. Imaging

Plain films of the abdomen may show radiopaque gallstones in 15% of cases. ^{99m}Tc hepatobiliary imaging (using iminodiacetic acid compounds), also known as the hepatic iminodiacetic acid (HIDA) scan, is useful in demonstrating an obstructed cystic duct, which is the cause of acute cholecystitis in most patients. This test is reliable if the bilirubin is under 5 mg/dL (98% sensitivity and 81% specificity for acute cholecystitis). False-positive results can occur with prolonged fasting, liver disease, and chronic cholecystitis, and the specificity can be improved by intravenous administration of morphine, which induces spasm of the sphincter of Oddi. Right upper quadrant abdominal ultrasound, which is often performed first, may show the presence of gallstones but is not as sensitive for acute cholecystitis (67% sensitivity, 82% specificity); findings suggestive of acute cholecystitis are gallbladder wall thickening, pericholecystic fluid, and sonographic Murphy sign.

▶ Differential Diagnosis

The disorders most likely to be confused with acute cholecystitis are perforated peptic ulcer, acute pancreatitis, appendicitis in a high-lying appendix, perforated colonic carci-

noma or diverticulum of the hepatic flexure, liver abscess, hepatitis, pneumonia with pleurisy on the right side, and even myocardial ischemia. Definite localization of pain and tenderness in the right hypochondrium, with radiation around to the infrascapular area, strongly favors the diagnosis of acute cholecystitis. True cholecystitis without stones suggests the rare possibility of polyarteritis nodosa affecting the cystic artery.

▶ Complications

A. Gangrene of the Gallbladder

Continuation or progression of right upper quadrant abdominal pain, tenderness, muscle guarding, fever, and leukocytosis after 24–48 hours suggests severe inflammation and possible gangrene of the gallbladder, resulting from ischemia due to splanchnic vasoconstriction and intravascular coagulation. Necrosis may occasionally develop without definite signs in the obese, diabetic, elderly, or immunosuppressed patient. Gangrene may lead to gallbladder perforation, usually with formation of a pericholecystic abscess and rarely to generalized peritonitis. Other serious acute complications include emphysematous cholecystitis (secondary infection with a gas-forming organism) and empyema.

B. Chronic Cholecystitis and Other Complications

Chronic cholecystitis results from repeated episodes of acute cholecystitis or chronic irritation of the gallbladder wall by stones and is characterized pathologically by varying degrees of chronic inflammation of the gallbladder. Calculi are usually present. In about 4–5% of cases, the villi of the gallbladder undergo polypoid enlargement due to deposition of cholesterol that may be visible to the naked eye (“strawberry gallbladder,” cholesterolosis). In other instances, hyperplasia of all or part of the gallbladder wall may be so marked as to give the appearance of a myoma (adenomyomatosis). Hydrops of the gallbladder results when acute cholecystitis subsides but cystic duct obstruction persists, producing distention of the gallbladder with a clear mucoïd fluid. Occasionally, a stone in the neck of the gallbladder may compress the bile duct and cause jaundice (Mirizzi syndrome). Xanthogranulomatous cholecystitis is a rare variant of chronic cholecystitis characterized by grayish-yellow nodules or streaks, representing lipid-laden macrophages, in the wall of the gallbladder.

Cholelithiasis with chronic cholecystitis may be associated with acute exacerbations of gallbladder inflammation, bile duct stone, fistulization to the bowel, pancreatitis and, rarely, carcinoma of the gallbladder. Calcified (porcelain) gallbladder has generally been thought to have a high association with gallbladder carcinoma and to be an indication for cholecystectomy, although the risk of gallbladder cancer may be higher when calcification is mucosal rather than intramural.

▶ Treatment

Acute cholecystitis will usually subside on a conservative regimen (withholding of oral feedings, intravenous ali-

mentation, analgesics, and intravenous antibiotics—generally a second- or third-generation cephalosporin such as cefoperazone, 1-2 g intravenously every 12 hours, with the addition of metronidazole, 500 mg intravenously every 6 hours); in severe cases, a fluoroquinolone such as ciprofloxacin, 250 mg intravenously every 12 hours, plus metronidazole may be given) Morphine or meperidine may be administered for pain. Because of the high risk of recurrent attacks (up to 10% by 1 month and over 30% by 1 year), cholecystectomy—generally laparoscopically—should generally be performed within 2–4 days after hospitalization. If nonsurgical treatment has been elected, the patient (especially if diabetic or elderly) should be watched carefully for recurrent symptoms, evidence of gangrene of the gallbladder, or cholangitis. In high-risk patients, ultrasound-guided aspiration of the gallbladder, if feasible, percutaneous cholecystostomy, or endoscopic insertion of a stent into the gallbladder may postpone or even avoid the need for surgery. Immediate cholecystectomy is mandatory when there is evidence of gangrene or perforation.

Surgical treatment of chronic cholecystitis is the same as for acute cholecystitis. If indicated, cholangiography can be performed during laparoscopic cholecystectomy. Cholelithiasis can also be excluded by either preoperative or postoperative ERCP or MRCP.

► Prognosis

The overall mortality rate of cholecystectomy is less than 0.2%, but hepatobiliary tract surgery is a more formidable procedure in the elderly, in whom mortality rates are higher. A technically successful surgical procedure in an appropriately selected patient is generally followed by complete resolution of symptoms.

► When to Admit

All patients with acute cholecystitis should be hospitalized.

PRE- & POSTCHOLECYSTECTOMY SYNDROMES

1. Precholecystectomy

In a small group of patients (mostly women) with biliary pain, conventional radiographic studies of the upper gastrointestinal tract and gallbladder—including cholangiography—are unremarkable. In some such cases, emptying of the gallbladder may be markedly reduced on gallbladder

scintigraphy following injection of cholecystokinin; cholecystectomy may be curative. Histologic examination of the resected gallbladder may show chronic cholecystitis or microlithiasis. An additional diagnostic consideration is sphincter of Oddi dysfunction (see below).

2. Postcholecystectomy

Following cholecystectomy, some patients complain of continuing symptoms, ie, right upper quadrant pain, flatulence, and fatty food intolerance. The persistence of symptoms in this group of patients suggests the possibility of an incorrect diagnosis prior to cholecystectomy, eg, esophagitis, pancreatitis, radiculopathy, or functional bowel disease. Cholelithiasis or bile duct stricture should be ruled out. Pain may also be associated with dilation of the cystic duct remnant, neuroma formation in the ductal wall, foreign body granuloma, or traction on the bile duct by a long cystic duct.

The clinical presentation of right upper quadrant pain, chills, fever, or jaundice suggests biliary tract disease. Endoscopic ultrasonography or retrograde cholangiography may be necessary to demonstrate a stone or stricture. Biliary pain associated with elevated liver tests or a dilated bile duct in the absence of an obstructing lesion suggests sphincter of Oddi dysfunction. Biliary manometry may be useful for documenting elevated baseline sphincter of Oddi pressures typical of sphincter dysfunction when biliary pain is associated with elevated liver tests (twofold) or a dilated bile duct (> 12 mm) (type II sphincter of Oddi dysfunction) but is not necessary when both are present (type I sphincter of Oddi dysfunction) and is associated with a high risk of pancreatitis. In the absence of either elevated liver tests or a dilated bile duct (type III sphincter of Oddi dysfunction), a nonbiliary source of symptoms should be suspected. (Analogous criteria have been developed for pancreatic sphincter dysfunction.) Biliary scintigraphy after intravenous administration of morphine and MRCP following intravenous administration of secretin are under study as screening tests for sphincter dysfunction. Endoscopic sphincterotomy is most likely to relieve symptoms in patients with types I or II sphincter of Oddi dysfunction or an elevated sphincter of Oddi pressure, although many patients continue to have some pain. In some cases, treatment with calcium channel blockers, long-acting nitrates, or possibly injection of the sphincter with botulinum toxin may be beneficial. In refractory cases, surgical sphincteroplasty or removal of the cystic duct remnant may be considered.

► When to Refer

Patients with sphincter of Oddi dysfunction should be referred for diagnostic procedures.

CHOLEDOCHOLITHIASIS & CHOLANGITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Often a history of biliary pain or jaundice.
- ▶ Sudden onset of severe right upper quadrant or epigastric pain, which may radiate to the right scapula or shoulder.
- ▶ Occasional patients present with painless jaundice.
- ▶ Nausea and vomiting.
- ▶ Fever, which may be followed by hypothermia and gram-negative shock, jaundice, and leukocytosis.
- ▶ Stones in bile duct most reliably detected by ERCP or endoscopic ultrasound.

▶ General Considerations

About 15% of patients with gallstones have choledocholithiasis (bile duct stones). The percentage rises with age, and the frequency in elderly people with gallstones may be as high as 50%. Bile duct stones usually originate in the gallbladder but may also form spontaneously in the bile duct after cholecystectomy. The risk is increased twofold in persons with a juxtapapillary duodenal diverticulum. Symptoms result if there is obstruction.

▶ Clinical Findings

A. Symptoms and Signs

A history of biliary pain or prior jaundice may be obtained. Biliary pain results from rapid increases in bile duct pressure due to obstructed bile flow. The features that suggest the presence of a bile duct stone are: (1) frequently recurring attacks of right upper abdominal pain that is severe and persists for hours; (2) chills and fever associated with severe pain; and (3) a history of jaundice associated with episodes of abdominal pain. The combination of pain, fever (and chills), and jaundice represents **Charcot triad** and denotes the classic picture of cholangitis. The addition of altered mental status and hypotension (Reynold pentad) signifies acute suppurative cholangitis and is an endoscopic emergency.

Hepatomegaly may be present in calculous biliary obstruction, and tenderness is usually present in the right upper quadrant and epigastrium. Bile duct obstruction lasting longer than 30 days results in liver damage leading to cirrhosis. Hepatic failure with portal hypertension occurs in untreated cases.

B. Laboratory Findings

Acute obstruction of the bile duct typically produces a transient albeit striking increase in serum aminotransferase levels (often > 1000 units/L). Bilirubinuria and elevation of serum bilirubin are present if the bile duct remains obstructed; levels commonly fluctuate. Serum alkaline phosphatase levels rise more slowly. Not uncommonly,

serum amylase elevations are present because of secondary pancreatitis. When extrahepatic obstruction persists for more than a few weeks, differentiation of obstruction from chronic cholestatic liver disease becomes more difficult. Leukocytosis is present in patients with cholangitis. Prolongation of the prothrombin time can result from the obstructed flow of bile to the intestine. In contrast to hepatocellular dysfunction, hypoprothrombinemia due to obstructive jaundice will respond to 10 mg of parenteral vitamin K or water-soluble oral vitamin K (phytonadione, 5 mg) within 24–36 hours.

C. Imaging

Ultrasonography and CT scan may demonstrate dilated bile ducts, and radionuclide imaging may show impaired bile flow. Endoscopic ultrasonography, helical CT, and magnetic resonance cholangiography are accurate in demonstrating bile duct stones and may be used in patients thought to be at low or intermediate risk for choledocholithiasis. ERCP (occasionally with intraductal ultrasound) or percutaneous transhepatic cholangiography provides the most direct and accurate means of determining the cause, location, and extent of obstruction. If the likelihood that obstruction is caused by a stone or that cholangitis is present is high, ERCP is the procedure of choice because it permits sphincterotomy with stone extraction or stent placement.

▶ Differential Diagnosis

The most common cause of obstructive jaundice is a bile duct stone. Next in frequency are neoplasms of the pancreas, ampulla of Vater, or bile duct. Extrinsic compression of the bile duct may result from metastatic carcinoma (usually from the gastrointestinal tract or breast) involving porta hepatis lymph nodes or, rarely, from a large duodenal diverticulum. Gallbladder cancer extending into the bile duct often presents as obstructive jaundice. Chronic cholestatic liver diseases (primarily biliary cirrhosis, sclerosing cholangitis, drug-induced) must be considered. Hepatocellular jaundice can usually be differentiated by the history, clinical findings, and liver tests, but liver biopsy is necessary on occasion. Recurrent pyogenic cholangitis should be considered in persons from Asia (and occasionally elsewhere) with intrahepatic biliary stones (particularly in the left ductal system) and with recurrent cholangitis.

▶ Treatment

Bile duct stone in a patient with cholelithiasis or cholecystitis is usually treated by endoscopic sphincterotomy and stone extraction followed by laparoscopic cholecystectomy. For the elderly (> 70 years) or poor-risk patient with cholelithiasis and choledocholithiasis, however, cholecystectomy may be deferred after endoscopic sphincterotomy because the risk of subsequent cholecystitis is low. ERCP with sphincterotomy should be performed before cholecystectomy in patients with gallstones and jaundice (serum total bilirubin > 5 mg/dL), a dilated bile duct (> 7 mm), or stones in the bile duct seen on ultrasound or CT scan. (Stones may ultimately recur in up to 12% of patients,

particularly in the elderly, when the bile duct diameter is ≥ 15 mm, or when brown pigment stones are found at time of the initial sphincterotomy.) Endoscopic balloon dilation of the sphincter of Oddi may be associated with a higher rate of pancreatitis than endoscopic sphincterotomy and is generally reserved for patients with coagulopathy, in whom the risk of bleeding is lower with balloon dilation than with sphincterotomy. In patients with biliary pancreatitis that resolves rapidly, the stone usually passes into the intestine, and ERCP prior to cholecystectomy is not necessary if an intraoperative cholangiogram is done.

Cholelithiasis discovered at laparoscopic cholecystectomy may be managed via laparoscopic or, if necessary, open bile duct exploration or by postoperative endoscopic sphincterotomy. Operative findings of cholelithiasis are palpable stones in the bile duct, dilation or thickening of the wall of the bile duct, or stones in the gallbladder small enough to pass through the cystic duct. Laparoscopic intraoperative cholangiography (or intraoperative ultrasonography) should be done at the time of cholecystectomy in patients with liver enzyme elevations but a bile duct diameter of less than 5 mm; if a ductal stone is found, the duct is explored. In the postcholecystectomy patient with cholelithiasis, endoscopic sphincterotomy with stone extraction is preferable to transabdominal surgery. Lithotripsy (endoscopic or external), direct choledoscopy (cholangioscopy), or biliary stenting may be a therapeutic consideration for large stones. For the patient with a T tube and bile duct stone, the stone may be extracted via the T tube.

Postoperative antibiotics are not administered routinely after biliary tract surgery. Cultures of the bile are always taken at operation. If biliary tract infection was present preoperatively or is apparent at operation, ampicillin (500 mg every 6 hours intravenously) with gentamicin (1.5 mg/kg intravenously every 8 hours) and metronidazole (500 mg intravenously every 6 hours) or ciprofloxacin (250 mg intravenously every 12 hours) or a third-generation cephalosporin (eg, cefoperazone, 1–2 g intravenous every 12 hours) is administered postoperatively until the results of sensitivity tests on culture specimens are available. A T-tube cholangiogram should be done before the tube is removed, usually about 3 weeks after surgery. A small amount of bile frequently leaks from the tube site for a few days.

Urgent ERCP with sphincterotomy and stone extraction is generally indicated for cholelithiasis complicated by ascending cholangitis and is preferred to surgery. Before ERCP, liver function should be evaluated thoroughly. Prothrombin time should be restored to normal by parenteral administration of vitamin K (see above). Ciprofloxacin, 250 mg intravenously every 12 hours, penetrates well into bile and is effective treatment for cholangitis. Alternative regimens in severely ill patients include mezlocillin, 3 g intravenously every 4 hours, plus either metronidazole or gentamicin (or both). The dose of metronidazole is 500 mg intravenously every 6 hours (if there has been no prior manipulation of the duct); the dose of gentamicin is 2 mg/kg intravenously as loading dose, plus 1.5 mg/kg every 8 hours adjusted for kidney function. Aminoglycosides should not be given for more than a few days because the risk of aminoglycoside nephrotoxicity is increased in

patients with cholestasis. Emergent decompression of the bile duct, generally by ERCP, is required for patients who are septic or fail to improve on antibiotics within 12–24 hours. Medical therapy alone is most likely to fail in patients with tachycardia, serum albumin < 3 g/dL, marked hyperbilirubinemia, and prothrombin time > 14 seconds on admission. If sphincterotomy cannot be performed, decompression by a biliary stent or nasobiliary catheter can be done. Once decompression is achieved, antibiotics are generally continued for at least another three days. Elective cholecystectomy can be undertaken after resolution of cholangitis, unless the patient remains unfit for surgery.

► When to Refer

All symptomatic patients with cholelithiasis should be referred.

► When to Admit

Patients with sepsis due to cholangitis should be hospitalized.

BILIARY STRICTURE

Benign biliary strictures are the result of surgical (including liver transplantation) anastomosis or injury in about 95% of cases. The remainder of cases are caused by blunt external injury to the abdomen, pancreatitis, erosion of the duct by a gallstone, or prior endoscopic sphincterotomy.

Signs of injury to the duct may or may not be recognized in the immediate postoperative period. If complete occlusion has occurred, jaundice will develop rapidly; more often, however, a tear has been accidentally made in the duct, and the earliest manifestation of injury may be excessive or prolonged loss of bile from the surgical drains. Bile leakage resulting in a bile collection (biloma) may predispose to localized infection, which in turn accentuates scar formation and the ultimate development of a fibrous stricture.

Cholangitis is the most common complication of stricture. Typically, the patient experiences episodes of pain, fever, chills, and jaundice within a few weeks to months after cholecystectomy. Physical findings may include jaundice during an attack of cholangitis and right upper quadrant abdominal tenderness. Serum alkaline phosphatase is

usually elevated. Hyperbilirubinemia is variable, fluctuating during exacerbations and usually remaining in the range of 5–10 mg/dL. Blood cultures may be positive during an episode of cholangitis. Secondary biliary cirrhosis will inevitably develop if a stricture is not treated.

MRCP can be valuable in demonstrating the stricture, whereas ERCP permits biopsy and cytologic specimens to exclude malignancy and allows sphincterotomy to allow closure of a bile leak and dilation and stent placement for a stricture, thereby avoiding surgical repair in some cases. When ERCP is unsuccessful, dilation of a stricture may be accomplished by PTC. Placement of multiple plastic stents appears to be more effective than placement of a single stent. Metal stents, which often cannot be removed endoscopically, are generally avoided in benign strictures unless life expectancy is less than 2 years. The use of covered metal stents, which are more easily removed endoscopically than uncovered metal stents, as well as bioabsorbable stents, is under study. Strictures related to chronic pancreatitis are more difficult to treat endoscopically than postsurgical strictures, and preliminary reports suggest that they may be best managed with a temporary covered metal stent. Following liver transplantation, endoscopic management is more successful for anastomotic than for nonanastomotic strictures, and results are disappointing for biliary strictures after live liver donor liver transplantation. When malignancy cannot be excluded with certainty, additional endoscopic diagnostic approaches may be considered—if available—including endoscopic ultrasonography, intraductal ultrasound, and direct cholangioscopy (cholangioscopy). Differentiation from cholangiocarcinoma may ultimately require surgical exploration. Operative treatment of a stricture frequently necessitates performance of an end-to-end ductal repair, choledochojejunostomy, or hepaticojejunostomy to reestablish bile flow into the intestine.

▶ When to Refer

All patients with biliary stricture should be referred.

▶ When to Admit

Patients with cholangitis should be hospitalized.

PRIMARY SCLEROSING CHOLANGITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Most common in men aged 20–50 years.

- ▶ Often associated with ulcerative colitis.
- ▶ Progressive jaundice, itching, and other features of cholestasis.
- ▶ Diagnosis based on characteristic cholangiographic findings.
- ▶ 10% risk of cholangiocarcinoma.

▶ General Considerations

Primary sclerosing cholangitis is an uncommon disease characterized by a diffuse inflammation of the biliary tract leading to fibrosis and strictures of the biliary system. The disease is most common in men aged 20–50 years, with an incidence rate of 1 per 100,000 and a prevalence rate of 21 per 100,000 men and 6 per 100,000 women in the United States. The disease is closely associated with ulcerative colitis (and in some cases with Crohn colitis), which is present in approximately two-thirds of patients with primary sclerosing cholangitis; however, clinically significant sclerosing cholangitis develops in only 1–4% of patients with ulcerative colitis. As in ulcerative colitis, smoking is associated with a decreased risk of primary sclerosing cholangitis. Primary sclerosing cholangitis is associated with the histocompatible antigens HLA-B8 and -DR3 or -DR4, and first-degree relatives of patients with primary sclerosing cholangitis have a fourfold increased risk of primary sclerosing cholangitis and a threefold increased risk of ulcerative colitis. The diagnosis of primary sclerosing cholangitis may be difficult to make after biliary surgery.

▶ Clinical Findings

A. Symptoms and Signs

Primary sclerosing cholangitis presents as progressive obstructive jaundice, frequently associated with fatigue, pruritus, anorexia, and indigestion. Patients may be diagnosed in the presymptomatic phase because of an elevated alkaline phosphatase level. Complications of chronic cholestasis, such as osteoporosis and malabsorption of fat-soluble vitamins, may occur late in the course. Esophageal varices are most likely in patients with a platelet count below 150,000/mcL, low serum albumin, and advanced histologic stage. In patients with primary sclerosing cholangitis, ulcerative colitis is frequently characterized by rectal sparing and backwash ileitis.

B. Diagnostic Findings

The diagnosis of primary sclerosing cholangitis is increasingly made by magnetic resonance cholangiography, the sensitivity of which approaches that of ERCP. Characteristic cholangiographic findings are segmental fibrosis of bile ducts with saccular dilatations between strictures. Biliary obstruction by a stone or tumor should be excluded. The disease may be confined to small intrahepatic bile ducts, in which case MRCP and ERCP are normal and the diagnosis is suggested by liver biopsy. These patients have a longer survival than patients with involvement of the large ducts and do not appear to be at increased risk for cholangiocar-

cinoma unless large-duct sclerosing cholangitis develops. Liver biopsy may show characteristic periductal fibrosis (“onion-skinning”) and allows staging, which is based on the degree of fibrosis. Perinuclear ANCA (directed against myeloid-specific tubulin-beta isotype 5) as well as antinuclear, anticardiolipin, antityroperoxidase, and anti-*Saccharomyces cerevisiae* antibodies, and rheumatoid factor are frequently detected in serum. Occasional patients have clinical and histologic features of both sclerosing cholangitis and autoimmune hepatitis. An association with autoimmune pancreatitis (IgG₄-associated cholangitis or sclerosing pancreaticocholangitis) is also seen, and this entity is often responsive to corticosteroids. Primary sclerosing cholangitis must be distinguished from idiopathic adulthood ductopenia (a rare disorder affecting young to middle-aged adults who manifest cholestasis resulting from loss of interlobular and septal bile ducts yet who have a normal cholangiogram and caused in some cases by a mutation in the canalicular phospholipid transporter gene *ABCB4*) and from other cholangiopathies (including primary biliary cirrhosis, cystic fibrosis, eosinophilic cholangitis, AIDS cholangiopathy, allograft rejection, graft-versus-host disease, ischemic damage (often with biliary “casts”) caused by hepatic artery thrombosis, shock, respiratory failure, or drugs, intra-arterial chemotherapy, and sarcoidosis).

► Complications

Cholangiocarcinoma may complicate the course of primary sclerosing cholangitis in up to 20% of cases (1.2% per year) and may be difficult to diagnose by cytologic examination or biopsy because of false-negative results. A serum CA 19-9 level > 100 units/mL is suggestive but not diagnostic of cholangiocarcinoma. Annual ultrasound and serum CA 19-9 testing are recommended for surveillance, with CT or MRI with MRCP and biliary cytology if the results are abnormal. Positron emission tomography and cholecystoscopy may play roles in the early detection of cholangiocarcinoma. Extensive surgical resection may result in 5-year survival rates of > 50%. Patients with ulcerative colitis and primary sclerosing cholangitis are at high risk for colorectal neoplasia. The risk of gallstones, cholecystitis, gallbladder polyps, and gallbladder carcinoma appears to be increased in patients with primary sclerosing cholangitis.

► Treatment

Episodes of acute bacterial cholangitis may be treated with ciprofloxacin (750 mg twice daily orally or intravenously). Ursodeoxycholic acid in standard doses (10–15 mg/kg/d orally) may improve liver biochemical test results but does not appear to alter the natural history. High-dose ursodeoxycholic acid (25–30 mg/kg/d) also has been shown not to reduce cholangiographic progression and liver fibrosis, nor to improve survival or prevent cholangiocarcinoma. Other drugs such as cyclosporine, tacrolimus, and minocycline are under study. Careful endoscopic evaluation of the biliary tree may permit balloon dilation of localized strictures, and repeated dilation of a dominant stricture may improve survival. Short-term placement of a stent in a major stricture also may relieve symptoms and improve biochemical abnor-

malities, with sustained improvement after the stent is removed. However, long-term stenting may increase the rate of complications such as cholangitis. In patients without cirrhosis, surgical resection of a dominant bile duct stricture may lead to longer survival than endoscopic therapy by decreasing the subsequent risk of cholangiocarcinoma. In patients with ulcerative colitis, primary sclerosing cholangitis is an independent risk factor for the development of colorectal dysplasia and cancer, and strict adherence to a colonoscopic surveillance program is recommended. Treatment with ursodeoxycholic acid has been reported to reduce the risk of colorectal dysplasia and carcinoma in patients with ulcerative colitis and primary sclerosing cholangitis. For patients with cirrhosis and clinical decompensation, liver transplantation is the procedure of choice.

► Prognosis

Survival of patients with primary sclerosing cholangitis averages 12–17 years. Adverse prognostic markers are older age, hepatosplenomegaly, higher serum bilirubin and AST levels, lower albumin levels, a history of variceal bleeding, a dominant bile duct stricture, and extrahepatic duct changes. Variceal bleeding is also a risk factor for cholangiocarcinoma. Actuarial survival rates with liver transplantation are as high as 85% at 3 years, but rates are much lower once cholangiocarcinoma has developed. Following transplantation, patients have an increased risk of nonanastomotic biliary strictures and—in those with ulcerative colitis—colon cancer. The retransplantation rate is higher than that for primary biliary cirrhosis. Those patients who are unable to undergo liver transplantation will ultimately require high-quality palliative care (see Chapter 5).

DISEASES OF THE PANCREAS

See Chapter 39 for Carcinoma of the Pancreas and Periapillary Area.

ACUTE PANCREATITIS

ESSENTIALS OF DIAGNOSIS

- Abrupt onset of deep epigastric pain, often with radiation to the back.

- ▶ History of previous episodes, often related to alcohol intake.
- ▶ Nausea, vomiting, sweating, weakness.
- ▶ Abdominal tenderness and distention and fever.
- ▶ Leukocytosis, elevated serum amylase, elevated serum lipase.

▶ General Considerations

Most cases of acute pancreatitis are related to biliary tract disease (a passed gallstone, usually < 5 mm in diameter) or heavy alcohol intake. The exact pathogenesis is not known but may include edema or obstruction of the ampulla of Vater, reflux of bile into pancreatic ducts, and direct injury of pancreatic acinar cells by prematurely activated pancreatic enzymes. Among the numerous other causes or associations are hypercalcemia, hyperlipidemias (chylomicronemia, hypertriglyceridemia, or both), abdominal trauma (including surgery), drugs (including azathioprine, mercaptopurine, asparaginase, pentamidine, didanosine, valproic acid, tetracyclines, dapsone, isoniazid, metronidazole, estrogen and tamoxifen [by raising serum triglycerides], sulfonamides, mesalamine, sulindac, thiazides, enalapril, methyl-dopa, procainamide, and possibly glucocorticoids and others), vasculitis, infections (eg, mumps, cytomegalovirus, *Mycobacterium avium* complex), peritoneal dialysis, cardiopulmonary bypass, ERCP, and genetic mutations that also predispose to chronic pancreatitis (see below). In patients with pancreas divisum, a congenital anomaly in which the dorsal and ventral pancreatic ducts fail to fuse, acute pancreatitis may result from stenosis of the minor papilla with obstruction to flow from the accessory pancreatic duct, although concomitant mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene have also been reported to account for acute pancreatitis in some patients with pancreas divisum. Acute pancreatitis may also result from anomalous union of the pancreaticobiliary duct. Rarely, acute pancreatitis may be the presenting manifestation of a pancreatic or ampullary neoplasm. Celiac disease appears to be associated with an increased risk of acute and chronic pancreatitis. Apparently “idiopathic” acute pancreatitis is often caused by occult biliary microlithiasis and may be caused by sphincter of Oddi dysfunction involving the pancreatic duct. Between 15% and 25% of cases are truly idiopathic. Smoking may increase the risk of alcoholic and idiopathic pancreatitis, and older age and obesity increase the risk of a severe course. The incidence of pancreatitis has increased since 1990.

▶ Clinical Findings

A. Symptoms and Signs

Epigastric abdominal pain, generally abrupt in onset, is steady, boring, and severe and often made worse by walking and lying supine and better by sitting and leaning forward. The pain usually radiates into the back but may radiate to the right or left. Nausea and vomiting are usually present. Weakness, sweating, and anxiety are noted in

severe attacks. There may be a history of alcohol intake or a heavy meal immediately preceding the attack, or a history of milder similar episodes or biliary pain in the past.

The abdomen is tender mainly in the upper part, most often without guarding, rigidity, or rebound. The abdomen may be distended, and bowel sounds may be absent with associated ileus. Fever of 38.4–39 °C, tachycardia, hypotension (even true shock), pallor, and cool clammy skin are often present. Mild jaundice is common. Occasionally, an upper abdominal mass due to the inflamed pancreas or a pseudocyst may be palpated. Acute kidney injury (usually due to prerenal cause) may occur early in the course of acute pancreatitis.

B. Assessment of Severity

The severity of acute alcoholic pancreatitis can be assessed using **Ranson criteria** (Table 16–8). The Sequential Organ Failure Assessment (SOFA) score can be used to assess injury to other organs, and the Acute Physiology and Chronic Health Evaluation (APACHE II) score is another tool for assessing severity. A simple 5-point clinical scoring system based on blood urea nitrogen > 25 mg/dL, impaired mental status, systemic inflammatory response syndrome, age > 60 years, and pleural effusion (BISAP) during the first 24 hours (before the onset of organ failure) has been proposed.

C. Laboratory Findings

Serum amylase and lipase are elevated—usually more than three times the upper limit of normal—within 24 hours in

Table 16–8. Ranson criteria for assessing the severity of acute pancreatitis.

| Three or more of the following predicts a severe course complicated by pancreatic necrosis with a sensitivity of 60–80% | |
|--|----------------|
| Age over 55 years | |
| White blood cell count > 16,000/mcl | |
| Blood glucose > 200 mg/dL | |
| Serum lactic dehydrogenase > 350 units/L | |
| Aspartate aminotransferase > 250 units/L | |
| Development of the following in the first 48 hours indicates a worsening prognosis | |
| Hematocrit drop of more than 10 percentage points | |
| Blood urea nitrogen rise > 5 mg/dL | |
| Arterial PO ₂ of < 60 mm Hg | |
| Serum calcium of < 8 mg/dL | |
| Base deficit over 4 mEq/L | |
| Estimated fluid sequestration of > 6 L | |
| Mortality rates correlate with the number of criteria present¹ | |
| Number of Criteria | Mortality Rate |
| 0–2 | 1% |
| 3–4 | 16% |
| 5–6 | 40% |
| 7–8 | 100% |

¹An APACHE II score ≥ 8 also correlates with mortality.

90% of cases; their return to normal is variable depending on the severity of disease. Lipase remains elevated longer than amylase and is slightly more accurate for the diagnosis of acute pancreatitis. Leukocytosis (10,000–30,000/mcL), proteinuria, granular casts, glycosuria (10–20% of cases), hyperglycemia, and elevated serum bilirubin may be present. Blood urea nitrogen and serum alkaline phosphatase may be elevated and coagulation tests abnormal. An elevated serum creatinine level (> 1.8 mg/dL) at 48 hours is associated with the development of pancreatic necrosis. In patients with clear evidence of acute pancreatitis, a serum ALT level of more than 150 units/L suggests biliary pancreatitis. Decrease in serum calcium may reflect saponification and correlates with severity of disease. Levels lower than 7 mg/dL (when serum albumin is normal) are associated with tetany and an unfavorable prognosis. Patients with acute pancreatitis caused by hypertriglyceridemia generally have fasting triglyceride levels above 1000 mg/dL. An early rise in the hematocrit value above 44% suggests hemoconcentration and predicts pancreatic necrosis. An elevated C-reactive protein (> 150 mg/L) concentration at 48 hours suggests severe disease.

Other tests that offer the possibility of simplicity, rapidity, ease of use, and low cost—including urinary trypsinogen-2, trypsinogen activation peptide, and carboxypeptidase B—are not widely available. In patients in whom ascites or left pleural effusions develop, fluid amylase content is high. Electrocardiography may show ST–T wave changes.

D. Imaging

Plain radiographs of the abdomen may show gallstones, a “sentinel loop” (a segment of air-filled small intestine most commonly in the left upper quadrant), the “colon cutoff sign”—a gas-filled segment of transverse colon abruptly ending at the area of pancreatic inflammation—or linear focal atelectasis of the lower lobe of the lungs with or without pleural effusion. Ultrasound is often not helpful in diagnosing acute pancreatitis because of intervening bowel gas but may identify gallstones in the gallbladder. Unenhanced CT scan is useful in demonstrating an enlarged pancreas when the diagnosis of pancreatitis is uncertain, in detecting pseudocysts, in differentiating pancreatitis from

other possible intra-abdominal catastrophes, and in providing an initial assessment of prognosis (Table 16-9). Rapid-bolus intravenous contrast-enhanced CT following aggressive volume resuscitation is of particular value after the first 3 days of severe acute pancreatitis to identify areas of necrotizing pancreatitis and to assess the degree of necrosis, although the use of intravenous contrast may increase the risk of complications of pancreatitis and of acute kidney injury and should be avoided when the serum creatinine level is greater than 1.5 mg/dL. MRI appears to be a suitable alternative to CT. Perfusion CT on day 3 demonstrating areas of ischemia in the pancreas has been reported to predict the development of pancreatic necrosis. The presence of a fluid collection in the pancreas correlates with an increased mortality rate. CT-guided needle aspiration of areas of necrotizing pancreatitis after the third day may disclose infection, usually by enteric organisms, which invariably leads to death unless surgical debridement is ultimately performed. The presence of gas bubbles on CT scan implies that infection by gas-forming organisms is present. Endoscopic ultrasonography is useful in identifying occult biliary disease (eg, small stones, sludge), which, including microlithiasis, is present in a majority of patients with apparently idiopathic acute pancreatitis, and is indicated in persons over age 40 to exclude malignancy. ERCP is generally not indicated after a first attack of acute pancreatitis unless there is associated cholangitis or jaundice or a bile duct stone is known to be present, but endoscopic ultrasonography or MRCP should be considered, especially after repeated attacks of idiopathic acute pancreatitis. In selected cases, aspiration of bile for crystal analysis may confirm the suspicion of microlithiasis, and manometry of the pancreatic duct sphincter may detect sphincter of Oddi dysfunction as a cause of recurrent pancreatitis.

► Differential Diagnosis

Acute pancreatitis must be differentiated from an acutely perforated duodenal ulcer, acute cholecystitis, acute intestinal obstruction, leaking aortic aneurysm, renal colic, and acute mesenteric ischemia. Serum amylase may also be elevated in high intestinal obstruction, in gastroenteritis, in

Table 16-9. Severity index for acute pancreatitis.

| CT Grade | Points | Pancreatic Necrosis | Additional Points | Severity Index ¹ | Mortality Rate ² |
|---|--------|---------------------|-------------------|-----------------------------|-----------------------------|
| A Normal pancreas | 0 | 0% | 0 | 0 | 0% |
| B Pancreatic enlargement | 1 | 0% | 0 | 1 | 0% |
| C Pancreatic inflammation and/or peripancreatic fat | 2 | < 30% | 2 | 4 | < 3% |
| D Single acute peripancreatic fluid collection | 3 | 30–50% | 4 | 7 | 6% |
| E Two or more acute peripancreatic fluid collections or retroperitoneal air | 4 | > 50% | 6 | 10 | > 17% |

¹Severity index = CT Grade Points + Additional Points.

²Based on the severity index.

Adapted with permission from Balthazar EJ. Acute pancreatitis: assessment of severity with clinical and CT evaluation. *Radiology*. 2002 Jun;223(3):603–13.

mumps not involving the pancreas (salivary amylase), in ectopic pregnancy, after administration of opioids, and after abdominal surgery. Serum lipase may also be elevated in many of these conditions.

► Complications

Intravascular volume depletion secondary to leakage of fluids in the pancreatic bed and ileus with fluid-filled loops of bowel may result in prerenal azotemia and even acute tubular necrosis without overt shock. This usually occurs within 24 hours of the onset of acute pancreatitis and lasts 8–9 days. Some patients require peritoneal dialysis or hemodialysis.

Sterile or infected necrotizing pancreatitis may complicate the course of 5–10% of cases and accounts for most of the deaths. The risk of infection does not correlate with the extent of necrosis. Pancreatic necrosis is often associated with fever, leukocytosis, and, in some cases, shock and is associated with organ failure (eg, pulmonary, renal, gastrointestinal bleeding) in 50% of cases. Because infected pancreatic necrosis is almost always an indication for operative treatment, fine-needle aspiration of necrotic tissue under CT guidance should be performed (if necessary, repeatedly) for Gram stain and culture.

A serious complication of acute pancreatitis is acute respiratory distress syndrome (ARDS); cardiac dysfunction may be superimposed. It usually occurs 3–7 days after the onset of pancreatitis in patients who have required large volumes of fluid and colloid to maintain blood pressure and urinary output. Most patients with ARDS require intubation and mechanical ventilation with positive end-expiratory pressure.

Pancreatic abscess (also referred to as infected or suppurative pseudocyst) is a suppurative process characterized by rising fever, leukocytosis, and localized tenderness and epigastric mass usually 6 or more weeks into the course of acute pancreatitis. This may be associated with a left-sided pleural effusion or an enlarging spleen secondary to splenic vein thrombosis. In contrast to infected necrosis, the mortality rate is low following drainage.

Pseudocysts, encapsulated fluid collections with high enzyme content, commonly appear in pancreatitis when CT scans are used to monitor the evolution of an acute attack. Pseudocysts that are smaller than 6 cm in diameter often resolve spontaneously. They most commonly are within or adjacent to the pancreas but can present anywhere (eg, mediastinal, retrorectal), by extension along anatomic planes. Multiple pseudocysts are seen in 14% of cases. Pseudocysts may become secondarily infected, necessitating drainage as for an abscess. Erosion of the inflammatory process into a blood vessel can result in a major hemorrhage into the cyst.

Pancreatic ascites may present after recovery from acute pancreatitis as a gradual increase in abdominal girth and persistent elevation of the serum amylase level in the absence of frank abdominal pain. Marked elevations in the ascitic protein (> 3 g/dL) and amylase (> 1000 units/L) concentrations are typical. The condition results from rupture of the pancreatic duct or drainage of a pseudocyst into the peritoneal cavity.

Rare complications of acute pancreatitis include hemorrhage caused by erosion of a blood vessel to form a

pseudoaneurysm and colonic necrosis. Chronic pancreatitis develops in about 10% of cases. Permanent diabetes mellitus and exocrine pancreatic insufficiency occur uncommonly after a single acute episode.

► Treatment

A. Management of Acute Disease

In most patients, acute pancreatitis is a mild disease (“non-severe acute pancreatitis”) that subsides spontaneously within several days. The pancreas is “rested” by a regimen of withholding food and liquids by mouth, bed rest, and, in patients with moderately severe pain or ileus and abdominal distention or vomiting, nasogastric suction. Pain is controlled with meperidine, up to 100–150 mg intramuscularly every 3–4 hours as necessary. In those with severe liver or kidney dysfunction, the dose may need to be reduced. Morphine has been thought to cause sphincter of Oddi spasm but is now considered an acceptable alternative, and given the potential side effects of meperidine, may even be preferable. Oral intake of fluid and foods can be resumed when the patient is largely free of pain and has bowel sounds (even if the serum amylase is still elevated). Clear liquids are given first (this step may be skipped in patients with mild acute pancreatitis), followed by gradual advancement to a low-fat diet, guided by the patient’s tolerance and by the absence of pain. Pain may recur on refeeding in 20% of patients. Following recovery from acute biliary pancreatitis, laparoscopic cholecystectomy is generally performed, although in selected cases endoscopic sphincterotomy alone may be done. In patients with recurrent pancreatitis associated with pancreas divisum, insertion of a stent in the minor papilla (or minor papilla sphincterotomy) may reduce the frequency of subsequent attacks, although complications of such therapy are frequent.

In more severe pancreatitis—particularly necrotizing pancreatitis—there may be considerable leakage of fluids, necessitating large amounts of intravenous fluids (eg, 500–1000 mL/h for several hours, then 250–300 mL/h) to maintain intravascular volume. Monitoring in an intensive care unit is required, and the importance of aggressive intravenous hydration cannot be overemphasized. Calcium gluconate must be given intravenously if there is evidence of hypocalcemia with tetany. Infusions of fresh frozen plasma or serum albumin may be necessary in patients with coagulopathy or hypoalbuminemia. With colloid solutions, there may be an increased risk of developing ARDS. If shock persists after adequate volume replacement (including packed red cells), pressors may be required. For the patient requiring a large volume of parenteral fluids, central venous pressure and blood gases should be monitored at regular intervals. Parenteral nutrition (including lipids) should be considered in patients who have severe pancreatitis and ileus and will be without oral nutrition for at least 7–10 days. Enteral nutrition via a nasojejunal or possibly nasogastric feeding tube is preferable but may not be tolerated in some patients with an ileus. The routine use of antibiotics to prevent conversion of sterile pancreatic necrosis to infected necrosis is still controversial and is not

indicated in those with < 30% pancreatic necrosis. Imipenem (500 mg every 8 hours intravenously) and possibly cefuroxime (1.5 g intravenously three times daily, then 250 mg orally twice daily) administered for no more than 14 days to patients with sterile pancreatic necrosis has been reported in some studies to reduce the risk of pancreatic infection and mortality; meropenem and the combination of ciprofloxacin and metronidazole do not appear to reduce the frequency of infected necrosis, multiorgan failure, or mortality. When infected necrosis is confirmed, imipenem or meropenem should be continued. The role of intravenous somatostatin in severe acute pancreatitis is uncertain, and octreotide is thought to have no benefit. To date, probiotic agents have not been shown to reduce infectious complications of severe pancreatitis and may increase mortality. There is conflicting evidence as to whether the risk of pancreatitis after ERCP can be reduced by the administration of somatostatin or gabexate mesilate, a protease inhibitor. Allopurinol, nonsteroidal anti-inflammatory drugs (administered rectally), and ulinastatin, another protease inhibitor, have been reported to reduce the frequency and severity of post-ERCP pancreatitis. Lexipafant, an antagonist of platelet-activating factor, appears to be of no benefit. Placement of a stent across the pancreatic duct or orifice has been shown to reduce the risk of post-ERCP pancreatitis and is an increasingly common practice.

B. Treatment of Complications and Follow-Up

A surgeon should be consulted in all cases of severe acute pancreatitis. If the diagnosis is in doubt and investigation indicates a strong possibility of a serious surgically correctable lesion (eg, perforated peptic ulcer), exploratory laparotomy is indicated. When acute pancreatitis is unexpectedly found, it is usually wise to close without intervention. If the pancreatitis appears mild and cholelithiasis or microlithiasis is present, cholecystectomy or cholecystostomy may be justified. When severe pancreatitis results from choledocholithiasis—particularly if jaundice (serum total bilirubin > 5 mg/dL) or cholangitis is present—ERCP with endoscopic sphincterotomy and stone extraction is indicated. MRCP may be useful in selecting patients for therapeutic ERCP. Endoscopic sphincterotomy does not appear to improve the outcome of severe pancreatitis in the absence of cholangitis or jaundice.

Operation may improve survival in patients with necrotizing pancreatitis and clinical deterioration with multiorgan failure or lack of resolution by 4 weeks. Surgery is nearly always indicated for infected necrosis. The goal of surgery is to debride necrotic pancreas and surrounding tissue and establish adequate drainage. Outcomes are best if surgery is delayed until the necrosis has organized, usually about 4 weeks after disease onset. In selected cases, nonsurgical drainage of walled-off pancreatic necrosis under radiologic, endoscopic (transgastric or transduodenal), or laparoscopic guidance may be feasible, at least as a temporizing measure, depending on local expertise. Peritoneal lavage has not been shown to improve survival in severe acute pancreatitis, in part because the risk of late septic complications is not reduced.

The development of a pancreatic abscess is an indication for prompt percutaneous or surgical drainage. Chronic pseudocysts require endoscopic, percutaneous catheter, or surgical drainage when infected or associated with persisting pain, pancreatitis, or common duct obstruction. For pancreatic infections, imipenem, 500 mg every 8 hours intravenously, is a good choice of antibiotic because it achieves bactericidal levels in pancreatic tissue for most causative organisms. Pancreatic duct leaks and fistulas may require endoscopic or surgical therapy.

► Prognosis

Mortality rates for acute pancreatitis have declined from at least 10% to around 5% since the 1980s, but the mortality rate for severe acute pancreatitis (more than three Ranson criteria; Table 16–8) remains at least 20%, with rates of 10% and 25% in those with sterile and infected necrosis, respectively. Half of the deaths occur within the first 2 weeks, usually from multiorgan failure. Multiorgan failure that persists beyond the first 48 hours is associated with a mortality rate of over 50%. Later deaths occur because of complications of infected necrosis. Hospital-acquired infections increase the mortality of acute pancreatitis, independent of severity. Recurrences are common in alcoholic pancreatitis.

► When to Admit

Nearly all patients with acute pancreatitis should be hospitalized.

CHRONIC PANCREATITIS

ESSENTIALS OF DIAGNOSIS

- Chronic or intermittent epigastric pain, steatorrhea, weight loss, abnormal pancreatic imaging.

- ▶ A mnemonic for the predisposing factors of chronic pancreatitis is TIGAR-O: toxic-metabolic, idiopathic, genetic, autoimmune, recurrent and severe acute pancreatitis, or obstructive.

▶ General Considerations

Chronic pancreatitis occurs most often in patients with alcoholism (70–80% of all cases). The risk of chronic pancreatitis increases with the duration and amount of alcohol consumed, but pancreatitis develops in only 5–10% of heavy drinkers. Tobacco smoking has been reported to accelerate progression of alcoholic chronic pancreatitis. About 2% of patients with hyperparathyroidism develop pancreatitis. In tropical Africa and Asia, tropical pancreatitis, related in part to malnutrition, is the most common cause of chronic pancreatitis. A stricture, stone, or tumor obstructing the pancreas can lead to obstructive chronic pancreatitis. Autoimmune pancreatitis is associated with hypergammaglobulinemia (IgG₄ in particular) and often with autoantibodies and other autoimmune diseases and is responsive to corticosteroids. About 10–20% of cases are idiopathic, with either early onset (median age 23) or late onset (median age 62). Genetic factors may predispose to chronic pancreatitis in some of these cases, including mutations of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene, the pancreatic secretory trypsin inhibitory gene (*PSTI*, serine protease inhibitor, *SPINK1*), and possibly the gene for uridine 5'-diphosphate glucuronosyltransferase. Mutation of the cationic trypsinogen gene on chromosome 7 (*serine protease 1*, *PRSS1*) is associated with hereditary pancreatitis, transmitted as an autosomal dominant trait with variable penetrance. A useful mnemonic for the predisposing factors to chronic pancreatitis is TIGAR-O: toxic-metabolic, idiopathic, genetic, autoimmune, recurrent and severe acute pancreatitis, or obstructive.

The pathogenesis of chronic pancreatitis may be explained by the SAPE (sentinel acute pancreatitis event) hypothesis by which the first (sentinel) acute pancreatitis event initiates an inflammatory process that results in injury and later fibrosis (“necrosis-fibrosis”). In many cases, chronic pancreatitis is a self-perpetuating disease characterized by chronic pain or recurrent episodes of acute pancreatitis and ultimately by pancreatic exocrine or endocrine insufficiency (sooner in alcoholic pancreatitis than in other types). After many years, chronic pain may resolve spontaneously or as a result of surgery tailored to the cause of pain. Over 80% of adults develop diabetes mellitus 25 years after the clinical onset of chronic pancreatitis.

▶ Clinical Findings

A. Symptoms and Signs

Persistent or recurrent episodes of epigastric and left upper quadrant pain with referral to the upper left lumbar region are typical. Anorexia, nausea, vomiting, constipation, flatulence, and weight loss are common. During attacks tenderness over the pancreas, mild muscle guarding, and ileus

may be noted. Attacks may last only a few hours or as long as 2 weeks; pain may eventually be almost continuous. Steatorrhea (as indicated by bulky, foul, fatty stools) may occur late in the course.

B. Laboratory Findings

Serum amylase and lipase may be elevated during acute attacks; however, a normal amylase does not exclude the diagnosis. Serum alkaline phosphatase and bilirubin may be elevated owing to compression of the common duct. Glycosuria may be present. Excess fecal fat may be demonstrated on chemical analysis of the stool. Pancreatic insufficiency generally is confirmed by response to therapy with pancreatic enzyme supplements; the secretin stimulation test can be used if available, as can detection of decreased fecal chymotrypsin or elastase levels, although the latter tests lack sensitivity and specificity. Vitamin B₁₂ malabsorption is detectable in about 40% of patients, but clinical deficiency of vitamin B₁₂ and fat-soluble vitamins is rare. Accurate diagnostic tests are available for the major trypsinogen gene mutations, but because of uncertainty about the mechanisms linking heterozygous *CFTR* and *PSTI* mutations with pancreatitis, genetic testing for mutations in these two genes is not currently recommended. Elevated IgG₄ levels, ANA, and antibodies to lactoferrin and carbonic anhydrase II are often found in patients with autoimmune pancreatitis; pancreatic biopsy shows a lymphoplasmacytic inflammatory infiltrate with characteristic IgG₄ immunostaining, which is also found in biopsy specimens of the major papilla, bile duct, and salivary glands.

C. Imaging

Plain films show calcifications due to pancreaticolithiasis in 30% of affected patients. CT may show calcifications not seen on plain films as well as ductal dilation and heterogeneity or atrophy of the gland. Occasionally, the findings raise suspicion of pancreatic cancer (“tumefactive chronic pancreatitis”). ERCP is the most sensitive imaging study for chronic pancreatitis and may show dilated ducts, intraductal stones, strictures, or pseudocyst, but the results may be normal in patients with so-called minimal change pancreatitis. MRCP and endoscopic ultrasonography (with pancreatic tissue sampling) are less invasive alternatives to ERCP. Characteristic imaging features of autoimmune pancreatitis include diffuse enlargement of the pancreas, a peripheral rim of hypoattenuation, and irregular narrowing of the main pancreatic duct.

▶ Complications

Opioid addiction is common. Other frequent complications include often brittle diabetes mellitus, pancreatic pseudocyst or abscess, cholestatic liver enzymes with or without jaundice, bile duct stricture, steatorrhea, malnutrition, and peptic ulcer. Pancreatic cancer develops in 4% of patients after 20 years; the risk may relate to tobacco and alcohol use. In patients with hereditary pancreatitis, the risk of pancreatic cancer rises after age 50 years and reaches 19% by age 70 years (see Chapter 39).

Table 16–10. Selected pancreatic enzyme preparations.

| Product | Enzyme Content in Units per Dose | | |
|--|----------------------------------|---------|----------|
| | Lipase | Amylase | Protease |
| Conventional preparations | | | |
| Viokase 8 | 8000 | 30,000 | 30,000 |
| Viokase 16 | 16,000 | 60,000 | 60,000 |
| Pancrelipase | 8000 | 30,000 | 30,000 |
| Enteric-coated microencapsulated preparations | | | |

► Treatment

Correctable coexistent biliary tract disease should be treated surgically.

A. Medical Measures

A low-fat diet should be prescribed. Alcohol is forbidden because it frequently precipitates attacks. Opioids should be avoided if possible. Preferred agents for pain are acetaminophen, nonsteroidal anti-inflammatory drugs, and tramadol, along with pain-modifying agents such as tricyclic antidepressants, selective serotonin uptake inhibitors, and gabapentin. Steatorrhea is treated with pancreatic supplements that are selected on the basis of their high lipase activity. A total dose of 30,000 units of lipase in capsules is given with meals (Table 16–10). Higher doses may be required in some cases. The tablets should be taken at the start of, during, and at the end of a meal. Concurrent administration of a H₂-receptor antagonist (eg, ranitidine, 150 mg orally twice daily), a proton pump inhibitor (eg, omeprazole, 20–60 mg orally daily), or sodium bicarbonate, 650 mg orally before and after meals, decreases the inactivation of lipase by acid and may thereby further decrease steatorrhea. In selected cases of alcoholic pancreatitis and in cystic fibrosis, enteric-coated microencapsu-

lated preparations may offer an advantage. However, in patients with cystic fibrosis, high-dose pancreatic enzyme therapy has been associated with strictures of the ascending colon. Pain secondary to idiopathic chronic pancreatitis may be alleviated in some cases by the use of pancreatic enzymes (not enteric-coated) or octreotide, 200 mcg subcutaneously three times daily. Associated diabetes mellitus should be treated (see Chapter 27). Autoimmune pancreatitis is treated with prednisone 40 mg/d orally for 1–2 months, followed by a taper of 5 mg every 2–4 weeks. Other immunosuppressive therapies are under study.

B. Surgical and Endoscopic Treatment

Endoscopic therapy or surgery may be indicated in chronic pancreatitis to treat underlying biliary tract disease, ensure free flow of bile into the duodenum, drain persistent pseudocysts, treat other complications, eliminate obstruction of the pancreatic duct, attempt to relieve pain, or exclude pancreatic cancer. Liver fibrosis may regress after biliary drainage. Distal bile duct obstruction may be relieved by endoscopic placement of multiple bile duct stents. When obstruction of the duodenal end of the pancreatic duct can be demonstrated by ERCP, dilation or placement of a stent in the duct or resection of the tail of the pancreas with implantation of the distal end of the duct

by pancreaticojejunostomy may be successful. When the pancreatic duct is diffusely dilated, anastomosis between the duct after it is split longitudinally and a defunctionalized limb of jejunum (modified Puestow procedure), in some cases combined with resection of the head of the pancreas, is associated with relief of pain in 80% of cases. In advanced cases, subtotal or total pancreatectomy may be considered as a last resort but has variable efficacy and causes pancreatic insufficiency and diabetes mellitus. Perioperative administration of somatostatin or octreotide may reduce the risk of postoperative pancreatic fistulas. Endoscopic or surgical drainage is indicated for symptomatic pseudocysts and, in many cases, those over 6 cm in diameter. Endoscopic ultrasonography may facilitate selection of an optimal site for endoscopic drainage. Pancreatic ascites or pancreaticopleural fistulas due to a disrupted pancreatic duct can be managed by endoscopic placement of a stent across the disrupted duct. Pancreatic sphincterotomy or fragmentation of stones in the pancreatic duct by lithotripsy and endoscopic removal of stones from the duct, may relieve pain in selected patients. For patients with chronic pain and nondilated ducts, a percutaneous celiac plexus nerve block may be considered under either CT or endoscopic ultrasound guidance, with pain relief (albeit often short-lived) in approximately 50% of patients.

▶ Prognosis

Chronic pancreatitis often leads to disability. The prognosis is best in patients with recurrent acute pancreatitis caused by a remediable condition such as cholelithiasis, choledocholithiasis, stenosis of the sphincter of Oddi, or

hyperparathyroidism. Medical management of the hyperlipidemia frequently associated with the condition may also prevent recurrent attacks of pancreatitis. In alcoholic pancreatitis, pain relief is most likely when a dilated pancreatic duct can be decompressed. In patients with disease not amenable to decompressive surgery, addiction to narcotics is a frequent outcome of treatment.

▶ When to Refer

All patients with chronic pancreatitis should be referred for diagnostic and therapeutic procedures.

▶ When to Admit

- Severe pain.
- New jaundice.
- New fever.

BENIGN BREAST DISORDERS

FIBROCYSTIC CONDITION

ESSENTIALS OF DIAGNOSIS

- ▶ Painful, often multiple, usually bilateral masses in the breast.
- ▶ Rapid fluctuation in the size of the masses is common.
- ▶ Frequently, pain occurs or worsens and size increases during premenstrual phase of cycle.
- ▶ Most common age is 30–50. Rare in postmenopausal women not receiving hormonal replacement.

▶ General Considerations

Fibrocystic condition is the most frequent lesion of the breast. Although commonly referred to as “fibrocystic disease,” it does not, in fact, represent a pathologic or anatomic disorder. It is common in women 30–50 years of age but rare in postmenopausal women who are not taking hormonal replacement. Estrogen is considered a causative factor. There may be an increased risk in women who drink alcohol, especially women between 18 and 22 years of age. Fibrocystic condition encompasses a wide variety of benign histologic changes in the breast epithelium, some of which are found so commonly in normal breasts that they are probably variants of normal but have nonetheless been termed a “condition” or “disease.”

The microscopic findings of fibrocystic condition include cysts (gross and microscopic), papillomatosis, adenosis, fibrosis, and ductal epithelial hyperplasia. Although fibrocystic condition has generally been considered to increase the risk of subsequent breast cancer, only the variants with a component of epithelial proliferation (especially with atypia) represent true risk factors.

▶ Clinical Findings

A. Symptoms and Signs

Fibrocystic condition may produce an asymptomatic mass in the breast that is discovered by accident, but pain or tenderness often calls attention to it. Discomfort often occurs or worsens during the premenstrual phase of the cycle, at which time the cysts tend to enlarge. Fluctuations in size and rapid appearance or disappearance of a breast mass are common with this condition as are multiple or bilateral masses and serous nipple discharge. Patients will give a history of a transient lump in the breast or cyclic breast pain.

B. Diagnostic Tests

Mammography and ultrasonography should be used to evaluate a mass in a patient with fibrocystic condition. Ultrasonography alone may be used in women under 30 years of age. Because a mass due to fibrocystic condition is difficult to distinguish from carcinoma on the basis of clinical findings, suspicious lesions should be biopsied. Fine-needle aspiration (FNA) cytology may be used, but if a suspicious mass that is nonmalignant on cytologic examination does not resolve over several months, it should be excised. Surgery should be conservative, since the primary objective is to exclude cancer. Occasionally, core needle biopsy or FNA cytology will suffice. Simple mastectomy or extensive removal of breast tissue is rarely, if ever, indicated for fibrocystic condition.

▶ Differential Diagnosis

Pain, fluctuation in size, and multiplicity of lesions are the features most helpful in differentiating fibrocystic condition from carcinoma. If a dominant mass is present, the diagnosis of cancer should be assumed until disproven by biopsy. Mammography may be helpful, but the breast tissue in these young women is usually too radiodense to permit a worthwhile study. Sonography is useful in differentiating a cystic mass from a solid mass, especially in women with dense breasts. Final diagnosis, however, depends on analysis of the excisional biopsy specimen or needle biopsy.

► Treatment

When the diagnosis of fibrocystic condition has been established by previous biopsy or is likely because the history is classic, aspiration of a discrete mass suggestive of a cyst is indicated to alleviate pain and, more importantly, to confirm the cystic nature of the mass. The patient is reexamined at intervals thereafter. If no fluid is obtained by aspiration, if fluid is bloody, if a mass persists after aspiration, or if at any time during follow-up a persistent or recurrent mass is noted, biopsy should be performed.

Breast pain associated with generalized fibrocystic condition is best treated by avoiding trauma and by wearing a good supportive brassiere during the night and day. Hormone therapy is not advisable, because it does not cure the condition and has undesirable side effects. Danazol (100–200 mg orally twice daily), a synthetic androgen, is the only treatment approved by the US Food and Drug Administration (FDA) for patients with severe pain. This treatment suppresses pituitary gonadotropins, but androgenic effects (acne, edema, hirsutism) usually make this treatment intolerable; in practice, it is rarely used. Similarly, tamoxifen reduces some symptoms of fibrocystic condition, but because of its side effects, it is not useful for young women unless it is given to reduce the risk of cancer. Postmenopausal women receiving hormone replacement therapy may stop or change doses of hormones to reduce pain. Oil of evening primrose (OEP), a natural form of gamma-linolenic acid, has been shown to decrease pain in 44–58% of users. The dosage of gamma-linolenic acid is six capsules of 500 mg orally twice daily. Studies have also demonstrated a low-fat diet or decreasing dietary fat intake may reduce the painful symptoms associated with fibrocystic condition. Further research is being done to determine the effects of topical treatments such as nonsteroidal anti-inflammatory drugs as well as topical hormonal drugs such as tamoxifen.

The role of caffeine consumption in the development and treatment of fibrocystic condition is controversial. Some studies suggest that eliminating caffeine from the diet is associated with improvement while other studies refute the benefit entirely. Many patients are aware of these studies and report relief of symptoms after giving up coffee, tea, and chocolate. Similarly, many women find vitamin E (400 international units daily) helpful; however, these observations remain anecdotal.

► Prognosis

Exacerbations of pain, tenderness, and cyst formation may occur at any time until menopause, when symptoms usually subside, except in patients receiving hormonal replacement. The patient should be advised to examine her own breasts regularly just after menstruation and to inform her practitioner if a mass appears. The risk of breast cancer developing in women with fibrocystic condition with a proliferative or atypical component in the epithelium is higher than that of the general population. These women should be monitored carefully with physical examinations and imaging studies.

FIBROADENOMA OF THE BREAST

This common benign neoplasm occurs most frequently in young women, usually within 20 years after puberty. It is somewhat more frequent and tends to occur at an earlier age in black women. Multiple tumors are found in 10–15% of patients.

The typical fibroadenoma is a round or ovoid, rubbery, discrete, relatively movable, nontender mass 1–5 cm in diameter. It is usually discovered accidentally. Clinical diagnosis in young patients is generally not difficult. In women over 30 years, fibrocystic condition of the breast and carcinoma of the breast must be considered. Cysts can be identified by aspiration or ultrasonography. Fibroadenoma does not normally occur after menopause but may occasionally develop after administration of hormones.

No treatment is usually necessary if the diagnosis can be made by needle biopsy or cytologic examination. Excision or vacuum-assisted core needle removal with pathologic examination of the specimen is performed if the diagnosis is uncertain. In a 2005 study, cryoablation, or freezing of the fibroadenoma, appears to be a safe procedure if the lesion is consistent with fibroadenoma on histology prior to ablation. Cryoablation is not appropriate for all fibroadenomas because some are too large to freeze or the diagnosis may not be certain. The advantages of cryoablation over observation are not clear. It is usually not possible to distinguish a large fibroadenoma from a phyllodes tumor on the basis of needle biopsy results or imaging alone.

Phyllodes tumor is a fibroadenoma-like tumor with cellular stroma that grows rapidly. It may reach a large size and, if inadequately excised, will recur locally. The lesion can be benign or malignant. If benign, phyllodes tumor is treated by local excision with a margin of surrounding breast tissue. The treatment of malignant phyllodes tumor is more controversial, but complete removal of the tumor with a rim of normal tissue avoids recurrence. Because these tumors may be large, simple mastectomy is sometimes necessary. Lymph node dissection is not performed, since the sarcomatous portion of the tumor metastasizes to the lungs and not the lymph nodes.

NIPPLE DISCHARGE

In order of decreasing frequency, the following are the most common causes of nipple discharge in the nonlactating breast: duct ectasia, intraductal papilloma, and carcinoma. The important characteristics of the discharge and some other factors to be evaluated by history and physical examination are as follows:

1. Nature of the discharge (serous, bloody, or other).
2. Association with a mass.
3. Unilateral or bilateral.
4. Single or multiple duct discharge.
5. Discharge is spontaneous (persistent or intermittent) or must be expressed.
6. Discharge is produced by pressure at a single site or by general pressure on the breast.
7. Relation to menses.
8. Premenopausal or postmenopausal.
9. Patient is taking contraceptive pills or estrogen.

Spontaneous, unilateral, serous or serosanguineous discharge from a single duct is usually caused by an intraductal papilloma or, rarely, by an intraductal cancer. A mass may not be palpable. The involved duct may be identified by pressure at different sites around the nipple at the margin of the areola. Bloody discharge is suggestive of cancer but is more often caused by a benign papilloma in the duct. Cytologic examination may identify malignant cells, but negative findings do not rule out cancer, which is more likely in women over age 50 years. In any case, the involved duct—and a mass if present—should be excised. A ductogram (a mammogram of a duct after radiopaque dye has been injected) is of limited value since excision of the suspicious ductal system is indicated regardless of findings. Ductoscopy, evaluation of the ductal system with a small scope inserted through the nipple, has been attempted but is not effective management.

In premenopausal women, spontaneous multiple duct discharge, unilateral or bilateral, most noticeable just before menstruation, is often due to fibrocystic condition. Discharge may be green or brownish. Papillomatosis and ductal ectasia are usually detected only by biopsy. If a mass is present, it should be removed.

A milky discharge from multiple ducts in the nonlactating breast may occur from hyperprolactinemia. Serum prolactin levels should be obtained to search for a pituitary tumor. Thyroid-stimulating hormone (TSH) helps exclude causative hypothyroidism. Numerous antipsychotic drugs and other drugs may also cause a milky discharge that ceases on discontinuance of the medication.

Oral contraceptive agents or estrogen replacement therapy may cause clear, serous, or milky discharge from a

single duct, but multiple duct discharge is more common. In the premenopausal woman, the discharge is more evident just before menstruation and disappears on stopping the medication. If it does not stop, is from a single duct, and is copious, exploration should be performed since this may be a sign of cancer.

A purulent discharge may originate in a subareolar abscess and require removal of the abscess and the related lactiferous sinus.

When localization is not possible, no mass is palpable, and the discharge is nonbloody, the patient should be reexamined every 3 or 4 months for a year, and a mammogram and an ultrasound should be performed. Although most discharge is from a benign process, patients may find it annoying or disconcerting. Cytologic examination of the nipple discharge for exfoliated cancer cells is rarely helpful in determining a diagnosis. To eliminate the discharge, proximal duct excision can be performed both for treatment and diagnosis.

Louie LD et al. Identification of breast cancer in patients with pathologic nipple discharge: does ductoscopy predict malignancy? *Am J Surg*. 2006 Oct;192(4):530–3. [PMID: 16978968]

FAT NECROSIS

Fat necrosis is a rare lesion of the breast but is of clinical importance because it produces a mass (often accompanied by skin or nipple retraction) that is indistinguishable from carcinoma even with imaging studies. Trauma is presumed to be the cause, though only about 50% of patients give a history of injury. Ecchymosis is occasionally present. If untreated, the mass effect gradually disappears. The safest course is to obtain a biopsy. Needle biopsy is often adequate, but frequently the entire mass must be excised, primarily to exclude carcinoma. Fat necrosis is common after segmental resection, radiation therapy, or flap reconstruction after mastectomy.

Li S et al. Surgical management of recurrent subareolar breast abscesses: Mayo Clinic experience. *Am J Surg*. 2006 Oct;192(4):528–9. [PMI: 16978967]

Tan PH et al. Fat necrosis of the breast—A review. *Breast*. 2006 Jun;15(3):313–8. [PMID: 16198567]

BREAST ABSCESS

During nursing, an area of redness, tenderness, and induration may develop in the breast. The organism most commonly found in these abscesses is *Staphylococcus aureus* (see Puerperal Mastitis, Chapter 19).

Infection in the nonlactating breast is rare. A subareolar abscess may develop in young or middle-aged women who are not lactating (Plate 71). These infections tend to recur

after incision and drainage unless the area is explored during a quiescent interval, with excision of the involved lactiferous duct or ducts at the base of the nipple. In the nonlactating breast, inflammatory carcinoma must always be considered. Thus, incision and biopsy of any indurated tissue with a small piece of erythematous skin is indicated when suspected abscess or cellulitis in the nonlactating breast does not resolve promptly with antibiotics. Often needle or catheter drainage is adequate to treat an abscess, but surgical incision and drainage may be necessary.

Scott BG et al. Rate of malignancies in breast abscesses and argument for ultrasound drainage. *Am J Surg.* 2006 Dec;192(6):869–72. [PMID: 17161110]

DISORDERS OF THE AUGMENTED BREAST

At least 4 million American women have had breast implants. Breast augmentation is performed by placing implants under the pectoralis muscle or, less desirably, in the subcutaneous tissue of the breast. Most implants are made of an outer silicone shell filled with a silicone gel, saline, or some combination of the two. Capsule contraction or scarring around the implant develops in about 15–25% of patients, leading to a firmness and distortion of the breast that can be painful. Some require removal of the implant and surrounding capsule. In 2006, the FDA reapproved silicone implants for augmentation cosmetic surgery.

Implant rupture may occur in as many as 5–10% of women, and bleeding of gel through the capsule is noted even more commonly. Although silicone gel may be an immunologic stimulant, there is no increase in autoimmune disorders in patients with such implants. The FDA has advised symptomatic women with ruptured implants to discuss possible surgical removal with their clinicians. However, women who are asymptomatic and have no evidence of rupture of a silicone gel prosthesis should probably not undergo removal of the implant. Women with symptoms of autoimmune illnesses should consider removal.

Studies have failed to show any association between implants and an increased incidence of breast cancer. However, breast cancer may develop in a patient with an augmentation prosthesis, as it does in women without them. Detection in patients with implants is more difficult because mammography is less able to detect early lesions. Mammography is better if the implant is subpectoral rather than subcutaneous. The prosthesis should be placed retropectorally after mastectomy to facilitate detection of a local recurrence of cancer, which is usually cutaneous or subcutaneous and is easily detected by palpation.

If a cancer develops in a patient with implants, it should be treated in the same manner as in women without implants. Such women should be offered the option of mastectomy or breast-conserving therapy, which may require removal or replacement of the implant. Radiotherapy of the augmented breast often results in marked capsular contracture. Adjuvant treatments should be given for the same indications as for women who have no implants.

CARCINOMA OF THE FEMALE BREAST

ESSENTIALS OF DIAGNOSIS

- ▶ Most women with breast cancer do not have identifiable risk factors.
- ▶ Risk factors include delayed childbearing, positive family history of breast cancer or genetic mutations (*BRCA1*, *BRCA2*), and personal history of breast cancer or some types of proliferative conditions.
- ▶ **Early findings:** Single, nontender, firm to hard mass with ill-defined margins; mammographic abnormalities and no palpable mass.
- ▶ **Later findings:** Skin or nipple retraction; axillary lymphadenopathy; breast enlargement, erythema, edema, pain; fixation of mass to skin or chest wall (Plate 72).

Incidence & Risk Factors

Breast cancer will develop in one of eight American women. Next to skin cancer, breast cancer is the most common cancer in women; it is second only to lung cancer as a cause of death. The probability of developing breast cancer increases throughout life. The mean age and the median age of women with breast cancer is 61 years.

In 2008, it is estimated there will be approximately 182,500 new cases of breast cancer annually and about 41,000 deaths from this disease in women in the United States. An additional 68,000 cases of ductal carcinoma in situ (DCIS) will be detected, principally by screening mammography. The incidence of breast cancer has slightly decreased, presumably because of decreased use of postmenopausal hormone replacement therapy. Mortality has also decreased slightly due to early detection and increased use of systemic therapy.

Although more than 75% of women in whom breast cancer has been diagnosed do not have an obvious risk factor, there are several that play a role in breast cancer development. Breast cancer is three to four times more likely to develop in women with a first-degree relative (mother, daughter, or sister) who had breast cancer than in those without a family history. Risk is further increased in patients whose mothers' or sisters' breast cancers occurred before menopause or were bilateral and in those with a family history of breast cancer in two or more first-degree relatives as well as in women of Ashkenazi Jewish descent.

Nulliparous women and women whose first full-term pregnancy was after age 35 have a 1.5 times higher incidence of breast cancer than multiparous women. Late menarche and artificial menopause are associated with a lower incidence, whereas early menarche (under age 12) and late natural menopause (after age 50) are associated with a slight increase in risk. Fibrocystic condition, when accompanied by proliferative changes, papillomatosis, or atypical epithelial hyperplasia, and increased breast density on mammogram are also associated with an increased incidence. A woman who had cancer in one breast is at increased risk for cancer developing in the other breast. In these women, a contralateral cancer develops at the rate of 1% or 2% per year. Women with cancer of the uterine corpus have a risk of breast cancer significantly higher than that of the general population, and women with breast cancer have a comparably increased risk for endometrial cancer. In the United States, breast cancer is more common in white women. The incidence of the disease among nonwhite (mostly black) women is increasing, especially in younger women. In general, rates reported from developing countries are low, whereas rates are high in developed countries, with the notable exception of Japan. Some of the variability may be due to underreporting in the developing countries, but a real difference probably exists. Dietary factors, particularly increased fat consumption, may account for some differences in incidence. Oral contraceptives do not appear to increase the risk of breast cancer. There is evidence that administration of estrogens to postmenopausal women may result in a slightly increased risk of breast cancer, but only with higher, long-term doses of estrogens. Concomitant administration of progesterone and estrogen may markedly increase the incidence of breast cancer compared with the use of estrogen alone. The Women's Health Initiative prospective randomized study of hormone replacement therapy stopped treatment with estrogen and progesterone early because of an increased risk of breast cancer compared with untreated controls or women treated with estrogen alone. With decreasing use of these hormones, breast cancer rates may continue to decrease. Alcohol consumption increases the risk very slightly.

Some inherited breast cancers have been found to be associated with a gene on chromosome 17. This gene, *BRCA1*, is mutated in families with early-onset breast and ovarian cancer. Breast cancer will develop in approximately 85% of women with *BRCA1* gene mutations during their lifetime. Other genes are associated with increased risk of breast and other cancers, such as *BRCA2* (associated with a gene on chromosome 13); ataxia-telangiectasia mutation; and mutation of *p53*, the tumor suppressor gene. Mutations to *p53* have been found in approximately 1% of breast cancers in women under 40 years of age. Genetic testing is commercially available for women at high risk for breast cancer. Women with genetic mutations in whom breast cancer develops may be treated in the same way as women who do not have mutations (ie, lumpectomy), though there is an increased ipsilateral and contralateral recurrence rate after lumpectomy for these women. Such women with mutations often elect bilateral mastectomy as treatment. Some states have enacted legislation to prevent insurance

Table 17-1. Factors associated with increased risk of breast cancer.

| | |
|--------------------------|--|
| Race | White |
| Age | Older |
| Family history | Breast cancer in mother, sister, or daughter (especially bilateral or premenopausal) |
| Genetics | <i>BRCA1</i> or <i>BRCA2</i> mutation |
| Previous medical history | Endometrial cancer Proliferative forms of fibrocystic disease Cancer in other breast |
| Menstrual history | Early menarche (under age 12) Late menopause (after age 50) |
| Reproductive history | Nulliparous or late first pregnancy |

companies from considering mutations as “preexisting conditions,” preventing insurability.

Women at greater than normal risk for developing breast cancer (Table 17-1) should be identified by their practitioners and monitored carefully. Those with an exceptional family history should be counseled about the option of genetic testing. Some of these high-risk women may consider prophylactic mastectomy, oophorectomy, or tamoxifen, an FDA-approved preventive agent.

▶ Prevention

The National Surgical Adjuvant Breast Project (NSABP) conducted the first Breast Cancer Prevention Trial (BCPT) P-1, which evaluated tamoxifen as a preventive agent in women with no personal history of breast cancer but at high risk for developing the disease. Women who received tamoxifen for 5 years had about a 50% reduction in noninvasive and invasive cancers compared with women taking placebo. However, women over age 50 who received the drug had an increased incidence of endometrial cancer and deep venous thrombosis. Unfortunately, no survival data will be produced from this trial because it was stopped.

The selective estrogen receptor modulator (SERM) raloxifene, effective in preventing osteoporosis, is also effective in preventing breast cancer. The initial study, Multiple Outcomes of Raloxifene Evaluations (MORE) trial, aimed at determining the effect of raloxifene on bone, demonstrated that raloxifene also reduced breast cancer risk in women being given the drug. After 8 years, raloxifene demonstrated an overall reduction of invasive breast cancer of 66%. Because this study was designed to determine the effect of raloxifene on bone density, it was conducted in women at lower risk for breast cancer. To better understand the preventive effect of raloxifene in the high-risk population, a randomized study comparing raloxifene with tamoxifen was conducted.

The Study of Tamoxifen and Raloxifene (STAR) P-2 trial, conducted by the National Surgical Adjuvant Breast and Bowel Project (NSABP) and completed in 2006, demonstrated that raloxifene and tamoxifen are equivalent in

preventing invasive breast cancer in the high-risk population. Many of the side effects of raloxifene are the same as tamoxifen with a slight decrease in cataracts and thromboembolic events in the raloxifene group. Surprisingly, noninvasive cancer (DCIS) occurred more commonly in women treated with raloxifene.

Similar to SERMs, aromatase inhibitors (AI) have shown great success in treating breast cancer with fewer side effects, although bone loss is a significant side effect of this long-term treatment. Several large multicenter studies (eg, International Breast Cancer Intervention Study II [IBIS-II] and National Cancer Institute of Canada Clinical Trials Group [NCIC CTG]) are underway to determine whether AIs have a role in preventing breast cancer.

In addition to pharmaceutical therapy, patients continue to seek a way to prevent breast cancer. There has been considerable research on incorporating diet and exercise into the lifestyle of women who may be at risk for cancer. The Women's Intervention Nutrition Study was conducted to determine whether decreasing dietary fat intake would reduce the incidence of breast cancer recurrence after initial treatment. Although the trial demonstrated a decrease in recurrence in the follow-up period, it did not reach statistical significance.

► Early Detection of Breast Cancer

A. Screening Programs

There have been a number of large screening programs conducted over the years. Such programs, consisting of physical and mammographic examination of asymptomatic women, identify about 10 cancers per 1000 women over the age of 50 and about 2 cancers per 1000 women under the age of 50. These studies show the increased survival benefit of screening programs, as screening detects cancer before it has spread to the lymph nodes in about 80% of the women evaluated. This increases the chance of survival to about 85% at 5 years.

Both physical examination and mammography are necessary for maximum yield in screening programs, since about 35–50% of early breast cancers can be discovered only by mammography and another 40% can be detected only by palpation. About one-third of the abnormalities detected on screening mammograms will be found to be malignant when biopsy is performed. The probability of cancer on a screening mammogram is directly related to the Breast Imaging and Reporting Data System (BIRADS) assessment, and work-up should be performed based on this classification. Women 20–40 years of age should have a breast examination as part of routine medical care every 2–3 years. Women over age 40 years should have annual breast examinations. The sensitivity of mammography varies from approximately 60% to 90%. This sensitivity depends on several factors, including patient age (breast density) and tumor size, location, and mammographic appearance. In young women with dense breasts, mammography is less sensitive than in older women with fatty breasts, in whom mammography can detect at least 90% of malignancies. Smaller tumors, particularly those without calcifications, are more difficult to detect, especially in dense breasts. The lack of sensitivity and the low incidence of breast cancer in young women have led to questions concerning the value of mammography for screening in women 40–50 years of age. The specificity of mammography in women under 50 years varies from about 30% to 40% for nonpalpable mammographic abnormalities to 85% to 90% for clinically evident malignancies.

Screening recommendations for women in their 40s are based, in part, on trials from Sweden. Two trials showed a statistical advantage for screening women in their 40s, and a meta-analysis similarly revealed a statistical survival advantage for screened women with longer follow-up. The National Cancer Advisory Board recommended that women in their 40s with average risk factors have screening mammography every 1–2 years and that women at higher risk seek medical advice on when to begin screening. Studies continue to support the value of screening mammography in women over 40 years (see Table 1–9). Such

women should have annual mammography and physical examination.

The beneficial effect of screening in women aged 50–69 years is undisputed and has been confirmed by all clinical trials. The efficacy of screening in older women—those older than 70 years—is inconclusive and is difficult to determine because few studies have examined this population.

B. Self-Examination

Breast self-exam (BSE) has not been shown to improve survival. Because of the lack of strong evidence demonstrating value, the American Cancer Society no longer recommends monthly BSE beginning at age 20 years. The recommendation is that patients be made aware of the potential benefits, limitations, and harms (increased biopsies or false-positive results) associated with BSE. Women who choose to perform BSE should be advised regarding the proper technique. Premenopausal women should perform the examination 7–8 days after the start of the menstrual period. First, breasts should be inspected before a mirror with the hands at the sides, overhead, and pressed firmly on the hips to contract the pectoralis muscles causing masses, asymmetry of breasts, and slight dimpling of the skin to become apparent. Next, in a supine position, each breast should be carefully palpated with the fingers of the opposite hand. Some women discover small breast lumps more readily when their skin is moist while bathing or showering. While BSE is not a recommended practice, patients should recognize and report any breast changes to their practitioners as it remains an important facet of proactive care.

C. Imaging

Mammography is the most reliable means of detecting breast cancer before a mass can be palpated. Slowly growing cancers can be identified by mammography at least 2 years before reaching a size detectable by palpation. Film screen mammography delivers less than 0.4 cGy to the mid breast per view. Although full-field digital mammography provides an easier method to maintain and review mammograms, it has not been proven that it provides better images or increases detection rates more than film mammography. In subset analysis of a large study, digital mammography seemed slightly superior in women with dense breasts. Computer-assisted detection (CAD) has not shown any increase in detection of cancers and is not routinely performed at centers with experienced mammographers.

Calcifications are the most easily recognized mammographic abnormality. The most common findings associated with carcinoma of the breast are clustered polymorphic microcalcifications. Such calcifications are usually at least five to eight in number, aggregated in one part of the breast and differing from each other in size and shape, often including branched or V- or Y-shaped configurations. There may be an associated mammographic mass density or, at times, only a mass density with no calcifications. Such a density usually has irregular or ill-defined borders and may lead to architectural distortion within the breast but may be subtle and difficult to detect.

Indications for mammography are as follows: (1) to screen at regular intervals asymptomatic women at high risk for developing breast cancer (see above); (2) to evaluate each breast when a diagnosis of potentially curable breast cancer has been made, and at yearly intervals thereafter; (3) to evaluate a questionable or ill-defined breast mass or other suspicious change in the breast; (4) to search for an occult breast cancer in a woman with metastatic disease in axillary nodes or elsewhere from an unknown primary; (5) to screen women prior to cosmetic operations or prior to biopsy of a mass, to examine for an unsuspected cancer; (6) to monitor those women with breast cancer who have been treated with breast-conserving surgery and radiation; and (7) to monitor the contralateral breast in those women with breast cancer treated with mastectomy.

Patients with a dominant or suspicious mass must undergo biopsy despite mammographic findings. The mammogram should be obtained prior to biopsy so that other suspicious areas can be noted and the contralateral breast can be evaluated. Mammography is never a substitute for biopsy because it may not reveal clinical cancer, especially in a very dense breast, as may be seen in young women with fibrocystic changes, and may not reveal medullary cancers.

Communication and documentation among the patient, the referring practitioner, and the interpreting physician are critical for high-quality screening and diagnostic mammography. The patient should be told about *how* she will receive timely results of her mammogram; that mammography does not “rule out” cancer; and that she may receive a correlative examination such as ultrasound at the mammography facility if referred for a suspicious lesion. She should also be aware of the technique and need for breast compression and that this may be uncomfortable. The mammography facility should be informed *in writing by the clinician* of abnormal physical examination findings. The Agency for Health Care Policy and Research (AHCPR) Clinical Practice Guidelines strongly recommend that all mammography reports be communicated in writing to the patient and referring practitioner. MRI and ultrasound may be useful screening modalities in women who are at high risk for breast cancer but not for the general population. The sensitivity of MRI is much higher than mammography; however, the specificity is significantly lower and this results in multiple unnecessary biopsies. The increased sensitivity despite decreased specificity may be considered a reasonable trade-off for those at increased risk for developing breast cancer but not for normal-risk population. MRI is useful in women with breast implants to determine the character of a lesion present in the breast and to search for implant rupture and at times is helpful in patients with prior lumpectomy and radiation. In addition, positron emission tomography (PET) may play a role in imaging atypical lesions but is less sensitive for early breast cancer than is MRI or mammography. The primary role remains evaluation of metastatic deposits.

► Clinical Findings Associated with Early Detection of Breast Cancer

A. Symptoms and Signs

The presenting complaint in about 70% of patients with breast cancer is a lump (usually painless) in the breast. About 90% of these breast masses are discovered by the patient. Less frequent symptoms are breast pain; nipple discharge; erosion, retraction, enlargement, or itching of the nipple; and redness, generalized hardness, enlargement, or shrinking of the breast. Rarely, an axillary mass or swelling of the arm may be the first symptom. Back or bone pain, jaundice, or weight loss may be the result of systemic metastases, but these symptoms are rarely seen on initial presentation.

The relative frequency of carcinoma in various anatomic sites in the breast is shown in Figure 17–1.

Inspection of the breast is the first step in physical examination and should be carried out with the patient sitting, arms at her sides and then overhead. Abnormal variations in breast size and contour, minimal nipple retraction, and slight edema, redness, or retraction of the skin can be identified. Asymmetry of the breasts and retraction or dimpling of the skin can often be accentuated by having the patient raise her arms overhead or press her

▲ **Figure 17-1.** Frequency of breast carcinoma at various anatomic sites.

hands on her hips to contract the pectoralis muscles. Axillary and supraclavicular areas should be thoroughly palpated for enlarged nodes with the patient sitting (Figure 17–2). Palpation of the breast for masses or other changes should be performed with the patient both seated and supine with the arm abducted (Figure 17–3). Palpation with a rotary motion of the examiner’s fingers as well as a horizontal stripping motion has been recommended.

Breast cancer usually consists of a nontender, firm or hard mass with poorly delineated margins (caused by local infiltration). Very small (1–2 mm) erosions of the nipple

▲ **Figure 17-2.** Palpation of axillary region for enlarged lymph nodes.

▲ **Figure 17-3.** Palpation of breasts. Palpation is performed with the patient supine and arm abducted.

epithelium may be the only manifestation of Paget carcinoma. Watery, serous, or bloody discharge from the nipple is an occasional early sign but is more often associated with benign disease.

A small lesion, less than 1 cm in diameter, may be difficult or impossible for the examiner to feel but may be discovered by the patient. She should always be asked to demonstrate the location of the mass; if the practitioner fails to confirm the patient's suspicions and imaging studies are normal, the examination should be repeated in 2–3 months, preferably 1–2 weeks after the onset of menses. During the premenstrual phase of the cycle, increased innocuous nodularity may suggest neoplasm or may obscure an underlying lesion. If there is any question regarding the nature of an abnormality under these circumstances, the patient should be asked to return after her period. Ultrasound is often valuable and mammography essential when an area is felt by the patient to be abnormal but the physician feels no mass. MRI may be considered, but the lack of specificity should be discussed by the practitioner and the patient. MRI should not be used to rule out cancer because MRI has a false-negative rate of about 3–5%. Although lower than mammography, this false-negative rate cannot permit safe elimination of the possibility of cancer. False negatives are more likely seen in infiltrating lobular carcinomas and DCIS.

Metastases tend to involve regional lymph nodes, which may be palpable. One or two movable, nontender, not particularly firm axillary lymph nodes 5 mm or less in diameter are frequently present and are generally of no significance. Firm or hard nodes larger than 1 cm are typical of metastases. Axillary nodes that are matted or fixed to skin or deep structures indicate advanced disease (at least stage III). On the other hand, if the examiner thinks that the axillary nodes are involved, that impression will be borne out by histologic section in about 85% of cases. The incidence of positive axillary nodes increases with the size of the primary tumor. Noninvasive cancers (in situ) do not metastasize. Metastases are present in about 30% of patients with clinically negative nodes.

In most cases, no nodes are palpable in the supraclavicular fossa. Firm or hard nodes of any size in this location or

just beneath the clavicle are suggestive of metastatic cancer and should be biopsied. Ipsilateral supraclavicular or infraclavicular nodes containing cancer indicate that the tumor is in an advanced stage (stage III or IV). Edema of the ipsilateral arm, commonly caused by metastatic infiltration of regional lymphatics, is also a sign of advanced cancer.

B. Laboratory Findings

A consistently elevated sedimentation rate may be the result of disseminated cancer. Liver or bone metastases may be associated with elevation of serum alkaline phosphatase. Hypercalcemia is an occasional important finding in advanced cancer of the breast. Carcinoembryonic antigen (CEA) and CA 15-3 or CA 27-29 may be used as markers for recurrent breast cancer but are not helpful in diagnosing early lesions. Many scientists are further investigating breast cancer markers through proteomics and hormone assays. These studies are ongoing and may prove to be helpful in early detection or evaluation of prognosis.

C. Imaging for Metastases

Chest radiographs may show pulmonary metastases. CT scanning of the liver and brain is of value only when metastases are suspected in these areas. Bone scans utilizing ^{99m}Tc -labeled phosphates or phosphonates are more sensitive than skeletal radiographs in detecting metastatic breast cancer. Bone scanning has not proved to be of clinical value as a routine preoperative test in the absence of symptoms, physical findings, or abnormal alkaline phosphatase or calcium levels. The frequency of abnormal findings on bone scan parallels the status of the axillary lymph nodes on pathologic examination. PET scanning is less useful than a bone scan to identify metastatic bone lesions. It is effective in soft tissue or visceral metastases in patients with signs or symptoms of metastatic disease. PET scanning combined with CT (PET-CT) is an effective screening method for detecting soft tissue metastases and is replacing CT scans.

D. Diagnostic Tests

1. Biopsy—The diagnosis of breast cancer depends ultimately on examination of tissue or cells removed by biopsy. Treatment should never be undertaken without an unequivocal histologic or cytologic diagnosis of cancer. The safest course is biopsy examination of all suspicious lesions found on physical examination or mammography, or both. About 60% of lesions clinically thought to be cancer prove on biopsy to be benign, while about 30% of clinically benign lesions are found to be malignant. These findings demonstrate the fallibility of clinical judgment and the necessity for biopsy.

All breast masses require a histologic diagnosis with one probable exception, a nonsuspicious, presumably fibrocystic mass, in a premenopausal woman. Rather, these masses can be observed through one or two menstrual cycles. However, if the mass is not cystic and does not completely resolve during this time, it must be biopsied. Figures 17-4 and 17-5 present algorithms for management of breast masses in premenopausal and postmenopausal patients.

▲ **Figure 17-4.** Evaluation of breast masses in premenopausal women. (Adapted, with permission, from Chang S, Haigh PI, Giuliano AE. Breast disease. In: Berek JS, Hacker NF [editors], *Practical Gynecologic Oncology*, 4th edition, LWW, 2004.)

The simplest biopsy method is needle biopsy, either by aspiration of tumor cells (FNA cytology) or by obtaining a small core of tissue with a hollow needle (core biopsy).

FNA cytology is a useful technique whereby cells are aspirated with a small needle and examined cytologically. This technique can be performed easily with virtually no morbidity and is much less expensive than excisional or open biopsy. The main disadvantages are that it requires a pathologist skilled in the cytologic diagnosis of breast cancer and that it is subject to sampling problems, particularly because deep lesions may be missed. Furthermore, noninvasive cancers usually cannot be distinguished from invasive cancers. The incidence of false-positive diagnoses is extremely low, perhaps 1–2%. The false-negative rate is as high as 10%. Most experienced clinicians would not leave a suspicious dominant mass in the breast even when

FNA cytology is negative unless the clinical diagnosis, breast imaging studies, and cytologic studies were all in agreement, such as a fibrocystic lesion or fibroadenoma.

Large-needle (core needle) biopsy removes a core of tissue with a large cutting needle. Hand-held biopsy devices make large-core needle biopsy of a palpable mass easy and cost effective in the office with local anesthesia. As in the case of any needle biopsy, the main problem is sampling error due to improper positioning of the needle, giving rise to a false-negative test result. Core biopsy has the advantage that tumor markers, such as estrogen receptor (ER), progesterone receptor (PR) and *HER-2/neu* over-expression can be performed on cores of tissue.

Open biopsy under local anesthesia as a separate procedure prior to deciding upon definitive treatment is the most reliable means of diagnosis. Needle biopsy or aspira-

¹Biopsy may be excisional or by needle cytology, but if cytology appears benign and the mass persists, it should be excised.

▲ **Figure 17-5.** Evaluation of breast masses in postmenopausal women. (Adapted, with permission, from Chang S, Haigh PI, Giuliano AE. Breast disease. In: Berek JS, Hacker NF [editors], *Practical Gynecologic Oncology*, 4th edition, LWW, 2004.)

tion, when positive, offers a more rapid approach with less expense and morbidity, but when nondiagnostic it must be followed by open biopsy. It generally consists of an excisional biopsy, which is done through an incision with the intent to remove the entire abnormality, not simply a sample. Additional evaluation for metastatic disease and therapeutic options can be discussed with the patient after the histologic or cytologic diagnosis of cancer has been established. In situ cancers are not easily diagnosed cytologically and usually require excisional biopsy.

As an alternative in highly suspicious circumstances, the diagnosis may be made on frozen section of tissue obtained by open biopsy under general anesthesia. If the frozen section is positive, the surgeon can proceed immediately with the definitive operation. This one-step method is rarely used today except when a cytologic study has suggested cancer but is not diagnostic and there is a high clinical suspicion of malignancy in a patient well prepared for the diagnosis of cancer and its treatment options.

In general, the two-step approach—outpatient biopsy followed by definitive operation at a later date—is preferred in the diagnosis and treatment of breast cancer, because patients can be given time to adjust to the diagnosis of cancer, can consider alternative forms of therapy, and can seek a second opinion if they wish. There is no adverse effect from the short delay of the two-step procedure.

2. Ultrasonography—Ultrasonography is performed primarily to differentiate cystic from solid lesions but may show signs suggestive of carcinoma. Ultrasonography may show an irregular mass within a cyst in the rare case of

intracystic carcinoma. If a tumor is palpable and feels like a cyst, an 18-gauge needle can be used to aspirate the fluid and make the diagnosis of cyst. If a cyst is aspirated and the fluid is nonbloody, it does not have to be examined cytologically. If the mass does not recur, no further diagnostic test is necessary. Nonpalpable mammographic densities that appear benign should be investigated with ultrasound to determine whether the lesion is cystic or solid. These may even be needle biopsied with ultrasound guidance.

3. Mammography—When a suspicious abnormality is identified by mammography alone and cannot be palpated by the clinician, the lesion should be biopsied under mammographic guidance. In the **computerized stereotactic guided core needle** technique, a biopsy needle is inserted into the lesion with mammographic guidance, and a core of tissue for histologic examination can then be examined. Vacuum assistance increases the amount of tissue obtained and improves diagnosis.

Mammographic localization biopsy is performed by obtaining a mammogram in two perpendicular views and placing a needle or hook-wire near the abnormality so that the surgeon can use the metal needle or wire as a guide during operation to locate the lesion. After mammography confirms the position of the needle in relation to the lesion, an incision is made and the subcutaneous tissue is dissected until the needle is identified. Often, the abnormality cannot even be palpated through the incision—as is the case with microcalcifications—and thus it is essential to obtain a mammogram of the specimen to document that the lesion was excised. At that time, a second marker needle can further localize the lesion for the pathologist. Stereotactic core needle biopsies have proved equivalent to mammographic localization biopsies. Core biopsy is preferable to mammographic localization for accessible lesions since an operation can be avoided. A metal clip should be placed after any image-guided core biopsy to facilitate finding the site of the lesion if subsequent treatment is necessary.

4. Other imaging modalities—Other modalities of breast imaging have been investigated for diagnostic purposes. Automated breast ultrasonography is useful in distinguishing cystic from solid lesions but should be used only as a supplement to physical examination and mammography. Ductography may be useful to define the site of a lesion causing a bloody discharge, but since biopsy is almost always indicated, ductography may be omitted and the blood-filled nipple system excised. Ductoscopy has shown some promise in identifying intraductal lesions, especially in the case of pathologic nipple discharge, but in practice, this technique is rarely used. MRI is highly sensitive but not specific and should not be used for screening except in highly selective cases. For example, MRI is useful in differentiating scar from recurrence postlumpectomy and may be valuable to screen high-risk women (eg, women with *BRCA* mutations). It may also be of value to examine for multicentricity when there is a known primary cancer; to examine the contralateral breast in women with cancer; to examine the extent of cancer, especially lobular carcinomas; or to determine the response to neoadjuvant chemotherapy. PET scanning does not appear useful in evaluating the

breast itself but is valuable to examine regional lymphatics and distant metastases.

5. Cytology—Cytologic examination of nipple discharge or cyst fluid may be helpful on rare occasions. As a rule, mammography (or ductography) and breast biopsy are required when nipple discharge or cyst fluid is bloody or cytologically questionable. Ductal lavage, a technique that washes individual duct systems with saline and loosens epithelial cells for cytologic evaluation, is being evaluated as a risk assessment tool but appears to be of little value.

► Differential Diagnosis

The lesions to be considered most often in the differential diagnosis of breast cancer are the following, in descending order of frequency: fibrocystic condition of the breast, fibroadenoma, intraductal papilloma, lipoma, and fat necrosis.

► Staging

The American Joint Committee on Cancer and the International Union Against Cancer have agreed on a TNM (tumor, regional lymph nodes, distant metastases) staging system for breast cancer. Using the TNM staging system enhances communication between researchers and clinicians. Table 17-2 outlines the TNM classification.

► Pathologic Types

Numerous pathologic subtypes of breast cancer can be identified histologically (Table 17-3).

Except for the in situ cancers, the histologic subtypes have only a slight bearing on prognosis when outcomes are compared after accurate staging. Various histologic parameters, such as invasion of blood vessels, tumor differentiation, invasion of breast lymphatics, and tumor necrosis have been examined, but other than tumor grade these have little prognostic value. Genetic analysis for certain high-risk genes in the primary tumor appears to offer prognostic and therapeutic information.

The noninvasive cancers by definition are confined by the basement membrane of the ducts and lack the ability to spread. However, in patients whose biopsies show noninvasive intraductal cancer, associated invasive ductal cancers metastasize to lymph nodes in about 1–3% of cases.

► Special Clinical Forms of Breast Cancer

1. Paget Carcinoma

Paget carcinoma is not common (about 1% of all breast cancers). It affects the nipple and may or may not be associated with a breast mass. The basic lesion is usually a well differentiated infiltrating ductal carcinoma or a ductal carcinoma in situ (DCIS). The ducts of the nipple epithelium are infiltrated, but gross nipple changes are often minimal, and a tumor mass may not be palpable.

Because the nipple changes appear innocuous, the diagnosis is frequently missed. The first symptom is often itching or burning of the nipple, with superficial erosion or

ulceration. These are often diagnosed and treated as dermatitis or bacterial infection, leading to delay or failure in detection. The diagnosis is established by biopsy of the area of erosion. When the lesion consists of nipple changes only, the incidence of axillary metastases is less than 5%, and the prognosis is excellent. When a breast mass is also present, the incidence of axillary metastases rises, with an associated marked decrease in prospects for cure by surgical or other treatment.

2. Inflammatory Carcinoma

This is the most malignant form of breast cancer and constitutes less than 3% of all cases. The clinical findings consist of a rapidly growing, sometimes painful mass that enlarges the breast. The overlying skin becomes erythematous, edematous, and warm. Often there is no distinct mass, since the tumor infiltrates the involved breast diffusely. The inflammatory changes, often mistaken for an infection, are caused by carcinomatous invasion of the subdermal lymphatics, with resulting edema and hyperemia. If the practitioner suspects infection but the lesion does not respond rapidly (1–2 weeks) to antibiotics, biopsy should be performed. The diagnosis should be made when the redness involves more than one-third of the skin over the breast and biopsy shows infiltrating carcinoma with invasion of the subdermal lymphatics. Metastases tend to occur early and widely, and for this reason inflammatory carcinoma is rarely curable. Radiation, hormone therapy, and chemotherapy are the measures most likely to be of value rather than operation. Mastectomy is indicated when chemotherapy and radiation have resulted in clinical remission with no evidence of distant metastases. In these cases, residual disease in the breast may be eradicated.

► Breast Cancer Occurring during Pregnancy or Lactation

Breast cancer complicates approximately one in 3000 pregnancies. The diagnosis is frequently delayed, because physiologic changes in the breast may obscure the lesion. When the cancer is confined to the breast, the 5-year survival rate is about 70%. In 60–70% of patients, axillary metastases are already present, conferring a 5-year survival rate of 30–40%. Pregnancy (or lactation) is not a contraindication to operation or treatment, and therapy should be based on the stage of the disease as in the nonpregnant (or nonlactating) woman. Overall survival rates have improved, since cancers are now diagnosed in pregnant women earlier than in the past and treatment has improved. Breast-conserving surgery may be performed—and radiation and chemotherapy given—even during the pregnancy.

► Bilateral Breast Cancer

Bilateral breast cancer occurs in less than 5% of cases, but there is as high as a 20–25% incidence of later occurrence of cancer in the second breast. Bilaterality occurs more often in familial breast cancer, in women under age 50 years, and when the tumor in the primary breast is lobular. The incidence of second breast cancers increases directly

Table 17-2. TNM staging for breast cancer.

| Primary Tumor (T) | | | | |
|--------------------------|--|--|--|--|
| | Definitions for classifying the primary tumor (T) are the same for clinical and for pathologic classification. If the measurement is made by physical examination, the examiner will use the major headings (T1, T2, or T3). If other measurements, such as mammographic or pathologic measurements, are used, the subsets of T1 can be used. Tumors should be measured to the nearest 0.1 cm increment. | N2a | Metastasis in ipsilateral axillary lymph nodes fixed to one another (matted) or to other structures | |
| TX | | Primary tumor cannot be assessed | N2b | Metastasis only in clinically apparent ¹ ipsilateral internal mammary nodes and in the <i>absence</i> of clinically evident axillary lymph node metastasis |
| T0 | | No evidence of primary tumor | N3 | Metastasis in ipsilateral infraclavicular lymph node(s) with or without axillary lymph node involvement, or in clinically apparent ¹ ipsilateral internal mammary lymph node(s) and in the <i>presence</i> of clinically evident axillary lymph node metastasis; or metastasis in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement |
| Tis | | Carcinoma in situ | N3a | Metastasis in ipsilateral infraclavicular lymph node(s) |
| Tis (DCIS) | | Ductal carcinoma in situ | N3b | Metastasis in ipsilateral internal mammary lymph node(s) and axillary lymph node(s) |
| Tis (LCIS) | | Lobular carcinoma in situ | N3c | Metastasis in ipsilateral supraclavicular lymph node(s) |
| Tis (Paget) | | Paget disease of the nipple with no tumor | | <i>Pathologic (pN)</i> ² |
| | | <i>Note:</i> Paget disease associated with a tumor is classified according to the size of the tumor. | pNX | Regional lymph nodes cannot be assessed (eg, previously removed, or not removed for pathologic study) |
| T1 | | Tumor 2 cm or less in greatest dimension | pN0 | No regional lymph node metastasis histologically, no additional examination for isolated tumor cells |
| T1mic | | Microinvasion 0.1 cm or less in greatest dimension | | <i>Note:</i> Isolated tumor cells (ITC) are defined as single tumor cells or small cell clusters not greater than 0.2 mm, usually detected only by immunohistochemical (IHC) or molecular methods but which may be verified on hematoxylin and eosin stains. ITCs do not usually show evidence of malignant activity, eg, proliferation or stromal reaction. |
| T1a | Tumor more than 0.1 cm but not more than 0.5 cm in greatest dimension | pN0(i-) | No regional lymph node metastasis histologically, negative IHC | |
| T1b | Tumor more than 0.5 cm but not more than 1 cm in greatest dimension | pN0(i+) | No regional lymph node metastasis histologically, positive IHC, no IHC cluster greater than 0.2 mm | |
| T1c | Tumor more than 1 cm but not more than 2 cm in greatest dimension | pN0(mol-) | No regional lymph node metastasis histologically, negative molecular findings (RT-PCR) | |
| T2 | Tumor more than 2 cm but not more than 5 cm in greatest dimension | pN0(mol+) | No regional lymph node metastasis histologically, positive molecular findings (RT-PCR) | |
| T3 | Tumor more than 5 cm in greatest dimension | pN1 | Metastasis in one to three axillary lymph nodes, and/or in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent ¹ | |
| T4 | Tumor of any size with direct extension to (a) chest wall or (b) skin, only as described below | pN1mi | Micrometastasis (greater than 0.2 mm, none greater than 2.0 mm) | |
| T4a | Extension to chest wall, not including petoralis muscle | pN1a | Metastasis in one to three axillary lymph nodes | |
| T4b | Edema (including peau d'orange) or ulceration of the skin of the breast, or satellite skin nodules confined to the same breast | pN1b | Metastasis in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent ¹ | |
| T4c | Both T4a and T4b | pN1c | Metastasis in one to three axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent. ¹ (If associated with greater than three positive axillary lymph nodes, the internal mammary nodes are classified as pN3b to reflect increased tumor burden) | |
| T4d | Inflammatory carcinoma | | | |
| Regional Lymph Nodes (N) | | | | |
| <i>Clinical</i> | | | | |
| NX | Regional lymph nodes cannot be assessed (eg, previously removed) | | | |
| N0 | No regional lymph node metastasis | | | |
| N1 | Metastasis to movable ipsilateral axillary lymph node(s) | | | |
| N2 | Metastases in ipsilateral axillary lymph nodes fixed or matted, or in clinically apparent ipsilateral internal mammary nodes in the <i>absence</i> of clinically evident axillary lymph node metastasis | | | |

(continued)

Table 17–2. TNM staging for breast cancer. (continued)

| pN2 | Metastasis in four to nine axillary lymph nodes, or in clinically apparent ¹ internal mammary lymph nodes in the <i>absence</i> of axillary lymph node metastasis | Distant Metastasis (M) | | | | | |
|------|--|------------------------|---------------------------------------|---|----|-------|----|
| | | MX | Distant metastasis cannot be assessed | | | | |
| | | M0 | No distant metastasis | | | | |
| pN2a | Metastasis in four to nine axillary lymph nodes (at least one tumor deposit greater than 2.0 mm) | M1 | Distant metastasis | | | | |
| pN2b | Metastasis in clinically apparent ¹ internal mammary lymph nodes in the <i>absence</i> of axillary lymph node metastasis | Stage Grouping | | | | | |
| | | Stage 0 | Tis | N0 | M0 | | |
| pN3 | Metastasis in 10 or more axillary lymph nodes, or in infraclavicular lymph nodes, or in clinically apparent ¹ ipsilateral internal mammary lymph nodes in the <i>presence</i> of one or more positive axillary lymph nodes; or in more than three axillary lymph nodes with clinically negative microscopic metastasis in internal mammary lymph nodes; or in ipsilateral supraclavicular lymph nodes | Stage 1 | T1 ³ | N0 | M0 | | |
| | | Stage IIA | T0 | N1 | M0 | | |
| | | | T1 ³ | N1 | M0 | | |
| | | | T2 | N0 | M0 | | |
| | | Stage IIB | T2 | N1 | M0 | | |
| T3 | N0 | | M0 | | | | |
| pN3a | Metastasis in 10 or more axillary lymph nodes (at least one tumor deposit greater than 2.0 mm), or metastasis to the infraclavicular lymph nodes | Stage IIIA | T0 | N2 | M0 | | |
| | | | T1 ³ | N2 | M0 | | |
| | | | T2 | N2 | M0 | | |
| | | | T3 | N1 | M0 | | |
| pN3b | Metastasis in clinically apparent ¹ ipsilateral internal mammary lymph nodes in the <i>presence</i> of one or more positive axillary lymph nodes; or in more than three axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent ¹ | Stage IIIB | T4 | N0 | M0 | | |
| | | | T4 | N1 | M0 | | |
| | | | T4 | N2 | M0 | | |
| pN3c | Metastasis in ipsilateral supraclavicular lymph nodes | Stage IIIC | Any T | | N3 | M0 | |
| | | | Stage IV | Any T | | Any N | M1 |
| | | | | Note: Stage designation may be changed if postsurgical imaging studies reveal the presence of distant metastases, provided that the studies are carried out within 4 months of diagnosis in the absence of disease progression and provided that the patient has not received neoadjuvant therapy. | | | |

¹*Clinically apparent* is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination or grossly visible pathologically. *Not clinically apparent* is defined as not detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.

²Classification is based on axillary lymph node dissection with or without sentinel lymph node dissection. Classification based solely on sentinel lymph node dissection without subsequent axillary lymph node dissection is designated (sn) for “sentinel node,” eg, pN0(i+)(sn).

³T1 includes T1mic.

with the length of time the patient is alive after her first cancer—about 1–2% per year.

In patients with breast cancer, mammography should be performed before primary treatment and at regular intervals thereafter, to search for occult cancer in the opposite breast or conserved ipsilateral breast. MRI may be useful in this high-risk group.

► Noninvasive Cancer

Noninvasive cancer can occur within the ducts (DCIS) or lobules (lobular carcinoma in situ, LCIS). LCIS, although thought to be a premalignant lesion or a risk factor for breast cancer, in fact may behave like DCIS. In a 2004 analysis of multiple NSABP studies, invasive lobular breast

cancer not only developed in patients with LCIS but it developed in the same breast and indexed location as the original LCIS. Although more research needs to be done in this area, the invasive potential of LCIS is being reconsidered. The subtype pleomorphic LCIS may behave more like DCIS. DCIS tends to be unilateral and most often progresses to invasive cancer if untreated. In approximately 40–60% of women who have DCIS treated with biopsy alone, invasive cancer develops within the same breast.

The treatment of intraductal lesions is controversial. DCIS can be treated by wide excision with or without radiation therapy or with total mastectomy. Conservative management is advised in patients with small lesions amenable to lumpectomy. Although research is defining the malignant potential of LCIS, it can be managed with

Table 17-3. Histologic types of breast cancer.

| Type | Frequency of Occurrence |
|--|-------------------------|
| Infiltrating ductal (not otherwise specified) | 80-90% |
| Medullary | 5-8% |
| Colloid (mucinous) | 2-4% |
| Tubular | 1-2% |
| Papillary | 1-2% |
| Invasive lobular | 6-8% |
| Noninvasive | 4-6% |
| Intraductal | 2-3% |
| Lobular in situ | 2-3% |
| Rare cancers | < 1% |
| Juvenile (secretory) | |
| Adenoid cystic | |
| Epidermoid | |
| Sudoriferous | |

observation. Patients unwilling to accept the increased risk of breast cancer may be offered surgical excision of the area in question or bilateral total mastectomy. Currently, the accepted standard of care offers the alternative of chemoprevention, which is effective in preventing invasive breast cancer in both LCIS and DCIS that has been completely excised. Axillary metastases from in situ cancers should not occur unless there is an occult invasive cancer. Sentinel node biopsy may be indicated in large DCIS treated with mastectomy.

BIOMARKERS

The ER and PR status and *HER-2/neu* status of the tumor should be determined at the time of initial biopsy. Other studies such as proliferation indices may be performed. These markers may be obtained on core biopsy specimens, which will be necessary to institute neoadjuvant therapy.

The presence or absence of ER and PR is a critical element of breast cancer management. Patients whose primary tumors are receptor-positive have a more favorable course than those whose tumors are receptor-negative. Up to 60% of patients with metastatic breast cancer will respond to hormonal manipulation if their tumors are ER-positive. Less than 5% of patients with metastatic, ER-negative tumors can be treated successfully in this fashion. Adjuvant hormonal therapy, with or without chemotherapy, in receptor-positive tumors and adjuvant chemotherapy alone in receptor-negative tumors improve survival rates even in the absence of lymph node metastases. Hormone receptors have no relationship to response to chemotherapy (see Adjuvant Therapy, below).

PR status may be more sensitive than ER status in determining which patients are likely to respond to hormonal manipulation. Up to 80% of patients with metastatic PR-positive tumors improve with hormonal manipulation.

In addition to ER status and PR status, the rate at which tumor divides and the differentiation of the cells (proliferative indices) are important. In order to establish the rate of growth and differentiation, the amount and type of DNA is measured with flow cytometry.

Another key element in determining treatment and prognosis is the amount of the *HER-2/neu* oncogene present in the cancer. *HER-2/neu* overexpression is scored using a numerical system: 1+ is not an overexpressor, 2+ is borderline, and 3+ is an overexpressor. In the case of 2+ expression, fluorescence in situ hybridization (FISH) is recommended to more accurately assess *HER-2/neu* amplification and provide better prognostic information. The presence of *HER-2/neu* amplification predicts the response to trastuzumab.

While individually these biomarkers provide insight to appropriate adjuvant therapy, when combined they provide a great deal of information regarding risk of recur-

rence. Several tests now predict relapse rates for patients treated with tamoxifen or chemotherapy. Oncotype DX combines 21 genetic markers, including ER, PR, and *HER2/neu* expression in a tumor specimen to categorize risk of recurrence into three groups: high risk, intermediate risk, and low risk. In addition, the test is able to identify that the high-risk group was more likely to benefit from chemotherapy in addition to tamoxifen while the low risk group did not. This type of test is quite helpful when the survival advantage of therapy is difficult to determine. It has been most used for ER-positive node-negative tumors but now may apply to node-positive tumors as well.

Another promising biomarker being studied is vascular endothelial growth factor (VEGF), a protein that stimulates the growth of blood vessels. Elevated levels of VEGF may be a marker for a tumor that is more aggressive since it has the ability to develop blood vessels and grow. While researchers look for more specific markers to determine the presence of breast cancer, these markers also provide insight to targeted methods of treatment. Other markers being evaluated are *p53*, nm23, DNA 5c exceeding rate (DNA 5cER), G-actin, urokinase-type plasminogen activator (u-PA), and its type-1 inhibitor (PAI-1).

▶ Treatment: Curative

Clearly, not all breast cancer is systemic at the time of diagnosis. For this reason, a pessimistic attitude concerning the management of breast cancer is unwarranted. Most patients with early breast cancer can be cured.

Treatment may be curative or palliative. Curative treatment is advised for clinical stage I, II, and III disease (see Tables 17–2, 39–3, 39–4). Patients with locally advanced (T3, T4) and even inflammatory tumors may be cured with multimodality therapy, but in most, palliation is all that can be expected. Palliative treatment is appropriate for all patients with stage IV disease and for previously treated patients in whom distant metastases develop or who have unresectable local cancers (see Palliative section below).

A. Choice of Primary Therapy

The extent of disease and its biologic aggressiveness are the principal determinants of the outcome of primary therapy. Clinical and pathologic staging help in assessing extent of disease (see Table 17–2), but each is to some extent

imprecise. Other factors such as DNA flow cytometry, tumor grade, hormone receptor assays, and oncogene amplification may be of prognostic value but are not important in determining the type of local therapy.

Controversy has surrounded the choice of primary therapy of stage I, II, and III breast carcinoma. A number of states require physicians to inform patients of alternative treatment methods in the management of breast cancer. Currently, the standard of care for stage I, stage II, and most stage III cancer is surgical resection followed by adjuvant radiation or systemic therapy, or both, when indicated. Neoadjuvant therapy is becoming more popular since large tumors may be shrunk by chemotherapy prior to surgery, making some patients who require mastectomy candidates for lumpectomy.

B. Surgical Resection

1. Breast-conserving therapy—Multiple, large, randomized studies including the Milan and NSABP trials show that disease-free and overall survival rates are similar for patients treated with partial mastectomy plus axillary dissection followed by radiation therapy and for those treated by modified radical mastectomy (total mastectomy plus axillary dissection).

Twenty years of follow-up of the NSABP trial has shown that lumpectomy with axillary dissection followed by postoperative radiation therapy is as effective as modified radical mastectomy for the management of patients with stage I and stage II breast cancer.

Tumor size is a major consideration in determining the feasibility of breast conservation. The lumpectomy trial of the NSABP randomized patients with tumors as large as 4 cm. To achieve an acceptable cosmetic result, the patient must have a breast of sufficient size to enable excision of a 4-cm tumor without considerable deformity. Therefore, large size is only a relative contraindication. Subareolar tumors, also difficult to excise without deformity, are not contraindications to breast conservation. Clinically detectable multifocality is a relative contraindication to breast-conserving surgery, as is fixation to the chest wall or skin or involvement of the nipple or overlying skin. The patient—not the surgeon—should be the judge of what is cosmetically acceptable.

Axillary dissection is valuable in preventing axillary recurrences, in staging cancer, and in planning therapy. Intraoperative lymphatic mapping and sentinel node biopsy identify lymph nodes most likely to harbor metastases if present in the axillary nodes (Plate 73). Sentinel node biopsy is a reasonable alternative to axillary dissection in selected patients with invasive cancer.

Breast-conserving surgery with radiation is the preferred form of treatment for patients with **early-stage breast cancer**. Despite the numerous randomized trials showing no survival benefit of mastectomy over breast-conserving partial mastectomy and irradiation, breast-conserving surgery still appears underutilized.

2. Mastectomy—Modified radical mastectomy was the standard therapy for most patients with early-stage breast cancer. This operation removes the entire breast, overlying

skin, nipple, and areolar complex as well as the underlying pectoralis fascia with the axillary lymph nodes in continuity. The major advantage of modified radical mastectomy is that radiation therapy may not be necessary, although radiation may be used when multiple lymph nodes are involved with cancer. The disadvantage of mastectomy is the cosmetic and psychological impact associated with breast loss. Radical mastectomy, which removes the underlying pectoralis muscle, should be performed rarely, if at all. Axillary node dissection is not indicated for noninfiltrating cancers because nodal metastases are rarely present. Skin-sparing mastectomy is currently gaining favor but is not appropriate for all patients. Breast-conserving surgery and radiation should be offered whenever possible, since most patients would prefer to save the breast. Breast reconstruction, immediate or delayed, should be discussed with patients who choose or require mastectomy. Patients should have an interview with a reconstructive plastic surgeon to discuss options prior to making a decision regarding reconstruction. Time is well spent preoperatively in educating the patient and family about these matters.

Radiotherapy after partial mastectomy consists of 5–7 weeks of five daily fractions to a total dose of 5000–6000 cGy. Most radiation oncologists use a boost dose to the cancer location. Several studies are underway examining the utility and recurrence rates after intraoperative radiation or dose dense radiation in which the time course of radiation is shortened. Accelerated partial breast irradiation, in which only the portion of the breast from which the tumor was resected is irradiated for 1–2 weeks, appears effective in achieving local control. A prospective randomized trial to examine the efficacy of this technique is underway. Accrual should be completed this year, but long-term follow-up will be necessary. Current studies suggest that radiotherapy after mastectomy may improve survival in a subset of patients and is being further researched in a large cooperative trial to better identify which subgroups will benefit. Researchers are also examining the utility of axillary irradiation as an alternative to axillary dissection in the clinically node-negative patient with sentinel node micrometastases.

C. Adjuvant Systemic Therapy

The goal of systemic therapy, including hormone modulating drugs and cytotoxic chemotherapy, is to kill cancer cells that have escaped the breast and axillary lymph nodes as micrometastases. In practice, most medical oncologists are currently using adjuvant chemotherapy for patients with either node-positive or higher-risk node-negative breast cancer and using hormonal therapy for all hormone receptor-positive invasive breast cancer unless contraindicated. Prognostic factors other than nodal status that are used to determine the patient's risks are tumor size, ER and PR status, nuclear grade, histologic type, proliferative rate, and oncogene expression (Table 17–4). In general, systemic chemotherapy decreases the chance of recurrence by about 30% and hormonal modulation decreases the risk of recurrence by 40–50% (for hormone receptor-positive cancer). In general, chemotherapy is given before

Table 17–4. Prognostic factors in node-negative breast cancer.

| Prognostic Factors | Increased Recurrence | Decreased Recurrence |
|----------------------------------|----------------------|----------------------|
| Size | T3, T2 | T1, T0 |
| Hormone receptors | Negative | Positive |
| DNA flow cytometry | Aneuploid | Diploid |
| Histologic grade | High | Low |
| Tumor labeling index | < 3% | > 3% |
| S phase fraction | > 5% | < 5% |
| Lymphatic or vascular invasion | Present | Absent |
| Cathepsin D | High | Low |
| <i>HER-2/neu</i> oncogene | High | Low |
| Epidermal growth factor receptor | High | Low |

radiation therapy and endocrine therapy is started after radiation therapy.

1. Chemotherapy—Systemic therapy improves survival and is advocated for most patients with curable breast cancer. In addition, chemotherapy may decrease local recurrence in patients treated with breast conservation, whereas hormonal manipulation decreases contralateral breast cancer occurrence as well as ipsilateral recurrence.

On the basis of the superiority of anthracycline-containing regimens in metastatic breast cancer, both doxorubicin and epirubicin have been studied extensively in the adjuvant setting. Studies comparing Adriamycin (doxorubicin) and cyclophosphamide (AC) or epirubicin and cyclophosphamide (EC) with cyclophosphamide-methotrexate-5-fluorouracil (CMF) have shown that treatments with anthracycline-containing regimens are at least as effective, and perhaps more effective, than treatment with CMF. A meta-analysis (Oxford Overview Early Breast Cancer Trialists' Collaborative Group), including over 14,000 patients enrolled in trials comparing anthracycline-based regimens to CMF, showed a small but statistically significant improved disease-free and overall survival with the use of anthracycline-based regimens. It should be noted, however, that most of these studies included a mixed population of *HER-2/neu*-positive and *HER-2/neu*-negative breast cancer patients and were performed before the development of trastuzumab. Retrospective analyses of a number of these studies (CALGB 8541, NSABP B11, MA-5, and others) suggest that anthracyclines may be primarily effective in tumors with *HER-2/neu* overexpression or alteration in the expression of topoisomerase IIa (the target of anthracyclines and close to the *HER-2/neu* gene). Given this, for *HER-2/neu*-negative, node-negative breast cancer, four cycles of AC or six cycles of CMF are probably equally effective.

When taxanes (T=paclitaxel and docetaxel) emerged in the 1990s, trials were conducted to evaluate their use in combination with anthracycline-based regimens. Initial studies demonstrated a 20% proportional reduction in

recurrence and a 4% absolute improvement in disease-free survival with the addition of paclitaxel to an AC (AC-T) regimen. A trial comparing six cycles of FAC to six cycles of docetaxel, doxorubicin, and cyclophosphamide (TAC) showed an improvement in disease-free and overall survival for patients receiving TAC. This benefit was most marked for patients with positive nodes and was seen in both ER-negative and ER-positive tumors. Results from CALGB 9741 showed that compared with a standard dose regimen, administration of “dose-dense” AC-P chemotherapy (that is, in an accelerated fashion, in which the frequency of administration is increased without changing total dose or duration) with filgrastim support led to improved both disease-free (82% vs 75% at 4 years) and overall survival (92% vs 90%). Exploratory subset analysis suggested that patients with hormone receptor–negative tumors derived the most benefit from the dose-dense approach.

Recently, the US Oncology trial 9735 compared four cycles of AC with four cycles of Taxotere (docetaxel) and cyclophosphamide (TC) and showed a statistically significantly improved disease-free survival and overall survival in the patients who received TC. Until this, no trial had compared a non-anthracycline, taxane-based regimen to an anthracycline-based regimen.

An important ongoing study (US Oncology 06090) is prospectively evaluating whether anthracyclines add any incremental benefit to a taxane-based regimen by comparing six cycles of TAC to six cycles of TC in *HER-2/neu* negative breast cancer patients. While awaiting the results of this trial, oncologists are faced with choosing between the above treatment regimens for *HER-2/neu*-negative breast cancer.

The overall duration of adjuvant chemotherapy still remains uncertain. However, based on the meta-analysis performed in the Oxford Overview (Early Breast Cancer Trialists' Collaborative Group), the current recommendation is for 3–6 months of the commonly used regimens. Although it is clear that dose intensity to a specific threshold is essential, there is little, if any, evidence to support the long-term survival benefit of high-dose chemotherapy with stem cell support.

Chemotherapy side effects are now generally well controlled. Nausea and vomiting are abated with drugs that directly affect the central nervous system, such as ondansetron and granisetron. Life-threatening neutropenia associated with chemotherapy can be prevented by use of growth factors such as pegfilgrastim and filgrastim (granulocyte colony-stimulating factor; G-CSF), which stimulate proliferation and differentiation of hematopoietic cells. These agents greatly diminish the incidence of infections that may complicate the use of myelosuppressive chemotherapy. Long-term toxicities from chemotherapy, including cardiomyopathy (anthracyclines) and leukemia/myelodysplasia (anthracyclines and alkylating agents), remain a small but significant risk.

2. Targeted therapy

A. *HER-2/NEU* OVEREXPRESSION—Trastuzumab (Herceptin [H]), a monoclonal antibody that binds to *HER-2/neu*

receptors, has proved effective in combination with chemotherapy in patients with *HER-2/neu* overexpressing metastatic and early breast cancer and has been FDA-approved for both of these patient populations. In the adjuvant setting, the first and most commonly studied chemotherapy backbone used with trastuzumab is AC-T. More recently, the BCIRG006 study showed equivalent efficacy for AC-TH versus TCH (docetaxel, carboplatin, trastuzumab). Both AC-TH and TCH are now FDA-approved for early, *HER-2/neu*-positive breast cancer. In these regimens, trastuzumab is given with chemotherapy and then continues beyond the course of chemotherapy to complete a full year. Other studies have evaluated use of a shorter course of trastuzumab (Finland Herceptin or FinHer trial) and use of trastuzumab sequentially (not concurrently) with chemotherapy (Herceptin Adjuvant or HERA trial). Although both of these studies showed benefits of adding trastuzumab to chemotherapy, the current standard remains 1 full year of trastuzumab for adjuvant therapy.

A small, but significant, percentage (1–4%) of patients who receive trastuzumab-based regimens develop cardiomyopathy. For this reason, anthracyclines and trastuzumab are never given concurrently and cardiac function is monitored periodically throughout therapy.

B. HORMONAL THERAPY—Adjuvant hormonal therapy is highly effective in decreasing recurrence and mortality by 25% in women with ER-positive tumors regardless of menopausal status. The standard regimen has been tamoxifen for 5 years, and this remains the standard for premenopausal women. Ovarian ablation in premenopausal patients with ER-positive tumors may produce a benefit similar to that of adjuvant systemic chemotherapy. Whether the use of ovarian ablation plus tamoxifen (or ovarian ablation plus an AI) is more effective than either measure alone is unclear and is currently being addressed in ongoing clinical trials (Suppression of Ovarian Function Trial [SOFT] and Tamoxifen and Exemestane Trial [TEXT]). AIs, including anastrozole, letrozole, and exemestane, are also effective in the adjuvant setting for postmenopausal women. Approximately seven large randomized trials enrolling more than 24,000 patients have compared the use of AIs with tamoxifen or placebo as adjuvant therapy. All of these studies have shown small but statistically significant improvements in disease-free survival (absolute benefits of 2–6%) with the use of AIs. In addition, AIs have been shown to reduce the risk of contralateral breast cancers and to have fewer associated side effects (such as endometrial cancers and thromboembolic events) than tamoxifen. However, they are associated with accelerated bone loss and an increased risk of fractures. The American Society of Clinical Oncology and National Comprehensive Cancer Network have recommended that postmenopausal women with hormone receptor–positive breast cancer be offered an AI either initially or after tamoxifen therapy. *HER-2/neu* status should not affect the use or choice of hormone therapy.

The long-term advantage of systemic therapy has been well established. Selection of patients for adjuvant treatment should be based on the patient's axillary nodal status, tumor size and grade, hormone receptor status, *HER-2/neu*

status, and age. The value of *p53*, angiogenesis factors, and vascular invasion is being investigated, but they remain to be proven prognostic factors. In general, adjuvant systemic chemotherapy should not be given to women who have small node-negative breast cancers with favorable histologic findings and tumor markers. The ability to predict more accurately which patients with *HER-2/neu*-negative, hormone receptor-positive, lymph node-negative tumors should receive chemotherapy is improving with the advent of prognostic tools, such as Oncotype DX and Mammaprint, which evaluate the gene expression profile of a given tumor and can stratify it into low or high risk types. These tests are now undergoing prospective evaluation in two clinical trials (TAILORx and MINDACT). All patients with invasive hormone receptor-positive tumors should consider the use of hormone-modulating therapy. Most patients with *HER-2/neu*-positive tumors receive trastuzumab-containing chemotherapy regimens.

D. Neoadjuvant Therapy

The use of chemotherapy or hormonal therapy prior to resection of the primary tumor (neoadjuvant) is gaining popularity. This enables the assessment of *in vivo* chemosensitivity. A complete pathologic response at the time of operation is associated with improvement in survival. Neoadjuvant chemotherapy also permits breast conservation by shrinking the primary tumor in women who would otherwise need mastectomy for local control. Survival after neoadjuvant chemotherapy has not been shown to be superior to that seen with postoperative adjuvant chemotherapy but is certainly no worse. There is considerable concern as to the timing of sentinel lymph node biopsy (SLNB), since the chemotherapy may affect any cancer present in the lymph nodes. Several studies have shown that sentinel node biopsy can be done after neoadjuvant therapy. However, a large multicenter study, NSABP B-27, demonstrated a false-negative rate of 10.7%, well above the false-negative rate outside the neoadjuvant setting (< 1–5%). Many physicians recommend performing SLNB before administering the chemotherapy in order to avoid a false-negative result and to aid in planning subsequent radiation therapy. If a complete dissection is necessary, this can be performed at the time of the definitive breast surgery.

Important questions remaining to be answered are the timing and duration of adjuvant and neoadjuvant chemotherapy, which chemotherapeutic agents should be applied for which subgroups of patients, the use of combinations of hormonal therapy and chemotherapy as well as possibly targeted therapy, and the value of prognostic factors other than hormone receptors in predicting response to therapy.

► Treatment: Palliative

A. Radiotherapy

Palliative radiotherapy may be advised for primary treatment of locally advanced cancers with distant metastases to control ulceration, pain, and other manifestations in the breast and regional nodes. Irradiation of the breast and

chest wall and the axillary, internal mammary, and supraclavicular nodes should be undertaken in an attempt to cure locally advanced and inoperable lesions when there is no evidence of distant metastases. A small number of patients in this group are cured in spite of extensive breast and regional node involvement.

Palliative irradiation is of value also in the treatment of certain bone or soft-tissue metastases to control pain or avoid fracture. Radiotherapy is especially useful in the treatment of isolated bony metastases, chest wall recurrences, brain metastases, and acute spinal cord compression.

B. Targeted Therapy

Targeted therapy refers to agents that are directed specifically against a protein or molecule expressed uniquely on tumor cells or in the tumor microenvironment. The first targeted therapy was the use of antiestrogen therapy in hormone receptor-positive breast cancer. The administration of hormones (eg, estrogens, androgens, progestins; see Table 17–5); ablation of the ovaries, adrenals, or pituitary; administration of drugs that block hormone receptors (eg, antiestrogens such as tamoxifen) or drugs that block the synthesis of hormones (eg, AIs) have all been shown to be effective in hormone receptor-positive metastatic breast cancer. Palliative treatment of metastatic cancer should be based on the ER status of the primary tumor or the metastases. Because only 5–10% of women with ER-negative tumors respond, they should not receive hormonal therapy except in unusual circumstances, eg, in an older patient who cannot tolerate chemotherapy. The rate of response is nearly equal in premenopausal and postmenopausal women with ER-positive tumors. A favorable response to hormonal manipulation occurs in about one-third of patients with metastatic breast cancer. Of those whose tumors contain ER, the response is about 60% and perhaps as high as 80% for patients whose tumors contain PR as well. The choice of endocrine therapy depends on the menopausal status of the patient. Women within 1 year of their last menstrual period are arbitrarily considered to be premenopausal and should receive tamoxifen therapy or ovarian ablation, whereas women whose menses ceased more than a year before are postmenopausal and may receive an AI. Women with ER-positive tumors who do not respond to hormone therapy or experience progression should be given a different form of hormonal manipulation. The initial endocrine treatment used is referred to as primary hormonal manipulation; subsequent endocrine treatment is called secondary or tertiary hormonal manipulation.

Because the quality of life during endocrine manipulation is usually superior to that during cytotoxic chemotherapy, it is best to try endocrine manipulation whenever possible. However, when receptor status is unknown, disease is progressing rapidly or involves visceral organs, chemotherapy should be used as first-line treatment.

In addition to radiotherapy, bisphosphonate therapy has shown excellent results in delaying and reducing skeletal events in women with bony metastases. Bisphosphonates are also sometimes used in conjunction with AIs to decrease the potential bony events associated with AIs.

Table 17-5. Agents commonly used for hormonal management of metastatic breast cancer.

| Drug | Action | Dose, Route, Frequency | Major Side Effects |
|-------------------------------|--|--------------------------------|--|
| Tamoxifen citrate (Nolvadex) | SERM | 20 mg orally daily | Hot flushes, uterine bleeding, thrombophlebitis, rash |
| Fulvestrant (Faslodex) | Steroidal estrogen receptor antagonist | 250 mg intramuscularly monthly | Gastrointestinal upset, headache, back pain, hot flushes, pharyngitis |
| Toremifene citrate (Fareston) | SERM | 40 mg orally daily | Hot flushes, sweating, nausea, vaginal discharge, dry eyes, dizziness |
| Diethylstilbestrol (DES) | Estrogen | 5 mg orally three times daily | Fluid retention, uterine bleeding, thrombophlebitis, nausea |
| Goserelin (Zoladex) | Synthetic luteinizing hormone releasing analogue | 3.6 mg subcutaneously monthly | Arthralgias, blood pressure changes, hot flushes, headaches, vaginal dryness |
| Megestrol acetate (Megace) | Progestin | 40 mg orally four times daily | Fluid retention |
| Letrozole (Femara) | AI | 2.5 mg orally daily | Hot flushes, arthralgia/arthritis, myalgia |
| Anastrozole (Arimidex) | AI | 1 mg orally daily | Hot flushes, skin rashes, nausea and vomiting |
| Exemestane (Aromasin) | AI | 25 mg orally daily | Hot flushes, increased arthralgia/arthritis, myalgia, and alopecia |

AI, aromatase inhibitor; SERM, selective estrogen receptor modulator.

Bisphosphonates are routinely given with AIs to patients with bone metastases.

In general, only one type of therapy should be given at a time unless it is necessary to irradiate a destructive lesion of weight-bearing bone while the patient is receiving another regimen. The regimen should be changed only if the disease is clearly progressing. This is especially important for patients with destructive bone metastases, since changes in the status of these lesions are difficult to determine radiographically.

For patients with *HER-2/neu* overexpressing tumors, trastuzumab plus chemotherapy has been shown to increase survival. Lapatinib is a newer oral targeted drug that works by inhibiting the intracellular tyrosine kinases of the EGF and *HER-2/neu* receptors. It was recently approved by the FDA for treatment of trastuzumab-resistant *HER-2/neu*-positive metastatic breast cancer in combination with capecitabine.

Bevacizumab is a monoclonal antibody directed against VEGF. This growth factor stimulates endothelial proliferation and neoangiogenesis in cancer. A phase III randomized trial in women with metastatic breast cancer showed increased response rate and progression-free survival rate with the combination of bevacizumab and paclitaxel as first-line treatment compared with paclitaxel alone; however, there was no significant overall survival benefit. This study led to the FDA approval of bevacizumab in early 2008. While these initial results are promising, studies are now underway to define which patients and tumor types are most likely to benefit from anti-angiogenic agents.

1. The Premenopausal Patient

A. PRIMARY HORMONAL THERAPY—The potent SERM tamoxifen is by far the most common and preferred method of hormonal manipulation in the premenopausal

patient, in large part because it can be given with less morbidity and fewer side effects than cytotoxic chemotherapy. Tamoxifen is given orally in a dose of 20 mg daily. The average remission associated with tamoxifen lasts about 12 months.

There is no significant difference in survival or response between tamoxifen therapy and bilateral oophorectomy. Bilateral oophorectomy is less desirable than tamoxifen in premenopausal women because tamoxifen is so well tolerated. However, oophorectomy can be achieved rapidly and safely either by surgery, by irradiation of the ovaries if the patient is a poor surgical candidate, or by chemical ovarian ablation using a gonadotropin-releasing hormone (GnRH) analog. Oophorectomy presumably works by eliminating estrogens, progestins, and androgens, which stimulate growth of the tumor. AIs should not be used in a patient with functioning ovaries since they do not block ovarian production of estrogen.

B. SECONDARY OR TERTIARY HORMONAL THERAPY

Although patients who do not respond to tamoxifen or oophorectomy should be treated with cytotoxic drugs, those who respond and then relapse may subsequently respond to another form of endocrine treatment (Table 17-5). The initial choice for secondary endocrine manipulation has not been clearly defined.

Patients who improve after oophorectomy but subsequently relapse should receive tamoxifen or an AI; if one fails, the other may be tried but is not likely to succeed. Megestrol acetate, a progesterone agent, may be considered. Tamoxifen, AIs, or megestrol cause less morbidity and mortality than surgical adrenalectomy, can be discontinued once the patient improves, and are not associated with the many problems of postsurgical adrenal insufficiency, so that patients who require chemotherapy are more easily managed. Adrenalectomy or hypophysectomy, procedures

rarely done today, induced regression in 30–50% of patients who previously responded to oophorectomy. Pharmacologic hormonal manipulation has replaced these invasive procedures. AIs are of value when a tumor responded to tamoxifen or oophorectomy but then progresses.

2. The Postmenopausal Patient

A. PRIMARY HORMONAL THERAPY—For postmenopausal women with metastatic breast cancer amenable to endocrine manipulation, tamoxifen, 20 mg orally daily, or an AI is the initial therapy of choice. AIs have fewer side effects than tamoxifen and may be more effective. The main side effects of tamoxifen are nausea, skin rash, and hot flushes. Rarely, tamoxifen induces hypercalcemia in patients with bony metastases. The main side effects of AIs include hot flushes, vaginal dryness, and joint stiffness; however, osteoporosis and bone fractures are significantly higher than tamoxifen. Tamoxifen therapy is also associated with a higher risk of uterine cancer and venous thromboembolic events compared with AIs.

B. SECONDARY OR TERTIARY HORMONAL THERAPY—AIs are also used for the treatment of advanced breast cancer in postmenopausal women after tamoxifen treatment. In the event that the patient responds to AI but then has progression of disease, an antiestrogen, fulvestrant, has shown efficacy with about 20–30% of women benefiting from use. Postmenopausal patients who do not respond to SERM or AI should be given cytotoxic drugs. Postmenopausal women who respond initially to a SERM or AI but later manifest progressive disease may be crossed over to another hormonal therapy. If they do not respond they should receive cytotoxic drugs. Androgens have many toxicities and should rarely be used. As in premenopausal patients, neither hypophysectomy nor adrenalectomy should be performed.

C. Chemotherapy

Cytotoxic drugs should be considered for the treatment of metastatic breast cancer (1) if visceral metastases are present (especially brain, liver, or lymphangitic pulmonary), (2) if hormonal treatment is unsuccessful or the disease has progressed after an initial response to hormonal manipulation, or (3) if the tumor is ER-negative. Prior adjuvant chemotherapy does not seem to alter response rates in patients who relapse. A number of chemotherapy drugs (including vinorelbine, paclitaxel, docetaxel, gemcitabine, ixabepilone, carboplatin, cisplatin, capecitabine, albumin-bound paclitaxel, and liposomal doxorubicin) may be used as single agents with first-line objective response rates ranging from 30% to 50%.

Combination chemotherapy yields statistically significantly higher response rates and progression-free survival rates, but has not been conclusively shown to improve overall survival rates compared with sequential single-agent therapy. Combinations that have been tested in phase III studies and have proven efficacy compared with single-agent therapy include capecitabine/docetaxel, gemcitabine/paclitaxel, capecitabine/ixabepilone, and bevacizumab/paclitaxel (see Tables 39–10 and 39–11). Various other combinations of drugs have been tested in phase II studies, and a number

of clinical trials are ongoing to identify effective combinations. For patients whose tumors have progressed after several lines of therapy and who are considering additional therapy, clinical trial participation with experimental drugs in phase I, II, or III testing should be encouraged.

In the past, high-dose chemotherapy and autologous bone marrow or stem cell transplantation aroused widespread interest for the treatment of metastatic breast cancer. However, multiple clinical trials failed to show any improvement in survival with high-dose chemotherapy with stem cell transplant over conventional chemotherapy and the procedure is now rarely, if ever, performed for stage IV breast cancer.

▶ Prognosis

Stage of breast cancer is the most reliable indicator of prognosis (Table 17–6). Patients with disease localized to the breast with no evidence of pathologic involvement of the lymph nodes have the most favorable prognosis. Axillary lymph node status is the best-analyzed prognostic factor and correlates with survival at all tumor sizes. In addition, increased number of axillary nodes involved correlates directly with lower survival rates. Increasingly, the use of biologic marker status, such as ER, PR, grade, and *HER-2/neu*, is helping to identify high-risk tumor types as well as direct treatment used (see Biomarkers). The histologic subtype of breast cancer (eg, medullary, lobular, colloid) seems to have little significance in prognosis of invasive carcinomas. Tumors with marked aneuploidy have a poor prognosis (see Table 17–4). Gene analysis studies, such as Oncotype Dx, can predict disease-free survival for some subsets of patients.

The mortality rate of breast cancer patients exceeds that of age-matched normal controls for nearly 20 years. Thereafter, the mortality rates are equal, though deaths that occur among breast cancer patients are often directly the result of tumor. Five-year statistics do not accurately reflect the final outcome of therapy.

Table 17–6. Approximate survival (%) of patients with breast cancer by TNM stage.

| TNM Stage | Five Years | Ten Years |
|-----------|------------|-----------|
| 0 | 95 | 90 |
| I | 85 | 70 |
| IIA | 70 | 50 |
| IIB | 60 | 40 |
| IIIA | 55 | 30 |
| IIIB | 30 | 20 |
| IV | 5–10 | 2 |
| All | 65 | 30 |

When cancer is localized to the breast, with no evidence of regional spread after pathologic examination, the clinical cure rate with most accepted methods of therapy is 75% to greater than 90%. Variations to this generalization may be related to the hormonal receptor content of the tumor, genetic markers, tumor size, host resistance, or associated illness. Patients with small mammographically detected biologically favorable tumors and no evidence of axillary spread have a 5-year survival rate greater than 95%. When the axillary lymph nodes are involved with tumor, the survival rate drops to 50–70% at 5 years and probably around 25–40% at 10 years. In general, breast cancer appears to be somewhat more malignant in younger than in older women, and this may be related to the fact that fewer younger women have ER-positive tumors. Adjuvant systemic chemotherapy, in general, improves survival by about 30% and adjuvant hormonal therapy by about 25%.

For those patients whose disease progresses despite treatment, studies suggest supportive group therapy may improve survival. As they approach the end of life, such patients will require meticulous efforts at palliative care (see Chapter 5).

Stuart K et al. Life after breast cancer. *Aust Fam Physician*. 2006 Apr;35(4):219–24. [PMID: 16642238]

► Follow-up Care

After primary therapy, patients with breast cancer should be monitored for life in order to detect recurrences and to observe the opposite breast for a second primary carcinoma. Local and distant recurrences occur most frequently within the first 2–5 years. During the first 2 years, most patients should be examined every 6 months, then annually thereafter. The patient should examine her own breasts monthly, and a mammogram should be obtained annually. Special attention is paid to the contralateral breast because a new primary breast malignancy will develop in 20–25% of patients. In some cases, metastases are dormant for long periods and may appear 10–15 years or longer after removal of the primary tumor. Although studies have failed to show an adverse effect of hormonal replacement in disease-free patients, it is rarely used after breast cancer treatment, particularly if the tumor was hormone receptor positive. Even pregnancy has not been clearly associated with shortened survival of patients rendered disease free—yet most oncologists are reluctant to advise a young patient with breast cancer that she may become pregnant, and most are less than enthusiastic about prescribing hormone replacement for the postmenopausal breast cancer patient. The use of estrogen replacement for conditions such as osteoporosis and hot flushes may be considered for a woman with a history of breast cancer after discussion of the benefits and risks, but it is not recommended.

A. Local Recurrence

The incidence of local recurrence correlates with tumor size, the presence and number of involved axillary nodes, the histologic type of tumor, the presence of skin edema or

skin and fascia fixation with the primary tumor, and the type of definitive surgery and local irradiation. Local recurrence on the chest wall after total mastectomy and axillary dissection develops in as many as 8% of patients. When the axillary nodes are not involved, the local recurrence rate is less than 5%, but the rate is as high as 25% when they are heavily involved. A similar difference in local recurrence rate was noted between small and large tumors. Factors such as multifocal cancer, in situ tumors, positive resection margins, chemotherapy, and radiotherapy have an effect on local recurrence in patients treated with breast-conserving surgery.

Chest wall recurrences usually appear within the first several years but may occur as late as 15 or more years after mastectomy. All suspicious nodules and skin lesions should be biopsied. Local excision or localized radiotherapy may be feasible if an isolated nodule is present. If lesions are multiple or accompanied by evidence of regional involvement in the internal mammary or supraclavicular nodes, the disease is best managed by radiation treatment of the entire chest wall including the parasternal, supraclavicular, and axillary areas and usually by systemic therapy.

Local recurrence after mastectomy usually signals the presence of widespread disease and is an indication for studies to search for evidence of metastases. Distant metastases will develop within a few years in most patients with locally recurrent tumor after mastectomy. When there is no evidence of metastases beyond the chest wall and regional nodes, irradiation for cure after complete local excision should be attempted. Patients with local recurrence may be cured with local resection and radiation. After partial mastectomy, local recurrence does not have as serious a prognostic significance as after mastectomy. However, those patients in whom a recurrence develops have a worse prognosis than those who do not. It is speculated that the ability of a cancer to recur locally after radiotherapy is a sign of aggressiveness and resistance to therapy. Completion of the mastectomy should be done for local recurrence after partial mastectomy; some of these patients will survive for prolonged periods, especially if the breast recurrence is DCIS or occurs more than 5 years after initial treatment. Systemic chemotherapy or hormonal treatment should be used for women in whom disseminated disease develops or those in whom local recurrence occurs.

B. Edema of the Arm

Significant edema of the arm occurs in about 10–30% of patients after axillary dissection with or without mastectomy. It occurs more commonly if radiotherapy has been given or if there was postoperative infection. Partial mastectomy with radiation to the axillary lymph nodes is followed by chronic edema of the arm in 10–20% of patients. Sentinel lymph node dissection has proved to be a more accurate form of axillary staging without the side effects of edema or infection. It does not replace axillary dissection if the sentinel lymph nodes are involved with metastases. Judicious use of radiotherapy, with treatment

fields carefully planned to spare the axilla as much as possible, can greatly diminish the incidence of edema, which will occur in only 5% of patients if no radiotherapy is given to the axilla after a partial mastectomy and lymph node dissection.

Late or secondary edema of the arm may develop years after treatment, as a result of axillary recurrence or infection in the hand or arm, with obliteration of lymphatic channels. When edema develops, a careful examination of the axilla for recurrence or infection is performed. Infection in the arm or hand on the dissected side should be treated with antibiotics, rest, and elevation. If there is no sign of recurrence or infection, the swollen extremity should be treated with rest and elevation. A mild diuretic may be helpful. If there is no improvement, a compressor pump or manual compression decreases the swelling, and the patient is then fitted with an elastic glove or sleeve. Most patients are not bothered enough by mild edema to wear an uncomfortable glove or sleeve and will treat themselves with elevation or manual compression alone. Benzopyrones have been reported to decrease lymphedema but are not approved for this use in the United States. Rarely, edema may be severe enough to interfere with use of the limb.

C. Breast Reconstruction

Breast reconstruction is usually feasible after total or modified radical mastectomy. Reconstruction should be discussed with patients prior to mastectomy, because it offers an important psychological focal point for recovery. Reconstruction is not an obstacle to the diagnosis of recurrent cancer. The most common breast reconstruction has been implantation of a silicone gel or saline prosthesis in the subpectoral plane between the pectoralis minor and pectoralis major muscles. Alternatively, autologous tissue can be used for reconstruction.

Autologous tissue flaps are aesthetically superior to implant reconstruction in most patients. They also have the advantage of not feeling like a foreign body to the patient. The most popular autologous technique currently is the trans-rectus abdominis muscle flap (TRAM flap), which is done by rotating the rectus abdominis muscle with attached fat and skin cephalad to make a breast mound. The free TRAM flap is done by completely removing a small portion of the rectus with overlying fat and skin and using microvascular surgical techniques to reconstruct the vascular supply on the chest wall. A latissimus dorsi flap can be swung from the back but offers less fullness than the TRAM flap and is therefore less acceptable cosmetically. An implant often is used to increase the fullness with a latissimus dorsi flap. Reconstruction may be performed immediately (at the time of initial mastectomy) or may be delayed until later, usually when the patient has completed adjuvant therapy. When considering reconstructive options, concomitant illnesses should be considered, since the ability of an autologous flap to survive depends on medical comorbidities. In addition, the need for radiotherapy may affect the choice of reconstruction as radiation may increase fibrosis around an implant or decrease the volume of a flap.

D. Risks of Pregnancy

Data are insufficient to determine whether interruption of pregnancy improves the prognosis of patients who are identified to have potentially curable breast cancer and who receive definitive treatment during pregnancy. Theoretically, the increasingly high levels of estrogen produced by the placenta as the pregnancy progresses could be detrimental to the patient with occult metastases of hormone-sensitive breast cancer. Moreover, occult metastases are present in most patients with positive axillary nodes, and treatment by adjuvant chemotherapy could be potentially harmful to the fetus early in gestation, although chemotherapy may be given to pregnant women later. Under these circumstances, interruption of early pregnancy seems reasonable, with progressively less rationale for the procedure as term approaches. The decision is affected by many factors, including the patient's desire to have the baby and the prognosis especially when axillary nodes are involved.

Equally important is the advice regarding future pregnancy (or abortion in case of pregnancy) to be given to women of child-bearing age who have had definitive treatment for breast cancer. It is assumed that pregnancy will be harmful if occult metastases are present, though this has not been demonstrated. Patients whose tumors are ER negative (most younger women) may not be affected by pregnancy. To date, no adverse effect of pregnancy on survival of pregnant women who have had breast cancer has been demonstrated, though most oncologists advise against it.

In patients with inoperable or metastatic cancer (stage IV disease), induced abortion is usually advisable because of the possible adverse effects of hormonal treatment, radiotherapy, or chemotherapy upon the fetus.

CARCINOMA OF THE MALE BREAST

ESSENTIALS OF DIAGNOSIS

- ▶ A painless lump beneath the areola in a man usually over 50 years of age.
- ▶ Nipple discharge, retraction, or ulceration may be present.
- ▶ Generally poorer prognosis than in women.

▶ General Considerations

Breast cancer in men is a rare disease; the incidence is only about 1% of that in women. The average age at occurrence is about 60—somewhat older than the most common presenting age in women. There may be an increased incidence of breast cancer in men with prostate cancer. As in women, hormonal influences are probably related to the development of male breast cancer. There is a high incidence of both breast cancer and gynecomastia in Bantu men, theoretically owing to failure of estrogen inactivation by a liver damaged by associated liver disease. It is important to note that first-degree relatives of men with breast cancer are considered to be at high risk. This risk should be taken into account when discussing options with the patient and family. In addition, *BRCA2* mutations are common in men with breast cancer. Men with breast cancer, especially with a history of prostate cancer, should receive genetic counseling. The prognosis, even in stage I cases, is worse in men than in women. Blood-borne metastases are commonly present when the male patient appears for initial treatment. These metastases may be latent and may not become manifest for many years.

▶ Clinical Findings

A painless lump, occasionally associated with nipple discharge, retraction, erosion, or ulceration, is the primary complaint. Examination usually shows a hard, ill-defined, nontender mass beneath the nipple or areola. Gynecomastia not uncommonly precedes or accompanies breast cancer in men. Nipple discharge is an uncommon presentation for breast cancer in men but is an ominous finding associated with carcinoma in nearly 75% of cases.

Breast cancer staging is the same in men as in women. Gynecomastia and metastatic cancer from another site (eg, prostate) must be considered in the differential diagnosis. Benign tumors are rare, and biopsy should be performed on all males with a defined breast mass.

▶ Treatment

Treatment consists of modified radical mastectomy in operable patients, who should be chosen by the same criteria as women with the disease. Breast conserving therapy is rarely performed. Irradiation is the first step in treating localized metastases in the skin, lymph nodes, or skeleton that are causing symptoms. Examination of the

cancer for hormone receptor proteins is of value in predicting response to endocrine ablation. Men commonly have ER-positive tumors and rarely have overexpression of *HER-2/neu*. Adjuvant systemic therapy and radiation is used for the same indications as in breast cancer in women.

Because breast cancer in men is frequently a disseminated disease, endocrine therapy is of considerable importance in its management. Tamoxifen is the main drug for management of advanced breast cancer in men. Tamoxifen (20 mg orally daily) should be the initial treatment. There is little experience with AIs though they should be effective. Castration in advanced breast cancer is a successful measure and more beneficial than the same procedure in women but is rarely used. Objective evidence of regression may be seen in 60–70% of men with hormonal therapy for metastatic disease—approximately twice the proportion in women. The average duration of tumor growth remission is about 30 months, and life is prolonged. Bone is the most frequent site of metastases from breast cancer in men (as in women), and hormonal therapy relieves bone pain in most patients so treated. The longer the interval between mastectomy and recurrence, the longer the remission following treatment is likely. As in women, there is correlation between ERs of the tumor and the likelihood of remission following hormonal therapy.

AIs should replace adrenalectomy in men as they have in women. Corticosteroid therapy alone has been considered to be efficacious but probably has no value when compared with major endocrine ablation. Either tamoxifen or AIs may be primary or secondary hormonal manipulation.

Estrogen therapy—5 mg of diethylstilbestrol three times daily orally—may be effective hormonal manipulation after others have been successful and failed, just as in women. Androgen therapy may exacerbate bone pain. Chemotherapy should be administered for the same indications and using the same dosage schedules as for women with metastatic disease or for adjuvant treatment.

▶ Prognosis

The prognosis of breast cancer is poorer in men than in women. The crude 5- and 10-year survival rates for clinical stage I breast cancer in men are about 58% and 38%, respectively. For clinical stage II disease, the 5- and 10-year survival rates are approximately 38% and 10%. The survival rates for all stages at 5 and 10 years are 36% and 17%. For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).

Gynecologic Disorders

H. Trent MacKay, MD, MPH

ABNORMAL PREMENOPAUSAL BLEEDING

ESSENTIALS OF DIAGNOSIS

- ▶ Blood loss of over 80 mL per cycle.
- ▶ Excessive bleeding, often with the passage of clots, may occur at regular menstrual intervals (menorrhagia) or irregular intervals (dysfunctional uterine bleeding).
- ▶ Etiology most commonly dysfunctional uterine bleeding on a hormonal basis.

▶ General Considerations

Normal menstrual bleeding lasts an average of 4 days (range, 2–7 days), with a mean blood loss of 40 mL. Blood loss of over 80 mL per cycle is abnormal and frequently produces anemia. When there are less than 21 days between the onset of bleeding episodes, the cycles are likely to be anovular. Ovulation bleeding, a single episode of spotting between regular menses, is quite common. Heavier or irregular intermenstrual bleeding warrants investigation.

Dysfunctional uterine bleeding is usually caused by overgrowth of endometrium due to estrogen stimulation without adequate progesterone to stabilize growth; this occurs in anovular cycles. Anovulation commonly occurs in teenagers, in women aged late 30s to late 40s, and in extremely obese women or those with polycystic ovary syndrome.

▶ Clinical Findings

A. Symptoms and Signs

The diagnosis usually depends on the following: (1) A careful description of the duration and amount of flow, related pain, and relationship to the last menstrual period (LMP). The presence of blood clots or the degree of inconvenience caused by the bleeding may be more useful indicators. (2) A history of pertinent illnesses or weight change. (3) A history of medications taken in the past month. (4) A history of coagulation disorders in the patient or family

members. (5) A careful pelvic examination to look for vaginal or cervical lesions, pregnancy, uterine myomas, adnexal masses, or infection.

B. Laboratory Studies

Cervical smears should be obtained as needed for cytologic and culture studies. Blood studies should include a complete blood count, sedimentation rate, and glucose level to rule out diabetes. Diabetes may occasionally initially present with abnormal bleeding. A pregnancy test and studies of thyroid function and coagulation disorders should be considered in the clinical evaluation. Up to 18% of women with severe menorrhagia may have a coagulopathy. Tests for ovulation in cyclic menorrhagia include basal body temperature records, serum progesterone measured 1 week before the expected onset of menses, or an endometrial biopsy specimen for secretory activity shortly before the onset of menstruation.

C. Imaging

Ultrasound may be useful to evaluate endometrial thickness or to diagnose intrauterine or ectopic pregnancy or adnexal masses. Endovaginal ultrasound with saline infusion sonohysterography may be used to diagnose endometrial polyps or subserous myomas. MRI can definitively diagnose submucous myomas and adenomyosis.

D. Cervical Biopsy and Endometrial Curettage

Biopsy, curettage, or aspiration of the endometrium and curettage of the endocervix may be necessary to diagnose the cause of bleeding. These and other invasive gynecologic diagnostic procedures are described in Table 18–1. Polyps, endometrial hyperplasia, and submucous myomas are commonly identified in this way. If cancer of the cervix is suspected, colposcopically directed biopsies and endocervical curettage are indicated as first steps.

E. Hysteroscopy

Hysteroscopy can visualize endometrial polyps, submucous myomas, and exophytic endometrial cancers, fol-

Table 18–1. Common gynecologic diagnostic procedures.

| | |
|--|---|
| Colposcopy | Visualization of cervical, vaginal, or vulvar epithelium under 5–50× magnification with and without dilute acetic acid to identify abnormal areas requiring biopsy. An office procedure. |
| D&C | Dilation of the cervix and curettage of the entire endometrial cavity, using a metal curette or suction cannula and often using forceps for the removal of endometrial polyps. Can usually be done in the office under local anesthesia. |
| Endometrial biopsy | Removal of one or more areas of the endometrium by means of a curette or small aspiration device without cervical dilation. Diagnostic accuracy similar to D&C. An office procedure performed under local anesthesia. |
| Endocervical curettage | Removal of endocervical epithelium with a small curette for diagnosis of cervical dysplasia and cancer. An office procedure performed under local anesthesia. |
| Hysteroscopy | Visual examination of the uterine cavity with a small fiberoptic endoscope passed through the cervix. Biopsies, and excision of myomas can be performed. Can be done in the office under local anesthesia or in the operating room under general anesthesia. |
| Saline infusion sonohysterography | Introduction of saline solution into endometrial cavity with catheter to visualize submucous myomas or endometrial polyps by transvaginal ultrasound. May be performed in the office with oral analgesia. |
| Hysterosalpingography | Injection of radiopaque dye through the cervix to visualize the uterine cavity and oviducts. Mainly used in investigation of infertility. |
| Laparoscopy | Visualization of the abdominal and pelvic cavity through a small fiberoptic endoscope passed through a subumbilical incision. Permits diagnosis, tubal sterilization, and treatment of many conditions previously requiring laparotomy. General anesthesia is usually used. |

lowed by removal of the polyp or myoma and endometrial sampling.

► Treatment

Premenopausal patients with abnormal uterine bleeding include those with submucosal myomas, infection, early abortion, thrombophilias, or pelvic neoplasms. The history, physical examination, laboratory findings, and endometrial sampling should identify such patients, who require definitive therapy. A large group of patients remain, most of whom have dysfunctional uterine bleeding on the basis of anovulation.

Dysfunctional uterine bleeding can usually be treated hormonally. Women over the age of 35 should routinely have endometrial sampling to rule out endometrial hyperplasia or carcinoma prior to initiation of hormonal therapy. Progestins, which limit and stabilize endometrial growth, are generally effective. Medroxyprogesterone acetate, 10 mg/d orally, or norethindrone acetate, 5 mg/d orally, should be given for 10–14 days starting on day 15 of

the cycle, following which withdrawal bleeding (so-called medical curettage) will occur. The treatment is repeated for several cycles; it can be reinstated if amenorrhea or dysfunctional bleeding recurs. In women who are bleeding actively, any of the combination oral contraceptives can be given four times daily for 1 or 2 days followed by two pills daily through day 5 and then one pill daily through day 20; after withdrawal bleeding occurs, pills are taken in the usual dosage for three cycles. In cases of intractable heavy bleeding, danazol, 200 mg orally four times daily, is sometimes used to create an atrophic endometrium. Alternatively, a GnRH agonist such as depot leuprolide, 3.75 mg intramuscularly monthly, or nafarelin, 0.2–0.4 mg intranasally twice daily, can be used for up to 6 months to create a temporary cessation of menstruation by ovarian suppression.

In cases of heavy bleeding, intravenous conjugated estrogens, 25 mg every 4 hours for three or four doses, can be used, followed by oral conjugated estrogens, 2.5 mg daily, or ethinyl estradiol, 20 mcg orally daily, for 3 weeks, with the addition of medroxyprogesterone acetate, 10 mg orally daily for the last 10 days of treatment, or a combination oral contraceptive daily for 3 weeks. This will thicken the endometrium and control the bleeding. Nonsteroidal anti-inflammatory drugs (NSAIDs), such as naproxen or mefenamic acid, in the usual anti-inflammatory doses will often reduce blood loss in menorrhagia—even that associated with a copper intrauterine device (IUD).

If the abnormal bleeding is not controlled by hormonal treatment, hysteroscopy, saline infusion sonohysterography, or a D&C is necessary to check for polyps, submucous myomas, or endometrial cancer. In the absence of specific pathology, bleeding unresponsive to medical therapy may be treated with endometrial ablation, levonorgestrel-releasing IUD, or hysterectomy. While hysterectomy was used commonly in the past for bleeding unresponsive to medical therapy, the low risk of complications and the good short-term results of both endometrial ablation and levonorgestrel-releasing IUD make them attractive alternatives to hysterectomy. Endometrial ablation may be performed through the hysteroscope with laser photocoagulation or electrocautery. Newer, nonhysteroscopic techniques include balloon thermal ablation, cryoablation, free-fluid thermal ablation, impedance bipolar radiofrequency ablation, and microwave ablation. The latter methods are well-adapted to outpatient therapy under local anesthesia.

The levonorgestrel-releasing IUD markedly reduces menstrual blood loss and may be a good alternative to other therapies. However, while short-term results with endometrial ablation and levonorgestrel-releasing IUD are satisfactory, at 5 years after either the endometrial ablation procedure or placement of the levonorgestrel IUD, up to 40% of women will have had either repeat ablation procedures or a hysterectomy.

► When to Refer

- If bleeding is not controlled with first-line therapy.
- If expertise is needed for a surgical procedure.

▶ When to Admit

If bleeding is uncontrollable with first-line therapy and the patient is not hemodynamically stable.

POSTMENOPAUSAL VAGINAL BLEEDING

ESSENTIALS OF DIAGNOSIS

- ▶ Vaginal bleeding that occurs 6 months or more following cessation of menstrual function.
- ▶ Bleeding is usually painless.
- ▶ Bleeding may be a single episode of spotting or profuse bleeding for days or months.

▶ General Considerations

Vaginal bleeding that occurs 6 months or more following cessation of menstrual function should be investigated. The most common causes are atrophic endometrium, endometrial proliferation or hyperplasia, endometrial or cervical cancer, and administration of estrogens with or without added progestin. Other causes include atrophic vaginitis, trauma, endometrial polyps, friction ulcers of the cervix associated with prolapse of the uterus, and blood dyscrasias. Uterine bleeding is usually painless, but pain will be present if the cervix is stenotic, if bleeding is severe and rapid, or if infection or torsion or extrusion of a tumor is present. The patient may report a single episode of spotting or profuse bleeding for days or months.

▶ Diagnosis

The vulva and vagina should be inspected for areas of bleeding, ulcers, or neoplasms. A cytologic smear of the cervix and vaginal pool should be taken. If available, transvaginal sonography should be used to measure endometrial thickness. A measurement of 5 mm or less indicates a low likelihood of hyperplasia or endometrial cancer, although up to 4% of endometrial cancers may be missed with sonography. If the thickness is greater than 5 mm or there is a heterogeneous appearance to the endometrium, endocervical curettage and endometrial biopsy or D&C, preferably with hysteroscopy, should be performed.

▶ Treatment

Endometrial biopsy or D&C may be curative. Simple endometrial hyperplasia calls for cyclic progestin therapy (medroxyprogesterone acetate, 10 mg/d orally, or norethin-

drone acetate, 5 mg/d orally) for 21 days of each month for 3 months. A repeat endometrial biopsy should be performed. If endometrial hyperplasia with atypical cells or carcinoma of the endometrium is found, hysterectomy is necessary.

▶ When to Refer

- Complex endometrial hyperplasia with atypia is present.
- Hysteroscopy is indicated.

Clark TJ et al. Investigating postmenopausal bleeding for endometrial cancer: cost-effectiveness of initial diagnostic strategies. *BJOG.* 2006 May;113(5):502–10. [PMID: 16637894]

PREMENSTRUAL SYNDROME (Premenstrual Tension)

The premenstrual syndrome (PMS) is a recurrent, variable cluster of troublesome physical and emotional symptoms that develop during the 7–14 days before the onset of menses and subside when menstruation occurs. PMS intermittently affects about 40% of all premenopausal women, primarily those 25–40 years of age. In about 5–8% of affected women, the syndrome may be severe. Although not every woman experiences all the symptoms or signs at one time, many describe bloating, breast pain, ankle swelling, a sense of increased weight, skin disorders, irritability, aggressiveness, depression, inability to concentrate, libido change, lethargy, and food cravings. When emotional or mood symptoms predominate, along with physical symptoms, and there is a clear functional impairment, the term “premenstrual dysphoric disorder” (PMDD) may be applied. The pathogenesis of PMS/PMDD is still uncertain, and current treatment methods are mainly empiric. The clinician should provide support for both the patient’s emotional and physical distress. This includes the following:

1. Careful evaluation of the patient, with understanding, explanation, and reassurance.
2. Advise the patient to keep a daily diary of all symptoms for 2–3 months, to evaluate the timing and characteristics of her symptoms. If her symptoms occur throughout the month rather than in the 2 weeks before menses, she may have depression or other emotional problems in addition to PMS.
3. For mild to moderate symptoms, a program of aerobic exercise; reduction of caffeine, salt, and alcohol intake; and an increase in dietary calcium (to 1200 mg per day), vitamin D (to 800 international units per day), and complex carbohydrates in the diet may be helpful.
4. When physical symptoms predominate, spironolactone, 100 mg orally daily during the luteal phase, is effective for reduction of bloating and breast tenderness. Oral contraceptives or injectable progestin medroxyprogesterone acetate (DMPA) will decrease breast pain and cramping. NSAIDs, such as mefenamic acid, 500 mg orally three times a day, will reduce a number of symptoms but not breast pain.
5. When mood disorders predominate, serotonin reuptake inhibitors such as fluoxetine, 20 mg orally, either

daily or only on symptom days, are effective in relieving tension, irritability, and dysphoria with few side effects.

- When the above regimens are not effective, ovarian function can be suppressed with continuous high-dose progestin (20–30 mg/d of oral medroxyprogesterone acetate [MPA] or 150 mg of DMPA orally every 3 months or GnRH agonist with add-back therapy, such as conjugated equine estrogen, 0.625 mg orally daily with medroxyprogesterone acetate, 2.5–5.0 mg orally daily.

Yonkers KA et al. Premenstrual syndrome. *Lancet*. 2008 Apr 5;371(9619):1200–10. [PMID: 18395582]

DYSMENORRHEA

1. Primary Dysmenorrhea

Primary dysmenorrhea is menstrual pain associated with ovulatory cycles in the absence of pathologic findings. The pain usually begins within 1–2 years after the menarche and may become more severe with time. The frequency of cases increases up to age 20 and then decreases with age and markedly with parity. Fifty to 75 percent of women are affected at some time and 5–6% have incapacitating pain.

Clinical Findings

Primary dysmenorrhea is low, midline, wave-like, cramp-like pelvic pain often radiating to the back or inner thighs. Cramps may last for 1 or more days and may be associated with nausea, diarrhea, headache, and flushing. The pain is produced by uterine vasoconstriction, anoxia, and sustained contractions mediated by prostaglandins. The pelvic examination is normal between menses; examination during menses may produce discomfort, but there are no pathologic findings.

Treatment

NSAIDs (ibuprofen, ketoprofen, mefenamic acid, naproxen) and the cyclooxygenase (COX)-2 inhibitor celecoxib are generally helpful. The medication should be started 1–2 days before expected menses. Ovulation can be suppressed and dysmenorrhea usually prevented by oral contraceptives, depot-medroxyprogesterone acetate, or levonorgestrel-releasing IUD. For women who do not wish to use hormonal contraception, other therapies that have shown at least some benefit include local heat; thiamine, 100 mg/d orally; vitamin E, 200 units/d orally from 2 days prior to and for the first 3 days of menses; and high-frequency transcutaneous electrical nerve stimulation.

2. Secondary Dysmenorrhea

Secondary dysmenorrhea is menstrual pain for which an organic cause exists. It usually begins well after menarche, sometimes even as late as the third or fourth decade of life.

Clinical Findings

The history and physical examination commonly suggest endometriosis or pelvic inflammatory disease (PID). Other

causes may be submucous myoma, IUD use, cervical stenosis with obstruction, or blind uterine horn (rare).

Diagnosis

Laparoscopy is often needed to differentiate endometriosis from PID. Submucous myomas can be detected most reliably by MRI but also by hysteroogram, by hysteroscopy, or by passing a sound or curette over the uterine cavity during D&C. Cervical stenosis may result from induced abortion, creating crampy pain at the time of expected menses with no blood flow; this is easily cured by passing a sound into the uterine cavity after administering a paracervical block.

Treatment

A. Specific Measures

Periodic use of analgesics, including the NSAIDs given for primary dysmenorrhea, may be beneficial, and oral contraceptives may give relief, particularly in endometriosis. Danazol and GnRH agonists are effective in the treatment of endometriosis (see below).

B. Surgical Measures

If disability is marked or prolonged, laparoscopy or exploratory laparotomy is usually warranted. Definitive surgery depends on the degree of disability and the findings at operation.

When to Refer

- Standard therapy fails to relieve pain.
- Suspicion of pelvic pathology, such as endometriosis.

VAGINITIS

ESSENTIALS OF DIAGNOSIS

- Vaginal irritation.
- Pruritus.
- Pain.
- Unusual discharge.

General Considerations

Inflammation and infection of the vagina are common gynecologic problems, resulting from a variety of pathogens, allergic reactions to vaginal contraceptives or other products, or the friction of coitus. The normal vaginal pH is 4.5 or less, and *Lactobacillus* is the predominant organism. At the time of the midcycle estrogen surge, clear, elastic, mucoid secretions from the cervical os are often profuse. In the luteal phase and

during pregnancy, vaginal secretions are thicker, white, and sometimes adherent to the vaginal walls. These normal secretions can be confused with vaginitis by concerned women.

► Clinical Findings

When the patient complains of vaginal irritation, pain, or unusual discharge, a history should be taken, noting the onset of the LMP; recent sexual activity; use of contraceptives, tampons, or douches; and the presence of vaginal burning, pain, pruritus, or unusually profuse or malodorous discharge. The physical examination should include careful inspection of the vulva and speculum examination of the vagina and cervix. The cervix is sampled for gonococcus or *Chlamydia* if applicable. A specimen of vaginal discharge is examined under the microscope in a drop of 0.9% saline solution to look for trichomonads or clue cells and in a drop of 10% potassium hydroxide to search for *Candida*. The vaginal pH should be tested; it is frequently greater than 4.5 in infections due to trichomonads and bacterial vaginosis. A bimanual examination to look for evidence of pelvic infection should follow.

A. Vulvovaginal Candidiasis

Pregnancy, diabetes, and use of broad-spectrum antibiotics or corticosteroids predispose patients to *Candida* infections. Heat, moisture, and occlusive clothing also contribute to the risk. Pruritus, vulvovaginal erythema, and a white curd-like discharge that is not malodorous are found (Plate 74). Microscopic examination with 10% potassium hydroxide reveals filaments and spores. Cultures with Nickerson medium may be used if *Candida* is suspected but not demonstrated.

B. *Trichomonas vaginalis* Vaginitis

This protozoal flagellate infects the vagina, Skene ducts, and lower urinary tract in women and the lower genitourinary tract in men. It is sexually transmitted. Pruritus and a malodorous frothy, yellow-green discharge occur, along with diffuse vaginal erythema and red macular lesions on the cervix in severe cases (Plate 75). Motile organisms with flagella are seen by microscopic examination of a wet mount with saline solution.

C. Bacterial Vaginosis

This condition is considered to be a polymicrobial disease that is not sexually transmitted. An overgrowth of *Gardnerella* and other anaerobes is often associated with increased malodorous discharge without obvious vulvitis or vaginitis. The discharge is grayish and sometimes frothy, with a pH of 5.0–5.5. An amine-like (“fishy”) odor is present if a drop of discharge is alkalinized with 10% potassium hydroxide. On wet mount in saline, epithelial cells are covered with bacteria to such an extent that cell borders are obscured (clue cells, Plate 76). Vaginal cultures are generally not useful in diagnosis.

D. Condylomata Acuminata (Genital Warts)

Warty growths on the vulva, perianal area, vaginal walls, or cervix are caused by various types of the human papilloma-

virus (HPV). They are sexually transmitted. Pregnancy and immunosuppression favor growth. Vulvar lesions may be obviously wart-like or may be diagnosed only after application of 4% acetic acid (vinegar) and colposcopy, when they appear whitish, with prominent papillae. Fissures may be present at the fourchette. Vaginal lesions may show diffuse hypertrophy or a cobblestone appearance. Cervical lesions may be visible only by colposcopy after pretreatment with 4% acetic acid. These lesions may be related to dysplasia and cervical cancer. Vulvar cancer is also currently considered to be associated with HPV infection.

► Treatment

A. Vulvovaginal Candidiasis

A variety of regimens are available to treat vulvovaginal candidiasis. Women with uncomplicated vulvovaginal candidiasis will usually respond to a 1- to 3-day regimen of a topical azole. Women with complicated infection (including four or more episodes in 1 year, severe signs and symptoms, non-albicans species, uncontrolled diabetes, HIV infection, corticosteroid treatment, or pregnancy) should receive 7–14 days of a topical regimen or two doses of fluconazole 3 days apart. (Pregnant women should use only topical azoles.)

1. Single-dose regimens—Effective single-dose regimens include miconazole, 1200-mg vaginal suppository; tioconazole, 6.5%, 5 g vaginally; or sustained-release butoconazole, 2% cream, 5 g vaginally.

2. Three-day regimens—Effective 3-day regimens include butoconazole (2% cream, 5 g once daily), clotrimazole (two 100-mg vaginal tablets once daily), terconazole (0.8% cream, 5 g, or 80-mg suppository once daily), or miconazole (200 mg vaginal suppository once daily).

3. Seven-day regimens—The following regimens are given once daily: clotrimazole (1% cream or 100-mg vaginal tablet), miconazole (2% cream, 5 g, or 100-mg vaginal suppository), or terconazole (0.4% cream, 5 g).

4. Fourteen-day regimen—An effective 14-day regimen is nystatin (100,000-unit vaginal tablet once daily).

5. Recurrent vulvovaginitis (maintenance therapy)—Clotrimazole (500-mg vaginal suppository once weekly or 200 mg cream twice weekly) or fluconazole (100, 150, or 200 mg orally once weekly) are effective regimens for maintenance therapy for up to 6 months.

B. *Trichomonas vaginalis* Vaginitis

Treatment of both partners simultaneously is recommended; metronidazole or tinidazole, 2 g orally as a single dose or 500 mg orally twice a day for 7 days, is usually used.

In the case of treatment failure with metronidazole in the absence of reexposure, the patient should be re-treated with metronidazole, 500 mg orally twice a day for 7 days, or tinidazole 2 g orally as a single dose. If treatment failure occurs again, give metronidazole or tinidazole, 2 g orally once daily for 5 days. If this is not effective in eradicating the organisms, metronidazole and tinidazole susceptibility

testing can be arranged with the CDC at 770-488-4115 or at <http://www.cdc.gov/std>.

C. Bacterial Vaginosis

The recommended regimens are metronidazole, 500 mg orally twice daily for 7 days, clindamycin vaginal cream (2%, 5 g), once daily for 7 days, or metronidazole gel (0.75%, 5 g), twice daily for 5 days. Alternative regimens include clindamycin, 300 mg orally twice daily for 7 days, or clindamycin ovules, 100 g intravaginally at bedtime for 3 days.

D. Condylomata Acuminata

Recommended treatments for vulvar warts include podophyllum resin 10–25% in tincture of benzoin (do not use during pregnancy or on bleeding lesions) or 80–90% trichloroacetic or bichloroacetic acid, carefully applied to avoid the surrounding skin. The pain of bichloroacetic or trichloroacetic acid application can be lessened by a sodium bicarbonate paste applied immediately after treatment. Podophyllum resin must be washed off after 2–4 hours. Freezing with liquid nitrogen or a cryoprobe and electrocautery are also effective. Patient-applied regimens include podofilox 0.5% solution or gel and imiquimod 5% cream. Vaginal warts may be treated with cryotherapy with liquid nitrogen, trichloroacetic acid, or podophyllum resin. Extensive warts may require treatment with CO₂ laser under local or general anesthesia. Interferon is not recommended for routine use because it is very expensive, associated with systemic side effects, and no more effective than other therapies. Routine examination of sex partners is not necessary for the management of genital warts since the risk of reinfection is probably minimal and curative therapy to prevent transmission is not available. However, partners may wish to be examined for detection and treatment of genital warts and other sexually transmitted diseases. While condom use does not appear to prevent HPV transmission, it may result in accelerated regression of associated lesions, including untreated cervical intraepithelial neoplasia (CIN) and in accelerated clearance of genital HPV infection in women.

CERVICAL POLYPS

Cervical polyps commonly occur after menarche and are occasionally noted in postmenopausal women. The cause is not known, but inflammation may play an etiologic role. The principal symptoms are discharge and abnormal vaginal bleeding. However, abnormal bleeding should not be ascribed to a cervical polyp without sampling the endocervix and endometrium. The polyps are visible in the cervical os on speculum examination.

Cervical polyps must be differentiated from polypoid neoplastic disease of the endometrium, small submucous pedunculated myomas, and endometrial polyps. Cervical polyps rarely contain dysplasia (0.5%) or malignant (0.5%) foci.

► Treatment

Cervical polyps can generally be removed in the office by avulsion with a uterine packing forceps or ring forceps. If the cervix is soft, patulous, or definitely dilated and the polyp is large, surgical D&C is required (especially if the pedicle is not readily visible). Hysteroscopy may aid removal and lead to identification of concomitant endometrial disease. Because of the possibility of endometrial disease, cervical polypectomy should routinely be accompanied by endometrial sampling.

► When to Refer

- Polyp with a wide base is present.
- Inability to differentiate endocervical from endometrial polyp.

Berzolla CF et al. Dysplasia and malignancy in endometrial polyps. *J Womens Health (Larchmt)*. 2007;16(9):1317–21. [PMID: 18001188]

CYST & ABSCESS OF BARTHOLIN DUCT

Trauma or infection may involve Bartholin duct, causing obstruction of the gland. Drainage of secretions is prevented, leading to pain, swelling, and abscess formation (Plate 77). The infection usually resolves and pain disappears, but stenosis of the duct outlet with distention often persists. Reinfection causes recurrent tenderness and further enlargement of the duct.

The principal symptoms are periodic painful swelling on either side of the introitus and dyspareunia. A fluctuant swelling 1–4 cm in diameter in the inferior portion of either labium minus is a sign of occlusion of Bartholin duct. Tenderness is evidence of active infection.

Pus or secretions from the gland should be cultured for *Chlamydia* and other pathogens and treated accordingly (see Chapter 33); frequent warm soaks may be helpful. If an abscess develops, aspiration or incision and drainage are the simplest forms of therapy, but the problem may recur. Marsupialization (in the absence of an abscess), incision and drainage with the insertion of an indwelling Word catheter, or laser treatment will establish a new duct opening. Antibiotics are unnecessary unless cellulitis is present. An asymptomatic cyst does not require therapy.

► When to Refer

Surgical therapy (marsupialization) is indicated.

Pundir J et al. A review of the management of diseases of the Bartholin's gland. *J Obstet Gynaecol*. 2008 Feb;28(2):161–5. [PMID: 18393010]

EFFECTS OF EXPOSURE TO DIETHYLSTILBESTROL IN UTERO

Between 1947 and 1971, diethylstilbestrol (DES) was widely used in the United States for diabetic women during pregnancy and to treat threatened abortion. It is estimated that at least 2–3 million fetuses were exposed. A relation-

ship between fetal DES exposure and clear cell carcinoma of the vagina was later discovered, and a number of other related anomalies have since been noted. In one-third of all exposed women, there are changes in the vagina (adenosis, septa), cervix (deformities and hypoplasia of the vaginal portion of the cervix), or uterus (T-shaped cavity).

All women known to be exposed prenatally are advised to have an initial colposcopic examination to outline vaginal and cervical areas of abnormal epithelium, followed by cytologic examination of the vagina (all four quadrants of the upper half of the vagina) and cervix at yearly intervals. Lugol iodine stain of the vagina and cervix will also outline areas of metaplastic squamous epithelium.

Many women are not aware of having been exposed to DES. Therefore, in the age groups at risk (37–61 years), examiners should pay attention to structural changes of the vagina and cervix that may signal the possibility of DES exposure and indicate the need for follow-up.

The incidence of clear cell carcinoma is approximately 1 in 1000 exposed women, and the incidence of cervical and vaginal intraepithelial neoplasia (dysplasia and carcinoma in situ) is twice as high as in unexposed women. DES daughters have more difficulty conceiving and have an increased incidence of early abortion, ectopic pregnancy, and premature births. In addition, mothers treated with DES in pregnancy appear to have a small increase in the incidence of breast cancer, beginning 20 years after exposure.

► When to Refer

All patients with a history of DES exposure should be monitored by an experienced colposcopist.

Rubin M. Antenatal exposure to DES: lessons learned...future concerns. *Obstet Gynecol Surv.* 2007 Aug;62(8):548–55. [PMID: 17634156]

CERVICAL INTRAEPITHELIAL NEOPLASIA (Dysplasia of the Cervix)

ESSENTIALS OF DIAGNOSIS

- The presumptive diagnosis is made by an abnormal Pap smear of an asymptomatic woman with no grossly visible cervical changes.
- Diagnose by colposcopically directed biopsy.
- Increased in women with HIV.

► General Considerations

The squamocolumnar junction of the cervix is an area of active squamous cell proliferation. In childhood, this junction is located on the exposed vaginal portion of the cervix. At puberty, because of hormonal influence and possibly because of changes in the vaginal pH, the squamous margin begins to encroach on the single-layered, mucus-secreting epithelium, creating an area of metaplasia (transformation zone). Factors associated with coitus (see Pre-

Table 18–2. Classification systems for Papanicolaou smears.

| Numerical | Dysplasia | CIN | Bethesda System |
|-----------|--------------------------|--------------------------|-----------------|
| 1 | Benign | Benign | Normal |
| 2 | Benign with inflammation | Benign with inflammation | Normal, ASC-US |
| 3 | Mild dysplasia | CIN I | Low-grade SIL |
| 3 | Moderate dysplasia | CIN II | High-grade SIL |
| 3 | Severe dysplasia | CIN III | |
| 4 | Carcinoma in situ | | |
| 5 | Invasive cancer | Invasive cancer | Invasive cancer |

ASC-US, atypical squamous cells of undetermined significance; CIN, cervical intraepithelial neoplasia; SIL, squamous intraepithelial lesion.

vention, below) may lead to cellular abnormalities, which over a period of time can result in the development of squamous cell dysplasia or cancer. There are varying degrees of dysplasia (Table 18–2), defined by the degree of cellular atypia; all types must be observed and treated if they persist or become more severe.

► Clinical Findings

There are no specific symptoms or signs of CIN. The presumptive diagnosis is made by cytologic screening of an asymptomatic population with no grossly visible cervical changes. All visibly abnormal cervical lesions should be biopsied (Plate 78).

► Diagnosis

A. Cytologic Examination (Papanicolaou Smear)

Screening should begin within 3 years of the onset of sexually activity or at age 21. Testing should be done annually for 3 years and then at least every 3 years if no abnormality is detected. After age 65 or 70, if there have been no abnormalities on the last 3 cytologic tests, screening may be discontinued. With liquid-based cytology (LBC), the initial interval may be increased to every 2 years. Specimens should be taken from a nonmenstruating patient, spread on a single slide, and fixed or rinsed directly into preservative solution if LBC is to be used. A specimen should be obtained from the squamocolumnar junction with a wooden or plastic spatula and from the endocervix with a cotton swab or nylon brush.

Cytologic reports from the laboratory may describe findings in one of several ways (see Table 18–2). The Bethesda System uses the terminology “atypical squamous cells of unknown significance” (ASC-US) and “squamous intraepithelial lesions,” either low-grade (LSIL) or high-

grade (HSIL). Cytopathologists consider a Pap smear to be a medical consultation and will recommend further diagnostic procedures, treatment for infection, and comments on factors preventing adequate evaluation of the specimen. Either immediate colposcopy or triage with reflex testing for high-risk HPV types with thin layer cytologic smears can be used for ASC-US in premenopausal women age 21 years or older. Women younger than 21 years with ASC-US should have repeat cytology at 12 months and be referred for colposcopy if ASC-US is present. The routine use of combined cytologic screening and reflex high-risk HPV testing is appropriate in women over the age of 30 who are being screened no more frequently than every 3 years. Women who have undergone complete hysterectomy for benign disease do not need to be screened.

B. Colposcopy

Women with ASC-US and a negative HPV screening may be followed-up in 1 year. If the HPV screen is positive, colposcopy should be performed. If HPV screening is unavailable, repeat cytology may be done at 4- to 6-month intervals until two consecutive normal results, or the patient may be referred directly for colposcopy. All patients with SIL or atypical glandular cells should undergo colposcopy. Viewing the cervix with 10–20× magnification allows for assessment of the size and margins of an abnormal transformation zone and determination of extension into the endocervical canal. The application of 3–5% acetic acid (vinegar) dissolves mucus, and the acid's desiccating action sharpens the contrast between normal and actively proliferating squamous epithelium. Abnormal changes include white patches and vascular atypia, which indicate areas of greatest cellular activity. Paint the cervix with Lugol solution (strong iodine solution [Schiller test]). Normal squamous epithelium will take the stain; nonstaining squamous epithelium should be biopsied. (The single-layered, mucus-secreting endocervical tissue will not stain either but can readily be distinguished by its darker pink, shinier appearance.)

C. Biopsy

Colposcopically directed punch biopsy and endocervical curettage are office procedures. If colposcopy is not available, the normal-appearing cervix shedding atypical cells can be evaluated by endocervical curettage and multiple punch biopsies of nonstaining squamous epithelium or biopsies from each quadrant of the cervix. Data from both cervical biopsy and endocervical curettage are important in deciding on treatment.

▶ Prevention

Cervical infection with the HPV is associated with a high percentage of all cervical dysplasias and cancers. There are over 70 recognized HPV subtypes, of which types 6 and 11 tend to cause genital warts and mild dysplasia, while types 16, 18, 31, and others cause higher-grade cellular changes. In 2006, the FDA approved a vaccine to prevent cervical cancer and vaginal and vulvar pre-cancers caused by HPV types 16 and 18, and to protect against low-grade and pre-cancerous

lesions and genital warts caused by HPV types 6, 11, 16, and 18. The quadrivalent HPV 6/11/16/18 L1 virus-like-particle vaccine (known as Gardasil) is recommended for all girls and women aged 11 to 26. Girls as young as 9 years should receive the vaccine at the judgment of the practitioner.

In addition to vaccination, measures to prevent cervical cancer include regular cytologic screening to detect abnormalities, limiting the number of sexual partners, using a diaphragm or condom for coitus, and stopping smoking or exposure to second-hand smoke.

Women with HIV infection appear to be at increased risk for the disease and for recurrent disease after treatment. Women with HIV infection should receive regular cytologic screening and should be monitored closely after treatment for CIN.

▶ Treatment

Treatment varies depending on the degree and extent of CIN. Biopsies should always precede treatment.

A. Cauterization or Cryosurgery

The use of either hot cauterization or freezing (cryosurgery) is effective for noninvasive small lesions visible on the cervix without endocervical extension.

B. CO₂ Laser

This well-controlled method minimizes tissue destruction. It is colposcopically directed and requires special training. It may be used with large visible lesions. In current practice, it involves the vaporization of the transformation zone on the cervix and the distal 5–7 mm of endocervical canal.

C. Loop Excision

When the CIN is clearly visible in its entirety, a wire loop can be used for excisional biopsy. Cutting and hemostasis are effected with a low-voltage electro-surgical machine. This office procedure with local anesthesia is quick and uncomplicated.

D. Conization of the Cervix

Conization is surgical removal of the entire transformation zone and endocervical canal. It should be reserved for cases of severe dysplasia or cancer in situ (CIN III), particularly those with endocervical extension. The procedure can be performed with the scalpel, the CO₂ laser, the needle electrode, or by large-loop excision.

E. Follow-Up

Because recurrence is possible—especially in the first 2 years after treatment—and because the false-negative rate of a single cervical cytologic test is 20%, close follow-up after colposcopy and biopsy is imperative. For CIN II or III, cytologic examination or cytology and colposcopy should be repeated at 4- to 6-month intervals for up to 2 years. For CIN I, cytology should be performed at 6 and 12 months or HPV DNA testing can be done at 12 months. If

testing is normal, then annual cytologic examination can be resumed.

▶ When to Refer

- Patients with CIN II/III should be referred to an experienced colposcopist.
- Patients requiring conization biopsy should be referred to a gynecologist.

Quadrivalent Human Papillomavirus Vaccine: Recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep.* 2007 Mar 23;56(RR-2):1–24. [PMID: 17380109]

CARCINOMA OF THE CERVIX

ESSENTIALS OF DIAGNOSIS

- ▶ Abnormal uterine bleeding and vaginal discharge.
- ▶ Cervical lesion may be visible on inspection as a tumor or ulceration.
- ▶ Vaginal cytology usually positive; must be confirmed by biopsy.

▶ General Considerations

Cervical cancer can be considered a sexually transmitted disease. Both squamous cell and adenocarcinoma of the cervix are etiologically related to infection with HPV, primarily types 16 and 18. Smoking and possibly dietary factors such as decreased circulating vitamin A appear to be cofactors. While squamous cell carcinoma (SCC) accounts for 85% of cervical cancers, the incidence of SCC is decreasing while the incidence of adenocarcinoma of the cervix is increasing.

SCC appears first in the intraepithelial layers (the preinvasive stage, or carcinoma in situ). Preinvasive cancer (CIN III) is a common diagnosis in women 25–40 years of age. Two to 10 years are required for carcinoma to penetrate the basement membrane and invade the tissues. After invasion, death usually occurs within 3–5 years in untreated or unresponsive patients.

▶ Clinical Findings

A. Symptoms and Signs

The most common signs are metrorrhagia, postcoital spotting, and cervical ulceration. Bloody or purulent, odorous, nonpruritic discharge may appear after invasion. Bladder and rectal dysfunction or fistulas and pain are late symptoms.

B. Cervical Biopsy and Endocervical Curettage, or Conization

These procedures are necessary steps after a positive Papanicolaou smear to determine the extent and depth of invasion of the cancer. Even if the smear is positive, treatment is never justified until definitive diagnosis has been established through biopsy.

C. “Staging,” or Estimate of Gross Spread of Cancer of the Cervix

The depth of penetration of the malignant cells beyond the basement membrane is a reliable clinical guide to the extent of primary cancer within the cervix and the likelihood of metastases. It is customary to stage cancers of the cervix under anesthesia. Further assessment may be carried out by abdominal and pelvic CT scanning or MRI.

▶ Complications

Metastases to regional lymph nodes occur with increasing frequency from stage I to stage IV. Paracervical extension occurs in all directions from the cervix. The ureters are often obstructed lateral to the cervix, causing hydronephrosis and hydronephrosis and consequently impaired kidney function. Almost two-thirds of patients with untreated carcinoma of the cervix die of uremia when ureteral obstruction is bilateral. Pain in the back, in the distribution of the lumbosacral plexus, is often indicative of neurologic involvement. Gross edema of the legs may be indicative of vascular and lymphatic stasis due to tumor.

Vaginal fistulas to the rectum and urinary tract are severe late complications. Hemorrhage is the cause of death in 10–20% of patients with extensive invasive carcinoma.

▶ Prevention

In 2006, the FDA approved a quadrivalent HPV 6/11/16/18 L1 virus-like-particle vaccine, known as Gardasil, to prevent cervical cancer caused by HPV types 16 and 18, and to protect against low-grade and precancerous lesions and genital warts caused by HPV types 6, 11, 16, and 18 (see Cervical Intraepithelial Neoplasia, above).

▶ Treatment

A. Emergency Measures

Vaginal hemorrhage originates from gross ulceration and cavitation in stage II–IV cervical carcinoma. Ligation and suturing of the cervix are usually not feasible, but ligation of the uterine or hypogastric arteries may be lifesaving when other measures fail. Styptics such as Monsel solution or acetone are effective, although delayed sloughing may result in further bleeding. Wet vaginal packing is helpful. Emergency irradiation usually controls bleeding.

B. Specific Measures

1. Carcinoma in situ (stage 0)—In women who have completed childbearing, total hysterectomy is the treat-

ment of choice. In women who wish to retain the uterus, acceptable alternatives include cervical conization or ablation of the lesion with cryotherapy or laser. Close follow-up with Papanicolaou smears every 3 months for 1 year and every 6 months for another year is necessary after cryotherapy or laser.

2. Invasive carcinoma—Microinvasive carcinoma (stage IA1) is treated with simple, extrafascial hysterectomy. Stages IA2, IB1, and IIA cancers may be treated with either radical hysterectomy with concomitant radiation and chemotherapy or with radiation plus chemotherapy alone. Stages IB2, IIB, III and IV cancers are treated with radiation therapy plus concurrent cisplatin-based chemotherapy.

► Prognosis

The overall 5-year relative survival rate for carcinoma of the cervix is 68% in white women and 55% in black women in the United States. Survival rates are inversely proportionate to the stage of cancer: stage 0, 99–100%; stage IA, > 95%; stage IB–IIA, 80–90%; stage IIB, 65%; stage III, 40%; and stage IV, < 20%.

► When to Refer

All patients with invasive cervical carcinoma (stage 1A or higher) should be referred to a gynecologic oncologist.

LEIOMYOMA OF THE UTERUS (Fibroid Tumor)

ESSENTIALS OF DIAGNOSIS

- Irregular enlargement of the uterus (may be asymptomatic).
- Heavy or irregular vaginal bleeding, dysmenorrhea.
- Acute and recurrent pelvic pain if the tumor becomes twisted on its pedicle or infarcted.
- Symptoms due to pressure on neighboring organs (large tumors).

► General Considerations

Uterine leiomyoma is the most common benign neoplasm of the female genital tract. It is a discrete, round, firm, often multiple uterine tumor composed of smooth muscle and connective tissue. The most convenient classification is by anatomic location: (1) intramural, (2) submucous, (3) subserous, (4) intraligamentous, (5) parasitic (ie, deriving its blood supply from an organ to which it becomes

attached), and (6) cervical. A submucous myoma may become pedunculated and descend through the cervix into the vagina.

► Clinical Findings

A. Symptoms and Signs

In nonpregnant women, myomas are frequently asymptomatic. However, they can cause urinary frequency, dysmenorrhea, heavy bleeding (often with anemia), or other complications due to the presence of an abdominal mass. Occasionally, degeneration occurs, causing intense pain. Infertility may be due to a myoma that significantly distorts the uterine cavity.

B. Laboratory Findings

Iron-deficiency anemia may result from blood loss; in rare cases, polycythemia is present, presumably as a result of the production of erythropoietin by the myomas.

C. Imaging

Ultrasonography will confirm the presence of uterine myomas and can be used sequentially to monitor growth. When multiple subserous or pedunculated myomas are being followed, ultrasonography is important to exclude ovarian masses. MRI can delineate intramural and submucous myomas accurately. Hystero-graphy or hysteroscopy can also confirm cervical or submucous myomas.

► Differential Diagnosis

Irregular myomatous enlargement of the uterus must be differentiated from the similar but symmetric enlargement that may occur with pregnancy or adenomyosis (the presence of endometrial glands and stroma in the myometrium). Subserous myomas must be distinguished from ovarian tumors. Leiomyosarcoma is an unusual tumor occurring in 0.5% of women operated on for symptomatic myoma. It is very rare under the age of 40 and increases in incidence thereafter.

► Treatment

A. Emergency Measures

If the patient is markedly anemic as a result of long, heavy menstrual periods, preoperative treatment with depot medroxyprogesterone acetate, 150 mg intramuscularly every 28 days, or danazol, 400–800 mg orally daily, will slow or stop bleeding, and medical treatment of anemia can be given prior to surgery. Emergency surgery is required for acute torsion of a pedunculated myoma. The only emergency indication for myomectomy during pregnancy is torsion; abortion is not an inevitable result.

B. Specific Measures

Women who have small asymptomatic myomas should be examined at 6-month intervals. If necessary, elective myomectomy can be done to preserve the uterus. Myomas do not require surgery on an urgent basis unless they cause

significant pressure on the ureters, bladder, or bowel or severe bleeding leading to anemia or unless they are undergoing rapid growth. Cervical myomas larger than 3–4 cm in diameter or pedunculated myomas that protrude through the cervix must be removed. Submucous myomas can be removed using a hysteroscope and laser or resection instruments.

Because the risk of surgical complications increases with the increasing size of the myoma, preoperative reduction of myoma size is desirable. GnRH analogs such as depot leuprolide, 3.75 mg intramuscularly monthly, or nafarelin, 0.2–0.4 mg intranasally twice a day, are used preoperatively for 3- to 4-month periods to induce reversible hypogonadism, which temporarily reduces the size of myomas, suppresses their further growth, and reduces surrounding vascularity.

C. Surgical Measures

Surgical measures available for the treatment of myoma are laparoscopic or abdominal myomectomy and total or subtotal abdominal, vaginal, or laparoscopy-assisted vaginal hysterectomy. Myomectomy is the treatment of choice for women who wish to preserve fertility. Transcatheter bilateral uterine artery embolization appears to be a safe and effective alternative to myomectomy, although comparative data on subsequent pregnancy outcomes is lacking. Myolysis with MRI-guided high frequency focused ultrasound is another alternative, but long-term outcome data, particularly on pregnancy outcomes, are lacking.

► Prognosis

Surgical therapy is curative. Future pregnancies are not endangered by myomectomy, although cesarean delivery may be necessary after wide dissection with entry into the uterine cavity.

► When to Refer

Refer to a gynecologist for treatment of symptomatic leiomyomata.

► When to Admit

For acute abdomen associated with an infarcted leiomyoma.

American College of Obstetricians and Gynecologists. ACOG Practice Bulletin. Alternatives to hysterectomy in the management of leiomyomas. *Obstet Gynecol.* 2008 Aug;112(2 Pt 1):387–400. [PMID: 18669742]

Edwards RD et al. Uterine-artery embolization versus surgery for symptomatic uterine fibroids. *N Engl J Med.* 2007 Jan 25;356(4):360–70. [PMID: 17251532]

CARCINOMA OF THE ENDOMETRIUM

ESSENTIALS OF DIAGNOSIS

- Abnormal bleeding is the presenting sign in 80% of cases.

- Pap smear is frequently negative.
- After a negative pregnancy test, endometrial tissue is required to confirm the diagnosis.

► General Considerations

Adenocarcinoma of the endometrium is the second most common cancer of the female genital tract. It occurs most often in women 50–70 years of age. Some patients will have taken unopposed estrogen in the past; their increased risk appears to persist for 10 or more years after stopping the drug. Obesity, nulliparity, diabetes, and polycystic ovaries with prolonged anovulation and the extended use of tamoxifen for the treatment of breast cancer are also risk factors. Women with a family history of colon cancer (hereditary nonpolyposis colorectal cancer, Lynch syndrome) are at significantly increased risk, with a lifetime incidence as high as 30%.

Abnormal bleeding is the presenting sign in 80% of cases. Endometrial carcinoma may cause obstruction of the cervix with collection of pus (pyometra) or blood (hematometra) causing lower abdominal pain. However, pain generally occurs late in the disease, with metastases or infection.

Papanicolaou smears of the cervix occasionally show atypical endometrial cells but are an insensitive diagnostic tool. Endocervical and endometrial sampling is the only reliable means of diagnosis. Simultaneous hysteroscopy can be a valuable addition in order to localize polyps or other lesions within the uterine cavity. Vaginal ultrasonography may be used to determine the thickness of the endometrium as an indication of hypertrophy and possible neoplastic change.

Pathologic assessment is important in differentiating hyperplasias, which often can be treated with cyclic oral progestins.

► Prevention

Prompt endometrial sampling for patients who report abnormal menstrual bleeding or postmenopausal uterine bleeding will reveal many incipient as well as clinical cases of endometrial cancer. Younger women with chronic anovulation are at risk for endometrial hyperplasia and subsequent endometrial cancer. They can reduce the risk of hyperplasia almost completely with the use of oral contraceptives or cyclic progestin therapy.

► Staging

Examination under anesthesia, endometrial and endocervical sampling, chest radiography, intravenous urography, cystoscopy, sigmoidoscopy, transvaginal sonography, and MRI will help determine the extent of the disease and its appropriate treatment. The staging is based on the surgical and pathologic evaluation.

► Treatment

Treatment consists of total hysterectomy and bilateral salpingo-oophorectomy. Peritoneal material for cytologic

examination is routinely taken and lymph node sampling may be done. If invasion deep into the myometrium has occurred or if sampled lymph nodes are positive for tumor, postoperative irradiation is indicated. The role of adjuvant chemotherapy alone or with irradiation is currently under investigation, although one study has shown a modest increase in survival with chemotherapy alone versus whole abdominal radiation alone in women with stage III–IV disease. Palliation of advanced or metastatic endometrial adenocarcinoma may be accomplished with large doses of progestins, eg, medroxyprogesterone, 400 mg intramuscularly weekly, or megestrol acetate, 80–160 mg daily orally.

► Prognosis

With early diagnosis and treatment, the overall 5-year survival is 80–85%. With stage I disease, the depth of myometrial invasion is the strongest predictor of survival, with a 98% 5-year survival with less than 66% depth of invasion and 78% survival with 66% or greater invasion.

► When to Refer

All patients with endometrial carcinoma should be referred to a gynecologist.

Amant F et al. Treatment modalities in endometrial cancer. *Curr Opin Oncol.* 2007 Sep;19(5):479–85. [PMID: 17762575]
Sorosky JL. Endometrial cancer. *Obstet Gynecol.* 2008 Feb;111(2 Pt 1):436–47. [PMID: 18238985]

CARCINOMA OF THE VULVA

ESSENTIALS OF DIAGNOSIS

- History of genital warts.
- History of prolonged vulvar irritation, with pruritus, local discomfort, or slight bloody discharge.
- Early lesions may suggest or include nonneoplastic epithelial disorders.
- Late lesions appear as a mass, an exophytic growth, or a firm, ulcerated area in the vulva.
- Biopsy is necessary to make the diagnosis.

► General Considerations

The majority of cancers of the vulva are squamous lesions that classically have occurred in women over 50 years of age. Several subtypes (particularly 16, 18, and 31) of HPV have been identified in some but not all vulvar cancers. As with squamous cell lesions of the cervix, a grading system of vulvar intraepithelial neoplasia (VIN) from mild dysplasia to carcinoma in situ has been established.

► Differential Diagnosis

Biopsy is essential for the diagnosis of VIN and vulvar cancer and should be performed with any localized atypical

vulvar lesion, including white patches. Multiple skin-punch specimens can be taken in the office under local anesthesia, with care to include tissue from the edges of each lesion sampled.

Benign vulvar disorders that must be excluded in the diagnosis of carcinoma of the vulva include chronic granulomatous lesions (eg, lymphogranuloma venereum, syphilis), condylomas, hidradenoma, or neurofibroma. Lichen sclerosus and other associated leukoplakic changes in the skin should be biopsied. The likelihood that a superimposed vulvar cancer will develop in a woman with a nonneoplastic epithelial disorder (vulvar dystrophy) ranges from 1% to 5%.

► Treatment

A. General Measures

Early diagnosis and treatment of irritative or other predisposing causes, such as lichen sclerosis and VIN, should be pursued. A 7:3 combination of betamethasone and crotamiton is particularly effective for itching. After an initial response, fluorinated steroids should be replaced with hydrocortisone because of their skin atrophying effect. For lichen sclerosis, recommended treatment is clobetasol propionate cream 0.05% twice daily for 2–3 weeks, then once daily until symptoms resolve. Application one to three times a week can be used for long-term maintenance therapy.

B. Surgical Measures

High-grade VIN may be treated with a variety of approaches including topical chemotherapy, laser ablation, wide local excision, skinning vulvectomy, and simple vulvectomy. Small, invasive basal cell carcinoma of the vulva should be excised with a wide margin. If the VIN is extensive or multicentric, laser therapy or superficial surgical removal of vulvar skin may be required. In this way, the clitoris and uninvolved portions of the vulva may be spared.

Invasive carcinoma confined to the vulva without evidence of spread to adjacent organs or to the regional lymph nodes is treated with wide local excision and inguinal lymphadenectomy or wide local excision alone if invasion is less than 1 mm. Patients with more advanced disease may receive preoperative radiation, chemotherapy, or both.

► Prognosis

Basal cell carcinomas very seldom metastasize, and carcinoma in situ by definition has not metastasized. With adequate excision, the prognosis for both lesions is excellent. Patients with invasive vulvar squamous cell carcinoma 2 cm in diameter or less, without inguinal lymph node metastases, have an 85–90% chance of a 5-year survival. If the lesion is greater than 2 cm and lymph node involvement is present, the likelihood of 5-year survival is approximately 40%.

► When to Refer

All patients with invasive vulvar carcinoma should be referred to a gynecologic oncologist.

American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 93: diagnosis and management of vulvar skin disorders. *Obstet Gynecol.* 2008 May;111(5):1243–53. [PMID: 18448767]

Duong TH et al. Vulvo-vaginal cancers: risks, evaluation, prevention and early detection. *Obstet Gynecol Clin North Am.* 2007 Dec;34(4):783–802. [PMID: 18061869]

ENDOMETRIOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Pelvic pain related to menstrual cycle.
- ▶ Dysmenorrhea.
- ▶ Dyspareunia.
- ▶ Increased frequency among infertile women.

▶ General Considerations

Endometriosis is an aberrant growth of endometrium outside the uterus, particularly in the dependent parts of the pelvis and in the ovaries and is the most common cause of secondary dysmenorrhea. While retrograde menstruation is the most widely accepted cause, its pathogenesis and natural course are not fully understood. The overall prevalence in the United States is 6–10% and is fourfold to fivefold greater among infertile women.

▶ Clinical Findings

Women with endometriosis will complain of pelvic pain, which may be associated with infertility, dyspareunia, or rectal pain with bleeding. Initially, pain tends to start 2–7 days before the onset of menses and becomes increasingly severe until flow slackens. With increasing duration of disease, pain may become continuous. Pelvic examination may disclose tender nodules in the cul-de-sac or rectovaginal septum, uterine retroversion with decreased uterine mobility, cervical motion tenderness, or an adnexal mass or tenderness. However, most women with endometriosis have a normal pelvic examination.

Endometriosis must be distinguished from PID, ovarian neoplasms, and uterine myomas. Bowel invasion by endometrial tissue may produce blood in the stool that must be distinguished from bowel neoplasm. Paradoxically, the severity of pain associated with endometriosis may be inversely related to the anatomic extent of the disease.

Imaging is of limited value. Ultrasound examination will often reveal complex fluid-filled masses that cannot be distinguished from neoplasms. MRI is more sensitive and specific than ultrasound, particularly in the diagnosis of retroperitoneal lesions. However, the clinical diagnosis of endometriosis is presumptive and usually confirmed by laparoscopy.

▶ Treatment

A. Medical Treatment

Medical treatment, using a variety of hormonal therapies, is effective in the amelioration of pain associated with

endometriosis. However, there is no evidence that any of these agents increase the likelihood of pregnancy. Their preoperative use is of questionable value in reducing the difficulty of surgery. Most of these regimens are designed to inhibit ovulation over 4–9 months and lower hormone levels, thus preventing cyclic stimulation of endometriotic implants and inducing atrophy. The optimum duration of therapy is not clear, and the relative merits in terms of side effects and long-term risks and benefits show insignificant differences when compared with each other and, in mild cases, with placebo. Current research for more effective and acceptable long-term medical therapy is focusing on aromatase inhibitors and selective progesterone receptor modulators. Commonly used medical regimens include the following:

1. The GnRH analogs such as nafarelin nasal spray, 0.2–0.4 mg twice daily, or long-acting injectable leuprolide acetate, 3.75 mg intramuscularly monthly, used for 6 months, suppress ovulation. Side effects of vasomotor symptoms and bone demineralization may be relieved by “add-back” therapy such as conjugated equine estrogen, 0.625 mg and norethindrone, 5 mg orally daily.
2. Danazol is used for 4–6 months in the lowest dose necessary to suppress menstruation, usually 200–400 mg orally twice daily. Danazol has a high incidence of androgenic side effects, including decreased breast size, weight gain, acne, and hirsutism.
3. Any of the combination oral contraceptives, the contraceptive patch, or vaginal ring may be used continuously for 6–12 months. Breakthrough bleeding can be treated with conjugated estrogens, 1.25 mg orally daily for 1 week, or estradiol, 2 mg daily orally for 1 week.
4. Medroxyprogesterone acetate, 100 mg intramuscularly every 2 weeks for four doses and then 100 mg every 4 weeks; add oral estrogen or estradiol valerate, 30 mg intramuscularly, for breakthrough bleeding. Use for 6–9 months.
5. Low-dose oral contraceptives can also be given cyclically; prolonged suppression of ovulation will often inhibit further stimulation of residual endometriosis, especially if taken after one of the therapies mentioned above.
6. Aromatase inhibitors, such as letrozole, 2.5 mg orally daily, have been shown, on an investigational basis, to be useful in the treatment of endometriosis resistant to other therapies.
7. Analgesics, with or without codeine, may be needed during menses. NSAIDs may be helpful.

B. Surgical Measures

Surgical treatment of endometriosis—particularly extensive disease—is effective both in reducing pain and in promoting fertility. Laparoscopic ablation of endometrial implants along with uterine nerve ablation significantly reduces pain. Ablation of implants and, if necessary, removal of ovarian endometriomas enhance fertility, although subsequent pregnancy rates are related to the severity of disease. Women with disabling pain who no longer desire childbearing can be

treated definitively with total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO).

► Prognosis

The prognosis for reproductive function in early or moderately advanced endometriosis is good with conservative therapy. TAH-BSO is curative for patients with severe and extensive endometriosis with pain.

► When to Refer

Refer to a gynecologist for laparoscopic diagnosis or treatment.

► When to Admit

Rarely necessary except for acute abdomen associated with ruptured or bleeding endometrioma.

PELVIC ORGAN PROLAPSE

► General Considerations

Cystocele, rectocele, and enterocele are vaginal hernias commonly seen in multiparous women. Cystocele is a hernia of the bladder wall into the vagina, causing a soft anterior fullness. Cystocele may be accompanied by urethrocele, which is not a hernia but a sagging of the urethra following its detachment from the pubic symphysis during childbirth. Rectocele is a herniation of the terminal rectum into the posterior vagina, causing a collapsible pouch-like fullness. Enterocele is a vaginal vault hernia containing small intestine, usually in the posterior vagina and resulting from a deepening of the pouch of Douglas. Two or all three types of hernia may occur in combination. Risk factors may include vaginal birth, genetic predisposition, advancing age, prior pelvic surgery, connective tissue disorders, and increased intra-abdominal pressure associated with obesity or straining associated with chronic constipation.

► Classification

A simple classification system, the Baden-Walker System, standardizes the degree of descent of the anterior vaginal wall, cervix or vaginal apex, and the posterior vaginal wall. The degree of prolapse can be evaluated by having the woman perform the Valsalva maneuver while in the lithotomy position. In stage I prolapse, the presenting anatomy descends halfway to the hymen; in stage II prolapse, to the hymen; in stage III prolapse, halfway past the hymen; and in stage IV prolapse, there is the maximum possible descent. Evaluation of the ability to empty the bladder should be evaluated by measuring postvoid residual. If stress incontinence is not present on Valsalva, the prolapse should be reduced to evaluate the possibility of potential post-repair incontinence.

► Clinical Findings

Symptoms of pelvic organ prolapse may include sensation of a bulge or protrusion in the vagina, urinary or fecal incontinence, a sense of incomplete bladder emptying, and dyspareunia. The cause of pelvic organ prolapse, including prolapse of the uterus, vaginal apex, and anterior or posterior vaginal walls, is likely multifactorial.

► Treatment

The type of therapy depends on the extent of prolapse and the patient's age and her desire for menstruation, pregnancy, and coitus.

A. General Measures

Supportive measures include a high-fiber diet. Weight reduction in obese patients and limitation of straining and lifting are helpful. Pessaries may reduce cystocele, rectocele, or enterocele temporarily and are helpful in women who do not wish to undergo surgery or who are chronically ill.

B. Surgical Measures

The only cure for symptomatic cystocele, rectocele, enterocele, or stress urinary incontinence is corrective surgery.

The most common surgical procedure is vaginal or abdominal hysterectomy with vaginal vault suspension by either uterosacral or sacrospinous fixation vaginally or abdominal sacral colpopexy. Since stress incontinence is common after vault suspension procedures, an anti-incontinence procedure should be considered. If the patient desires pregnancy, a partial resection of the cervix with plication of the cardinal ligaments can be attempted. For elderly women who do not desire coitus, colpocleisis, the partial obliteration of the vagina, is surgically simple and effective. Uterine suspension with sacrospinous cervicocolpopexy may be an effective approach in older women who wish to avoid hysterectomy but preserve coital function.

► When to Refer

- Refer to urogynecologist or gynecologist for stress urinary incontinence or stage III prolapse.
- Refer if nonsurgical therapy is ineffective.

ACOG Committee on Practice Bulletins—Gynecology. ACOG Practice Bulletin No. 85: Pelvic organ prolapse. *Obstet Gynecol*. 2007 Sep;110(3):717–29. [PMID: 17766624]

PELVIC INFLAMMATORY DISEASE (Salpingitis, Endometritis)

ESSENTIALS OF DIAGNOSIS

- Uterine, adnexal, or cervical motion tenderness.
- Absence of a competing diagnosis.

▶ General Considerations

PID is a polymicrobial infection of the upper genital tract associated with the sexually transmitted organisms *N gonorrhoeae* and *Chlamydia trachomatis* as well as endogenous organisms, including anaerobes, *Haemophilus influenzae*, enteric gram-negative rods, and streptococci. It is most common in young, nulliparous, sexually active women with multiple partners. Other risk markers include non-white race, douching, and smoking. The use of oral contraceptives or barrier methods of contraception may provide significant protection.

Tuberculous salpingitis is rare in the United States but more common in developing countries; it is characterized by pelvic pain and irregular pelvic masses not responsive to antibiotic therapy. It is not sexually transmitted.

▶ Clinical Findings

A. Symptoms and Signs

Patients with PID may have lower abdominal pain, chills and fever, menstrual disturbances, purulent cervical discharge, and cervical and adnexal tenderness. Right upper quadrant pain (Fitz-Hugh and Curtis syndrome) may indicate an associated perihepatitis. However, diagnosis of PID is complicated by the fact that many women may have subtle or mild symptoms that are not readily recognized as PID.

B. Minimum Diagnostic Criteria

Women with uterine adnexal or cervical motion tenderness should be considered to have PID and be treated with antibiotics unless there is a competing diagnosis such as ectopic pregnancy or appendicitis.

C. Additional Criteria

The following criteria may be used to enhance the specificity of the diagnosis: (1) oral temperature greater than 38.3 °C, (2) abnormal cervical or vaginal discharge with white cells on saline microscopy, (3) elevated erythrocyte sedimentation rate, (4) elevated C-reactive protein, and (5) laboratory documentation of cervical infection with *N gonorrhoeae* or *C trachomatis*. Endocervical culture should be performed routinely, but treatment should not be delayed while awaiting results.

D. Definitive Criteria

In selected cases where the diagnosis based on clinical or laboratory evidence is uncertain, the following criteria may be used: (1) histopathologic evidence of endometritis on endometrial biopsy, (2) transvaginal sonography or MRI showing thickened fluid-filled tubes with or without free pelvic fluid or tubo-ovarian complex, and (3) laparoscopic abnormalities consistent with PID.

▶ Differential Diagnosis

Appendicitis, ectopic pregnancy, septic abortion, hemorrhagic or ruptured ovarian cysts or tumors, twisted ovarian cyst, degeneration of a myoma, and acute enteritis must be

considered. PID is more likely to occur when there is a history of PID, recent sexual contact, recent onset of menses, or an IUD in place or if the partner has a sexually transmitted disease. Acute PID is highly unlikely when recent intercourse has not taken place or an IUD is not being used. A sensitive serum pregnancy test should be obtained to rule out ectopic pregnancy. Culdocentesis will differentiate hemoperitoneum (ruptured ectopic pregnancy or hemorrhagic cyst) from pelvic sepsis (salpingitis, ruptured pelvic abscess, or ruptured appendix). Pelvic and vaginal ultrasonography is helpful in the differential diagnosis of ectopic pregnancy of over 6 weeks. Laparoscopy is often used to diagnose PID, and it is imperative if the diagnosis is not certain or if the patient has not responded to antibiotic therapy after 48 hours. The appendix should be visualized at laparoscopy to rule out appendicitis. Cultures obtained at the time of laparoscopy are often specific and helpful.

▶ Treatment

A. Antibiotics

Early treatment with appropriate antibiotics effective against *N gonorrhoeae*, *C trachomatis*, and the endogenous organisms listed above is essential to prevent long-term sequelae. The sexual partner should be examined and treated appropriately.

Two inpatient regimens have been shown to be effective in the treatment of acute PID: (1) Cefoxitin, 2 g intravenously every 6 hours, or cefotetan, 2 g intravenously every 12 hours, plus doxycycline, 100 mg intravenously or orally every 12 hours. This regimen is continued for at least 24 hours after the patient shows significant clinical improvement. Doxycycline, 100 mg twice daily, should be continued to complete a total of 14 days therapy. If a tubo-ovarian abscess is present, it is advisable to add clindamycin, 450 mg orally four times daily, or metronidazole, 500 mg twice daily, for 14 days to the doxycycline to provide more effective anaerobic coverage. (2) Clindamycin, 900 mg intravenously every 8 hours, plus gentamicin intravenously in a loading dose of 2 mg/kg followed by 1.5 mg/kg every 8 hours. This regimen is continued for at least 24 hours after the patient shows significant clinical improvement and is followed by either clindamycin, 450 mg four times daily, or doxycycline, 100 mg twice daily, to complete a total of 14 days of therapy. When a tubo-ovarian abscess is present, clindamycin, rather than doxycycline, should be given.

Data on the role of ampicillin-sulbactam, 3 g intravenously every 6 hours, plus doxycycline, 100 mg intravenously or orally every 12 hours, are limited.

The recommended outpatient regimen is either a single dose of cefoxitin, 2 g intramuscularly, with probenecid, 1 g orally, ceftriaxone, 250 mg intramuscularly, or a single dose of another parenteral third-generation cephalosporin plus doxycycline, 100 mg orally twice daily, for 14 days. If parenteral cephalosporin cannot be used, levofloxacin (500 mg orally once daily) or ofloxacin (400 mg twice daily) for 14 days with or without metronidazole (500 mg twice daily) for 14 days may be used if the community prevalence and the individual risk of gonorrhea is low (see Chapter 33).

B. Surgical Measures

Tubo-ovarian abscesses may require surgical excision or transcuteaneous or transvaginal aspiration. Unless rupture is suspected, institute high-dose antibiotic therapy in the hospital, and monitor therapy with ultrasound. In 70% of cases, antibiotics are effective; in 30%, there is inadequate response in 48–72 hours, and surgical intervention is required. Unilateral adnexectomy is acceptable for unilateral abscess. Hysterectomy and bilateral salpingo-oophorectomy may be necessary for overwhelming infection or in cases of chronic disease with intractable pelvic pain.

► Prognosis

In spite of treatment, long-term sequelae, including repeated episodes of infection, chronic pelvic pain, dyspareunia, ectopic pregnancy, or infertility, develop in one-fourth of women with acute disease. The risk of infertility increases with repeated episodes of salpingitis: it is estimated at 10% after the first episode, 25% after a second episode, and 50% after a third episode.

► When to Admit

The following patients with acute PID should be admitted for intravenous antibiotic therapy:

- The patient has a tubo-ovarian abscess.
- The patient is pregnant.
- The patient is unable to follow or tolerate an outpatient regimen.
- The patient has not responded clinically to outpatient therapy.
- The patient has severe illness, nausea and vomiting, or high fever.
- Another surgical emergency such as appendicitis cannot be ruled out.

OVARIAN CANCER & OVARIAN TUMORS

ESSENTIALS OF DIAGNOSIS

- Vague gastrointestinal discomfort.
- Pelvic pressure and pain.
- Many cases of early-stage cancer are asymptomatic.
- Pelvic examination, serum CA 125, and ultrasound are mainstays of diagnosis.

► General Considerations

Ovarian tumors are common. Most are benign, but malignant ovarian tumors are the leading cause of death from reproductive tract cancer. The wide range of types and patterns of ovarian tumors is due to the complexity of ovarian embryology and differences in tissues of origin.

In women with no family history of ovarian cancer, the lifetime risk is 1.6%, whereas a woman with one affected first-degree relative has a 5% lifetime risk. With two or more affected first-degree relatives, the risk is 7%. Approximately 3% of women with two or more affected first-degree relatives will have a hereditary ovarian cancer syndrome with a lifetime risk of 40%. Women with a *BRCA1* gene mutation have a 45% lifetime risk of ovarian cancer and those with a *BRCA2* mutation a 25% risk. These women should be screened annually with transvaginal sonography and serum CA 125 testing, and prophylactic oophorectomy is recommended by age 35 or whenever childbearing is completed because of the high risk of disease. The benefits of such screening for women with one or no affected first-degree relatives are unproved, and the risks associated with unnecessary surgical procedures may outweigh the benefits in low-risk women.

► Clinical Findings

A. Symptoms and Signs

Unfortunately, most women with both benign and malignant ovarian neoplasms are either asymptomatic or experience only mild nonspecific gastrointestinal symptoms or pelvic pressure. Women with early disease are typically detected on routine pelvic examination. Women with advanced malignant disease may experience abdominal pain and bloating, and a palpable abdominal mass with ascites is often present.

B. Laboratory Findings

An elevated serum CA 125 (> 35 units) indicates a greater likelihood that an ovarian tumor is malignant. CA 125 is elevated in 80% of women with epithelial ovarian cancer overall but in only 50% of women with early disease. Furthermore, serum CA 125 may be elevated in premenopausal women with benign disease such as endometriosis.

C. Imaging Studies

Transvaginal sonography is useful for screening high-risk women but has inadequate sensitivity for screening low-risk women. Ultrasound is helpful in differentiating ovarian masses that are benign and likely to resolve spontaneously from those with malignant potential. Color Doppler imaging may further enhance the specificity of ultrasound diagnosis.

► Differential Diagnosis

Once an ovarian mass has been detected, it must be categorized as functional, benign neoplastic, or potentially malignant. Predictive factors include age, size of the mass, ultra-

sound configuration, CA 125 levels, the presence of symptoms, and whether the mass is unilateral or bilateral. In a premenopausal woman, an asymptomatic, mobile, unilateral, simple cystic mass less than 7.5 cm may be observed for 4–6 weeks. Most will resolve spontaneously. If the mass is larger or unchanged on repeat pelvic examination and transvaginal sonography, surgical evaluation is required.

Most ovarian masses in postmenopausal women require surgical evaluation. However, a postmenopausal woman with an asymptomatic unilateral simple cyst less than 5 cm in diameter and a normal CA 125 level may be followed closely with transvaginal sonography. All others require surgical evaluation.

Laparoscopy may be used when an ovarian mass is small enough to be removed with a laparoscopic approach. If malignancy is suspected, preoperative workup should include chest radiograph, evaluation of liver and kidney function, and hematologic indices.

► Treatment

If a malignant ovarian mass is suspected, surgical evaluation should be performed by a gynecologic oncologist. For benign neoplasms, tumor removal or unilateral oophorectomy is usually performed. For ovarian cancer in an early stage, the standard therapy is complete surgical staging followed by abdominal hysterectomy and bilateral salpingo-oophorectomy with omentectomy and selective lymphadenectomy. With more advanced disease, aggressive removal of all visible tumor improves survival. Except for women with low-grade ovarian cancer in an early stage, postoperative chemotherapy is indicated (Table 39–10). Several chemotherapy regimens are effective, such as the combination of cisplatin or carboplatin with paclitaxel, with clinical response rates of up to 60–70% (Table 39–11).

► Prognosis

Unfortunately, approximately 75% of women with ovarian cancer are diagnosed with advanced disease after regional or distant metastases have become established. The overall 5-year survival is approximately 17% with distant metastases, 36% with local spread, and 89% with early disease.

► When to Refer

If a malignant mass is suspected, surgical evaluation should be performed by a gynecologic oncologist.

American College of Obstetricians and Gynecologists Practice Bulletin. ACOG Practice Bulletin No. 89. Elective and risk-reducing salpingo-oophorectomy. *Obstet Gynecol.* 2008 Jan;111(1):231–41. [PMID: 18165419]
Chobanian N et al. Ovarian cancer. *Surg Clin North Am.* 2008 Apr;88(2):285–99. [PMID: 18381114]

POLYCYSTIC OVARY SYNDROME

ESSENTIALS OF DIAGNOSIS

- Clinical or biochemical evidence of hyperandrogenism.

- Oligoovulation or anovulation.
- Polycystic ovaries on ultrasonography.

► General Considerations

Polycystic ovary syndrome (PCOS) is a common endocrine disorder affecting 5–10% of women of reproductive age and is a common source of chronic anovulation. The underlying etiology is unknown, although most of these women have an aberration of gonadotropin stimulation. This is manifested by an increased release of luteinizing hormone (LH) relative to follicle-stimulating hormone (FSH), resulting in an increased production of androstenedione and testosterone by ovarian theca cells. The androstenedione undergoes aromatization to estrone and converted to estradiol in the ovarian granulosa cells. The high estrone levels are believed to cause suppression of pituitary FSH and constant LH stimulation of the ovary results in anovulation, multiple cysts, and theca cell hyperplasia with excess androgen output.

Women with Cushing syndrome, congenital adrenal hyperplasia, and androgen-secreting adrenal tumors also tend to have high circulating androgen levels and anovulation with polycystic ovaries; these disorders must be ruled out in women with presumed PCOS.

► Clinical Findings

PCOS is manifested by hirsutism (50% of cases), obesity (40%), and virilization (20%). Fifty percent of patients have amenorrhea, 30% have abnormal uterine bleeding, and 20% have normal menstruation. In addition, they show insulin resistance and hyperinsulinemia, and these women are at increased risk for early-onset type 2 diabetes. The patients are generally infertile, although they may ovulate occasionally. They have an increased long-term risk of cancer of the endometrium because of unopposed estrogen secretion.

► Differential Diagnosis

Anovulation in the reproductive years may also be due to: (1) premature menopause (high FSH and LH levels); (2) rapid weight loss, extreme physical exertion (normal FSH and LH levels for age), or obesity; (3) discontinuation of hormonal contraceptives (anovulation for 6 months or more occasionally occurs); (4) pituitary adenoma with elevated prolactin (galactorrhea may or may not be present); and (5) hyperthyroidism or hypothyroidism. When amenorrhea has persisted for 6 months or more without a diagnosis, FSH, LH, prolactin, and TSH should be checked. Women with clinical evidence of androgen excess should have total testosterone, DHEA-S, and 17-hydroxyprogesterone measured. A 10-day course of progestin (eg, medroxyprogesterone acetate, 10 mg/d orally) will cause withdrawal bleeding if estrogen levels are high. This will aid in the diagnosis and prevent endometrial hyperplasia. Because of the high risk of insulin resistance and dyslipidemia, all women with PCOS should have a 2-hour glucose determination after a 75-g glucose load and a lipoprotein profile.

► Treatment

In obese patients with PCOS, weight reduction is often effective. If the patient wishes to become pregnant, clomiphene or other drugs can be used for ovulatory stimulation. (See Infertility, this chapter.) The addition of dexamethasone, 0.5 mg orally at bedtime, to a clomiphene regimen may increase the likelihood of ovulation by suppression of ACTH and any circulating adrenal androgens. For women who are unresponsive to clomiphene, 3- to 6-month courses of the oral hypoglycemic agents, metformin, 500 mg three times daily, or pioglitazone, 30–45 mg daily, may bring resumption of regular cycles and ovulation. These agents reduce the hyperinsulinemia and hyperandrogenemia in PCOS.

If the patient does not desire pregnancy, medroxyprogesterone acetate, 10 mg/d orally for the first 10 days of each month, should be given to ensure regular shedding of the endometrium and avoid hyperplasia. If contraception is desired, a low-dose combination oral contraceptive can be used; this is also useful in controlling hirsutism, for which treatment must be continued for 6–12 months before results are seen.

Hirsutism may be managed with epilation and electrolysis. Dexamethasone, 0.5 mg orally each night, is helpful in women with excess adrenal androgen secretion. Spironolactone, an aldosterone antagonist, is also useful for hirsutism in doses of 25 mg three or four times daily. Flutamide, 250 mg orally daily, and finasteride, 5 mg orally daily, are also effective for treating hirsutism. Because these three agents are potentially teratogenic, they should be used only in conjunction with secure contraception.

► When to Refer

- If expertise in diagnosis is needed.
- If patient is infertile.

FEMALE SEXUAL DYSFUNCTION

► General Considerations

Female sexual dysfunction is a common problem. Depending on the questions asked, surveys have shown that from 35% to 98% of women report sexual concerns. Questions related to sexual functioning should be asked as part of the routine medical history. Three helpful questions are, “Are you currently involved in a sexual relationship?” “With men, women, or both?” and “Are there any sexual concerns or pain with sex?”. If the woman is not involved in a sexual relationship, she should be asked about any concerns that are contributing to a lack of sexual behavior. If a history of sexual dysfunction is elicited, a complete history of factors that may affect sexual function should be taken. These factors include her reproductive history (including

pregnancies and mode of delivery) as well as history of infertility, sexually transmitted diseases, rape, gynecologic or urologic disorders, endocrine abnormalities (such as diabetes mellitus or thyroid disease), neurologic problems, cardiovascular disease, psychiatric disease, and current prescription and over-the-counter drug use. A detailed history of the specific sexual dysfunction should be elicited, and a gynecologic examination should focus on findings that may contribute to her sexual complaints.

► Etiology

A. Disorders of Sexual Desire

Sexual desire in women is a complex and poorly understood phenomenon. Emotion is a key factor in sexual desire. Anger toward a partner, fear or anxiety related to previous sexual encounters, or history of sexual abuse may contribute. Physical factors, such as chronic illness, fatigue, depression, and specific medical disorders (such as diabetes mellitus, thyroid disease, or adrenal insufficiency) may contribute to a lack of desire. Attitudes toward aging and menopause may play a role. In addition, sexual desire may be influenced by other sexual dysfunctions, such as arousal disorders, dyspareunia, or anorgasmia.

B. Sexual Arousal Disorders

Sexual arousal disorders may be both subjective and objective. Sexual stimulation normally leads to genital vasocongestion and lubrication. Some women may have a physiologic response to sexual stimuli but may not subjectively feel aroused because of factors such as distractions; negative expectations; anxiety; fatigue; depression; or medications, such as selective serotonin reuptake inhibitors (SSRIs) or oral contraceptives. Other women may lack both a subjective and physiologic response to sexual stimuli related to vaginal atrophy.

C. Orgasmic Disorders

In spite of subjective and physiologic arousal, women may experience a marked delay in orgasm, diminished sensation of an orgasm, or anorgasmia. The etiology is complex and typically multifactorial, but the disorder is usually amenable to treatment.

D. Dyspareunia

Dyspareunia may be caused by vulvovaginitis, pelvic disease (such as endometriosis or chronic pelvic inflammatory disease), vulvodinia, vaginal atrophy, or vaginismus. Vulvodinia is the most frequent cause of dyspareunia in premenopausal women. It is characterized by a sensation of burning along with other symptoms, including pain, itching, stinging, irritation, and rawness. The discomfort may be constant or intermittent, focal or diffuse, and experienced as either deep or superficial. There are generally no physical findings except minimal erythema that may be associated in a subset of patients with vulvodinia, those with vulvar vestibulitis. Vulvar vestibulitis is normally asymptomatic, but pain is associated with touching or

pressure on the vestibule, such as with vaginal entry or insertion of a tampon. Pain occurring with deep thrusting during coitus is usually due to acute or chronic infection of the cervix, uterus, or adnexa; endometriosis; adnexal tumors; or adhesions resulting from prior pelvic disease or operation. Vaginismus is voluntary or involuntary contraction of the muscles around the introitus. It results from fear, pain, sexual trauma, or a negative attitude toward sex, often learned in childhood.

► Treatment

A. Disorders of Sexual Desire

In the absence of specific medical disorders, arousal or orgasmic disorders or dyspareunia, the focus of therapy is psychological. Cognitive behavioral therapy, sexual therapy, and marital therapy may all play a role. Success with pharmacologic therapy, particularly the use of dopamine agonists or testosterone with estrogen has been reported, but data from large long-term clinical trials are lacking.

B. Sexual Arousal Disorders

As with disorders of sexual desire, arousal disorders may respond to psychological therapy. Specific pharmacologic therapy is lacking. The use of the phosphodiesterase inhibitors used in men does not appear to benefit the majority of women with sexual arousal disorders.

C. Orgasmic Disorders

For many women, brief sexual counseling along with the use of educational books (such as *For Yourself*, by Lonnie Barbach) may be adequate therapy. Also, the FDA has approved a vacuum device, the EROS-CTD, that increases clitoral enlargement and improves the likelihood of orgasm.

D. Dyspareunia

Specific medical disorders, such as endometriosis, vulvovaginitis, or vaginal atrophy, should be treated as outlined in other sections of this chapter. Vaginismus may be treated initially with sexual counseling and education on anatomy and sexual functioning. The patient can be instructed in self-dilation, using a lubricated finger or test tubes of graduated sizes. Before coitus (with adequate lubrication) is attempted, the patient—and then her partner—should be able to easily and painlessly introduce two fingers into the vagina. Penetration should never be forced, and the woman should always be the one to control the depth of insertion during dilation or intercourse. Injection of botulinum toxin has been used successfully in refractory cases.

Since the cause of vulvodynia is unknown, management is difficult. Few treatment approaches have been subjected to methodologically rigorous trials. A variety of topical agents have been tried, although only topical anesthetics (eg, estrogen cream and a compounded mixture of topical amitriptyline 2% and baclofen 2% in a water washable base) have been useful in relieving vulvodynia. Useful oral medications include tricyclic antidepressants,

such as amitriptyline in gradually increasing doses from 10 mg/d to 75–100 mg/d; various SSRIs; and anticonvulsants, such as gabapentin, starting at 300 mg three times daily and increasing to 1200 mg three times daily. Biofeedback and physical therapy, with a physical therapist experienced with the treatment of vulvar pain, have been shown to be helpful. Surgery—usually consisting of vestibulectomy—has been useful for women with introital dyspareunia.

► When to Refer

- When symptoms or concerns persist despite first-line therapy.
- For expertise in surgical procedures.

INFERTILITY

A couple is said to be infertile if pregnancy does not result after 1 year of normal sexual activity without contraceptives. About 25% of couples experience infertility at some point in their reproductive lives; the incidence of infertility increases with age. The male partner contributes to about 40% of cases of infertility, and a combination of factors is common.

A. Initial Testing

During the initial interview, the clinician can present an overview of infertility and discuss a plan of study. Separate private consultations are then conducted, allowing appraisal of psychosexual adjustment without embarrassment or criticism. Pertinent details (eg, sexually transmitted disease or prior pregnancies) must be obtained. The ill effects of cigarettes, alcohol, and other recreational drugs on male fertility should be discussed. Prescription drugs that impair male potency should be discussed as well. The gynecologic history should include queries regarding the menstrual pattern. The present history includes use and types of contraceptives, douches, libido, sex techniques, frequency and success of coitus, and correlation of intercourse with time of ovulation. Family history includes repeated spontaneous abortions and maternal DES use.

General physical and genital examinations are performed on the female partner, including screening pelvic ultrasound and hysterosalpingography if there is a history suggestive of pelvic disease. Basic laboratory studies include complete blood count, urinalysis, cervical culture for *Chlamydia*, rubella antibody determination, and thyroid function tests. Tay-Sachs screening should be offered if both parents are Ashkenazi Jews as well as couples of French-Canadian or Cajun ancestry; sickle cell screening should be offered if both parents are black.

If the woman has regular menses, the likelihood of ovulatory cycles is very high. A luteal phase serum progesterone

terone above 3 ng/mL establishes ovulation. Couples should be advised that coitus resulting in conception occurs during the 6-day period ending with the day of ovulation. Self-performed urine tests for the midcycle LH surge at ovulation can enhance basal temperature charting. Semen analysis is recommended; the male partner is instructed to bring a complete ejaculate for analysis. Men must abstain from sexual activity for at least 3 days before the semen is obtained. A clean, dry, wide-mouthed bottle for collection is preferred. Semen should be examined within 1–2 hours after collection. Semen is considered normal with the following minimum values: volume, 2.0 mL; concentration, 20 million sperm per milliliter; motility, $\geq 50\%$ forward progression, $\geq 25\%$ rapid progression; and normal forms, 30%. If the sperm count is abnormal, further evaluation includes physical examination of the male partner and a search for exposure to environmental and workplace toxins, alcohol or drug abuse.

B. Further Testing

1. Gross deficiencies of sperm (number, motility, or appearance) require repeat analysis. Zona-free hamster egg penetration tests are available to evaluate the ability of human sperm to fertilize an egg.
2. Obvious obstruction of the uterine tubes requires assessment for microsurgery or in vitro fertilization.
3. Absent or infrequent ovulation requires additional laboratory evaluation. Elevated FSH and LH levels indicate ovarian failure causing premature menopause. Elevated LH levels in the presence of normal FSH levels confirm the presence of polycystic ovaries. Elevation of blood prolactin (PRL) levels suggests pituitary microadenoma.
4. Ultrasound monitoring of folliculogenesis may reveal the occurrence of unruptured luteinized follicles.
5. Endometrial biopsy in the luteal phase associated with simultaneous serum progesterone levels will rule out luteal phase deficiency.
6. Hysterosalpingography using an oil dye is performed within 3 days following the menstrual period if structural abnormalities are suspected. This radiographic study will demonstrate uterine abnormalities (septa, polyps, submucous myomas) and tubal obstruction. A repeat radiograph 24 hours later will confirm tubal patency if there is wide pelvic dispersion of the dye. This test has been associated with an increased pregnancy rate if an oil-based rather than water-soluble contrast medium is used. If the woman has had prior pelvic inflammation, one should give doxycycline, 100 mg orally twice daily, beginning immediately before and for 7 days after the radiographic study.
7. If hysterosalpingography or history suggests tubal disease, and in vitro fertilization (IVF) is recommended as the primary treatment option, laparoscopy is indicated. In unexplained infertility, approximately 25% of women whose basic evaluation is normal will have abnormal findings on laparoscopy that explain their infertility (eg, peritubal adhesions, endometriotic implants).

► Treatment

A. Medical Measures

Fertility may be restored by treatment of endocrine abnormalities, particularly hypothyroidism or hyperthyroidism. Antibiotic treatment of cervicitis is of value. Women who engage in vigorous athletic training often have low sex hormone levels; fertility improves with reduced exercise and some weight gain.

B. Surgical Measures

Excision of ovarian tumors or ovarian foci of endometriosis can improve fertility. Microsurgical relief of tubal obstruction due to salpingitis or tubal ligation will reestablish fertility in a significant number of cases, although with severe disease or proximal obstruction, IVF is preferable. Peritubal adhesions or endometriotic implants often can be treated via laparoscopy.

In a male with a varicocele, sperm characteristics are often improved following surgical treatment.

C. Induction of Ovulation

1. Clomiphene citrate—Clomiphene citrate stimulates gonadotropin release, especially LH. Consequently, plasma estrone (E_1) and estradiol (E_2) also rise, reflecting ovarian follicle maturation. If E_2 rises sufficiently, an LH surge occurs to trigger ovulation.

After a normal menstrual period or induction of withdrawal bleeding with progestin, one should give 50 mg of clomiphene orally daily for 5 days. If ovulation does not occur, the dosage is increased to 100 mg daily for 5 days. If ovulation still does not occur, the course is repeated with 150 mg daily and then 200 mg daily for 5 days, with the addition of chorionic gonadotropin, 10,000 units intramuscularly, 7 days after clomiphene.

The rate of ovulation following this treatment is 90% in the absence of other infertility factors. The pregnancy rate is high. Twinning occurs in 5% of these patients, and three or more fetuses are found in rare instances (< 0.5% of cases).

In the presence of increased androgen production (DHEA-S > 200 mcg/dL), the addition of dexamethasone, 0.5 mg orally, or prednisone, 5 mg orally, at bedtime, improves the response to clomiphene. Dexamethasone should be discontinued after pregnancy is confirmed.

2. Bromocriptine—Bromocriptine is used only if PRL levels are elevated and there is no withdrawal bleeding following progesterone administration (otherwise, clomiphene is used). To minimize side effects (nausea, diarrhea, dizziness, headache, fatigue), bromocriptine should be taken with meals. The initial dosage is 2.5 mg orally once daily, increased to two or three times daily in increments of 1.25 mg. The drug is discontinued once pregnancy has occurred.

3. Human menopausal gonadotropins (hMG)—hMG or recombinant FSH is indicated in cases of hypogonadotropism and most other types of anovulation (exclusive of ovarian failure). Because of the complexities, laboratory tests, and expense associated with this treatment, these patients should be referred to an infertility specialist.

D. Treatment of Endometriosis

See above.

E. Artificial Insemination in Azoospermia

If azoospermia is present, artificial insemination by a donor usually results in pregnancy, assuming female function is normal. The use of frozen sperm is currently preferable to fresh sperm because the frozen specimen can be held pending cultures and blood test results for sexually transmitted diseases, including HIV infection.

F. Assisted Reproductive Technologies (ART)

Couples who have not responded to traditional infertility treatments, including those with tubal disease, severe endometriosis, oligospermia, and immunologic or unexplained infertility, may benefit from IVF, gamete intrafallopian transfer (GIFT), and zygote intrafallopian transfer (ZIFT). These techniques are complex and require a highly organized team of specialists. All of the procedures involve ovarian stimulation to produce multiple oocytes, oocyte retrieval by transvaginal sonography–guided needle aspiration, and handling of the oocytes outside the body. With IVF, the eggs are fertilized in vitro and the embryos transferred to the uterine fundus. Intracytoplasmic sperm injection (ICSI) allows fertilization with a single sperm. It was originally intended for couples with male factor infertility, but it is now used in more than half of all IVF procedures in the United States.

GIFT involves the placement of sperm and eggs in the uterine tube by laparoscopy or minilaparotomy. With ZIFT, fertilization occurs in vitro, and the early development of the embryo occurs in the uterine tube after transfer by laparoscopy or minilaparotomy. The latter two procedures are used infrequently.

► Prognosis

The prognosis for conception and normal pregnancy is good if minor (even multiple) disorders can be identified and treated; it is poor if the causes of infertility are severe, untreatable, or of prolonged duration (over 3 years).

It is important to remember that in the absence of identifiable causes of infertility, 60% of couples will achieve a pregnancy within 3 years. Couples with unexplained infertility who do not achieve pregnancy within 3 years may be offered ovulation induction or assisted reproductive technology. Also, offering appropriately timed information about adoption is considered part of a complete infertility regimen.

► When to Refer

Refer to reproductive endocrinologist if ART are indicated.

CONTRACEPTION

Voluntary control of childbearing benefits women, men, and their children. Contraception should be available to all women and men of reproductive ages. Education about contraception and access to contraceptive pills or devices are especially important for sexually active teenagers and for women following childbirth or abortion.

1. Oral Contraceptives

A. Combined Oral Contraceptives

1. Efficacy and methods of use—Oral contraceptives have a perfect use failure rate of 0.3% and a typical use failure rate of 8%. Their primary mode of action is suppression of ovulation. The pills can be initially started on the first day of the menstrual cycle, the first Sunday after the onset of the cycle or on any day of the cycle. If started on any day other than the first day of the cycle, a backup method should be used. There are also pills packaged to be taken continuously for 84 days, followed by 7 days of placebos. If an active pill is missed at any time, and no intercourse occurred in the past 5 days, two pills should be taken immediately and a backup method should be used for 7 days. If intercourse occurred in the previous 5 days, emergency contraception should be used immediately, and the pills restarted the following day. A backup method should be used for 5 days.

2. Benefits of oral contraceptives—Noncontraceptive benefits of oral contraceptives include lighter menses, reducing the likelihood of anemia. Dysmenorrhea is relieved for most women. Functional ovarian cysts are less likely with oral contraceptive use. The risk of ovarian and endometrial cancer is decreased. The risks of salpingitis and ectopic pregnancy may be diminished. Acne is usually improved. The frequency of developing myomas is lower in long-term users (> 4 years). There is a beneficial effect on bone mass.

3. Selection of an oral contraceptive—Any of the combination oral contraceptives containing 35 mcg or less of estrogen are suitable for most women. There is some variation in potency of the various progestins in the pills, but there are essentially no clinically significant differences for most women among the progestins in the low-dose pills. Women who have acne or hirsutism may benefit from use of one of the pills containing the third-generation progestins, desogestrel, drospirenone, or norgestimate, as they are the least androgenic. A combination regimen with 84 active and 7 inert pills that results in only four menses per year is available. There is also a combination regimen that is taken continuously with no regular menses. At the end of one year's use, 58% of the women had amenorrhea, and nearly 80% reported no bleeding requiring sanitary protection. The low-dose oral contraceptives commonly used in the United States are listed in Table 18–3.

4. Drug interactions—Several drugs interact with oral contraceptives to decrease their efficacy by causing induction of microsomal enzymes in the liver, or by other

Table 18–3. Commonly used low-dose oral contraceptives.

³Multiple other brands available.

mechanisms. Some commonly prescribed drugs in this category are phenytoin, phenobarbital (and other barbiturates), primidone, topiramate, carbamazepine, and rifampin and St. John's Wort. Women taking these drugs should use another means of contraception for maximum safety.

5. Contraindications and adverse effects—Oral contraceptives have been associated with many adverse effects; they are contraindicated in some situations and should be used with caution in others (Table 18-4).

A. MYOCARDIAL INFARCTION—The risk of heart attack is higher with use of oral contraceptives, particularly with pills containing 50 mcg of estrogen or more. Cigarette smoking, obesity, hypertension, diabetes, or hypercholesterolemia increases the risk. Young nonsmoking women have minimal increased risk. Smokers over age 35 and women with other cardiovascular risk factors should use other methods of birth control.

Table 18-4. Contraindications to use of oral contraceptives.

| |
|---|
| Absolute contraindications |
| Pregnancy |
| Thrombophlebitis or thromboembolic disorders (past or present) |
| Stroke or coronary artery disease (past or present) |
| Cancer of the breast (known or suspected) |
| Undiagnosed abnormal vaginal bleeding |
| Estrogen-dependent cancer (known or suspected) |
| Benign or malignant tumor of the liver (past or present) |
| Uncontrolled hypertension |
| Diabetes mellitus with vascular disease |
| Age over 35 and smoking > 15 cigarettes daily |
| Known thrombophilia |
| Migraine with aura |
| Active hepatitis |
| Surgery or orthopedic injury requiring prolonged immobilization |
| Relative contraindications |
| Migraine without aura |
| Hypertension |
| Heart or kidney disease |
| Diabetes mellitus |
| Gallbladder disease |
| Cholestasis during pregnancy |
| Sickle cell disease (S/S or S/C type) |
| Lactation |

B. THROMBOEMBOLIC DISEASE—An increased rate of venous thromboembolism is found in oral contraceptive users, especially if the dose of estrogen is 50 mcg or more. While the overall risk is very low (15 per 100,000 woman-years), several studies have reported a twofold increased risk in women using oral contraceptives containing the progestins gestodene (not available in the United States) or desogestrel compared with women using oral contraceptives with levonorgestrel and norethindrone. Women in whom thrombophlebitis develops should stop using this method, as should those at risk for thrombophlebitis because of surgery, fracture, serious injury, or immobilization. Women with a known thrombophilia should not use oral contraceptives.

C. CEREBROVASCULAR DISEASE—Overall, a small increased risk of hemorrhagic stroke and subarachnoid hemorrhage and a somewhat greater increased risk of thrombotic stroke has been found; smoking, hypertension, and age over 35 years are associated with increased risk. Women should stop using contraceptives if such warning symptoms as severe headache, blurred or lost vision, or other transient neurologic disorders develop.

D. CARCINOMA—A relationship between long-term (3–4 years) oral contraceptive use and occurrence of cervical dysplasia and cancer has been found in various studies. A 2002 study showed that there is no increased risk of breast cancer in women aged 35–64 who are current or former users of oral contraceptives. Women with a family history of breast cancer or women who started oral contraceptive use at a young age are not at increased risk. Combination oral contraceptives reduce the risk of endometrial carcinoma by 40% after 2 years of use and 60% after 4 or more years of use. The risk of ovarian cancer is reduced by 30% with pill use for less than 4 years, by 60% with use for 5–11 years, and by 80% after 12 or more years. Rarely, oral contraceptives have been associated with the development of benign or malignant hepatic tumors; this may lead to rupture of the liver, hemorrhage, and death. The risk increases with higher dosage, longer duration of use, and older age.

E. HYPERTENSION—Oral contraceptives may cause hypertension in some women; the risk is increased with longer duration of use and older age. Women in whom hypertension develops while using oral contraceptives should use other contraceptive methods. However, with regular blood

pressure monitoring, nonsmoking women under the age of 40 with well-controlled mild hypertension may use oral contraceptives.

F. HEADACHE—Migraine or other vascular headaches may occur or worsen with pill use. If severe or frequent headaches develop while using this method, it should be discontinued. Women with migraine headaches with an aura should not use oral contraceptives.

G. LACTATION—Combined oral contraceptives can impair the quantity and quality of breast milk. While it is preferable to avoid the use of combination oral contraceptives during lactation, the effects on milk quality are small and are not associated with developmental abnormalities in infants. Combination oral contraceptives should be started no earlier than 6 weeks postpartum to allow for establishment of lactation. Progestin-only pills, levonorgestrel implants, and depot medroxyprogesterone acetate are alternatives with no adverse effects on milk quality.

H. OTHER DISORDERS—Depression may occur or be worsened with oral contraceptive use. Fluid retention may occur. Patients who had cholestatic jaundice during pregnancy may develop it while taking birth control pills.

6. Minor side effects—Nausea and dizziness may occur in the first few months of pill use. A weight gain of 2–5 lb commonly occurs. Spotting or breakthrough bleeding between menstrual periods may occur, especially if a pill is skipped or taken late; this may be helped by switching to a pill of slightly greater potency (see section C, above). Missed menstrual periods may occur, especially with low-dose pills. A pregnancy test should be performed if pills have been skipped or if two or more menstrual periods are missed. Depression, fatigue, and decreased libido can occur. Chloasma may occur, as in pregnancy, and is increased by exposure to sunlight.

B. Progestin Minipill

1. Efficacy and methods of use—Formulations containing 0.35 mg of norethindrone or 0.075 mg of norgestrel are available in the United States. Their efficacy is similar to that of combined oral contraceptives. The minipill is believed to prevent conception by causing thickening of the cervical mucus to make it hostile to sperm, alteration of ovum transport (which may account for the higher rate of ectopic pregnancy with these pills), and inhibition of implantation. Ovulation is inhibited inconsistently with this method. The minipill is begun on the first day of a menstrual cycle and then taken continuously for as long as contraception is desired.

2. Advantages—The low dose and absence of estrogen make the minipill safe during lactation; it may increase the flow of milk. It is often tried by women who want minimal doses of hormones and by patients who are over age 35. They lack the cardiovascular side effects of combination pills. The minipill can be safely used by women with sickle cell disease (S/S or S/C).

3. Complications and contraindications—Minipill users often have bleeding irregularities (eg, prolonged flow,

spotting, or amenorrhea); such patients may need regular pregnancy tests. Ectopic pregnancies are more frequent, and complaints of abdominal pain should be investigated with this in mind. The absolute contraindications and many of the relative contraindications listed in Table 18–4 apply to the minipill. Minor side effects of combination oral contraceptives such as weight gain and mild headache may also occur with the minipill.

2. Contraceptive Injections & Implants (Long-Acting Progestins)

The injectable progestin medroxyprogesterone acetate (DMPA) is approved for contraceptive use in the United States. There is extensive worldwide experience with this method over the past 3 decades. The medication is given as a deep intramuscular injection of 150 mg every 3 months and has a contraceptive efficacy of 99.7%. A subcutaneous preparation, containing 104 mg of DMPA is available in the United States. Common side effects include irregular bleeding, amenorrhea, weight gain, and headache. It is associated with bone mineral loss that is usually reversible after discontinuation of the method. Users commonly have irregular bleeding initially and subsequently develop amenorrhea. Ovulation may be delayed after the last injection. Contraindications are similar to those for the minipill.

A single-rod, subdermal progestin implant, Implanon, is approved for use in the United States. Implanon is a 40-mm by 2-mm rod containing 68 mg of the progestin etonogestrel that is inserted in the inner aspect of the nondominant arm. Insertion and removal are much simpler and faster than with Norplant. Hormone levels drop rapidly after removal, and there is no delay in the return of fertility. In clinical trials, the pregnancy rate was 0.0% with 3 years of use. The side effect profile is similar to minipills, Depo-Provera, and Norplant. Irregular bleeding has been the most common reason for discontinuation.

Isley MM et al. Contraceptive implants: an overview and update. *Obstet Gynecol Clin North Am.* 2007 Mar;34(1):73–90. [PMID: 17472866]

3. Other Hormonal Methods

A transdermal contraceptive patch containing 150 mcg norelgestromin and 20 mcg ethinyl estradiol and measuring 20 cm² is available. The patch is applied to the lower abdomen, upper torso, or buttock once a week for 3 consecutive weeks, followed by 1 week without the patch. It appears that the average steady-state concentration of ethi-

nyl estradiol with the patch is approximately 60% higher than with a 35 mcg pill. However, there is currently no evidence for an increased incidence of estrogen-related side effects. The mechanism of action, side effects, and efficacy are similar to those associated with oral contraceptives, although compliance may be better.

A contraceptive vaginal ring that releases 120 mcg of etonogestrel and 15 mcg of ethinyl estradiol daily is available. The ring is soft and flexible and is placed in the upper vagina for 3 weeks, removed, and replaced 1 week later. The efficacy, mechanism of action, and systemic side effects are similar to those associated with oral contraceptives. In addition, users may experience an increased incidence of vaginal discharge.

4. Intrauterine Devices

IUDs available in the United States include the Mirena (which releases levonorgestrel) and the copper-bearing TCu380A. The mechanism of action of IUDs is thought to involve either spermicidal or inhibitory effects on sperm capacitation and transport. IUDs are not abortifacients.

The Mirena is effective for 5 years, and the TCu380A for 10 years. The hormone-containing IUDs have the advantage of reducing cramping and menstrual flow.

The IUD is an excellent contraceptive method for most women. The devices are highly effective, with failure rates similar to those achieved with surgical sterilization. Nulliparity is not a contraindication to IUD use. Women who are not in mutually monogamous relationships should use condoms for protection from sexually transmitted diseases. The Mirena may have a protective effect against upper tract infection similar to that of the oral contraceptives.

A. Insertion

Insertion can be performed during or after the menses, at midcycle to prevent implantation, or later in the cycle if the patient has not become pregnant. Most clinicians wait for 6–8 weeks postpartum before inserting an IUD. When insertion is performed during lactation, there is greater risk of uterine perforation or embedding of the IUD. Insertion immediately following abortion is acceptable if there is no sepsis and if follow-up insertion a month later will not be possible; otherwise, it is wise to wait until 4 weeks post-abortion.

B. Contraindications & Complications

Contraindications to use of IUDs are outlined in Table 18–5.

1. Pregnancy—A copper-containing IUD can be inserted within 5 days following a single episode of unprotected mid-cycle coitus as a postcoital contraceptive. An IUD should not be inserted into a pregnant uterus. If pregnancy occurs as an IUD failure, there is a greater chance of spontaneous abortion if the IUD is left in situ (50%) than if it is removed (25%). Spontaneous abortion with an IUD in place is associated with a high risk of severe sepsis, and death can occur rapidly. Women using an IUD who become pregnant should have the IUD removed if the string is visible. It can be removed at the time of abortion if this is desired. If the

Table 18–5. Contraindications to IUD use.

Absolute contraindications

Pregnancy
Acute or subacute pelvic inflammatory disease or purulent cervicitis
Significant anatomic abnormality of uterus
Unexplained uterine bleeding
Active liver disease (Mirena only)

Relative contraindications

History of pelvic inflammatory disease since the last pregnancy
Lack of available follow-up care
Menorrhagia or severe dysmenorrhea (copper IUD)
Cervical or uterine neoplasia

IUD, intrauterine device.

string is not visible and the patient wants to continue the pregnancy, she should be informed of the serious risk of sepsis and, occasionally, death with such pregnancies. She should be informed that any flu-like symptoms such as fever, myalgia, headache, or nausea warrant immediate medical attention for possible septic abortion.

Since the ratio of ectopic to intrauterine pregnancies is increased among IUD wearers, clinicians should search for adnexal masses in early pregnancy and should always check the products of conception for placental tissue following abortion.

2. Pelvic infection—There is an increased risk of pelvic infection during the first month following insertion. The subsequent risk of pelvic infection appears to be primarily related to the risk of acquiring sexually transmitted infections. Infertility rates do not appear to be increased among women who have previously used the currently available IUDs. At the time of insertion, women with an increased risk of sexually transmitted diseases should be screened for gonorrhea and *Chlamydia*. Women with a history of recent or recurrent pelvic infection are not good candidates for IUD use.

3. Menorrhagia or severe dysmenorrhea—The copper IUD can cause heavier menstrual periods, bleeding between periods, and more cramping, so it is generally not suitable for women who already suffer from these problems. However, hormone-releasing IUDs can be tried in these cases, as they often cause decreased bleeding and cramping with menses. NSAIDs are also helpful in decreasing bleeding and pain in IUD users.

4. Complete or partial expulsion—Spontaneous expulsion of the IUD occurs in 10–20% of cases during the first year of use. Any IUD should be removed if the body of the device can be seen or felt in the cervical os.

5. Missing IUD strings—If the transcervical tail cannot be seen, this may signify unnoticed expulsion, perforation of the uterus with abdominal migration of the IUD, or simply retraction of the string into the cervical canal or uterus owing to movement of the IUD or uterine growth with pregnancy. Once pregnancy is ruled out, one should probe for the IUD with a sterile sound or forceps designed for

IUD removal, after administering a paracervical block. If the IUD cannot be detected, pelvic ultrasound will demonstrate the IUD if it is in the uterus. Alternatively, obtain anteroposterior and lateral x-rays of the pelvis with another IUD or a sound in the uterus as a marker, to confirm an extrauterine IUD. If the IUD is in the abdominal cavity, it should generally be removed by laparoscopy or laparotomy. Perforations of the uterus are less likely if insertion is performed slowly, with meticulous care taken to follow directions applicable to each type of IUD.

Thonneau PF et al. Contraceptive efficacy of intrauterine devices. *Am J Obstet Gynecol*. 2008 Mar;198(3):248–53. [PMID: 18221924]

5. Diaphragm & Cervical Cap

The diaphragm (with contraceptive jelly) is a safe and effective contraceptive method with features that make it acceptable to some women and not others. Failure rates range from 6% to 16%, depending on the motivation of the woman and the care with which the diaphragm is used. The advantages of this method are that it has no systemic side effects and gives significant protection against pelvic infection and cervical dysplasia as well as pregnancy. The disadvantages are that it must be inserted near the time of coitus and that pressure from the rim predisposes some women to cystitis after intercourse.

The cervical cap (with contraceptive jelly) is similar to the diaphragm but fits snugly over the cervix only (the diaphragm stretches from behind the cervix to behind the pubic symphysis). The cervical cap is more difficult to insert and remove than the diaphragm. The main advantages are that it can be used by women who cannot be fitted for a diaphragm because of a relaxed anterior vaginal wall or by women who have discomfort or develop repeated bladder infections with the diaphragm. However, failure rates are 9% (perfect use) and 16% (typical use) in nulliparous women and 26% (perfect use) and 32% (typical use) in parous women.

Because of the small risk of toxic shock syndrome, a cervical cap or diaphragm should not be left in the vagina for over 12–18 hours, nor should these devices be used during the menstrual period.

6. Contraceptive Foam, Cream, Film, Sponge, Jelly, & Suppository

These products are available without prescription, are easy to use, and are fairly effective, with typical failure rates of 10–22%. All contain the spermicide nonoxynol-9, which also has some virucidal and bactericidal activity. Nonoxynol-9 does not appear to adversely affect the vaginal colonization of hydrogen peroxide-producing lactobacilli. A 2002 study suggests that nonoxynol-9 is not protective against HIV infection, particularly in women who have frequent intercourse. The FDA now requires products containing nonoxynol-9 to include a warning that the products do not protect against HIV or other sexually

transmitted diseases and that use of these products can irritate the vagina and rectum and may increase the risk of getting the AIDS virus from an infected partner. Recent data suggest that low-risk women using a nonoxynol-9 product, with coital activity two to three times per week, are not at increased risk for epithelial disruption, compared with couples using condoms alone.

Harwood B et al. Cervicovaginal colposcopic lesions associated with 5 nonoxynol-9 spermicide formulations. *Am J Obstet Gynecol*. 2008 Jan;198(1):32.e1–7. [PMID: 18166301]

7. Condom

The male condom of latex or animal membrane affords good protection against pregnancy—equivalent to that of a diaphragm and spermicidal jelly; latex (but not animal membrane) condoms also offer protection against many sexually transmitted diseases, including HIV. When a spermicide, such as vaginal foam, is used with the condom, the failure rate approaches that of oral contraceptives. The disadvantages of condoms are dulling of sensation and spillage of semen due to tearing, slipping, or leakage with detumescence of the penis.

A female condom made of polyurethane is available in the United States. The reported failure rates range from 5% to 21%; the efficacy is comparable to that of the diaphragm. This is the only female-controlled method that offers significant protection from both pregnancy and sexually transmitted diseases.

8. Contraception Based on Awareness of Fertile Periods

These methods are most effective when the couple restricts intercourse to the postovular phase of the cycle or uses a barrier method at other times. Well-instructed, motivated couples may be able to achieve low pregnancy rates with fertility awareness methods. However, properly done randomized clinical trials comparing the efficacy of most of these methods with other contraceptive methods do not exist.

Grimes DA et al. Fertility awareness-based methods for contraception: systematic review of randomized controlled trials. *Contraception*. 2005 Aug;72(2):85–90. [PMID: 16022845]

A. “Symptothermal” Natural Family Planning

The basis for this approach is patient-observed increase in clear elastic cervical mucus, brief abdominal midcycle discomfort (“mittelschmerz”), and a sustained rise of the basal body temperature about 2 weeks after onset of menstruation. Unprotected intercourse is avoided from shortly after the menstrual period, when fertile mucus is first identified, until 48 hours after ovulation, as identified by a sustained rise in temperature and the disappearance of clear elastic mucus.

B. Calendar Method

After the length of the menstrual cycle has been observed for at least 8 months, the following calculations are made:

(1) The first fertile day is determined by subtracting 18 days from the shortest cycle, and (2) the last fertile day is determined by subtracting 11 days from the longest cycle. For example, if the observed cycles run from 24 to 28 days, the fertile period would extend from the sixth day of the cycle (24 minus 18) through the 17th day (28 minus 11). Day 1 of the cycle is the first day of menses.

C. Basal Body Temperature Method

This method indicates the safe time for intercourse after ovulation has passed. The temperature must be taken immediately upon awakening, before any activity. A slight drop in temperature often occurs 12–24 hours before ovulation, and a rise of about 0.4 °C occurs 1–2 days after ovulation. The elevated temperature continues throughout the remainder of the cycle. Data suggest that the risk of pregnancy increases starting 5 days prior to the day of ovulation, peaks on the day of ovulation, and then rapidly decreases to zero by the day after ovulation.

D. Standard Days Method

This fertility awareness method requires the use of a set of beads that reminds the couple to avoid intercourse (or use a barrier method of contraception) during days 8 through 19 of the menstrual cycle. The beads are in a circle and color-coded to show the days when a woman is likely to become pregnant and the days that are “safe” during the cycle. A movable ring is repositioned to a new bead each day starting on the first day of menses. In a small multicenter trial, the perfect use failure rate was 5% and the typical use failure rate was 12%. The method is applicable to women with a history of menstrual cycles between 29 and 32 days.

E. TwoDay Method

The TwoDay method requires that women be able to identify cervical secretions by observation or touching them in underwear or toilet paper, by touching the genitals, or by the sensation of wetness in the genital area or on underwear. The woman then uses a two-question algorithm to determine whether she is fertile. She asks herself: (1) Did I note secretions today? and (2) Did I note secretions yesterday? If the answer to either of these questions is “yes,” she should consider herself fertile. In a multicenter study of 450 women, effectiveness with perfect use was 96.5% and with typical use 76.3%.

Germano E et al. New approaches to fertility awareness-based methods: incorporating the Standard Days and TwoDay Methods into practice. *J Midwifery Womens Health*. 2006 Nov–Dec;51(6):471–7. [PMID: 17081938]

9. Emergency Contraception

If unprotected intercourse occurs in midcycle and if the woman is certain she has not inadvertently become pregnant earlier in the cycle, the following regimens are effective in preventing implantation. These methods should be started as soon as possible and within 120 hours after unprotected coitus. (1) Levonorgestrel, 1.5 mg orally

as a single dose (available in the United States prepackaged as Plan B and available over-the-counter for women aged 17 years and above), has a 1% failure rate, when taken within 72 hours. It remains efficacious up to 120 hours after intercourse, though less so compared with earlier use. (2) If the levonorgestrel regimen is not available, a combination oral contraceptive containing ethinyl estradiol and levonorgestrel given in a regimen of two to six tablets initially, followed by two to six tablets 12 hours later may be used. At least 20 brands of pills may be used in this way. For specific instructions for each pill brand, consult www.not-2-late.com. Used within 72 hours, the failure rate of these regimens is approximately 3%, and anti-nausea medication is often necessary. (3) Mifepristone, 10 mg orally as a single dose, has been shown to have the same failure rate as the levonorgestrel regimen. It is not currently available at this dose in the United States. (4) IUD insertion within 5 days after one episode of unprotected midcycle coitus will also prevent pregnancy; copper-bearing IUDs have been tested for this purpose.

Information on clinics or individual clinicians providing emergency contraception in the United States may be obtained by calling 1-888-668-2528.

Allen RH et al. Emergency contraception: a clinical review. *Clin Obstet Gynecol*. 2007 Dec;50(4):927–36. [PMID: 17982335]

10. Abortion

Since the legalization of abortion in the United States in 1973, the related maternal mortality rate has fallen markedly, because illegal and self-induced abortions have been replaced by safer medical procedures. Abortions in the first trimester of pregnancy are performed by vacuum aspiration under local anesthesia or with medical regimens. Dilation and evacuation, a variation of vacuum aspiration is generally used in the second trimester. Techniques utilizing intra-amniotic instillation of hypertonic saline solution or various prostaglandins regimens, along with medical or osmotic dilators are occasionally used after 18 weeks. Several medical abortion regimens utilizing mifepristone and multiple doses of misoprostol have been reported as being effective in the second trimester. Overall, legal abortion in the United States has a mortality rate of less than 1:100,000. Rates of morbidity and mortality rise with length of gestation. Currently in the United States, 88% of abortions are performed before 13 weeks' gestation and only 1.3% are performed after 20 weeks. If abortion is chosen, every effort should be made to encourage the patient to seek an early procedure. While numerous state laws limiting access to abortion and a federal law banning a rarely-used variation of dilation and evacuation have been enacted, abortion remains legal and available until fetal viability under *Roe v. Wade*.

Complications resulting from abortion include retained products of conception (often associated with infection and heavy bleeding) and unrecognized ectopic pregnancy. Immediate analysis of the removed tissue for placenta can exclude or corroborate the diagnosis of ectopic pregnancy. Women who have fever, bleeding, or abdominal pain after abortion should be examined; use of broad-

spectrum antibiotics and reaspiration of the uterus are frequently necessary. Hospitalization is advisable if acute salpingitis requires intravenous administration of antibiotics. Complications following illegal abortion often need emergency care for hemorrhage, septic shock, or uterine perforation.

Rh immune globulin should be given to all Rh-negative women following abortion. Prophylactic antibiotics are indicated for surgical abortion; for example a one-dose regimen of doxycycline, 200 mg orally 1 hour before the procedure. Many clinics prescribe tetracycline, 500 mg orally four times daily for 5 days after the procedure, as presumptive treatment for *Chlamydia*.

Mifepristone (RU 486) is approved by the FDA as an oral abortifacient at a dose of 600 mg on day 1, followed by 400 mcg orally of misoprostol on day 3. This combination is 95% successful in terminating pregnancies of up to 9 weeks' duration with minimum complications. A more commonly used, evidence-based regimen is mifepristone, 200 mg orally on day 1, followed by misoprostol, 800 mcg vaginally either immediately or within 6–8 hours. Although not approved by the FDA for this indication, a combination of intramuscular methotrexate, 50 mg/m² of body surface area, followed 3–7 days later by vaginal misoprostol, 800 mcg, is 98% successful in terminating pregnancy at 8 weeks or less. Minor side effects, such as nausea, vomiting, and diarrhea, are common with these regimens. There is a 5–10% incidence of hemorrhage or incomplete abortion requiring curettage. There is a 2005 report of four deaths occurring within 1 week of medical abortion, associated with endometritis and toxic shock caused by *Clostridium sordellii*. To improve diagnosis and treatment of this entity, clinicians should be aware of the constellation of presenting symptoms of tachycardia, hypotension, edema, hemoconcentration, profound leukocytosis, and absence of fever.

ACOG. ACOG practice bulletin: Clinical management guidelines of Obstetrician-Gynecologists. Number 67, October 2005. Medical management of abortion. *Obstet Gynecol.* 2005 Oct;106(4):871–82. [PMID: 16199653]

Lipp A. A review of developments in medical termination of pregnancy. *J Clin Nurs.* 2008 Jun;17(11):1411–8. [PMID: 18482139]

11. Sterilization

In the United States, sterilization is the most popular method of birth control for couples who want no more children. Although sterilization is reversible in some instances, reversal surgery in both men and women is costly, complicated, and not always successful. Therefore, patients should be counseled carefully before sterilization and should view the procedure as final.

Vasectomy is a safe, simple procedure in which the vas deferens is severed and sealed through a scrotal incision under local anesthesia. Long-term follow-up studies on vasectomized men show no excess risk of cardiovascular disease. Several studies have shown a possible association with prostate cancer, but the evidence is weak and inconsistent.

Female sterilization procedures include laparoscopic bipolar electrocoagulation, or plastic ring application on the uterine tubes, or minilaparotomy with Pomeroy tubal resection. The advantages of laparoscopy are minimal postoperative pain, small incisions, and rapid recovery. The advantages of minilaparotomy are that it can be performed with standard surgical instruments under local or general anesthesia. However, there is more postoperative pain and a longer recovery period. The cumulative 10-year failure rate for all methods combined is 1.85%, varying from 0.75% for postpartum partial salpingectomy and laparoscopic unipolar coagulation to 3.65% for spring clips; this fact should be discussed with women preoperatively. Some studies have found an increased risk of menstrual irregularities as a long-term complication of tubal ligation, but findings in different studies have been inconsistent. A new method of transcervical sterilization, Essure, is approved by the FDA. The method involves the placement of an expanding microcoil of titanium into the proximal uterine tube under hysteroscopic guidance. The efficacy rate at 1 year is 99.8%.

▶ When to Refer

Refer to experienced clinicians for Implanon or other subcutaneous insertion, IUD insertion, tubal occlusion or ligation, vasectomy, or therapeutic abortion.

RAPE

ESSENTIALS OF DIAGNOSIS

- ▶ Women neither secretly want to be raped nor do they expect, encourage, or enjoy rape.
- ▶ Rape is always a terrifying experience in which most victims fear for their lives.
- ▶ The rapist is usually a hostile man who uses sexual intercourse to terrorize and humiliate a woman.

▶ General Considerations

Rape, or sexual assault, is legally defined in different ways in various jurisdictions. Clinicians and emergency department personnel who deal with rape victims should be familiar with the laws pertaining to sexual assault in their own state. From a medical and psychological viewpoint, it is essential that persons treating rape victims recognize the nonconsensual and violent nature of the crime. About 95% of reported rape victims are women. Penetration may be vaginal, anal, or oral and may be by the penis, hand, or a foreign object. The absence of genital injury does not imply consent by the victim. The assailant may be unknown to

the victim or, more frequently, may be an acquaintance or even the spouse.

“Unlawful sexual intercourse,” or statutory rape, is intercourse with a female before the age of majority even with her consent.

Rape represents an expression of anger, power, and sexuality on the part of the rapist. The rapist is usually a hostile man who uses sexual intercourse to terrorize and humiliate a woman. Women neither secretly want to be raped nor do they expect, encourage, or enjoy rape.

Rape involves severe physical injury in 5–10% of cases and is always a terrifying experience in which most victims fear for their lives. Consequently, all victims suffer some psychological aftermath. Moreover, some rape victims may acquire sexually transmissible disease or become pregnant.

Because rape is a personal crisis, each patient will react differently. The rape trauma syndrome comprises two principal phases. (1) Immediate or acute: Shaking, sobbing, and restless activity may last from a few days to a few weeks. The patient may experience anger, guilt, or shame or may repress these emotions. Reactions vary depending on the victim’s personality and the circumstances of the attack. (2) Late or chronic: Problems related to the attack may develop weeks or months later. The lifestyle and work patterns of the individual may change. Sleep disorders or phobias often develop. Loss of self-esteem can rarely lead to suicide.

Clinicians and emergency department personnel who deal with rape victims should work with community rape crisis centers whenever possible to provide ongoing support and counseling.

► General Office Procedures

The clinician who first sees the alleged rape victim should be empathetic. Begin with a statement such as, “This is a terrible thing that has happened to you. I want to help.”

- Secure written consent from the patient, guardian, or next of kin for gynecologic examination and for photographs if they are likely to be useful as evidence. If police are to be notified, do so, and obtain advice on the preservation and transfer of evidence.
- Obtain and record the history in the patient’s own words. The sequence of events, ie, the time, place, and circumstances, must be included. Note the date of the LMP, whether or not the woman is pregnant, and the time of the most recent coitus prior to the sexual assault. Note the details of the assault such as body cavities penetrated, use of foreign objects, and number of assailants. Note whether the victim is calm, agitated, or confused (drugs or alcohol may be involved). Record whether the patient came directly to the hospital or whether she bathed or changed her clothing. Record findings but do not issue even a tentative diagnosis lest it be erroneous or incomplete.
- Have the patient disrobe while standing on a white sheet. Hair, dirt, and leaves, underclothing, and any torn or stained clothing should be kept as evidence. Scrape material from beneath fingernails and comb

pubic hair for evidence. Place all evidence in separate clean paper bags or envelopes and label carefully.

- Examine the patient, noting any traumatized areas that should be photographed. Examine the body and genitals with a Wood light to identify semen, which fluoresces; positive areas should be swabbed with a premoistened swab and air-dried in order to identify acid phosphatase. Colposcopy can be used to identify small areas of trauma from forced entry especially at the posterior fourchette.
- Perform a pelvic examination, explaining all procedures and obtaining the patient’s consent before proceeding gently with the examination. Use a narrow speculum lubricated with water only. Collect material with sterile cotton swabs from the vaginal walls and cervix and make two air-dried smears on clean glass slides. Wet and dry swabs of vaginal secretions should be collected and refrigerated for subsequent acid phosphatase and DNA evaluation. Swab the mouth (around molars and cheeks) and anus in the same way, if appropriate. Label all slides carefully. Collect secretions from the vagina, anus, or mouth with a premoistened cotton swab, place at once on a slide with a drop of saline, and cover with a coverslip. Look for motile or nonmotile sperm under high, dry magnification, and record the percentage of motile forms.
- Perform appropriate laboratory tests as follows. Culture the vagina, anus, or mouth (as appropriate) for *N gonorrhoeae* and *Chlamydia*. Perform a Papanicolaou smear of the cervix, a wet mount for *T vaginalis*, a baseline pregnancy test, and VDRL test. A confidential test for HIV antibody can be obtained if desired by the patient and repeated in 2–4 months if initially negative. Repeat the pregnancy test if the next menses is missed, and repeat the VDRL test in 6 weeks. Obtain blood (10 mL without anticoagulant) and urine (100 mL) specimens if there is a history of forced ingestion or injection of drugs or alcohol.
- Transfer clearly labeled evidence, eg, laboratory specimens, directly to the clinical pathologist in charge or to the responsible laboratory technician, in the presence of witnesses (never via messenger), so that the rules of evidence will not be breached.

► Treatment

Give analgesics or sedatives if indicated. Administer tetanus toxoid if deep lacerations contain soil or dirt particles.

Give ceftriaxone, 125 mg intramuscularly, to prevent gonorrhea. In addition, give metronidazole, 2 g as a single dose, and azithromycin 1 g orally or doxycycline, 100 mg orally twice daily for 7 days to treat chlamydial infection. Incubating syphilis will probably be prevented by these medications, but the VDRL test should be repeated 6 weeks after the assault.

Prevent pregnancy by using one of the methods discussed under Emergency Contraception, if necessary (this chapter).

Vaccinate against hepatitis B. Consider HIV prophylaxis (see Chapter 31).

Make sure the patient and her family and friends have a source of ongoing psychological support.

▶ When to Refer

All women who seek care for sexual assault should be referred to a facility that has expertise in the management of victims of sexual assault and is capable of performing expert forensic examination, if requested.

Martin SL et al. Health-care based interventions for women who have experienced sexual violence: a review of the literature. *Trauma Violence Abuse*. 2007 Jan;8(1):3–18. [PMID: 17204597]

MENOPAUSAL SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Cessation of menses due to aging or to bilateral oophorectomy.
- ▶ Elevation of FSH and LH levels.
- ▶ Hot flushes and night sweats (in 80% of women).
- ▶ Decreased vaginal lubrication; thinned vaginal mucosa with or without dyspareunia.

▶ General Considerations

The term “menopause” denotes the final cessation of menstruation, either as a normal part of aging or as the result of surgical removal of both ovaries. In a broader sense, as the term is commonly used, it denotes a 1- to 3-year period during which a woman adjusts to a diminishing and then absent menstrual flow and the physiologic changes that may be associated—hot flushes, night sweats, and vaginal dryness.

The average age at menopause in Western societies today is 51 years. Premature menopause is defined as ovarian failure and menstrual cessation before age 40; this often has a genetic or autoimmune basis. Surgical menopause due to bilateral oophorectomy is common and can cause more severe symptoms owing to the sudden rapid drop in sex hormone levels.

There is no objective evidence that cessation of ovarian function is associated with severe emotional disturbance or personality changes. However, mood changes toward depression and anxiety can occur at this time. Furthermore, the time of menopause often coincides with other major life changes, such as departure of children from the home, a midlife identity crisis, or divorce. These events, coupled with a sense of the loss of youth, may exacerbate the symptoms of menopause and cause psychological distress.

▶ Clinical Findings

A. Symptoms and Signs

1. Cessation of menstruation—Menstrual cycles generally become irregular as menopause approaches. Anovular cycles occur more often, with irregular cycle length and

occasional menorrhagia. Menstrual flow usually diminishes in amount owing to decreased estrogen secretion, resulting in less abundant endometrial growth. Finally, cycles become longer, with missed periods or episodes of spotting only. When no bleeding has occurred for 1 year, the menopausal transition can be said to have occurred. Any bleeding after this time warrants investigation by endometrial curettage or aspiration to rule out endometrial cancer.

2. Hot flushes—Hot flushes (feelings of intense heat over the trunk and face, with flushing of the skin and sweating) occur in 80% of women as a result of the decrease in ovarian hormones. Hot flushes can begin before the cessation of menses. An increase in pulsatile release of GnRH from the hypothalamus is believed to trigger the hot flushes by affecting the adjacent temperature-regulating area of the brain. Hot flushes are more severe in women who undergo surgical menopause. Flushing is more pronounced late in the day, during hot weather, after ingestion of hot foods or drinks, or during periods of tension. Occurring at night, they often cause sweating and insomnia and result in fatigue on the following day.

3. Vaginal atrophy—With decreased estrogen secretion, thinning of the vaginal mucosa and decreased vaginal lubrication occur and may lead to dyspareunia. The introitus decreases in diameter. Pelvic examination reveals pale, smooth vaginal mucosa and a small cervix and uterus. The ovaries are not normally palpable after the menopause. Continued sexual activity will help prevent tissue shrinkage.

4. Osteoporosis—Osteoporosis may occur as a late sequela of menopause.

B. Laboratory Findings

Serum FSH and LH levels are elevated. Vaginal cytologic examination will show a low estrogen effect with predominantly parabasal cells, indicating lack of epithelial maturation due to hypoestrogenism.

▶ Treatment

A. Natural Menopause

Education and support from health providers, midlife discussion groups, and reading material will help most women having difficulty adjusting to the menopause. Physiologic symptoms can be treated as follows.

1. Vasomotor symptoms—Oral conjugated estrogens, 0.3 mg or 0.625 mg, estradiol, 0.5 or 1 mg, or estrone sulfate, 0.625 mg; or estradiol can be given transdermally as skin patches that are changed once or twice weekly and secrete 0.05–0.1 mg of hormone daily. When either form of estrogen is used, add a progestin (medroxyprogesterone acetate) to prevent endometrial hyperplasia or cancer. There is also a patch available containing estradiol and the progestin levonorgestrel. The oral hormones can be given in several differing regimens. Give estrogen on days 1–25 of each calendar month, with 5–10 mg of oral medroxyprogesterone acetate added on days 14–25. Withhold hor-

mones from day 26 until the end of the month, when the endometrium will be shed, producing a light, generally painless monthly period. Alternatively, give the estrogen along with 2.5 mg of oral medroxyprogesterone acetate daily, without stopping. This regimen causes some initial bleeding or spotting, but within a few months it produces an atrophic endometrium that will not bleed. If the patient has had a hysterectomy, a progestin need not be used.

Data from the Women's Health Initiative (WHI) study suggest that women should not use combination progestin-estrogen therapy for more than 3 or 4 years. In this study, the increased risk of cardiovascular disease, cerebrovascular disease, and breast cancer with this regimen outweighed the benefits. Women who cannot find relief with alternative approaches may wish to consider continuing use of combination therapy after a thorough discussion of the risks and benefits. Alternatives to hormone therapy for vasomotor symptoms include SSRIs such as paroxetine, 12.5 mg or 25 mg/d orally, or venlafaxine, 75 mg/d orally. Gabapentin, an antiseizure medication, is also effective at 900 mg/d orally. Clonidine given orally or transdermally, 100–150 mcg daily, may also reduce the frequency of hot flashes, but its use is limited by side effects, including dry mouth, drowsiness, and hypotension.

2. Vaginal atrophy—A vaginal ring containing 2 mg of estradiol can be left in place for 3 months and is suitable for long-term use, providing effective relief of vaginal atrophy. There is minimal systemic absorption of estradiol with the ring, and progestin therapy to protect the endometrium is unnecessary. A higher-dose ring with 12.4 mg or 24.8 mg of estradiol acetate delivers a systemic dose and is not appropriate for treatment of vaginal atrophy alone. Short-term use of estrogen vaginal cream will relieve symptoms of atrophy, but because of variable absorption, therapy with either the vaginal ring or systemic hormone replacement is preferable. Testosterone propionate 1–2%, 0.5–1 g, in a vanishing cream base used in the same manner is also effective if estrogen is contraindicated. A bland lubricant such as unscented cold cream or water-soluble gel can be helpful at the time of coitus.

3. Osteoporosis—(See also discussion in Chapter 26.) Women should ingest at least 800 mg of calcium daily throughout life. In addition, 1 g of elemental calcium should be taken as a daily supplement at the time of the menopause and thereafter; calcium supplements should be taken with meals to increase their absorption. Vitamin D, 800 international units/d from food, sunlight, or supplements, is necessary to enhance calcium absorption and maintain bone mass. A daily program of energetic walking and exercise to strengthen the arms and upper body helps maintain bone mass.

Women most at risk for osteoporotic fractures should consider bisphosphonates, raloxifene, or hormone replacement therapy. This includes white and Asian women, especially if they have a family history of osteoporosis; are thin, short, cigarette smokers, and physically inactive; or have had a low calcium intake in adult life.

B. Risks of Hormone Therapy

Double-blinded randomized, controlled trials have shown no overall cardiovascular benefit with estrogen-progestin replacement therapy in a group of postmenopausal women with or without established coronary disease. Both in the WHI trial and the Heart and Estrogen/Progestin Replacement Study (HERS), the overall health risks (increased risk of coronary heart events, strokes, thromboembolic disease, breast cancers, gallstones) exceeded the benefits from the use of combination estrogen and progesterone. Progestins counteract some but not all favorable effects of estrogen. Women who have been receiving long-term estrogen-progestin hormone replacement therapy (HRT), even in the absence of complications should be encouraged to stop, especially if they do not have menopausal symptoms. An ancillary study of the WHI study showed that not only did estrogen-progestin HRT not benefit cognitive function but there was a small increased risk of cognitive decline in that group compared with women in the placebo group. The unopposed estrogen arm of the WHI trial demonstrated a decrease in the risk of hip fracture, a small but nonsignificant decrease in breast cancer, but an increased risk of stroke and no evidence of protection from coronary heart disease. The study also showed a small increase in the combined risk of mild cognitive impairment and dementia with estrogen use compared with placebo, similar to the estrogen-progestin arm. (See also discussions of estrogen and progestin replacement therapy in Chapter 26.)

C. Surgical Menopause

The abrupt hormonal decrease resulting from oophorectomy generally results in severe vasomotor symptoms and rapid onset of dyspareunia and osteoporosis unless treated. Estrogen replacement is generally started immediately after surgery. Conjugated estrogens 1.25 mg orally, estrone sulfate 1.25 mg orally, or estradiol 2 mg orally is given for 25 days of each month. After age 45–50 years, this dose can be tapered to 0.625 mg of conjugated estrogens or equivalent.

DIAGNOSIS OF PREGNANCY

It is advantageous to diagnose pregnancy as promptly as possible when a sexually active woman misses a menstrual period or has symptoms suggestive of pregnancy. In the event of a desired pregnancy, prenatal care can begin early, and potentially harmful medications and activities such as drug and alcohol use, smoking, and occupational chemical exposure can be halted. In the event of an unwanted pregnancy, counseling about adoption or termination of the pregnancy can be provided at an early stage.

► Pregnancy Tests

All urine or blood pregnancy tests rely on the detection of human chorionic gonadotropin (hCG) produced by the placenta. hCG levels increase shortly after implantation, approximately double every 48 hours, reach a peak at 50–75 days, and fall to lower levels in the second and third trimesters. Laboratory and home pregnancy tests use monoclonal antibodies specific for hCG. These tests are performed on serum or urine and are accurate at the time of the missed period or shortly after it.

Compared with intrauterine pregnancies, ectopic pregnancies may show lower levels of hCG that level off or fall in serial determinations. Quantitative assays of hCG repeated at 48-hour intervals are used in the diagnosis of ectopic pregnancy as well as in cases of molar pregnancy, threatened abortion, and missed abortion. Comparison of hCG levels between laboratories may be misleading in a given patient because different international standards may produce results that vary by as much as twofold. hCG levels can also be problematic because they require a series of measurements. Progesterone levels, however, remain relatively stable in the first trimester and a single measurement can be used to determine whether a pregnancy is viable; a value of less than 5 ng/mL predicts pregnancy failure with a sensitivity of 60%, while a value of 20 ng/mL or higher reflects a viable pregnancy with a sensitivity of 100%.

Mol BW et al. The accuracy of single serum progesterone measurement in the diagnosis of ectopic pregnancy: a meta-analysis. *Hum Reprod.* 1998;13(11):3220–27. [PMID: 9853884]

► Manifestations of Pregnancy

The following symptoms and signs are usually due to pregnancy, but none are diagnostic. A record of the time and frequency of coitus is helpful for diagnosing and dating a pregnancy.

A. Symptoms

Amenorrhea, nausea and vomiting, breast tenderness and tingling, urinary frequency and urgency, “quickening” (perception of first movement noted at about the 18th week), weight gain.

B. Signs (in Weeks from Last Menstrual Period)

Breast changes (enlargement, vascular engorgement, colostrum) start to occur very early in pregnancy and continue until the postpartum period. Cyanosis of vagina and cervical portio and softening of the cervix occur in about the seventh week. Softening of the cervicouterine junction takes place in the eighth week, and generalized enlargement and diffuse softening of the corpus occurs after the eighth week. When a woman’s abdomen will start to enlarge depends on her body habitus but typically starts in the sixteenth week.

The uterine fundus is palpable above the pubic symphysis by 12–15 weeks from the last menstrual period and reaches the umbilicus by 20–22 weeks. Fetal heart tones can be heard by Doppler at 10–12 weeks of gestation and at 20 weeks with an ordinary fetoscope.

► Differential Diagnosis

The nonpregnant uterus enlarged by myomas can be confused with the gravid uterus, but it is usually very firm and irregular. An ovarian tumor may be found midline, displacing the nonpregnant uterus to the side or posteriorly. Ultrasonography and a pregnancy test will provide accurate diagnosis in these circumstances.

ESSENTIALS OF PRENATAL CARE

The first prenatal visit should occur as early as possible after the diagnosis of pregnancy and should include the

Table 19–1. Common drugs that are teratogenic or fetotoxic.¹

| | |
|---|--|
| ACE inhibitors | Lithium |
| Alcohol | Methotrexate |
| A-II antagonists | Misoprostol |
| Androgens | NSAIDs (third trimester) |
| Anticonvulsants (phenytoin, valproic acid, carbamazepine) | Opioids (prolonged use) |
| Benzodiazepines | Progestins |
| Carbarsone (amebicide) | Radioiodine (antithyroid) |
| Chloramphenicol (third trimester) | Reserpine |
| Cyclophosphamide | Ribavirin |
| Diazoxide | Sulfonamides (third trimester) |
| Diethylstilbestrol | SSRIs |
| Disulfiram | Tetracycline (third trimester) |
| Ergotamine | Thalidomide |
| Estrogens | Tobacco smoking |
| Griseofulvin | Trimethoprim (third trimester) |
| Isotretinoin | Warfarin and other coumarin anticoagulants |

¹Many other drugs are also contraindicated during pregnancy. Evaluate any drug for its need versus its potential adverse effects. Further information can be obtained from the manufacturer or from any of several teratogenic registries around the country. ACE, angiotensin-converting enzyme; A-II antagonists, angiotensin II receptor blocking agents; NSAIDs, nonsteroidal anti-inflammatory drugs; SSRIs, selective serotonin reuptake inhibitors.

following: history, physical examination, laboratory tests, advice to patients, and tests and procedures.

► History

The patient's age, ethnic background, and occupation should be obtained. The onset of the last menstrual period and its normality, possible conception dates, bleeding after the last menstruation, medical history, all prior pregnancies (duration, outcome, and complications), and symptoms of present pregnancy should be documented. The patient's nutritional habits should be discussed with her, as well as any use of caffeine, tobacco, alcohol, or drugs (Table 19–1). Determine whether there is any family history of congenital anomalies and heritable diseases, a personal history of childhood varicella, or prior sexually transmitted diseases (STDs) or risk factors for HIV infection.

► Physical Examination

Height, weight, and blood pressure should be measured, and a general physical examination should be done, including a breast examination. Abdominal and pelvic examination should include the following: (1) estimate of uterine size or measure of fundal height; (2) evaluation of bony pelvis for symmetry and adequacy; (3) evaluation of cervix for structural anatomy, infection, effacement, dilation; (4) detection of fetal heart sounds by Doppler device after 10 weeks.

► Laboratory Tests

Urinalysis, culture of a clean-voided midstream urine sample, random blood glucose, complete blood count with red

cell indices, serologic test for syphilis, rubella antibody titer, varicella immunity, blood group, Rh type, antibody screening, and hepatitis B surface antigen (HBsAg) should be performed. HIV screening should be offered to all pregnant women. Cervical cultures are usually obtained for *Neisseria gonorrhoeae* and *Chlamydia*, along with a Papanicolaou smear of the cervix. All black women should have sickle cell screening. Women of African, Asian, or Mediterranean ancestry with anemia or low mean corpuscular volume (MCV) values should have hemoglobin electrophoresis performed to identify abnormal hemoglobins (Hb S, C, F, α -thalassemia, β -thalassemia). Tuberculosis skin testing is indicated for high-risk populations. Aneuploidy screening is available in the first and second trimester and should be offered to all women, ideally before 20 weeks gestation. Noninvasive first trimester screening for Down syndrome includes ultrasonographic nuchal translucency and serum levels of PAPP-A (pregnancy-associated plasma protein A) and the free β subunit of hCG. In the second trimester, a “quad screen” blood test can be performed; it measures serum alpha-fetoprotein (msAFP), hCG, unconjugated estriol, and inhibin A. First and second trimester tests have similar detection rates. When first and second trimester screening are combined (integrated screening), the detection rates are even higher. Women at increased risk for aneuploidy can then be offered chorionic villus sampling or genetic amniocentesis, depending on gestational age. Blood screening for Tay-Sachs, Canavan disease, and familial dysautonomia is offered to couples who are of Eastern European Jewish (Ashkenazi) descent. Couples of French-Canadian or Cajun ancestry should also be screened as possible Tay-Sachs carriers. Screening for cystic fibrosis is offered to all pregnant women. Hepatitis C antibody screening should be offered to pregnant women who are at high risk for infection.

Pregnant women with high-risk professions and those who are household contacts of a hepatitis B virus carrier or a hemodialysis patient and are HBsAg-negative at prenatal screening are at high risk for acquiring hepatitis B. They should be vaccinated during pregnancy. All women who are pregnant during flu season should receive vaccination for influenza regardless of gestational age.

► Advice to Patients

A. Prenatal Visits

Prenatal care should begin early and maintain a schedule of regular prenatal visits: 0–28 weeks, every 4 weeks; 28–36 weeks, every 2 weeks; 36 weeks on, weekly.

B. Diet

Eat a balanced diet containing the major food groups.

1. Take prenatal vitamins with iron and folic acid. Supplements that are not specified for pregnant women should be avoided as they may contain dangerous amounts of certain vitamins.
2. Expect to gain 20–40 lb. Do not diet to lose weight during pregnancy.

3. Decrease caffeine intake to 0–1 cup of coffee, tea, or caffeinated cola daily.
4. Avoid eating raw or rare meat as well as fish known to contain elevated levels of mercury.
5. Eat fresh fruits and vegetables and wash them before eating.

C. Medications

Do not take medications unless prescribed or authorized by your provider.

D. Alcohol and Other Drugs

Abstain from alcohol, tobacco, and all recreational (“street”) drugs. No safe level of alcohol intake has been established for pregnancy. Fetal effects are manifest in the **fetal alcohol syndrome**, which includes growth restriction; facial, skeletal, and cardiac abnormalities; and serious central nervous system dysfunction. These effects are thought to result from direct toxicity of ethanol as well as of its metabolites such as acetaldehyde.

Cigarette smoking results in fetal exposure to carbon monoxide and nicotine, and this is thought to eventuate in a number of adverse pregnancy outcomes. An increased risk of abruptio placentae, placenta previa, and premature rupture of the membranes is documented among women who smoke. Premature delivery occurs 20% more frequently among smoking pregnant women, and the birth weights of their infants are on average 200 g lighter than infants of nonsmokers. Women who smoke should quit smoking or at least reduce the number of cigarettes smoked per day to as few as possible. Clinicians should offer smoking cessation counseling during pregnancy, since women are more motivated to change at this time. Pregnant women should also avoid exposure to environmental smoke (“passive smoking”).

Sometimes compounding the above effects on pregnancy outcome are the independent adverse effects of illicit drugs. Cocaine use in pregnancy is associated with an increased risk of premature rupture of membranes, preterm delivery, placental abruption, intrauterine growth restriction, neurobehavioral deficits, and sudden infant death syndrome. Similar adverse pregnancy effects are associated with amphetamine use, perhaps reflecting the vasoconstrictive potential of both amphetamines and cocaine. Adverse effects associated with opioid use include intrauterine growth restriction, prematurity, and fetal death.

E. Radiographs and Noxious Exposures

Avoid radiographs unless essential and approved by a physician. Abdominal shielding should be used whenever possible. Inform your dentist and your providers that you are pregnant. Avoid chemical or radiation hazards. Avoid excessive heat in hot tubs or saunas. Avoid handling cat feces or cat litter. Wear gloves when gardening.

F. Rest and Activity

Obtain adequate rest each day. Abstain from strenuous physical work or activities, particularly when heavy lifting

or weight bearing is required. Regular exercise can be continued at a mild to moderate level. Avoid exhausting or hazardous exercises or new athletic training programs during pregnancy. Heart rate should be kept below 140 beats/min during exercise.

G. Birth Classes

Enroll with your partner in a childbirth preparation class well before your due date.

▶ Tests & Procedures

A. Each Visit

Weight, blood pressure, fundal height, fetal heart rate are measured, and a urine specimen is obtained and tested for protein and glucose. Review any concerns the patient may have about pregnancy, health, and nutrition.

B. 6–12 Weeks

Confirm uterine size and growth by pelvic examination. Document fetal heart tones (audible at 10–12 weeks of gestation by Doppler). Choices of aneuploidy screening should be discussed at this time (see above). First trimester screening (see Laboratory Tests, above) and transvaginal chorionic villus sampling are performed during this period.

C. 16–20 Weeks

The “quad screen” and amniocentesis are performed as indicated and requested by the patient during this time (see Laboratory Tests, above). Fetal ultrasound examination to determine pregnancy dating and evaluate fetal anatomy is also done. An earlier examination provides the most accurate dating, and a later examination demonstrates fetal anatomy in greatest detail. The best compromise is at 18–20 weeks of gestation.

D. 20–24 Weeks

Instruct patient about symptoms and signs of preterm labor and rupture of membranes. Consider cervical length measurement by ultrasound after 18 weeks with history of prior preterm delivery (> 2.5 cm is normal).

E. 24 Weeks to Delivery

Ultrasound examination is performed as indicated. Typically, fetal size and growth are evaluated when fundal height is 3 cm less than or more than expected for gestational age. In multiple pregnancies, ultrasound should be performed every 4–6 weeks to evaluate for discordant growth.

F. 24–28 Weeks

Screening for gestational diabetes is performed using a 50-g glucose load (Glucola) and a 1-hour post-Glucola blood glucose determination. Abnormal values (≥ 140 mg/dL) should be followed up with a 3-hour glucose tolerance test (see Table 19–4).

G. 28 Weeks

If initial antibody screen is negative, repeat antibody testing for Rh-negative patients is performed, but the result is not required before Rh₀(D) immune globulin is administered.

H. 28–32 Weeks

Repeat the complete blood count to evaluate for anemia of pregnancy. Screening for syphilis is also frequently performed at this time.

I. 28 Weeks to Delivery

Determine fetal position and presentation. Question the patient at each visit for symptoms or signs of preterm labor or rupture of membranes. Assess maternal perception of fetal movement at each visit. Antepartum fetal testing is performed as medically indicated.

J. 36 Weeks to Delivery

Repeat syphilis and HIV testing, cervical cultures for *N gonorrhoeae* and *Chlamydia trachomatis* should be performed in at-risk patients. Discuss with the patient the indicators of onset of labor, admission to hospital, management of labor and delivery, and options for analgesia and anesthesia. Weekly cervical examinations are not necessary unless indicated to assess a specific clinical situation. Elective delivery (whether by induction or cesarean section) prior to 39 weeks of gestation requires confirmation of fetal lung maturity.

The CDC has recommended universal prenatal culture-based screening for group B streptococcal colonization in pregnancy. A single standard culture of the distal vagina and anorectum is collected at 35–37 weeks. No prophylaxis is needed if the screening culture is negative. Patients whose cultures are positive receive intrapartum penicillin prophylaxis during labor. Except when group B streptococci are found in urine, asymptomatic colonization is not to be treated before labor. Patients who have had a previous infant with invasive group B streptococcal disease or who have group B streptococcal bacteriuria during this pregnancy should receive intrapartum prophylaxis regardless, so rectovaginal cultures are not needed. Patients whose cultures at 35–37 weeks were not done or whose results are not known should receive prophylaxis if they have a risk factor for early-onset neonatal disease, including intrapartum temperature greater than 38 °C, membrane rupture greater than 18 hours, or delivery before 37 weeks gestation.

The routine recommended regimen for prophylaxis is penicillin G, 5 million units intravenously as a loading dose and then 2.5 million units intravenously every 4 hours until delivery. In penicillin-allergic patients not at high risk for anaphylaxis, 2 g of cefazolin can be given intravenously as an initial dose and then 1 g intravenously every 8 hours until delivery. In patients at high risk for anaphylaxis, use vancomycin 1 g intravenously every 12 hours until delivery or, after confirmed susceptibility testing of group B streptococcal isolate, clindamycin 900 mg intravenously every 8 hours or erythromycin 500 mg intravenously every 6 hours until delivery.

K. 41 Weeks

Examine the cervix to determine the probability of successful induction of labor. Based on this, induction of labor is undertaken if the cervix is favorable (generally, cervix ≥ 2 cm dilated $\geq 50\%$ effaced, vertex at -1 station, soft cervix, and midposition); if unfavorable, antepartum fetal testing is begun.

NUTRITION IN PREGNANCY

Nutrition in pregnancy can affect maternal health and infant size and well-being. Pregnant women should have nutrition counseling early in prenatal care and access to supplementary food programs if necessary. Counseling should stress abstinence from alcohol, smoking, and recreational drugs. Caffeine and artificial sweeteners should be used only in small amounts. “Empty calories” should be avoided, and the diet should contain the following foods: protein foods of animal and vegetable origin, milk and milk products, whole-grain cereals and breads, and fruits and vegetables—especially green leafy vegetables.

Weight gain in pregnancy should be 20–40 lb, which includes the added weight of the fetus, placenta, and amniotic fluid and of maternal reproductive tissues, fluid, blood, increased fat stores, and increased lean body mass. Maternal fat stores are a caloric reserve for pregnancy and lactation; weight restriction in pregnancy to avoid developing such fat stores may affect the development of other fetal and maternal tissues and is not advisable. Obese women can have normal infants with less weight gain (15–20 lb) but should be encouraged to eat high-quality foods. Normally, a pregnant woman gains 2–5 lb in the first trimester and slightly less than 1 lb/wk thereafter. She needs approximately an extra 200–300 kcal/d (depending on energy output) and 30 g/d of additional protein for a total protein intake of about 75 g/d. Appropriate caloric intake in pregnancy helps prevent the problems associated with low birth weight.

Rigid salt restriction is not necessary. While consumption of highly salted snack foods and prepared foods is not desirable, 2–3 g/d of sodium is permissible. The increased calcium needs of pregnancy (1200 mg/d) can be met with milk, milk products, green vegetables, soybean products, corn tortillas, and calcium carbonate supplements.

The increased need for iron and folic acid should be met from foods as well as vitamin and mineral supplements. (See section on anemia in pregnancy.) Megavitamins should not be taken in pregnancy, as they may result in fetal malformation or disturbed metabolism. However, a balanced prenatal supplement containing 30–60 mg of elemental iron,

0.5–0.8 mg of folate, and the recommended daily allowances of various vitamins and minerals is widely used in the United States and is probably beneficial to many women with marginal diets. There is evidence that periconceptional folic acid supplements can decrease the risk of neural tube defects in the fetus. For this reason, the United States Public Health Service recommends the consumption of 0.4 mg of folic acid per day for all pregnant and reproductive age women. Women with a prior pregnancy complicated by neural tube defect may require higher supplemental doses as determined by their providers. Lactovegetarians and ovo-lactovegetarians do well in pregnancy; vegetarian women who eat neither eggs nor milk products should have their diets assessed for adequate calories and protein and should take oral vitamin B₁₂ supplements during pregnancy and lactation.

PREVENTION OF HEMOLYTIC DISEASE OF THE NEWBORN (Erythroblastosis Fetalis)

The antibody anti-Rh₀(D) is responsible for most severe instances of hemolytic disease of the newborn (erythroblastosis fetalis). About 15% of whites and much lower proportions of blacks and Asians are Rh₀(D)-negative. If an Rh₀(D)-negative woman carries an Rh₀(D)-positive fetus, antibodies against Rh₀(D) may develop in the mother when fetal red cells enter her circulation during small fetomaternal bleeding episodes in the early third trimester or during delivery, abortion, ectopic pregnancy, abruptio placentae, or other instances of antepartum bleeding. This antibody, once produced, remains in the woman's circulation and poses the threat of hemolytic disease for subsequent Rh-positive fetuses.

Passive immunization against hemolytic disease of the newborn is achieved with Rh₀(D) immune globulin, a purified concentrate of antibodies against Rh₀(D) antigen. The Rh₀(D) immune globulin (one vial of 300 mcg intramuscularly) is given to the mother within 72 hours after delivery (or spontaneous or induced abortion or ectopic pregnancy). The antibodies in the immune globulin destroy fetal Rh-positive cells so that the mother will not produce anti-Rh₀(D). During her next Rh-positive gestation, erythroblastosis will be prevented. An additional safety measure is the routine administration of the immune globulin at the 28th week of pregnancy. The passive antibody titer that results is too low to significantly affect an Rh-positive fetus. The maternal clearance of the globulin is slow enough that protection will continue for 12 weeks.

Hemolytic disease of varying degrees, from mild to serious, continues to occur in association with Rh subgroups (C, c, or E) or Kell, Kidd, and other factors. Therefore, the presence of atypical antibodies should be checked in the third trimester of all pregnancies.

LACTATION

Breastfeeding should be encouraged by education throughout pregnancy and the puerperium. Mothers should be told the benefits of breastfeeding, including infant immunity, emotional satisfaction, mother-infant bonding, and economic savings. The period of amenorrhea associated with frequent and consistent breastfeeding provides some (although not completely reliable) birth control until menstruation begins at 6–12 months postpartum or the intensity of breastfeeding diminishes. If the mother must return to work, even a brief period of nursing is beneficial. Transfer of immunoglobulins in colostrum and breast milk protects the infant against many systemic and enteric infections. Macrophages and lymphocytes transferred to the infant from breast milk play an immunoprotective role. The intestinal flora of breastfed infants inhibits the growth of pathogens. Breastfed infants have fewer bacterial and viral infections, less severe diarrhea, and fewer allergy problems than bottle-fed infants and are less apt to be obese as children and adults.

Frequent breastfeeding on an infant-demand schedule enhances milk flow and successful breastfeeding. Mothers breastfeeding for the first time need help and encouragement from providers, nurses, and other nursing mothers. Milk supply can be increased by increased suckling and increased rest.

Nursing mothers should have a fluid intake of over 2 L/d. The United States RDA calls for 21 g of extra protein (over the 44 g/d baseline for an adult woman) and 550 extra kcal/d in the first 6 months of nursing. Calcium intake should be 1200 mg/d. Continuation of a prenatal vitamin and mineral supplement is wise. Strict vegetarians who eschew both milk and eggs should always take vitamin B₁₂ supplements during pregnancy and lactation.

1. Effects of Drugs in a Nursing Mother

Drugs taken by a nursing mother may accumulate in milk and be transmitted to the infant (Table 19–2). The amount of drug entering the milk depends on the drug's lipid solubility, mechanism of transport, and degree of ionization.

2. Suppression of Lactation

A. Mechanical Suppression

The simplest and safest method of suppressing lactation after it has started is to gradually transfer the baby to a bottle or a cup over a 3-week period. Milk supply will decrease with decreased demand, and minimal discomfort ensues. If nursing must be stopped abruptly, the mother should avoid nipple stimulation, refrain from expressing milk, and use a snug brassiere. Ice packs and analgesics can be helpful. This same technique can be used in cases where suppression is desired before nursing has begun. Engorgement will gradually recede over a 2- to 3-day period.

B. Hormonal Suppression

Oral and long-acting injections of hormonal preparations were used at one time to suppress lactation. Because of

Table 19–2. Drugs and substances that require a careful assessment of risk before they are prescribed for breast-feeding women.¹

²The use of this drug or these drugs by breast-feeding women is contraindicated according to the American Academy of Pediatrics.

their questionable efficacy and particularly because of associated side effects such as thromboembolic episodes and hair growth, their use for this purpose has been abandoned. Similarly, lactation suppression with bromocriptine is to be avoided because of reports of severe hypertension, seizures, strokes, and myocardial infarctions associated with its use.

TRAVEL & IMMUNIZATIONS DURING PREGNANCY

During an otherwise normal low-risk pregnancy, travel can be planned most safely between the 18th and 32nd weeks. Commercial flying in pressurized cabins does not pose a threat to the fetus. An aisle seat will allow frequent walks. Adequate fluids should be taken during the flight.

It is not advisable to travel to endemic areas of yellow fever in Africa or Latin America; similarly, it is inadvisable

to travel to areas of Africa or Asia where chloroquine-resistant falciparum malaria is a hazard, since complications of malaria are more common in pregnancy.

Ideally, all immunizations should precede pregnancy. Live virus products are contraindicated during pregnancy (measles, rubella, yellow fever), including smallpox. Inactivated polio vaccine (IPV) should be given subcutaneously instead of the oral live-attenuated vaccine. Vaccines against pneumococcal pneumonia, meningococcal meningitis, and hepatitis A can be used as indicated. Influenza vaccine is indicated in all women who will be pregnant during “flu season.” The CDC lists pregnant women as a high-risk group.

Hepatitis A vaccine contains formalin-inactivated virus and can be given in pregnancy when needed. Chloroquine can be used for malaria prophylaxis in pregnancy, and proguanil is also safe. Pooled immune globulin to prevent hepatitis A is safe and does not carry a risk of HIV transmission.

Water should be purified by boiling, since iodine purification may provide more iodine than is safe during pregnancy.

Do not use prophylactic antibiotics or bismuth subsalicylate during pregnancy to prevent diarrhea. Use oral rehydration, and treat bacterial diarrhea with erythromycin or ampicillin if necessary.

OBSTETRIC COMPLICATIONS OF THE FIRST & SECOND TRIMESTER

VOMITING OF PREGNANCY (Morning Sickness) & HYPEREMESIS GRAVIDARUM (Pernicious Vomiting Of Pregnancy)

ESSENTIALS OF DIAGNOSIS

- ▶ Morning or evening nausea and vomiting.
- ▶ Persistent vomiting severe enough to result in weight loss, dehydration, starvation ketosis, hypochloremic alkalosis, hypokalemia.
- ▶ May have transient elevation of liver enzymes.
- ▶ Appears related to high or rising serum hCG.
- ▶ More common with multiple gestation or hydatidiform mole.

▶ General Considerations

Nausea and vomiting begin soon after the first missed period and cease by the fifth month of gestation. Up to three-fourths of women complain of nausea and vomiting during early pregnancy, with the vast majority noting nausea throughout the day. This problem exerts no adverse effects on the pregnancy and does not presage other complications.

Persistent, severe vomiting during pregnancy—hyperemesis gravidarum—can be disabling and require hospital-

ization. Thyroid dysfunction can be associated with hyperemesis gravidarum, so it is advisable to determine thyroid-stimulating hormone (TSH) and free thyroxine (T_4) values in these patients.

▶ Treatment

A. Mild Nausea and Vomiting of Pregnancy

Reassurance and dietary advice are all that is required in most instances. Because of possible teratogenicity, drugs used during the first half of pregnancy should be restricted to those of major importance to life and health. Antiemetics, antihistamines, and antispasmodics are generally unnecessary to treat nausea of pregnancy. Vitamin B₆ (pyridoxine), 50–100 mg/d orally, is nontoxic and may be helpful in some patients.

B. Hyperemesis Gravidarum

With more severe nausea and vomiting, it may become necessary to hospitalize the patient. In this case, a private room with limited activity is preferred. Give nothing by mouth for 48 hours, and maintain hydration and electrolyte balance by giving appropriate parenteral fluids and vitamin supplements as indicated. Antiemetics such as promethazine (25 mg orally, rectally, or intravenously every 4–6 hours) and metoclopramide (10 mg orally or intravenously every 6 hours) should be started. Antiemetics will likely need to be given intravenously initially. Rarely, total parenteral nutrition may become necessary. As soon as possible, place the patient on a dry diet consisting of six small feedings daily plus clear liquids 1 hour after eating. Antiemetics may be continued orally as needed. After in-patient stabilization, the patient can be maintained at home even if she requires intravenous fluids in addition to her oral intake. There are conflicting studies regarding the use of corticosteroids for the control of hyperemesis gravidarum. Therefore, this treatment should be withheld until more accepted treatments have been exhausted.

▶ When to Refer

- Patient is unable to tolerate any food or water.
- There is concern for other pathology (ie, hydatidiform mole).
- Patient requires hospitalization.

▶ When to Admit

- Patient is unable to tolerate any food or water.
- Condition precludes the patient from ingesting necessary medications.
- Weight loss.
- Presence of a hydatidiform mole.

Dodds L et al. Outcomes of pregnancies complicated by hyperemesis gravidarum. *Obstet Gynecol.* 2006 Feb;107(2 Pt 1):285–92. [PMID: 16449113]

SPONTANEOUS ABORTION

ESSENTIALS OF DIAGNOSIS

- ▶ Intrauterine pregnancy at less than 20 weeks.
- ▶ Low or falling levels of hCG.
- ▶ Bleeding, midline cramping pain.
- ▶ Open cervical os.
- ▶ Complete or partial expulsion of products of conception.

▶ General Considerations

About three-fourths of spontaneous abortions occur before the 16th week; of these, three-fourths occur before the eighth week. Almost 20% of all clinically recognized pregnancies terminate in spontaneous abortion.

More than 60% of spontaneous abortions result from chromosomal defects due to maternal or paternal factors; about 15% appear to be associated with maternal trauma, infections, dietary deficiencies, diabetes mellitus, hypothyroidism, the lupus anticoagulant-anticardiolipin-antiphospholipid antibody syndrome, or anatomic malformations. There is no reliable evidence that abortion may be induced by psychic stimuli such as severe fright, grief, anger, or anxiety. In about one-fourth of cases, the cause of abortion cannot be determined. There is no evidence that video display terminals or associated electromagnetic fields are related to an increased risk of spontaneous abortion.

It is important to distinguish women with a history of incompetent cervix from those with more typical early abortion. Characteristically, incompetent cervix presents as “silent” cervical dilation (ie, with minimal uterine contractions) in the second trimester. Women with incompetent cervix often present with significant cervical dilation (2 cm or more) and minimal symptoms. When the cervix reaches 4 cm or more, active uterine contractions or rupture of the membranes may occur secondary to the degree of cervical dilation. This does not change the primary diagnosis. Factors that predispose to incompetent cervix are a history of incompetent cervix with a previous pregnancy, cervical conization or surgery, cervical injury, diethylstilbestrol (DES) exposure, and anatomic abnormalities of the cervix. Prior to pregnancy or during the first trimester, there are no methods for determining whether the cervix will eventually be incompetent. After 14–16 weeks, ultrasound may be used to evaluate the internal anatomy of the lower uterine segment and cervix for the funneling and shortening abnormalities consistent with cervical incompetence.

▶ Clinical Findings

A. Symptoms and Signs

- 1. Threatened abortion**—Bleeding or cramping occurs, but the pregnancy continues. The cervix is not dilated.
- 2. Inevitable abortion**—The cervix is dilated and the membranes may be ruptured, but passage of the products

of conception has not yet occurred. Bleeding and cramping persist, and passage of the products of conception is considered inevitable.

3. Complete abortion—The fetus and placenta are completely expelled. Pain ceases, but spotting may persist.

4. Incomplete abortion—The cervix is dilated. Some portion of the products of conception (usually placental) remain in the uterus. Only mild cramps are reported, but bleeding is persistent and often excessive.

5. Missed abortion—The pregnancy has ceased to develop, but the conceptus has not been expelled. Symptoms of pregnancy disappear. There is a brownish vaginal discharge but no free bleeding. Pain does not develop. The cervix is semifirm and slightly patulous; the uterus becomes smaller and irregularly softened; the adnexa are normal.

B. Laboratory Findings

Pregnancy tests show low or falling levels of hCG. A complete blood count should be obtained if bleeding is heavy. Determine Rh type, and give Rh₀(D) immune globulin if Rh-negative. All tissue recovered should be assessed by a pathologist and may be sent for genetic analysis in selected cases.

C. Ultrasonographic Findings

The gestational sac can be identified at 5–6 weeks from the last menstruation, a fetal pole at 6 weeks, and fetal cardiac activity at 6–7 weeks. Serial observations are often required to evaluate changes in size of the embryo. A small, irregular sac without a fetal pole with accurate dating is diagnostic of an abnormal pregnancy.

▶ Differential Diagnosis

The bleeding that occurs in abortion of a uterine pregnancy must be differentiated from the abnormal bleeding of an ectopic pregnancy and anovular bleeding in a nonpregnant woman. The passage of hydropic villi in the bloody discharge is diagnostic of hydatidiform mole.

▶ Treatment

A. General Measures

1. Threatened abortion—Place the patient on bed rest for 24–48 hours followed by gradual resumption of usual activities, with abstinence from coitus and douching. Hormonal treatment is contraindicated. Antibiotics should be used only if there are signs of infection.

2. Missed abortion—This calls for counseling regarding the fate of the pregnancy and planning for its elective termination at a time chosen by the patient and clinician. Insertion of laminaria to dilate the cervix followed by aspiration is the method of choice for a missed abortion. Prostaglandin vaginal tablets (misoprostol 800 mcg per vagina, repeated 3 days later if products of conception are not expelled) are an effective alternative.

B. Surgical Measures

1. Incomplete or inevitable abortion—Prompt removal of any products of conception remaining within the uterus is required to stop bleeding and prevent infection. Analgesia and a paracervical block are useful, followed by uterine exploration with ovum forceps or uterine aspiration. Regional anesthesia may be required.

2. Cerclage and restriction of activities—A cerclage is the treatment of choice for incompetent cervix, but a viable intrauterine pregnancy should be confirmed prior to placement of the cerclage.

A variety of suture materials including a 5-mm Mersilene band can be used to create a purse-string type of stitch around the cervix, using either the McDonald or Shirodkar method. Cerclage should be undertaken with caution when there is advanced cervical dilation or when the membranes are prolapsed into the vagina. Rupture of the membranes and infection are specific contraindications to cerclage. Cervical cultures for *N gonorrhoeae*, *Chlamydia*, and group B streptococci should be obtained and treated before elective placement of a cerclage.

▶ When to Refer

- Patient with history of two second-trimester losses
- Vaginal bleeding in a pregnant patient that resembles menstruation in a nonpregnant woman.
- Patient with an open cervical os.
- No signs of uterine growth in serial examinations of a pregnant patient.
- Leakage of amniotic fluid.

▶ When to Admit

- Open cervical os.
- Heavy vaginal bleeding.
- Leakage of amniotic fluid.

Maconochie N et al. Risk factors for first trimester miscarriage—results from a UK-population-based case-control study. *BJOG*. 2007 Feb;114(2):170–86. [PMID: 17305901]

Trinder J et al. Management of miscarriage: expectant, medical, or surgical? Results of randomized controlled trial (miscarriage treatment (MIST) trial). *BMJ*. 2006 May 27;332(7552):1235–40. [PMID: 16707509]

RECURRENT (HABITUAL) ABORTION

Recurrent abortion has been defined as the loss of three or more previable (< 500 g) pregnancies in succession. Recurrent abortion occurs in about 0.4–0.8% of all pregnancies. Abnormalities related to recurrent abortion can be identified in approximately half of the couples. If a woman has lost three previous pregnancies without identifiable cause, she still has a 70–80% chance of carrying a fetus to viability. If she has aborted four or five times, the likelihood of a successful pregnancy is 65–70%.

Recurrent abortion is a clinical rather than pathologic diagnosis. The clinical findings are similar to those observed in other types of abortion (see above).

► Treatment

A. Preconception Therapy

Preconception therapy is aimed at detection of maternal or paternal defects that may contribute to abortion. A thorough general and gynecologic examination is essential. A random blood glucose test and thyroid function studies (including thyroid antibodies) should be done. Detection of lupus anticoagulant and other hemostatic abnormalities (proteins S and C and antithrombin III deficiency, hyperhomocysteinemia, anticardiolipin antibody, factor V Leiden mutations) and an antinuclear antibody test may be indicated. Endometrial tissue should be examined in the postovulation stage of the cycle to determine the adequacy of the response of the endometrium to hormones. The competency of the cervix must be determined and hysteroscopy or hysterothorography used to exclude submucosal myomas and congenital anomalies. Chromosomal (karyotype) analysis of both partners can be done to rule out balanced translocations (found in 5% of infertile couples).

Studies have focused on the major histocompatibility complex of chromosome 6, which carries HLA loci and other genes that may influence reproductive success. Some women demonstrate a lack of maternal antibody response to paternal lymphocytes, which is customarily found in normal women after successful childbearing. However, several randomized controlled trials have found no benefit of intravenous immunoglobulin therapy for recurrent spontaneous abortion.

B. Postconception Therapy

Provide early prenatal care and schedule frequent office visits. Bed rest is justified only for bleeding or pain. Empiric sex steroid hormone therapy is contraindicated.

► Prognosis

The prognosis is excellent if the cause of abortion can be corrected or treated.

Stephenson M et al. Evaluation and management of recurrent early pregnancy loss. *Clin Obstet Gynecol.* 2007 Mar;50(1):132–45. [PMID: 17304030]

ECTOPIC PREGNANCY

ESSENTIALS OF DIAGNOSIS

- Amenorrhea or irregular bleeding and spotting.
- Pelvic pain, usually adnexal.
- Adnexal mass by clinical examination or ultrasound.
- Failure of serum level of hCG to double every 48 hours.
- No intrauterine pregnancy on transvaginal ultrasound with serum β -hCG of > 2000 mU/mL.

► General Considerations

Ectopic implantation occurs in about one out of 150 live births. About 98% of ectopic pregnancies are tubal. Other sites of ectopic implantation are the peritoneum or abdominal viscera, the ovary, and the cervix. Any condition that prevents or retards migration of the fertilized ovum to the uterus can predispose to an ectopic pregnancy, including a history of infertility, pelvic inflammatory disease, ruptured appendix, and prior tubal surgery. Combined intrauterine and extrauterine pregnancy (heterotopic) may occur rarely. In the United States, undiagnosed or undetected ectopic pregnancy is currently the most common cause of maternal death during the first trimester.

► Clinical Findings

A. Symptoms and Signs

They may be acute or chronic.

1. Acute (40%)—Severe lower quadrant pain occurs in almost every case. It is sudden in onset, lancinating, intermittent, and does not radiate. Backache is present during attacks. Shock occurs in about 10%, often after pelvic examination. At least two-thirds of patients give a history of abnormal menstruation; many have been infertile.

2. Chronic (60%)—Blood leaks from the tubal ampulla over a period of days, and considerable blood may accumulate in the peritoneum. Slight but persistent vaginal spotting is reported, and a pelvic mass can be palpated. Abdominal distention and mild paralytic ileus are often present.

B. Laboratory Findings

Blood studies may show anemia and slight leukocytosis. Quantitative serum pregnancy tests will show levels generally lower than expected for normal pregnancies of the same duration. If pregnancy tests are followed over a few days, there may be a slow rise or a plateau rather than the near doubling every 2 days associated with normal early intrauterine pregnancy or the falling levels that occur with spontaneous abortion. A progesterone level can also be measured to assess the viability of the pregnancy.

C. Imaging

Ultrasonography can reliably demonstrate a gestational sac 6 weeks from the last menstruation and a fetal pole at 7 weeks if located in the uterus. An empty uterine cavity raises a strong suspicion of extrauterine pregnancy, which can occasionally be revealed by transvaginal ultrasound. Specified levels of serum hCG have been reliably correlated with ultrasound findings of an intrauterine pregnancy. For example, an hCG level of 6500 mU/mL with an empty uterine cavity by transabdominal ultrasound is virtually diagnostic of an ectopic pregnancy. Similarly, an hCG value of 2000 mU/mL or more can be indicative of an ectopic pregnancy if no products of conception are detected within the uterine cavity by transvaginal ultrasound.

D. Special Examinations

With the advent of high-resolution transvaginal ultrasound, culdocentesis is rarely used in evaluation of possible ectopic pregnancy. Laparoscopy is the surgical procedure of choice both to confirm an ectopic pregnancy and in most cases to permit removal of the ectopic pregnancy without the need for exploratory laparotomy.

► Differential Diagnosis

Clinical and laboratory findings suggestive or diagnostic of pregnancy will distinguish ectopic pregnancy from many acute abdominal illnesses such as acute appendicitis, acute pelvic inflammatory disease, ruptured corpus luteum cyst or ovarian follicle, and urinary calculi. Uterine enlargement with clinical findings similar to those found in ectopic pregnancy is also characteristic of an aborting uterine pregnancy or hydatidiform mole. Ectopic pregnancy should be suspected when postabortal tissue examination fails to reveal chorionic villi. Steps must be taken for immediate diagnosis, including prompt microscopic tissue examination, ultrasonography, and serial hCG titers every 48 hours. Patients must be warned about the complications of an ectopic pregnancy and monitored very closely.

► Treatment

In a stable patient, methotrexate (50 mg/m²) intramuscularly—given as single or multiple doses—is acceptable medical therapy for early ectopic pregnancy. Favorable criteria are that the pregnancy should be less than 3.5 cm in largest dimension and unruptured, with no active bleeding and no fetal heart tones.

When a patient with an ectopic pregnancy is unstable or when surgical therapy is planned, the patient is hospitalized. Blood is typed and cross-matched. Ideally, diagnosis and operative treatment should precede frank rupture of the tube and intra-abdominal hemorrhage.

Surgical treatment is definitive. In a stable patient, diagnostic laparoscopy is the initial surgical procedure performed. Depending on the size of the ectopic pregnancy and whether or not it has ruptured, salpingostomy with removal of the ectopic or a partial or complete salpingectomy can usually be performed. Clinical conditions permitting, patency of the contralateral tube can be established by injection of indigo carmine into the uterine cavity and flow through the contralateral tube confirmed visually by the surgeon.

Iron therapy for anemia may be necessary during convalescence. Rh₀(D) immune globulin (300 mcg) should be given to Rh-negative patients.

► Prognosis

Repeat tubal pregnancy occurs in about 12% of cases. This should not be regarded as a contraindication to future pregnancy, but the patient requires careful observation and early ultrasound confirmation of an intrauterine pregnancy.

► When to Refer

- Severe abdominal pain.

- Palpation of an adnexal mass on pelvic examination.
- Abdominal pain and vaginal bleeding in a pregnant patient.

► When to Admit

- Presence of symptoms or signs of a ruptured ectopic pregnancy; methotrexate use is contraindicated.

Alleyassin A et al. Comparison of success rates in the medical management of ectopic pregnancy with single-dose and multiple-dose administration of methotrexate: a prospective, randomized clinical trial. *Fertil Steril*. 2006 Jun;85(6):1661–6. [PMID: 16650421]

GESTATIONAL TROPHOBLASTIC DISEASE (Hydatidiform Mole & Choriocarcinoma)

ESSENTIALS OF DIAGNOSIS

Hydatidiform Mole

- Amenorrhea.
- Irregular uterine bleeding.
- Serum hCG β -subunit > 40,000 mU/mL.
- Passage of grape-like clusters of enlarged edematous villi per vagina.
- Ultrasound of uterus with characteristic heterogeneous echogenic image and no fetus or placenta.
- Cytogenetic composition is 46,XX (85%), completely of paternal origin.

Choriocarcinoma

- Persistence of detectable hCG after mole evacuation

► General Considerations

Gestational trophoblastic disease is a spectrum of disorders that includes hydatidiform mole, invasive mole, and choriocarcinoma. Partial moles generally show evidence of an embryo or gestational sac; are polyploid, slower-growing, and less symptomatic; and often present clinically as a missed abortion. Partial moles tend to follow a benign course, while complete moles have a greater tendency to become choriocarcinomas.

The highest rates of gestational trophoblastic disease occur in some developing countries, with rates of 1:125 pregnancies in certain areas of Asia. In the United States, the frequency is 1:1500 pregnancies. Risk factors include low socioeconomic status, a history of mole, and age younger than 18 or older than 40. Approximately 10% of women require further treatment after evacuation of the mole; 5% develop choriocarcinoma.

► Clinical Findings

A. Symptoms and Signs

Excessive nausea and vomiting occur in over one-third of patients with hydatidiform mole. Uterine bleeding, beginning

at 6–8 weeks, is observed in virtually all instances. In about one-fifth of cases, the uterus is larger than would be expected in a normal pregnancy of the same duration. Bilaterally enlarged cystic ovaries are sometimes palpable. They are the result of ovarian hyperstimulation due to excess of hCG.

Preeclampsia-eclampsia, frequently of the fulminating type, may develop during the second trimester of pregnancy, but this is unusual.

Choriocarcinoma may be manifested by continued or recurrent uterine bleeding after evacuation of a mole or following delivery, abortion, or ectopic pregnancy. The presence of an ulcerative vaginal tumor, pelvic mass, or evidence of distant metastatic tumor may be the presenting observation. The diagnosis is established by pathologic examination of curettings or by biopsy.

B. Laboratory Findings

Hydatidiform moles are generally characterized by high serum hCG β -subunit values which can range from high normal to the millions. Serum hCG values are more helpful in managing response to treatment than they are for diagnosis.

C. Imaging

Ultrasound has virtually replaced all other means of preoperative diagnosis of hydatidiform mole. Placental vesicles can be easily seen on transvaginal ultrasound. A preoperative chest film is indicated to rule out pulmonary metastases of the trophoblast.

► Treatment

A. Specific (Surgical) Measures

The uterus should be emptied as soon as the diagnosis of hydatidiform mole is established, preferably by suction. Ovarian cysts should not be resected nor ovaries removed; spontaneous regression of theca lutein cysts will occur with elimination of the mole.

If malignant tissue is discovered at surgery or during the follow-up examination, chemotherapy is indicated.

Thyrotoxicosis indistinguishable clinically from that of thyroid origin may occur. While hCG usually has minimal TSH-like activity, the very high hCG levels associated with moles result in the release of triiodothyronine (T_3) and T_4 and cause hyperthyroidism. Patients who are thyrotoxic on this basis should be stabilized with β -blockers prior to induction of anesthesia. Surgical removal of the mole promptly corrects the thyroid overactivity.

B. Follow-Up Measures

Effective contraception (preferably birth control pills) should be prescribed. Weekly quantitative hCG level measurements are initially required. Following successful surgical evacuation, moles show a progressive decline in hCG. After two negative weekly tests (< 5 mU/mL), the interval may be increased to monthly for 6 months and then to every 2 months for a total of 1 year. If levels plateau or begin to rise, the patient should be evaluated by repeat chest film and dilatation and curettage (D&C) before the initiation of chemotherapy.

C. Antitumor Chemotherapy

For low-risk patients with a good prognosis, methotrexate is considered first-line therapy followed by dactinomycin (see Table 39–10). The side effects—anorexia, nausea and vomiting, stomatitis, rash, diarrhea, and bone marrow depression—usually are reversible in about 3 weeks and can be ameliorated by the administration of leucovorin (0.1 mg/kg) intramuscularly. Repeated courses of methotrexate 2 weeks apart generally are required to destroy the trophoblast and maintain a zero chorionic gonadotropin titer, as indicated by β -hCG determination. Patients with a poor prognosis should be referred to a cancer center, where multiple-agent chemotherapy probably will be given.

D. Supportive Measures

Oral contraceptives (if acceptable) or another reliable birth control method should be prescribed to avoid the hazard and confusion of elevated hCG from a new pregnancy. The hCG levels should be negative for 6 months to 1 year before pregnancy is again attempted. In the pregnancy following a mole, the hCG level should be checked 6 weeks postpartum.

► Prognosis

Five year survival after courses of chemotherapy, even when metastases have been demonstrated, can be expected in at least 85% of cases of choriocarcinoma.

► When to Refer

- Uterine size exceeds that anticipated for gestational age.
- Vaginal bleeding similar to menstruation.
- Pregnant patient with a history of a molar pregnancy.

► When to Admit

- Confirmed molar pregnancy by ultrasound and laboratory studies.
- Heavy vaginal bleeding in a pregnant patient under evaluation.

OBSTETRIC COMPLICATIONS OF THE SECOND & THIRD TRIMESTER

PREECLAMPSIA-ECLAMPSIA

ESSENTIALS OF DIAGNOSIS

Preeclampsia

- Blood pressure of ≥ 140 mm Hg systolic or ≥ 90 mm Hg diastolic after 20 weeks of gestation.

- ▶ Proteinuria of ≥ 0.3 g in 24 hours.

Severe Preeclampsia

- ▶ Blood pressure of ≥ 160 mm Hg systolic or ≥ 110 mm Hg diastolic.
- ▶ Proteinuria ≥ 5 g in 24 hours or 4+ on dipstick.
- ▶ Thrombocytopenia.
- ▶ Hemolysis, elevated liver enzymes, low platelets (HELLP).
- ▶ Pulmonary edema.
- ▶ Fetal growth restriction.

Eclampsia

- ▶ Seizures in a patient with evidence of preeclampsia.

▶ General Considerations

Preeclampsia is defined as the presence of elevated blood pressure and proteinuria during pregnancy. Eclampsia is diagnosed when seizures develop in a patient with evidence of preeclampsia. Historically, the presence of three elements was required for the diagnosis of preeclampsia: hypertension, proteinuria, and edema. Edema was difficult to objectively quantify and is no longer a required element.

Preeclampsia-eclampsia can occur any time after 20 weeks of gestation and up to 6 weeks postpartum. It is a disease unique to pregnancy, with the only cure being delivery of the fetus and placenta. Preeclampsia-eclampsia develops in approximately 7% of pregnant women in the United States. Primiparas are most frequently affected; however, the incidence of preeclampsia-eclampsia is increased with multiple pregnancies, chronic hypertension, diabetes, kidney disease, collagen-vascular and autoimmune disorders, and gestational trophoblastic disease. Five percent of women with preeclampsia progress to eclampsia. Uncontrolled eclampsia is a significant cause of maternal death.

The cause of preeclampsia-eclampsia is not known. Epidemiologic studies suggest an immunologic cause for preeclampsia, since it occurs predominantly in women who have had minimal exposure to sperm (having used barrier methods of contraception) or have new consorts, in primigravidas, and in women both of whose parents have similar HLA antigens. Preeclampsia is an endothelial disorder resulting from poor placental perfusion, which releases a factor that injures the endothelium, causing activation of coagulation and an increased sensitivity to pressors. Before the syndrome becomes clinically manifest in the second half of pregnancy, there has been vasospasm in various small vessel beds, accounting for the pathologic changes in maternal organs and the placenta with consequent adverse effects on the fetus. Investigators have suggested an etiologic role for circulating angiogenic factors in preeclampsia based on studies in an animal model and in women with preeclampsia.

▶ Clinical Findings

Clinically, the severity of preeclampsia-eclampsia can be measured with reference to the six major sites in which it exerts its effects: the central nervous system, the kidneys,

the liver, the hematologic and vascular systems, and the fetal-placental unit. By evaluating each of these areas for the presence of mild to severe preeclampsia, the degree of involvement can be assessed, and an appropriate management plan can be formulated that balances the severity of disease and gestational age (Table 19–3).

A. Preeclampsia

1. Mild—With mild preeclampsia, patients usually have few complaints, and the diastolic blood pressure is less than 110 mm Hg. Edema may be present. The platelet count is over 100,000/mcL, antepartum fetal testing is reassuring, central nervous system irritability is minimal, epigastric pain is not present, and liver enzymes are not elevated.

2. Severe—Symptoms are more dramatic and persistent. Patients may complain of headache and vision changes. The blood pressure is often quite high, with readings over 160/110 mm Hg. Thrombocytopenia (platelet counts $< 100,000$ /mcL) may be present and progress to disseminated intravascular coagulation. Severe epigastric pain may be present from hepatic subcapsular hemorrhage with significant stretch or rupture of the liver capsule. HELLP syndrome (hemolysis, elevated liver enzymes, low platelets) is a form of severe preeclampsia.

B. Eclampsia

The occurrence of seizures defines eclampsia. It is a manifestation of severe central nervous system involvement. Other findings of preeclampsia are observed.

▶ Differential Diagnosis

Preeclampsia-eclampsia can mimic and be confused with many other diseases, including chronic hypertension, chronic kidney disease, primary seizure disorders, gallbladder and pancreatic disease, immune or thrombotic thrombocytopenic purpura, and hemolytic-uremic syndrome. It must always be considered a possibility in any pregnant woman beyond 20 weeks of gestation. It is particularly difficult to diagnose when a preexisting disease such as hypertension is present. Uric acid values can be quite helpful in such situations, since hyperuricemia is uncommon in pregnancy except with gout, kidney disease, or preeclampsia-eclampsia.

▶ Treatment

The use of diuretics, dietary restriction or enhancement, sodium restriction, aspirin, and vitamin-mineral supplements such as calcium or vitamin C and E have not been confirmed to be useful in clinical studies. The only cure is termination of the pregnancy at a time as favorable as possible for fetal survival. Magnesium sulfate should be given intravenously, 4- to 6-g load followed by 2–3 g/h maintenance, for seizure prophylaxis in patients with severe preeclampsia.

A. Preeclampsia

Early recognition is the key to treatment. This requires careful attention to the details of prenatal care—especially

Table 19–3. Indicators of mild versus severe preeclampsia-eclampsia.

| Site | Indicator | Mild to Moderate | Severe |
|------------------------|---|--|---|
| Central nervous system | Symptoms and signs | Hyperreflexia | Seizures Blurred vision Scotomas Headache Clonus Irritability |
| Kidney | Proteinuria Uric acid Urinary output | 0.3–5 g/24 h ↑ > 4.5 mg/dL > 30 mL/h | > 5 g/24 h or catheterized urine with 4+ protein ↑↑ > 4.5 mg/dL < 30 mL/h |
| Liver | AST, ALT, LDH | Normal | Elevated LFTs Epigastric pain Ruptured liver |
| Hematologic | Platelets Hemoglobin | > 100,000/mcL Normal range | < 100,000/mcL Elevated |
| Vascular | Blood pressure Retina | < 160/110 mm Hg Arteriolar spasm | > 160/110 mm Hg Retinal hemorrhages |
| Fetal-placental unit | Growth restriction Oligohydramnios Fetal distress | Absent Absent Absent | Present Present Present |

AST, aspartate aminotransferase; ALT, alanine aminotransferase; LDH, lactate dehydrogenase; LFTs, liver function tests.

subtle changes in blood pressure and weight. The objectives are to prolong pregnancy if possible, to allow fetal lung maturity while preventing progression to severe disease and eclampsia. The critical factors are the gestational age of the fetus, fetal pulmonary maturity, and the severity of maternal disease. Preeclampsia-eclampsia at term is managed by delivery. Prior to term, severe preeclampsia-eclampsia requires delivery with very few exceptions. Epigastric pain, severe range blood pressures, thrombocytopenia, and visual disturbances are strong indications for delivery of the fetus. Severe disease by protein alone can be managed more conservatively.

For mild preeclampsia, bed rest is the cornerstone of therapy. This increases central blood flow to the kidneys, heart, brain, liver, and placenta and may stabilize or even improve the degree of preeclampsia-eclampsia for a period of time.

Bed rest may be attempted at home or in the hospital. Prior to making this decision, the clinician should evaluate the six sites of involvement listed in Table 19–3 and make an assessment about the severity of disease.

1. Home management—Home management with bed rest may be attempted for patients with mild preeclampsia and a stable home situation. This requires assistance at home, rapid access to the hospital, a reliable patient, and the ability to obtain frequent blood pressure readings. A home health nurse can often provide frequent home visits and assessment.

2. Hospital care—Hospitalization is required for women with severe preeclampsia or those with unreliable home

situations. Regular assessment of blood pressure, reflexes, urine protein, and fetal heart tones and activity are required. A complete blood count, platelet count, and electrolyte panel including liver enzymes should be checked every 1 or 2 days. A 24-hour urine collection for creatinine clearance and total protein should be obtained on admission and repeated as indicated. Magnesium sulfate is not used until the diagnosis of severe preeclampsia is made and delivery planned.

Fetal evaluation should be obtained as part of the workup. If the patient is being admitted to the hospital, fetal testing should be performed on the same day to assess fetal wellbeing. This may be done by fetal heart rate testing with nonstress or stress testing or by biophysical profile. A regular schedule of fetal surveillance must then be followed. Daily fetal kick counts can be recorded by the patient herself. Consideration can be given to amniocentesis to evaluate fetal lung maturity if hospitalization occurs at 30–37 weeks of gestation. If immaturity is suspected, corticosteroids (betamethasone 12 mg intramuscularly every 24 h for two doses, or dexamethasone 6 mg intramuscularly every 12 h for four doses) can be administered to the mother. Fetuses between 26 and 30 weeks of gestation can be presumed to be immature, and corticosteroids should be given.

The method of delivery is determined by the maternal and fetal status. A vaginal delivery is preferred because it has less blood loss than a cesarean section and requires less coagulation factors. Cesarean section is reserved for the usual fetal indications.

B. Eclampsia

1. Emergency care—If the patient is convulsing, she is turned on her side to prevent aspiration and to improve blood flow to the placenta. Fluid or food is aspirated from the glottis or trachea. The seizure may be stopped by giving an intravenous bolus of either magnesium sulfate, 4–6 g, or lorazepam, 2–4 mg over 4 minutes or until the seizure stops. Magnesium sulfate is the preferred agent, and alternatives should only be used if magnesium sulfate is unavailable. A continuous intravenous infusion of magnesium sulfate is then started at a rate of 2–3 g/h unless the patient is known to have significantly reduced kidney function. Magnesium blood levels are then checked every 4–6 hours and the infusion rate adjusted to maintain a therapeutic blood level (4–6 mEq/L). Urinary output is checked hourly and the patient assessed for signs of possible magnesium toxicity such as loss of deep tendon reflexes or decrease in respiratory rate and depth, which can be reversed with calcium gluconate, 1 g intravenously over 2 minutes.

2. General care—The occurrence of eclampsia necessitates delivery once the patient is stabilized. It is important, however, that assessment of the status of the patient and fetus take place first. Continuous fetal monitoring must be performed and blood typed and cross-matched quickly. A urinary catheter is inserted to monitor urinary output, and blood is tested for complete blood count, platelets, liver enzymes, uric acid, creatinine, and electrolytes. If hypertension is present with systolic values of ≥ 160 mm Hg or diastolic values ≥ 110 mm Hg, antihypertensive medications should be administered to reduce the blood pressure to 140–150/90–100 mm Hg. Lower blood pressures than this may induce placental insufficiency through reduced perfusion. Hydralazine given in 5- to 10-mg increments intravenously every 20 minutes is frequently used to lower blood pressure. Labetalol, 10–20 mg intravenously, every 20 minutes as needed, can also be used.

3. Delivery—Delivery is mandated once eclampsia has occurred. Vaginal delivery is preferred. The rapidity with which delivery must be achieved depends on the fetal and maternal status following the seizure and the availability of laboratory data on the patient. Oxytocin may be used to induce or augment labor. Regional analgesia or general anesthesia is acceptable. Cesarean section is used for the usual obstetric indications.

4. Postpartum—Magnesium sulfate infusion (2–3 g/h) should be continued until preeclampsia-eclampsia has begun to resolve postpartum (which may take 1–7 days), but in any case for at least 24 hours. The most reliable indicator of this resolution is the onset of diuresis with urinary output of over 100–200 mL/h. When this occurs, magnesium sulfate can be discontinued. Late-onset preeclampsia-eclampsia can occur during the postpartum period. It is usually manifested by either hypertension or seizures. Treatment is the same as prior to delivery—ie, with hydralazine and magnesium sulfate.

► When to Refer

- New onset of hypertension and proteinuria in a pregnant patient > 20 weeks gestation.

- New onset of seizure activity in a pregnant patient.
- Symptoms of severe preeclampsia in a pregnant patient with elevated blood pressure above baseline.

► When to Admit

- Evidence of severe preeclampsia or eclampsia.
- Evaluation for preeclampsia when severe disease is suspected.
- Evaluation for preeclampsia in a patient with an unstable home environment.

ACUTE FATTY LIVER OF PREGNANCY

Acute fatty liver of pregnancy is a disorder limited to the gravid state. It occurs in the third trimester of pregnancy and involves acute hepatic failure. With improved recognition and immediate delivery, the mortality rate is now 20–30%. The disorder is usually seen after the 35th week of gestation and is more common in primigravidas and those with twins. The incidence is about 1:14,000 deliveries.

The cause of acute fatty liver of pregnancy is not known. However, as many as 20% of cases may be due to a homozygous fetal deficiency of long-chain 3-hydroxyacyl-coenzyme A dehydrogenase (LCHAD) deficiency in a heterozygous mother.

► Clinical Findings

Pathologic findings are unique to the disorder, with fatty engorgement of hepatocytes. Clinical onset is gradual, with flu-like symptoms that progress to the development of abdominal pain, jaundice, encephalopathy, disseminated intravascular coagulation, and death. On examination, the patient shows signs of hepatic failure.

Laboratory findings show marked elevation of alkaline phosphatase but only moderate elevations of alanine aminotransferase (ALT) and aspartate aminotransferase (AST). Prothrombin time and bilirubin are also elevated. The white blood cell count is elevated, and the platelet count is depressed. Hypoglycemia may be extreme.

► Differential Diagnosis

The differential diagnosis is that of fulminant hepatitis. However, liver aminotransferases for fulminant hepatitis are higher (> 1000 units/mL) than those for acute fatty liver of pregnancy (usually 500–1000 units/mL). It is also important to review the appropriate history and perform the appropriate tests for toxins that cause liver failure. Preeclampsia may involve the liver but typically does not cause jaundice. The elevations in liver function tests in patients with preeclampsia usually do not reach the levels seen in patients with acute fatty liver of pregnancy.

▶ Treatment

Diagnosis of acute fatty liver of pregnancy mandates immediate delivery. Supportive care during labor includes administration of glucose, platelets, and fresh frozen plasma as needed. Vaginal delivery is preferred. Resolution of encephalopathy occurs over days, and supportive care with a low-protein diet is needed.

▶ Prognosis

Recurrence rates for this liver disorder are unclear but probably increased in families with proven LCHAD deficiency. Most authorities advise against subsequent pregnancy, but there have been reported cases of successful outcomes in later pregnancies.

Ko H et al. Acute fatty liver of pregnancy. *Can J Gastroenterol*. 2006 Jan;20(1):25–30. [PMID: 16432556]

PRETERM (Premature) LABOR

ESSENTIALS OF DIAGNOSIS

- ▶ Regular, rhythmic contractions 5 minutes apart.
- ▶ Contractions are painful and result in cervical change.
- ▶ Cervical effacement occurs.

▶ General Considerations

Preterm (premature) labor is labor that begins before the 37th week of gestation; it is responsible for 85% of neonatal morbidity and mortality. Risk factors for preterm labor include a past history of preterm delivery, premature rupture of the membranes, urinary tract infection, exposure to DES, multiple gestation, and abdominal or cervical surgery. In high-risk women (prior preterm birth), ultrasound measurement of cervical length (< 25 mm) in the second trimester may also identify risk. Several prospective randomized controlled trials have failed to demonstrate a benefit of home uterine activity monitoring in preventing preterm birth.

▶ Clinical Findings

Distinguishing true from false labor in patients with a history of previous preterm births can be facilitated by the use of fetal fibronectin measurement in cervicovaginal specimens. Its absence (< 50 ng/mL) in the face of uterine contractions in a patient with a previous preterm birth has a negative predictive value of 93–97% for delivery within 7–14 days.

▶ Treatment

Patients must be educated to identify regular, frequent uterine contractions so they can be evaluated early and treatment initiated if necessary.

Numerous agents have been given in an attempt to stop preterm birth. **Magnesium sulfate** is commonly used. Magnesium sulfate is given intravenously as a 4- to 6-g

bolus followed by a continuous infusion of 2–3 g/h. The rate may be increased by 1 g/h every 30 minutes to 2 hours until contractions cease or a maximum blood magnesium concentration of 6–8 mg/dL is reached. Magnesium levels are determined every 4–6 hours to monitor the blood level. After contractions have ceased for 12–24 hours, magnesium can be stopped and the situation reassessed.

β-Adrenergic drugs such as terbutaline have also been used. Terbutaline can be given as an intravenous infusion starting at 2.5 mcg/min and increased by 2.5 mcg/min every 20 minutes until contractions cease or until a maximum dose of 20 mcg/min is reached. Terbutaline can also be administered as subcutaneous injections of 250 mcg every 30 minutes up to 1 mg/4 h. Oral terbutaline therapy following parenteral treatment is often elected and consists of giving 2.5–5 mg every 4–6 hours. With terbutaline, a dose-related elevation of heart rate of 20–40 beats/min may occur. An increase of systolic blood pressure up to 10 mm Hg is likely, and the diastolic pressure may fall 10–15 mm Hg during the infusion. Transient elevation of blood glucose, insulin, and fatty acids together with slight reduction of serum potassium have been reported with β-adrenergic drugs. Fetal tachycardia may be slight or absent. No drug-related perinatal deaths have been reported with β-agonists. Maternal side effects requiring dose limitation are tachycardia (≥ 120 beats/min), palpitations, and nervousness. Fluids should be limited to 2500 mL/24 h. Serious side effects (pulmonary edema, chest pain with or without electrocardiographic changes) are often idiosyncratic, not dose-related, and warrant termination of therapy.

Nifedipine, 20 mg orally every 6 h, and indomethacin, 50 mg orally once then 25 mg orally every 6 h up to 48 h, have also been used with limited success. It is recommended that nifedipine not be given in conjunction with magnesium sulfate. Other tocolytics have been given simultaneously in an attempt to stop advanced preterm labor.

Before attempts are made to prevent labor with medication, the patient should be assessed for any conditions that would prompt iatrogenic preterm delivery. Severe preeclampsia, certain fetal anomalies, abruption, and intrauterine infection are all indications for preterm delivery. In these cases, it would be inappropriate to delay delivery with tocolytics.

In pregnancies between 24 and 34 weeks gestation where preterm birth is anticipated, betamethasone, 12 mg intramuscularly repeated once 24 hours later, or dexamethasone, 6 mg intramuscularly, repeated every 12 hours for four doses, is administered to hasten fetal lung maturation. Repeat courses are not recommended.

A prospective randomized controlled study has suggested that weekly injections of 17α-hydroxyprogesterone caproate from 16 to 36 weeks of gestation in women with a history of preterm delivery can reduce the rate of recurrent preterm birth.

▶ When to Refer

- Contractions 5 minutes apart for > 2 hours.
- Rupture of membranes.
- Vaginal bleeding.

▶ When to Admit

- Cervical dilation of ≥ 2 cm prior to 34 weeks gestation.
- Contractions that cause cervical change.
- Rupture of membranes.

Spong CY. Prediction and prevention of recurrent spontaneous preterm birth. *Obstet Gynecol.* 2007 Aug;110(2 Pt 1):405–15. [PMID: 17666618]

THIRD-TRIMESTER BLEEDING

Five to 10 percent of women have vaginal bleeding in late pregnancy. The clinician must distinguish between placental causes (placenta previa, placental abruption, vasa previa) and nonplacental causes (infection, disorders of the lower genital tract, systemic disease). The approach to bleeding in late pregnancy should be conservative and expectant unless fetal distress or excessive maternal hemorrhage occurs.

The patient should be hospitalized and placed on bed rest with continuous fetal monitoring. A complete blood count (including platelets) should be obtained and two to four units of blood typed and cross-matched. Coagulation studies should be ordered as clinically indicated. Ultrasound examination should be performed to determine placental location. Digital pelvic examinations are done only after ultrasound examination has ruled out placenta previa. Continuous electronic fetal monitoring is required to assess for fetal distress. While uterine contractions, pain, or tenderness often indicate placental abruption, an ultrasound examination that is negative for retroplacental clot does not exclude it. In most cases, abruption is an indication for immediate delivery because of the high risk of fetal death. Hypertension is a known risk factor for abruption, and the patient should be assessed with this in mind. Other risk factors include multiparity, cocaine use, smoking, previous abruption, and thrombophilias.

Placenta previa occurs when the placenta grows over the internal cervical os. Its presence at term is an indication for cesarean section. If the patient presents with bleeding at less than 36 weeks of gestation, continued hospitalization and bed rest may be necessary, especially during the initial 7–10 days. If the patient lives in close proximity to the hospital, has immediate access to the hospital, can be on bed rest, and has complete resolution of bleeding and uterine contractions, home management may be considered. She must be well instructed and counseled regarding the risks. Patients with vaginal bleeding at less than 36 weeks of gestation should also be considered for amniocentesis to test for fetal lung maturity. Corticosteroid therapy is indicated if fetal lung maturity is not present.

Usta IM et al. Placenta previa-accreta: risk factors and complications. *Am J Obstet Gynecol.* 2005 Sep;193(3 Pt 2):1045–9. [PMID: 16157109]

OBSTETRIC COMPLICATIONS OF THE PERIPARTUM PERIOD

PUERPERAL MASTITIS (See Also Chapter 17)

Postpartum mastitis occurs sporadically in nursing mothers shortly after they return home, or it may occur in epidemic form in the hospital. *Staphylococcus aureus* is usually the causative agent. Inflammation is generally unilateral, and women nursing for the first time are more often affected. Rarely, inflammatory carcinoma of the breast can be mistaken for puerperal mastitis.

Mastitis frequently begins within 3 months after delivery and may start with a sore or fissured nipple. There is obvious cellulitis in an area of breast tissue, with redness, tenderness, local warmth, and fever. Treatment consists of antibiotics effective against penicillin-resistant staphylococci (dicloxacillin or a cephalosporin, 500 mg orally every 6 hours for 5–7 days) and regular emptying of the breast by nursing followed by expression of any remaining milk by hand or with a mechanical suction device. Failure to respond to usual antibiotics within 3 days or the presence of an abscess should prompt consideration of resistant staphylococci (methicillin-resistant *S aureus* [MRSA]).

If the mother begins antibiotic therapy before suppuration begins, infection can usually be controlled in 24 hours. If delay is permitted, breast abscess can result. Incision and drainage are required for abscess formation. Despite puerperal mastitis, the baby usually thrives without prophylactic antimicrobial therapy.

CHORIOAMNIONITIS & ENDOMETRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Fever not attributable to another source.
- ▶ Uterine tenderness.
- ▶ Foul smelling vaginal discharge.
- ▶ Tachycardia in the mother or fetus, or both.

▶ General Considerations

Peripartum infection of the uterus is a common problem encountered during labor and postpartum. Uterine infection when still pregnant is referred to as chorioamnionitis, since the infection involves the chorion. Uterine infection after delivery is called endometritis, endomyometritis, or metritis. It is a polymicrobial infection most commonly attributed to urogenital pathogens. Risk factors include cesarean section, prolonged labor, use of internal monitors, many pelvic exams, prolonged rupture of membranes, and lower genital tract infections.

▶ Clinical Findings

Chorioamnionitis and endometritis are diagnosed by the presence of fever (≥ 38 °C) in the absence of any other

source and one or more of the following signs: maternal tachycardia, fetal tachycardia, foul-smelling lochia, and uterine tenderness. Cultures of the cervix are not done because of the polymicrobial nature of the infection.

▶ Treatment

Treatment is with broad-spectrum antibiotics that will cover gram-positive organisms and gram-negative organisms if still pregnant and gram-negative organisms and anaerobes if postpartum. A common regimen for chorioamnionitis is ampicillin, 2 g intravenously every 6 hours, and gentamicin, 2 mg/kg intravenous load then 1.5 mg/kg intravenously every 8 hours. A common regimen for metritis is gentamicin, 2 mg/kg intravenous load then 1.5 mg/kg intravenously every 8 hours, and clindamycin, 900 mg intravenously every 8 hours. Antibiotics are stopped when the patient has been afebrile for 24 hours. No oral antibiotics are given. Patients with metritis who do not respond in the first 24–48 hours may have enterococcus and require the addition of ampicillin to the regimen.

MEDICAL CONDITIONS COMPLICATING PREGNANCY

ANEMIA

Plasma volume increases 50% during pregnancy, while red cell volume increases 25%, causing lower hemoglobin and hematocrit values, which are maximally changed around the 24th to 28th weeks. Anemia in pregnancy is often defined as a hemoglobin measurement below 10 g/dL or hematocrit below 30%. Anemia is very common in pregnancy, causing fatigue, anorexia, dyspnea, and edema. Prevention through optimal nutrition and iron and folic acid supplementation is desirable.

A. Iron Deficiency Anemia

Many women enter pregnancy with low iron stores resulting from heavy menstrual periods, previous pregnancies, breastfeeding, or poor nutrition. It is difficult to meet the increased requirement for iron through diet, and anemia often develops unless iron supplements are given. Red cells may not become hypochromic and microcytic until the hematocrit has fallen significantly. When this occurs, a serum iron level below 40 mcg/dL and transferrin saturation less than 10% are consistent with iron deficiency anemia (see Chapter 13). Treatment consists of a diet containing iron-rich foods and 60 mg of oral elemental iron (eg, 300 mg of ferrous sulfate) three times a day with meals. Iron is best absorbed if taken with a source of vitamin C (raw fruits and vegetables, lightly cooked greens). All pregnant women should take daily iron supplements.

B. Folic Acid Deficiency Anemia

Folic acid deficiency anemia is the main cause of macrocytic anemia in pregnancy, since vitamin B₁₂ deficiency anemia is rare in the childbearing years. The daily require-

ment of folic acid doubles from 0.4 mg to 0.8 mg in pregnancy. Twin pregnancies, infections, malabsorption, and use of anticonvulsant drugs such as phenytoin can precipitate folic acid deficiency. The anemia may first be seen in the puerperium owing to the increased need for folate during lactation.

The diagnosis is made by finding macrocytic red cells and hypersegmented neutrophils in a blood smear (see Chapter 13). However, blood smears in pregnancy may be difficult to interpret, since they frequently show iron deficiency changes as well. Because the deficiency is hard to diagnose and folate intake is inadequate in some socioeconomic groups, 0.8–1 mg of oral folic acid is given as a supplement in pregnancy; the dose in established deficiency is 1–5 mg/d.

Good sources of folate in food are leafy green vegetables, orange juice, peanuts, and beans. Cooking and storage of food destroy folic acid. Strict vegetarians who eat no eggs or milk products should take vitamin B₁₂ supplements during pregnancy and lactation.

C. Sickle Cell Anemia

Women with sickle cell anemia are subject to serious complications in pregnancy. The anemia becomes more severe, and crises may occur more frequently. Complications include infections, bone pain, pulmonary infarction, congestive heart failure, and preeclampsia. There is an increased rate of spontaneous abortion and higher maternal and perinatal mortality rates. Intensive medical treatment may improve the outcome for mother and fetus. Frequent transfusions of packed cells or leukocyte-poor washed red cells to lower the level of hemoglobin S and elevate the level of hemoglobin A is controversial. Management decisions should be made in conjunction with a maternal fetal medicine specialist and a hematologist.

Genetic counseling should be offered to patients with sickle cell disease or sickle trait. They may wish to undergo first-trimester chorionic villus biopsy or second-trimester amniocentesis to determine whether the abnormality has been passed to the fetus. Intrauterine devices and oral contraceptives are relatively contraindicated, but progestin-only contraceptives may be used. Women with sickle cell trait alone usually have an uncomplicated pregnancy except for an increased risk of urinary tract infection. Sickle cell-hemoglobin C disease in pregnancy is similar to sickle cell anemia and is treated similarly.

ACOG Committee on Obstetrics. ACOG Practice Bulletin No. 78: hemoglobinopathies in pregnancy. *Obstet Gynecol.* 2007 Jan;109(1):229–37. [PMID: 17197616]

LUPUS ANTICOAGULANT-ANTICARDIOLIPIN-ANTIPHOSPHOLIPID ANTIBODY SYNDROME

The presence of antibodies to phospholipids and a variety of clinical symptoms, including vascular thromboses, thrombocytopenia, and recurrent pregnancy loss, characterize the lupus anticoagulant-anticardiolipin-antiphospholipid antibody syndrome. Many of these patients have systemic lupus erythematosus–like symptoms but do not meet specific

diagnostic criteria for that disease. The lupus anticoagulant and anticardiolipin antibody may occur in these patients, and both may cause arterial and venous thromboses. Detection of these antiphospholipid antibodies may require a combination of laboratory tests. The lupus anticoagulant will prolong both the partial thromboplastin time and the Russell viper venom time. The latter is a more sensitive predictor of disease. Such patients should also be screened for the presence of the factor V Leiden mutation. Anticardiolipin antibody may be detected with enzyme-linked immunosorbent assay (ELISA) testing. Either antibody may cause false-positive serologic tests for syphilis.

This syndrome may require treatment with anticoagulant medications. In a small number of patients with recurrent pregnancy loss and a diagnosis of lupus anticoagulant syndrome, improved outcomes have been reported following treatment with heparin anticoagulation (8000–20,000 units subcutaneously in two or three doses daily) or low-molecular-weight heparin (1 mg/kg subcutaneously twice daily) and low-dose (81 mg) aspirin begun before or early in pregnancy and continued until the postpartum period. The addition of monthly infusions of intravenous immunoglobulin to this regimen did not improve outcomes in such patients.

Tincani A et al. Pregnancy, lupus and antiphospholipid syndrome (Hughes syndrome). *Lupus.* 2006;15(3):156–60. [PMID: 16634369]

THYROID DISEASE

Thyrotoxicosis during pregnancy may result in fetal anomalies, late abortion, or preterm labor, and fetal hyperthyroidism with goiter. Thyroid storm in late pregnancy or labor is a life-threatening emergency.

Radioactive isotope therapy must never be given during pregnancy. The thyroid inhibitor of choice is propylthiouracil, which acts to prevent further T_4 formation by blocking iodination of tyrosine. There is a 2- to 3-week delay before the pretreatment hormone level begins to fall. The initial dose of propylthiouracil is 100–150 mg orally three times a day; the dose is lowered as the euthyroid state is approached. It is desirable to keep free T_4 in the high normal range during pregnancy. A maintenance dose of 100 mg/d minimizes the chance of fetal hypothyroidism and goiter. While waiting for the propylthiouracil to take effect, the patient's symptoms can be treated with a β -blocker.

Recurrent postpartum thyroiditis occurs 3–6 months after delivery. A hyperthyroid state of 1–3 months' duration is followed by hypothyroidism, sometimes misdiagnosed as depression. Thyroperoxidase antibodies and thyroglobulin antibodies are present. Recovery is spontaneous in over 90% of cases after 3–6 months.

Maternal hypothyroidism may adversely affect the neuropsychological development of the child. Mothers with known or suspected hypothyroidism should have their TSH and free T_4 level measured at the first prenatal

visit. It is not clear if there is a benefit to treating subclinical hypothyroidism. In patients with overt hypothyroidism, replacement therapy with levothyroxine should be adjusted to maintain levels of TSH in the normal range. Levels should be checked every 6–8 weeks. Because of the increased volume of distribution in pregnant women, it is likely that a woman will need a higher dose of levothyroxine than she would when she is not pregnant.

Casey BM et al. Thyroid disease in pregnancy. *Obstet Gynecol.* 2006 Nov;108(5):1283–92. [PMID: 17077257]

DIABETES MELLITUS

Pregnancy is associated with increased tissue resistance to insulin, resulting in increased levels of blood insulin as well as glucose and triglycerides. These changes are due to placental lactogen and elevated circulating estrogens and progesterone. Although pregnancy does not appear to alter the long-term consequences of diabetes, retinopathy and nephropathy may first appear or become worse during pregnancy. Debate continues over whether gestational diabetics are women whose glucose intolerance is solely a function of their pregnancy compared with their nonpregnant state. Alternatively, pregnancy may merely serve to unmask an underlying propensity for glucose intolerance, which will be evident even in the nonpregnant state at some time in the future if not in the immediate postpartum period. Indeed, 50% of women with gestational diabetes are diagnosed with overt diabetes at some point in their lifetime. The goals for glycemic control during pregnancy are the same whether the diagnosis is made before or during the pregnancy.

Pregnancy counseling and evaluation of diabetic women should include a complete chemistry panel, HbA_{1c} determination, 24-hour urine collection for total protein and creatinine clearance, fundoscopic examination, and an ECG. Any medical problems should be addressed, and HbA_{1c} levels of 6% should be achieved before pregnancy. Euglycemia should be established before conception and maintained during pregnancy with daily home glucose monitoring by the patient. A well-planned dietary program is a key component, with an intake of 1800–2200 kcal/d divided into three meals and three snacks. Insulin is given subcutaneously in a split-dose regimen with frequent dosage adjustments. Patients taking some oral agents prior to pregnancy should be switched to insulin. However, limited information suggests that agents such as glyburide may be safe and effective in pregnancy. The use of continuous insulin pump therapy has been found to be very useful during pregnancy in women with type 1 diabetes mellitus.

Congenital anomalies result from hyperglycemia during the first 4–8 weeks of pregnancy. They occur in 4–10% of diabetic pregnancies (two to three times the rate in nondiabetic pregnancies). Rates are even higher in women with excessive HbA_{1c} levels. Euglycemia in the early weeks of pregnancy, when organogenesis is occurring, reduces the rate of anomalies to near-normal levels. Even so, because few women with diabetes begin a rigorous program to achieve euglycemia until well after they have become preg-

nant, congenital anomalies are the principal cause of perinatal fetal deaths in diabetic pregnancies. All women with diabetes should receive counseling about pregnancy and, when the decision has been made to start a family, should receive pre-pregnancy management by providers experienced in diabetic pregnancies.

Fasting and preprandial glucose values are lower during pregnancy in both diabetic and nondiabetic women. Euglycemia is considered to be 60–90 mg/dL while fasting and 30–45 minutes before meals and < 120 mg/dL 2 hours after meals. This is the target for good diabetic control during pregnancy. Glycated hemoglobin levels help determine the quality of glucose control both before and during pregnancy.

While perinatal problems for mother and baby are decreased by fastidious diabetic control, the incidence of hydramnios, preeclampsia-eclampsia, infections, and prematurity is increased even in carefully managed diabetic pregnancies. Diabetes is an inherently unstable disease characterized by fluctuations of blood glucose levels, particularly late in pregnancy. The risk of fetal demise in the third trimester (stillbirth) and neonatal death increases with the level of hyperglycemia. Consequently, pregnant women with diabetes must receive regular antepartum fetal testing (nonstress testing, contraction stress testing, biophysical profile) during the third trimester. The timing of delivery is dictated by the quality of diabetic control, the presence or absence of medical complications, and fetal status. The goal is to reach 39 weeks (38 completed weeks) and then proceed with delivery. Confirmation of lung maturity is necessary only for delivery prior to 39 weeks. Cesarean sections are performed for obstetric indications.

Because 15% of patients with gestational diabetes require insulin during pregnancy and because the infants of gestational diabetics have some risks similar to those of infants of diabetic mothers (particularly macrosomia), screening of women for glucose intolerance has been recommended between the 24th and 28th weeks of pregnancy (Table 19–4). Patients with gestational diabetes should be evaluated 6–8 weeks postpartum by a 2-hour oral glucose tolerance test (75 g glucose load).

HYPERTENSIVE DISEASE

Hypertensive disease in women of childbearing age is usually essential hypertension, but secondary causes should be considered: coarctation of the aorta, pheochromocytoma, hyperaldosteronism, and renovascular and renal hypertension.

Preeclampsia is superimposed on 20% of pregnancies in hypertensive women and appears earlier, is more severe,

Table 19–4. Screening and diagnostic criteria for gestational diabetes mellitus.

Screening for gestational diabetes mellitus

1. 50-g oral glucose load, administered between the 24th and 28th weeks, without regard to time of day or time of last meal. Universal blood glucose screening is indicated for patients who are of Hispanic, African, Native American, South or East Asian, Pacific Island, or Indigenous Australian ancestry. Other patients who have no known diabetes in first-degree relatives, are under 25 years of age, have normal weight before pregnancy, and have no history of abnormal glucose metabolism or poor obstetric outcome do not require routine screening.
2. Venous plasma glucose measure 1 hour later.
3. Value of 140 mg/dL (7.8 mmol/L) or above in venous plasma indicates the need for a full diagnostic glucose tolerance test.

Diagnosis of gestational diabetes mellitus

1. 100-g oral glucose load, administered in the morning after overnight fast lasting at least 8 hours but not more than 14 hours, and following at least 3 days of unrestricted diet (> 150 g carbohydrate) and physical activity.
2. Venous plasma glucose is measured fasting and at 1, 2, and 3 hours. Subject should remain seated and should not smoke throughout the test.
3. Two or more of the following venous plasma concentrations must be equaled or exceeded for a diagnosis of gestational diabetes: fasting, 95 mg/dL (5.3 mmol/L); 1 hour, 180 mg/dL (10 mmol/L); 2 hours, 155 mg/dL (8.6 mmol/L); 3 hours, 140 mg/dL (7.8 mmol/L).

and is more often associated with intrauterine growth restriction. It may be difficult to determine whether or not hypertension in a pregnant woman precedes or derives from the pregnancy if she is not examined until after the 20th week. Serum uric acid can help differentiate, since it is elevated with preeclampsia and generally normal in chronic hypertension unless the patient is receiving diuretics. If hypertension persists for 6–8 weeks postpartum, essential hypertension is likely.

Pregnant women with chronic hypertension require medication only if the blood pressure is sustained at or above 150/100 mm Hg. For initiation of treatment, methyldopa has the longest record of safety in a starting dosage of 250 mg orally twice daily. Therapy with β -blockers or calcium channel blockers is also acceptable (see Tables 11–7, 11–9). The goal is to keep the blood pressure between 130–150/80–100 mm Hg.

If a hypertensive woman is being managed successfully by medical treatment when she registers for antenatal care, one may generally continue the antihypertensive medication. Diuretics, not usually started in pregnancy, may be continued in patients taking them prior to pregnancy. Angiotensin-converting enzyme inhibitors should be replaced with a drug of another class because of reports of fetal and neonatal kidney failure with these compounds.

Use of antihypertensive medications in preeclampsia remains controversial. This should be attempted only with significant fetal prematurity, absence of fetal compromise, and close supervision of the patient by a maternal fetal medicine specialist.

Therapeutic abortion may be considered in cases of severe hypertension during pregnancy. If pregnancy is allowed to continue, the risk to the fetus must be assessed periodically in anticipation of early delivery. An early first-trimester ultrasound examination will confirm the duration of pregnancy, and follow-up examinations after 26 weeks will evaluate intrauterine growth restriction.

Karthikeyan VJ et al. Hypertension in pregnancy: pathophysiology and management strategies. *Curr Pharm Des.* 2007;13(25):2567–79. [PMID: 17897001]

HEART DISEASE

Overall, 5% of maternal deaths are due to heart disease. Most heart disease complicating pregnancy in the United States is congenital heart disease. Normal pregnancy causes a faster pulse, an increase of cardiac output of more than 30%, and a rise in plasma volume greater than red cell mass with relative hemodilution. Vital capacity and oxygen consumption rise only slightly.

For practical purposes, the functional capacity of the heart is the best single measurement of cardiopulmonary status (see box, Functional Cardiac Assessment). In general, patients with class I or class II functional disability (80% of pregnant women with heart disease) do well obstetrically, with four-fifths of maternal deaths due to heart disease occurring in women with class III or class IV disability. Congestive failure is the usual cause of death. Most deaths occur in the early puerperium. Pregnancy is contraindicated in Eisenmenger complex, in primary pulmonary hypertension, in severe mitral stenosis with secondary pulmonary hypertension, and in Marfan syndrome, in which the aorta is prone to dissection and rupture. In addition, pregnancy is poorly tolerated in patients with aortic stenosis, aortic coarctation, tetralogy of Fallot, and active rheumatic carditis.

Therapeutic abortion and elective sterilization should be offered to patients with significant cardiac disease. Cesarean section should be performed only for obstetric indications. Women with valvular heart disease, mitral valve prolapse associated with mitral regurgitation, or idiopathic hypertrophic cardiomyopathy should receive appropriate antibiotic prophylaxis against infective endocarditis during labor and delivery or termination of pregnancy.

FUNCTIONAL CARDIAC ASSESSMENT

| | |
|-----------|--|
| Class I | Ordinary physical activity causes no discomfort (perinatal mortality rate about 5%). |
| Class II | Ordinary activity causes discomfort and slight disability (perinatal mortality rate 10–15%). |
| Class III | Less than ordinary activity causes discomfort or disability; patient is barely compensated (perinatal mortality rate about 35%). |
| Class IV | Patient decompensated; any physical activity causes acute distress (perinatal mortality rate over 50%). |

Women intending to carry the pregnancy to term should be monitored in conjunction with a cardiologist. The first 24 hours postpartum, in particular, are a critical time in fluid management, and patients require close observation.

Drenthen W et al. Outcome of pregnancy in women with congenital heart disease: a literature review. *J Am Coll Cardiol.* 2007 Jun 19;49(24):2303–11. [PMID: 17572244]
Elkayam U et al. Valvular heart disease and pregnancy: part II: prosthetic valves. *J Am Coll Cardiol.* 2005 Aug 2;46(3):403–10. [PMID: 16053950]

ASTHMA

The effect of pregnancy on asthma is unpredictable. About 50% of patients have no change, 25% improve, and 25% get worse. Management of acute and chronic asthma during pregnancy does not differ significantly from that of non-pregnant women. The goal is to maintain maternal $P_{O_2} > 80$ mm Hg to sustain normal fetal oxygenation (see Chapter 9).

Namazy JA et al. Current guidelines for the management of asthma during pregnancy. *Immunol Allergy Clin North Am.* 2006 Feb;26(1):93–102. [PMID: 16443145]

SEIZURE DISORDERS

Epileptic women contemplating pregnancy who have not had a seizure for 5 years should consider a prepregnancy trial of withdrawal from treatment. Those with recurrent epilepsy should use a single drug with blood level monitoring. Commonly used antiepileptics have known teratogenicity. Selecting a medication should be based on the type of seizure disorder and the risks associated with each medication. Phenytoin and levetiracetam are often used. There is promising but limited information available on the safety of newer antiepilepsy drugs (eg, lamotrigine), and they should be used with caution.

Serum levels should be measured as needed, including in cases of ongoing seizure activity or suspected noncompliance. Pregnant women taking phenobarbital and phenytoin should receive vitamin supplements, including folic acid and vitamin D, throughout pregnancy. Oral vitamin K is administered during the last month of pregnancy. Infants should receive an injection of vitamin K_1 subcutaneously immediately after delivery and should have clotting studies 2–4 hours later. Breastfeeding is not contraindicated for infants of mothers taking antiseizure medications.

Tettenborn B et al. Management of epilepsy in women of childbearing age: practical recommendations. *CNS Drugs.* 2006;20(5):373–87. [PMID: 16696578]

INFECTIOUS CONDITIONS COMPLICATING PREGNANCY

URINARY TRACT INFECTION

The urinary tract is especially vulnerable to infections during pregnancy because the altered secretions of steroid

sex hormones and the pressure exerted by the gravid uterus upon the ureters and bladder cause hypotonia and congestion and predispose to urinary stasis. Labor and delivery and urinary retention postpartum also may initiate or aggravate infection. *Escherichia coli* is the offending organism in over two-thirds of cases.

From 2% to 8% of pregnant women have asymptomatic bacteriuria, which some believe to be associated with an increased risk of preterm birth. It is estimated that pyelonephritis will develop in 20–40% of these women if untreated.

An evaluation for asymptomatic bacteriuria at the first prenatal visit is recommended for all pregnant women. If a urine culture is positive, treatment should be initiated. Nitrofurantoin (100 mg orally twice daily), ampicillin (250 mg orally four times daily), and cephalosporins (250 mg orally four times daily) are acceptable medications for 3–7 days. Sulfonamides should be avoided in the third trimester because they may interfere with bilirubin binding and thus impose a risk of neonatal hyperbilirubinemia and kernicterus. Fluoroquinolones are also contraindicated because of their potential teratogenic effects on fetal cartilage and bone. Patients with recurrent bacteriuria should receive suppressive medication (once daily dosing of an appropriate antibiotic) for the remainder of the pregnancy. Acute pyelonephritis requires hospitalization for intravenous administration of antibiotics and crystalloids until the patient is afebrile; this is followed by a full course of oral antibiotics.

Smaill F et al. Antibiotics for asymptomatic bacteriuria in pregnancy. *Cochrane Database Syst Rev.* 2007 Apr 18;(2):CD000490. [PMID: 17443502]

GROUP B STREPTOCOCCAL INFECTION

Group B streptococci frequently colonize the lower female genital tract, with an asymptomatic carriage rate in pregnancy of 5–30%. This rate depends on maternal age, gravidity, and geographic variation. Vaginal carriage is asymptomatic and intermittent, with spontaneous clearing in approximately 30% and recolonization in about 10% of women. Adverse perinatal outcomes associated with group B streptococcal colonization include urinary tract infection, intrauterine infection, premature rupture of membranes, preterm delivery, and postpartum endometritis.

Women with postpartum endometritis due to infection with group B streptococci, especially after cesarean section, develop fever, tachycardia, and abdominal distention, usually within 24 hours after delivery. Approximately 35% of these women are bacteremic.

Group B streptococcal infection is a common cause of neonatal sepsis. Transmission rates are high, yet the rate of neonatal sepsis is surprisingly low at less than 4:1000 live births. Unfortunately, the mortality rate associated with early-onset disease can be as high as 50% in premature infants and approaches 25% even in those at term. Moreover, these infections can contribute markedly to chronic morbidity, including mental retardation and neurologic disabilities. Late-onset disease develops through contact with hospital nursery personnel. Up to 45% of these health

care workers can carry the bacteria on their skin and transmit the infection to newborns.

CDC recommendations for screening and prophylaxis for group B streptococcal colonization are set forth in this chapter in the section on tests and procedures.

Akker-van Marle ME et al. Cost-effectiveness of different treatment strategies with intrapartum antibiotic prophylaxis to prevent early-onset group B streptococcal disease. *BJOG.* 2005 Jun;112(6):820–6. [PMID: 15924544]

VARICELLA

Commonly known as chickenpox, varicella-zoster virus (VZV) infection has a fairly benign course when incurred during childhood but may result in serious illness in adults, particularly during pregnancy. Infection results in lifelong immunity. Approximately 95% of women born in the United States have VZV antibodies by the time they reach reproductive age. The incidence of VZV infection during pregnancy has been reported as up to 7:10,000.

The incubation period for this infection is 10–20 days. A primary infection follows and is characterized by a flu-like syndrome with malaise, fever, and development of a pruritic maculopapular rash on the trunk which becomes vesicular and then crusts. Pregnant women are prone to the development of VZV pneumonia, often a fulminant infection sometimes requiring respiratory support. After primary infection, the virus becomes latent, ascending to dorsal root ganglia. Subsequent reactivation can occur as zoster, often under circumstances of immunocompromise, although this is rare during pregnancy.

Two types of fetal infection have been documented. The first is congenital VZV syndrome, which typically occurs in 0.4–2% of fetuses exposed to primary VZV infection during the first trimester. Anomalies include limb and digit abnormalities, microphthalmos, and microcephaly.

Infection during the second and third trimesters is less threatening. Maternal IgG crosses the placenta, protecting the fetus. The only infants at risk for severe infection are those born after maternal viremia but before development of maternal protective antibody. Maternal infection manifesting 5 days before or after delivery is the time period believed to be most hazardous for transmission to the fetus.

Diagnosis is commonly made on clinical grounds. Laboratory verification of recent infection is made most often by antibody detection techniques, including ELISA, fluorescent antibody, and hemagglutination inhibition. Serum obtained by cordocentesis may be tested for VZV IgM to document fetal infection.

Varicella-zoster immune globulin (VZIG) has been shown to prevent or modify the symptoms of infection in some women but is no longer readily available. Treatment success depends on identification of susceptible women at or just following exposure. Women with a questionable or negative history of chickenpox should be checked for antibody, since the overwhelming majority will have been previously exposed. If the antibody is negative, VZIG (625 units intramuscularly) should be given within 96 hours after exposure. There are no known adverse effects of

VZIG administration during pregnancy, although the incubation period for disease can be lengthened. Infants born within 5 days after onset of maternal infection should also receive VZIG (125 units).

Infected pregnant women should be closely observed and hospitalized at the earliest signs of pulmonary involvement. Intravenous acyclovir (10 mg/kg intravenously every 8 hours) is recommended in the treatment of VZV pneumonia.

Tan MP et al. Chickenpox in pregnancy: revisited. *Reprod Toxicol.* 2006 May;21(4):410–20. [PMID: 15979274]

TUBERCULOSIS

The diagnosis of tuberculosis in pregnancy is made by history taking, physical examination, and skin testing, with special attention to women in high-risk groups. Women at high risk include those who are from endemic areas, those infected with HIV, drug users, health care workers, and close contacts of people with tuberculosis. Chest radiographs should not be obtained as a routine screening measure in pregnancy but should be used only in patients with a skin test conversion or with suggestive findings in the history and physical examination. Abdominal shielding must be used if a chest radiograph is obtained.

Decisions on treatment depend on whether the patient has active disease or is at high risk for progression to active disease. Women who are PPD positive but not at high risk for disease progression can receive treatment postpartum, which does not preclude breastfeeding. The concentration of medication in breast milk is neither toxic nor adequate for treatment of the newborn. Treatment is with isoniazid and ethambutol or isoniazid and rifampin (see Chapters 9 and 33). Because isoniazid therapy may result in vitamin B₆ deficiency, a supplement of 50 mg/d of vitamin B₆ should be given simultaneously. Isoniazid, particularly in pregnant women, can cause hepatitis. Liver function tests should be performed regularly in pregnant women who receive treatment. Streptomycin, ethionamide, and most other antituberculous drugs should be avoided in pregnancy. If adequately treated, tuberculosis in pregnancy has an excellent prognosis.

HIV/AIDS DURING PREGNANCY

Heterosexual acquisition and injection drug use are the principal identified modes of HIV infection in women. Asymptomatic infection is associated with a normal pregnancy rate and no increased risk of adverse pregnancy outcomes. There is no evidence that pregnancy causes AIDS progression.

Previously, two-thirds of HIV-positive neonates acquired their infection close to, or during, the time of delivery. Routine HIV screening in pregnancy, including the use of rapid HIV tests in Labor and Delivery units, and the use of highly active antiretroviral therapy (HAART) therapy has markedly reduced this transmission risk. Zidovudine alone (500 mg/d orally) given to the mother antenatally starting at 14 weeks of gestation and during labor (1 mg/kg/h intravenously) and then to the infant (2 mg/kg orally four times daily) for the first 6 weeks of life reduces the transmission rate

from 25% to 8%. HAART reduced the risk even further, to approximately 2%, and has become the standard of care risk. HIV-positive pregnant women should be assessed by CD4 count, plasma RNA levels, resistance testing, and prior or current antiretroviral use. They should also be tested for hepatitis C, toxoplasmosis, and cytomegalovirus.

Pregnant HIV-positive women should be offered HAART with three drugs (commonly two nucleoside analogues and one protease inhibitor, including zidovudine whenever possible) after counseling regarding the potential impact of therapy on both mother and fetus. HAART should be offered regardless of viral load and CD4 count. The majority of drugs used to treat HIV/AIDS have thus far proven to be safe in pregnancy with an acceptable risk/benefit ratio. Efavirenz has been clearly linked with anomalies (myelomeningocele) and should not be used in pregnancy.

The use of prophylactic elective cesarean section before the onset of labor or rupture of the membranes to prevent vertical transmission of HIV infection from mother to fetus has been shown to further reduce the transmission rate. There is limited information on the impact of elective cesarean section on transmission rates in infants of mothers on HAART or with viral loads less than 1000 copies/mL. However, with HAART therapy and undetectable viral loads (< 50 copies/mL), the transmission risk has been estimated to be 1% or less and there may be no additional benefit of cesarean delivery. Women with viral loads less than 1000 copies/mL on HAART can be offered a vaginal delivery. Amniotomy should not be performed and internal monitors, particularly the fetal scalp electrode, should be avoided. HIV-infected women should be advised not to breastfeed their infants.

The Public Health Task Force provides guidelines for the management of HIV/AIDS in pregnancy that are regularly updated and available at <http://www.aidsinfo.nih.gov/>.

Centers for Disease Control and Prevention (CDC). Achievements in public health. Reduction in perinatal transmission of HIV infection—United States, 1985–2005. *MMWR Morb Mortal Wkly Rep.* 2006 Jun 2;55(21):592–7. [PMID: 16741495]
Public Health Service Task Force Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1 Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV-1 Transmission in the United States, October, 2006. <http://www.hivatis.org>.

MATERNAL HEPATITIS B & C CARRIER STATE

There are an estimated 200 million chronic carriers of hepatitis B virus worldwide. Among these people there is an increased incidence of chronic active hepatitis, cirrhosis, and hepatocellular carcinoma. The frequency of the hepatitis B carrier state varies from 1% in the United States and Western Europe to 35% in parts of Africa and Asia. All pregnant women should be screened for HBsAg. Transmission of the virus to the baby after delivery is likely if both surface antigen and e antigen are positive. Vertical transmission can be blocked by the immediate postdelivery administration to the newborn of 0.5 mL hepatitis B immunoglobulin and hepatitis B vaccine intramuscularly. The vaccine dose is repeated at 1 and 6 months of age.

Successful, but limited, experience has also been reported with lamivudine (150 mg/d) during the last 4 weeks of gestation to prevent vertical transmission of hepatitis B in mothers with high HBV viral loads.

Hepatitis C virus infection is the most common chronic blood-borne infection in the United States. Risk factors for transmission include blood transfusion, injection drug use, employment in patient care or clinical laboratory work, exposure to a sex partner or household member who has had a history of hepatitis, exposure to multiple sex partners, and low socioeconomic level. The average rate of hepatitis C virus (HCV) infection among infants born to HCV-positive, HIV-negative women is 5–6%. However, the average infection rate increases to 14% when mothers are coinfecting with HCV and HIV. The principal factor associated with transmission is the presence of HCV RNA in the mother at the time of birth.

Lee C et al. Effect of hepatitis B immunisation in newborn infants of mothers positive for hepatitis B surface antigen: systematic review and meta-analysis. *BMJ*. 2006 Feb 11;332(7537):328–36. [PMID: 16443611]

HERPES GENITALIS

Infection of the lower genital tract by herpes simplex virus type 2 (HSV-2) (see also Chapter 6) is a common STD of potential seriousness to pregnant women and their newborn infants. Although up to 20% of women in an obstetric practice may have antibodies to HSV-2, a history of the infection is unreliable and the incidence of neonatal infection is low (1:20,000–1:3000 live births). Most infected neonates are born to women with no symptoms, signs, or history of infection.

Women who have had *primary* herpes infection late in pregnancy are at high risk for shedding virus at delivery. Some authors suggest use of prophylactic acyclovir, 400 mg orally twice daily, to decrease the likelihood of active lesions at the time of labor and delivery.

Women with a history of *recurrent* genital herpes have a neonatal attack rate of $\leq 5\%$ and should be monitored by clinical observation and culture of any suspicious lesions. Since asymptomatic viral shedding is not predictable by antepartum cultures, current recommendations do not include routine cultures in individuals with a history of herpes without active disease. However, when labor begins, vulvar and cervical inspection should be performed. Cesarean section is indicated at the time of labor if there are prodromal symptoms, active genital lesions, or a positive cervical culture obtained within the preceding week.

For treatment, see Chapter 32. The use of acyclovir in pregnancy is acceptable, and prophylaxis starting at 36 weeks gestation has been shown to decrease the number of cesarean sections performed for active disease.

Gardella C et al. Managing genital herpes infections in pregnancy. *Cleve Clin J Med*. 2007 Mar;74(3):217–24. [PMID: 17375803]

SYPHILIS, GONORRHEA, & CHLAMYDIA TRACHOMATIS INFECTION (See Also Chapters 33 and 34)

These STDs have significant consequences for mother and child. Untreated syphilis in pregnancy can cause late abortion, stillbirth, transplacental infection, and congenital syphilis. Gonorrhea can produce large-joint arthritis by hematogenous spread as well as ophthalmia neonatorum. Maternal chlamydial infections are largely asymptomatic but are manifested in the newborn by inclusion conjunctivitis and, at age 2–4 months, by pneumonia. The diagnosis of each can be reliably made by appropriate laboratory tests. All women should be tested for syphilis as part of their routine prenatal care. Women at risk should be tested for gonorrhea and chlamydia. The sexual partners of women with STDs should be identified and treated also if possible; the local health department can assist.

Centers for Disease Control and Prevention. Sexually transmitted disease treatment guidelines 2006. *MMWR Recomm Rep*. 2006 Aug 4;55(RR-11):1–94. [PMID: 16888612]

SURGICAL COMPLICATIONS DURING PREGNANCY

Elective major surgery should be avoided during pregnancy. Normal uncomplicated pregnancy does not alter operative risk except as it may interfere with the diagnosis of abdominal disorders and increase the technical problems of intra-abdominal surgery. Abortion is not a serious hazard after operation unless peritoneal sepsis or other significant complications occur. During the first trimester, congenital anomalies may theoretically be induced in the developing fetus. Thus, the second trimester is usually the optimal time for operative procedures.

CHOLEDOCHOLITHIASIS, CHOLECYSTITIS, & IDIOPATHIC CHOLESTASIS OF PREGNANCY

Severe cholelithiasis and cholecystitis are not uncommon during pregnancy. They usually occur in late pregnancy or in the puerperium. About 90% of patients with cholecystitis have gallstones; 90% of stones will be visualized by ultrasonography. Symptomatic relief may be all that is required.

Conventional gallbladder surgery by laparotomy or laparoscopy in pregnant women should be performed when indicated. Traditionally, surgery is considered safest in the second trimester, but it has been successfully performed in all stages of pregnancy. Withholding surgery may result in necrosis and perforation of the gallbladder, pancreatitis, and peritonitis. Cholangitis due to impacted bile duct stone requires surgical removal of gallstones and establishment of biliary drainage. Endoscopic retrograde cholangiopancreatography and endoscopic retrograde sphincterotomy can be performed safely in pregnant women if precautions are taken to minimize exposure to radiation. In the early to mid second trimester, laparo-

scopic cholecystectomy can be performed with minimal maternal morbidity and fetal mortality.

Idiopathic cholestasis of pregnancy is due to a hereditary metabolic (hepatic) deficiency aggravated by the high estrogen levels of pregnancy. It causes intrahepatic biliary obstruction of varying degrees. The rise in serum bile acids is sufficient in the third trimester to cause severe, intractable, generalized itching and sometimes clinical jaundice. There may be mild elevations in blood bilirubin and alkaline phosphatase levels. The fetus is also threatened by this condition. An increased incidence of preterm delivery has been reported as well as unexplained intrauterine fetal demise. For this reason, antenatal surveillance of the fetus is needed in patients with this diagnosis. Resins such as cholestyramine (4 g orally three times a day) absorb bile acids in the large bowel and relieve pruritus but are difficult to take and may cause constipation. Their use requires vitamin K supplementation. Very encouraging experience has been reported with ursodeoxycholic acid, 8–10 mg/kg/d. The disorder is relieved once the infant has been delivered, but it recurs in subsequent pregnancies and sometimes with the use of oral contraceptives.

APPENDICITIS

Appendicitis occurs in about 1 of 1500 pregnancies. Diagnosis may be difficult, since the appendix is often carried high and to the right, away from McBurney point, as the uterus enlarges, and localization of pain does not always occur. Nausea, vomiting, fever, and leukocytosis occur regularly. Any right-sided abdominal pain associated with these symptoms should arouse suspicion. In at least 20% of obstetric patients, the diagnosis of appendicitis is not made until rupture occurs and peritonitis has become established. Such a delay may lead to premature labor or abortion. With early diagnosis and appendectomy, the prognosis is good for mother and baby.

Parangi S et al. Surgical gastrointestinal disorders during pregnancy. *Am J Surg*. 2007 Feb;193(2):223–32. [PMID: 17236852]

CARCINOMA OF THE BREAST

Cancer of the breast (see also Chapter 17) is diagnosed approximately once in 3500 pregnancies. Pregnancy may accelerate the growth of cancer of the breast, and delay in

diagnosis affects the outcome of treatment. Inflammatory carcinoma is an extremely virulent type of breast cancer that occurs most commonly during lactation. Prepregnancy mammography should be encouraged for women over age 35 who are anticipating a pregnancy.

Breast enlargement during pregnancy obscures parenchymal masses, and breast tissue hyperplasia decreases the accuracy of mammography. Any discrete mass should be evaluated by aspiration to verify its cystic structure, with fine-needle biopsy if it is solid. A definitive diagnosis may require excisional biopsy under local anesthesia. If breast biopsy confirms the diagnosis of cancer, surgery should be done regardless of the stage of the pregnancy. If spread to the regional glands has occurred, irradiation or chemotherapy should be considered. Under these circumstances, the alternatives are termination of an early pregnancy or delay of therapy for fetal maturation.

OVARIAN TUMORS

The most common adnexal mass in early pregnancy is the corpus luteum, which may become cystic and enlarge to 6 cm in diameter. Any persistent mass should be evaluated by ultrasound examination; unilocular cysts are likely to be corpus luteum cysts, whereas septated or semisolid tumors are likely to be neoplasms. The incidence of malignancy in ovarian masses over 6 cm in diameter is 2.5%. Ovarian tumors may undergo torsion and cause abdominal pain and nausea and vomiting and must be differentiated from appendicitis, other bowel disease, and ectopic pregnancy. Patients with suspected ovarian cancer should be referred to a tertiary perinatal center to determine whether the pregnancy can progress to fetal viability or whether treatment should be instituted without delay. There is a paucity of data regarding the removal of adnexal masses in pregnancy. It should certainly receive strong consideration in cases where the mass is suspicious for malignancy. If the decision is made to remove the adnexal mass, the second trimester of pregnancy is considered the best time. Removal of a large corpus luteum cyst in the first trimester requires progesterone supplementation and should be avoided.

Giuntoli RL et al. Evaluation and management of adnexal masses during pregnancy. *Clin Obstet Gynecol*. 2006 Sep;49(3):492–505. [PMID: 16885656]

Musculoskeletal & Immunologic Disorders

► Diagnosis & Evaluation

A. Examination of the Patient

In the patient with arthritis, the two clinical clues most helpful for diagnosis are the joint pattern and the presence or absence of extra-articular manifestations. The joint pattern is defined by the answers to three questions: (1) Is inflammation present? (2) How many joints are involved? and (3) What joints are affected? Joint inflammation manifests as redness, warmth, swelling, and morning stiffness of at least 30 minutes' duration. Both the number of affected joints and the specific sites of involvement affect the differential diagnosis (Table 20–1). Some diseases—gout, for example—are characteristically monoarticular, whereas other diseases, such as rheumatoid arthritis, are usually polyarticular. The location of joint involvement can also be distinctive. Only two diseases frequently cause prominent involvement of the distal interphalangeal (DIP) joint: osteoarthritis and psoriatic arthritis. Extra-articular manifestations such as fever (eg, gout, Still disease, endocarditis), rash (eg, systemic lupus erythematosus, psoriatic arthritis, Still disease), nodules (eg, rheumatoid arthritis, gout), or neuropathy (eg, polyarteritis nodosa, Wegener granulomatosis) narrow the differential diagnosis further.

B. Arthrocentesis and Examination of Joint Fluid

If the diagnosis is uncertain, synovial fluid should be examined whenever possible (Table 20–2). Most large joints are easily aspirated, and contraindications to arthrocentesis are few. The aspirating needle should never be passed through an overlying cellulitis or psoriatic plaque because of the risk of introducing infection. For patients who are receiving long-term anticoagulation therapy with warfarin, joints can be aspirated with a small-gauge needle (eg, 22F) if the international normalized ratio (INR) is less than 3.0.

1. Types of studies

A. GROSS EXAMINATION—Clarity is an approximate guide to the degree of inflammation. Noninflammatory fluid is transparent, mild inflammation produces translucent fluid, and purulent effusions are opaque. Bleeding disorders,

trauma, and traumatic taps are the most common causes of bloody effusions.

B. CELL COUNT—The synovial fluid white cell count discriminates between **noninflammatory** (< 2000 white cells/mcL), **inflammatory** (2000–75,000 white cells/mcL), and **purulent** (> 100,000 white cells/mcL) joint effusions. Synovial fluid glucose and protein levels add little information and should not be ordered.

C. MICROSCOPIC EXAMINATION—Compensated polarized light microscopy identifies and distinguishes monosodium urate (gout, negatively birefringent) and calcium pyrophosphate (pseudogout, positive birefringent) crystals. Gram stain has specificity but limited sensitivity (50%) for septic arthritis.

D. CULTURE—Bacterial cultures as well as special studies for gonococci, tubercle bacilli, or fungi are ordered as appropriate.

2. Interpretation—Synovial fluid analysis is diagnostic in infectious or microcrystalline arthritis. Although the severity of inflammation in synovial fluid can overlap among various conditions, the synovial fluid white cell count is a helpful guide to diagnosis (Table 20–3).

DEGENERATIVE & CRYSTAL-INDUCED ARTHRITIS

DEGENERATIVE JOINT DISEASE (Osteoarthritis)

ESSENTIALS OF DIAGNOSIS

- ▶ A degenerative disorder; no systemic symptoms.
- ▶ Commonly secondary to other articular disease.
- ▶ Pain relieved by rest; morning stiffness brief; articular inflammation minimal.
- ▶ Radiographic findings: narrowed joint space, osteophytes, increased density of subchondral bone, bony cysts.

Table 20-1. Diagnostic value of the joint pattern.

| Characteristic | Status | Representative Disease |
|---------------------------|----------------------------------|---|
| Inflammation | Present | Rheumatoid arthritis, systemic lupus erythematosus, gout |
| | Absent | Osteoarthritis |
| Number of involved joints | Monarticular | Gout, trauma, septic arthritis, Lyme disease, osteoarthritis |
| | Oligoarticular (2-4 joints) | Reactive arthritis, psoriatic arthritis, inflammatory bowel disease |
| | Polyarticular (≥ 5 joints) | Rheumatoid arthritis, systemic lupus erythematosus |
| Site of joint involvement | Distal interphalangeal | Osteoarthritis, psoriatic arthritis (not rheumatoid arthritis) |
| | Metacarpophalangeal, wrists | Rheumatoid arthritis, systemic lupus erythematosus (not osteoarthritis) |
| | First metatarsal phalangeal | Gout, osteoarthritis |

► General Considerations

Osteoarthritis, the most common form of joint disease, is chiefly a disease of aging. Ninety percent of all people have radiographic features of osteoarthritis in weight-bearing joints by age 40. Symptomatic disease also increases with age.

This arthropathy is characterized by degeneration of cartilage and by hypertrophy of bone at the articular margins. Inflammation is usually minimal. Hereditary and mechanical factors may be involved in the pathogenesis.

Obesity is a risk factor for osteoarthritis of the knee and probably of the hip. Recreational running does not increase the incidence of osteoarthritis, but participation in competitive contact sports does. Jobs requiring frequent bending and carrying increase the risk of knee osteoarthritis.

► Clinical Findings

A. Symptoms and Signs

Degenerative joint disease is divided into two types: (1) primary, which most commonly affects some or all of the following: the DIP and the proximal interphalangeal (PIP) joints of the fingers, the carpometacarpal joint of the thumb, the hip, the knee, the metatarsophalangeal (MTP) joint of the big toe, and the cervical and lumbar spine; and (2) secondary, which may occur in any joint as a sequela to articular injury resulting from either intra-articular (including rheumatoid arthritis) or extra-articular causes. The injury may be acute, as in a fracture; or chronic, as that due to occupational overuse of a joint, metabolic disease (eg, hyperparathyroidism, hemochromatosis, ochronosis), or neurologic disorders (tabes dorsalis; see below).

The onset is insidious. Initially, there is articular stiffness, seldom lasting more than 15 minutes; this develops later into pain on motion of the affected joint and is made worse by activity or weight bearing and relieved by rest. Bony enlargement of the DIP (Heberden nodes) and PIP (Bouchard nodes) joints are occasionally prominent, and flexion contracture or varus deformity of the knee is not unusual (Plate 79). There is no ankylosis, but limitation of motion of the affected joint or joints is common. Crepitus may often be felt in the joint. Joint effusion and other articular signs of inflammation are mild. There are no systemic manifestations.

B. Laboratory Findings

Osteoarthritis does not cause elevation of the erythrocyte sedimentation rate (ESR) or other laboratory signs of inflammation.

C. Imaging

Radiographs may reveal narrowing of the joint space; osteophyte formation and lipping of marginal bone; and thickened, dense subchondral bone. Bone cysts may also be present.

Table 20-2. Examination of joint fluid.

| Measure | (Normal) | Group I (Noninflammatory) | Group II (Inflammatory) | Group III (Purulent) |
|------------------------------|-------------|---------------------------|--------------------------|-------------------------------|
| Volume (mL) (knee) | < 3.5 | Often > 3.5 | Often > 3.5 | Often > 3.5 |
| Clarity | Transparent | Transparent | Translucent to opaque | Opaque |
| Color | Clear | Yellow | Yellow to opalescent | Yellow to green |
| WBC (per mL) | < 200 | 200-300 | 2000-75,000 ¹ | > 100,000 ² |
| Polymorphonuclear leukocytes | < 25% | < 25% | 50% or more | 75% or more |
| Culture | Negative | Negative | Negative | Usually positive ² |

¹Gout, rheumatoid arthritis, and other inflammatory conditions occasionally have synovial fluid WBC counts > 75,000/mL but rarely > 100,000/mL.

²Most purulent effusions are due to septic arthritis. Septic arthritis, however, can present with group II synovial fluid, particularly if infection is caused by organisms of low virulence (eg, *Neisseria gonorrhoeae*) or if antibiotic therapy has been started.

WBC, white blood cell count.

Table 20–3. Differential diagnosis by joint fluid groups.

| Group I (Noninflammatory) (< 2000 white cells/mcl) | Group II (Inflammatory) (2000 – $75,000$ white cells/mcl) | Group III (Purulent) ($> 100,000$ white cells/mcl) | Hemorrhagic |
|---|---|--|---|

► Differential Diagnosis

Because articular inflammation is minimal and systemic manifestations are absent, degenerative joint disease should seldom be confused with other arthritides. The distribution of joint involvement in the hands also helps distinguish osteoarthritis from rheumatoid arthritis. Osteoarthritis chiefly affects the DIP and PIP joints and spares the wrist and metacarpophalangeal (MCP) joints; rheumatoid arthritis involves the wrists and MCP joints and spares the DIP joints. Furthermore, the joint enlargement is bony-hard and cool in osteoarthritis but spongy and warm in rheumatoid arthritis. Skeletal symptoms due to degenerative changes in joints—especially in the spine—may cause coexistent metastatic neoplasia, osteoporosis, multiple myeloma, or other bone disease to be overlooked.

► Prevention

Weight reduction reduces the risk of developing symptomatic knee osteoarthritis. Maintaining normal vitamin D levels may reduce the occurrence and progression of osteoarthritis, in addition to being important for bone health.

► Treatment

A. General Measures

For patients with mild to moderate osteoarthritis of weight-bearing joints, moderate physical activity (eg, a supervised walking program, hydrotherapy classes, or Tai Chi classes) may result in clinical improvement of functional status without aggravating the joint pain. Weight loss can also improve the symptoms.

B. Analgesic and Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) (see Table 5–3) are more effective (and more toxic) than

acetaminophen for osteoarthritis of the knee or hip. Their superiority is most convincing in persons with severe disease. Patients with mild disease should start with acetaminophen (2.6–4 g/d). NSAIDs should be considered for patients who do not respond to acetaminophen. (See discussion of NSAID toxicity in the section on treatment of rheumatoid arthritis.) High doses of NSAIDs, as used in the inflammatory arthritides, are unnecessary. Chondroitin sulfate and glucosamine, alone or in combination, are no better than placebo in reducing pain in patients with knee or hip osteoarthritis.

For many patients, it is possible eventually to reduce the dosage or limit use of drugs to periods of exacerbation. For patients with knee osteoarthritis and effusion, intra-articular injection of triamcinolone (20–40 mg) may obviate the need for analgesics or NSAIDs. Corticosteroid injections up to four times a year appear to be safe. Intra-articular injections of sodium hyaluronate reduce symptoms moderately in some patients. Capsaicin cream 0.025–0.075% applied three or four times a day can also reduce knee pain without NSAIDs. Doxycycline, though not approved by the US Food and Drug Administration (FDA) for treating osteoarthritis, has shown promise in slowing the progression of knee osteoarthritis.

C. Surgical Measures

Total hip and knee replacements provide excellent symptomatic and functional improvement when involvement of that joint severely restricts walking or causes pain at rest, particularly at night. Arthroscopic surgery for knee osteoarthritis is ineffective.

► Prognosis

Marked disability is less common in patients with osteoarthritis than in those with rheumatoid arthritis, but symptoms may be quite severe and limit activity considerably (especially with involvement of the hips, knees, and cervical spine).

▶ When to Refer

Refer patients to an orthopedic surgeon when recalcitrant symptoms or functional impairment, or both, warrant consideration of joint replacement surgery of the hip or knee.

CRYSTAL DEPOSITION ARTHRITIS

1. Gouty Arthritis

ESSENTIALS OF DIAGNOSIS

- ▶ Acute onset, typically nocturnal and usually monarticular, often involving the first MTP joint.
- ▶ Polyarticular involvement more common in patients with long-standing disease.
- ▶ Identification of urate crystals in joint fluid or tophi is diagnostic.
- ▶ Dramatic therapeutic response to NSAIDs.
- ▶ With chronicity, urate deposits in subcutaneous tissue, bone, cartilage, joints, and other tissues.

▶ General Considerations

Gout is a metabolic disease of a heterogeneous nature, often familial, associated with abnormal amounts of urates in the body and characterized early by a recurring acute arthritis, usually monarticular, and later by chronic deforming arthritis. The associated hyperuricemia is due to overproduction or underexcretion of uric acid—sometimes both. The disease is especially common in Pacific islanders, eg, Filipinos and Samoans. Primary gout has a heritable component, and genome-wide surveys have linked risk of gout to several genes whose products regulate urate handling by the kidney. Secondary gout, which may have a heritable component, is related to acquired causes of hyperuricemia, eg, medication use (especially diuretics, low-dose aspirin, cyclosporine, and niacin), myeloproliferative disorders, multiple myeloma, hemoglobinopathies, chronic kidney disease, hypothyroidism, psoriasis, sarcoidosis, and lead poisoning (Table 20–4). Alcohol ingestion promotes hyperuricemia by increasing urate production and decreasing the renal excretion of uric acid. Finally, hospitalized patients frequently suffer attacks of gout because of changes in diet, fluid intake, or medications that lead either to rapid reductions or increases in the serum urate level.

About 90% of patients with primary gout are men, usually over 30 years of age. In women, the onset is typically postmenopausal. The characteristic lesion is the tophus, a nodular deposit of monosodium urate monohy-

Table 20–4. Origin of hyperuricemia.

Primary hyperuricemia

- A. Increased production of purine
 1. Idiopathic
 2. Specific enzyme defects (eg, Lesch-Nyhan syndrome, glyco-gen storage diseases)
- B. Decreased renal clearance of uric acid (idiopathic)

Secondary hyperuricemia

- A. Increased catabolism and turnover of purine
 1. Myeloproliferative disorders
 2. Lymphoproliferative disorders
 3. Carcinoma and sarcoma (disseminated)
 4. Chronic hemolytic anemias
 5. Cytotoxic drugs
 6. Psoriasis
- B. Decreased renal clearance of uric acid
 1. Intrinsic kidney disease
 2. Functional impairment of tubular transport
 - a. Drug-induced (eg, thiazides, low-dose aspirin)
 - b. Hyperlactacidemia (eg, lactic acidosis, alcoholism)
 - c. Hyperketoacidemia (eg, diabetic ketoacidosis, starvation)
 - d. Diabetes insipidus (vasopressin-resistant)
 - e. Bartter syndrome

Modified, with permission, from Rodnan GP. Gout and other crystalline forms of arthritis. *Postgrad Med.* 1975 Oct;58(5):6–14.

drate crystals with an associated foreign body reaction. Tophi are found in cartilage, subcutaneous and periarticular tissues, tendon, bone, the kidneys, and elsewhere. Urates have been demonstrated in the synovial tissues (and fluid) during acute arthritis; indeed, the acute inflammation of gout is believed to be activated by the phagocytosis by polymorphonuclear cells of urate crystals with the ensuing release from the neutrophils of chemotactic and other substances capable of mediating inflammation. The precise relationship of hyperuricemia to gouty arthritis is still obscure, since chronic hyperuricemia is found in people who never develop gout or uric acid stones. Rapid fluctuations in serum urate levels, either increasing or decreasing, are important factors in precipitating acute gout. The mechanism of the late, chronic stage of gouty arthritis is better understood. This is characterized pathologically by tophaceous invasion of the articular and periarticular tissues, with structural derangement and secondary degeneration (osteoarthritis).

Uric acid kidney stones are present in 5–10% of patients with gouty arthritis. Hyperuricemia correlates highly with the likelihood of developing stones, with the risk of stone formation reaching 50% in patients with a serum urate level above 13 mg/dL. Chronic urate nephropathy is caused by the deposition of monosodium urate crystals in the renal medulla and pyramids. Although progressive chronic kidney disease occurs in a substantial percentage of patients with chronic gout, the role of hyperuricemia in causing this outcome is controversial, because many patients with gout have numerous confounding risk factors for chronic kidney disease (eg, hypertension, alcohol use, lead exposure, and other risk factors for vascular disease).

► Clinical Findings

A. Symptoms and Signs

Acute gouty arthritis is sudden in onset and frequently nocturnal. It may develop without apparent precipitating cause or may follow rapid increases or decreases in serum urate levels. Common precipitants are alcohol excess (particularly beer), changes in medications that affect urate metabolism, and, in the hospitalized patient, fasting before medical procedures. The MTP joint of the great toe is the most susceptible joint (“podagra”), although others, especially those of the feet, ankles, and knees, are commonly affected. Gouty attacks may develop in periarticular soft tissues such as the arch of the foot. Hips and shoulders are rarely affected. More than one joint may occasionally be affected during the same attack; in such cases, the distribution of the arthritis is usually asymmetric. As the attack progresses, the pain becomes intense. The involved joints are swollen and exquisitely tender and the overlying skin tense, warm, and dusky red. Fever is common and may reach 39 °C. Local desquamation and pruritus during recovery from the acute arthritis are characteristic of gout but are not always present. Tophi may be found in the external ears, hands, feet, and olecranon and prepatellar bursae (Plate 80). They usually develop years after the initial attack of gout.

Asymptomatic periods of months or years commonly follow the initial acute attack. After years of recurrent severe monarthritis attacks of the lower extremities and untreated hyperuricemia, gout can evolve into a chronic, deforming polyarthritis of upper and lower extremities that mimics rheumatoid arthritis.

B. Laboratory Findings

The serum uric acid is elevated (> 7.5 mg/dL) in 95% of patients who have serial measurements during the course of an attack. However, a single uric acid determination is normal in up to 25% of cases, so it does not exclude gout, especially in patients taking urate-lowering drugs. During an acute attack, the ESR and white cell count are frequently elevated. Identification of sodium urate crystals in joint fluid or material aspirated from a tophus establishes the diagnosis. The crystals, which may be extracellular or found within neutrophils, are needle-like and negatively birefringent when examined by polarized light microscopy.

C. Imaging

Early in the disease, radiographs show no changes. Later, punched-out erosions with an overhanging rim of cortical bone (“rat bite”) develop. When these are adjacent to a soft tissue tophus, they are diagnostic of gout.

► Differential Diagnosis

Acute gout is often confused with cellulitis. Bacteriologic studies usually exclude acute pyogenic arthritis. Pseudogout is distinguished by the identification of calcium pyrophosphate crystals (positive birefringence) in the joint fluid, usually normal serum uric acid, and the radiographic appearance of chondrocalcinosis.

Chronic tophaceous arthritis may resemble chronic rheumatoid arthritis; gout is suggested by an earlier history of monarthritis and is established by the demonstration of urate crystals in a suspected tophus. Likewise, hips and shoulders are generally spared in tophaceous gout. Biopsy may be necessary to distinguish tophi from rheumatoid nodules. A radiographic appearance similar to that of gout may be found in rheumatoid arthritis, sarcoidosis, multiple myeloma, hyperparathyroidism, or Hand-Schüller-Christian disease. Chronic lead intoxication may result in attacks of gouty arthritis (saturnine gout); abdominal pain, peripheral neuropathy, chronic kidney disease, and basophilic stippling of red cells are clues to the diagnosis.

► Treatment

A. Asymptomatic Hyperuricemia

Asymptomatic hyperuricemia should not be treated; uric acid-lowering drugs need not be instituted until arthritis, renal calculi, or tophi become apparent.

B. Acute Attack

Arthritis is treated first and hyperuricemia weeks or months later, if at all. Sudden reduction of serum uric acid often precipitates further episodes of gouty arthritis.

1. NSAIDs—These drugs (see Table 5–3) are the treatment of choice for acute gout. Traditionally, indomethacin has been the most frequently used agent, but all of the other newer NSAIDs are probably equally effective. Indomethacin is initiated at a dosage of 25–50 mg orally every 8 hours and continued until the symptoms have resolved (usually 5–10 days). Active peptic ulcer disease, impaired kidney function, and a history of allergic reaction to NSAIDs are contraindications. For patients at high risk for upper gastrointestinal bleeding, a cyclooxygenase type 2 (COX-2) inhibitor may be an appropriate first choice for management of an acute gout attack. Long-term use of COX-2 inhibitors is not advised because of the association with increased risk of cardiovascular events, which has led to the removal of some drugs from the US market (eg, rofecoxib and valdecoxib).

2. Colchicine—Neither oral nor intravenous colchicine should be used for the treatment of acute gout flares. The use of oral colchicine during the intercritical period to prevent gout attacks is discussed below.

3. Corticosteroids—Corticosteroids often give dramatic symptomatic relief in acute episodes of gout and will control most attacks. They are most useful in patients with contraindications to the use of NSAIDs. If the patient's gout is monarticular, intra-articular administration (eg, triamcinolone, 10–40 mg depending on the size of the joint) is most effective. For polyarticular gout, corticosteroids may be given intravenously (eg, methylprednisolone, 40 mg/d tapered over 7 days) or orally (eg, prednisone, 40–60 mg/d tapered over 7 days). Gouty and septic arthritis can coexist, albeit rarely. Therefore, joint aspiration and Gram stain with culture of synovial fluid should be performed before corticosteroids are given.

C. Management between Attacks

Treatment during symptom-free periods is intended to minimize urate deposition in tissues, which causes chronic tophaceous arthritis, and to reduce the frequency and severity of recurrences.

1. Diet—Potentially reversible causes of hyperuricemia are a high-purine diet, obesity, alcohol consumption, and use of certain medications (see below). Beer consumption appears to confer a higher risk of gout than does whiskey or wine. Higher levels of meat and seafood consumption are associated with increased risks of gout, whereas a higher level of dairy products consumption is associated with a decreased risk. Although dietary purines usually contribute only 1 mg/dL to the serum uric acid level, moderation in eating foods with high purine content is advisable (Table 20–5). A high liquid intake and, more importantly, a daily urinary output of 2 L or more will aid urate excretion and minimize urate precipitation in the urinary tract.

2. Avoidance of hyperuricemic medications—Thiazide and loop diuretics inhibit renal excretion of uric acid and should be avoided in patients with gout. Similarly, low doses of aspirin aggravate hyperuricemia, as does niacin.

3. Colchicine—Patients with a single episode of gout who are willing to lose weight and stop drinking alcohol are at low risk for another attack and unlikely to benefit from chronic medical therapy. In contrast, older individuals with mild chronic kidney disease who require diuretic use and have a history of multiple attacks of gout are more likely to benefit from pharmacologic treatment. In general, the higher the

uric acid level and the more frequent the attacks, the more likely that chronic medical therapy will be beneficial.

There are two indications for daily colchicine administration. First, colchicine can be used to prevent future attacks. For the person who has mild hyperuricemia and occasional attacks of gouty arthritis, chronic colchicine prophylaxis may be all that is needed. The usual dose is 0.6 mg either once or twice a day. Patients who have coexisting moderate chronic kidney disease or heart failure should take colchicine only once a day in order to avoid the peripheral neuromyopathy that can complicate the use of higher doses. Second, colchicine can also be used when uricosuric drugs or allopurinol (see below) are started, to suppress attacks precipitated by abrupt changes in the serum uric acid level.

4. Reduction of serum uric acid—Indications for a urate lowering intervention include frequent acute arthritis not controlled by colchicine prophylaxis, tophaceous deposits, or kidney damage. Hyperuricemia with infrequent attacks of arthritis may not require treatment. If instituted, the goal of medical treatment is to maintain the serum uric acid at or below 5 mg/dL, which should prevent crystallization of urate.

Two classes of agents may be used to lower the serum uric acid—the uricosuric drugs and allopurinol (neither is of value in the treatment of acute gout). The choice of one or the other depends on the result of a 24-hour urine uric acid determination. A value under 800 mg/d indicates undersecretion of uric acid, which is amenable to uricosuric agents if kidney function is preserved or to allopurinol if kidney function is limited. Patients with more than 800 mg of uric acid in a 24-hour urine collection are overproducers and require allopurinol.

A. URICOSURIC DRUGS—Uricosuric drugs, which block the tubular reabsorption of filtered urate thereby reducing the metabolic urate pool, prevent the formation of new tophi and reduce the size of those already present. When administered concomitantly with colchicine, they may lessen the frequency of recurrences of acute gout. The indication for uricosuric treatment is the increasing frequency or severity of acute attacks. Uricosuric agents are ineffective in patients with chronic kidney disease, with a serum creatinine of more than 2 mg/dL.

The following uricosuric drugs may be used: (1) Probenecid, 0.5 g orally daily initially, with gradual increase to 1–2 g daily; or (2) sulfapyrazone, 50–100 mg orally twice daily initially, with gradual increase to 200–400 mg twice daily. Hypersensitivity to either with fever and rash occurs in 5% of cases; gastrointestinal complaints are observed in 10%. Probenecid also inhibits the excretion of penicillin, indomethacin, dapsone, and acetazolamide.

Precautions with uricosuric drugs include maintaining a daily urinary output of 2000 mL or more in order to minimize the precipitation of uric acid in the urinary tract. This can be further prevented by giving alkalinizing agents (eg, potassium citrate, 30–80 mEq/d orally) to maintain a urine pH of above 6.0. Uricosuric drugs should not be used in patients with a history of uric acid nephrolithiasis. Aspirin in moderate doses antagonizes the action of uricosuric

Table 20–5. The purine content of foods.¹

| Low-purine foods | |
|---|--|
| Refined cereals and cereal products, cornflakes, white bread, pasta, flour, arrowroot, sago, tapioca, cakes | |
| Milk, milk products, and eggs | |
| Sugar, sweets, and gelatin | |
| Butter, polyunsaturated margarine, and all other fats | |
| Fruit, nuts, and peanut butter | |
| Lettuce, tomatoes, and green vegetables (except those listed below) | |
| Cream soups made with low-purine vegetables but without meat or meat stock | |
| Water, fruit juice, cordials, and carbonated drinks | |
| High-purine foods | |
| All meats, including organ meats, and seafood | |
| Meat extracts and gravies | |
| Yeast and yeast extracts, beer, and other alcoholic beverages | |
| Beans, peas, lentils, oatmeal, spinach, asparagus, cauliflower, and mushrooms | |

¹The purine content of a food reflects its nucleoprotein content and turnover. Foods containing many nuclei (eg, liver) have many purines, as do rapidly growing foods such as asparagus. The consumption of large amounts of a food containing a small concentration of purines may provide a greater purine load than consumption of a small amount of a food containing a large concentration of purines.

Reproduced, with permission, from Emmerson BT. The management of gout. *N Engl J Med.* 1996 Feb 15;334(7):445–51.

agents, but low doses (325 mg or less per day) do not; doses of aspirin greater than 3 g daily are themselves uricosuric.

B. ALLOPURINOL—The xanthine oxidase inhibitor allopurinol promptly lowers plasma urate and urinary uric acid concentrations and facilitates tophus mobilization. The drug is of special value in uric acid overproducers; in tophaceous gout; in patients unresponsive to the uricosuric regimen; and in gouty patients with uric acid renal calculi. It should be used in low doses in patients with chronic kidney disease and is not indicated in asymptomatic hyperuricemia. The most frequent adverse effect is the precipitation of an acute gouty attack. Hypersensitivity to allopurinol occurs in 2% of cases and can be life-threatening. The most common sign of hypersensitivity is a pruritic rash that may progress to toxic epidermal necrolysis, particularly if allopurinol is continued; vasculitis and hepatitis are other manifestations.

The initial daily dose of allopurinol is 300 mg/d for patients who have normal kidney function and who are taking prophylactic colchicine. In the absence of prophylactic colchicine, the initial dose should be 100 mg/d orally. The dose of allopurinol can be increased in a week if needed to achieve the desired serum uric acid level of ≤ 5.0 mg/dL. Successful treatment usually requires a dose of 300–400 mg of allopurinol daily. The maximum daily dose is 800 mg. Allopurinol can be used in chronic kidney disease, but the dose must be reduced to decrease the chance of side effects.

Allopurinol interacts with other drugs. The combined use of allopurinol and ampicillin causes a drug rash in 20% of patients. Allopurinol can increase the half-life of probenecid, while probenecid increases the excretion of allopurinol. Thus, a patient taking both drugs may need to use slightly higher than usual doses of allopurinol and lower doses of probenecid.

D. Chronic Tophaceous Arthritis

With rigorous medical compliance, allopurinol shrinks tophi and in time can lead to their disappearance. Resorption of extensive tophi requires maintaining a serum uric acid below 5 mg/dL, which may be achievable only with concomitant use of allopurinol and a uricosuric agent. Surgical excision of large tophi offers mechanical improvement in selected deformities.

E. Gout in the Transplant Patient

Hyperuricemia and gout commonly develop in many transplant patients because they have decreased kidney function and require drugs that inhibit uric acid excretion (especially cyclosporine and diuretics). Treating these patients is challenging: NSAIDs are usually contraindicated because of underlying chronic kidney disease; intravenous colchicine should not be used because of its narrow therapeutic index (particularly in kidney dysfunction); and corticosteroids are already being used. Often the best approach for monarticular gout—after excluding infection—is injecting corticosteroids into the joint (see above). For polyarticular gout, increasing the dose of systemic corticosteroid may be the

only alternative. Since transplant patients often have multiple attacks of gout, long-term relief requires lowering the serum uric acid with allopurinol. (Kidney dysfunction seen in many transplant patients makes uricosuric agents ineffective.) Allopurinol should be started at a low dose in patients with kidney dysfunction and then adjusted according to its effect on the serum uric acid level. Allopurinol potentiates the effect of azathioprine. If allopurinol cannot be avoided, the dose of azathioprine should be reduced by 75% before allopurinol is started.

▶ Prognosis

Without treatment, the acute attack may last from a few days to several weeks. The intervals between acute attacks vary up to years, but the asymptomatic periods often become shorter if the disease progresses. Chronic gouty arthritis occurs after repeated attacks of acute gout, but only after inadequate treatment. The younger the patient at the onset of disease, the greater the tendency to a progressive course. Destructive arthropathy is rarely seen in patients whose first attack is after age 50.

Patients with gout are anecdotally thought to have an increased incidence of hypertension, kidney disease (eg, nephrosclerosis, interstitial nephritis, pyelonephritis), diabetes mellitus, hypertriglyceridemia, and atherosclerosis.

Dehghan A et al. Association of three genetic loci with uric acid concentration and risk of gout: a genome-wide association study. *Lancet*. 2008 Dec 6;372(9654):1953–61. [PMID: 18834626]
Janssens HJ et al. Use of oral prednisolone or naproxen for the treatment of gout arthritis: a double-blind, randomised equivalence trial. *Lancet*. 2008 May 31;371(9627):1854–60. [PMID: 18514729]

2. Chondrocalcinosis & Pseudogout

Chondrocalcinosis is the presence of calcium-containing salts in articular cartilage. Diagnosed radiologically, it may be familial and is commonly associated with a wide variety of metabolic disorders, eg, hemochromatosis, hyperparathyroidism, ochronosis, diabetes mellitus, hypothyroidism, Wilson disease, and gout. Pseudogout (also called calcium pyrophosphate dihydrate [CPPD] deposition disease) is most often seen in persons age 60 or older, is characterized by acute, recurrent and rarely chronic arthritis involving large joints (most commonly the knees and the wrists) and is almost always accompanied by chondrocalcinosis of the affected joints. Other joints frequently affected are the MCPs, hips, shoulders, elbows, and ankles. Involvement of the DIP and PIP joints is no more common in CPPD deposition disease than in other age-matched controls. Pseudogout, like gout, frequently develops 24–48 hours after major surgery. Identification of calcium pyrophosphate crystals in joint aspirates is diagnostic of pseudogout. With light microscopy, the rhomboid-shaped crystals differ from the needle-shaped gout crystals. A red compensator is used for positive identification, since pseudogout crystals are blue when parallel and yellow when perpendicular to the axis of the compensator. Urate crystals give the opposite pattern. X-ray examination shows not only calcification

(usually symmetric) of cartilaginous structures but also signs of degenerative joint disease (osteoarthritis). Unlike gout, pseudogout is usually associated with normal serum urate levels.

Treatment of chondrocalcinosis is directed at the primary disease, if present. NSAIDs (salicylates, indomethacin, naproxen, and other drugs) are helpful in the treatment of acute episodes. Patients at increased risk for upper gastrointestinal bleeding may use a COX-2 inhibitor to treat acute attacks of pseudogout. Long-term use of COX-2 inhibitors is not advised because of the association with increased risk of cardiovascular events. Colchicine, 0.6 mg orally twice daily, is more effective for prophylaxis than for acute attacks. Aspiration of the inflamed joint and intra-articular injection of triamcinolone, 10–40 mg, depending on the size of the joint, are also of value in resistant cases.

Annon N et al. Treating difficult crystal pyrophosphate dihydrate deposition disease. *Curr Rheumatol Rep.* 2008 Jul;10(3):228–34. [PMID: 18638432]

PAIN SYNDROMES

NECK PAIN

ESSENTIALS OF DIAGNOSIS

- ▶ Most chronic neck pain is caused by degenerative joint disease and responds to conservative approaches.
- ▶ Whiplash is the most common type of traumatic injury to the neck.
- ▶ Serious erosive disease of joints in the neck that may lead to neurologic complications sometimes occurs in rheumatoid arthritis and occasionally in ankylosing spondylitis; the usual joint involved in these disorders is the atlantoaxial joint (C1–2).

▶ General Considerations

At any point in time, about 15% of adults are experiencing neck pain. The prevalence of neck pain peaks at age 50 and develops more commonly in women than in men. A large group of articular and extra-articular disorders are characterized by pain that may involve simultaneously the neck, shoulder girdle, and upper extremity. Diagnostic differentiation may be difficult. Some represent primary disorders of the cervicobrachial region; others are local manifestations of systemic disease. It is frequently not possible to make a specific diagnosis.

▶ Clinical Findings

A. Symptoms and Signs

Neck pain may be limited to the posterior region or, depending on the level of the symptomatic joint, may radiate segmentally to the occiput, anterior chest, shoulder

girdle, arm, forearm, and hand. It may be intensified by active or passive neck motions. The general distribution of pain and paresthesias corresponds roughly to the involved dermatome in the upper extremity. Radiating pain in the upper extremity is often intensified by hyperextension of the neck and deviation of the head to the involved side. Limitation of cervical movements is the most common objective finding. Neurologic signs depend on the extent of compression of nerve roots or the spinal cord. Compression of the spinal cord may cause paraparesis or paraplegia.

B. Imaging

The radiographic findings depend on the cause of the pain; many plain radiographs are completely normal in patients who have suffered an acute cervical strain. Loss of cervical lordosis is often seen but is nonspecific. In osteoarthritis, comparative reduction in height of the involved disk space is a frequent finding. The most common late radiographic finding is osteophyte formation anteriorly, adjacent to the disk; other chronic abnormalities occur around the apophyseal joint clefts, chiefly in the lower cervical spine.

Use of advanced imaging techniques is indicated in the patient who has severe pain of unknown cause that fails to respond to conservative therapy or in the patient who has evidence of myelopathy. MRI is more sensitive than CT in detecting disk disease, extradural compression, and intramedullary cord disease. CT is preferable for demonstration of fractures.

▶ Differential Diagnosis & Treatment

The causes of neck pain include acute and chronic cervical strain or sprains, herniated nucleus pulposus, osteoarthritis, ankylosing spondylitis, rheumatoid arthritis, fibromyalgia, osteomyelitis, neoplasms, polymyalgia rheumatica, compression fractures, pain referred from visceral structures (eg, angina), and functional disorders.

A. Nonspecific Neck Pain

In the absence of trauma or evidence of infection, malignancy, neurologic findings, or systemic inflammation, the patient can be treated conservatively. Conservative therapy can include rest, analgesics, or physical therapy.

B. Acute Cervical Musculotendinous Strain

Cervical strain is generally caused by mechanical postural disorders, overexertion, or injury (eg, whiplash). Acute episodes are associated with pain, decreased cervical spine motion, and paraspinal muscle spasm, resulting in stiffness of the neck and loss of motion. Muscle trigger points can often be localized. After whiplash injury, patients often experience not only neck pain but also shoulder girdle discomfort and headache. Management includes administration of analgesics. Soft cervical collars are commonly recommended, but evidence suggests they may delay recovery. Acupuncture, manipulation, or physical therapy can help some patients, but the precise role of these treatments is not well established. Corticosteroid injection into cervical facet joints is ineffective. Gradual return to full activity is encouraged.

C. Herniated Nucleus Pulposus

Rupture or prolapse of the nucleus pulposus of the cervical disks into the spinal canal causes pain radiating at a C6–7 level. When intra-abdominal pressure is increased by coughing, sneezing, or other movements, symptoms are aggravated, and cervical muscle spasm may occur. Neurologic abnormalities include decreased reflexes of the deep tendons of the biceps and triceps and decreased sensation and muscle atrophy or weakness in the forearm or hand. Cervical traction, bed rest, and other conservative measures are usually successful. Radicular symptoms usually respond to conservative therapy, including NSAIDs, activity modification, intermittent cervical traction, and neck immobilization. Cervical epidural corticosteroid injections may help those who fail conservative therapy. Surgery is indicated for unremitting pain and progressive weakness despite a full trial of conservative therapy and if a surgically correctable abnormality is identified by MRI or CT myelography. Surgical decompression achieves excellent results in 70–80% of such patients.

D. Arthritic Disorders

Cervical spondylosis (degenerative arthritis) is a collective term describing degenerative changes that occur in the apophysial joints and intervertebral disk joints, with or without neurologic signs. Osteoarthritis of the articular facets is characterized by progressive thinning of the cartilage, subchondral osteoporosis, and osteophytic proliferation around the joint margins. Degeneration of cervical disks and joints may occur in adolescents but is more common after age 40. Degeneration is progressive and is marked by gradual narrowing of the disk space, as demonstrated by radiography. Osteocartilaginous proliferation occurs around the margin of the vertebral body and gives rise to osteophytic ridges that may encroach upon the intervertebral foramina and spinal canal, causing compression of the neurovascular contents.

Osteoarthritis of the cervical spine is often asymptomatic but may cause diffuse neck pain. A minority of patients with neck pain also suffer from radicular pain or myelopathy. Myelopathy develops insidiously and is manifested by sensory dysfunction and clumsy hands. Some patients also complain of unsteady walking, urinary frequency and urgency, or electrical shock sensations with neck flexion or extension (Lhermitte sign). Weakness, sensory loss, and spasticity with exaggerated reflexes develop below the level of spinal cord compression. Amyotrophic lateral sclerosis, multiple sclerosis, syringomyelia, spinal cord tumors, and tropical spastic paresis from HTLV-1 infection can mimic myelopathy from cervical arthritis. The mainstay of conservative therapy is immobilizing the cervical spine with a collar. With moderate to severe neurologic symptoms, surgical treatment is indicated.

Atlantoaxial subluxation may occur in patients with either rheumatoid arthritis or ankylosing spondylitis. Inflammation of the synovial structures resulting from erosion and laxity of the transverse ligament can lead to neurologic signs of spinal cord compression. Treatment may vary from use of a cervical collar or more rigid bracing

to operative treatment, depending on the degree of subluxation and neurologic progression. Surgical treatment for stabilization of the cervical spine is a last resort.

E. Other Disorders

Osteomyelitis and neoplasms are discussed below. Osteoporosis is discussed in Chapter 26.

Gross AR et al. Conservative management of mechanical neck disorders: a systematic review. *J Rheumatol.* 2007 May;34(5):1083–102. [PMID: 17295434]

THORACIC OUTLET SYNDROMES

Thoracic outlet syndromes result from compression of the neurovascular structures supplying the upper extremity. Symptoms and signs arise from intermittent or continuous pressure on elements of the brachial plexus (> 90% of cases) or the subclavian or axillary vessels (veins or arteries) by a variety of anatomic structures of the shoulder girdle region. The neurovascular bundle can be compressed between the anterior or middle scalene muscles and a normal first thoracic rib or a cervical rib. Most commonly thoracic outlet obstruction is caused by scarred scalene neck muscle secondary to neck trauma or sagging of the shoulder girdle resulting from aging, obesity, or pendulous breasts. Faulty posture, occupation, or thoracic muscle hypertrophy from physical activity (eg, weight-lifting, baseball pitching) may be other predisposing factors.

Thoracic outlet obstruction presents in most patients with some combination of four symptoms involving the upper extremity, namely pain, numbness, weakness, and swelling. The predominant symptoms depend on whether the obstruction chiefly affects neural or vascular structures. The onset of symptoms is usually gradual but can be sudden. Some patients spontaneously notice aggravation of symptoms with specific positioning of the arm. Pain radiates from the point of compression to the base of the neck, the axilla, the shoulder girdle region, arm, forearm, and hand. Paresthesias are common and distributed to the volar aspect of the fourth and fifth digits. Sensory symptoms may be aggravated at night or by prolonged use of the extremities. Weakness and muscle atrophy are the principal arterial abnormalities. Vascular symptoms consist of arterial ischemia characterized by pallor of the fingers on elevation of the extremity, sensitivity to cold, and, rarely, gangrene of the digits or venous obstruction marked by edema, cyanosis, and engorgement.

The symptoms of thoracic outlet obstruction can be provoked within 60 seconds over 90% of the time by having a patient elevate the arms in a “stick-em-up” position (ie, abducted 90 degrees in external rotation). Reflexes are usually not altered. Obliteration of the radial pulse with certain maneuvers of the arm or neck, once considered a highly sensitive sign of thoracic outlet obstruction, does not occur in most cases.

Chest radiography will identify patients with cervical rib (although most patients with cervical ribs are asymptomatic). MRI with the arms held in different positions is useful in identifying sites of impaired blood flow. Intra-

arterial or venous obstruction is confirmed by angiography. Determination of conduction velocities of the ulnar and other peripheral nerves of the upper extremity may help localize the site of their compression.

Thoracic outlet syndrome must be differentiated from osteoarthritis of the cervical spine, tumors of the superior pulmonary sulcus, cervical spinal cord, or nerve roots, and peri-arthritis of the shoulder.

Treatment is directed toward relief of compression of the neurovascular bundle. Greater than 95% of patients can be treated successfully with conservative therapy consisting of physical therapy and avoiding postures or activities that compress the neurovascular bundle. Some women will benefit from a support bra. Operative treatment, required by less than 5% of patients, is more likely to relieve the neurologic rather than the vascular component that causes symptoms.

Sadat U et al. Thoracic outlet syndrome: an overview. *Br J Hosp Med (Lond)*. 2008 May;69(5):260–3. [PMID: 18557546]

LOW BACK PAIN

Up to 80% of the population experience low back pain at some time. The differential diagnosis is broad and includes muscular strain, primary spine disease (eg, disk herniation, degenerative arthritis), systemic diseases (eg, metastatic cancer), and regional diseases (eg, aortic aneurysm). A precise diagnosis cannot be made in the majority of cases. Even when anatomic defects—such as vertebral osteophytes or a narrowed disk space—are present, causality cannot be assumed since such defects are common in asymptomatic patients. Most patients will improve in 1–4 weeks and need no evaluation beyond the initial history and physical examination. The diagnostic challenge is to identify those patients who require more extensive or urgent evaluation. In practice, this means identifying those patients with pain caused by (1) infection, (2) cancer, (3) inflammatory back disease such as ankylosing spondylitis, or (4) pain referred from abdominal or pelvic processes, such as penetrating peptic ulcer or expanding aortic aneurysm. Significant or progressive neurologic deficits also require identification. If there is no evidence of these problems, conservative therapy is called for.

1. Clinical Approach to Diagnosis

▶ General History & Physical Examination

Low back pain is a final common pathway of many processes; the pain of vertebral osteomyelitis, for example, is not very different in quality and intensity from that due to back strain of the weekend gardener. Historical factors of importance include smoking, weight loss, age over 50, and cancer, all of which are risk factors for vertebral body metastasis. Osteomyelitis most frequently occurs in adults with a history of recurrent urinary tract infections and is especially common in diabetics and injection drug users. A history of a cardiac murmur should raise concern about endocarditis, since back pain is not an uncommon manifestation. A background of renal calculi might indicate another cause of referred back pain.

▶ History of the Back Pain

Certain qualities of a patient's pain can indicate a specific diagnosis. Low back pain radiating down the buttock and below the knee suggests a herniated disk causing nerve root irritation. Other conditions—including sacroiliitis, facet joint degenerative arthritis, spinal stenosis, or irritation of the sciatic nerve from a wallet—also cause this pattern.

The diagnosis of disk herniation is further suggested by physical examination (see below) and confirmed by imaging techniques. Disk herniation can be asymptomatic, so its presence does not invariably link it to the symptom.

Low back pain at night, unrelieved by rest or the supine position, suggests the possibility of malignancy, either vertebral body metastasis (chiefly from prostate, breast, lung, multiple myeloma, or lymphoma) or a cauda equina tumor. Similar pain can also be caused by compression fractures (from osteoporosis or myeloma).

Symptoms of large or rapidly evolving neurologic deficits identify patients who need urgent evaluation for possible cauda equina tumor, epidural abscess or, rarely, massive disk herniation. When a herniated disk impinges a nerve root, pain is the most prominent symptom; numbness and weakness are less common and, when present, are of the magnitude consistent with compression of a single nerve root. Symptoms of bilateral leg weakness (from multiple lumbar nerve root compressions) or of saddle area anesthesia, bowel or bladder incontinence, or impotence (indicating multiple sacral nerve root compressions) indicate a cauda equina process.

Low back pain that worsens with rest and improves with activity is characteristic of ankylosing spondylitis or other seronegative spondyloarthropathies, especially when the onset is insidious and begins before age 40. Most degenerative back diseases produce precisely the opposite pattern, with rest alleviating and activity aggravating the pain. Low back pain causing the patient to writhe occurs in renal colic but can also indicate a leaking aneurysm. The pain associated with pseudoclaudication from lumbar spinal stenosis is discussed below.

▶ Physical Examination of the Back

Several physical findings should be sought because they help identify those few patients who need more than conservative management.

Neurologic examination of the lower extremities will detect the small deficits produced by disk disease and the large deficits complicating such problems as cauda equina tumors. A positive straight leg raising test indicates nerve root irritation. The examiner performs the test on the supine patient by passively raising the patient's ipsilateral leg. The test is positive if radicular pain is produced with the leg raised 60 degrees or less. It has a specificity of 40% but is 95% sensitive in patients with herniation at the L4–5 or L5–S1 level (the sites of 95% of disk herniations). It can be falsely negative, especially in patients with herniation above the L4–5 level. The crossed straight leg sign is positive when raising the contralateral leg reproduces the sciatica. It has a sensitivity of 25% but is 90% specific for disk herniation.

Table 20–6. Neurologic testing of lumbosacral nerve disorders.

| Nerve Root | Motor | Reflex | Sensory Area |
|------------|---------------------------|------------|-----------------|
| L4 | Dorsiflexion of foot | Knee jerk | Medial calf |
| L5 | Dorsiflexion of great toe | None | Medial forefoot |
| S1 | Eversion of foot | Ankle jerk | Lateral foot |

Detailed examination of the sacral and lumbar nerve roots, especially L5 and S1, is essential for detecting neurologic deficits associated with back pain. Disk herniation produces deficits predictable for the site involved (Table 20–6). Deficits of multiple nerve roots suggest a cauda equina tumor or an epidural abscess, both requiring urgent evaluation and treatment.

Measurement of spinal motion in the patient with acute pain is rarely of diagnostic utility and usually simply confirms that pain limits motion. An exception is the decreased range of motion in multiple regions of the spine (cervical, thoracic, and lumbar) in a diffuse spinal disease such as ankylosing spondylitis. By the time the patient has such limits, however, the diagnosis is usually straightforward.

If back pain is not severe and does not itself limit motion, the modified Schober test of lumbar motion is helpful in early diagnosis of ankylosing spondylitis. To perform this test, two marks are made with the patient upright: one 10 cm above the sacral dimples and another 5 cm below. The patient then bends forward as far as possible, and the distance between the points is measured. Normally, the distance increases from 15 cm to at least 20 cm. Anything less indicates reduced lumbar motion.

Palpation of the spine usually does not yield diagnostic information. Point tenderness over a vertebral body is reported to suggest osteomyelitis, but this association is uncommon. A step-off noted between the spinous process of adjacent vertebral bodies may indicate spondylolisthesis, but the sensitivity of this finding is extremely low. Tenderness of the soft tissues overlying the greater trochanter of the hip is a manifestation of trochanteric bursitis.

Inspection of the spine is not often of value in identifying serious causes of low back pain. The classic posture of ankylosing spondylitis is a late finding. Scoliosis of mild degree is not associated with an increased risk of clinical back disease. Cutaneous neurofibromas can identify the rare patient with nerve root encasement.

Examination of the hips should be part of the complete examination. While hip arthritis usually produces pain chiefly in the groin area, some patients have buttock or low back symptoms.

► Further Examination

If the history and physical examination do not suggest the presence of infection, cancer, inflammatory back disease, major neurologic deficits, or pain referred from abdominal or pelvic disease, further evaluation can be eliminated or

deferred while conservative therapy is tried. The great majority of patients will improve with conservative care over 1–4 weeks.

Regular radiographs of the lumbosacral spine give 20 times the radiation dose of a chest radiograph and provide limited, albeit important, information. Oblique films double the radiation dose and are not routinely needed. Radiographs can provide evidence of vertebral body osteomyelitis, cancer, fractures, or ankylosing spondylitis. Degenerative changes in the lumbar spine are ubiquitous in patients over 40 and do not prove clinical disease. Plain radiographs have very low sensitivity or specificity for disk disease. Thus, plain radiographs are warranted promptly for patients suspected of having infection, cancer, or fractures; selected other patients who do not improve after 2–4 weeks of conservative therapy are also candidates. The Agency for Healthcare Research and Quality guidelines for obtaining lumbar radiographs are summarized in Table 20–7.

MRI provides exquisite anatomic detail but is reserved for patients who are considering surgery or have evidence of a systemic disease. For example, MRI is needed urgently for any patient in whom an epidural mass or cauda equina tumor is suspected but not for a patient believed to have a routine disk herniation, since most will improve over 4–6 weeks of conservative therapy. Noncontrast CT does not image cauda equina tumors or other intradural lesions, and if used instead of MRI it must include intrathecal contrast.

Radionuclide bone scanning has limited usefulness. It is most useful for early detection of vertebral body osteomyelitis or osteoblastic metastases. The bone scan is normal in multiple myeloma because lytic lesions do not take up isotope.

2. Management

While any management plan must be individualized, key elements of most conservative treatments for back pain include analgesia and education. Analgesia can usually be provided with NSAIDs (see Table 5–3), but severe pain

may require opioids (see Table 5–4). Rarely does the need for opioids extend beyond 1–2 weeks.

Diazepam, cyclobenzaprine, carisoprodol, and methocarbamol have been prescribed as muscle relaxants, though their sedative effects may limit their use. They should be reserved for patients who do not respond to NSAIDs and usually are needed only for 1–2 weeks, which reduces the chance of dependence. Their use should be avoided in older patients, who are at risk for falling. All patients should be taught how to protect the back in daily activities—ie, not to lift heavy objects, to use the legs rather than the back when lifting, to use a chair with arm rests, and to rise from bed by first rolling to one side and then using the arms to push to an upright position. Back manipulation for benign, mechanical low back pain appears safe and as effective as therapies provided by clinicians.

Rest and back exercises, once thought to be cornerstones of conservative therapy, are now known to be ineffective for acute back pain. Advice to rest in bed is less effective than advice to remain active. No bed rest with continuation of ordinary activities as tolerated is superior to 2 days of bed rest, 7 days of bed rest, and back mobilizing exercises. Similarly, for acute back pain, exercise therapy is not effective. The value of corsets or traction is dubious. Epidural corticosteroid injections can provide short-term relief of sciatica but do not improve functional status or reduce the need for surgery. In double-blind studies, repeated injections have been no more effective than a single injection. For chronic low back pain, yoga is as effective as a back exercise program and more effective than a self-care book. Corticosteroid injections into facet joints are ineffective for chronic low back pain.

Surgical consultation is needed urgently for any patient with a major or evolving neurologic deficit. Randomized controlled trials have shown that for sciatica caused by disk herniation, conservative treatment and surgery achieve similar 1-year outcomes; however, pain relief and perceived recovery were obtained more quickly with surgery. Surgery tends to ameliorate leg pain more quickly and fully than back pain.

Complaints without objective findings suggest a psychological role in symptom formation. Treatment includes reassurance and nonopioid analgesics.

▶ When to Refer

- Suspected malignancy.
- Inflammatory low back pain.

▶ When to Admit

- Neurologic signs indicative of cauda equina syndrome.
- Vertebral osteomyelitis.

LUMBAR SPINAL STENOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Most patients are older than 60 years.
- ▶ Presenting symptom is often back pain radiating to the buttocks and thighs.
- ▶ Pain often interferes with walking, worsens with lumbar extension, and improves with lumbar flexion.
- ▶ Back and leg pain often associated with numbness and paresthesias.
- ▶ Preservation of pedal pulses helps exclude vascular claudication.
- ▶ Diagnosis best confirmed by MRI.

▶ General Considerations

Lumbar spinal stenosis, defined as narrowing of the spinal canal with compression of the nerve roots, may be congenital or (more commonly) acquired. It most frequently results from enlarging osteophytes at the facet joints, hypertrophy of the ligamentum flavum, and protrusion or bulging of intervertebral disks. Lumbar spinal stenosis may produce symptoms by directly compressing nerve roots or by compressing nutrient arterioles that supply the nerve roots.

▶ Clinical Findings

A. Symptoms and Signs

Since age is the greatest risk factor for spinal degenerative changes, most patients with lumbar spinal stenosis are over 60 years old. Patients typically complain of either leg pain or trouble walking. The pain may originate in the low back but will extend below the buttock into the thigh in nearly 90% of patients. In approximately 50% of patients, the pain will extend below the knee. The pain is often a combination of aching and numbness, which characteristically worsens with walking. The pain can also be brought on by prolonged standing. Not infrequently the symptoms are bilateral. Many patients are more troubled by poor balance, unsteadiness of gait, or leg weakness that develops as they walk. Some describe these neuroclaudication symptoms as developing “spaghetti legs” or “walking like a drunk sailor.” Because the lumbar spinal canal volume increases with back flexion and decreases with extension, some patients observe that they have fewer symptoms walking uphill than down. The back and lower extremity examination in patients with lumbar spinal stenosis is often unimpressive. Less than 10% have a positive straight leg raise sign, 25% have diminished deep tendon reflexes, and 60% have slight proximal weakness. Walking with the patient may reveal unsteadiness, although usually the patient’s perception of gait disturbance is greater than that of an observer.

B. Imaging

The diagnosis of spinal stenosis in a patient with symptoms is best confirmed by MRI.

► Differential Diagnosis

The onset of symptoms with standing, the location of the maximal discomfort to the thighs, and the preservation of pedal pulses help distinguish the “pseudoclaudication” of spinal stenosis from true claudication caused by vascular insufficiency. Distinguishing spinal stenosis from disk herniation can be challenging since both conditions can produce pain radiating down the back of the leg. Features that favor spinal stenosis are the gradual onset of symptoms, the marked exacerbation with walking, and the amelioration of symptoms with sitting or lumbar flexion. Complaints of bilateral aching in the buttocks associated with stiffness may make some practitioners consider the diagnosis of polymyalgia rheumatica. However, patients with lumbar spinal stenosis do not have the shoulder or neck symptoms characteristic of polymyalgia rheumatica.

► Treatment

Weight loss and exercises aimed at reducing lumbar lordosis, which aggravates symptoms of spinal stenosis, can help. Lumbar epidural corticosteroid injections provide some immediate relief for about 50% of patients and more sustained relief for approximately 25%. When disabling symptoms persist, surgery will reduce pain and improve function substantially in approximately 75% of patients at 1 and 2 years; only about 25% of patients treated conservatively will experience a similar improvement.

Weinstein JN et al. Surgical versus nonsurgical treatment for lumbar degenerative spondylolisthesis. *N Engl J Med.* 2007 May 31;356(22):2257–70. [PMID: 17538085]

FIBROMYALGIA

ESSENTIALS OF DIAGNOSIS

- Most frequent in women aged 20–50.
- Chronic widespread musculoskeletal pain syndrome with multiple tender points.
- Fatigue, headaches, numbness common.
- Objective signs of inflammation absent; laboratory studies normal.
- Partially responsive to exercise, tricyclic antidepressants.

► General Considerations

Fibromyalgia is one of the most common rheumatic syndromes in ambulatory general medicine affecting 3–10% of the general population. It shares many features with the chronic fatigue syndrome, namely, an increased frequency among women aged 20–50, absence of objective findings, and absence of diagnostic laboratory test results. While

many of the clinical features of the two conditions overlap, musculoskeletal pain predominates in fibromyalgia whereas lassitude dominates the chronic fatigue syndrome.

The cause is unknown, but aberrant perception of painful stimuli, sleep disorders, depression, and viral infections have all been proposed. Fibromyalgia can be a rare complication of hypothyroidism, rheumatoid arthritis or, in men, sleep apnea.

► Clinical Findings

The patient complains of chronic aching pain and stiffness, frequently involving the entire body but with prominence of pain around the neck, shoulders, low back, and hips. Fatigue, sleep disorders, subjective numbness, chronic headaches, and irritable bowel symptoms are common. Even minor exertion aggravates pain and increases fatigue. Physical examination is normal except for “trigger points” of pain produced by palpation of various areas such as the trapezius, the medial fat pad of the knee, and the lateral epicondyle of the elbow.

► Differential Diagnosis

Fibromyalgia is a diagnosis of exclusion. A detailed history and repeated physical examination can obviate the need for extensive laboratory testing. Rheumatoid arthritis and systemic lupus erythematosus (SLE) present with objective physical findings or abnormalities on routine testing, including the ESR and C-reactive protein. Thyroid function tests are useful, since hypothyroidism can produce a secondary fibromyalgia syndrome. Polymyositis produces weakness rather than pain. The diagnosis of fibromyalgia probably should be made hesitantly in a patient over age 50 and should never be invoked to explain fever, weight loss, or any other objective signs. Polymyalgia rheumatica produces shoulder and pelvic girdle pain, is associated with anemia and an elevated ESR, and occurs after age 50. Hypophosphatemic states, such as oncogenic osteomalacia, should also be included in the differential diagnosis of musculoskeletal pain unassociated with physical findings. In contrast to fibromyalgia, oncogenic osteomalacia usually produces pain in only a few areas and is associated with a low serum phosphate level.

► Treatment

Patient education is essential. Patients can be comforted that they have a diagnosable syndrome treatable by specific though imperfect therapies and that the course is not progressive. There is modest efficacy of amitriptyline, fluoxetine, chlorpromazine, cyclobenzaprine, pregabalin, or gabapentin. Amitriptyline is initiated at a dosage of 10 mg orally at bedtime and gradually increased to 40–50 mg depending on efficacy and toxicity. Less than 50% of the patients experience a sustained improvement. Exercise programs are also beneficial. NSAIDs are generally ineffective. Tramadol and acetaminophen combinations have ameliorated symptoms modestly in short-term trials. Opioids and corticosteroids are ineffective and should not be used to treat fibromyalgia. Acupuncture is also ineffective.

▶ Prognosis

All patients have chronic symptoms. With treatment, however, many do eventually resume increased activities. Progressive or objective findings do not develop.

Carville SF et al. EULAR evidence-based recommendations for the management of fibromyalgia syndrome. *Ann Rheum Dis.* 2008 Apr;67(4):536–41. [PMID: 17644548]

CARPAL TUNNEL SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Begins as pain, burning, and tingling in the distribution of the median nerve.
- ▶ Symptoms initially most bothersome at night.
- ▶ Weakness or atrophy, especially of the thenar eminence, appears later.
- ▶ Common in occupations that require repetitive wrist motion and in pregnancy, diabetes, and rheumatoid arthritis.

▶ General Considerations

An entrapment neuropathy, carpal tunnel syndrome is a painful disorder caused by compression of the median nerve between the carpal ligament and other structures within the carpal tunnel. The contents of the tunnel can be compressed by synovitis of the tendon sheaths or carpal joints, recent or malhealed fractures, tumors, and occasionally congenital anomalies. Even though no anatomic lesion is apparent, flattening or even circumferential constriction of the median nerve may be observed during operative section of the ligament. The disorder may occur in pregnancy, is seen in individuals with a history of repetitive use of the hands, and may follow injuries of the wrists. There is a familial type of carpal tunnel syndrome in which no etiologic factor can be identified.

Carpal tunnel syndrome can also be a feature of many systemic diseases: rheumatoid arthritis and other rheumatic disorders (inflammatory tenosynovitis); myxedema, localized amyloidosis in chronic kidney disease, sarcoidosis, and leukemia (tissue infiltration); acromegaly; and hyperparathyroidism.

▶ Clinical Findings

The initial symptoms are pain, burning, and tingling in the distribution of the median nerve (the palmar surfaces of the thumb, the index and long fingers, and the radial half of the ring finger). Aching pain may radiate proximally into the forearm and occasionally proximally to the shoulder and over the neck and chest. Pain is exacerbated by manual activity, particularly by extremes of volar flexion or

dorsiflexion of the wrist. It is most bothersome at night. Impairment of sensation in the median nerve distribution may or may not be demonstrable. Subtle disparity between the affected and opposite sides can be shown by testing for two-point discrimination or by requiring the patient to identify different textures of cloth by rubbing them between the tips of the thumb and the index finger. Tinel or Phalen sign may be positive. (Tinel sign is tingling or shock-like pain on volar wrist percussion; Phalen sign is pain or paresthesia in the distribution of the median nerve when the patient flexes both wrists to 90 degrees for 60 seconds.) The carpal compression test, in which numbness and tingling are induced by the direct application of pressure over the carpal tunnel, may be more sensitive and specific than the Tinel and Phalen tests. Muscle weakness or atrophy, especially of the thenar eminence, appears later than sensory disturbances. Specific examinations include electromyography and determinations of segmental sensory and motor conduction delay. Sensory conduction delay is evident before motor delay.

▶ Differential Diagnosis

This syndrome should be differentiated from other cervicobrachial pain syndromes, from compression syndromes of the median nerve in the forearm or arm, and from mononeuritis multiplex. When left-sided, it may be confused with angina pectoris.

▶ Treatment

Treatment is directed toward relief of pressure on the median nerve. When a causative lesion is discovered, it is treated appropriately. Otherwise, patients in whom carpal tunnel syndrome is suspected should modify their hand activities and have the affected wrist splinted for 2–6 weeks. NSAIDs can also be added. Patients should be referred to a specialist for injection of corticosteroid into the carpal tunnel or for operation when they do not improve or when thenar muscle atrophy or weakness develops. Muscle strength returns gradually, but complete recovery cannot be expected when atrophy is pronounced.

▶ When to Refer

- Refer to an orthopedic hand surgeon if symptoms persist despite the use of wrist splints.
- Refer to an orthopedic hand surgeon if weakness or thenar atrophy develops.

Scholten RJ et al. Surgical treatment options for carpal tunnel syndrome. *Cochrane Database Syst Rev.* 2007 Oct 17;(4):CD003905. [PMID: 17943805]

DUPUYTREN CONTRACTURE

This relatively common disorder is characterized by hyperplasia of the palmar fascia and related structures, with nodule formation and contracture of the palmar fascia. The cause is unknown, but the condition has a genetic predisposition and occurs primarily in white men over 50

years of age. The incidence is higher among alcoholic patients and those with chronic systemic disorders (especially cirrhosis). It is also associated with systemic fibrosing syndrome, which includes Peyronie disease, mediastinal and retroperitoneal fibrosis, and Riedel struma. The onset may be acute, but slowly progressive chronic disease is more common.

Dupuytren contracture manifests itself by nodular or cord-like thickening of one or both hands, with the fourth and fifth fingers most commonly affected. The patient may complain of tightness of the involved digits, with inability to satisfactorily extend the fingers, and on occasion there is tenderness. The resulting cosmetic problems may be unappealing, but in general the contracture is well tolerated since it exaggerates the normal position of function of the hand. Fasciitis involving other areas of the body may lead to plantar fibromatosis (10% of patients) or Peyronie disease (1–2%).

If the palmar nodule is growing rapidly, injections of triamcinolone into the nodule may be of benefit. Surgical intervention is indicated in patients with significant flexion contractures, depending on the location, but recurrence is not uncommon.

Townley WA et al. Dupuytren's contracture unfolded. *BMJ*. 2006 Feb 18;332(7538):397–400. [PMID: 16484265]

COMPLEX REGIONAL PAIN SYNDROME (Reflex Sympathetic Dystrophy)
