disease, are small vessel disease, peripheral neuropathy with loss of both pain sensation and neurogenic inflammatory responses, and secondary infection. In two-thirds of patients with ischemic gangrene, pedal pulses are not palpable. In the remaining one-third who have palpable pulses, reduced blood flow through these vessels can be demonstrated by plethysmographic or Doppler ultrasound examination. Prevention of foot injury is imperative. Agents that reduce peripheral blood flow such as tobacco and propranolol should be avoided. Control of other risk factors such as hypertension is essential. Cholesterol-lowering agents are useful as adjunctive therapy when early ischemic signs are detected and when dyslipidemia is present. Patients should be advised to seek immediate medical care if a diabetic foot ulcer develops. Improvement in peripheral blood flow with endarterectomy and bypass operations is possible in certain patients.

E. Skin and Mucous Membrane Complications

Chronic pyogenic infections of the skin may occur, especially in poorly controlled diabetic patients. Eruptive xanthomas can result from hypertriglyceridemia, associated with poor glycemic control. An unusual lesion termed **neurobiosis lipoidica diabetorum** is usually located over the anterior surfaces of the legs or the dorsal surfaces of the ankles. They are oval or irregularly shaped plaques with demarcated borders and a glistening yellow surface and occur in women two to four times more frequently than in men.

“Shin spots” are not uncommon in adult diabetics. They are brownish, rounded, painless atrophic lesions of the skin in the pretibial area. Candidal infection can produce erythema and edema of intertriginous areas below the breasts, in the axillas, and between the fingers. It causes vulvovaginitis in most chronically uncontrolled diabetic women with persistent glucosuria and is a frequent cause of pruritus.

While antifungal creams containing miconazole or clotrimazole offer immediate relief of vulvovaginitis, recurrence is frequent unless glucosuria is reduced.

F. Special Situations

1. Insulin replacement during surgery—A number of studies have observed that hospitalized patients with diabetes and those with new-onset hyperglycemia (ie, those without a preadmission diagnosis of diabetes) have higher inpatient morbidity and mortality. These observations have led to the question of whether tight glycemic control in the hospital improves outcomes.

A prospective trial in surgical ICU patients (Leuven 1 study) reported that aggressive treatment of hyperglycemia (blood glucose > 110 mg/dL) reduced mortality and morbidity. Only a small number of persons in this study (204 of 1548) had a diagnosis of diabetes preoperatively, and so this study suggests that controlling hyperglycemia per se (independent of a diagnosis of diabetes) was beneficial. The benefits, however, were principally seen in patients who were in the ICU for longer than 5 days, and it is unclear whether the benefits also apply to most surgical patients who stay in the ICU for only 1 to 2 days.

The same investigators performed a similar prospective trial among 1200 medical ICU patients (Leuven 2 study) and reported that aggressive treatment of hyperglycemia reduced morbidity (decreased acquired kidney injury and increased early weaning from mechanical ventilation) but not mortality. Again, as in the surgical ICU study, only a small number of persons (16.9%) had a diagnosis of diabetes at admission. One of the inclusion criteria for the study was that patients would only be enrolled if they were likely to stay in the ICU for 3 days or longer. Some patients stayed in the ICU less than 3 days, and in that subgroup, intensive insulin therapy was associated with *increased* mortality. On the other hand, patients who stayed in the ICU for 3 days or longer had *reduced* mortality (and morbidity).

The findings of the Leuven studies have not been independently confirmed. Two other ICU-based studies (Glucontrol and VISEP) that attempted to confirm the findings were unable to do so. These two studies, however, were stopped prematurely for the following reasons: an interim analysis (falsely) suggested increased mortality in the test group in the Glucontrol study and hypoglycemic events increased sevenfold in the intensive treatment group in the VISEP study.

A study on tight intraoperative glycemic control during cardiac surgery also failed to show any benefit; if anything, the intensively treated group had more events. The United Kingdom Glucose Insulin in Stroke Trial (GIST-UK) failed to show beneficial effect of tight glycemic control in stroke patients; however, the investigators acknowledged that, because of slow recruitment, the study was underpowered. A large multicenter, multinational study (NICE-SUGAR) is currently reenrolling patients and the results of this study will hopefully resolve the question of how tightly to control glucose levels in the ICU.

Thus, based on the evidence available so far, keeping blood glucose values close to 100 mg/dL should be considered in the surgical and medical ICUs. When patients leave the ICU, target glucose values between 100 mg/dL and 180 mg/dL may be appropriate, although this view is based on clinical observations rather than conclusive evidence.

During major surgery and in the immediate recovery period in patients with type 1 diabetes—and in most patients with type 2 diabetes—regular insulin (25 units insulin in 250 mL 0.9% saline) is infused at a rate of 1-3 units/h. The insulin infusion is “piggy backed” onto a 5% dextrose in physiologic saline containing 20 mEq of potassium chloride, which is infused intravenously at a rate of ~100 mL/h. The patient’s blood glucose should be monitored every 30 minutes to 2 hours and the insulin dose adjusted to maintain target blood glucose levels. Type 2 patients facing minor surgical procedures not requiring general anesthesia who have previously been controlled on oral agents or diet alone do not generally require insulin infusions. Glucose-containing solutions should be avoided during surgery in these patients, and blood glucose levels should be monitored every 4 hours. Regular human insulin or one of the rapidly acting insulin analogs should be administered subcutaneously if needed to maintain blood glucose below 200 mg/dL (see Chapter 3).

2. Pregnancy and the diabetic patient—Tight glycemic control with normal HbA_{1c} levels is very important during pregnancy. Early in pregnancy, poor control increases the risk of spontaneous abortion and congenital malformations. Late in pregnancy, poor control can result in polyhydramnios, preterm labor, stillbirth, and fetal macrosomia with its associated problems. Diabetes complications can impact both maternal and fetal health. Diabetic retinopathy can first develop during pregnancy or retinopathy that is already present can worsen. Diabetic women with microalbuminuria can have worsening albuminuria during pregnancy and are at higher risk for preeclampsia. Patients who have preexisting kidney failure (prepregnancy creatinine clearance less than 80 mL/min) are at high risk for further decline in kidney function during the pregnancy, and this may not reverse after delivery. Diabetic gastroparesis can severely exacerbate the nausea and vomiting of pregnancy and some patients may require fluid and nutritional support.

Although there is evidence that glyburide is safe during pregnancy, the current practice is to control diabetes with insulin therapy. Every effort should be made, utilizing multiple injections of insulin or a continuous infusion of insulin by pump, to maintain near-normalization of fasting and preprandial blood glucose values while avoiding hypoglycemia. The fast-acting insulin analogs insulin aspart and insulin lispro can be used, but data on using the long-acting insulin analogs are limited. A small study using insulin glargine in 32 pregnancies did not reveal any problems. There are no data on insulin detemir use in pregnancy. NPH is currently the preferred intermediate insulin for basal coverage during pregnancy.

Unless there are fetal or maternal complications, diabetic women should be able to carry the pregnancy to full-term, delivering at 38 to 41 weeks. Induction of labor before 39 weeks may be considered if there is concern about increasing fetal weight. See Chapter 19 for further details.

► Prognosis

The DCCT showed that the previously poor prognosis for as many as 40% of patients with type 1 diabetes is markedly improved by optimal care. DCCT participants were generally young and highly motivated and were cared for in academic centers by skilled diabetes educators and endocrinologists who were able to provide more attention and services that are usually available. Improved training of primary care providers may be beneficial.

For type 2 diabetes, the UKPDS documented a reduction in microvascular disease with glycemic control, although this was not apparent in the obese subgroup. Cardiovascular outcomes were not improved by glycemic control, although antihypertensive therapy showed benefit in reducing the number of adverse cardiovascular complications as well as in reducing the occurrence of microvascular disease among hypertensive patients. In patients with visceral obesity, successful management of type 2 diabetes remains a major challenge in the attempt to achieve appropriate control of hyperglycemia, hypertension, and dyslipidemia. Once safe and effective methods are devised to prevent or manage

obesity, the prognosis of type 2 diabetes with its high cardiovascular risks should improve considerably.

In addition to poorly understood genetic factors relating to differences in individual susceptibility to development of long-term complications of hyperglycemia, it is clear that in both types of diabetes, the diabetic patient's intelligence, motivation, and awareness of the potential complications of the disease contribute significantly to the ultimate outcome.

DIABETIC COMA

Coma may be due to a variety of causes not directly related to diabetes. Certain causes directly related to diabetes require differentiation: (1) Hypoglycemic coma resulting from excessive doses of insulin or oral hypoglycemic agents. (2) Hyperglycemic coma associated with either severe insulin deficiency (diabetic ketoacidosis) or mild to moderate insulin deficiency (hyperglycemic hyperosmolar state). (3) Lactic acidosis associated with diabetes, particularly in diabetics stricken with severe infections or with cardiovascular collapse.

DIABETIC KETOACIDOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Hyperglycemia > 250 mg/dL.
- ▶ Acidosis with blood pH < 7.3.
- ▶ Serum bicarbonate < 15 mEq/L.
- ▶ Serum positive for ketones.

▶ General Considerations

Diabetic ketoacidosis may be the initial manifestation of type 1 diabetes or may result from increased insulin requirements in type 1 diabetes patients during the course of infection, trauma, myocardial infarction, or surgery. It is a

life-threatening medical emergency with a mortality rate just under 5% in individuals under 40 years of age, but with a more serious prognosis in the elderly, who have mortality rates over 20%. The National Data Group report an annual incidence of five to eight episodes of diabetic ketoacidosis per 1000 diabetic persons. Ketoacidosis may develop in patients with type 2 diabetes when severe stress such as sepsis or trauma is present. Diabetic ketoacidosis has been found to be one of the more common serious complications of insulin pump therapy, occurring in approximately 1 per 80 patient-months of treatment. Many patients who monitor capillary blood glucose regularly ignore urine ketone measurements, which would signal the possibility of insulin leakage or pump failure before serious illness develops. Poor compliance is one of the most common causes of diabetic ketoacidosis, particularly when episodes are recurrent.

► Clinical Findings

A. Symptoms and Signs

The appearance of diabetic ketoacidotic coma is usually preceded by a day or more of polyuria and polydipsia associated with marked fatigue, nausea and vomiting, and, finally, mental stupor that can progress to coma. On physical examination, evidence of dehydration in a stuporous patient with rapid deep breathing and a “fruity” breath odor of acetone would strongly suggest the diagnosis. Hypotension with tachycardia indicates profound fluid and electrolyte depletion, and mild hypothermia is usually present. Abdominal pain and even tenderness may be present in the absence of abdominal disease. Conversely, cholecystitis or pancreatitis may occur with minimal symptoms and signs.

B. Laboratory Findings

(Table 27–13.) Glycosuria of 4+ and strong ketonuria with hyperglycemia, ketonemia, low arterial blood pH, and low plasma bicarbonate are typical of diabetic ketoacidosis. Serum potassium is often elevated despite total body potassium depletion resulting from protracted polyuria or vomiting. Elevation of serum amylase is common but often

represents salivary as well as pancreatic amylase. Thus, in this setting, an elevated serum amylase is not specific for acute pancreatitis. Serum lipase may be useful if the diagnosis of acute pancreatitis is being seriously considered. Azotemia may be a better indicator of renal status than serum creatinine, since multichannel chemical analysis of serum creatinine (SMA-6) is falsely elevated by nonspecific chromogenicity of keto acids and glucose. Most laboratories, however, now routinely eliminate this interference. Leukocytosis as high as 25,000/mcL with a left shift may occur with or without associated infection. The presence of an elevated or even a normal temperature would suggest the presence of an infection, since patients with diabetic ketoacidosis are generally hypothermic if uninfected.

► Complications

Hyperglycemia and ketoacidemia are due to insulin lack, hyperglucagonemia, and elevated levels of the stress hormones catecholamines, cortisol, and growth hormone.

A. Hyperglycemia

Hyperglycemia results from increased hepatic production of glucose as well as diminished glucose uptake by peripheral tissues. Hepatic glucose output is a consequence of increased gluconeogenesis resulting from insulinopenia as well as from an associated hyperglucagonemia.

B. Ketoacidemia

Ketoacidemia represents the effect of insulin lack at multiple enzyme loci. Insulin lack associated with elevated levels of growth hormone, catecholamines, and glucagon contributes to an increase in lipolysis from adipose tissue and in hepatic ketogenesis. In addition, there is evidence that reduced ketolysis by insulin-deficient peripheral tissues contributes to the ketoacidemia. The only true “keto” acid present is acetoacetic acid, which, along with its by-product acetone, is measured by nitroprusside reagents (Acetest and Ketostix). The sensitivity for acetone, however, is poor, requiring over 10 mmol, which is seldom reached in the plasma of ketoacidotic subjects—

Table 27–13. Laboratory diagnosis of coma in diabetic patients.

| | Urine Glucose | Acetone | Plasma Glucose | Bicarbonate | Acetone |
|---|----------------|---------|-----------------------|----------------------------|---------|
| Related to diabetes | | | | | |
| Hypoglycemia | 0 ¹ | 0 or + | Low | Normal | 0 |
| Diabetic ketoacidosis | ++++ | ++++ | High | Low | ++++ |
| Hyperglycemic hyperosmolar state coma | ++++ | 0 | High | Normal or slightly low | 0 |
| Lactic acidosis | 0 or + | 0 or + | Normal or low or high | Low | 0 or + |
| Unrelated to diabetes | | | | | |
| Alcohol or other toxic drugs | 0 or + | 0 or + | May be low | Normal or low ² | 0 or + |
| Cerebrovascular accident or head trauma | + or 0 | 0 | Often high | Normal | 0 |
| Uremia | 0 or + | 0 | High or normal | Low | 0 or + |

¹Leftover urine in bladder might still contain glucose from earlier hyperglycemia.

²Alcohol can elevate plasma lactate as well as keto acids to reduce pH.

although this detectable concentration is readily achieved in urine. Thus, in the plasma of ketotic patients, only acetoacetate is measured by these reagents. The more prevalent β -hydroxybutyric acid has no ketone group and is therefore not detected by conventional nitroprusside tests. This takes on special importance in the presence of circulatory collapse during diabetic ketoacidosis, wherein an increase in lactic acid can shift the redox state to increase β -hydroxybutyric acid at the expense of the readily detectable acetoacetic acid. Bedside diagnostic reagents would then be unreliable, suggesting no ketonemia in cases where β -hydroxybutyric acid is a major factor in producing the acidosis. A combined glucose and ketone meter (Precision Xtra, Abbott Diabetes Care) that is able to measure blood β -hydroxybutyrate concentration on capillary blood is available. Many clinical laboratories now offer β -hydroxybutyrate measurement.

C. Fluid and Electrolyte Depletion

Hyperglycemia results in an osmotic diuresis and dehydration and secondary loss of electrolytes. Ketonuria similarly causes loss of water and electrolytes. Balance studies during withdrawal of insulin and treatment in patients with type 1 diabetes show that on average the water depletion is about 5 L; sodium, 300–500 mmol; potassium, 270–400 mmol; chloride, 100–400 mmol.

Drowsiness is fairly common but frank coma only occurs in about 10% of patients. There is a correlation between the degree of depression of the sensorium and extracellular osmolality. When serum hyperosmolality exceeds 320–330 mosm/L, central nervous system depression or coma may ensue. Coma in a diabetic patient with a lower osmolality should prompt a search for cause of coma other than hyperosmolality.

► Treatment

A. Prevention

Education of diabetic patients to recognize the early symptoms and signs of ketoacidosis has done a great deal to prevent severe acidosis. Urine ketones or capillary blood β -hydroxybutyrate should be measured in patients with signs of infection or in insulin pump-treated patients when capillary blood glucose is unexpectedly and persistently high. When heavy ketonuria and glycosuria persist on several successive examinations, supplemental regular insulin should be administered and liquid foods such as lightly salted tomato juice and broth should be ingested to replenish fluids and electrolytes. The patient should be instructed to contact the physician if ketonuria persists, and especially if vomiting develops or if appropriate adjustment of the infusion rate on an insulin pump does not correct the hyperglycemia and ketonuria. In juvenile-onset diabetics, particularly in the teen years, recurrent episodes of severe ketoacidosis often indicate poor compliance with the insulin regimen, and these patients will require intensive family counseling.

B. Emergency Measures

If ketosis is severe, the patient should be placed in the hospital for correction of the hyperosmolality as well as the

ketoacidemia. An ICU or, at the least, a step-down unit is preferable for more severe cases.

1. Therapeutic flow sheet—One of the most important steps in initiating therapy is to start a flow sheet listing vital signs and the time sequence of diagnostic laboratory values in relation to therapeutic maneuvers. Indices of the metabolic defects include urine glucose and ketones as well as arterial pH, plasma glucose, acetone, bicarbonate, serum urea nitrogen, and electrolytes. Serum osmolality should be measured or estimated and tabulated during the course of therapy.

A convenient method of estimating effective serum osmolality is as follows (normal values in humans are 280–300 mosm/kg):

$$\text{mosm/kg} = 2[\text{Na}^+] + \frac{\text{Glucose (mg/dL)}}{18}$$

These calculated estimates are usually 10–20 mosm/kg lower than values measured by standard cryoscopic techniques in patients with diabetic coma. Urea is freely permeable across cell membranes and therefore not included in calculations of effective serum osmolality. One physician should be responsible for maintaining this therapeutic flow sheet and prescribing therapy. An indwelling urinary catheter is required in all comatose patients but should be avoided if possible in a fully cooperative diabetic because of the risk of introducing bladder infection. Fluid intake and output should be recorded. Gastric intubation is recommended in the comatose patient to correct the commonly associated gastric dilatation that may lead to vomiting and aspiration. The patient should not receive sedatives or opioids.

2. Insulin replacement—Only regular insulin should be used initially in all cases of severe ketoacidosis, and it should be given immediately after the diagnosis is established. Regular insulin can be given in a loading dose of 0.15 unit/kg as an intravenous bolus to prime the tissue insulin receptors. Following the initial bolus, doses of insulin as low as 0.1 unit/kg/h are continuously infused or given hourly as an intramuscular injection; this is sufficient to replace the insulin deficit in most patients. Replacement of insulin deficiency helps correct the acidosis by reducing the flux of fatty acids to the liver, reducing ketone production by the liver, and also improving removal of ketones from the blood. Insulin treatment reduces the hyperosmolality by reducing the hyperglycemia. It accomplishes this by increasing removal of glucose through peripheral utilization as well as by decreasing production of glucose by the liver. This latter effect is accomplished by direct inhibition of gluconeogenesis and glycogenolysis, as well as by lowered amino acid flux from muscle to liver and reduced hyperglucagonemia.

The insulin dose should be “piggy-backed” into the fluid line so the rate of fluid replacement can be changed without altering the insulin delivery rate. If the plasma glucose level fails to fall at least 10% in the first hour, a repeat loading dose is recommended. The availability of bedside glucometers and of laboratory instruments for rapid and accurate glucose analysis (Beckman or Yellow Springs glucose ana-

lyzer) has contributed much to achieving optimal insulin replacement. Rarely, a patient with immune insulin resistance is encountered, and this requires doubling the insulin dose every 2–4 hours if hyperglycemia does not improve after the first two doses of insulin.

3. Fluid replacement—In most patients, the fluid deficit is 4–5 L. Initially, 0.9% saline solution is the solution of choice to help reexpand the contracted vascular volume and should be started in the emergency department as soon as the diagnosis is established. The saline should be infused rapidly to provide 1 L/h over the first 1–2 hours. After the first 2 L of fluid have been given, the intravenous infusion should be at the rate of 300–400 mL/h. Use 0.9% (“normal”) saline unless the serum sodium is greater than 150 mEq/L, when 0.45% (“half normal”) saline solution should be used. The volume status should be very carefully monitored. Failure to give enough volume replacement (at least 3–4 L in 8 hours) to restore normal perfusion is one of the most serious therapeutic shortcomings adversely influencing satisfactory recovery. Excessive fluid replacement (more than 5 L in 8 hours) may contribute to acute respiratory distress syndrome or cerebral edema. When blood glucose falls to approximately 250 mg/dL, the fluids should be changed to a 5% glucose-containing solution to maintain serum glucose in the range of 250–300 mg/dL. This will prevent the development of hypoglycemia and will also reduce the likelihood of cerebral edema, which could result from too rapid decline of blood glucose. Intensive insulin therapy should be continued until the ketoacidosis is corrected.

4. Sodium bicarbonate—The use of sodium bicarbonate in management of diabetic ketoacidosis has been questioned since clinical benefit was not demonstrated in one prospective randomized trial and because of the following potentially harmful consequences: (1) development of hypokalemia from rapid shift of potassium into cells if the acidosis is overcorrected, (2) tissue anoxia from reduced dissociation of oxygen from hemoglobin when acidosis is rapidly reversed (leftward shift of the oxygen dissociation curve), and (3) cerebral acidosis resulting from lowering of cerebrospinal fluid pH. It must be emphasized, however, that these considerations are less important when severe acidosis exists. It is therefore recommended that bicarbonate be administered to diabetic patients in ketoacidosis if the arterial blood pH is 7.0 or less, with careful monitoring to prevent overcorrection. One or two ampules of sodium bicarbonate (one ampule contains 44 mEq/50 mL) should be added to 1 L of 0.45% saline. (**Note:** Addition of sodium bicarbonate to 0.9% saline would produce a markedly hypertonic solution that could aggravate the hyperosmolar state already present.) This should be administered rapidly (over the first hour). It can be repeated until the arterial pH reaches 7.1, but it should not be given if the pH is 7.1 or greater since additional bicarbonate would increase the risk of rebound metabolic alkalosis as ketones are metabolized. Alkalosis shifts potassium from serum into cells, which could precipitate a fatal cardiac arrhythmia.

5. Potassium—Total body potassium loss from polyuria and vomiting may be as high as 200 mEq. However, because

of shifts of potassium from cells into the extracellular space as a consequence of acidosis, serum potassium is usually normal to slightly elevated prior to institution of treatment. As the acidosis is corrected, potassium flows back into the cells, and hypokalemia can develop if potassium replacement is not instituted. If the patient is not uremic and has an adequate urinary output, potassium chloride in doses of 10–30 mEq/h should be infused during the second and third hours after beginning therapy as soon as the acidosis starts to resolve. Replacement should be started sooner if the initial serum potassium is inappropriately normal or low and should be delayed if serum potassium fails to respond to initial therapy and remains above 5 mEq/L, as in cases of chronic kidney disease. An ECG can be of help in monitoring the patient’s potassium status: High peaked T waves are a sign of hyperkalemia, and flattened T waves with U waves are a sign of hypokalemia. Foods high in potassium content should be prescribed when the patient has recovered sufficiently to take food orally. Tomato juice has 14 mEq of potassium per 240 mL, and a medium-sized banana provides about 10 mEq.

6. Phosphate—Phosphate replacement is seldom required in treating diabetic ketoacidosis. However, if severe hypophosphatemia of less than 1 mg/dL (< 0.32 mmol/L) develops during insulin therapy, a small amount of phosphate can be replaced per hour as the potassium salt. Correction of hypophosphatemia helps restore the buffering capacity of the plasma, thereby facilitating renal excretion of hydrogen. It also corrects the impaired oxygen dissociation from hemoglobin by regenerating 2,3-diphosphoglycerate. However, three randomized studies in which phosphate was replaced in only half of a group of patients with diabetic ketoacidosis did not show any apparent clinical benefit from phosphate administration. Moreover, attempts to use the phosphate salt of potassium as the sole means of replacing potassium have led to a number of reported cases of severe hypocalcemia with tetany. To minimize the risk of inducing tetany from too-rapid replacement of phosphate, the average deficit of 40–50 mmol of phosphate should be replaced intravenously at a rate *no greater than 3–4 mmol/h* in a 60–70-kg person. A stock solution (Abbott) provides a mixture of 1.12 g KH_2PO_4 and 1.18 g K_2HPO_4 in a 5-mL single-dose vial (this equals 22 mmol of potassium and 15 mmol of phosphate). One-half of this vial (2.5 mL) should be added to 1 L of either 0.45% saline or 5% dextrose in water. Two liters of this solution, infused at a rate of 400 mL/h, will correct the phosphate deficit at the optimal rate of 3 mmol/h while providing 4.4 mEq of potassium per hour. (Additional potassium should be administered as potassium chloride to provide a total of 10–30 mEq of potassium per hour, as noted above.) If the serum phosphate remains below 2.5 mg/dL after this infusion, a repeat 5-hour infusion can be given.

7. Hyperchloremic acidosis during therapy—Because of the considerable loss of keto acids in the urine during the initial phase of therapy, substrate for subsequent regeneration of bicarbonate is lost and correction of the total bicarbonate deficit is hampered. A portion of the bicarbonate deficit is replaced with chloride ions infused in large amounts as saline to correct the dehydration. In most

patients, as the ketoacidosis clears during insulin replacement, a hyperchloremic, low-bicarbonate pattern emerges with a normal anion gap. This is a relatively benign condition that reverses itself over the subsequent 12–24 hours once intravenous saline is no longer being administered.

8. Treatment of associated infection—Antibiotics are prescribed as indicated. Cholecystitis and pyelonephritis may be particularly severe in these patients.

► Prognosis

The frequency of deaths due to diabetic ketoacidosis has been dramatically reduced by improved therapy of young diabetics, but this complication remains a significant risk in the aged and in patients in profound coma in whom treatment has been delayed. Acute myocardial infarction and infarction of the bowel following prolonged hypotension worsen the outlook. A serious prognostic sign is end-stage chronic kidney disease, and prior kidney dysfunction worsens the prognosis considerably because the kidney plays a key role in compensating for massive pH and electrolyte abnormalities. Cerebral edema has been reported to occur rarely as metabolic deficits return to normal. This is best prevented by avoiding sudden reversal of marked hyperglycemia. Maintaining glycemic levels of 200–300 mg/dL for the initial 24 hours after correction of severe hyperglycemia reduces this risk.

Kitabchi AE et al. Management of hyperglycemic crises in patients with diabetes. *Diabetes Care*. 2001 Jan;24(1):131–53. [PMID: 11194218]

HYPERGLYCEMIC HYPEROSMOLAR STATE

ESSENTIALS OF DIAGNOSIS

- Hyperglycemia > 600 mg/dL.
- Serum osmolality > 310 mosm/kg.
- No acidosis; blood pH above 7.3.
- Serum bicarbonate > 15 mEq/L.
- Normal anion gap (< 14 mEq/L).

► General Considerations

This second most common form of hyperglycemic coma is characterized by severe hyperglycemia in the absence of significant ketosis, with hyperosmolality and dehydration. It occurs in patients with mild or occult diabetes, and most patients are at least middle-aged to elderly. Accurate figures are not available as to its true incidence, but from data on hospital discharges it is rarer than diabetic ketoacidosis even in older age groups. Lethargy and confusion develop as serum osmolality exceeds 310 mosm/kg, and coma can occur if osmolality exceeds 320–330 mosm/kg. A committee of the ADA has recommended replacing the previous name of this disorder (hyperglycemic, hyperosmolar, non-ketotic coma) with the consensus term “hyperglycemic hyperosmolar state.” Underlying chronic kidney disease or

congestive heart failure is common, and the presence of either worsens the prognosis. A precipitating event such as infection, myocardial infarction, stroke, or recent operation is often present. Certain drugs such as phenytoin, diazoxide, corticosteroids, and diuretics have been implicated in its pathogenesis, as have procedures associated with glucose loading such as peritoneal dialysis.

► Pathogenesis

A partial or relative insulin deficiency may initiate the syndrome by reducing glucose utilization of muscle, fat, and liver while inducing hyperglucagonemia and increasing hepatic glucose output. With massive glycosuria, obligatory water loss ensues. If a patient is unable to maintain adequate fluid intake because of an associated acute or chronic illness or has suffered excessive fluid loss, marked dehydration results. As plasma volume contracts, chronic kidney disease develops, and the resultant limitation of renal glucose loss leads to increasingly higher blood glucose concentrations. Severe hyperosmolality develops that causes mental confusion and finally coma. It is not clear why ketosis is virtually absent under these conditions of insulin insufficiency, although reduced levels of growth hormone may be a factor, along with portal vein insulin concentrations sufficient to restrain ketogenesis.

► Clinical Findings

A. Symptoms and Signs

Onset may be insidious over a period of days or weeks, with weakness, polyuria, and polydipsia. The lack of features of ketoacidosis may retard recognition of the syndrome and delay therapy until dehydration becomes more profound than in ketoacidosis. Reduced intake of fluid is not an uncommon historical feature, due to either inappropriate lack of thirst, nausea, or inaccessibility of fluids to elderly, bedridden patients. Lethargy and confusion develop, progressing to convulsions and deep coma. Physical examination confirms the presence of profound dehydration in a lethargic or comatose patient without Kussmaul respirations.

B. Laboratory Findings

(Table 27–13.) Severe hyperglycemia is present, with blood glucose values ranging from 600 mg/dL to 2400 mg/dL. In mild cases, where dehydration is less severe, dilutional hyponatremia as well as urinary sodium losses may reduce serum sodium to 120–125 mEq/L, which protects to some extent against extreme hyperosmolality. However, as dehydration progresses, serum sodium can exceed 140 mEq/L, producing serum osmolality readings of 330–440 mosm/kg. Ketosis and acidosis are usually absent or mild. Prerenal azotemia is the rule, with serum urea nitrogen elevations over 100 mg/dL being typical.

► Treatment

A. Saline

Fluid replacement is of paramount importance in treating nonketotic hyperglycemic coma. The onset of hyperosmo-

larity is more insidious in elderly people without ketosis than in younger individuals with high serum ketone levels, which provide earlier indicators of severe illness (vomiting, rapid deep breathing, acetone odor, etc). Consequently, diagnosis and treatment are often delayed until fluid deficit has reached levels of 6–10 L.

If hypovolemia is present as evidenced by hypotension and oliguria, fluid therapy should be initiated with 0.9% saline. In all other cases, 0.45% saline appears to be preferable as the initial replacement solution because the body fluids of these patients are markedly hyperosmolar. As much as 4–6 L of fluid may be required in the first 8–10 hours. Careful monitoring of the patient is required for proper sodium and water replacement. Once blood glucose reaches 250 mg/dL, fluid replacement should include 5% dextrose in either water, 0.45% saline solution, or 0.9% saline solution. The rate of dextrose infusion should be adjusted to maintain glycemic levels of 250–300 mg/dL in order to reduce the risk of cerebral edema. An important end point of fluid therapy is to restore urinary output to 50 mL/h or more.

B. Insulin

Less insulin may be required to reduce the hyperglycemia in nonketotic patients as compared to those with diabetic ketoacidotic coma. In fact, fluid replacement alone can reduce hyperglycemia considerably by correcting the hypovolemia, which then increases both glomerular filtration and renal excretion of glucose. An initial dose of 0.15 unit/kg is followed by an insulin infusion of 1–2 units/h, which is titrated to lower blood glucose levels by 50–70 mg/dL per hour.

C. Potassium

With the absence of acidosis, there may be no initial hyperkalemia unless associated end-stage chronic kidney disease is present. This results in less severe total potassium depletion than in diabetic ketoacidosis, and less potassium replacement is therefore needed. However, because initial serum potassium is usually not elevated and because it declines rapidly as a result of insulin's effect on driving potassium intracellularly, it has been recommended that potassium replacement be initiated earlier than in ketotic patients, assuming that no chronic kidney disease or oliguria is present. Potassium chloride (10 mEq/L) can be added to the initial bottle of fluids administered if the patient's serum potassium is not elevated.

D. Phosphate

If severe hypophosphatemia (serum phosphate < 1 mg/dL [< 0.32 mmol/L]) develops during insulin therapy, phosphate replacement can be given as described for ketoacidotic patients (at 3 mmol/h).

► Prognosis

The overall mortality rate of hyperglycemic hyperosmolar state coma is more than ten times that of diabetic ketoacidosis, chiefly because of its higher incidence in older patients, who may have compromised cardiovascular systems or associated major illnesses and whose dehydration

is often excessive because of delays in recognition and treatment. (When patients are matched for age, the prognoses of these two hyperglycemic emergencies are reasonably comparable.) When prompt therapy is instituted, the mortality rate can be reduced from nearly 50% to that related to the severity of coexistent disorders.

American Diabetes Association. Hyperglycemic crises in patients with diabetes mellitus. *Diabetes Care*. 2001 Jan;24(1):154–61. [PMID: 11221603]

LACTIC ACIDOSIS

ESSENTIALS OF DIAGNOSIS

- Severe acidosis with hyperventilation.
- Blood pH below 7.30.
- Serum bicarbonate < 15 mEq/L.
- Anion gap > 15 mEq/L.
- Absent serum ketones.
- Serum lactate > 5 mmol/L.

► General Considerations

Lactic acidosis is characterized by accumulation of excess lactic acid in the blood. Normally, the principal sources of this acid are the erythrocytes (which lack enzymes for aerobic oxidation), skeletal muscle, skin, and brain. Conversion of lactic acid to glucose and its oxidation principally by the liver but also by the kidneys represent the chief pathways for its removal. Overproduction of lactic acid (tissue hypoxia), deficient removal (hepatic failure), or both (circulatory collapse) can cause accumulation. Lactic acidosis is not uncommon in any severely ill patient suffering from cardiac decompensation, respiratory or hepatic failure, septicemia, or infarction of bowel or extremities. With the discontinuance of phenformin therapy in the United States, lactic acidosis in patients with diabetes mellitus has become uncommon but occasionally occurs in metformin-treated patients (see above) and it still must be considered in the acidotic diabetic, especially if the patient is seriously ill.

► Clinical Findings

A. Symptoms and Signs

The main clinical feature of lactic acidosis is marked hyperventilation. When lactic acidosis is secondary to tissue hypoxia or vascular collapse, the clinical presentation is variable, being that of the prevailing catastrophic illness. However, in the idiopathic, or spontaneous, variety, the onset is rapid (usually over a few hours), blood pressure is normal, peripheral circulation is good, and there is no cyanosis.

B. Laboratory Findings

Plasma bicarbonate and blood pH are quite low, indicating the presence of severe metabolic acidosis. Ketones are usu-

ally absent from plasma and urine or at least not prominent. The first clue may be a high anion gap (serum sodium minus the sum of chloride and bicarbonate anions [in mEq/L] should be no greater than 15). A higher value indicates the existence of an abnormal compartment of anions. If this cannot be clinically explained by an excess of keto acids (diabetes), inorganic acids (uremia), or anions from drug overdosage (salicylates, methyl alcohol, ethylene glycol), then lactic acidosis is probably the correct diagnosis. (See also Chapter 21.) In the absence of azotemia, hyperphosphatemia may be a clue to the presence of lactic acidosis for reasons that are not clear. The diagnosis is confirmed by demonstrating, in a sample of blood that is promptly chilled and separated, a plasma lactic acid concentration of 5 mmol/L or higher (values as high as 30 mmol/L have been reported). Normal plasma values average 1 mmol/L, with a normal lactate/pyruvate ratio of 10:1. This ratio is greatly exceeded in lactic acidosis.*

► Treatment

Aggressive treatment of the precipitating cause of lactic acidosis is the main component of therapy, such as ensuring adequate oxygenation and vascular perfusion of tissues. Empiric antibiotic coverage for sepsis should be given after culture samples are obtained in any patient in whom the cause of the lactic acidosis is not apparent.

Alkalinization with intravenous sodium bicarbonate to keep the pH above 7.2 has been recommended by some in the emergency treatment of lactic acidosis; as much as 2000 mEq in 24 hours has been used. However, there is no evidence that the mortality rate is favorably affected by administering bicarbonate, and its use remains controversial. Hemodialysis may be useful in cases where large sodium loads are poorly tolerated.

► Prognosis

The mortality rate of spontaneous lactic acidosis is high. The prognosis in most cases is that of the primary disorder that produced the lactic acidosis.

THE HYPOGLYCEMIC STATES

Spontaneous hypoglycemia in adults is of two principal types: fasting and postprandial. Symptoms begin at plasma glucose levels in the range of 60 mg/dL and impairment of brain function at approximately 50 mg/dL. Fasting hypoglycemia is often subacute or chronic and usually presents with

Table 27–14. Common causes of hypoglycemia in adults.¹

| |
|--|
| Fasting hypoglycemia |
| Hyperinsulinism |
| Pancreatic B cell tumor |
| Surreptitious administration of insulin or sulfonylureas |
| Extrapancreatic tumors |
| Postprandial (reactive) hypoglycemia |
| Early hypoglycemia (alimentary) |
| Postgastrectomy |
| Functional (increased vagal tone) |
| Late hypoglycemia (occult diabetes mellitus) |
| Delayed insulin release due to B cell dysfunction |
| Counterregulatory hormone and neurogenic autonomic response deficiency |
| Idiopathic |
| Alcohol-related hypoglycemia |
| Immunopathologic hypoglycemia |
| Idiopathic anti-insulin antibodies (which release their bound insulin) |
| Antibodies to insulin receptors (which act as agonists) |
| Drug-induced hypoglycemia |

¹In the absence of clinically obvious endocrine, renal, or hepatic disorders and exclusive of diabetes mellitus treated with hypoglycemic agents.

neuroglycopenia as its principal manifestation; postprandial hypoglycemia is relatively acute and is often heralded by symptoms of neurogenic autonomic discharge (sweating, palpitations, anxiety, tremulousness).

► Differential Diagnosis (Table 27–14)

Fasting hypoglycemia may occur in certain endocrine disorders, such as hypopituitarism, Addison disease, or myxedema; in disorders related to liver malfunction, such as acute alcoholism or liver failure; and in instances of end-stage chronic kidney disease, particularly in patients requiring dialysis. These conditions are usually obvious, with hypoglycemia being only a secondary feature. When fasting hypoglycemia is a primary manifestation developing in adults without apparent endocrine disorders or inborn metabolic diseases from childhood, the principal diagnostic possibilities include: (1) hyperinsulinism, due to either pancreatic B cell tumors or islet hyperplasia or surreptitious administration of insulin (or sulfonylureas), and (2) hypoglycemia due to non–insulin-producing extrapancreatic tumors.

Postprandial (reactive) hypoglycemia may be classified as early (within 2–3 hours after a meal) or late (3–5 hours after eating). Early, or alimentary, hypoglycemia occurs when there is a rapid discharge of ingested carbohydrate into the small bowel followed by rapid glucose absorption and hyperinsulinism. It may be seen after gastrointestinal surgery and is particularly associated with the dumping syndrome after gastrectomy and Roux-en-Y gastric bypass surgery. In some cases, it is functional and may represent overactivity of the parasympathetic nervous system mediated via the vagus nerve. Rarely, it results from defective counterregulatory responses such as deficiencies of growth hormone, glucagon, cortisol, or autonomic responses.

*In collecting samples, it is essential to rapidly chill and separate the blood in order to remove red cells, whose continued glycolysis at room temperature is a common source of error in reports of high plasma lactate. Frozen plasma remains stable for subsequent assay.

Alcohol-related hypoglycemia is due to hepatic glycogen depletion combined with alcohol-mediated inhibition of gluconeogenesis. It is most common in malnourished alcohol abusers but can occur in anyone who is unable to ingest food after an acute alcoholic episode followed by gastritis and vomiting.

Immunopathologic hypoglycemia is an extremely rare condition in which anti-insulin antibodies or antibodies to insulin receptors develop spontaneously. In the former case, the mechanism appears to relate to increasing dissociation of insulin from circulating pools of bound insulin. When antibodies to insulin receptors are found, most patients do not have hypoglycemia but rather severe insulin-resistant diabetes and acanthosis nigricans. However, during the course of the disease in these patients, certain anti-insulin receptor antibodies with agonist activity mimicking insulin action may develop, producing severe hypoglycemia.

Factitious hypoglycemia is self-induced hypoglycemia due to surreptitious administration of insulin or sulfonylureas.

HYPOGLYCEMIA DUE TO PANCREATIC B CELL TUMORS

ESSENTIALS OF DIAGNOSIS

- ▶ Hypoglycemic symptoms—frequently neuroglycopenic (confusion, blurred vision, diplopia, anxiety, convulsions).
- ▶ Immediate recovery upon administration of glucose.
- ▶ Blood glucose < 40 mg/dL with a serum insulin level of 6 microunit/mL or more.

▶ General Considerations

Fasting hypoglycemia in an otherwise healthy, well-nourished adult is rare and is most commonly due to an adenoma of the islets of Langerhans. Ninety percent of such tumors are single and benign, but multiple adenomas can occur as well as malignant tumors with functional metastases. Adenomas may be familial, and multiple adenomas have been found in conjunction with tumors of the parathyroids and pituitary (multiple endocrine neoplasia type 1 [MEN 1]).

▶ Clinical Findings

A. Symptoms and Signs

The most important prerequisite to diagnosing an insulinoma is simply to consider it, particularly in relatively healthy-appearing persons who have fasting hypoglycemia associated with some degree of central nervous system dysfunction such as confusion or abnormal behavior. A delay in diagnosis can result in unnecessary treatment for psychomotor epilepsy or psychiatric disorders and may cause irreversible brain damage. In longstanding cases, obesity can result as a consequence of overeating to relieve symptoms.

The so-called **Whipple triad** is characteristic of hypoglycemia regardless of the cause. It consists of: (1) a history of

hypoglycemic symptoms; (2) an associated fasting blood glucose of 40 mg/dL or less; and (3) immediate recovery upon administration of glucose. The hypoglycemic symptoms in insulinoma often develop in the early morning or after missing a meal. Occasionally, they occur after exercise. They typically begin with evidence of central nervous system glucose lack and can include blurred vision or diplopia, headache, feelings of detachment, slurred speech, and weakness. Personality and mental changes vary from anxiety to psychotic behavior, and neurologic deterioration can result in convulsions or coma. Sweating and palpitations may not occur.

Hypoglycemic unawareness is very common in patients with insulinoma. They adapt to chronic hypoglycemia by increasing their efficiency in transporting glucose across the blood-brain barrier, which masks awareness that their blood glucose is approaching critically low levels. Counterregulatory hormonal responses as well as neurogenic symptoms such as tremor, sweating, and palpitations are therefore blunted during hypoglycemia. If lack of these warning symptoms prevents recognition of the need to eat to correct the problem, patients can lapse into severe hypoglycemic coma. However, symptoms and normal hormone responses during experimental insulin-induced hypoglycemia have been shown to be restored after successful surgical removal of the insulinoma. Presumably with return of euglycemia, adaptive effects on glucose transport into the brain are corrected, and thresholds of counterregulatory responses and neurogenic autonomic symptoms are therefore restored to normal.

B. Laboratory Findings

B cell adenomas do not reduce secretion in the presence of hypoglycemia, and the critical diagnostic test is to demonstrate inappropriately elevated serum insulin levels at a time when hypoglycemia is present. A reliable serum insulin level (radioimmunoassay) of 6 microunit/mL or more in the presence of blood glucose values below 40 mg/dL is diagnostic of inappropriate hyperinsulinism. Immunochemiluminometric assays (ICMA) have sensitivities of less than 1 microunit/mL, and with these assays, the cutoffs for insulinomas is insulin level of 3 microunit/mL or higher. Other causes of hyperinsulinemic hypoglycemia must be considered, including factitious administration of insulin or sulfonylureas. Factitious use of insulin will result in suppression of endogenous insulin secretion and a low C-peptide levels. An elevated circulating proinsulin level in the presence of fasting hypoglycemia is characteristic of most B cell adenomas and does not occur in factitious hyperinsulinism. Thus, C-peptide and proinsulin levels (by ICMA) of > 200 pmol/L and > 5 pmol/L, respectively, are characteristic of insulinomas.

In patients with epigastric distress, a history of renal calculi, or menstrual or erectile dysfunction, a serum calcium, gastrin, or prolactin level may be useful in screening for MEN 1 associated with insulinoma.

C. Diagnostic Tests

1. Prolonged fasting—Prolonged fasting under hospital supervision until hypoglycemia is documented is probably

the most dependable means of establishing the diagnosis, especially in men. In 30% of patients with insulinoma, the blood glucose levels often drop below 40 mg/dL after an overnight fast, but some patients require up to 72 hours to develop symptomatic hypoglycemia. However, the term “72-hour fast” is actually a misnomer in most cases since the fast should be immediately terminated as soon as symptoms appear and laboratory confirmation of hypoglycemia is available. In normal male subjects, the blood glucose does not fall below 55–60 mg/dL during a 3-day fast. In contrast, in normal premenopausal women who have fasted for only 24 hours, the plasma glucose may fall normally to such an extent that it can reach values as low as 35 mg/dL. In these cases, however, the women are not symptomatic, presumably owing to the development of sufficient ketonemia to supply energy needs to the brain. Insulinoma patients, on the other hand, become symptomatic when plasma glucose drops to subnormal levels, since inappropriate insulin secretion restricts ketone formation. Moreover, the demonstration of a nonsuppressed insulin level ≥ 6 microunit/mL using a RIA assay (> 3 microunit/mL using an ICMA assay) in the presence of hypoglycemia suggests the diagnosis of insulinoma. If hypoglycemia does not develop in a male patient after fasting for up to 72 hours—and particularly when this prolonged fast is terminated with a period of moderate exercise—insulinoma must be considered an unlikely diagnosis. A suggested protocol for the supervised fast is shown in Table 27–15.

2. Stimulation tests—Stimulation with pancreatic B cell secretagogues such as tolbutamide, glucagon, or leucine is generally not needed in most cases if basal insulin is found

Table 27–15. Suggested hospital protocol for supervised fast in diagnosis of insulinoma.

- (1) Obtain baseline serum glucose, insulin, proinsulin, and C-peptide measurements at onset of fast and place intravenous cannula.
- (2) Permit only calorie-free and caffeine-free fluids and encourage supervised activity (such as walking).
- (3) Measure urine for ketones at the beginning and every 12 hours and at end of fast.
- (4) Obtain capillary glucose measurements with a reflectance meter every 4 hours until values < 60 mg/dL are obtained. Then increase the frequency of fingersticks to each hour, and when capillary glucose value is < 49 mg/dL send a venous blood sample to the laboratory for serum glucose, insulin, proinsulin, and C-peptide measurements. Check frequently for manifestations of neuroglycopenia.
- (5) If symptoms of hypoglycemia occur or if a laboratory value of serum glucose is < 45 mg/dL, or if 72 hours have elapsed then conclude the fast with a final blood sample for serum glucose, insulin, proinsulin, C-peptide, β -hydroxybutyrate or acetone and sulfonyleurea measurements. Then give oral fast-acting carbohydrate followed by a meal. If the patient is confused or unable to take oral agents, then administer 50 mL of 50% dextrose intravenously over 3 to 5 minutes. Do not conclude a fast based simply on a capillary blood glucose measurement—wait for the laboratory glucose value—unless the patient is very symptomatic and it would be dangerous to wait.

to be nonsuppressible and therefore inappropriately elevated during fasting hypoglycemia.

Intravenous glucagon (1 mg over 1 minute) can be useful in patients with “borderline” fasting inappropriate hyperinsulinism. A serum insulin rise above baseline of 200 microunit/mL or more at 5 and 10 minutes strongly suggests insulinoma, although poorly differentiated tumors may not respond. Glucagon has the advantage over tolbutamide of correcting rather than provoking hypoglycemia during stimulation testing and is diagnostic in 60–70% of patients with insulinoma. False-negative results can occur if the tumor is poorly differentiated and agranular.

D. Preoperative Localization of B Cell Tumors

After the diagnosis of insulinoma has been unequivocally made by clinical and laboratory findings, studies to localize the tumor should be initiated. The focus of attention should be directed to the pancreas since that is where virtually all insulinomas originate.

A spiral CT angiography of the pancreas should be performed to rule out a large tumor of the pancreas or hepatic metastases from a malignant islet cell tumor. Endoscopic ultrasonographic examination of the pancreas can also be helpful in identifying the pancreatic lesions. Because of the small size of these tumors (averaging 1.5 cm in diameter in one large series), imaging studies do not necessarily identify all the tumors. Patients who do not have an obvious tumor on imaging (but have a definite biochemical diagnosis) should undergo selective calcium-stimulated angiography. In this test, angiography is combined with injections of calcium gluconate into the gastroduodenal, splenic, and superior mesenteric arteries and insulin levels are measured in the hepatic vein effluent. Calcium stimulates insulin release from insulinomas but not normal islets, and so a step-up of insulin levels regionalizes the hyperinsulinism to the head of the pancreas for the gastroduodenal artery, to the uncinate process for the superior mesenteric artery, and to the body and tail of the pancreas for the splenic artery. This technique may also provide data that are particularly helpful when multiple insulinomas are suspected (MEN 1) and it has become a major tool in confirming the diagnosis of diffuse islet hyperplasia in the recently described noninsulinoma pancreatogenous hypoglycemia syndrome (NIPHS) (see below). Since diazoxide might interfere with this test, it should be discontinued for at least 48–72 hours before sampling. An infusion of dextrose may be required, therefore, and patients should be closely monitored during the procedure to avoid hypoglycemia (as well as hyperglycemia, which could affect insulin gradients). These studies combined with careful intraoperative ultrasonography and palpation by a surgeon experienced in insulinoma surgery identifies up to 98% of tumors.

▶ Treatment

A. Surgical Measures

It is imperative that the surgeon be convinced that the diagnosis of insulinoma has been unequivocally made by clinical and laboratory findings. Only then should surgery be

considered, as there is no justification for exploratory operation—just as there is none for the use of current localization techniques as a preoperative diagnostic tool. Resection by a surgeon with previous experience in removing pancreatic B cell tumors is the treatment of choice. In patients with a single benign adenoma, 90–95% have a successful cure at the first surgical attempt when intraoperative ultrasound is used by a skilled surgeon. Blood glucose should be monitored throughout surgery, and 10% dextrose in water should be infused at a rate of 100 mL/h or faster. In cases where the diagnosis has been established but no adenoma is located after careful palpation and use of intraoperative ultrasound, it is no longer advisable to blindly resect the body and tail of the pancreas, since a nonpalpable tumor missed by ultrasound is most likely embedded within the fleshy head of the pancreas that is left behind with subtotal resections. Most surgeons prefer to close the incision and schedule a selective arterial calcium stimulation with hepatic venous sampling to locate the tumor site prior to a repeat operation. Laparoscopy using ultrasound and enucleation has been successful with a single tumor of the body or tail of the pancreas, but open surgery remains necessary for tumors in the head of the pancreas.

B. Diet and Medical Therapy

In patients with inoperable functioning islet cell carcinoma and in approximately 5–10% of MEN 1 cases when subtotal removal of the pancreas has failed to produce cure, reliance on frequent feedings is necessary. Since most tumors are not responsive to glucose, carbohydrate feedings every 2–3 hours are usually effective in preventing hypoglycemia, although obesity may become a problem. Diazoxide, 300–600 mg (or 3 mg to 8 mg/kg; 50 mg/mL oral suspension) daily orally in two or three divided doses, is the treatment of choice. Hydrochlorothiazide, 25–50 mg daily, should also be prescribed to counteract the sodium retention and edema secondary to diazoxide therapy as well as to potentiate its hyperglycemic effect. If patients are unable to tolerate diazoxide because of gastrointestinal upset, hirsutism, or edema, the calcium channel blocker verapamil may be beneficial in view of its inhibitory effect on insulin release from insulinoma cells. Octreotide, a potent long-acting synthetic octapeptide analog of somatostatin, has been used to inhibit release of hormones from a number of endocrine tumors. A dose of 50 mcg of octreotide injected subcutaneously twice daily has been tried in cases where surgery failed to remove the source of hyperinsulinism. However, its effectiveness is limited since its affinity for somatostatin receptors of the pancreatic B cell is very much less than for those of the anterior pituitary somatotrophs for which it was originally designed as treatment for acromegaly. When hypoglycemia persists after attempted surgical removal of the insulinoma and if diazoxide or verapamil is poorly tolerated or ineffective, multiple small feedings may be the only recourse until more selective somatostatin receptor agonists are available. Streptozocin can decrease insulin secretion in islet cell carcinomas, and effective doses have been delivered via selective arterial catheter so that the undue renal toxicity that characterized early experience is less of a problem.

► Prognosis

When insulinoma is diagnosed early and cured surgically, complete recovery is likely, although brain damage following prolonged severe hypoglycemia is not reversible. A significant increase in survival rate has been shown in streptozocin-treated patients with islet cell carcinoma, with reduction in tumor mass as well as decreased hyperinsulinism.

PERSISTENT ISLET HYPERPLASIA (Noninsulinoma Pancreatogenous Hypoglycemia Syndrome)

In a very small number of patients with organic hyperinsulinism, islet hyperplasia rather than an adenoma is present. These patients typically have documented hyperinsulinemic hypoglycemia after meals but not with fasting up to 72 hours. The patients have a positive response to calcium-stimulated angiography. A gradient-guided partial pancreatectomy leads to clinical remission, and the pathology of the pancreas shows evidence of islet hyperplasia and nesidioblastosis. These patients do not have mutations in the *Kir 6.2* and *SURI* genes, which has been reported in children with familial hyperinsulinemic hypoglycemia.

HYPOGLYCEMIA DUE TO EXTRAPANCREATIC TUMORS

These rare causes of hypoglycemia include mesenchymal tumors such as retroperitoneal sarcomas, hepatocellular carcinomas, adrenocortical carcinomas, and miscellaneous epithelial-type tumors. The tumors are frequently large and readily palpated or visualized on CT scans or MRI.

The expression and release of an incompletely processed insulin-like growth factor-2 (IGF-2) has provided the best explanation for the clinical manifestations of hypoglycemia in these cases. A larger immature form of the IGF-2 molecule is released which binds to a carrier protein but not to an acid-labile component of serum which inactivates normal IGF-2. This immature IGF-2 complex therefore remains active and binds to insulin receptors in muscle to promote glucose transport and to insulin receptors in liver and kidney to reduce glucose output. It also binds to receptors for IGF-1 in the pancreatic B cell to inhibit insulin secretion. Serum levels of IGF-2 may be increased but often are “normal” in quantity, despite the presence of the immature, higher-molecular-weight form of IGF-2, which can only be detected by special laboratory techniques. Laboratory diagnosis depends on document-

ing fasting hypoglycemia associated with undetectable serum insulin levels.

The prognosis for these tumors is generally poor, and surgical removal should be attempted when feasible. Dietary management of the hypoglycemia is the mainstay of medical treatment, since diazoxide is usually ineffective.

POSTPRANDIAL HYPOGLYCEMIA (Reactive Hypoglycemia)

1. Postgastrectomy Alimentary Hypoglycemia

Reactive hypoglycemia following gastrectomy is a consequence of hyperinsulinism resulting from rapid gastric emptying of ingested food. Symptoms result from adrenergic hyperactivity in response to the hypoglycemia. Treatment consists of more frequent feedings with smaller portions of less rapidly assimilated carbohydrate combined with more slowly absorbed fat and protein. Cases of hypoglycemia have been reported in patients who have undergone Roux-en-Y gastric bypass surgery for the treatment of obesity. The hypoglycemia occurs after meals and can be severe. There have been case reports of islet hyperplasia but this is probably uncommon; other studies report normal islet pathology.

2. Functional Alimentary Hypoglycemia

This syndrome is classified as functional when no postsurgical explanation exists for the presence of early alimentary type reactive hypoglycemia. It is most often associated with chronic fatigue, anxiety, irritability, weakness, poor concentration, decreased libido, headaches, hunger after meals, and tremulousness. However, most patients with these symptoms do not have hypoglycemia after a mixed meal. (See Chronic Fatigue Syndrome in Chapter 2.)

Indiscriminate use and overinterpretation of glucose tolerance tests have led to an unfortunate tendency to overdiagnose functional hypoglycemia. As many as one-third or more of normal subjects have blood glucose levels as low as 40–50 mg/dL with or without symptoms during a 4-hour glucose tolerance test. Accordingly, to increase diagnostic reliability, hypoglycemia should preferably be documented during a spontaneous symptomatic episode accompanying routine daily activity, with clinical improvement following feeding. Oral glucose tolerance tests are overly sensitive and mixed meals are relatively insensitive in detecting postprandial reactive hypoglycemia. It has been shown that a high-carbohydrate breakfast has proved useful in differentiating persons with postprandial reactive hypoglycemia from normal controls. The test resulted in reactive hypoglycemia to levels below 59 mg/dL in 47% of 38 subjects, in contrast to only 2.2% of the 43 controls. This test was found to be much more sensitive than a standard mixed meal, which was also given to these two groups.

In patients with documented postprandial hypoglycemia on a functional basis, there is no harm and occasional benefit in reducing the proportion of carbohydrate in the diet while increasing the frequency and reducing the size of meals. Acarbose has also been reported to provide symptomatic relief and can be tried if dietary manipulations alone are ineffective.

3. Late Hypoglycemia (Occult Diabetes)

This condition is characterized by a delay in early insulin release from pancreatic B cells, resulting in initial exaggeration of hyperglycemia during a glucose tolerance test. In response to this hyperglycemia, an exaggerated insulin release produces a late hypoglycemia 4–5 hours after ingestion of glucose. These patients are usually quite different from those with early hypoglycemia occurring 2–3 hours after glucose ingestion, often being obese and frequently having a family history of diabetes mellitus.

In obese patients, treatment is directed at weight reduction to achieve ideal weight. Like all patients with postprandial hypoglycemia, regardless of cause, these patients often respond to reduced carbohydrate intake with multiple, spaced, small feedings. They should be considered potential diabetics and advised to have periodic medical evaluations.

Service GJ et al. Hyperinsulinemic hypoglycemia with nesidioblastosis after gastric-bypass surgery. *N Engl J Med*. 2005 Jul 21;353(3):249–54. [PMID: 16034010]

ALCOHOL-RELATED HYPOGLYCEMIA

1. Fasting Hypoglycemia after Ethanol

During the postabsorptive state, normal plasma glucose is maintained by hepatic glucose output derived from both glycogenolysis and gluconeogenesis. With prolonged starvation, glycogen reserves become depleted within 18–24 hours and hepatic glucose output becomes totally dependent on gluconeogenesis. Under these circumstances, a blood concentration of ethanol as low as 45 mg/dL can induce profound hypoglycemia by blocking gluconeogenesis. Neuroglycopenia in a patient whose breath smells of alcohol may be mistaken for alcoholic stupor. Prevention consists of adequate food intake during ethanol ingestion. Therapy consists of glucose administration to replenish glycogen stores until gluconeogenesis resumes.

▶ Postethanol Reactive Hypoglycemia

When sugar-containing soft drinks are used as mixers to dilute alcohol in beverages (gin and tonic, rum and cola), there seems to be a greater insulin release than when the soft drink alone is ingested and a tendency for more of a late hypoglycemic overswing to occur 3–4 hours later. Prevention would consist of avoiding sugar mixers while ingesting alcohol and ensuring supplementary food intake to provide sustained absorption.

van de Wiel A. Diabetes mellitus and alcohol. *Diabetes Metab Res Rev*. 2004 Jul–Aug;20(4):263–7. [PMID: 15250029]

FACTITIOUS HYPOGLYCEMIA

Factitious hypoglycemia may be difficult to document. A suspicion of self-induced hypoglycemia is supported when the patient is associated with the health professions or has access to insulin or sulfonylurea drugs taken by a diabetic member of the family. The triad of hypoglycemia, high immunoreactive insulin, and suppressed plasma C peptide immunoreactivity is pathognomonic of exogenous insulin administration. Demonstration of circulating insulin antibodies supports this diagnosis in suspected cases. When sulfonylureas, repaglinide and nateglinide are suspected as a cause of factitious hypoglycemia, a plasma level of these drugs to detect their presence may be required to distinguish laboratory findings from those of insulinoma.

IMMUNOPATHOLOGIC HYPOGLYCEMIA

This rare cause of hypoglycemia, documented in isolated case reports, may occur as two distinct disorders: one associated with spontaneous development of circulating anti-insulin antibodies and another associated with antibodies to insulin receptors, in which the antibodies apparently have agonist capabilities. This latter disorder is extremely rare, having been documented in no more than five cases. However, development of anti-insulin antibodies has been reported in over 200 patients most of whom were being treated with methimazole for thyrotoxicosis. In Western countries, 23 cases have been reported and include patients with a lupus-like syndrome or with various paraproteinemias. The hypoglycemia occurs 3–4 hours after meals following an initial postprandial hyperglycemic phase that is

due to the antibodies interfering with the exit of insulin from the plasma to reach its target tissues. Later, after most of the meal is absorbed, inappropriate high levels of insulin dissociate from this antibody-bound compartment, resulting in hypoglycemia. Insulin levels in excess of 1000 pmol/L are observed at time of hypoglycemia, and these persons have high titers of insulin autoantibodies.

DRUG-INDUCED HYPOGLYCEMIA

A number of drugs apart from the sulfonylureas can occasionally cause hypoglycemia, especially when ingested in large amounts. These include quinine, quinidine, disopyramide, and salicylates. ACE inhibitors, when taken with antidiabetic drugs, can cause hypoglycemia possibly by improving insulin sensitivity. Recently, it has been reported that the use of gatifloxacin (an antibiotic that is no longer available in the United States) in diabetic patients is associated with serious hypoglycemic and hyperglycemic reactions.

Ten to 20 percent of patients receiving pentamidine for *Pneumocystis jiroveci* pneumonia develop symptomatic hypoglycemia, particularly when the drug is administered intravenously. This apparently is due to lytic destruction of pancreatic B cells, causing acute hyperinsulinemia and hypoglycemia. It is later followed by insulinopenia and hyperglycemia, which occasionally is persistent. Since other drugs have been found to be as effective in treating *Pneumocystis* pneumonia, pentamidine administration and its hypoglycemic sequelae are less frequently encountered.

Lipid Disorders

Robert B. Baron, MD, MS

28

For patients with known cardiovascular disease (secondary prevention), cholesterol lowering leads to a consistent reduction in total mortality and recurrent cardiovascular events in men and women and in middle-aged and older patients. Among patients without cardiovascular disease (primary prevention), the data are less conclusive, with rates of cardiovascular events, heart disease mortality, and all-cause mortality differing among studies. Nonetheless, treatment algorithms have been designed to assist clinicians in selecting patients for cholesterol-lowering therapy based on their lipid levels and their overall risk of developing cardiovascular disease.

LIPOPROTEINS & ATHEROGENESIS

The plaques in the arterial walls of patients with atherosclerosis contain large amounts of cholesterol. The higher the level of low-density lipoproteins (LDL) cholesterol, the greater the risk of atherosclerotic heart disease; conversely, the higher the high-density lipoproteins (HDL) cholesterol, the lower the risk of coronary heart disease (CHD). This is true in men and women, in different racial and ethnic groups, and at all ages up to age 75 years. Because most cholesterol in serum is LDL, high total cholesterol levels are also associated with an increased risk of CHD. Middle-aged men whose serum cholesterol levels are in the highest quintile for age (above about 230 mg/dL) have a risk of coronary death before age 65 years of about 10%; men in the lowest quintile (below about 170 mg/dL) have a 3% risk. Death from CHD before age 65 years is less common in women, with equivalent risks one-third those of men. In men, each 10-mg/dL increase in cholesterol (or LDL cholesterol) increases the risk of CHD by about 10%; each 5-mg/dL increase in HDL reduces the risk by about 10%. The effect of HDL cholesterol is greater in women, whereas the effects of total and LDL cholesterol are smaller.

There are several genetic disorders that provide insight into the pathogenesis of lipid-related diseases. **Familial hypercholesterolemia**, rare in the homozygous state (about one per million) is a condition in which the cell-surface receptors for the LDL molecule are absent or defective, resulting in unregulated synthesis of LDL. Patients with two abnormal genes (homozygotes) have extremely

high levels—up to eight times normal—and present with atherosclerotic disease in childhood. Homozygotes may require liver transplantation to correct their severe lipid abnormalities. Those with one defective gene (heterozygotes) have LDL concentrations twice normal; persons with this condition may develop CHD in their 30s or 40s.

Another rare condition is caused by an abnormality of lipoprotein lipase, the enzyme that enables peripheral tissues to take up triglyceride from chylomicrons and very-low-density lipoproteins (VLDL) particles. Patients with this condition, one cause of **familial hyperchylomicronemia**, have marked hypertriglyceridemia with recurrent pancreatitis and hepatosplenomegaly in childhood.

Numerous other genetic abnormalities of lipid metabolism are named for the abnormality noted when serum is electrophoresed (eg, dysbetalipoproteinemia) or from combinations of lipid abnormalities in families (eg, familial combined hyperlipidemia). Thus, family members of patients with severe lipid disorders are appropriately studied. Other patients have abnormalities in the production of apoproteins, such as increased apoprotein B and its affiliated lipoproteins, LDL and VLDL; reduced apoprotein AII and its affiliated particle; or excess lipoprotein(a). Other mutations occur in lipoprotein lipase and in the gene encoding for cholesterol efflux regulatory protein.

▶ When to Refer

- Known genetic lipid disorders.
- Striking family history of hyperlipidemia or premature atherosclerosis.
- Extremely high serum LDL cholesterol or triglyceride, or extremely low serum HDL cholesterol.

LIPID FRACTIONS & THE RISK OF CORONARY HEART DISEASE

In fasting serum, cholesterol is carried primarily on three different lipoproteins—the VLDL, LDL, and HDL molecules. Total cholesterol equals the sum of these three components:

$$\text{Total cholesterol} = \text{HDL cholesterol} + \text{VLDL cholesterol} + \text{LDL cholesterol}$$

Most clinical laboratories measure the total cholesterol, the total triglycerides, and the amount of cholesterol found in the HDL fraction, which is easily precipitated from serum. Most triglyceride is found in VLDL particles, which contain five times as much triglyceride by weight as cholesterol. The amount of cholesterol found in the VLDL fraction can be estimated by dividing the triglyceride by 5:

$$\text{VLDL cholesterol} = \frac{\text{Triglycerides}}{5}$$

Because the triglyceride level is used as a proxy for the amount of VLDL, this formula works only in fasting samples and when the triglyceride level is less than 400 mg/dL. At higher triglyceride levels, LDL and VLDL cholesterol levels can be determined after ultracentrifugation or by direct chemical measurement.

The total cholesterol is reasonably stable over time; however, measurements of HDL and especially triglycerides may vary considerably because of analytic error in the laboratory and biologic variation in a patient's lipid level. Thus, the LDL should always be estimated as the mean of at least two determinations; if those two estimates differ by more than 10%, a third lipid profile is obtained. The LDL is estimated as follows:

$$\text{LDL cholesterol} = \text{Total cholesterol} - \text{HDL cholesterol} - \frac{\text{Triglycerides (mg/dL)}}{5}$$

When using SI units, the formula becomes

$$\text{LDL cholesterol} = \text{Total cholesterol} - \text{HDL cholesterol} - \frac{\text{Triglycerides (mmol/L)}}{2.2}$$

Understanding the relationships of the different lipid fractions leads to a more accurate understanding of a patient's lipid-related coronary risk than the total ches-

terol. Two persons with the same total cholesterol of 275 mg/dL may have very different lipid profiles. One may have an HDL cholesterol of 110 mg/dL with a triglyceride of 150 mg/dL, giving an estimated LDL cholesterol of 135 mg/dL; the other may have an HDL cholesterol of 25 mg/dL with a triglyceride of 200 mg/dL and an LDL cholesterol of 210 mg/dL. The second would have more than a tenfold higher CHD risk than the first, assuming no differences in other factors. Because of high HDL cholesterol levels in women, many with apparently high total cholesterol levels have favorable lipid profiles. Thus, evaluation of the lipid fractions is essential before therapy is initiated.

Some authorities use the ratio of the total to HDL cholesterol as an indicator of lipid-related coronary risk: the lower this ratio is, the better. (In the example above, the first person would have a ratio of $275 \div 110 = 2.5$, while the second would have a much less favorable ratio of $275 \div 25 = 11$.) Although ratios are useful predictors within populations of patients, they may obscure important information in individual patients. (A total cholesterol of 300 mg/dL and an HDL of 60 mg/dL result in the same ratio of 5 as a total cholesterol of 150 mg/dL with an HDL of 30 mg/dL.) Moreover, the total cholesterol-to-HDL cholesterol ratio will magnify the importance of variations in HDL measurement.

There is no true “normal” range for serum lipids. In Western populations, cholesterol values are about 20% higher than in Asian populations and exceed 300 mg/dL in nearly 5% of adults. About 10% of adults have LDL cholesterol levels above 200 mg/dL. Total and LDL cholesterol levels tend to rise with age in persons who are otherwise in good health.

Declines are seen in acute illness, and lipid studies in such patients are of little value with the exception of the serum triglyceride level in a patient with pancreatitis. Cholesterol levels (even when expressed as an age-matched percentile rank, such as the highest 20%) do not remain constant over time, especially from childhood through adolescence and young adulthood. Thus, children and young adults with relatively high cholesterol may have lower levels later in life, whereas those with low cholesterol may show increases.

THERAPEUTIC EFFECTS OF LOWERING CHOLESTEROL

Reducing cholesterol levels in healthy middle-aged men without CHD (primary prevention) reduces their risk in proportion to the reduction in LDL cholesterol and the increase in HDL cholesterol. Treated patients have statistically significant and clinically important reductions in the rates of myocardial infarctions, new cases of angina, and need for coronary artery bypass procedures. The West of Scotland Study showed a 31% decrease in myocardial infarctions in middle-aged men treated with pravastatin compared with placebo. The Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS) study showed similar results with lovastatin. As with any primary prevention interventions, large numbers of healthy patients need to be treated to prevent a single event. The numbers of patients needed to treat (NNT) to prevent a nonfatal myo-

cardial infarction or a coronary artery disease death in these two studies were 46 and 50, respectively. The Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT) study of atorvastatin in subjects with hypertension and other risk factors but without CHD also demonstrated a convincing 36% reduction in CHD events. The Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER) showed a 44% reduction in a combined end point of myocardial infarction, stroke, revascularization, hospitalization for unstable angina, or death from cardiovascular causes. The NNT for 1 year to prevent one event was 169.

Primary prevention studies have found a less consistent effect on total mortality. The West of Scotland study found a 20% decrease in total mortality, tending toward statistical significance. The AFCAPS/TexCAPS study with lovastatin showed no difference in total mortality. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT-LLT) also showed no reduction either in all-cause mortality or in CHD events when pravastatin was compared with usual care. Subjects treated with atorvastatin in the ASCOT study had a 13% reduction in mortality, but the result was not statistically significant. This study, however, was stopped early due to the marked reduction in CHD events. The JUPITER trial demonstrated a statistically significant 20% reduction in death from any cause. The NNT for 1 year was 400.

In patients with CHD, the benefits of cholesterol lowering are clearer. Major studies with statins have shown significant reductions in cardiovascular events, cardiovascular deaths, and all-cause mortality in men and women with coronary artery disease. The NNT to prevent a nonfatal myocardial infarction or a coronary artery disease death in these three studies were between 12 and 34. Aggressive cholesterol lowering with these agents causes regression of atherosclerotic plaques in some patients, reduces the progression of atherosclerosis in saphenous vein grafts, and can slow or reverse carotid artery atherosclerosis. Meta-analysis suggests that this latter effect results in a significant decrease in strokes. Results with other classes of medications have been less consistent. For example, gemfibrozil treatment subjects had fewer cardiovascular events, but there was no benefit in all-cause mortality when compared with placebo.

The disparities in results between primary and secondary prevention studies highlight several important points. The benefits and adverse effects of cholesterol lowering may be specific to each type of drug; the clinician cannot assume that the effects will generalize to other classes of medication. Second, the net benefits from cholesterol lowering depend on the underlying risk of CHD and of other disease. In patients with atherosclerosis, morbidity and mortality rates associated with CHD are high, and measures that reduce it are more likely to be beneficial even if they have no effect—or even slightly harmful effects—on other diseases.

SECONDARY CONDITIONS THAT AFFECT LIPID METABOLISM

Several factors, including drugs, can influence serum lipids (Table 28–1). These are important for two reasons: Abnormal lipid levels (or changes in lipid levels) may be the presenting sign of some of these conditions, and correction of the underlying condition may obviate the need to treat an apparent lipid disorder. Diabetes and alcohol use, in particular, are commonly associated with high triglyceride levels that decline with improvements in glycemic control or reduction in alcohol use, respectively. Thus, secondary causes of high blood lipids should be considered in each patient with a lipid disorder before lipid-lowering therapy is started. In most instances, special testing is not needed: a history and physical examination are sufficient. However, screening for hypothyroidism in patients with hyperlipidemia is cost effective.

CLINICAL PRESENTATIONS

Most patients with high cholesterol levels have no specific symptoms or signs. The vast majority of patients with lipid abnormalities are detected by the laboratory, either as part of the workup of a patient with cardiovascular disease or as part of a preventive screening strategy. Extremely high levels of chylomicrons or VLDL particles (triglyceride level above 1000 mg/dL) result in the formation of **eruptive xanthomas** (Plate 93) (red-yellow papules, especially on the buttocks). High LDL concentrations result in **tendinous xanthomas** on certain tendons (Achilles, patella, back of the hand). Such xanthomas usually indicate one of the underlying genetic hyperlipidemias. **Lipemia retinalis**

Table 28-1. Secondary causes of lipid abnormalities.

| Cause | Associated Lipid Abnormality |
|---|--|
| Obesity | Increased triglycerides, decreased HDL cholesterol |
| Sedentary lifestyle | Decreased HDL cholesterol |
| Diabetes mellitus | Increased triglycerides, increased total cholesterol |
| Alcohol use | Increased triglycerides, increased HDL cholesterol |
| Hypothyroidism | Increased total cholesterol |
| Hyperthyroidism | Decreased total cholesterol |
| Nephrotic syndrome | Increased total cholesterol |
| Chronic kidney disease | Increased total cholesterol, increased triglycerides |
| Liver disease (cirrhosis) | Decreased total cholesterol |
| Obstructive liver disease | Increased total cholesterol |
| Malignancy | Decreased total cholesterol |
| Cushing disease (or corticosteroid use) | Increased total cholesterol |
| Oral contraceptives | Increased triglycerides, increased total cholesterol |
| Diuretics ¹ | Increased total cholesterol, increased triglycerides |
| β -Blockers ^{1,2} | Increased total cholesterol, decreased HDL |

¹Short-term effects only.

² β -Blockers with intrinsic sympathomimetic activity, such as pindolol and acebutolol, do not affect lipid levels.

(cream-colored blood vessels in the fundus) is seen with extremely high triglyceride levels (above 2000 mg/dL).

SCREENING FOR HIGH BLOOD CHOLESTEROL

All patients with CHD or CHD risk equivalents (other clinical forms of atherosclerosis such as peripheral artery disease, abdominal aortic aneurysm, and symptomatic carotid artery disease; patients with diabetes mellitus; and patients with multiple risk factors that confer a greater than 20% 10-year risk for developing CHD) should be screened for elevated lipids. The only exceptions are patients in whom lipid lowering is not indicated or desirable for other reasons. Patients who already have evidence of atherosclerosis are the group at highest risk of suffering additional manifestations in the near term and thus have the most to gain from reduction of blood lipids. Additional risk reduction measures for atherosclerosis are discussed in Chapter 10; lipid lowering should be just one aspect of a program to reduce the progression and effects of the disease.

In patients with cardiovascular disease, a complete lipid profile (total cholesterol, HDL cholesterol, and triglyceride levels) after an overnight fast should be obtained as a screening test. Those whose estimated LDL cholesterol level is high should have at least one repeat measurement.

Specific treatments for high LDL cholesterol levels are discussed below. The goal of therapy should be to reduce the LDL cholesterol to below 100 mg/dL or optimally to below 70 mg/dL. Evidence suggests that treatment with a statin is effective even if the starting LDL cholesterol is below 100 mg/dL. These data suggest that most patients with CHD or CHD risk equivalents should be treated with statin therapy.

The best screening and treatment strategy for adults who do not have atherosclerotic cardiovascular disease is less clear. Several algorithms have been developed to guide the clinician in treatment decisions, but management decisions are individualized based on the patient's risk.

Although the National Cholesterol Education Program (NCEP) recommends screening of all adults aged 20 years or older for high blood cholesterol, the United States Preventive Services Task Force (USPSTF) suggests beginning at age 35 years in men and age 45 years in women unless there are other risk factors for CHD. For men and women with an increased risk for CHD, however, screening should begin at age 20. Although there is no established interval for screening, screening can be repeated every 5 years for those with average or low risk and more often for those whose levels are close to therapeutic thresholds. This strategy focuses cholesterol screening on those at the greatest risk of coronary artery disease and increases the cost effectiveness of cholesterol screening.

Individuals without cardiovascular disease can then be stratified according to risk factors as defined by the NCEP. Those with two or more risk factors are considered to be at intermediate risk of coronary artery disease, and those with less than two are at low risk. These include age and gender (men aged 45 years or older, women aged 55 years or older), a family history of premature CHD (myocardial infarction or sudden cardiac death before age 55 years in a first-degree male relative or before age 65 years in a first-degree female relative), hypertension (whether treated or not), current cigarette smoking (10 or more cigarettes per day), and low HDL cholesterol (< 40 mg/dL). Because HDL cholesterol is protective against CHD, a risk factor is subtracted if the level is greater than 60 mg/dL. Patients with two or more risk factors are then further stratified by evaluating their 10-year risk of developing CHD using Framingham projections of 10-year risk (Table 28-2). Because risk factors alone are an imprecise measure of CHD risk, estimating the 10-year risk using Framingham data is helpful even in patients with one or no risk factors. Other measures may also be useful to further refine risk in selected patients. For example, high-sensitivity C-reactive protein (hs-CRP) may be useful in intermediate-risk patients if the decision to initiate medications might change based on the hs-CRP level.

Several strategies for obtaining the initial cholesterol measurement have been proposed, including: (1) measuring total cholesterol alone, (2) measuring total cholesterol and HDL cholesterol, or (3) measuring LDL and HDL cholesterol. Each is acceptable, but treatment decisions are based on the LDL and HDL cholesterol levels. Measurement of the total cholesterol alone is the least expensive strategy and is adequate for low-risk individuals; those with total cholesterol greater than 200 mg/dL should then be reevaluated

Reproduced from Executive Summary of the Third Report of The National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol In Adults (Adult Treatment Panel III). JAMA. 2001 May 16;285(19):2486–97. <http://www.nhlbi.nih.gov/guidelines/cholesterol/index.htm>.

with a fasting LDL and HDL cholesterol measurement. Measurement of the total cholesterol and HDL cholesterol allows for better characterization of the risk factor profile but also requires reevaluation if the total cholesterol is greater than 200 mg/dL as recommended by the USPSTF. Initial measurement of the LDL and HDL cholesterol is least likely to lead to patient misinformation and misclassification and is the strategy recommended by the NCEP.

Treatment decisions are based on the LDL cholesterol, and the patient's risk factor profile (including the HDL cholesterol level) and estimated 10-year risk. Patients in the intermediate-risk group (two or more risk factors) are selected for diet therapy (therapeutic lifestyle changes) if LDL cholesterol is greater than 130 mg/dL. If the 10-year risk of CHD is < 10%, drug treatment is recommended if LDL is > 160 mg/dL; if the 10-year CHD risk is between 10% and 20%, drug treatment is recommended if LDL is > 130 mg/dL. Low-risk individuals with one or no risk factors and estimated 10-year CHD risk less than 10% are selected for diet therapy if LDL cholesterol is greater than 160 mg/dL and for drug therapy if it is greater than 190 mg/dL (Table 28–3).

► Screening in Women

The foregoing screening and treatment guidelines, based largely on LDL cholesterol levels, are designed for both men

and women. Yet several observational studies suggest that a low HDL cholesterol is a more important risk factor for CHD in women than a high LDL cholesterol. Meta-analysis of studies including women with known heart disease, however, has found that medications that primarily lower LDL cholesterol do prevent recurrent myocardial infarctions in women. There is insufficient evidence to be certain of a similar effect from LDL-lowering therapy in women without evidence of CHD. Although most experts recommend application of the same primary prevention guidelines for women as for men, clinicians should be aware of the uncertainty in this area. Using estimates of 10-year CHD risk may be particularly helpful in women since a larger percentage of women than men will have estimated 10-year CHD risks below 10% per year and thus women are less likely to benefit from therapy unless their LDL cholesterol is extremely high (greater than 190 mg/dL).

► Screening in Older Patients

Meta-analysis of evidence relating cholesterol to CHD in the elderly suggests that cholesterol is not a risk factor for CHD for persons over age 75 years. Clinical trials have rarely included such individuals. One exception is the Prospective Study of Pravastatin in the Elderly at Risk (PROSPER). In this study, elderly patients with cardiovascular disease (sec-

Table 28-3. LDL goals and treatment cutpoints: Recommendations of the NCEP Adult Treatment Panel III.

| Risk Category | LDL Goal (mg/dL) | LDL Level at Which to Initiate Lifestyle Changes (mg/dL) | LDL Level at Which to Consider Drug Therapy ¹ (mg/dL) |
|--|--|--|--|
| <i>High risk:</i> CHD ² or CHD risk equivalents ³ (10-year risk > 20%) | < 100 (optional goal: < 70 mg/dL) ⁴ | ≥ 100 ⁵ | ≥ 100 ⁶ (< 100: consider drug options) ¹ |
| <i>Moderately high risk:</i> 2+ risk factors ⁷ (10-year risk 10% to 20%) ⁸ | < 130 ⁹ | ≥ 130 ⁵ | ≥ 130 (100–129; consider drug options) ¹⁰ |
| <i>Moderate risk:</i> 2+ risk factors ⁷ (10-year risk < 10%) ⁸ | < 130 | ≥ 130 | ≥ 160 |
| <i>Low risk:</i> 0–1 risk factors ¹¹ | < 160 | ≥ 160 | ≥ 190 (160–189: LDL-lowering drug optional) |

¹When LDL-lowering drug therapy is used, it is advised that intensity of therapy be sufficient to achieve at least a 30–40% reduction in LDL cholesterol levels.

²CHD includes history of myocardial infarction, unstable angina, coronary artery procedures (angioplasty or bypass surgery), or evidence of clinically significant myocardial ischemia.

³CHD risk equivalents include clinical manifestations of noncoronary forms of atherosclerotic disease (peripheral arterial disease, abdominal aortic aneurysm, and carotid artery disease [transient ischemic attacks or stroke of carotid origin with > 50% obstruction of a carotid artery]), diabetes mellitus, and ≥ 2 risk factors with 10-year risk for CHD > 20%.

⁴Very high risk favors the optional LDL cholesterol goal of < 70 mg/dL, or in patients with high triglycerides, non-high density lipoprotein (HDL) cholesterol < 100 mg/dL.

⁵Any person at high risk or moderately high risk who has lifestyle-related risk factors (eg, obesity, physical inactivity, elevated triglyceride, low HDL cholesterol, or metabolic syndrome) is a candidate for therapeutic lifestyle changes to modify these risk factors regardless of LDL cholesterol.

⁶If baseline LDL cholesterol is < 100 mg/dL, institution of an LDL-lowering drug is a therapeutic option on the basis of available clinical trial results. If a high-risk person has high triglycerides or low HDL cholesterol, combining a fibrate or nicotinic acid with an LDL-lowering drug can be considered.

⁷Risk factors include cigarette smoking, hypertension (blood pressure ≥ 140/90 mm Hg or on antihypertensive medication), low HDL cholesterol (< 40 mg/dL), family history of premature CHD (CHD in male first-degree relative < 55 years of age; CHD in female first-degree relative < 65 years of age), and age (men ≥ 45 years; women ≥ 55 years).

⁸Electronic 10-year risk calculators are available at www.nhlbi.nih.gov/guidelines/cholesterol.

⁹Optional LDL cholesterol goal < 100 mg/dL.

¹⁰For moderately high-risk persons, when the LDL cholesterol level is 100–129 mg/dL at baseline or on lifestyle therapy, initiation of an LDL-lowering drug to achieve an LDL cholesterol level < 100 mg/dL is a therapeutic option on the basis of available clinical trial results.

¹¹Almost all people with zero or one risk factor have a 10-year CHD risk < 10%, and 10-year risk assessment in these people is thus not necessary.

ondary prevention) benefited from statin therapy, whereas those without cardiovascular disease (primary prevention) did not. Although the NCEP recommends continuing treatment in the elderly, many clinicians will prefer to stop screening and treatment in patients age 75 years or older who do not have CHD. In patients age 75 years or older who have CHD, LDL-lowering therapy can be continued as recommended for younger patients with the disease. Decisions to discontinue therapy should be based on overall functional status and life expectancy, comorbidities, and patient preference and should be made in context with overall therapeutic goals and end-of-life decisions.

TREATMENT OF HIGH LOW-DENSITY LIPOPROTEIN CHOLESTEROL

Reduction of LDL cholesterol is just one part of a program to reduce the risk of cardiovascular disease. Other measures—including smoking cessation, hypertension control, and aspirin—are also of central importance. Less well studied but of potential value is raising the HDL cholesterol level. Quitting smoking reduces the effect of other cardiovascular risk factors (such as a high cholesterol level); it may also increase the HDL cholesterol level. Exercise (and weight loss) may reduce the LDL cholesterol and increase the HDL. Modest alcohol use (1–2 ounces a day) also raises HDL levels and appears to have a salutary effect on CHD rates.

Several new classes of medications are being actively tested to raise HDL cholesterol levels. One such class of these medications, the cholesteryl ester transfer protein inhibitors, raises HDL cholesterol levels. However, studies to date of one agent in this class, torcetrapib, have shown adverse effects on cardiovascular outcomes. The effects of reconstituted HDL infusions have also been studied but have shown only modest effects on indirect measures of atherosclerosis.

► Diet Therapy

Studies of nonhospitalized adults have reported only modest cholesterol-lowering benefits of dietary therapy, typically in the range of a 5–10% decrease in LDL cholesterol, with even less in the long term. The effect of diet therapy, however, varies considerably among individuals, as some patients will have striking reductions in LDL cholesterol—up to a 25–30% decrease—whereas others will have clinically important increases. Thus, the results of diet therapy should be assessed about 4 weeks after initiation.

Cholesterol-lowering diets may also have a variable effect on lipid fractions. Diets very low in total fat or in saturated fat may lower HDL cholesterol as much as LDL cholesterol. It is not known how these diet-induced changes affect coronary risk.

Several nutritional approaches to diet therapy are available. Most Americans currently eat over 35% of calories as fat, of which 15% is saturated fat. Dietary cholesterol intake averages 400 mg/d. A cholesterol-lowering diet recommends reducing total fat to 25–30% and saturated fat to less than 7% of calories. Dietary cholesterol should be limited to less than 200 mg/d. These diets replace fat, particularly saturated fat, with carbohydrate. In most instances, this approach will also result in fewer total calories consumed and will facilitate weight loss in overweight patients. Other diet plans, including the Dean Ornish Diet, the Pritikin Diet, and most vegetarian diets, restrict fat even further. Low-fat, high-carbohydrate diets may, however, result in reductions in HDL cholesterol.

An alternative strategy is the “Mediterranean diet,” which maintains total fat at approximately 35–40% of total calories but replaces saturated fat with monounsaturated fat such as that found in canola oil and in olives, peanuts, avocados, and their oils. This diet is equally effective at lowering LDL cholesterol but is less likely to lead to reductions in HDL cholesterol. Recent studies have demon-

strated that this approach may also be associated with reductions in endothelial dysfunction, insulin resistance, and markers of vascular inflammation and may result in better resolution of the metabolic syndrome than traditional cholesterol-lowering diets.

Other dietary changes may also result in beneficial changes in blood lipids. Soluble fiber, such as that found in oat bran or psyllium, may reduce LDL cholesterol by 5–10%. Garlic, soy protein, vitamin C, pecans, and plant sterols may also result in reduction of LDL cholesterol. Because oxidation of LDL cholesterol is a potential initiating event in atherogenesis, diets rich in antioxidants, found primarily in fruits and vegetables, may be helpful (see Chapter 29). Studies have suggested that when all of these elements are combined into a single dietary prescription, the impact of diet on LDL cholesterol may approach that of statin medications, lowering LDL cholesterol by close to 30%.

► Pharmacologic Therapy

All patients whose risk from CHD is considered high enough to warrant pharmacologic therapy of an elevated LDL cholesterol should be given aspirin prophylaxis at a dose of 81 mg/d unless there are contraindications such as aspirin sensitivity, bleeding diatheses, or active peptic ulcer disease. The benefit of aspirin in reducing the risk of CHD is equivalent to that of cholesterol lowering. Other CHD risk factors, such as hypertension and smoking, should also be controlled.

If the decision to treat a patient with an LDL-lowering drug is made, a goal for treatment is set. The National Cholesterol Education Program’s Adult Treatment Panel III (NCEP ATP III) published revised, more intensive LDL treatment goals in 2004, and these guidelines remain the mainstay of clinical practice. For patients with CHD or CHD risk equivalents, the goal is LDL < 100 mg/dL, but for patients with very high risk, a goal of LDL < 70 mg/dL is a

therapeutic option (see Table 28–3). This goal may also be appropriate for patients with very high risk who have a baseline LDL < 100 mg/dL. For patients with two or more risk factors and a 10-year CHD risk of 10–20%, the recommended goal is LDL < 130 mg/dL, but a goal of < 100 mg/dL is optional. For those with two or more risk factors and a 10-year CHD risk of < 10%, the goal is < 130 mg/dL. For those with zero or one risk factor, the goal is LDL < 160 mg/dL (see Table 28–3). In most instances, intensity of therapy should be sufficient to achieve a 30–40% reduction in LDL cholesterol. Combinations of drugs may be necessary. Once the goal is reached, the lipid profile should be monitored periodically (every 6–12 months), with consideration given to periodic reductions in drug dose. Most lipid-lowering agents are expensive and may need to be given for decades. Thus, their cost effectiveness is low for some groups of patients, especially in primary prevention.

A. Niacin (Nicotinic Acid)

Niacin was the first lipid-lowering agent that was associated with a reduction in total mortality. Long-term follow-up of a secondary prevention trial of middle-aged men with previous myocardial infarction disclosed that about half of those who had been previously treated with niacin had died, compared with nearly 60% of the placebo group. This favorable effect on mortality was not seen during the trial itself, though there was a reduction in the incidence of recurrent coronary events.

Niacin reduces the production of VLDL particles, with secondary reduction in LDL and increases in HDL cholesterol levels. The average effect of full-dose niacin therapy, 3–4.5 g/d, is a 15–25% reduction in LDL cholesterol and a 25–35% increase in HDL cholesterol. Full doses are required to obtain the LDL effect, but the HDL effect is observed at lower doses, eg, 1 g/d. Niacin will also reduce triglycerides by half and will lower lipoprotein(a) [Lp(a)] levels and will increase plasma homocysteine levels. Thus, its effect on blood lipids and CHD risk is nearly optimal. Intolerance to niacin is common; only 50–60% of patients can take full doses. Niacin causes a prostaglandin-mediated flushing that patients may describe as “hot flashes” or pruritus and that can be decreased with aspirin (81–325 mg/d) or other nonsteroidal anti-inflammatory agents taken during the same day. Flushing may also be decreased by initiating niacin therapy with a very small dose, eg, 100 mg with the evening meal. The dose can be doubled each week until 1.5 g/d is tolerated. After rechecking blood lipids, the dose is increased and divided over three meals until the goal of 3–4.5 g/d is reached (eg, 1 g with each meal). Extended-release niacin is also available and is better tolerated by most patients. It is not known whether routine monitoring of liver enzymes results in early detection and thus reduced severity of this side effect. Niacin can also exacerbate gout and peptic ulcer disease. Although niacin may increase blood sugar in some patients, clinical trials have shown that niacin can be safely used in diabetics.

B. Bile Acid–Binding Resins

The bile acid–binding resins include cholestyramine, colestevlam, and colestipol. Treatment with these agents

reduces the incidence of coronary events in middle-aged men by about 20%, with no significant effect on total mortality. The resins work by binding bile acids in the intestine. The resultant reduction in the enterohepatic circulation causes the liver to increase its production of bile acids, using hepatic cholesterol to do so. Thus, hepatic LDL receptor activity increases, with a decline in plasma LDL levels. The triglyceride level tends to increase slightly in some patients treated with bile acid–binding resins; they should be used with caution in those with elevated triglycerides and probably not at all in patients who have triglyceride levels above 500 mg/dL. The clinician can anticipate a reduction of 15–25% in the LDL cholesterol level, with insignificant effects on the HDL level.

The usual dose of cholestyramine is 12–36 g of resin per day in divided doses with meals, mixed in water or, more palatably, juice. Doses of colestipol are 20% higher (each packet contains 5 g of resin). The dose of colestevlam is 625 mg, 6–7 tablets per day.

These agents often cause gastrointestinal symptoms, such as constipation and gas. They may interfere with the absorption of fat-soluble vitamins (thereby complicating the management of patients receiving warfarin) and may bind other drugs in the intestine. Concurrent use of psyllium may ameliorate the gastrointestinal side effects.

C. Hydroxymethylglutaryl-Coenzyme A (HMG-CoA) Reductase Inhibitors (Statins)

The HMG-CoA reductase inhibitors include atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, and simvastatin. These agents work by inhibiting the rate-limiting enzyme in the formation of cholesterol. They reduce myocardial infarctions and total mortality in secondary prevention, as well as in older middle-aged men free of CHD. A meta-analysis has demonstrated significant reduction in risk of stroke. Cholesterol synthesis in the liver is reduced, with a compensatory increase in hepatic LDL receptors (presumably so that the liver can take more of the cholesterol that it needs from the blood) and a reduction in the circulating LDL cholesterol level by up to 35%. There are also modest increases in HDL levels and decreases in triglyceride levels.

Oral doses are as follows: atorvastatin, 10–80 mg/d; fluvastatin, 20–40 mg/d; lovastatin, 10–80 mg/d; pravastatin, 10–40 mg/d; rosuvastatin, 5–40 mg/d; and simvastatin, 5–40 mg/d. These agents are usually given once a day in the evening (most cholesterol synthesis takes place overnight); at the high end of the dose ranges, twice-a-day dosing may be used. Side effects include myositis, whose incidence may be higher in patients concurrently taking fibrates or niacin. Manufacturers recommend monitoring liver and muscle enzymes. Several agents (notably erythromycin, cyclosporine, and azole antifungals) reduce the metabolism of these agents.

D. Fibric Acid Derivatives

The fibric acid derivatives or fibrates approved for use in the United States are gemfibrozil and fenofibrate. Ciprofibrate and bezafibrate are also available for use internationally. Gemfibrozil reduced CHD rates in hypercholesterolemic middle-aged men free of coronary disease in the Helsinki

Heart Study. The effect was observed only among those who also had lower HDL cholesterol levels and high triglyceride levels. In a VA study, gemfibrozil was also shown to reduce cardiovascular events in men with existing CHD whose primary lipid abnormality was a low HDL cholesterol. There was no effect on all-cause mortality.

The fibrates are peroxisome proliferative-activated receptor-alpha (PPAR-alpha) agonists that result in potent reductions of plasma triglycerides and increases in HDL cholesterol. They reduce LDL levels by about 10–15%, although the result is quite variable, and triglyceride levels by about 40% and raise HDL levels by about 15–20%. The usual dose of gemfibrozil is 600 mg once or twice a day. Side effects include cholelithiasis, hepatitis, and myositis. The incidence of the latter two conditions may be higher among patients also taking other lipid-lowering agents. In the largest clinical trial that used clofibrate, there were significantly more deaths—especially due to cancer—in the treatment group; it should not be used.

E. Ezetimibe

Ezetimibe is a lipid-lowering drug that inhibits the intestinal absorption of dietary and biliary cholesterol by blocking passage across the intestinal wall by inhibiting a cholesterol transporter. The usual dose of ezetimibe is 10 mg/d orally. Ezetimibe reduces LDL cholesterol between 15% and 20% when used as monotherapy and can further reduce LDL in patients taking statins who are not yet at therapeutic goal.

However, the effects of ezetimibe on CHD and its long-term safety are not yet known. Results from one small clinical trial, ENHANCE (a study of 720 persons with heterozygous familial hypercholesterolemia), showed no significant difference of intimal media thickness with ezetimibe plus an HMG-CoA reductase inhibitor compared with an HMG-CoA reductase inhibitor alone. Concern has also been raised about a greater risk of cancer with ezetimibe. A meta-analysis of three trials of ezetimibe showed no increase in cancer incidence but did find a nonsignificant increase in deaths from cancer.

► Initial Selection of Medication

At present there are no absolute guidelines for selection of available lipid-modifying medications in particular patients. Nonetheless, clinical trials provide guidance (Table 28–4). For most patients who require a lipid-modifying medication, an HMG-CoA reductase inhibitor is preferred. Although niacin will also have beneficial effects on lipids in both men and women with CHD, there is less evidence demonstrating the desired effects on CHD and all-cause mortality. Resins are the only lipid-modifying medication considered safe in pregnancy.

Combination therapy may be used to meet lipid targets in some patients or to achieve other therapeutic goals. For example, ezetimibe plus an HMG-CoA reductase inhibitor will typically lower the LDL cholesterol more than either medication alone. Similarly, low-dose niacin (0.5–1 g/d),

Table 28–4. Effects of selected lipid-modifying drugs.

| Drug | Lipid-Modifying Effects | | Triglyceride | Initial Daily Dose | Maximum Daily Dose | Cost for 30 Days Treatment with Dose Listed ¹ |
|-----------------------------------|-------------------------|------------|--------------|--------------------------|--------------------------|--|
| | LDL | HDL | | | | |
| Atorvastatin (Lipitor) | -25 to -40% | +5 to 10% | ↓↓ | 10 mg once | 80 mg once | \$130.87 (20 mg once) |
| Cholestyramine (Questran, others) | -15 to -25% | +5% | ± | 4 g twice a day | 24 g divided | \$126.65 (8 g divided) |
| Colesevelam (WelChol) | -10 to -20% | +10% | ± | 625 mg, 6–7 tablets once | 625 mg, 6–7 tablets once | \$222.48 (6 tablets once) |
| Colestipol (Colestid) | -15 to -25% | +5% | ± | 5 g twice a day | 30 g divided | \$120.00 (10 g divided) |
| Ezetimibe (Zetia) | -20% | +5% | ± | 10 mg once | 10 mg once | \$108.66 (10 mg once) |
| Fenofibrate (Tricor, others) | -10 to -15% | +15 to 25% | ↓↓ | 48 mg once | 145 mg once | \$130.06 (145 mg once) |
| Fenofibric Acid (Trilipix) | -10 to -15% | +15 to 25% | ↓↓ | 45 mg once | 135 mg once | \$124.00 (135 mg once) |
| Fluvastatin (Lescol) | -20 to -30% | +5 to 10% | ↓ | 20 mg once | 40 mg once | \$90.40 (20 mg once) |
| Gemfibrozil (Lopid) | -10 to -15% | +15 to 20% | ↓↓ | 600 mg once | 1200 mg divided | \$74.80 (600 mg twice a day) |
| Lovastatin (Mevacor) | -25 to -40% | +5 to 10% | ↓ | 10 mg once | 80 mg divided | \$71.19 (20 mg once) |
| Niacin (OTC, Niaspan) | -15 to -25% | +25 to 35% | ↓↓ | 100 mg once | 3–4.5 g divided | \$15.28 (1.5 g twice a day, OTC) \$254.00 (2 g Niaspan) |
| Pravastatin (Pravachol) | -25 to -40% | +5 to 10% | ↓ | 20 mg once | 40 mg once | \$98.01 (20 mg once) |
| Rosuvastatin (Crestor) | -40 to -50% | +10 to 15% | ↓↓ | 10 mg once | 40 mg once | \$114.37 (20 mg once) |
| Simvastatin (Zocor) | -25 to -40% | +5 to 10% | ↓↓ | 5 mg once | 80 mg once | \$84.60 (10 mg once) |

will substantially increase the HDL cholesterol when added to an HMG-CoA reductase inhibitor. Despite improvements in the lipid profile, however, there are few data demonstrating improved clinical outcomes of combination therapy when compared with HMG-CoA reductase inhibitors alone. Combinations may also increase the risk of complications of drug therapy. The combination of gemfibrozil and HMG-CoA reductase inhibitors increases the risk of myopathy more than either drug alone.

HIGH BLOOD TRIGLYCERIDES

Patients with very high levels of serum triglycerides are at risk for pancreatitis. The pathophysiology is not certain, since pancreatitis never develops in some patients with very high triglyceride levels. Most patients with congenital abnormalities in triglyceride metabolism present in childhood; hypertriglyceridemia-induced pancreatitis first presenting in adults is more commonly due to an acquired problem in lipid metabolism.

Although there are no clear triglyceride levels that predict pancreatitis, most clinicians treat fasting levels above 500 mg/dL. The risk of pancreatitis may be more related to the triglyceride level following consumption of a fatty meal. Because postprandial increases in triglyceride are inevitable if fat-containing foods are eaten, fasting triglyceride levels in persons prone to pancreatitis should be kept well below that level.

The primary therapy for high triglyceride levels is dietary, avoiding alcohol, simple sugars, refined starches, saturated and trans fatty acids, and restricting total calories. Control of secondary causes of high triglyceride levels (see Table 28–1) may also be helpful. In patients with fasting triglycerides \geq 500 mg/dL despite adequate dietary compliance—and certainly in those with a previous episode of pancreatitis—therapy with a triglyceride-lowering drug (eg, niacin, a fibric acid derivative, or an HMG-CoA reductase inhibitor) is indicated.

Whether patients with elevated triglycerides ($>$ 150 mg/dL) should be treated to prevent CHD is not known. Meta-analysis of 17 observational studies suggests that after adjustment for other risk factors, elevated triglycerides increased CHD risk in men by 14% and in women by 37%. Triglyceride-rich lipoproteins (partially degraded VLDL, commonly called remnant lipoproteins) have been found in human atheromas, and elevated triglycerides are associated with small dense LDL in most instances. Elevated triglycerides are also an important feature of the metabolic syndrome, found in an estimated 25% of Americans—defined by three or more of the following five abnormalities: waist circumference $>$ 102 cm in men or $>$ 88 cm in women, serum triglyceride level of at least 150 mg/dL, HDL level of $<$ 40 mg/dL in men or $<$ 50 mg/dL in women, blood pressure of at least 130/85 mm Hg, and serum glucose level of at least 110 mg/dL. Other data, however, suggest that triglyceride measurements do not improve discrimination between those with and without CHD events, and clinical trial data are not available to support the routine treatment of high triglycerides in all patients.

The NCEP ATP III guidelines, however, recommend an aggressive approach to triglyceride management. For those with borderline levels (150–199 mg/dL), emphasis is placed on calorie restriction and exercise. For patients with high triglycerides ($>$ 200 mg/dL), the non-HDL cholesterol should be measured (total cholesterol – HDL cholesterol). The ATP III report recommends that non-HDL cholesterol should be treated with diet and medications to result in levels 30 mg/dL higher than the LDL goal. The ATP III report does not differentiate between primary and secondary prevention. It is reasonable to use this approach for patients with CHD and risk equivalents for that disease but not for lower-risk patients.

Nutritional Disorders

Robert B. Baron, MD, MS

PROTEIN-ENERGY MALNUTRITION

ESSENTIALS OF DIAGNOSIS

- ▶ History of decreased intake of energy or protein, increased nutrient losses, or increased nutrient requirements.
- ▶ Manifestations range from weight loss and growth failure to distinct syndromes, kwashiorkor, and marasmus.
- ▶ In severe cases, virtually all organ systems are affected.
- ▶ Protein loss correlates with weight loss: 35–40% total body weight loss is usually fatal.

▶ General Considerations

Protein–energy malnutrition occurs as a result of a relative or absolute deficiency of energy and protein. It may be primary, due to inadequate food intake, or secondary, as a result of other illness. For most developing nations, primary protein–energy malnutrition remains among the most significant health problems. Protein–energy malnutrition has been described as two distinct syndromes. **Kwashiorkor**, caused by a deficiency of protein in the presence of adequate energy, is typically seen in weaning infants at the birth of a sibling in areas where foods containing protein are insufficiently abundant. **Marasmus**, caused by combined protein and energy deficiency, is most commonly seen where adequate quantities of food are not available.

In industrialized societies, protein–energy malnutrition is most often secondary to other diseases. **Kwashiorkor-like secondary protein–energy malnutrition** occurs primarily in association with hypermetabolic acute illnesses such as trauma, burns, and sepsis. **Marasmus-like secondary protein–energy malnutrition** typically results from chronic diseases such as chronic obstructive pulmonary disease (COPD), congestive heart failure, cancer, or AIDS. These syndromes have been estimated to be present in at

least 20% of hospitalized patients. A substantially greater number of patients have risk factors that could result in these syndromes. In both syndromes, protein–energy malnutrition is caused either by decreased intake of energy and protein, increased nutrient losses, or increased nutrient requirements dictated by the underlying illness. For example, diminished oral intake may result from poor dentition or various gastrointestinal disorders. Loss of nutrients results from malabsorption and diarrhea as well as from glycosuria. Nutrient requirements are increased by fever, surgery, neoplasia, and burns.

▶ Pathophysiology

Protein–energy malnutrition affects every organ system. The most obvious results are loss of body weight, adipose stores, and skeletal muscle mass. Weight losses of 5–10% are usually tolerated without loss of physiologic function; losses of 35–40% of body weight usually result in death. Loss of protein from skeletal muscle and internal organs is usually proportionate to weight loss. Protein mass is lost from the liver, gastrointestinal tract, kidneys, and heart.

As protein–energy malnutrition progresses, organ dysfunction develops. Hepatic synthesis of serum proteins decreases, and depressed levels of circulating proteins are observed. Cardiac output and contractility are decreased, and the electrocardiogram (ECG) may show decreased voltage and a rightward axis shift. Autopsies of patients who die with severe undernutrition show myofibrillar atrophy and interstitial edema of the heart.

Respiratory function is affected primarily by weakness and atrophy of the muscles of respiration. Vital capacity and tidal volume are depressed, and mucociliary clearance is abnormal. The gastrointestinal tract is affected by mucosal atrophy and loss of villi of small intestine, resulting in malabsorption. Intestinal disaccharidase deficiency and mild pancreatic insufficiency also occur.

Changes in immunologic function are among the most important changes seen in protein–calorie undernutrition. T lymphocyte number and function are depressed. Changes in B cell function are more variable. Impaired complement activity, granulocyte function, and anatomic barriers to infection are noted, and wound healing is poor.

► Clinical Findings

The clinical manifestations of protein–energy malnutrition range from mild growth retardation and weight loss to a number of distinct clinical syndromes. Children in the developing world manifest marasmus and kwashiorkor. In secondary protein–energy malnutrition as seen in industrialized nations, clinical manifestations are affected by the degree of protein and energy deficiency, the underlying illness that resulted in the deficiency, and the patient's nutritional status prior to illness.

Progressive wasting that begins with weight loss and proceeds to more severe cachexia typically develops in most patients with marasmus-like secondary protein–energy malnutrition. In the most severe form of this disorder, most body fat stores disappear and muscle mass decreases, most noticeably in the temporalis and interosseous muscles. Laboratory studies may be unremarkable—serum albumin, for example, may be normal or slightly decreased, rarely decreasing to < 2.8 g/dL. In contrast, owing to its rapidity of onset, kwashiorkor-like secondary protein–energy malnutrition may develop in patients with normal subcutaneous fat and muscle mass or, if the patient is obese, in patients with excess fat and muscle. The serum protein level, however, typically declines and the serum albumin is often < 2.8 g/dL. Dependent edema, ascites, or anasarca may develop. As with primary protein–energy malnutrition, combinations of the marasmus-like and kwashiorkor-like syndromes can occur simultaneously, typically in patients with progressive chronic disease in whom a superimposed acute illness develops.

► Treatment

The treatment of severe protein–energy malnutrition is a slow process requiring great care. Initial efforts should be directed at correcting fluid and electrolyte abnormalities and infections. Of particular concern are depletion of potassium, magnesium, and calcium and acid–base abnormalities. The second phase of treatment is directed at repletion of protein, energy, and micronutrients. Treatment is started with modest quantities of protein and calories calculated according to the patient's actual body weight. Adult patients are given 1 g of protein and 30 kcal/kg. Concomitant administration of vitamins and minerals is obligatory. Either the enteral or parenteral route can be used, although the former is preferable. Enteral fat and lactose are withheld initially. Patients with less severe protein–calorie undernutrition can be given calories and protein simultaneously with the correction of fluid and electrolyte abnormalities. Similar quantities of protein and calories are recommended for initial treatment.

Patients treated for protein–energy malnutrition require close follow-up. In adults, both calories and protein are advanced as tolerated, adults to 1.5 g/kg/d of protein and 40 kcal/kg/d of calories.

Patients who are re-fed too rapidly may develop a number of untoward clinical sequelae. During refeeding, circulating potassium, magnesium, phosphorus, and glucose move intracellularly and can result in low serum levels of each. The administration of water and sodium with

carbohydrate refeeding can overload hearts with depressed cardiac function and result in congestive heart failure. Enteral refeeding can lead to malabsorption and diarrhea due to abnormalities in the gastrointestinal tract.

Refeeding edema is a benign condition to be differentiated from congestive heart failure. Changes in renal sodium reabsorption and poor skin and blood vessel integrity result in the development of dependent edema without other signs of heart disease. Treatment includes reassurance, elevation of the dependent area, and modest sodium restriction. Diuretics are usually ineffective, may aggravate electrolyte deficiencies, and should not be used.

The prevention and early detection of protein–energy malnutrition in hospitalized patients require awareness of its risk factors and early symptoms and signs. Patients at risk require formal assessment of nutritional status and close observation of dietary intake, body weight, and nutritional requirements during the hospital stay.

OBESITY

ESSENTIALS OF DIAGNOSIS

- Excess adipose tissue, resulting in BMI > 30 .
- Upper body obesity (abdomen and flank) of greater health consequence than lower body obesity (buttocks and thighs).
- Associated with multiple metabolic and structural disorders, including diabetes mellitus, hypertension, and hyperlipidemia.

► General Considerations

Obesity is one of the most common disorders in medical practice and among the most frustrating and difficult to manage. Little progress has been made in prevention or

treatment, yet major changes have occurred in our understanding of its causes and its implications for health.

► Definition & Measurement

Obesity is defined as an excess of adipose tissue. Accurate quantification of body fat requires sophisticated techniques not usually available in clinical practice. Physical examination is usually sufficient to detect excess body fat. More quantitative evaluation is performed by calculating the BMI.

The **BMI** closely correlates with excess adipose tissue. It is calculated by dividing measured body weight in kilograms by the height in meters squared.

The National Institutes of Health (NIH) define a normal BMI as 18.5–24.9. Overweight is defined as BMI = 25–29.9. Class I obesity is 30–34.9, class II obesity is 35–39.9, and class III (extreme) obesity is BMI > 40. Factors other than total weight, however, are also important. Upper body obesity (excess fat around the waist and flank) is a greater health hazard than lower body obesity (fat in the thighs and buttocks). Obese patients with increased abdominal circumference (> 102 cm in men and 88 cm in women) or with high waist–hip ratios (> 1.0 in men and > 0.85 in women) have a greater risk of diabetes mellitus, stroke, coronary artery disease, and early death than equally obese patients with lower ratios. Further differentiation of the location of excess fat suggests that visceral fat within the abdominal cavity is more hazardous to health than subcutaneous fat around the abdomen.

Current U.S. survey data demonstrate that 65% of Americans are overweight and 30.4% are obese. Women in the United States are more apt to be obese than men, and African-American and Mexican-American women are more obese than whites. The poor are more obese than the rich regardless of race.

► Health Consequences of Obesity

Obesity is associated with significant increases in both morbidity and mortality. A great many disorders occur with greater frequency in obese people. The most important and common of these are hypertension, type 2 diabetes mellitus, hyperlipidemia, coronary artery disease, degenerative joint disease, and psychosocial disability. Approximately 60% of individuals with obesity in the United States have the metabolic syndrome (including three or more of the following factors: elevated abdominal circumference, blood pressure, blood triglycerides, and fasting blood sugar, and low high-density lipoprotein [HDL] cholesterol). Certain cancers (colon, ovary, and breast), thromboembolic disorders, digestive tract diseases (gallbladder disease, gastroesophageal reflux disease), and skin disorders are also more prevalent in the obese. Surgical and obstetric risks are greater. Obese patients also have a greater risk of pulmonary functional impairment including sleep apnea, endocrine abnormalities, proteinuria, and increased hemoglobin concentration. Patients with obesity have increased rates of major depression and binge eating disorder. Several studies have documented that obese individuals are also subject to various forms of social discrimination.

In young and middle-aged adults, mortality from all causes and mortality from cardiovascular disease increase in proportion to the degree of obesity. The relative risk associated with obesity, however, decreases with age, and weight is no longer a risk factor in adults over age 75 years. Recent analysis of data from the National Health and Nutrition Examination Survey (NHANES) has suggested that lesser amounts of excess weight (BMI between 25 and 29.9) may not be associated with excess mortality.

► Etiology

Until recently, obesity was considered to be the direct result of a sedentary lifestyle plus chronic ingestion of excess calories. Although these factors are undoubtedly the principal cause in many cases, there is evidence for strong genetic influences on the development of obesity. Adopted children demonstrate a close relationship between their body mass index and that of their biologic parents. No such relationship is found between the children and their adoptive parents. Twin studies also demonstrate substantial genetic influences on BMI with little influence from the childhood environment. As much as 40–70% of obesity may be explained by genetic influences.

Genetic determinants of some types of obesity have now been established. Five genes affecting control of appetite have been identified in mice. Mutations of each gene result in obesity, and each has a human homolog. One gene codes for a protein expressed by adipose tissue—leptin—and another for the leptin receptor in the brain. The other three genes affect brain pathways downstream from the leptin receptor. Numerous other candidate genes for human obesity have been identified. Only a small percentage (4–6%) of human obesity is thought to be due to single gene mutations. Most human obesity undoubtedly develops from the interactions of multiple genes, environmental factors, and behavior. The rapid increase in obesity in the last several decades clearly points to a major role of environmental factors in the development of obesity.

► Medical Evaluation of the Obese Patient

Historical information should be obtained about age at onset, recent weight changes, family history of obesity, occupational history, eating and exercise behavior, cigarette and alcohol use, previous weight loss experience, and psychosocial factors including assessment for depression and eating disorders. Particular attention should be directed at use of laxatives, diuretics, hormones, nutritional supplements, and over-the-counter medications.

Physical examination should assess the degree and distribution of body fat, overall nutritional status, and signs of secondary causes of obesity.

Less than 1% of obese patients have an identifiable secondary, nonpsychiatric, cause of obesity. Hypothyroidism and Cushing syndrome are important examples that can usually be diagnosed by physical examination in patients with unexplained recent weight gain. Such patients require further endocrinologic evaluation, including serum thyroid-stimulating hormone (TSH) determination and dexamethasone suppression testing (see Chapter 26).

All obese patients should be assessed for medical consequences of their obesity by screening for the metabolic syndrome. Blood pressure, waist circumference, fasting glucose, low-density lipoprotein (LDL) and HDL cholesterol, and triglycerides should be measured.

► Treatment

Using conventional dietary techniques, only 20% of patients will lose 20 lb and maintain the loss for over 2 years; 5% will maintain a 40-lb loss. Average weight loss is approximately 7% of baseline weight. Continued close provider–patient contact appears to be more important for success of treatment than the specific features of any given treatment regimen. Careful patient selection will improve success rates and decrease frustration of both patients and therapists. Only sufficiently motivated patients should enter active treatment programs. Specific attempts to identify motivated patients—eg, requesting a 3-day diet record—are often useful.

Most successful programs employ a multidisciplinary approach to weight loss, with hypocaloric diets, behavior modification to change eating behavior, aerobic exercise, and social support. Emphasis must be on *maintenance* of weight loss.

Dietary instructions for most patients incorporate the same principles that apply to healthy people who are not obese. This is achieved by emphasizing intake of a wide variety of predominantly “unprocessed” foods. Special attention is usually paid to limiting foods that provide large amounts of calories without other nutrients, ie, fat, sucrose, and alcohol. There is no physiologic advantage to diets that restrict carbohydrates, advocate relatively larger amounts of protein or fats, or recommend ingestion of foods one at a time. Diets that are restricted in carbohydrates, however, can be effective in achieving a lower total calorie intake. Several studies have demonstrated that low-carbohydrate diets can be used safely for weight loss without adverse effects on lipids or other metabolic parameters. Meal replacement diets can also be used effectively and safely to achieve weight loss.

Long-term changes in eating behavior are required to maintain weight loss. Although formal **behavior modification** programs are available to which patients can be referred, the clinician caring for obese patients can teach a number of useful behavioral techniques. The most important technique is to emphasize planning and record keeping. Patients can be taught to plan menus and exercise sessions and to record their actual behavior. Record keeping not only aids in behavioral change, but also helps the provider to make specific suggestions for problem solving. Patients can be taught to recognize “eating cues” (emotional, situational, etc) and how to avoid or control them. Regular self-monitoring of weight is also associated with improved long-term weight maintenance.

Exercise offers a number of advantages to patients trying to lose weight and keep it off. Aerobic exercise directly increases the daily energy expenditure and is particularly useful for long-term weight maintenance. Exercise will also preserve lean body mass and partially prevent the

decrease in basal energy expenditure (BEE) seen with semi-starvation. When compared with no treatment, exercise alone results in small amounts of weight loss. Exercise plus diet results in greater weight loss than diet alone. A greater intensity of exercise is associated with a greater amount of weight loss. Up to 1 hour of moderate exercise per day is associated with long-term weight maintenance in individuals who have successfully lost weight. **Social support** is essential for a successful weight loss program. Continued close contact with clinicians and involvement of the family and peer group are useful techniques for reinforcing behavioral change and preventing social isolation.

Patients with severe obesity may require more aggressive treatment regimens. Very-low-calorie diets (≤ 800 kcal/d) result in rapid weight loss and marked initial improvement in obesity-related metabolic complications. Patients are commonly maintained on such programs for 4–6 months and lose an average of 2 lb per week. Average weight loss is approximately 15% of initial weight. Most programs use meal replacement diets to achieve the very-low-calorie intake. Long-term weight maintenance is less predictable and requires concurrent behavior modification, long-term use of low-calorie diets, careful self-monitoring, and regular exercise. Side effects such as fatigue, orthostatic hypotension, cold intolerance, and fluid and electrolyte disorders are observed in proportion to the degree of calorie reduction and require regular supervision by a physician. Other less common complications include gout, gallbladder disease, and cardiac arrhythmias. Although weight loss is more rapidly achieved with very-low-calorie diets as compared with traditional diets, long-term outcomes are equivalent.

Medications for the treatment of obesity are available both over the counter and by prescription. Considerable controversy exists as to the appropriate use of medications for obesity. NIH clinical obesity guidelines state that obesity drugs may be used as part of a comprehensive weight loss program for patients with BMI > 30 or those with BMI > 27 with obesity-related risk factors. There are few data, however, to suggest that medications can improve long-term outcomes associated with obesity.

Several medications are approved by the US Food and Drug Administration (FDA) for treatment of obesity. Catecholaminergic medications (eg, phentermine, diethylpropion, mazindol) are approved for short-term use only and have limited utility. Two additional medications are approved for weight loss: sibutramine and orlistat. Sibutramine blocks uptake of both serotonin and norepinephrine in the central nervous system. Orlistat reduces fat absorption in the gastrointestinal tract.

Sibutramine, typically at doses of 10 mg/d, results in average weight losses of 3–5 kg more than placebo in studies extending over 6–12 months. Sibutramine also appears to improve 1-year outcomes in patients on very-low-calorie diets. Side effects include dry mouth, anorexia, constipation, insomnia, and dizziness. In some patients ($< 5\%$), sibutramine may substantially increase blood pressure.

Orlistat is the first approved medication for obesity that works in the gastrointestinal tract rather than the central nervous system. By inhibiting intestinal lipase, orlistat reduces fat absorption. As expected, orlistat may

result in diarrhea, gas, and cramping and perhaps also reduced absorption of fat-soluble vitamins. In randomized trials with up to 2 years of follow-up, orlistat has resulted in 2–4 kg greater weight loss than placebo. The recommended dose of orlistat is 120 mg three times daily with meals. A 60-mg dose is available over-the-counter in the United States. Despite FDA approval of sibutramine and orlistat and NIH guidelines supporting their use, long-term clinical benefits have not been demonstrated. Although these medications result in some additional weight loss at the end of 1- and 2-year clinical trials and, in some studies, improved obesity-related metabolic parameters, a beneficial impact of these medications on obesity-related clinical outcomes has not been established. Another class of medications under investigation is selective cannabinoid-1 receptor antagonists (eg, rimonabant). In four initial year-long studies of rimonabant, a 20-mg dose resulted in 5 kg greater weight loss than placebo. Rimonabant, however, caused more adverse effects than placebo, including nervous system, psychiatric, and gastrointestinal symptoms, and attrition rates at 1 year were approximately 40%. Because of concerns related to depression and suicidality, the FDA did not approve rimonabant for use in the United States.

Bariatric surgery is an increasingly prevalent treatment option for patients with severe obesity. In the United States, gastric operations are considered the procedures of choice. Most popular is the Roux-en-Y gastric bypass (RYGB). In most centers, the operation can be done laparoscopically. RYGB typically results in substantial amounts of weight loss—close to 50% of initial body weight in some studies. Complications occur in up to 40% of persons undergoing RYGB surgery and include peritonitis due to anastomotic leak, abdominal wall hernias, staple line disruption, gallstones, neuropathy, marginal ulcers, stomal stenosis, wound infections, thromboembolic disease, gastrointestinal symptoms, and nutritional deficiencies including iron, vitamin B₁₂, folate, calcium, and vitamin D. Operative mortality rates within 30 days are nil to 1% in low-risk populations but have been reported to be substantially higher in Medicare beneficiaries. One-year mortality rates have been reported as high as 7.5% in men with Medicare. The surgical volume (the number of cases performed by the surgeon or hospital) has been demonstrated to be an important predictor of outcome. Gastric banding (GB) surgeries are increasing as an alternative procedure. GB results in less dramatic weight loss than RYGB but with fewer short-term complications. Frequent follow-up is required to adjust the gastric band. Longer-term follow-up suggests that both procedures are associated with significant regaining of weight. NIH consensus panel recommendations are to limit obesity surgery to patients with BMIs over 40, or over 35 if obesity-related comorbidities are present. The procedure is cost-effective for patients with severe obesity and most third-party payers now cover the procedure in selected patients. Recent outcomes studies have suggested that bariatric surgery is associated with a significant reduction in deaths at 11-year follow-up. In one prospective study, the number needed to treat to prevent one death in 11 years was 77 operations.

EATING DISORDERS

ANOREXIA NERVOSA

ESSENTIALS OF DIAGNOSIS

- ▶ Disturbance of body image and intense fear of becoming fat.

- ▶ Weight loss leading to body weight 15% below expected.
- ▶ In females, absence of three consecutive menstrual cycles.

▶ General Considerations

Anorexia nervosa typically begins in the years between adolescence and young adulthood. Ninety percent of patients are females, most from the middle and upper socioeconomic strata. The diagnosis is based on weight loss leading to body weight 15% below expected, a distorted body image, fear of weight gain or of loss of control over food intake and, in females, the absence of at least three consecutive menstrual cycles. Other medical or psychiatric illnesses that can account for anorexia and weight loss must be excluded.

The prevalence of anorexia nervosa is greater than previously suggested. In Rochester, Minnesota, for example, the prevalence per 100,000 population is estimated to be 270 for females and 22 for males. Many other adolescent girls have features of the disorder without the severe weight loss.

The cause of anorexia nervosa is not known. Although multiple endocrinologic abnormalities exist in these patients, most authorities believe they are secondary to malnutrition and not primary disorders. Most experts favor a primary psychiatric origin, but no hypothesis explains all cases. The patient characteristically comes from a family whose members are highly goal and achievement oriented. Interpersonal relationships may be inadequate or destructive. The parents are usually overly directive and concerned with slimness and physical fitness, and much of the family conversation centers around dietary matters. One theory holds that the patient's refusal to eat is an attempt to regain control of her body in defiance of parental control. The patient's unwillingness to inhabit an "adult body" may also represent a rejection of adult responsibilities and the implications of adult interpersonal relationships. Patients are commonly perfectionistic in behavior and exhibit obsessional personality characteristics. Marked depression or anxiety may be present.

▶ Clinical Findings

A. Symptoms and Signs

Patients with anorexia nervosa may exhibit severe emaciation and may complain of cold intolerance or constipation. Amenorrhea is almost always present. Bradycardia, hypotension, and hypothermia may be present in severe cases. Examination demonstrates loss of body fat, dry and scaly skin, and increased lanugo body hair. Parotid enlargement and edema may also occur.

B. Laboratory Findings

Laboratory findings are variable but may include anemia, leukopenia, electrolyte abnormalities, and elevations of blood urea nitrogen (BUN) and serum creatinine. Serum cholesterol levels are often increased. Endocrine abnormal-

ities include depressed levels of luteinizing and follicle-stimulating hormones and impaired response of luteinizing hormone to luteinizing hormone-releasing hormone.

▶ Diagnosis & Differential Diagnosis

The diagnosis can be difficult, since many common social and cultural factors promote and maintain anorexic behavior. The diagnosis depends on identification of the common behavioral features and exclusion of medical disorders that would account for weight loss.

Behavioral features required for the diagnosis include intense fear of becoming obese, disturbance of body image, weight loss of at least 15%, and refusal to exceed a minimal normal weight.

The differential diagnosis includes endocrine and metabolic disorders, such as panhypopituitarism, Addison disease, hyperthyroidism, and diabetes mellitus; gastrointestinal disorders, such as Crohn disease and celiac sprue; chronic infections and cancers, such as tuberculosis and lymphoma; and rare central nervous system disorders, such as hypothalamic tumors.

▶ Treatment

The goal of treatment is restoration of normal body weight and resolution of psychological difficulties. Hospitalization may be necessary. Treatment programs conducted by experienced teams are successful in about two-thirds of cases, restoring normal weight and menstruation. One-half continue to experience difficulties with eating behavior and psychiatric problems. Occasional patients with anorexia develop obesity after treatment. Two to 6% of patients die of the complications of the disorder or commit suicide.

Various treatment methods have been used without clear evidence of superiority of one over another. Supportive care by physicians and nurses is probably the most important feature of therapy. Structured behavioral therapy, intensive psychotherapy, and family therapy may be tried. A variety of medications including tricyclic antidepressants, SSRIs, and lithium carbonate are effective in some cases; overall, however, clinical trial results have been disappointing. Patients with severe malnutrition must be hemodynamically stabilized and may require enteral or parenteral feeding. Forced feedings should be reserved for life-threatening situations, since the goal of treatment is to reestablish normal eating behavior.

▶ When to Refer

- Adolescents and young adults with otherwise unexplained weight loss should be evaluated by a psychiatrist.
- All patients with diagnosed anorexia nervosa should be co-managed with a psychiatrist.

▶ When to Admit

- Signs of hypovolemia, major electrolyte disorders, and severe protein-energy malnutrition.
- Failure to improve with outpatient management.

BULIMIA NERVOSA

ESSENTIALS OF DIAGNOSIS

- ▶ Uncontrolled episodes of binge eating at least twice weekly for 3 months.
- ▶ Recurrent inappropriate compensation to prevent weight gain such as self-induced vomiting, laxatives, diuretics, fasting, or excessive exercise.
- ▶ Overconcern with weight and body shape.

▶ General Considerations

Bulimia nervosa is the episodic uncontrolled ingestion of large quantities of food followed by recurrent inappropriate compensatory behavior to prevent weight gain such as self-induced vomiting, diuretic or cathartic use, or strict dieting or vigorous exercise.

Like anorexia nervosa, bulimia nervosa is predominantly a disorder of young, white, middle- and upper-class women. It is more difficult to detect than anorexia, and some studies have estimated that the prevalence may be as high as 19% in college-aged women.

▶ Clinical Findings

Patients with bulimia nervosa typically consume large quantities of easily ingested high-calorie foods, usually in secrecy. Some patients may have several such episodes a day for a few days; others report regular and persistent patterns of binge eating. Binging is usually followed by vomiting, cathartics, or diuretics and is usually accompanied by feelings of guilt or depression. Periods of binging may be followed by intervals of self-imposed starvation. Body weights may fluctuate but generally are within 20% of desirable weights.

Some patients with bulimia nervosa also have a cryptic form of anorexia nervosa with significant weight loss and amenorrhea. Family and psychological issues are generally similar to those encountered among patients with anorexia nervosa. Bulimics, however, have a higher incidence of

premorbid obesity, greater use of cathartics and diuretics, and more impulsive or antisocial behavior. Menstruation is usually preserved.

Medical complications are numerous. Gastric dilatation and pancreatitis have been reported after binges. Vomiting can result in poor dentition, pharyngitis, esophagitis, aspiration, and electrolyte abnormalities. Cathartic and diuretic abuse also cause electrolyte abnormalities or dehydration. Constipation and hemorrhoids are common.

▶ Treatment

Treatment of bulimia nervosa and bulimarexia requires supportive care and psychotherapy. Individual, group, family, and behavioral therapy have all been utilized. Antidepressant medications may be helpful. The best results have been with fluoxetine hydrochloride and other SSRIs. Although death from bulimia is rare, the long-term psychiatric prognosis in severe bulimia is worse than that in anorexia nervosa.

▶ When to Refer

All patients with diagnosed bulimia should be co-managed with a psychiatrist.

DISORDERS OF VITAMIN METABOLISM

THIAMINE (B₁) DEFICIENCY

ESSENTIALS OF DIAGNOSIS

- ▶ Most common in patients with chronic alcoholism.
- ▶ Early symptoms of anorexia, muscle cramps, paresthesias, irritability.
- ▶ Advanced syndromes of high output heart failure (“wet beriberi”), peripheral nerve disorders, and Wernicke-Korsakoff syndrome (“dry beriberi”).

▶ Clinical Findings

Most thiamine deficiency in the United States is due to alcoholism. Patients with chronic alcoholism may have

poor dietary intakes of thiamine and impaired thiamine absorption, metabolism, and storage. Thiamine deficiency is also associated with malabsorption, dialysis, and other causes of chronic protein-calorie undernutrition. Thiamine deficiency can be precipitated in patients with marginal thiamine status with intravenous dextrose solutions.

Early manifestations of thiamine deficiency include anorexia, muscle cramps, paresthesias, and irritability. Advanced deficiency primarily affects the cardiovascular system (“wet beriberi”) or the nervous system (“dry beriberi”). Wet beriberi occurs in thiamine deficiency accompanied by severe physical exertion and high carbohydrate intakes. Dry beriberi occurs in thiamine deficiency accompanied by inactivity and low calorie intake.

Wet beriberi is characterized by marked peripheral vasodilation resulting in high-output heart failure with dyspnea, tachycardia, cardiomegaly, and pulmonary and peripheral edema, with warm extremities mimicking cellulitis.

Dry beriberi involves both the peripheral and the central nervous systems. Peripheral nerve involvement is typically a symmetric motor and sensory neuropathy with pain, paresthesias, and loss of reflexes. The legs are affected more than the arms. Central nervous system involvement results in Wernicke-Korsakoff syndrome. Wernicke encephalopathy consists of nystagmus progressing to ophthalmoplegia, truncal ataxia, and confusion. Korsakoff syndrome includes amnesia, confabulation, and impaired learning.

► Diagnosis

A variety of biochemical tests are available to assess thiamine deficiency. In most instances, however, the clinical response to empiric thiamine therapy is used to support a diagnosis of thiamine deficiency. The most commonly used and widely available biochemical tests are measurement of erythrocyte transketolase activity and urinary thiamine excretion. A transketolase activity coefficient greater than 15–20% suggests thiamine deficiency.

► Treatment

Thiamine deficiency is treated with large parenteral doses of thiamine. Fifty to 100 mg/d is administered intravenously for the first few days, followed by daily oral doses of 5–10 mg/d. All patients should simultaneously receive therapeutic doses of other water-soluble vitamins. Although treatment results in complete resolution in half of patients (one-fourth immediately and another one-fourth over days), the other half obtain only partial resolution or no benefit.

► When to Refer

Patients with signs of beriberi or Wernicke-Korsakoff syndrome should be referred to a neurologist.

THIAMINE TOXICITY

There is no known toxicity of thiamine.

RIBOFLAVIN (B₂) DEFICIENCY

► Clinical Findings

Riboflavin deficiency almost always occurs in combination with deficiencies of other vitamins. Dietary inadequacy, interactions with a variety of medications, alcoholism, and other causes of protein-calorie undernutrition are the most common causes of riboflavin deficiency.

Manifestations of riboflavin deficiency include cheilosis, angular stomatitis, glossitis, seborrheic dermatitis, weakness, corneal vascularization, and anemia.

► Diagnosis

Riboflavin deficiency can be confirmed by measuring the riboflavin-dependent enzyme erythrocyte glutathione reductase. Activity coefficients greater than 1.2–1.3 are suggestive of riboflavin deficiency. Urinary riboflavin excretion and serum levels of plasma and red cell flavins can also be measured.

► Treatment

Riboflavin deficiency is usually treated empirically when the diagnosis is suspected. It is easily treated with foods such as meat, fish, and dairy products or with oral preparations of the vitamin. Administration of 5–15 mg/d until clinical findings are resolved is usually adequate. Riboflavin can also be given parenterally, but it is poorly soluble in aqueous solutions.

RIBOFLAVIN TOXICITY

There is no known toxicity of riboflavin.

Said HM et al. Intestinal absorption of water-soluble vitamins: an update. *Curr Opin Gastroenterol*. 2006 Mar;22(2):140–6. [PMID: 16462170]

NIACIN DEFICIENCY

► General Considerations

Niacin is a generic term for nicotinic acid and other derivatives with similar nutritional activity. Unlike most other vitamins, niacin can be synthesized from the amino acid tryptophan. Niacin is an essential component of the coenzymes nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which are involved in many oxidation-reduction reactions. The major food sources of niacin are protein foods containing tryptophan and numerous cereals, vegetables, and dairy products.

Niacin in the form of nicotinic acid is used therapeutically for the treatment of hypercholesterolemia and hypertriglyceridemia. Daily doses of 3–6 g can result in significant reductions in levels of LDL and very-low-density lipoproteins (VLDL) and in elevation of HDL. Niacinamide (the form of niacin usually used to treat niacin deficiency) does not exhibit the lipid-lowering effects of nicotinic acid. Historically, niacin deficiency occurred when corn, which is relatively deficient in both tryptophan and niacin, was the major source of calories. Currently, niacin deficiency is more commonly due to alcoholism and nutrient–drug interactions. Niacin deficiency can also occur in inborn errors of metabolism.

► Clinical Findings

As with other B vitamins, the early manifestations of niacin deficiency are nonspecific. Common complaints include anorexia, weakness, irritability, mouth soreness, glossitis, stomatitis, and weight loss. More advanced deficiency results in the classic triad of pellagra: dermatitis, diarrhea, and dementia. The dermatitis is symmetric, involving sun-exposed areas. Skin lesions are dark, dry, and scaling. The dementia begins with insomnia, irritability, and apathy and progresses to confusion, memory loss, hallucinations, and psychosis. The diarrhea can be severe and may result in malabsorption due to atrophy of the intestinal villi. Advanced pellagra can result in death.

► Diagnosis

In early deficiency, diagnosis requires a high index of suspicion and attempts at confirmation of niacin deficiency. Niacin metabolites, particularly *N*-methylnicotinamide, can be measured in the urine. Low levels suggest niacin deficiency but may also be found in patients with generalized undernutrition. Serum and red cell levels of NAD and NADP are also low but are similarly nonspecific. In advanced cases, the diagnosis of pellagra can be made on clinical grounds.

► Treatment

Niacin deficiency can be effectively treated with oral niacin, usually given as nicotinamide. Doses ranging from 10 mg/d to 150 mg/d have been used without difficulty.

NIACIN TOXICITY

At the high doses of niacin used to treat hyperlipidemia, side effects are common. These include cutaneous flushing

(partially prevented by pretreatment with aspirin, 325 mg/d, and use of extended-release preparations) and gastric irritation. Elevation of liver enzymes, hyperglycemia, and gout are less common untoward effects.

VITAMIN B₆ DEFICIENCY

Vitamin B₆ deficiency most commonly occurs as a result of interactions with medications—especially isoniazid, cycloserine, penicillamine, and oral contraceptives—or of alcoholism. A number of inborn errors of metabolism and other pyridoxine-responsive syndromes, particularly pyridoxine-responsive anemia, are not clearly due to vitamin deficiency but commonly respond to high doses of the vitamin.

► Clinical Findings

Vitamin B₆ deficiency results in a clinical syndrome similar to that seen with deficiencies of other B vitamins, including mouth soreness, glossitis, cheilosis, weakness, and irritability. Severe deficiency can result in peripheral neuropathy, anemia, and seizures. Recent studies have suggested a potential relationship of low vitamin B₆ levels and a variety of clinical conditions including cardiovascular diseases, inflammatory diseases, and certain cancers.

► Diagnosis

The diagnosis of vitamin B₆ deficiency can be confirmed by measurement of pyridoxal phosphate in blood. Normal levels are greater than 50 ng/mL.

► Treatment

Vitamin B₆ deficiency can be effectively treated with oral vitamin B₆ supplements. Doses of 10–20 mg/d are usually adequate, though some patients taking medications that interfere with pyridoxine metabolism may need doses as high as 100 mg/d. Inborn errors of metabolism and the pyridoxine-responsive syndromes often require doses up to 600 mg/d.

Vitamin B₆ should be routinely prescribed for patients receiving medications (such as isoniazid) that interfere with pyridoxine metabolism to prevent vitamin B₆ deficiency. This is particularly true for elderly patients, the urban poor, and alcoholics, who are more likely to have

diets marginally adequate in vitamin B₆. Recent clinical trials have shown that vitamin B₆ supplementation, combined with other B vitamins, has no benefit on cardiovascular disease outcomes.

VITAMIN B₆ TOXICITY

A sensory neuropathy, at times irreversible, occurs in patients receiving large doses of vitamin B₆. Although most patients have taken 2 g or more per day, some patients have taken only 200 mg/d.

VITAMIN B₁₂ & FOLATE

Vitamin B₁₂ (cobalamin) and folate are discussed in Chapter 13.

VITAMIN C (Ascorbic Acid) DEFICIENCY

Most cases of vitamin C deficiency seen in the United States are due to dietary inadequacy in the urban poor, the elderly, and chronic alcoholics. Patients with chronic illnesses such as cancer and chronic kidney disease and individuals who smoke cigarettes are also at risk.

► Clinical Findings

Early manifestations of vitamin C deficiency are nonspecific and include malaise and weakness. In more advanced stages, the typical features of scurvy develop. Manifestations include perifollicular hemorrhages, perifollicular hyperkeratotic papules, petechiae and purpura, splinter hemorrhages, bleeding gums, hemarthroses, and subperiosteal hemorrhages. Periodontal signs do not occur in edentulous patients. Anemia is common, and wound healing is impaired. The late stages of scurvy are characterized by edema, oliguria, neuropathy, intracerebral hemorrhage, and death.

► Diagnosis

The diagnosis of advanced scurvy can be made clinically on the basis of the skin lesions in the proper clinical situation. Atraumatic hemarthrosis is also highly suggestive. The

diagnosis can be confirmed with decreased plasma ascorbic acid levels, typically below 0.1 mg/dL.

► Treatment

Adult scurvy can be treated orally with 300–1000 mg of ascorbic acid per day. Improvement typically occurs within days. Clinical trials have shown that supplemental vitamin C has no benefit on cardiovascular disease or cancer outcomes.

VITAMIN C TOXICITY

Very large doses of vitamin C can cause gastric irritation, flatulence, or diarrhea. Oxalate kidney stones are of theoretic concern because ascorbic acid is metabolized to oxalate, but stone formation has not been frequently reported. Vitamin C can also confound common diagnostic tests by causing false-negative tests for fecal occult blood and both false-negative and false-positive tests for urine glucose.

VITAMIN A DEFICIENCY

► Clinical Findings

Vitamin A deficiency is one of the most common vitamin deficiency syndromes, particularly in developing countries. In many such regions, it is the most common cause of blindness. In the United States, vitamin A deficiency is usually due to fat malabsorption syndromes or mineral oil laxative abuse and occurs most commonly in the elderly and urban poor.

Night blindness is the earliest symptom. Dryness of the conjunctiva (xerosis) and the development of small white patches on the conjunctiva (Bitot spots) are early signs. Ulceration and necrosis of the cornea (keratomalacia), perforation, endophthalmitis, and blindness are late manifestations. Xerosis and hyperkeratinization of the skin and loss of taste may also occur.

► Diagnosis

Abnormalities of dark adaptation are strongly suggestive of vitamin A deficiency. Serum levels below the normal range of 30–65 mg/dL are commonly seen in advanced deficiency.

▶ Treatment

Night blindness, poor wound healing, and other signs of early deficiency can be effectively treated orally with 30,000 international units of vitamin A daily for 1 week. Advanced deficiency with corneal damage calls for administration of 20,000 international units/kg orally for at least 5 days. The potential antioxidant effects of β -carotene can be achieved with supplements of 25,000–50,000 international units of β -carotene.

VITAMIN A TOXICITY

Excess intake of β -carotenes (hypercarotenosis) results in staining of the skin a yellow-orange color but is otherwise benign. Skin changes are most marked on the palms and soles, while the scleras remain white, clearly distinguishing hypercarotenosis from jaundice.

Excessive vitamin A (hypervitaminosis A), on the other hand, can be quite toxic. Chronic toxicity usually occurs after ingestion of daily doses of over 50,000 international units/d for more than 3 months. Early manifestations include dry, scaly skin, hair loss, mouth sores, painful hyperostoses, anorexia, and vomiting. More serious findings include hypercalcemia; increased intracranial pressure, with papilledema, headaches, and decreased cognition; and hepatomegaly, occasionally progressing to cirrhosis. Excessive vitamin A has also recently been related to increased risk of hip fracture. Acute toxicity can result from ingestion of massive doses of vitamin A, such as in drug overdoses or consumption of polar bear liver. Manifestations include nausea, vomiting, abdominal pain, headache, papilledema, and lethargy.

The diagnosis can be confirmed by elevations of serum vitamin A levels. The only treatment is withdrawal of vitamin A from the diet. Most symptoms and signs improve rapidly.

VITAMIN D

Vitamin D is discussed in Chapter 26. The major food source of vitamin D is fortified milk, but sunlight on the skin is a prime resource as well.

VITAMIN E DEFICIENCY

▶ Clinical Findings

Clinical deficiency of vitamin E is most commonly due to severe malabsorption, the genetic disorder abetalipoproteinemia, or, in children with chronic cholestatic liver disease, biliary atresia or cystic fibrosis. Manifestations of deficiency include areflexia, disturbances of gait, decreased proprioception and vibration, and ophthalmoplegia.

▶ Diagnosis

Plasma vitamin E levels can be measured; normal levels are 0.5–0.7 mg/dL or higher. Since vitamin E is normally transported in lipoproteins, the serum level should be interpreted in relation to circulating lipids.

▶ Treatment

The optimum therapeutic dose of vitamin E has not been clearly defined. Large doses, often administered parenterally, can be used to improve the neurologic complications seen in abetalipoproteinemia and cholestatic liver disease. The potential antioxidant benefits of vitamin E can be achieved with supplements of 100–400 international units/d. Clinical trials of supplemental vitamin E to prevent cardiovascular disease, however, have shown no beneficial effects.

VITAMIN E TOXICITY

Vitamin E has been thought to be the least toxic of the fat-soluble vitamins. Large doses—many times the recommended daily requirement—have been taken for extended periods of time without apparent harm, though nausea, flatulence, and diarrhea have been reported. Clinical trials, however, have suggested an increase in all-cause mortality with high dose (≥ 400 international units/d) vitamin E supplements. Large doses of vitamin E can also increase the vitamin K requirement and can result in bleeding in patients taking oral anticoagulants.

VITAMIN K

Vitamin K is discussed in Chapter 13. Vitamin K is synthesized by intestinal bacteria.

DIET THERAPY

Specific therapeutic diets can be designed to facilitate the medical management of most common illnesses. In most cases, consultation with a registered dietitian is necessary in order to design and implement major dietary changes. Clinicians should be familiar with the indications for special diets and their basic composition to facilitate patient referrals and to maximize patient compliance. Diet therapy is a difficult process, and not all patients are able to cooperate fully. Requesting the patient to record dietary intake for 3–5 days may provide useful insight into the patient's motivation as well as providing nutrient information about the current diet.

Therapeutic diets can be divided into three groups: (1) diets that alter the consistency of food, (2) diets that restrict or otherwise modify dietary components, and (3) diets that supplement dietary components.

DIETS THAT ALTER CONSISTENCY

► Clear Liquid Diet

This diet provides adequate water, 500–1000 kcal as simple sugar, and some electrolytes. It is fiber free and requires minimal digestion or intestinal motility.

A clear liquid diet is useful for patients with resolving postoperative ileus, acute gastroenteritis, partial intestinal obstruction, and as preparation for diagnostic gastrointestinal procedures. It is commonly used as the first diet for patients who have been taking nothing by mouth for long periods. Because of the low calorie and minimal protein content of the clear liquid diet, it is used only for short periods.

► Full Liquid Diet

The full liquid diet provides adequate water and can be designed to provide adequate calories and protein. Vitamins and minerals—especially folic acid, iron, and vitamin B₆—may be inadequate and should be provided in the form of supplements. Dairy products, soups, eggs, and soft cereals are used to supplement clear liquids. Commercial oral supplements can also be incorporated into the diet or used alone.

This diet is low in residue and can be used in many instances instead of the clear liquid diet described above—especially in patients with difficulty in chewing or swallowing, with partial obstructions, or in preparation for some diagnostic procedures. Full liquid diets are commonly used following clear liquid diets to advance diets in patients who have been taking nothing by mouth for long periods.

► Soft Diets

Soft diets are designed for patients unable to chew or swallow hard or coarse food. Tender foods are used, and

most raw fruits and vegetables and coarse breads and cereals are eliminated. Soft diets are commonly used to assist in progression from full liquid diets to regular diets in postoperative patients, in patients who are too weak or those whose dentition is too poor to handle a general diet, in head and neck surgical patients, in patients with esophageal strictures, and in other patients who have difficulty with chewing or swallowing.

The soft diet can be designed to meet all nutritional requirements.

DIETS THAT RESTRICT NUTRIENTS

Diets can be designed to restrict (or eliminate) virtually any nutrient or food component. The most commonly used restricted diets are those that limit sodium, fat, and protein. Other restrictive diets include gluten restriction in sprue, potassium and phosphate reduction in chronic kidney disease, and various elimination diets for food allergies.

► Sodium-Restricted Diets

Low-sodium diets are useful in the management of hypertension and in conditions in which sodium retention and edema are prominent features, particularly congestive heart failure, chronic liver disease, and chronic kidney disease. Sodium restriction is beneficial with or without diuretic therapy. When used in conjunction with diuretics, sodium restriction allows lower dosage of the diuretic medication and may prevent side effects. Potassium excretion, in particular, is directly related to distal renal tubule sodium delivery, and sodium restriction will decrease diuretic-related potassium losses.

Typical American diets contain a minimum of 4–6 g (175–260 mEq) of sodium per day. A no-added-salt diet contains approximately 3 g (132 mEq) of sodium per day. Further restriction can be achieved with sodium diets of 2 or 1 g/d. Diets with more severe restriction are poorly accepted by patients and are rarely used.

Dietary sodium includes sodium naturally occurring in foods, sodium added during food processing, and sodium added by the consumer during cooking and at the table. About a third of current dietary intake is derived from each. Diets that allow 2000 mg of sodium daily are easiest to design and implement. Such diets generally eliminate added salt, most processed foods, and selected foods with particularly high sodium content. Patients who follow such diets for 2–3 months lose their craving for salty foods and can often continue to restrict their sodium intake indefinitely. Many patients with mild hypertension will achieve significant reductions in blood pressure (approximately 5 mm Hg diastolic) with this degree of sodium restriction. Other patients require more severe sodium restriction (approximately 1000 mg of sodium per day) for reduction in blood pressure.

Diets allowing 1000 mg of sodium require further restriction of commonly eaten foods. Special “low-sodium” products are now available to facilitate such diets. These diets are difficult for most people to follow and are generally reserved for hospitalized patients and highly

motivated outpatients—most commonly those with severe liver disease and ascites.

► Fat-Restricted Diets

Traditional fat-restricted diets are useful in the treatment of fat malabsorption syndromes. Such diets will improve the symptoms of diarrhea with steatorrhea independently of the primary physiologic abnormality by limiting the quantity of fatty acids that reach the colon. The degree of fat restriction necessary to control symptoms must be individualized. Patients with severe malabsorption can be limited to 40–60 g of fat per day. Diets containing 60–80 g of fat per day can be designed for patients with less severe abnormalities.

In general, fat-restricted diets require broiling, baking, or boiling meat and fish; discarding the skin of poultry and fish and using those foods as the main protein source; using nonfat dairy products; and avoiding desserts, sauces, and gravies.

► Low-Cholesterol, Low-Saturated-Fat Diets

Fat-restricted diets that specifically restrict saturated fats and dietary cholesterol are the mainstay of dietary treatment of hyperlipidemia (see Chapter 28). Similar diets are recommended also for diabetes mellitus (see Chapter 27) and for the prevention of coronary artery disease (see Chapter 10). Current recommendations for the prevention of cancer by dietary modification also include fat restriction. The large Women's Health Initiative Dietary Modification Trial, however, did not show any significant benefit of a low-fat diet on weight control or prevention of cardiovascular disease or cancer.

The aim of these diets is to restrict total fat to less than 30% of calories and to achieve a normal body weight by caloric restriction and increased physical activity. Saturated fat is restricted to 7% of calories and dietary cholesterol to 200 mg/d. Saturated fat can be replaced either with complex carbohydrates or, if energy balance permits, with monounsaturated fats. Saturated fat, total fat, and dietary cholesterol can be restricted further, but studies suggest that more extreme restriction offers little further advantage in overall modification of serum lipids. Cholesterol-lowering diets can be further augmented with the addition of plant stanols and sterols and with soluble dietary fiber.

► Protein-Restricted Diets

Protein-restricted diets are most commonly used in patients with hepatic encephalopathy due to chronic liver disease and in patients with advanced chronic kidney disease to slow the progression of early disease and to decrease symptoms of uremia in more severe disease. Patients with selected inborn errors of amino acid metabolism and other abnormalities resulting in hyperammonemia also require restriction of protein or of specific amino acids.

Protein restriction is intended to limit the production of nitrogenous waste products. Energy intake must be adequate to facilitate the efficient use of dietary protein. Proteins must be of high biologic value and be provided in

sufficient quantity to meet minimal requirements. For most patients, the diet should contain at least 0.6 g/kg/d of protein. Patients with encephalopathy who do not respond to this degree of restriction are unlikely to respond to more severe restriction.

DIETS THAT SUPPLEMENT NUTRIENTS

► High-Fiber Diet

Dietary fiber is a diverse group of plant constituents that is resistant to digestion by the human digestive tract. Typical American diets contain about 5–10 g of dietary fiber per day. Epidemiologic evidence has suggested that populations consuming greater quantities of fiber have a lower incidence of certain gastrointestinal disorders, including diverticulitis and colon cancer. Most authorities currently recommend higher intakes of dietary fiber for health maintenance.

Diets high in dietary fiber (20–35 g/d) are also commonly used in the management of a variety of gastrointestinal disorders, particularly irritable bowel syndrome and recurrent diverticulitis. Diets high in fiber may also be useful to reduce blood sugar in patients with diabetes and to reduce cholesterol levels in patients with hypercholesterolemia. Such diets include greater intakes of fresh fruits and vegetables, whole grains, legumes and seeds, and bran products. For some patients, the addition of psyllium seed (2 tsp per day) or natural bran (one-half cup per day) may be preferable.

► High-Potassium Diets

Potassium-supplemented diets are used most commonly to compensate for potassium losses caused by diuretics. Although potassium losses can be partially prevented by using lower doses of diuretics, concurrent sodium restriction, and potassium-sparing diuretics, some patients require additional potassium to prevent hypokalemia. High-potassium diets may also have a direct antihypertensive effect. Typical American diets contain about 3 g (80 mEq) of potassium per day. High-potassium diets commonly contain 4.5–7 g (120–180 mEq) of potassium per day.

Most fruits, vegetables, and their juices contain high concentrations of potassium. Supplemental potassium can also be provided with potassium-containing salt substitutes (up to 20 mEq in one-quarter tsp) or as potassium chloride in solution or capsules, but this is rarely necessary if the above measures are followed to prevent potassium losses and supplement dietary potassium.

► High-Calcium Diets

Additional intakes of dietary calcium have been recommended for the prevention of postmenopausal osteoporosis, the prevention and treatment of hypertension, and the prevention of colon cancer. The recent Women's Health Initiative, however, suggested that calcium and vitamin D supplementation did not prevent fractures or colon cancer. Nonetheless, many authorities recommend intakes of 1 g of calcium per day for most adults and 1.5 g/d for postmenopausal women. Average American daily intakes are approximately 700 mg/d.

Dairy products are the primary dietary sources of calcium in the United States. Patients with lactose intolerance who cannot tolerate liquid dairy products may be able to tolerate nonliquid products such as cheese and yogurt. Leafy green vegetables and canned fish with bones also contain high concentrations of calcium, although the latter is also high in sodium.

NUTRITIONAL SUPPORT

Nutritional support is the provision of nutrients to patients who cannot meet their nutritional requirements by eating standard diets. Nutrients may be delivered enterally, using oral nutritional supplements, nasogastric and nasoduodenal feeding tubes, and tube enterostomies, or parenterally, using lines or catheters placed in peripheral or central veins, respectively. Current nutritional support techniques permit adequate nutrient delivery to most patients. Nutrition support should be utilized, however, only if it is likely to improve the patient's clinical outcome. The financial costs and risks of side effects must be balanced against the potential advantages of improved nutritional status in each clinical situation.

INDICATIONS FOR NUTRITIONAL SUPPORT

The precise indications for nutritional support remain controversial. Most authorities agree that nutritional support is indicated for at least four groups of adult patients: (1) those with inadequate bowel syndromes, (2) those with severe prolonged hypercatabolic states (eg, due to extensive burns, multiple trauma, mechanical ventilation), (3) those requiring

prolonged therapeutic bowel rest, and (4) those with severe protein–calorie undernutrition with a treatable disease who have sustained a loss of over 25% of body weight.

It has been difficult to prove the efficacy of nutritional support in the treatment of most other conditions. In most cases it has not been possible to show a clear advantage of treatment by means of nutritional support over treatment without such support.

The American Society for Parenteral and Enteral Nutrition (ASPEN) has published recommendations for the rational use of nutritional support. The recommendations emphasize the need to individualize the decision to begin nutritional support, weighing the risks and costs against the benefits to each patient. They also reinforce the need to identify high-risk malnourished patients by nutritional assessment.

NUTRITIONAL SUPPORT METHODS

Selection of the most appropriate nutritional support method involves consideration of gastrointestinal function, the anticipated duration of nutritional support, and the ability of each method to meet the patient's nutritional requirements. The method chosen should meet the patient's nutritional needs with the lowest risk and lowest cost possible. For most patients, enteral feeding is safer and cheaper and offers significant physiologic advantages. An algorithm for selection of the most appropriate nutritional support method is presented in Figure 29–1.

Prior to initiating specialized enteral nutritional support, efforts should be made to supplement food intake. Attention to patient preferences, timing of meals and diagnostic procedures and use of medications, and the use of foods brought to the hospital by family and friends can often increase oral intake. Patients unable to eat enough at regular mealtimes to meet nutritional requirements can be given **oral supplements** as snacks or to replace low-calorie beverages. Oral supplements of differing nutritional composition are available for the purpose of individualizing the diet in accordance with specific clinical requirements (see below). Fiber and lactose content, caloric density, protein level, and amino acid profiles can all be modified as necessary.

Patients unable to take adequate oral nutrients who have functioning gastrointestinal tracts and who meet the criteria for nutritional support are candidates for **tube feedings**. Small-bore feeding tubes are placed via the nose into the stomach or duodenum. Patients able to sit up in bed who can protect their airways can be fed into the stomach. Because of the increased risk of aspiration, patients who cannot adequately protect their airways should be fed nasoduodenally. Feeding tubes can usually be passed into the duodenum by leaving an extra length of tubing in the stomach and placing the patient in the right decubitus position. Metoclopramide, 10 mg intravenously, can be given 20 minutes prior to insertion and continued every 6 hours thereafter to facilitate passage through the pylorus. Occasionally patients will require fluoroscopic or endoscopic guidance to insert the tube distal to the pylorus. Placement of nasogastric and, particularly, nasoduodenal tubes should be confirmed radiographically before delivery of feeding solutions.

▲ **Figure 29-1.** Nutritional support method decision tree.

Feeding tubes can also be placed directly into the gastrointestinal tract using **tube enterostomies**. Most tube enterostomies are placed in patients who require long-term enteral nutritional support. Gastrostomies have the advantage of allowing bolus feedings, while jejunostomies require continuous infusions. Gastrostomies—like nasogastric feeding—should be used only in patients at low risk for aspiration. Gastrostomies can also be placed percutaneously with the aid of endoscopy. These tubes can then be advanced to jejunostomies. Tube enterostomies can also be placed surgically.

Patients who require nutritional support but whose gastrointestinal tracts are nonfunctional should receive **parenteral nutritional support**. Most patients receive parenteral feedings via a central vein—most commonly the subclavian vein. Peripheral veins can be used in some patients, but because of the high osmolality of parenteral solutions this is rarely tolerated for more than a few weeks.

Peripheral vein nutritional support is most commonly used in patients with nonfunctioning gastrointestinal tracts who require immediate support but whose clinical status is expected to improve within 1–2 weeks, allowing enteral feeding. Peripheral vein nutritional support is administered via standard intravenous lines. Solutions should always include lipid and dextrose in combination with amino acids to provide adequate nonprotein calories. Serious side effects are infrequent, but there is a high incidence of phlebitis and infiltration of intravenous lines.

Central vein nutritional support is delivered via intravenous catheters placed percutaneously using aseptic technique. Proper placement in the superior vena cava is documented radiographically before the solution is infused. Catheters must be carefully maintained by experienced nursing personnel and used solely for nutritional support to prevent infection and other catheter-related complications.

NUTRITIONAL REQUIREMENTS

Each patient's nutritional requirements should be determined independently of the method of nutritional sup-

port. In most situations, solutions of equal nutrient value can be designed for delivery via enteral and parenteral routes, but differences in absorption must be considered. A complete nutritional support solution must contain water, energy, amino acids, electrolytes, vitamins, minerals, and essential fatty acids.

▶ Water

For most patients, water requirements can be calculated by allowing 1500 mL for the first 20 kg of body weight plus 20 mL for every kilogram over 20. Additional losses should be replaced as they occur. For average-sized adult patients, fluid needs are about 30–35 mL/kg, or approximately 1 mL/kcal of energy required (see below).

▶ Energy

Energy requirements can be estimated by one of three methods: (1) by using standard equations to calculate BEE plus additional calories for activity and illness, (2) by applying a simple calculation based on calories per kilogram of body weight, or (3) by measuring energy expenditure with indirect calorimetry.

BEE can be estimated by the **Harris-Benedict equation**: for men, $BEE = 666 + (13.7 \times \text{weight in kg}) + (5 \times \text{height in cm}) - (6.8 \times \text{age in years})$. For women, $BEE = 655 + (9.5 \times \text{weight in kg}) + (1.8 \times \text{height in cm}) - (4.7 \times \text{age in years})$. For undernourished patients, actual body weight should be used; for obese patients, ideal body weight should be used. For most patients, an additional 20–50% of BEE is administered as nonprotein calories to accommodate energy expenditures during activity or relating to the illness. Occasional patients are noted to have energy expenditures greater than 150% of BEE.

Energy requirements can be estimated also by multiplying actual body weight in kilograms (for obese patients, ideal body weight) by 30–35 kcal.

Both of these methods provide imprecise estimates of actual energy expenditures, especially for the markedly

underweight, overweight, and critically ill patient. Studies using indirect calorimetry have demonstrated that as many as 30–40% of patients will have measured expenditures 10% above or below estimated values. For accurate determination of energy expenditure, indirect calorimetry should be used.

▶ Protein

Protein and energy requirements are closely related. If adequate calories are provided, most patients can be given 0.8–1.2 g of protein per kilogram per day. Patients undergoing moderate to severe stress should receive up to 1.5 g/kg/d. As in the case of energy requirements, actual weights should be used for normal and underweight patients and ideal weights for patients with significant obesity.

Patients who are receiving protein without adequate calories will catabolize protein for energy rather than utilizing it for protein synthesis. Thus, when energy intake is low, excess protein is needed for nitrogen balance. If both energy and protein intakes are low, extra energy will have a more significant positive effect on nitrogen balance than extra protein.

▶ Electrolytes & Minerals

Requirements for sodium, potassium, and chloride vary widely. Most patients require 45–145 mEq/d of each. The actual requirement in individual patients will depend on the patient's cardiovascular, renal, endocrine, and gastrointestinal status as well as measurements of serum concentration.

Patients receiving enteral nutritional support should receive adequate vitamins and minerals according to the recommended daily allowances. Most premixed enteral solutions provide adequate vitamins and minerals as long as adequate calories are administered.

Patients receiving parenteral nutritional support require smaller amounts of minerals: calcium, 10–15 mEq/d; phosphorus, 15–20 mEq per 1000 nonprotein calories; and magnesium, 16–24 mEq/d. Most patients receiving nutritional support do not require supplemental iron because body stores are adequate. Iron nutrition should be monitored closely by following the hemoglobin concentration, mean corpuscular volume, and iron studies. Parenteral administration of iron is associated with a number of adverse effects and should be reserved for iron-deficient patients unable to take oral iron.

Patients receiving parenteral nutritional support should be given the trace elements zinc (about 5 mg/d) and copper (about 2 mg/d). Patients with diarrhea will require additional zinc to replace fecal losses. Additional trace elements—especially chromium, manganese, and selenium—are provided to patients receiving long-term parenteral nutrition.

Parenteral vitamins are provided daily. Standardized multivitamin solutions are currently available to provide adequate quantities of vitamins A, B₁₂, C, D, E, thiamine, riboflavin, niacin, pantothenic acid, pyridoxine, folic acid, and biotin. Vitamin K is not given routinely but administered when the prothrombin time becomes abnormal.

▶ Essential Fatty Acids

Patients receiving nutritional support should be given 2–4% of their total calories as linoleic acid to prevent essential fatty acid deficiency. Most prepared enteral solutions contain adequate linoleic acid. Patients receiving parenteral nutrition should be given at least 250 mL of a 20% intravenous fat (emulsified soybean or safflower oil) about two or three times a week. Intravenous fat can also be used as an energy source in place of dextrose.

ENTERAL NUTRITIONAL SUPPORT SOLUTIONS

Most patients who require enteral nutritional support can be given commercially prepared enteral solutions (Table 29–1). Nutritionally complete solutions have been designed to provide adequate proportions of water, energy, protein, and micronutrients. Nutritionally incomplete solutions are also available to provide specific macronutrients (eg, protein, carbohydrate, and fat) to supplement complete solutions for patients with unusual requirements or to design solutions that are not available commercially.

Nutritionally complete solutions are characterized as follows: (1) by osmolality (isotonic or hypertonic), (2) by

Table 29–1. Enteral solutions.

| |
|--|
| Complete |
| Blenderized (eg, Compleat Regular, Compleat Modified, ¹ Vitaneed ¹) |
| Whole protein, lactose-containing (eg, Mentene, Carnation and Delmark Instant Breakfast, Forta Shake) |
| Whole protein, lactose-free, low-residue: |
| 1 kcal/mL (eg, Ensure, Isocal, Osmolite, Nutren 1.0, ¹ Nutrilan, Isolan, ¹ Sustacal, Resource) |
| 1.5 kcal/mL (eg, Ensure Plus, Sustacal HC, Comply, Nutren 1.5, Resource Plus) |
| 2 kcal/mL (eg, Isocal HCN, Magnacal, TwoCal HN) |
| High-nitrogen: > 15% total calories from protein (eg, Ensure HN, Attain, ¹ Osmolite HN, ¹ Replete, Entrition HN, ¹ Isolan, ¹ Isocal HN, ¹ Sustacal HC, Isosource HN, ¹ Ultralan) |
| Whole protein, lactose-free, high-residue: |
| 1 kcal/mL (eg, Jevity, ¹ Profiber, ¹ Nutren 1.0 with fiber, ¹ Fiberian, ¹ Sustacal with fiber, Ultracal, ¹ Ensure with fiber, Fibersource) |
| Chemically defined peptide- or amino acid-based (eg, Accu-pep HPF, Criticare HN, Peptamen, ¹ Reabfin, Vital HN, AlitraQ, Tolerex, Vivonex TEN) |
| “Disease-specific” formulas |
| Advanced chronic kidney disease: with essential amino acids (eg, Amin-Aid, Travasorb Renal, Aminess) |
| Malabsorption: with medium-chain triglycerides (eg, Portagen, ¹ Travasorb MCT) |
| Respiratory failure: with > 50% calories from fat (eg, Pulmocare, NutriVent) |
| Hepatic encephalopathy: with high amounts of branched-chain amino acids (eg, Hepatic-Acid II, Travasorb Hepatic) |
| Incomplete (modular) |
| Protein (eg, Nutrisource Protein, Promed, Propac) |
| Carbohydrate (eg, Nutrisource Carbohydrate, Polycose, Sumacal) |
| Fat (eg, MCT Oil, Microlipid, Nutrisource Lipid) |
| Vitamins (eg, Nutrisource Vitamins) |
| Minerals (eg, Nutrisource Minerals) |

¹Isotonic.

lactose content (present or absent), (3) by the molecular form of the protein component (intact proteins; peptides or amino acids), (4) by the quantity of protein and calories provided, and (5) by fiber content (present or absent). For most patients, isotonic solutions containing no lactose or fiber are preferable. Such solutions generally contain moderate amounts of fat and intact protein. Most commercial isotonic solutions contain 1000 kcal and about 37–45 g of protein per liter.

Solutions containing hydrolyzed proteins or crystalline amino acids and with no significant fat content are called elemental solutions, since macronutrients are provided in their most “elemental” form. These solutions have been designed for patients with malabsorption, particularly pancreatic insufficiency and limited fat absorption. Elemental diets are extremely hypertonic and often result in more severe diarrhea. Their use should be limited to patients who cannot tolerate isotonic solutions.

Although formulas have been designed for specific clinical situations—solutions containing primarily essential amino acids (for advanced chronic kidney disease), medium-chain triglycerides (for fat malabsorption), more fat (for respiratory failure and CO₂ retention), and more branched-chain amino acids (for hepatic encephalopathy and severe trauma)—they have not been shown to be superior to standard formulas for most patients.

Enteral solutions should be administered via continuous infusion, preferably with an infusion pump. Isotonic feedings should be started at full strength at about 25–33% of the estimated final infusion rate. Feedings can be advanced by similar amounts every 12 hours as tolerated. Hypertonic feedings should be started at half strength. The strength and the rate can then be advanced every 6 hours as tolerated.

COMPLICATIONS OF ENTERAL NUTRITIONAL SUPPORT

Minor complications of tube feedings occur in 10–15% of patients. Gastrointestinal complications include diarrhea (most common), inadequate gastric emptying, emesis, esophagitis, and occasionally gastrointestinal bleeding. Diarrhea associated with tube feeding may be due to intolerance to the osmotic load or to one of the macronutrients (eg, fat, lactose) in the solution. Patients being fed in this way may also have diarrhea from other causes (as side effects of antibiotics or other drugs, associated with infection, etc), and these possibilities should always be investigated in appropriate circumstances.

Mechanical complications of tube feedings are potentially the most serious. Of particular importance is aspiration. All patients receiving nasogastric tube feedings are at risk for this life-threatening complication. Limiting nasogastric feedings to those patients who can adequately protect their airway and careful monitoring of patients being fed by tube should limit these serious complications to 1–2% of cases. Minor mechanical complications are common and include tube obstruction and dislodgment.

Metabolic complications during enteral nutritional support are common but in most cases are easily managed.

The most important problem is hypernatremic dehydration, most commonly seen in elderly patients given excessive protein intake who are unable to respond to thirst. Abnormalities of potassium, glucose, and acid–base balance may also occur.

PARENTERAL NUTRITIONAL SUPPORT SOLUTIONS

Parenteral nutritional support solutions can be designed to deliver adequate nutrients to most patients. The basic parenteral solution is composed of dextrose, amino acids, and water. Electrolytes, minerals, trace elements, vitamins, and medications can also be added. Most commercial solutions contain the monohydrate form of dextrose that provides 3.4 kcal/g. Crystalline amino acids are available in a variety of concentrations, so that a broad range of solutions can be made up that will contain specific amounts of dextrose and amino acids as required.

Typical solutions for central vein nutritional support contain 25–35% dextrose and 2.75–6% amino acids depending upon the patient’s estimated nutrient and water requirements. These solutions typically have osmolalities in excess of 1800 mosm/L and require infusion into a central vein. A typical formula for patients without organ failure is shown in Table 29–2.

Solutions with lower osmolalities can also be designed for infusion into peripheral veins. Typical solutions for peripheral infusion contain 5–10% dextrose and 2.75–4.25% amino acids. These solutions have osmolalities between 800 and 1200 mosm/L and result in a high inci-

Table 29–2. Typical parenteral nutrition solution (for stable patients without organ failure).

| | |
|------------------------------|--|
| Dextrose (3.4 kcal/g) | 25% |
| Amino acids (4 kcal/g) | 6% |
| Na ⁺ | 50 mEq/L |
| K ⁺ | 40 mEq/L |
| Ca ²⁺ | 5 mEq/L |
| Mg ²⁺ | 8 mEq/L |
| Cl ⁻ | 60 mEq/L |
| P | 12 mEq/L |

| MVI-12 (vitamins) | 10 mL/d |
| MTE (trace elements) | 5 mL/d |
| Fat emulsion 20% | 250 mL five times a week |
| Typical rate | Day 1: 30 mL/h Day 2: 60 mL/h |
| By day 2, solution provides: | Calories: 1925 kcal total Protein: 86 g Fat: 19% of total kcal Fluid: 1690 mL |

dence of thrombophlebitis and line infiltration. These solutions will provide adequate protein for most patients but inadequate energy. Additional energy must be provided in the form of emulsified soybean or safflower oil. Such intravenous fat solutions are currently available in 10% and 25% solutions providing 1.1 and 2.2 kcal/mL, respectively. Intravenous fat solutions are isosmotic and well tolerated by peripheral veins.

Typical patients are given 200–500 mL of a 20% solution each day. As much as 60% of total calories can be administered in this manner.

Intravenous fat can also be provided to patients receiving central vein nutritional support. In this instance, dextrose concentrations should be decreased to provide a fixed concentration of energy. Intravenous fat has been shown to be equivalent to intravenous dextrose in providing energy to spare protein. Intravenous fat is associated with less glucose intolerance, less production of carbon dioxide, and less fatty infiltration of the liver and has been increasingly utilized in patients with hyperglycemia, respiratory failure, and liver disease. Intravenous fat has also been increasingly used in patients with large estimated energy requirements. Recent studies suggest that the maximum glucose utilization rate is approximately 5–7 mg/min/kg. Patients who require additional calories can be given them as fat to prevent excess administration of dextrose. Intravenous fat can also be used to prevent essential fatty acid deficiency. The optimal ratio of carbohydrate and fat in parenteral nutritional support has not been determined.

Infusion of parenteral solutions should be started slowly to prevent hyperglycemia and other metabolic complications. Typical solutions are given initially at a rate of 50 mL/h and advanced by about the same amount every 24 hours until the desired final rate is reached.

COMPLICATIONS OF PARENTERAL NUTRITIONAL SUPPORT

Complications of central vein nutritional support occur in up to 50% of patients. Although most are minor and easily managed, significant complications will develop in about

5% of patients. Complications of central vein nutritional support can be divided into catheter-related complications and metabolic complications.

Catheter-related complications can occur during insertion or while the catheter is in place. Pneumothorax, hemothorax, arterial laceration, air emboli, and brachial plexus injury can occur during catheter placement. The incidence of these complications is inversely related to the experience of the physician performing the procedure but will occur in at least 1–2% of cases even in major medical centers. Each catheter placement should be documented by chest radiograph prior to initiation of nutritional support.

Catheter thrombosis and catheter-related sepsis are the most important complications of indwelling catheters. Patients with indwelling central vein catheters in whom fever develops without an apparent source should have their lines changed over a wire or removed immediately, the tip quantitatively cultured, and antibiotics begun empirically. Quantitative tip cultures and blood cultures will help guide further antibiotic therapy. Catheter-related sepsis occurs in 2–3% of patients even if maximal efforts are made to prevent infection.

Metabolic complications of central vein nutritional support occur in over 50% of patients (Table 29–3). Most are minor and easily managed, and termination of support is seldom necessary.

PATIENT MONITORING DURING NUTRITIONAL SUPPORT

Every patient receiving enteral or parenteral nutritional support should be monitored closely. Formal nutritional support teams composed of a physician, a nurse, a dietitian, and a pharmacist have been shown to decrease the rate of complications.

Patients should be monitored both for the adequacy of treatment and to prevent complications or detect them early when they occur. Because estimates of nutritional requirements are imprecise, frequent reassessment is necessary. Daily intakes should be recorded and compared with estimated requirements. Body weight, hydration status, and

Table 29–3. Metabolic complications of parenteral nutritional support.

| Complication | Common Causes | Possible Solutions |
|--|---|--|
| Hyperglycemia | Too rapid infusion of dextrose, “stress,” corticosteroids | Decrease glucose infusion; insulin; replacement of dextrose with fat |
| Hyperosmolar nonketotic dehydration | Severe, undetected hyperglycemia | Insulin, hydration, potassium |
| Hyperchloremic metabolic acidosis | High chloride administration | Decrease chloride |
| Azotemia | Excessive protein administration | Decrease amino acid concentration |
| Hyperphosphatemia, hypokalemia, hypomagnesemia | Extracellular to intracellular shifting with refeeding | Increase solution concentration |
| Liver enzyme abnormalities | Lipid trapping in hepatocytes, fatty liver | Decrease dextrose |
| Acalculous cholecystitis | Biliary stasis | Oral fat |
| Zinc deficiency | Diarrhea, small bowel fistulas | Increase concentration |
| Copper deficiency | Biliary fistulas | Increase concentration |

overall clinical status should be followed. Patients who do not appear to be responding as anticipated can be evaluated for nitrogen balance by means of the following equation:

$$\text{Nitrogen balance} = \frac{\text{24-hour protein intake (g)}}{6.25} - \left(\frac{\text{25-hour urinary nitrogen (g)}}{\text{nitrogen (g)}} + 4 \right)$$

Patients with positive nitrogen balances can be continued on their current regimens; patients with negative balances should receive moderate increases in calorie and protein intake and then be reassessed. Monitoring for metabolic complications includes daily measurements of electrolytes; serum glucose, phosphorus, magnesium, calcium, and creatinine; and BUN until the patient is stabilized. Once the patient is stabilized, electrolytes, phosphorus, calcium, magnesium, and glucose should be obtained at least twice weekly. Red blood cell folate, zinc, and copper should be checked at least once a month.

30

COMMON PROBLEMS IN INFECTIOUS DISEASES

FEVER OF UNKNOWN ORIGIN (FUO)

ESSENTIALS OF DIAGNOSIS

- ▶ Illness of at least 3 weeks duration.
- ▶ Fever over 38.3 °C on several occasions.
- ▶ Diagnosis has not been made after three outpatient visits or 3 days of hospitalization.

▶ General Considerations

The intervals specified in the criteria for the diagnosis of FUO are arbitrary ones intended to exclude patients with protracted but self-limited viral illnesses and to allow time for the usual radiographic, serologic, and cultural studies to be performed. Because of costs of hospitalization and the availability of most screening tests on an outpatient basis, the original criterion requiring 1 week of hospitalization has been modified to accept patients in whom a diagnosis has not been made after three outpatient visits or 3 days of hospitalization.

Several additional categories of FUO have been added: (1) Hospital-associated FUO refers to the hospitalized patient with fever of 38.3 °C or higher on several occasions, due to a process not present or incubating at the time of admission, in whom initial cultures are negative and the diagnosis remains unknown after 3 days of investigation (see Hospital-Associated Infections, below). (2) Neutropenic FUO includes patients with fever of 38.3 °C or higher on several occasions with less than 500 neutrophils per microliter in whom initial cultures are negative and the diagnosis remains uncertain after 3 days (see Chapter 2 and Infections in the Immunocompromised Patient, below). (3) HIV-associated FUO pertains to HIV-positive patients with fever of 38.3 °C or higher who have been febrile for 4 weeks or more as an outpatient or 3 days as an inpatient, in whom the diagnosis remains uncertain after 3 days of

investigation with at least 2 days for cultures to incubate (see Chapter 31). Although not usually considered separately, FUO in solid organ transplant recipients is a common scenario with a unique differential diagnosis and is discussed below.

For a general discussion of fever, see the section on fever and hyperthermia in Chapter 2.

A. Common Causes

Most cases represent unusual manifestations of common diseases and not rare or exotic diseases—eg, tuberculosis, endocarditis, gallbladder disease, and HIV (primary infection or opportunistic infection) are more common causes of FUO than Whipple disease or familial Mediterranean fever.

B. Age of Patient

In adults, infections (25–40% of cases) and cancer (25–40% of cases) account for the majority of FUOs. In children, infections are the most common cause of FUO (30–50% of cases) and cancer a rare cause (5–10% of cases). Autoimmune disorders occur with equal frequency in adults and children (10–20% of cases), but the diseases differ. Juvenile rheumatoid arthritis is particularly common in children, whereas systemic lupus erythematosus, Wegener granulomatosis, and polyarteritis nodosa are more common in adults. Still disease, giant cell arteritis, and polymyalgia rheumatica occur exclusively in adults. In the elderly (over 65 years of age), multisystem immune-mediated diseases such as temporal arteritis, polymyalgia rheumatica, sarcoidosis, rheumatoid arthritis, and Wegener granulomatosis account for 25–30% of all FUOs.

C. Duration of Fever

The cause of FUO changes dramatically in patients who have been febrile for 6 months or longer. Infection, cancer, and autoimmune disorders combined account for only 20% of FUOs in these patients. Instead, other entities such as granulomatous diseases (granulomatous hepatitis, Crohn disease, ulcerative colitis) and factitious fever become important causes. One-fourth of patients who say they have been febrile for 6 months or longer actually have

no true fever or underlying disease. Instead, the usual normal circadian variation in temperature (temperature 0.5–1 °C higher in the afternoon than in the morning) is interpreted as abnormal. Patients with episodic or recurrent fever (ie, those who meet the criteria for FUO but have fever-free periods of 2 weeks or longer) are similar to those with prolonged fever. Infection, malignancy, and autoimmune disorders account for only 20–25% of such fevers, whereas various miscellaneous diseases (Crohn disease, familial Mediterranean fever, allergic alveolitis) account for another 25%. Approximately 50% of cases remain undiagnosed but have a benign course with eventual resolution of symptoms.

D. Immunologic Status

In the neutropenic patient, fungal infections and occult bacterial infection are important causes of FUO. In the patient taking immunosuppressive medications (particularly organ transplant patients), cytomegalovirus (CMV) infections are a frequent cause of fever, as are fungal infections, nocardiosis, *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) pneumonia, and mycobacterial infections.

E. Classification of Causes of FUO

Most patients with FUO will fit into one of five categories.

1. Infection—Both systemic and localized infections can cause FUO. Tuberculosis and endocarditis are the most common systemic infections, but mycoses, viral diseases (particularly infection with Epstein-Barr virus and CMV), toxoplasmosis, brucellosis, Q fever, cat-scratch disease, salmonellosis, malaria, and many other less common infections have been implicated. Primary infection with HIV or opportunistic infections associated with AIDS—particularly mycobacterial infections—can also present as FUO. The most common form of localized infection causing FUO is an occult abscess. Liver, spleen, kidney, brain, and bone abscesses may be difficult to detect. A collection of pus may form in the peritoneal cavity or in the subdiaphragmatic, subhepatic, paraocolic, or other areas. Cholangitis, osteomyelitis, urinary tract infection, dental abscess, or paranasal sinusitis may cause prolonged fever.

2. Neoplasms—Many cancers can present as FUO. The most common are lymphoma (both Hodgkin and non-Hodgkin) and leukemia. Other diseases of lymph nodes, such as angioimmunoblastic lymphoma and Castleman disease, can also cause FUO. Primary and metastatic tumors of the liver are frequently associated with fever, as are renal cell carcinomas. Atrial myxoma is an often forgotten neoplasm that can result in fever. Chronic lymphocytic leukemia and multiple myeloma are rarely associated with fever, and the presence of fever in patients with these diseases should prompt a search for infection.

3. Autoimmune disorders—Still disease, systemic lupus erythematosus, cryoglobulinemia, and polyarteritis nodosa are the most common causes of autoimmune-associated FUO. Giant cell arteritis and polymyalgia rheumatica are seen almost exclusively in patients over 50 years of age and

are nearly always associated with an elevated erythrocyte sedimentation rate (> 40 mm/h).

4. Miscellaneous causes—Many other conditions have been associated with FUO but less commonly than the foregoing types of illness. Examples include thyroiditis, sarcoidosis, Whipple disease, familial Mediterranean fever, recurrent pulmonary emboli, alcoholic hepatitis, drug fever, and factitious fever.

5. Undiagnosed FUO—Despite extensive evaluation, the diagnosis remains elusive in 15% or more of patients. Of these patients, the fever abates spontaneously in about 75% with no diagnosis; in the remainder, more classic manifestations of the underlying disease appear over time.

► Clinical Findings

Because the evaluation of a patient with FUO is costly and time-consuming, it is imperative to first document the presence of fever. This is done by observing the patient while the temperature is being taken to ascertain that fever is not factitious (self-induced). Associated findings that accompany fever include tachycardia, chills, and piloerection. A thorough history—including family, occupational, social (sexual practices, use of injection drugs), dietary (unpasteurized products, raw meat), exposures (animals, chemicals), and travel—may give clues to the diagnosis. Repeated physical examination may reveal subtle, evanescent clinical findings essential to diagnosis.

A. Laboratory Tests

In addition to routine laboratory studies, blood cultures should always be obtained, preferably when the patient has not taken antibiotics for several days, and should be held by the laboratory for 2 weeks to detect slow-growing organisms. Cultures on special media are requested if *Legionella*, *Bartonella*, or nutritionally deficient streptococci are possible pathogens. “Screening tests” with immunologic or microbiologic serologies (“febrile agglutinins”) are of low yield and should not be done. If the history or physical examination suggests a specific diagnosis, specific serologic tests with an associated fourfold rise or fall in titer may be useful. Because infection is the most common cause of FUO, other body fluids are usually cultured, ie, urine, sputum, stool, cerebrospinal fluid, and morning gastric aspirates (if one suspects tuberculosis). Direct examination of blood smears may establish a diagnosis of malaria or relapsing fever (*Borrelia*).

B. Imaging

All patients with FUO should have a chest radiograph. Studies such as sinus films, upper gastrointestinal series with small bowel follow-through, barium enema, proctosigmoidoscopy, and evaluation of gallbladder function are reserved for patients who have symptoms, signs, or a history that suggest disease in these body regions. CT scan of the abdomen and pelvis is also frequently performed and is particularly useful for looking at the liver, spleen, and retroperitoneum. When the CT scan is abnormal, the findings often lead to a specific

diagnosis. A normal CT scan is not quite as useful; more invasive procedures such as biopsy or exploratory laparotomy may be needed. The role of MRI in the investigation of FUO has not been evaluated. In general, however, MRI is better than CT for detecting lesions of the nervous system and is useful in diagnosing various vasculitides. Ultrasound is sensitive for detecting lesions of the kidney, pancreas, and biliary tree. Echocardiography should be used if one is considering endocarditis or atrial myxoma. Transesophageal echocardiography is more sensitive than surface echocardiography for detecting valvular lesions, but even a negative transesophageal study does not exclude endocarditis (10% false-negative rate). The usefulness of radionuclide studies in diagnosing FUO is variable. Theoretically, a gallium or positron emission tomography (PET) scan would be more helpful than an indium-labeled white blood cell scan, because gallium and fluorodeoxy-glucose may be useful for detecting infection, inflammation, and neoplasm whereas the indium scan is useful only for detecting infection. Indium-labeled immunoglobulin may prove to be useful in detecting infection and neoplasm and can be used in the neutropenic patient. It is not sensitive for lesions of the liver, kidney, and heart because of high background activity. In general, radionuclide scans are plagued by high rates of false-positive and false-negative results that are not useful when used as screening tests and, if done at all, are limited to those patients whose history or examination suggests local inflammation or infection.

C. Biopsy

Invasive procedures are often required for diagnosis. Any abnormal finding should be aggressively evaluated: Headache calls for lumbar puncture to rule out meningitis; skin rash should be biopsied for cutaneous manifestations of collagen vascular disease or infection; and enlarged lymph nodes should be aspirated or biopsied for neoplasm and sent for culture. Bone marrow aspiration with biopsy is a relatively low-yield procedure (except in HIV-positive patients, in whom mycobacterial infection is a common cause of FUO), but the risk is low and the procedure should be done if other less invasive tests have not yielded a diagnosis. Liver biopsy will yield a specific diagnosis in 10–15% of patients with FUO and should be considered in any patient with abnormal liver function tests even if the liver is normal in size. CT scanning and MRI have decreased the need for exploratory laparotomy; however, surgical intervention should be considered with continued deterioration or lack of diagnosis.

▶ Treatment

An empiric course of antimicrobials should be considered if an infectious diagnosis is strongly suspected. However, if there is no clinical response, it is imperative to stop therapy and reevaluate. Once definitive culture results return, streamlining therapy to the most narrow spectrum antimicrobial should take place. Antituberculosis medications (particularly in the elderly or foreign-born) and broad-spectrum antibiotics may be reasonable in this setting.

Empiric administration of corticosteroids should be discouraged because they can suppress fever and exacerbate many infections.

▶ When to Refer

- Any patient with FUO and progressive weight loss and other constitutional signs.
- Any immunocompromised patient (eg, transplant recipients and HIV-infected patients).
- Infectious diseases specialists may also be able to coordinate and interpret specialized testing (eg, Q fever serologies) with outside agencies, such as the US Centers for Disease Control and Prevention.

▶ When to Admit

- Any patient who is rapidly declining with weight loss where hospital admission may expedite work-up.
- If FUO is present in immunocompromised patients, such as those who are neutropenic from recent chemotherapy or those who have undergone transplantation (particularly in the previous 6 months).

INFECTIONS IN THE IMMUNOCOMPROMISED PATIENT

ESSENTIALS OF DIAGNOSIS

- ▶ Fever and other symptoms may be blunted because of immunosuppression.
- ▶ A contaminating organism in an immunocompetent individual may be a pathogen in an immunocompromised one.
- ▶ The interval since transplantation and the degree of immunosuppression can narrow the differential diagnosis.
- ▶ Empiric broad-spectrum antibiotics may be appropriate in high-risk patients whether or not symptoms are localized.

▶ General Considerations

Immunocompromised patients have defects in their natural defense mechanisms resulting in an increased risk for infection. In addition, infection is often severe, rapidly progressive, and life-threatening. Organisms that are not usually

problematic in the immunocompetent person may be important pathogens in the compromised patient (eg, *Staphylococcus epidermidis*, *Corynebacterium jeikeium*, *Propionibacterium acnes*, *Bacillus* species). Therefore, culture results must be interpreted with caution, and isolates should not be disregarded as merely contaminants. Although the type of immunodeficiency is associated with specific infectious disease syndromes, any pathogen can cause infection in any immunosuppressed patient at any time. Thus, a systematic evaluation is required to identify a specific organism.

A. Impaired Humoral Immunity

Defects in humoral immunity are often congenital, although hypogammaglobulinemia can occur in multiple myeloma, chronic lymphocytic leukemia, and in patients who have undergone splenectomy. Patients with ineffective humoral immunity lack opsonizing antibodies and are at particular risk for infection with encapsulated organisms, such as *Haemophilus influenzae*, *Neisseria meningitidis* and *Streptococcus pneumoniae*.

B. Granulocytopenia (Neutropenia)

Granulocytopenia is common following hematopoietic cell transplantation (“stem cell transplantation”) and among patients with solid tumors—as a result of myelosuppressive chemotherapy—and in acute leukemias. The risk of infection begins to increase when the absolute granulocyte count falls below 1000/mcL, with a dramatic increase in frequency and severity when the granulocyte count falls below 100/mcL. The infection risk is also increased with a rapid rate of decline of neutrophils and with a prolonged period of neutropenia. The granulocytopenic patient is particularly susceptible to infections with gram-negative enteric organisms, *Pseudomonas*, gram-positive cocci (particularly *Staphylococcus aureus*, *S epidermidis*, and viridans streptococci), *Candida*, *Aspergillus*, and other fungi that have recently emerged as pathogens such as *Trichosporon*, *Scedosporium*, *Fusarium*, and the mucormycoses.

C. Impaired Cellular Immunity

Patients with cellular immune deficiency encompass a large and heterogeneous group, including patients with HIV infection (see Chapter 31); patients with lymphoreticular malignancies, such as Hodgkin disease; and patients receiving immunosuppressive medications, such as corticosteroids, cyclosporine, tacrolimus, and other cytotoxic drugs. This latter group—those who are immunosuppressed as a result of medications—includes patients who have undergone solid organ transplantation, many patients receiving therapy for solid tumors, and patients receiving prolonged high-dose corticosteroid treatment (eg, for asthma, temporal arteritis, systemic lupus). Patients taking tumor necrosis factor (TNF)- α inhibitors, such as etanercept and infliximab, for a variety of inflammatory conditions are also included in this category. Patients with cellular immune dysfunction are susceptible to infections by a large number of organisms, particularly ones that replicate intracellularly. Examples include bacteria, such as *Listeria*, *Legionella*, *Salmonella*, and

Mycobacterium; viruses, such as herpes simplex, varicella, and CMV; fungi, such as *Cryptococcus*, *Coccidioides*, *Histoplasma*, and *Pneumocystis*; and protozoa, such as *Toxoplasma*. Patients taking TNF- α inhibitors have specific defects that increase risk of bacterial, mycobacterial (particularly tuberculosis), and fungal infections (primary and reactivation).

D. Hematopoietic Cell Transplant Recipients

The length of time it takes for complications to occur in hematopoietic cell transplant recipients can be helpful in determining the etiologic agent. In the early (preengraftment) posttransplant period (day 1–21), patients will become severely neutropenic for 7–21 days. Patients are at risk for gram-positive (particularly catheter-related) and gram-negative bacterial infections, as well as herpes simplex virus, respiratory syncytial virus, and fungal infections. In contrast to solid organ transplant recipients, the source of fever is unknown in 60–70% of hematopoietic cell transplant patients. Between 3 weeks and 3 months posttransplant, infections with CMV, adenovirus, *Aspergillus*, and *Candida* are most common. *P jiroveci* pneumonia is possible, particularly in patients in whom graft-versus-host disease has developed resulting in additional immunosuppression. Patients continue to be at risk for infectious complications beyond 3 months following transplantation, particularly those who have received allogeneic transplantation and those who are taking immunosuppressive therapy for chronic graft-versus-host disease. Varicella-zoster is common, and *Aspergillus* and CMV infections are increasingly seen in this period as well.

E. Solid Organ Transplant Recipients

The length of time it takes for infection to occur following solid organ transplantation can also be helpful in determining the infectious origin. Immediate postoperative infections often involve the transplanted organ. Following lung transplantation, pneumonia and mediastinitis are particularly common; following liver transplantation, intra-abdominal abscess, cholangitis, and peritonitis may be seen; after kidney transplantation, urinary tract infections, perinephric abscesses, and infected lymphoceles can occur.

Most infections that occur in the first 2–4 weeks posttransplant are related to the operative procedure and to hospitalization itself (wound infection, intravenous catheter infection, urinary tract infection from a Foley catheter) or are related to the transplanted organ. Infections that occur between the first and sixth months are often related to immunosuppression. During this period, reactivation of viruses, such as herpes simplex, varicella-zoster, and CMV is quite common. Opportunistic infections with fungi (eg, *Candida*, *Aspergillus*, *Cryptococcus*, *Pneumocystis*), *Listeria monocytogenes*, *Nocardia*, and *Toxoplasma* are also common. After 6 months, if immunosuppression has been reduced to maintenance levels, infections that would be expected in any population occur. Patients with poorly functioning allografts receiving long-term immunosuppression therapy continue to be at risk for opportunistic infections.

F. Other Immunocompromised States

A large group of patients who are not specifically immunodeficient are at increased risk for infection due to debilitating injury (eg, burns or severe trauma), invasive procedures (eg, chronic central intravenous catheters, Foley catheters, dialysis catheters), central nervous system dysfunction (which predisposes patients to aspiration pneumonia and decubitus ulcers), obstructing lesions (eg, pneumonia due to an obstructed bronchus, pyelonephritis due to nephrolithiasis, cholangitis secondary to cholelithiasis), and use of broad-spectrum antibiotics. Patients with diabetes mellitus have alterations in cellular immunity, resulting in mucormycosis, emphysematous pyelonephritis, and foot infections.

► Clinical Findings

A. Laboratory Findings

Routine evaluation includes complete blood count with differential, chest radiograph, and blood cultures; urine and respiratory cultures should be obtained if indicated clinically or radiographically. Any focal complaints (localized pain, headache, rash) should prompt imaging and cultures appropriate to the site.

Patients who remain febrile without an obvious source should be evaluated for viral infection (serum CMV antigen test or polymerase chain reaction), abscesses (which usually occur near previous operative sites), candidiasis involving the liver or spleen, or aspergillosis. Serologic evaluation may be helpful if toxoplasmosis, aspergillosis (detected by galactomannan level in serum), or an endemic fungal infection (coccidioidomycosis, histoplasmosis) is a possible cause.

B. Special Diagnostic Procedures

Special diagnostic procedures should also be considered. The cause of pulmonary infiltrates can be easily determined with simple techniques in some situations—eg, induced sputum yields a diagnosis of *Pneumocystis* pneumonia in 50–80% of AIDS patients with this infection. In other situations, more invasive procedures may be required (bronchoalveolar lavage, transbronchial biopsy, open lung biopsy). Skin, liver, or bone marrow biopsy may be helpful in establishing a diagnosis.

► Differential Diagnosis

Transplant rejection, organ ischemia and necrosis, thrombophlebitis, and lymphoma (posttransplant lymphoproliferative disease) may all present as fever and must be considered in the differential diagnosis.

► Prevention

There is great interest in preventing infection with prophylactic antimicrobial regimens but no uniformity of opinion about optimal drugs or dosage regimens. Hand washing is the simplest and most effective means of decreasing hospital-associated infections, especially in the compromised patient. Invasive devices such as central and peripheral

lines and Foley catheters are potential sources of infection. Some centers use laminar airflow isolation or high-efficiency particulate air (HEPA) filtering in hematopoietic cell transplant patients. Rates of infection and episodes of febrile neutropenia, but not mortality, are decreased if colony-stimulating factors are used during chemotherapy or during stem-cell transplantation.

A. *Pneumocystis* & Herpes Simplex Infections

Trimethoprim-sulfamethoxazole (TMP-SMZ), one double-strength tablet orally three times a week, one double-strength tablet twice daily on weekends, or one single-strength tablet daily for 3–6 months, is frequently used to prevent *Pneumocystis* infections in transplant patients. In patients allergic to TMP-SMZ, dapsone, 50 mg orally daily or 100 mg three times weekly, is recommended. Glucose-6-phosphate dehydrogenase (G6PD) levels should be determined before therapy when the latter is instituted. Acyclovir prevents herpes simplex infections in bone marrow and solid organ transplant recipients and is given to seropositive patients who are not receiving acyclovir or ganciclovir for CMV prophylaxis. The usual dose is 200 mg orally three times daily for 4 weeks (hematopoietic cell transplants) to 12 weeks (other solid organ transplants).

B. CMV

No uniformly accepted approach has been adopted for prevention of CMV. Prevention strategies often depend on the serologic status of the donor and recipient and the organ transplanted, which determines the level of immunosuppression after transplant. In solid organ transplants (liver, kidney, heart, lung), the greatest risk of developing CMV disease is in seronegative patients who receive organs from seropositive donors. These high-risk patients usually receive oral valganciclovir, 900 mg daily, or oral ganciclovir, 1 g three times daily for 3 months. Other solid organ transplant recipients (seropositive recipients) are at lower risk for developing CMV disease but still usually receive either oral valganciclovir or oral ganciclovir for 3 months. The lowest risk group for the development of CMV disease is in seronegative patients who receive organs from seronegative donors. Typically, no CMV prophylaxis is used in this group. Ganciclovir and valganciclovir also prevent herpes virus reactivation. Because immunosuppression is increased during periods of rejection, patients treated for rejection usually receive CMV prophylaxis during rejection therapy.

Recipients of hematopoietic cell transplants are more severely immunosuppressed than recipients of solid organ transplants, are at greater risk for developing serious CMV infection (usually CMV reactivation), and thus usually receive more aggressive prophylaxis. Two approaches have been used: universal prophylaxis or preemptive therapy. In the former, all high-risk patients (seropositive patients who receive allogeneic transplants) may receive oral valganciclovir, 900 mg daily to day 100. This method is costly and associated with significant bone marrow toxicity. Alternatively, patients can be monitored without specific prophylaxis and have blood sampled weekly for the presence of CMV. If CMV is detected by an antigenemia assay

or by polymerase chain reaction, preemptive therapy is instituted with oral valganciclovir, 900 mg twice daily for a minimum of 2–3 weeks followed by oral valganciclovir at 900 mg daily until day 100. This preemptive approach is effective but does miss a small number of patients in whom CMV disease would have been prevented had prophylaxis been used. Other preventive strategies include use of CMV-negative or leukocyte-depleted blood products for CMV-seronegative recipients.

C. Other Organisms

Routine decontamination of the gastrointestinal tract to prevent bacteremia in the neutropenic patient is not recommended. Prophylactic administration of antibiotics in the afebrile, asymptomatic neutropenic patient is controversial, although many centers have adopted this strategy. Rates of bacteremia are decreased, but overall mortality is not affected and emergence of resistant organisms is a risk. Use of intravenous immunoglobulin is reserved for the small number of patients with severe hypogammaglobulinemia following bone marrow transplantation and should not be routinely administered to all transplant patients.

Prophylaxis with antifungal agents to prevent invasive mold (primarily *Aspergillus*) and yeast (primarily *Candida*) infections is routinely used, but the optimal agent, dose, and duration have not been standardized. Moderate-dose (0.5 mg/kg/d) and low-dose (0.1–0.25 mg/kg/d) intravenous amphotericin, lipid-based preparations of amphotericin B, aerosolized amphotericin B, intravenous and oral voriconazole, and oral posaconazole solution have all been used in the neutropenic patient. Because voriconazole appears to be more effective than amphotericin for documented *Aspergillus* infections and because posaconazole prophylaxis (compared with fluconazole) has been shown to result in fewer cases of invasive aspergillosis among allogeneic stem cell transplant recipients with graft-versus-host disease, one approach to prophylaxis is to use oral fluconazole (400 mg/d) for patients at low risk for developing fungal infections (those who receive autologous bone marrow transplants) and oral voriconazole (200 mg twice daily) or oral posaconazole (200 mg solution three times daily) for those at high risk (allogeneic transplants, graft-versus-host disease) at least until engraftment (usually 30 days). In solid organ transplant recipients, the risk of invasive fungal infection varies considerably (1–2% in liver, pancreas, and kidney transplants and 6–8% in heart and lung transplants). Whether universal prophylaxis or observation with preemptive therapy is the best approach has not been determined. Although fluconazole is effective in preventing yeast infections, emergence of fluconazole-resistant *Candida* and molds (*Fusarium*, *Aspergillus*, *Mucor*) has raised concerns about its routine use as a prophylactic agent.

Given the high risk of reactivation of tuberculosis in patients taking TNF- α inhibitors, all patients should be screened for latent tuberculosis infection (LTBI) with a tuberculin skin test or an interferon-gamma release assay prior to the start of therapy. If LTBI is diagnosed, treatment with the TNF- α inhibitors should be delayed until treatment for LTBI is completed.

► Treatment

A. General Measures

Because infections in the immunocompromised patient can be rapidly progressive and life-threatening, diagnostic procedures must be performed promptly, and empiric therapy is usually instituted.

While reduction or discontinuation of immunosuppressive medication may jeopardize the viability of the transplanted organ, this measure may be necessary if the infection is life-threatening. Hematopoietic growth factors (granulocyte and granulocyte-macrophage colony-stimulating factors) stimulate proliferation of bone marrow stem cells, resulting in an increase in peripheral leukocytes. These agents shorten the period of neutropenia and have been associated with reduction in infection.

B. Specific Measures

Antimicrobial drug therapy ultimately should be based on culture results. While combinations of antimicrobials may be used to provide synergy or to prevent resistance, the primary reason for empiric combination therapy is broad-spectrum coverage of multiple pathogens (since infections in these patients are often polymicrobial).

Empiric therapy is often instituted at the earliest sign of infection in the immunosuppressed patient because prompt therapy favorably affects outcome. The antibiotic or combination of antibiotics used depends on the type of immunocompromise and the site of infection. For example, in the febrile neutropenic patient, an algorithmic approach to therapy is often used. Febrile neutropenic patients should be empirically treated with broad-spectrum agents active against gram-positive organisms, *Pseudomonas aeruginosa*, and other gram-negative bacilli (such as cefepime 2 g every 8 hours intravenously). The addition of vancomycin, 10–15 mg/kg/dose intravenously every 12 hours, should be considered in those patients with suspected infection due to methicillin-resistant *S aureus* (MRSA), *S epidermidis*, and enterococcus. Continued neutropenic fever necessitates broadening of antibacterial coverage from cefepime to agents such as imipenem 500 mg every 6 hours intravenously with or without tobramycin, 5 mg/kg intravenously every 24 hours. Antifungal agents (such as voriconazole 200 mg intravenously or orally every 12 hours, or caspofungin, 50 mg daily intravenously) should be added if fevers continue after 5–7 days of broad-spectrum antibacterial therapy. Regardless of whether the patient becomes afebrile, therapy is continued until resolution of neutropenia. Failure to continue antibiotics through the period of neutropenia has been associated with increase morbidity and mortality.

Patients with fever and low-risk neutropenia (neutropenia expected to persist for less than 10 days, no comorbid complications requiring hospitalization, and cancer adequately treated) can be treated with oral antibiotic regimens, such as ciprofloxacin, 750 mg every 12 hours, plus amoxicillin-clavulanic acid, 500 mg every 8 hours. Antibiotics are continued as long as the patient is neutropenic even if a source is not identified. In the organ

transplant patient with interstitial infiltrates, the main concern is infection with *Pneumocystis* or *Legionella* species, so that empiric treatment with a macrolide (or fluoroquinolone) and TMP-SMZ, 15 mg/kg/d orally or intravenously (based on trimethoprim component) would be reasonable in those patients not receiving TMP-SMZ prophylaxis. If the patient does not respond to empiric treatment, a decision must be made to add more antimicrobial agents or perform invasive procedures (see above) to make a specific diagnosis. By making a specific diagnosis, therapy can be specific and polypharmacy with multiple potentially toxic agents can be avoided.

▶ When to Refer

- Any immunocompromised patient with an opportunistic infection.
- Patients with potential drug toxicities and drug interactions related to antimicrobials where alternative agents are sought.
- Patients with LTBI in whom therapy with TNF- α inhibitors is planned.

▶ When to Admit

Immunocompromised patients who are febrile, or those without fevers in whom an infection is suspected, particularly in the following groups: solid-organ or hematopoietic stem cell transplant recipient (particularly in the first 6 months), neutropenic patients, patients receiving TNF- α inhibitors, transplant recipients who have had recent rejection episodes (including graft-versus-host disease).

HOSPITAL-ASSOCIATED INFECTIONS

ESSENTIALS OF DIAGNOSIS

- ▶ Hospital-associated infections are defined as those not present or incubating at the time of hospital admission and developing 48–72 hours after admission.

- ▶ Hand washing is the most effective means of preventing hospital-associated infections and should be done routinely even when gloves are worn.

▶ General Considerations

In the United States, approximately 5% of patients acquire a hospital-associated infection, resulting in prolongation of the hospital stay, increase in cost of care, significant morbidity, and a 5% mortality rate. The most common infections are urinary tract infections, usually associated with Foley catheters or urologic procedures; bloodstream infections, most commonly from indwelling catheters but also from secondary sites, such as surgical wounds, abscesses, pneumonia, the genitourinary tract, and the gastrointestinal tract; pneumonia in intubated patients or those with altered levels of consciousness; surgical wound infections; MRSA infections; and *Clostridium difficile* colitis.

Some general principles are helpful in preventing, diagnosing, and treating hospital-associated infections:

1. Many infections are a direct result of the use of invasive devices for monitoring or therapy, such as intravenous catheters, Foley catheters, shunts, surgical drains, catheters placed by interventional radiology for drainage, nasogastric tubes, and orotracheal or nasotracheal tubes for ventilatory support. Early removal of such devices reduces the possibility of infection.
2. Patients in whom hospital-associated infections develop are often critically ill, have been hospitalized for extended periods, and have received several courses of broad-spectrum antibiotic therapy. As a result, hospital-associated infections are often due to multidrug resistant pathogens and are different from those encountered in community-acquired infections. For example, *S aureus* and *S epidermidis* (a frequent cause of prosthetic device infection) are often resistant to nafcillin and cephalosporins and require vancomycin for therapy; *Enterococcus faecium* resistant to ampicillin and vancomycin; gram-negative infections caused by *Pseudomonas*, *Citrobacter*, *Enterobacter*, *Acinetobacter*, and *Stenotrophomonas*, which may be resistant to most antibacterials. When choosing antibiotics to treat the seriously ill patient with a hospital-associated infection, antimicrobial history and the “local ecology” must be considered. In seriously ill patients, broad-spectrum coverage with vancomycin and a carbapenem with or without an aminoglycoside is recommended. Once a pathogen is isolated and susceptibilities are known, the most narrow spectrum, least toxic, most cost-effective drug should be used.

Widespread use of antimicrobial drugs contributes to the selection of drug-resistant organisms, thus every effort should be made to limit the spectrum of coverage and unnecessary duration. All too often, unreliable or uninterpretable specimens are obtained for culture that result in unnecessary use of antibiotics. The best example of this principle is the diagnosis of line-related or bloodstream infection in the febrile patient (see below). To avoid

unnecessary use of antibiotics, thoughtful consideration of culture results is mandatory. A positive wound culture without signs of inflammation or infection, a positive sputum culture without pulmonary infiltrates on chest radiograph, or a positive urine culture in a catheterized patient without symptoms or signs of pyelonephritis are all likely to represent colonization, not infection.

► Clinical Findings

A. Symptoms and Signs

Catheter-associated infections have a variable presentation, depending on the type of catheter used (peripheral or central venous catheters, nontunneled or tunneled). Local signs of infection may be present at the insertion site, with pain, erythema, and purulence. Fever is often absent in uncomplicated infections and if present, may indicate more disseminated disease such as bacteremia, cellulitis and septic thrombophlebitis. Often signs of infection at the insertion site are absent.

1. Fever in an intensive care unit patient—Fever complicates up to 70% of patients in intensive care units, and the etiology of the fever may be infectious or noninfectious. Common infectious causes include catheter-associated infections, hospital-acquired and ventilator-associated pneumonia (see Chapter 9), surgical site infections, urinary tract infections, and sepsis. Clinically relevant sinusitis is relatively uncommon in the patient in the intensive care unit.

An important noninfectious cause is thromboembolic disease. Fever in conjunction with refractory hypotension and shock may suggest sepsis; however, adrenal insufficiency, thyroid storm, and transfusion reaction may have a similar clinical presentation. Drug fever is difficult to diagnose and is usually a diagnosis of exclusion unless there are other signs of hypersensitivity, such as a typical maculopapular rash.

2. Fever in the postoperative patient—Postoperative fever is very common and in many cases resolves spontaneously. Etiologies are both infectious and noninfectious. Timing of the fever in relation to the surgery and the nature of the surgical procedure may help diagnostically.

A. IMMEDIATE FEVER (IN THE FIRST FEW HOURS AFTER SURGERY)—Immediate fever can be due to medications that were given perioperatively, to the trauma of surgery itself, or to infections that were present before surgery. Necrotizing fasciitis due to group A streptococci or mixed organisms may present in this period. Malignant hyperthermia is rare and presents 30 minutes to several hours following inhalational anesthesia and is characterized by extreme hyperthermia, muscle rigidity, rhabdomyolysis, electrolyte abnormalities, and hypotension. Aggressive cooling and dantrolene are the mainstays of therapy. Aspiration of acidic gastric contents during surgery can cause a chemical pneumonitis (Mendelson syndrome) that rapidly develops but is transient and does not require intervention. Fever due to the trauma of surgery itself usually resolves in 2–3 days, longer in more complicated operative cases and in patients with head trauma.

B. ACUTE FEVER (WITHIN 1 WEEK OF SURGERY)—Acute fever is usually due to common causes of hospital-associated infections, such as ventilator-associated pneumonia (including aspiration pneumonia in patients with decreased gag reflex) and line infections. Noninfectious causes include alcohol withdrawal, gout, pulmonary embolism, and pancreatitis. Atelectasis following surgery is commonly invoked as a cause of postoperative fever but there is no good evidence to support a causal association between the presence or degree of atelectasis and fever.

C. SUBACUTE FEVER (AT LEAST 1 WEEK AFTER SURGERY)—Surgical site infections commonly present at least 1 week after surgery. The type of surgery that was performed predicts specific infectious etiologies. Patients undergoing cardiothoracic surgery may be at higher risk for pneumonia and deep and superficial sternal wound infections. Meningitis without typical signs of meningismus may complicate neurosurgical procedures. Abdominal surgery may result in deep abdominal abscesses that require drainage.

B. Laboratory Findings

Blood cultures are universally recommended, and chest radiographs are frequently obtained. A properly prepared sputum Gram stain and semi-quantitative sputum cultures may be useful in selected patients where there is a high pretest probability of pneumonia but multiple exclusion criteria probably limit generalizability in most patients, such as immunocompromised patients and those with drug resistance. Other diagnostic strategies will be dictated by the clinical context (eg, transesophageal echocardiogram in a patient with *S aureus* bacteremia).

Any fever in a patient with a central venous catheter should prompt the collection of blood. The best method to evaluate bacteremia is to gather at least two peripherally obtained blood cultures. Blood cultures from unidentified sites, a single blood culture from any site, or a blood culture through an existing line will often be positive for *S epidermidis*, resulting in the inappropriate use of vancomycin. Unless two separate venipuncture cultures are obtained—not through catheters—interpretation of results is impossible and unnecessary therapy may be given. Every such “pseudobacteremia” increases laboratory costs, antibiotic use, and length of stay. Microbiologic evaluation of the removed catheter can sometimes be helpful, but only in addition to (not instead of) blood cultures drawn from peripheral sites. The differential time to positivity measures the difference in time that cultures simultaneously drawn through a catheter and a peripheral site become positive. A positive test (about 120 minutes difference in time) supports a catheter-related bloodstream infection, and a negative test may permit catheters to be retained.

► Complications

Patients who have persistent bacteremia and fever despite removal of the infected catheter may have complications such as septic thrombophlebitis, endocarditis, or metastatic foci of infection (particularly with *S aureus*). Additional studies such as venous Doppler studies, transesophageal

echocardiogram, and chest radiographs may be indicated, and 4–6 weeks of antibiotics may be needed. In the case of septic thrombophlebitis, anticoagulation with heparin is also recommended if there are no contraindications.

► Differential Diagnosis

Although most fevers are due to infections, about 25% of patients will have fever of noninfectious origin, including drug fever, nonspecific postoperative fevers (tissue damage or necrosis), hematoma, pancreatitis, pulmonary embolism, myocardial infarction, and ischemic bowel disease.

► Prevention

The concept of universal precautions emphasizes that all patients are treated as though they have a potential blood-borne transmissible disease, and thus all body secretions are handled with care to prevent spread of disease. Body substance isolation requires use of gloves whenever a health care worker anticipates contact with blood or other body secretions. Even though gloves are worn, health care workers should routinely wash their hands, since it is the easiest and most effective means of preventing hospital-associated infections. Application of a rapid drying, alcohol-based antiseptic is simple, takes less time than traditional hand washing with soap and water, is more effective at reducing hand colonization, and promotes compliance with hand decontamination.

Peripheral intravenous lines should be replaced every 3 days, and arterial lines should be replaced every 4 days. Lines in the central venous circulation (including those placed peripherally) can be left in place indefinitely and are changed or removed when they are clinically suspected of being infected, when they are nonfunctional, or when they are no longer needed. Using sterile barrier precautions (including cap, mask, gown, gloves, and drape) is recommended while inserting central venous catheters. Silver alloy–impregnated Foley catheters reduce the incidence of catheter-associated bacteriuria, and antibiotic-impregnated (minocycline plus rifampin or chlorhexidine plus silver sulfadiazine) venous catheters reduce line infections and bacteremia. Silver-coated endotracheal tubes may reduce the incidence of ventilator-associated pneumonia. Whether the increased cost of these devices justifies their routine use should be determined by individual institutions. Perioperative administration of chlorhexidine intranasal ointment and oropharyngeal rinse has been shown to reduce the incidence of infection following surgery. Daily bathing of ICU patients with chlorhexidine-impregnated washcloths versus soap and water may result in lower risk of catheter-associated bloodstream infections. Selective decontamination of the digestive tract with nonabsorbable or parenteral antibiotics, or both, may prevent hospital-acquired pneumonia and decrease mortality.

Attentive nursing care (positioning to prevent decubitus ulcers, wound care, elevating the head during tube feedings to prevent aspiration) is critical in preventing hospital-associated infections. In addition, monitoring of high-risk areas by hospital epidemiologists is critical in the prevention of infection. Some guidelines advocate rapid screening for MRSA on admission to acute care facilities

among certain subpopulations of patients (eg, those recently hospitalized, admission to the intensive care unit, patients undergoing hemodialysis). However, it is not clear whether this strategy decreases the incidence of hospital-associated MRSA infections.

Vaccines, including hepatitis A, hepatitis B, and the varicella, pneumococcal, influenza vaccination are important adjuncts. (See section below on Immunization against Infectious Diseases.)

► Treatment

A. Fever in an Intensive Care Unit Patient

Unless the patient has a central neurologic injury with elevated intracranial pressure or has a temperature $> 41^{\circ}\text{C}$, there is less physiologic need to maintain euthermia. Empiric broad-spectrum antibiotics (as noted above) are recommended for neutropenic and other immunocompromised patients and in patients who are clinically unstable.

B. Catheter-Associated Infections

Factors that inform treatment decisions include the type of catheter, the causative pathogen, the availability of alternate catheter access sites, the need for ongoing intravascular access, and the severity of disease.

In general, catheters should be removed if there is purulence at the exit site; if the organism is *S aureus*, gram-negative rods, or *Candida* species; if there is persistent bacteremia (> 48 hours while receiving antibiotics); or if complications, such as septic thrombophlebitis, endocarditis, or other metastatic disease exist. Central venous catheters may be exchanged over a guidewire provided there is no erythema or purulence at the exit site and the patient does not appear to be septic. Methicillin-resistant, coagulase-negative staphylococci are the most common pathogens; thus, empiric therapy with vancomycin, 15 mg/kg IV twice daily, should be given assuming normal kidney function. Empiric gram-negative coverage may be considered in patients who are immunocompromised or who are critically ill.

Antibiotic treatment duration depends on the pathogen and the extent of disease. For uncomplicated bacteremia, 5–7 days of therapy is usually sufficient for coagulase-negative staphylococci, even if the original catheter is retained. Fourteen days of therapy is generally recommended for uncomplicated bacteremia caused by gram-negative rods, *Candida* species, and *S aureus*.

► When to Refer

- Any patient with multidrug-resistant infection.
- Any patient with fungemia or persistent bacteremia.
- Patients with multisite infections.
- Patients with impaired or fluctuating kidney function for assistance with dosing of antimicrobials.

INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

ESSENTIALS OF DIAGNOSIS

- ▶ Central nervous system infection is a medical emergency.
- ▶ Symptoms and signs common to all central nervous system infections include headache, fever, sensorial disturbances, neck and back stiffness, positive Kernig and Brudzinski signs, and cerebrospinal fluid abnormalities.

▶ General Considerations

Infections of the central nervous system can be caused by almost any infectious agent, including bacteria, mycobacteria, fungi, spirochetes, protozoa, helminths, and viruses. The classic triad of fever, stiff neck and altered mental status has a low sensitivity (44%) for bacterial meningitis. However, nearly all patients with bacterial meningitis have at least two of the following symptoms—fever, headache, stiff neck, or altered mental status.

▶ Etiologic Classification

Central nervous system infections can be divided into several categories that usually can be readily distinguished from each other by cerebrospinal fluid examination as the first step toward etiologic diagnosis (Table 30–1).

A. Purulent Meningitis

Patients with bacterial meningitis usually seek medical attention within hours or 1–2 days after onset of symptoms. The organisms responsible depend primarily on the age of the patient as summarized in Table 30–2. The diagnosis is usually based on the Gram-stained smear (positive in 60–90%) or culture (positive in over 90%).

B. Chronic Meningitis

The presentation of chronic meningitis is less acute than purulent meningitis. Patients with chronic meningitis usually have a history of symptoms lasting weeks to months. The most common pathogens are *Mycobacterium tuberculosis*, atypical mycobacteria, fungi (*Cryptococcus*, *Coccidioides*, *Histoplasma*), and spirochetes (*Treponema pallidum* and *Borrelia burgdorferi*, the cause of Lyme disease). The diagnosis is made by culture or in some cases by serologic tests (cryptococcosis, coccidioidomycosis, syphilis, Lyme disease).

Table 30–1. Typical cerebrospinal fluid findings in various central nervous system diseases.

| Diagnosis | Cells/mcl | Glucose (mg/dl) | Protein (mg/dl) | Opening Pressure |
|--|---|--------------------|------------------------|-----------------------------|
| Normal | 0–5 lymphocytes | 45–85 ¹ | 15–45 | 70–180 mm H ₂ O |
| Purulent meningitis (bacterial) ² community-acquired | 200–20,000 polymorphonuclear neutrophils | Low (< 45) | High (> 50) | Markedly elevated |
| Granulomatous meningitis (mycobacterial, fungal) ³ | 100–1000, mostly lymphocytes ³ | Low (< 45) | High (> 50) | Moderately elevated |
| Spirochetal meningitis | 100–1000, mostly lymphocytes ³ | Normal | Moderately high (> 50) | Normal to slightly elevated |
| Aseptic meningitis, viral or meningoencephalitis ⁴ | 25–2000, mostly lymphocytes ³ | Normal or low | High (> 50) | Slightly elevated |
| “Neighborhood reaction” ⁵ | Variably increased | Normal | Normal or high | Variable |

¹Cerebrospinal fluid glucose must be considered in relation to blood glucose level. Normally, cerebrospinal fluid glucose is 20–30 mg/dL lower than blood glucose, or 50–70% of the normal value of blood glucose.

²Organisms in smear or culture of cerebrospinal fluid; counterimmunoelectrophoresis or latex agglutination may be diagnostic.

³Polymorphonuclear neutrophils may predominate early.

⁴Viral isolation from cerebrospinal fluid early; antibody titer rise in paired specimens of serum; polymerase chain reaction for herpesvirus.

⁵May occur in mastoiditis, brain abscess, epidural abscess, sinusitis, septic thrombus, brain tumor. Cerebrospinal fluid culture results usually negative.

Table 30–2. Initial antimicrobial therapy for purulent meningitis of unknown cause.

| Population | Common Microorganisms | Standard Therapy |
|-------------------------------|---|---|
| 18–50 years | <i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i> | Vancomycin ¹ plus cefotaxime or ceftriaxone ² |
| Over 50 years | <i>S pneumoniae</i> , <i>N meningitidis</i> , <i>Listeria monocytogenes</i> , gram-negative bacilli | Vancomycin ¹ plus ampicillin, ³ plus cefotaxime or ceftriaxone ² |
| Impaired cellular immunity | <i>L monocytogenes</i> , gram-negative bacilli, <i>S pneumoniae</i> | Vancomycin ¹ plus ampicillin ³ plus ceftazidime ⁴ |
| Postsurgical or posttraumatic | <i>Staphylococcus aureus</i> , <i>S pneumoniae</i> , gram-negative bacilli | Vancomycin ¹ plus ceftazidime ⁴ |

¹The dose of vancomycin is 10–15 mg/kg/dose IV every 6 hours.

²The usual dose of cefotaxime is 2 g IV every 6 hours and that of ceftriaxone is 2 g IV every 12 hours. If the organism is sensitive to penicillin, 3–4 million units IV every 4 hours is given.

³The dose of ampicillin is usually 2 g IV every 4 hours.

⁴Ceftazidime is given in a dose of 50–100 mg/kg IV every 8 hours.

C. Aseptic Meningitis

Aseptic meningitis—a much more benign and self-limited syndrome than purulent meningitis—is caused principally by viruses, especially herpes simplex virus and the enterovirus group (including coxsackieviruses and echoviruses). Infectious mononucleosis may be accompanied by aseptic meningitis. Leptospiral infection is also usually placed in the aseptic group because of the lymphocytic cellular response and its relatively benign course. This type of meningitis also occurs during secondary syphilis and disseminated Lyme disease. Prior to the routine administration of measles-mumps-rubella (MMR) vaccines, mumps was the most common cause of viral meningitis.

D. Encephalitis

Encephalitis (due to herpesviruses, arboviruses, rabies virus, flaviviruses [West Nile encephalitis, Japanese encephalitis], and many others) produces disturbances of the sensorium, seizures, and many other manifestations. Patients are more ill than those with aseptic meningitis. Cerebrospinal fluid may be entirely normal or may show some lymphocytes and in some instances (eg, herpes simplex) red cells as well.

E. Partially Treated Bacterial Meningitis

Previous effective antibiotic therapy given for 12–24 hours will decrease the rate of positive Gram stain results by 20% and culture by 30–40% but will have little effect on cell count, protein, or glucose. Occasionally, previous antibiotic therapy will change a predominantly polymorphonuclear response to a lymphocytic pleocytosis, and some of the cerebrospinal fluid findings may be similar to those seen in aseptic meningitis.

F. Neighborhood Reaction

As noted in Table 30–1, this term denotes a purulent infectious process in close proximity to the central nervous system that spills some of the products of the inflammatory process—white blood cells or protein—into the cerebrospinal fluid. Such an infection might be a brain abscess,

osteomyelitis of the vertebrae, epidural abscess, subdural empyema, or bacterial sinusitis or mastoiditis.

G. Noninfectious Meningeal Irritation

Carcinomatous meningitis, sarcoidosis, systemic lupus erythematosus, chemical meningitis, and certain drugs—nonsteroidal anti-inflammatory drugs, muromonab-CD3 (OKT3), TMP-SMZ, and others—can also produce symptoms and signs of meningeal irritation with associated cerebrospinal fluid pleocytosis, increased protein, and low or normal glucose. Meningismus with normal cerebrospinal fluid findings occurs in the presence of other infections such as pneumonia and shigellosis.

H. Brain Abscess

Brain abscess presents as a space-occupying lesion; symptoms may include vomiting, fever, change of mental status, or focal neurologic manifestations. When brain abscess is suspected, a CT scan should be performed. If positive, lumbar puncture should *not* be performed since results rarely provide clinically useful information and herniation can occur. The bacteriology of brain abscess is usually polymicrobial and includes *S aureus*, gram-negative bacilli, streptococci, and anaerobes (including anaerobic streptococci and *Prevotella* species).

I. Amebic Meningoencephalitis

These infections are caused by free-living amoebas and present as two distinct syndromes. The diagnosis is confirmed by culture (*Acanthamoeba* species and *Balamuthia mandrillaris*) or identification of the organism in a wet mount of cerebrospinal fluid (*Naegleria fowleri*) or on biopsy specimens. No effective therapy is available.

Primary amebic meningoencephalitis is caused by *N fowleri* and is an acute fulminant disease, usually seen in children and young adults with recent fresh water exposure, and is characterized by signs of meningeal irritation that rapidly progresses to encephalitis and death. Rare cures have been reported with intravenous and intraventricular administration of amphotericin B.

Granulomatous amebic encephalitis is caused by *Acanthamoeba* species. It is an indolent disease, frequently seen in immunocompromised patients and associated with cutaneous lesions. Central nervous system disease is characterized by headache, nausea, vomiting, cranial neuropathies, seizures, and hemiparesis. Infections with *Balamuthia* are similar to *Acanthamoeba* in that the course is subacute to chronic, but unlike *Acanthamoeba* both immunocompromised and immunocompetent persons can be affected.

► Clinical Findings

A. Laboratory Tests

Evaluation of a patient with suspected meningitis includes a history, physical examination, blood count, blood culture, lumbar puncture followed by careful study and culture of the cerebrospinal fluid, and a chest film. The fluid must be examined for cell count, glucose, and protein, and a smear stained for bacteria (and acid-fast organisms when appropriate) and cultured for pyogenic organisms and for mycobacteria and fungi when indicated. Latex agglutination tests can detect antigens of encapsulated organisms (*S pneumoniae*, *H influenzae*, *N meningitidis*, and *Cryptococcus neoformans*) but are rarely used except for detection of *Cryptococcus* or in partially treated patients. Polymerase chain reaction (PCR) testing of cerebrospinal fluid has been used to detect bacteria (*S pneumoniae*, *H influenzae*, *N meningitidis*, *M tuberculosis*, *B burgdorferi*, and *Tropheryma whippelii*) and viruses (herpes simplex, varicella-zoster, CMV, Epstein-Barr virus, and enteroviruses) in patients with meningitis. The greatest experience is with PCR for herpes simplex and varicella-zoster, and the tests are very sensitive (> 95%) and specific. Tests to detect the other organisms may not be any more sensitive than culture, but the real value is the rapidity with which results are available, ie, hours compared with days or weeks. At present, with the exception of PCR for herpes simplex, these tests are performed only in reference laboratories. Although it is difficult to prove with existing clinical data that early antibiotic therapy improves outcome in bacterial meningitis, prompt therapy is still recommended.

B. Lumbar Puncture and Imaging

Since performing a lumbar puncture in the presence of a space-occupying lesion (brain abscess, subdural hematoma, subdural empyema, necrotic temporal lobe from herpes encephalitis) may result in brainstem herniation, a CT scan is performed prior to lumbar puncture if a space-occupying lesion is suspected on the basis of papilledema, seizures, or focal neurologic findings. Other indications for CT scan are an immunocompromised patient or moderate to severely impaired level of consciousness. If delays are encountered in obtaining a CT scan and bacterial meningitis is suspected, blood cultures should be drawn and antibiotics and corticosteroids administered even before cerebrospinal fluid is obtained for culture to avoid delay in treatment (Table 30–1). Antibiotics given within 4 hours

before obtaining cerebrospinal fluid probably do not affect culture results.

► Treatment

Increased intracranial pressure due to brain edema often requires therapeutic attention. Hyperventilation, mannitol (25–50 g as a bolus intravenous infusion), and even drainage of cerebrospinal fluid by repeated lumbar punctures or by placement of ventricular catheters have been used to control cerebral edema and increased intracranial pressure. Dexamethasone (4 mg intravenously every 4–6 hours) may also decrease cerebral edema. In purulent meningitis, the identity of the causative microorganism may remain unknown or doubtful for a few days and initial antibiotic treatment as set forth in Table 30–2 should be directed against the microorganisms most common for each age group.

The duration of therapy for bacterial meningitis varies depending on the etiologic agent: *H influenzae*, 7 days; *N meningitidis*, 3–7 days; *S pneumoniae*, 10–14 days; *L monocytogenes*, 14–21 days; and gram-negative bacilli, 21 days.

Dexamethasone therapy is recommended for adults with pneumococcal meningitis. Ten milligrams of dexamethasone administered intravenously 15–20 minutes before or simultaneously with the first dose of antibiotics and continued every 6 hours for 4 days decreases morbidity and mortality. Patients most likely to benefit from corticosteroids are those infected with gram-positive organisms (*Streptococcus pneumoniae* or *Streptococcus suis*), and those who are HIV negative. The number of patients with meningitis due to *N meningitidis* and other bacterial pathogens studied does not support similar conclusions.

Therapy of brain abscess consists of drainage (excision or aspiration) in addition to 3–4 weeks of systemic antibiotics directed against organisms isolated. An empiric regimen often includes metronidazole, 500 mg intravenously or orally every 8 hours, plus ceftriaxone, 2 g intravenously every 12 hours, with or without vancomycin, 10–15 mg/kg/dose intravenously every 12 hours. In cases where abscesses are less than 2 cm in size, where there are multiple abscesses that cannot be drained, or if an abscess is located in an area where significant neurologic sequelae would result from drainage, antibiotics for 6–8 weeks without drainage can be used.

Therapy of other types of meningitis is discussed elsewhere in this book (fungal meningitis, Chapter 36; syphilis and Lyme borreliosis, Chapter 34; tuberculous meningitis, Chapter 33; herpes encephalitis, Chapter 32).

► When to Refer

- Patients with acute meningitis, particularly if culture negative or atypical (eg, fungi, syphilis, Lyme disease, *M tuberculosis*), or if the patient is immunosuppressed.
- Patients with chronic meningitis.
- All patients with brain abscesses and encephalitis.
- Patients with suspected hospital-acquired meningitis (eg, in patients who have undergone recent neurosurgery).
- Patients with recurrent meningitis.

▶ When to Admit

- Patients with suspected acute meningitis, encephalitis, and brain abscess should be admitted for urgent evaluation and treatment.
- There is less urgency to admit patients with chronic meningitis; these patients may be admitted to expedite diagnostic procedures and coordinate care, particularly if no diagnosis has been made in the outpatient setting.

ANIMAL & HUMAN BITE WOUNDS

ESSENTIALS OF DIAGNOSIS

- ▶ Cat and human bites have higher rates of infection than dog bites.
- ▶ Hand bites are particularly concerning for the possibility of closed-space infection.
- ▶ Antibiotic prophylaxis indicated for noninfected bites of the hand and hospitalization required for infected hand bites.
- ▶ All infected wounds need to be cultured to direct therapy.

▶ General Considerations

About 1000 dog bite injuries require emergency department attention each day, most often in urban areas. Dog bites occur most commonly in the summer months. Biting animals are usually known by their victims, and most biting incidents are provoked (ie, bites occur while playing with the animal or after surprising the animal or waking it abruptly from sleep). Failure to elicit a history of provocation is important, because an unprovoked attack raises the possibility of rabies. Human bites are usually inflicted by children while playing or fighting; in adults, bites are associated with alcohol use and closed-fist injuries that occur during fights.

The animal inflicting the bite, the location of the bite, and the type of injury inflicted are all important determi-

nants of whether they become infected. Cat bites are more likely to become infected than human bites—between 30% and 50% of all cat bites become infected. Infections following human bites are variable: Those inflicted by children rarely become infected because they are superficial, and bites by adults become infected in 15–30% of cases, with a particularly high rate of infection in closed-fist injuries. “Through and through” bites (eg involving the mucosa and the skin) have an infection rate similar to closed-fist injuries. Dog bites, for unclear reasons, become infected only 5% of the time. Bites of the head, face, and neck are less likely to become infected than bites on the extremities. Puncture wounds become infected more frequently than lacerations, probably because the latter are easier to irrigate and debride.

The bacteriology of bite infections is polymicrobial. Following dog and cat bites, over 50% of infections are caused by aerobes and anaerobes and 36% are due to aerobes alone. Pure anaerobic infections are rare. *Pasteurella* species are the single most common isolate (75% of cat bites and 50% of dog bites). Other common aerobic isolates include streptococci, staphylococci, *Moraxella*, and *Neisseria*; the most common anaerobes are *Fusobacterium*, *Bacteroides*, *Porphyromonas*, and *Prevotella*. The median number of isolates following human bites is four (three aerobes and one anaerobe). Like dog and cat bites, most human bites are a mixture of aerobes and anaerobes (54%) or are due to aerobes alone (44%). *Streptococcus*, *Staphylococcus*, and *Eikenella corrodens* (found in 30% of patients) are the most common aerobes. *Prevotella* and *Fusobacterium* are the most common anaerobes. Although the organisms noted are the most common, innumerable others have been isolated—including *Capnocytophaga* (dog and cats), *Pseudomonas*, and *Haemophilus*—emphasizing the point that all infected bites should be cultured to define the microbiology.

HIV can be transmitted from bites (either from biting or receiving a bite from an HIV-infected patient) but has rarely been reported.

▶ Treatment

A. Local Care

Vigorous cleansing and irrigation of the wound as well as debridement of necrotic material are the most important factors in decreasing the incidence of infections. Radiographs should be obtained to look for fractures and the presence of foreign bodies. Careful examination to assess the extent of the injury (tendon laceration, joint space penetration) is critical to appropriate care.

B. Suturing

If wounds require closure for cosmetic or mechanical reasons, suturing can be done. However, one should never suture an infected wound, and wounds of the hand should generally not be sutured since a closed-space infection of the hand can result in loss of function.

C. Prophylactic Antibiotics

Prophylaxis is indicated in high-risk bites and in high-risk patients. Cat bites in any location and hand bites by any

animal, including humans, should receive prophylaxis. Individuals with certain comorbidities (diabetes, liver disease) are at increased risk for severe complications and should receive prophylaxis even for low-risk bites, as should patients without functional spleens who are at increased risk for overwhelming sepsis (primarily with *Capnocytophaga* species). Amoxicillin-clavulanate (Augmentin) 500 mg orally three times daily for 5–7 days is the regimen of choice. For patients with serious allergy to penicillin, a combination of clindamycin 300 mg orally three times daily plus doxycycline 100 mg orally twice daily, or double-strength TMP-SMZ orally twice daily, or a fluoroquinolone (ciprofloxacin 500 mg orally twice daily or levofloxacin 500–750 mg orally once daily) is recommended. Agents such as dicloxacillin, cephalexin, erythromycin, and clindamycin should not be used alone because they lack activity against *Pasteurella* species. Doxycycline and TMP-SMZ have poor activity against anaerobes and should only be used in combination with clindamycin. Moxifloxacin, a fluoroquinolone with good aerobic and anaerobic activity, may be suitable as monotherapy.

Because the risk of HIV transmission is so low following a bite, routine postexposure prophylaxis is not recommended. Each case should be evaluated individually and consideration for prophylaxis should be given to those who present within 72 hours of the incident, the source is known to be HIV infected, and the exposure is high risk.

D. Antibiotics for Documented Infection

For wounds that are infected, antibiotics are clearly indicated. How they are given (orally or intravenously) and the need for hospitalization are individualized clinical decisions. The most commonly encountered pathogens are adequately covered by a combination of a β -lactam plus a β -lactamase inhibitor (ampicillin-sulbactam [Unasyn], 1.5–3.0 g intravenously every 6–8 hours; piperacillin-tazobactam [Zosyn], 3.375 g intravenously every 6–8 hours; or amoxicillin-clavulanate [Augmentin], 500 mg orally three times daily) or carbapenems (ertapenem, 1 g intravenously daily; imipenem, 500 mg intravenously every 6–8 hours; meropenem, 1 g intravenously every 8 hours). For the patient with severe penicillin allergy, a combination of clindamycin 600–900 mg intravenously every 8 hours plus a fluoroquinolone (ciprofloxacin, 400 mg intravenously every 12 hours; levofloxacin, 500–750 mg intravenously once daily) or TMP-SMZ (10 mg/kg of trimethoprim daily in two or three divided doses) is indicated. Duration of therapy is usually 2–3 weeks unless complications such as septic arthritis or osteomyelitis are present; if these complications are present, therapy should be extended to 4 and 6 weeks, respectively.

E. Tetanus and Rabies

All patients must be evaluated for the need for tetanus (see Chapter 33) and rabies (see Chapter 32) prophylaxis.

► When to Refer

- If septic arthritis or osteomyelitis is suspected.

- For exposure to bites by dogs, cats, reptiles, amphibians, and rodents.
- When rabies is a possibility.

► When to Admit

- Patients with infected hand bites.
- Deep bites, particularly if over joints.

SEXUALLY TRANSMITTED DISEASES

ESSENTIALS OF DIAGNOSIS

- All sexually transmitted diseases (STDs) have subclinical or latent periods, and patients may be asymptomatic.
- Simultaneous infection with several organisms is common.
- All patients who seek STD testing should be offered HIV screening.
- Partner notification and treatment are important to prevent further transmission and reinfection in the index case.

► General Considerations

The most common STDs are gonorrhea,* syphilis,* human papillomavirus (HPV)-associated condyloma acuminatum, chlamydial genital infections,* herpesvirus genital infections, trichomonas vaginitis, chancroid,* granuloma inguinale, scabies, louse infestation, and bacterial vaginosis (among women who have sex with women). However, shigellosis*; hepatitis A, B, and C*; amebiasis; giardiasis*; cryptosporidiosis*; salmonellosis*; and campylobacteriosis may also be transmitted by sexual (oral-anal) contact, especially in men who have sex with men. Both homosexual and heterosexual contact are risk factors for the transmission of HIV (see Chapter 31). All STDs have subclinical or latent phases that play an important role in long-term persistence of the infection or in its transmission from infected (but largely asymptomatic) persons to other contacts. Simultaneous infection by several different agents is common.

Infections typically present in one of several ways, each of which has a defined differential diagnosis, which should prompt appropriate diagnostic tests.

*Reportable to public health authorities.

A. Genital Ulcers

Potential etiologies include herpes simplex virus, primary syphilis, and chancroid most commonly. Other possibilities include lymphogranuloma venerum (see Chapter 33), granuloma inguinale caused by *Klebsiella granulomatis* (see Chapter 33), as well as lesions caused by infection with Epstein-Barr virus and HIV. Noninfectious causes are Behçet disease (see Chapter 20), neoplasm, trauma, drugs, and irritants.

B. Urethritis with or without Urethral Discharge

The most common infections causing urethral discharge are *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. *N gonorrhoeae* and *C trachomatis* are also frequent causes of prostatitis among sexually active men. Other sexually transmitted infections that can cause urethritis include *Mycoplasma genitalium*, *Ureaplasma urealyticum*, and *Trichomonas vaginalis*. Noninfectious causes of urethritis includes reactive arthritis with associated urethritis (Reiter syndrome).

C. Vaginal Discharge

Common causes of vaginitis are bacterial vaginosis (caused by overgrowth of anaerobes such as *Gardnerella vaginalis*), candidiasis, and *T vaginalis* (see Chapter 18). Less common infectious causes of vaginitis include HPV-associated condyloma acuminata and group A streptococcus. Noninfectious causes are physiologic changes related to the menstrual cycle, irritants, and lichen planus. Even though *N gonorrhoeae* and *C trachomatis* are frequent causes of cervicitis, they rarely produce vaginal discharge.

► Clinical Findings

Any person with an STD should be tested for syphilis; a repeat study should be performed in 3 months if results are negative, since seroconversion is delayed after primary infection. All persons who seek STD testing should also undergo routine screening for HIV infection, using rapid HIV-testing (if patients may not follow-up for results obtained by standard methods) or nucleic acid amplification followed by confirmatory serology (if primary HIV infection may be a possibility) as indicated. Although it is not recommended to perform tests-of-cure for those in whom STDs have been diagnosed and treated, these patients are at a high risk for reinfection and should be encouraged to be rescreened for STDs at 3 months following the initial STD diagnosis.

► Screening & Prevention

Asymptomatic patients often request STD screening at the time of initiating a new sexual relationship. Routine HIV testing and hepatitis B serology testing should be offered to all such patients. In sexually active women who have not been recently screened, cervical Papanicolaou testing and nucleic acid amplification testing of a urine specimen for gonorrhea and chlamydia are recommended. Among men who have sex with men, additional screening is recom-

mended for syphilis; hepatitis A; urethral, pharyngeal, and rectal gonorrhea; as well as urethral and rectal chlamydia. Nucleic acid amplification testing is FDA-cleared for testing urine for gonorrhea or chlamydia. However, the use of nucleic acid amplification testing in the rectum and pharynx has not been validated in many laboratories. The periodicity of screening thereafter depends on sexual risk, but most screening should be offered at least annually to sexually active adults. If not immune, hepatitis B vaccination is recommended for all sexually active adults, and hepatitis A vaccination in men who have sex with men. Girls and women between the ages of 9 and 26 may be offered vaccination against HPV.

The risk of developing an STD following a **sexual assault** has not been established. Victims of assault have a high baseline rate of infection (*N gonorrhoeae*, 6%; *C trachomatis*, 10%; *T vaginalis*, 15%; and bacterial vaginosis, 34%), and the risk of acquiring infection as a result of the assault is significant but is often lower than the preexisting rate (*N gonorrhoeae*, 6–12%; *C trachomatis*, 4–17%; *T vaginalis*, 12%; syphilis, 0.5–3%; and bacterial vaginosis, 19%). Victims should be evaluated within 24 hours after the assault, and cultures or nucleic acid amplification tests for *N gonorrhoeae* and *C trachomatis* should be obtained. Vaginal secretions are cultured and examined for *Trichomonas*. If a discharge is present, if there is itching, or if secretions are malodorous, a wet mount should be examined for *Candida* and bacterial vaginosis. In addition, a blood sample should be obtained for immediate serologic testing for syphilis, hepatitis B, and HIV. Follow-up examination for STD should be repeated within 1–2 weeks, since concentrations of infecting organisms may not have been sufficient to produce a positive test at the time of initial examination. If prophylactic treatment was given (may include postexposure hepatitis B vaccination without hepatitis B immune globulin; treatment for chlamydial, gonorrheal, or trichomonal infection; and emergency contraception), tests should be repeated only if the victim has symptoms. If prophylaxis was not administered, the individual should be seen in 1 week so that any positive tests can be treated. Follow-up serologic testing for syphilis and HIV infection should be performed in 6, 12, and 24 weeks if the initial tests are negative. The usefulness of presumptive therapy is controversial, some feeling that all patients should receive it and others that it should be limited to those in whom follow-up cannot be ensured or to patients who request it.

Although seroconversion to HIV has been reported following sexual assault when this was the only known risk, this risk is believed to be low. The likelihood of HIV transmission from vaginal or anal receptive intercourse when the source is known to be HIV positive is 1 per 1000 and 5 per 1000, respectively. Although prophylactic antiretroviral therapy has not been studied in this setting, the Department of Health and Human Services recommends the prompt institution of postexposure prophylaxis with highly active antiretroviral therapy if the person seeks care within 72 hours of the assault, the source is known to be HIV positive, and the exposure presents a substantial risk of transmission.

In addition to screening asymptomatic patients with STDs, other strategies for preventing further transmission

include evaluating sex partners and administering preexposure vaccination of preventable STDs to individuals at risk; other strategies include the consistent use of male and female condoms. For each patient, there are one or more sexual contacts who require diagnosis and treatment. Prompt treatment of contacts by giving antibiotics to the index case to distribute all sexual contacts (patient-delivered therapy) is an important strategy for preventing further transmission and to prevent reinfection in the index case.

Note that vaginal spermicides and condoms containing nonoxynol-9 provide no additional protection against STDs. Male circumcision has been demonstrated to protect against HIV and HPV acquisition in heterosexual men with HIV-infected partners.

▶ When to Refer

- Patients with a new diagnosis of HIV.
- Patients with persistent, refractory or recurrent STDs, particularly when drug resistance is suspected.

INFECTIONS IN DRUG USERS

ESSENTIALS OF DIAGNOSIS

Common infections that occur with greater frequency in drug users include:

- ▶ Skin infections, aspiration pneumonia, tuberculosis.
- ▶ Hepatitis A, B, C, D; STDs; AIDS.
- ▶ Pulmonary septic emboli, infective endocarditis.
- ▶ Osteomyelitis and septic arthritis.
- ▶ Rare infections in the United States include tetanus, malaria, and melioidosis.

▶ General Considerations

The use of parenterally administered recreational drugs has increased enormously in recent years. There are now

an estimated 300,000 or more injection drug users in the United States.

1. Common Infections That Occur with Greater Frequency in Drug Users

Skin infections are associated with poor hygiene and use of nonsterile technique when injecting drugs. *S aureus* (including community-acquired methicillin-resistant strains) and oral flora (streptococci, *Eikenella*, *Fusobacterium*, *Peptostreptococcus*) are the most common organisms, with enteric gram-negatives generally more likely seen in those who inject into the groin. Cellulitis and subcutaneous abscesses occur most commonly, particularly in association with subcutaneous (“skin-popping”) or intramuscular injections and the use of cocaine and heroin mixtures (probably due to ischemia). Myositis, clostridial myonecrosis, and necrotizing fasciitis occur infrequently but are life-threatening. Wound botulism in association with black tar heroin occurs sporadically but often in clusters.

Aspiration pneumonia and its complications (lung abscess, empyema, brain abscess) result from altered consciousness associated with drug use. Mixed aerobic and anaerobic mouth flora are usually involved.

Tuberculosis also occurs in drug users, and infection with HIV has fostered the spread of tuberculosis in this population. Morbidity and mortality rates are increased in HIV-infected individuals with tuberculosis. Classic radiographic findings are often absent; tuberculosis is suspected in any patient with infiltrates who does not respond to antibiotics.

Hepatitis is very common among habitual drug users and is transmissible both by the parenteral (hepatitis B, C, and D) and by the fecal-oral route (hepatitis A). Multiple episodes of hepatitis with different agents can occur.

Pulmonary septic emboli may originate from venous thrombi or right-sided endocarditis.

STDs are not directly related to drug use, but the practice of exchanging sex for drugs has resulted in an increased frequency of STDs. Syphilis, gonorrhea, and chancroid are the most common.

AIDS has a high incidence among injection drug users and their sexual contacts and among the offspring of infected women (see Chapter 31).

Infective endocarditis in persons who use drugs intravenously is most commonly caused by *S aureus*, *Candida* (usually *C albicans* or *C parapsilosis*), *Enterococcus faecalis*, other streptococci, and gram-negative bacteria (especially *Pseudomonas* and *Serratia marcescens*). See Chapter 33.

Other vascular infections include septic thrombophlebitis and mycotic aneurysms. Mycotic aneurysms resulting from direct trauma to a vessel with secondary infection most commonly occur in femoral arteries and less commonly in arteries of the neck. Aneurysms resulting from hematogenous spread of organisms frequently involve intracerebral vessels and thus are seen in association with endocarditis.

Osteomyelitis and septic arthritis involving vertebral bodies, sternoclavicular joints, the pubic symphysis, the sacroiliac joints, and other sites usually results from hema-

togenous distribution of injected organisms or septic venous thrombi. Pain and fever precede radiographic changes, sometimes by several weeks. While staphylococci—often methicillin-resistant—are common organisms, *Serratia*, *Pseudomonas*, *Candida* (often not *C. albicans*), and other pathogens rarely encountered in spontaneous bone or joint disease are found in injection drug users.

2. Infections Rare in United States

A. Tetanus

In the 1950s and 1960s, tetanus was commonly seen in drug users, especially in unimmunized women who injected drugs subcutaneously (“skin-popping”). Increased tetanus immunization among drug users has resulted in a decline in this disease, although cases are still reported.

B. Malaria

Needle transmission occurs from injection drug users who acquired the infection in malaria-endemic areas outside the United States.

C. Melioidosis

This chronic pulmonary infection caused by *Burkholderia pseudomallei* occurs occasionally in debilitated drug users, but most cases are reported in Asia and Australia.

▶ Treatment

A common and difficult clinical problem is management of the parenteral drug user who presents with fever. In general, after obtaining appropriate cultures (blood, urine, and sputum if the chest radiograph is abnormal), empiric therapy is begun. If the chest radiograph is suggestive of a community-acquired pneumonia (consolidation), therapy for outpatient pneumonia is begun with a third-generation cephalosporin, such as ceftriaxone, 1 g intravenously every 24 hours, plus azithromycin, 500 mg orally or intravenously every 24 hours, or doxycycline, 100 mg orally or intravenously twice daily. If the chest radiograph is suggestive of septic emboli (nodular infiltrates), therapy for presumed endocarditis is initiated, usually with a combination of vancomycin 15 mg/kg/dose every 12 hours intravenously (due to the high prevalence of MRSA and the possibility of enterococcus) and gentamicin, 3 mg/kg/d in two to three doses intravenously. If the chest radiograph is normal and no focal site of infection can be found, endocarditis is presumed. While awaiting the results of blood cultures, empiric treatment with vancomycin and gentamicin is started. If blood cultures are positive for organisms that frequently cause endocarditis in drug users (see above), endocarditis is presumed to be present and treated accordingly. If blood cultures are positive for an organism that is an unusual cause of endocarditis, evaluation for an occult source of infection should go forward. In this setting, a transesophageal echocardiogram may be quite helpful since it is 90% sensitive in detecting vegetations and a negative study is strong evidence against endocarditis. If blood cultures are negative and the patient responds

to antibiotics, therapy should be continued for 7–14 days (oral therapy can be given once an initial response has occurred). In every patient, careful examination for an occult source of infection (eg, genitourinary, dental, sinus, gallbladder) should be done.

▶ When to Refer

- Any patient with suspected or proven infective endocarditis.
- Patients with persistent bacteremia.

▶ When to Admit

- Injection drug users with fever.
- Patients with abscesses or progressive skin and soft tissue infection that require debridement.

ACUTE INFECTIOUS DIARRHEA

ESSENTIALS OF DIAGNOSIS

- ▶ Diarrhea is acute if lasts < 2 weeks and chronic if lasts > 2 weeks.
- ▶ Disease is mild if there are three or fewer stools per day, moderate if there are four or more stools in association with local symptoms (abdominal cramps, nausea, tenesmus), and severe if there are four or more stools per day with systemic symptoms (fevers, chills, dehydration).

▶ General Considerations

Acute diarrhea can be caused by a number of different factors, including emotional stress, food intolerance, inorganic agents (eg, sodium nitrite), organic substances (eg, mushrooms, shellfish), drugs, and infectious agents (including viruses, bacteria, and protozoa) (Table 30–3). From a diagnostic and therapeutic standpoint, it is helpful to classify infectious diarrhea into syndromes that produce inflammatory or bloody diarrhea and those that are noninflammatory, nonbloody, or watery. In general, the term “inflammatory diarrhea” suggests colonic involvement by invasive bacteria or parasites or by toxin production. Patients complain of frequent bloody, small-volume stools, often associated with fever, abdominal cramps, tenesmus, and fecal urgency. Common causes of this

Table 30-3. Acute bacterial diarrheas and “food poisoning.”

| Organism | Incubation Period | Vomiting | Diarrhea | Fever | Associated Foods | Diagnosis | Clinical Features and Treatment |
|---|--|----------|----------|-------|---|--|--|
| <i>Staphylococcus</i> (preformed toxin) | 1-8 hours | +++ | ± | ± | Staphylococci grow in meats, dairy, and bakery products and produce enterotoxin. | Clinical. Food and stool can be tested for toxin. | Abrupt onset, intense nausea and vomiting for up to 24 hours, recovery in 24-48 hours. Supportive care. |
| <i>Bacillus cereus</i> (preformed toxin) | 1-8 hours | +++ | ± | - | Reheated fried rice causes vomiting or diarrhea. | Clinical. Food and stool can be tested for toxin. | Acute onset, severe nausea and vomiting lasting 24 hours. Supportive care. |
| <i>B. cereus</i> (diarrheal toxin) | 10-16 hours | ± | +++ | - | Toxin in meats, stews, and gravy. | Clinical. Food and stool can be tested for toxin. | Abdominal cramps, watery diarrhea, and nausea lasting 24-48 hours. Supportive care. |
| <i>Clostridium perfringens</i> | 8-16 hours | ± | +++ | - | Clostridia grow in rewarmed meat and poultry dishes and produce an enterotoxin. | Stools can be tested for enterotoxin or cultured. | Abrupt onset of profuse diarrhea, abdominal cramps, nausea; vomiting occasionally. Recovery usual without treatment in 24-48 hours. Supportive care; antibiotics not needed. |
| <i>Clostridium botulinum</i> | 12-72 hours | ± | - | - | Clostridia grow in anaerobic acidic environment eg, canned foods, fermented fish, foods held warm for extended periods. | Stool, serum, and food can be tested for toxin. Stool and food can be cultured. | Diplopia, dysphagia, dysphonia, respiratory embarrassment. Treatment requires clear airway, ventilation, and intravenous polyvalent antitoxin (see text). Symptoms can last for days to months. |
| <i>Clostridium difficile</i> | Usually occurs after 7-10 days of antibiotics. Can occur after a single dose or several weeks after completion of antibiotics. | - | +++ | ++ | Associated with antimicrobial drugs; clindamycin and cephalosporins most commonly implicated. | Stool tested for toxin. | Abrupt onset of diarrhea that may be bloody; fever. Oral metronidazole first-line therapy. If no response, oral vancomycin can be given. |
| Enterohemorrhagic <i>Escherichia coli</i> , including <i>E. coli</i> O157:H7 and other Shiga-toxin producing strains (STEC) | 1-8 days | + | +++ | - | Undercooked beef, especially hamburger; unpasteurized milk and juice; raw fruits and vegetables. | <i>E. coli</i> O157:H7 can be cultured on special medium. Other toxins can be detected in stool. | Usually abrupt onset of diarrhea, often bloody; abdominal pain. In adults, it is usually self-limited to 5-10 days. In children, it is associated with hemolytic-uremic syndrome (HUS). Antibiotic therapy may increase risk of HUS. |
| Enterotoxigenic <i>E. coli</i> (ETEC) | 1-3 days | ± | +++ | ± | Water, food contaminated with feces. | Stool culture. Special tests required to identify toxin-producing strains. | Watery diarrhea and abdominal cramps, usually lasting 3-7 days. In travelers, fluoroquinolones shorten disease. |
| <i>Vibrio parahaemolyticus</i> | 2-48 hours | + | + | ± | Undercooked or raw seafood. | Stool culture on special medium. | Abrupt onset of watery diarrhea, abdominal cramps, nausea and vomiting. Recovery is usually complete in 2-5 days. |

| | | | | | | | |
|--------------------------------------|-------------|----|-----|---|---|--|---|
| <i>Vibrio cholerae</i> | 24-72 hours | + | +++ | - | Contaminated water, fish, shellfish, street vendor food. | Stool culture on special medium. | Abrupt onset of liquid diarrhea in endemic area. Needs prompt intravenous or oral replacement of fluids and electrolytes. Tetracyclines shorten excretion of vibrios. |
| <i>Campylobacter jejuni</i> | 2-5 days | ± | +++ | + | Raw or undercooked poultry, unpasteurized milk, water. | Stool culture on special medium. | Fever, diarrhea that can be bloody, cramps. Usually self-limited in 2-10 days. Early treatment (erythromycin) shortens course. May be associated with Guillain-Barré syndrome. |
| <i>Shigella</i> species (mild cases) | 24-48 hours | ± | + | + | Food or water contaminated with human feces. Person to person spread. | Routine stool culture. | Abrupt onset of diarrhea, often with blood and pus in stools, cramps, tenesmus, and lethargy. Stool cultures are positive. Therapy depends on sensitivity testing, but the fluoroquinolones are most effective. Do not give opioids. Often mild and self-limited. |
| <i>Salmonella</i> species | 1-3 days | - | ++ | + | Eggs, poultry, unpasteurized milk, cheese, juices, raw fruits and vegetables. | Routine stool culture. | Gradual or abrupt onset of diarrhea and low-grade fever. No antimicrobials unless high risk (see text) or systemic dissemination is suspected, in which case give a fluoroquinolone. Prolonged carriage can occur. |
| <i>Yersinia enterocolitica</i> | 24-48 hours | ± | + | + | Undercooked pork, contaminated water, unpasteurized milk, tofu. | Stool culture on special medium. | Severe abdominal pain, (appendicitis-like symptoms) diarrhea, fever. Polyarthritits, erythema nodosum in children. If severe, give tetracycline or fluoroquinolone. Without treatment, self-limited in 1-3 weeks. |
| Rotavirus | 1-3 days | ++ | +++ | + | Fecally contaminated foods touched by infected food handlers. | Immunoassay on stool. | Acute onset, vomiting, watery diarrhea that lasts 4-8 days. Supportive care. |
| Noroviruses and other caliciviruses | 12-48 hours | ++ | +++ | + | Shell fish and fecally contaminated foods touched by infected food handlers. | Clinical diagnosis with negative stool cultures. PCR available on stool. | Nausea, vomiting (more common in children) diarrhea (more common in adults), fever, myalgias, abdominal cramps. Lasts 12-60 hours. Supportive care. |

PCR, polymerase chain reaction.

syndrome include *Shigella*, *Salmonella*, *Campylobacter*, *Yersinia*, invasive strains of *Escherichia coli*, *E coli* O157:H7, *Entamoeba histolytica*, and *C difficile*. Tests for fecal leukocytes or the neutrophil marker lactoferrin are frequently positive, and definitive etiologic diagnosis requires stool culture. Non-inflammatory diarrhea is generally milder and is caused by viruses or toxins that affect the small intestine and interfere with salt and water balance, resulting in large-volume watery diarrhea, often with nausea, vomiting, and cramps. Common causes of this syndrome include viruses (eg, rotavirus, Norwalk virus, enteric adenoviruses, astrovirus, coronavirus), vibrios (*Vibrio cholerae*, *Vibrio parahaemolyticus*), enterotoxin-producing *E coli*, *Giardia lamblia*, cryptosporidia, and agents that can cause food-borne gastroenteritis.

The term “food poisoning” denotes diseases caused by toxins present in consumed foods. When the incubation period is short (1–6 hours after consumption), the toxin is usually preformed. Vomiting is usually a major complaint, and fever is usually absent. Examples include intoxication from *S aureus* or *Bacillus cereus*, and toxin can be detected in the food. When the incubation period is longer—between 8 hours and 16 hours—the organism is present in the food and produces toxin after being ingested. Vomiting is less prominent, abdominal cramping is frequent, and fever is often absent. The best example of this disease is that due to *Clostridium perfringens*. Toxin can be detected in food or stool specimens.

The inflammatory and noninflammatory diarrheas discussed above can also be transmitted by food and water and usually have incubation periods between 12 and 72 hours. *Cyclospora*, cryptosporidia, and *Isospora* are protozoans capable of causing disease in both immunocompetent and immunocompromised patients. Characteristics of disease include profuse watery diarrhea that is prolonged but usually self-limited (1–2 weeks) in the immunocompetent patient but can be chronic in the compromised host. Epidemiologic features may be helpful in determining etiology. Recent hospitalization or antibiotic use suggests *C difficile*; recent foreign travel suggests *Salmonella*, *Shigella*, *Campylobacter*, *E coli*, or *V cholerae*; undercooked hamburger suggests *E coli*, especially O157:H7; and fried rice consumption is associated with *B cereus* toxin. Prominent features of some of these causes of diarrhea are listed in Table 30–3.

▶ Treatment

Treatment usually consists of replacement of fluids and electrolytes and, very rarely, management of hypovolemic shock and respiratory compromise. In mild diarrhea, increasing ingestion of juices and clear soups is adequate. In more severe cases of dehydration (postural lightheadedness, decreased urination), oral glucose-based rehydration solutions can be used (Ceralyte, Pedialyte). In general, most cases of acute gastroenteritis are self-limited and do not require therapy other than supportive measures. When symptoms persist beyond 3–4 days, initial presentation is accompanied by fever or bloody diarrhea, or if the patient is immunocompromised, cultures of stool are usually obtained. Symptoms have often resolved by the time cultures are completed. In this case, even if a pathogen is isolated, therapy is not needed (except for *Shigella*, since the infecting dose is so small that

therapy to eradicate organisms from the stool is indicated for epidemiologic reasons). If symptoms persist and a pathogen is isolated, it is reasonable to institute specific treatment even though therapy has not been conclusively shown to alter the natural history of disease for most pathogens. Exceptions include infection with *Shigella* where antibiotic therapy has been shown to shorten the duration of symptoms by 2–3 days, infections with *E coli* O157:H7 (antibiotic therapy does not ameliorate symptoms and may increase the risk of developing hemolytic-uremic syndrome), and *Campylobacter* infections (early therapy, within 4 days of onset of symptoms, shortens the course of disease). Uncomplicated gastroenteritis due to *Salmonella* does not require therapy because the disease is usually self-limited and therapy may prolong carriage and perhaps increase relapses. Because bacteremia with complications can occur in high-risk patients, some experts have recommended therapy for *Salmonella* in patients over the age of 50, in organ transplant recipients, in those with HIV, in patients taking corticosteroids, in those with lymphoproliferative diseases, and in those with vascular grafts. Ciprofloxacin, 500 mg every 12 hours for 5 days, is effective in shortening the course of illness compared with placebo in patients presenting with diarrhea, whether a pathogen is isolated or not. However, because of concerns about selecting for resistant organisms (especially *Campylobacter*, where increasing resistance to fluoroquinolones has been documented and erythromycin is the drug of choice) coupled with the fact that most infectious diarrhea is self-limited, routine use of antibiotics for all patients with diarrhea is not recommended. Antibiotics should be considered in patients with evidence of invasive disease (white cells in stool, dysentery), with symptoms 3–4 days or more in duration, with multiple stools (eight to ten or more per day), and in those with impaired immune responses. Antimotility drugs are useful in mild cases. Their use should be limited to patients without fever and without dysentery (bloody stools), and they should be used in low doses because of the risk of producing toxic megacolon.

Therapeutic recommendations for specific agents can be found elsewhere in this book.

INFECTIOUS DISEASES IN THE RETURNING TRAVELER

ESSENTIALS OF DIAGNOSIS

- ▶ Most infections are common and self-limited.

- ▶ Identify patients with transmissible diseases that require isolation.
- ▶ The incubation period may be helpful in diagnosis.
- ▶ Less than 3 weeks following exposure may suggest dengue, leptospirosis and yellow fever; greater than 3 weeks suggest typhoid fever, malaria, and tuberculosis.

▶ General Considerations

The differential diagnosis of fever in the returning traveler is broad, ranging from self-limited viral infections to life-threatening illness. The evaluation is best done by identifying whether a particular syndrome is present, then refining the differential diagnosis based on an exposure history. The travel history should include directed questions regarding geography (rural versus urban), animal or arthropod contact, unprotected sexual intercourse, ingestion of untreated water or raw foods, historical or pretravel immunizations, and adherence to malaria prophylaxis.

▶ Etiologies

The most common infectious causes of fever—excluding simple causes such as upper respiratory infections, bacterial pneumonia and urinary tract infections—in returning travelers are malaria (see Chapter 35), diarrhea (see next section), and dengue (see Chapter 32). Others include respiratory infections, leptospirosis (see Chapter 34), typhoid fever (see Chapter 33), and rickettsial infections (see Chapter 32). Systemic febrile illnesses without a diagnosis also occurs commonly, particularly in travelers returning from sub-Saharan Africa or Southeast Asia.

A. Fever and Rash

Potential etiologies include dengue, Chikungunya, viral hemorrhagic fever, leptospirosis, meningococemia, yellow fever, typhus, *Salmonella typhi*, and acute HIV infection.

B. Pulmonary Infiltrates

Tuberculosis, ascaris, *Paragonimus*, and *Strongyloides* can all cause pulmonary infiltrates.

C. Meningoencephalitis

Etiologies include *N meningitidis*, leptospirosis, arboviruses, rabies, and (cerebral) malaria.

D. Jaundice

Consider hepatitis A, yellow fever, hemorrhagic fever, leptospirosis, and malaria.

E. Fever without Localizing Symptoms or Signs

Malaria, typhoid fever, acute HIV infection, rickettsial illness, visceral leishmaniasis, trypanosomiasis, and dengue are possible etiologies.

F. Traveler's Diarrhea

See next section.

▶ Clinical Findings

Fever and rash in the returning traveler should prompt blood cultures and various serologic tests based on the exposure history. The work-up of a pulmonary infiltrate should include the placement of a PPD, examination of sputum for acid-fast bacilli and possibly for ova and parasites. Patients with evidence of meningoencephalitis should receive lumbar puncture, blood cultures, thick/thin smears of peripheral blood, history-guided serologies, and a nape biopsy (if rabies is suspected). Jaundice in a returning traveler should be evaluated for hemolysis, and the following tests should be performed: liver function tests, thick/thin smears of peripheral blood, and directed serologic testing. The work-up of traveler's diarrhea is presented in the following section. Finally, patients with fever but no localizing signs or symptoms should have blood cultures performed. Routine laboratory studies usually include complete blood count with differential, electrolytes, liver function tests, urine analysis, and blood cultures. Thick and thin peripheral blood smears should be done (and repeated in 12–24 hours if clinical suspicion remains high) for malaria if there has been travel to endemic areas. Other studies are directed by the results of history, physical examination, and initial laboratory tests. They may include stool for ova and parasites, chest radiograph, HIV test, and specific serologies (eg, dengue, leptospirosis, rickettsial disease, schistosomiasis, *Strongyloides*). Bone marrow biopsy to diagnose typhoid fever could be helpful in the appropriate patient.

▶ When to Refer

Travelers with fever, particularly if immunocompromised.

▶ When to Admit

Any evidence of hemorrhage, respiratory distress, hemodynamic instability, and neurologic deficits.

TRAVELER'S DIARRHEA

ESSENTIALS OF DIAGNOSIS

- ▶ Usually a benign, self-limited disease occurring about 1 week into travel.

- ▶ Prophylaxis not recommended unless there is a comorbid disease (inflammatory bowel syndrome, HIV, immunosuppressive medication).
- ▶ Single-dose therapy of a fluoroquinolone usually effective if significant symptoms develop.

▶ General Considerations

Whenever a person travels from one country to another—particularly if the change involves a marked difference in climate, social conditions, or sanitation standards and facilities—diarrhea may develop within 2–10 days. Bacteria cause 80% of cases of traveler's diarrhea, with enterotoxigenic *E coli*, *Shigella* species, and *Campylobacter jejuni* being the most common pathogens. Less common are *Aeromonas*, *Salmonella*, noncholera vibrios, *E histolytica*, and *G lamblia*. Contributory causes include unusual food and drink, change in living habits, occasional viral infections (adenoviruses or rotaviruses), and change in bowel flora. Chronic watery diarrhea may be due to amebiasis or giardiasis or, rarely, tropical sprue.

▶ Clinical Findings

A. Symptoms and Signs

There may be up to ten or even more loose stools per day, often accompanied by abdominal cramps and nausea, occasionally by vomiting, and rarely by fever. The stools are usually watery and not associated with fever when caused by enterotoxigenic *E coli*. With invasive bacterial pathogens (*Shigella*, *Campylobacter*, *Salmonella*) stools can be bloody and fever may be present. The illness usually subsides spontaneously within 1–5 days, although 10% remain symptomatic for 1 week or longer, and symptoms persist for longer than 1 month in 2%. Traveler's diarrhea is also a significant risk factor for developing irritable bowel syndrome.

B. Laboratory Findings

In patients with fever and bloody diarrhea, stool culture is indicated, but in most cases, cultures are reserved for those who do not respond to antibiotics.

▶ Prevention

A. General Measures

Avoidance of fresh foods and water sources that are likely to be contaminated is recommended for travelers to developing countries, where infectious diarrheal illnesses are endemic.

B. Specific Measures

Prophylaxis is recommended for those with significant underlying disease (inflammatory bowel disease, AIDS, diabetes, heart disease in the elderly, conditions requiring immunosuppressive medications) and for those whose full activity status during the trip is so essential that even short periods of diarrhea would be unacceptable. Prophylaxis is started upon entry into the destination country and is

continued for 1 or 2 days after leaving. For stays of more than 3 weeks, prophylaxis is not recommended because of the cost and increased toxicity. For prophylaxis, numerous oral antimicrobial once-daily regimens are effective, such as norfloxacin, 400 mg; ciprofloxacin, 500 mg; or rifaximin, 200 mg. Bismuth subsalicylate is effective but turns the tongue and the stools black and can interfere with doxycycline absorption, which may be needed for malaria prophylaxis; it is rarely used.

Because not all travelers will have diarrhea and because most episodes are brief and self-limited, an alternative approach currently recommended is to provide the traveler with a supply of antimicrobials to be taken if significant diarrhea occurs during the trip. In areas where toxin-producing bacteria are the major cause of diarrhea (Latin America and Africa), loperamide (4 mg oral loading dose, then 2 mg after each loose stool to a maximum of 16 mg/d) with a single oral dose of ciprofloxacin (750 mg), levofloxacin (500 mg), or ofloxacin (200 mg), cures most cases of traveler's diarrhea. If diarrhea is associated with bloody stools or persists despite a single dose of a fluoroquinolone, 1000 mg of azithromycin should be taken. In pregnant women and in areas where invasive bacteria more commonly cause diarrhea (Indian subcontinent, Asia, especially Thailand where fluoroquinolone-resistant *Campylobacter* is prevalent), azithromycin is the drug of choice. Rifaximin, a nonabsorbable agent, is also approved for therapy of traveler's diarrhea at a dose of 200 mg orally three times per day or 400 mg twice a day for 3 days. Because luminal concentrations are high, but tissue levels are insufficient, it should not be used in situations where there is a high likelihood of invasive disease (eg, fever, systemic toxicity, or bloody stools).

▶ Treatment

For most individuals, the affliction is short-lived, and symptomatic therapy with loperamide is all that is required, provided the patient is not systemically ill (fever ≥ 39 °C) and does not have dysentery (bloody stools), in which case antimotility agents should be avoided. Packages of oral rehydration salts to treat dehydration are available over the counter in the United States (Infalyte, Pedialyte, others) and in many foreign countries.

▶ When to Refer

- Cases refractory to treatment.
- Persistent infection.
- Immunocompromised patient.

▶ When to Admit

Patients who are severely dehydrated or hemodynamically unstable should be admitted to the hospital.

ANTIMICROBIAL THERAPY

SELECTED PRINCIPLES OF ANTIMICROBIAL THERAPY

Specific steps (outlined below) are required when considering antibiotic therapy for patients. Drugs within classes, drugs of first choice, and alternative drugs are presented in Tables 30–4, 30–5, 30–6, 30–7, and 30–8.

A. Etiologic Diagnosis

Based on the organ system involved, the organism causing infection can often be predicted. See Tables 30–9 and 30–10.

B. “Best Guess”

Select an empiric regimen that is likely to be effective against the suspected pathogens.

C. Laboratory Control

Specimens for laboratory examination should be obtained before institution of therapy to determine susceptibility.

D. Clinical Response

Based on clinical response and other data, the laboratory reports are evaluated and then the desirability of changing the regimen is considered. If the specimen was obtained from a normally sterile site (eg, blood, cerebrospinal fluid, pleural fluid, joint fluid), the recovery of a microorganism in significant amounts is meaningful even if the organism recovered is different from the clinically suspected agent, and this may force a change in treatment. Isolation of unexpected microorganisms from the respiratory tract, gastrointestinal tract, or surface lesions (sites that have a complex flora) may represent colonization or contamination, and cultures must be critically evaluated before drugs are abandoned that were judiciously selected on a “best guess” basis.

E. Drug Susceptibility Tests

Some microorganisms are predictably inhibited by certain drugs; if such organisms are isolated, they need not be tested for drug susceptibility. For example, all group A hemolytic streptococci are inhibited by penicillin. Other organisms (eg, enteric gram-negative rods) are variably susceptible and generally require susceptibility testing whenever they are isolated. Organisms that once had predictable susceptibility patterns have now become resistant and require testing. Examples include the pneumococci, which may be resistant to multiple drugs (including penicillin, macrolides, and TMP-SMZ); the enterococci, which may be resistant to penicillin, aminoglycosides, and

vancomycin; and extended-spectrum β -lactamase producing-*E coli* resistant to third-generation cephalosporins and fluoroquinolones.

Over the past 10 years, pharmaceutical companies have shifted away from developing and producing antibacterial medications, particularly those active against gram-negative pathogens. The lack of new drugs and increasing bacterial resistance reinforce the need to use these drugs judiciously.

Antimicrobial drug susceptibility tests may be performed on solid media as disk diffusion tests, in broth in tubes, in wells of microdilution plates, or as E-tests (strips with increasing concentration of antibiotic). The latter three methods yield results expressed as MIC (minimal inhibitory concentration), and the broth and microdilution techniques can be modified to give MBC (minimal bactericidal concentration) results. In most infections, the MIC is the appropriate in vitro test to guide selection of an antibacterial agent. When there appear to be marked discrepancies between susceptibility testing and clinical response, the following possibilities must be considered:

1. Selection of an inappropriate drug, drug dosage, or route of administration.
2. Failure to drain a collection of pus or to remove a foreign body.
3. Failure of a poorly diffusing drug to reach the site of infection (eg, central nervous system) or to reach intracellular phagocytosed bacteria.
4. Superinfection in the course of prolonged chemotherapy.
5. Emergence of drug-resistant organisms.
6. Participation of two or more microorganisms in the infectious process, of which only one was originally detected and used for drug selection.
7. Inadequate host defenses, including immunodeficiencies and diabetes.
8. Noninfectious causes, including drug fever, malignancy, and autoimmune disease.

F. Promptness of Response

Response depends on a number of factors, including the patient (immunocompromised patients respond slower than immunocompetent patients), the site of infection (deep-seated infections such as osteomyelitis and endocarditis respond more slowly than superficial infections such as cystitis or cellulitis), the pathogen (virulent organisms such as *S aureus* respond more slowly than viridans streptococci; mycobacterial and fungal infections respond slower than bacterial infections), and the duration of illness (in general, the longer the symptoms are present, the longer it takes to respond). Thus, depending on the clinical situation, persistent fever and leukocytosis several days after initiation of therapy may not indicate improper choice of antibiotics but may be due to the natural history of the disease being treated. In most infections, either a bacteriostatic or a bactericidal agent can be used. In some infections (eg, infective endocarditis and meningitis), a bactericidal agent should be used. When potentially toxic drugs (eg, aminoglycosides, flucytosine) are used, serum levels of the drug are measured

Table 30-4. Drugs of choice for suspected or proved microbial pathogens, 2009.¹

| Suspected or Proved Etiologic Agent | Drug(s) of First Choice | Alternative Drug(s) |
|--|--|---|
| Gram-negative cocci | | |
| <i>Moraxella catarrhalis</i> | TMP-SMZ, ² a fluoroquinolone ³ | Cefuroxime, cefotaxime, ceftriaxone, cefuroxime axetil, an erythromycin, ⁴ a tetracycline, ⁵ azithromycin, amoxicillin-clavulanic acid, clarithromycin |
| <i>Neisseria gonorrhoeae</i> (gonococcus) | Cefixime, ceftriaxone | Cefpodoxime proxetil |
| <i>Neisseria meningitidis</i> (meningococcus) | Penicillin ⁶ | Cefotaxime, ceftriaxone, ampicillin |
| Gram-positive cocci | | |
| <i>Streptococcus pneumoniae</i> ⁸ (pneumococcus) | Penicillin ⁶ | An erythromycin, ⁴ a cephalosporin, ⁷ vancomycin, TMP-SMZ, ² clindamycin, azithromycin, clarithromycin, a tetracycline, ⁵ certain fluoroquinolones ³ |
| <i>Streptococcus</i> , hemolytic, groups A, B, C, G | Penicillin ⁶ | An erythromycin, ⁴ a cephalosporin, ⁷ vancomycin, clindamycin, azithromycin, clarithromycin |
| Viridans streptococci | Penicillin ⁶ ± gentamicin | Cephalosporin, ⁷ vancomycin |
| <i>Staphylococcus</i> , methicillin-resistant | Vancomycin ± gentamicin | TMP-SMZ, ² doxycycline, minocycline, a fluoroquinolone, ³ linezolid, daptomycin, quinupristin-dalfopristin |
| <i>Staphylococcus</i> , non-penicillinase-producing | Penicillin ⁶ | A cephalosporin, ⁸ clindamycin |
| <i>Staphylococcus</i> , penicillinase-producing | Penicillinase-resistant penicillin ⁹ | Vancomycin, a cephalosporin, ⁷ clindamycin, amoxicillin-clavulanic acid, ampicillin-sulbactam, piperacillin-tazobactam, TMP-SMZ ² |
| <i>Enterococcus faecalis</i> | Ampicillin ± gentamicin ¹⁰ | Vancomycin ± gentamicin |
| <i>Enterococcus faecium</i> | Vancomycin ± gentamicin ¹⁰ | Linezolid, quinupristin-dalfopristin, daptomycin |
| Gram-negative rods | | |
| <i>Acinetobacter</i> | Imipenem, meropenem | Tigecycline, minocycline, doxycycline, aminoglycosides, ¹¹ colistin |
| <i>Prevotella</i> , oropharyngeal strains | Clindamycin | Metronidazole |
| <i>Bacteroides</i> , gastrointestinal strains | Metronidazole | Clindamycin, ampicillin-sulbactam, piperacillin-tazobactam |
| <i>Brucella</i> | Tetracycline + rifampin ⁵ | TMP-SMZ ² ± gentamicin; chloramphenicol ± gentamicin; doxycycline ± gentamicin |
| <i>Campylobacter jejuni</i> | Erythromycin ⁴ or azithromycin | Tetracycline, ⁵ a fluoroquinolone ³ |
| <i>Enterobacter</i> | TMP-SMZ, ² imipenem, meropenem | Aminoglycoside, a fluoroquinolone, ³ cefepime |
| <i>Escherichia coli</i> (sepsis) | Cefotaxime, ceftriaxone, | Imipenem or meropenem, aminoglycosides, ¹¹ a fluoroquinolone ³ |
| <i>Escherichia coli</i> (uncomplicated outpatient urinary infection) | Fluoroquinolones, ³ nitrofurantoin | TMP-SMZ, ² oral cephalosporin |
| <i>Haemophilus</i> (meningitis and other serious infections) | Cefotaxime, ceftriaxone | Aztreonam |
| <i>Haemophilus</i> (respiratory infections, otitis) | TMP-SMZ ² | Ampicillin, amoxicillin, doxycycline, azithromycin, clarithromycin, cefotaxime, ceftriaxone, cefuroxime, cefuroxime axetil, ampicillin-clavulanate |
| <i>Helicobacter pylori</i> | Amoxicillin + clarithromycin + proton pump inhibitor (PPI) | Bismuth subsalicylate + tetracycline + metronidazole + PPI |
| <i>Klebsiella</i> | A cephalosporin | TMP-SMZ, ² aminoglycoside, ¹¹ imipenem or meropenem, a fluoroquinolone, ³ aztreonam |
| <i>Legionella</i> species (pneumonia) | Erythromycin ⁴ or clarithromycin or azithromycin, or fluoroquinolones ³ ± rifampin | Doxycycline ± rifampin |
| <i>Proteus mirabilis</i> | Ampicillin | An aminoglycoside, ¹¹ TMP-SMZ, ² a fluoroquinolone, ³ a cephalosporin ⁷ |

Table 30–4. Drugs of choice for suspected or proved microbial pathogens, 2009.¹ (continued)

| Suspected or Proved Etiologic Agent | Drug(s) of First Choice | Alternative Drug(s) |
|-------------------------------------|--------------------------|--|
| <i>C pneumoniae</i> | Doxycycline ⁵ | Erythromycin, ⁴ clarithromycin, azithromycin, a fluoroquinolone ^{3,14} |
| Rickettsiae | Doxycycline ⁵ | Chloramphenicol, a fluoroquinolone ³ |

¹Adapted, with permission, from Treat Guide Med Lett. 2007 May;5(57):33–50.

²TMP-SMZ is a mixture of 1 part trimethoprim and 5 parts sulfamethoxazole.

³Fluoroquinolones include ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin, and others (see text). Gemifloxacin, levofloxacin, and moxifloxacin have the best activity against gram-positive organisms, including penicillin-resistant *S pneumoniae* and methicillin-sensitive *S aureus*. Activity against enterococci and *S epidermidis* is variable.

⁴Erythromycin estolate is best absorbed orally but carries the highest risk of hepatitis; erythromycin stearate and erythromycin ethylsuccinate are also available.

⁵All tetracyclines have similar activity against most microorganisms. Minocycline and doxycycline have increased activity against *S aureus*.

⁶Penicillin G is preferred for parenteral injection; penicillin V for oral administration—to be used only in treating infections due to highly sensitive organisms.

⁷Most intravenous cephalosporins (with the exception of ceftazidime) have good activity against gram-positive cocci.

⁸Infections caused by isolates with intermediate resistance may respond to high doses of penicillin, cefotaxime, or ceftriaxone. Infections caused by highly resistant strains should be treated with vancomycin. Many strains of penicillin-resistant pneumococci are resistant to macrolides, cephalosporins, tetracyclines, and TMP-SMZ.

⁹Parenteral nafcillin or oxacillin; oral dicloxacillin, cloxacillin, or oxacillin.

¹⁰Addition of gentamicin indicated only for severe enterococcal infections (eg, endocarditis, meningitis).

¹¹Aminoglycosides—gentamicin, tobramycin, amikacin, netilmicin—should be chosen on the basis of local patterns of susceptibility.

¹²Antipseudomonal penicillins: ticarcillin, piperacillin.

¹³Resistance is common and susceptibility testing should be done.

¹⁴Ciprofloxacin has inferior antichlamydial activity compared with newer fluoroquinolones.

Key: ±, alone or combined with.

to minimize toxicity and ensure appropriate dosage. In patients with altered renal or hepatic clearance of drugs, the dosage or frequency of administration must be adjusted; it is best to measure levels in the elderly, morbidly obese patients, or those with altered kidney function when possible and adjust therapy accordingly.

In kidney disease or liver failure, the dosage should be adjusted as shown in Table 30–11.

G. Duration of Antimicrobial Therapy

Generally, effective antimicrobial treatment results in reversal of the clinical and laboratory parameters of active

infection and marked clinical improvement. However, varying periods of treatment may be required for cure. Key factors include (1) the type of infecting organism (bacterial infections generally can be cured more rapidly than fungal or mycobacterial ones), (2) the location of the process (eg, endocarditis and osteomyelitis require prolonged therapy), and (3) the immunocompetence of the patient. Recommendations about duration of therapy are often given based on clinical experience, not prospective controlled studies of large numbers of patients.

H. Adverse Reactions and Toxicity

These include hypersensitivity reactions, direct toxicity, superinfection by drug-resistant microorganisms, and drug interactions. If the infection is life-threatening and treatment cannot be stopped, the reactions are managed symptomatically or another drug is chosen that does not cross-react with the offending one (Table 30–4). If the infection is less serious, it may be possible to stop all antimicrobials and monitor the patient closely.

I. Route of Administration

Parenteral therapy is preferred for acutely ill patients with serious infections (eg, endocarditis, meningitis, sepsis, severe pneumonia) when dependable levels of antibiotics are required for successful therapy. Certain drugs (eg, fluconazole, voriconazole, rifampin, metronidazole, TMP-SMZ, and fluoroquinolones) are so well absorbed that they generally can be administered orally in seriously ill—but not hemodynamically unstable—patients.

Table 30–5. Major groups of cephalosporins.

| First Generation | Second Generation | Third Generation | Fourth Generation |
|--|---|---|-------------------|
| Cephalothin Cephapirin Cefazolin Cephalexin ¹ Cephadrine ¹ Cefadroxil | Cefamandole Cefuroxime Cefotetan Cefaclor ¹ Cefoxitin Cefprozil ¹ Cefuroxime axetil ¹ | Cefotaxime Ceftizoxime Ceftriaxone Ceftazidime Cefoperazone Cefpodoxime proxitel ¹ Ceftibuten ¹ Cefdinir ¹ Cefditoren pivoxil ¹ | Cefepime |

¹Oral agents.

Food does not significantly influence the bioavailability of most oral antimicrobial agents. However, the tetracyclines and the quinolones chelate heavy metals resulting in decreased antibacterial absorption. Azithromycin capsules

are associated with decreased bioavailability when taken with food and should be given 1 hour before or 2 hours after meals. Posaconazole solution should always be administered with food.

Table 30-6. Pharmacology of the cephalosporins.

| Drug | Peak Serum Level (mcg/mL) after 1 g IV | Serum Half-Life (min) | Total Daily Dose (mg/kg) | Dosage Interval (hrs) | Dosage Adjustments in Kidney Disease | | |
|-------------------------------------|--|-----------------------|--------------------------|-----------------------|--|---------------------------------------|------------------------|

¹Oral agents. Serum levels based on 0.5 g oral dose.

Table 30-7. Dosing of aminoglycosides.¹

| Drug (IV) | Creatinine Clearance (mL/min) | | | | |
|------------------------------------|-------------------------------|--------------------|--------------------|-----------------------|--|
| | > 80 | 60-80 | 40-60 | 20-40 | < 20 |
| Gentamicin, tobramycin, netilmicin | 5 mg/kg q24h | 1.5-2.5 mg/kg q12h | 1.2-1.5 mg/kg q24h | 1.2-1.5 mg/kg q12-24h | 2 mg/kg as loading dose and then 1-1.5 mg/kg q24-48h |
| Amikacin | 15 mg/kg q24h | 4.5-7.5 mg/kg q12h | 3.5-4.5 mg/kg q12h | 3.5-4.5 mg/kg q12-24h | 7.5 mg/kg as loading dose and then 3-4.5 mg/kg q24-48h |

¹Traditional dosing should be guided by serum level measurements (peaks 30 minutes after the end of intravenous infusion and troughs ≤ 30 minutes before the next dose). When a single large daily dose is given, peak levels are not required. Trough levels should be undetectable with high-dose (5 mg/kg) once-daily gentamicin or amikacin. For those patients with creatinine clearances less than 80 mL/min, the dosage ranges in the table are used to treat gram-negative infections and are intended to achieve, for gentamicin, tobramycin, and netilmicin, peak levels of 6-10 mg/L and trough levels of ≤ 2 mg/L; for amikacin, peak levels of 20-30 mg/L and trough levels of ≤ 5 mg/L. (See text.)

Table 30–8. Pharmacology of the quinolones.

| Drug | Peak Serum Levels (mcg/mL) | Serum Half-Life (h) | Total Daily Dose | Dosage Adjustments in Kidney Disease | | | |
|---------------|--------------------------------|---------------------|----------------------------------|--------------------------------------|------------------------------------|---------------------------------|------------------------|
| | | | | Dosage Interval (h) | Moderate (Cl_{cr} 10–50 mL/min) | Severe (Cl_{cr} < 10 mL/min) | Post-hemodialysis Dose |
| Ciprofloxacin | 3–4 (400 mg IV, 500–750 mg PO) | 3–6 | 800–1200 mg (IV), 0.5–1.5 g (PO) | 8–12 | 400 mg q12h | 200 mg q12h | None |
| Gemifloxacin | 2–4 (320 mg PO) | 7 | 320 mg PO | Not known | Not known | Not known | Not known |
| Levofloxacin | 5–7 (500 mg PO or IV) | 6–8 | 250–750 mg (PO/IV) | 24 | 250–500 mg q24–48h | 250–500 mg q48h | None |
| Moxifloxacin | 3–4 (400 mg PO) | 12 | 400 mg (PO) | 24 | 400 mg q24h | 400 mg q24h | Not known |
| Ofloxacin | 5–7 (400 mg PO or IV) | 6–8 | 400–800 mg (PO/IV) | 12 | 200–400 mg q24h | 200 mg q24h | None |

A major complication of intravenous antibiotic therapy is catheter infections. Peripheral catheters are changed every 48–72 hours to prevent phlebitis, and antimicrobial-coated central venous catheters (minocycline and rifampin, chlorhexidine and sulfadiazine) have been associated with a decreased incidence of catheter-related infections. Most of these infections present with local signs of infection (erythema, tenderness) at the insertion site. In a patient with fever who is receiving intravenous therapy, the catheter must always be considered a potential source. Small-gauge (20–23F) peripherally inserted silicone or polyurethane catheters (Per Q Cath, A-Cath, Ven-A-Cath, and others) are associated with a low infection rate and can be maintained for 3–6 months without replacement. Such catheters are ideal for long-term outpatient antibiotic therapy.

J. Cost of Antibiotics

The cost of these agents can be substantial. In addition to acquisition cost, monitoring costs, (drug levels, liver function tests, electrolytes, etc), the cost of treating adverse reactions, the cost of treatment failure, and the costs associated with drug administration must be considered.

HYPERSENSITIVITY TESTS & DESENSITIZATION

► Penicillin Allergy

All penicillins are cross-sensitizing and cross-reacting. The responsible antigenic determinants appear to be degradation products of penicillins, particularly penicilloic acid and products of alkaline hydrolysis (minor antigenic determinants) bound to host protein. Skin tests with penicilloyl-

polylysine, with minor antigenic determinants, and with undegraded penicillin can identify most individuals with IgE-mediated reactions (hives, bronchospasm). Among positive reactors to skin tests, the incidence of subsequent immediate severe penicillin reactions is high. Although IgG antibodies to antigenic determinants of penicillin develop in many persons, the presence of such antibodies is not correlated with allergic reactivity (except for rare instances of hemolytic anemia), and serologic tests have little predictive value. A history of a penicillin reaction in the past is not reliable. Only 15–20% of patients with a history of penicillin allergy have an adverse reaction when challenged with the drug. The decision to administer penicillin or related drugs (other β -lactams) to patients with an allergic history depends on the severity of the reported reaction, the severity of the infection being treated, and the availability of alternative drugs. For patients with a history of severe reaction (anaphylaxis), alternative drugs should be used. In the rare situations when there is a strong indication for using penicillin (eg, syphilis in pregnancy) in allergic patients, desensitization can be performed. If the reaction is mild (nonurticarial rash), the patient may be rechallenged with penicillin or may be given another β -lactam antibiotic.

Allergic reactions include anaphylaxis, serum sickness (urticaria, fever, joint swelling, angioedema 7–12 days after exposure), skin rashes, fever, interstitial nephritis, eosinophilia, hemolytic anemia, other hematologic disturbances, and vasculitis. The incidence of hypersensitivity to penicillin is estimated to be 1–5% among adults in the United States. Life-threatening anaphylactic reactions are very rare (0.05%). Ampicillin produces maculopapular skin rashes more frequently than other penicillins, but many ampicillin (and other β -lactam) rashes are not allergic in origin. The nonallergic ampicillin rash usually occurs after 3–4 days of therapy, is maculopapular, is more common in patients with coexisting viral illness (especially Epstein-Barr infection), and resolves with continued therapy. The maculopapular rash may or may not reappear with rechallenge. Rarely, penicillins can induce nephritis with primary tubular lesions associated with anti-base-membrane antibodies.

Table 30–9. Examples of initial antimicrobial therapy for acutely ill, hospitalized adults pending identification of causative organism.

| Suspected Clinical Diagnosis | Likely Etiologic Diagnosis | Drugs of Choice |
|--|---|---|
| (A) Meningitis, bacterial, community-acquired | <i>Pneumococcus</i> , ¹ meningococcus | Cefotaxime, ² 2–3 g IV every 6 hours; or ceftriaxone, 2 g IV every 12 hours plus vancomycin, 10 mg/kg IV every 8 hours |
| (B) Meningitis, bacterial, age > 50, community-acquired | <i>Pneumococcus</i> , meningococcus, <i>Listeria monocytogenes</i> , ³ gram-negative bacilli | Ampicillin, 2 g IV every 4 hours, plus cefotaxime or ceftriaxone and vancomycin as in (A) |
| (C) Meningitis, postoperative (or posttraumatic) | <i>S aureus</i> , gram-negative bacilli (<i>pneumococcus</i> , in posttraumatic) | Vancomycin, 10 mg/kg IV every 8 hours, plus ceftazidime, 3 g IV every 8 hours |
| (D) Brain abscess | Mixed anaerobes, pneumococci, streptococci | Penicillin G, 4 million units IV every 4 hours, plus metronidazole, 500 mg orally every 8 hours; or cefotaxime or ceftriaxone as in (A) plus metronidazole, 500 mg orally every 8 hours |
| (E) Pneumonia, acute, community-acquired, severe | Pneumococci, <i>M pneumoniae</i> , <i>Legionella</i> , <i>C pneumoniae</i> | Cefotaxime, 2 g IV every 8 hours (or ceftriaxone, 1 g IV every 24 hours or ampicillin 2 g IV every 6 hours) plus azithromycin 500 mg IV every 24 hours; or a fluoroquinolone ⁵ alone |
| (F) Pneumonia, postoperative or nosocomial | <i>S aureus</i> , mixed anaerobes, gram-negative bacilli | Cefepime, 2 g IV every 8 hours; or ceftazidime, 2 g IV every 8 hours; or piperacillin-tazobactam, 45 g IV every 6 hours; or imipenem, 500 mg IV every 6 hours; or meropenem, 1 g IV every 8 hours plus tobramycin, 5 mg/kg IV every 24 hours; or ciprofloxacin, 400 mg IV every 12 hours; or levofloxacin, 500 mg IV every 24 hours plus vancomycin, 15 mg/kg IV every 12 hours |
| (G) Endocarditis, acute (including injection drug user) | <i>S aureus</i> , <i>E faecalis</i> , gram-negative aerobic bacteria, viridans streptococci | Vancomycin, 15 mg/kg IV every 12 hours, plus gentamicin, 1 mg/kg every 8 hours |
| (H) Septic thrombophlebitis (eg, IV tubing, IV shunts) | <i>S aureus</i> , gram-negative aerobic bacteria | Vancomycin, 15 mg/kg IV every 12 hours plus ceftriaxone, 1 g IV every 24 hours |
| (I) Osteomyelitis | <i>S aureus</i> | Nafcillin, 2 g IV every 4 hours; or cefazolin, 2 g IV every 8 hours |
| (J) Septic arthritis | <i>S aureus</i> , <i>N gonorrhoeae</i> | Ceftriaxone, 1–2 g IV every 24 hours |
| (K) Pyelonephritis with flank pain and fever (recurrent urinary tract infection) | <i>E coli</i> , <i>Klebsiella</i> , <i>Enterobacter</i> , <i>Pseudomonas</i> | Ceftriaxone, 1g IV every 24 hours; or ciprofloxacin, 400 mg IV every 12 hours (500 mg orally); or levofloxacin, 500 mg once daily (IV/PO) |
| (L) Fever in neutropenic patient receiving cancer chemotherapy | <i>S aureus</i> , <i>Pseudomonas</i> , <i>Klebsiella</i> , <i>E coli</i> | Ceftazidime, 2 g IV every 8 hours; or cefepime, 2 g IV every 8 hours |
| (M) Intra-abdominal sepsis (eg, postoperative, peritonitis, cholecystitis) | Gram-negative bacteria, <i>Bacteroides</i> , anaerobic bacteria, streptococci, clostridia | Piperacillin-tazobactam as in (F) or ertapenem, 1 g every 24 hours |

¹Some strains may be resistant to penicillin. Vancomycin can be used with or without rifampin.²Cefotaxime, ceftriaxone, ceftazidime, or ceftizoxime can be used. Most studies on meningitis have been with cefotaxime or ceftriaxone (see text).³TMP-SMZ can be used to treat *Listeria monocytogenes* in patients allergic to penicillin in a dosage of 15–20 mg/kg of TMP in three or four divided doses.⁴Depending on local drug susceptibility pattern, use tobramycin, 5 mg/kg/d, or amikacin, 15 mg/kg/d, in place of gentamicin.⁵Levofloxacin 750 mg/d, moxifloxacin 400 mg/d.

If the intradermal test described below is negative, desensitization is not necessary, and a full dose of the material may be given. If the test is positive, alternative drugs should be strongly considered. If that is not feasible, desensitization is necessary.

Patients with a history of allergy to penicillin are also at an increased risk for having a reaction to **cephalosporins**. Since the specific immunogens responsible for anaphylaxis are not known for drugs other than penicillin, skin testing with cephalosporins is not recommended. A common

approach to these patients is to assess the severity of the reaction. If an IgE-mediated reaction to penicillin can be excluded by history, a cephalosporin can be administered. When the history justifies concern about an immediate-type reaction, penicillin skin testing should be performed. If the test is negative, a cephalosporin can be given. If the test is positive, there is a 5–10% chance of cross reactivity, and the decision whether to use cephalosporins depends on the availability of alternative agents and the severity of the infection.

Table 30–10. Examples of empiric choices of antimicrobials for adult outpatient infections.

| Suspected Clinical Diagnosis | Likely Etiologic Agents | Drugs of Choice | Alternative Drugs |
|--|---|--|---|
| Erysipelas, impetigo, cellulitis, ascending lymphangitis | Group A streptococcus | Phenoxymethyl penicillin, 0.5 g orally four times daily for 7–10 days | Cephalexin, 0.5 g orally four times daily for 7–10 days; or azithromycin, 500 mg on day 1 and 250 mg on days 2–5 |
| Furuncle with surrounding cellulitis | <i>Staphylococcus aureus</i> | Dicloxacillin, 0.5 g orally four times daily for 7–10 days (If high-risk for MRSA, clindamycin 0.3 g orally four times daily for 7–10 days) | Cephalexin, 0.5 g orally four times daily for 7–10 days. (If high-risk for MRSA, TMP-SMZ two double strength tablets twice daily for 7–10 days) |
| Pharyngitis | Group A streptococcus | Phenoxymethyl penicillin, 0.5 g orally four times daily for 10 days | Clindamycin, 300 mg orally four times daily for 10 days; or erythromycin, 0.5 g orally four times daily for 10 days; or azithromycin, 500 mg on day 1 and 250 mg on days 2–5; or clarithromycin, 500 mg twice daily for 10 days |
| Otitis media | <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Moraxella catarrhalis</i> | Amoxicillin, 0.5–1.0 g orally three times daily for 10 days | Augmentin, ² 0.875 g orally twice daily; or cefuroxime, 0.5 g orally twice daily; or cefpodoxime, 0.2–0.4 g daily; or doxycycline, 100 mg twice daily; or TMP-SMZ, ¹ one double-strength tablet twice daily (all regimens for 10 days). |
| Acute sinusitis | <i>S pneumoniae</i> , <i>H influenzae</i> , <i>M catarrhalis</i> | Amoxicillin, 0.5–1.0 g orally three times daily; or TMP-SMZ, one double-strength tablet twice daily for 10 days | Augmentin, ² 0.875 g orally twice daily; or cefuroxime, 0.5 g orally twice daily; or cefpodoxime, 0.2–0.4 g daily; or doxycycline, 100 mg twice daily (all regimens for 10 days) |
| Aspiration pneumonia | Mixed oropharyngeal flora, including anaerobes | Clindamycin, 0.3 g orally four times daily for 10–14 days | Phenoxymethyl penicillin, 0.5 g orally four times daily for 10–14 days |
| Pneumonia | <i>S pneumoniae</i> , <i>Mycoplasma pneumoniae</i> , <i>Legionella pneumophila</i> , <i>Chlamydia pneumoniae</i> | Doxycycline, 100 mg orally twice daily; or clarithromycin, 0.5 g orally twice daily, for 10–14 days; or azithromycin, 0.5 g orally on day 1 and 0.25 g on days 2–5 | Amoxicillin, 0.5–1.0 g orally four times daily; or a fluoroquinolone ³ for 10–14 days |
| Cystitis | <i>Escherichia coli</i> , <i>Klebsiella pneumoniae</i> , <i>Proteus</i> species, <i>Staphylococcus saprophyticus</i> | Fluoroquinolones, ⁴ 3 days for uncomplicated cystitis, nitrofurantoin macrocrystals, 100 mg orally four times daily for 7 days; nitrofurantoin monohydrate macrocrystals, 100 mg twice daily for 7 days | TMP-SMZ, ¹ one double-strength tablet twice daily for 3 days; or cephalexin, 0.5 g orally four times daily for 7 days |
| Pyelonephritis | <i>E coli</i> , <i>K pneumoniae</i> , <i>Proteus</i> species, <i>S saprophyticus</i> | Fluoroquinolones ⁴ for 7–14 days | TMP-SMZ, ¹ one double-strength tablet twice daily for 7–14 days |
| Gastroenteritis | <i>Salmonella</i> , <i>Shigella</i> , <i>Campylobacter</i> , <i>Entamoeba histolytica</i> | See Note 3. | |
| Urethritis, epididymitis | <i>Neisseria gonorrhoeae</i> , <i>Chlamydia trachomatis</i> | Ceftriaxone, 250 mg IM once or cefpodoxime 200–400 mg orally once, for <i>N gonorrhoeae</i> ; plus doxycycline, 100 mg orally twice daily for 10 days, for <i>C trachomatis</i> | Ciprofloxacin, 500 mg orally once, for <i>N gonorrhoeae</i> ; plus doxycycline, 100 mg orally twice daily for 10 days, or ofloxacin, 300 mg orally twice daily for 10 days |
| Pelvic inflammatory disease | <i>N gonorrhoeae</i> , <i>C trachomatis</i> , anaerobes, gram-negative rods | Ofloxacin, 400 mg orally twice daily, for 14 days, plus metronidazole, 500 mg orally twice daily, for 14 days | Cefoxitin, 2 g IM, with probenecid, 1 g orally, followed by doxycycline, 100 mg orally twice daily for 14 days; or ceftriaxone, 250 mg IM once, followed by doxycycline, 100 mg orally twice daily for 14 days |

(continued)

Table 30–10. Examples of empiric choices of antimicrobials for adult outpatient infections. (continued)

| Suspected Clinical Diagnosis | Likely Etiologic Agents | Drugs of Choice | Alternative Drugs |
|---|---------------------------|--|---|
| Syphilis | | | |
| Early syphilis (primary, secondary, or latent of < 1 year's duration) | <i>Treponema pallidum</i> | Benzathine penicillin G, 2.4 million units IM once | Doxycycline, 100 mg orally twice daily for 2 weeks |
| Latent syphilis of > 1 year's duration or cardiovascular syphilis | <i>T pallidum</i> | Benzathine penicillin G, 2.4 million units IM once a week for 3 weeks (total: 7.2 million units) | Doxycycline, 100 mg orally twice daily, for 4 weeks |
| Neurosyphilis | <i>T pallidum</i> | Aqueous penicillin G, 12–24 million units/d IV for 10–14 days | |

¹TMP-SMZ is a fixed combination of 1 part trimethoprim and 5 parts sulfamethoxazole. Single-strength tablets: 80 mg TMP, 400 mg SMZ; double-strength tablets: 160 mg TMP, 800 mg SMZ.

²Augmentin is a combination of amoxicillin, 250 mg, 500 mg, or 875 mg, plus 125 mg of clavulanic acid. Augmentin XR is a combination of amoxicillin 1 g and clavulanic acid 62.5 mg.

³The diagnosis should be confirmed by culture before therapy. *Salmonella* gastroenteritis does not require therapy. For susceptible *Shigella* isolates, give TMP-SMZ double-strength tablets twice daily for 5 days; or ampicillin, 0.5 g orally four times daily for 5 days; or ciprofloxacin, 0.5 g orally twice daily for 5 days. For *Campylobacter* infection, give azithromycin, 1 g orally times one dose, or ciprofloxacin, 0.5 g orally twice daily for 5 days. For *E histolytica* infection, give metronidazole, 750 mg orally three times daily for 5–10 days, followed by diiodohydroxyquin, 600 mg orally three times daily for 3 weeks.

⁴Fluoroquinolones and dosages include ciprofloxacin, 500 mg orally twice daily; ofloxacin, 400 mg orally twice daily; levofloxacin, 500 mg orally daily. For others see text.

⁵Fluoroquinolones with activity against *S pneumoniae*, including penicillin-resistant isolates, include levofloxacin (500 mg orally once daily), gemifloxacin (320 mg orally once daily), and moxifloxacin (400 mg orally once daily).

MRSA, methicillin-resistant *Staphylococcus aureus*; TMP-SMZ, trimethoprim-sulfamethoxazole.

▶ Intradermal Test for Hypersensitivity

Penicillin is the drug that most frequently serves as an indication for sensitivity testing and desensitization. A clinical history of penicillin allergy has a positive predictive value of only 15%. In determining whether allergy testing should be performed, its nature should be determined. IgG-mediated delayed reactions such as erythematous or maculopapular skin rash or serum sickness should be distinguished from immediate-type IgE-mediated reactions, such as urticaria, angioedema, and anaphylaxis. Only patients with the latter history who require penicillin or a cephalosporin should undergo hypersensitivity testing. Skin testing requires two preparations: PPL (penicilloyl-polylysine) and a minor determinant mixture. Several points should be emphasized in performing and interpreting these tests. Whenever possible, both PPL and a minor determinant should be used, since 85% of skin test reactors are positive to PPL but 15% react only to the minor determinant mixture. In addition, if penicillin G is used instead of the minor determinant mixture, some allergic patients will be missed. About 25% of individuals who react to minor determinant mixture may not react to penicillin G, and such patients may still have an anaphylactic or accelerated reaction to penicillin. A pinprick test is performed with each solution at different sites by placing a small drop of solution on the skin and making small indentations of the skin with a needle. If there is no reaction within 10 minutes, 0.01–0.02 mL is injected intradermally, raising a small bleb. Development of a wheal greater than 5 mm in diameter is considered a positive test

and an indication for desensitization. Even if the test is negative, about 1–2% of patients will have an immediate or accelerated reaction, but an anaphylactic reaction is rare. Thus, if the test is negative, the drug can be administered with relative safety, but the first dose should be medically supervised and the patient observed for 1 hour (serious reactions after 1 hour are rare).

▶ Desensitization

A. Precautions

1. The desensitization procedure is not innocuous—deaths from anaphylaxis have been reported. If extreme hypersensitivity is suspected, it is advisable to use an alternative structurally unrelated drug and to reserve desensitization for situations when treatment cannot be withheld and no alternative drug is available.
2. An antihistaminic drug (25–50 mg of hydroxyzine or diphenhydramine intramuscularly or orally) should be administered before desensitization is begun in order to lessen any reaction that occurs.
3. Desensitization should be conducted in an intensive care unit where cardiac monitoring and emergency endotracheal intubation can be performed.
4. Epinephrine, 1 mL of 1:1000 solution, must be ready for immediate administration.

B. Desensitization Method

Several methods of desensitization have been described for penicillin, including use of both oral and intravenous

Table 30–11. Use of antimicrobials in patients with kidney failure¹ and liver failure.

| Drug | Principal Mode of Excretion or Detoxification | Approximate Half-Life in Serum | | Proposed Dosage Regimen in End-Stage Kidney Disease (all doses IV unless stated otherwise) | | Removal of Drug by Hemodialysis | Dose after Hemodialysis | Dosage in Hepatic Failure |

¹For cephalosporins, see text and Tables 30-5 and 30-6; for aminoglycosides, see Table 30-7.

²Considered here to be marked by creatinine clearance of 10 mL/min or less.

³For a 70-kg adult with a serious systemic infection.

⁴Dose adjustment in hepatic failure has not been studied, but because clearance of the drug is principally hepatic, dose reduction may be required.

⁵Pharmacokinetics and dosing are in reference to the active agent, penciclovir.

⁶When creatinine clearance is 30 mL/min, a dose of 60 mg/kg is given once daily. For clearances less than 30 mL/min, the dose has not been established.

⁷Oral valganciclovir is same as IV ganciclovir except that the initial dose is 900 mg, maintenance dose is 450 mg twice weekly in patients with creatinine clearance 10-40 mL/min. Post doses not known.

⁸When serum levels reach 10-15 mcg/mL, another dose should be given.

preparations. All methods start with very small doses of drug and gradually increase the dose until therapeutic doses are achieved. For penicillin, 1 unit of drug is given intravenously and the patient observed for 15–30 minutes. If there is no reaction, some recommend doubling the dose while others recommend increasing it tenfold every 15–30 minutes until a dosage of 2 million units is reached; then give the remainder of the desired dose.

For recommendations on skin testing and desensitization for other preparations (eg, botulism antitoxin and diphtheria antitoxin), the manufacturer's package inserts should be consulted.

▶ Treatment of Reactions

A. Mild Reactions

If a mild reaction occurs, drop back to the next lower dose and continue with desensitization. If a severe reaction occurs, administer epinephrine (see below) and discontinue the drug unless treatment is urgently needed. If desensitization is imperative, continue slowly, increasing the dosage of the drug more gradually.

B. Severe Reactions

If bronchospasm occurs, epinephrine, 0.3–0.5 mL of 1:1000 dilution, should be given subcutaneously every 10–20 minutes, followed by corticosteroids (250 mg of hydrocortisone or 50 mg of methylprednisolone intravenously every 6 hours for two to four doses), if needed. Hypotension should be treated with intravenous fluids (saline or colloid), epinephrine (1 mL of 1:1000 dilution in 500 mL of D₅W intravenously at a rate of 0.5–5 mcg/min), and antihistamines (25–50 mg of hydroxyzine or diphenhydramine intramuscularly or orally every 6–8 hours as needed). Cutaneous reactions, manifested as urticaria or angioedema, respond to epinephrine subcutaneously and antihistamines in the doses set forth above.

IMMUNIZATION AGAINST INFECTIOUS DISEASES

RECOMMENDED IMMUNIZATION OF INFANTS, CHILDREN, & ADOLESCENTS

The recommended schedules and dosages of vaccination change often, so the manufacturer's package inserts should always be consulted.

The schedule for active immunizations in children is presented in Table 30–12 (see also www.cdc.gov/vaccines/recs/schedules). All adolescents should see a health care provider to ensure vaccination of those who have not received varicella or hepatitis B vaccine, to make certain that a second dose of MMR has been given, to receive a

booster of tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine (Tdap adolescent preparation), to receive meningococcal vaccine conjugate vaccine, and to receive immunizations (influenza and pneumococcal vaccines) that may be indicated for certain high-risk individuals.

RECOMMENDED IMMUNIZATION OF ADULTS

Several vaccines are recommended for adults depending on the individual's previous vaccination status and the risks of exposure to certain diseases. Recommendations are summarized in Table 30–13.

▶ Hepatitis A

Two inactivated hepatitis A vaccines (Havrix, VAQTA) are approved for use in the United States for individuals 12 months of age or older. Hepatitis A vaccination is recommended as part of the routine childhood vaccination for all those 1 year of age or older. Vaccination is also recommended for adults at increased risk for developing infection, including travelers to areas where hepatitis is endemic (Africa, Asia, Central and South America, Mexico, parts of the Caribbean); certain populations that experience outbreaks (such as indigenous Alaskans, certain American Indian reservations, various religious communities and states where the risk of hepatitis A is high among children); employees of day care centers, caretakers for developmentally impaired institutionalized individuals, and laboratory workers who handle live hepatitis A virus or work closely with nonhuman primates; men who have sex with men; illicit drug users; persons who receive clotting factor concentrates; and those with chronic liver disease. A single intramuscular injection of vaccine in adults elicits antibodies in 55–60% of individuals at 2 weeks and 95% by 1 month, although rates of seroconversion may be lower in immunocompromised individuals. The different formulations come in different strengths, and dosage depends on the age of the vaccine and the preparation used (see package insert). In general, two doses are required, the second 6–18 months after the first. The duration of immunity may be lifelong, and at present, repeat vaccination is not recommended. A single dose of hepatitis A vaccine can be used as postexposure prophylaxis and is recommended for those between the ages of 12 months and 40 years of age. For those older than 40 years of age, 0.02 mL/kg of immunoglobulin is recommended. Preparation of immunoglobulin from plasma involves steps that inactivate HIV, thus making it incapable of transmitting HIV infection.

▶ Hepatitis B

Recombinant hepatitis B vaccine is recommended for all individuals at increased risk for developing hepatitis B, including individuals at risk for acquiring disease by sexual exposure (sex partners of hepatitis B surface antigen (HBsAg)-positive individuals, persons with more than one sex partner in the last 6 months, persons seeking evaluation and treatment for STDs, and men who have sex with

men) and those at risk for infection from percutaneous or mucosal exposure to blood (current or recent injection drug users; household contacts of HBsAg-positive individuals; residents and staff of facilities for developmentally disabled individuals; healthcare and public safety workers with likely exposure to infected blood or body fluids; and persons with end-stage renal disease, including predialysis and dialysis patients). Others who are candidates for vaccination include travelers to regions with high rates of endemic disease, those with chronic liver disease or HIV infection, and anyone who wants protection from hepatitis B. In settings where a high proportion of individuals are likely to be at risk for hepatitis B (such as STD and HIV screening and treatment facilities, drug abuse treatment centers, health care settings targeting care for men who have sex with men, and correctional facilities), all patients who seek care at those facilities be vaccinated. In addition, it is recommended that primary and specialty care practices establish standing orders to identify adults at risk for hepatitis B and administer vaccine as part of their routine services. In immunocompromised patients and individuals undergoing hemodialysis, seroresponse to standard doses of vaccine is low, and a special preparation delivering a higher vaccine dose (40 mcg/mL) is recommended. In addition to higher vaccine doses, these patients may require more frequent immunizations, and some authorities recommend annual screening to determine whether booster doses are needed. Although most often used for preexposure prophylaxis, the vaccine is also given as post-exposure prophylaxis along with hepatitis B immunoglobulin following needlestick injury or mucous membrane exposure to blood from an individual who is HBsAg-positive. It is also given along with hepatitis B immunoglobulin to infants of mothers who are HBsAg-positive (Table 30–12). Immunity wanes with time, but protection against infection lasts at least 20 years, making periodic serologic monitoring and routine administration of booster doses unnecessary.

Ten micrograms of recombinant hepatitis B vaccine is given intramuscularly in the deltoid (gluteal injection often results in deposition of vaccine in fat rather than muscle with fewer serologic conversions) on three separate occasions: the first two doses 1 month apart and the last dose 5 months after the second one. Seroconversion occurs after the first dose in 30–55% of healthy adults less than 40 years of age, in 75% after two doses, and in greater than 90% after 3 doses. No apparent effect on immunogenicity has been documented if this timing is not strictly adhered to. A number of factors decrease serologic response, including age over 40, kidney disease, HIV infection, diabetes, chronic liver disease, obesity, and smoking. Post-vaccination serologic testing is not routinely performed. It is reserved for those whose clinical management would be influenced by their immune status (eg, health care workers, infants born to HBsAg-positive mothers, dialysis patients), and those who may have an impaired response. Those who do not respond should receive a second three-dose vaccine series with serologic testing 1–2 months after completion. Those who do not respond are unlikely to respond to further vaccination even with a different recombinant

vaccine and should be considered susceptible; if exposed, they should receive hepatitis B immune globulin.

▶ Herpes Zoster

Waning cell-mediated immunity that occurs with aging increases the risk of reactivation of latent varicella virus, as does immunosuppression. More than 90% of adults have been exposed to varicella and are at risk for developing herpes zoster. Most cases of herpes zoster occur in those over the age of 60 years, and postherpetic neuralgia (a severe and debilitating sequela that can last months to years) occurs in about 30% of those over age 60 in whom herpes zoster develops.

Zostavax is a live attenuated varicella-zoster vaccine that contains 14 times as much virus as that used for varicella vaccination (see above). Compared with placebo, a single subcutaneous dose of vaccine significantly decreased the incidence of herpes zoster, the incidence of postherpetic neuralgia, and the severity and duration of pain in those in whom postherpetic neuralgia developed.

A single dose of zoster vaccine is recommended for adults 60 years of age or older whether or not they have had a prior episode of herpes zoster. Serologic status should be checked prior to immunization. Individuals lacking immunity should be vaccinated against varicella (see above).

▶ Human Papillomavirus

Genital HPV is the most common STD in the United States with more than 6 million new cases annually. There are over 100 different types of virus, about 40 of which cause genital disease. “Low risk” strains are associated with genital warts or benign low-grade cervical cell changes, whereas “high-risk” strains are associated with cervical and other anogenital neoplasms. Although most HPV infections are transient, those that persist can be associated with cervical intraepithelial neoplasia and may progress to cervical cancer. Approximately 70% of cervical cancers are associated with HPV types 16 and 18, and 90% of anogenital warts are associated with types 6 and 11.

A recombinant quadrivalent HPV vaccine (Gardasil) composed of the L1 major capsid protein from “low risk” types 6 and 11 and “high risk” types 16 and 18 has been approved for use in girls and women 9–26 years of age to prevent disease associated with these HPV types. Clinical studies indicated a high efficacy of prevention of vaccine type persistent infections, cervical intraepithelial neoplasia, and genital warts. There was no evidence of protection against nonvaccine strains or protection against strains that were present before vaccination. The Advisory Committee on Immunization Practices (ACIP) recommends routine vaccination of females 11–12 years of age with three intramuscular doses; the second and third doses should be given 2 and 6 months after the first. No changes in cervical cancer screening have been recommended in vaccinated individuals. The vaccine has also been evaluated in boys, heterosexual men, and men who have sex with men. Currently, there are no guidelines for vaccination in these groups pending final analysis and review of the data.

Range of recommended ages

Certain high-risk groups

This schedule indicates the recommended ages for routine administration of currently licensed vaccines, as of December 1, 2008, for children aged 0 through 6 years. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. Licensed combination vaccines may be used whenever any component of the combination is indicated and other components are not contraindicated and if approved by the Food and Drug Administration for that dose of the series.

1. Hepatitis B vaccine (HepB). (Minimum age: birth)

At birth:

- Administer monovalent HepB to all newborns before hospital discharge.
- If mother is hepatitis B surface antigen (HBsAg)-positive, administer HepB and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth.
- If mother's HBsAg status is unknown, administer HepB within 12 hours of birth. Determine mother's HBsAg status as soon as possible and, if HBsAg-positive, administer HBIG (no later than age 1 week).

After the birth dose:

- The HepB series should be completed with either monovalent HepB or a combination vaccine containing HepB. The second dose should be administered at age 1 or 2 months. The final dose should be administered no earlier than age 24 weeks.
- Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg (anti-HBs) after completion of at least 3 doses of the HepB series, at age 9 through 18 months (generally at the next well-child visit).

4-month dose:

- Administration of 4 doses of HepB to infants is permissible when combination vaccines containing HepB are administered after the birth dose.

2. Rotavirus vaccine (RV). (Minimum age: 6 weeks)

- Administer the first dose at age 6 through 14 weeks (maximum age: 14 weeks 6 days). Vaccination should not be initiated for infants aged 15 weeks or older (i.e., 15 weeks 0 days or older).
- Administer the final dose in the series by age 8 months 0 days.
- If Rotarix® is administered at ages 2 and 4 months, a dose at 6 months is not indicated.

3. Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).

(Minimum age: 6 weeks)

- The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose.
- Administer the final dose in the series at age 4 through 6 years.

4. Haemophilus influenzae type b conjugate vaccine (Hib).

(Minimum age: 6 weeks)

- If PRP-OMP (PedvaxHIB® or Comvax® [HepB-Hib]) is administered at ages 2 and 4 months, a dose at age 6 months is not indicated.
- TriHiBit® (DTaP/Hib) should not be used for doses at ages 2, 4, or 6 months but can be used as the final dose in children aged 12 months or older.

5. Pneumococcal vaccine. (Minimum age: 6 weeks for pneumococcal conjugate vaccine [PCV]; 2 years for pneumococcal polysaccharide vaccine [PPSV])

- PCV is recommended for all children aged younger than 5 years. Administer 1 dose of PCV to all healthy children aged 24 through 59 months who are not completely

vaccinated for their age.

Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations, including high-risk conditions: <http://www.cdc.gov/vaccines/pubs/acip-list.htm>. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at <http://www.vaers.hhs.gov> or by telephone, 800-822-7967.

vaccinated for their age.

- Administer PPSV to children aged 2 years or older with certain underlying medical conditions (see MMWR 2000;49[No. RR-9]), including a cochlear implant.

6. Influenza vaccine. (Minimum age: 6 months for trivalent inactivated influenza vaccine [TIV]; 2 years for live, attenuated influenza vaccine [LAIV])

- Administer annually to children aged 6 months through 18 years.
- For healthy nonpregnant persons (i.e., those who do not have underlying medical conditions that predispose them to influenza complications) aged 2 through 49 years, either LAIV or TIV may be used.
- Children receiving TIV should receive 0.25 mL if aged 6 through 35 months or 0.5 mL if aged 3 years or older.
- Administer 2 doses (separated by at least 4 weeks) to children aged younger than 9 years who are receiving influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.

7. Measles, mumps, and rubella vaccine (MMR). (Minimum age: 12 months)

- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 28 days have elapsed since the first dose.

8. Varicella vaccine. (Minimum age: 12 months)

- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 3 months have elapsed since the first dose.
- For children aged 12 months through 12 years the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.

9. Hepatitis A vaccine (HepA). (Minimum age: 12 months)

- Administer to all children aged 1 year (i.e., aged 12 through 23 months). Administer 2 doses at least 6 months apart.
- Children not fully vaccinated by age 2 years can be vaccinated at subsequent visits.
- HepA also is recommended for children older than 1 year who live in areas where vaccination programs target older children or who are at increased risk of infection. See MMWR 2006;55(No. RR-7).

10. Meningococcal vaccine. (Minimum age: 2 years for meningococcal conjugate vaccine [MCV] and for meningococcal polysaccharide vaccine [MPSV])

- Administer MCV to children aged 2 through 10 years with terminal complement component deficiency, anatomic or functional asplenia, and certain other high-risk groups. See MMWR 2005;54(No. RR-7).
- Persons who received MPSV 3 or more years previously and who remain at increased risk for meningococcal disease should be revaccinated with MCV.

The Recommended Immunization Schedules for Persons Aged 0 Through 18 Years are approved by the [Advisory Committee on Immunization Practices](http://www.cdc.gov/vaccines/recs/acip) (www.cdc.gov/vaccines/recs/acip), the [American Academy of Pediatrics](http://www.aap.org) (<http://www.aap.org>), and the [American Academy of Family Physicians](http://www.aafp.org) (<http://www.aafp.org>).

 Range of recommended ages

 Catch-up immunization

 Certain high-risk groups

This schedule indicates the recommended ages for routine administration of currently licensed vaccines, as of December 1, 2008, for children aged 7 through 18 years. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. Licensed combination vaccines may be used whenever any component of the combination is indicated and other components are not contraindicated and if approved by the Food and Drug Administration for that dose of the

1. Tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap).
(Minimum age: 10 years for BOOSTRIX® and 11 years for ADACEL®)

- Administer at age 11 or 12 years for those who have completed the recommended childhood DTP/DTaP vaccination series and have not received a tetanus and diphtheria toxoid (Td) booster dose.
- Persons aged 13 through 18 years who have not received Tdap should receive a dose.
- A 5-year interval from the last Td dose is encouraged when Tdap is used as a booster dose; however, a shorter interval may be used if pertussis immunity is needed.

2. Human papillomavirus vaccine (HPV). *(Minimum age: 9 years)*

- Administer the first dose to females at age 11 or 12 years.
- Administer the second dose 2 months after the first dose and the third dose 6 months after the first dose (at least 24 weeks after the first dose).
- Administer the series to females at age 13 through 18 years if not previously vaccinated.

3. Meningococcal conjugate vaccine (MCV).

- Administer at age 11 or 12 years, or at age 13 through 18 years if not previously vaccinated.
- Administer to previously unvaccinated college freshmen living in a dormitory.
- MCV is recommended for children aged 2 through 10 years with terminal complement component deficiency, anatomic or functional asplenia, and certain other groups at high risk. See MMWR 2005;54(No. RR-7).
- Persons who received MPSV 5 or more years previously and remain at increased risk for meningococcal disease should be revaccinated with MCV.

4. Influenza vaccine.

- Administer annually to children aged 6 months through 18 years.
- For healthy nonpregnant persons (i.e., those who do not have underlying medical conditions that predispose them to influenza complications) aged 2 through 49 years, either LAIV or TIV may be used.
- Administer 2 doses (separated by at least 4 weeks) to children aged younger than 9 years who are receiving influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.

series. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations, including high-risk conditions: <http://www.cdc.gov/vaccines/pubs/acip-list.htm>. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at <http://www.vaers.hhs.gov> or by telephone, 800-822-7967.

5. Pneumococcal polysaccharide vaccine (PPSV).

- Administer to children with certain underlying medical conditions (see MMWR 1997;46[No. RR-8]), including a cochlear implant. A single revaccination should be administered to children with functional or anatomic asplenia or other immunocompromising condition after 5 years.

6. Hepatitis A vaccine (HepA).

- Administer 2 doses at least 6 months apart.
- HepA is recommended for children older than 1 year who live in areas where vaccination programs target older children or who are at increased risk of infection. See MMWR 2006;55(No. RR-7).

7. Hepatitis B vaccine (HepB).

- Administer the 3-dose series to those not previously vaccinated.
- A 2-dose series (separated by at least 4 months) of adult formulation Recombivax HB® is licensed for children aged 11 through 15 years.

8. Inactivated poliovirus vaccine (IPV).

- For children who received an all-IPV or all-oral poliovirus (OPV) series, a fourth dose is not necessary if the third dose was administered at age 4 years or older.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.

9. Measles, mumps, and rubella vaccine (MMR).

- If not previously vaccinated, administer 2 doses or the second dose for those who have received only 1 dose, with at least 28 days between doses.

10. Varicella vaccine.

- For persons aged 7 through 18 years without evidence of immunity (see MMWR 2007;56[No. RR-4]), administer 2 doses if not previously vaccinated or the second dose if they have received only 1 dose.
- For persons aged 7 through 12 years, the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.
- For persons aged 13 years and older, the minimum interval between doses is 28 days.

The Recommended Immunization Schedules for Persons Aged 0 Through 18 Years are approved by the [Advisory Committee on Immunization Practices](http://www.cdc.gov/vaccines/recs/acip) (www.cdc.gov/vaccines/recs/acip), the [American Academy of Pediatrics](http://www.aap.org) (<http://www.aap.org>), and the [American Academy of Family Physicians](http://www.aafp.org) (<http://www.aafp.org>).

Catch-up Immunization Schedule for Persons Aged 4 Months Through 18 Years Who Start Late or Who Are More Than 1 Month Behind—United States • 2009

The table below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age.

| CATCH-UP SCHEDULE FOR PERSONS AGED 4 MONTHS THROUGH 6 YEARS | | | | | |
|---|------------------------|---|--|--|-----------------------|
| Vaccine | Minimum Age for Dose 1 | Minimum Interval Between Doses | | | |
| | | Dose 1 to Dose 2 | Dose 2 to Dose 3 | Dose 3 to Dose 4 | Dose 4 to Dose 5 |
| Hepatitis B ¹ | Birth | 4 weeks | 8 weeks (and at least 16 weeks after first dose) | | |
| Rotavirus ² | 6 wks | 4 weeks | 4 weeks ² | | |
| Diphtheria, Tetanus, Pertussis ³ | 6 wks | 4 weeks | 4 weeks | 6 months | 6 months ³ |
| <i>Haemophilus influenzae</i> type b ⁴ | 6 wks | 4 weeks if first dose administered at younger than age 12 months 8 weeks (as final dose) if first dose administered at age 12–14 months No further doses needed if first dose administered at age 15 months or older | 4 weeks ⁴ if current age is younger than 12 months 8 weeks (as final dose)⁴ if current age is 12 months or older and second dose administered at younger than age 15 months No further doses needed if previous dose administered at age 15 months or older | 8 weeks (as final dose) This dose only necessary for children aged 12 months through 59 months who received 3 doses before age 12 months | |
| Pneumococcal ⁵ | 6 wks | 4 weeks if first dose administered at younger than age 12 months 8 weeks (as final dose for healthy children) if first dose administered at age 12 months or older or current age 24 through 59 months No further doses needed for healthy children if first dose administered at age 24 months or older | 4 weeks if current age is younger than 12 months 8 weeks (as final dose for healthy children) if current age is 12 months or older No further doses needed for healthy children if previous dose administered at age 24 months or older | 8 weeks (as final dose) This dose only necessary for children aged 12 months through 59 months who received 3 doses before age 12 months or for high-risk children who received 3 doses at any age | |
| Inactivated Poliovirus ⁶ | 6 wks | 4 weeks | 4 weeks | 4 weeks ⁶ | |

| Measles, Mumps, Rubella ⁷ | 12 mos | 4 weeks | | | |
| Varicella ⁸ | 12 mos | 4 weeks if the person is younger than age 13 years 4 weeks if the person is aged 13 years or older | | | |

1. Hepatitis B vaccine (HepB).

- Administer the 3-dose series to those not previously vaccinated.
- A 2-dose series (separated by at least 4 months) of adult formulation Recombivax HB® is licensed for children aged 11 through 15 years.

2. Rotavirus vaccine (RV).

- The maximum age for the first dose is 14 weeks 6 days. Vaccination should not be initiated for infants aged 15 weeks or older (i.e., 15 weeks 0 days or older).
- Administer the final dose in the series by age 8 months 0 days.
- If Rotarix® was administered for the first and second doses, a third dose is not indicated.

3. Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).

- The fifth dose is not necessary if the fourth dose was administered at age 4 years or older.

4. Haemophilus influenzae type b conjugate vaccine (Hib).

- Hib vaccine is not generally recommended for persons aged 5 years or older. No efficacy data are available on which to base a recommendation concerning use of Hib vaccine for older children and adults. However, studies suggest good immunogenicity in persons who have sickle cell disease, leukemia, or HIV infection, or who have had a splenectomy; administering 1 dose of Hib vaccine to these persons is not contraindicated.
- If the first 2 doses were PRP-OMP (PedvaxHIB® or Comvax®), and administered at age 11 months or younger, the third (and final) dose should be administered at age 12 through 15 months and at least 8 weeks after the second dose.
- If the first dose was administered at age 7 through 11 months, administer 2 doses separated by 4 weeks and a final dose at age 12 through 15 months.

5. Pneumococcal vaccine.

- Administer 1 dose of pneumococcal conjugate vaccine (PCV) to all healthy children aged 24 through 59 months who have not received at least 1 dose of PCV on or after age 12 months.
- For children aged 24 through 59 months with underlying medical conditions, administer 1 dose of PCV if 3 doses were received previously or administer 2 doses of PCV at least 8 weeks apart if fewer than 3 doses were received previously.
- Administer pneumococcal polysaccharide vaccine (PPSV) to children aged 2 years or older with certain underlying medical conditions (see MMWR 2000;49[No. RR-9]), including a cochlear implant, at least 8 weeks after the last dose of PCV.

6. Inactivated poliovirus vaccine (IPV).

- For children who received an all-IPV or all-oral poliovirus (OPV) series, a fourth dose is not necessary if the third dose was administered at age 4 years or older.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.

7. Measles, mumps, and rubella vaccine (MMR).

- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 28 days have elapsed since the first dose.
- If not previously vaccinated, administer 2 doses with at least 28 days between doses.

8. Varicella vaccine.

- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 3 months have elapsed since the first dose.
- For persons aged 12 months through 12 years, the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.
- For persons aged 13 years and older, the minimum interval between doses is 28 days.

9. Hepatitis A vaccine (HepA).

- HepA is recommended for children older than 1 year who live in areas where vaccination programs target older children or who are at increased risk of infection. See MMWR 2006;55(No. RR-7).

10. Tetanus and diphtheria toxoids vaccine (Td) and tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap).

- Doses of DTaP are counted as part of the Td/Tdap series
- Tdap should be substituted for a single dose of Td in the catch-up series or as a booster for children aged 10 through 18 years; use Td for other doses.

11. Human papillomavirus vaccine (HPV).

- Administer the series to females at age 13 through 18 years if not previously vaccinated.
- Use recommended routine dosing intervals for series catch-up (i.e., the second and third doses should be administered at 2 and 6 months after the first dose). However, the minimum interval between the first and second doses is 4 weeks. The minimum interval between the second and third doses is 12 weeks, and the third dose should be given at least 24 weeks after the first dose.

Information about reporting reactions after immunization is available online at <http://www.vaers.hhs.gov> or by telephone, **800-822-7967**. Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for immunization, is available from the National Center for Immunization and Respiratory Diseases at <http://www.cdc.gov/vaccines> or telephone, **800-CDC-INFO (800-232-4636)**.

Table 30-13. Recommended adult immunization schedule—United States, 2009.

Recommended Adult Immunization Schedule UNITED STATES · 2009

Note: These recommendations *must* be read with the footnotes that follow containing number of doses, intervals between doses, and other important information.

Recommended adult immunization schedule, by vaccine and age group

| VACCINE ▼ | AGE GROUP ► | 19–26 years | 27–49 years | 50–59 years | 60–64 years | ≥ 65 years |
|---|-------------|--|-------------|-------------|-------------|-------------------------|
| Tetanus, diphtheria, pertussis (Td/Tdap) ^{1,*} | | Substitute 1-time dose of Tdap for Td booster; then boost with Td every 10 yrs | | | | Td booster every 10 yrs |
| Human papillomavirus (HPV) ^{2,*} | | 3 doses (females) | | | | |
| Varicella ^{3,*} | | 2 doses | | | | |
| Zoster ⁴ | | | | | 1 dose | |
| Measles, mumps, rubella (MMR) ^{5,*} | | 1 or 2 doses | | 1 dose | | |
| Influenza ^{6,*} | | 1 dose annually | | | | |
| Pneumococcal (polysaccharide) ^{7,8} | | 1 or 2 doses | | | | 1 dose |

| Hepatitis B ^{10,*} | | 3 doses | | | | |
| Meningococcal ^{11,*} | | 1 or more doses | | | | |

*Covered by the Vaccine Injury Compensation Program.

For all persons in this category who meet the age requirements and who lack evidence of immunity (e.g., lack documentation of vaccination or have no evidence of prior infection)

Recommended if some other risk factor is present (e.g., on the basis of medical, occupational, lifestyle, or other indications)

No recommendation

Report all clinically significant postvaccination reactions to the Vaccine Adverse Event Reporting System (VAERS). Reporting forms and instructions on filing a VAERS report are available at www.vaers.hhs.gov or by telephone, 800-822-7967.

Information on how to file a Vaccine Injury Compensation Program claim is available at www.hrsa.gov/vaccinecompensation or by telephone, 800-338-2382. To file a claim for vaccine injury, contact the U.S. Court of Federal Claims, 717 Madison Place, N.W., Washington, D.C. 20005; telephone, 202-357-6400.

Additional information about the vaccines in this schedule, extent of available data, and contraindications for vaccination is also available at www.cdc.gov/vaccines or from the CDC-INFO Contact Center at 800-CDC-INFO (800-232-4636) in English and Spanish, 24 hours a day, 7 days a week.

Use of trade names and commercial sources is for identification only and does not imply endorsement by the U.S. Department of Health and Human Services.

*Covered by the Vaccine Injury Compensation Program.

For all persons in this category who meet the age requirements and who lack evidence of immunity (e.g., lack documentation of vaccination or have no evidence of prior infection)
 Recommended if some other risk factor is present (e.g., on the basis of medical, occupational, lifestyle, or other indications)
 No recommendation

These schedules indicate the recommended age groups and medical indications for which administration of currently licensed vaccines is commonly indicated for adults ages 19 years and older, as of January 1, 2009. Licensed combination vaccines may be used whenever any components of the combination are indicated and when the vaccine's other components are not contraindicated. For detailed recommendations on all vaccines, including those used primarily for travelers or that are issued during the year, consult the manufacturers' package inserts and the complete statements from the Advisory Committee on Immunization Practices (www.cdc.gov/vaccines/pubs/acip-list.htm).

The Recommended Immunization Schedules for Persons Aged 0 Through 18 Years are approved by the [Advisory Committee on Immunization Practices](http://www.cdc.gov/vaccines/recs/acip) (www.cdc.gov/vaccines/recs/acip), the [American Academy of Pediatrics](http://www.aap.org) (<http://www.aap.org>), and the [American Academy of Family Physicians](http://www.aafp.org) (<http://www.aafp.org>).

(continued)

Footnotes

Recommended Adult Immunization Schedule—UNITED STATES • 2009

For complete statements by the Advisory Committee on Immunization Practices (ACIP), visit www.cdc.gov/vaccines/pubs/ACIP-list.htm.

1. Tetanus, diphtheria, and acellular pertussis (Td/Tdap) vaccination

Tdap should replace a single dose of Td for adults aged 19 through 64 years who have not received a dose of Tdap previously.

Adults with uncertain or incomplete history of primary vaccination series with tetanus and diphtheria toxoid-containing vaccines should begin or complete a primary vaccination series. A primary series for adults is 3 doses of tetanus and diphtheria toxoid-containing vaccines; administer the first 2 doses at least 4 weeks apart and the third dose 6–12 months after the second. However, Tdap can substitute for any one of the doses of Td in the 3-dose primary series. The booster dose of tetanus and diphtheria toxoid-containing vaccine should be administered to adults who have completed a primary series and if the last vaccination was received 10 or more years previously. Tdap or Td vaccine may be used, as indicated.

If a woman is pregnant and received the last Td vaccination 10 or more years previously, administer Td during the second or third trimester. If the woman received the last Td vaccination less than 10 years previously, administer Tdap during the immediate postpartum period. A dose of Tdap is recommended for postpartum women, close contacts of infants aged less than 12 months, and all health-care personnel with direct patient contact if they have not previously received Tdap. An interval as short as 2 years from the last Td is suggested; shorter intervals can be used. Td may be deferred during pregnancy and Tdap substituted in the immediate postpartum period, or Tdap may be administered instead of Td to a pregnant woman after an informed discussion with the woman.

Consult the ACIP statement for recommendations for administering Td as prophylaxis in wound management.

2. Human papillomavirus (HPV) vaccination

HPV vaccination is recommended for all females aged 11 through 26 years (and may begin at 9 years) who have not completed the vaccine series. History of genital warts, abnormal Papanicolaou test, or positive HPV DNA test is not evidence of prior infection with all vaccine HPV types; HPV vaccination is recommended for persons with such histories.

Ideally, vaccine should be administered before potential exposure to HPV through sexual activity; however, females who are sexually active should still be vaccinated consistent with age-based recommendations. Sexually active females who have not been infected with any of the four HPV vaccine types receive the full benefit of the vaccination. Vaccination is less beneficial for females who have already been infected with one or more of the HPV vaccine types.

A complete series consists of 3 doses. The second dose should be administered 2 months after the first dose; the third dose should be administered 6 months after the first dose.

HPV vaccination is not specifically recommended for females with the medical indications described in Figure 2. "Vaccines that might be indicated for adults based on medical and other indications." Because HPV vaccine is not a live-virus vaccine, it may be administered to persons with the medical indications described in Figure 2. However, the immune response and vaccine efficacy might be less for persons with the medical indications described in Figure 2 than in persons who do not have the medical indications described or who are immunocompetent. Health-care personnel are not at increased risk because of occupational exposure, and should be vaccinated consistent with age-based recommendations.

3. Varicella vaccination

All adults without evidence of immunity to varicella should receive 2 doses of single-antigen varicella vaccine if not previously vaccinated or the second dose if they have received only one dose unless they have a medical contraindication. Special consideration should be given to those who 1) have close contact with persons at high risk for severe disease (e.g., health-care personnel and family contacts of persons with immunocompromising conditions) or 2) are at high risk for exposure or transmission (e.g., teachers; child care employees; residents and staff members of institutional settings, including correctional institutions; college students; military personnel; adolescents and adults living in households with children; nonpregnant women of childbearing age; and international travelers).

Evidence of immunity to varicella in adults includes any of the following: 1) documentation of 2 doses of varicella vaccine at least 4 weeks apart; 2) U.S.-born before 1980 (although for health-care personnel and pregnant women, birth before 1980 should not be considered evidence of immunity); 3) history of varicella based on diagnosis or verification of varicella by a health-care provider (for a patient reporting a history of or presenting with an atypical case, a mild case, or both, health-care providers should seek either an epidemiologic link with a typical varicella case or to a laboratory-confirmed case or evidence of laboratory confirmation, if it was performed at the time of acute disease); 4) history of herpes zoster based on health-care provider diagnosis or verification of herpes zoster by a health-care provider; or 5) laboratory evidence of immunity or laboratory confirmation of disease.

Pregnant women should be assessed for evidence of varicella immunity. Women who do not have evidence of immunity should receive the first dose of varicella vaccine upon completion or termination of pregnancy and before discharge from the health-care facility. The second dose should be administered 4–8 weeks after the first dose.

4. Herpes zoster vaccination

A single dose of zoster vaccine is recommended for adults aged 60 years and older regardless of whether they report a prior episode of herpes zoster. Persons with chronic medical conditions may be vaccinated unless their condition constitutes a contraindication.

5. Measles, mumps, rubella (MMR) vaccination

Measles component: Adults born before 1957 generally are considered immune to measles. Adults born during or after 1957 should receive 1 or more doses of MMR unless they have a medical contraindication, documentation of 1 or more doses, history of measles based on health-care provider diagnosis, or laboratory evidence of immunity.

A second dose of MMR is recommended for adults who 1) have been recently exposed to measles or are in an outbreak setting; 2) have been vaccinated previously with killed measles vaccine; 3) have been vaccinated with an unknown type of measles vaccine during 1963–1967; 4) are students in postsecondary educational institutions; 5) work in a health-care facility; or 6) plan to travel internationally.

Mumps component: Adults born before 1957 generally are considered immune to mumps. Adults born during or after 1957 should receive 1 dose of MMR unless they have a medical contraindication, history of mumps based on health-care provider diagnosis, or laboratory evidence of immunity.

A second dose of MMR is recommended for adults who 1) live in a community experiencing a mumps outbreak and are in an affected age group; 2) are students in postsecondary educational institutions; 3) work in a health-care facility; or 4) plan to travel internationally. For unvaccinated health-care personnel born before 1957 who do not have other evidence of mumps immunity, administering 1 dose on a routine basis should be considered and administering a second dose during an outbreak should be strongly considered.

Rubella component: 1 dose of MMR vaccine is recommended for women whose rubella vaccination history is unreliable or who lack laboratory evidence of immunity. For women of childbearing age, regardless of birth year, rubella immunity should be determined and women should be counseled regarding congenital rubella syndrome. Women who do not have evidence of immunity should receive MMR upon completion or termination of pregnancy and before discharge from the health-care facility.

6. Influenza vaccination

Medical indications: Chronic disorders of the cardiovascular or pulmonary systems, including asthma; chronic metabolic diseases, including diabetes mellitus, renal or hepatic dysfunction, hemoglobinopathies, or immunocompromising conditions (including immunocompromising conditions caused by medications or human immunodeficiency virus [HIV]); any condition that compromises respiratory function or the handling of respiratory secretions or that can increase the risk of aspiration (e.g., cognitive dysfunction, spinal cord injury, or seizure disorder or other neuromuscular disorder); and pregnancy during the influenza season. No data exist on the risk for severe or complicated influenza disease among persons with asplenia; however, influenza is a risk factor for secondary bacterial infections that can cause severe disease among persons with asplenia.

Occupational indications: All health-care personnel, including those employed by long-term care and assisted-living facilities, and caregivers of children less than 5 years old.

Other indications: Residents of nursing homes and other long-term care and assisted-living facilities; persons likely to transmit influenza to persons at high risk (e.g., in-home household contacts and caregivers of children aged less than 5 years old, persons 65 years old and older and persons of all ages with high-risk condition[s]); and anyone who would like to decrease their risk of getting influenza. Healthy, nonpregnant adults aged less than 50 years without high-risk medical conditions who are not contacts of severely immunocompromised persons in special care units can receive either intranasally administered live, attenuated influenza vaccine (FluMist®) or inactivated vaccine. Other persons should receive the inactivated vaccine.

7. Pneumococcal polysaccharide (PPSV) vaccination

Medical indications: Chronic lung disease (including asthma); chronic cardiovascular diseases; diabetes mellitus; chronic liver diseases, cirrhosis; chronic alcoholism, chronic renal failure or nephrotic syndrome; functional or anatomic asplenia (e.g., sickle cell disease or splenectomy [if elective splenectomy is planned, vaccinate at least 2 weeks before surgery]); immunocompromising conditions; and cochlear implants and cerebrospinal fluid leaks. Vaccinate as close to HIV diagnosis as possible.

Other indications: Residents of nursing homes or long-term care facilities and persons who smoke cigarettes. Routine use of PPSV is not recommended for Alaska Native or American Indian persons younger than 65 years unless they have underlying medical conditions that are PPSV indications. However, public health authorities may consider recommending PPSV for Alaska Natives and American Indians aged 50 through 64 years who are living in areas in which the risk of invasive pneumococcal disease is increased.

8. Revaccination with PPSV

One-time revaccination after 5 years for persons with chronic renal failure or nephrotic syndrome; functional or anatomic asplenia (e.g., sickle cell disease or splenectomy); and for persons with immunocompromising conditions. For persons aged 65 years and older, one-time revaccination if they were vaccinated 5 or more years previously and were aged less than 65 years at the time of primary vaccination.

9. Hepatitis A vaccination

Medical indications: Persons with chronic liver disease and persons who receive clotting factor concentrates.

Behavioral indications: Men who have sex with men and persons who use illegal drugs.

Occupational indications: Persons working with hepatitis A virus (HAV)-infected primates or with HAV in a research laboratory setting.

Other indications: Persons traveling to or working in countries that have high or intermediate endemicity of hepatitis A (a list of countries is available at www.cdc.gov/travel/content/diseases.aspx) and any person seeking protection from HAV infection.

Single-antigen vaccine formulations should be administered in a 2-dose schedule at either 0 and 6–12 months (Havrix®), or 0 and 6–18 months (Vaqta®). If the combined hepatitis A and hepatitis B vaccine (Twinrix®) is used, administer 3 doses at 0, 1, and 6 months; alternatively, a 4-dose schedule, administered on days 0, 7 and 21 to 30 followed by a booster dose at month 12 may be used.

10. Hepatitis B vaccination

Medical indications: Persons with end-stage renal disease, including patients receiving hemodialysis; persons with HIV infection; and persons with chronic liver disease.

Occupational indications: Health-care personnel and public-safety workers who are exposed to blood or other potentially infectious body fluids.

Behavioral indications: Sexually active persons who are not in a long-term, mutually monogamous relationship (e.g., persons with more than 1 sex partner during the previous 6 months); persons seeking evaluation or treatment for a sexually transmitted disease (STD); current or recent injection-drug users; and men who have sex with men.

Other indications: Household contacts and sex partners of persons with chronic hepatitis B virus (HBV) infection; clients and staff members of institutions for persons with developmental disabilities; international travelers to countries with high or intermediate prevalence of chronic HBV infection (a list of countries is available at www.cdc.gov/travel/content/diseases.aspx); and any adult seeking protection from HBV infection.

Hepatitis B vaccination is recommended for all adults in the following settings: STD treatment facilities; HIV testing and treatment facilities; facilities providing drug-abuse treatment and prevention services; health-care settings targeting services to injection-drug users or men who have sex with men; correctional facilities; end-stage renal disease programs and facilities for chronic hemodialysis patients; and institutions and nonresidential daycare facilities for persons with developmental disabilities.

If the combined hepatitis A and hepatitis B vaccine (Twinrix®) is used, administer 3 doses at 0, 1, and 6 months; alternatively, a 4-dose schedule, administered on days 0, 7 and 21 to 30 followed by a booster dose at month 12 may be used.

Special formulation indications: For adult patients receiving hemodialysis or with other immunocompromising conditions, 1 dose of 40 µg/mL (Recombivax HB®) administered on a 3-dose schedule or 2 doses of 20 µg/mL (Engerix-B®) administered simultaneously on a 4-dose schedule at 0, 1, 2 and 6 months.

11. Meningococcal vaccination

Medical indications: Adults with anatomic or functional asplenia, or terminal complement component deficiencies.

Other indications: First-year college students living in dormitories; microbiologists who are routinely exposed to isolates of *Neisseria meningitidis*; military recruits; and persons who travel to or live in countries in which meningococcal disease is hyperendemic or epidemic (e.g., the "meningitis belt" of sub-Saharan Africa during the dry season [December–June]), particularly if their contact with local populations will be prolonged. Vaccination is required by the government of Saudi Arabia for all travelers to Mecca during the annual Hajj.

Meningococcal conjugate (MCV) vaccine is preferred for adults with any of the preceding indications who are aged 55 years or younger, although meningococcal polysaccharide vaccine (MPSV) is an acceptable alternative. Revaccination with MCV after 5 years might be indicated for adults previously vaccinated with MPSV who remain at increased risk for infection (e.g., persons residing in areas in which disease is epidemic).

12. Selected conditions for which *Haemophilus influenzae* type b (Hib) vaccine may be used

Hib vaccine generally is not recommended for persons aged 5 years and older. No efficacy data are available on which to base a recommendation concerning use of Hib vaccine for older children and adults. However, studies suggest good immunogenicity in persons who have sickle cell disease, leukemia, or HIV infection or who have had a splenectomy; administering 1 dose of vaccine to these persons is not contraindicated.

13. Immunocompromising conditions

Inactivated vaccines generally are acceptable (e.g., pneumococcal, meningococcal, and influenza [trivalent inactivated influenza vaccine]), and live vaccines generally are avoided in persons with immune deficiencies or immunocompromising conditions.

Information on specific conditions is available at www.cdc.gov/vaccines/pubs/acip-list.htm.

The vaccine is not advised for pregnant women at this time. Unanswered questions include the need for booster doses to prevent the development of cervical cancer and whether males should also be vaccinated.

▶ Influenza

Influenza vaccination is recommended yearly for all children aged 6 months-18 years and any adult wishing to reduce the likelihood of either becoming infected with or transmitting influenza. However, those at greatest risk for severe complications of influenza should have priority in vaccination programs: (1) Adults and children with chronic cardiopulmonary disease, including asthmatics. (2) Residents, health care workers, and employees of long-term care facilities. (3) Healthy adults 50 years of age or older. (4) Adults and children who have required either regular medical follow-up or hospitalization in the last year for chronic metabolic disorders (including diabetes) or kidney disease, those with hemoglobinopathies, and those receiving immunosuppressive drugs. (5) Children and teenagers (age 6 months to 18 years) who are receiving long-term aspirin therapy and would be at increased risk for developing Reye syndrome following influenza. (6) Women who will become pregnant during the influenza season. (7) Persons who are likely to transmit influenza to persons of high risk as defined above, such as in-home or out-of-home caregivers or household and close contacts of persons at high risk.

Certain high-risk groups of patients (the elderly, persons with AIDS, transplant patients) may have a poor antibody response to vaccine, but they should still be vaccinated. Concern that vaccination of HIV-positive patients may result in a brief (2- to 4-week) period of increased HIV viremia and viral replication has been raised, but the clinical significance is unclear and should not preclude vaccination.

A trivalent, live-attenuated influenza vaccine administered as a single-dose intranasal spray is as effective as inactivated vaccine in preventing disease. It is approved for use in otherwise healthy individuals between the ages of 2 and 49 years. Because the risk of transmission of the live-attenuated vaccine virus to immunocompromised individuals is unknown, it should not be used in household members of immunosuppressed individuals, health care workers, or others with close contact with immunosuppressed persons. Two neuraminidase inhibitors (zanamivir and oseltamivir) are available for prevention and therapy of influenza A and B. The dose of oseltamivir is 75 mg/d for prophylaxis and 75 mg twice daily for 5 days for therapy. Zanamivir is administered by inhaler (10 mg dose) and is given twice daily for therapy and once daily for prophylaxis. The duration of prophylaxis depends on the clinical setting. The 2008-2009 flu season was associated with a very high rate of oseltamavir-resistant virus, particularly in influenza A (H1N1 virus). Current recommendations are that influenza A be treated with zanamivir or a combination of oseltamavir and rimantadine. Influenza B can be treated with either oseltamavir or zanamivir. For chemoprophylaxis against influenza A, zanamivir should be used. If this is contraindicated, patients should be given rimantadine. In an outbreak associated with influenza B, either oseltamavir or zanamivir can be used for prophylaxis.

▶ Measles, Mumps, & Rubella (MMR)

A. Measles

Adults born before 1957 are considered immune to measles. Adults born in 1957 or later who lack documentation of immunization after age 1 or who do not have a provider-documented history or laboratory evidence of previous infection should receive at least one dose of vaccine. Persons born between 1963 and 1967—a period when less effective inactivated measles vaccine was the only product available—and persons vaccinated before their first birthday should receive a single dose of vaccine. Because most adults do not have detailed information about childhood immunization or illnesses, a practical approach is to administer a single dose of MMR to all healthy adults born after 1956. Because outbreaks of measles have occurred in young adults who have received a single dose of measles vaccine, revaccination is recommended, particularly before going to college, entering a health care profession, or embarking on foreign travel to areas where measles is endemic. Even though birth before 1957 implies immunity, unvaccinated health care workers (especially women of childbearing age) who do not have a history of measles or laboratory evidence of immunity should be vaccinated. Entrants to colleges and universities and employees of health care institutions who have not previously been vaccinated should receive two doses of vaccine at least 1 month apart. Revaccination of an immune person is not associated with adverse effects—if the vaccination status is unknown and an indication for vaccination exists, it can be safely done. Vaccination of susceptible adults within 72 hours after exposure to an active case of measles is protective.

B. Mumps

Mumps vaccine is recommended for all adults thought to be susceptible. Persons born before 1957 are considered to be naturally immune. Those born in 1957 or later are believed to be susceptible unless they can document infection, prove vaccination, or have laboratory evidence of immunity. Because of recent outbreaks of mumps, the definition of adequate vaccination is more stringent—it is one dose of vaccine for preschool-aged children and adults not at high risk and two doses for school-aged children (grades kindergarten through high school) and for adults at high risk (health care workers, international travelers, and students at post high school institutions). Thus, all health care workers should have evidence of immunity or should have received two doses of vaccine. Because birth before 1957 is only presumptive evidence of immunity, healthcare workers born before 1957 should receive a single dose of vaccine unless they have laboratory evidence of immunity or have a history of physician diagnosed mumps.

C. Rubella

The purpose of rubella vaccination is to prevent transmission to the fetus. Immunization is recommended for all adults but particularly for women of childbearing age not previously immunized. Although persons born before 1957 are considered immune, this is not an acceptable

criterion of immunity for women who could become pregnant. Thus, women of childbearing age, regardless of birth year, should have rubella immunity checked and should be vaccinated if they lack evidence of antibody. They should be counseled not to become pregnant within 4 weeks of immunization. Women who are already pregnant and lack immunity should be vaccinated in the postpartum period. In addition, both male and female hospital workers who may be exposed to patients with rubella or who might have contact with pregnant patients should be immunized. A single immunization is given. MMR trivalent vaccine is recommended, but if immunity to one or more of the components can be demonstrated, monovalent or bivalent vaccines can be used.

► Meningococcal Disease

Two vaccines are currently available, a polysaccharide vaccine (MPSV4) and the newer protein conjugated vaccine (MCV4). Both are highly immunogenic to serogroups A, C, Y, and W-135 and well tolerated. Whereas the polysaccharide vaccine requires revaccination of at-risk groups every 3–5 years due to waning immunity, the protein conjugated vaccine likely will provide longer protection, although data on need for revaccination with MCV4 are not available. Both vaccines are approved for individuals 2 years and older.

Vaccination with MCV4 is routinely recommended for adolescents aged 11–12. For those who miss that vaccination, “catch up” is recommended at high school entry (approximately age 15). MCV4 is also recommended for certain high-risk groups, including college freshman living in dormitories (the risk to nonfreshman and freshman not living in dormitories is the same as the general population and vaccination of these groups is elective), microbiologists who are routinely exposed to *N meningitidis*, military recruits, persons who travel to or reside in areas in which *N meningitidis* is hyperendemic or epidemic (see below), those with terminal complement deficiencies, and persons with anatomic or functional asplenia. HIV-infected patients may be at increased risk for meningococcal disease, and vaccination should be considered elective in that group. MCV4 is the preferred preparation, but if availability is an issue, MPSV4 can be substituted. MCV4 is administered as a single 0.5-mL dose intramuscularly and MPSV4 as a single 0.5-mL dose subcutaneously. Both can be administered with other vaccines, but at different sites and both produce an antibody response in 7–10 days. Both are inactivated vaccines and can be administered to immunocompromised patients. MPSV4 is safe in pregnancy, but there are no safety or efficacy data for MCV4 in pregnancy.

► Pneumococcal Disease

Pneumococcal vaccine contains purified polysaccharide from 23 of the most common strains of *S pneumoniae*, which cause 90% of bacteremic episodes in the United States. Antibody response following vaccination depends on the patient's immune status and the presence of concomitant disease. Healthy adults have an excellent antibody response, as do patients who are postsplenectomy

and those with sickle cell disease. Elderly individuals and those with chronic diseases (diabetes mellitus, alcoholic cirrhosis, chronic obstructive pulmonary disease, chronic kidney disease, lupus erythematosus, rheumatoid arthritis) have less vigorous response than young healthy adults. Patients with Hodgkin disease respond to vaccination if it is given before splenectomy, radiation, or chemotherapy, whereas patients with leukemia, lymphoma, and HIV infection respond sluggishly.

Although the efficacy of pneumococcal vaccine has been questioned, most authorities believe that vaccination is about 60–70% effective in preventing bacteremic disease in immunocompetent persons, but less effective at preventing pneumonia. Fifty percent efficacy is observed in patients with underlying diseases (not severely immunocompromised), and less in immunocompromised patients (10%), largely because of inability to mount an antibody response in this population. It is presently recommended for patients at increased risk for developing severe pneumococcal disease, especially asplenic patients and those with sickle cell disease. It is also indicated for adults at increased risk for developing pneumococcal disease, including those with chronic illnesses (eg, cardiopulmonary disease, alcoholism, cirrhosis, chronic kidney disease, nephrotic syndrome, cerebrospinal fluid leaks), those with asthma, cigarette smokers, those who are immunocompromised (eg, patients with Hodgkin disease, lymphoma, chronic lymphocytic leukemia, multiple myeloma, congenital immunodeficiency, asymptomatic or symptomatic HIV infection, organ or bone marrow transplant recipients), those receiving immunosuppressive therapy (eg, long-term systemic corticosteroids, alkylating agents, and antimetabolites) and Alaskan Natives. Because of the increased risk of developing pneumococcal meningitis following cochlear implants, patients receiving these implants should be given age-appropriate vaccination. In addition, it is recommended for all individuals over 65 years of age. A single dose of vaccine usually confers lifelong immunity. One-time revaccination 5 years after initial vaccination is recommended for those at highest risk (see list above). In addition, a single revaccination is recommended for those 65 or more years of age who received the vaccine 5 years or more previously and were under age 65 at the time of primary vaccination. Elderly individuals with unknown vaccination status should be immunized once. Revaccination should also be considered for high-risk individuals previously immunized with the older 14-valent vaccine. Since immunocompetent patients respond best to the vaccine, it should be given 2 weeks before splenectomy or before starting chemotherapy if that can be anticipated.

A protein-conjugated heptavalent pneumococcal vaccine used in children under 2 years of age is very effective at preventing meningitis and pneumonia but only modestly effective at preventing otitis media. Unlike the adult polysaccharide vaccine, the pediatric conjugated vaccine decreases nasopharyngeal colonization, which results in less transmission to nonimmunized children and adults (herd immunity). Limited information about use of this vaccine in adults suggests that those with poor antibody response to the 23-valent vaccine (such as kidney transplant recipients)

also have poor antibody response to the protein-conjugated vaccine despite its higher immunogenicity.

► Tetanus, Diphtheria, & Pertussis

A tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine (Tdap) is approved for use in persons 11–64 years of age. All should receive a primary series of immunizations against tetanus, diphtheria, and pertussis (Table 30–12). Adults who have not previously been immunized should receive a dose of Tdap followed by a dose Td 4 weeks later, and a booster with Td 6–12 months after the second dose.

The ACIP recommends that adults aged 19–64 years should receive a single dose of Tdap to replace tetanus and diphtheria toxoids vaccine (Td) for booster immunization if they received their last dose of Td \geq 10 years earlier and they have not previously received Tdap. To prevent pertussis among infants less than 12 months of age, a single dose of Tdap is recommended at an interval as short as 2 years from the previous Td vaccination for those adults anticipating close contact with these infants (eg, parents, grandparents aged < 65 years, child-care providers). When possible, women should receive Tdap before becoming pregnant. Women who have not previously received Tdap should receive a dose of Tdap in the immediate postpartum period. Health-care personnel who work in hospitals or ambulatory care settings and have direct patient contact should receive a single dose of Tdap as soon as feasible if they have not previously received Tdap. For wound management, adults between the ages of 19 and 64 should receive Tdap instead of Td if they have not previously received Tdap. Tdap is contraindicated if there is a history of anaphylaxis to vaccine components or if there is a history of unexplained encephalitis within 7 days of administration of a pertussis-containing vaccine.

► Varicella

A live attenuated varicella virus vaccine is currently recommended as part of routine childhood immunization (Table 30–12) and its use has been associated with decreased mortality due to varicella across all age ranges. Although only 10% of adults remain susceptible, varicella in adolescents and adults is a more serious disease. Only about 2% of all cases of varicella occur in adults, but almost 50% of all deaths are in adults. Thus, all susceptible adolescents and adults should be immunized, with special emphasis on certain high-risk groups, ie, health care workers; household contacts of immunosuppressed individuals; persons who live or work in environments where transmission can occur, eg, teachers in day care centers or elementary schools, residents and workers in institutional settings such as military and correctional institutions, college students; nonpregnant women of childbearing age; and international travelers. The role of the present vaccine in postexposure prophylaxis has not been widely studied, but it has been suggested that it is 90% effective in preventing varicella in an outbreak, particularly when given within 3–5 days after exposure. The ACIP recommends vaccination in susceptible persons following exposure. The vaccine is very immunogenic. Sero-

conversion occurs in 95% of children after a single dose. In adolescents (older than 12 years of age) and adults, seroconversion is seen in 78% after one dose and 99% after two doses. For this reason, two doses given 4–8 weeks apart are recommended in persons 12 years of age and older. The duration of immunity is not known but is probably 10 years.

RECOMMENDED IMMUNIZATIONS FOR TRAVELERS

Individuals traveling to other countries frequently require immunizations in addition to those listed above and may benefit from chemoprophylaxis against various diseases. These are listed in *Health Information for International Travel*, published by the CDC. An updated version is published yearly and is available from the Superintendent of Documents, United States Government Printing Office, Washington, DC 20402, or on the Internet: <http://www.cdc.gov/nip>.

Various vaccines can be given simultaneously at different sites. Some, such as cholera, plague, and typhoid vaccine, cause significant discomfort and are best given at different times. In general, live attenuated vaccines (measles, mumps, rubella, yellow fever, and oral typhoid vaccine) should not be given to immunosuppressed individuals or household members of immunosuppressed people or to pregnant women. Immunoglobulin should not be given for 3 months before or at least 2 weeks after live virus vaccines, because it may attenuate the antibody response.

Chemoprophylaxis of malaria is discussed in Chapter 35.

► Cholera

Because cholera among travelers is rare and the vaccine marginally effective, the World Health Organization (WHO) does not require immunization for persons traveling to endemic areas. The only cholera vaccine licensed in the United States is no longer manufactured. Two oral vaccines are available in other countries and appear to be slightly more immunogenic than previous vaccines. However, the CDC does not recommend either of these two vaccines, and they are not available in the United States. No country requires vaccination for entry, but some local authorities may require documentation for entry. In such cases, a medical waiver will suffice or a single dose of the oral vaccine is usually sufficient. Information is available at <http://www.bernaproducts.com>.

► Hepatitis B

The risk of hepatitis B infection for most international travelers is low. Hepatitis B vaccination should be considered for those traveling to areas with high (\geq 8%) or intermediate (2–7%) rates of endemic hepatitis B infection if the individual will have contact with blood or secretions, have unprotected sex, or will be using illicit drugs. Examples of high and intermediate risk areas include all of Africa, South Asia (except Sri Lanka), the Middle East (except Cyprus), Eastern Europe (except Hungary), Newly Independent States of the former Soviet Union, Italy, Spain, Portugal, Greenland, Belize, Guatemala, Honduras, Panama, Argentina, Bolivia, Brazil, Ecuador, Venezuela,

certain Caribbean Islands. Alaskan natives and indigenous populations of Northern Canada are at intermediate and high risk for hepatitis B infection. Vaccination should begin at least 6 months before travel to allow for completion of the series.

▶ Hepatitis A

Protection is recommended for susceptible persons traveling to areas where sanitation is poor and the risk of exposure to hepatitis A high because of contaminated food and water supplies and contact with infected persons (eg, anywhere except Canada, western Europe, Japan, Australia, and New Zealand). Either hepatitis A vaccine or immunoglobulin can be used, although vaccination is preferred. The first dose of vaccine should be given as soon as travel is considered. In healthy individuals, a single dose of vaccine administered any time prior to travel will provide adequate protection. In older patients, those who are immunocompromised, and those with chronic liver disease or other chronic medical problems who are planning to travel in 2 weeks or less should receive hepatitis A vaccine and immunoglobulin 0.02 mL/kg simultaneously at different anatomic sites. Those who choose not to receive vaccine should receive immunoglobulin.

▶ Meningococcal Meningitis

If travel is contemplated to an area where meningococcal meningitis is epidemic (Nepal, sub-Saharan Africa, the "meningitis belt" from Senegal in the west to Ethiopia in the east, northern India) or highly endemic, vaccination with MCV4 is indicated for those 2–55 years of age, otherwise MPSV should be used. (Saudi Arabia requires immunization for pilgrims to Mecca.)

▶ Plague

The risk of plague is so small to travelers that vaccine is no longer commercially available and vaccination is not required for entry into any country. Travelers at unavoidable high risk of exposure to rodents should consider chemoprophylaxis with doxycycline or TMP-SMZ.

▶ Poliomyelitis

Polio remains endemic in five countries (Afghanistan, India, Pakistan, Nigeria, and Niger), and sporadic outbreaks from reinfection continues to occur in Somalia, Ethiopia, Angola, and Bangladesh. Adults traveling to endemic or epidemic areas who have not previously been immunized against poliomyelitis should receive a primary series of three doses of inactivated enhanced-potency poliovaccine (IPV), as follows: two doses of 0.5 mL subcutaneously 4–8 weeks apart and then a third dose 6–12 months after the second dose. If more than 8 weeks will elapse before travel, three doses of IPV can be given 4 weeks apart. If 4–8 weeks will elapse before travel, two doses are given 4 weeks apart, and if less than 4 weeks will elapse, a single dose is given. Vaccination can be completed upon return if continued or future exposure to polio is anticipated. Travelers who have previously been fully immunized with OPV

or IPV should receive a one-time booster dose with IPV. Data do not indicate the need for more than one adult booster. Live attenuated poliovaccine is no longer recommended because of the risk of vaccine-associated disease and is no longer available in the United States, although it continues to be used in many other countries.

▶ Rabies

For travelers to areas where rabies is common in domestic animals (eg, India, Asia, Mexico, Africa, areas of Central and South America), with extensive outdoor activities or certain professional activities (veterinarians, animal handlers, field biologists), preexposure prophylaxis with human diploid cell vaccine (HDCV), rabies vaccine adsorbed (RVA), or purified chick embryo cell culture (PCEC) vaccine should be considered. It usually consists of two intramuscular (deltoid area) injections of 1 mL given 1 week apart with a booster dose 2–3 weeks later. Alternatively, two intradermal injections of 0.1 mL of HDCV are given 1 week apart, with a booster dose given 2–3 weeks later. Chloroquine can blunt the immunologic response to rabies vaccine. If malaria prophylaxis with chloroquine is required, vaccination should be given intramuscularly (*not* intradermally) to ensure adequate antibody response. Until further studies are done, interaction between mefloquine and rabies vaccine, while not established, makes intramuscular administration prudent if mefloquine is to be given.

▶ Typhoid

Typhoid vaccination is recommended for travelers to developing countries (especially the Indian subcontinent, Asia, Africa, Central and South America, and the Caribbean) who will have prolonged exposure to contaminated food and water. Two preparations of approximately equal efficacy (50–75% effective) are available in the United States: (1) an oral live-attenuated Ty21a vaccine supplied as enteric-coated capsules, and (2) a Vi capsular polysaccharide (Vi CPS) vaccine for parenteral use. The Ty21a vaccine is given as one capsule every other day for four doses. The capsules must be refrigerated and taken with cool liquids (37 °C or less) at least 1 hour before meals. All four doses must be taken for maximum protection and should be completed 1 week before travel. It is not recommended for infants or children younger than 6 years. Adverse effects are minimal and consist primarily of gastrointestinal upset. The Vi CPS vaccine is given as a single intramuscular injection at least 2 weeks prior to travel. It is not recommended for infants younger than 2 years. Adverse effects consist mainly of local irritation at the site of injection, but fever and headache occur. If continued or repeated exposures are anticipated, boosters are recommended every 2 years for the Vi CPS and every 5 years for the Ty21a. The live attenuated vaccine should not be used in immunosuppressed patients, including those with HIV infection.

▶ Yellow Fever

The live attenuated yellow fever virus vaccine is administered once subcutaneously. Although the risk of yellow fever

Table 30–14. Adverse effects and contraindications to vaccinations.

| Vaccine | Adverse Effects | Contraindications |
|---|---|---|
| Hepatitis A | Minimal Consist mainly of pain at the injection site | |
| Hepatitis B | Minimal Consist mainly of pain at the injection site | Hypersensitivity to yeast Severe reaction to a previous dose |
| Human papillomavirus | Minimal Consists mainly of mild to moderate localized pain, erythema, swelling Systemic reactions, mainly fever, seen in 4% of recipients | History of hypersensitivity to yeast or to any vaccine component |
| Influenza (intramuscular inactivated and intranasal live attenuated vaccines) | Intramuscular, inactivated vaccine: Local reactions (erythema and tenderness) at the site of injection common, but fevers, chills, and malaise (which last in any case only 2–3 days) rare. Either inactivated or live attenuated vaccine: The risk of Guillain-Barré syndrome is not increased following vaccination. Influenza vaccination may be associated with multiple false-positive serologic tests to HIV, HTLV-1, and hepatitis C, but it is self-limited, lasting 2–5 months. | Intranasal, live attenuated vaccine [FluMist]: Should not be used in: People 50 years of age and over Household members of immunosuppressed individuals Health care workers, or others with close contact with immunosuppressed persons Presence of reactive airway disease; chronic underlying metabolic, pulmonary, or cardiovascular diseases (use intramuscular inactivated vaccine) Long-term aspirin therapy in children or adolescents (because of the risk of Reye syndrome) Pregnancy ¹ Contraindication to both inactivated and live attenuated vaccine: History of Guillain-Barré syndrome, especially within 6 weeks of receiving a previous influenza vaccine History of egg allergy ² |
| Measles, mumps, and rubella (MMR) ³ | Fever will develop in about 5–15% of unimmunized individuals, and a mild rash will develop in about 5% 5–12 days after vaccination. Fever and rash are self-limiting, lasting only 2–3 days. Local swelling and induration are particularly common in individuals previously vaccinated with inactivated vaccine. | Pregnancy ⁴ Immunosuppressed persons should not be vaccinated (with the exception of asymptomatic HIV-infected individuals whose CD4 count is > 200/mcL). History of anaphylaxis to neomycin or to related agents such as streptomycin |
| Meningococcal | Minor reactions (fever, redness, swelling, erythema, pain) occur slightly more commonly with MCV4. Major reactions are rare. A potential association between Guillain-Barré syndrome and vaccination with MCV4 has been reported, but current recommendations favor continued use of MCV4, since the benefits of preventing the serious consequences of meningococcal infection outweigh the theoretical risk of Guillain-Barré syndrome. | Persons with history of adverse reaction to diphtheria toxoid should not receive MCV4 since the protein conjugate used in MCV4 is diphtheria toxoid |
| Pneumococcal (polysaccharide) | Mild local reactions (erythema and tenderness) occur in up to 50% of recipients, but systemic reactions are uncommon. Similarly, revaccination at least 5 years after initial vaccination is associated with mild self-limited local but not systemic reactions. | Revaccination is not recommended for those who had a severe reaction (anaphylaxis or Arthus reaction) to the initial vaccination. |
| Tetanus, diphtheria, and pertussis | Minimal Consist mainly of pain at the injection site | Any history of anaphylaxis to vaccine components or if there is a history of unexplained encephalitis within 7 days of administration of a pertussis-containing vaccine. |

(continued)

Table 30-14. Adverse effects and contraindications to vaccinations. (continued)

| Vaccine | Adverse Effects | Contraindications |
|-----------|---|---|
| Varicella | <p>Can occur as late as 4–6 weeks after vaccination.</p> <p>Tenderness and erythema at the injection site are seen in 25%, fever in 10–15%, and a localized maculopapular or vesicular rash in 5%; a diffuse rash, usually with five or fewer vesicular lesions, develops in a smaller percentage.</p> <p>Spread of virus from vaccinees to susceptible individuals is possible, but the risk of such transmission even to immunocompromised patients is small and disease, when it develops, is mild and treatable with acyclovir.</p> | <p>Allergy to neomycin</p> <p>Avoid in immunocompromised individuals, including HIV-positive children and adults, or pregnant women.</p> <p>For theoretic reasons, it is recommended that salicylates should be avoided for 6 weeks following vaccination (to prevent Reye syndrome).</p> |
| Zoster | <p>Mild and limited to local reactions</p> <p>Although it is theoretically possible to transmit the virus to susceptible contacts, no such cases have been reported.</p> | <p>Presence of primary or acquired immunodeficiency state (leukemia, lymphoma, any malignant neoplasm affecting the bone marrow, HIV infection)</p> <p>Therapy with immunosuppressive medications (including high-dose corticosteroids)</p> <p>Pregnancy</p> <p>Persons with an anaphylactic type reaction to gelatin or neomycin should not receive the vaccine.</p> |

¹The inactivated influenza vaccine can be given during any trimester.

²The vaccine is prepared using embryonated chicken eggs.

³MMR vaccine can be safely given to patients with a history of egg allergy even when severe.

⁴Although vaccination of pregnant women is *not* recommended, with the currently available RA27/3 vaccine strain the congenital rubella syndrome does not occur in the offspring of those inadvertently vaccinated during pregnancy or within 3 months before conception.

is low for most travelers, a number of countries require vaccination for all visitors and others require it for travelers to or from endemic areas (mainly equatorial Africa and parts of South and Central America). The WHO certificate requires registration of the manufacturer and the batch number of the vaccine. Vaccination is available in the United States only at approved centers; the local health department should be contacted for available resources. Reimmunization is recommended at 10-year intervals if continued risk exists.

Because it is a live attenuated vaccine prepared in embryonated eggs, the yellow fever vaccine should not be given to immunosuppressed individuals or those with a history of anaphylaxis to eggs. Pregnancy is a relative contraindication to vaccination.

Two very severe adverse reactions have been associated with yellow fever vaccination. Viscerotropic disease presents with fever, jaundice, and multiple organ system failure within 30 days of yellow fever vaccination. Clinically and histopathologically, the illness is identical to yellow fever and is associated with a high mortality rate. The other adverse reaction is neurotropic disease and presents as encephalitis, encephalomyelitis, and Guillain-Barré syndrome. Because yellow fever is a severe disease and deaths have been reported in travelers, and these serious adverse reactions are rare (3–5 cases of viscerotropic disease and 4–6 cases of neurotropic disease per 1,000,000 doses of vaccine distributed), vaccination is still recommended but limited to those traveling to areas reporting epidemic or endemic yellow fever. (Current information about the vaccine and yellow

fever activity can be found at <http://www2.ncid.cdc.gov/travel/yb/utills/ybGet.asp?section=dis&obj=yellowfever.htm>.) The risk for serious adverse reactions are age-related (infants < 9 months; age > 60 years) and is greater in those with a history of thymus disease.

▶ Japanese B Encephalitis

Japanese B encephalitis is a mosquito-borne viral encephalitis that affects primarily children and older adults (65 years and older) and usually occurs from May to September. It is the leading cause of encephalitis in Asia. Because the risk of infection is low and because adverse effects of the vaccine can be serious, not all travelers to Asia should be vaccinated. Vaccine should be given to travelers to endemic areas who will be staying at least 30 days and who are traveling during the transmission season, particularly if they are visiting rural areas. Travelers who spend less than 30 days in the region should be considered for vaccination if they intend to visit areas of epidemic transmission or if extensive outdoor activities are planned in rural rice-growing areas. The recommended primary immunization schedule is 1 mL of vaccine administered subcutaneously on days 0, 7, and 30. If time constraints are compelling, the last dose can be given on day 14. The last dose should be given at least 10 days before embarkation because urticaria and angioedema have been described, occurring from minutes up to 10 days after vaccination. Following vaccination, patients should be observed for 30 minutes and advised of the possibility of delayed reactions of angioedema and urticaria. In addition,

local reactions have been reported in 20% of vaccinees and systemic reactions (fever, chills, malaise, headache) in 10%.

VACCINE SAFETY

Most vaccines are safe to administer. In general, it is recommended that the use of live vaccines be avoided in immunocompromised patients, including pregnant women. Vaccines are generally not contraindicated in the following situations: mild, acute illness with low-grade fevers (<40.5 °C); concurrent antibiotic therapy; soreness or redness at the site; family history of adverse reactions to vaccinations. Absolute contraindications to vaccines are rare (Table 30–14).

HIV Infection & AIDS

Andrew R. Zolopa, MD
Mitchell H. Katz, MD

31

ESSENTIALS OF DIAGNOSIS

- ▶ Risk factors: sexual contact with an infected person, parenteral exposure to infected blood by transfusion or needle sharing, perinatal exposure.
- ▶ Prominent systemic complaints such as sweats, diarrhea, weight loss, and wasting.
- ▶ Opportunistic infections due to diminished cellular immunity—often life-threatening.
- ▶ Aggressive cancers, particularly Kaposi sarcoma and extranodal lymphoma.
- ▶ Neurologic manifestations, including dementia, aseptic meningitis, and neuropathy.

General Considerations

When AIDS was first recognized in the United States in 1981, cases were identified by finding severe opportunistic infections such as *Pneumocystis* pneumonia that indicated profound defects in cellular immunity in the absence of other causes of immunodeficiency. When the syndrome was found to be caused by HIV, it became obvious that severe opportunistic infections and unusual neoplasms were at one end of a spectrum of disease, while healthy seropositive individuals were at the other end.

The Centers for Disease Control and Prevention (CDC) AIDS case definition (Table 31-1) includes opportunistic infections and malignancies that rarely occur in the absence of severe immunodeficiency (eg, *Pneumocystis* pneumonia, central nervous system lymphoma). It also classifies persons as having AIDS if they have positive HIV serology and certain infections and malignancies that can occur in immunocompetent hosts but that are more common among persons infected with HIV (pulmonary tuberculosis, invasive cervical cancer). Several nonspecific conditions, including dementia and wasting (documented weight loss)—in the presence of a positive HIV serology—are considered AIDS. The definition includes criteria for both definitive and presumptive diagnoses of certain infections and malignancies. Finally, persons with positive HIV

serology who have ever had a CD4 lymphocyte count below 200 cells/mcL or a CD4 lymphocyte percentage below 14% are considered to have AIDS. Inclusion of persons with low CD4 counts as AIDS cases reflects the recognition that immunodeficiency is the defining characteristic of AIDS. The choice of a cutoff point at 200 cells/mcL is supported by several cohort studies showing that AIDS will develop within 3 years in over 80% of persons with counts below this level in the absence of effective antiretroviral therapy (ART). The 1993 definition was also expanded to include persons with positive HIV serology and pulmonary tuberculosis (Plate 66), recurrent pneumonia, and invasive cervical cancer. The prognosis of persons with HIV/AIDS has dramatically improved due to the introduction of highly active antiretroviral therapy (HAART) in the mid 1990s. One consequence is that fewer persons with HIV ever develop an infection or malignancy or have a low enough CD4 count to classify them as having AIDS, which means that the CDC definition has become a less useful measure of the impact of HIV/AIDS in the United States. Conversely, persons in whom AIDS had been diagnosed based on a serious opportunistic infection, malignancy, or immunodeficiency may now be markedly healthier, with high CD4 counts, due to the use of HAART. Therefore, the Social Security Administration as well as most social service agencies focus on functional assessment for determining eligibility for benefits rather than the simple presence or absence of an AIDS-defined illness.

Epidemiology

The modes of transmission of HIV are similar to those of hepatitis B, in particular with respect to sexual, parenteral, and vertical transmission. Although certain sexual practices (eg, receptive anal intercourse) are significantly riskier than other sexual practices (eg, oral sex), it is difficult to quantify per-contact risks. The reason is that studies of sexual transmission of HIV show that most people at risk for HIV infection engage in a variety of sexual practices and have sex with multiple persons, only some of whom may actually be HIV infected. Thus, it is difficult to determine which practice with which person actually resulted in HIV transmission.

Table 31–1. CDC AIDS case definition for surveillance of adults and adolescents.

| Definitive AIDS diagnoses (with or without laboratory evidence of HIV infection) |
|--|
| 1. Candidiasis of the esophagus, trachea, bronchi, or lungs. |
| 2. Cryptococcosis, extrapulmonary. |
| 3. Cryptosporidiosis with diarrhea persisting > 1 month. |
| 4. Cytomegalovirus disease of an organ other than liver, spleen, or lymph nodes. |
| 5. Herpes simplex virus infection causing a mucocutaneous ulcer that persists longer than 1 month; or bronchitis, pneumonitis, or esophagitis of any duration. |
| 6. Kaposi sarcoma in a patient < 60 years of age. |
| 7. Lymphoma of the brain (primary) in a patient < 60 years of age. |
| 8. <i>Mycobacterium avium</i> complex or <i>Mycobacterium kansasii</i> disease, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes). |
| 9. <i>Pneumocystis jiroveci</i> pneumonia. |
| 10. Progressive multifocal leukoencephalopathy. |
| 11. Toxoplasmosis of the brain. |
| Definitive AIDS diagnoses (with laboratory evidence of HIV infection) |
| 1. Coccidioidomycosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes). |
| 2. HIV encephalopathy. |
| 3. Histoplasmosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes). |
| 4. Isosporiasis with diarrhea persisting > 1 month. |
| 5. Kaposi sarcoma at any age. |
| 6. Lymphoma of the brain (primary) at any age. |
| 7. Other non-Hodgkin lymphoma of B cell or unknown immunologic phenotype. |
| 8. Any mycobacterial disease caused by mycobacteria other than <i>Mycobacterium tuberculosis</i> , disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes). |
| 9. Disease caused by extrapulmonary <i>M tuberculosis</i> . |
| 10. <i>Salmonella</i> (nontyphoid) septicemia, recurrent. |
| 11. HIV wasting syndrome. |
| 12. CD4 lymphocyte count below 200 cells/m ³ or a CD4 lymphocyte percentage below 14%. |
| 13. Pulmonary tuberculosis. |
| 14. Recurrent pneumonia. |
| 15. Invasive cervical cancer. |
| Presumptive AIDS diagnoses (with laboratory evidence of HIV infection) |
| 1. Candidiasis of esophagus: (a) recent onset of retrosternal pain on swallowing; and (b) oral candidiasis. |
| 2. Cytomegalovirus retinitis. A characteristic appearance on serial ophthalmoscopic examinations. |
| 3. Mycobacteriosis. Specimen from stool or normally sterile body fluids or tissue from a site other than lungs, skin, or cervical or hilar lymph nodes, showing acid-fast bacilli of a species not identified by culture. |
| 4. Kaposi sarcoma. Erythematous or violaceous plaque-like lesion on skin or mucous membrane. |
| 5. <i>Pneumocystis jiroveci</i> pneumonia: (a) a history of dyspnea on exertion or nonproductive cough of recent onset (within the past 3 months); and (b) chest x-ray evidence of diffuse bilateral interstitial infiltrates or gallium scan evidence of diffuse bilateral pulmonary disease; and (c) arterial blood gas analysis showing an arterial oxygen partial pressure of < 70 mm Hg or a low respiratory diffusing capacity of < 80% of predicted values or an increase in the alveolar-arterial oxygen tension gradient; and (d) no evidence of a bacterial pneumonia. |
| 6. Toxoplasmosis of the brain: (a) recent onset of a focal neurologic abnormality consistent with intracranial disease or a reduced level of consciousness; and (b) brain imaging evidence of a lesion having a mass effect or the radiographic appearance of which is enhanced by injection of contrast medium; and (c) serum antibody to toxoplasmosis or successful response to therapy for toxoplasmosis. |
| 7. Recurrent pneumonia: (a) more than one episode in a 1-year period; and (b) acute pneumonia (new symptoms, signs, or radiologic evidence not present earlier) diagnosed on clinical or radiologic grounds by the patient's physician. |
| 8. Pulmonary tuberculosis: (a) apical or miliary infiltrates and (b) radiographic and clinical response to antituberculous therapy. |

Nonetheless, the best available estimates indicate that the risk of HIV transmission with receptive anal intercourse is between 1:100 and 1:30, with insertive anal intercourse 1:1000, with receptive vaginal intercourse 1:1000, with insertive vaginal intercourse 1:10,000, and with receptive fellatio with ejaculation 1:1000. The per-contact risk of HIV transmission with other behaviors, including receptive fellatio without ejaculation, insertive fellatio, and cunnilingus, is not known.

All per-contact risk estimates assume that the source is HIV infected. If the HIV status of the source is unknown, the risk of transmission is the risk of transmission multiplied by the probability that the source is HIV infected. This would vary by risk practices, age, and geographic area. A number of cofactors are known to increase the risk of HIV transmission during a given encounter, including the presence of ulcerative or inflammatory sexually transmitted diseases, trauma, menses, and lack of male circumcision.

The risk of acquiring HIV infection from a needlestick with infected blood is approximately 1:300. Factors known to increase the risk of transmission include depth of penetration, hollow bore needles, visible blood on the needle, and advanced stage of disease in the source. The risk of HIV transmission from a mucosal splash with infected blood is unknown but is assumed to be significantly lower.

The risk of acquiring HIV infection from illicit drug use with sharing of needles from an HIV-infected source is estimated to be 1:150. Use of clean needles markedly decreases the chance of HIV transmission but does not eliminate it if other drug paraphernalia are shared (eg, cookers).

When blood transfusion from an HIV-infected donor occurs, the risk of transmission is 95%. Fortunately, since 1985, blood donor screening using the HIV enzyme-linked immunosorbent assay (ELISA) has been universally practiced in the United States. Also, persons who have recently engaged in unsafe behaviors (eg, sex with a person at risk for HIV, injection drug use) are not allowed to donate. This eliminates donations from persons who are HIV infected but have not yet developed antibodies (ie, persons in the "window" period). In recent years, HIV antigen and viral load testing have been added to the screening of blood to further lower the chance of HIV transmission. With these precautions, the chance of HIV transmission with receipt of blood transfusion is about 1:1,000,000.

In the absence of perinatal HIV prophylaxis, between 13% and 40% of children born to HIV-infected mothers contract HIV infection. The risk is higher with vaginal than with cesarean delivery, higher among mothers with high viral loads, and higher among those who breast-feed their children. The risk can be decreased by administering antiretroviral treatment to the mother during pregnancy and to the infant immediately after birth (see below).

HIV has not been shown to be transmitted by respiratory droplet spread, by vectors such as mosquitoes, or by casual nonsexual contact.

Current estimates are that about 950,000 Americans are infected with HIV, and there are about 53,000 new infections each year. At the end of 2006, there were an estimated 448,871 persons in the United States living with AIDS. Of those, 76% are men, of whom 60% were exposed through

male-to-male sexual contact, 19% were exposed through injection drug use, 12% were exposed through heterosexual contact, and 8% were exposed through male-to-male sexual contact and injection drug use. Women account for 23% of living persons, of whom 66% were infected through heterosexual contact and 32% were exposed through injection drug use. Children account for less than 1% of living cases. African Americans have been disproportionately hard hit by the epidemic. The estimated rate in 2006 of new AIDS cases in the United States per 100,000 population was 60.3 among African Americans, 20.8 among Latinos, 7.8 among native Americans and native Alaskans, 6.4 among whites, and 4.4 among Asians and Pacific Islanders.

In general, the progression of HIV-related illness is similar in men and women. However, there are some important differences. Women are at risk for gynecologic complications of HIV, including recurrent candidal vaginitis, pelvic inflammatory disease, and cervical dysplasia. Violence directed against women, pregnancy, and frequent occurrence of drug use and poverty all complicate the treatment of HIV-infected women. Although "safer sex" campaigns dramatically decreased the rates of seroconversions among men who have sex with men (MSM) living in metropolitan areas in the United States by the mid 1980s, relapse to unsafe sexual practices among MSM in several large cities in the United States and in western Europe has been observed. The higher rates of unsafe sex appear to be related to decreased concern about acquiring HIV due to the availability of HAART. Decreased interest in following safer sex recommendations and increasing use of crystal methamphetamine among certain risk groups also appears to be playing a role in the increased unsafe sex rates.

Worldwide there are an estimated 33 million persons infected with HIV. In Central and East Africa in some urban areas, as many as one-third of sexually active adults are infected. HIV infection began to spread in Asia in the late 1980s. The most common mode of transmission is bidirectional heterosexual spread. The reason for the greater risk for transmission with heterosexual intercourse in Africa and Asia than in the United States may relate to cofactors such as general health status, the presence of genital ulcers, relative lack of male circumcision, the number of sexual partners, and different HIV serotypes.

► Etiology

HIV, like other retroviruses, depends on a unique enzyme, reverse transcriptase (RNA-dependent DNA polymerase), to replicate within host cells. The other major pathogenic human retrovirus, human T cell lymphotropic/leukemia virus (HTLV)-I, is associated with lymphoma, while HIV is not known to be directly oncogenic. The HIV genomes contain genes for three basic structural proteins and at least five other regulatory proteins; *gag* codes for group antigen proteins, *pol* codes for polymerase, and *env* codes for the external envelope protein. The greatest variability in strains of HIV occurs in the viral envelope. Since neutralizing activity is found in antibodies directed against the envelope, this variability presents problems for vaccine development.

In addition to the classic AIDS virus (HIV-1), a group of related viruses, HIV-2, has been isolated in West African patients. HIV-2 has the same genetic organization as HIV-1, but there are significant differences in the envelope glycoproteins. Some infected individuals exhibit AIDS-like illnesses, but the rate of progression in individuals infected with HIV-2 appears to be slower than that of HIV-1 infection. HIV-2 remains relatively rare in the United States but has become more common in Western Europe due to immigration from endemic areas. Cases have been documented in which AIDS-like illnesses have occurred in the absence of HIV infection or other known infectious causes of immunodeficiency.

► Pathogenesis

The hallmark of symptomatic HIV infection is immunodeficiency caused by continuing viral replication. The virus can infect all cells expressing the T4 (CD4) antigen, which HIV uses to attach to the cell. Chemokine co-receptors (CCR5 and CXCR4) are required for virus entry, and individuals with CCR5 deletions are less likely to become infected and, once infected, the disease is more likely to progress slowly. Once it enters a cell, HIV can replicate and cause cell fusion or death. A latent state is also established, with integration of the HIV genome into the cell's genome. The cell principally infected is the CD4 (helper-inducer) lymphocyte, which directs many other cells in the immune network. With increasing duration of infection, the number of CD4 lymphocytes falls. Some of the immunologic defects, however, are explained not by *quantitative* abnormalities of lymphocyte subsets but by *qualitative* defects in CD4 responsiveness induced by HIV.

Other cells in the immune network that are infected by HIV include B lymphocytes and macrophages. The defect in B cells is partly due to disordered CD4 lymphocyte function. These direct and indirect effects can lead to

generalized hypergammaglobulinemia and can also depress B cell responses to new antigen challenges. Because of these defects, the immunodeficiency of HIV is mixed. Elements of humoral and cellular immunodeficiency are present, especially in children. Macrophages act as a reservoir for HIV and serve to disseminate it to other organ systems (eg, the central nervous system).

Apart from the immunologic effects of HIV, the virus can also directly cause a variety of neurologic effects. Neuropathology largely results from the release of cytokines and other neurotoxins by infected macrophages. Perturbations of excitatory neurotransmitters and calcium flux may contribute to neurologic dysfunction. Direct HIV infection of renal tubular cells and gastrointestinal epithelium may contribute to these organ system manifestations of infection.

► Pathophysiology

Clinically, the syndromes caused by HIV infection are usually explicable by one of three known mechanisms: immunodeficiency, autoimmunity, and allergic and hypersensitivity reactions.

A. Immunodeficiency

Immunodeficiency is a direct result of the effects of HIV upon immune cells. A spectrum of infections and neoplasms is seen, as in other congenital or acquired immunodeficiency states. Two remarkable features of HIV immunodeficiency are the low incidence of certain infections such as listeriosis and aspergillosis and the frequent occurrence of certain neoplasms such as lymphoma or Kaposi sarcoma. This latter complication has been seen primarily in MSM or in bisexual men, and its incidence has steadily declined through the first 15 years of the epidemic. A herpesvirus (KSHV or HHV-8) is the cause of Kaposi sarcoma.

B. Autoimmunity/Allergic & Hypersensitivity Reactions

Autoimmunity can occur as a result of disordered cellular immune function or B lymphocyte dysfunction. Examples of both lymphocytic infiltration of organs (eg, lymphocytic interstitial pneumonitis) and autoantibody production (eg, immunologic thrombocytopenia) occur. These phenomena may be the only clinically apparent disease or may coexist with obvious immunodeficiency. Moreover, HIV-infected individuals appear to have higher rates of allergic reactions to unknown allergens as seen with eosinophilic pustular folliculitis (“itchy red bump syndrome”) as well as increased rates of hypersensitivity reactions to medications (for example, the fever and sunburn-like rash seen with trimethoprim-sulfamethoxazole reactions).

► Clinical Findings

The complications of HIV-related infections and neoplasms affect virtually every organ. The general approach to the HIV-infected person with symptoms is to evaluate the organ systems involved, aiming to diagnose treatable conditions rapidly. As can be seen in Figure 31–1, the CD4

▲ **Figure 31-1.** Relationship of CD4 count to development of opportunistic infections. MAC, *Mycobacterium avium* complex; CMV, cytomegalovirus; CNS, central nervous system.

lymphocyte count provides very important prognostic information. Certain infections may occur at any CD4 count, while others rarely occur unless the CD4 lymphocyte count has dropped below a certain level. For example, a patient with a CD4 count of 600 cells/mcL, cough, and fever may have a bacterial pneumonia but would be very unlikely to have *Pneumocystis* pneumonia.

A. Symptoms and Signs

Many individuals with HIV infection remain asymptomatic for years even without antiretroviral therapy, with a mean time of approximately 10 years between exposure and development of AIDS. When symptoms occur, they may be remarkably protean and nonspecific. Since virtually all the findings may be seen with other diseases, a combination of complaints is more suggestive of HIV infection than any one symptom.

Physical examination may be entirely normal. Abnormal findings range from completely nonspecific to highly specific for HIV infection. Those that are specific for HIV infection include hairy leukoplakia of the tongue, disseminated Kaposi sarcoma, and cutaneous bacillary angiomatosis. Generalized lymphadenopathy is common early in infection.

1. Systemic complaints—Fever, night sweats, and weight loss are common symptoms in HIV-infected patients and may occur without a complicating opportunistic infection. Patients with persistent fever and no localizing symptoms should nonetheless be carefully examined, and evaluated with a chest radiograph (*Pneumocystis* pneumonia can

present without respiratory symptoms), bacterial blood cultures if the fever is greater than 38.5 °C, serum cryptococcal antigen, and mycobacterial cultures of the blood. Sinus CT scans or sinus radiographs should be considered to evaluate occult sinusitis. If these studies are normal, patients should be observed closely. Antipyretics are useful to prevent dehydration.

Weight loss is a particularly distressing complication of long-standing HIV infection. Patients typically have disproportionate loss of muscle mass, with maintenance or less substantial loss of fat stores. The mechanism of HIV-related weight loss is not completely understood but appears to be multifactorial.

AIDS patients frequently suffer from anorexia, nausea, and vomiting, all of which contribute to weight loss by decreasing caloric intake. In some cases, these symptoms are secondary to a specific infection, such as viral hepatitis. In other cases, however, evaluation of the symptoms yields no specific pathogen, and it is assumed to be due to a primary effect of HIV. Malabsorption also plays a role in decreased caloric intake. Patients may suffer diarrhea from infections with bacterial, viral, or parasitic agents.

Exacerbating the decrease in caloric intake, many AIDS patients have an increased metabolic rate. This increased rate has been shown to exist even among asymptomatic HIV-infected persons, but it accelerates with disease progression and secondary infection. AIDS patients with secondary infections also have decreased protein synthesis, which makes maintaining muscle mass difficult.

Several strategies have been developed to slow AIDS wasting. Effective fever control decreases the metabolic

rate and may slow the pace of weight loss, as does treating the underlying opportunistic infection. Food supplementation with high-calorie drinks may enable patients with not much appetite to maintain their intake. Selected patients with otherwise good functional status and weight loss due to unrelenting nausea, vomiting, or diarrhea may benefit from total parenteral nutrition (TPN). It should be noted, however, that TPN is more likely to increase fat stores than to reverse the muscle wasting process.

Two pharmacologic approaches for increasing appetite and weight gain are the progestational agent megestrol acetate (80 mg four times a day) and the antiemetic agent dronabinol (2.5–5 mg three times a day). Side effects from megestrol acetate are rare, but thromboembolic phenomena, edema, nausea, vomiting, and rash have been reported. Euphoria, dizziness, paranoia, and somnolence and even nausea and vomiting have been reported in 3–10% of patients using dronabinol. Dronabinol contains only one of the active ingredients in smoked marijuana, and many patients report better relief of nausea and improvement of appetite with smoking marijuana. Several states allow physicians to recommend the use of smoked marijuana to their patients. However, it is still illegal in the United States to sell marijuana. Thus, a physician's recommendation may at best decrease the chance that patients will be prosecuted for use of marijuana. Unfortunately, neither megestrol acetate nor dronabinol increases lean body mass.

Two regimens that have resulted in increases in lean body mass are growth hormone and anabolic steroids. Growth hormone at a dose of 0.1 mg/kg/d (up to 6 mg) subcutaneously for 12 weeks has resulted in modest increases in lean body mass. Treatment with growth hormone can cost as much as \$10,000 per month. Anabolic steroids also increase lean body mass among HIV-infected patients. They seem to work best for patients who are able to do weight training. The most commonly used regimens are testosterone enanthate or testosterone cypionate (100–200 mg intramuscularly every 2–4 weeks). Testosterone transdermal system (apply 5 mg system each evening) and testosterone gel (1%; apply a 5-g packet [50 mg testosterone] to clean, dry skin daily) are also available. The anabolic steroid oxandrolone (20 mg orally in two divided doses) has also been found to increase lean body mass.

Nausea leading to weight loss is sometimes due to esophageal candidiasis. Patients with oral candidiasis and nausea should be empirically treated with an oral antifungal agent. Patients with weight loss due to nausea of unclear origin may benefit from use of antiemetics prior to meals (prochlorperazine, 10 mg three times daily; metoclopramide, 10 mg three times daily; or ondansetron, 8 mg three times daily). Dronabinol (5 mg three times daily) can also be used to increase appetite. Depression and adrenal insufficiency are two potentially treatable causes of weight loss.

2. Pulmonary disease

A. PNEUMOCYSTIS PNEUMONIA—(See also discussions in Chapter 36.) *Pneumocystis jiroveci* pneumonia is the most common opportunistic infection associated with AIDS. *Pneumocystis* pneumonia may be difficult to diagnose because the symptoms—fever, cough, and shortness of

breath—are nonspecific. Furthermore, the severity of symptoms ranges from fever and no respiratory symptoms through mild cough or dyspnea to frank respiratory distress.

Hypoxemia may be severe, with a P_{O_2} less than 60 mm Hg. The cornerstone of diagnosis is the chest radiograph. Diffuse or perihilar infiltrates are most characteristic, but only two-thirds of patients with *Pneumocystis* pneumonia have this finding. Normal chest radiographs are seen in 5–10% of patients with *Pneumocystis* pneumonia, while the remainder have atypical infiltrates. Apical infiltrates are commonly seen among patients with *Pneumocystis* pneumonia who have been receiving aerosolized pentamidine prophylaxis. Large pleural effusions are uncommon with *Pneumocystis* pneumonia; their presence suggests bacterial pneumonia, other infections such as tuberculosis, or pleural Kaposi sarcoma.

Definitive diagnosis can be obtained in 50–80% of cases by Wright-Giemsa stain or direct fluorescence antibody (DFA) test of induced sputum. Sputum induction is performed by having patients inhale an aerosolized solution of 3% saline produced by an ultrasonic nebulizer. Patients should not eat for at least 8 hours and should not use toothpaste or mouthwash prior to the procedure since they can interfere with test interpretation. The next step for patients with negative sputum examinations in whom *Pneumocystis* pneumonia is still suspected should be bronchoalveolar lavage. This technique establishes the diagnosis in over 95% of cases.

In patients with symptoms suggestive of *Pneumocystis* pneumonia but with negative or atypical chest radiographs and negative sputum examinations, other diagnostic tests may provide additional information in deciding whether to proceed to bronchoalveolar lavage. Elevation of serum lactate dehydrogenase occurs in 95% of cases of *Pneumocystis* pneumonia, but the specificity of this finding is at best 75%. Either a normal diffusing capacity of carbon monoxide (DL_{CO}) or a high-resolution CT scan of the chest that demonstrates no interstitial lung disease makes the diagnosis of *Pneumocystis* pneumonia very unlikely. In addition, a CD4 count above 250 cells/mL within 2 months prior to evaluation of respiratory symptoms makes a diagnosis of *Pneumocystis* pneumonia unlikely; only 1–5% of cases occur above this CD4 count level (Figure 31–1). This is true even if the patient previously had a CD4 count lower than 200 cells/mL but has had an increase with antiretroviral therapy. Pneumothoraces can be seen in HIV-infected patients with a history of *Pneumocystis* pneumonia, especially if they have received aerosolized pentamidine treatment.

B. OTHER INFECTIOUS PULMONARY DISEASES—Other infectious causes of pulmonary disease in AIDS patients include bacterial, mycobacterial, and viral pneumonias. Community-acquired pneumonia is the most common cause of pulmonary disease in HIV-infected persons. An increased incidence of pneumococcal pneumonia with septicemia and *Haemophilus influenzae* pneumonia has been reported. *Pseudomonas aeruginosa* is an important respiratory pathogen in advanced disease. The incidence of infection with *Mycobacterium tuberculosis* has markedly increased in metropolitan areas because of HIV infection as well as home-

lessness. Tuberculosis occurs in an estimated 4% of persons in the United States who have AIDS. Apical infiltrates and disseminated disease occur more commonly than among immunocompetent persons. Although a purified protein derivative (PPD) test should be performed on all HIV-infected persons in whom a diagnosis of tuberculosis is being considered, the lower the CD4 cell count, the greater the likelihood of anergy. Because “anergy” skin test panels do not accurately classify those patients who are infected with tuberculosis but unreactive to the PPD, they are not recommended. Treatment of HIV-infected persons with active tuberculosis is similar to treatment of HIV-uninfected tubercular individuals (see Figure 31-1). However, rifampin should not be given to patients receiving indinavir, nelfinavir, amprenavir, lopinavir, or delavirdine. In these cases, rifabutin may be substituted, but it may require dosing modifications depending on the antiretroviral regimen. Multidrug-resistant tuberculosis is a major problem in several metropolitan areas. Noncompliance with prescribed antituberculous drugs is a major risk factor. Several of the reported outbreaks appear to implicate nosocomial spread. The emergence of drug resistance makes it essential that antibiotic sensitivities be performed on all positive cultures. Drug therapy should be individualized. Patients with multidrug-resistant *M tuberculosis* infection should receive at least three drugs to which their organism is sensitive. Atypical mycobacteria can cause pulmonary disease in AIDS patients with or without preexisting lung disease and responds variably to treatment. Making a distinction between *M tuberculosis* and atypical mycobacteria requires culture of sputum specimens. If culture of the sputum produces acid-fast bacilli, definitive identification may take several weeks using traditional techniques. DNA probes allow for presumptive identification usually within days of a positive culture. While awaiting definitive diagnosis, clinicians should err on the side of treating patients as if they have *M tuberculosis* infection. In cases in which the risk of atypical mycobacteria is very high (eg, a person without risk for tuberculosis exposure with a CD4 count under 50 cells/mL—see Figure 31-1), clinicians may wait for definitive diagnosis if the person is smear-negative for acid-fast bacilli, clinically stable, and not living in a communal setting. Isolation of cytomegalovirus (CMV) from bronchoalveolar lavage fluid occurs commonly in AIDS patients but does not establish a definitive diagnosis. Diagnosis of CMV pneumonia requires biopsy; response to treatment is poor. Histoplasmosis, coccidioidomycosis, and cryptococcal disease should also be considered in the differential diagnosis of unexplained pulmonary infiltrates.

C. NONINFECTIOUS PULMONARY DISEASES—Noninfectious causes of lung disease include Kaposi sarcoma, non-Hodgkin lymphoma, and interstitial pneumonitis. In patients with known Kaposi sarcoma, pulmonary involvement complicates the course in approximately one-third of cases. However, pulmonary involvement is rarely the presenting manifestation of Kaposi sarcoma. Non-Hodgkin lymphoma may involve the lung as the sole site of disease but more commonly involves other organs as well, especially the brain, liver, and gastrointestinal tract. Both of

these processes may show nodular or diffuse parenchymal involvement, pleural effusions, and mediastinal adenopathy on chest radiographs.

Nonspecific interstitial pneumonitis may mimic *Pneumocystis* pneumonia. Lymphocytic interstitial pneumonitis seen in lung biopsies has a variable clinical course. Typically, these patients present with several months of mild cough and dyspnea; chest radiographs show interstitial infiltrates. Many patients with this entity undergo transbronchial biopsies in an attempt to diagnose *Pneumocystis* pneumonia. Instead, the tissue shows interstitial inflammation ranging from an intense lymphocytic infiltration (consistent with lymphoid interstitial pneumonitis) to a mild mononuclear inflammation. Corticosteroids may be helpful in some cases refractory to antiretroviral therapy.

D. SINUSITIS—Chronic sinusitis can be a frustrating problem for HIV-infected patients even in those on adequate antiretroviral therapy. Symptoms include sinus congestion and discharge, headache, and fever. Some patients may have radiographic evidence of sinus disease on sinus CT scan or sinus x-ray in the absence of significant symptoms. Nonsmoking patients with purulent drainage should be treated with amoxicillin (500 mg orally three times a day). Patients who smoke should be treated with amoxicillin-potassium clavulanate (500 mg orally three times a day) to cover *H influenzae*. Prolonged treatment (3–6 weeks) with an antibiotic and guaifenesin (600 mg orally twice daily) to decrease sinus congestion may be required. For patients not responding to amoxicillin-potassium clavulanate, levofloxacin should be tried (400 mg orally daily). Some patients may require referral to an otolaryngologist for sinus drainage.

3. Central nervous system disease—Central nervous system disease in HIV-infected patients can be divided into intracerebral space-occupying lesions, encephalopathy, meningitis, and spinal cord processes. Many of these complications have declined markedly in prevalence in the era of HAART.

A. TOXOPLASMOSIS—Toxoplasmosis is the most common space-occupying lesion in HIV-infected patients. Headache, focal neurologic deficits, seizures, or altered mental status may be presenting symptoms. The diagnosis is usually made presumptively based on the characteristic appearance of cerebral imaging studies in an individual known to be seropositive for *Toxoplasma*. Typically, toxoplasmosis appears as multiple contrast-enhancing lesions on CT scan. Lesions tend to be peripheral, with a predilection for the basal ganglia.

Single lesions are atypical of toxoplasmosis. When a single lesion has been detected by CT scanning, MRI scanning may reveal multiple lesions because of its greater sensitivity. If a patient has a single lesion on MRI and is neurologically stable, clinicians may pursue a 2-week empiric trial of toxoplasmosis therapy. A repeat scan should be performed at 2 weeks. If the lesion has not diminished in size, biopsy of the lesion should be performed. Since many HIV-infected patients will have detectable titers, a positive *Toxoplasma* serologic test does not confirm the diagnosis. Conversely, less

than 3% of patients with toxoplasmosis have negative titers. Therefore, negative *Toxoplasma* titers in an HIV-infected patient with a space-occupying lesion should be a cause for aggressively pursuing an alternative diagnosis.

B. CENTRAL NERVOUS SYSTEM LYMPHOMA—Primary non-Hodgkin lymphoma is the second most common space-occupying lesion in HIV-infected patients. Symptoms are similar to those with toxoplasmosis. While imaging techniques cannot distinguish these two diseases with certainty, lymphoma more often is solitary. Other less common lesions should be suspected if there is preceding bacteremia, positive tuberculin test, fungemia, or injection drug use. These include bacterial abscesses, cryptococcomas, tuberculomas, and *Nocardia* lesions.

Because techniques for stereotactic brain biopsy have improved, this procedure plays an increasing role in diagnosing cerebral lesions. Biopsy should be strongly considered if lesions are solitary or do not respond to toxoplasmosis treatment, especially if they are easily accessible. Diagnosis of lymphoma is important because many patients benefit from treatment (radiation therapy). In the future, it may be possible to avoid brain biopsy by utilizing polymerase chain reaction (PCR) assay of cerebrospinal fluid for Epstein-Barr virus DNA, which is present in 90% of CNS lymphoma cases.

C. AIDS DEMENTIA COMPLEX—The diagnosis of AIDS dementia complex (HIV-associated cognitive-motor complex) is one of exclusion based on a brain imaging study and on spinal fluid analysis that excludes other pathogens. Neuropsychiatric testing is helpful in distinguishing patients with dementia from those with depression. Patients with AIDS dementia complex typically have difficulty with cognitive tasks and exhibit diminished motor speed. Patients may first notice a deterioration in their handwriting. The manifestations of dementia may wax and wane, with persons exhibiting periods of lucidity and confusion over the course of a day. Many patients improve with effective antiretroviral treatment. Metabolic abnormalities may also cause changes in mental status: hypoglycemia, hyponatremia, hypoxia, and drug overdose are important considerations in this population. Other less common infectious causes of encephalopathy include progressive multifocal leukoencephalopathy (discussed below), CMV, syphilis, and herpes simplex encephalitis.

D. CRYPTOCOCCAL MENINGITIS—Cryptococcal meningitis typically presents with fever and headache. Less than 20% of patients have meningismus. Diagnosis is based on a positive latex agglutination test that detects cryptococcal antigen (or “CRAG”) or positive culture of spinal fluid for *Cryptococcus*. Seventy to 90% of patients with cryptococcal meningitis have a positive serum CRAG. Thus, a negative serum CRAG test makes a diagnosis of cryptococcal meningitis unlikely and can be useful in the initial evaluation of a patient with headache, fever, and normal mental status. HIV meningitis, characterized by lymphocytic pleocytosis of the spinal fluid with negative culture, is common early in HIV infection.

E. HIV MYELOPATHY—Spinal cord function may also be impaired in HIV-infected individuals. HIV myelopathy

presents with leg weakness and incontinence. Spastic paraparesis and sensory ataxia are seen on neurologic examination. Myelopathy is usually a late manifestation of HIV disease, and most patients will have concomitant HIV encephalopathy. Pathologic evaluation of the spinal cord reveals vacuolation of white matter. Because HIV myelopathy is a diagnosis of exclusion, symptoms suggestive of myelopathy should be evaluated by lumbar puncture to rule out CMV polyradiculopathy (described below) and an MRI or CT scan to exclude epidural lymphoma.

F. PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY (PML)—PML is a viral infection of the white matter of the brain seen in patients with very advanced HIV infection. It typically results in focal neurologic deficits such as aphasia, hemiparesis, and cortical blindness. Imaging studies are strongly suggestive of the diagnosis if they show nonenhancing white matter lesions without mass effect. Extensive lesions may be difficult to differentiate from the changes caused by HIV. Several patients have stabilized or improved after the institution of combination antiretroviral therapy or cidofovir.

4. Peripheral nervous system—Peripheral nervous system syndromes include inflammatory polyneuropathies, sensory neuropathies, and mononeuropathies.

An inflammatory demyelinating polyneuropathy similar to Guillain-Barré syndrome occurs in HIV-infected patients, usually prior to frank immunodeficiency. The syndrome in many cases improves with plasmapheresis, supporting an autoimmune basis of the disease. CMV can cause an ascending polyradiculopathy characterized by lower extremity weakness and a neutrophilic pleocytosis on spinal fluid analysis with a negative bacterial culture. Transverse myelitis can be seen with herpes zoster or CMV.

Peripheral neuropathy is common among HIV-infected persons. Patients typically complain of numbness, tingling, and pain in the lower extremities. Symptoms are disproportionate to findings on gross sensory and motor evaluation. Beyond HIV infection itself, the most common cause is prior antiretroviral therapy with stavudine or didanosine. Patients who report these symptoms should be switched to an alternative agent if possible. Caution should be used when administering these agents to patients with a history of peripheral neuropathy. Unfortunately, drug-induced neuropathy is not always reversed when the offending agent is discontinued. Patients with advanced disease may also develop peripheral neuropathy even if they have never taken antiretroviral therapy. Evaluation should rule out other causes of sensory neuropathy such as alcoholism, thyroid disease, vitamin B₁₂ deficiency, and syphilis.

Treatment of peripheral neuropathy is aimed at symptomatic relief. Patients should be initially treated with gabapentin (start at 300 mg at bedtime and increase to 300–900 mg orally three times a day).

5. Rheumatologic manifestations—Arthritis, involving single or multiple joints, with or without effusion, has been commonly noted in HIV-infected patients. Involvement of large joints is most common. Although the cause of HIV-related arthritis is unknown, most patients will respond to

nonsteroidal anti-inflammatory drugs. Patients with a sizable effusion, especially if the joint is warm or erythematous, should have the joint tapped, followed by culture of the fluid to rule out suppurative arthritis as well as fungal and mycobacterial disease.

Several rheumatologic syndromes, including reactive arthritis (Reiter syndrome), psoriatic arthritis, sicca syndrome, and systemic lupus erythematosus, have been reported in HIV-infected patients (see Chapter 20). However, it is unclear if the prevalence is greater than in the general population. Cases of avascular necrosis of the femoral heads have been reported sporadically, generally in the setting of advanced disease with long-standing infection and in patients receiving long-term antiretroviral therapy. The etiology is not clear but is probably multifactorial in nature.

6. Myopathy—Myopathies are infrequent in the era of effective antiretroviral therapy but can be related to either HIV-infection or antiretroviral therapy, particularly with use of zidovudine (azidothymidine [AZT]). Proximal muscle weakness is typical, and patients may have varying degrees of muscle tenderness. A muscle biopsy can distinguish HIV myopathy from zidovudine myopathy and should be considered in patients for whom continuation of zidovudine is essential.

7. Retinitis—Complaints of visual changes must be evaluated immediately in HIV-infected patients. CMV retinitis, characterized by perivascular hemorrhages and white fluffy exudates, is the most common retinal infection in AIDS patients and can be rapidly progressive. In contrast, cotton wool spots, which are also common in HIV-infected people, are benign, remit spontaneously, and appear as small indistinct white spots without exudation or hemorrhage. This distinction may be difficult at times for the nonspecialist, and patients with visual changes should be seen by an ophthalmologist. Other rare retinal processes include other herpesvirus infections or toxoplasmosis.

8. Oral lesions—The presence of oral candidiasis or hairy leukoplakia is significant for several reasons. First, these lesions are highly suggestive of HIV infection in patients who have no other obvious cause of immunodeficiency. Second, several studies have indicated that patients with candidiasis have a high rate of progression to AIDS even with statistical adjustment for CD4 count.

Hairy leukoplakia is caused by the Epstein-Barr virus. The lesion is not usually troubling to patients and sometimes regresses spontaneously. Hairy leukoplakia is commonly seen as a white lesion on the lateral aspect of the tongue. It may be flat or slightly raised, is usually corrugated, and has vertical parallel lines with fine or thick (“hairy”) projections. Oral candidiasis can be bothersome to patients, many of whom report an unpleasant taste or mouth dryness. There are two major types of oral candidiasis: pseudomembranous (removable white plaques) and erythematous (red friable plaques). Treatment is with topical agents such as clotrimazole 10-mg troches (one troche four or five times a day). Patients with candidiasis who do not respond to topical antifungals can be treated

with fluconazole (50–100 mg orally once a day for 3–7 days). Chronic suppression of oral candidiasis with fluconazole has been associated with development of candidiasis resistant to all available azoles and thus should be avoided except in frequently recurring cases.

Angular cheilitis—fissures at the sides of the mouth—is usually due to *Candida* as well and can be treated topically with ketoconazole cream (2%) twice a day.

Gingival disease is common in HIV-infected patients and is thought to be due to an overgrowth of microorganisms. It usually responds to professional dental cleaning and chlorhexidine rinses. A particularly aggressive gingivitis or periodontitis will develop in some HIV-infected patients; these patients should be given antibiotics that cover anaerobic oral flora (eg, metronidazole, 250 mg four times a day for 4 or 5 days) and referred to oral surgeons with experience with these entities.

Aphthous ulcers are painful and may interfere with eating. They can be treated with fluocinonide (0.05% ointment mixed 1:1 with plain Orabase and applied six times a day to the ulcer). For lesions that are difficult to reach, patients should use dexamethasone swishes (0.5 mg in 5 mL elixir three times a day). The pain of the ulcers can be relieved with use of an anesthetic spray (10% lidocaine). For patients with refractory ulcers, thalidomide, starting at a dose of 50 mg orally daily and increasing to 100–200 mg daily, has proved useful. Because it is teratogenic; it should be administered only to patients at zero risk of procreation. The most common side effects are sedation and peripheral neuropathy. Other lesions seen in the mouths of HIV-infected patients include Kaposi sarcoma (usually on the hard palate) and warts.

9. Gastrointestinal manifestations

A. CANDIDAL ESOPHAGITIS—(See also discussion in Chapter 15.) Esophageal candidiasis is a common AIDS complication. In a patient with characteristic symptoms, empiric antifungal treatment is begun with fluconazole (200 mg daily for 10–14 days). Further evaluation to identify other causes of esophagitis (herpes simplex, CMV) is reserved for patients who do not improve with antifungal treatment.

B. HEPATIC DISEASE—Autopsy studies have demonstrated that the liver is a frequent site of infections and neoplasms in HIV-infected patients. However, many of these infections are not clinically symptomatic. Clinicians may note elevations of alkaline phosphatase and aminotransferases on routine chemistry panels. Mycobacterial disease, CMV, hepatitis B virus, hepatitis C virus, and lymphoma cause liver disease and can present with varying degrees of nausea, vomiting, right upper quadrant abdominal pain, and jaundice. Sulfonamides, imidazole drugs, antituberculous medications, pentamidine, clarithromycin, and didanosine have also been associated with hepatitis. HIV-infected patients with chronic hepatitis may have more rapid progression of liver disease because of the concomitant immunodeficiency or hepatotoxicity of antiretroviral therapy. Percutaneous liver biopsy may be helpful in diagnosing liver disease, but some common causes of liver disease (eg, *Mycobacterium avium* complex, lymphoma) can be determined by less

invasive measures (eg, blood culture, biopsy of a more accessible site). With patients living longer as a result of advances in antiretroviral therapy, advanced liver disease and hepatic failure due to chronic active hepatitis B and or C are increasing causes of morbidity and mortality. HIV-infected individuals who are coinfecting with hepatitis B, should be treated with antiretroviral regimens that include drugs with activity against both viruses (eg, lamivudine [3TC], emtricitabine [FTC], tenofovir [TDF]). Treatment of HIV-infected persons with hepatitis C with peginterferon and ribavirin has been shown to be efficacious, although less so than in HIV-uninfected persons. HIV-infected persons are also more likely to have difficulty tolerating treatment with peginterferon than uninfected persons. Liver transplants have been performed successfully in HIV-infected patients. This strategy is most likely to be successful in persons who have CD4 counts above 100 cells/mL and nondetectable viral loads.

C. BILIARY DISEASE—Cholecystitis presents with manifestations similar to those seen in immunocompetent hosts but is more likely to be acalculous. Sclerosing cholangitis and papillary stenosis have also been reported in HIV-infected patients. Typically, the syndrome presents with severe nausea, vomiting, and right upper quadrant pain. Liver function tests generally show alkaline phosphatase elevations disproportionate to elevation of the aminotransferases. Although dilated ducts can be seen on ultrasound, the diagnosis is made by endoscopic retrograde cholangiopancreatography, which reveals intraluminal irregularities of the proximal intrahepatic ducts with “pruning” of the terminal ductal branches. Stenosis of the distal common bile duct at the papilla is commonly seen with this syndrome. CMV, *Cryptosporidium*, and microsporidia are thought to play inciting roles in this syndrome.

D. ENTEROCOLITIS—Enterocolitis is a common problem in HIV-infected individuals. Organisms known to cause enterocolitis include bacteria (*Campylobacter*, *Salmonella*, *Shigella*), viruses (CMV, adenovirus), and protozoans (*Cryptosporidium*, *Entamoeba histolytica*, *Giardia*, *Isospora*, microsporidia). HIV itself may cause enterocolitis. Several of the organisms causing enterocolitis in HIV-infected individuals also cause diarrhea in immunocompetent persons. However, HIV-infected patients tend to have more severe and more chronic symptoms, including high fevers and severe abdominal pain that can mimic acute abdominal catastrophes. Bacteremia and concomitant biliary involvement are also more common with enterocolitis in HIV-infected patients. Relapses of enterocolitis following adequate therapy have been reported with both *Salmonella* and *Shigella* infections.

Because of the wide range of agents known to cause enterocolitis, a stool culture and multiple stool examinations for ova and parasites (including modified acid-fast staining for *Cryptosporidium*) should be performed. Those patients who have *Cryptosporidium* in one stool with improvement in symptoms in less than 1 month should not be considered to have AIDS, as *Cryptosporidium* is a cause of self-limited diarrhea in HIV-negative persons. More commonly, HIV-infected patients with *Cryptosporo-*

ridium infection have persistent enterocolitis with profuse watery diarrhea.

To date, no consistently effective treatments have been developed for *Cryptosporidium* infection. The most effective treatment of cryptosporidiosis is to improve immune function through the use of effective antiretroviral treatment. The diarrhea can be treated symptomatically with diphenoxylate with atropine (one or two tablets orally three or four times a day). Those who do not respond may be given paregoric with bismuth (5–10 mL orally three or four times a day). Octreotide in escalating doses (starting at 0.05 mg subcutaneously every 8 hours for 48 hours) has been found to ameliorate symptoms in approximately 40% of patients with cryptosporidia or idiopathic HIV-associated diarrhea.

Patients with a negative stool examination and persistent symptoms should be evaluated with colonoscopy and biopsy. Patients whose symptoms last longer than 1 month with no identified cause of diarrhea are considered to have a presumptive diagnosis of AIDS enteropathy. Patients may respond to institution of effective antiretroviral treatment. Upper endoscopy with small bowel biopsy is not recommended as a routine part of the evaluation.

E. OTHER DISORDERS—Two other important gastrointestinal abnormalities in HIV-infected patients are gastropathy and malabsorption. It has been documented that some HIV-infected patients do not produce normal levels of stomach acid and therefore are unable to absorb drugs that require an acid medium. This decreased acid production may explain, in part, the susceptibility of HIV-infected patients to *Campylobacter*, *Salmonella*, and *Shigella*, all of which are sensitive to acid concentration. There is no evidence that *Helicobacter pylori* is more common in HIV-infected persons.

A malabsorption syndrome occurs commonly in HIV-infected patients. It can be due to infection of the small bowel with *M avium* complex, *Cryptosporidium*, or microsporidia.

10. Endocrinologic manifestations—Hypogonadism is probably the most common endocrinologic abnormality in HIV-infected men. The adrenal gland is also a commonly afflicted endocrine gland in patients with AIDS. Abnormalities demonstrated on autopsy include infection (especially with CMV and *M avium* complex), infiltration with Kaposi sarcoma, and injury from hemorrhage and presumed autoimmunity. The prevalence of clinically significant adrenal insufficiency is low. Patients with suggestive symptoms should undergo a cosyntropin stimulation test.

Although frank deficiency of cortisol is rare, an isolated defect in mineralocorticoid metabolism may lead to salt-wasting and hyperkalemia. Such patients should be treated with fludrocortisone (0.1–0.2 mg daily).

AIDS patients appear to have abnormalities of thyroid function tests different from those of patients with other chronic diseases. AIDS patients have been shown to have high levels of triiodothyronine (T_3), thyroxine (T_4), and thyroid-binding globulin and low levels of reverse triiodothyronine (rT_3). The causes and clinical significance of these abnormalities are unknown.

11. Skin manifestations—The skin manifestations that commonly develop in HIV-infected patients can be grouped into viral, bacterial, fungal, neoplastic, and non-specific dermatitides.

Herpes simplex infections occur more frequently, tend to be more severe, and are more likely to disseminate in AIDS patients than in immunocompetent persons. Because of the risk of progressive local disease, all herpes simplex attacks should be treated with acyclovir (400 mg orally three times a day until healed, usually 7 days), famciclovir (500 mg orally twice daily until healed), or valacyclovir (500 mg orally twice daily until healed). To avoid the complications of attacks, many clinicians recommend suppressive therapy for HIV-infected patients with a history of recurrent herpes. Options for suppressive therapy include acyclovir (400 mg orally twice daily), famciclovir (250 mg orally twice daily), and valacyclovir (500 mg orally daily). A randomized trial of women infected with both herpes simplex and HIV showed that suppressive therapy with valacyclovir at a dose of 500 mg orally twice daily decreased genital and plasma HIV-1 RNA levels, suggesting the possibility that suppressive treatment may reduce HIV transmission.

Herpes zoster is a common manifestation of HIV infection. As with herpes simplex infections, patients with zoster should be treated with acyclovir to prevent dissemination (800 mg orally four or five times per day for 7 days). Alternatively, famciclovir (500 mg orally three times a day) or valacyclovir (500 mg three times a day) may be used. Vesicular lesions should be cultured if there is any question about their origin, since herpes simplex responds to much lower doses of acyclovir. Disseminated zoster and cases with ocular involvement should be treated with intravenous (10 mg/kg every 8 hours for 7–10 days) rather than oral acyclovir.

Molluscum contagiosum caused by a pox virus is seen in HIV-infected patients, as in other immunocompromised patients. The characteristic umbilicated fleshy papular lesions have a propensity for spreading widely over the patient's face and neck and should be treated with topical liquid nitrogen.

Staphylococcus is the most common bacterial cause of skin disease in HIV-infected patients; it usually presents as **folliculitis**, **superficial abscesses (furuncles)**, or **bullous impetigo**. Because dissemination with sepsis has been reported, attempts should be made to treat these lesions aggressively. Folliculitis is initially treated with topical clindamycin or mupirocin, and patients may benefit from regular washing with an antibacterial soap such as chlorhexidine. Intranasal mupirocin has been used successfully for staphylococcal decolonization in other settings. In HIV-infected patients with recurrent staphylococcal infections, weekly intranasal mupirocin should be considered in addition to topical care and systemic antibiotics. Abscesses often require incision and drainage. Patients may need antistaphylococcal antibiotics as well. Due to high frequency of methicillin-resistant *Staphylococcus aureus* (MRSA) skin infections in HIV-infected populations, lesions should be cultured prior to initiating empiric antistaphylococcal therapy. Although there is limited experience treating MRSA with oral antibiotics, current recommendations for empiric

treatment are trimethoprim-sulfamethoxazole (one double-strength tablet orally twice daily) or doxycycline (100 mg orally twice daily) with close follow-up.

Bacillary angiomatosis is a well-described entity in HIV-infected patients. It is caused by two closely related organisms: *Bartonella henselae* and *Bartonella quintana*. The epidemiology of these infections suggests zoonotic transmission from fleas of infected domestic cats. The most common manifestation is raised, reddish, highly vascular skin lesions that can mimic the lesions of Kaposi sarcoma. Fever is a common manifestation of this infection; involvement of bone, lymph nodes, and liver has also been reported. The infection responds to doxycycline, 100 mg orally twice daily, or erythromycin, 250 mg orally four times daily. Therapy is continued for at least 14 days, and patients who are seriously ill with visceral involvement may require months of therapy.

The majority of **fungal rashes** afflicting AIDS patients are due to dermatophytes and *Candida*. These are particularly common in the inguinal region but may occur anywhere on the body. Fungal rashes generally respond well to topical clotrimazole (1% twice a day) or ketoconazole (2% twice a day).

Seborrheic dermatitis is more common in HIV-infected patients. Scrapings of seborrhea have revealed *Malassezia furfur* (*Pityrosporum ovale*), implying that the seborrhea is caused by this fungus. Consistent with the isolation of this fungus is the clinical finding that seborrhea responds well to topical clotrimazole (1% cream) as well as hydrocortisone (1% cream).

Xerosis presents in HIV-infected patients with severe pruritus. The patient may have no rash, or nonspecific excoriations from scratching. Treatment is with emollients (eg, absorption base cream) and antipruritic lotions (eg, camphor 9.5% and menthol 0.5%).

Psoriasis can be very severe in HIV-infected patients. Phototherapy and etretinate (0.25–9.75 mg/kg/d orally in divided doses) may be used for recalcitrant cases in consultation with a dermatologist. Because of the underlying immunodeficiency, methotrexate should be avoided.

12. HIV-related malignancies—Four cancers are currently included in the CDC classification of AIDS: Kaposi sarcoma, non-Hodgkin lymphoma, primary lymphoma of the brain, and invasive cervical carcinoma. Epidemiologic studies have shown that between 1973 and 1987 among single men in San Francisco, the risk of Kaposi sarcoma increased more than 5000-fold and the risk of non-Hodgkin lymphoma more than tenfold. The increase in incidence of malignancies is probably a function of impaired cell-mediated immunity.

Kaposi sarcoma lesions may appear anywhere; careful examination of the eyelids, conjunctiva, pinnae, palate, and toe webs is mandatory to locate potentially occult lesions. In light-skinned individuals, Kaposi lesions usually appear as purplish, nonblanching lesions that can be papular or nodular (Plate 41). In dark-skinned individuals, the lesions may appear more brown. In the mouth, lesions are most often palatal papules, though exophytic lesions of the tongue and gingivae may also be seen. Kaposi lesions may be confused

with other vascular lesions such as angiomas and pyogenic granulomas. Visceral disease (eg, gastrointestinal, pulmonary) will develop in about 40% of patients with dermatologic Kaposi sarcoma. Rapidly progressive dermatologic or visceral disease is best treated with systemic chemotherapy. Liposomally encapsulated doxorubicin given intravenously every 3 weeks has a response rate of approximately 70%. α -Interferon (10 million units subcutaneously three times a week) also has activity against Kaposi sarcoma. However, symptoms such as malaise and anorexia limit the utility of this therapy. Patients with milder forms of Kaposi sarcoma do not require specific treatment as the lesions usually improve and can completely resolve with antiretroviral therapy. However, it should be noted that the lesions may flare when antiretroviral therapy is first initiated—probably as a result of an immune reconstitution process (see Inflammatory reactions below).

Non-Hodgkin lymphoma in HIV-infected persons tends to be very aggressive. The malignancies are usually of B cell origin and characterized as diffuse large-cell tumors. Over 70% of the malignancies are extranodal.

The prognosis of patients with systemic non-Hodgkin lymphoma depends primarily on the degree of immunodeficiency at the time of diagnosis. Patients with high CD4 counts do markedly better than those diagnosed at a late stage of illness. Patients with primary central nervous system lymphoma are treated with radiation. Response to treatment is good, but prior to the availability of HAART, most patients died within a few months after diagnosis due to their underlying disease. Systemic disease is treated with chemotherapy. Common regimens are CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) and modified M-BACOD (methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, and dexamethasone). Granulocyte colony-stimulating factor (G-CSF; filgrastim) is used to maintain white blood counts with this latter regimen. Intrathecal chemotherapy is administered to prevent or treat meningeal involvement.

Although **Hodgkin disease** is not included as part of the CDC definition of AIDS, studies have found that HIV infection is associated with a fivefold increase in the incidence of Hodgkin disease. HIV-infected persons with Hodgkin disease are more likely to have mixed cellularity and lymphocyte depletion subtypes of Hodgkin disease and to seek medical attention at an advanced stage of disease.

Anal dysplasia and squamous cell carcinoma have been noted in HIV-infected men and women. These lesions have been strongly correlated with previous infection by human papillomavirus (HPV). Although many of the infected MSM report a history of anal warts or have visible warts, a significant percentage have silent papillomavirus infection. Cytologic (using Papanicolaou smears) and papillomavirus DNA studies can easily be performed on specimens obtained by anal swab. Because of the risk of progression from dysplasia to cancer in immunocompromised patients, some experts suggest that annual anal swabs for cytologic examination should be done in all HIV-infected persons. An anal Papanicolaou smear is performed by rotating a moistened Dacron swab about 2 cm into the anal canal. The swab is immediately inserted into a cytology bottle.

HPV also appears to play a causative role in **cervical dysplasia and neoplasia**. The incidence and clinical course of cervical disease in HIV-infected women are discussed below.

13. Gynecologic manifestations—Vaginal candidiasis, cervical dysplasia and neoplasia, and pelvic inflammatory disease are more common in HIV-infected women than in uninfected women. These manifestations also tend to be more severe when they occur in association with HIV infection. Therefore, HIV-infected women need frequent gynecologic care. Vaginal candidiasis may be treated with topical agents (see Chapter 36). However, HIV-infected women with recurrent or severe vaginal candidiasis may need systemic therapy.

The incidence of cervical dysplasia in HIV-infected women is 40%. Because of this finding, HIV-infected women should have Papanicolaou smears every 6 months (as opposed to the Agency for Healthcare Research and Quality [AHRQ] Guideline recommendation for every 12 months). Some clinicians recommend routine colposcopy or cervicography because cervical intraepithelial neoplasia has occurred in women with negative Papanicolaou smears. Cone biopsy is indicated in cases of serious cervical dysplasia. For 1 year following treatment of an abnormal Papanicolaou smear, women should have repeat smears every 3 to 4 months.

Cervical neoplasia appears to be more aggressive among HIV-infected women. Most HIV-infected women with cervical cancer die of that disease rather than of AIDS. Because of its frequency and severity, cervical neoplasia was added to the CDC definition of AIDS in 1993.

While pelvic inflammatory disease appears to be more common in HIV-infected women, the bacteriology of this condition appears to be the same as among HIV-uninfected women. At present, HIV-infected women with pelvic inflammatory disease should be treated with the same regimens as uninfected women (see Chapter 18). However, inpatient therapy is generally recommended.

14. Coronary artery disease—HIV-infected persons are at higher risk for coronary artery disease than age- and sex-matched controls. Part of this increase in coronary artery disease is due to changes in lipids caused by antiretroviral agents (see Treatment section on Antiretroviral Therapy below), especially stavudine and most of the protease inhibitors. However, some of the risk appears to be due to HIV infection, independent of its therapy. It is important that clinicians pay close attention to this issue because the first presentation of coronary artery disease in HIV-infected persons may be sudden death. HIV-infected patients with symptoms of coronary artery disease such as chest pain or dyspnea should be rapidly evaluated. Clinicians should aggressively treat conditions that result in increased risk of heart disease, especially smoking, hypertension, hyperlipidemia, obesity, diabetes mellitus, and sedentary lifestyle.

15. Inflammatory reactions (immune reconstitution syndromes)—With initiation of HAART, some patients experience inflammatory reactions that appear to be associated with immune reconstitution as indicated by a rapid

increase in CD4 count. These inflammatory reactions may present with generalized signs of fevers, sweats, and malaise with or without more localized manifestations that usually represent unusual presentations of opportunistic infections. For example, vitreitis has developed in patients with CMV retinitis after they have been treated with HAART. *M avium* can present as focal lymphadenitis or granulomatous masses in patients receiving HAART. Tuberculosis may paradoxically worsen with new or evolving pulmonary infiltrates and lymphadenopathy. PML and cryptococcal meningitis may also behave atypically. Clinicians should be alert to these syndromes, which are most often seen in patients who have initiated antiretroviral therapy in the setting of advanced disease and who show rapid increases in CD4 counts with treatment. The diagnosis of IRIS is one of exclusion and can be made only after recurrence or new opportunistic infection has been ruled out as the cause of the clinical deterioration. Management of IRIS is conservative and supportive with use of corticosteroids only for severe reactions. Most authorities recommend that antiretroviral therapy be continued unless the reaction is life-threatening.

B. Laboratory Findings

Specific tests for HIV include antibody and antigen detection (Table 31–2). Conventional HIV antibody testing is done by ELISA. Positive specimens are then confirmed by a different method (eg, Western blot). The sensitivity of screening serologic tests is greater than 99.5%. The specificity of positive results by two different techniques approaches 100% even in low-risk populations. False-positive screening tests may occur as normal biologic variants or in association with recent influenza vaccination or other disease states, such as connective tissue disease. These are usually detected by negative confirmatory tests. Molecular biology techniques (PCR) show a small incidence of individuals (< 1%)

who are infected with HIV for up to 36 months without generating an antibody response. However, antibodies that are detectable by screening serologic tests will develop in 95% of persons within 6 weeks after infection.

Rapid HIV antibody tests are now available. They provide results within 10–20 minutes and can be performed in physician offices, including by personnel without laboratory training and without a Clinical Laboratory Improvement Amendment (CLIA) approved laboratory. Persons who test positive on a rapid test should be told that they may be HIV-infected or their test may be falsely reactive. Standard testing (ELISA with Western blot confirmation) should be performed to distinguish these two possibilities. Rapid testing is particularly helpful in settings where a result is needed immediately (eg, a woman in labor who has not recently been tested for HIV) or when the patient is unlikely to return for a result.

Nonspecific laboratory findings with HIV infection may include anemia, leukopenia (particularly lymphopenia), and thrombocytopenia in any combination, elevation of the erythrocyte sedimentation rate, polyclonal hypergammaglobulinemia, and hypocholesterolemia. Cutaneous anergy is common.

Several laboratory markers are available to provide prognostic information and guide therapy decisions (Table 31–2). The most widely used marker is the absolute CD4 lymphocyte count. As counts decrease, the risk of serious opportunistic infection over the subsequent 3–5 years increases (Figure 31–1).

There are many limitations to using the CD4 count, including diurnal variation, depression with intercurrent illness, and intralaboratory and interlaboratory variability. Therefore, the trend is more important than a single determination. The frequency of performance of counts depends on the patient's health status. Patients whose CD4 counts are substantially above the threshold for initiation of anti-

Table 31–2. Laboratory findings with HIV infection.

| Test | Significance |
|---|---|
| HIV enzyme-linked immunosorbent assay (ELISA) | Screening test for HIV infection. Of ELISA tests 50% are positive within 22 days after HIV transmission; 95% are positive within 6 weeks after transmission. Sensitivity > 99.9%; to avoid false-positive results, repeatedly reactive results must be confirmed with Western blot. |
| Western blot | Confirmatory test for HIV. Specificity when combined with ELISA > 99.99%. Indeterminate results with early HIV infection, HIV-2 infection, autoimmune disease, pregnancy, and recent tetanus toxoid administration. |
| HIV rapid antibody test | Screening test for HIV. Produces results in 10–20 minutes. Can be performed by personnel with limited training. Positive results must be confirmed with standard HIV test (ELISA and Western blot). |
| Complete blood count | Anemia, neutropenia, and thrombocytopenia common with advanced HIV infection. |
| Absolute CD4 lymphocyte count | Most widely used predictor of HIV progression. Risk of progression to an AIDS opportunistic infection or malignancy is high with CD4 < 200 cells/mcl in the absence of treatment. |
| CD4 lymphocyte percentage | Percentage may be more reliable than the CD4 count. Risk of progression to an AIDS opportunistic infection or malignancy is high with percentage < 14% in the absence of treatment. |
| HIV viral load tests | These tests measure the amount of actively replicating HIV virus. Correlate with disease progression and response to antiretroviral drugs. Best tests available for diagnosis of acute HIV infection (prior to seroconversion); however, caution is warranted when the test result shows low-level viremia (ie, < 500 copies/mL) as this may represent a false-positive test. |

ral therapy (350 cells/mcL) should have counts performed every 6 months. Those who have counts near or below 350 cells/mcL should have counts performed every 3 months. This is necessary for evaluating the efficacy of antiviral therapy and for initiating *P jiroveci* prophylactic therapy when the CD4 count drops below 200 cells/mcL. Some studies suggest that the percentage of CD4 lymphocytes is a more reliable indicator of prognosis than the absolute counts because the percentage does not depend on calculating a manual differential. While the CD4 count measures immune dysfunction, it does not provide a measure of how actively HIV is replicating in the body. HIV viral load tests (discussed below) assess the level of viral replication and provide useful prognostic information that is independent of the information provided by CD4 counts.

▶ Differential Diagnosis

HIV infection may mimic a variety of other medical illnesses. Specific differential diagnosis depends on the mode of presentation. In patients presenting with constitutional symptoms such as weight loss and fevers, differential considerations include cancer, chronic infections such as tuberculosis and endocarditis, and endocrinologic diseases such as hyperthyroidism. When pulmonary processes dominate the presentation, acute and chronic lung infections must be considered as well as other causes of diffuse interstitial pulmonary infiltrates. When neurologic disease is the mode of presentation, conditions that cause mental status changes or neuropathy—eg, alcoholism, liver disease, kidney dysfunction, thyroid disease, and vitamin deficiency—should be considered. If a patient presents with headache and a cerebrospinal fluid pleocytosis, other causes of chronic meningitis enter the differential. When diarrhea is a prominent complaint, infectious enterocolitis, antibiotic-associated colitis, inflammatory bowel disease, and malabsorptive symptoms must be considered.

▶ Prevention

A. Primary Prevention

Until vaccination is a reality, prevention of HIV infection will depend on effective precautions regarding sexual practices and injection drug use, use of perinatal HIV prophylaxis, screening of blood products, and infection control practices in the health care setting. Primary care clinicians should routinely obtain a sexual history and provide risk factor assessment of their patients. Because approximately one-fourth of the HIV-infected persons in the United States do not know they are infected, the CDC recommends all adults be routinely tested for HIV. Prior to testing, clinicians should obtain informed consent and review the risk factors for HIV infection with the patient and discuss safer sex and safer needle use as well as the meaning of a positive test. For persons whose test results are positive, information on available medical and mental health services should be provided as well as guidance for contacting sexual or needle-sharing partners. Interventions focused on the importance of HIV-infected persons not putting others at risk have been successful. For patients whose test results are negative, clinicians should review safer sex and needle use practices, including counseling not to exchange bodily fluids unless they are in a long-term mutually monogamous relationship with someone who has tested HIV antibody-negative and has not engaged in unsafe sex, injection drug use, or other HIV risk behaviors for at least 6 months prior to or at any time since the negative test.

Only latex condoms should be used, along with a water-soluble lubricant. Although nonoxynol-9, a spermicide, kills HIV, it is contraindicated because in some patients it

may cause genital ulcers that could facilitate HIV transmission. Patients should be counseled that condoms are not 100% effective. They should be made familiar with the use of condoms, including, specifically, the advice that condoms must be used every time, that space should be left at the tip of the condom as a receptacle for semen, that intercourse with a condom should not be attempted if the penis is only partially erect, that men should hold on to the base of the condom when withdrawing the penis to prevent slippage, and that condoms should not be reused. Although anal intercourse remains the sexual practice at highest risk for transmitting HIV, seroconversions have been documented with vaginal and oral intercourse as well. Therefore, condoms should be used when engaging in these activities. Women as well as men should understand how to use condoms so as to be sure that their partners are using them correctly. A randomized trial in Africa demonstrated that male circumcision significantly reduced HIV incidence in men, but there are a number of barriers to performing widespread circumcisions among men in Africa.

Persons using injection drugs should be cautioned never to exchange needles or other drug paraphernalia. When sterile needles are not available, bleach does appear to inactivate HIV and should be used to clean needles.

Current efforts to screen blood and blood products have lowered the risk of HIV transmission with transfusion of a unit of blood to 1:1,000,000.

In the hospital, concerns about nosocomial infection have led to the recommendation for universal body fluid precautions. This involves the rigorous use of gloves when handling any body fluid and the addition of gown, mask, and goggles for procedures that may result in splash or droplet spread as well as the use of specially designed needles with sheath devices to decrease the risk of needle sticks. Reports of transmission of drug-resistant tuberculosis in health care settings also have had infection control implications. All patients with cough in outpatient settings should be encouraged to wear masks. Hospitalized HIV-infected patients with cough should be placed in respiratory isolation until tuberculosis can be excluded by chest radiograph and sputum smear examination.

Primate model data have suggested that development of a protective vaccine may be possible, but clinical trials in humans using gp120 or its precursor gp160 have shown development of neutralizing antibodies to laboratory but not field isolates of HIV and may not be protective of infection. Many scientists have abandoned the quest for a fully protective HIV vaccine and are focusing on developing a vaccine that would reduce the chances of HIV transmission given a particular exposure.

B. Secondary Prevention

In the era prior to the development of highly effective antiretroviral treatment, cohort studies of individuals with documented dates of seroconversion demonstrate that AIDS develops within 10 years in approximately 50% of untreated seropositive persons. With currently available treatment, progression of disease has been markedly decreased. In addition to antiretroviral treatment, prophylactic regimens can prevent opportunistic infections and improve survival.

Prophylaxis and early intervention prevent several infectious diseases, including tuberculosis and syphilis, which are transmissible to others. Recommendations for screening tests, vaccinations, and prophylaxis are listed in Table 31–3.

Because of the increased occurrence of tuberculosis among HIV-infected patients, all such individuals should undergo PPD testing. Although anergy is common among AIDS patients, the likelihood of a false-negative result is much lower when the test is done early in infection. Those with positive tests (defined for HIV-infected patients as > 5 mm of induration) need a chest radiograph. Patients with an infiltrate in any location, especially if accompanied by mediastinal adenopathy, should have sputum sent for acid-fast staining. Patients with a positive PPD but negative evaluations for active disease should receive isoniazid (300 mg daily) with pyridoxine (50 mg daily) for 9 months to a year. An alternative regimen of rifampin plus pyrazinamide for 2 months is no longer recommended because of the high associated incidence of hepatotoxicity. Recent analysis suggests also that HIV-infected individuals at high risk for tuberculosis should receive a course of isoniazid

Table 31–3. Health care maintenance of HIV-infected individuals.

For all HIV-infected individuals:

- CD4 counts every 3–6 months
- Viral load tests every 3–6 months and 1 month following a change in therapy
- PPD
- INH for those with positive PPD and normal chest radiograph
- RPR or VDRL
- Toxoplasma IgG serology
- Hepatitis serologies: hepatitis A antibody, hepatitis B surface antigen, hepatitis B surface antibody, hepatitis B core antibody, hepatitis C antibody.
- Pneumococcal vaccine
- Inactivated influenza vaccine in season
- Hepatitis A vaccine for those without immunity to hepatitis A.
- Hepatitis B vaccine for those who are hepatitis B surface antigen and antibody negative. (Use 40 mcg formulation at 0, 1, and 6 months; repeat if no immunity 1 month after three-shot series.)
- Tetanus/diphtheria vaccine
- Human papillomavirus vaccine for HIV-infected women age 26 years or less.
- Haemophilus influenzae* type b vaccination
- Papanicolaou smears every 6 months for women
- Consider anal swabs for cytologic evaluation.

For HIV-infected individuals with CD4 < 200 cells/mcl:

- Pneumocystis jiroveci* prophylaxis (see Prophylaxis of Opportunistic Infections section under Treatment and Table 31–4)

For HIV-infected individuals with CD4 < 75 cells/mcl:

- Mycobacterium avium* complex prophylaxis (see Prophylaxis of Opportunistic Infections section under Treatment)

For HIV-infected individuals with CD4 < 50 cells/mcl:

- Consider CMV prophylaxis

PPD, purified protein derivative; INH, isoniazid; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratories; IgG, immunoglobulin G.

prophylaxis regardless of the PPD status. This may include homeless individuals and injection drug users. Although not yet widely available, a blood test (QuantiFERON Gold test) can be used to assess prior tuberculosis exposure. Blood samples are mixed with synthetic antigens representing *M tuberculosis*. Patients infected with *M tuberculosis* produce interferon-gamma in response to contact with the antigens. Unlike the PPD, the patient does not have to return for a second visit. The test is less likely to result in false-positive results than a PPD. Unfortunately, HIV-infected persons may not produce sufficient interferon-gamma, in which case the test may be falsely negative.

Because of recent increases in the number of cases of syphilis among MSM, including those who are HIV infected, all such men should be screened for syphilis by rapid plasma reagin (RPR) or Venereal Disease Research Laboratories (VDRL) test every 6 months. Increases of syphilis cases among HIV-infected persons are of particular concern because these individuals are at increased risk for reactivation of syphilis and progression to tertiary syphilis despite standard treatment. Because the only widely available tests for syphilis are serologic and because HIV-infected individuals are known to have disordered antibody production, there is concern about the interpretation of these titers. This concern has been fueled by a report of an HIV-infected patient with secondary syphilis and negative syphilis serologic testing. Furthermore, HIV-infected individuals may lose fluorescent treponemal antibody absorption (FTA-ABS) reactivity after treatment for syphilis, particularly if they have low CD4 counts. Thus, in this population, a nonreactive treponemal test does not rule out a past history of syphilis. In addition, persistence of treponemes in the spinal fluid after one dose of benzathine penicillin has been demonstrated in HIV-infected patients with primary and secondary syphilis. Therefore, the CDC has recommended an aggressive diagnostic approach to HIV-infected patients with reactive RPR or VDRL tests of greater than 1 year or unknown duration. All such patients should have a lumbar puncture with cerebrospinal fluid cell count and cerebrospinal fluid VDRL. Those with a normal cerebrospinal fluid evaluation are treated as having late latent syphilis (benzathine penicillin G, 2.4 million units intramuscularly weekly for 3 weeks) with follow-up titers. Those with a pleocytosis or a positive cerebrospinal fluid-VDRL test are treated as having neurosyphilis (aqueous penicillin G, 2–4 million units intravenously every 4 hours, or procaine penicillin G, 2.4 million units intramuscularly daily, with probenecid, 500 mg four times daily, for 10 days). Some clinicians take a less aggressive approach to patients who have low titers (less than 1:8), a history of having been treated for syphilis, and a normal neurologic examination. Close follow-up of titers is mandatory if such a course is taken. For a more detailed discussion of this topic, see Chapter 34.

HIV-infected individuals should receive the pneumococcal vaccine and the inactivated influenza vaccine. Patients without immunity to hepatitis A should be vaccinated against it. Patients without evidence of hepatitis B surface antigen or surface antibody should receive hepatitis B vaccination, using the 40 mcg formulation; the higher dose is to increase the chance of developing protective

immunity. If the patient does not have immunity 1 month after the three-shot series, then the series should be repeated. HIV-infected persons should also receive the standard inactivated vaccines such as tetanus and diphtheria boosters that would be given to uninfected persons. Live vaccines, such as yellow fever vaccine, should be avoided. Measles vaccination, while a live virus vaccine, appears relatively safe when administered to HIV-infected individuals and should be given if the patient has never had measles or been adequately vaccinated. Herpes zoster vaccine is contraindicated in HIV-infected persons with evidence of immune suppression.

A randomized study found that multivitamin supplementation decreased HIV disease progression and mortality in HIV-infected women in Africa. However, supplementation is unlikely to be as effective in well-nourished populations.

HIV-infected individuals should be counseled with regard to safe sex. Because of the risk of transmission, they should be warned to use condoms with sexual intercourse, including oral intercourse. Partners of HIV-infected women should use latex barriers such as dental dams (available at dental supply stores) to prevent direct oral contact with vaginal secretions. Substance abuse treatment should be recommended for persons who are using recreational drugs. They should be warned to avoid consuming raw meat or eggs to avoid infections with *Toxoplasma*, *Campylobacter*, and *Salmonella*. HIV-infected patients should wash their hands thoroughly after cleaning cat litter or should forgo this household chore to avoid possible exposure to toxoplasmosis. To reduce the likelihood of infection with *Bartonella* species, patients should avoid activities that might result in cat scratches or bites. Although the data are not conclusive, many clinicians recommend that HIV-infected persons—especially those with low CD4 counts—drink bottled water instead of tap water to prevent cryptosporidia infection.

Because of the emotional impact of HIV infection and subsequent illness, many patients will benefit from supportive counseling.

C. HIV Risk for Health Care Professionals

Epidemiologic studies show that needle sticks occur commonly among health care professionals, especially among surgeons performing invasive procedures, inexperienced hospital house staff, and medical students. Efforts to reduce needle sticks should focus on avoiding recapping needles and use of safety needles whenever doing invasive procedures under controlled circumstances. The risk of HIV transmission from a needle stick with blood from an HIV-infected patient is about 1:300. The risk is higher with deep punctures, large inocula, and source patients with high viral loads. The risk from mucous membrane contact is too low to quantitate.

Health care professionals who sustain needle sticks should be counseled and offered HIV testing as soon as possible. HIV testing is done to establish a negative baseline for worker's compensation claims in case there is a subsequent conversion. Follow-up testing is usually performed at 6 weeks, 3 months, and 6 months.

A case-control study by the CDC indicates that administration of zidovudine following a needle stick decreases the rate of HIV seroconversion by 79%. Therefore, providers should be offered therapy with Combivir (zidovudine 300 mg plus lamivudine 150 mg orally twice daily). Providers who have exposures to persons who are likely to have antiretroviral drug resistance (eg, persons receiving therapy who have detectable viral loads) should have their therapy individualized, using at least two drugs to which the source is unlikely to be resistant. Some clinicians recommend triple combination regimens, including a protease inhibitor for all occupational exposures, because of uncertainty about drug resistance. Others save these more aggressive regimens for the higher-risk exposures listed above. Because reports have noted hepatotoxicity due to nevirapine in this setting, this agent should be avoided. Therapy should be started as soon as possible after exposure and continued for 4 weeks. Unfortunately, there have been documented cases of seroconversion following potential parenteral exposure to HIV despite prompt use of zidovudine prophylaxis. Counseling of the provider should include “safer sex” guidelines.

D. Postexposure Prophylaxis for Sexual and Drug Use Exposures to HIV

Following publication of a case-control study indicating that antiretroviral therapy decreased the odds of seroconversion among health care workers who had occupational exposure, some experts have recommended offering antiretroviral therapy following potential exposure to HIV through sexual activity or drug use. Although there are no efficacy data to support this practice, there are similarities between the immune response following transcutaneous and transmucosal exposures. The goal of postexposure prophylaxis is to reduce or prevent local viral replication prior to dissemination such that the infection can be aborted.

The choice of antiretroviral agents and the duration of treatment are the same as those for exposures that occur through the occupational route (see above). In contrast to those with occupational exposures, some individuals may present very late after exposure. Because the likelihood of success declines with length of time from HIV exposure, it is not recommended that treatment be offered after 72 hours. In addition, because the psychosocial issues involved with postexposure prophylaxis for sexual and drug use exposures are complex, it should be offered only in the context of prevention counseling. Counseling should focus on how to prevent future exposures. Clinicians needing more information on postexposure prophylaxis for occupational or nonoccupational exposures should contact the National Clinician's Post-exposure Hotline (1-888-448-4911; www.ucsf.edu/hivcntr/PEpline/).

E. Preventing Perinatal Transmission of HIV

A multicenter trial showed that when zidovudine is administered to women during pregnancy, labor, and delivery and to their newborns, the rate of HIV transmission is decreased by two-thirds. An observational trial demonstrated that

zidovudine treatment is almost as effective when begun during labor or when administered only to the infant, as long as treatment is begun within 48 hours after birth. Nonetheless, treatment begun by at least the second trimester is still recommended. Many women are currently being offered combination antiretroviral treatment to further lower the risk of transmission. The availability of treatment makes it essential that all women who are pregnant or considering pregnancy be offered HIV counseling and testing. Many obstetricians recommend combination antiretroviral treatment, especially if zidovudine resistance is suspected. HIV-infected women receiving antiretroviral therapy in whom pregnancy is recognized during the first trimester should be counseled about the benefits and potential risks to the fetus of treatment during the first trimester. Because healthy mothers make healthy babies, continuation of therapy should be strongly considered. Because about half of fetal infections in non-breast-feeding women occur shortly before or during the birth process, antiretroviral therapy should be administered whenever a woman initiates perinatal care even if she did not begin therapy in the second trimester. Breast-feeding is thought to increase the rate of transmission by 10–20% and should be avoided.

▶ Treatment

Treatment for HIV infection can be broadly divided into the following categories: (1) prophylaxis for opportunistic infections, malignancies, and other complications of HIV infection; (2) treatment of opportunistic infections, malignancies, and other complications of HIV infection; and (3) treatment of the HIV infection itself with combination ART.

Treatment regimens for HIV infection are constantly changing. Clinicians may obtain up-to-date information on new and experimental treatments by calling the AIDS Clinical Trials Information Service (ACTIS), 800-TRIALS-A (English and Spanish), and the National AIDS Hot Line, 800-342-AIDS (English), 800-344-SIDA (Spanish), and 800-AIDS-TTY (hearing-impaired).

A. Prophylactic Treatment of Complications of HIV Infection

In general, decisions about prophylaxis of opportunistic infections are based on the CD4 count, other evidence of severe immunosuppression (eg, oral candidiasis), and a history of having had the infection in the past. In the era prior to HAART, patients who started taking prophylactic regimens were maintained on them indefinitely. However, studies have shown that in patients with robust improvements in immune function—as measured by increases in CD4 counts above the levels that are used to initiate treatment—prophylactic regimens can safely be discontinued.

Because individuals with advanced HIV infection are susceptible to a number of opportunistic pathogens, the use of agents with activity against more than one pathogen is preferable. It has been shown, for example, that trimethoprim-sulfamethoxazole confers some protection against toxoplasmosis in individuals receiving this drug for *Pneumocystis* prophylaxis.

1. Prophylaxis against *Pneumocystis pneumonia*—Patients with CD4 counts below 200 cells/mcL, a CD4 lymphocyte percentage below 14%, or weight loss or oral candidiasis should be offered primary prophylaxis for *Pneumocystis pneumonia*. Patients with a history of *Pneumocystis pneumonia* should receive secondary prophylaxis until they have had a durable virologic response to HAART for at least 3–6 months and maintain a CD4 count of > 250 cells/mcL. Regimens for *Pneumocystis* prophylaxis are given in Table 31–4.

2. Prophylaxis against *M avium* complex infection—Patients whose CD4 counts fall to below 75–100 cells/mcL should be given prophylaxis against *M avium* complex infection. Clarithromycin (500 mg orally twice daily) and azithromycin (1200 mg orally weekly) have both been shown to decrease the incidence of disseminated *M avium* complex infection by approximately 75%, with a low rate of breakthrough of resistant disease. The azithromycin regimen is generally preferred based on high compliance and low cost. Adding rifabutin increases the toxicity of the

regimen but does not significantly increase its efficacy and is therefore not recommended. Prophylaxis against *M avium* complex infection may be discontinued in patients whose CD4 counts rise above 100 cells/mcL in response to HAART and whose plasma viral load has been optimally suppressed to < 50–75 copies/mL.

3. Prophylaxis against *M tuberculosis* infection—Isoniazid, 300 mg daily, plus pyridoxine, 50 mg orally daily, for 9–12 months should be given to all HIV-infected patients with positive PPD reactions (defined as > 5 mm of induration for HIV-infected patients).

4. Prophylaxis against toxoplasmosis—Toxoplasmosis prophylaxis is desirable in patients with a positive IgG toxoplasma serology and CD4 counts below 100 cells/mcL. Trimethoprim-sulfamethoxazole (one double-strength tablet daily) offers good protection against toxoplasmosis, as does a combination of pyrimethamine, 25 mg orally once a week, plus dapsone, 50 mg orally daily, plus leucovorin, 25 mg orally once a week. A glucose-6-phosphate dehydrogenase (G6PD) level should be checked prior to dapsone therapy, and a methemoglobin level should be checked at 1 month.

5. Prophylaxis against CMV infection—Oral ganciclovir (1000 mg orally three times daily with food) is approved for CMV prophylaxis among HIV-infected persons with advanced disease (eg, CD4 counts below 50 cells/mcL). However, because the drug causes neutropenia, it is not widely used. Clinicians should consider performing serum CMV IgG antibody testing prior to starting ganciclovir. Persons who are CMV IgG-negative are not at risk for development of CMV disease, although it is important that such patients receive only CMV-negative blood if they require transfusion. Because over 99% of MSM are positive for CMV IgG, it is appropriate to reserve such testing for heterosexuals with HIV.

6. Prophylaxis against cryptococcosis, candidiasis, and endemic fungal diseases—One trial showed a decreased incidence of cryptococcal disease with prophylaxis

Table 31–4. *Pneumocystis jiroveci* prophylaxis.

| Drug | Dose | Side Effects | Limitations |
|-------------------------------|---|--|---|
| Trimethoprim-sulfamethoxazole | One double-strength tablet three times a week to one tablet daily | Rash, neutropenia, hepatitis, Stevens-Johnson syndrome | Hypersensitivity reaction is common but, if mild, it may be possible to treat through. |
| Dapsone | 50–100 mg daily or 100 mg two or three times per week | Anemia, nausea, methemoglobinemia, hemolytic anemia | Less effective than above. Glucose-6-phosphate dehydrogenase (G6PD) level should be checked prior to therapy. Check methemoglobin level at 1 month. |
| Atovaquone | 1500 mg daily with a meal | Rash, diarrhea, nausea | Less effective than suspension trimethoprim-sulfamethoxazole; equal efficacy to dapsone, but more expensive. |
| Aerosolized pentamidine | 300 mg monthly | Bronchospasm (pretreat with bronchodilators); rare reports of pancreatitis | Apical <i>Pneumocystis jiroveci</i> pneumonia, extrapulmonary <i>P jiroveci</i> infections, pneumothorax. |

laxis using fluconazole, 200 mg orally daily, but the treated group had no benefit in terms of mortality. Fluconazole (200 mg orally once a week) was found to prevent oral and vaginal candidiasis in women with CD4 counts below 300 cells/mcL. In areas of the world where histoplasmosis and coccidioidomycosis are endemic and are frequent complications of HIV infection, prophylactic use of fluconazole or itraconazole may prove to be useful strategies. However, the problem of identifying individuals at highest risk makes appropriate targeting of prophylaxis difficult.

B. Treatment of Complications of HIV Infection

Treatment of common AIDS-related complications is detailed in Table 31–5. In the era prior to the use of HAART, patients required lifelong treatment for many infections, including CMV retinitis, toxoplasmosis, and cryptococcal meningitis. However, among patients who have a good response to HAART, maintenance therapy for some opportunistic infections can be terminated. For example, in consultation with an ophthalmologist, maintenance treatment for CMV infection can be discontinued when persons receiving HAART have durable suppression of viral load (ie, < 50 copies/mL) and a CD4 count > 100–150 cells/mcL. Similar results have been observed in patients with *M avium* complex bacteremia. Prophylaxis for *Pneumocystis* pneumonia is also commonly discontinued in patients who have achieved and maintained a CD4 > 200 cells/mcL with good virologic control.

Treating patients with repeated episodes of the same opportunistic infection can pose difficult therapeutic challenges. For example, patients with second or third episodes of *Pneumocystis* pneumonia may have developed allergic reactions to standard treatments with a prior episode. Fortunately, there are several alternatives available for the treatment of *Pneumocystis* infection. Trimethoprim with dapson and primaquine with clindamycin are two combinations that often are tolerated in patients with a prior allergic reaction to trimethoprim-sulfamethoxazole and intravenous pentamidine. On the positive side, patients in whom second episodes of *Pneumocystis* pneumonia develop while taking prophylaxis tend to have milder courses.

Well-established alternative regimens now also exist for most AIDS-related opportunistic infections: amphotericin B or fluconazole for cryptococcal meningitis; ganciclovir, cidofovir, or foscarnet for CMV infection; and sulfadiazine or clindamycin with pyrimethamine for toxoplasmosis.

Adjunctive Treatments Although conceptually it would seem that **corticosteroids** should be avoided in HIV-infected patients, corticosteroid therapy has been shown to improve the course of patients with moderate to severe *Pneumocystis jiroveci* pneumonia (oxygen saturation < 90%, P_{O_2} < 65 mm Hg) when administered within 72 hours after diagnosis. The mechanism of action is presumed to be a decrease in alveolar inflammation.

Corticosteroids have also been used to treat immune reconstitution and inflammatory syndromes (IRIS) that can sometimes complicate the early treatment course when ART is initiated in patients with advanced AIDS (see

section Inflammatory reactions [immune reconstitution syndromes]).

Epoetin alfa (erythropoietin) is approved for use in HIV-infected patients with anemia, including those with anemia secondary to zidovudine use. It has been shown to decrease the need for blood transfusions. The drug is expensive, and therefore an erythropoietin level < 500 mU/mL should be demonstrated before starting therapy. The starting dose of epoetin alfa is 8000 units subcutaneously three times a week. The target hematocrit is 35–40%. The dose may be increased by 12,000 units every 4–6 weeks as needed to a maximum dose of 48,000 units per week. Hypertension is the most common side effect.

Human G-CSF (filgrastim) and granulocyte-macrophage colony-stimulating factor (GM-CSF [sargramostim]) have been shown to increase the neutrophil counts of HIV-infected patients. Because of the high cost of this therapy, the dosage should be closely monitored and minimized, aiming for a neutrophil count of 1000/mcL. When the drug is used for indications other than cytotoxic chemotherapy, one or two doses at 5 mcg/kg per week are usually sufficient.

C. Antiretroviral Therapy

The availability of agents that in combination suppress HIV replication (Table 31–6) has had a profound impact on the natural history of HIV infection. Patients who achieve excellent suppression of HIV generally have stabilization or improvement of their clinical course that results from immunologic reconstitution and a subsequent decrease in AIDS-related complications. The greater potency and the improved side effect profile have led to recommendations to start treatment earlier in the course of HIV disease. Treatment should be initiated for all symptomatic patients, and for asymptomatic persons who (1) have CD4 cell counts below 350 cells/mcL; (2) have rapidly dropping CD4 counts or very high viral loads (> 100,000/mcL); (3) have dual infection with hepatitis B or C (rapid HIV replication is thought to hasten progression of hepatitis B and C); (4) have risk factors for cardiac disease (rapid HIV replication may increase the risk of cardiac disease); or (5) have risk factors for non-AIDS-related cancers (rapid HIV replication may increase such cancers). However, for patients who might have difficulty adhering to such therapy, deferring ART for some time may be a better strategy. In addition, because 5–20% of patients in developed countries who are treatment-naïve have a virus that is resistant to some drugs, resistance testing is recommended for all patients prior to initiating ART.

Once a decision to initiate therapy has been made, several important principles should guide therapy. First, because drug resistance to antiretroviral agents develops in HIV-infected patients, a primary goal of therapy should be complete suppression of viral replication as measured by the serum viral load. Therapy that achieves a plasma viral load of < 40 or < 50 copies/mL (depending on the test used) has been shown to provide a durable response to the therapy. To achieve this and maintain virologic control over time, combination therapy with at least 3 drugs from at least two different classes is necessary, and partially suppressive combinations such as dual nucleoside therapy

Table 31–5. Treatment of AIDS-related opportunistic infections and malignancies.¹

| Infection or Malignancy | Treatment | Complications |
|---|---|--|
| <i>Pneumocystis jiroveci</i> infection ² | Trimethoprim-sulfamethoxazole, 15 mg/kg/d (based on trimethoprim component) orally or intravenously for 14–21 days. Pentamidine, 3–4 mg/kg/d intravenously for 14–21 days. Trimethoprim, 15 mg/kg/d orally, with dapsone, 100 mg/d orally, for 14–21 days. ³ Primaquine, 15–30 mg/d orally, and clindamycin, 600 mg every 8 hours orally, for 14–21 days. Atovaquone, 750 mg orally three times daily for 14–21 days. Trimetrexate, 45 mg/m ² intravenously for 21 days (given with leucovorin calcium) if intolerant of all other regimens. | Nausea, neutropenia, anemia, hepatitis, drug rash, Stevens-Johnson syndrome. Hypotension, hypoglycemia, anemia, neutropenia, pancreatitis, hepatitis. Nausea, rash, hemolytic anemia in G6PD ³ -deficient patients. Methemoglobinemia (weekly levels should be < 10% of total hemoglobin). Hemolytic anemia in G6PD-deficient patients. Methemoglobinemia, neutropenia, colitis. Rash, elevated aminotransferases, anemia, neutropenia. Leukopenia, rash, mucositis. |
| <i>Mycobacterium avium</i> complex infection | Clarithromycin, 500 mg orally twice daily with ethambutol, 15 mg/kg/d orally (maximum, 1 g). May also add: Rifabutin, 300 mg orally daily. | Clarithromycin: hepatitis, nausea, diarrhea; ethambutol: hepatitis, optic neuritis. Rash, hepatitis, uveitis. |
| Toxoplasmosis | Pyrimethamine, 100–200 mg orally as loading dose, followed by 50–75 mg/d, combined with sulfadiazine, 4–6 g orally daily in four divided doses, and folinic acid, 10 mg daily for 4–8 weeks; then pyrimethamine, 25–50 mg/d, with clindamycin, 2–2.7 g/d in three or four divided doses, and folinic acid, 5 mg/d, until clinical and radiographic resolution is achieved. | Leukopenia, rash. |
| Lymphoma | Combination chemotherapy (eg, modified CHOP, M-BACOD, with or without G-CSF or GM-CSF). Central nervous system disease: radiation treatment with dexamethasone for edema. | Nausea, vomiting, anemia, leukopenia, cardiac toxicity (with doxorubicin). |
| Cryptococcal meningitis | Amphotericin B, 0.6 mg/kg/d intravenously, with or without flucytosine, 100 mg/kg/d orally in four divided doses for 2 weeks, followed by: Fluconazole, 400 mg orally daily for 6 weeks, then 200 mg orally daily. | Fever, anemia, hypokalemia, azotemia. Hepatitis. |
| Cytomegalovirus infection | Valganciclovir, 900 mg orally twice a day for 21 days with food (induction), followed by 900 mg daily with food (maintenance). Ganciclovir, 10 mg/kg/d intravenously in two divided doses for 10 days, followed by 6 mg/kg 5 days a week indefinitely. (Decrease dose for kidney disease.) May use ganciclovir as maintenance therapy (1 g orally with fatty foods three times a day). Foscarnet, 60 mg/kg intravenously every 8 hours for 10–14 days (induction), followed by 90 mg/kg once daily. (Adjust for changes in kidney function.) | Neutropenia, anemia, thrombocytopenia. Neutropenia (especially when used concurrently with zidovudine), anemia, thrombocytopenia. Nausea, hypokalemia, hypocalcemia, hyperphosphatemia, azotemia. |
| Esophageal candidiasis or recurrent vaginal candidiasis | Fluconazole, 100–200 mg orally daily for 10–14 days. | Hepatitis, development of imidazole resistance. |
| Herpes simplex infection | Acyclovir, 400 mg orally three times daily until healed; or acyclovir, 5 mg/kg intravenously every 8 hours for severe cases. Famciclovir, 500 mg orally twice daily until healed. Valacyclovir, 500 mg orally twice daily until healed. Foscarnet, 40 mg/kg intravenously every 8 hours, for acyclovir-resistant cases. (Adjust for changes in kidney function.) | Resistant herpes simplex with chronic therapy. Nausea. Nausea. See above. |

(continued)

Table 31–5. Treatment of AIDS-related opportunistic infections and malignancies.¹ (continued)

| Infection or Malignancy | Treatment | Complications |
|---|--|--|
| Herpes zoster | Acyclovir, 800 mg orally four or five times daily for 7 days. Intravenous therapy at 10 mg/kg every 8 hours for ocular involvement, disseminated disease. Famciclovir, 500 mg orally three times daily for 7 days. Valacyclovir, 500 mg orally three times daily for 7 days. Foscarnet, 40 mg/kg intravenously every 8 hours for acyclovir-resistant cases. (Adjust for changes in kidney function.) | See above. Nausea. Nausea. See above. |
| Kaposi sarcoma | | |
| Limited cutaneous disease | Observation, intralesional vinblastine. | Inflammation, pain at site of injection. |
| Extensive or aggressive cutaneous disease | Systemic chemotherapy (eg, liposomal doxorubicin). Interferon- α (for patients with CD4 > 200 cells/mcL and no constitutional symptoms). Radiation (amelioration of edema). | Bone marrow suppression, peripheral neuritis, flu-like syndrome. |
| Visceral disease (eg, pulmonary) | Combination chemotherapy (eg, daunorubicin, bleomycin, vinblastine). | Bone marrow suppression, cardiac toxicity, fever. |

¹For treatment of *Mycobacterium tuberculosis* infection, see Chapter 9.

²For moderate to severe *P jirovecii* infection (oxygen saturation < 90%), corticosteroids should be given with specific treatment. The dose of prednisone is 40 mg orally twice daily for 5 days, then 40 mg daily for 5 days, and then 20 mg daily until therapy is complete.

³When considering use of dapsone, check glucose-6-phosphate dehydrogenase (G6PD) level in black patients and those of Mediterranean origin.

CHOP, cyclophosphamide, doxorubicin (hydroxydaunomycin), vincristine (Oncovin), and prednisone; G-CSF, granulocyte-colony stimulating factor (filgrastim); GM-CSF, granulocyte-macrophage colony-stimulating factor (sargramostim); modified M-BACOD, methotrexate, bleomycin, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), and dexamethasone.

should be avoided. Similarly, if toxicity develops, it is preferable to either interrupt the entire regimen or change the offending drug rather than reduce individual doses.

A recent randomized trial compared early initiation of ART (within 2 weeks of starting treatment for an opportunistic infection) with ART that was deferred until after treatment of the opportunistic infection was completed (6 weeks after its start); results demonstrated that early initiation reduced death or AIDS progression by 50%. The reduced progression rates were related to more rapid improvements in CD4 counts in patients with advanced immunodeficiency. Furthermore, IRIS and other adverse events were no more frequent in the early ART arm. Based on these results, most treatment guidelines recommend that ART be initiated as early as is clinically feasible for patients with an acute AIDS-related opportunistic infection. For hospitalized patients, this recommendation requires close coordination between inpatient and outpatient physicians to ensure that treatment is continued once patients are discharged.

The current standard is to use at least three agents simultaneously usually from at least two different classes. Because the number of drugs and potential combinations is finite and the development of drug resistance may severely compromise the efficacy of treatment, patients must be able to adhere to these regimens. Adherence can be promoted through the use of medication boxes with compartments (eg, Medisets), supportive counseling, or daily supervision of therapy. Therefore, decisions to withhold treatment should not be based on a patient's circumstances (eg, active

drug use or housing status) alone. Often, a trial intervention such as offering *Pneumocystis* pneumonia prophylaxis may be helpful in determining the likelihood of adherence to a more complex antiretroviral regimen.

Monitoring of ART has two goals. Laboratory evaluation for toxicity depends on the specific drugs in the combination but generally should be done approximately every 3 months once a patient is on a stable regimen. Patients who are intolerant of their initial regimen (eg, patients who cannot tolerate the neurologic side effects of efavirenz) should be changed to an alternative drug or regimen. The second aspect of monitoring is to regularly measure objective markers of efficacy. The CD4 cell count and HIV viral load should be repeated 1–2 months after the initiation or change of antiretroviral regimen and every 3–4 months thereafter in clinically stable patients. In a patient who is adherent to an effective regimen, viral loads should be undetectable within 12–24 weeks. For patients in whom viral loads are not suppressed or who have viral rebound after suppression, the major question facing the clinician is whether the patient is nonadherent or has resistance to the regimen, or both. The issue is complicated because many patients report being more compliant than they really are, not because they wish to be untruthful but because they wish to tell the clinician what he or she wants to hear. Patients who are having trouble adhering to their treatment should receive counseling on how to better comply to their treatment. In patients who are adherent or who have missed enough doses to make resistance possible, resistance testing

Table 31-6. Antiretroviral therapy.

| Drug | Dose | Common Side Effects | Special Monitoring ¹ | Cost ² | Cost/Month |
|--|--|--|---|--------------------------------|--|
| Nucleoside reverse transcriptase inhibitors | | | | | |
| Zidovudine (AZT) (Retrovir) | 600 mg orally daily in two divided doses | Anemia, neutropenia, nausea, malaise, headache, insomnia, myopathy | No special monitoring | \$6.08/300 mg | \$365.09 |
| Didanosine (ddl) (Videx) | 400 mg orally daily (enteric-coated capsule) for persons \geq 60 kg | Peripheral neuropathy, pancreatitis, dry mouth, hepatitis | Bimonthly neurologic questionnaire for neuropathy, K ⁺ , amylase, bilirubin, triglycerides | \$10.70/400 mg | \$321.00 |
| Zalcitabine (ddC) (Hivid) | 0.375-0.75 mg orally three times daily | Peripheral neuropathy, aphthous ulcers, hepatitis | Monthly neurologic questionnaire for neuropathy | \$3.03/0.75 mg | \$272.70 |
| Stavudine (d4T) (Zerit) | 40 mg orally twice daily for persons \geq 60 kg | Peripheral neuropathy, hepatitis, pancreatitis | Monthly neurologic questionnaire for neuropathy, amylase | \$7.31/40 mg | \$438.61 |
| Lamivudine (3TC) (EpiVir) | 150 mg orally twice daily | Rash, peripheral neuropathy | No special monitoring | \$6.80/150 mg | \$408.00 |
| Emtricitabine (Emtriva) | 200 mg orally once daily | Skin discoloration palms/soles (mild) | No special monitoring | \$13.15/200 mg | \$394.38 |
| Abacavir (Ziagen) | 300 mg orally twice daily | Rash, fever—if occur, rechallenge may be fatal | No special monitoring | \$9.14/300 mg | \$548.21 |
| Nucleotide reverse transcriptase inhibitors | | | | | |
| Tenofovir (Viread) | 300 mg orally once daily | Gastrointestinal distress | Kidney function | \$22.09/300 mg | \$662.70 |
| Protease inhibitors (PIs) | | | | | |
| Indinavir (Crixivan) | 800 mg orally three times daily | Renal calculi | Cholesterol, triglycerides, bilirubin level | \$3.05/400 mg | \$548.12 |
| Saquinavir hard gel (Invirase) | 1000 mg orally twice daily with 100 mg ritonavir orally twice daily | Gastrointestinal distress | Cholesterol, triglycerides | \$6.91/500 mg | \$829.18 (plus cost of ritonavir) |
| Ritonavir (Norvir) | 600 mg orally twice daily or in lower doses (eg, 100 mg orally once or twice daily) for boosting other PIs | Gastrointestinal distress, peripheral paresthesias | Cholesterol, triglycerides | \$10.29/100 mg | \$3703.20 (\$617.20 in lower doses) |
| Nelfinavir (Viracept) | 750 mg orally three times daily or 1250 mg twice daily | Diarrhea | Cholesterol, triglycerides | \$2.52/250 mg \$6.30/625 mg | \$680.99 \$726.40 |
| Fosamprenavir (Lexiva) | For PI-experienced patients: 700 mg orally twice daily and 100 mg of ritonavir 100 orally twice daily. For PI-naïve patients: above or 1400 mg orally twice daily or 1400 mg orally once daily and 200 mg of ritonavir orally once daily | Gastrointestinal rash | Cholesterol, triglycerides | \$12.91/700 mg | \$774.52- \$1549.04 (plus cost of ritonavir for lower dose) |
| Lopinavir/ritonavir (Kaletra) | 400 mg/100 mg orally twice daily | Diarrhea | Cholesterol, triglycerides | \$7.02/200 mg (lopinavir) | \$841.90 |
| Atazanavir (Reyataz) | 400 mg orally once daily | Hyperbilirubinemia | Bilirubin level; when used with ritonavir: cholesterol and triglycerides | \$17.12/200 mg | \$1026.90 |

(continued)

Table 31–6. Antiretroviral therapy. (continued)

| Drug | Dose | Common Side Effects | Special Monitoring ¹ | Cost ² | Cost/Month |
|--|---|--|---------------------------------|--|--------------------------------|
| Tipranavir/ ritonavir (Aptivus/ Norvir) | 500 mg of tipranavir and 200 mg of ritonavir orally twice daily | Gastrointestinal, rash | Cholesterol, triglycerides | \$8.94/250 mg (tipranavir) \$10.29/100 mg (ritonavir) | \$2307.20 (for combination) |
| Darunavir/ ritonavir (Prezista/ Norvir) | 600 mg of darunavir and 100 mg of ritonavir orally twice daily | Rash | Cholesterol, triglycerides | \$7.80/300 mg (darunavir) \$10.29/100 mg (ritonavir) | \$1553.40 (for combination) |
| Nonnucleoside reverse transcriptase inhibitors (NNRTIs) | | | | | |
| Nevirapine (Viramune) | 200 mg orally daily for 2 weeks, then 200 mg orally twice daily | Rash | No special monitoring | \$8.56/200 mg | \$513.80 |
| Delavirdine (Rescriptor) | 400 mg orally three times daily | Rash | No special monitoring | \$1.69/200 mg | \$303.70 |
| Efavirenz (Sustiva) | 600 mg orally daily | Neurologic distur- bances | No special monitoring | \$20.07/600 mg | \$602.00 |
| Etravirine (Intenceo) | 200 mg orally daily | Rash, nausea | No special monitoring | | |
| Entry inhibitors | | | | | |
| Enfuvirtide (Fuzeon) | 90 mg subcutaneously twice daily | Injection site pain and allergic reaction | No special monitoring | \$42.89/90 mg | \$2573.16 |
| Maraviroc (Selzentry) | 150–300 mg orally daily | Cough, fever, rash | No special monitoring | \$17.40/150 mg or 300 mg | \$1044.00 |
| Integrase inhibitor | | | | | |
| Raltegravir (Isentress) | 400 mg orally twice daily | Diarrhea, nausea, headache | No special monitoring | \$16.20/400 mg | \$972.00 |

¹Standard monitoring is complete blood count (CBC) and differential, and serum aminotransferases.

must be performed. Based on the results of resistance testing, and assessment of the patient's capability to comply with complicated regimens or to tolerate predictable side effects, the clinician should prescribe a combination of three medications to which there is no or only minimal resistance. Some patients whose counts rise dramatically on ART and who are fully suppressed (ie, plasma viral load < 50 copies/mL) may be successfully transitioned from a high potency regimen to a lower potency regimen with fewer side effects; however, this "induction-maintenance" strategy is still being evaluated in clinical trials. Stopping therapy in patients with high CD4 counts will generally result in patients reverting to their pretreatment nadir CD4 count in a matter of months and is therefore not recommended.

Although the ideal combination of drugs has not yet been defined for all possible clinical situations, possible choices can be better understood after a review of the available agents. These drugs can be grouped into five major categories: nucleoside and nucleotide reverse transcriptase inhibitors (NRTI), protease inhibitors (PI), nonnucleoside reverse transcriptase inhibitors (NNRTI), entry inhibitors (including fusion inhibitors and CCR5 antagonists), and integrase inhibitors. Once ART has been initiated in a

patient, it is not advisable to stop the therapy unless there is a compelling reason (eg, toxicity, poor adherence, etc). So-called "drug holidays" or "structured treatment interruptions" have been shown to increase risk of AIDS-related complications, increase CD4 declines, and increase morbidity from non-AIDS-related complications (eg, myocardial infarctions and liver failure) and are not recommended.

1. Nucleoside and nucleotide reverse transcriptase inhibitors

—There are currently seven nucleoside or nucleotide agents approved for use. The choice of which agent to use depends primarily on the patient's prior treatment experience, results of resistance testing, drug side effects, other underlying conditions, and convenience of formulation. However, most clinicians use fixed-dose combinations of either tenofovir/emtricitabine (TDF/FTC) or abacavir/lamivudine (ABC/3TC), both of which can be given once a day. Zidovudine/lamivudine (AZT/3TC) is usually reserved for second- or third-line regimens because of toxicity and dosing schedule. Recent studies have raised some concerns about the efficacy of ABC/3TC in patients with high viral loads (eg, > 100,000 copies/mL) as well as concerns about increase risks of myocardial infarction with

abacavir. Therefore, TDF/FTC is the preferred fixed-dose combination as part of initial treatment regimens.

Of the available agents, zidovudine is the most likely to cause anemia. Zidovudine and didanosine are the most likely to cause neutropenia. Stavudine is the most likely to cause lipoatrophy (loss of fat in the face, extremities, and buttocks) followed by zidovudine. Zalcitabine and didanosine are the most likely to cause peripheral neuropathy. Lamivudine, emtricitabine, and tenofovir have activity against hepatitis B. Didanosine, lamivudine, emtricitabine, and tenofovir can be administered daily. Generally, didanosine and tenofovir should not be given together due to toxicity of the combination that can result in decreasing CD4 counts. Information specific to each drug is given below, and recommendations on how to combine them appear in the Constructing regimens section below.

A. ZIDOVUDINE—Zidovudine was the first approved antiviral drug for HIV infection and remains an important agent. It is administered at a dose of 300 mg orally twice daily. A combination of zidovudine 300 mg and lamivudine 150 mg (Combivir) allows more convenient dosing of medication for individuals taking both of these agents. Side effects seen with zidovudine are listed in Table 31–6. Approximately 40% of patients experience subjective side effects that usually remit within 6 weeks. The common dose-limiting side effects are anemia and neutropenia, which require ongoing laboratory monitoring. Long-term use has been associated with lipoatrophy.

B. DIDANOSINE—The most convenient formulation of didanosine (ddI) is the enteric-coated capsule. For adults weighing at least 60 kg, the dose is one 400-mg enteric-coated capsule orally daily; for those 30–59 kg, the dose is one 250-mg enteric-coated capsule orally daily. Didanosine should be taken on an empty stomach.

Didanosine does not cause anemia but may cause neutropenia. It has also been associated with pancreatitis. The incidence of pancreatitis with didanosine is 5–10%—of fatal pancreatitis, less than 0.4%. Patients with a history of pancreatitis, as well as those taking other medications associated with pancreatitis (including trimethoprim-sulfamethoxazole and intravenous pentamidine) are at higher risk for this complication. Patients should be warned to use alcohol judiciously while taking didanosine. Other common side effects with didanosine include a dose-related, reversible, painful peripheral neuropathy, which occurs in about 15% of patients, and dry mouth. Fulminant hepatic failure and electrolyte abnormalities, including hypokalemia, hypocalcemia, and hypomagnesemia, have been reported in patients taking didanosine.

C. STAVUDINE—Stavudine (d4T) has shown good activity as an antiretroviral drug. The dose is 40 mg orally twice daily for individuals weighing 60 kg or more. However, because of its side effects including lipoatrophy, lipodystrophy (see below), peripheral neuropathy and, rarely, lactic acidosis and hepatitis, this drug should no longer be used except when there is no alternative. Patients taking stavudine should be routinely changed to abacavir or tenofovir, both of which are less likely to cause lipoatrophy.

D. LAMIVUDINE—Lamivudine (3TC) is a safe and well-tolerated agent. The dosage is 150 mg orally twice daily or 300 mg orally once a day. The dose should be reduced with chronic kidney disease. There are no significant side effects with lamivudine, and it has activity also against hepatitis B.

E. EMTRICITABINE—Emtricitabine is a nucleoside analog that is dosed at 200 mg orally. It was developed primarily as a once a day alternative to lamivudine. However, lamivudine can be dosed daily, eliminating the special indication for emtricitabine. As is true of lamivudine, emtricitabine has activity against hepatitis B and its dosage should be reduced in patients with chronic kidney disease.

F. ABACAVIR—A daily dose of 300 mg orally twice daily results in potent antiretroviral activity. Prior to initiation of abacavir, patients should undergo testing for HLA typing. Those with the B*5701 allele should not be treated with abacavir because the likelihood of a hypersensitivity reaction developing is high; the reaction is characterized by a flu-like syndrome with rash and fever that worsens with successive doses. Unfortunately, the absence of this allele does not guarantee that the patient will avoid the hypersensitivity reaction. Individuals in whom the hypersensitivity reaction develops *should not* be rechallenged with this agent because subsequent hypersensitivity reactions can be fatal. Two studies have reported an apparent increased risk of myocardial infarctions with abacavir use in patients who have underlying risks of cardiovascular disease. Consequently, abacavir should be avoided in such patients if effective alternative nucleoside or nucleotide analog agents exist.

Abacavir is formulated with zidovudine and lamivudine in a single pill (Trizivir, one tablet orally twice daily). Trizivir is not recommended as solo treatment for HIV because it is not as efficacious as combining two nucleoside/nucleotide analogs with a PI/ritonavir or an NNRTI; its use as a sole regimen should be reserved only for exceptional cases. Abacavir is also available as a fixed dose combination pill with lamivudine for use as a once daily pill (Epzicom).

G. ZALCITABINE—Zalcitabine (ddC) is thought to be one of the least effective antiretroviral agents and is therefore not commonly used. Zalcitabine, like didanosine, may cause peripheral neuropathy. It is also associated with aphthous ulcers, rash, and rare cases of pancreatitis.

H. TENOFOVIR—Tenofovir is the only licensed nucleotide analog. It is given as a single daily oral dose of 300 mg and is generally well tolerated. Tenofovir is available in a fixed dose combination pill with emtricitabine (Truvada) for daily dosing and is the only recommended fixed-dose combination for initial regimens. A once-a-day single fixed-dose combination pill that contains tenofovir, emtricitabine, and efavirenz (Atripla) is also available. Tenofovir is active against hepatitis B, including isolates that have resistance to lamivudine.

2. Protease inhibitors—Ten PIs—indinavir, nelfinavir, ritonavir, saquinavir, amprenavir, fosamprenavir, lopinavir (in combination with ritonavir), atazanavir, darunavir, and

tipranavir are available. PIs have been shown to potently suppress HIV replication and are administered as part of a combination regimen.

All the PIs—to differing degrees—are metabolized by the cytochrome P450 system, and each can inhibit and induce various P450 isoenzymes. Therefore, drug interactions are common and difficult to predict. Clinicians should consult the product inserts before prescribing PIs with other medications. Drugs such as rifampin that are known to induce the P450 system should be avoided.

The fact that the PIs are dependent on metabolism through the cytochrome P450 system has led to the use of ritonavir to boost the drug levels of saquinavir, lopinavir, indinavir, atazanavir, tipranavir, darunavir and amprenavir, allowing use of lower doses and simpler dosing schedules of these PIs. In fact, current guidelines recommend that all PI-containing regimens use ritonavir boosting if possible. The only PIs that can be safely used without ritonavir boosting are nelfinavir and atazanavir.

When choosing which PI to use, prior patient experience, resistance patterns, side effects, and ease of administration are the major considerations. The first three PIs to be developed—indinavir, saquinavir, and ritonavir (as single agents)—are now rarely used because of the superiority of the second generation of PIs. Amprenavir has been almost entirely replaced by its prodrug, fosamprenavir. Unfortunately, all PIs, with the exception of unboosted atazanavir have been linked to a constellation of metabolic abnormalities, including elevated cholesterol levels, elevated triglyceride levels, insulin resistance, diabetes mellitus, and changes in body fat composition (eg, buffalo hump, abdominal obesity). The lipid abnormalities and body habitus changes are referred to as lipodystrophy. Although lipodystrophy is commonly associated with PIs, it has been seen also in HIV-infected persons who have never been treated with these agents. In particular, the lipodystrophy effects seen in patients receiving ART appears to be more related to the nucleoside toxicity and in particular to the thymidine analogs (stavudine and zidovudine).

Of the different manifestations of lipodystrophy, the dyslipidemias that occur are of particular concern because of the likelihood that increased levels of cholesterol and triglycerides will result in increased prevalence of heart disease. All patients taking PIs or NRTIs should have fasting serum cholesterol, low-density lipoprotein (LDL) cholesterol, and triglyceride levels performed every 3–6 months. Clinicians should calculate the Framingham 10-year coronary heart disease risk (see Chapter 28) and consider initiating dietary or drug therapy (or both) to achieve target LDL levels depending on the individual's risk factors. Patients who are unable to meet their LDL goal based solely on dietary interventions should be given pravastatin (20 mg daily orally) or atorvastatin (10 mg daily orally). Lovastatin and simvastatin should be avoided because of their interactions with PIs. Fish oil (3000 mg daily) combined with exercise and dietary counseling has been found to decrease triglycerides levels by 25%. Patients with persistently elevated fasting serum triglyceride levels of 500 mg/dL or more who do not respond to dietary

intervention should be treated with gemfibrozil (600 mg twice daily prior to the morning and evening meals).

A. INDINAVIR—The standard dose of indinavir is 800 mg orally three times a day, although it is usually dosed twice daily in combination with ritonavir. Nausea and headache are common complaints with this drug. Indinavir crystals are present in the urine in approximately 40% of patients; this results in clinically apparent nephrolithiasis in about 15% of patients receiving indinavir. Lower urinary tract symptoms and acute kidney injury also have been reported. Patients taking this drug should be instructed to drink at least 48 ounces of fluid a day to ensure adequate hydration in an attempt to limit these complications. Mild indirect hyperbilirubinemia is also commonly observed in patients taking indinavir but is not an indication for discontinuation of the drug.

B. SAQUINAVIR—Saquinavir is formulated only as a hard-gel capsule (Invirase). It should only be used with ritonavir (1000 mg of hard-gel saquinavir with 100 mg of ritonavir orally twice daily). The soft-gel capsule (Fortovase) has been removed from the market in the United States. The most common side effects with saquinavir are diarrhea, nausea, dyspepsia, and abdominal pain.

C. RITONAVIR—Use of this potent PI at full dose (600 mg orally twice daily) has been limited by its inhibition of the cytochrome P450 pathway causing a large number of drug–drug interactions and by its frequent side effects of fatigue, nausea, and paresthesias. However, it is widely used in lower dose (eg, 100 mg daily to 100 mg twice daily) as a booster of other PIs.

D. NELFINAVIR—Nelfinavir is the only PI for which ritonavir boosting is not recommended. Unboosted nelfinavir is generally not as potent as a boosted PI regimen (eg, lopinavir plus ritonavir). The dose of nelfinavir is 1250 mg orally twice daily. Diarrhea is a side effect in 25% of patients taking nelfinavir, but this symptom may be controlled with over-the-counter antidiarrheal agents in most patients.

E. AMPRENAVIR—Amprenavir has efficacy and side effects similar to those of other PIs. Common side effects are nausea, vomiting, diarrhea, rash, and perioral paresthesia. The dose is 1200 mg orally twice daily. The concentration of amprenavir decreases when coadministered with ethinyl estradiol; therefore, amprenavir should be used with circumspection in the treatment of transgender persons requiring high-dose estrogen.

F. FOSAMPRENAVIR—Fosamprenavir is a prodrug of amprenavir. Its major advantage over using amprenavir is a much lower pill burden. For PI-naïve patients, it can be dosed at 1400 mg orally twice daily (four capsules a day) or at 1400 mg orally daily (two capsules) with ritonavir 200 mg orally daily (two capsules) or at 700 mg orally with ritonavir 100 mg orally twice daily. Patients previously treated with PIs should receive 700 mg orally with ritonavir 100 mg orally twice daily. Side effects are similar to those with amprenavir—most commonly gastrointestinal distress and hyperlipidemia. As with amprenavir, the concentration of fosamprenavir decreases when coadministered with ethinyl

estradiol; therefore, fosamprenavir should be used with circumspection in the treatment of transgender persons requiring high-dose estrogens.

G. LOPINAVIR/R—Lopinavir/r is lopinavir (200 mg) coformulated with a low dose of ritonavir (50 mg) to maximize the bioavailability of lopinavir. It has been shown to be more effective than nelfinavir when used in combination with stavudine and lamivudine. The usual dose is 400 mg lopinavir with 100 mg of ritonavir (two tablets) orally twice daily with food. When given along with efavirenz or nevirapine, a higher dose (600 mg/150 mg—three tablets) is usually prescribed. The most common side effect is diarrhea, and lipid abnormalities are frequent.

H. ATAZANAVIR—Atazanavir can be dosed only once daily (two 200-mg capsules with food) or 300 mg in combination with 100 mg of ritonavir once daily). When used without ritonavir, it has only minimal or no impact on cholesterol and triglyceride levels. The most common side effect is mild hyperbilirubinemia that resolves with discontinuation of the drug. Both tenofovir and efavirenz lower the serum concentration of atazanavir. Therefore, when either of these two drugs is used with atazanavir, it should be boosted by administering ritonavir. Proton pump inhibitors are contraindicated in patients taking atazanavir because atazanavir requires an acidic pH to remain in solution.

I. TIPRANAVIR—Tipranavir is the only nonpeptidic PI currently approved by the US Food and Drug Administration (FDA). Because of its unique structure, it is active against some strains of HIV that are resistant to other PIs. It is dosed with ritonavir (two 250 mg capsules of tipranavir with two 100 mg capsules of ritonavir orally twice daily with food). The most common side effects are nausea, vomiting, diarrhea, fatigue, and headache. Tipranavir/ritonavir has been also associated with liver damage and should be used very cautiously in patients with underlying liver disease. Recent reports of intracranial hemorrhage in patients taking tipranavir-containing regimens have raised additional safety concerns about this potent PI. Because it is a sulfa-containing drug, its use should be closely monitored in patients with sulfa allergy.

J. DARUNAVIR—Darunavir is the most recently approved PI with impressive antiviral activity in the setting of significant PI resistance and in treatment-naïve patients. Darunavir has been added to the list of recommended PIs for initial treatment of HIV where it can be dosed daily (darunavir, 800 mg, with ritonavir, 100 mg). Darunavir, 600 mg orally twice daily, with ritonavir, 100 mg orally twice daily, is recommended for patients with prior PI treatment experience or PI resistance. Darunavir appears to be reasonably well tolerated with a safety profile similar to other PIs, such as lopinavir/ritonavir. Like tipranavir, darunavir is a sulfa-containing drug, and its use should be closely monitored in patients with sulfa allergy.

3. Nonnucleoside reverse transcriptase inhibitors—NNRTIs inhibit reverse transcriptase at a site different from that of the nucleoside and nucleotide agents described above. All four NNRTIs have shown antiviral

activity as measured by HIV viral load and CD4 responses. The major advantage of the NNRTIs is that two of them (nevirapine and efavirenz) have potencies comparable to that of PIs—with lower pill burden and fewer side effects. In particular, they do not appear to cause lipodystrophy; patients with cholesterol and triglyceride elevations who are switched from a PI to an NNRTI may have improvement in their lipids. The resistance patterns of the NNRTIs are distinct from those of the PIs, so their use still leaves open the option for future PI use.

The NNRTIs can be used with PIs in patients who are difficult to suppress on simpler regimens or when it is difficult to identify at least two nucleoside/nucleotide agents to which the patient is not resistant. Because these agents may cause alterations in the clearance of PIs, dose modifications may be necessary when these two classes of medications are administered concomitantly. There is a high degree of cross-resistance between the “first generation” NNRTIs, such that resistance to one drug in this class uniformly predicts resistance to other drugs. However, etravirine has been approved as a “second-generation” NNRTI and appears to have consistent antiviral activity in patients with prior exposure and resistance to the “first generation” drugs of this class. In particular, the K103N mutation, which is associated with a high level of resistance to nevirapine, efavirenz, and delavirdine, does not appear to have an impact on etravirine. There is no therapeutic reason for using more than one NNRTI at the same time.

A. EFAVIRENZ—The major advantage of efavirenz is that it can be given once daily in a single dose (600 mg orally). The side effects are neurologic, with patients reporting symptoms ranging from lack of concentration and strange dreams to delusions and mania. Fortunately, the neurologic side effects of efavirenz subside over time, usually within a month. Administration of efavirenz with food, especially fatty food, may increase its serum levels and consequent neurotoxicity. Due to teratogenicity, efavirenz should be avoided in women who wish to conceive or are already pregnant. A once-daily fixed-dose combination of efavirenz, tenofovir, and emtricitabine in a single pill (Atripla) is available and is probably the best first choice for treatment-naïve patients without significant drug resistance.

B. NEVIRAPINE—The target dose of nevirapine is 200 mg orally twice daily, but it is initiated at a dose of 200 mg once a day to decrease the incidence of rash, which is as high as 40% when full doses are begun immediately. If rash develops while the patient is taking 200 mg a day, liver enzymes should be checked and the dose should not be increased until the rash resolves. Patients with mild rash and no evidence of hepatotoxicity can continue to be treated with nevirapine. Nevirapine should not be used in treatment-naïve women with high CD4 counts (> 250/mcL). Because of potential fatal hepatotoxicity, nevirapine should only be used in patients who cannot tolerate efavirenz.

C. DELAVIRDINE—Of the available “first generation” NNRTIs, delavirdine is used the least largely because of its less convenient dosing and pill burden compared with the other available NNRTIs. Unlike nevirapine and efavirenz,

delavirdine inhibits P450 cytochromes rather than inducing these enzymes. This means that delavirdine can act like ritonavir and boost other antiretrovirals, although delavirdine is not as potent as ritonavir in this capacity. The dosage is 400 mg orally three times a day. The major side effect is rash.

D. ETRAVIRINE—Etravirine is the most recently approved NNRTI for the treatment of patients with prior NNRTI intolerance or resistance. The DUET trials demonstrated potent and durable antiviral activity in patients with NNRTI resistance to “first-generation” NNRTIs. Etravirine dosage is two 100-mg tablets twice daily. It should be used with a PI and a nucleoside/nucleotide analog and not just with two nucleoside/nucleotide analogs. The most common side effects are rash and nausea. Prior rash due to treatment with one of the other NNRTIs does not make rash more likely with etravirine.

4. Entry inhibitors

A. ENFUVIRTIDE—Enfuvirtide (Fuzeon) is known as a fusion inhibitor; it blocks the entry of HIV into cells by blocking the fusion of the HIV envelope to the cell membrane. The addition of enfuvirtide to an optimized antiretroviral regimen improved CD4 counts and lowered viral loads in heavily pretreated patients with multidrug-resistant HIV. Unfortunately, resistance develops rapidly in patients receiving nonsuppressive treatment. The dose is 90 mg by subcutaneous injection twice daily; unfortunately, painful injection site reactions develop in most patients.

B. MARAVIROC—Maraviroc is the first CCR5 co-receptor antagonist to be approved for use. Drugs in this class work by preventing the virus from entering uninfected cells by blocking the CCR5 co-receptor. Unfortunately, this class of entry inhibitors is only active against “CCR5-tropic virus.” This form of the HIV-1 virus tends to predominate early in infection, while so-called “dual/mixed tropic virus” (which utilizes either R5 or CXCR4 co-receptors) emerges later as infection progresses. Approximately 50–60% of previously treated HIV-infected patients have circulating CCR5-tropic HIV. The drug has been shown to be effective in HIV-infected persons with ongoing viral replication despite being heavily treated and who have CCR5-tropic virus. Tropism testing should be performed before beginning the medication. The dose of maraviroc is 150–300 mg orally twice daily, based on the other drugs the patient is taking at the time. Common side effects are cough, fever, rash, musculoskeletal problems, abdominal pain, and dizziness.

5. Integrase inhibitors

A. RALTEGRAVIR—Raltegravir is the first HIV integrase inhibitor to be approved by the FDA. Integrase inhibitors slow HIV replication by blocking the HIV integrase enzyme needed for the virus to multiply. Raltegravir was impressively effective (when combined with other active drugs) in the treatment of HIV-infected patients with documented resistance to at least one drug in each of the three main classes of antiretroviral medications (nucleoside analogs, PIs, NNRTIs). Clinical trials of integrase inhibitors reveal a consistent pattern of more rapid decline in viral load compared with more standard PI/r or NNRTI-

based regimens. The clinical significance of this observation is yet to be defined. Despite the impressive antiviral potency of this new exciting class of antiretroviral drugs, it appears that high-level resistance to integrase inhibitors emerges quickly in the setting of virologic failure (much like with the NNRTIs). Therefore, it is critical that raltegravir be used in combination with other active antiretroviral agents.

Recent studies in treatment-naïve patients have demonstrated that raltegravir in combination with TDF/FTC is as effective as the current first-line choice of EFV/TDF/FTC for daily treatment and has fewer side effects. Furthermore, the CD4 response appeared better in patients treated with the raltegravir combination. These results led to FDA approval for raltegravir in treatment-naïve patients. The dose of raltegravir is 400 mg orally twice daily. Common side effects are diarrhea, nausea, and headache.

B. ELVITEGRAVIR—Elvitegravir is another integrase inhibitor that is in phase 3 studies. The dose is 125 mg once daily, given with ritonavir (100 mg) for boosting. Elvitegravir showed impressive short-term virologic responses in phase 2 studies.

6. Constructing regimens—There is now little debate about the necessity for combining drugs to achieve long-term suppression of HIV and its associated clinical benefit. Only combinations of three or more drugs have been able to decrease HIV viral load by 2–3 logs and allow long-term suppression of HIV RNA to below the threshold of detection.

Current evidence supports the use of Truvada (tenofovir and emtricitabine) as the “nucleoside/nucleotide backbone” combined with efavirenz as the initial regimen. This regimen has been shown to be more effective and better tolerated than Combivir (zidovudine and lamivudine) and Epzicom (abacavir/lamivudine). It has the advantages of once daily dosing and is available as a single pill (Atripla). Because 8–10% of newly infected persons in some urban areas of the United States have NNRTI resistance, resistance testing should be performed before initiating efavirenz in this population. Regimens that include only nucleoside and nucleotide analogs without nonnucleoside agents or PIs are clinically inferior and should only be used for patients that cannot adhere to a more complicated regimen.

In the absence of head-to-head comparisons of different regimens in different situations, several general principles should guide the choice of combinations. The most important determinant of treatment efficacy is adherence to the regimen. Therefore, it is vitally important that the regimen chosen be one to which the patient can easily adhere. In general, patients are more compliant with medication regimens that are once or twice a day only, do not require special timing with regard to meals, can be taken at the same time as other medications, do not require refrigeration or special preparation, and do not have bothersome side effects. To the extent possible, agents to which the patient has not been exposed are preferable to drugs for which resistance mutations may have already occurred. Toxicities should ideally be nonoverlapping. An individual's relative contraindications to a given drug or drugs

should be considered. The regimen should not include agents that are either virologically antagonistic or incompatible in terms of drug–drug interactions. For example, etravirine should not be used with boosted tipranavir because of drug–drug interactions. Compatible dosing schedules—prescribing medications that can be taken at the same time—improve adherence to treatment. Finally, highly complex therapeutic regimens should be reserved for individuals who are capable of adhering to the rigorous demands of taking multiple medications and having this therapy closely monitored. Conversely, simplified regimens that deliver the lowest number of pills given at the longest possible dosing intervals are desirable for patients who have difficulty taking multiple medications.

Possible ways of incorporating nonnucleoside agents and PIs into combinations are displayed in Figure 31–2.

A number of points about the “nucleoside/nucleotide backbone” of regimens have become clearer. The combination of stavudine plus didanosine should be avoided, since there is increased risk of toxicities, in particular in pregnant women because of the increased risk of lactic acidosis, which can be fatal. Moreover, the nucleoside pair of zidovudine and stavudine should be avoided because of increased toxicity and the potential for antagonism that results from intracellular competition for phosphorylation. Finally, the

combination of didanosine with tenofovir should be avoided due to observed declines in CD4 counts.

In choosing which agents to include in an initial antiretroviral regimen, ease of administration, minimization of side effects, drug resistance pattern, and future treatment options should all be considered. In designing second-line regimens for patients with resistance to initial therapy, the goal is to identify three drugs from at least two different classes to which the virus is not resistant. This can be quite complicated because of the problem of cross-resistance between drugs within a class. For example, the resistance patterns of lopinavir/ritonavir and indinavir are overlapping, and patients with virus resistant to these agents are unlikely to respond to nelfinavir or saquinavir even though they have never received treatment with these agents. Similarly, the resistance patterns of nevirapine and efavirenz are overlapping. With several new classes of drugs and new generations of existing drug classes now available, the ability to provide fully suppressive regimens even to patients with extensive treatment experience and drug resistance has become more realistic. The goal of therapy, therefore, should be to fully suppress viral loads to < 50 copies/mL even for highly treatment-experienced patients.

In addition to taking a careful history of what antiretroviral agents a patient has taken and for how long, genotypic

▲ **Figure 31–2.** Approach to initial and subsequent antiretroviral therapy.

and phenotypic resistance testing can provide useful information in designing second-line regimens (see below).

Whatever regimen is chosen, patients should be coached in ways to improve adherence. For certain populations (eg, unstably housed individuals), specially tailored programs that include drug dispensing are needed.

For some patients, it is impossible to construct a tolerable regimen that fully suppresses HIV. In such cases, clinicians and patients should consider their goals. Patients maintained on effective antiretroviral agents often benefit from these regimens (eg, higher CD4 counts, fewer opportunistic infections) even if their virus is detectable. In some cases, patients may request a drug holiday during which they are taken off all medications. Patients often immediately feel better because of the absence of drug side effects. Unfortunately, structured treatment interruptions generally result in viral rebound and CD4 decline, and patients who interrupt their treatment fare poorly compared with patients who continue their regimens without interruption.

7. The challenge of drug resistance—HIV-1 drug resistance limits the ability to fully control HIV replication and is a leading cause for antiretroviral regimen failure. Resistance has been documented for all currently available antiretrovirals including the new classes of fusion inhibitors, CCR5 inhibitors, and integrase inhibitors. The problem of drug resistance is widespread in HIV-infected patients undergoing treatment in countries where ART is widely available. A cohort study revealed that some degree of resistance developed over the first 30 months of therapy in nearly one-third of patients starting a HAART regimen. Patients who have taken various antiretroviral regimens and who now have resistant HIV-1 represent a major challenge for the treating clinician. Resistance is now also documented in patients who are ART-naïve, but who have been infected with a drug resistant strain—“primary resistance.” Cohort studies of antiretroviral treatment-naïve patients entering care in North America and Western Europe show that roughly 10–12% (and as high as 25%) of recently infected individuals have been infected with a drug-resistant strain of HIV-1.

Current expert guidelines recommend resistance testing as part of standard baseline testing in all patients. Resistance testing is also recommended for patients who are on an antiretroviral regimen and have suboptimal viral suppression (ie, viral loads > 1000 copies/mL). Both genotypic and phenotypic tests are commercially available and in randomized controlled studies their use has been shown to result in improved short-term virologic outcomes compared to making treatment choices without resistance testing. Furthermore, multiple retrospective studies have conclusively demonstrated that resistance tests provide prognostic information about virologic response to newly initiated therapy that cannot be gleaned from standard clinical information (ie, treatment history, examination, CD4 count, and viral load tests).

Because of the complexity of resistance tests, many clinicians require expert interpretation of results. In the case of genotypic assays, results may show that the mutations that are selected for during ART are drug-specific or contribute

to broad cross-resistance to multiple drugs within a therapeutic class. An example of a drug-specific mutation for the reverse transcriptase inhibitors would be the M184V mutation that is selected for by lamivudine or emtricitabine therapy—this mutation causes resistance only to those two drugs. Conversely, the thymidine analog mutations (“TAMs”) of M41L, D67N, K70R, L210W, T215Y/F, and T219Q/K/E are selected for by either zidovudine or stavudine therapy, but cause resistance to all the drugs in the class and often extend to the nucleotide inhibitor tenofovir when three or more of these TAMs are present. Further complicating the interpretation of genotypic tests is the fact that some mutations that cause resistance to one drug can actually make the virus that contains this mutation more sensitive to another drug. The M184V mutation, for example, is associated with increased sensitivity to zidovudine, stavudine, and tenofovir. The most common mutations associated with drug resistance and cross-resistance patterns for NRTIs, NNRTIs, and PIs can be found at <http://hivdb.stanford.edu>. Phenotypic tests also require interpretation in that the distinction between a resistant virus and sensitive one is not fully defined for all available drugs.

Both methods of resistance testing are limited by the fact that they may measure resistance in only some of the viral strains present in an individual. Resistance results may also be misleading if a patient is not taking antiretroviral medications at the time of testing. Thus, resistance results must be viewed cumulatively—ie, if resistance is reported to an agent on one test, it should be presumed to be present thereafter even if subsequent tests do not give the same result.

► Course & Prognosis

With improvements in therapy, patients are living longer after the diagnosis of AIDS. A population-based study conducted in Denmark found that HIV-infected persons at age 25 years without hepatitis C had a life expectancy of 39 additional years. Unfortunately, not all HIV-infected persons have access to treatment. Studies consistently show less access to treatment for blacks, the homeless, and injection drug users. In addition to access to treatment, sustaining lower mortality will require developing new treatments for patients in whom resistance to existing agents develops. For patients whose disease progresses even though they are receiving appropriate treatment, meticulous palliative care must be provided (see Chapter 5), with attention to pain control, spiritual needs, and family (biologic and chosen) dynamics.

► When to Refer

- Clinicians with limited experience in HIV/AIDS should refer HIV-infected patients to specialists with experience, given the increasing number and complexity of treatment regimens available.
- Extra efforts should be made to obtain specialty consultation for those patients with detectable viral loads on ART; those intolerant of standard medications; those in need of systemic chemotherapy; and those with complicated opportunistic infections, particularly when invasive procedures or experimental therapies are needed.

▶ When to Admit

Patients with opportunistic infections who are acutely ill (eg, who are febrile, who have had rapid change of mental status, or who are in respiratory distress) or who require intravenous medications.

VIRAL DISEASES

HUMAN HERPESVIRUSES

Herpesviruses cause a wide spectrum of human disease. Eight identified human herpesviruses (HHV) include herpes simplex virus (HSV) (type 1), HSV (type 2), varicella zoster virus (VZV) (type 3), Epstein–Barr infectious mononucleosis virus (type 4), and cytomegalovirus (CMV) (type 5). A sixth type (HHV-6) has been identified as a causative agent of roseola (exanthema subitum), and a seventh (HHV-7) is serologically associated with several syndromes. Another herpesvirus (HHV-8) is linked with Kaposi sarcoma (see Chapter 31).

Subclinical primary infection with the herpesviruses is more common than clinically manifest illness. Each persists in a latent state for the remainder of the person's life. With HSV and VZV, virus remains latent in sensory ganglia; upon reactivation, lesions appear in the distal sensory nerve distribution. As a result of disease-, drug-, or radiation-induced immunosuppression, virus reactivation may lead to widespread lesions in affected organs such as the viscera or the central nervous system (CNS). Severe or fatal illness may occur in infants and immunodeficient persons. Herpesviruses can transform cells in tissue culture. Associations with malignancies include Epstein–Barr virus (EBV) with Burkitt lymphoma and nasopharyngeal carcinoma and HHV-8 with primary effusion lymphoma and Kaposi sarcoma.

1. Herpesviruses 1 & 2

ESSENTIALS OF DIAGNOSIS

- ▶ Spectrum of illness from stomatitis and urogenital lesions to facial nerve paralysis (Bell palsy) and encephalitis.
- ▶ Variable intervals between exposure and clinical disease, since HSV causes both primary (which may be subclinical) and reactivation disease.

- ▶ Successful management with acyclovir or related acyclic compounds (valacyclovir, famciclovir).

▶ General Considerations

Herpesviruses 1 and 2 affect primarily the oral and genital areas, respectively. Seroprevalence to both viruses increases with age; seroprevalence to HSV-2 increases with sexual activity. Disease is typically a manifestation of reactivation. Although HSV-2 is the most common cause of genital ulcers in the developed world, HSV-1 is increasingly recognized as causing primary urogenital infections. Genital recurrences are much more frequent with HSV-2 and gradually decrease over time, whereas HSV-1 recurrences are rare after the first year. Risk factors for HSV transmission include black race, female gender, a history of sexually transmitted infections (STIs), an increased number of partners, contact with commercial sex workers, lower socioeconomic status, young age of onset of sexual activity, and total duration of sexual activity. Asymptomatic shedding of either virus is common, especially following primary infection or symptomatic recurrences, and may be responsible for transmission. HSV-2 increases the risk of HIV acquisition, and in advanced HIV infection, HSV reactivates more frequently. HIV replication is increased by interaction with HSV proteins; suppression of HSV-2 can decrease genital tract shedding of HIV as well as plasma HIV RNA levels.

▶ Clinical Findings

A. Symptoms and Signs

1. Mucocutaneous disease—HSV-1 mucocutaneous disease largely involves the mouth and oral cavity (“herpes labialis” or “gingivostomatitis;” the latter largely in children). Digital lesions (**whitlows**) are an occupational hazard in medicine, nursing, and dentistry (Plate 94). Certain contact sports (eg, wrestling) are associated with outbreaks of skin infections (“herpes gladiatorum”). Asymptomatic shedding of HSV-1 is frequent, with most infected individuals shedding virus at least once a month.

Vesicles form moist ulcers after several days and epithelialize over 1–2 weeks if untreated. Primary infection is

usually more severe than recurrences but may be asymptomatic. Recurrences often involve fewer lesions, tend to be labial, heal faster, and are induced by stress, fever, infection, sunlight, chemotherapy (eg, fludarabine), or other undetermined factors.

HSV-2 lesions largely involve the genital tract. Virus remains latent in presacral ganglia. Lesions arising on the external genitalia are multiple, painful, small, grouped, and vesicular. Occasionally, lesions arise in the perianal region or on the buttocks and upper thighs. Dysuria, cervicitis, and urinary retention may occur in women.

Proctitis and sacral lesions in HIV-infected persons with CD4 cytopenia may present with extensive, ulcerating, weeping lesions. Large ulcerations and atypical lesions suggest drug-resistant isolates (see below).

2. Ocular disease—HSV can cause keratitis, blepharitis, and keratoconjunctivitis. Keratitis is usually unilateral, often with impaired visual acuity. Lesions limited to the epithelium usually heal without affecting vision, whereas stromal involvement can cause uveitis, scarring, and eventually blindness. Recurrences are frequent. HSV is the second most common cause, after VZV, of acute retinal necrosis.

3. Neonatal and congenital infection—Both herpesviruses can infect the fetus and induce congenital malformations (organomegaly, bleeding, and CNS abnormalities). Neonatal transmission during delivery is more common than intrauterine infection. Maternal infection during the third trimester is associated with the highest risk of neonatal transmission; about 70% of these infections are asymptomatic or unrecognized. Invasive fetal monitoring and vacuum or forceps delivery can facilitate the risk of transmitting herpes.

4. Central nervous system disease—HSV-1 predominantly causes herpes simplex encephalitis, while HSV-1 and HSV-2 are both associated with benign recurrent lymphocytic (Mollaret) meningitis. Primary HSV-2 infection in women often presents as aseptic meningitis. HSV-1 and HSV-2 are increasingly recognized as a cause of mild, non-specific neurologic symptoms.

Herpes simplex encephalitis presents with nonspecific symptoms: a flu-like prodrome, followed by headache, fever, behavioral and speech disturbances, and focal or generalized seizures. The temporal lobe is often involved. Untreated disease and presentation with coma carry a high mortality rate, with many survivors suffering neurologic sequelae. In children, nonspecific symptoms may complicate establishing a diagnosis.

5. Disseminated infection—Disseminated HSV infection occurs in the setting of immunosuppression, either primary or iatrogenic, or rarely with pregnancy. In disseminated disease, skin lesions are not always present. Disseminated skin lesions are a particular complication in patients with atopic eczema (eczema herpeticum) and burns.

6. Bell palsy—An association between HSV-1 and Bell palsy is established.

7. Esophagitis and proctitis—HSV-1 can cause esophagitis in those with AIDS and other immunocompromised patients. CMV esophagitis is distinguished by the size and

depth of the lesion (smaller and deeper for HSV). HSV-1 is also postulated to activate mononuclear cells in the pathogenesis of achalasia. Proctitis often occurs mainly in men who have sex with men.

8. Erythema multiforme—Herpes simplex viruses remain, with drugs, the leading association with erythema multiforme and with the more severe, mucosally involved Stevens–Johnson syndrome.

9. Other—Rarely, HSV causes fulminant hepatitis. HSV lower respiratory tract infection is common in mechanically ventilated patients, but its clinical significance is unknown. HSV-1 is associated with *Helicobacter pylori*-negative upper gastrointestinal tract ulcers. An association between HSV-1 and endocardial inflammation in the pathogenesis of atrial myxoma is postulated.

B. Laboratory Findings

1. Mucocutaneous disease—Diagnosis is usually made clinically, but viral cultures of vesicular fluid or direct fluorescent antibody staining of scraped lesions remain the standard of diagnosis. Polymerase chain reaction (PCR) is a more sensitive diagnostic assay. The presence of intranuclear inclusion bodies and multinucleated giant cells on a Tzanck preparation or Calcofluor stain is supportive of a diagnosis of herpetic viral infection. Type-specific serologies are useful for counseling HIV-infected individuals; pregnant women; sexual partners of persons infected with HSV; and those with an uncertain clinical history, high-risk behavior, or increased number of sexual partners.

2. Ocular disease—Keratitis is diagnosed by branching (dendritic) ulcers that stain with fluorescein.

3. Encephalitis and recurrent meningitis—Cerebrospinal fluid pleocytosis is common, with roughly equal numbers of red cells. HSV DNA PCR of the cerebrospinal fluid is a rapid, sensitive, and specific tool for early diagnosis. Antibodies to HSV in cerebrospinal fluid can confirm the diagnosis but appear late in the course of the disease. Viral culture shows a sensitivity of only 10%. MRI scanning is often a useful adjunct showing increased signal in the temporal and frontal lobes. Temporal lobe seizure foci may be demonstrated on electroencephalograms (EEGs).

4. Esophagitis and proctitis—Esophagitis is diagnosed by endoscopic biopsy and cultures. Proctitis may be diagnosed by rectal swab for PCR or culture, or both, although complicated cases may require biopsy.

► Prevention

Besides antiviral suppressive therapy, prevention also requires counseling and the use of barrier precautions during sexual activity. Disclosure of partner status is associated with about a 50% reduction in the HSV-2 acquisition. Arguments favoring partner testing include confirming exposure, assistance with management, reducing the risk of transmission, and aiding in public health strategies.

Preventing spread to hospital staff and other patients from cases with mucocutaneous, disseminated, or genital

disease requires isolation and the usage of handwashing and gloving—gowning precautions. Staff with active lesions (eg, whitlows) should not have contact with patients. Asymptomatic transmission occurs, especially with HSV-2. An HSV-2 glycoprotein-D vaccine under development appears to prevent infection and disease among women who are seronegative at baseline.

► Treatment & Prophylaxis

Drugs that inhibit replication of HSV-1 and HSV-2 include trifluridine and vidarabine (both for keratitis), acyclovir and related compounds, foscarnet, and cidofovir (Table 32–1).

A. Mucocutaneous Disease

While treatment is often not necessary in immunocompetent patients, it can ameliorate and shorten the duration of symptoms if initiated early. For primary genital infection, oral agents are generally used and include acyclovir, 200 mg five times a day or 400 mg three times a day; valacyclovir, 1 g twice daily; or famciclovir, 250 mg three times daily; all given for 7–10 days. Most experience in treating primary herpes labialis is with acyclovir (same doses and duration as for genital infection). Intravenous acyclovir (5–10 mg/kg every 8 hours for 7–14 days) should be considered in immunosuppressed patients.

For recurrent genital disease, acyclovir, 800 mg three times daily for 2 days; valacyclovir, 500 mg twice daily for 3 days; or famciclovir, 1 g twice daily for 1 day all show efficacy in controlled trials. Patient-initiated therapy with short courses of antivirals at first symptoms of recurrence is a frequently used and favorable approach. For the treatment of recurrences of herpes labialis, lesions heal faster with topical penciclovir than with topical acyclovir. Docosanol cream offers modest benefit. Oral acyclovir (same doses as above for 5 days) is more effective than topical agents. Recent data promote short-course therapy with higher doses of antivirals (eg, valacyclovir, 2 g twice daily for 1 day, or famciclovir, 1.5 g single dose).

Atypical isolates, large ulcerations, new lesions, or poor response to therapy suggest acyclovir resistance, which often occurs in immunodeficient patients. Alternatives include high dose acyclovir (4–5 g), which is effective in treating proctitis in the HIV-positive population, or foscarnet (40–60 mg/kg intravenously every 8 hours), adjusting the dose interval in patients with kidney dysfunction. Cidofovir is used in rare cases of infection resistant to both acyclovir and foscarnet.

Patients with frequent recurrent genital infections may be given **secondary prophylaxis** with acyclovir, 400 mg twice a day; valacyclovir, 500–1000 mg once daily; or famciclovir, 250 mg twice a day. For herpes labialis, valacyclovir, 500 mg daily, is the best option. Sunscreen may be useful for recurrences associated with sunlight exposure. Advantages of suppressive therapy include a significant reduction in acquisition of disease among the HSV-2 discordant heterosexual partners. AIDS patients with a history of mucocutaneous disease should continue receiving suppressive therapy unless a sustained improve-

ment of immune status occurs. Among the HIV-infected, the use of highly active antiretroviral therapy (HAART) is associated with fewer days of HSV-1 or -2 lesions.

B. Keratitis

For the treatment of acute epithelial keratitis, topical antivirals (ophthalmic trifluridine, vidarabine, acyclovir, and ganciclovir are all nearly equivalent in efficacy) are recommended. Combination of topical antivirals with interferon or debridement (or both) hastens healing. The usage of topical corticosteroids may exacerbate the infection, although systemic corticosteroids may help with selected cases of stromal infection. Long-term treatment (greater than 1 year) with acyclovir at a dosage of 800 mg/d orally decreases recurrence rates.

C. Neonatal Disease

Acyclovir intravenously is effective for disseminated lesions in neonatal disease. The dosage is 20 mg/kg intravenously every 8 hours for 14–21 days. Counseling with serologic screening should be offered to pregnant mothers. The use of maternal antenatal suppressive therapy with acyclovir (typically, 400 mg three times daily) beginning at 36 weeks gestation decreases the presence of detectable HSV, the rates of recurrence at delivery, and the need for cesarean section. Cesarean section is recommended for pregnant women with active genital lesions or typical prodromal symptoms.

D. Encephalitis

Because of the need for rapid treatment and the difficulties associated with brain biopsy, patients with suspected HSV encephalitis are given intravenous acyclovir (10 mg/kg every 8 hours for 10 days or more, adjusting for kidney dysfunction), starting upon suspicion of diagnosis, and stopping if another diagnosis is established. If the PCR is negative and clinical suspicion remains high in the absence of a biopsy, treatment should be continued for 10 days because the false-negative rate for PCR can be as high as 25% (especially in children) and acyclovir is relatively nontoxic. Long-term neurologic sequelae are common and late pediatric relapse is recognized.

E. Disseminated Disease

Disseminated disease responds best to parenteral acyclovir (see the preceding paragraph for dosages) when treatment is initiated early.

F. Bell Palsy

Prednisolone, 25 mg orally twice daily for 10 days started within 72 h of onset, significantly increases the rate of recovery. Valacyclovir (but not acyclovir), 1 g orally daily for 5 days, may be beneficial if started within 7 days of onset along with corticosteroid therapy.

G. Esophagitis and Proctitis

Patients with esophagitis should receive either intravenous acyclovir at a dosage of 5–10 mg/kg every 8 hours or oral

Table 32-1. Agents for viral infections.¹

| Drug | Dosing | Spectrum | Renal Clearance/ Hemodialysis | CNS/CSF Penetration | Toxicities |
|-------------------------|--|---|----------------------------------|---------------------|---|
| Acyclovir | 200-800 mg orally five times daily; 250-500 mg/m ² intravenously every 8 hours for 7 days | HSV, VZV | Yes/Yes | Yes | Neurotoxic reactions, reversible renal dysfunction, local reactions |
| Adefovir | 10 mg daily orally | HBV | Yes/Yes | NA | Gastrointestinal symptoms, transaminitis, lactic acidosis, nephrotoxicity |
| Cidofovir | 5 mg/kg intravenously weekly for 2 weeks, then every other week | CMV | Yes/NA | NA | Neutropenia, renal failure, ocular hypotonia |
| Entecavir | 0.5 mg orally daily, increase to 1 mg orally daily in lamivudine-resistant patients | HBV | Yes/NA | NA | Lactic acidosis, rare exacerbation of HBV infection |
| Famciclovir | 500 mg orally three times daily for 7 days for acute VZV; 250 mg three times daily for 7-10 days for genital or cutaneous HSV-1/HSV-2 infection; 125 mg twice daily for 5 days for recurrences (500 mg twice daily for 7 days if HIV-infected) | HSV, VZV | Yes/NA | NA | NA |
| Fomivirsen | 165 mcg by intravitreal injection once weekly for 3 weeks, then every other week | CMV | NA | NA | Ocular inflammation, retinal detachment |
| Foscarnet | 20 mg/kg intravenous bolus, then 120 mg/kg intravenously every 8 hours for 2 weeks; maintain with 60 mg/kg/d intravenously for 5 days each week | CMV, HSV resistant to acyclovir, VZV, HIV-1 | Yes/Yes | Variable | Nephrotoxicity, genital ulcerations, calcium disturbances |
| Ganciclovir | 5 mg/kg intravenous bolus every 12 hours for 14-21 days; maintain with 3.75 mg/kg/d intravenously for 5 days each week | CMV | Yes/Yes | Yes | Neutropenia, thrombocytopenia, CNS side effects |
| Idoxuridine | Topical, 0.1% every 1-2 hours for 3-5 days | HSV keratitis | — | — | Local reactions |
| Interferon α -2b | 3-5 million international units subcutaneously three times weekly to daily. Intralesionally: 1 million international units per 0.1 mL in up to five warts three times weekly for 3 weeks | HBV, HCV, HPV | Yes/Yes | — | Influenza-like syndrome, myelosuppression, neurotoxicity |
| Interferon α -n3 | 0.05 mL/wart biweekly up to 8 weeks 3 mU intravenously three times per week | HPV ? HCV | NA/NA NA/NA | NA NA | Local reactions Influenza-like syndrome, myelosuppression, neurotoxicity |
| Lamivudine (3TC) | 12 mg/kg/d | HIV-1, ?HIV-2, HBV | Yes/NA | Yes | Skin rash, headache, insomnia |
| Oseltamivir | 75 mg twice daily for 5 days beginning 48 hours after onset of symptoms | Influenza A and B | Yes/NA | NA | Few |
| Penciclovir | Topical, 1% cream every 2 hours for 4 days | HSV | No/No | No | Local reactions |
| Palivizumab | 15 mg/kg intramuscularly every month in RSV season | RSV | No/No | No | Upper respiratory infection symptoms |
| Ribavirin | Aerosol: 1.1 g/d as 20 mg/mL dilution over 12-18 hours for 3-7 days (See text for Lassa fever doses.) | RSV, severe influenza A or B, Lassa fever | Yes/No | Yes | Wheezing |

(continued)

Table 32-1. Agents for viral infections.¹ (continued)

| Drug | Dosing | Spectrum | Renal Clearance/ Hemodialysis | CNS/CSF Penetration | Toxicities |
|----------------|--|-------------------|----------------------------------|---------------------|--|
| Trifluridine | Topical, 1% drops every 2 hours to 9 drops/d | HSV keratitis | — | — | Local reactions |
| Valacyclovir | 1 g orally three times daily for 7 days for acute VZV; 1 g twice daily for primary genital HSV-1/HSV-2 infection with 500 mg three times daily for recurrences | VZV, HSV | Yes/Poorly | NA | Thrombotic thrombocytopenic purpura or hemolytic-uremic syndrome in AIDS |
| Valganciclovir | 900 mg orally twice daily for 3 weeks; 900 mg daily as maintenance | CMV | Yes/Yes | Yes | See ganciclovir |
| Vidarabine | 15 mg/kg/d intravenously for 10 days | HSV, VZV | Yes/Yes | Yes | Teratogenic, megaloblastosis, neurotoxicity |
| Zanamivir | 2-5 mg inhalations twice daily for 5 days | Influenza A and B | Yes/NA | NA | Few |

¹Agents used exclusively in the management of HIV infection and AIDS are found in Chapter 31.

CNS, central nervous system; CSF, cerebrospinal fluid; HSV, herpes simplex virus; VZV, varicella-zoster virus; HBV, hepatitis B virus; CMV, cytomegalovirus; HPV, human papillomavirus; HCV, hepatitis C virus; RSV, respiratory syncytial virus.

acyclovir, 400 mg five times daily. Maintenance therapy for AIDS patients is acyclovir at a dosage of 400 mg three to five times daily. Proctitis is treated with similar dosages and usually responds within 5 days.

H. Erythema Multiforme

Suppressive therapy with oral acyclovir (400 mg twice a day for 6 months) decreases the recurrence rate of HSV-associated erythema multiforme. Valacyclovir (500 mg twice a day) may be effective in cases unresponsive to acyclovir.

2. Varicella (Chickenpox) & Herpes Zoster (Shingles)

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure 14–21 days before onset.
- ▶ Fever and malaise just before or with eruption.
- ▶ Rash: pruritic, centrifugal, papular, changing to vesicular (“dewdrops on a rose petal”), pustular, and finally crusting.

▶ General Considerations

Varicella zoster virus (VZV) is HHV-3. Disease manifestations include chickenpox (varicella) and shingles (herpes zoster). Chickenpox is generally a disease of the childhood. It has an incubation period of 10–20 days (average 2 weeks) and is highly contagious, spreading by inhalation of infective droplets or contact with lesions.

The incidence and severity of herpes zoster (“shingles”) increases with age due to an age-related decline in immunity against VZV. More than half of all patients in whom herpes zoster develops are older than 60 years. The annual incidence of herpes zoster in the United States is at least 1 million cases, which is expected to increase as the mean population age increases.

▶ Clinical Findings

A. Varicella

1. Symptoms and signs—(Table 32-2.) Fever and malaise are mild in children and more marked in adults. The pruritic rash begins prominently on the face, scalp, and trunk, and later involves the extremities. Maculopapules change in a few hours to vesicles that become pustular and eventually form crusts (Plates 95 and 96). New lesions may erupt for 1–5 days, so that different stages of the eruption are usually present simultaneously. The crusts slough in 7–14 days. The vesicles and pustules are superficial and elliptical, with slightly serrated borders. Pitted scars are frequent sequelae.

After the primary infection, the virus remains dormant in cranial nerves sensory ganglia and spinal dorsal root ganglia. Latent VZV will reactivate as herpes zoster in about 10–30% of persons (see below). Varicella is more severe in older patients and immunocompromised persons. In the latter, atypical presentations, including widespread dissemination in the absence of skin lesions, are often described.

Table 32–2. Diagnostic features of some acute exanthems.

| Disease | Prodromal Signs and Symptoms | Nature of Eruption | Other Diagnostic Features | Laboratory Tests |
|---------------------------------------|--|--|--|--|
| Eczema herpeticum | None. | Vesiculopustular lesions in area of eczema. | | Herpes simplex virus isolated in cell culture. Multinucleate giant cells in smear of lesion. |
| Varicella (chickenpox) | 0–1 day of fever, anorexia, headache. | Rapid evolution of macules to papules, vesicles, crusts; all stages simultaneously present; lesions superficial, distribution centripetal. | Lesions on scalp and mucous membranes. | Specialized complement fixation and virus neutralization in cell culture. Fluorescent antibody test of smear of lesions. |
| Infectious mononucleosis (EBV) | Fever, adenopathy, sore throat. | Maculopapular rash resembling rubella, rarely papulovesicular. | Splenomegaly, tonsillar exudate. | Atypical lymphocytes in blood smears; heterophil agglutination (Monospot test). |
| Exanthema subitum (HHV-6, 7; roseola) | 3–4 days of high fever. | As fever falls by crisis, pink maculopapules appear on chest and trunk; fade in 1–3 days. | | White blood count low. |
| Measles (rubeola) | 3–4 days of fever, coryza, conjunctivitis, and cough. | Maculopapular, brick-red; begins on head and neck; spreads downward and outward, in 5–6 days rash brownish, desquamating. See atypical measles, below. | Koplik spots on buccal mucosa. | White blood count low. Virus isolation in cell culture. Antibody tests by hemagglutination inhibition or neutralization. |
| Atypical measles | Same as measles. | Maculopapular centripetal rash, becoming confluent. | History of measles vaccination. | Measles antibody present in past, with titer rise during illness. |
| Rubella | Little or no prodrome. | Maculopapular, pink; begins on head and neck, spreads downward, fades in 3 days. No desquamation. | Lymphadenopathy, postauricular or occipital. | White blood count normal or low. Serologic tests for immunity and definitive diagnosis (hemagglutination inhibition). |
| Erythema infectiosum (parvovirus B19) | None. Usually in epidemics. | Red, flushed cheeks; circumoral pallor; maculopapules on extremities. | “Slapped face” appearance. | White blood count normal. |
| Enterovirus infections | 1–2 days of fever, malaise. | Maculopapular rash resembling rubella, rarely papulovesicular or petechial. | Aseptic meningitis. | Virus isolation from stool or cerebrospinal fluid; complement fixation titer rise. |
| Typhus | 3–4 days of fever, chills, severe headaches. | Maculopapules, petechiae, initial distribution centrifugal (trunk to extremities). | Endemic area, lice. | Complement fixation. |
| Rocky Mountain spotted fever | 3–4 days of fever, vomiting. | Maculopapules, petechiae, initial distribution centripetal (extremities to trunk, including palms). | History of tick bite. | Indirect fluorescent antibody; complement fixation. |
| Ehrlichiosis | Headache, malaise. | Rash in one-third, similar to Rocky Mountain spotted fever. | Pancytopenia, elevated liver function tests. | Polymerase chain reaction, immunofluorescent antibody. |
| Scarlet fever | One-half to 2 days of malaise, sore throat, fever, vomiting. | Generalized, punctate, red; prominent on neck, in axillae, groin, skin folds; circumoral pallor; fine desquamation involves hands and feet. | Strawberry tongue, exudative tonsillitis. | Group A β -hemolytic streptococci in cultures from throat; antistreptolysin O titer rise. |
| Meningococemia | Hours of fever, vomiting. | Maculopapules, petechiae, purpura. | Meningeal signs, toxicity, shock. | Cultures of blood, cerebrospinal fluid. High white blood count. |
| Kawasaki disease | Fever, adenopathy, conjunctivitis. | Cracked lips, strawberry tongue, maculopapular polymorphous rash, peeling skin on fingers and toes. | Edema of extremities. Angiitis of coronary arteries. | Thrombocytosis, electrocardiographic changes. |
| Smallpox (based on prior experience) | Fever, malaise, prostration. | Maculopapules to vesicles to pustules to scars (lesions develop at the same pace). | Centrifugal rash; fulminant sepsis in small percentage of patients, gastrointestinal and skin hemorrhages. | Contact CDC ¹ for suspicious rash; EM and gel diffusion assays. |

¹<http://www.bt.cdc.gov/agent/smallpox/response-plan/>.

EBV, Epstein-Barr virus; EM, electron microscopy HHV, human herpesvirus.

2. Laboratory findings—Diagnosis is usually made clinically, with confirmation by direct immunofluorescent antibody (DFA) staining or PCR of scrapings from lesions. Multinucleated giant cells are usually apparent on a Tzanck smear or Calcofluor stain of material from the vesicle bases. Leukopenia and subclinical transaminase elevation are often present and thrombocytopenia occasionally occurs.

B. Herpes Zoster

Herpes zoster (“shingles”) usually occurs among adults, but cases are reported among infants and children. Skin lesions resemble those of chickenpox. Pain is often severe and commonly precedes the appearance of rash. Lesions follow a dermatomal distribution, with thoracic and lumbar roots being the most common. In most cases, a single unilateral dermatome is involved, but occasionally, neighboring and distant areas are involved. Lesions on the tip of the nose, inner corner of the eye, and root and side of the nose (Hutchinson sign) indicate involvement of the trigeminal nerve (herpes zoster ophthalmicus). Facial palsy, lesions of the external ear with or without tympanic membrane involvement, vertigo and tinnitus, and deafness signify geniculate ganglion involvement (Ramsay Hunt syndrome).

► Complications

A. Varicella

Secondary bacterial skin superinfections, particularly with group A β -hemolytic streptococci and *Staphylococcus aureus*, are the most common complications in children. Cellulitis, erysipelas, and scarlet fever are described. Bullous impetigo and necrotizing fasciitis are less often seen. Other associations with varicella include epiglottitis, necrotizing pneumonia, osteomyelitis, septic arthritis, epidural abscess, meningitis, endocarditis, and purpura fulminans. Toxic shock syndrome can also occur.

Interstitial VZV pneumonia is more common in adults (especially smokers, HIV-infected patients, and pregnant women) and may result in acute respiratory distress syndrome (ARDS). After healing, numerous densely calcified lesions are seen throughout the lung fields on chest radiographs.

Cerebellar ataxia occurs among younger people at a frequency of 1:4000. A limited course and complete recovery are the rule. Encephalitis is infrequent (1:1000), occurs mostly in adults, and is characterized by delirium, seizures, and focal neurologic signs. Both mortality and long-term neurologic sequelae rates are about 10%. Ischemic strokes in the wake of acute VZV infection present a mean of 4 months after rashes and may be due to an associated vasculitis. Multifocal encephalitis, ventriculitis, myelodysplasia, arterial aneurysm formation, and arteritis are also described in immunosuppressed persons.

Clinical hepatitis is uncommon and mostly presents in the immunosuppressed patient but can be fulminant and fatal. Reye syndrome (fatty liver with encephalopathy) also complicates varicella (and other viral infections, especially influenza B), usually in childhood, and is associated with aspirin therapy (see Influenza, below).

When contracted during the first or second trimesters of pregnancy, varicella carries a very small risk of congenital malformations, including cicatricial lesions of an extremity, growth retardation, microphthalmia, cataracts, chorioretinitis, deafness, and cerebrocortical atrophy. If varicella develops around the time of delivery, the newborn is at risk for disseminated disease.

B. Herpes Zoster

Postherpetic neuralgia occurs in 60–70% of patients who have herpes zoster and are older than 60 years. The pain can be prolonged and debilitating. Risk factors for postherpetic neuralgia include age, female sex, prodrome, and severity of rash or pain.

Other less common complications include bacterial skin superinfections; herpes zoster ophthalmicus, which occurs with involvement of the trigeminal nerve and is a sight-threatening complication, especially when it involves the cornea or the iris; involvement of the geniculate ganglion of cranial nerve VII as well as cranial nerves V, VIII, IX, and X; aseptic meningitis; peripheral motor neuropathy; transverse myelitis; encephalitis; vasculopathy; acute retinal necrosis; and progressive outer retinal necrosis (largely among HIV infected persons). VZV is a major cause of Bell palsy in patients who are HSV seronegative. Diagnosis of neurologic complications requires the detection of VZV DNA or anti-VZV IgG in cerebrospinal fluid or the detection of VZV DNA in tissue. Zoster sine herpette (pain without rash) can also be associated with most of the above complications.

► Prevention

Health care workers should be screened for varicella and vaccinated if seronegative. Patients with active varicella or herpes zoster are promptly separated from seronegative patients. For those with varicella, airborne and contact isolation is recommended, whereas for those with zoster, contact precautions are sufficient. For immunosuppressed patients with zoster, precautions should be the same as if the patient had varicella. Exposed serosusceptible patients should be placed in isolation and exposed serosusceptible employees should stay away from work between days 10 and 21 after exposure. Health care workers with zoster should receive antivirals during the first 72 hours of disease and withdraw from work until lesions are crusted. Postexposure prophylaxis should be evaluated (see below).

A. Varicella

1. Vaccination—Universal childhood vaccination against varicella is effective. A single antigen live attenuated vaccine (VARIVAX) or a quadrivalent measles, mumps, rubella, and varicella vaccine (ProQuad) are available. The first dose should be administered at 12–15 months of age and the second at 4–6 years. Aspirin should be avoided for at least 6 weeks because of the risk of Reye syndrome. This vaccine is safe, well tolerated, and is not associated with neurologic sequelae. Rashes, when secondary to the varicella vaccine, appear 15–42 days after vaccination.

For serosusceptible individuals older than 13 years, two doses of varicella vaccine (single antigen) administered 4 to 8 weeks apart is recommended. For those who received a single dose in the past, a catch-up second dose is advised. Household contacts of immunocompromised patients should adhere to these recommendations. Susceptible pregnant women need to receive the first dose of vaccine before discharge after delivery and the second dose 4–8 weeks later.

The vaccine, administered 3 months apart, should also be considered for HIV-infected children with age-specific CD4+ T lymphocyte percentages of 15–24% and adolescents and adults with CD4+ T lymphocyte counts \geq 200 cells/mL. The vaccine may also be given to patients with impaired humoral immunity or receiving corticosteroids at a dose $<$ 2 mg/kg or a total of $<$ 20 mg/d of prednisone. Persons who are receiving higher doses for over 2 weeks may be vaccinated after the corticosteroid therapy has been discontinued for over 1 month. Patients with leukemia, lymphoma, or other malignancies whose disease is in remission and who have not undergone chemotherapy for at least 3 months may be vaccinated, although the presence of both ancillary antiviral treatment and expert guidance are encouraged.

2. Postexposure—Postexposure vaccination is recommended for unvaccinated persons without other evidence of immunity. Varicella-zoster immune globulin (VZIG) (in short supply with production stopped in 2004) or VariZIG (a lyophilized product available under expanded access since December 2007) should be considered for susceptible exposed patients who cannot receive the vaccine, including immunosuppressed patients, neonates from mothers with varicella around the time of delivery, exposed premature infants born from serosusceptible mothers at $>$ 28 weeks of gestation, neonates born at $<$ 28 weeks of gestation regardless of maternal serostatus, and pregnant women. No controlled studies have evaluated the use of acyclovir in this setting. VZIG is given by intramuscular injection in a dosage of 12.5 units/kg up to a maximum of 625 units, with a repeat identical dose in 3 weeks if a high-risk patient remains exposed. VZIG has no place in therapy of established disease.

Further information may be obtained by calling the Centers for Disease Control and Prevention's Immunization Information Hotline (800-232-2522).

B. Herpes Zoster

A live attenuated VZV vaccine is available and should be offered to persons 60 years and older. In this population, the vaccine reduces the incidence of postherpetic neuralgia and herpes zoster by 67% and 51%, respectively.

Prophylaxis with acyclovir, 800 mg twice daily, can be considered in patients at high risk for reactivation (eg, allogeneic hematopoietic cell transplant patients).

► Treatment

A. General Measures

In general, patients with varicella should be isolated until primary crusts have disappeared and kept at bed rest until

afebrile. The skin is kept clean. Pruritus can be relieved with antihistamines, calamine lotion, and colloidal oatmeal baths. As an antipyretic, acetaminophen is used. Fingernails can be closely cropped to avoid skin excoriation and infection.

B. Antiviral Therapy

Acyclovir, 20 mg/kg (up to 800 mg per dose) orally four times daily for 5 days, should be given within the first 24 hours after the onset of rash and should be considered for patients older than 12 years, secondary household contacts (secondary cases tend to be more severe disease), patients with chronic cutaneous and cardiopulmonary diseases, and children receiving long-term therapy with salicylates (to decrease the risk of Reye syndrome). Experience with valacyclovir and famciclovir in these settings is scant.

In immunocompromised patients, in pregnant women during the third trimester, and in patients with extracutaneous disease (encephalitis, pneumonitis), antiviral therapy with high-dose acyclovir (30 mg/kg/d in three divided doses intravenously for at least 7 days) should be started once the diagnosis is suspected. Corticosteroids may be useful in the presence of pneumonia.

For uncomplicated herpes zoster, acyclovir (800 mg orally five times daily) or valacyclovir (1 g three times daily) for 7 days is recommended. Therapy should start within the first 72 hours of the onset of the lesions. Intravenous acyclovir is used for extradermatomal complications of zoster, although acyclovir is not fully effective in retinal disease. Foscarnet may be used for acyclovir-resistant VZV infections seen in immunosuppressed patients. The Ramsay Hunt syndrome is less responsive to antiviral therapy.

C. Treatment of Complications

Once established, postherpetic neuralgia may respond to gabapentin or lidocaine patches (FDA approved drugs for neuropathic pain). Tricyclic antidepressants, opioids, and capsaicin cream are also widely used and effective. The epidural injection of corticosteroids and local anesthetics appears to modestly reduce herpetic pain at 1 month but is not effective for prevention of long-term postherpetic neuralgia. Secondary bacterial infections are treated with antibiotics providing coverage for staphylococci.

► Prognosis

The total duration of varicella from onset of symptoms to disappearance of crusts rarely exceeds 2 weeks. Fatalities are rare except in immunosuppressed patients.

Herpes zoster resolves in 2–6 weeks. Antibodies persist longer and at higher levels than with primary varicella. Eye involvement with herpes zoster necessitates periodic future examinations.

3. Epstein-Barr Virus & Infectious Mononucleosis

ESSENTIALS OF DIAGNOSIS

- ▶ Malaise, fever, and sore throat, sometimes with exudates.
- ▶ Palatal petechiae, lymphadenopathy, splenomegaly, and, occasionally, a maculopapular rash.
- ▶ Positive heterophil agglutination test (Monospot).
- ▶ Atypical large lymphocytes in blood smear; lymphocytosis.
- ▶ Possible complications: hepatitis, myocarditis, neuropathy, encephalitis, airway obstruction secondary to lymph node enlargement, anti-i hemolytic anemia, thrombocytopenia.

▶ General Considerations

Infectious mononucleosis is usually due to the EBV (HHV-4). More than 90% of adults worldwide are seropositive for EBV. Infectious mononucleosis may be seen at any age but usually occurs in the United States in persons between the ages of 10 and 35 years, sporadically or epidemically. In the developing world, infectious mononucleosis occurs at younger ages and tends to be less symptomatic. Rare cases in the elderly occur usually without the full symptomatology. EBV is largely transmitted by saliva but can also be recovered from genital secretions. Saliva may remain infectious during convalescence for 6 months or longer from symptom onset. The incubation period lasts several weeks.

▶ Clinical Findings

A. Symptoms and Signs

The protean manifestations of infectious mononucleosis reflect the dissemination of the virus in the oral cavity and through peripheral blood lymphocytes and cell-free plasma (Plate 97). Fever, sore throat, fatigue, malaise, anorexia, and myalgia typically occur in the early phase of the illness. Physical findings include lymphadenopathy (discrete, non-suppurative, slightly painful, especially along the posterior cervical chain) and splenomegaly (in up to 50% of patients). A maculopapular or occasionally petechial rash occurs in less than 15% of patients unless ampicillin has been given (when rash is seen in > 90%). Exudative pharyngitis, tonsillitis, or gingivitis may occur and soft palatal petechiae may be noted.

Other manifestations include hepatitis, cholestasis, nervous system involvement (mononeuropathies and occasionally aseptic meningitis, encephalitis, optic neuritis, transverse myelitis, or Guillain-Barré syndrome), kidney disease (mostly interstitial nephritis), pneumonia, pleural involvement, and myocarditis. Airway obstruction from lymph node enlargement, pericarditis, life-threatening thrombocytopenia, severe CNS complications, and massive splenomegaly are all considered indications for hospitalization or close observation. Mesenteric adenitis may mimic acute abdomen.

B. Laboratory Findings

Initially infectious mononucleosis is associated with granulocytopenia followed within 1 week by a lymphocytic leukocytosis (> 50% of all leukocytes) with atypical lymphocytes (larger than normal mature lymphocytes, staining more darkly, and showing vacuolated, foamy cytoplasm and dark nuclear chromatin) comprising more than 10% of the leukocyte count. Hemolytic anemia, with anti-i antibodies, occurs occasionally as does thrombocytopenia (at times marked).

Heterophil (sheep cell agglutination) antibody tests and the correlated mononucleosis spot (Monospot) test usually become positive within 4 weeks after onset of illness and are specific but often not sensitive in early illness. During acute illness, there occurs a rise and fall in immunoglobulin M (IgM) antibody to EB virus capsid antigen (VCA) and a rise in IgG antibody to VCA, which persists for life. Antibodies (IgG) to EBV nuclear antigen (EBNA) appear after 4 weeks of onset and also persist. Absence of IgG and IgM VCA or the presence of IgG EBNA should make one reconsider the diagnosis of acute EBV infection. PCR for EBV DNA is useful in the evaluation of malignancies associated with EBV. For instance, detection of EBV DNA in cerebrospinal fluid shows a sensitivity of 90% and specificity of nearly 100% for the diagnosis of primary CNS lymphoma in patients with AIDS. Monitoring of EBV DNA load in blood may be useful in early detection of posttransplant lymphoproliferative disorder in high-risk patients. PCR analysis may also be helpful in detecting primary infection and infectious mononucleosis in children, in narrowing the differential diagnosis of CNS processes, and in monitoring disease and treatment response in primary CNS lymphoma and posttransplant lymphoproliferative disorder. Detection of specific IgA antibodies is also being studied as a marker of primary infection in children. Hepatic aminotransferases and bilirubin are commonly elevated. In aseptic meningitis, the cerebrospinal fluid may show increased opening pressure, lymphocytosis with abnormal morphology, and increased protein concentration.

▶ Differential Diagnosis

CMV infection, toxoplasmosis, acute HIV infection, secondary syphilis, HHV-6, rubella, and drug hypersensitivity reactions may be indistinguishable from infectious mononucleosis due to EBV, but exudative pharyngitis is usually absent and the heterophil antibody tests are negative. With acute HIV infection, rash and mucocutaneous ulceration are common but atypical lymphocytosis is much less common. Heterophil-negative infectious mononucleosis

with nonsignificant lymphocytosis (especially if rash or mucocutaneous ulcers are present) should prompt investigation for acute HIV infection. Heterophil-negative infectious mononucleosis with atypical lymphocytosis can be caused by CMV, toxoplasmosis and, on occasion, EBV itself. Mycoplasmal infection may also present as pharyngitis, though lower respiratory symptoms usually predominate. A hypersensitivity syndrome induced by carbamazepine or phenytoin may mimic infectious mononucleosis.

The differential diagnosis of acute exudative pharyngitis includes diphtheria, gonococcal and streptococcal infections, and infections with adenovirus and herpes simplex. Head and neck soft tissue infections (pharyngeal and tonsillar abscesses) may occasionally be mistaken as the lymphadenopathy of mononucleosis.

► Complications

Secondary bacterial pharyngitis can occur and is often streptococcal. Splenic rupture is a rare but dramatic complication, and a history of preceding trauma can be elicited in 50% of the cases. Acalculous cholecystitis, fulminant hepatitis with massive necrosis, pericarditis and myocarditis are also infrequent complications. Neurologic involvement—including transverse myelitis, encephalitis, and Guillain-Barré syndrome—is infrequent.

► Treatment

A. General Measures

Over 95% of patients recover without specific antiviral therapy. Treatment is symptomatic with acetaminophen or other nonsteroidal anti-inflammatory drugs and warm saline throat irrigations or gargles three or four times daily. Acyclovir decreases viral shedding but has no clinical benefit. Corticosteroid therapy, although widespread, is not recommended in uncomplicated cases; its use is reserved for impending airway obstruction from enlarged lymph nodes, hemolytic anemia, and severe thrombocytopenia. The value of corticosteroid therapy in impending splenic rupture, pericarditis, myocarditis, and nervous system involvement is less well defined. If a throat culture grows β -hemolytic streptococci, a 10-day course of penicillin or erythromycin is indicated. Ampicillin and amoxicillin are avoided because of the frequent association with rash.

B. Treatment of Complications

Hepatitis, myocarditis, and encephalitis are treated symptomatically. Rupture of the spleen requires splenectomy and is most often caused by deep palpation of the spleen or vigorous activity. Patients should avoid contact or collision sports for at least 4 weeks to decrease the risk of splenic rupture (even if splenomegaly is not detected by physical examination which can be insensitive).

► Prognosis

In cases without complications, fever disappears in 10 days and lymphadenopathy and splenomegaly in 4 weeks. The debility sometimes lingers for 2–3 months.

Death is uncommon and is usually due to splenic rupture, hypersplenic phenomena (severe hemolytic anemia, thrombocytopenic purpura), or encephalitis.

4. Other Epstein-Barr Virus Syndromes

EBV viral antigens have been found in over 90% of patients with African Burkitt lymphoma or nasopharyngeal carcinoma (among whom quantified EBV DNA can be used to follow disease). A causative role for EBV has been postulated with both neoplasms. Chronic EBV infection is associated with aberrant cellular immunity (a low frequency of EBV-specific CD8 cells), an X-linked lymphoproliferative syndrome (Duncan disease), lymphomatoid granulomatosis, and a fatal T cell lymphoproliferative disorder in children. EBV is an important cause of hemophagocytic lymphohistiocytosis EBV-induced lymphoproliferation gives rise to B-cell lymphomas among immunodeficient patients, such as primary CNS lymphoma in HIV-infected individuals or posttransplant lymphoproliferative disorder in persons who have undergone transplantation. Rituximab (CD20 monoclonal antibody) is effective in treating some cases of posttransplant lymphoproliferative disorder and is often administered in conjunction with monitoring levels of EBV DNA load in the blood and, if indicated, CNS. Infusion of EBV-specific cytotoxic T cell lymphocytes (adoptive cell therapy) is also used but with a less established role.

Age is a major determinant of the type of tumor EBV causes, with T and NK cell tumors in childhood caused by chronic active EBV infections and peripheral T cell lymphomas and diffuse large B cell lymphomas in the elderly due to waning immunity. EBV is also associated with leiomyomas in children with AIDS and with nasal T cell lymphomas. There is no persuasive evidence that chronic fatigue syndrome is caused by EBV infection. Oral hairy leukoplakia and its association with EBV are discussed in Chapter 8.

EBV is also implicated in the pathogenesis of a host of disorders from Hodgkin disease and gastric carcinoma to multiple sclerosis, chronic obstructive pulmonary disease (COPD), and rheumatic diseases.

► When to Admit

- Acute meningitis, encephalitis, or acute Guillain-Barré.
- Severe thrombocytopenia.
- Potential splenic rupture.
- Airway obstruction from severe adenitis.
- Significant hemolysis.
- Pericarditis.
- Abdominal findings mimicking an acute abdomen.

5. Cytomegalovirus Disease

ESSENTIALS OF DIAGNOSIS

- ▶ Mononucleosis-like syndrome.
- ▶ Frequent pathogen seen in transplant populations.
- ▶ Diverse clinical syndromes in HIV (retinitis, esophagitis, pneumonia, encephalitis).
- ▶ Major pathogen to consider in neonates in the differential of maternally transmitted agents.

▶ General Considerations

Most CMV infections are asymptomatic. After primary infection, the virus remains latent in different cells including vascular endothelium, monocytes, macrophages, polymorphonuclear neutrophils, and renal and pulmonary epithelial cells. Seroprevalence in adults of Western developed countries is about 60–80% but is higher in developing countries. CMV seroprevalence increases with age, number of sexual partners, history of prior STIs, and low socioeconomic status. The virus can be isolated from a variety of tissues under nonpathogenic conditions. Transmission occurs through sexual contact, breastfeeding, blood products, or transplantation; it may also occur person-to-person (eg, day care centers) or be congenital. Serious disease occurs primarily in immunocompromised persons.

There are three recognizable clinical syndromes: (1) perinatal disease and CMV inclusion disease; (2) diseases in immunocompetent persons; and (3) diseases in immunocompromised persons. **Congenital CMV infection** is the most common congenital infection in developed countries (1% of all neonates). Transmission is much higher from mothers with primary disease than those with reactivation. About 10% of infected newborns will be symptomatic with CMV inclusion disease. In **immunocompetent persons**, acute CMV infection is the most common cause of mononucleosis-like syndrome with negative heterophil antibodies. CMV appears to play a role in critically ill immunocompetent adults wherein it is reactivated and associated with prolonged hospitalization and death. Other syndromes associated with CMV and whose role in pathogenesis requires further elucidation include inflammatory bowel disease, atherosclerosis, cognitive decline, and breast cancer. In **immunocompromised persons**, tissue and bone marrow transplant patients are mainly at risk in the first 100 days after allograft transplantation and in particular when graft-versus-host disease or CMV seropositivity, or both, are present in the donor and recipient. Depending on the serostatus of the donor and recipient, disease may present as primary infection or reactivation. The risk of CMV disease is proportionate to the intensity of immunosuppression. CMV is itself immunosuppressive. CMV may contribute to trans-

planted organ dysfunction, which often mimics organ rejection. CMV disease in HIV-infected patients (retinitis, serious gastrointestinal disease) occurs most prominently when the CD4 count is < 50 cells/mL. HAART reduces the frequency of retinitis and may reverse active disease. CMV retinitis may also develop after solid organ or bone marrow transplantation. CMV retinitis associated with intravitreal delivery of corticosteroids (injections or implants) or systemic anti-tumor necrosis factor- α antibodies is also described. Occasionally, CMV retinitis presents in immunocompetent persons. Serious gastrointestinal CMV disease also occurs after organ transplantation, cancer chemotherapy, or corticosteroid therapy. CMV has been identified—often with other pathogens such as *Cryptosporidium*—in up to 15% of patients with AIDS cholangiopathy. CMV pneumonitis occurs in transplant recipients (mainly bone marrow and lung) with a mortality rate up to 60–80%, and less commonly in AIDS patients. CMV pneumonitis in hematologic malignancies (eg, lymphoma) is increasingly reported. Neurologic CMV in patients with advanced AIDS is usually associated with disseminated CMV infection.

▶ Clinical Findings

A. Symptoms and Signs

1. Perinatal disease and CMV inclusion disease—CMV inclusion disease in infected newborns is characterized by jaundice, hepatosplenomegaly, thrombocytopenia, purpura, microcephaly, periventricular CNS calcifications, mental retardation, and motor disability. Hearing loss develops in greater than 50% of infants who are symptomatic at birth. Most infected neonates are asymptomatic, but neurologic deficits may ensue later in life. Perinatal infection acquired through breastfeeding or blood products typically shows a benign clinical course.

2. Disease in immunocompetent persons—Acute acquired CMV infection is characterized by fever, malaise, myalgias and arthralgias, and splenomegaly. Exudative pharyngitis or cervical lymphadenopathies are uncommon, but cutaneous rashes (including the typical maculopapular rash after exposure to ampicillin) are common. The mean duration of symptoms is 7–8 weeks. Notorious complications include mucosal gastrointestinal damage, encephalitis, severe hepatitis, Guillain-Barré syndrome, pericarditis, and myocarditis.

3. Disease in immunocompromised persons

A. CMV RETINITIS—A fundoscopic examination reveals neovascular, proliferative lesions (“pizza-pie” retinopathy). Immune restoration with HAART is associated with CMV vitreitis and cystoid macular edema. Infants with CMV retinitis tend to have more macular than peripheral disease.

B. GASTROINTESTINAL AND HEPATOBILIARY CMV—Esophagitis presents with odynophagia. Gastritis can occasionally cause bleeding, and small bowel disease may mimic inflammatory bowel disease or may present as ulceration or perforation. Colonic CMV disease causes diarrhea, hematochezia, abdominal pain, fever, and weight loss. CMV hepatitis commonly complicates liver transplantation.

C. RESPIRATORY CMV—CMV pneumonitis is characterized by cough, dyspnea, and relatively little sputum production.

D. NEUROLOGIC CMV—Neurologic syndromes associated with CMV include polyradiculopathy, transverse myelitis, ventriculoencephalitis (suspected with ependymitis), and focal encephalitis. These manifestations are more prominent in patients with advanced AIDS in whom the encephalitis has a subacute onset.

B. Laboratory Findings

PCR assays of dried blood samples from neonates are becoming the easiest method of diagnosing congenital CMV infection and are preferred over serologies or classic throat or urine cultures.

1. Immunocompetent persons—The acute mononucleosis-like syndrome is characterized by initial leukopenia; within 1 week, it is followed by absolute lymphocytosis with atypical lymphocytes. Abnormal liver function tests are common in the first 2 weeks of the disease (often 2 weeks after the fever). Detection of specific IgM or a fourfold increase of specific IgG levels support the diagnosis of acute infection.

2. Immunocompromised persons—CMV retinitis is diagnosed on the basis of the characteristic ophthalmoscopic findings. In HIV-infected patients, negative CMV serologies lower the possibility of the diagnosis but do not eliminate it. Cultures alone are of little use in diagnosing AIDS-related CMV infections, since viral shedding of CMV is common. PCR analysis should be used to diagnose CNS infection since cultures are insensitive.

Detection of pp65 antigen in blood and determination of CMV viral load by PCR are increasingly used in post-transplant patients for guidance on both treatment and prevention and should be interpreted in the context of clinical and pathologic findings. PCR appears to be more useful in predicting clinical disease. Quantitative PCR of bronchoalveolar lavage fluid seems to be useful for diagnosing CMV pneumonia.

Rapid shell-vial cultures for detection of early CMV antigens with fluorescent antibodies have largely replaced the conventional tube culture (for detection of cytopathic changes) since the time to positivity is greatly reduced (24–48 hours compared to weeks).

A variety of false-positive immunologic assays occur in the setting of acute CMV infections, including positive rheumatoid factor, direct Coombs test, cryoglobulins, and speckled antinuclear antibody.

C. Imaging

The chest radiographic findings of CMV pneumonitis are consistent with interstitial pneumonia.

D. Biopsy

Tissue confirmation is especially useful in diagnosing CMV pneumonitis and CMV gastrointestinal disease; the diagnosis of colonic CMV disease is made by mucosal biopsy showing characteristic CMV histopathologic findings of intranuclear (“owl’s eye”) and intracytoplasmic inclusions.

► Prevention

No vaccine is currently available. HAART is effective in preventing CMV infections in HIV-infected patients. Use of leukocyte-depleted blood products effectively reduces the incidence of CMV disease in patients who have undergone transplantation. Prophylactic and preemptive strategies (eg, antivirals only when antigen detection or PCR assays show evidence of active CMV replication) are effective in preventing disease in the early transplantation period but are associated with a risk of a late-onset form of the disease after the prophylaxis is discontinued. All effective anti-CMV agents can serve as prophylactic agents for CMV-seropositive transplants or for CMV-seronegative recipients of CMV-positive organ transplants. CMV immune globulin may be useful in reducing the incidence of bronchiolitis obliterans in the bone marrow transplant population and is used in some centers as part of the prophylaxis in kidney, liver, and lung transplantation patients.

Withdrawal of infected children from day care centers, reduction of patient contact by health care workers, screening for women of childbearing age, or restrictions to breastfeeding are not recommended because the virus is ubiquitous.

► Treatment

Sight-threatening CMV retinitis (lesions close to the fovea or optic nerve head) is treated with ganciclovir induction therapy (5 mg/kg intravenously every 12 hours for 14–21 days) followed by maintenance therapy at lower doses (5 mg/kg intravenously daily). Sustained-release ganciclovir intraocular implants (always accompanied by systemic valganciclovir) are another option. In less severe retinal disease, valganciclovir (900 mg twice daily for 14–21 days followed by 900 mg/d maintenance) is preferred. Due to potential toxicities, foscarnet, cidofovir, and fomivirsen are usually reserved for CMV infections that are resistant to ganciclovir. Combinations of ganciclovir and foscarnet are shown to be safe and effective in treating clinically resistant CMV retinitis. The role of HAART in reducing the need for CMV antivirals is essential. Other forms of CMV disease in AIDS are managed initially with intravenous ganciclovir and subsequently with oral valganciclovir; alternative agents (listed above) are used when resistance evolves.

Therapy for CMV disease resulting from a transplantation procedure is ganciclovir (at same doses as for retinitis) for 2–3 weeks. Oral valganciclovir (900 mg twice daily for 21 days followed by 900 mg daily for 28 days) is noninferior to intravenous ganciclovir-based therapy in solid organ transplant patients with CMV disease and is associated with less clinical resistance than ganciclovir. Dosage adjustments of all medications are needed for kidney dysfunction. Reduction of immunosuppression should be attempted when possible (especially for muromonab, azathioprine, or mycophenolate mofetil). New agents that may be useful in resistant CMV infections include leflunomide, sirolimus-based therapy, and artemunate.

In pregnant women with primary CMV infection, passive immunization with hyperimmune globulin appears

preliminarily to be effective in both treatment and prevention of fetal infection, but controlled clinical trials are lacking.

▶ When to Refer

- Neonatal infections consistent with CMV inclusion disease.
- AIDS patients with retinitis, esophagitis, colitis, hepatobiliary disease, or encephalitis.
- Organ transplants with suspected reactivation CMV.

▶ When to Admit

- Risk of colonic perforation.
- Evaluation of unexplained, advancing encephalopathy.
- Biopsy of tissues in the differential diagnosis of transplant rejection vs infection.
- Initiation of treatment with intravenous anti-CMV agents.

6. Human Herpesviruses 6, 7, & 8

HHV-6 is a B cell lymphotropic virus that is the principal cause of exanthema subitum (roseola infantum, sixth disease). Primary HHV-6 infection occurs most commonly in children under 2 years of age and is a major cause of infantile febrile seizures. HHV-6 is also associated with encephalitis and with acute liver failure. Primary infection in immunocompetent adults is rare and can produce a mononucleosis-like illness. Reactivation of HHV-6 in immunocompetent adults is rare and can present as encephalitis. Infection during pregnancy and congenital transmission is recognized. Most cases of reactivation, however, occur in immunocompromised persons. Reactivation is associated with graft rejection and bone marrow suppression in transplant patients and with encephalitis and pneumonitis in AIDS patients and in recipients of hematopoietic cell transplants. HHV-6 is on occasion also associated with drug-induced hypersensitivity syndromes that may evolve into diabetes mellitus. The roles of HHV-6 in multiple sclerosis, chronic fatigue syndrome, certain malignancies, myocarditis and progressive multifocal leukoencephalopathy remain unproven.

Two variants (A and B) of HHV-6 have been identified. HHV-6B is the predominant strain found in both normal and immunocompromised persons. Ganciclovir and foscarnet (but not acyclovir) appear to be clinically active against HHV-6.

HHV-7 is a T cell lymphotropic virus that is associated with roseola (serologically), seizures and, rarely, encephalitis. Pregnant women are often infected. Infection with HHV-7 is synergistic with CMV in kidney transplant recipients. The membrane glycoprotein CD4 is involved in HHV-7 recognition, but a clinical interaction between HHV-7 and HIV is not established.

HHV-8 is associated with Kaposi sarcoma, multicentric Castleman disease and primary effusion (body cavity) lymphoma. See Chapter 31 for pathogenesis and management.

MAJOR VACCINE-PREVENTABLE VIRAL INFECTIONS

1. Measles

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure 10–14 days before onset in an unvaccinated patient.
- ▶ Prodrome of fever, coryza, cough, conjunctivitis, malaise, irritability, photophobia, Koplik spots.
- ▶ Rash: brick-red, irregular, maculopapular; onset 3–4 days after onset of prodrome; begins on the face and proceeds “downward and outward,” affecting the palms and soles last.
- ▶ Leukopenia.

▶ General Considerations

Measles is a reportable acute systemic paramyxoviral infection transmitted by inhalation of infective droplets. It is a major worldwide cause of pediatric morbidity and mortality, with nearly 800,000 estimated deaths annually. Illness confers permanent immunity. It is highly contagious and communicability is greatest during the preeruptive and catarrhal stages but continues as long as the rash remains. The largest recent outbreak in the Americas was in São Paulo, Brazil, in 1997, with over 42,000 cases among largely unvaccinated young adults. This and other sporadic recent outbreaks of the disease in adults, adolescents, and unvaccinated preschool children in dense urban areas and among sporting events participants emphasize the need for specific recommendations concerning prevention (see below).

In the United States, measles was declared eliminated in 2000. The few reported cases since then are largely imported and geographically dispersed, and the associated isolates fail to show a recurrent strain. Although the number of cases reported during the first half of 2008 was significantly higher than that for previous years, most cases were again associated with importation, especially from

Europe. New immigrants and refugees can show serosusceptibility rates to measles in excess of 35%.

► Clinical Findings

A. Symptoms and Signs

(Table 32–2.) Fever is often as high as 40–40.6 °C. It persists through the prodrome and early rash (about 5–7 days). Malaise may be marked. Coryza (nasal obstruction, sneezing, and sore throat) resembles that seen with upper respiratory infections. Cough is persistent and nonproductive. Conjunctivitis manifests as redness, swelling, photophobia, and discharge. These symptoms intensify over the 2–4 days before the onset of the rash and peak on the first day of the rash.

Koplik spots (small, irregular, and red with whitish center on the mucous membranes) are pathognomonic of measles. They appear about 2 days before the rash and last 1–4 days as tiny “table salt crystals” in the buccal mucosa opposite the molars and vaginal membranes. The rash usually appears on the face and behind the ears 4 days after the onset of symptoms. The initial lesions are pinhead-sized papules that coalesce to form a brick-red, irregular, blotchy maculopapular rash. In severe cases, the rash coalesces to form a nearly uniform erythema on some body areas. The rash next appears on the trunk, followed by the extremities, including the palms (25–50% of those infected) and soles. The rash lasts for 3–7 days and fades in the same manner it appeared. Hyperpigmentation remains in fair-skinned individuals and severe cases. Slight desquamation may follow.

Other findings in measles include pharyngeal erythema, a tonsillar yellowish exudate, coating of the tongue in the center with a red tip and margins, moderate generalized lymphadenopathy and, at times, splenomegaly.

Atypical measles is a syndrome occurring in adults who received inactivated measles vaccine (1963–1968) or who received live measles vaccine before age 12 months and as a result developed hypersensitivity rather than protective immunity. When persons are infected later with wild measles virus, a potentially fatal illness may develop, with high fever; unusual rashes (papular, hemorrhagic), most prominent on the extremities, without Koplik spots; headache; arthralgias; hepatitis; a high rate of pneumonitis, and sometimes pleural effusions. Measles antibody titers tend to be very high after the appearance of the exanthem.

Measles may be distinctive in HIV-infected individuals, with higher rates of pneumonitis, higher mortality, and prolonged viral shedding. Vaccine failure rates, primary and secondary, are higher in HIV-infected children. The frequent difficulty in establishing a diagnosis suggests that measles may be more prevalent in epidemics than heretofore recognized.

Measles during pregnancy is not known to cause congenital abnormalities of the fetus. It is, however, associated with spontaneous abortion and premature delivery and can cause severe disease in the mother. Although measles does not always develop in the offspring of mothers with the disease, it can be severe when it does. It is therefore

recommended that infants born to such mothers be passively immunized with immunoglobulin at birth.

The virologic clearance of measles can take months.

B. Laboratory Findings

Leukopenia is usually present unless secondary bacterial complications exist. A lymphocyte count under 2000/mcL is a poor prognostic sign. Thrombocytopenia is common. Proteinuria is often observed. Although technically difficult, virus can be cultured from nasopharyngeal washings and from blood. Detection of IgM measles antibodies with enzyme-linked immunosorbent assay (ELISA) or a fourfold rise in serum hemagglutination inhibition antibody supports the diagnosis. Fluorescent antibody staining of respiratory or urinary epithelial cells can also confirm the diagnosis. PCR techniques are available in research settings.

► Differential Diagnosis

Measles is usually diagnosed clinically but may be mistaken for other exanthematous infections (see Table 32–2).

► Complications

A. Central Nervous System

Postinfectious encephalomyelitis occurs in about 0.05–0.1% of cases. Higher rates of encephalitis occur in adolescents and adults than in school-aged children. Its onset is usually 3–7 days after the rash. Vomiting, convulsions, coma, and diverse, severe neurologic symptoms and signs may develop. Treatment is symptomatic and supportive. Virus is usually not found in the CNS, though demyelination is prominent. There is an appreciable mortality rate (10–20%), and 33% of survivors are left with neurologic deficit.

A similar form, “inclusion body encephalitis,” occurs months after exposure. This complication is reported to occur after measles vaccination in patients with inadequate cellular immunity but is associated with isolation of the measles virus.

Subacute sclerosing panencephalitis (SSPE) is a very late CNS complication (5–15 years after infection); the measles virus acts as a “slow virus” to produce degenerative CNS disease years after the initial infection. SSPE is rare (1:100,000 cases of measles) and occurs more often when measles develops early in life among males who live in rural environments. SSPE very rarely develops in adults.

Measles virus can opportunistically invade the CNS. An acute progressive encephalitis (subacute measles encephalitis), characterized by seizures, neurologic deficits, and often progressive stupor and death, can occur among immunosuppressed patients. Treatment is supportive, withholding immunosuppressive chemotherapy when feasible. Interferon and ribavirin are variably successful.

B. Respiratory Tract Disease

Early in the course of the disease, bronchopneumonia or bronchiolitis due to the measles virus may occur in up to 5% of patients and result in serious respiratory difficulties.

Bronchiectases may occur in up to a quarter of nonvaccinated children. Pneumonia occurring with or without an evanescent rash is seen in atypical measles.

C. Secondary Bacterial Infections

Immediately following measles, secondary bacterial infection, particularly cervical adenitis, otitis media (the most common complication), and pneumonia, occurs in about 15% of patients.

D. Immune Reactivity

Measles produces temporary anergy to cell-mediated skin tests.

E. Gastroenteritis

Diarrhea and protein-losing enteropathy (prodromal rectal Koplik spots may be seen) are significant complications among malnourished children.

F. Other Complications

Other complications include conjunctivitis, keratitis, and otosclerosis.

► Prevention

In the United States, children receive their first vaccine dose at 12–15 months and a second at age 4–6 years prior to entry into school (see Table 32–2). Combination measles-mumps-rubella-varicella vaccines (MMRV) can be used in place of the traditional measles, mumps, and rubella (MMR) vaccine.

American students beyond high school and medical staff starting employment require documentation of the above vaccination schedule or must show serologic evidence of immunity if they were born after 1956. For individuals born before 1957, herd immunity is assumed. Health care workers, immigrants, and refugees should be screened and vaccinated if necessary regardless of date of birth.

In outbreaks occurring in infants under 1 year of age, initial vaccination may be given at 6 months, with repeat at 15 months. When outbreaks take place in day care centers, K–12 institutions, or colleges and universities, revaccination is probably indicated for all, in particular for students and their siblings born after 1956 who do not have documentation of immunity as defined above. Susceptible personnel who have been exposed should be isolated from patient contact between the fifth and the twenty-first day after exposure regardless of whether they were vaccinated or given immune globulin. If measles develop in these persons, they should be isolated from patient contact until 7 days after the rash develops.

When susceptible individuals are exposed to measles, the live virus vaccine can prevent disease if given within 5 days of exposure. In addition, immune globulin (0.25 mL/kg [0.11 mL/lb] body weight) can be injected intramuscularly for prevention or modification of clinical illness if given within 6 days after exposure. This must be followed by active immunization with live measles vaccine 3 months

later. Vaccination of all immunocompetent persons born after 1956 who travel to the developing world is important. In the developing world, the use of the second vaccine dose is an important aspect of achieving control of measles in the community-at-large.

Pregnant women and immunosuppressed persons should *not* receive this vaccine. The exception to this contraindication is asymptomatic HIV-infected patients including children, who have not shown adverse effects from measles vaccination. In asymptomatic HIV-infected children, exposure to vaccines improves survival after measles, and HAART therapy is associated with an improved vaccine response. Repeat vaccination may be necessary in HIV-infected children. Immune globulin should be considered for postexposure prophylaxis in any high-risk person exposed to measles. This group includes children with malignant disease and patients with AIDS, in whom severe disease or fatal measles is likely to develop. To be effective, immune globulin should be administered within 6 days after an exposure.

Severe allergic reactions to the MMR vaccine are rare, though fever and rash appear to occur slightly more often among female recipients. An aerosolized measles vaccine shows promising results in small clinical trials with hopes for availability in the near future. Future vaccines for a variety of infectious agents may utilize measles vectors, thereby augmenting immunity to measles.

► Treatment

A. General Measures

The patient should be isolated for the week following onset of rash and kept at bed rest until afebrile. Treatment is symptomatic including antipyretics and fluids as needed. Vitamin A, 200,000 units/d orally for 2 days (the benefit being maintenance of gastrointestinal and respiratory epithelial mucosa), reduces pediatric morbidity rates although high-dose vitamin A exposure increases the severity and risk of antibiotic failure in nonmeasles pneumonia. Measles virus is susceptible to ribavirin *in vitro* and has been used in selected severe cases of pneumonitis (35 mg/kg/d intravenously in three divided doses for 2 days, followed by 20 mg/kg/d intravenously in three divided doses for 5 days).

B. Treatment of Complications

Secondary bacterial infections, including pneumonia, are treated with appropriate antibacterial antibiotics. Post-measles encephalitis, including SSPE, can be managed only symptomatically.

► Prognosis

Between 1999 and 2005, measles mortality rate was reduced an estimated 60%. In the last decade, the case-fatality rate in the United States stayed around 3 per 1000 reported cases, with deaths principally due to encephalitis (15% mortality rate) and secondary bacterial pneumonia. Deaths in the developing world are mainly related to diarrhea and protein-losing enteropathy.

▶ When to Refer

- Any suspect cases should be reported to public health authorities.
- HIV infection.
- Pregnancy.

▶ When to Admit

- Meningitis, encephalitis, or myelitis.
- Severe pneumonia.
- Diarrhea that significantly compromises fluid or electrolyte status.

2. Mumps

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure 14–21 days before onset.
- ▶ Painful, swollen salivary glands, usually parotid.
- ▶ Frequent involvement of testes, pancreas, and meninges in unvaccinated individuals.

▶ General Considerations

Mumps is a paramyxoviral disease spread by respiratory droplets. While children are the age group most affected, recent outbreaks involved patients in the late second or early third decades of life. The incidence of mumps is highest in spring. The incubation period is 14–21 days (average, 18 days). Infectivity occurs via saliva and urine and precedes the symptoms by about 1 day and is maximal for 3 days, although it may last a week. Up to one-third of affected individuals have subclinical infection. In 2006, an outbreak of mumps in the United States occurred and involved over 6000 persons; 85% of these cases were reported from eight Midwestern states.

▶ Clinical Findings

A. Symptoms and Signs

Mumps is more serious in adults than in children. Parotid tenderness and overlying facial edema are the most com-

mon physical findings (Plate 98) and typically develop within 48 hours of the prodromal symptoms. Usually, one parotid gland enlarges before the other, but unilateral parotitis alone occurs in 25% of patients. The orifice of Stensen duct may be red and swollen. Trismus may result from parotitis. The parotid glands return to normal within a week. Involvement of other salivary glands (submaxillary and sublingual) occurs in 10% of cases.

Fever and malaise are variable but often minimal in young children. High fever accompanies meningitis or orchitis. Neck stiffness, headache, and lethargy suggest meningitis. Testicular swelling and tenderness (unilateral in 75% of cases) denote orchitis; the testes are the most common extrasalivary site of disease in adults. Orchitis develops 7–10 days after the onset of parotitis in about 25–40% of postpubertal men, but sterility is rare. Upper abdominal pain, nausea, and vomiting suggest pancreatitis. Mumps is the leading cause of pancreatitis in children. Lower abdominal pain and ovarian enlargement suggest oophoritis (which occurs in 5% of postpubertal women, usually unilateral); it is a difficult diagnosis to establish.

B. Laboratory Findings

Mild leukopenia with relative lymphocytosis may be present. Serum amylasemia usually reflects salivary gland involvement rather than pancreatitis. Lymphocytic pleocytosis (and hypoglycorrhachia) of the cerebrospinal fluid in meningitis may be asymptomatic. Mild kidney function abnormalities are found in up to 60% of patients.

A characteristic clinical picture is usually sufficient for diagnosis. A confirmatory diagnosis of mumps is made by isolating the virus preferably from a swab of the duct of the parotid or other affected salivary gland. The virus can also be isolated from cerebrospinal fluid early in the course of aseptic meningitis. Isolation from urine is no longer advised. Nucleic acid amplification techniques are more sensitive than viral cultures but their availability is limited. An elevated serum IgM is also considered diagnostic and a repeat test 2–3 weeks after the onset of symptoms is recommended if the first assay is negative due to a delay in IgM rise, especially in vaccinated persons. A fourfold rise in complement-fixing antibodies to mumps virus in paired serum IgG also confirms infection.

▶ Differential Diagnosis

Swelling of the parotid gland may be due to calculi in the parotid ducts, tumors, or cysts, or to a reaction to iodides. Other causes include starch ingestion, sarcoidosis, cirrhosis, diabetes, bulimia, pilocarpine usage, and Sjögren syndrome. Parotitis may be produced by pyogenic organisms (eg, *S aureus*, gram-negative organisms), particularly in debilitated individuals with poor oral intake, drug reaction (phenothiazines, propylthiouracil), and other viruses (influenza A, parainfluenza, EBV infection, coxsackieviruses, adenoviruses, HHV-6). Swelling of the parotid gland must be differentiated from inflammation of the lymph nodes located more posteriorly and inferiorly than the parotid gland.

► Complications

Other manifestations of the disease are less common. These usually follow the parotitis but may precede it or occur without salivary gland involvement and include meningitis (30%), orchitis (which on rare occasion leads to priapism or testicular infarction), pancreatitis (usually mild), oophoritis, thyroiditis, neuritis, hepatitis, myocarditis, thrombocytopenia, migratory arthralgias (noted infrequently among adults and rarely in children), and nephritis. Mumps has also been associated with cases of endocardial fibroelastosis.

Rare neurologic complications include encephalitis, Guillain-Barré syndrome, cerebellar ataxia, facial palsy, and transverse myelitis. Encephalitis is associated with cerebral edema, serious neurologic manifestations, and sometimes death. Deafness develops from eighth nerve neuritis, and data from Japan report an incidence of 0.3% among patients.

► Prevention

Mumps live virus vaccine is safe and highly effective with long lasting immunity. It is recommended for routine immunization for children over age 1 year, either alone or in combination with other virus vaccines (eg, in the measles-mumps-rubella (MMR) vaccine or as a quadrivalent vaccine with varicella). A second dose is recommended for children (ages 4–6 years) before starting school. Two doses of the vaccine should also be considered for high-risk individuals (eg, health care workers) born before 1957 and without evidence of immunity. There are no known cases of long-term sequelae associated with mumps vaccination and the currently used mumps strain (Jeryl Lynn) shows the lowest associated incidence of postvaccine aseptic meningitis (from 1 in 150,000 to 1 in 1.8 million). This vaccine is less effective in epidemic than in nonepidemic settings. Reactions are reviewed in the measles section. It should not be given to pregnant women or to immunocompromised individuals, though the vaccine has been given to asymptomatic HIV-infected individuals without adverse sequelae especially when the individuals are taking HAART. In the developed world, persons in whom mumps develops are less likely to have received a second vaccine dose. The mumps skin tests are less reliable than serum neutralization titers in determining immunity.

► Treatment

A. General Measures

The patient should be isolated until swelling subsides (about 9 days from onset) and kept at bed rest while febrile. Treatment is symptomatic. Topical application of compresses may relieve parotid discomfort.

B. Management of Complications

1. Meningitis—The treatment of aseptic meningitis is symptomatic. The management of encephalitis requires attention to cerebral edema, the airway, and vital functions.

2. Orchitis—The scrotum should be supported with a suspensory or toweling “bridge” and ice bags applied.

Incision of the tunica may be necessary in severe cases. Pain can be relieved with opioids, or by injecting the spermatic cord at the external inguinal ring with 10–20 mL of 1% procaine solution. The merit of hydrocortisone sodium succinate (100 mg intravenously, followed by 20 mg orally every 6 hours for 2 or 3 days) in reducing inflammation is not firmly established.

3. Pancreatitis—Symptomatic treatment should be provided, with emphasis on parenteral hydration.

► Prognosis

The entire course of mumps rarely exceeds 2 weeks. Rare fatalities are usually due to encephalitis.

► When to Refer

Any suspect cases should be reported to public health authorities.

► When to Admit

- Trismus.
- Meningitis, encephalitis.
- Severe abdominal pain or vomiting suggesting pancreatitis.
- Severe testicular pain.
- Priapism.
- Severe thrombocytopenia.
- Myocarditis.

3. Poliomyelitis

ESSENTIALS OF DIAGNOSIS

- Incubation period 9–12 days from exposure.
- Muscle weakness, headache, stiff neck, fever, nausea and vomiting, sore throat.
- Lower motor neuron lesion (flaccid paralysis) with decreased deep tendon reflexes and muscle wasting.
- Cerebrospinal fluid shows excess leukocytes, with lymphocytic predominance; count is rarely more than 500/mcl.

► General Considerations

Poliomyelitis virus, an enterovirus, is present in throat washings and stools (excretion may last for several weeks after infection). Infection is highly contagious through the fecal–oral route, especially during the first week of the

disease. The global poliomyelitis eradication initiative was launched in 1988 and led to the virtual elimination of wild poliovirus from the Western hemisphere (a few cases of vaccine-associated disease were reported in Hispaniola, see below). The Pacific Rim and much of Central Asia also appear to be polio free. Between 1988 and 2007, the number of cases decreased globally from 350,000 to just over 1000. Only four countries had not yet documented interruption of wild poliovirus transmission (Afghanistan, India, Nigeria, and Pakistan). Resurgence in wildtype polio cases and vaccine-derived poliomyelitis still pose problems for elimination of poliomyelitis virus. Recent vaccine-associated cases were reported from Cambodia, Myanmar, and Nigeria, and cases among immunodeficient persons were reported from China, Iran, Syria, and Egypt. The last vaccine-associated case in the United States occurred in 2005; the woman acquired the infection while traveling in Central America.

Three antigenically distinct types of poliomyelitis virus are recognized, with little cross-immunity between them. Disease with type 2 in particular is on the verge of extinction.

► Clinical Findings

A. Symptoms and Signs

At least 95% of infections are asymptomatic, but in those who become ill, manifestations include abortive poliomyelitis (minor illness), nonparalytic poliomyelitis, and paralytic poliomyelitis.

1. Abortive poliomyelitis (minor illness)—Such minor illness occurs in 4–8% of infections and the symptoms are fever, headache, vomiting, diarrhea, constipation, and sore throat lasting 2–3 days. This entity is suspected clinically only during an epidemic.

2. Nonparalytic poliomyelitis—In addition to the above symptoms, signs of meningeal irritation and muscle spasm occur in the absence of frank paralysis. This disease is indistinguishable from aseptic meningitis caused by other viruses.

3. Paralytic poliomyelitis—Paralytic poliomyelitis represents 0.1% of all poliomyelitis cases (the incidence is higher when infections are acquired later in life). Paralysis may occur at any time during the febrile period. Tremors, muscle weakness, constipation, and ileus may appear. Paralytic poliomyelitis is divided into two forms, which may coexist: (1) **spinal poliomyelitis**, with involvement of the muscles innervated by the spinal nerves, and (2) **bulbar poliomyelitis**, with weakness of the muscles supplied by the cranial nerves (especially nerves IX and X) and of the respiratory and vasomotor centers.

In spinal poliomyelitis, paralysis of the shoulder girdle often precedes intercostal and diaphragmatic paralysis, which leads to diminished chest expansion and decreased vital capacity. The paralysis occurs over 2–3 days, is flaccid, has an asymmetric distribution, and affects the proximal muscles of the lower extremities more frequently. Sensory loss is very rare.

In bulbar poliomyelitis, symptoms include diplopia (uncommonly), facial weakness, dysphagia, dysphonia,

nasal voice, weakness of the sternocleidomastoid and trapezius muscles, difficulty in chewing, inability to swallow or expel saliva, and regurgitation of fluids through the nose. The most life-threatening aspect of bulbar poliomyelitis is respiratory paralysis. Lethargy or coma may be due to hypoxia, most often from hypoventilation. Vasomotor disturbances in blood pressure and heart rate may occur. Convulsions are rare. Bulbar poliomyelitis is more common in adults.

B. Laboratory Findings

The peripheral white blood cell count may be normal or mildly elevated. Cerebrospinal fluid pressure and protein are normal or slightly increased. Glucose is not decreased. White blood cells usually number < 500/mcL and are principally lymphocytes after the first 24 hours. Cerebrospinal fluid is normal in 5% of patients. The virus may be recovered from throat washings (early) and stools (early and late). Neutralizing and complement-fixing antibodies appear during the first or second week of illness. Serologic testing cannot distinguish between wild-type and vaccine-related virus infections.

► Differential Diagnosis

Nonparalytic poliomyelitis is similar to other forms of enteroviral meningitis; the distinction is made serologically. Acute flaccid paralysis is the term used in the developing world for the variety of neurologic illnesses that both include and mimic poliomyelitis. Acute flaccid paralysis due to poliomyelitis is distinguished by the greater frequency of fever and asymmetric neurologic signs. Acute inflammatory polyneuritis (Guillain–Barré syndrome), Japanese B virus encephalitis, West Nile virus infection, and tick paralysis may resemble poliomyelitis. In Guillain–Barré syndrome (see Chapter 24), the weakness is more symmetric and ascending in most cases, but the Miller–Fisher variant is quite similar to bulbar polio. Paresthesias are uncommon in poliomyelitis but common in Guillain–Barré syndrome. The cerebrospinal fluid usually has a high protein content but normal cell count in Guillain–Barré syndrome.

► Complications

Urinary tract infection, atelectasis, pneumonia, myocarditis, paralytic ileus, gastric dilation, and pulmonary edema may occur. Respiratory failure may be a result of paralysis of respiratory muscles, airway obstruction from involvement of cranial nerve nuclei, or lesions of the respiratory center.

► Prevention

Given the epidemiologic distribution of poliomyelitis and the continued concern about vaccine-associated disease (estimated in 1:750,000 recipients) with the trivalent oral live poliovirus vaccine (OPV), the inactive (Salk) parenteral vaccination is currently used in the United States for all four recommended doses (at ages 2 months, 4 months, and 6–18 months and at 4–6 years). Inactivated vaccine is also routinely used elsewhere in the developed world. Oral vaccines are limited to usage for outbreak control, travel to

endemic areas within the ensuing month, and protection of children whose parents do not comply with the recommended number of immunizations. The advantages of oral vaccination are the ease of administration, low cost, effective local gastrointestinal and circulating immunity, and herd immunity.

Routine immunization of adults in the United States is no longer recommended because of the low incidence of the disease. Exceptions include adults not vaccinated within the prior decade who are exposed to poliomyelitis or who plan to travel to endemic areas (mentioned above). Vaccination should also be considered for adults engaged in high-risk activities (eg, laboratory workers handling stools). Such adults should be given inactivated poliomyelitis vaccine (Salk) as should immunodeficient or immunosuppressed individuals and members of their households.

In the developing world, three doses of OPV seem sufficient for adequate immunization and the interval between doses should probably be longer than 1 month (because of interference from enteric pathogens). Intramuscular injections should be routinely avoided during the month following oral poliomyelitis vaccination to prevent provocation paralysis. Ancillary useful control measures in polio-endemic countries include national immunization days (mass campaigns in which all children are vaccinated twice, 4–6 weeks apart, regardless of vaccine history); cross-border vaccination activities; surveillance for acute flaccid paralysis, an indicator for poliomyelitis; and aggressive outbreak responses as well as intensified immunization activities in countries recently affected by armed conflicts. Vaccine-associated poliomyelitis with the oral Sabin vaccination is due to mutations leading to neurovirulence. Outbreaks of vaccine-derived poliomyelitis are reported sporadically globally (listed above) with the last major outbreak in the Western Hemisphere occurring in Hispaniola (both Haiti and the Dominican Republic) from 2000 to 2001. Such incidents serve as a reminder of the need to maintain high levels of immunization coverage even in the absence of overt disease. A monovalent type 1 oral vaccine that seems more immunogenic than the three-valent OPV and has the advantage of single administration was successfully used in India, Egypt, and Nigeria. Cost considerations along with effective herd immunity remain major reasons the oral Sabin is still administered.

There is no epidemiologic evidence to implicate poliomyelitis vaccination as a cause for recurrent worsening wheezing or eczema in childhood.

► Treatment

In the acute phase of paralytic poliomyelitis patients should be hospitalized. Strict bed rest in the first few days of illness reduces the rate of paralysis. Cranial nerve involvement must be vigilantly sought. Comfortable but rotating positions should be maintained in a “polio bed”: firm mattress, footboard, sponge rubber pads or rolls, sandbags, and light splints. Intensive physiotherapy may help recover some motor function with paralysis. Fecal impaction and urinary retention (especially with paraplegia) are managed appropriately. In cases of respiratory weakness or paralysis, inten-

sive care is needed. The antiviral pleconaril shows no clear benefit in cases of polio meningoencephalitis.

► Prognosis

During the febrile period, paralysis may develop or progress. Mild weakness of small muscles is more likely to regress than is severe weakness of large muscles. Bulbar poliomyelitis carries a mortality rate of up to 50%. New muscle weakness and pain may develop and progress slowly years after recovery from acute paralytic poliomyelitis. This entity is called **postpoliomyelitis syndrome** and presents with signs of chronic and new denervation, is not infectious in origin, and patients do not shed the virus. The syndrome is associated with increasing dysfunction of surviving motor neurons. Different immune modulators such as prednisone, interferon, and intravenous immunoglobulin have been tested for treatment of postpoliomyelitis syndrome but have not shown clear benefits. Series that report increased incidences of multiple sclerosis or other motor neuron diseases among poliomyelitis survivors need to be evaluated in the context of what is known about the postpoliomyelitis syndrome. Although bulbar poliomyelitis causes the greatest threat to life, it is rarely responsible for permanent damage among surviving patients.

► When to Refer

- Neurologic compromise.
- Any suspicious cases should be referred to public health authorities.

► When to Admit

Patients with neurologic compromise should be admitted to the hospital.

4. Rubella

ESSENTIALS OF DIAGNOSIS

- Exposure 14–21 days before onset.
- Arthralgia, particularly in young women.
- No prodrome in children, mild prodrome in adults; mild symptoms (fever, malaise, coryza) coinciding with eruption.
- Posterior cervical and postauricular lymphadenopathy 5–10 days before rash.

- ▶ Fine maculopapular rash of 3 days duration; face to trunk to extremities.
- ▶ Leukopenia, thrombocytopenia.

▶ General Considerations

Rubella is a systemic disease caused by a togavirus transmitted by inhalation of infective droplets. It is only moderately communicable. One attack usually confers permanent immunity but reinfection is possible. The incubation period is 14–21 days (average, 16 days). The disease is transmissible from 1 week before the rash appears until 15 days afterward.

The clinical picture of rubella is difficult to distinguish from other viral illnesses such as infectious mononucleosis, measles, echovirus infections, and coxsackievirus infections; however, arthritis is more prominent in rubella. In the United States, endemic rubella and congenital rubella syndrome are eliminated. Surveillance of female military recruits suggests, however, that serologic protection against rubella, measles, and mumps are inadequate. In 2004, fewer than ten cases were reported to the Centers for Disease Control and Prevention (CDC) with all them likely imported from other countries. In parts of the world (eg, Eastern Europe) where vaccination against rubella was more recently introduced, significant outbreaks still occur. Serosusceptibility to the infection in immigrants to developed countries is still significant.

The principal importance of rubella lies in its devastating effects on the fetus in utero, producing teratogenic effects and a continuing congenital infection. More than 100,000 cases of **congenital rubella syndrome** are reported annually in the developing world.

▶ Clinical Findings

A. Symptoms and Signs

While fetal rubella can be devastating, postnatally acquired rubella is usually innocuous with up to 50% cases asymptomatic. In the postnatally acquired infection, fever and malaise, usually mild, accompanied by tender suboccipital adenitis, may precede the eruption by 1 week. Mild coryza may be present. Polyarticular arthritis occurs in about 25% of adult cases and involves the fingers, wrists, and knees. Rarely does chronic arthritis develop. The polyarthritis usually subsides within 7 days but may persist for weeks. Early posterior cervical and postauricular lymphadenopathy is very common. Erythema of the palate and throat, sometimes patchy, may be noted.

A fine, pink maculopapular rash appears on the face, trunk, and extremities in rapid progression (2–3 days) and fades quickly, usually lasting 1 day in each area (Table 32–2). Rubella without rash may be at least as common as the exanthematous disease. Diagnosis, when suspected because of disease in the community, requires serologic confirmation.

B. Laboratory Findings

Leukopenia may be present early and may be followed by an increase in plasma cells. The definitive diagnosis of acute

rubella infection is based on elevated IgM antibody, fourfold or greater rise in IgG antibody titers, or isolation of the virus. False-positive IgM antibodies, however, are associated with Epstein-Barr virus, cytomegalovirus, parvovirus, and rheumatoid factor. Detection of antibodies against rubella in other body fluids, such as urine and saliva, seem promising diagnostic aids. PCR techniques are also available.

▶ Complications

A. Exposure during Pregnancy

When a pregnant woman is exposed to a possible case of rubella, an immediate hemagglutination-inhibiting rubella antibody level should be obtained to document immunity, since fetal infection during the first trimester leads to congenital rubella in at least 80% of fetuses.

Positive tests for IgG antibodies alone indicate past infection or vaccination. If no antibodies are found, clinical observation and serologic follow-up are essential. An isolated IgM-positive test needs to be interpreted with caution because it does not necessarily imply acute infection. Confirmation of rubella in the expectant mother raises the question of therapeutic abortion, an alternative to be considered in light of personal, religious, legal, and other factors.

B. Congenital Rubella

An infant acquiring the infection in utero may be normal at birth but probably—50% in a series of nearly 70 pregnant women with rubella in Mexico—will have a wide variety of manifestations, including early-onset cataracts and glaucoma, microphthalmia, hearing deficits, psychomotor retardation, congenital heart defects, organomegaly, and maculopapular rash. In general, the younger the fetus when infected, the more severe the illness. Deafness is the primary complication in the second trimester. Viral excretion in the throat and urine persists for many months despite high antibody levels. A specific test for IgM rubella antibody is useful for diagnosis in the newborn. A confirmatory diagnosis is made by isolation of the virus or PCR detection of viral RNA in tissues. Treatment is directed toward the many anomalies.

C. Postinfectious Encephalopathy

In 1:6000 cases, postinfectious encephalopathy develops 1–6 days after the rash; the virus cannot always be isolated. The mortality rate is 20%, but residual deficits are rare among the recovered. The mechanism is unknown.

Other unusual complications of rubella include hemorrhagic manifestations due to thrombocytopenia and vascular damage, duodenal stenosis, and mild hepatitis.

▶ Prevention

Live attenuated rubella virus vaccine should be given to all infants and to susceptible girls before the menarche. When women are immunized, they should not be pregnant, and the absence of antibodies should be established. (In the United States, about 80% of 20-year-old women are immune to rubella.) Postpartum administration to susceptible female hospital employees is recommended. It is recommended that

women not become pregnant for at least 3 months after vaccine administration. Nonetheless, there are no reports of congenital rubella syndrome after rubella immunization, and inadvertent immunization of a pregnant woman is not considered an indication for therapeutic abortion. Arthritis is more marked after rubella vaccination than in native disease and appears to be immunologically mediated. The association between chronic arthropathies and rubella vaccination is controversial. MMR may be given in conjunction with diphtheria–pertussis–tetanus (DPT) boosters as adequate serologic responses are documented. The administration of two or more doses appears to overcome an immunogenetic risk for vaccine failure in some vaccinees.

▶ Treatment

Acetaminophen provides symptomatic relief. Encephalitis and non-life-threatening thrombocytopenia should be treated symptomatically.

▶ Prognosis

Rubella is a mild illness and rarely lasts more than 3–4 days. Congenital rubella, on the other hand, has a high mortality rate, and the associated congenital defects are largely permanent.

▶ When to Refer

- Pregnancy.
- Meningitis/encephalitis.
- Any suspect cases should be reported to public health authorities.

OTHER NEUROTROPIC VIRUSES

1. Rabies

ESSENTIALS OF DIAGNOSIS

- ▶ History of animal bite.
- ▶ Paresthesia, hydrophobia, rage alternating with calm.
- ▶ Convulsions, paralysis, thick tenacious saliva.

▶ General Considerations

Rabies is a viral (rhabdovirus) encephalitis transmitted by infected saliva that gains entry into the body by an animal

bite or an open wound. Globally, an estimated 50,000 to 100,000 deaths occur annually from rabies, mostly in rural areas of Africa and Asia. In the United States, domestically acquired rabies cases are rare but probably underreported. One bat-associated human case was reported from Minnesota in 2007. Raccoons, skunks, bats, and foxes are common wildlife reservoirs. Unique geographic biting species that cause rabies in the United States include raccoons in the East, including New England; skunks in the Midwest, Southwest, and in California; and foxes in the Southwest and in Alaska. Bats are the second most reported rabid animal behind raccoons and most cases in the United States from 2000 through 2006 (17 of 24 total) were associated with bat rabies virus variants. Hawaii is the only rabies-free state. Vaccination campaigns are very successful in preventing dog-associated cases. Cats are rarely infected in the United States, although an increase in the number of cases was reported in 2006. Rodents and lagomorphs (eg, rabbits) are unlikely to spread rabies because they cannot survive the disease long enough to transmit it, although woodchucks and groundhogs can become infected and transmit the virus. In developing countries, greater than 90% of human cases are due to infected dog bites. Rabies among travelers to rabies-endemic areas (usually the Middle East and sub-Saharan Africa) is usually associated with animal injuries.

The virus gains entry into the salivary glands of dogs 5–7 days before their death from rabies, thus limiting their period of infectivity. Less common routes of transmission include contamination of mucous membranes with saliva or brain tissue, aerosol transmission, and corneal transplantation. Transmission through solid organ and vascular segment transplantation from donors with unrecognized infection is also reported.

The incubation period may range from 10 days to many years but is usually 3–7 weeks depending in part on the distance of the wound from the CNS. The virus travels in the nerves to the brain, multiplies there, and then migrates along the efferent nerves to the salivary glands.

Rabies is almost uniformly fatal, with only six documented surviving cases to date. Five received either preexposure or postexposure prophylaxis. In 2004, a teenager survived with only naturally acquired immunity, but received intense treatment including antiviral therapy and an intentionally induced drug coma. The most common clinical problem confronting clinicians is the management of a patient bitten by an animal.

▶ Clinical Findings

A. Symptoms and Signs

While there is usually a history of animal bite, bat bites may not be recognized. The prodromal syndrome consists of pain at the site of the bite in association with fever, malaise, headache, nausea, and vomiting. The skin is sensitive to changes of temperature, especially air currents (aerophobia). Percussion myoedema can be present and persist throughout the disease. The CNS stage begins about 10 days after the prodrome and may be either encephalitic (“furious”) or paralytic (“dumb”). The encephalitic form (about 80% of the cases) produces the classic rabies mani-

festations of delirium alternating with periods of calm, extremely painful laryngeal spasms on attempting drinking (hydrophobia), autonomic stimulation (hypersalivation), and seizures. In the less common paralytic form, an acute ascending paralysis resembling Guillain-Barré syndrome predominates with relative sparing of higher cortical functions initially. Both forms progress relentlessly to coma, autonomic nervous system dysfunction, and death.

B. Laboratory Findings

Biting animals that appear well should be quarantined and observed for 10 days. Sick or dead animals should be tested for rabies. A wild animal, if captured, should be sacrificed and the head shipped on ice to the nearest laboratory qualified to examine the brain for evidence of rabies virus. When the animal cannot be examined, raccoons, skunks, bats, and foxes should be presumed to be rabid.

Direct fluorescent antibody testing of skin biopsy material from the posterior neck (where hair follicles are highly innervated) has a sensitivity of 60–80%.

Reverse transcriptase PCR (RT-PCR), nucleic acid sequence-based amplification, and viral isolation from the cerebrospinal fluid or saliva are being advocated as definitive diagnostic assays. Antibodies can be detected in the serum and the cerebrospinal fluid. Pathologic specimens often demonstrate round or oval eosinophilic inclusion bodies (Negri bodies) in the cytoplasm of neuronal cells, but the finding is neither sensitive nor specific. MRI signs are diffuse and nonspecific.

► Prevention

Immunization of household dogs and cats and active immunization of persons with significant animal exposure (eg, veterinarians) are important. The most important decisions, however, concern animal bites.

In the developing world, education, surveillance, and animal (particularly dog) vaccination programs are preferred over mass destruction of dogs, which is followed typically by invasion of susceptible feral animals into urban areas. In some Western European countries, campaigns of oral vaccination of wild animals led to the elimination of rabies in wildlife.

A. Local Treatment of Animal Bites and Scratches

Thorough cleansing, debridement, and repeated flushing of wounds with soap and water are important. Rabies immune globulin or antiserum should be given as stated below. Wounds caused by animal bites should not be sutured.

B. Postexposure Immunization

The decision to treat should be based on the circumstances of the bite, including the extent and location of the wound, the biting animal, the history of prior vaccination, and the local epidemiology of rabies. Any contact or suspect contact with a bat is usually deemed a sufficient indication to warrant prophylaxis. Consultation with state and local health departments is recommended. Postexposure treatment including

both immune globulin and vaccination should be administered as promptly as possible when indicated.

The optimal form of passive immunization is human rabies immune globulin (HRIG; 20 international units/kg), administered once. As much as possible of the full dose should be infiltrated around the wound, with any remaining injected intramuscularly at a site distant from the wound. Finger spaces can be safely injected without development of a compartment syndrome. If HRIG is not available, equine rabies antiserum (20–40 international units/kg) can be used if available (it was last produced in 2001) after appropriate tests for horse serum sensitivity.

Two vaccines are licensed and available for use in humans in the United States: a human diploid cell vaccine (HDCV) and a purified chick embryo cell vaccine (PCEC). The current vaccines are given as five injections of 1 mL intramuscularly in the deltoid or, in small children, into the anterolateral thigh muscles on days 0, 3, 7, 14, and 28 after exposure. The vaccine should not be given in the gluteal area due to suboptimal response.

Rabies vaccines and HRIG should never be given in the same syringe or at the same site. Allergic reactions to the vaccine are rare, although local reactions (pruritus, erythema, tenderness) occur in about 25% and mild systemic reactions (headaches, myalgias, nausea) in about 20% of recipients. Adverse reactions to HRIG seem to be more frequent in women and rare in young children. The vaccine is commercially available or can be obtained through health departments.

Globally diverse anti-rabies vaccines are used. After Pasteur's research in the 19th century with increasingly virulent strains, the first licensed vaccine (1911) was inactivated and grown on bovine brain tissue. Subsequent vaccines were grown using duck or chick embryo cells but remained allergenic. Recent increasingly purified vaccines were grown on verocells, and a sixth-generation verocell rabies vaccine (VRVg) is under development. In some countries, the full spectrum of vaccines, from human diploid rabies (HDRV) to chromatographically purified rabies vaccine (CPRV) are available, whereas in others, the gamut is smaller and intradermal application of smaller vaccine doses at multiple sites and at different times is commonly practiced in an attempt to lower costs, and is deemed safe and effective by the World Health Organization.

In patients with history of past vaccination, the need for HRIG is eliminated (RIG is in short supply worldwide) but postexposure vaccination is still required. The vaccine should be given 1 mL in the deltoid twice (on days 0 and 3). Neither the passive nor the active form of postexposure prophylaxis is associated with fetal abnormalities and thus pregnancy is not considered a contraindication to vaccination.

C. Preexposure Immunization

Preexposure prophylaxis with three injections of HDCV intramuscularly (1 mL on days 0, 7, and 21 or 28) is recommended for persons at high risk for exposure: veterinarians (who should have rabies antibody titers checked every 2 years and be boosted with 1 mL intramuscularly or 0.1 mL intradermally if seronegative); animal handlers; lab-

oratory workers; Peace Corps workers; and travelers with stays over 1 month to remote areas in endemic countries in Africa, Asia, and Latin America. An intradermal route is also available. Intradermal preexposure prophylaxis (0.1 mL on days 0, 7, and 21 over the deltoid) is not available in the United States. Immunosuppressive illnesses and agents including corticosteroids as well as antimalarials—in particular chloroquine—may diminish the antibody response.

► Treatment

Management requires intensive care with attention to the airway, maintenance of oxygenation, and control of seizures. Universal precautions are essential. The induction of coma by ketamine, midazolam, and supplemental barbiturates along with the use of amantadine and ribavirin, was reportedly helpful in one case but has failed to reproduce success in two subsequent cases. Corticosteroids are of no use.

► Prognosis

If postexposure prophylaxis is given expeditiously, before clinical signs develop, it is nearly 100% successful in prevention of disease. Once the symptoms have appeared, death almost inevitably occurs after 7 days, usually from respiratory failure. Most deaths occur in persons with unrecognized disease who do not seek medical care or in individuals who do not receive postexposure prophylaxis.

► When to Refer

Suspicion of rabies requires contact with public health personnel to initiate appropriate passive and active prophylaxis and observation of suspect cases.

► When to Admit

- Respiratory, neuromuscular, or CNS dysfunction consistent with rabies.
- Patients with suspect rabies require initiation of therapy until the disease is ruled out in suspect animals, and this requires coordination of care based on likelihood of patient compliance, availability of inpatient and outpatient facilities, and response of local public health teams.

2. Arbovirus Encephalitides

ESSENTIALS OF DIAGNOSIS

- Fever, malaise, stiff neck, sore throat, and nausea and vomiting, progressing to stupor, coma, and convulsions.

- Signs of an upper motor neuron lesion (exaggerated deep tendon reflexes, absent superficial reflexes, pathologic reflexes, and spastic paralysis).
- Cerebrospinal fluid protein and opening pressure often increased, with lymphocytic pleocytosis.

► General Considerations

The arboviruses are arthropod-borne pathogens that produce clinical manifestations in humans. The **mosquito-borne pathogens** that cause encephalitis include three togaviruses (causing Western, Eastern, and Venezuelan equine encephalitis), five flaviviruses (causing West Nile fever, St. Louis encephalitis, Japanese B encephalitis, dengue, and Murray Valley encephalitis), and bunyaviruses (the California serogroup of viruses, including the Lacrosse agent of California encephalitis). The **tick-borne** causes of encephalitis include the flavivirus of the Powassan encephalitis (northeastern United States and Canada) and tick-borne encephalitis virus of Europe; and the Colorado tick fever reovirus. Tick-borne encephalitis virus, Colorado tick fever, and the arboviruses associated with viral hemorrhagic fever (including dengue) are discussed below, and only those viruses causing primarily encephalitis in the United States will be discussed here.

Infection with West Nile virus was first identified in the United States in the New York City area in 1999. The virus spread rapidly, and current cases are reported throughout the continental United States. The homeless appear to be at increased risk for infection. In 2008, 1370 cases of WNV infection were reported to the CDC with more than half of them occurring in four states: California (411), Arizona (109), Mississippi (99), and Colorado (95). The highest incidences (> 100 per million population), however, were reported from Midwestern states (North Dakota, South Dakota, Nebraska, and Kansas).

Pathogen-specific reservoirs (typically small mammals or birds) are responsible for maintaining the encephalitis-producing viruses in nature. Birds are the main reservoir for West Nile virus and substantial avian mortality accompanies West Nile fever outbreaks. Outbreaks tend to occur in late summer and early fall. Real-time data at the county-level for sentinel cases (animal and human) of this infection in the United States can be found at <http://diseasemaps.usgs.gov/>.

Only dengue and Venezuelan equine encephalitis viruses produce viremias high enough to allow continued transmission to other mosquitoes and ticks. Human to human transmission of the other arboviruses are usually related to blood transfusion or organ transplantation. West Nile virus perinatal, transplacental, breast-feeding (rarely), laboratory, and possibly aerosol transmission can also occur. It is estimated that fever develops in 1 of 5 patients infected with West Nile virus, while severe neurologic disease presents in 1 of 150. St. Louis encephalitis and Powassan encephalitis occur among adults; Western equine encephalitis, Venezuelan equine encephalitis, and California encephalitis occur primarily among children, while West Nile fever and Eastern equine encephalitis are diseases of both children and adults.

► Clinical Findings

A. Symptoms and Signs

The human incubation period for arboviral encephalitides is 2–14 days. Symptoms include fever, malaise, sore throat, headache, gastrointestinal upset, lethargy, and stupor progressing to coma. A nonpruritic maculopapular rash is variably present. Stiff neck and mental status changes are the most common neurologic signs. About 50% of hospitalized patients with West Nile virus infection in the United States have significant muscle weakness that may be initially confused with the Guillain–Barré syndrome. Acute flaccid (poliomyelitis-like) paralysis is seen in 10% of West Nile virus neuroinvasive disease and less commonly with the other arboviruses. Other signs include tremors, seizures, cranial nerve palsies, and pathologic reflexes. Myocarditis and hearing loss are also reported. The disease manifestations associated with West Nile virus infection are strongly age-dependent: the acute febrile syndrome and mild neurologic symptoms are more common in the young, aseptic meningitis and poliomyelitis-like syndromes are seen in the middle aged, and frank encephalopathy is seen in the elderly.

B. Laboratory Findings

The peripheral white blood cell count is variable. Cerebrospinal fluid protein is elevated; cerebrospinal fluid glucose is normal; there is usually a lymphocytic pleocytosis; and polymorphonuclear cells may predominate early. The diagnosis of arboviral encephalitides depends on serologic tests. Antibodies to arboviruses persist for life and the presence of IgG in the absence of a rising titer of IgM may indicate past exposure rather than acute infection. Documentation of a four-fold increase in acute/convalescence titers IgG or the presence of IgM antibodies is confirmatory. For West Nile virus, an IgM capture ELISA in serum or cerebrospinal fluid is almost always positive by the time the disease is clinically evident, and the presence of IgM in cerebrospinal fluid indicates neuroinvasive disease. These tests are commercially available but also obtainable through local or state health departments. Serologic tests specific for other arboviral encephalitides can be obtained through the CDC (<http://www.cdc.gov/ncidod/dvbid/misc/specimen-submission.htm>). Cross-reactivity exists among the different flaviviruses, so a plaque reduction assay may be needed to definitively distinguish between West Nile fever and St. Louis encephalitis. PCR assays (also available through the CDC) are less sensitive than serologic tests for the diagnosis of acute infections but are the preferred method for screening blood products and may be particularly useful in immunocompromised patients with abnormal antibody responses. CT scans of the brain usually show no acute disease, but MRI may reveal leptomeningeal, basal ganglia, thalamic, or periventricular enhancement.

► Differential Diagnosis

Mild forms of encephalitis must be differentiated from aseptic meningitis, lymphocytic choriomeningitis, and non-paralytic poliomyelitis.

Severe forms of arbovirus encephalitides (Table 32–2) are to be differentiated from other causes of viral encephalitis (HSV, mumps virus, poliovirus or other enteroviruses, HIV), encephalitis accompanying exanthematous diseases of childhood (measles, varicella, infectious mononucleosis, rubella), encephalitis following vaccination (a demyelinating type following rabies, measles, pertussis), toxic encephalitis (from drugs, poisons, or bacterial toxins such as *Shigella dysenteriae* type 1), Reye syndrome, and severe forms of stroke, brain tumors, brain abscess, autoimmune processes such as lupus cerebritis, and intoxications. In the California Encephalitis Project, the cause for most cases of encephalitis was not identified.

► Complications

Bronchial pneumonia, urinary retention and infection, prolonged weakness, and decubitus ulcers may occur. St. Louis encephalitis is reportedly associated with a postinfectious encephalomyelitis.

► Prevention

No human vaccine is currently available for the arboviruses prevalent in North America, although yellow fever virus-based chimeric vaccines and recombinant vaccines are under development for West Nile virus. Mosquito control (repellents, protective clothing, and insecticides) is effective in prevention. Since 2003, all blood donations in the United States are screened with nucleic acid amplification tests for West Nile virus. Laboratory precautions are indicated for handling all these pathogens, in particular the West Nile virus.

A vaccine against Japanese B encephalitis is recommended for travelers to rural areas of East Asia, though the risk of disease acquisition among the exposed is estimated at only 1:1,000,000. This vaccination appears to provide some protection against West Nile virus (both agents are related flaviviruses).

► Treatment

Although specific antiviral therapy is not available for most causative entities, vigorous supportive measures can be helpful. Such measures include reduction of intracranial pressure (mannitol) and monitoring of intraventricular pressure. The efficacy of corticosteroids in these infections is not established. Preliminary evidence that ribavirin was useful in West Nile virus encephalitis is not substantiated. Other therapeutic options such as IVIG or interferon- α await confirmation of effectiveness.

► Prognosis

Although most infections are mild or asymptomatic, the prognosis is always guarded, especially at the extremes of age. Homozygosity for a 32bp deletion in the gene coding for the chemokine receptor CCR5, associated with complete loss of function, predisposes to symptomatic West Nile virus infection. People with this mutation are resistant to HIV infection. The case fatality rate for West Nile virus neuroinvasive disease in the United States was 5.8% in 2008. Age

older than 50 years is the most important risk factor for severe disease and death. Other risk factors for mortality include black race, chronic kidney disease, hepatitis C virus infection, and immunosuppression. Recovery of persons with severe neurologic compromise may take months. Sequelae of West Nile virus infection include a poliomyelitis-like syndrome, cognitive complaints, movement disorders, epilepsy, and depression; and they may become apparent late in the course of what appears to be a successful recovery. The prognosis is generally better for Western equine than for Eastern equine or St. Louis encephalitis.

3. Lymphocytic Choriomeningitis

ESSENTIALS OF DIAGNOSIS

- ▶ “Influenza-like” prodrome of fever, chills, malaise, and cough, followed by meningitis with associated stiff neck.
- ▶ Aseptic meningitis with positive Kernig sign, headache, nausea, vomiting, and lethargy.
- ▶ Cerebrospinal fluid: slight increase of protein, lymphocytic pleocytosis (500–3000/mcL); low glucose in 25% of patients.
- ▶ Complement-fixing antibodies within 2 weeks.

▶ General Considerations

The lymphocytic choriomeningitis virus is an arenavirus (related to the pathogen causing Lassa fever, discussed below) that causes infection of the CNS. The main reservoir for lymphocytic choriomeningitis virus is the house mouse. Other rodents (such as rats, guinea pigs, and even pet hamsters), monkeys, dogs, and swine are also potential reservoirs. Lymphocytic choriomeningitis virus is shed by the infected animal via nasal secretions, urine, and feces; transmission to humans probably occurs through aerosolized particles, direct contact, or animal bites. Human cases are most common in autumn. The virus is typically not spread person to person, though vertical transmission occurs, and lymphocytic choriomeningitis virus is an underrecognized neuroteratogen. Rare cases related to solid organ transplantation and autopsies of infected individuals are reported. Outbreaks tend to occur among persons with rodent exposure (eg, in the laboratory setting). Complications of clinical disease are rare.

This disease is principally confined to the eastern seaboard and northeastern states of the United States. Serologic evidence of past infection is present in 5% of adults in some urban areas of those regions and is higher in women, the elderly, and members of lower socioeconomic groups.

▶ Clinical Findings

A. Symptoms and Signs

The incubation period is 8–13 days to the appearance of systemic manifestations and 15–21 days to the appearance of meningeal symptoms. Symptoms are biphasic, with a prodromal illness characterized by fever, chills, headache, myalgia, cough, and vomiting, occasionally with lymphadenopathy and maculopapular rash. After 3–5 days, the fever subsides and recurs in 2–4 days with the meningeal phase, characterized by headache, nausea and vomiting, lethargy, and variably present meningeal signs. Obstructive hydrocephalus is a rare complication. Arthralgias can develop late.

Chorioretinitis also appears to be a sequela. Occasionally, a syndrome resembling the viral hemorrhagic fevers (see below) is described in transplant recipients of infected organs and in patients with lymphoma.

B. Laboratory Findings

Leukocytosis or leukopenia and thrombocytopenia may be present. Cerebrospinal fluid lymphocytic pleocytosis (total count is often 500–3000/mcL) may occur, with a slight increase in protein and normal to low glucose in at least 25%. The virus may be recovered from the blood and cerebrospinal fluid by mouse inoculation. Complement-fixing antibodies appear during or after the second week. Detection of specific IgM by ELISA is becoming widely used. Detection of lymphocytic choriomeningitis virus by PCR is available in research settings.

▶ Differential Diagnosis

The influenza-like prodrome and latent period may distinguish this from other aseptic meningitides, and bacterial and granulomatous meningitis. A history of exposure to mice or other potential vectors is an important diagnostic clue.

▶ Prevention

Pregnant women should be advised of the dangers to their unborn children inherent in exposure to rodents.

▶ Treatment

Treatment is supportive. In the survivor of a transplant-associated outbreak, ribavirin (which is effective against other arenaviruses) was used successfully along with decreasing immunosuppression.

▶ Prognosis

Fatalities are rare. The illness usually lasts 1–2 weeks, though convalescence may be prolonged. Congenital infection is more severe with about 30% mortality rate among

infected infants, and more than 90% of survivors suffering long-term neurologic abnormalities.

4. Prion Diseases

ESSENTIALS OF DIAGNOSIS

- ▶ Rare in humans.
- ▶ Cognitive decline.
- ▶ Myoclonic fasciculations, ataxia, visual disturbances, pyramidal and extrapyramidal symptoms.
- ▶ Variant disease in younger people with prominent psychiatric or sensory symptoms.
- ▶ Specific EEG patterns.

▶ General Considerations

Several non-treatable neurodegenerative diseases are caused by communicable pathogens that contain protein but apparently lack nucleic acid as they are resistant to most procedures that modify it. They are called “prions” for proteinaceous infectious particles. These agents show slow replicative capacity and long latent intervals in the host. They induce the conformational change of a normal brain protein (prion protein; PrP^C) into an abnormal isoform (PrP^{Sc}) that accumulates and causes neuronal vacuolation (spongiosis), reactive proliferation of astrocytes and microglia and, in some cases, amyloid plaques. The term “transmissible spongiform encephalopathies” (TSE) refers to the spongiform appearance of the brain tissue observed in these conditions. A variety of animal diseases exhibit characteristics of TSE but those affecting humans include **classic Creutzfeldt–Jakob disease (cCJD)** and its **variant form (vCJD)**, **kuru**, **Gerstmann–Sträussler–Scheinker syndrome (GSS)**, and **fatal familial insomnia (FFI)**. Infectious transmission of disease has only been described for vCJD, kuru and the iatrogenic form of cCJD (see below), whereas genetically determined mutations of PrP^C are the cause for the remainder. **Kuru** (characterized by cerebellar ataxia, tremors, dysarthria and emotional lability) was once prevalent in central New Guinea but now rare since the abandonment of cannibalism in the late 1950s. **FFI** occurs in kindreds (rarely sporadic) and **GSS** (ataxia and dysarthria, progressing to dementia and spastic paraparesis) is extremely rare. Only cCJD and vCJD will be further discussed here.

There are three forms cCJD: sporadic (80–85%), familial (15%), and iatrogenic (< 1%). There are no definitive risk factors for cCJD, and its annual incidence is about 1 in

one million people per year. Familial cases are inherited in an autosomal dominant pattern with variable penetrance.

vCJD probably results from ingestion of beefsteak contaminated with neural tissue (brain, spinal cord) from livestock infected with **bovine spongiform encephalopathy (BSE)** (“mad cow disease”). A genetic variation in codon 129 of the PrP^C is highly prevalent in those patients affected. Since the first documented cases in Great Britain in the mid 1990s, more than 200 cases of vCJD have been reported with most cases reported from the United Kingdom. Only three cases of vCJD to date were reported in the United States (the last one in 2005), and all had documented former residence in the United Kingdom or Saudi Arabia. As of January 2009, only three cases of BSE were documented in the United States (from Washington, Texas, and Alabama), the last one in 2006. Canada in turn, has reported 15 cases to date, the last three in 2008. The risk for vCJD associated with the ingestion of beef products in these countries, thus, is very small. There is no animal-to-animal spread of BSE and milk and its derived products are not infected. Transmission through blood transfusions is documented in the United Kingdom.

▶ Clinical Findings

A. Symptoms and Signs

The sporadic and familial cases of cCJD usually present in the sixth or seventh decade of life, whereas the iatrogenic form tends to occur in much younger patients. The typical clinical picture is dementia that progresses over several months, myoclonic fasciculations, ataxia, visual disturbances, pyramidal or extrapyramidal symptoms (or both), and akinetic mutism. vCJD, in contrast, usually affects younger people, the duration of disease is longer, and the clinical symptoms are unique (prominent psychiatric and sensory symptoms).

B. Laboratory Findings

The diagnosis of CJD should be considered in the proper clinical setting and in the absence of alternative diagnoses after routine investigations. Abnormalities in cerebrospinal fluid are subtle and rarely helpful. The detection of 14-3-3 protein in the cerebrospinal fluid is supportive of the diagnosis of cCJD but is not helpful in vCJD. Cerebrospinal fluid detection of other proteins like tau and neuron-specific enolase do not as yet show clinical utility. EEG typically shows a pattern of paroxysms with high voltages and slow waves in cCJD, and the MRI is characteristic for bilateral areas of increased signal intensity, predominantly in the caudate and putamen. vCJD, in contrast, shows diffusely abnormal but not diagnostic EEGs; and the MRI characteristically reveals hyperintensity of the posterior thalamus (“pulvinar sign”). The differentiation and definitive diagnosis of these diseases are ultimately established by neuropathologic confirmation.

▶ Treatment & Prevention

There is no specific treatment for CJD and once symptoms appear, the infection invariably leads to death. Flupirtine

(an analgesic drug) may slow cognitive decline but does not affect survival.

Iatrogenic vCJD can be prevented by limiting patient exposure to potentially infectious sources, which include human cadaveric growth hormones, gonadotrophins, corneal grafts, and dural grafts, and by restricting unnecessary exposure to stereotactic electroencephalography electrodes. Disinfection of equipment requires autoclaving at 15 psi for 1 hour, and disinfection of contaminated surfaces requires 5% hypochlorite or 0.1 N sodium hydroxide solution. Prevention of vCJD relies on surveillance of potentially infected livestock.

5. Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is a rare demyelinating CNS disorder caused by the reactivation of JC virus (JCV; a polyomavirus). JCV infects children and has a reported seropositivity in adults of greater than 60%. The virus stays latent in the kidneys and lymphoid organs until reactivation. PML mainly occurs in adults with impaired cell-mediated immunity, especially AIDS patients but also in those with lymphoproliferative and myeloproliferative disorders, granulomatous, inflammatory and rheumatic diseases, solid and hematopoietic cell transplantation. Use of natalizumab, an anti-integrin monoclonal antibody used in multiple sclerosis and inflammatory bowel disease is associated with a reported incidence of PML of 1:1000 after 18 months of therapy. Case reports also implicate rituximab use. JCV causes lytic infection of oligodendocytes in the white matter and the symptoms presenting subacutely reflect the diverse areas of CNS involvement. Symptoms include altered mental status, aphasia, ataxia, hemiparesis or hemiplegia and visual field disturbances. Seizures occur in about 18%. Involvement of cranial nerves and cervical spine is rare.

PCR for JCV in cerebrospinal fluid is used for diagnosis in patients with compatible clinical and radiologic findings. MRI of the brain shows multifocal areas of white matter demyelination with no mass effect nor contrast enhancement. HAART for HIV improves survival as well as the clinical and radiographic features, although a small number of cases appear to worsen with immune restoration. Immune reconstitution syndromes do not alter mortality but are associated with a distinct form of PML called non-determined leukoencephalopathy associated with a distinct chemokine polymorphism. Significant neurologic sequelae to PML infections are the rule.

Decreasing immunosuppression in non-AIDS patients with PML (eg, transplant patients) is typically beneficial. Cidofovir may be beneficial in non-AIDS related cases;

corticosteroids may be useful with immune reconstitution. Anecdotal responses to risperidone and mirtazapine are reported (The JC virus infects cells through serotonin receptors). Future reports will assess the role of small inhibitory RNAs.

6. Human T Cell Lymphotropic Virus (HTLV)

HTLV-1 and -2 are retroviruses. HTLV-1 is endemic to many regions in the world including the Caribbean, southern Japan (where more than 10% of the population is infected), sub-Saharan Africa, Latin America, Eastern Europe, Oceania, and the southeastern United States (where seroprevalence is most common among injection drug users). The virus is transmitted horizontally (sex), vertically (intrauterine, peripartum, and breast-feeding), and parenterally (injection drug use and blood transfusion).

The association of HTLV-1 with adult T cell lymphoma/leukemia (ATL) is well established. The lifetime risk of developing ATL among seropositive persons is estimated to be 3% in women and 7% in men, with an incubation period of at least 15 years. The mean age of diagnosis of ATL is 40–50 years in Central and South America but 60 years in Japan.

ATL clinical syndromes may be classified as chronic, acute (leukemic), smoldering, or lymphomatous. Presentation as a primary cutaneous tumor is also described and has a prognosis worse than the smoldering type. Clinical features of ATL include diffuse lymphadenopathy, maculopapular skin lesions that may evolve into erythroderma, organomegaly, lytic bone lesions, and hypercalcemia. Opportunistic infections, such as *Pneumocystis jiroveci* pneumonia and cryptococcal meningitis, are more common. HTLV seropositivity is associated with an increased risk of tuberculosis. The identification of HTLV-1 antibodies supports the diagnosis. The peripheral smear can show atypical lymphoid cells with basophilic cytoplasm and convoluted nuclei (flower cells) but the diagnostic standard is evidence of clonal integration of the proviral DNA genome into tumor cell. Management of ATL is similar to that for non-Hodgkin lymphoma. The use of interferon- α , zidovudine, monoclonal antibodies or protein inhibitors is under evaluation.

HTLV-1 also causes HTLV-associated myelopathy (HAM; tropical spastic paraparesis). HAM develops in 0.3–4% of seropositive individuals and is more common in

women. A chronic inflammation of the spinal cord leads to progressive motor weakness and symmetric spastic paraparesis or paraplegia with hyperreflexia. Bladder and sexual disorders, sensory disturbances, and constipation are also common.

HTLV-1 provirus load in peripheral blood mononuclear cells and in cerebrospinal fluid cells, and HTLV-1 mRNA load have all been proposed as markers of HAM risk and progression. HTLV positivity is associated with erythrocytosis and lymphocytosis (HTLV-II) and with thrombocytosis (HTLV-I and -II).

HAM is treated with a variety of immune-modulating agents (including corticosteroids) without consistent results. Combination of antiretrovirals does not show benefit. Interferon- α may be of some efficacy.

Patients infected with HTLV-1 show a risk of *Strongyloides stercoralis* hyperinfection. Other associations are with tuberculosis, crusted scabies, and infective dermatitis. Inflammatory states associated with HTLV-1 infection include arthropathy, polymyositis, uveitis, Sjögren syndrome, vasculitis, cryoglobulinemia, infiltrative pneumonitis, and ichthyosis.

HTLV-2 is no longer considered associated with hairy cell leukemia. HTLV-2 seropositivity is common in injection drug users. HTLV-2 causes a myelopathy that is milder and slower to progress than HAM.

HTLV-1/HIV coinfection is associated both with higher CD4 counts and a higher risk of HAM.

Screening of the blood supply for HTLV-1 is required in the United States. There is significant cross-reactivity between HTLV-1 and HTLV-2 by serologic studies, but PCR can distinguish the two.

OTHER SYSTEMIC VIRAL DISEASES

1. Hemorrhagic Fevers

This diverse group of illnesses results from infection with one of several single-stranded RNA viruses (members of the families Arenaviridae, Bunyaviridae, Filoviridae, and Flaviviridae). Flaviviruses, such as the pathogens causing dengue and yellow fever (both with occasional hemorrhagic complications), are discussed in the following sections.

Modes of transmission are diverse. Lassa fever (an Old World arenavirus) is rodent associated and transmission usually occurs through aerosolized particles (from rodents or infected individuals) although contagion through direct contact with infected biologic fluids or tissues is also documented. Similar modes of transmission are assumed for Junin hemorrhagic fever and other diseases due to New World Arenaviridae. Ebola fever and Marburg fever (outbreaks in the Democratic Republic of Congo from 1998 to 2000 and in Angola from 2004 to 2005) are due to filoviruses with unknown vectors. Bats are the suspected reser-

voir for Ebola and Marburg viruses, and infection with the latter is associated with mining in the Congo. The bunyaviruses include the tick-borne Crimean-Congo hemorrhagic fever, the mosquito-borne Rift Valley fever (cause of a major outbreak in Saudi Arabia in 2000–2001 involving over 800 persons), and the hantaviruses (associated with rodent exposure and discussed separately below). Hospital-associated transmission of Crimean-Congo hemorrhagic fever is well documented in Iran.

Clinical Findings

A. Symptoms and Signs

The incubation period can be as short as 2 days for the Rift Valley fever or as long as 21 days for Lassa fever. The clinical symptoms in the early phase of a viral hemorrhagic fever are very similar, irrespective of the causative virus, and resemble a flu-like illness or gastroenteritis. Hepatitis is common.

The late phase is more specific and is characterized by organ failure, persistent leukopenia, altered mental status, and hemorrhage. Exanthemas and mucosal lesions can occur. Adrenal dysfunction is a common sequela and a cause for the development of the late-stage shock associated with these infections. The case-fatality rate ranges from 5% to 30% and may be as high as 90% in Ebola fever. The convalescence period can be long and complicated. There is no evidence of chronic infection among survivors.

B. Laboratory Findings

Laboratory features usually include thrombocytopenia, leukopenia, (although with Lassa fever leukocytosis is noted), anemia, increased hematocrit, often elevated liver function tests, and findings consistent with disseminated intravascular coagulation (although less prominently in Lassa fever). Urinalysis can reveal proteinuria and hematuria.

Special care should be taken for handling clinical specimens of suspected cases. Laboratory personnel should be warned about the diagnostic suspicion and the CDC must be contacted for guidance (Special Pathogens Branch, 404-639-1115). Diagnosis may be made by growing the virus from blood obtained early in the disease, antigen detection (by ELISA), nucleic acid amplification (PCR techniques), or by demonstration of a significant specific fourfold or greater rise in antibody titer. Detection of Ebola virus antigen in oral fluid samples by ELISA and RT-PCR may be possible; sample collection in this manner will be useful since certain ethnic customs prohibit blood collection. These tests are generally available only through the CDC.

Differential Diagnosis

The differential diagnosis for hemorrhagic fever includes meningococcemia or other septicemias, Rocky Mountain spotted fever, dengue, typhoid fever, and malaria. The likelihood of acquiring hemorrhagic fevers among travelers is low.

Treatment

Patients should be placed in private rooms with standard contact and droplet precautions. Barrier precautions to

prevent contamination of skin or mucous membranes should also be adopted by the caring personnel. Airborne precautions should be considered in patients with significant pulmonary involvement or undergoing procedures that stimulate cough.

Certain arenaviruses (the Lassa pathogen, Junin virus in its viscerotropic phase, Machupo virus) and bunyaviruses (the Congo-Crimean hemorrhagic fever and Rift Valley fever pathogens) respond to oral ribavirin if it is started promptly: 30 mg/kg as loading dose, followed by 16 mg/kg every 6 hours for 4 days and then 8 mg/kg every 8 hours for 3 days. The filoviruses and the flaviviruses do not respond to ribavirin. Live attenuated vaccines are available for Junin hemorrhagic fever and the Rift Valley fever, and they are under study for the Crimean-Congo hemorrhagic fever, Ebola, and Marburg viruses. In addition, recombinant vaccines are under development for most of these pathogens (including the Lassa fever virus but not the Junin hemorrhagic fever virus). Therapeutic interventions that target the hematologic system are either ineffective or only marginally effective.

▶ When to Admit

- Persons with symptoms compatible with those of any hemorrhagic fever and who have traveled from a possible endemic area should be isolated for diagnosis and symptomatic treatment.
- Isolation is particularly important because diseases due to some of these agents, such as Ebola virus, are highly transmissible and carry a mortality rate of 50–90%.

2. Dengue

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure 7–10 days before onset.
- ▶ Sudden onset of high fever, chills, severe myalgias and arthralgias, headache, sore throat, and depression.
- ▶ Biphasic fever curve: initial phase, 3–7 days; remission, few hours to 2 days; second phase, 1–2 days.

- ▶ Biphasic rash: evanescent, then maculopapular, scarlatiniform, morbilliform, or petechial changes from extremities to torso.
- ▶ Leukopenia and thrombocytopenia in the hemorrhagic form.

▶ General Considerations

Dengue is due to a flavivirus transmitted by the bite of the *Aedes* mosquito. It may be caused by one of four serotypes widely distributed globally between the tropics of Capricorn and Cancer. An estimated 50–100 million cases of dengue fever and several hundred thousand cases of dengue hemorrhagic fever occur each year. The incubation period is 3–15 days (usually 7–10 days). When the virus is introduced into susceptible populations, usually by viremic travelers, epidemic attack rates range from 50% to 70%. Dengue is endemic in the lower Rio Grande Valley and adjacent border towns, with 40% of Brownsville, Texas residents showing serologic evidence of past infection and the virus being detected in mosquito larvae among 30% of households.

Severe epidemics of dengue hemorrhagic fever (serotype 3) occurred over the past 20 years in East Africa, Sri Lanka, and Latin America. In general, the more advanced forms of disease (hemorrhagic fever and shock) occur less often in the Americas than in Asia. In 2005, the first outbreak of dengue hemorrhagic fever in the continental United States was documented. The outbreak was binational and involved more than 6000 persons in Brownsville, Texas and Matamoros, Mexico with primarily serotype 2. Dengue is the second most common cause of fever (after malaria) in the traveler returning from developing countries. Nosocomial (via needlesticks or mucocutaneous exposure) and vertical transmission occur rarely.

▶ Clinical Findings

A. Symptoms and Signs

Dengue infection may range from asymptomatic to severe hemorrhagic fever and fatal shock (**dengue shock syndrome**). Dengue fever is usually a nonspecific, self-limited biphasic febrile illness. More than half of infected children are asymptomatic. The illness is more severe and begins more suddenly in adults. After an incubation period of 4–5 days, there is a sudden onset of high fever, chills, and “break bone” aching of the head, back, and extremities accompanied by sore throat, prostration, and malaise. There may be conjunctival redness. Initially, the skin appears flushed or blotched, but 3–4 days after the lysis of the fever, a maculopapular rash, which spares palms and soles, appears in over 50% of cases. As the rash fades, localized clusters of petechiae on the extensor surface of the limbs become apparent. Hepatitis frequently complicates dengue fever.

Dengue hemorrhagic fever usually affects children living in endemic areas and is most likely to occur in secondary infections and in infections with serotype 2. A few days into the illness, signs of hemorrhage such as

ecchymoses, gastrointestinal bleeding, and epistaxis appear. Symptoms found more often among the hemorrhagic fever subset of patients include restlessness, epistaxis, and abdominal pain.

A subset of patients, often with secondary infection, may progress to dengue shock syndrome in which acute fever, hemorrhagic manifestations, and marked capillary leak are prominent; the latter manifests as pleural effusions and ascites, and there is a tendency for shock to develop. While the infection is difficult to distinguish from malaria, yellow fever, or influenza, the rash makes dengue far more likely. Continuous abdominal pain with vomiting, bleeding, a decrease in the level of consciousness, and hypothermia should raise concern about dengue shock syndrome. A history of travel to a dengue-endemic area within 14 days of symptom onset is helpful for diagnosis.

B. Laboratory Findings

Leukopenia is characteristic, and elevated transaminases are found frequently in dengue fever. Thrombocytopenia, increased fibrinolysis, and hemoconcentration occur more often in the hemorrhagic form of the disease. Liver function abnormalities are nearly universal. The nonspecific nature of the illness mandates laboratory verification for diagnosis, usually with IgM and IgG ELISAs after the febrile phase. Virus may be recovered from the blood during the acute phase. PCR or detection of the specific viral protein NS1 by ELISA may be diagnostic during the first few days of infection. Immunohistochemistry for antigen detection in tissue samples can also be used. Chest radiographs in dengue hemorrhagic fever show infiltrates and effusions, which follow the course of laboratory abnormalities.

► Complications

Usual complications include pneumonia; bone marrow failure; hepatitis; iritis, retinal hemorrhages, and maculopathy; orchitis; and oophoritis. Depression and chronic fatigue, occurring more often in older women, are also reported. Neurologic complications, such as encephalitis, Guillain-Barré syndrome, and transverse myelitis, are less common. Bacterial superinfection occurs more commonly with advanced age, higher fever, gastrointestinal bleeding, kidney disease, and altered consciousness.

► Prevention

Available prophylactic measures include control of mosquitoes by screening and insect repellents, particularly during early morning and late afternoon exposures.

Tetravalent live attenuated vaccines and genetically modified chimeric virus vaccines are under study and entering clinical trials.

► Treatment

Treatment entails the appropriate use of volume support (with Ringer lactate in moderately severe shock and colloids in more severe cases), blood products, and pressor agents, and acetaminophen rather than nonsteroidal anti-inflammatory drugs for analgesia. Activities are gradually

restored during prolonged convalescences. Endoscopic therapy is useful in evaluating and managing gastrointestinal hemorrhage, although injection therapy with sclerosing agents is not beneficial in most dengue hemorrhagic states. Platelet counts do not usefully predict clinically significant bleeding. Platelet transfusions, however, should be considered for severe thrombocytopenia (< 10,000/mL) or when there is evidence of bleeding. Monitoring for hemoconcentration may help in anticipating the complications of dengue hemorrhagic fever or shock syndrome.

► Prognosis

Fatalities are rare but do occur, especially during epidemic outbreaks, with occasional patients dying of fulminant hepatitis. Convalescence for most patients is slow.

3. Hantaviruses

Hantaviruses are rodent-borne enveloped RNA bunyaviruses with several distinct serotypes. These differ in rodent hosts, geographic distribution, and degree of pathogenicity for humans. They cause two major clinical syndromes: **hemorrhagic fever** (discussed above) and the **hantavirus pulmonary syndrome** (HPS). Each year, over 150,000 cases of these two syndromes occur globally, with HPS being far less common. Aerosols of virus-contaminated rodent urine and perhaps feces are thought to be the main vehicle for transmission to humans. The ubiquity of hantaviruses is recognized, with descriptions of infections from North and South America (New World hantaviruses) and additional infections from Europe and Asia (Old World hantaviruses). The Hantaan serotype viruses cause severe hemorrhagic fever with renal syndrome and are found primarily in Korea, China, and eastern Russia. The Seoul viruses produce a less severe form and are found primarily in Korea and China. The Puumala and Dobrava viruses are found in Scandinavia and Europe and are associated with a milder form of the syndrome, nephropathia epidemica, which usually presents with fever, headache, gastrointestinal symptoms, and impaired kidney function.

The Sin Nombre (Muerto Canyon, Four Corners) virus is the most common hantavirus infection in the United States and is the chief North American virus responsible for HPS; it is usually seen in the southwestern United States. Between 1993 and 2006, 438 cases were reported in 32 states in an area roughly coterminous with the distribution of plague. Outbreaks of HPS with other hantavirus types are

also reported from Central and South America. HPS (the mean incubation period for which is 18 days) begins as a nonspecific febrile illness followed by a severe increase in pulmonary vascular permeability associated with a CD8 immune response, leading to respiratory failure, and rapid progression to a shock-like state. Laboratory features include thrombocytopenia, hemoconcentration, leukocytosis (with abnormal lymphocytes and immature myeloid cells), and elevated lactate dehydrogenase and transaminases. Clinical similarities, including a propensity toward kidney involvement exist between the New World hantaviruses and their Old World counterparts.

Diagnosis can be made serologically, with most patients having both IgM and IgG antibodies at the time of presentation; by immunohistochemical staining; or by PCR amplification of viral tissue DNA (the agents may be isolated from blood or saliva). A viral load assay correlates with severity of disease among patients with HPS caused by the Sin Nombre virus.

Treatment is mainly supportive. Intravenous ribavirin has been used with some success in hemorrhagic fever with renal syndrome (Hantaan virus), but studies in HPS suggest it is not effective. Cardiorespiratory support with pressors and sometimes extracorporeal membrane oxygenation may be considered. Because infection is thought to occur by inhalation of rodent wastes, prevention is aimed at eradication of rodents in houses and avoidance of exposure to rodent excreta in rural settings, including forest service facilities.

Jonsson CB et al. Treatment of hantavirus pulmonary syndrome. *Antiviral Res*. 2008 Apr;78(1):162–9. [PMID: 18093668]

4. Yellow Fever

ESSENTIALS OF DIAGNOSIS

- ▶ Endemic area exposure (tropical South and Central America, Africa, but not Asia).
- ▶ Sudden onset of severe headache, aching in legs, and tachycardia.
- ▶ Brief (1 day) remission, followed by bradycardia, hypotension, jaundice, hemorrhagic tendency.
- ▶ Proteinuria, leukopenia, bilirubinemia, bilirubinuria.
- ▶ Rare and potentially fatal reactions to vaccination.

▶ General Considerations

Yellow fever is a zoonotic flavivirus infection transmitted by *Aedes* and jungle mosquitoes. It occurs in an urban and

jungle cycle in Africa and in a jungle cycle in South America (where genetic studies suggest it arose through the slave trade 300–400 years ago). Epidemics have extended far into the temperate zone during warm seasons.

The mosquito transmits the infection by first biting an individual having the disease and then biting a susceptible individual after the virus has multiplied within the mosquito's body. The incubation period in humans is 3–6 days. Adults and children are equally susceptible, though attack rates are highest among adult males because of their work habits. Between 5% and 50% of infections are asymptomatic.

▶ Clinical Findings

A. Symptoms and Signs

1. Mild form—Symptoms are malaise, headache, fever, retroorbital pain, nausea, vomiting, and photophobia. Relative bradycardia, conjunctival injection, and facial flushing may be present.

2. Severe form—Severe illness develops in about 15%. Initial symptoms are similar to the mild form, but a brief fever remission lasting hours to a few days is followed by a “period of intoxication” manifested by fever and relative bradycardia (Faget sign), hypotension, jaundice, hemorrhage (gastrointestinal, nasal, oral), and delirium that may progress to coma.

B. Laboratory Findings

Leukopenia occurs, although it may not be present at the onset. Kidney disease with proteinuria is present, sometimes as high as 5–6 g/L, and usually disappears completely with recovery. Levels of liver enzymes and bilirubin can be remarkably abnormal with the levels of aspartate aminotransferase (AST) usually doubling those of alanine aminotransferase (ALT). Prothrombin time may be elevated as well. Serologic diagnosis is primarily by measurement of IgM by capture ELISA during the acute and convalescent phases. Viral culture is possible and has been used in epidemic settings. Rapid test involving PCR protocols and immunoassays of monoclonal antibodies against circulating viral antigens are becoming more widely available.

▶ Differential Diagnosis

It may be difficult to distinguish yellow fever from hepatitis, malaria, leptospirosis, louse-borne relapsing fever, dengue, and other hemorrhagic fevers on clinical evidence alone. Albuminuria is a constant feature in yellow fever patients and its presence helps differentiate yellow fever from other viral hepatitises. Serologic confirmation is often needed.

▶ Prevention

Transmission is prevented through mosquito control. Live virus vaccine is highly effective and should be provided for immunocompetent persons over 9 months of age living in or traveling to endemic areas. Revaccination is recommended every 10 years for persons with continued exposure. Vaccine-induced reactions, including neurotropic

(encephalitis-like syndrome) and viscerotropic (resembling yellow fever) diseases are reported (particularly among patients of 60 years or older and patients with thymic dysfunction; the former should probably not be vaccinated and the latter definitely not be vaccinated). The safety of the vaccine in pregnant patients is not verified, and pregnant women should, if possible, defer travel to endemic areas (see Chapter 30). Eradication is difficult because of the sylvatic cycle (mainly maintained by non-human primates).

► Treatment

No specific antiviral therapy is available. Treatment is directed toward symptomatic relief and management of complications. If not in an endemic area, the patient should be isolated from mosquitoes to prevent transmission, since blood in the acute phase is potentially infectious.

► Prognosis

The mortality rate of the severe form is 20–50%, with death occurring most commonly between the sixth and the tenth days. In survivors, the temperature returns to normal by the seventh or eighth day. The prognosis in any individual case is guarded at the onset, since sudden changes for the worse are common. Intractable hiccups, copious black vomitus, melena, anuria, jaundice, and elevated AST are unfavorable signs. Convalescence is prolonged, including 1–2 weeks of asthenia. Infection confers lifelong immunity to those who recover.

5. Tick-Borne Encephalitis

ESSENTIALS OF DIAGNOSIS

- Flaviviral encephalitis found in Eastern, Central, and occasionally Northern Europe and Asia.
- Transmitted via ticks or ingestion of unpasteurized milk.
- Long-term neurologic sequelae occur in 2–25% of cases.
- Therapy is largely supportive.
- Prevention is based on avoiding tick exposure, pasteurization of milk, and vaccination.

► General Considerations

Tick-borne encephalitis (TBE) is a flaviviral infection caused by TBE virus. This infection is endemic in Russia and in eastern and central Europe, but cases are also well recognized in western Europe, China, and Japan. An estimated 10,000 to 12,000 cases occur each year in parts of Europe and the Baltic, with annual increases thought to be

a function of increased recognition, climatic changes, and personal or social habits. TBE occurs predominantly in the late spring through fall. It is usually a consequence of exposure to infected ticks, although unpasteurized milk from viremic livestock is also a recognized form of transmission. The incubation period is 7–14 days for tick-borne exposures but only 3–4 days for milk ingestion. The principal reservoirs for TBE virus are small rodents; humans are an accidental host. The vectors for most cases are *Ixodes ricinus* (most of Europe, including Turkey, Iran, and the Caucasus) and *Ixodes persulcatus* (in the belt from eastern Europe to China and Japan).

► Clinical Findings

A. Symptoms and Signs

Most cases are subclinical and many resemble a flu-like syndrome. There are two variants of clinical presentation: the Western subtype occurs mainly in the fall and is most severe among the elderly, and the Eastern subtype is more severe among children.

Western subtype disease is biphasic in which after 2–10 days of fever (usually with malaise, headache, and myalgias), a 1–21 day symptom-free interval leads to a second phase with resumed fevers followed by neurologic symptoms. Eastern subtype disease is progressive without an asymptomatic interval. The neurologic manifestations range from febrile headache (accounting for up to 50% of Eastern subtype cases) to aseptic meningitis and encephalitis with or without myelitis (preferentially of the cervical anterior horn) and spinal paralysis (usually flaccid). A myeloradiculitic form can also develop but is less common. Double infection with *Borrelia burgdorferi* (the agent of Lyme disease; transmitted by the same tick vector) may result in a more severe disease. Homozygosity for a 32bp deletion in the gene coding for the chemokine receptor CCR5, producing its complete loss of function, predisposes to severe disease. People with this mutation are, however, naturally resistant to HIV infection and CCR5 is the target of blockage by newer antiretroviral medications (eg, maraviroc and vicriviroc). Mortality in TBE is usually a consequence of brain edema or bulbar involvement.

B. Diagnosis

Leukocytosis and neutrophilia are common. Abnormal cerebrospinal fluid findings include a pleocytosis that may persist for up to 4 months. Neuroimaging shows hyperintense lesions in the thalamus, brainstem, and basal ganglia. TBE virus IgM and IgG are detected by ELISA techniques when neurologic symptoms occur. Cross-reactivity with other flaviviruses or a vaccinated state (see below) may require confirmation by detection of TBE virus-specific antibodies in cerebrospinal fluid. RT-PCR of blood (at earlier stages of the disease) or cerebrospinal fluid can sometimes, if available, assist with the diagnosis.

► Complications

The main sequela of disease is paresis, which occurs in up to 10% of Western and up to 25% of Eastern subtype

disease. Other causes of long-term morbidity include protracted cognitive dysfunction and persistent spinal nerve paralysis. The postencephalitic syndrome, characterized by headache, difficulties concentrating, balance disorders, dysphasia, hearing defects, and chronic fatigue, occurs with both subtypes. A progressive motor neuron disease may occur with the Eastern subtype.

► Differential Diagnosis

The differential diagnosis includes other causes of aseptic meningitis such as enteroviral infections, herpes simplex encephalitis, and a variety of tick-borne pathogens including tularemia, the rickettsial diseases, babesiosis, Lyme disease, poliomyelitis (no longer reported from Eastern Europe) and other flaviviral infections.

► Prevention

There are two inactivated TBE virus vaccines for adults and two vaccines for children licensed in Europe. Their effectiveness is about 99% when properly administered. The initial vaccination schedule requires 1 year with boosters every 3–5 years. Other prevention recommendations include avoidance of tick exposure and pasteurization of milk.

► Treatment

Therapy is largely supportive. Some clinicians believe corticosteroids may be useful, although no controlled clinical trials exist.

 Kindberg E et al. A deletion in the chemokine receptor 5 (CCR5) gene is associated with tickborne encephalitis. *J Infect Dis.* 2008 Jan 15;197(2):266–9. [PMID: 18179389]
 Lindquist L et al. Tick-borne encephalitis. *Lancet.* 2008 May 31;371(9627):1861–71. [PMID: 18514730]

6. Colorado Tick Fever

ESSENTIALS OF DIAGNOSIS

- Onset 1–19 days (average, 4 days) following tick bite.
- Fever, chills, myalgia, headache, prostration.
- Leukopenia, thrombocytopenia.
- Second attack of fever after remission lasting 2–3 days.

► General Considerations

Colorado tick fever is a reportable acute reovirus infection transmitted by *Dermacentor andersoni* bites. The disease is limited to the western United States and Canada and is most prevalent during the tick season (March to November). There is a discrete history of tick bite or exposure in 90% of cases. The virus infects the marrow erythrocyte precursors, leading to viremia lasting the life span of the infected red cells. Blood transfusions can be a vehicle of transmission.

► Clinical Findings

A. Symptoms and Signs

The incubation period is 3–6 days. The onset is usually abrupt with fever (to 38.9–40.6 °C), sometimes with chills. Severe myalgia, headache, photophobia, anorexia, nausea and vomiting, and generalized weakness are prominent. Physical findings are limited to an occasional faint rash. The acute symptoms resolve within a week. The remission is followed in 50% of cases by recurrent fever and a full recrudescence lasting 2–4 days. In an occasional case, there may be three bouts of fever.

The differential diagnosis includes influenza, Rocky Mountain spotted fever, numerous other viral infections and, in the right setting, relapsing fevers.

B. Laboratory Findings

Leukopenia (2000–3000/mcL) with a shift to the left and atypical lymphocytes occurs, reaching a nadir 5–6 days after the onset of illness. Thrombocytopenia may occur. Viremia may be demonstrated by inoculation of blood into mice or by fluorescent antibody staining of the patient's red cells (with adsorbed virus). An RT-PCR assay may be used to detect early viremia. Detection of IgM by capture ELISA or plaque reduction neutralization is possible after 2 weeks from symptom onset and is the most frequently used diagnostic tool.

► Complications

Aseptic meningitis (particularly in children), encephalitis, and hemorrhagic fever occur rarely. Malaise may last weeks to months. Fatalities are very rare. There is one reported case of spontaneous abortion and multiple congenital anomalies associated with Colorado tick fever infection during pregnancy.

► Treatment

No specific treatment is available. Ribavirin has shown efficacy in an animal model. Antipyretics are used, although aspirin should be avoided. Tick-avoidance is the best prevention.

► Prognosis

The disease is usually self-limited and benign.

Romero JR et al. Powassan encephalitis and Colorado tick fever. *Infect Dis Clin North Am.* 2008 Sep;22(3):545–59. [PMID: 18755390]

7. Chikungunya Fever

Chikungunya (“that which bends up” in Bantu) is a flaviviral infection transmitted to humans by *Aedes aegypti* and *Aedes albopictus*. While historically limited to tropical Africa and Asia, a major ongoing outbreak starting in 2004 spread the disease to the Indian subcontinent and to northeastern Italy, with attack rates of around 50% in some regions. Travelers return often viremic from these areas. The endemicity of *A. aegypti* in the Americas and the introduction of

A. albopictus into Europe and the New World raise the concerns of a global extension of the epidemic.

► Clinical Findings

A. Symptoms and Signs

After an incubation period of 1–12 days (average 2–4), there is an abrupt onset of fever; headache; intestinal complaints; myalgias; and arthralgias/arthritis affecting small, large, and axial joints. The simultaneous involvement of more than 10 joints and the presence of tenosynovitis (especially in the wrist) are characteristic. The stooped posture of patients gives the disease its name. Joint symptoms persist for 4 months in 33% and linger for years in about 10%. A centrally distributed pruritic maculopapular rash is reported in 50% of the patients, but it can be bullous with sloughing in children. Facial edema and localized petechiae are reported. Meningoencephalitis is occasional and hemorrhagic fever-like presentation exceptional. Coinfection with other respiratory viruses is common. Death is rare and usually related to underlying comorbidities.

B. Laboratory Findings

Diagnosis is made epidemiologically and clinically. Mild leukopenia occurs as does thrombocytopenia, which is seldom severe. Elevated inflammatory markers do not correlate with the severity of arthritis. Radiographs of affected joints are normal.

Serologic confirmation requires elevated IgM titers or fourfold increases in convalescent IgG levels. RT-PCR and culture techniques (viral isolation in insect or mammalian cell lines or by inoculation of mosquitoes or mice) are seldom available. Suspected cases in the United States should be promptly reported to public health authorities including the CDC Arboviral Diseases Branch, 970-221-6400. The differential includes other tropical febrile diseases, such as malaria or dengue.

Treatment

Treatment is largely supportive with nonsteroidal anti-inflammatory drugs. Chloroquine may be useful for managing refractory arthritis. No vaccine is available, and prevention relies on avoidance of the mosquito vectors. Vertical transmission is documented, but teratogenicity is not established.

COMMON VIRAL RESPIRATORY INFECTIONS

1. Respiratory Syncytial Virus & Other Paramyxoviruses

► General Considerations

Respiratory syncytial virus (RSV) is a paramyxovirus that causes annual outbreaks, in winter and early spring, of

pneumonia, bronchiolitis, and tracheobronchitis, with the majority of cases occurring in the very young. Risk factors include prematurity, low birth weight, younger age (especially younger than 6 months), bronchopulmonary dysplasia, congenital heart disease, later birth order, and day care exposure. Reinfections are common but usually milder. In older children and adults, RSV infection is typically manifested as an upper respiratory tract infection and tracheobronchitis. The virus enters through contact with mucosal surfaces, as the eye or nose. The average incubation period is 5 days. RSV infection in children has been associated with persistence of airway reactivity later in life in some studies.

In immunocompromised patients, such as bone marrow transplant recipients, serious pneumonia can occur and outbreaks with a high mortality rate (> 70%) are reported. RSV infection is also an important illness in elderly and other high-risk adults (eg, those with chronic heart or lung diseases).

Other paramyxoviruses important in human disease include human metapneumovirus and parainfluenza virus. **Human metapneumovirus** is less common and less pathogenic than RSV. It appears to cause bronchiolitis; croup; exacerbation of pneumonia; and pneumonia during the winter and spring among slightly older children and is responsible for lower respiratory tract infections among immunocompromised and elderly adults. **Parainfluenza viruses**, the most common cause of croup, also causes respiratory tract infections in the very young, the elderly, the immunocompromised, and those with chronic illnesses. **Bocavirus** infections are discussed under parvoviruses.

► Clinical Findings

A. Symptoms and Signs

In RSV bronchiolitis, proliferation and necrosis of bronchiolar epithelium develop, producing obstruction from sloughed epithelium and increased mucus secretion. Signs include low-grade fever, tachypnea, and wheezes. Apnea is a common presenting symptom. Hyperinflated lungs, decreased gas exchange, and increased work of breathing are present. In children, RSV is a common cause of acute and recurrent otitis media. RSV-confirmed bronchiolitis in children under age 13 is associated with the development of asthma. RSV pneumonia is a serious condition in the elderly and debilitated patient as well as in the immunocompromised person.

B. Laboratory Findings

A rapid diagnosis of RSV infection is made by viral antigen identification of nasal washings using an ELISA or immunofluorescent assay. Culture of nasopharyngeal or lower respiratory tract secretions remain the standard of diagnosis, although PCR is increasingly used. Coinfection with bacteria is relatively uncommon in industrialized countries. Coinfection with *B pertussis* and other viruses occurs in a subset of patients hospitalized for RSV infection. Detection of parainfluenza virus usually requires culture, but tests for rapid detection of viral antigens with immunofluorescence or ELISA, and PCR techniques are also available. Human metapneumovirus is best diagnosed by PCR.

▶ Treatment

Treatment of RSV consists of supportive care, including hydration, humidification of inspired air, and ventilatory support as needed. Neither bronchodilating agents nor corticosteroids have demonstrated efficacy in bronchiolitis although individual patients with significant bronchospasm or history of asthma might respond to them. Use of nebulized ribavirin might be considered in some high risk and very sick children (eg, immunosuppressed, those with underlying pulmonary or congenital heart conditions, and those with severe respiratory compromise) but the evidence of its efficacy is not well documented and this therapy is expensive and cumbersome. There is no evidence that macrolides are beneficial to infants or children with lower respiratory tract disease caused by RSV.

Ribavirin can also be considered in high-risk adults, such as those with a history of bone marrow transplantation. Pregnant women, including hospital staff, should avoid ribavirin exposure. Therapy with surfactant lacks evidence to make recommendations on its use. Passive immunotherapy has no role in treating acute infections in children. The combination of hyperimmune RSV immunoglobulin G (RSVIG) and ribavirin appears to be beneficial in uncontrolled studies of infected adult bone marrow transplant patients. In the United States, RSVIG is no longer available and has been replaced with palivizumab, a monoclonal RSV antibody. Administration of palivizumab prophylactically (parenterally at 15 mg/kg monthly during the season of high transmission) to infants with high-risk factors, such as congenital heart disease, is well recommended. Future studies may entail the use of small inhibitory RNA molecules and of newer generation monoclonal antibodies, such as motavizumab.

Live attenuated vaccines fail to show significant clinical protection or immunogenicity in adults and their use in infants raises safety concerns. Prevention in hospitals entails rapid diagnosis, handwashing, contact isolation, and perhaps passive immunization. Therapeutic modalities for human metapneumovirus and parainfluenzavirus infections under investigation include ribavirin administration. The use of conjugated pneumococcal vaccination appears to decrease the incidence of concomitant pneumonia associated with viral infections in children in some countries.

2. Influenza

ESSENTIALS OF DIAGNOSIS

- ▶ Cases usually in epidemic pattern.

- ▶ Abrupt onset with fever, chills, malaise, cough, coryza, and myalgias.
- ▶ Aching, fever, and prostration out of proportion to catarrhal symptoms.
- ▶ Leukopenia.

▶ General Considerations

Influenza (an orthomyxovirus) is a highly contagious disease transmitted by the respiratory route. In contrast to RSV and rhinoviruses, transmission occurs primarily by droplet nuclei rather than fomites or large particle aerosols. There are three types of influenza viruses. While type A can infect a variety of mammals (humans, swine, horses, etc) and birds, types B and C almost exclusively infect humans. Type A viruses are further divided into subtypes based on the hemagglutinin (H) and the neuraminidase (N) expressed in their surface. There are 16 subtypes of hemagglutinin and 9 subtypes of neuraminidase. Annual epidemics usually appear in the fall or winter (although sporadic cases occur as summer outbreaks in northern areas such as Alaska); they affect 10–20% of the global population on average each year and are rarely the result of frequent minor antigenic variations of the virus, or antigenic drift, which are more common in influenza A virus. On the other hand, pandemics—associated with higher mortality—appear at longer (3–5 decades) and varying intervals as a consequence of a major genetic reassortment of the virus (antigenic shift) or the mutation of an animal virus that adapts to the human (as with the avian-origin (H5N1) pandemic virus of 1918). Currently, the main circulating influenza viruses are the human-origin A (H1N1) and (H3N2) subtypes, as well as type B. A novel swine-origin influenza A (H1N1) virus of pandemic potential emerged in Mexico in March of 2009 and quickly spread through North America and elsewhere. In addition, a highly pathogenic avian (H5N1) subtype that caused occasional human infections in Asia and Europe over the last decade is still cause of ongoing global concern. The infections with influenza viruses of human origin will be discussed here, whereas those due to avian- and swine-origin viruses will be covered in the next sections.

▶ Clinical Findings

A. Symptoms and Signs

Human-origin influenza viruses of antigenic types A and B produce clinically indistinguishable infections, whereas type C usually causes a minor illness. Typically, the infection has an incubation period is 1–4 days. In unvaccinated persons, typical uncomplicated influenza often begins abruptly. Symptoms include fever, chills, malaise, myalgias, substernal soreness, headache, nasal stuffiness, and occasionally nausea. Fever lasts 1–7 days (usually 3–5). Coryza, nonproductive cough, and sore throat are present. Elderly patients may present with only lassitude and confusion, often without fever or respiratory symptoms. Signs include mild pharyngeal injection, flushed face, and conjunctival redness. Moderate enlargement of the cervical lymph nodes may be observed. The presence of fever (> to

38.2 °C) and cough during influenza season is highly predictive of influenza infection in those older than 4 years of age.

B. Laboratory Findings

Leukopenia is common, but leukocytosis can occur. Proteinuria may be present. The virus may be isolated from throat swabs or nasal washings by inoculation of embryonated eggs or cell cultures. Rapid immunofluorescence assays and enzyme immunoassays for detection of influenza antigens from nasal or throat swabs are becoming widely available; however, their sensitivity is suboptimal (60–80%) and only a few can distinguish between influenza A and B. Nucleic acid (PCR) techniques still remain less accessible. Complement-fixing and hemagglutination-inhibiting antibodies appear during the second week. Microarrays may be used in the future to monitor the spread of pathogenic viral variants.

► Complications

Influenza causes necrosis of the respiratory epithelium, which predisposes to secondary bacterial infections. In turn, bacterial enzymes (eg, proteases, trypsin-like compounds, streptokinase) activate influenza viruses. Frequent complications are acute sinusitis, otitis media, purulent bronchitis, and pneumonia. Children (6–59 months), pregnant women, the elderly (aged 65 years or older), and the chronically ill (including HIV-infected individuals) are at high risk for complications.

Primary viral pneumonia (caused by the influenza virus itself) may occur, particularly in patients with cardiovascular disease and pregnant women and has a high mortality. Secondary bacterial pneumonia due to pneumococci or, less often, staphylococci or *Haemophilus* spp is common. Pericarditis and myocarditis occur infrequently. Rhabdomyolysis is a rare late complication.

Reye syndrome (fatty liver with encephalopathy) is a rare and severe complication of influenza (usually B type) and other viral diseases (eg, varicella), particularly in young children. It consists of rapidly progressive hepatic failure and encephalopathy, and there is a 30% mortality rate. The pathogenesis is unknown, but the syndrome is associated with aspirin use in a variety of viral infections. Hypoglycemia, elevation of serum aminotransferases and blood ammonia, prolonged prothrombin time, and change in mental status all occur within 2–3 weeks after onset of the viral infection. Histologically, the periphery of liver lobules shows striking fatty infiltration and glycogen depletion. Treatment is supportive and directed toward the management of cerebral edema. Other encephalopathic complications of influenza are equally rare and include an acute necrotizing encephalopathy associated with disseminated intravascular coagulation and cytokine storm, with worsening when treated with certain nonsteroidal anti-inflammatory drugs (diclofenac and mefenamic acid), and an acute encephalopathy associated with febrile seizures and the use of theophylline. Influenza infections appear to be an infrequent trigger of Guillain-Barré syndrome.

► Prevention

If no contraindication is present, influenza vaccination in October or November each year is recommended for persons over 50 years of age; children (6 months–18 years of age); nursing home residents; patients of any age with chronic medical problems, including lung or heart disease, active malignancy, diabetes, kidney disease, chronic liver disease, immunodeficiencies (such as HIV infection or organ transplant), hemoglobinopathies, or neurologic conditions that impair the clearance of respiratory secretions; pregnant women; and contacts of these high-risk groups, including health care workers, service personnel, and caretakers of children younger than 2 years (see Chapter 30).

The vaccine is contraindicated in persons with well-substantiated hypersensitivity to chicken eggs (based on dietary history) or other components of the vaccine (skin testing can be performed by an allergist), in persons with Guillain-Barré syndrome, or in persons with an acute febrile illness until symptomatic improvement. Concomitant warfarin or corticosteroid therapy is not a contraindication. Side effects are infrequent and include tenderness, redness, or induration at the site for the trivalent inactivated vaccine (intramuscular); and respiratory symptoms for the live attenuated intranasal vaccine.

Chemoprophylaxis can be considered for certain individuals (see Treatment section for definitions) exposed to an infected patient within 2 weeks after vaccination with the trivalent inactivated vaccine; this does not apply for the intranasal live attenuated vaccine since it confers more rapid protection. Chemoprophylaxis may also be considered for those in whom vaccination is contraindicated or not available. Special circumstances that may also warrant consideration of chemoprophylaxis include outbreaks in long-term care facilities, persons living with or in close contact with high risk unvaccinated individuals (eg, health-care providers), persons with immune deficiencies who might not respond to vaccination, unvaccinated staff during response to an outbreak in a closed institutional setting with residents at high risk, and first responders to epidemic situations. Chemoprophylaxis against influenza A and B is traditionally accomplished with the neuraminidase inhibitors oseltamivir (75 mg/d, oral) and zanamivir (10 mg/d, inhaled) but resistance to the former is increasingly prevalent in H1N1 strains. These agents reduce the attack rate among unvaccinated individuals if begun within 48 hours after exposure. In the United States, the M2 inhibitors amantadine and rimantadine are effective against current human H1N1 strains but not the epidemic H1N1 virus of swine origin (see below). In addition, these drugs are not active against other circulating influenza A viruses (H3N2) or B viruses and hence, their use as first-line agents is limited. Occasionally, chemoprophylaxis may need to be continued for the duration of influenza activity in the community, but cost, compliance, and potential adverse effects should be considered as well.

► Treatment

Many patients with influenza prefer to rest in bed. Analgesics and a cough mixture may be used. Treatment should

be considered for those with a suggestive clinical presentation or with laboratory confirmed influenza and at high risk for developing complications (nursing home residents; patients with chronic pulmonary, cardiovascular, kidney, or liver disease; those with diabetes, active malignancy, immunosuppression, or impairment for managing respiratory secretions), or living with persons at significant risk for them. Maximum benefit is expected with the earliest initiation of therapy. Although the benefit of antiviral therapy after 48 hours of illness is unproven, it should be considered if the patient is hospitalized.

The neuraminidase inhibitors, either inhaled zanamivir (two 5-mg inhalations twice daily for 5 days) or oral oseltamivir (75 mg twice daily for 5 days), are equally effective in the treatment of susceptible strains of influenza. Clinical trials have shown a reduction in the duration of symptoms as well as secondary complications such as otitis, sinusitis, or pneumonia, but not in the rate of hospitalizations or mortality when using these agents. These drugs, when administered early, are effective mainly in high-risk patients over age 12 years. Resistance to neuraminidase inhibitors can occur with prolonged use in immunocompromised patients or in avian (H5N1)-infected patients. High rates (greater than 25%) of oseltamivir resistance in influenza A viruses are reported in surveillance data from several areas of Europe and Africa. In the United States, unfortunately, resistance to oseltamivir is also progressively becoming more prevalent, especially among influenza A (H3N2) strains. No comprehensive data on global emergence of resistance to zanamivir are available. Both oseltamivir and zanamivir appear less effective in treating influenza B than influenza A viruses. Zanamivir is relatively contraindicated among persons with asthma because of the risk of bronchospasm. Transient neuropsychiatric events, occasionally resulting in self-injury and death, have been reported postmarketing for both neuraminidase inhibitors. Patients receiving these drugs should be closely monitored for any unusual behavior, and healthcare professionals should be notified immediately if such signs occur. Ribavirin (unlabeled usage, 1.1 g/d, diluted to 20 mg/mL, delivered as particulate aerosol with oxygen over 12–18 hours a day for 3–7 days [see Table 32–1]) may be effective in severely ill patients with influenza A or B. Amantadine and rimantadine are inactive against influenza A (H3N2) and influenza B, but they can be used for treatment in the United States, in conjunction with neuraminidase inhibitors, when human-origin influenza A (H1N1) is the predominant viral strain in the community.

Antibacterial antibiotics should be reserved for treatment of bacterial complications. Acetaminophen rather than aspirin should be used for fever in children.

▶ Prognosis

The duration of the uncomplicated illness is 1–7 days, and the prognosis is excellent in healthy, nonelderly adults. Purulent bronchitis and bronchiectasis may result in chronic pulmonary disease and fibrosis that persist throughout life. Most fatalities are due to bacterial pneumonia although exacerbations of other diseases processes,

in particular cardiac diseases, occur which contributed to the overall increase in fatalities. Influenza pneumonia has a high mortality rate among pregnant women and persons with a history of rheumatic heart disease. In recent epidemics, the mortality rate has been low except in debilitated individuals.

If the fever persists for more than 4 days with productive cough and white cell count over 10,000/mcL, secondary bacterial infection should be suspected. Pneumococcal pneumonia is the most common such infection, and staphylococcal pneumonia is the most serious.

▶ When to Admit

- Limited availability of supporting services.
- Pneumonia.
- Changes in mental status.

3. Avian Influenza (H5N1)

ESSENTIALS OF DIAGNOSIS

- ▶ Cases to date in humans, mostly from Southeast Asia.
- ▶ Clinically indistinguishable from influenza.
- ▶ Epidemiologic factors assist in diagnosis.
- ▶ Rapid antigen assays are the means of confirming diagnosis.

▶ General Considerations

The normal hosts for avian influenza viruses are aquatic waterfowl. Although avian influenza was first recognized in Italy in 1878, the current outbreak of highly pathogenic influenza A subtype (H5N1) in poultry was recognized in 1997 in Hong Kong and was followed by the first documented human cases. A massive slaughter of poultry was attempted to contain the disease. New outbreaks of H5N1 influenza in poultry emerged, however, in 2003 and now involve more than 65 countries of East and Southeast Asia, Eurasia, Western and Eastern Europe, and Northern Africa. The 387 confirmed human cases as of January 2009 include 245 deaths (from Azerbaijan, Bangladesh,

Cambodia, China, Djibouti, Egypt, Indonesia, Iraq, Lao PDR, Myanmar, Nigeria, Pakistan, Thailand, Turkey, and Vietnam).

Although highly contagious among birds, the transmission of this H5N1 strain from human to human is relatively inefficient and not sustained. The result is only rare cases of person-to-person infection. Occasional transmission to other mammals, including domestic cats and dogs, is also documented.

Most human cases occur after exposure to infected poultry or surfaces contaminated with poultry droppings. Because infection in humans is associated with a mortality rate greater than 50% (over 80% [91 of 113] for Indonesian cases) and the avian H5N1 subtype continues to spread among birds (with many parts of Southeast Asia now considered endemic for the virus), there is worldwide concern that the virus may undergo genetic reassortment or mutation (as with the 1918 strain) and develop greater human-human transmissibility with the potential to produce a global pandemic.

► Clinical Findings

A. Symptoms and Signs

Distinguishing avian influenza from regular influenza is difficult. History of exposure to dead or ill poultry in the prior 10 days, recent travel to Southeast Asia, or contact with known cases should be investigated. The symptoms and signs include predominantly respiratory symptoms (cough and dyspnea), but a variety of other systems may be involved, producing headaches and gastrointestinal complaints in particular. Subclinical disease is relatively rare. With high levels of cytokines being responsible for much of the pathology, prolonged febrile states and generalized malaise are common. Children are preferentially impacted. Most patients die of respiratory failure.

B. Laboratory Findings

Current commercial rapid antigen tests are not optimally sensitive or specific for detection of H5N1 influenza but are still first-line diagnostic tests because of their widespread availability. Diagnostic yield can be improved by earlier collection of samples. More sensitive RT-PCR assays are usually available through state health departments. An initial negative result in the right clinical setting warrants retesting. Throat or lower respiratory swabs may provide higher yield of detection than nasal swabs. When highly pathogenic strains (eg, H5N1) are suspected, extreme care in the handling of these samples must be observed during preliminary testing. Positive samples must then be forwarded to the appropriate public health authorities for further investigations (eg, culture) in laboratories with the adequate level of biosafety (level 3).

► Treatment

Resistance of asian H5N1 influenza strains to amantadine and rimantadine is present in most geographic areas where the virus is found. Reacquisition of sensitivity to

these drugs through genetic reassortment is possible. The current first-line recommendation is to use the neuraminidase inhibitor oseltamivir, 75 mg twice daily for 5 days administered within 48 hours from onset of illness. A higher dose (150 mg twice daily), longer duration, and possible combination therapy with amantadine or rimantadine (in countries where A (H5N1) viruses are likely to be susceptible to adamantanes) may be considered in those patients with pneumonia or progressive disease. Recent evidence of resistance to oseltamivir is reported. Although inhaled zanamivir has proven effective in treating seasonal influenza, no data of its efficacy against H5N1 strains are available. Therapy should still be considered for patients with severe avian influenza disease even after several days of onset. Postexposure prophylaxis with 75 mg of oseltamivir once daily for 7–10 days should be given to household contacts of documented cases. Personnel exposed to those patients should be monitored for symptoms. Careful surveillance of new human cases and prudent stockpiling of medications with establishment of an infrastructure for dissemination are essential modalities of control. Nonpharmacologic means of control include masks; social distancing; quarantine; travel limitations; and infrastructure development, particularly for emergency departments.

One human vaccine against H5N1 influenza is licensed but not yet marketed in the United States. This vaccine does not contain adjuvant and as a result, its immunogenicity is only modest. A vaccine with oil-in-water emulsion-based adjuvant is available in Europe. Several other vaccine candidates are undergoing clinical trials. Conventional tricomponent inactivated influenza vaccines provide only partial protection.

Prevention of exposure to avian influenza strains also includes hygienic practices during handling of poultry products, including handwashing and prevention of cross-contamination, as well as thorough cooking of poultry products (to 70 °C). Nonetheless, the risk of acquiring avian influenza through the consumption of poultry products is still very small.

4. Swine-origin Influenza (H1N1/A/California/04/2009)

ESSENTIALS OF DIAGNOSIS

- ▶ Influenza-like illness with consistent epidemiologic background.
- ▶ Respiratory swab allows local screen and more specific analysis by state public health laboratories.

▶ General Considerations

Because the human influenza virus of avian, human, and swine sources can grow readily in the respiratory tract of pigs, they are considered a “mixing vessel” for gene reassortment between strains. A current outbreak of pandemic swine-origin (H1N1) influenza virus (S-OIV) emerged in Mexico City in March 2009. In the United States, the first cases occurred in metropolitan San Diego and San Antonio, and the outbreak rapidly spread throughout the United States. As of June 1, 2009, cases were also reported from over 40 nations among the five continents. Although referred in the popular press to as “swine flu,” this infection is caused by a new influenza A strain that is a reassortment of swine, avian, and human influenza strains (eg, triple-reassortant); thus, “swine flu” is a misnomer. The WHO guidelines suggest that influenza viruses be named after their viral type (A, B, or C), host (if non-human), place of isolation, isolation number, and year of isolation (separated by slashes). Hence, a more appropriate term to identify this virus is influenza A/California/04/2009, but its utility might be restricted to physicians and scientists.

▶ Clinical Findings

A. Symptoms and Signs

This current strain of S-OIV appears to cause typical influenza symptoms (fever, malaise, myalgias, cough, sore throat, rhinorrhea, shortness of breath) commonly accompanied by gastrointestinal manifestations (especially diarrhea). The disease has an incubation period of 2–9 days and preferentially impacts young adults. This age specificity might reflect previous exposure with related strains in people over the age of 40 years (conferring some degree of cross-protection) but also to some case-ascertainment bias due to more young people being tested as part of outbreaks in schools or the workplace. The infectivity of the new strain appears to be unusually high. Most patients report a relatively mild illness with full recovery. While a number of deaths were reported from early cases in metropolitan Mexico City, S-OIV seems less likely to cause death than other pandemic viruses (ie, 1918 pandemic virus). The mortality rate of S-OIV seems to be similar to seasonal influenza (mortality rate < 0.5%); however, this could change as the pandemic evolves.

B. Laboratory Findings

A respiratory swab for novel S-OIV testing should be taken and placed in a refrigerator (not a freezer). State public

health laboratories can then perform a PCR and subtype testing on identified samples. For current case definitions and guidelines on specimen collecting and processing and for confirmation testing, see www.cdc.gov/h1n1flu/ or contact the local public health department. While waiting for confirmatory results, local laboratories can perform rapid immunofluorescence or enzyme immunoassays that can differentiate between influenza viruses types A and B, but their results should be interpreted with caution due to their limited sensitivity (typically about 60%) and inability to differentiate between human- and swine-origin viruses.

▶ Treatment

Treatment entails using neuraminidase inhibitors (oseltamivir or zanamivir) at standard dosages. The virus is usually resistant to the adamantanes (amantadine or rimantadine). Please see the regular influenza section for side effects and concerns with these medications. At the time of this review, the recommendations on which patients should receive specific antiviral therapy for S-OIV infections are similar to those for seasonal influenza. As additional information becomes available, however, specific recommendations may change. Updated advice can be found at <http://www.cdc.gov/h1n1flu/recommendations.htm>.

▶ Prevention

A polyvalent vaccine is under development, and this vaccine may require that patients at risk take the vaccine (which may be two dosages) plus the standard vaccine (for a total of three dosages). In general, persons with S-OIV infection should be considered potentially infectious from 1 day before to 7 days following illness onset. Children, especially younger ones, may be infectious up to 10 days. Any hospital patient in whom the infection is suspected should be isolated in individual rooms with standard and contact precautions plus eye protection. Strict adherence to hand hygiene with soap and water or an alcohol-based hand sanitizer and immediate removal of gloves and other equipment after contact with respiratory secretions is essential. For procedures likely to generate aerosols (eg, bronchoscopy, elective intubation, suctioning, administering nebulized medications), an airborne infection isolation room (AIIR) can be used, with air exhausted directly outside or recirculated after filtration by a high efficiency particulate air (HEPA) filter. The patient should wear surgical masks to contain secretions when outside a patient room, and healthcare personnel in contact with patients should wear a fit-tested disposable N95 respirator or equivalent (eg, powered air purifying respirator). This latter recommendation differs from that for cases of seasonal influenza because of the undetermined potential transmissibility of this new reassortment virus. Precautions should be maintained until 7 days from symptom onset or until the resolution of symptoms, whichever is longer. Post-exposure prophylaxis should be considered for close contacts of patients (confirmed, probable, or suspected) who are at high risk for complications of influenza (see section on seasonal influenza) as well as for healthcare personnel, public health workers, or first responders who have had a recognized, unprotected close contact exposure to a person

with novel (H1N1) influenza virus infection (confirmed, probable, or suspected) during that person's infectious period. Despite limited data of the safety of neuraminidase inhibitors, the CDC recommends considering postexposure prophylaxis as well in this population. Healthcare professionals should frequently refer to the CDC guidelines for changes in these recommendations (<http://www.cdc.gov/h1n1flu/recommendations.htm>). There are no currently documented or substantiated indications for travel restrictions, culling of animals, or widespread school closures. There is concern that in heavily impacted, dense urban areas (major cities of Asia or Africa, for example) the number of cases may significantly increase in the winter of 2009–2010. Concerned professionals should refer to MMWR or the CDC (www.cdc.gov/h1n1flu/) and WHO websites (<http://www.who.int/csr/disease/swineflu/en/>) for evolving updates about this pandemic.

5. Severe Acute Respiratory Syndrome (SARS)

ESSENTIALS OF DIAGNOSIS

- ▶ Mild, moderate, or severe respiratory illness.
- ▶ Travel to endemic area within 10 days before symptom onset, including mainland China, Hong Kong, Singapore, Taiwan, Vietnam, and Toronto.
- ▶ Persistent fever; dry cough, dyspnea in most.
- ▶ Diagnosis confirmed by antibody testing or isolation of virus.
- ▶ No specific treatment; mortality as high as 10% in clinically diagnosed cases.

▶ General Considerations

SARS is a respiratory syndrome of varying severity but capable of causing death in as many as 10% of clinically established cases. It is caused by an apparently unique coronavirus. The earliest cases were traced to a health care worker in Guangdong Province in China in late 2002, with rapid spread thereafter to Hong Kong, Singapore, Vietnam, Taiwan, and Toronto. The primary mode of transmission appears to be through direct or indirect contact of mucous membranes (eyes, nose, or mouth) with infectious

respiratory droplets or fomites. Epidemiologic data also suggest airborne spread. The use of aerosol-generating procedures (endotracheal intubation, bronchoscopy, nebulization treatments) in hospitals may amplify the transmission of the SARS coronavirus. The virus is shed in stools but the role of fecal–oral transmission is unknown. The natural reservoir appears to be the horseshoe bat (which eats and drops fruits ingested by civets, the earlier presumed reservoir and a likely amplifying host).

The variable distribution of cases throughout Asia and Canada is considered a consequence of spread through travel. The virus is sufficiently virulent that it may be transmitted and acquired by patients during brief stops in airports. As a result, sporadic confirmed and suspected cases have appeared throughout the United States. The 2003 outbreak involved 8096 probable cases in about 28 countries, with 774 fatalities. In 2004, nine cases associated with laboratory and subsequent secondary exposure were reported from Beijing, China. No new cases have been reported since then.

▶ Clinical Findings

A. Symptoms and Signs

SARS is considered an atypical pneumonia that affects persons in all age groups. The CDC recognizes asymptomatic or mild cases, moderate disease, and severe respiratory illness. The incubation period is 2–7 days, and it can be spread to contacts of affected patients for 10 days. The mean time from onset of clinical symptoms to hospital admission is 3–5 days. In all clinical cases, persistent fever is present; chills or rigor (or both), cough, shortness of breath, rales, and rhonchi are the rule. Many patients report headache, myalgias, and sore throat as well. A watery diarrhea occurs in some patients during the course of the illness. Elderly patients may report malaise and delirium, without the typical febrile response. No single symptom or sign is diagnostic or highly suggestive, and the history and physical examination of a patient in whom SARS is suspected are to be interpreted in this context.

B. Laboratory Findings and Imaging

Leukopenia and especially lymphopenia are observed commonly. A low-grade disseminated intravascular coagulation (thrombocytopenia, prolonged activated thromboplastin time, and elevated D-dimer level) is present in many patients. Other abnormalities include modest elevations of ALT and creatine kinase. Arterial oxygen saturation is less than 95% in 80% of affected individuals, and pulmonary infiltrates are noted in all. The roentgenographic pattern is not specific, and severe cases may progress to ARDS, with extensive bilateral consolidation. A high-resolution CT scan is abnormal (ground-glass opacifications or focal consolidation) in 67% of patients with initially normal chest radiographs. Serum serologies, including enzyme immunoassays and fluorescent antibody assays, are available through public health departments at the state level, although seroconversion may not occur until 3 weeks after the onset of symptoms.

The detection rates for the virus using conventional RT-PCR are generally low in the first week of illness. Urine, nasopharyngeal aspirate, and stool specimens are positive in 42%, 68%, and 97%, respectively, on day 14 of illness. Although viral isolation is possible, it is a technically laborious and time-consuming procedure.

► Complications

As with any viral pneumonia, pulmonary decompensation is the most feared problem. ARDS occurs in about 16% patients, and about 20–30% of patients require intubation and mechanical ventilation. Sequelae of intensive care include infection with nosocomial pathogens, tension pneumothorax from ventilation at high peak pressures, and noncardiogenic pulmonary edema.

► Prevention

Health care workers engaged in procedures that involve activities such as intubation, suctioning, and nebulization are at high risk for acquiring the virus. Transmission may occur shortly after the development of symptoms and perhaps before the appearance of fever, cough, and dyspnea. Thus, an increased level of suspicion is critical, and isolation of high-risk patients is essential. Simple hygienic measures (such as handwashing after touching patients, use of appropriate and well-fitted face masks, and early introduction of infection control measures, including quarantine) may help reduce transmission.

Measures enacted for air travelers have included screening for fever and compatible symptoms and quarantining in the home for high-risk exposed persons. Continual reporting of suspected cases is crucial, as is awareness of restrictions on international travel. The most cautious modalities include monitoring for 10 days after the last potential exposure and confinement of recovering patients for a similar interval. The efficacy of facemasks is established for preventing hospital-acquired infections, although the validity for their usage in the community remains unsubstantiated.

► Treatment

Severe cases require intensive support. Although a number of different agents including ribavirin (400–600 mg/d and 4 g/d), lopinavir/ritonavir (400 mg/100 mg), interferon type I, intravenous immunoglobulin, and systemic corticosteroids were used to treat SARS patients during the 2003 epidemic, the treatment efficacy of these therapeutic agents remains inconclusive and further research is needed. Subsequent studies with ribavirin show no activity against the virus *in vitro*, and a retrospective analysis of the epidemic in Toronto suggests worse outcomes in patients who receive the drug.

► Prognosis

The overall mortality rate of identified cases is about 14%. Mortality is age-related, ranging from less than 1% in persons under 24 years of age to greater than 50% in persons over 65 years of age. Poor prognostic factors

include advanced age, chronic hepatitis B infection treated with lamivudine, high initial or high peak lactate dehydrogenase concentration, high neutrophil count on presentation, diabetes mellitus, acute kidney disease, and low counts of CD4 and CD8 on presentation. Many subclinical cases probably go undiagnosed. Seasonality, as with influenza, is not established.

ADENOVIRUS INFECTIONS

Adenoviruses (there are over at least 52 serotypes) produce a variety of clinical syndromes. These infections are usually self-limited or clinically inapparent and most common among infants, young children, and military recruits. Adenoviruses, however, may cause significant morbidity and mortality in immunocompromised persons, such as HIV-infected persons and liver, kidney, and lung and hematopoietic stem cell transplant, cancer chemotherapy, and COPD patients. The incubation period is 4–9 days. Adenoviruses, although a common cause of human disease, also receive particular recognition through their role as vectors in gene therapy.

Clinical syndromes of adenovirus infection, often overlapping, include the following. The common cold (see Chapter 8) is characterized by rhinitis, pharyngitis, and mild malaise without fever. Nonstreptococcal exudative pharyngitis is characterized by fever lasting 2–12 days and accompanied by malaise and myalgia. Conjunctivitis is often present. Lower respiratory tract infection may occur, including bronchiolitis, suggested by cough and rales, or pneumonia (types 3, 4, and 7 commonly cause acute respiratory disease and pneumonia). Adenovirus type 14 is increasingly reported as a cause of severe and sometimes fatal pneumonia in those with chronic lung disease, but it is also seen in healthy young adults. Pharyngoconjunctival fever is manifested by fever and malaise, conjunctivitis (often unilateral), mild pharyngitis, and cervical adenitis. Epidemic keratoconjunctivitis (transmissible person to person) occurs in adults and is manifested by bilateral conjunctival redness, pain, tearing, and an enlarged preauricular lymph node (multiple types may be involved in a single outbreak). Keratitis may lead to subepithelial opacities (especially with types 8, 19, or 37). Acute hemorrhagic cystitis is a disorder of children often associated with adenovirus type 11 and 21. Sexually transmitted genitourinary ulcers and urethritis may be caused by types 2, 8, and 37 in particular. Adenoviruses also cause acute gastroenteritis (types 40 and 41), mesenteric adenitis, acute appendicitis

tis, and intussusception. Rarely, they are associated with encephalitis, acute flaccid paralysis, and pericarditis. Adenovirus is commonly identified in endomyocardial tissue of patients with myocarditis and dilated cardiomyopathy. Risk factors associated with severity of infection include youth, chronic underlying infections, recent transplantation, and serotypes 5 or 21.

Hepatitis (type 5 adenovirus), pneumonia, and hemorrhagic cystitis (types 11 and 34) tend to develop in infected liver, lung, or kidney transplant recipients, respectively. Syndromes that may develop in hematopoietic stem cell transplant patients, include hepatitis, pneumonia, hemorrhagic cystitis, tubulointerstitial nephritis, colitis, and encephalitis.

A rapid diagnostic direct fluorescence assay or enzyme immunoassay may assist with diagnosis and a quantitative real-time rapid-cycle PCR is useful in distinguishing disease from colonization, especially in hematologic cell transplant patients. Viral culture remains the gold standard, but cultures delay the diagnosis.

Treatment is symptomatic. Ribavirin and cidofovir are used in immunocompromised individuals with occasional success, although the latter is attendant with significant renal toxicity, in immunocompromised persons among whom reduced immunosuppression is indicated. Adoptive immunotherapy with transfusion of adenovirus-specific T cells is currently being investigated. Typing of isolates is useful epidemiologically and in distinguishing transmission from endogenous reactivation. Complications of adenovirus pneumonia in children include bronchiolitis obliterans.

Vaccines are not available for general use. Live oral vaccines containing attenuated type 4 and type 7 were used in military personnel, but they have been discontinued.

OTHER EXANTHEMATOUS VIRAL INFECTIONS

1. Parvovirus Infections

Parvovirus B19 infects human erythroid precursor cells. It is quite widespread (by age 15 years about 50% of children have detectable IgG) and its transmission occurs through respiratory secretions and saliva, through the placenta (vertical transmission), and through administration of blood products. The incubation period is 4–14 days. Chronic forms of the infection can occur. **Bocavirus**, another parvovirus, was recently uncovered as a cause of winter acute respiratory disease in children and adults.

▶ Clinical Findings

A. Symptoms and Signs

Parvovirus B19 causes several syndromes and manifests differently in various populations.

1. Children—In children, an exanthematous illness (“fifth disease,” erythema infectiosum) is characterized by a fiery

red “slapped cheek” appearance, circumoral pallor, and a subsequent lacy, maculopapular, evanescent rash on the trunk and limbs. Malaise, headache, and pruritus (especially on the palms and soles) occur. Systemic symptoms and fever are mostly abated by the time of rash appearance.

2. Immunocompromised patients—In immunosuppressed patients, including those with HIV infection or transplanted organs, or with hematologic conditions such as sickle cell disease, transient aplastic crisis and pure red blood cell aplasia may occur. Bone marrow aspirates reveal absence of mature erythroid precursors and characteristic giant pronormoblasts.

3. Adults—A limited nonerosive symmetric polyarthritides that mimics lupus erythematosus and rheumatoid arthritis, preferentially involving the metacarpophalangeal joints of the hands and the wrists and knees, can develop in middle-aged persons (especially women) but can also occur in children. Rashes, especially facial, are less common in adults.

Rare reported presentations include myocarditis with infarction, constrictive pericarditis, hepatitis, pneumonitis, neutropenia, thrombocytopenia, a lupus-like syndrome, glomerulopathy, CNS vasculitis, and a chronic fatigue syndrome. Subclinical infection is documented among patients with sickle cell disease.

In pregnancy, fetal loss and hydrops fetalis are reported sequelae. Pregnant women with a recent exposure or with suggestive symptoms should be tested for the disease and carefully monitored if results are positive.

B. Laboratory Findings

The diagnosis is clinical (Table 32–2) but may be confirmed by an elevated titer of IgM anti-parvovirus antibodies in serum or with PCR in serum or bone marrow. Autoimmune antibodies (antiphospholipid and antineutrophil cytoplasmic antibodies) can be present and are thought to be a consequence of molecular mimicry.

▶ Complications

Uncommon complications include encephalitis, chronic hemolytic anemia, thrombotic thrombocytopenic purpuric syndrome, acute postinfectious glomerulonephritis, and hepatitis.

▶ Treatment

Treatment in healthy persons is symptomatic (nonsteroidal anti-inflammatory drugs are used to treat arthralgias, and transfusions are used to treat transient aplastic crises). In immunosuppressed patients, intravenous immunoglobulin can aid in the reduction of anemia. Intrauterine blood transfusion can be considered in severe fetal anemia.

▶ Prevention & Prognosis

Screening of donated blood could potentially prevent transfusion-related infection. Several nosocomial outbreaks have been documented. In these cases, standard containment guidelines, including handwashing after patient exposure and avoiding contact with pregnant women are paramount.

The prognosis is generally excellent in immunocompetent individuals. In immunosuppressed patients, persistent anemia may require prolonged transfusion dependence. Remission of parvovirus infection in AIDS patients may occur with HAART, though the immune restoration syndrome is also reported.

Christensen A et al. Human bocavirus commonly involved in multiple viral airway infections. *J Clin Virol*. 2008 Jan;41(1):34–7. [PMID: 18069504]

Servey JT et al. Clinical presentations of parvovirus B19 infection. *Am Fam Physician*. 2007 Feb 1;75(3):373–6. [PMID: 17304869]

2. Poxvirus Infections

Among the nine poxviruses causing disease in humans, the following are clinically important.

1. **Variola/vaccinia:** Smallpox (variola) was a highly contagious disease associated with high mortality and disabling sequelae. Its manifestations included severe headache, acute onset of fever, prostration and a rash characterized by the uniform progression from macules to papules to firm, deep seated vesicles or pustules. The synchronous progression in smallpox readily differentiates lesions from those of varicella (see also Chapter 6).

Complications of smallpox included bacterial superinfections (cellulitis and pneumonia), encephalitis, and keratitis with corneal ulcerations a risk factor for blindness. Effective vaccination led to its global elimination by 1979 and routine vaccination stopped in 1985. Despite the recommendation of destroying remaining samples of this virus, significant concern exists for the potential misuse of these repositories in military or terrorist activities. Smallpox should be considered, in concordance with the CDC's Smallpox Response Plan (www.bt.cdc.gov/agent/smallpox/response-plan/index.asp), in any patient with fever and a characteristic rash (see above) for which other etiologies such as herpes infections, drug reactions, erythema multiforme or other infections are unlikely. Such patients should be placed in airborne and contact isolation and the official agency contacted (CDC Emergency Preparedness and Response Branch; 770-488-7100). The Department of Defense and the US Department of Health and Human Services (DHHS) launched military and civilian vaccination programs by January 2003.

The presence of any of the following in the person being vaccinated or in his or her household contacts is a contraindication to vaccination: any form of immunosuppression, eczema or other forms of dermatitis (active or in remission), or allergy to any component of the vaccine. Infants younger than 1 year and pregnant or breastfeeding women should not receive the vaccine.

Adverse reactions to the vaccine include generalized vaccinia; eczema vaccinatum, which is a more serious local or disseminated vesicular rash in patients with preexisting eczema or atopic dermatitis; and progressive vaccinia occurring in immunocompromised persons associated with significant widespread necrosis and a high mortality even after administration of vaccinia immune globulin (VIG). Other adverse reactions are generalized symptoms

(fatigue, headache, muscle aches, and fever, referred as the **acute vaccinia syndrome**), myocarditis, pericarditis, unexpected ischemic cardiac events, postvaccinial encephalitis, and erythema multiforme major. The occurrence of vaccinia-related disease is also described in contacts of vaccinees, including rare cases of sexually transmitted disease. Inoculation of the vaccine in inappropriate sites (eg, eyes) is unfortunately common. Asymptomatic vaccinia viremia can be detected up to 21 days post vaccination and no blood donation should occur during this interval. Cidofovir shows activity against poxviruses and can be considered for treatment of these poxviral conditions.

2. **Molluscum contagiosum** may be transmitted sexually or by other close contact. It is manifested by pearly, raised, umbilicated skin nodules sparing the palms and soles. Keratoconjunctivitis can occur. Marked and persistent lesions in AIDS patients respond readily to combination antiretroviral therapy. Curettage is most effective for limited lesions. Reportedly effective forms of therapy include cathartidin (blisters are a side effect), cimetidine and CO₂ laser therapy combined with natural interferon- β gel, salicylic and glycolic acids, and imiquimod cream (5%). Multiple courses of therapy are often needed.

3. **Orf** (contagious pustular dermatitis, or ecthyma contagiosa) and **paravaccinia** (milker's nodules) are occupational diseases acquired by contact with sheep and cattle, respectively. Orf also occurs among children with ruminant exposures. Orf anecdotally responds to imiquimod.

4. **Monkeypox**, first identified in 1970, is zoonotic in the rain forests of equatorial Africa and presents in humans as a syndrome similar to smallpox. The incubation period is about 12 days, and limited person-to-person spread occurs. African mortality rates vary from 3% to 11% depending on the immune status of the patient. Secondary attack rates appear to be about 10%. The first community-acquired outbreak in the United States of monkeypox occurred in 2003 in Wisconsin and other states of the upper Midwest. The source appeared to be imported Gambian giant rats via consequent exposure of prairie dogs. Other susceptible animals include nonhuman primates, rabbits, and rodents. Confusion with smallpox and varicella occurs; however, lymphadenopathy is a prominent feature of monkeypox infection (seen in up to 90% of unvaccinated persons), and skin lesions of the palms and soles, frequently seen in these poxviruses, are uncommon in varicella infection. Suspected cases should be placed on standard, contact and droplet precautions; and local and state public health officials, and the CDC should be notified for assistance with the confirmation of the diagnosis (electron microscopy, viral culture, ELISA, PCR). Cidofovir is effective against monkeypox, and IVIG can be used in selected cases.

Other general precautions that should be taken are avoidance of contact with prairie dogs and Gambian giant rats (whose illness is manifested by alopecia, rash, and ocular or nasal discharge), appropriate care and isolation of those exposed within 3 prior weeks to such animals, and veterinary examination and investigation of suspect animals through health departments. Vaccinia immunization is effective against monkeypox and is recommended, if no contraindication exists (outlined above), for those involved

in the investigation of the outbreak and for healthcare workers caring for those infected with monkeypox. Post exposure vaccination is also advised for documented contacts of infected persons or animals. US federal agencies currently prohibit the importation of African rodents.

VIRUSES & GASTROENTERITIS

Viruses are responsible for at least 30–40% of cases of infectious diarrhea in the United States. These agents include rotaviruses; caliciviruses, including noroviruses such as Norwalk virus; astroviruses; enteric adenoviruses; and, less often, toroviruses, coronaviruses, picornaviruses, and pestiviruses.

Rotaviruses are the leading worldwide cause of dehydrating gastroenteritis in young children and are associated with significant morbidity and mortality (nearly 600,000 persons die each year in developing countries). Children aged 6 months to 2 years are the most affected. By age 5, virtually every child has been infected with this pathogen. There are **seven groups of rotaviruses** (A–G), but group A strains cause the vast majority of these infections while group B and C strains are limited to outbreaks in more restricted settings. Rotavirus infections follow an endemic pattern, especially in the tropics, although they peak during the winter in temperate regions. The virus is transmitted by fecal-oral route and can be shed in feces for up to 3 weeks in severe infections. In outbreak settings (eg, daycare centers), the virus is ubiquitously found in the environment, and secondary attack rates are between 16% and 30% (including household contacts). The disease is usually mild and self-limiting. A 2- to 3-day prodrome of fever and vomiting is followed by nonbloody diarrhea (up to 10–20 bowel movements per day) lasting for 1–4 days. The method of choice for diagnosis is PCR of the stool. Treatment is symptomatic, with fluid and electrolyte replacement. Local intestinal immunity gives protection against successive infection. Two oral rotavirus vaccines are available in the United States: pentavalent human-bovine reassortment rotavirus vaccine (PRV, RotaTeq; to be given at 2, 4, and 6 months of age) and attenuated human rotavirus vaccine (HRV, Rotarix; to be given at 2 and 4 months of age). Contraindications include allergy to any of the vaccine ingredients, previous allergic reaction to the vaccine, and immunodeficiency.

Noroviruses, such as **Norwalk virus**, are the major cause of epidemic gastroenteritis. They appear to evolve by antigenic drift (similar to influenza). While 90% of young adults show serologic evidence of past infection, no long-lasting

protective immunity develops and reinfections are common. In the United States, noroviruses are responsible for over 90% of reported nonbacterial gastroenteritis outbreaks during cold weather intervals (hence the colloquial name “gastric flu”). Outbreak environments include restaurants, long-term care facilities, hospitals, schools, daycare centers, vacation destinations (including cruise ships), and Middle Eastern military bases deployed abroad. Although transmission is usually fecal–oral, airborne and waterborne transmission are also documented. A short incubation period (24–48 hours), a short symptomatic illness (12–60 hours), a high frequency (> 50%) of vomiting, and absence of bacterial pathogens in stool samples are highly predictive of norovirus gastroenteritis. RT-PCR of stool samples is used for epidemiologic purposes. Treatment is largely symptomatic.

Outbreak control for both rotavirus and norovirus infections include strict adherence to general hygienic measures, cohorting of sick patients, contact precautions for symptomatic hospitalized patients, exclusion from work of symptomatic staff until symptom resolution (or 48–72 h after this for norovirus disease), and proper decontamination procedures.

The presence of antibodies is not associated with protection against reinfection.

ENTEROVIRUSES THAT PRODUCE SEVERAL SYNDROMES

1. Coxsackievirus Infections

Coxsackievirus infections cause several clinical syndromes. As with other enteroviruses, infections are most common during the summer. Two groups, A and B, are defined either serologically or by mouse bioassay. There are more than 50 serotypes.

▶ Clinical Findings

A. Symptoms and Signs

The clinical syndromes associated with coxsackievirus infection may be described briefly as follows.

1. Summer gripe (A and B)—A febrile illness, principally of children, summer gripe usually lasts 1–4 days. Minor symptoms of upper respiratory tract infection are often present.

2. Herpangina (A2–6, 10; B3)—Sudden onset of fever, which may be as high as 40.6 °C, sometimes with febrile convulsions; headache, myalgia, and vomiting; and sore

throat, characterized early by petechiae or papules on the soft palate that become shallow ulcers in about 3 days and then heal. Treatment is symptomatic.

3. Epidemic pleurodynia (Bornholm disease) (B1-5)—Pleuritic pain is prominent, and tenderness, hyperesthesia, and muscle swelling are present over the area of diaphragmatic attachment. Other findings include headache, sore throat, malaise, nausea, and fever. Orchitis and aseptic meningitis occur in less than 10% of patients. Most patients are ill for 4–6 days.

4. Aseptic meningitis (A and B) and other neurologic syndromes—Fever, headache, nausea, vomiting, stiff neck, drowsiness, and cerebrospinal fluid lymphocytosis without chemical abnormalities may occur, and pediatric clusters of group B (especially B5) meningitis are reported. Focal encephalitis and transverse myelitis are reported with coxsackievirus group A. A disseminated encephalitis occurs after group B infection, and acute flaccid paralysis is reported with both coxsackievirus group A and B. Severe neonatal illnesses are reported including encephalomyocarditis.

5. Acute nonspecific pericarditis (B types)—Sudden onset of anterior chest pain, often worse with inspiration and in the supine position, is typical. Fever, myalgia, headache, and pericardial friction rub appear early and these symptoms are often transient. Evidence for pericardial effusion on imaging studies is often present, and the occasional patient has a paradoxical pulse. Electrocardiographic evidence of pericarditis is often present. Relapses may occur.

6. Myocarditis (B1-5)—Heart failure in the neonatal period secondary to in utero myocarditis and over 20% of adult cases of myocarditis and dilated cardiomyopathy are associated with group B (especially B3) infections.

7. Hand, foot, and mouth disease (A5, 10, 16)—This disease is sometimes epidemic and is characterized by stomatitis and a vesicular rash on hands and feet. Enterovirus 71 is also a causative agent.

8. Epidemic conjunctivitis—As with enterovirus 70 (see below), the A24 variant of coxsackievirus is associated with acute epidemic hemorrhagic conjunctivitis in tropical areas with recent outbreaks in southern China and Pakistan.

9. Other syndromes associated with coxsackievirus infections—These include rhabdomyolysis, fulminant neonatal hepatitis (occurs rarely), glomerulopathy (group B infections), and type 1 diabetes mellitus (mainly with group B infections), although definitive causality is not established. A pathogenic role in primary Sjögren syndrome and acute myocardial infarction has also been proposed for group B coxsackievirus infections.

B. Laboratory Findings

Routine laboratory studies show no characteristic abnormalities. Neutralizing antibodies appear during convalescence. The virus may be isolated from throat washings or stools inoculated into suckling mice. Viral culture is expensive, labor demanding, and requires several days for

results. A PCR test for enterovirus RNA is available and, although it cannot identify the serotype, it appears to be useful, particularly in cases of meningitis.

► Treatment & Prognosis

Treatment is symptomatic. With the exception of meningitis, myocarditis, pericarditis, perhaps diabetes, and rare illnesses such as pancreatitis or polio-like syndrome, the syndromes caused by coxsackieviruses are benign and self-limited. Two controlled trials showed a potential clinical benefit with pleconaril for patients with enteroviral meningitis although the compassionate use of this drug has stopped. There are anecdotal reports of success with intravenous immunoglobulin in severe disease.

Brunetti L et al. Treatment of viral myocarditis caused by coxsackievirus B. *Am J Health Syst Pharm.* 2008 Jan 15;65(2):132–7. [PMID: 18192257]

Centers for Disease Control and Prevention (CDC). Increased detections and severe neonatal disease associated with coxsackievirus B1 infection—United States, 2007. *MMWR Morb Mortal Wkly Rep.* 2008 May 23;57(20):553–6. [PMID: 18496504]

2. Echovirus Infections

Echoviruses are enteroviruses that produce several clinical syndromes, particularly in children. Infection is most common during summer. Among reported specimens, death ensues in about 3%. Males younger than 20 years are more commonly infected than other persons.

Over 30 serotypes have been demonstrated and the most common serotypes for disease are types 6, 9, 11, and 30. Most can cause aseptic meningitis, which may be associated with a rubelliform rash. Types 30 and 13 (the latter also associated with meningitis) outbreaks are increasingly reported globally, including five epidemics of the latter in the United States. Transmission is primarily fecal–oral. Handwashing is an effective control measure in outbreaks of aseptic meningitis. Outbreaks related to fecal contamination of water sources, including drinking water and swimming and bathing pools, were reported in the past.

Besides meningitis, other conditions associated with echoviruses range from common respiratory diseases (bronchiolitis occurs often in children) and epidemic diarrhea to myocarditis, a hemorrhagic obstetric syndrome, keratoconjunctivitis, hepatitis with coagulopathy, leukocytoclastic vasculitis, and neonatal as well as adult cases of encephalitis and sepsis, interstitial pneumonitis, hemophagocytic syndromes (in children with cancer), sudden deafness, encephalitis, optic neuritis, uveitis, and septic shock. Echoviruses, and enteroviruses in general, are also a common cause of nonspecific exanthems.

The role of enteroviruses in the development of type 1 diabetes mellitus and in the chronic fatigue syndrome are under study.

As with other enterovirus infections, diagnosis is best established by correlation of clinical, epidemiologic, and laboratory evidence. Cytopathic effects are produced in tissue culture after recovery of virus from throat washings, blood, or cerebrospinal fluid. An enterovirus PCR of the

cerebrospinal fluid can assist in the diagnosis. Fourfold or greater rises in antibody titer signify systemic infection.

Treatment is usually symptomatic, and the prognosis is excellent, though there are reports of mild paralysis after CNS infection. Pleconaril, investigational, appears to be of some use among meningitis patients with more severe disease in shortening the course of illness.

From a public health standpoint, the prevention of fecal-oral contamination and the maintenance of pool hygiene through chlorination and pH control are important.

Jacques J et al. Epidemiological, molecular, and clinical features of enterovirus respiratory infections in French children between 1999 and 2005. *J Clin Microbiol.* 2008 Jan;46(1):206–13. [PMID: 18003804]

3. Enteroviruses 70 & 71

Several clinical syndromes are being described in association with newer enteroviruses. **Enterovirus 70**, a ubiquitous agent first identified in 1969 and responsible for abrupt bilateral eye discharge and subconjunctival hemorrhage with occasional systemic symptoms, is most commonly associated with **acute hemorrhagic conjunctivitis**. **Enterovirus 71** is associated with **hand, foot, and mouth disease** (HFMD) as well as a form of **epidemic encephalitis** associated on occasion with pulmonary edema, and **acute flaccid paralysis**. Because of lower herd immunity, HFMD tends to infect the very young (under age 5) in nonendemic areas. Disease is usually more severe and sequelae more common than with other enteroviruses. The sequelae include central hypoventilation, dysphagia, and limb weakness. An outbreak of enterovirus 71 infections occurred in Colorado between 2003 and 2005.

Diagnosis of both entities is facilitated by the clinical and epidemiologic findings with the isolation of the suspect agent from conjunctival scraping for enterovirus 70 or vesicle swabs, body secretions, or cerebrospinal fluid for enterovirus 71. An IgM capture ELISA is being developed for the latter agent.

Treatment of both entities remains largely symptomatic, though pleconaril (see above) may be of some use. The major complication associated with enterovirus 70 is the rare development of an acute neurologic illness with motor paralysis akin to poliomyelitis. Attention-deficit with hyperactivity occurs in about 20% with confirmed infection.

Household contacts, especially children under 6 months of age, are at particular risk for enterovirus 71 acquisition. A commercial disinfectant, Virkon S, at 1–2% application, appears to reduce infectivity titers. A stage-based supportive treatment for enterovirus 71 infections, recognizing the potential for late onset CNS disease and cardiopulmonary failure is important.

Enterovirus 72 is another term for hepatitis A virus (see Chapter 16).

Gau SS et al. Attention-deficit/hyperactivity-related symptoms among children with enterovirus 71 infection of the central nervous system. *Pediatrics.* 2008 Aug;122(2):e452–8. [PMID: 18606624]

Qiu J. Enterovirus 71 infection: a new threat to global public health? *Lancet Neurol.* 2008 Oct;7(10):868–9. [PMID: 18848307]

4. Human Parechovirus Infection

Four types of parechovirus (a picornavirus first recognized in 2000) were recognized by 2007. They are responsible for otitis, respiratory, and gastrointestinal illness in young children; neonatal sepsis; flaccid paralysis; and cerebral infections, including aseptic meningitis and encephalitis. Severe disease is most often found with the third serotype. Cases are reported from Europe and North America. Disease can also occur in older adults. Treatment at this stage is largely supportive. Reported complications of neonatal cerebral infections include learning disabilities, epilepsy, and cerebral palsy.

RICKETTSIAL DISEASES

TYPHUS GROUP

1. Epidemic Louse-Borne Typhus

ESSENTIALS OF DIAGNOSIS

- ▶ Prodrome of headache, then chills and fever.
- ▶ Severe, intractable headaches, prostration, persisting high fever.
- ▶ Macular rash appearing on the fourth to seventh days on the trunk and in the axillae, spreading to the rest of the body but sparing the face, palms, and soles.
- ▶ Diagnosis confirmed by specific antibodies using complement fixation, microagglutination, or immunofluorescence.

▶ General Considerations

Epidemic louse-borne typhus is due to infection with *Rickettsia prowazekii*, a parasite of the body louse (Table 32–3). Transmission is favored by crowded, unsanitary living conditions, famine, war, or any circumstances that predispose to heavy infestation with lice. When the louse sucks the blood of a person infected with *R. prowazekii*, the organism becomes established in the gut of the louse and grows there. When the louse is transmitted to another person (through contact or clothing) and has a blood meal,

Table 32–3. Rickettsial diseases.

| Disease | Rickettsial Pathogen | Geographic Areas of Prevalence | Insect Vector | Mammalian Reservoir | Travel Association |
|---|---|--|-------------------|--------------------------|--------------------|
| Typhus group | | | | | |
| Epidemic (louse-borne) typhus | <i>Rickettsia prowazekii</i> | South America, Central Africa | Louse | Humans, flying squirrels | Rare |
| Endemic (murine) typhus | <i>Rickettsia typhi</i> | Worldwide; small foci (United States: southeastern gulf coast) | Flea | Rodents | Often |
| Scrub typhus group | | | | | |
| Scrub typhus | <i>Orientia tsutsugamushi</i> | Southeast Asia, Japan, Australia, Western Siberia | Mite ¹ | Rodents | Often |
| Spotted fever group | | | | | |
| Rocky Mountain spotted fever | <i>Rickettsia rickettsii</i> | Western Hemisphere; United States (especially mid-Atlantic coast region) | Tick ¹ | Rodents, dogs | Rare |
| California flea rickettsiosis | <i>Rickettsia felis</i> | Worldwide? | Flea | Cats, opossums | |
| Mediterranean spotted fever, Boutonneuse fever, Kenya tick typhus, South African tick fever, Indian tick typhus | <i>Rickettsia conorii</i> | Africa, India, Mediterranean regions | Tick ¹ | Rodents, dogs | Often |
| Queensland tick typhus | <i>Rickettsia australis</i> | Eastern Australia | Tick ¹ | Rodents, marsupials | Rare |
| Siberian Asian tick typhus | <i>Rickettsia sibirica</i> | Siberia, Mongolia | Tick ¹ | Rodents | Rare |
| African tick bite fever | <i>Rickettsia africae</i> | Rural sub-Saharan Africa, Eastern Caribbean | Tick ¹ | Cattle | Often |
| Rickettsialpox | <i>Rickettsia akari</i> | United States, Korea, former USSR | Mite ¹ | Mice | |
| Other | | | | | |
| Ehrlichiosis and anaplasmosis, human Monocytic | <i>Ehrlichia chaffeensis</i> , <i>Anaplasma equi</i> , <i>Ehrlichia canis</i> | Southeastern United States | Tick ¹ | Dogs | |
| Granulocytic | <i>Anaplasma phagocytophilum</i> , <i>Ehrlichia ewingii</i> | Northeastern United States | Tick ¹ | Rodents, deer, sheep | |
| Q fever | <i>Coxiella burnetii</i> | Worldwide | None ² | Cattle, sheep, goats | |

¹Also serve as arthropod reservoir by maintaining rickettsiae through transovarian transmission.

²Human infection results from inhalation of dust.

it defecates simultaneously, and the infected feces are rubbed into the itching bite wound or mucous membranes. Dry, infectious louse feces may also enter the respiratory tract. Cases can be acquired by travel to pockets of infection (eg, central and northeastern Africa, Central and South America). Recent outbreaks were reported from Peru, Burundi, and Russia. *R. prowazekii* is considered a possible bioterrorist agent.

R. prowazekii can survive in lymphoid tissues after primary infection, and years later, produce recrudescence of disease (Brill-Zinsser disease) without exposure to infected lice. This phenomenon can serve as a point source for future outbreaks.

An extrahuman reservoir of *R. prowazekii* in the United States is flying squirrels. Transmission to humans can occur through their ectoparasites, usually causing atypical mild disease.

► Clinical Findings

A. Symptoms and Signs

(Table 32–2.) Prodromal malaise, cough, headache, backache, arthralgia, and chest pain begin after an incubation period of 10–14 days, followed by an abrupt onset of chills, high fever, and prostration, with flu-like symptoms progressing to delirium and stupor. The headache is severe and the fever is prolonged.

Other findings consist of conjunctivitis, hearing loss from neuropathy of the eighth cranial nerve, flushed facies, rales at the lung bases, and often splenomegaly. A macular rash (that may become confluent) appears first in the axillae and then over the trunk, spreading to the extremities but rarely involving the face, palms, or soles. In severely ill patients, the rash becomes hemorrhagic, and hypotension becomes marked. There may be acute kidney injury, stupor,

and delirium. In spontaneous recovery, improvement begins 13–16 days after onset with a rapid drop of fever.

B. Laboratory Findings

The white blood cell count is variable. Thrombocytopenia, elevated liver enzymes, proteinuria and hematuria commonly occur. Serum obtained 5–12 days after onset of symptoms usually shows specific antibodies for *R prowazekii* antigens as demonstrated by complement fixation, microagglutination, or immunofluorescence. In primary rickettsial infection, early antibodies are IgM; in recrudescence (Brill disease), early antibodies are predominantly IgG. A PCR test is developed, but its availability is limited. *R prowazekii* is differentiated into 7 genotypes.

C. Imaging

Radiographs of the chest may show patchy consolidation.

► Differential Diagnosis

The prodromal symptoms and the early febrile stage are not specific enough to permit diagnosis in nonepidemic situations. The rash is usually sufficiently distinctive for diagnosis, but it may be absent in up to 50% of cases or may be difficult to observe in dark-skinned persons. A variety of other acute febrile diseases should be considered, including typhoid fever, meningococcemia, and measles.

Brill-Zinsser disease (recrudescence epidemic typhus) has a more gradual onset than primary *R prowazekii* infection, fever and rash are of shorter duration, and the disease is milder and rarely fatal.

► Complications

Pneumonia, thromboses, vasculitis with major vessel obstruction and gangrene, circulatory collapse, myocarditis, and uremia may occur.

► Prevention

Prevention consists of louse control with insecticides, particularly by applying chemicals to clothing or treating it with heat, and frequent bathing. A deloused and bathed typhus patient is not infectious. The disease is not transmitted from person to person. Patients are infectious for the lice during the febrile period and perhaps 2–3 days after the fever returns to normal. Infected lice pass rickettsiae in their feces within 2–6 days after the blood meal and can be infectious earlier if crushed. Rickettsiae remain viable in a dead louse for weeks.

No vaccine is currently available for the prevention of *R prowazekii* infection. Past use of crude antigen or inactivated *Rickettsia* provided partial protection but was associated with undesirable toxic reactions and difficulties in standardization. Efforts to identify new candidate antigens through DNA technology are underway.

► Treatment

Treatment consists of either doxycycline (100 mg orally twice daily for adults and children weighing > 45 kg, and

2.2 mg/kg twice daily for children weighing < 45 kg) or chloramphenicol (50–100 mg/kg/d in four divided doses, orally or intravenously; it is the drug of choice in pregnant women) for 4–10 days. In epidemic conditions, a single dose of doxycycline can be effective and is less costly.

► Prognosis

The prognosis depends greatly on the patient's age and immune status. In children under age 10 years, the disease is usually mild. The mortality rate is 10% in the second and third decades but in the past reached 60% in the sixth decade.

Azad AF et al. Pathogenic rickettsiae as bioterrorism agents. *Clin Infect Dis.* 2007 Jul 15;45 (Suppl 1):S52–5. [PMID: 17582570]

 Zhu Y et al. Genotyping *Rickettsia prowazekii* isolates. *Emerg Infect Dis.* 2008 Aug;14(8):1300–2. [PMID: 18680662]

2. Endemic Flea-Borne Typhus (Murine Typhus)

Rickettsia typhi, a ubiquitous pathogen recognized on all continents, is transmitted from rat to rat through the rat flea (Table 32–3). Humans usually acquire the infection in an urban or suburban setting when bitten by an infected flea, which releases infected feces while sucking blood. Rare human cases in the developed world follow travel, usually to Southeast Asia. Seroprevalence to *R typhi* among children in South Texas is reported as high as 14% and among the homeless in Houston about 10%.

Endemic typhus resembles recrudescence epidemic typhus in that it has a gradual onset, less severe symptoms, and a shorter duration of illness than epidemic typhus (7–10 days versus 14–21 days). The presentation is nonspecific, including fever, headache, and chills. Maculopapular rash occurs in around 50% of cases; it is concentrated on the trunk and fades fairly rapidly. Peripheral facial paralysis and splenic infarction are reported to occur. Severe disease with mental confusion and signs of hepatic, cardiac, renal, and pulmonary involvement may develop. Fatalities are uncommon but occur especially in the elderly. Jaundice, bradycardia, and the absence of a headache are correlated with a delayed defervescence (in both epidemic and endemic typhus).

The most common entity in the differential diagnosis is Rocky Mountain spotted fever, usually occurring after a rural exposure and with a different rash (centripetal versus centrifugal for endemic typhus). Serologic confirmation may be necessary for differentiation, with complement-fixing or immunofluorescent antibodies detectable within 15 days after onset, with specific *R typhi* antigens. A fourfold rise in serum antibody titers between the acute and the convalescence phase is diagnostic.

Preventive measures are directed at control of rats and ectoparasites (rat fleas) with insecticides, rat poisons, and rat-proofing of buildings. Antibiotic treatment is the same as for epidemic typhus (see above). Ciprofloxacin (500–

750 mg orally twice a day) is another alternative in pregnant women.

Lai CH et al. Clinical characteristics of acute Q fever, scrub typhus, and murine typhus with delayed defervescence despite doxycycline treatment. *Am J Trop Med Hyg.* 2008 Sep;79(3):441–6. [PMID: 18784240]

Reeves WK et al. Serological evidence of typhus group rickettsia in a homeless population in Houston, Texas. *J Vector Ecol.* 2008 Jun;33(1):205–7. [PMID: 18697325]

3. Scrub Typhus (Tsutsugamushi Fever)

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure to mites in endemic area of Southeast Asia, the western Pacific (including Korea), and Australia.
- ▶ Black eschar at site of the bite, with regional and generalized lymphadenopathy.
- ▶ Conjunctivitis and a short-lived macular rash.
- ▶ Frequent pneumonitis, encephalitis, and cardiac failure.

▶ General Considerations

Scrub typhus is caused by *Orientia tsutsugamushi*, which is principally a parasite of rodents transmitted by mites in the endemic areas listed above (Table 32–3). The mites live on vegetation but complete their maturation cycle by biting humans who come in contact with infested vegetation. Vertical transmission occurs, and blood transfusions may transmit the pathogen as well. Rare occupational transmission via inhalation is documented among laboratory workers. The disease is endemic in Korea; China; Taiwan; Japan; Pakistan; India; Thailand; Malaysia; and Queensland, Australia.

▶ Clinical Findings

A. Symptoms and Signs

After a 1- to 3-week incubation period, malaise, chills, severe headache, and backache develop. At the site of the bite, a papule evolves into a flat black eschar. The regional lymph nodes are enlarged and tender, and there may be generalized adenopathy. Fever rises gradually, and a macular rash appears primarily on the trunk after a week of fever and may be fleeting or may last a week. The patient may become obtunded. During the second or third week, pneumonitis, myocarditis and cardiac failure, encephalitis or meningitis, acute abdominal pain, granulomatous hepatitis, disseminated intravascular coagulation, acute respiratory distress syndrome, or acute kidney disease may develop, although not often. Gastrointestinal symptoms including nausea, vomiting, and diarrhea occur in nearly two-thirds of patients and correspond to the presence of superficial mucosal hemorrhage, multiple erosions, or ulcers in the gastrointestinal tract. An attack confers prolonged immunity against homologous strains and transient immunity against heterologous strains. Heterologous strains produce mild disease if infection occurs within a year after the first episode.

B. Laboratory Findings

Thrombocytopenia and elevation of liver enzymes, bilirubin, and creatinine are common. Serologic testing with immunofluorescence and immunoperoxidase assays or commercial dot-blot ELISA dipstick assays are convenient diagnostic aids, but a conclusive diagnosis requires documentation of a fourfold increase between acute and convalescence titers of antibodies. PCR (from the eschar or blood) may be the most sensitive diagnostic test while culture of the organism (by mouse inoculation) from blood obtained during the first few days of illness is another diagnostic modality. Unfortunately, both tests are of limited availability. A reticulonodular infiltrate is the most common finding on chest radiograph.

▶ Differential Diagnosis

Leptospirosis, typhoid, dengue, malaria, hemorrhagic fevers, and other rickettsial infections should be considered. The headache may mimic trigeminal neuralgia. Scrub typhus is a recognized cause of obscure tropical fevers, especially in children.

▶ Prevention

Repeated application of long-acting miticides can make endemic areas safe. Insect repellents on clothing and skin provide some protection. For short exposure, chemoprophylaxis with doxycycline (200 mg weekly) can prevent the disease but permits infection. No effective vaccines are available.

▶ Treatment & Prognosis

Without treatment, fever subsides spontaneously after 2 weeks, but the mortality rate may be 10–30%. Empiric treatment for 3 days with doxycycline, 100 mg orally twice daily, or for 7 days with chloramphenicol, 25 mg/kg/d orally or intravenously in four divided doses, eliminates most deaths and relapses. Chloramphenicol- and tetracycline-resistant strains have been reported from Southeast Asia, where azithromycin or roxythromycin may become the drug of choice for children, pregnant women, and patients with refractory disease. Rifampin reduces the duration of fever by 1 day when used with doxycycline. HIV infection does not appear to influence the severity of scrub typhus.

SPOTTED FEVERS

1. Rocky Mountain Spotted Fever

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure to tick bite in an endemic area.

- ▶ An influenza-like prodrome followed by chills, fever, severe headache, myalgias, restlessness, and prostration; occasionally, delirium and coma.
- ▶ Red macular rash appears between the second and sixth days of fever, first on the wrists and ankles and then spreading centrally; it may become petechial.
- ▶ Serial serologic examinations by indirect fluorescent antibody (IFA) confirm the diagnosis retrospectively.

▶ General Considerations

Despite its name, most cases of Rocky Mountain spotted fever (RMSF) occur outside the Rocky Mountain area. Passive surveillance data from 1997 to 2002 reported cases of RMSF from each of the contiguous states except Vermont and Maine. More than half (56%) of these cases were from only five states: North Carolina, South Carolina, Tennessee, Oklahoma, and Arkansas. The causative agent, *Rickettsia*, is transmitted to humans by the bite of ticks, including the Rocky Mountain wood tick, *D. andersoni*, in the western United States, and the American dog tick, *Dermacentor variabilis*, in the eastern United States. The brown dog tick, *Rhipicephalus sanguineus*, is a vector in eastern Arizona. In the United States, the estimated annual incidence of RMSF is 2.2 cases per million persons with cases primarily occurring from April through September, and with a higher incidence among children and men.

Other hard ticks transmit the organism in the southern United States and in Central and South America and are responsible for transmitting it among rodents, dogs, porcupines, and other animals.

▶ Clinical Findings

A. Symptoms and Signs

Two to 14 days (mean, 7 days) after the bite of an infectious tick, symptoms begin with fever, chills, headache, nausea and vomiting, myalgias, restlessness, insomnia, and irritability. Cough and pneumonitis may develop. Delirium, lethargy, seizures, stupor, and coma may appear. The face is flushed and the conjunctiva injected (Plate 99). The rash (faint macules that progress to maculopapules and then petechiae) appears between days 2 and 6 of fever, first on the wrists and ankles, spreading centrally to the arms, legs, and trunk for 2–3 days; involvement of the palms and soles is characteristic. About 10% of cases, however, occur without rash or with minimal rash. In some cases there is splenomegaly, hepatomegaly, jaundice, myocarditis (which may mimic an acute coronary syndrome), or uremia. ARDS and necrotizing vasculitis are of greatest concern.

B. Laboratory Findings

Thrombocytopenia, hyponatremia, elevated aminotransferases, and hyperbilirubinemia are common. Cerebrospinal fluid may show hypoglycorrhachia and mild pleocytosis. Disseminated intravascular coagulation is observed in severe cases. Diagnosis during the acute phase of the illness can be made by immunohistologic demonstration of *Rickettsia*

in skin biopsy specimens, but this must be performed as soon as skin lesions become apparent and before antibiotics are started to achieve maximum sensitivity. Isolation of the organism using the shell-vial technique is available in some laboratories but is hazardous.

Serologic studies confirm the diagnosis, but most patients do not mount an antibody response until the second week of illness. The indirect fluorescent antibody test is most commonly used. No PCR technique has been validated for clinical use.

▶ Differential Diagnosis

The diagnosis is challenging. Up to 40% of patients do not recall a tick bite, and initial diagnosis is made clinically. Early symptoms may resemble those of many other infections. The rash may be confused with that of measles, typhoid, and ehrlichiosis, or—most importantly—meningococemia. Blood cultures and examination of cerebrospinal fluid establish the latter.

▶ Prevention

Protective clothing, tick-repellent chemicals, and the removal of ticks at frequent intervals are helpful measures. Prophylactic therapy after a tick bite is not currently recommended.

▶ Treatment & Prognosis

Treatment with doxycycline or, in pregnant women, chloramphenicol at similar doses and duration as for epidemic typhus (see above) is recommended. Patients usually defervesce within 48–72 hours. Therapy should be maintained for at least 3 days after defervescence. Mild cases in low-risk individuals may be observed without treatment.

Although the reported mortality rate in the United States is about 3–5%, it can be as high as 70% in the untreated elderly. Myocarditis is the leading cause of death. Other risk factors for a fatal outcome include very young age, atypical clinical features (absence of headache, no history of tick attachment, gastrointestinal symptoms), underlying chronic diseases, and a delay in initiation of appropriate antibiotic therapy. The usual cause of death is pneumonitis with respiratory or cardiac failure. Sequelae, more common than formerly recognized, may include seizures, encephalopathy, peripheral neuropathy, paraparesis, bowel and bladder incontinence, cerebellar and vestibular dysfunction, hearing loss, and motor deficits.

Cunha BA. Clinical features of Rocky Mountain spotted fever. *Lancet Infect Dis*. 2008 Mar;8(3):143–4. [PMID: 18291332]

2. Rickettsialpox

Rickettsia akari is a parasite of mice, transmitted by mites *Liponyssoides sanguineus* (Table 32–2). Rickettsialpox occurs in humans when crowded conditions and mouse-infested housing allow transmission of the pathogen to

humans. In a free clinic in downtown Los Angeles, California, serologic evidence of infection was detected in 8% of patients. The incubation period is 7–12 days. Onset is sudden, with chills, fever, headache, photophobia, and disseminated aches and pains. The primary lesion is a painless red papule that vesiculates and forms a black eschar. Two to 4 days after onset of symptoms, a widespread papular eruption appears that becomes vesicular and forms crusts that are shed in about 10 days. Early lesions may resemble those of chickenpox (typically vesicular versus papulovesicular in rickettsialpox). Pathologic findings include dermal edema, subepidermal vesicles, and at times a lymphocytic vasculitis.

Transient leukopenia and thrombocytopenia and acute hepatitis can occur. A fourfold rise in serum antibody titers to rickettsial antigen, detected by complement fixation or indirect fluorescent assays, is diagnostic. Conjugated anti-rickettsial globulin can identify antigen in punch biopsies of skin lesions. PCR detection of rickettsial DNA in fresh tissue also appears of value. *R akari* is also reported to be isolable from eschar biopsy specimens.

Treatment includes doxycycline (200 mg/d) for 7 days. The disease is usually mild and self-limited without treatment, but occasionally severe symptoms may require hospitalization. Control requires the elimination of mice from human habitations and insecticide applications to suppress the mite vectors.

Bennett SG et al. Serologic evidence of a *Rickettsia akari*-like infection among wild-caught rodents in Orange County and humans in Los Angeles County, California. *J Vector Ecol.* 2007 Dec;32(2):198–201. [PMID: 18260508]

3. Tick Typhus (Rickettsial Fever)

The term “tick typhus” denotes a variety of spotted rickettsial fevers. They are often named by geography, eg, Mediterranean spotted fever, Queensland tick typhus, Oriental spotted fever, African tick bite fever, Siberian tick typhus, North Asian tick typhus, or by morphology, eg, boutonneuse fever. These illnesses are transmitted by tick vectors of the rickettsial organisms *R conorii*, *R australis*, *R japonica*, *R africae*, and *R sibirica* (Table 32–3). Dogs and wild animals, usually rodents but even reptiles, may serve as reservoirs. Travel is a risk factor for disease, particularly among elderly ecotourists. The pathogens usually produce an eschar or black spot (tâche noire) at the site of the tick bite that may be useful in diagnosis, though spotless boutonneuse fever occurs. Symptoms include fever, headache, myalgias, and rash. Rarely, papulovesicular lesions may resemble rickettsialpox. Endothelial injury produces perivascular edema and dermal necrosis. Regional adenopathy, disseminated lesions, kidney disease, splenic rupture, and focal hepatic necrosis may occur. Diabetes, dehydration, and uremia were risk factors for mortality in one series. The disease occurs among travelers, the most common travel-associated rickettsiosis being African tick bite fever. Diagnosis is clinical, with serologic or PCR confirmation. Prevention entails protective clothing, repellents, and inspection for and removal of ticks. Treatment is with the following drugs given for 7–10 days: doxycycline (200 mg/d), chloramphenicol (50–75 mg/kg/d

in four divided doses), or ciprofloxacin (500 mg twice daily). The combination of erythromycin and rifampin is effective and safe in pregnancy. Delayed therapy is the usual cause of morbidity.

Another rickettsial infection, formerly classified as an endemic or murine typhus, is more properly classified as a spotted fever. The causative agent, *R felis*, is an organism that has been linked to the cat flea and opossum exposures. Most cases in the United States occur in the spring and summer, are reported from southern Texas and California; it also appears to be present in Hawaii. Cases are treated as above.

OTHER RICKETTSIAL & RICKETTSIAL-LIKE DISEASES

1. Ehrlichiosis & Anaplasmosis

ESSENTIALS OF DIAGNOSIS

- ▶ Infection of monocyte or granulocyte by tick-borne gram-negative bacteria.
- ▶ Nine-day incubation period, with variable clinical illness, ranging from asymptomatic to persistent or life-threatening.
- ▶ Common symptoms are malaise, nausea, fever, and headaches.
- ▶ Excellent response to therapy with tetracyclines.

▶ General Considerations

Ehrlichiae and anaplasmae are small tick-borne gram-negative obligate intracellular bacteria that infect monocytes or granulocytes. Human monocytic ehrlichiosis is caused by *Ehrlichia chaffeensis* (Table 32–3). Human granulocytic anaplasmosis is caused by *Anaplasma phagocytophilum*. *Ehrlichia ewingii* (infecting primarily dogs) can rarely cause human granulocytic ehrlichiosis similar to human granulocytic anaplasmosis. Another ehrlichia-like organism, *Neorickettsia sennetsu*, is the etiologic agent of sennetsu fever, which is confined to western Japan.

Human monocytic ehrlichiosis is seen primarily in the Southeast, mid-Atlantic, and South Central states of the United States, though cases are also recognized in Israel, Japan, Mexico, South America, and Europe. Human granulocytic anaplasmosis is more frequent in Northeastern and Midwestern United States; but infections in Europe and China are also well documented. Human infection with *E ewingii* is limited to Missouri, Oklahoma, and Tennessee and occurs mainly among the immunocompromised. In

North America, the major vectors for these pathogens are the Lone Star tick (*Amblyomma americanus* for *E chaffeensis* and *E ewingii*), the western black-legged tick (*Ixodes pacificus*, for *E chaffeensis*), and *Ixodes scapularis* (the same vector for Lyme disease and babesiosis) for *A phagocytophilium*). Reported incidences of both human monocytic and granulocytic ehrlichiosis are about 0.6 and 1.4 per million, respectively, with higher rates in the summer. The highest attack rate is in men over 60 years of age.

The principal reservoirs for human monocytic ehrlichiosis and human granulocytic anaplasmosis are the white tail deer and the white footed mouse, respectively. Other mammals can be implicated as well. A nosocomial outbreak was recently reported from China. Perinatal transmission of human granulocytic anaplasmosis is also documented.

► Clinical Findings

A. Symptoms and Signs

Clinical disease of human monocytic ehrlichiosis ranges from mild to life-threatening. Typically, after about a 9-day incubation period and a prodrome consisting of malaise, rigors, and nausea, worsening fever and headache develop. A pleomorphic rash may occur. The presentation in immunosuppressed patients and the elderly tends to be more severe than in immunocompetent and younger patients. Serious sequelae include acute respiratory failure and ARDS, encephalopathy, and acute kidney disease, which may mimic thrombotic thrombocytopenic purpura.

The symptoms of human granulocytic ehrlichiosis and *E ewingii* infection are similar to those seen with human monocytic ehrlichiosis. Rash, however, is infrequent in human granulocytic ehrlichiosis and should prompt the consideration of other infections (eg, Lyme disease). Persistent fever and malaise are reported to occur for 2 or more years. Coinfection with Lyme disease or babesiosis may occur.

B. Laboratory Findings

Diagnosis can be made by the history of tick exposure followed by a characteristic clinical presentation. Leukopenia, absolute lymphopenia, thrombocytopenia, and transaminitis occur often. Thrombocytopenia occurs more often than leukopenia in human granulocytic ehrlichiosis. Examination of peripheral blood with Giemsa stain may reveal characteristic intraleukocytic vacuoles (morulae). An indirect fluorescent antibody assay is available through the CDC and requires acute and convalescent sera. A PCR assay, if available, is a rapid diagnostic tool, especially for early disease.

► Treatment

Treatment for both forms of ehrlichiosis is with doxycycline, 100 mg twice daily (orally or intravenously) for at least 10 days or until 3 days of defervescence. Rifampin is an alternative in pregnant women and children. Treatment should not be withheld while awaiting confirmatory serol-

ogy when suspicion is high. Lack of clinical improvement and defervescence 48 hours after doxycycline initiation suggests an alternate diagnosis.

2. Q Fever

ESSENTIALS OF DIAGNOSIS

- Exposure to sheep, goats, cattle, or their products is common; some infections are laboratory acquired.
- An acute or chronic febrile illness with severe headache, cough, prostration, and abdominal pain.
- Extensive pneumonitis, hepatitis, or encephalopathy; less often, endocarditis, vascular infections, or chronic fatigue syndrome.
- A common cause of culture-negative endocarditis.

► General Considerations

Q fever (for “query” in view of its formerly unknown cause) is a reportable disease in the United States caused by *Coxiella burnetii*, an organism previously classified as a rickettsia but now considered a proteobacteria. Unlike rickettsiae, *C burnetii* is usually transmitted to humans not by arthropods but by inhalation or ingestion. *Coxiella* infections occur mostly in cattle, sheep, and goats, in which they cause mild or subclinical disease (Table 32–3). In these animals, reactivation of the infection occurs during pregnancy and causes abortions or low birth weight offspring. *Coxiella* is resistant to heat and drying and remains infective in the environment for months. Humans become infected by inhalation of aerosolized bacteria (in dust or droplets) from feces, urine, milk, or products of conception of infected animals. Ingestion and skin penetration are recognized routes of transmission as well. Outbreaks associated with other mammals such as cats and dogs are also described. There is an occupational risk for animal handlers, slaughterhouse workers, veterinarians, laboratory workers, and other workers exposed to animal products. Outbreaks in military personnel returning from Iraq and Afghanistan were recently described. Endocarditis, an uncommon but serious form of *Coxiella* infection, has been linked to preexisting valvular conditions, immunocompromise, urban residence, and raw milk ingestion. Horizontal spread from one human to another does not seem to occur even in the presence of florid pneumonitis, but maternal–fetal infection can occur.

► Clinical Findings

A. Symptoms and Signs

Asymptomatic infection is common. For the remaining cases, a febrile illness develops after an incubation period of 1–3 weeks, usually accompanied by headache, prostration, and muscle pains. The clinical course may be acute, chronic (duration ≥ 6 months), or relapsing. Pneumonia and granulomatous hepatitis are the predominant manifestation in the acute form, whereas other less common manifestations include skin rashes (maculopapular or purpuric), fever of unknown origin, myocarditis, pericarditis, aseptic meningitis, encephalitis, hemolytic anemia, orchitis, acute kidney disease, spondylodiscitis, tenosynovitis, and regional (mediastinal) or diffuse lymphadenopathies. The most common presentation of chronic Q fever is culture-negative endocarditis, which occurs in less than 1% of infected individuals. It is found mainly in the setting of preexisting valve disease. Vascular infections, particularly of the aorta (and potentially causing aneurysms) are the second most common form of Q fever and are associated with a high mortality (25%). A Q fever chronic fatigue syndrome is thought by some experts to involve bacteremic shedding from bone marrow reservoirs and to be immunogenetically determined.

Reactivation of Q fever in pregnant women may cause spontaneous abortions, intrauterine growth retardation, intrauterine fetal death, premature delivery, and oligamnios.

B. Laboratory Findings

Laboratory examination during the acute phase may show elevated liver function tests and occasional leukocytosis. Patients with acute Q fever usually produce antibodies to *C burnetii* phase II antigen. A fourfold rise between acute and convalescent sera by indirect immunofluorescence is diagnostic.

The diagnosis of chronic Q fever is established on the basis of serologic tests done at 3- and 6-month intervals. The IgG titer against phase I antigen is usually 1:200 or greater. In some cases, the diagnosis is not made until the time of valve replacement, with PCR of tissue samples. Isolation of *C burnetii* from affected valves is also possible using the shell-vial technique, but the organism is highly transmissible to laboratory workers and culture techniques should be carried out in biosafety level 3 settings.

C. Imaging

Radiographs of the chest show patchy pulmonary infiltrates, often more prominent than the physical signs would suggest.

► Differential Diagnosis

Viral, mycoplasmal, and bacterial pneumonias, viral hepatitis, brucellosis, tuberculosis, psittacosis, and other animal-borne diseases must be considered. Q fever should be considered in cases of unexplained fevers with negative blood cultures in association with embolic or cardiac disease.

► Prevention

Prevention is based on detection of the infection in live-stock, reduction of contact with infected animals or dusts contaminated by them, special care when working with animal tissues, and effective pasteurization of milk. No Q fever vaccine is approved for use in the United States, although a whole-cell vaccine, with a 5-year efficacy of more than 95%, is available in Australia for persons with high-risk exposures.

C burnetii is category B bioterrorism agent. In the setting of a bioterrorist attack, postexposure prophylaxis should be started 8–12 days after exposure, doxycycline (100 mg orally twice daily) should be taken for 5 days, and a pregnant woman should take trimethoprim-sulfamethoxazole (160 mg/800 mg twice daily) for the duration of the pregnancy.

► Treatment & Prognosis

For acute infection, treatment with doxycycline (100 mg orally twice daily) for 14 days or at least 3 full days after defervescence is recommended. Even in untreated patients, the mortality rate is usually low, except when endocarditis develops.

For the treatment of endocarditis, most experts recommend a combination of oral doxycycline (200 mg/d) plus oral hydroxychloroquine (600 mg/d) for at least 2 years. Serologic responses can be monitored to determine cessation of therapy. Heart valve replacement may be necessary in refractory disease. Given the difficulty in treating endocarditis, transthoracic echocardiography is recommended for all patients with acute Q fever, and the same aforementioned therapy for 1 year should be offered if a valvulopathy is observed.

Because of the many and serious obstetric complications that occur among pregnant women in whom Q fever develops (listed above), a regimen of long-term trimethoprim-sulfamethoxazole (320/1600 mg for at least 5 weeks) should be given to all infected, pregnant women.

KAWASAKI DISEASE

ESSENTIALS OF DIAGNOSIS

- Fever, bilateral conjunctivitis, oral mucosal changes, rash, cervical lymphadenopathy, peripheral extremity changes.
- Elevated erythrocyte sedimentation rate and C-reactive protein levels.

▶ General Considerations

Kawasaki disease is a worldwide multisystemic disease initially described by Tomisaku Kawasaki in 1967. It is also known as the “mucocutaneous lymph node syndrome.” It occurs mainly in children between the ages of 3 months and 5 years but can occur occasionally in adults as well. Kawasaki disease occurs more frequently in Asians or Pacific Islanders but rarely in whites. It is a vasculitis characterized by the infiltration of vessel walls with mononuclear cells and later by IgA secreting plasma cells that can result in the destruction of the media and aneurysm formation. Several infectious agents (New Haven coronavirus, parvovirus, bocavirus, CMV, *Yersinia pseudotuberculosis*), bacterial superantigens, and genetic polymorphisms in components of the immune system have been implicated in its pathogenesis.

▶ Clinical Findings

A clinical diagnosis of “complete” Kawasaki disease requires, in the absence of other processes, explaining the current illness of fever and four of the following criteria for at least 5 days: bilateral nonexudative conjunctivitis, mucous membrane changes of at least one type (injected pharynx, erythema, swelling and fissuring of the lips, strawberry tongue), peripheral extremity changes of at least one type (edema, desquamation, erythema of the palms and soles, induration of the hands and feet, Beau lines [transverse grooves of the nails]), a polymorphous rash, and cervical lymphadenopathy greater than 1.5 cm. An “incomplete” form is diagnosed when only two criteria are met.

A major complication is arteritis of the coronary vessels, occurring in about 25% of untreated patients, on occasion causing myocardial infarction. It is more common among patients over 6 years or below 1 year of age. Noninvasive diagnosis of this complication can be made with magnetic resonance angiography or transthoracic echocardiography. Other factors associated with the development of coronary aneurysms are relentless fever (after the administration of IVIG), high C-reactive protein, anemia, hypoalbuminemia, hyponatremia, thrombocytopenia, and male gender. Pericardial effusions, myocarditis, and mitral regurgitation (usually mild) are also common. Arteritis of extremity vessels, peripheral gangrene, syndrome of inappropriate secretion of antidiuretic hormone (SIADH), and the hemophagocytic syndrome are also reported. Cerebrospinal fluid pleocytosis is found in one-third of cases.

Differentiation from disseminated adenovirus infection is important and can be performed with rapid adenovirus assays.

▶ Treatment

Every patient with a clinical diagnosis of Kawasaki disease (complete or incomplete) should be treated. IVIG (2 g/kg over 10–12 hours) is given within the first 10 days of illness. For those presenting later, but with persistent fever, ongoing systemic inflammation, or aneurysm formation, IVIG should be offered as well. Concomitant aspirin should be started at 80–100 mg/kg/d (divided into four doses and not exceeding 4 g/d) until the patient is afebrile for 48 hours and then reduced to 3–5 mg/kg/d until markers of acute inflammation normalize. Aspirin therapy is continued if coronary aneurysm develops. If fevers persist beyond 36 hours after the initial IVIG infusion, a new dose of 2 g/kg should be given if no other source of fever is found. Methylprednisolone (30 mg/kg/d for a maximum of 3 days) should follow if the disease persists after the second IVIG administration. Further options for refractory cases include TNF- α blockers (eg, infliximab), cyclophosphamide, methotrexate, and plasmapheresis. An echocardiogram is essential in the acute phase of illness and 6–8 weeks after onset. Warfarin is indicated along with low-dose aspirin in patients with aneurysms larger than 8 mm in diameter. If myocardial infarction occurs, therapy with thrombolytics, percutaneous coronary intervention, coronary artery bypass grafts, and even cardiac transplantation should be considered. Manifestation of coronary aneurysms can occur as late as in the third or fourth decade of life and regular follow-up with a cardiologist is recommended for those with coronary complications.

▶ When to Refer

All cases of Kawasaki disease merit referral to specialists.

Bacterial & Chlamydial Infections

Brian S. Schwartz, MD
Henry F. Chambers, MD

33

INFECTIONS CAUSED BY GRAM-POSITIVE BACTERIA

STREPTOCOCCAL INFECTIONS

1. Pharyngitis

ESSENTIALS OF DIAGNOSIS

- ▶ Abrupt onset of sore throat, fever, malaise, nausea, and headache.
- ▶ Throat red and edematous, with or without exudate; cervical nodes tender.
- ▶ Diagnosis confirmed by culture of throat.

▶ General Considerations

Group A β -hemolytic streptococci (*Streptococcus pyogenes*) are the most common bacterial cause of pharyngitis. Transmission occurs by droplets of infected secretions. Group A streptococci producing erythrogenic toxin may cause scarlet fever in susceptible persons.

▶ Clinical Findings

A. Symptoms and Signs

“Strep throat” is characterized by a sudden onset of fever, sore throat, pain on swallowing, tender cervical adenopathy, malaise, and nausea. The pharynx, soft palate, and tonsils are red and edematous. There may be a purulent exudate. The Centor clinical criteria for the diagnosis of streptococcal pharyngitis are temperature $> 38^\circ\text{C}$, tender anterior cervical adenopathy, lack of a cough, and pharyngotonsillar exudate.

The rash of scarlet fever is diffusely erythematous, resembling a sunburn, with superimposed fine red papules, and is most intense in the groin and axillas. It blanches on pressure, may become petechial, and fades in 2–5 days, leaving a fine desquamation. The face is flushed, with circumoral pallor, and the tongue is coated with enlarged red papillae (strawberry tongue).

B. Laboratory Findings

Leukocytosis with neutrophil predominance is common. Throat culture onto a single blood agar plate has a sensitivity of 80–90%. Rapid diagnostic tests based on detection of streptococcal antigen are slightly less sensitive than culture.

▶ Complications

Suppurative complications include sinusitis, otitis media, mastoiditis, peritonsillar abscess, and suppuration of cervical lymph nodes.

Nonsuppurative complications are rheumatic fever and glomerulonephritis. Rheumatic fever may follow recurrent episodes of pharyngitis beginning 1–4 weeks after the onset of symptoms. Glomerulonephritis follows a single infection with a nephritogenic strain of streptococcus group A (eg, types 4, 12, 2, 49, and 60), more commonly on the skin than in the throat, and begins 1–3 weeks after the onset of the infection.

▶ Differential Diagnosis

Streptococcal sore throat resembles (and cannot be reliably distinguished clinically from) pharyngitis caused by adenoviruses, Epstein-Barr virus, *Arcanobacterium haemolyticum* (which also may cause a rash), and other agents. Pharyngitis and lymphadenopathy are common findings in primary HIV infection. Generalized lymphadenopathy, splenomegaly, atypical lymphocytosis, and a positive serologic test distinguish mononucleosis from streptococcal pharyngitis. Diphtheria is characterized by a pseudomembrane; candidiasis shows white patches of exudate and less erythema; and necrotizing ulcerative gingivostomatitis (Vincent fusospirochetal gingivitis or stomatitis) presents with shallow ulcers in the mouth. Retropharyngeal abscess or bacterial epiglottitis should be considered when odynophagia and difficulty in handling secretions are present and when the severity of symptoms is disproportionate to findings on examination of the pharynx.

▶ Treatment

Antimicrobial therapy has a modest effect on resolution of symptoms and primarily is administered for prevention of

complications. Antibiotic therapy can be safely delayed until the diagnosis is established on the basis of a positive antigen test or culture. Empiric therapy usually is not a cost-effective approach to the management of most adults with pharyngitis because in typical clinical settings, the prevalence of streptococcal pharyngitis is likely to be no more than 10–20% and the positive predictive value of clinical criteria is low. Clinical criteria, such as the Centor criteria, are useful for identifying patients in whom a rapid antigen test or throat culture is indicated. Patients who meet two or more of these criteria merit further testing. When three of the four are present, laboratory sensitivity of rapid antigen testing exceeds 90%. When only one criterion is present, streptococcal pharyngitis is unlikely. In high-prevalence settings or if clinical suspicion for streptococcal pharyngitis is high, a negative antigen test or culture should be confirmed by a follow-up culture.

A. Benzathine Penicillin G

Benzathine penicillin G, 1.2 million units intramuscularly as a single dose, is optimal therapy.

B. Penicillin VK

Penicillin VK, 500 mg orally four times a day (or amoxicillin, 750 mg orally twice daily) for 10 days, is effective, but compliance may be poor after the patient becomes asymptomatic in 2–4 days.

C. Cephalosporins

Cefdinir, 300 mg orally twice daily for 5–10 days or 600 mg orally once daily for 10 days, and cefpodoxime, 100 mg orally twice daily for 5–10 days, are both approved by the US Food and Drug Administration (FDA) for the treatment of streptococcal pharyngitis but should be reserved for penicillin-allergic patients able to tolerate cephalosporins.

D. Macrolides

Erythromycin, 500 mg orally four times a day, or azithromycin, 500 mg orally once daily for 3 days, is an alternative for the penicillin-allergic patient. Macrolides are less effective than penicillins and are considered second-line agents. Macrolide-resistant strains almost always are susceptible to clindamycin, a suitable alternative to penicillins; a 10-day course of 300 mg orally twice daily is effective.

► Prevention of Recurrent Rheumatic Fever

Effectively controlling rheumatic fever depends on identification and treatment of primary streptococcal infection and secondary prevention of recurrences. Patients who have had rheumatic fever should be treated with a continuous course of antimicrobial prophylaxis for at least 5 years. Effective regimens are erythromycin, 250 mg orally twice daily, or penicillin G, 500 mg orally daily.

Casey JR et al. The evidence base for cephalosporin superiority over penicillin in streptococcal pharyngitis. *Diagn Microbiol Infect Dis.* 2007 Mar;57(3 Suppl):39S–45S. [PMID: 17292576]

Falagas ME et al. Effectiveness and safety of short-course vs long-course antibiotic therapy for group A beta hemolytic streptococcal tonsillopharyngitis: a meta-analysis of randomized trials. *Mayo Clin Proc.* 2008 Aug;83(8):880–9. [PMID: 18674472]

2. Streptococcal Skin Infections

Group A β -hemolytic streptococci are not normal skin flora. Streptococcal skin infections result from colonization of normal skin by contact with other infected individuals or by preceding streptococcal respiratory infection.

► Clinical Findings

A. Symptoms and Signs

Impetigo is a focal, vesicular, pustular lesion with a thick, amber-colored crust with a “stuck-on” appearance.

Erysipelas is a painful superficial cellulitis that frequently involves the face. It is well demarcated from the surrounding normal skin. It affects skin with impaired lymphatic drainage, such as edematous lower extremities or wounds.

B. Laboratory Findings

Cultures obtained from a wound or pustule are likely to grow group A streptococci. Blood cultures are occasionally positive.

► Treatment

Parenteral antibiotics are indicated for patients with facial erysipelas or evidence of systemic infection. Penicillin, 2 million units intravenously every 4 hours, is the drug of choice. However, staphylococci infections may at times be difficult to differentiate from streptococcal infections. In practice, initial therapy for patients with risk factors for *Staphylococcus aureus* (eg, injection drug use, diabetes, wound infection) should cover this organism. Nafcillin, 1.5 g every 6 hours intravenously, and cefazolin, 1 g intravenously or intramuscularly every 8 hours, are reasonable choices. In the patient at risk for methicillin-resistant *S aureus* infection or with a serious penicillin allergy (ie, anaphylaxis), vancomycin, 1000 mg intravenously every 12 hours, should be used.

Patients who do not require parenteral therapy may be treated with amoxicillin, 750 mg twice daily for 7–10 days. A first-generation oral cephalosporin, eg, cephalexin, 500 mg four times daily, or clindamycin, 300 mg orally three times daily, is an alternative to amoxicillin.

3. Other Group A Streptococcal Infections

Arthritis, pneumonia, empyema, endocarditis, and necrotizing fasciitis are relatively uncommon infections that may be caused by group A streptococci. Toxic shock-like syndrome also occurs.

Arthritis generally occurs in association with cellulitis. In addition to intravenous therapy with penicillin G, 2 million units every 4 hours (or cefazolin or vancomycin in doses recommended above for penicillin-allergic patients),

frequent percutaneous needle aspiration should be performed to remove joint effusions. Open surgical drainage may be necessary when the hip or shoulder is infected.

Pneumonia and empyema often are characterized by extensive tissue destruction and an aggressive, rapidly progressive clinical course associated with significant morbidity and mortality. High-dose penicillin and chest tube drainage are indicated for treatment of empyema. Vancomycin is an acceptable substitute in penicillin-allergic patients.

Group A streptococci can cause **endocarditis**. Endocarditis should be treated with 4 million units of penicillin G intravenously every 4 hours for 4–6 weeks. Vancomycin, 1 g intravenously every 12 hours, is recommended for persons allergic to penicillin.

Necrotizing fasciitis is a rapidly spreading infection involving the fascia of deep muscle. The clinical findings at presentation may be those of severe cellulitis, but the presence of systemic toxicity and severe pain, which may be followed by anesthesia of the involved area due to destruction of nerves as infection advances through the fascial planes, is a clue to the diagnosis. Surgical exploration is mandatory when the diagnosis is suspected. Early and extensive debridement is essential for survival.

Any streptococcal infection—and necrotizing fasciitis in particular—can be associated with **streptococcal toxic shock syndrome**, typified by invasion of skin or soft tissues, acute respiratory distress syndrome, and kidney failure. The very young, the elderly, and those with underlying medical conditions are at particularly high risk for invasive disease. Bacteremia occurs in most cases. Skin rash and desquamation may not be present. Mortality rates can be up to 80%. The syndrome is due to elaboration of pyrogenic erythrotoxin (which also causes **scarlet fever**), a superantigen that stimulates massive release of inflammatory cytokines believed to mediate the shock. A β -lactam remains the drug of choice for treatment of serious streptococcal infections, but clindamycin, which is a potent inhibitor of toxin production, should also be administered at a dose of 600 mg every 8 hours intravenously for invasive disease, especially in the presence of shock. Intravenous immune globulin has also been recommended for streptococcal toxic shock syndrome for presumed, although unproven, therapeutic benefit from specific antibody to streptococcal exotoxins in immune globulin preparations. Two dosage regimens have been used: 450 mg/kg once daily for 5 days or a single dose of 2 g/kg with a repeat dose at 48 hours if the patient remains unstable.

Outbreaks of invasive disease have been associated with colonization by invasive clones that can be transmitted to close contacts who, though asymptomatic, may be a reservoir for disease. Tracing contacts of patients with invasive disease is controversial.

4. Non-Group A Streptococcal Infections

Non-group A hemolytic streptococci (eg, groups B, C, and G) produce a spectrum of disease similar to that of group A streptococci. The treatment of infections caused by these strains is the same as for group A streptococci.

Group B streptococci are an important cause of sepsis, bacteremia, and meningitis in the neonate. Antepartum screening to identify carriers and peripartum antimicrobial prophylaxis are recommended in pregnancy. This organism, part of the normal vaginal flora, may cause septic abortion, endometritis, or peripartum infections and, less commonly, cellulitis, bacteremia, and endocarditis in adults. Treatment of infections caused by group B streptococci is with either penicillin or vancomycin in doses recommended for group A streptococci. Because of in vitro synergism, some experts recommend the addition of low-dose gentamicin, 1 mg/kg every 8 hours.

Viridans streptococci, which are nonhemolytic or α -hemolytic (ie, producing a green zone of hemolysis on blood agar), are part of the normal oral flora. Although these strains may produce focal pyogenic infection, they are most notable as the leading cause of native valve endocarditis (see below).

Group D streptococci include *Streptococcus bovis* and the enterococci. *S bovis* is a cause of endocarditis in association with bowel neoplasia or cirrhosis and is treated like viridans streptococci.

Larsen JW et al. Group B Streptococcus and pregnancy: a review. *Am J Obstet Gynecol*. 2008 Apr;198(4):440–8. [PMID: 18201679]

ENTEROCOCCAL INFECTIONS

Two species, *Enterococcus faecalis* and *Enterococcus faecium*, are responsible for most human enterococcal infections. Enterococci cause wound infections, urinary tract infections, bacteremia, and endocarditis. Infections caused by penicillin-susceptible strains should be treated with penicillin 3–4 million units every 4 hours; ampicillin 3 g every 6 hours; or if the patient is penicillin-allergic, vancomycin 15 mg/kg every 12 hours intravenously. If the patient has endocarditis or meningitis, gentamicin 1 mg/kg every 8 hours intravenously should be added to the regimen in order to achieve the bactericidal activity that is required to cure these infections.

Resistance to vancomycin, penicillin, and gentamicin is common among enterococcal isolates, especially *E faecium*; it is essential to determine antimicrobial susceptibility of isolates. Infection control measures that may be indicated to limit their spread include isolation, barrier precautions, and avoidance of overuse of vancomycin and gentamicin. Consultation with an infectious diseases specialist is strongly advised when treating infections caused by resistant strains of enterococci. Quinupristin/dalfopristin and linezolid are approved by the FDA for treatment of infections caused by vancomycin-resistant strains of enterococci. Quinupristin/dalfopristin is not active against strains of *E faecalis* and should be used only for infections caused by *E faecium*. The dose is 7.5 mg/kg intravenously

every 8–12 hours. Phlebitis and irritation at the infusion site (often requiring a central line) and an arthralgia-myalgia syndrome are relatively common side effects. Linezolid, an oxazolidinone, is active against both *E faecalis* and *E faecium*. The dose is 600 mg twice daily, and both intravenous and oral preparations are available. Its two principal side effects are thrombocytopenia and bone marrow suppression; however, peripheral neuropathy, optic neuritis, and lactic acidosis have been observed with prolonged use due to mitochondrial toxicity. Emergence of resistance has occurred during therapy with either quinupristin/dalfopristin or linezolid.

PNEUMOCOCCAL INFECTIONS

1. Pneumococcal Pneumonia

ESSENTIALS OF DIAGNOSIS

- ▶ Productive cough, fever, rigors, dyspnea, early pleuritic chest pain.
- ▶ Consolidating lobar pneumonia on chest radiograph.
- ▶ Gram-positive diplococci on Gram stain of sputum.

▶ General Considerations

The pneumococcus is the most common cause of community-acquired pyogenic bacterial pneumonia. Alcoholism, asthma, HIV infection, sickle cell disease, splenectomy, and hematologic disorders are predisposing factors. The mortality rate remains high in the setting of advanced age, multilobar disease, severe hypoxemia, extrapulmonary complications, and bacteremia.

▶ Clinical Findings

A. Symptoms and Signs

Presenting symptoms and signs include high fever, productive cough, occasionally hemoptysis, and pleuritic chest pain. Rigors occur within the first few hours of infection but are uncommon thereafter. Bronchial breath sounds are an early sign.

B. Laboratory Findings

Pneumococcal pneumonia classically is a lobar pneumonia with radiographic findings of consolidation and occasionally effusion. However, differentiating it from other pneumonias is not possible radiographically or clinically because of significant overlap in presentations. Diagnosis requires isolation of the organism in culture, although the Gram stain appearance of sputum can be suggestive. Sputum and

blood cultures, positive in 60% and 25% of cases of pneumococcal pneumonia, respectively, should be obtained prior to initiation of antimicrobial therapy in patients who are admitted to the hospital. A good-quality sputum sample (less than 10 epithelial cells and more than 25 polymorphonuclear leukocytes per high-power field) shows gram-positive diplococci in 80–90% of cases. A rapid urinary antigen test for *S pneumoniae*, with sensitivity of 70–80% and specificity greater than 95%, can assist with early diagnosis.

▶ Complications

Parapneumonic (sympathetic) effusion is common and may cause recurrence or persistence of fever. These sterile fluid accumulations need no specific therapy. Empyema occurs in 5% or less of cases and is differentiated from sympathetic effusion by the presence of organisms on Gram-stained fluid or positive pleural fluid cultures.

Pneumococcal pericarditis is a rare complication that can cause tamponade. Pneumococcal arthritis also is uncommon. Pneumococcal endocarditis usually involves the aortic valve and often occurs in association with meningitis and pneumonia (sometimes referred to as Austrian or Osler triad). Early heart failure and multiple embolic events are typical.

▶ Treatment

A. Specific Measures

Initial antimicrobial therapy for pneumonia is empiric (see Chapter 9 for specific recommendations) pending isolation and identification of the causative agent. Once the pneumonia is determined to be caused by *Streptococcus pneumoniae*, any of several antimicrobials may be used depending on the clinical setting, community patterns of penicillin resistance, and susceptibility of the particular isolate. Uncomplicated pneumococcal pneumonia (ie, arterial $PO_2 > 60$ mm Hg, no coexisting medical problems, and single-lobe disease without signs of extrapulmonary infection) caused by penicillin-susceptible strains of pneumococcus may be treated on an outpatient basis with amoxicillin, 750 mg orally twice daily for 7–10 days. For penicillin-allergic patients, alternatives are azithromycin, one 500-mg dose orally on the first day and 250 mg for the next 4 days; clarithromycin, 500 mg orally twice daily for 10 days; doxycycline, 100 mg orally twice daily for 10 days; levofloxacin, 750 mg orally for 5 days; or moxifloxacin, 400 mg orally for 7–14 days. Patients should be monitored for clinical response (eg, less cough, defervescence within 2–3 days) because pneumococci have become increasingly resistant to penicillin and the second-line agents.

Parenteral therapy is generally recommended for the hospitalized patient at least until there has been clinical improvement. Aqueous penicillin G, 2 million units intravenously every 4 hours, or ceftriaxone, 1 g intravenously every 24 hours, is effective for strains that are not highly penicillin-resistant (ie, strains for which the minimum inhibitory concentration [MIC] of penicillin is ≤ 1 mcg/mL). For serious penicillin allergy or infection caused by a highly penicillin-resistant strain, vancomycin, 1 g intravenously

every 12 hours, is effective. Alternatively, a fluoroquinolone (eg, levofloxacin, 500 mg, or a comparable dose of any one of several newer fluoroquinolones now on the market, orally or intravenously) can be used. The total duration of therapy is not well defined but 10–14 days is standard.

B. Treatment of Complications

Pleural effusions developing after initiation of antimicrobial therapy usually are sterile, and thoracentesis need not be performed if the patient is otherwise improving. Thoracentesis is indicated for an effusion present prior to initiation of therapy and in the patient who has not responded to antibiotics after 3–4 days. Chest tube drainage may be required if pneumococci are identified by culture or Gram stain, especially if aspiration of the fluid is difficult.

Echocardiography should be done if pericardial effusion is suspected. Patients with pericardial effusion who are responding to therapy and have no signs of tamponade may be monitored and treated with indomethacin, 50 mg orally three times daily, for pain. In patients with increasing effusion, unsatisfactory clinical response, or evidence of tamponade, pericardiocentesis will determine whether the pericardial space is infected. Infected fluid must be drained either percutaneously (by tube placement or needle aspiration), by placement of a pericardial window, or by pericardiectomy. Pericardiectomy eventually may be required to prevent or treat constrictive pericarditis, a common sequela of bacterial pericarditis.

Endocarditis should be treated for 4 weeks with 3–4 million units of penicillin G every 4 hours intravenously; ceftriaxone, 2 g once daily intravenously; or vancomycin, 15 mg/kg every 12 hours intravenously. Mild heart failure may respond to medical therapy, but moderate to severe heart failure is an indication for prosthetic valve implantation, as are systemic emboli or large friable vegetations as determined by echocardiography.

C. Penicillin-Resistant Pneumococci

Susceptibility breakpoints defining penicillin-resistant pneumococci for isolates causing pneumonia were revised in 2008. Resistance breakpoints for parenterally administered penicillin and high-dose oral amoxicillin (2 g twice daily) are as follows: susceptible, penicillin MIC \leq 2 mcg/mL; intermediate, MIC = 4 mcg/mL; resistant, MIC \geq 8 mcg/mL. This change reflected results from studies demonstrating equivalent cure rates when high doses of parenteral penicillin were used for treatment of pneumococcal pneumonia due to isolates with penicillin MIC \leq 2 mcg/mL. Note, however, that these new breakpoints do not apply to orally administered penicillin, which are the same as for use of penicillin in treatment of meningitis (see below). In cases of pneumococcal pneumonia where the isolate has a penicillin MIC $>$ 2 mcg/mL, cephalosporin cross-resistance is common, and a non- β -lactam antimicrobial, such as vancomycin, 1 g intravenously every 12 hours or a fluoroquinolone with enhanced gram-positive activity (eg, levofloxacin, 750 mg intravenously or orally once daily or moxifloxacin, 400 mg intravenously or orally once daily), is recommended. Penicillin-resistant strains of

pneumococci may be resistant to macrolides, trimethoprim-sulfamethoxazole, and chloramphenicol, and susceptibility must be documented prior to their use. All blood and cerebrospinal fluid isolates should still be tested for resistance to penicillin. There has been no change to the penicillin susceptibility breakpoint for pneumococcal isolates causing meningitis, nor any change in treatment recommendations (see below).

2. Pneumococcal Meningitis

ESSENTIALS OF DIAGNOSIS

- ▶ Fever, headache, altered mental status.
- ▶ Meningismus.
- ▶ Gram-positive diplococci on Gram stain of cerebrospinal fluid.

▶ General Considerations

S pneumoniae is the most common cause of meningitis in adults. Head trauma, with cerebrospinal fluid leaks, sinusitis, and pneumonia may precede it.

▶ Clinical Findings

A. Symptoms and Signs

The onset is rapid, with fever, headache, meningismus, and altered mentation. Pneumonia may be present. Compared with meningitis caused by the meningococcus, pneumococcal meningitis lacks a rash, and focal neurologic deficits, cranial nerve palsies, and obtundation are more prominent features.

B. Laboratory Findings

The cerebrospinal fluid typically has more than 1000 white blood cells per microliter, over 60% of which are polymorphonuclear leukocytes; the glucose concentration is less than 40 mg/dL, or less than 50% of the simultaneous serum concentration; and the protein usually exceeds 150 mg/dL. Not all cases of meningitis will have these typical findings, and alterations in cerebrospinal fluid cell counts and chemistries may be surprisingly minimal, overlapping with those of aseptic meningitis.

Gram stain of cerebrospinal fluid shows gram-positive cocci in 80–90% of cases, and in untreated cases, blood or cerebrospinal fluid cultures are almost always positive.

▶ Treatment

Antibiotics should be given as soon as the diagnosis is suspected. If lumbar puncture must be delayed (eg, while awaiting results of an imaging study to exclude a mass lesion), the patient should be treated empirically for presumed meningitis with intravenous ceftriaxone, 2 g, plus vancomycin, 15 mg/kg, plus dexamethasone, 0.15 mg/kg administered concomitantly after blood cultures (positive in 50% of cases) have been obtained. Once susceptibility to penicillin has been confirmed, penicillin, 24 million units intravenously daily in six divided doses, or ceftriaxone, 2 g every 12 hours intravenously, is continued for 10–14 days in documented cases.

The best therapy for penicillin-resistant strains is not known. Penicillin-resistant strains (MIC > 0.06 mcg/mL) are often cross-resistant to the third-generation cephalosporins as well as other antibiotics. Susceptibility testing is essential to proper management of this infection. If the MIC of ceftriaxone or cefotaxime is ≤ 0.5 mcg/mL, single-drug therapy with either of these cephalosporins is likely to be effective; when the MIC is ≥ 1 mcg/mL, treatment with a combination of ceftriaxone, 2 g intravenously every 12 hours, plus vancomycin, 30 mg/kg/d intravenously in two or three divided doses, is recommended. If a patient with a penicillin-resistant organism is slow to respond clinically, repeat lumbar puncture may be indicated to assess bacteriologic response.

Dexamethasone administered with antibiotic to adults has been associated with a 60% reduction in mortality and a 50% reduction in unfavorable outcomes, primarily in patients with pneumococcal meningitis. It is recommended that adults with acute bacterial meningitis be given 10 mg of dexamethasone intravenously immediately prior to or concomitantly with the first dose of appropriate antibiotic and continued in those with pneumococcal disease every 6 hours thereafter for a total of 4 days. Patients with pneumococcal meningitis and AIDS who do not have access to resources may not benefit from dexamethasone. The effect of dexamethasone on outcome of meningitis caused by penicillin-resistant organisms is not known.

STAPHYLOCOCCUS AUREUS INFECTIONS

1. Skin & Soft Tissue Infections

ESSENTIALS OF DIAGNOSIS

- ▶ Localized erythema with induration and purulent drainage.

- ▶ Abscess formation.
- ▶ Folliculitis commonly observed.
- ▶ Gram stain of pus with gram-positive cocci in clusters; cultures usually positive.

▶ General Considerations

Approximately one-quarter of people are asymptomatic nasal carriers of *S aureus*, which is spread by direct contact. Carriage often precedes infection, which occurs as a consequence of disruption of the cutaneous barrier or impairment of host defenses. *S aureus* tends to cause more localized skin infections than streptococci, and abscess formation is common. The prevalence of methicillin-resistant strains in community settings is increasing, and these strains have been associated with recurrent and severe skin and soft tissue infections, including necrotizing fasciitis.

▶ Clinical Findings

A. Symptoms and Signs

S aureus skin infections may begin around one or more hair follicles, causing folliculitis; may become localized to form boils (or furuncles); or may spread to adjacent skin and deeper subcutaneous tissue (ie, a carbuncle) (Plate 100). Deep abscesses involving muscle or fascia may occur, often in association with a deep wound or other inoculation or injection. Necrotizing fasciitis, a rare form of *S aureus* skin and soft tissues infection, has been reported with community strains of methicillin-resistant *S aureus*.

B. Laboratory Findings

Cultures of the wound or abscess material will almost always yield the organism. In patients with systemic signs of infection, blood cultures should be obtained because of potential endocarditis, osteomyelitis, or metastatic seeding of other sites. Patients who are bacteremic should have blood cultures taken early during therapy to exclude persistent bacteremia, an indicator of severe or complicated infection.

▶ Treatment

Proper drainage of abscess fluid or other focal infections is the mainstay of therapy. Incision and drainage alone may be sufficient for cutaneous abscess. For uncomplicated skin infections, oral antimicrobial therapy is satisfactory. Before the emergence of community methicillin-resistant strains of *S aureus*, an oral penicillinase-resistant penicillin or cephalosporin, such as dicloxacillin or cephalexin, 500 mg four times a day for 7–10 days, was the drug of choice for empiric therapy. However, increasing prevalence of methicillin-resistant strains of *S aureus* among community isolates may necessitate use of other oral agents to which the isolate is susceptible in vitro, such as clindamycin, 300 mg three times daily; doxycycline or minocycline, 100 mg twice daily; or trimethoprim-sulfamethoxazole, given in two divided doses based on 5–10 mg/kg/d of the trimethoprim component. Unfortunately, the efficacy of these agents is not well defined and not evidence based. Because of the

high prevalence of macrolide resistance among *S aureus* strains, these agents should not be used unless susceptibility is documented.

For more complicated infections with extensive cutaneous or deep tissue involvement or fever, parenteral therapy is indicated initially. A penicillinase-resistant penicillin such as nafcillin or oxacillin in a dosage of 1.5 g every 6 hours intravenously or cefazolin 1 g intravenously or intramuscularly is preferred for infections caused by methicillin-susceptible isolates. In patients with a serious allergy to β -lactam antibiotics or if the strain is methicillin-resistant, vancomycin, 1 g intravenously every 12 hours, is a drug of choice. If the local prevalence of methicillin-resistance is high (eg, 10% or more), and particularly if the patient is seriously ill, vancomycin is indicated empirically pending strain isolation and determination of susceptibility.

Linezolid is FDA-approved for treatment of skin and skin-structure infections as well as hospital-acquired pneumonia caused by methicillin-resistant strains of *S aureus* and clinically is as effective as vancomycin. The dose is 600 mg orally (bioavailability of 100%) or intravenously twice a day for 10–14 days. Its considerable cost makes it an unattractive choice for most routine outpatient infections, and its safety in treatment courses lasting longer than 2–3 weeks is not well characterized; nevertheless, it is the only proven effective oral alternative to parenteral vancomycin. Daptomycin, 4 mg/kg once daily (or every other day in the patient with creatinine clearance < 30 mL/min) intravenously for 7–14 days, is also an option for treatment of complicated skin and skin structure infections. Tigecycline, a glycylicycline class antimicrobial, has been approved by the FDA for treatment of complicated skin and skin structure infections due to methicillin-resistant strains of *S aureus* at a dose of 100 mg intravenously once followed by 50 mg intravenously twice a day for 10–14 days.

Hersh AL et al. National trends in ambulatory visits and antibiotic prescribing for skin and soft-tissue infections. *Arch Intern Med.* 2008 Jul 28;168(14):1585–91. [PMID: 18663172]

Stryjewski ME et al. Skin and soft-tissue infections caused by community-acquired methicillin-resistant *Staphylococcus aureus*. *Clin Infect Dis.* 2008 Jun 1;46(Suppl 5):S368–77. [PMID: 18462092]

2. Osteomyelitis

S aureus causes approximately 60% of all cases of osteomyelitis. Osteomyelitis may be caused by direct inoculation, eg, from an open fracture or as a result of surgery; by extension from a contiguous focus of infection or open wound; or by hematogenous spread. Long bones and vertebrae are the usual sites. Epidural abscess is a common complication of vertebral osteomyelitis and should be suspected if fever and severe back or neck pain are accompanied by radicular pain or symptoms or signs indicative of spinal cord compression (eg, incontinence, extremity weakness, pathologic reflexes).

Clinical Findings

A. Symptoms and Signs

The infection may be acute, with abrupt development of local symptoms and systemic toxicity, or indolent, with insidious onset of vague pain over the site of infection, progressing to local tenderness. Fever is absent in one-third or more of cases. Abscess formation is a late and unusual manifestation. Draining sinus tracts occur in chronic infections or infections of foreign body implants.

B. Laboratory Findings

The diagnosis is established by isolation of *S aureus* from the blood, bone, or a contiguous focus of a patient with signs and symptoms of focal bone infection. Blood culture will be positive in approximately 60% of untreated cases. Bone biopsy and culture are indicated if blood cultures are sterile.

C. Imaging

Bone scan and gallium scan, each with a sensitivity of approximately 95% and a specificity of 60–70%, are useful in identifying or confirming the site of bone infection. Plain bone films early in the course of infection are often normal but will become abnormal in most cases even with effective therapy. Spinal infection (unlike malignancy) traverses the disk space to involve the contiguous vertebral body. CT is more sensitive than plain films and helps localize associated abscesses. MRI is slightly less sensitive than bone scan but has a specificity of 90%. It is indicated when epidural abscess is suspected in association with vertebral osteomyelitis.

Treatment

Prolonged therapy is required to cure staphylococcal osteomyelitis. Durations of 4–6 weeks or longer are recommended. In cases of staphylococcal osteomyelitis with associated epidural abscess and spinal cord compression, other abscesses (psoas, paraspinal) or extensive disease, surgical treatment is often indicated. Although oral regimens can be effective, parenteral therapy is preferred, particularly during the acute phase of the infection for patients with systemic toxicity. Nafcillin or oxacillin, 9–12 g/d in six divided doses, is the drug of choice for infection with methicillin-sensitive isolates. Cefazolin, 2 g every 6–8 hours, also is effective. Patients with infections due to methicillin-resistant strains of *S aureus* or who have severe penicillin allergies should be treated with vancomycin, 30 mg/kg/d intravenously divided in two or three doses. Doses should be adjusted to achieve a vancomycin trough of 15–20 mcg/mL. Oral step-down therapy to a rifampin combination regimen appears to be as effective as parenterally administered regimens. The role of newer agents, daptomycin or linezolid, remains to be defined.

Daver NG et al. Oral step-down therapy is comparable to intravenous therapy for *Staphylococcus aureus* osteomyelitis. *J Infect.* 2007 Jun;54(60):539–44. [PMID: 17198732]

Lamp KC et al. Clinical experience with daptomycin for the treatment of patients with osteomyelitis. *Am J Med.* 2007 Oct;120(10 Suppl 1):S13–20. [PMID: 17904946]

3. Staphylococcal Bacteremia

S aureus readily invades the bloodstream and infects sites distant from the primary site of infection, which may be relatively minor or even inapparent. Whenever *S aureus* is recovered from blood cultures, the possibility of endocarditis, osteomyelitis, or other metastatic deep infection must be considered. Bacteremia that persists for more than 48 to 96 hours after initiation of therapy is strongly predictive of worse outcome and complicated infection. The appropriate duration of therapy for uncomplicated bacteremia arising from a removable source (eg, intravenous device) or drainable focus (eg, skin abscess) has not been well defined, but a 10- to 14-day course of therapy appears to be the minimum. However, 5% or more of patients may relapse, usually with endocarditis or osteomyelitis, even if treated for 2 weeks.

Nafcillin or oxacillin, 2 g intravenously every 4 hours or cefazolin, 2 g every 8 hours is recommended for uncomplicated methicillin-susceptible *S aureus* bacteremia. Vancomycin, 30 mg/kg/d intravenously in two or three divided doses, as definitive therapy should be reserved for patients with serious penicillin allergy or with infections caused by methicillin-resistant strains because it is less active than β -lactam antibiotics and treatment failures are more common than with β -lactams. Maintaining a vancomycin trough concentration of 15–20 mcg/mL may improve outcomes and is recommended. Transesophageal echocardiography (TEE) is a sensitive and cost-effective method for excluding underlying endocarditis. It is considered for patients for whom the pretest probability of endocarditis is 5% or higher—and for all patients with unexplained *S aureus* bacteremia.

Vancomycin treatment failures are relatively common, particularly for complicated bacteremia, in foreign body infection, or when the MIC of the isolate is ≥ 2 mcg/mL. Consultation should be sought with an infectious diseases specialist when vancomycin treatment failure is encountered. Daptomycin, 6 mg/kg once daily, is approved by the FDA for treatment of *S aureus* bacteremia and is an alternative to vancomycin, especially if a β -lactam cannot be used or if the patient is not responding to vancomycin. Cases of vancomycin treatment failures in which the staphylococcal isolate exhibits a vancomycin MIC ≥ 4 mcg/mL should be reported to the Centers for Disease Control and Prevention (CDC) to help track this potentially serious and emerging problem of vancomycin resistance.

Empiric therapy of suspected staphylococcal infection, whether of community or hospital onset, depends on the severity of the infection and the likelihood that it is caused by methicillin-resistant strains. If the prevalence exceeds 5–10% for more seriously ill patients, initial therapy should include vancomycin, 30 mg/kg/d intravenously divided in two or three doses, until results of susceptibility tests are known. Resistance to vancomycin fortunately remains rare and should not affect the choice of empiric therapy.

4. Toxic Shock Syndrome

S aureus produces toxins that cause three important entities: “scalded skin syndrome” in children, toxic shock syndrome in adults, and enterotoxin food poisoning. Toxic shock syndrome is characterized by abrupt onset of high fever, vomiting, and watery diarrhea. Sore throat, myalgias, and headache are common. Hypotension with kidney and heart failure is associated with a poor outcome. A diffuse macular erythematous rash (Plate 101) and nonpurulent conjunctivitis are common, and desquamation, especially of palms and soles, is typical during recovery. Fatality rates may be as high as 15%. Although originally associated with tampon use, any focus (eg, nasopharynx, bone, vagina, rectum, abscess, or wound) harboring a toxin-producing *S aureus* strain can cause toxic shock syndrome and nonmenstrual cases of toxic shock syndrome are common. Classically, blood cultures are negative because symptoms are due to the effects of the toxin and not systemic infection.

Important aspects of treatment include rapid rehydration, antistaphylococcal drugs, management of kidney or heart failure, and addressing sources of toxin, eg, removal of tampon or drainage of abscess.

5. Infections Caused by Coagulase-Negative Staphylococci

Coagulase-negative staphylococci are an important cause of infections of intravascular and prosthetic devices and of wound infection following cardiothoracic surgery. These organisms infrequently cause infections such as osteomyelitis and endocarditis in the absence of a prosthesis, but rates may be increasing. Most human infections are caused by *Staphylococcus epidermidis*, *Staphylococcus haemolyticus*, *Staphylococcus hominis*, *Staphylococcus warnerii*, *Staphylococcus saprophyticus*, *Staphylococcus saccharolyticus*, and *Staphylococcus cohnii*. These common hospital-acquired pathogens are less virulent than *S aureus*, and infections caused by them tend to be more indolent.

Because coagulase-negative staphylococci are normal inhabitants of human skin, it is difficult to distinguish infection from contamination, the latter perhaps accounting for three-fourths of blood culture isolates. Infection is more likely if the patient has a foreign body (eg, sternal wires, prosthetic joint, prosthetic cardiac valve, pacemaker, intracranial pressure monitor, cerebrospinal fluid shunt, peritoneal dialysis catheter) or an intravascular device in place. Purulent or serosanguineous drainage, erythema, pain, or tenderness at the site of the foreign body or device suggests infection. Instability and pain are signs of prosthetic joint infection. Fever, a new murmur, instability of the prosthesis, or signs of systemic emboliza-

tion are evidence of prosthetic valve endocarditis. Immunosuppression and recent antimicrobial therapy are risk factors.

Infection is also more likely if the same strain is consistently isolated from two or more blood cultures (particularly if samples were obtained at different times) and from the foreign body site. Contamination is more likely when a single blood culture is positive or if more than one strain is isolated from blood cultures. The antimicrobial susceptibility pattern and speciation are used to determine whether one or more strains have been isolated. More sophisticated typing methods, eg, pulse-field gel electrophoresis of restriction enzyme digested chromosomal DNA, may be required to identify distinct strains.

Whenever possible, the intravascular device or foreign body suspected of being infected by coagulase-negative staphylococci should be removed. However, removal and replacement of some devices (eg, prosthetic joint, prosthetic valve, cerebrospinal fluid shunt) can be a difficult or risky procedure, and it may sometimes be preferable to treat with antibiotics alone with the understanding that the probability of cure is reduced and that surgical management may eventually be necessary.

Coagulase-negative staphylococci are commonly resistant to β -lactams and multiple other antibiotics. For patients with normal kidney function, vancomycin, 1 g intravenously every 12 hours, is the treatment of choice for suspected or confirmed infection caused by these organisms until susceptibility to penicillinase-resistant penicillins or other agents has been confirmed. Duration of therapy has not been established for relatively uncomplicated infections, such as those secondary to intravenous devices, which may be eliminated by simply removing the infected device. Infection involving bone or a prosthetic valve should be treated for 6 weeks. A combination regimen of vancomycin plus rifampin, 300 mg orally twice daily, and gentamicin, 1 mg/kg intravenously every 8 hours, is recommended for treatment of prosthetic valve endocarditis caused by methicillin-resistant strains.

Chu VH et al. Emergence of coagulase-negative staphylococci as a cause of native valve endocarditis. *Clin Infect Dis*. 2008 Jan 15;46(2):232–42. [PMID: 18171255]

CLOSTRIDIAL DISEASES

1. Clostridial Myonecrosis (Gas Gangrene)

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden onset of pain and edema in an area of wound contamination.
- ▶ Prostration and systemic toxicity.
- ▶ Brown to blood-tinged watery exudate, with skin discoloration of surrounding area.
- ▶ Gas in the tissue by palpation or radiograph.
- ▶ Gram-positive rods in culture or smear of exudate.

▶ General Considerations

Gas gangrene or clostridial myonecrosis is produced by any one of several clostridia (*Clostridium perfringens*, *Clostridium ramosum*, *Clostridium bifermentans*, *Clostridium histolyticum*, *Clostridium novyi*, etc). Trauma and injection drug use are common predisposing conditions. Toxins produced in devitalized tissues under anaerobic conditions result in shock, hemolysis, and myonecrosis.

▶ Clinical Findings

A. Symptoms and Signs

The onset is usually sudden, with rapidly increasing pain in the affected area, hypotension, and tachycardia. Fever is present but is not proportionate to the severity of the infection. In the last stages of the disease, severe prostration, stupor, delirium, and coma occur.

The wound becomes swollen, and the surrounding skin is pale. There is a foul-smelling brown, blood-tinged serous discharge. As the disease advances, the surrounding tissue changes from pale to dusky and finally becomes deeply discolored, with coalescent, red, fluid-filled vesicles. Gas may be palpable in the tissues.

B. Laboratory Findings

Gas gangrene is a clinical diagnosis, and empiric therapy is indicated if the diagnosis is suspected. Radiographic studies may show gas within the soft tissues, but this finding is not specific. The smear shows absence of neutrophils and the presence of gram-positive rods. Anaerobic culture confirms the diagnosis.

▶ Differential Diagnosis

Other bacteria can produce gas in infected tissue, eg, enteric gram-negative organisms, or anaerobes.

▶ Treatment

Penicillin, 2 million units every 3 hours intravenously, is effective. Other agents (eg, tetracycline, clindamycin, metronidazole, chloramphenicol, cefoxitin) are active against *Clostridium* species in vitro and probably in vivo as well. Adequate surgical debridement and exposure of infected areas are essential, with radical surgical excision often necessary. Hyperbaric oxygen therapy has been used empirically but must be used in conjunction with administration of an appropriate antibiotic and surgical debridement.

2. *Clostridium sordellii* Toxic Shock Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden onset after medical abortion.
- ▶ Abdominal pain.
- ▶ Absence of fever.

- ▶ Tachycardia, severe hypotension, capillary leak syndrome with edema.
- ▶ Profound leukocytosis, hemoconcentration.

▶ General Considerations & Clinical Findings

C. sordellii is a rare cause of endometritis and toxic shock syndrome following childbirth. Four cases, all fatal, of uterine infection following medically induced abortion with mifepristone were reported in 2005. Onset of illness was within 4–5 days of ingestion of mifepristone and the clinical course fulminant. Infection appeared to be limited to the uterus, which showed necrosis, edema, hemorrhage, and acute inflammatory changes.

▶ Treatment

Early recognition, aggressive resuscitation from shock, immediate surgical debridement with hysterectomy, and administration of an antimicrobial that is active against *C. sordellii* are essential to survival. Based on in vitro susceptibility data, any of several agents should be active, including penicillin, ampicillin, a macrolide, clindamycin, a tetracycline, or metronidazole. Whether a protein synthesis inhibitor to block further toxin production offers any advantage over a β -lactam is unknown.

Cohen AL et al. Toxic shock associated with *Clostridium sordellii* and *Clostridium perfringens* after medical and spontaneous abortion. *Obstet Gynecol.* 2007 Nov;110(5):1027–33. [PMID: 17978116]

3. Tetanus

ESSENTIALS OF DIAGNOSIS

- ▶ History of wound and possible contamination.
- ▶ Jaw stiffness followed by spasms of jaw muscles (trismus).
- ▶ Stiffness of the neck and other muscles, dysphagia, irritability, hyperreflexia.
- ▶ Finally, painful convulsions precipitated by minimal stimuli.

▶ General Considerations

Tetanus is caused by the neurotoxin tetanospasmin, elaborated by *Clostridium tetani*. Spores of this organism are ubiquitous in soil and may germinate when introduced into a wound. The vegetative bacteria produce tetanospasmin, a zinc metalloprotease that cleaves synaptobrevin, a protein essential for neurotransmitter release. Tetanospasmin interferes with neurotransmission at spinal synapses of inhibitory neurons. As a result, minor stimuli result in uncontrolled spasms, and reflexes are exaggerated. The incubation period is 5 days to 15 weeks, with the average being 8–12 days.

Most cases occur in unvaccinated individuals. Persons at risk are the elderly, migrant workers, newborns, and injec-

tion drug users. While puncture wounds are particularly prone to causing tetanus, any wound, including bites or decubiti, may become colonized and infected by *C. tetani*.

▶ Clinical Findings

A. Symptoms and Signs

The first symptom may be pain and tingling at the site of inoculation, followed by spasticity of the muscles nearby. Stiffness of the jaw, neck stiffness, dysphagia, and irritability are other early signs. Hyperreflexia develops later, with spasms of the jaw muscles (trismus) or facial muscles and rigidity and spasm of the muscles of the abdomen, neck, and back. Painful tonic convulsions precipitated by minor stimuli are common. Spasms of the glottis and respiratory muscles may cause acute asphyxia. The patient is awake and alert throughout the illness. The sensory examination is normal. The temperature is normal or only slightly elevated.

B. Laboratory Findings

The diagnosis of tetanus is made clinically.

▶ Differential Diagnosis

Tetanus must be differentiated from various acute central nervous system infections such as meningitis. Trismus may occasionally develop with the use of phenothiazines. Strychnine poisoning should also be considered.

▶ Complications

Airway obstruction is common. Urinary retention and constipation may result from spasm of the sphincters. Respiratory arrest and cardiac failure are late, life-threatening events.

▶ Prevention

Tetanus is completely preventable by active immunization. For primary immunization of adults, Td (tetanus and diphtheria toxoids vaccine) is administered as two doses 4–6 weeks apart, with a third dose 6–12 months later. For one of the doses, Tdap (tetanus toxoid, reduced dose diphtheria toxoid, acellular pertussis vaccine) should be substituted for Td. Booster doses are given every 10 years or at the time of major injury if it occurs more than 5 years after a dose. A single dose of Tdap is preferred to Td for wound prophylaxis if the patient has not been previously vaccinated with Tdap.

Passive immunization should be used in nonimmunized individuals and those whose immunization status is uncertain whenever a wound is contaminated or likely to have devitalized tissue. Tetanus immune globulin, 250 units, is given intramuscularly. Active immunization with tetanus toxoid is started concurrently. Table 33–1 provides a guide to prophylactic management.

▶ Treatment

A. Specific Measures

Human tetanus immune globulin, 500 units, should be administered intramuscularly within the first 24 hours of

Table 33–1. Guide to tetanus prophylaxis in wound management.

| History of Absorbed Tetanus Toxoid | Clean, Minor Wounds | | All Other Wounds ¹ | |
|------------------------------------|-------------------------|------------------|-------------------------------|------------------|
| | Tdap or Td ² | TIG ³ | Tdap or Td ² | TIG ³ |
| Unknown or < 3 doses | Yes | No | Yes | Yes |
| 3 or more doses | No ⁴ | No | No ⁵ | No |

¹Such as, but not limited to, wounds contaminated with dirt, feces, soil, saliva, etc; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

²Td indicates tetanus toxoid and diphtheria toxoid, adult form. Tdap indicates tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine, which may be substituted as a single dose for Td. Unvaccinated individuals should receive a complete series of three doses, one of which is Tdap.

³Human tetanus immune globulin, 250 units intramuscularly.

⁴Yes if more than 10 years have elapsed since last dose.

⁵Yes if more than 5 years have elapsed since last dose. (More frequent boosters are not needed and can enhance side effects.) Tdap has been safely administered within 2 years of Td vaccination, although local reactions to the vaccine may be increased.

presentation. Whether intrathecal administration has any additional benefit is controversial. An unblinded, randomized trial comparing intramuscular tetanus immune globulin to intramuscular plus intrathecal tetanus immune globulin found more rapid resolution of spasms, fewer days of ventilatory support, and a shorter hospital stay in the intrathecal group. However, the exact immunoglobulin preparation that was used was not specified and the total dose was 4000 units. Tetanus does not produce natural immunity, and a full course of immunization with tetanus toxoid should be administered once the patient has recovered.

B. General Measures

Minimal stimuli can provoke spasms, so the patient should be placed at bed rest and monitored under the quietest conditions possible. Sedation, paralysis with curare-like agents, and mechanical ventilation are often necessary to control tetanic spasms. Penicillin, 20 million units intravenously daily, is given to all patients—even those with mild illness—to eradicate toxin-producing organisms.

► Prognosis

High mortality rates are associated with a short incubation period, early onset of convulsions, and delay in treatment. Contaminated lesions about the head and face are more dangerous than wounds on other parts of the body.

Kretsinger K et al; Centers for Disease Control and Prevention; Advisory Committee on Immunization Practices; Healthcare Infection Control Practices Advisory Committee. Preventing tetanus, diphtheria, and pertussis among adults: use of tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine recommendations of the Advisory Committee on Immunization Practices (ACIP) and recommendation of ACIP, supported by the Healthcare Infection Control Practices Advisory Committee (HICPAC), for use of Tdap among health-care personnel. *MMWR Recomm Rep.* 2006 Dec 15; 55(RR-17):1–37. [PMID: 17167397]

Thwaites CL et al. Magnesium sulphate for treatment of severe tetanus: a randomised controlled trial. *Lancet.* 2006 Oct 21; 368(9545):1436–43. [PMID: 17055945]

4. Botulism

ESSENTIALS OF DIAGNOSIS

- History of recent ingestion of home-canned or smoked foods or of injection drug use and demonstration of toxin in serum or food.
- Sudden onset of diplopia, dry mouth, dysphagia, dysphonia, and muscle weakness progressing to respiratory paralysis.
- Pupils are fixed and dilated in most cases.

► General Considerations

Botulism is a paralytic disease caused by botulinum toxin, which is produced by *Clostridium botulinum*, a ubiquitous, strictly anaerobic, spore-forming bacillus found in soil. Four toxin types—A, B, E, and F—cause human disease. Botulinum toxin is a zinc metalloprotease that cleaves a specific component of the synaptic vesicle membrane docking and fusion complex at the neuromuscular junction blocking release of the neurotransmitter acetylcholine. Botulinum toxin is extremely potent and is classified by the CDC as a high-priority agent because of its potential for use as an agent of bioterrorism. Naturally occurring botulism occurs in one of three forms: food-borne botulism, infant botulism, or wound botulism. Food-borne botulism is caused by ingestion of preformed toxin present in canned, smoked, or vacuum-packed foods such as home-canned vegetables, smoked meats, and vacuum-packed fish. Commercial foods have also been associated with outbreaks of botulism. Infant botulism (associated with ingestion of honey) and wound botulism (which typically occurs in

association with injection drug use) result from organisms present in the gut or wound that elaborate toxin *in vivo*.

► Clinical Findings

A. Symptoms and Signs

Twelve to 36 hours after ingestion of the toxin, visual disturbances appear, particularly diplopia and loss of accommodation. Ptosis, cranial nerve palsies with impairment of extraocular muscles, and fixed dilated pupils are characteristic signs. The sensory examination is normal. Other symptoms are dry mouth, dysphagia, and dysphonia. Nausea and vomiting may be present, particularly with type E toxin. The sensorium remains clear and the temperature normal. Paralysis progressing to respiratory failure and death may occur unless mechanical assistance is provided.

B. Laboratory Findings

Toxin in patients' serum and in suspected foods can be demonstrated by mouse inoculation and identified with specific antiserum.

► Differential Diagnosis

Because the clinical presentation of botulism is so distinctive and the differential diagnosis limited, botulism once considered is not easily confused with other diseases. Cranial nerve involvement may be seen with verteobasilar insufficiency, the C. Miller Fisher variant of Guillain-Barré syndrome, myasthenia gravis, or any basilar meningitis (infectious or carcinomatous). Intestinal obstruction or other types of food poisoning are considered when nausea and vomiting are present.

► Treatment

If botulism is suspected, the practitioner should contact the state health authorities or the CDC for advice and help with procurement of botulinus antitoxin and for assistance in obtaining assays for toxin in serum, stool, or food. Skin testing is recommended to exclude hypersensitivity to the antitoxin preparation. Antitoxin should be administered as early as possible, ideally within 24 hours of the onset of symptoms or signs, to arrest progression of disease; its administration should not be delayed for laboratory confirmation of the diagnosis. Respiratory failure is managed with intubation and mechanical ventilation. Parenteral fluids or alimentation should be given while swallowing difficulty persists. The removal of unabsorbed toxin from the gut may be attempted. Any remnants of suspected foods should be assayed for toxin. Persons who might have eaten the suspected food must be located and observed.

ANTHRAX

ESSENTIALS OF DIAGNOSIS

- Appropriate epidemiologic setting, eg, exposure to animals or animal hides, or potential exposure resulting from an act of bioterrorism.
- A painless cutaneous black eschar on exposed areas of the skin, with marked surrounding edema and vesicles.
- Nonspecific flu-like symptoms that rapidly progress to extreme dyspnea and shock in association with mediastinal widening and pleural effusions on chest radiograph.

► General Considerations

The death of a Florida photo editor from inhalational anthrax acquired from a letter deliberately contaminated with spores of *Bacillus anthracis* thrust this extremely rare infection into the public awareness. Between September 18 and November 21 of 2001, there were 13 cases of cutaneous anthrax and 11 cases of inhalational anthrax associated with exposure to anthrax spores in contaminated mail.

Naturally occurring anthrax is a disease of sheep, cattle, horses, goats, and swine. *B anthracis* is a gram-positive spore-forming aerobic rod. Spores—not vegetative bacteria—are the infectious form of the organism. These are transmitted to humans from contact with contaminated animals, animal products, or animal hides, or from soil by inoculation of broken skin or mucous membranes; by inhalation of aerosolized spores; or, rarely, by ingestion resulting in cutaneous, inhalational, or gastrointestinal forms of anthrax, respectively. Spores germinate into vegetative bacteria that multiply locally in cutaneous and gastrointestinal anthrax but may also disseminate to cause systemic infection. Inhaled spores are ingested by pulmonary macrophages and carried via lymphatics to regional lymph nodes, where they germinate. The bacteria rapidly multiply within the lymphatics, causing a hemorrhagic lymphadenitis. Invasion of the bloodstream leads to overwhelming sepsis, killing the host.

► Clinical Findings

A. Symptoms and Signs

1. Cutaneous anthrax—This occurs within 2 weeks after exposure to spores; there is no latency period for cutaneous disease. The initial lesion is an erythematous papule, often on an exposed area of skin that vesiculates and then ulcerates and undergoes necrosis, ultimately progressing to a purple to black eschar. The eschar typically is painless; pain indicates secondary staphylococcal or streptococcal infection. The surrounding area is edematous and vesicular but not purulent. Regional adenopathy, fever, malaise, headache, and nausea and vomiting may be present. The infection is self-limited in most cases, but hematogenous spread with sepsis or meningitis may occur.

2. Inhalational anthrax—Illness occurs in two stages, beginning on average 10 days after exposure, but may begin up to 6 weeks after exposure. Nonspecific viral-like symptoms such as fever, malaise, headache, dyspnea, cough, and congestion of the nose, throat, and larynx are characteristic of the initial stage. Anterior chest pain is an early symptom of mediastinitis. Within hours to a few days, progression to the fulminant stage of infection occurs in which symptoms or signs of overwhelming sepsis predominate. Delirium, obtundation, or findings of meningeal irritation suggest an accompanying hemorrhagic meningitis.

3. Gastrointestinal anthrax—This form has not been reported in the United States. Fever, diffuse abdominal pain, rebound abdominal tenderness, vomiting, constipation, and diarrhea occur 2–5 days after ingestion of meat contaminated with anthrax spores. The primary lesion is ulcerative, producing emesis that may be blood-tinged or coffee-ground and stool that may be blood-tinged or melanic. Bowel perforation can occur. The oropharyngeal form of the disease is characterized by local lymphadenopathy, cervical edema, dysphagia, and upper respiratory tract obstruction.

B. Laboratory Findings

Laboratory findings are nonspecific. The white blood cell count initially may be normal or modestly elevated, with polymorphonuclear predominance and an increase in early forms. Pleural fluid from patients with inhalational anthrax is typically hemorrhagic with few white cells. Cerebrospinal fluid from meningitis cases is also hemorrhagic. Gram stain of pleural fluid, cerebrospinal fluid, unspun blood, blood culture, or fluid from a cutaneous lesion may show the characteristic boxcar-shaped encapsulated rods in chains.

The diagnosis is established by isolation of the organism from culture of the skin lesion (or fluid expressed from it), blood, or pleural fluid—or cerebrospinal fluid in cases of meningitis. In the absence of prior antimicrobial therapy, cultures are invariably positive. Cultures obtained after initiation of antimicrobial therapy may be negative. If anthrax is suspected on clinical or epidemiologic grounds, immunohistochemical tests (eg, to detect capsular antigen), polymerase chain reaction assays, and serologic tests (useful for documenting past cutaneous infection) are available through the CDC and should be used to establish the diagnosis. Any suspected case of anthrax should be immediately reported to the CDC so that a complete investigation can be conducted.

C. Imaging

The chest radiograph is the most sensitive test for inhalational disease, being abnormal (though the findings can be subtle) initially in every case of bioterrorism-associated disease. Mediastinal widening due to hemorrhagic lymphadenitis, a hallmark feature of the disease, has been present in 70% of the bioterrorism-related cases. Pleural effusions were present initially or occurred over the course of illness in all cases, and approximately three-fourths had pulmonary infiltrates or signs of consolidation.

Differential Diagnosis

Cutaneous anthrax, despite its characteristic appearance, can be confused with a variety of other also uncommon or rare conditions such as ecthyma gangrenosum, rat-bite fever, ulceroglandular tularemia, plague, glanders, rickettsialpox, orf (parapoxvirus infection), or cutaneous mycobacterial infection. Inhalational anthrax must be differentiated from mediastinitis due to other bacterial causes, fibrous mediastinitis due to histoplasmosis, coccidioidomycosis, atypical or viral pneumonia, silicosis, sarcoidosis, and other causes of mediastinal widening (eg, superior vena cava syndrome or aortic aneurysm or dissection). Gastrointestinal anthrax shares clinical features with a variety of common intra-abdominal disorders, including bowel obstruction, perforated viscus, peritonitis, gastroenteritis, and peptic ulcer disease.

Treatment

Strains of *B anthracis* (including the strain isolated in the bioterrorism cases) are susceptible in vitro to penicillin, amoxicillin, chloramphenicol, clindamycin, imipenem, doxycycline, ciprofloxacin (as well as other fluoroquinolones), macrolides, rifampin, and vancomycin. Susceptibility to cephalosporins is variable. *B anthracis* may express β -lactamases that confer resistance to cephalosporins and penicillins. For this reason, penicillin or amoxicillin is no longer recommended for use as a single agent in treatment of disseminated disease. Based on results of animal experiments and because of concern for engineered drug resistance in strains of *B anthracis* used in bioterrorism or weaponized, ciprofloxacin is considered the drug of choice (Table 33–2) for treatment and for prophylaxis following exposure to anthrax spores. Other fluoroquinolones with activity against gram-positive bacteria (eg, levofloxacin, moxifloxacin) are likely to be just as effective as ciprofloxacin. Doxycycline is an alternative first-line agent. Combination therapy with at least one additional agent is recommended for inhalational or disseminated disease and in cutaneous infection involving the face, head, and neck or associated with extensive local edema or systemic signs of

Table 33–2. Antimicrobial agents for treatment of anthrax or for prophylaxis against anthrax.

First-line agents and recommended doses

Ciprofloxacin, 500 mg twice daily orally or 400 mg every 12 hours intravenously

Doxycycline, 100 mg every 12 hours orally or intravenously

Second-line agents and recommended doses

Amoxicillin, 500 mg three times daily orally

Penicillin G, 2–4 million units every 4 hours intravenously

Alternative agents with in vitro activity and suggested doses

Rifampin, 10 mg/kg/d orally or intravenously

Clindamycin, 450–600 mg every 8 hours orally or intravenously

Clarithromycin, 500 mg orally twice daily

Erythromycin, 500 mg every 6 hours intravenously

Vancomycin, 1 g every 12 hours intravenously

Imipenem, 500 mg every 6 hours intravenously

infection, eg, fever, tachycardia and elevated white blood cell count. Anecdotally, four of the six survivors of the 2001 inhalational cases were treated with combinations that included both a fluoroquinolone and rifampin. Single-drug therapy is recommended for prophylaxis following exposure to spores.

The required duration of therapy is poorly defined. In naturally occurring disease, treatment for 7–10 days for cutaneous disease and for at least 2 weeks following clinical response for disseminated, inhalational, or gastrointestinal infection have been standard recommendations. Because of concern about relapse from latent spores acquired by inhalation of aerosol in bioterrorism-associated cases, the initial recommendation was treatment for 60 days. In 2001, the CDC offered one of two options for postal workers receiving prophylaxis for exposure to contaminated mail: (1) antibiotics for 100 days (fearing that even with 60 days of treatment late relapses might occur) or (2) vaccination with an investigative agent (three doses administered over a 1-month period) in conjunction with 40 days of antibiotic administration to cover the time required for a protective antibody response to develop. Insufficient information exists to favor one recommendation over the other.

There is also an FDA-approved vaccine for persons at high risk for exposure to anthrax spores. The vaccine is cell-free antigen prepared from an attenuated strain of *B anthracis*. Multiple injections over 18 months and an annual booster dose are required to achieve and maintain protection. Existing supplies have been reserved for vaccination of military personnel.

The prognosis in cutaneous infection is excellent. Death is unlikely if the infection has remained localized, and lesions heal without complications in most cases. The reported mortality rate for gastrointestinal and inhalational infections is up to 85%. The experience with bioterrorism-associated inhalational cases in which six of eleven victims survived suggests a somewhat better outcome with modern supportive care and antibiotics provided that treatment is initiated before the patient has progressed to the fulminant stage of disease. No cases of anthrax have occurred among the several thousand individuals receiving antimicrobial prophylaxis following exposure to spores.

Kyriacou DN et al. Discriminating inhalational anthrax from community-acquired pneumonia using chest radiograph findings and a clinical algorithm. *Chest*. 2007 Feb;131(2):489–96. [PMID: 17296652]

DIPHTHERIA

ESSENTIALS OF DIAGNOSIS

- ▶ Tenacious gray membrane at portal of entry in pharynx.
- ▶ Sore throat, nasal discharge, hoarseness, malaise, fever.
- ▶ Myocarditis, neuropathy.
- ▶ Culture confirms the diagnosis.

General Considerations

Diphtheria is an acute infection caused by *Corynebacterium diphtheriae* that usually attacks the respiratory tract but may involve any mucous membrane or skin wound. The organism is spread chiefly by respiratory secretions. Exotoxin produced by the organism is responsible for myocarditis and neuropathy. This exotoxin inhibits elongation factor, which is required for protein synthesis.

Clinical Findings

A. Symptoms and Signs

Nasal, laryngeal, pharyngeal, and cutaneous forms of diphtheria occur. Nasal infection produces few symptoms other than a nasal discharge. Laryngeal infection may lead to upper airway and bronchial obstruction. In pharyngeal diphtheria, the most common form, a tenacious gray membrane covers the tonsils and pharynx. Mild sore throat, fever, and malaise are followed by toxemia and prostration.

Myocarditis and neuropathy are the most common and most serious complications. Myocarditis causes cardiac arrhythmias, heart block, and heart failure. The neuropathy usually involves the cranial nerves first, producing diplopia, slurred speech, and difficulty in swallowing.

B. Laboratory Findings

The diagnosis is made clinically but can be confirmed by culture of the organism.

Differential Diagnosis

Diphtheria must be differentiated from streptococcal pharyngitis, infectious mononucleosis, adenovirus or herpes simplex infection, Vincent angina, pharyngitis due to *Arcanobacterium haemolyticum*, and candidiasis. A presumptive diagnosis of diphtheria should be made on clinical grounds without waiting for laboratory verification, since emergency treatment is needed.

Prevention

Active immunization with diphtheria toxoid is part of routine childhood immunization with appropriate booster injections. The immunization schedule for adults is the same as for tetanus.

Susceptible persons exposed to diphtheria should receive a booster dose of diphtheria toxoid (or a complete series if previously unimmunized), as well as a course of penicillin or erythromycin.

Treatment

Antitoxin, which is prepared from horse serum, must be given in all cases when diphtheria is suspected. For mild early pharyngeal or laryngeal disease, the dose is 20,000–40,000 units; for moderate nasopharyngeal disease, 40,000–60,000 units; for severe, extensive, or late (3 days or more) disease, 80,000–100,000 units. Diphtheria equine antitoxin can be obtained from the CDC.

Removal of membrane by direct laryngoscopy or bronchoscopy may be necessary to prevent or alleviate airway obstruction.

Either penicillin, 250 mg orally four times daily, or erythromycin, 500 mg orally four times daily, for 14 days is effective therapy, although erythromycin is slightly more effective in eliminating the carrier state. Azithromycin or clarithromycin is probably as effective as erythromycin. The patient should be isolated until three consecutive cultures at the completion of therapy have documented elimination of the organism from the oropharynx. Contacts to a case should receive erythromycin, 500 mg orally four times daily for 7 days, to eradicate carriage.

LISTERIOSIS

Listeria monocytogenes is a facultative, motile, gram-positive rod that is capable of invading several cell types and causes intracellular infection. Most cases of infection caused by *L. monocytogenes* are sporadic, but outbreaks have been traced to eating contaminated food, including unpasteurized dairy products, hot dogs, and delicatessen meats. Five types of infection are recognized:

(1) **Infection during pregnancy**, usually in the last trimester, is a mild febrile illness without an apparent primary focus. This relatively benign disease for the mother may resolve without specific therapy. However, approximately one in five pregnancies complicated by listeriosis result in spontaneous abortion or stillbirth and surviving infants are at high risk for clinical neonatal listeriosis.

(2) **Granulomatosis infantisepticum** is a neonatal infection acquired in utero, characterized by disseminated abscesses, granulomas, and a high mortality rate.

(3) **Bacteremia** with or without sepsis syndrome is an infection of neonates or immunocompromised adults. The presentation is of a febrile illness without a recognized source.

(4) **Meningitis** caused by *L. monocytogenes* affects infants under 2 months of age as well as older adults, ranking third after the meningococcus and pneumococcus among the common causes of bacterial meningitis. Cerebrospinal fluid shows a *neutrophilic* pleocytosis. Adults with meningitis are often immunocompromised, and cases have been associated with HIV infection and therapy with tumor necrosis factor- α (TNF- α) inhibitors such as infliximab.

(5) Finally, **focal infections**, including adenitis, brain abscess, endocarditis, osteomyelitis, and arthritis, occur rarely.

Ampicillin, 8–12 g/d intravenously in four to six divided doses (the higher dose for meningitis) is considered the treatment of choice. It penetrates well into cerebrospinal fluid, and clinical response is better than with penicillin, erythromycin, or chloramphenicol. Gentamicin is synergistic with ampicillin against *Listeria* in vitro and in animal models, and the use of combination therapy may be considered during the first few days of treatment to enhance eradication of organisms. Mortality and morbidity rates still are high, and relapses occur, perhaps related to poor intracellular penetration of ampicillin. Trimethoprim-sulfamethoxazole with its excellent intracellular and cerebrospi-

nal fluid penetration may be more efficacious. The dose is 10–20 mg/kg/d intravenously of the trimethoprim component. Therapy should be administered for at least 2–3 weeks. Longer durations—between 3 and 6 weeks—have been recommended for treatment of meningitis, especially in immunocompromised persons.

Bennion JR et al. Decreasing listeriosis mortality in the United States, 1990–2005. *Clin Infect Dis*. 2008 Oct 1;47(7):867–74. [PMID: 18752441]

INFECTIVE ENDOCARDITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Fever
- ▶ Preexisting organic heart lesion.
- ▶ Positive blood cultures.
- ▶ Evidence of vegetation on echocardiography.
- ▶ New or changing heart murmur.
- ▶ Evidence of systemic emboli.

General Considerations

Endocarditis is a bacterial or fungal infection of the valvular or endocardial surface of the heart. The clinical presentation depends on the infecting organism and the valve or valves that are infected. More virulent organisms—*S. aureus* in particular—tend to produce a more rapidly progressive and destructive infection. Endocarditis caused by more virulent organisms often presents as an acute febrile illness and is complicated by early embolization, acute valvular regurgitation, and myocardial abscess formation. Viridans strains of streptococci, enterococci, other bacteria, yeasts, and fungi tend to cause a more subacute picture.

Underlying valvular disease, less common than in the past, is present in about 50% of cases. Valvular disease alters blood flow and produces jet effects that disrupt the endothelial surface, providing a nidus for attachment and infection of microorganisms that enter the bloodstream. Predisposing valvular abnormalities include rheumatic involvement of any valve, bicuspid aortic valves, calcific or sclerotic aortic valves, hypertrophic subaortic stenosis, mitral valve prolapse, and a variety of congenital disorders such as ventricular septal defect, tetralogy of Fallot, coarctation of the aorta, or patent ductus arteriosus. Rheumatic disease is no longer the major predisposing factor in developed countries. Regurgitation lesions are more susceptible than stenotic ones.

The initiating event in native valve endocarditis is colonization of the valve by bacteria or yeast that gain access to the bloodstream. Transient bacteremia is common during dental, upper respiratory, urologic, and lower gastrointestinal diagnostic and surgical procedures. It is less common during upper gastrointestinal and gynecologic procedures.

Intravascular devices are increasingly implicated as a portal of access of microorganisms into the bloodstream. A large proportion of cases of *S aureus* endocarditis are attributable to healthcare-associated bacteremia.

Native valve endocarditis is usually caused by viridans streptococci, group D streptococci, *S aureus*, enterococci, or HACEK organisms (an acronym for *Haemophilus aphrophilus*, *Haemophilus parainfluenzae*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*). Streptococcal species formerly accounted for the majority of native valve endocarditis cases, but the proportion of cases caused by *S aureus* has been increasing, and this organism is now the leading cause. Gram-negative organisms and fungi account for a small percentage.

In injection drug users, *S aureus* accounts for over 60% of all endocarditis cases and for 80–90% of cases in which the tricuspid valve is infected. Enterococci and streptococci comprise the balance in about equal proportions. Gram-negative aerobic bacilli, fungi, and unusual organisms may cause endocarditis in injection drug users.

The microbiology of prosthetic valve endocarditis also is distinctive. Early infections (ie, those occurring within 2 months after valve implantation) are commonly caused by staphylococci—both coagulase-positive and coagulase-negative—gram-negative organisms, and fungi. In late prosthetic valve endocarditis, streptococci are commonly identified, although coagulase-negative and coagulase-positive staphylococci still cause many cases.

▶ Clinical Findings

A. Symptoms and Signs

Virtually all patients have fever at some point in the illness, although it may be very low grade (less than 38 °C) in elderly individuals and in patients with heart failure or kidney failure. Rarely, there may be no fever at all.

The duration of illness typically is a few days to a few weeks. Nonspecific symptoms are common. The initial symptoms and signs of endocarditis may be caused by direct arterial, valvular, or cardiac damage. Although a changing regurgitant murmur is significant diagnostically, it is the exception rather than the rule. Symptoms also may occur as a result of embolization, metastatic infection or immunologically mediated phenomena. These include cough; dyspnea; arthralgias or arthritis; diarrhea; and abdominal, back, or flank pain.

The characteristic peripheral lesions—petechiae (on the palate or conjunctiva or beneath the fingernails), subungual (“splinter”) hemorrhages, Osler nodes (painful, violaceous raised lesions of the fingers, toes, or feet), Janeway lesions (painless erythematous lesions of the palms or soles), and Roth spots (exudative lesions in the retina)—occur in about 25% of patients (Plates 102 and 103). Strokes and major systemic embolic events are present in about 25% of patients, and tend to occur before or within the first week of antimicrobial therapy. Hematuria and proteinuria may result from emboli or immunologically mediated glomerulonephritis, which can cause kidney dysfunction.

B. Diagnostic Studies

Blood cultures establish the diagnosis. Three sets of blood cultures at least 1 hour apart before starting antibiotics are recommended to maximize the opportunity for a microbiologic diagnosis. Approximately 5% of cases will be culture-negative, usually attributable to administration of antimicrobials prior to obtaining cultures. If antimicrobial therapy has been administered prior to obtaining cultures and the patient is clinically stable, it is reasonable to withhold further antimicrobial therapy for 2–3 days so that appropriate cultures can be obtained. Culture-negative endocarditis may also be due to a fungus, organisms that require special media for growth (eg, *Legionella*, *Bartonella*, *Abiotrophia* species, formerly referred to as nutritionally deficient streptococci), organisms that do not grow on artificial media (*Tropheryma whippelii*, or pathogens of Q fever or psittacosis), or those that are slow-growing and may require prolonged incubation (eg, *Brucella*, anaerobes, HACEK organisms). *Bartonella quintana* has emerged as an important cause of culture-negative endocarditis.

Chest radiograph may show evidence for the underlying cardiac abnormality and, in right-sided endocarditis, pulmonary infiltrates. The electrocardiogram is nondiagnostic, but new conduction abnormalities suggest myocardial abscess formation. Echocardiography is useful in identifying vegetations and other characteristic features suspicious for endocarditis and may provide adjunctive information about the specific valve or valves that are infected. The sensitivity of transthoracic echocardiography is between 55% and 65%; it cannot reliably rule out endocarditis but may confirm a clinical suspicion. TEE is 90% sensitive in detecting vegetations and is particularly useful for identifying valve ring abscesses as well as prosthetic valve endocarditis.

Clinical criteria, referred to as the **Modified Duke criteria**, for the diagnosis of endocarditis have been proposed. Major criteria include: (1) two positive blood cultures for a microorganism that typically causes infective endocarditis or persistent bacteremia; (2) evidence of endocardial involvement documented by echocardiography (eg, definite vegetation, myocardial abscess, or new partial dehiscence of a prosthetic valve); or (3) development of a new regurgitant murmur. Minor criteria include the presence of a predisposing condition; fever ≥ 38 °C; vascular phenomena, such as cutaneous hemorrhages, aneurysm, systemic emboli, pulmonary infarction; immunologic phenomena, such as glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor; and positive blood cultures not meeting the major criteria or serologic evidence of an active infection. A definite diagnosis can be made with 80% accuracy if two major criteria, one major criterion and three minor criteria, or five minor criteria are fulfilled. A possible diagnosis of endocarditis is made if one major and one minor criterion or three minor criteria are met. If fewer criteria are found, or a sound alternative explanation for illness is identified, or the endocarditis syndrome has resolved and the patient has defervesced within 4 days, endocarditis is unlikely.

▶ Complications

The course of infective endocarditis is determined by the degree of damage to the heart, by the site of infection (right-

versus left-sided, aortic versus mitral valve), by the presence of metastatic foci of infection, by the occurrence of embolization, and by immunologically mediated processes. Destruction of infected heart valves is especially common and precipitous with *S aureus* but can occur with any organism and can progress even after bacteriologic cure. The infection can also extend into the myocardium, resulting in abscesses leading to conduction disturbances, and involving the wall of the aorta, creating sinus of Valsalva aneurysms.

Peripheral embolization to the brain and myocardium may result in infarctions. Embolization to the spleen and kidneys is also common. Peripheral emboli may initiate metastatic infections or may become established in vessel walls, leading to mycotic aneurysms. Right-sided endocarditis, which usually involves the tricuspid valve, causes septic pulmonary emboli, occasionally with infarction and lung abscesses.

► Prevention

In 2007, the American Heart Association made major revisions to their recommendation on antibiotic prophylaxis for infective endocarditis. The committee determined that only a few cases of infective endocarditis would be prevented by antibiotic prophylaxis for dental procedures even if the prophylactic therapy were 100% effective. Therefore, they limited their recommendations for prophylaxis to a small group of patients with predisposing congenital or valvular anomalies (Table 33–3) undergoing select dental procedures, operations involving the respiratory tract, or operations of infected skin, skin structure, or musculoskeletal tissue (Table 33–4). Current antimicrobial recommendations are given in Table 33–5.

► Treatment

Empiric regimens for endocarditis while culture results are pending should include agents active against staphylococci,

Table 33–3. Cardiac conditions with high risk of adverse outcomes from endocarditis for which prophylaxis with dental procedures is recommended.^{1,2}

| |
|---|
| Prosthetic cardiac valve |
| Previous infective endocarditis |
| Congenital heart disease (CHD) ³ |
| Unrepaired cyanotic CHD, including palliative shunts and conduits |
| Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure ⁴ |
| Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device |
| Cardiac transplantation recipients in whom cardiac valvulopathy develops |

¹Based on recommendations by the American Heart Association. *Circulation*. 2007 Oct 9;116(15):1736–54.

²See Table 33–5 for prophylactic regimens.

³Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for other forms of CHD.

⁴Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after procedure.

Table 33–4. Recommendations for administration of bacterial endocarditis prophylaxis for patients according to type of procedure.¹

streptococci, and enterococci. Vancomycin 1 g every 12 hours intravenously plus ceftriaxone 2 g every 24 hours provides appropriate coverage pending definitive diagnosis.

A. Viridans Streptococci

For penicillin-susceptible viridans streptococcal endocarditis (ie, MIC \leq 0.1 mcg/mL), penicillin G, 2–3 million units intravenously every 4 hours for 4 weeks, is recommended. The duration of therapy can be shortened to 2 weeks if gentamicin, 1 mg/kg intravenously every 8 hours, is used with penicillin. Ceftriaxone, 2 g once daily intravenously or intramuscularly for 4 weeks, is also effective therapy for penicillin-susceptible strains and is a convenient regimen for home therapy. For the penicillin-allergic patient, vancomycin, 15 mg/kg intravenously every 12 hours for 4 weeks, is given. The 2-week regimen is not recommended for patients with symptoms of more than 3 months' duration or with complications such as myocardial abscess or extracardiac infection. Prosthetic valve endocarditis is treated with a 6-week course of penicillin with at least 2 weeks of gentamicin.

Viridans streptococci relatively resistant to penicillin (ie, MIC $>$ 0.1 mcg/mL but \leq 0.5 mcg/mL) should be treated for 4 weeks. Penicillin G, 3 million units intravenously every 4 hours, is combined with gentamicin, 1 mg/kg intravenously every 8 hours for the first 2 weeks. In the patient with IgE-mediated allergy to penicillin, vancomycin alone, 15 mg/kg intravenously every 12 hours for 4 weeks, should be administered.

Endocarditis caused by viridans streptococci with an MIC $>$ 0.5 mcg/mL or by nutritionally deficient streptococci should be treated the same as enterococcal endocarditis (see below).

B. Other Streptococci

Endocarditis caused by *S pneumoniae*, *S pyogenes* (group A streptococcus), or groups B, C, and G streptococci is unusual. *S pneumoniae* sensitive to penicillin (MIC $<$ 0.1 mcg/mL)

Table 33-5. American Heart Association recommendations for endocarditis prophylaxis for dental procedures for patients with cardiac conditions.¹⁻³

²For patients undergoing respiratory tract procedures involving incision of respiratory tract mucosa to treat an established infection or a procedure on infected skin, skin structure, or musculoskeletal tissue known or suspected to be caused by *S aureus*, the regimen should contain an anti-staphylococcal penicillin or cephalosporin. Vancomycin can be used to treat patients unable to tolerate a β -lactam or if the infection is known or suspected to be caused by a methicillin-resistant strain of *S aureus*.

³See Table 33-3 for list of cardiac conditions.

can be treated with penicillin alone, 2–3 million units intravenously every 4 hours for 4–6 weeks. Vancomycin should be effective for endocarditis caused by strains resistant to penicillin. Group A streptococcal infection can be treated with penicillin, ceftriaxone, or vancomycin for 4–6 weeks. Groups B, C, and G streptococci tend to be more resistant to penicillin than group A streptococci, and some experts have recommended adding gentamicin, 1 mg/kg intravenously every 8 hours, to penicillin for the first 2 weeks of a 4- to 6-week course. Endocarditis caused by *S bovis* is associated with liver disease and gastrointestinal abnormalities, especially colon cancer. Colonoscopy should be performed to exclude the latter.

C. Enterococci

For enterococcal endocarditis, penicillin alone is inadequate; either streptomycin or gentamicin must be included in the regimen. Because aminoglycoside resistance occurs in enterococci, susceptibility should be documented. Gentamicin is the aminoglycoside of choice, because streptomycin resistance is more common and the nephrotoxicity of gentamicin is generally more easily managed than the vestibular toxicity of streptomycin. Ampicillin, 2 g intravenously every 4 hours, or penicillin G, 3–4 million units intravenously every 4 hours (or, in the penicillin-allergic patient, vancomycin, 15 mg/kg intravenously every 12 hours), plus gentamicin, 1 mg/kg intravenously every 8 hours, are recommended. The recommended duration of combination therapy is 4–6 weeks (the longer duration for patients with symptoms for more than 3 months, relapse, or prosthetic valve endocarditis), although a study from Sweden found that discontinuing the aminoglycoside before 4 weeks did not reduce efficacy. Experience is more

extensive with penicillin and ampicillin than with vancomycin for treatment of enterococcal endocarditis, and penicillin and ampicillin are superior to vancomycin in vitro. Thus, whenever possible, either ampicillin or penicillin should be used.

Endocarditis caused by strains resistant to penicillin, vancomycin, or aminoglycosides is particularly difficult to treat. Such cases should be treated according to recent American Heart Association guidelines and managed in consultation with an infectious diseases specialist.

D. Staphylococci

For methicillin-susceptible *S aureus*, nafcillin or oxacillin, 1.5–2 g intravenously every 4 hours for 6 weeks, is the preferred therapy. Uncomplicated tricuspid valve endocarditis probably can be treated for 2 weeks with nafcillin or oxacillin alone. For penicillin-allergic patients, cefazolin, 2 g intravenously every 8 hours, or vancomycin, 30 mg/kg/d intravenously divided in two or three doses, may be used. For methicillin-resistant strains, vancomycin remains the preferred agent. Aminoglycoside combination regimens are probably of no benefit and in general should be avoided. The effect of rifampin with antistaphylococcal drugs is variable, and its routine use is not recommended.

Because coagulase-negative staphylococci—a common cause of prosthetic valve endocarditis—are routinely resistant to methicillin, β -lactam antibiotics should not be used for this infection unless the isolate is demonstrated to be susceptible. A combination of vancomycin, 30 mg/kg/d intravenously divided in two or three doses for 6 weeks; rifampin, 300 mg every 8 hours for 6 weeks; and gentamicin, 1 mg/kg intravenously every 8 hours for the first 2 weeks is recommended for prosthetic valve infection. If the organism

is sensitive to methicillin, either nafcillin or oxacillin or cefazolin can be used in combination with rifampin and gentamicin. Combination therapy with nafcillin or oxacillin (vancomycin for methicillin-resistant strains or patients allergic to β -lactams), rifampin, and gentamicin is also recommended for treatment of *S aureus* prosthetic valve infection.

E. HACEK Organisms

HACEK organisms are slow-growing, fastidious gram-negative coccobacilli or bacilli that are normal oral flora and cause less than 5% of all cases of endocarditis. They may produce β -lactamase, and thus the treatment of choice is ceftriaxone (or some other third-generation cephalosporin), 2 g intravenously once daily for 4 weeks. Prosthetic valve endocarditis should be treated for 6 weeks. In the penicillin-allergic patient, experience is limited, but trimethoprim-sulfamethoxazole, quinolones, and aztreonam have in vitro activity and should be considered; desensitization may be preferable.

F. Role of Surgery

While many cases can be successfully treated medically, operative management is frequently required. Acute heart failure unresponsive to medical therapy is an indication for valve replacement even if active infection is present, especially for aortic valve infection. Infections unresponsive to appropriate antimicrobial therapy after 7–10 days (ie, persistent fevers, positive blood cultures despite therapy) are more likely to be eradicated if the valve is replaced. Surgery is nearly always required for cure of fungal endocarditis and is more often necessary with gram-negative bacilli. It is also indicated when the infection involves the sinus of Valsalva or produces septal abscesses. Recurrent infection with the same organism prompts an operative approach, especially with infected prosthetic valves. Continuing embolization presents a difficult problem when the infection is otherwise responding; surgery may be the proper approach. Particularly challenging is a large and fragile vegetation demonstrated by echo in the absence of embolization. Most clinicians favor an operative approach, vegetectomy with valve repair if the patient is a good candidate. Embolization after bacteriologic cure does not necessarily imply recurrence of endocarditis.

G. Role of Anticoagulation

Anticoagulation is contraindicated in native valve endocarditis because of an increased risk of intracerebral hemorrhage. The role of anticoagulant therapy during active prosthetic valve endocarditis is more controversial. Reversal of anticoagulation may result in thrombosis of the mechanical prosthesis, particularly in the mitral position. On the other hand, anticoagulation during active prosthetic valve endocarditis caused by *S aureus* has been associated with fatal intracerebral hemorrhage. One approach is to discontinue anticoagulation during the septic phase of *S aureus* prosthetic valve endocarditis. In patients with *S aureus* prosthetic valve endocarditis complicated by a central ner-

vous system embolic event, anticoagulation should be discontinued for the first 2 weeks of therapy. Indications for anticoagulation following prosthetic valve implantation for endocarditis are the same as for patients with prosthetic valves without endocarditis (eg, nonporcine mechanical valves and valves in the mitral position).

▶ Response to Therapy

If infection is caused by viridans streptococci, enterococci, or coagulase-negative staphylococci, defervescence occurs in 3–4 days on average; with *S aureus* or *Pseudomonas aeruginosa*, fever commonly persists for 9–12 days. Blood cultures should be obtained to document sterilization of the blood. Other causes of persistent fever are myocardial or metastatic abscess, sterile embolization, superimposed hospital-acquired infection, and drug reaction. Most relapses occur within 1–2 months after completion of therapy. Obtaining one or two blood cultures during this period is prudent.

INFECTIONS CAUSED BY GRAM-NEGATIVE BACTERIA

BORDETELLA PERTUSSIS INFECTION (Whooping Cough)

ESSENTIALS OF DIAGNOSIS

- ▶ Predominantly in infants under age 2 years. Adolescents and adults are an important reservoir of infection.
- ▶ Two-week prodromal catarrhal stage of malaise, cough, coryza, and anorexia.

- ▶ Paroxysmal cough ending in a high-pitched inspiratory “whoop.”
- ▶ Absolute lymphocytosis, often striking; culture confirms diagnosis.

▶ General Considerations

Pertussis is an acute infection of the respiratory tract caused by *B pertussis* that is transmitted by respiratory droplets. The incubation period is 7–17 days. Half of all cases occur before age 2 years. Neither immunization nor disease confers lasting immunity to pertussis. Consequently, adults are an important reservoir of the disease.

▶ Clinical Findings

The symptoms of classic pertussis last about 6 weeks and are divided into three consecutive stages. The catarrhal stage is characterized by its insidious onset, with lacrimation, sneezing, and coryza, anorexia and malaise, and a hacking night cough that becomes diurnal. The paroxysmal stage is characterized by bursts of rapid, consecutive coughs followed by a deep, high-pitched inspiration (whoop). The convalescent stage begins 4 weeks after onset of the illness with a decrease in the frequency and severity of paroxysms of cough. The diagnosis often is not considered in adults, who may not have a typical presentation. Cough persisting more than 2 weeks is suggestive. Infection may also be asymptomatic.

The white blood cell count is usually 15,000–20,000/mcL (rarely, as high as 50,000/mcL or more), 60–80% of which are lymphocytes. The diagnosis is established by isolating the organism from nasopharyngeal culture. A special medium (eg, Bordet-Gengou agar) must be requested. Polymerase chain reaction assays for diagnosis of pertussis may be available in some clinical or health department laboratories.

▶ Prevention

Acellular pertussis vaccine is recommended for all infants, combined with diphtheria and tetanus toxoids (DTaP). Infants and susceptible adults with significant exposure should receive prophylaxis with an oral macrolide (see below). In recognition of their importance as a reservoir of disease, vaccination of adolescents and adults against pertussis is now recommended. The FDA licensed two tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine (Tdap) products (BOOSTRIX, GlaxoSmithKline and ADACEL, Sanofi Pasteur) in 2005. Adolescents aged 11–18 years who have completed the DTP or DTaP vaccination series should receive a single dose of either Tdap product instead of Td (tetanus and diphtheria toxoids vaccine) for booster immunization against tetanus, diphtheria, and pertussis. Either vaccine may be used in place of Td for prophylaxis of tetanus in wound management. The ADACEL vaccine is indicated as a one-time dose for booster immunization for pertussis in children and adults (ages 11 through 64 years). It may be used as a replacement dose for one of the Td doses when completing a primary

immunization series or in place of Td for tetanus wound prophylaxis. Postpartum women and adults who have not been previously vaccinated with Tdap and who have close contact to an infant younger than 12 months should receive a single dose of Tdap. Women of childbearing age are also candidates for one dose of Tdap.

▶ Treatment

Erythromycin, 500 mg four times a day orally for 7 days, shortens the duration of carriage. It also may diminish the severity of coughing paroxysms. Azithromycin, 500 mg orally on day 1 and 250 mg for 4 more days; or clarithromycin, 500 mg orally twice daily for 7 days, is probably as effective as erythromycin and likely to be better tolerated. Trimethoprim-sulfamethoxazole 160 mg–800 mg orally twice a day for 7 days also is effective. These same regimens are indicated for prophylaxis of contacts to an active case of pertussis who are exposed within 3 weeks of the onset of cough in the index case.

OTHER *BORDETELLA* INFECTIONS

Bordetella bronchiseptica is a pleomorphic gram-negative coccobacillus causing kennel cough in dogs. On occasion it causes upper and lower respiratory infection in humans, principally HIV-infected patients. Infection has been associated with contact with dogs and cats, suggesting animal-to-human transmission. Treatment of *B bronchiseptica* infection is guided by results of in vitro susceptibility tests.

MENINGOCOCCAL MENINGITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Fever, headache, vomiting, confusion, delirium, convulsions.
- ▶ Petechial rash of skin and mucous membranes in many.
- ▶ Neck and back stiffness with positive Kernig and Brudzinski signs is characteristic.
- ▶ Purulent spinal fluid with gram-negative intracellular and extracellular diplococci.
- ▶ Culture of cerebrospinal fluid, blood, or petechial aspiration confirms the diagnosis.

► General Considerations

Meningococcal meningitis is caused by *Neisseria meningitidis* of groups A, B, C, Y, and W-135, among others. Meningitis due to serogroup A is uncommon in the United States. Serogroup B generally causes sporadic cases. The frequency of outbreaks of meningitis caused by group C *meningococcus* has increased, and this serotype is the most common cause of epidemic disease in the United States. Up to 40% of persons are nasopharyngeal carriers of meningococci, but disease develops in relatively few of these persons. Infection is transmitted by droplets. The clinical illness may take the form of meningococcemia (a fulminant form of septicemia without meningitis), meningococcemia with meningitis, or meningitis. Recurrent meningococcemia with fever, rash, and arthritis is seen rarely in patients with certain terminal complement deficiencies.

► Clinical Findings

A. Symptoms and Signs

High fever, chills, and headache; back, abdominal, and extremity pains; and nausea and vomiting are typical. Rapidly developing confusion, delirium, seizures, and coma occur in some.

On examination, nuchal and back rigidity are typical, with positive Kernig and Brudzinski signs. (Kernig sign is pain in the hamstrings upon extension of the knee with the hip at 90-degree flexion; Brudzinski sign is flexion of the knee in response to flexion of the neck.) A petechial rash appearing in the lower extremities and at pressure points is found in most cases. Petechiae may vary in size from pinpoint lesions to large ecchymoses or even skin gangrene that may later slough if the patient survives.

B. Laboratory Findings

Lumbar puncture typically reveals a cloudy or purulent cerebrospinal fluid, with elevated pressure, increased protein, and decreased glucose content. The fluid usually contains more than 1000 cells/mcL, with polymorphonuclear cells predominating and containing gram-negative intracellular diplococci. The absence of organisms in a Gram-stained smear of the cerebrospinal fluid sediment does not rule out the diagnosis. The capsular polysaccharide can be demonstrated in cerebrospinal fluid or urine by latex agglutination; this is useful in partially treated patients, though sensitivity is 60–80%. The organism is usually demonstrated by smear and culture of the cerebrospinal fluid, oropharynx, blood, or aspirated petechiae.

Disseminated intravascular coagulation is an important complication of meningococcal infection and is typically present in toxic patients with ecchymotic skin lesions.

► Differential Diagnosis

Meningococcal meningitis must be differentiated from other meningitides. In small infants and in the elderly, fever or stiff neck is often missing, and altered mental status may dominate the picture.

Rickettsial, echovirus and, rarely, other bacterial infections (eg, staphylococcal infections, scarlet fever) also cause petechial rash.

► Prevention

Two vaccines, meningococcal polysaccharide vaccine (MPSV4, indicated for vaccination of persons over age 55) and a conjugate vaccine (MCV4, indicated for persons aged 2–55 years) are effective for meningococcal groups A, C, Y, and W-135. The Advisory Committee on Immunization Practices recommends immunization with a single dose of MCV4 for preadolescents ages 11–12, and for those not previously vaccinated, upon entry into high school. MCV4 is also recommended for college freshmen—particularly those living in dormitories (see Tables 30–12 and 30–13). Vaccine is also recommended for military recruits, asplenic individuals, those with deficiencies in terminal component of complement, and exposed persons during outbreaks.

Eliminating nasopharyngeal carriage of meningococci is an effective prevention strategy in closed populations and to prevent secondary cases in household or otherwise close contacts. Rifampin, 600 mg orally twice a day for 2 days, ciprofloxacin, 500 mg orally once, or one intramuscular 250-mg dose of ceftriaxone is effective. A cluster of cases of fluoroquinolone-resistant meningococcal infections was recently identified in the United States. However, ciprofloxacin remains a recommended empiric agent for eradication of nasopharyngeal carriage. School and work contacts ordinarily need not be treated. Hospital contacts receive therapy only if intense exposure has occurred (eg, mouth-to-mouth resuscitation). Accidentally discovered carriers without known close contact with meningococcal disease do not require prophylactic antimicrobials.

► Treatment

Blood cultures must be obtained and intravenous antimicrobial therapy started immediately. This may be done prior to lumbar puncture in patients in whom the diagnosis is not straightforward and for those in whom MR or CT imaging is indicated to exclude mass lesions. Aqueous penicillin G is the antibiotic of choice (24 million units/24 h intravenously in divided doses every 4 hours). The prevalence of strains of *N meningitidis* with intermediate resistance to penicillin in vitro (MICs 0.1 to 1 mcg/mL) is increasing, particularly in Europe. At what level of resistance penicillin treatment failure can occur is not known. Penicillin-intermediate strains thus far remain fully susceptible to ceftriaxone and other third-generation cephalosporins used to treat meningitis, and these should be effective alternatives to penicillin. In penicillin-allergic patients or those in whom *Haemophilus influenzae* or gram-negative meningitis is a consideration, ceftriaxone, 2 g intravenously every 12 hours, should be used. Treatment should be continued in full doses by the intravenous route until the patient is afebrile for 5 days. Shorter courses—as few as 4 days if ceftriaxone is used—are also effective.

Heckenberg SG et al. Clinical features, outcome, and meningococcal genotype in 258 adults with meningococcal meningitis: a prospective cohort study. *Medicine* (Baltimore). 2008 Jul;87(4):185–92. [PMID: 18626301]

Stephens DS et al. Epidemic meningitis, meningococcaemia, and *Neisseria meningitidis*. *Lancet*. 2007 Jun 30;369(9580):2196–210. [PMID: 17604802]

INFECTIONS CAUSED BY HAEMOPHILUS SPECIES

H influenzae and other *Haemophilus* species may cause sinusitis, otitis, bronchitis, epiglottitis, pneumonia, cellulitis, arthritis, meningitis, and endocarditis. Nontypeable strains are responsible for most disease in adults. Alcoholism, smoking, chronic lung disease, advanced age, and HIV infection are risk factors. *Haemophilus* species colonize the upper respiratory tract in patients with chronic obstructive pulmonary disease and frequently cause purulent bronchitis.

β -Lactamase-producing strains are less common in adults than in children. For adults with sinusitis, otitis, or respiratory tract infection, oral amoxicillin, 750 mg twice daily for 10–14 days, is adequate. For β -lactamase-producing strains, use of the oral fixed drug combination of amoxicillin, 875 mg, with clavulanate, 125 mg, is indicated. For the penicillin-allergic patient, oral cefuroxime axetil, 250 mg twice daily; trimethoprim-sulfamethoxazole, 800/160 mg orally twice daily; or a fluoroquinolone (ciprofloxacin, 500 mg orally twice daily; levofloxacin, 500 mg orally once daily; or moxifloxacin, 400 mg orally once daily) for 10 days is effective. Azithromycin and clarithromycin are less effective.

In the more seriously ill patient (eg, the toxic patient with multilobar pneumonia), ceftriaxone, 1 g/d intravenously is recommended pending determination of whether the infecting strain is a β -lactamase producer. Trimethoprim-sulfamethoxazole administered intravenously based on a dose of 10 mg/kg/d of trimethoprim or a fluoroquinolone (see above for dosages) can be used for the penicillin-allergic patient. A 10- to 14-day course of therapy is adequate for most cases.

Epiglottitis is characterized by an abrupt onset of high fever, drooling, and inability to handle secretions. An important clue to the diagnosis is complaint of a severe sore throat despite an unimpressive examination of the pharynx. Stridor and respiratory distress result from laryngeal obstruction. The diagnosis is best made by direct visualization of the cherry-red, swollen epiglottis at laryngoscopy. Because laryngoscopy may provoke laryngospasm and obstruction, especially in children, it should be performed in an intensive care unit or similar setting, and only at a time when intubation can be performed promptly. Ceftriaxone, 1 g intravenously every 24 hours for 7–10 days, is the drug of choice. Trimethoprim-sulfamethoxazole or a fluoroquinolone (see above for dosage) may be used in the patient with serious penicillin allergy.

Meningitis, rare in adults, is a consideration in the patient who has meningitis associated with sinusitis or otitis. Initial therapy for suspected *H influenzae* meningitis should be with ceftriaxone, 4 g/d in two divided doses, until the strain is proved not to produce β -lactamase. Meningitis is treated for 10–14 days. Dexamethasone, 0.15 mg/kg intravenously every 6 hours may reduce the incidence of long-term sequelae, principally hearing loss.

Tristram S et al. Antimicrobial resistance in *Haemophilus influenzae*. Clin Microbiol Rev. 2007 Apr;20(2):368–89. [PMID: 17428889]

INFECTIONS CAUSED BY MORAXELLA CATARRHALIS

M catarrhalis is a gram-negative aerobic coccus morphologically and biochemically similar to *Neisseria*. It causes sinusitis, bronchitis, and pneumonia. Bacteremia and meningitis have also been reported in immunocompromised patients. The organism frequently colonizes the respiratory tract, making differentiation of colonization from infection difficult. If *M catarrhalis* is the predominant isolate, therapy is directed against it. *M catarrhalis* typically produces β -lactamase and therefore is usually resistant to ampicillin and amoxicillin. It is susceptible to amoxicillin-clavulanate, ampicillin-sulbactam, trimethoprim-sulfamethoxazole, ciprofloxacin, and second- and third-generation cephalosporins.

Heininger N et al. A reservoir of *Moraxella catarrhalis* in human pharyngeal lymphoid tissue. J Infect Dis. 2007 Oct 1;196(7):1080–7. [PMID: 17763332]

LEGIONNAIRES DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Patients are often immunocompromised, smokers, or have chronic lung disease.
- ▶ Scant sputum production, pleuritic chest pain, toxic appearance.
- ▶ Chest radiograph shows focal patchy infiltrates or consolidation.
- ▶ Gram stain of sputum shows polymorphonuclear leukocytes and no organisms.

▶ General Considerations

Legionella infection ranks among the three or four most common causes of community-acquired pneumonia and is considered whenever the etiology of a pneumonia is in question. Legionnaires disease is more common in immunocompromised persons, in smokers, and in those with chronic lung disease. Outbreaks have been associated with contaminated water sources, such as showerheads and faucets in patient rooms and air conditioning cooling towers.

▶ Clinical Findings

A. Symptoms and Signs

Legionnaires disease is one of the atypical pneumonias, so called because a Gram-stained smear of sputum does not show organisms. However, many features of Legionnaires disease are more like typical pneumonia, with high fevers, a toxic patient, pleurisy, and grossly purulent sputum. Classically, this pneumonia is caused by *Legionella pneumophila*, though other species can cause identical disease.

B. Laboratory Findings

Several laboratory abnormalities can be associated with Legionnaires disease, which include hyponatremia, elevated liver enzymes, and elevated creatine kinase. Culture of *Legionella* species onto charcoal-yeast extract agar or similar enriched medium is the most sensitive method (80–90% sensitivity) for diagnosis and permits identification of infections caused by species and serotypes other than *L pneumophila* serotype 1. Dieterle silver staining of tissue, pleural fluid, or other infected material is also a reliable method for detecting *Legionella* species. Direct fluorescent antibody stains and serologic testing are less sensitive because these will detect only *L pneumophila* serotype 1. In addition, making a serologic diagnosis requires that the host respond with sufficient specific antibody production. Urinary antigen tests, which are targeted for detection of *L pneumophila* serotype 1, are also less sensitive than culture.

► Treatment

Azithromycin (500 mg orally once daily), clarithromycin (500 mg orally twice daily), or a fluoroquinolone (eg, levofloxacin 500 mg orally once daily), and not erythromycin, are the drugs of choice for treatment of legionellosis because of their excellent intracellular penetration and in vitro activity, as well as desirable pharmacokinetic properties that permit oral administration and once or twice daily dosing. Duration of therapy is 10–14 days, although a 21-day course of therapy is recommended for immunocompromised patients.

Bartlett JG. Is activity against “atypical” pathogens necessary in the treatment protocols for community-acquired pneumonia? Issues with combination therapy. *Clin Infect Dis*. 2008 Dec 1;47(Suppl 3):S232–6. [PMID: 18986295]

Jacobson KL et al. *Legionella* pneumonia in cancer patients. *Medicine* (Baltimore). 2008 May;87(3):152–9. [PMID: 18520324]

GRAM-NEGATIVE BACTEREMIA & SEPSIS

Gram-negative bacteremia can originate in a number of sites, the most common being the genitourinary system, hepatobiliary tract, gastrointestinal tract, and lungs. Less common sources include intravenous lines, infusion fluids, surgical wounds, drains, and decubitus ulcers.

Patients with potentially fatal underlying conditions in the short term such as neutropenia or immunoparesis have a mortality rate of 40–60%; those with serious underlying diseases likely to be fatal in 5 years, such as solid tumors, cirrhosis, and aplastic anemia, die in 15–20% of cases; and individuals with no underlying diseases have a mortality rate of 5% or less.

► Clinical Findings

A. Symptoms and Signs

Most patients have fevers and chills, often with abrupt onset. However, 15% of patients are hypothermic (temperature ≤ 36.4 °C) at presentation, and 5% never develop a temperature above 37.5 °C. Hyperventilation with respiratory alkalosis and changes in mental status are important

early manifestations. Hypotension and shock, which occur in 20–50% of patients, are unfavorable prognostic signs.

B. Laboratory Findings

Neutropenia or neutrophilia, often with increased numbers of immature forms of polymorphonuclear leukocytes, is the most common laboratory abnormality in septic patients. Thrombocytopenia occurs in 50% of patients, laboratory evidence of coagulation abnormalities in 10%, and overt disseminated intravascular coagulation in 2–3%. Both clinical manifestations and the laboratory abnormalities are nonspecific and insensitive, which accounts for the relatively low rate of blood culture positivity (approximately 20–40%). If possible, three blood cultures from separate sites should be obtained in rapid succession before starting antimicrobial therapy. The chance of recovering the organism in at least one of the three blood cultures is greater than 95%. The false-negative rate for a single culture of 5–10 mL of blood is 30%. This may be reduced to 5–10% (albeit with a slight false-positive rate due to isolation of contaminants) if a single volume of 30 mL is inoculated into several blood culture bottles. Because blood cultures may be falsely negative, when a patient with presumed septic shock, negative blood cultures, and inadequate explanation for the clinical course responds to antimicrobials, therapy should be continued for 10–14 days.

► Treatment

Several factors are important in the management of patients with sepsis.

A. Removal of Predisposing Factors

This usually means decreasing or stopping immunosuppressive medications and in certain circumstances (eg, positive blood cultures) giving granulocyte colony-stimulating factor (filgrastim; G-CSF) to the neutropenic patient.

B. Identifying the Source of Bacteremia

By simply finding the source of bacteremia and removing it (intravenous line) or draining it (abscess), a fatal disease becomes easily treatable.

C. Supportive Measures

The use of fluids and pressors for maintaining blood pressure is discussed in Chapter 12; management of disseminated intravascular coagulation is discussed in Chapter 13.

D. Antibiotics

Antibiotics should be given as soon as the diagnosis is suspected, since delays in therapy have been associated with increased mortality rates, particularly once hypotension develops. In general, bactericidal antibiotics should be used and given intravenously to ensure therapeutic serum levels. Penetration of antibiotics into the site of primary infection is critical for successful therapy—ie, if the infection originates in the central nervous system, antibiotics that penetrate the blood-brain barrier should be used—eg,

penicillin, ampicillin, chloramphenicol, and third-generation cephalosporins—but not first-generation cephalosporins or aminoglycosides, which penetrate poorly. Sepsis caused by gram-positive organisms cannot be differentiated on clinical grounds from that due to gram-negative bacteria. Therefore, initial therapy should include antibiotics active against both types of organisms.

The number of antibiotics necessary remains controversial and depends on the cause. Table 30–9 provides a guide for empiric therapy. Although a combination of antibiotics is often recommended for “synergism,” combination therapy has not been shown to be superior to a single-drug regimen with any of several broad-spectrum antibiotics (eg, a third-generation cephalosporin, piperacillin-tazobactam, carbapenem). If multiple drugs are used initially, the regimen should be modified and coverage narrowed based on the results of culture and sensitivity testing.

E. Corticosteroids

The role of corticosteroids in treatment of septic shock is still quite controversial. Clinical data have suggested an association between mortality in patients with septic shock and poor adrenal reserve to cosyntropin (Cortrosyn) stimulation testing. Administration of “stress doses” of hydrocortisone to patients with relative adrenal insufficiency and pressor-dependent septic shock was shown to reduce mortality in earlier studies. However, the CORTICUS trial, the largest randomized control trial to evaluate the effect of stress-dose hydrocortisone on mortality in septic shock, refuted these earlier findings. This study failed to demonstrate a survival benefit from the addition of stress-dose hydrocortisone, 50 mg intravenously four times a day for 5 days followed by a 6-day tapering dose regimen, in subjects with or without a normal cosyntropin stimulation test. The usefulness of cosyntropin stimulation testing and use of stress-dose hydrocortisone in patients with septic shock are therefore not considered to be standard care.

F. Adjunctive Therapy

Expanded knowledge of the pathophysiology of sepsis and septic shock and recognition that cytokines play a critical role suggest novel approaches to therapy. Strategies include blocking the effects of endotoxin with anti-endotoxin monoclonal antibodies; blockade of TNF- α , a potent cytokine mediator of septic shock, with anti-TNF monoclonal antibody or soluble TNF receptor; use of IL-1 receptor antagonists to inhibit the proinflammatory effects of IL-1 binding to its receptor; use of corticosteroids; and blocking platelet or thrombin activation. None of these strategies have been met with improved survival. However, a single randomized placebo-controlled trial showed that recombinant human activated protein C (drotrecogin alfa) reduced mortality of septic patients with APACHE II scores ≥ 25 , but the benefits of this agent remain controversial. This drug should be used cautiously because of the risk of bleeding. Drotrecogin alfa is not beneficial for patients with severe sepsis and low risk of death (eg, APACHE II score < 25 or single organ failure), and since it is associated with serious bleeding complications, it should not be used in these patients. Patients considered to have an

infectious cause of severe sepsis (defined as three or more signs of systemic inflammation—eg, fever or hypothermia, tachycardia, tachypnea—plus sepsis-induced dysfunction of at least one organ system) of less than 24 hours’ duration are the best candidates. Platelet counts less than 30,000/mcL, conditions associated with an increased risk of bleeding (eg, recent trauma, surgery, or bleeding episode; anticoagulation), or hypercoagulable states have not been investigated. These criteria should be followed when selecting candidates for treatment with drotrecogin alfa (activated). The agent is administered intravenously by constant infusion at a dosage of 24 mcg/kg/h for 96 hours.

SALMONELLOSIS

Salmonellosis includes infection by any of approximately 2000 serotypes of salmonellae. The taxonomy of *Salmonella* species has been confusing. All *Salmonella* serotypes are members of a single species, *Salmonella enterica*. Human infections are caused almost exclusively by *S enterica* subspecies *enterica*, of which three serotypes—*typhi*, *typhimurium*, and *choleraesuis*—are predominantly isolated. Three clinical patterns of infection are recognized: (1) enteric fever, the best example of which is typhoid fever, due to serotype *typhi*; (2) acute enterocolitis, caused by serotype *typhimurium*, among others; and (3) the “septicemic” type, characterized by bacteremia and focal lesions, exemplified by infection with serotype *choleraesuis*. All types are transmitted by ingestion of the organism, usually from contaminated food or drink.

1. Enteric Fever (Typhoid Fever)

ESSENTIALS OF DIAGNOSIS

- ▶ Gradual onset of malaise, headache, nausea, vomiting, abdominal pain.
- ▶ Rose spots, relative bradycardia, splenomegaly, and abdominal distention and tenderness.
- ▶ Slow (stepladder) rise of fever to maximum and then slow return to normal.
- ▶ Leukopenia; blood, stool, and urine culture positive for salmonella.

▶ General Considerations

Enteric fever is a clinical syndrome characterized by constitutional and gastrointestinal symptoms and by headache. It can be caused by any *Salmonella* species. The term “typhoid fever” applies when serotype *typhi* is the cause. Infection is transmitted by consumption of contaminated food or drink. The incubation period is 5–14 days. *Salmonella* is an intracellular

pathogen. Infection begins when organisms breach the mucosal epithelium of the intestines by transcytosis, an organism-mediated transport process through the cell via an endocytic vesicle. Having crossed the epithelial barrier, organisms invade and replicate in macrophages in Peyer patches, mesenteric lymph nodes, and the spleen. Serotypes other than *typhi* usually do not cause invasive disease, presumably because they lack the necessary human-specific virulence factors. Bacteremia occurs, and the infection then localizes principally in the lymphoid tissue of the small intestine (particularly within 60 cm of the ileocecal valve). Peyer patches become inflamed and may ulcerate, with involvement greatest during the third week of disease. The organism may disseminate to the lungs, gallbladder, kidneys, or central nervous system.

▶ Clinical Findings

A. Symptoms and Signs

During the prodromal stage, there is increasing malaise, headache, cough, and sore throat, often with abdominal pain and constipation, while the fever ascends in a stepwise fashion. After about 7–10 days, it reaches a plateau and the patient is much more ill, appearing exhausted and often prostrated. There may be marked constipation, especially early, or “pea soup” diarrhea; marked abdominal distention occurs as well. If there are no complications, the patient’s condition will gradually improve over 7–10 days. However, relapse may occur for up to 2 weeks after defervescence.

During the early prodrome, physical findings are few. Later, splenomegaly, abdominal distention and tenderness, relative bradycardia, and occasionally meningismus appear. The rash (rose spots) commonly appears during the second week of disease. The individual spot, found principally on the trunk, is a pink papule 2–3 mm in diameter that fades on pressure. It disappears in 3–4 days.

B. Laboratory Findings

Typhoid fever is best diagnosed by blood culture, which is positive in the first week of illness in 80% of patients who have not taken antimicrobials. The rate of positivity declines thereafter, but one-fourth or more of patients still have positive blood cultures in the third week. Cultures of bone marrow occasionally are positive when blood cultures are not. Stool culture is unreliable because it may be positive in gastroenteritis without typhoid fever. Relative bradycardia and leukopenia are typical.

▶ Differential Diagnosis

Enteric fever must be distinguished from other gastrointestinal illnesses and from other infections that have few localizing findings. Examples include tuberculosis, infective endocarditis, brucellosis, lymphoma, and Q fever. Often there is a history of recent travel to endemic areas, and viral hepatitis, malaria, or amebiasis may be in the differential as well.

▶ Complications

Complications occur in about 30% of untreated cases and account for 75% of deaths. Intestinal hemorrhage, mani-

festated by a sudden drop in temperature and signs of shock followed by dark or fresh blood in the stool, or intestinal perforation, accompanied by abdominal pain and tenderness, is most likely to occur during the third week. Appearance of leukocytosis and tachycardia should suggest these complications. Urinary retention, pneumonia, thrombophlebitis, myocarditis, psychosis, cholecystitis, nephritis, osteomyelitis, and meningitis are less often observed.

▶ Prevention

Immunization is not always effective but should be considered for household contacts of a typhoid carrier, for travelers to endemic areas, and during epidemic outbreaks. A multiple-dose oral vaccine and a single-dose parenteral vaccine are available. Their efficacies are similar, but oral vaccine causes fewer side effects. Boosters, when indicated, should be given every 5 years and 2 years for oral and parenteral preparations, respectively.

Adequate waste disposal and protection of food and water supplies from contamination are important public health measures to prevent salmonellosis. Carriers cannot work as food handlers.

▶ Treatment

A. Specific Measures

Several antibiotics, including ampicillin, azithromycin, chloramphenicol, third-generation cephalosporins, and trimethoprim-sulfamethoxazole all are effective for treatment of enteric fever caused by drug-susceptible strains. These drugs can be given orally or intravenously depending on the patient’s condition. Because many salmonella strains are resistant to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole, a fluoroquinolone—such as ciprofloxacin 750 mg orally twice daily or levofloxacin 500 mg orally once daily, 5–7 days for uncomplicated enteric fever and 10–14 days for severe infection—is the agent of choice for treatment of salmonella infections. Ceftriaxone, 2 g intravenously for 7 days, is also effective. Although resistance to fluoroquinolones or cephalosporins occurs uncommonly, the prevalence appears to be increasing. When an infection is caused by a multidrug-resistant strain, select an antibiotic to which the isolate is susceptible in vitro. Alternatively, increasing the dose of ceftriaxone to 4 g/d and treating for 10–14 days or using azithromycin 500 mg orally for 7 days in uncomplicated cases may be effective.

B. Treatment of Carriers

Chemotherapy often is unsuccessful in eradicating the carrier state. While treatment of carriage with ampicillin, trimethoprim-sulfamethoxazole, or chloramphenicol may be successful, ciprofloxacin, 750 mg orally twice a day for 4 weeks, has proved to be highly effective. Cholecystectomy may also achieve this goal.

▶ Prognosis

The mortality rate of typhoid fever is about 2% in treated cases. Elderly or debilitated persons are likely to do poorly.

With complications, the prognosis is poor. Relapses occur in up to 15% of cases. A residual carrier state frequently persists in spite of chemotherapy.

Fraser A et al. Vaccines for preventing typhoid fever. *Cochrane Database Syst Rev.* 2007 Jul 18;(3):CD001261. [PMID: 17636661]
 Parry CM et al. A randomised controlled comparison of ofloxacin, azithromycin and an ofloxacin-azithromycin combination for treatment of multidrug-resistant and nalidixic acid resistant typhoid fever. *Antimicrob Agents Chemother.* 2007 Mar;51(3):819–25. [PMID: 17145784]

2. *Salmonella* Gastroenteritis

By far the most common form of salmonellosis is acute enterocolitis caused by numerous *Salmonella* serotypes. The incubation period is 8–48 hours after ingestion of contaminated food or liquid.

Symptoms and signs consist of fever (often with chills), nausea and vomiting, cramping abdominal pain, and diarrhea, which may be grossly bloody, lasting 3–5 days. Differentiation must be made from viral gastroenteritis, food poisoning, shigellosis, amebic dysentery, and acute ulcerative colitis. The diagnosis is made by culturing the organism from the stool.

The disease is usually self-limited, but bacteremia with localization in joints or bones may occur, especially in patients with sickle cell disease.

Treatment of uncomplicated enterocolitis is symptomatic only. Malnourished or severely ill patients, those with sickle cell disease, and HIV-positive patients should be treated for 3–5 days with trimethoprim-sulfamethoxazole (one double-strength tablet twice a day), ampicillin (100 mg/kg intravenously or orally), or ciprofloxacin (750 mg orally twice a day).

Swanson SJ et al. Multidrug-resistant *Salmonella enterica* serotype *Typhimurium* associated with pet rodents. *N Engl J Med.* 2007 Jan 4;356(1):21–8. [PMID: 17202452]

3. *Salmonella* Bacteremia

Salmonella infection may be manifested by prolonged or recurrent fevers accompanied by bacteremia and local infection in bone, joints, pleura, pericardium, lungs, or other sites. Mycotic abdominal aortic aneurysms may also occur. Serotypes other than typhi usually are isolated. This complication tends to occur in immunocompromised persons and is seen in HIV-infected individuals, who typically have bacteremia without an obvious source. Treatment is the same as for typhoid fever, plus drainage of any abscesses. In HIV-infected patients, relapse is common, and lifelong suppressive therapy may be needed. Ciprofloxacin, 750 mg orally twice a day, is effective both for therapy of acute infection and for suppression of recurrence. Incidence of infections caused by drug-resistant strains may be on the rise.

SHIGELLOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Diarrhea, often with blood and mucus.

- ▶ Crampy abdominal pain and systemic toxicity.
- ▶ White blood cells in stools; organism isolated on stool culture.

▶ General Considerations

Shigella dysentery is a common disease, often self-limited and mild but occasionally serious. *Shigella sonnei* is the leading cause in the United States, followed by *Shigella flexneri*. *Shigella dysenteriae* causes the most serious form of the illness. Shigellae are invasive organisms. The infective dose is 10^2 – 10^3 organisms. There has been a rise in strains resistant to multiple antibiotics.

▶ Clinical Findings

A. Symptoms and Signs

The illness usually starts abruptly, with diarrhea, lower abdominal cramps, and tenesmus. The diarrheal stool often is mixed with blood and mucus. Systemic symptoms are fever, chills, anorexia and malaise, and headache. The abdomen is tender. Sigmoidoscopic examination reveals an inflamed, engorged mucosa with punctate and sometimes large areas of ulceration.

B. Laboratory Findings

The stool shows many leukocytes and red cells. Stool culture is positive for shigellae in most cases, but blood cultures grow the organism in less than 5% of cases.

▶ Differential Diagnosis

Bacillary dysentery must be distinguished from salmonella enterocolitis and from disease due to enterotoxigenic *Escherichia coli*, *Campylobacter*, and *Yersinia enterocolitica*. Amebic dysentery may be similar clinically and is diagnosed by finding amebas in the fresh stool specimen. Ulcerative colitis is also an important cause of bloody diarrhea.

▶ Complications

Temporary disaccharidase deficiency may follow the diarrhea. Reactive arthritis is an uncommon complication, usually occurring in HLA-B27 individuals infected by *Shigella*. Hemolytic-uremic syndrome occurs rarely.

▶ Treatment

Treatment of dehydration and hypotension is lifesaving in severe cases. The antimicrobial treatments of choice are trimethoprim-sulfamethoxazole, one double-strength tablet twice a day for 7–10 days, or a fluoroquinolone (ciprofloxacin 750 mg orally twice daily for 7–10 days, or levofloxacin, 500 mg orally once daily) for 3 days. Fluoroquinolones are contraindicated in pregnancy. Shigellae resistant to ampicillin are common, but if the isolate is susceptible, a dose of 500 mg orally four times a day is also effective. Amoxicillin, which is less effective, should not be used.

Aragón TJ et al. Case-control study of shigellosis in San Francisco: the role of sexual transmission and HIV infection. *Clin Infect Dis.* 2007 Feb 1;44(3):327–34. [PMID: 17205436]

GASTROENTERITIS CAUSED BY *ESCHERICHIA COLI*

E coli causes gastroenteritis by a variety of mechanisms. Enterotoxigenic *E coli* (ETEC) elaborates either a heat-stable or heat-labile toxin that mediates the disease. ETEC is an important cause of traveler's diarrhea. Enteroinvasive *E coli* (EIEC) differs from other *E coli* bowel pathogens in that these strains invade cells, causing bloody diarrhea and dysentery similar to infection with *Shigella* species. EIEC is uncommon in the United States. Neither ETEC nor EIEC strains are routinely isolated and identified from stool cultures because there is no selective medium. Antimicrobial therapy directed against *Salmonella* and *Shigella* shortens the clinical course, but the disease is self-limited.

Enterohemorrhagic *E coli* (EHEC) produces two shiga-like toxins that mediate the clinical manifestations, which include an asymptomatic carriage stage, nonbloody diarrhea, hemorrhagic colitis, hemolytic-uremic syndrome, and thrombotic thrombocytopenic purpura. Although there are several serotypes of EHEC, O157:H7 is responsible for most cases in the United States. *E coli* O157:H7 has caused several outbreaks of diarrhea and hemolytic-uremic syndrome related to consumption of undercooked hamburger and unpasteurized apple juice. Older individuals and young children are most affected, with hemolytic-uremic syndrome being more common in the latter group. *E coli* O157:H7 is not identified by routine stool cultures. Isolation requires identification of sorbitol-negative colonies of *E coli* on sorbitol-MacConkey agar followed by serologic testing to confirm the serotype. Antimicrobial therapy does not alter the course of the disease, and may increase the risk of hemolytic-uremic syndrome. Treatment is primarily supportive. Hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura occurring in association with a diarrheal illness suggests the diagnosis and should prompt evaluation for EHEC. Confirmed infections should be reported to public health officials.

Riddle MS. Effect of adjunctive loperamide in combination with antibiotics on treatment outcomes in traveler's diarrhea: a systematic review and meta-analysis. *Clin Infect Dis*. 2008 Oct 15;47(8):1007-14. [PMID: 18781873]

Serna A 4th et al. Pathogenesis and treatment of Shiga toxin-producing *Escherichia coli* infections. *Curr Opin Gastroenterol*. 2008 Jan;24(1):38-47. [PMID: 18043231]

CHOLERA

ESSENTIALS OF DIAGNOSIS

- ▶ History of travel in endemic area or contact with infected person.
- ▶ Voluminous diarrhea.
- ▶ Stool is liquid, gray, turbid, and without fecal odor, blood, or pus ("rice water stool").
- ▶ Rapid development of marked dehydration.
- ▶ Positive stool cultures and agglutination of vibrios with specific sera.

General Considerations

Cholera is an acute diarrheal illness caused by certain serotypes of *Vibrio cholerae*. The disease is toxin-mediated, and fever is unusual. The toxin activates adenyl cyclase in intestinal epithelial cells of the small intestines, producing hypersecretion of water and chloride ion and a massive diarrhea of up to 15 L/d. Death results from profound hypovolemia.

Cholera occurs in epidemics under conditions of crowding, war, and famine (eg, in refugee camps) and where sanitation is inadequate. Infection is acquired by ingestion of contaminated food or water. Cholera was rarely seen in the United States until 1991, when epidemic cholera returned to the Western Hemisphere, originating as an outbreak in coastal cities of Peru. The epidemic spread to involve several countries in South and Central America as well as Mexico, and cases have been imported into the United States. Cholera should be considered in the differential diagnosis of severe watery diarrhea, especially in those who have traveled to affected countries.

Clinical Findings

Cholera is characterized by a sudden onset of severe, frequent watery diarrhea (up to 1 L/h). The liquid stool is gray; turbid; and without fecal odor, blood, or pus ("rice water stool"). Dehydration and hypotension develop rapidly. Stool cultures are positive, and agglutination of vibrios with specific sera can be demonstrated.

Prevention

A vaccine is available that confers short-lived, limited protection and may be required for entry into or reentry after travel to some countries. It is administered in two doses 1-4 weeks apart. A booster dose every 6 months is recommended for persons remaining in areas where cholera is a hazard.

Vaccination programs are expensive and not particularly effective in managing outbreaks of cholera. When outbreaks occur, efforts should be directed toward establishing clean water and food sources and proper waste disposal.

Treatment

Treatment is by replacement of fluids. In mild or moderate illness, oral rehydration usually is adequate. A simple oral replacement fluid can be made from 1 teaspoon of table salt and 4 heaping teaspoons of sugar added to 1 L of water. Intravenous fluids are indicated for persons with signs of severe hypovolemia and those who cannot take adequate fluids orally. Lactated Ringer infusion is satisfactory.

Antimicrobial therapy will shorten the course of illness. Several antimicrobials are active against *V cholerae*, including tetracycline, ampicillin, chloramphenicol, trimethoprim-sulfamethoxazole, fluoroquinolones, and azithromycin. Multiple drug-resistant strains are increasingly encountered, so susceptibility testing, if available, is advisable. A single 1 g oral dose of azithromycin was effective for severe cholera caused by strains with reduced susceptibility to fluoroquinolones, but resistance is emerging to this drug as well.

Tobin-D'Angelo M et al. Severe diarrhea caused by cholera toxin-producing *Vibrio cholerae* serogroup O75 infections acquired in the southeastern United States. *Clin Infect Dis*. 2008 Oct 15;47(8):1035–40. [PMID: 18781876]
 Zuckerman JN et al. The true burden and risk of cholera: implications for prevention and control. *Lancet Infect Dis*. 2007 Aug;7(8):521–30. [PMID: 17584531]

INFECTIONS CAUSED BY OTHER *VIBRIO* SPECIES

Vibrios other than *V cholerae* that cause human disease are *Vibrio parahaemolyticus*, *Vibrio vulnificus*, and *Vibrio alginolyticus*. All are halophilic marine organisms. Infection is acquired by exposure to organisms in contaminated, undercooked, or raw crustaceans or shellfish and warm (> 20 °C) ocean waters and estuaries. Infections are more common during the summer months from regions along the Atlantic coast and the Gulf of Mexico in the United States and from tropical waters around the world. Oysters are implicated in up to 90% of food-related cases. *V parahaemolyticus* causes an acute watery diarrhea with crampy abdominal pain and fever, typically occurring within 24 hours after ingestion of contaminated shellfish. The disease is self-limited, and antimicrobial therapy is usually not necessary. *V parahaemolyticus* may also cause cellulitis and sepsis, though these findings are more characteristic of *V vulnificus* infection.

V vulnificus and *V alginolyticus*—neither of which is associated with diarrheal illness—are important causes of cellulitis and primary bacteremia following ingestion of contaminated shellfish or exposure to sea water. Cellulitis with or without sepsis may be accompanied by bulla formation and necrosis with extensive soft tissue destruction, at times requiring debridement and amputation. The infection can be rapidly progressive and is particularly severe in immunocompromised individuals—especially those with cirrhosis—with death rates as high as 50%. Patients with chronic liver disease and those who are immunocompromised should be cautioned to avoid eating raw oysters.

Tetracycline at a dose of 500 mg orally four times a day for 7–10 days is the drug of choice for treatment of suspected or documented primary bacteremia or cellulitis caused by *Vibrio* species. *V vulnificus* is susceptible in vitro to penicillin, ampicillin, cephalosporins, chloramphenicol, aminoglycosides, and fluoroquinolones, and these agents may also be effective. *V parahaemolyticus* and *V alginolyticus* produce β-lactamase and therefore are resistant to penicillin and ampicillin, but susceptibilities otherwise are similar to those listed for *V vulnificus*.

Bross MH et al. *Vibrio vulnificus* infection: diagnosis and treatment. *Am Fam Physician*. 2007 Aug 15;76(4):539–44. [PMID: 17853628]

INFECTIONS CAUSED BY *CAMPYLOBACTER* SPECIES

Campylobacter organisms are microaerophilic, motile, gram-negative rods. Two species infect humans: *Campylo-*

bacter jejuni, an important cause of diarrheal disease, and *Campylobacter fetus* subsp *fetus*, which typically causes systemic infection and not diarrhea. Dairy cattle and poultry are an important reservoir for campylobacters. Outbreaks of enteritis have been associated with consumption of raw milk. *Campylobacter* gastroenteritis is associated with fever, abdominal pain, and diarrhea characterized by loose, watery, or bloody stools. The differential diagnosis includes shigellosis, *Salmonella* gastroenteritis, and enteritis caused by *Y enterocolitica* or invasive *E coli*. The disease is self-limited, but its duration can be shortened with antimicrobial therapy. Either azithromycin, 1 g orally as a single dose, or ciprofloxacin, 500 mg orally twice daily for 3 days, is effective therapy. However, fluoroquinolone resistance among *C jejuni* isolates has been increasing and susceptibility testing should be routinely performed.

C fetus causes systemic infections that can be fatal, including primary bacteremia, endocarditis, meningitis, and focal abscesses. It infrequently causes gastroenteritis. Patients infected with *C fetus* are often older, debilitated, or immunocompromised. Closely related species, collectively termed “campylobacter-like organisms,” cause bacteremia in HIV-infected individuals. Systemic infections respond to therapy with gentamicin, chloramphenicol, ceftriaxone, or ciprofloxacin. Ceftriaxone or chloramphenicol should be used to treat infections of the central nervous system because of their ability to penetrate the blood-brain barrier.

BRUCELLOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ History of animal exposure, ingestion of unpasteurized milk or cheese.
- ▶ Insidious onset: easy fatigability, headache, arthralgia, anorexia, sweating, irritability.
- ▶ Intermittent and persistent fever.
- ▶ Cervical and axillary lymphadenopathy; hepatosplenomegaly.
- ▶ Lymphocytosis, positive blood culture, positive serologic test.

▶ General Considerations

The infection is transmitted from animals to humans. *Brucella abortus* (cattle), *Brucella suis* (hogs), and *Brucella melitensis* (goats) are the main agents. Transmission to humans occurs by contact with infected meat (slaughterhouse workers), placentae of infected animals (farmers, veterinarians), or ingestion of infected unpasteurized milk

or cheese. The incubation period varies from a few days to several weeks. Brucellosis is a systemic infection that may become chronic. In the United States, brucellosis is very rare. Almost all US cases are imported from countries where brucellosis is endemic (eg, Mexico, Mediterranean Europe, Spain, South American countries).

► Clinical Findings

A. Symptoms and Signs

The onset may be acute, with fever, chills, and sweats, but more often is insidious with symptoms of weakness, weight loss, low-grade fevers, sweats, and exhaustion upon minimal activity. Headache, abdominal or back pain with anorexia and constipation, and arthralgias are also common. The chronic form may assume an undulant nature, with periods of normal temperature between acute attacks; symptoms may persist for years, either continuously or intermittently.

Fever, hepatosplenomegaly, and lymphadenopathy are the most common physical findings. Infection may present with or be complicated by specific organ involvement with signs of endocarditis, meningitis, epididymitis, orchitis, arthritis (especially sacroilitis), spondylitis, or osteomyelitis.

B. Laboratory Findings

The organism can be recovered from cultures of blood, cerebrospinal fluid, urine, bone marrow, or other sites. Modern automated systems have shortened the time to detection of the organism in blood culture. Cultures are more likely to be negative in chronic cases. The diagnosis often is made by serologic testing. Rising serologic titers or an absolute agglutination titer of greater than 1:160 supports the diagnosis.

► Differential Diagnosis

Brucellosis must be differentiated from any other acute febrile disease, especially influenza, tularemia, Q fever, mononucleosis, and enteric fever. In its chronic form it resembles Hodgkin disease, tuberculosis, HIV infection, malaria, and disseminated fungal infections such as histoplasmosis and coccidioidomycosis.

► Complications

The most frequent complications are bone and joint lesions such as spondylitis and suppurative arthritis (usually of a single joint), endocarditis, and meningoenphalitis. Less common complications are pneumonitis with pleural effusion, hepatitis, and cholecystitis.

► Treatment

Single-drug regimens are not recommended because the relapse rate may be as high as 50%. Combination regimens of two or three drugs are most effective. Regimens of doxycycline (200 mg/d orally for 6 weeks) plus rifampin (600 mg/d orally for 6 weeks) or streptomycin (1 g/d intramuscularly for 2 weeks) or gentamicin (240 mg intramuscularly once daily for 7 days) have the lowest recurrence

rates. Longer courses of therapy may be required to prevent relapse of meningitis, osteomyelitis, or endocarditis.

Skalsky K et al. Treatment of human brucellosis: systematic review and meta-analysis of randomised controlled trials. *BMJ*. 2008 Mar 29;336(7646):701–4. [PMID: 18321957]

TULAREMIA

ESSENTIALS OF DIAGNOSIS

- History of contact with rabbits, other rodents, and biting arthropods (eg, ticks in summer) in endemic area.
- Fever, headache, nausea, and prostration.
- Papule progressing to ulcer at site of inoculation.
- Enlarged regional lymph nodes.
- Serologic tests or culture of ulcer, lymph node aspirate, or blood confirm the diagnosis.

► General Considerations

Tularemia is a zoonotic infection of wild rodents and rabbits caused by *Francisella tularensis*. Humans usually acquire the infection by contact with animal tissues (eg, trapping muskrats, skinning rabbits) or from a tick or insect bite. Hamsters and prairie dogs also may carry the organism. An investigation of an outbreak of pneumonic tularemia on Martha's Vineyard in Massachusetts implicated lawn-mowing and brush-cutting as risk factors for infection, underscoring the potential for probable aerosol transmission of the organism. *F tularensis* has been classified as a high-priority agent for potential bioterrorism use because of its virulence and relative ease of dissemination. Infection in humans often produces a local lesion and widespread organ involvement but may be entirely asymptomatic. The incubation period is 2–10 days.

► Clinical Findings

A. Symptoms and Signs

Fever, headache, and nausea begin suddenly, and a local lesion—a papule at the site of inoculation—develops and soon ulcerates. Regional lymph nodes may become enlarged and tender and may suppurate. The local lesion may be on the skin of an extremity or in the eye. Pneumonia may develop from hematogenous spread of the organism or may be primary after inhalation of infected aerosols, which are responsible for human-to-human transmission. Following ingestion of infected meat or water, an enteric form may be manifested by gastrointestinal symptoms, stupor, and delirium. In any type of involvement, the spleen may be enlarged and tender and there may be nonspecific rashes, myalgias, and prostration.

B. Laboratory Findings

Culturing the organism from blood or infected tissue requires special media. For this reason and because cultures

of *F tularensis* may be hazardous to laboratory personnel, the diagnosis is usually made serologically. A positive agglutination test (> 1:80) develops in the second week after infection and may persist for several years.

▶ Differential Diagnosis

Tularemia must be differentiated from rickettsial and meningococcal infections, cat-scratch disease, infectious mononucleosis, and various bacterial and fungal diseases.

▶ Complications

Hematogenous spread may produce meningitis, perisplenitis, pericarditis, pneumonia, and osteomyelitis.

▶ Treatment

Streptomycin is drug of choice for treatment of tularemia. The recommended dose is 7.5 mg/kg intramuscularly every 12 hours for 7–14 days. Gentamicin, which has good in vitro activity against *F tularensis*, is generally less toxic than streptomycin and probably just as effective. Doxycycline (200 mg/d orally) is also effective but has a higher relapse rate. A variety of other agents (eg, fluoroquinolones) are active in vitro but their clinical effectiveness is less well established.

Nigrovic LE et al. Tularemia. *Infect Dis Clin North Am*. 2008 Sep;22(3):489–504. [PMID: 18755386]

PLAGUE

ESSENTIALS OF DIAGNOSIS

- ▶ History of exposure to rodents in endemic area.
- ▶ Sudden onset of high fever, malaise, muscular pains, and prostration.
- ▶ Axillary or inguinal lymphadenitis (bubo).
- ▶ Bacteremia, pneumonitis, and meningitis may occur.
- ▶ Positive smear and culture from bubo and positive blood culture.

▶ General Considerations

Plague is an infection of wild rodents with *Yersinia pestis*, a small bipolar-staining gram-negative rod. It is endemic in California, Arizona, Nevada, and New Mexico. It is transmitted among rodents and to humans by the bites of fleas or from contact with infected animals. Following a fleabite, the organisms spread through the lymphatics to the lymph nodes, which become greatly enlarged (bubo). They may then reach the bloodstream to involve all organs. When pneumonia or meningitis develops, the outcome is often fatal. The patient with pneumonia can transmit the infection to other individuals by droplets. The incubation

period is 2–10 days. Because of its extreme virulence, its potential for dissemination and person-to-person transmission, and efforts to develop the organism as an agent of biowarfare, plague bacillus is considered a high-priority agent for bioterrorism.

▶ Clinical Findings

A. Symptoms and Signs

The onset is sudden, with high fever, malaise, tachycardia, intense headache, delirium, and severe myalgias. The patient appears profoundly ill. If pneumonia develops, tachypnea, productive cough, blood-tinged sputum, and cyanosis also occur. There may be signs of meningitis. A pustule or ulcer at the site of inoculation and lymphangitis may be observed. Axillary, inguinal, or cervical lymph nodes become enlarged and tender and may suppurate and drain. With hematogenous spread, the patient may rapidly become toxic and comatose, with purpuric spots (black plague) appearing on the skin.

Primary plague pneumonia is a fulminant pneumonitis with bloody, frothy sputum and sepsis. It is usually fatal unless treatment is started within a few hours after onset.

B. Laboratory Findings

The plague bacillus may be found in smears from aspirates of buboes examined with Gram stain. Cultures from bubo aspirate or pus and blood are positive but may grow slowly. In convalescing patients, an antibody titer rise may be demonstrated by agglutination tests.

▶ Differential Diagnosis

The lymphadenitis of plague is most commonly mistaken for the lymphadenitis accompanying staphylococcal or streptococcal infections of an extremity, sexually transmitted diseases such as lymphogranuloma venereum or syphilis, and tularemia. The systemic manifestations resemble those of enteric or rickettsial fevers, malaria, or influenza. The pneumonia resembles other bacterial pneumonias, and the meningitis is similar to those caused by other bacteria.

▶ Prevention

Drug prophylaxis may provide temporary protection for persons exposed to the risk of plague infection, particularly by the respiratory route. Tetracycline hydrochloride, 500 mg orally once or twice daily for 5 days, is effective.

Plague vaccines—both live and killed—have been used for many years, but their efficacy is not clearly established.

▶ Treatment

Therapy should be started immediately once plague is suspected. Either streptomycin (the agent with which there is greatest experience), 1 g every 12 hours intravenously, or gentamicin, administered as a 2-mg/kg loading dose, then 1.7 mg/kg every 8 hours intravenously, is effective. Alternatively, doxycycline, 100 mg orally or intravenously, may be used. The duration of therapy is 10 days. Patients with plague pneumonia are placed in strict respiratory isolation,

and prophylactic therapy is given to any person who came in contact with the patient.

GONOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS

- ▶ Purulent and profuse urethral discharge, especially in men, with dysuria, yielding positive smear.
- ▶ Epididymitis, prostatitis, periurethral inflammation, proctitis in men.
- ▶ Cervicitis in women with purulent discharge, or asymptomatic, yielding positive culture; vaginitis, salpingitis, proctitis also occur.
- ▶ Fever, rash, tenosynovitis, and arthritis with disseminated disease.
- ▶ Gram-negative intracellular diplococci seen in a smear or cultured from any site, particularly the urethra, cervix, pharynx, and rectum.

▶ General Considerations

Gonorrhea is caused by *Neisseria gonorrhoeae*, a gram-negative diplococcus typically found inside polymorphonuclear cells. It is transmitted during sexual activity and has its greatest incidence in the 15- to 29-year-old age group. The incubation period is usually 2–8 days.

▶ Classification

A. Urethritis and Cervicitis

In men, there is initially burning on urination and a serous or milky discharge. One to 3 days later, the urethral pain is more pronounced and the discharge becomes yellow, creamy, and profuse, sometimes blood-tinged. The disorder may regress and become chronic or progress to involve the prostate, epididymis, and periurethral glands with painful inflammation. Chronic infection leads to prostatitis and urethral strictures. Rectal infection is common in homosexual men. Atypical sites of primary infection (eg, the pharynx) must always be considered. Asymptomatic infection is common and occurs in both sexes.

Gonococcal infection in women often becomes symptomatic during menses. Women may have dysuria, urinary frequency, and urgency, with a purulent urethral discharge. Vaginitis and cervicitis with inflammation of Bartholin glands are common. Infection may be asymptomatic, with only slightly increased vaginal discharge and moderate cervicitis on examination. Infection may remain as a chronic cervicitis—an important reservoir of gonococci. It can progress to involve the uterus and tubes with acute and chronic salpingitis, with scarring of tubes and

sterility. In pelvic inflammatory disease, anaerobes and chlamydiae often accompany gonococci. Rectal infection may result from spread of the organism from the genital tract or from anal coitus.

Gram stain of urethral discharge in men, especially during the first week after onset, shows gram-negative diplococci in polymorphonuclear leukocytes. Gram stain is less often positive in women. Culture has been the gold standard for diagnosis, particularly when the Gram stain is negative. Nucleic acid amplification tests for *N gonorrhoeae* in cervical and urethral swab specimens and urine permit rapid diagnosis, have excellent sensitivity and specificity, and have largely replaced culture. Identification of *N gonorrhoeae* from rectal or pharyngeal sites, blood, and in joint fluid still requires culture.

B. Disseminated Disease

Systemic complications follow the dissemination of gonococci from the primary site via the bloodstream. Gonococcal bacteremia is associated with intermittent fever, arthralgia, and skin lesions ranging from maculopapular to pustular or hemorrhagic, which tend to be few in number and peripherally located. Rarely, gonococcal endocarditis or meningitis develops. Arthritis and tenosynovitis are common complications, particularly involving the knees, ankles, and wrists. One or occasionally a few joints usually are involved. Gonococci are isolated by culture from less than half of patients with gonococcal arthritis.

C. Conjunctivitis

The most common form of eye involvement is direct inoculation of gonococci into the conjunctival sac. In adults, this occurs by autoinoculation of a person with genital infection. The purulent conjunctivitis may rapidly progress to panophthalmitis and loss of the eye unless treated promptly. A single 1-g dose of ceftriaxone is effective.

▶ Differential Diagnosis

Gonococcal urethritis or cervicitis must be differentiated from nongonococcal urethritis; cervicitis or vaginitis due to *Chlamydia trachomatis*, *Gardnerella vaginalis*, *Trichomonas*, *Candida*, and many other pathogens associated with sexually transmitted diseases; and pelvic inflammatory disease, arthritis, proctitis, and skin lesions. Often, several such pathogens coexist in a patient. Reactive arthritis (urethritis, conjunctivitis, arthritis) may mimic gonorrhea or coexist with it.

▶ Prevention

Prevention is based on education and mechanical or chemical prophylaxis. The condom, if properly used, can reduce the risk of infection. Effective drugs taken in therapeutic doses within 24 hours of exposure can abort an infection. Partner notification and referral of contacts for treatment has been the standard method used to control sexually transmitted diseases. Expedited treatment of sex partners by patient-delivered partner therapy is more effective than partner notification in reducing persistence and recurrence

rates of gonorrhea and chlamydia. This strategy is being increasingly adopted as a means of disease control.

► Treatment

Therapy typically is administered before antimicrobial susceptibilities are known. The choice of which regimen to use should be based on the national prevalences of antibiotic-resistant organisms. Nationwide, strains of gonococci that are resistant to penicillin, tetracycline, or ciprofloxacin have been increasingly observed. Consequently, these drugs can no longer be considered first-line therapy. All sexual partners should be treated and tested for HIV infection and syphilis, as should the patient.

A. Uncomplicated Gonorrhea

For uncomplicated gonococcal infections of the cervix, urethra, and rectum, either ceftriaxone (125 mg intramuscularly) or cefixime (400 mg orally as a single dose) is the treatment of choice. Fluoroquinolones are no longer recommended because of high rates of resistance. Spectinomycin, 1 g intramuscularly once, may be used for the penicillin-allergic patient but is not currently available in the United States. Other single-dose cephalosporin therapies that are considered alternative treatment regimens for uncomplicated urogenital and anorectal gonococcal infections include ceftizoxime, 500 mg intramuscularly once; or cefoxitin, 2 g intramuscularly once, administered with probenecid, 1 g orally; or cefotaxime, 500 mg intramuscularly once. Some evidence indicates that single-dose cefpodoxime, 400 mg and cefuroxime axetil, 1 g might be oral alternatives.

Pharyngeal gonorrhea is treated by ceftriaxone, 125 mg intramuscularly. Since coexistent chlamydial infection is common, doxycycline, 100 mg orally twice daily for 7 days, or azithromycin, given as a single 1-g oral dose, concurrently, should be administered unless chlamydial infection has been ruled out with a negative nucleic acid amplification test for *C trachomatis*; women should have a pregnancy test before a tetracycline (such as doxycycline) is prescribed.

B. Treatment of Other Infections

Disseminated gonococcal infection should be treated with ceftriaxone, 1 g intravenously daily, until 48 hours after improvement begins, at which time therapy may be switched to cefixime, 400 mg orally daily to complete at least 1 week of antimicrobial therapy. An oral fluoroquinolone (ciprofloxacin, 500 mg twice daily, or levofloxacin, 500 mg once daily) for 7 days also is effective, provided the isolate is susceptible. Endocarditis should be treated with ceftriaxone, 2 g every 24 hours intravenously, for at least 3 weeks. Postgonococcal urethritis and cervicitis, which are usually caused by chlamydia, are treated with a regimen of erythromycin, doxycycline, or azithromycin as described above.

Pelvic inflammatory disease requires cefoxitin, 2 g parenterally every 6 hours, or cefotetan, 2 g intravenously every 12 hours. Clindamycin, 900 mg intravenously every 8 hours, plus gentamicin, administered intravenously as a 2-mg/kg loading dose followed by 1.5 mg/kg every 8 hours, is also effective. Cefoxitin, 2 g intramuscularly, plus

probenecid, 1 g orally as a single dose, followed by a 14-day oral regimen of doxycycline, 100 mg twice a day, with or without metronidazole, 500 mg twice daily, is an effective outpatient regimen. Concurrent treatment for chlamydial infection also is indicated.

Workowski KA et al; Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2006. MMWR Recomm Rep. 2006 Aug 4;55(RR-11):1–94. [PMID: 16888612]

CHANCROID

Chancroid is a sexually transmitted disease caused by the short gram-negative bacillus *Haemophilus ducreyi*. The incubation period is 3–5 days. At the site of inoculation, a vesicopustule develops that breaks down to form a painful, soft ulcer with a necrotic base, surrounding erythema, and undermined edges. There may be multiple lesions due to autoinoculation. The adenitis is usually unilateral and consists of tender, matted nodes of moderate size with overlying erythema. These may become fluctuant and rupture spontaneously. With lymph node involvement, fever, chills, and malaise may develop. Balanitis and phimosis are frequent complications in men. Women may have no external signs of infection. The diagnosis is established by culturing a swab of the lesion onto a special medium.

Chancroid must be differentiated from other genital ulcers. The chancre of syphilis is clean and painless, with a hard base. Mixed sexually transmitted disease is very common (including syphilis, herpes simplex, and HIV infection), as is infection of the ulcer with fusiforms, spirochetes, and other organisms.

A single dose of either azithromycin, 1 g orally, or ceftriaxone, 250 mg intramuscularly, is effective treatment. Effective multiple-dose regimens are erythromycin, 500 mg orally four times a day for 7 days, or ciprofloxacin, 500 mg orally twice a day for 3 days.

Mohammed TT et al. Chancroid and human immunodeficiency virus infection—a review. Int J Dermatol. 2008 Jan;47(1):1–8. [PMID: 18173591]

GRANULOMA INGUINALE

Granuloma inguinale is a chronic, relapsing granulomatous anogenital infection due to *Calymmatobacterium (Donovania) granulomatis*. The pathognomonic cell, found in tissue scrapings or secretions, is large (25–90 μm) and contains intracytoplasmic cysts filled with bodies (Donovan bodies) that stain deeply with Wright stain.

The incubation period is 8 days to 12 weeks. The onset is insidious. The lesions occur on the skin or mucous mem-

branes of the genitalia or perineal area. They are relatively painless infiltrated nodules that soon slough. A shallow, sharply demarcated ulcer forms, with a beefy-red friable base of granulation tissue. The lesion spreads by contiguity. The advancing border has a characteristic rolled edge of granulation tissue. Large ulcerations may advance onto the lower abdomen and thighs. Scar formation and healing occur along one border while the opposite border advances.

Superinfection with spirochete-fusiform organisms is common. The ulcer then becomes purulent, painful, foul-smelling, and extremely difficult to treat.

Several therapies are available. Because of the indolent nature of the disease, duration of therapy is relatively long. The following recommended regimens should be given for 3 weeks or until all lesions have healed: doxycycline, 100 mg orally twice daily; or azithromycin, 1 g orally once weekly; or ciprofloxacin, 750 mg orally twice daily; or erythromycin, 500 mg orally four times a day.

BARTONELLA SPECIES

Bartonella species are responsible for a wide variety of clinical syndromes. **Bacillary angiomatosis**, an important manifestation of bartonellosis, is discussed in Chapter 31. A variety of atypical infections, including retinitis, encephalitis, osteomyelitis, and persistent bacteremia and endocarditis have been described.

Trench fever is a self-limited, louse-borne relapsing febrile disease caused by *B quintana*. The disease has occurred epidemically in louse-infested troops and civilians during wars and endemically in residents of scattered geographic areas (eg, Central America). An urban equivalent of trench fever has been described among the homeless. Humans acquire infection when infected lice feces enter sites of skin breakdown. Onset of symptoms is abrupt and fever lasts 3–5 days, with relapses. The patient complains of weakness and severe pain behind the eyes and typically in the back and legs. Lymphadenopathy, splenomegaly, and a transient maculopapular rash may appear. Subclinical infection is frequent, and a carrier state is recognized. The differential diagnosis includes other febrile, self-limited states such as dengue, leptospirosis, malaria, relapsing fever, and typhus. Recovery occurs regularly even in the absence of treatment.

Cat-scratch disease is an acute infection of children and young adults caused by *Bartonella henselae*. It is transmitted from cats to humans as the result of a scratch or bite. Within a few days, a papule or ulcer will develop at the inoculation site in one-third of patients. One to 3 weeks later, fever, headache, and malaise occur. Regional lymph nodes become enlarged, often tender, and may suppurate. Lymphadenopathy from cat scratches resembles that due to neoplasm, tuberculosis, lymphogranuloma venereum, and bacterial lymphadenitis. The diagnosis is usually made clinically. Special cultures for bartonellae, serology, or excisional biopsy, though rarely necessary, confirm the diagnosis. The biopsy reveals necrotizing lymphadenitis and is itself not specific for cat-scratch disease. Cat-scratch disease is usually self-limited, requiring no specific therapy. Encephalitis occurs rarely.

Disseminated forms of the disease—bacillary angiomatosis, peliosis hepatis, and retinitis—occur in HIV-infected persons. The lesions are vasculoproliferative and histopathologically distinct from those of cat-scratch disease. Unexplained fever in patients with late stages of HIV infection is not uncommonly due to bartonellosis. *B quintana*, the agent of trench fever, can also cause bacillary angiomatosis and persistent bacteremia or endocarditis (which will be “culture-negative” unless specifically sought), the latter two entities being associated with homelessness. Due to the fastidious nature of the organism and its special growth requirements, serologic testing (eg, demonstration of a high antibody titer in an indirect immunofluorescence assay) or nucleic acid amplification tests are often required to establish a diagnosis.

Bacillary angiomatosis responds to treatment with a macrolide or doxycycline administered in standard doses for 4–8 weeks. Bacteremia and endocarditis can be effectively treated with a 6-week course of doxycycline (200 mg orally or intravenously in two divided doses per day) plus gentamicin 3 mg/kg/d intravenously for the first 2 weeks. Relapse may occur.

ANAEROBIC INFECTIONS

Anaerobic bacteria comprise the majority of normal human flora. Normal microbial flora of the mouth (anaerobic spirochetes, *Prevotella*, fusobacteria), the skin (anaerobic diphtheroids), the large bowel (bacteroides, anaerobic streptococci, clostridia), and the female genitourinary tract (bacteroides, anaerobic streptococci, fusobacteria) produce disease when displaced from their normal sites into tissues or closed body spaces.

Anaerobic infections tend to be polymicrobial and abscesses are common. Pus and infected tissue often are malodorous. Septic thrombophlebitis and metastatic infection are frequent and may require incision and drainage. Diminished blood supply that favors proliferation of anaerobes because of reduced tissue oxygenation may interfere with the delivery of antimicrobials to the site of anaerobic infection. Cultures, unless carefully collected under anaerobic conditions, may yield negative results.

Important types of infections that are most commonly caused by anaerobic organisms are listed below. Treatment of all these infections consists of surgical exploration and judicious excision in conjunction with administration of antimicrobial drugs.

1. Head & Neck Infections

Prevotella melaninogenica (formerly *Bacteroides melaninogenicus*) and anaerobic spirochetes are commonly involved

in periodontal infections. These organisms, fusobacteria, and peptostreptococci may cause chronic sinusitis, peritonsillar abscess, chronic otitis media, and mastoiditis. Hygiene, drainage, and surgical debridement are as important in treatment as antimicrobials. Oral anaerobic organisms have been uniformly susceptible to penicillin, but there has been a recent trend of increasing penicillin resistance, usually due to β -lactamase production. Penicillin, 1–2 million units intravenously every 4 hours (if parenteral therapy is required) or 0.5 g orally four times daily for less severe infections, or clindamycin can be used (600 mg intravenously every 8 hours or 300 mg orally every 6 hours). Antimicrobial treatment is continued for a few days after signs and symptoms of infection have resolved. Indolent, established infections (eg, mastoiditis or osteomyelitis) may require prolonged courses of therapy, eg, 4–6 weeks or longer.

2. Chest Infections

Usually in the setting of poor oral hygiene and periodontal disease, aspiration of saliva (which contains 10^8 anaerobic organisms per milliliter in addition to aerobes) may lead to necrotizing pneumonia, lung abscess, and empyema. Polymicrobial infection is the rule and anaerobes—particularly *P melaninogenica*, fusobacteria, and peptostreptococci—are common etiologic agents. Septic internal jugular thrombophlebitis (Lemierre syndrome) may originate from mouth anaerobes, classically *Fusobacterium necrophorum*, and cause septic pulmonary embolization. Severe sore throat is a concomitant symptom. Most pulmonary infections respond to antimicrobial therapy alone. Percutaneous chest tube or surgical drainage is indicated for empyema.

Penicillin-resistant *Bacteroides fragilis* and *P melaninogenica* are commonly isolated and have been associated with clinical failures. Clindamycin, 600 mg intravenously once, followed by 300 mg orally every 6–8 hours, is the treatment of choice for these infections. Metronidazole does not cover facultative streptococci, which often are present, and if used, a second agent that is active against streptococci, such as ceftriaxone 1 g intravenously or intramuscularly daily, should be added. Penicillin, 2 million units intravenously every 4 hours, followed by amoxicillin, 500 mg every 8 hours orally, is an alternative; however, increasing prevalence of β -lactamase producing organisms is a concern. Moxifloxacin, 400 mg orally or intravenously once daily, may be used. Because these infections respond slowly, a prolonged course of therapy (eg, 4–6 weeks) is generally recommended.

Bartlett JG. The role of anaerobic bacteria in lung abscess. Clin Infect Dis. 2005 Apr 1;40(7):923–5. [PMID: 15824980]

3. Central Nervous System

Anaerobes are a common cause of brain abscess, subdural empyema, or septic central nervous system thrombophlebitis. The organisms reach the central nervous system by direct extension from sinusitis, otitis, or mastoiditis or by hematogenous spread from chronic lung infections. Antimicrobial therapy—eg, ceftriaxone, 2 g intravenously every

12 hours, plus metronidazole, 750 mg intravenously every 8 hours—is an important adjunct to surgical drainage. Duration of therapy is 6–8 weeks. Some small multiple brain abscesses can be treated with antibiotics alone without surgical drainage.

Menon S et al. Current epidemiology of intracranial abscesses: a prospective 5 year study. J Med Microbiol. 2008 Oct;57(Pt 10):1259–68. [PMID: 18809555]

4. Intra-abdominal Infections

In the colon there are up to 10^{11} anaerobes per gram of content—predominantly *B fragilis*, clostridia, and peptostreptococci. These organisms play a central role in most intra-abdominal abscesses following trauma to the colon, diverticulitis, appendicitis, or perirectal abscess and may also participate in hepatic abscess and cholecystitis, often in association with aerobic coliform bacteria. The bacteriology includes anaerobes as well as enteric gram-negative rods and on occasion enterococci. Therapy should be directed both against anaerobes and gram-negative aerobes. Agents that are active against *B fragilis* include metronidazole, chloramphenicol, moxifloxacin, tigecycline, ertapenem, imipenem, doripenem, ampicillin-sulbactam, ticarcillin-clavulanic acid, and piperacillin-tazobactam. Resistance to cefoxitin, cefotetan, and clindamycin is increasingly encountered. Most third-generation cephalosporins have poor efficacy. Non-fragilis species of bacteroides may be less susceptible to the cephalosporins.

Table 33–6 summarizes the antibiotic regimens for management of moderate to moderately severe infections (eg, patient hemodynamically stable, good surgical drainage possible or established, low APACHE score, no multiple organ failure) and severe infections (eg, major peritoneal soiling, large or multiple abscesses, patient hemodynamically unstable), particularly if drug-resistant organisms are suspected. An effective oral regimen for patients able to take it is presented also.

Table 33–6. Treatment of anaerobic intra-abdominal infections.

Oral therapy

Moxifloxacin 400 mg every 24 hours

Intravenous therapy

Moderate to moderately severe infections:

Ertapenem 1 g every 24 hours

or—

Ceftriaxone 1 g every 24 hours (or ciprofloxacin 400 mg every 12 hours, if penicillin allergic) plus metronidazole 500 mg every 8 hours

or—

Tigecycline 100 mg once followed by 50 mg every 12 hours

or—

Moxifloxacin 400 mg every 24 hours

Severe infections:

Imipenem, 0.5 g every 6–8 hours; meropenem 1 g every 8 hours; doripenem 0.5 g every 8 hours; piperacillin/tazobactam 3.75 g every 6 hours

Brook I. Treatment of anaerobic infection. *Expert Rev Anti Infect Ther.* 2007 Dec;5(6):991–1006. [PMID: 18039083]

5. Female Genital Tract & Pelvic Infections

The normal flora of the vagina and cervix includes several species of bacteroides, peptostreptococci, group B streptococci, lactobacilli, coliform bacteria, and, occasionally, spirochetes and clostridia. These organisms commonly cause genital tract infections and may disseminate from there.

While salpingitis is often caused by gonococci and chlamydiae, tubo-ovarian and pelvic abscesses are associated with anaerobes in most cases. Postpartum infections may be caused by aerobic streptococci or staphylococci, but anaerobes are often found, and the worst cases of postpartum or postabortion sepsis are associated with clostridia and bacteroides. These have a high mortality rate, and treatment requires both antimicrobials directed against anaerobes and coliforms (see above) and abscess drainage or early hysterectomy.

Trigg BG et al. Sexually transmitted infections and pelvic inflammatory disease in women. *Med Clin North Am.* 2008 Sep;92(5):1083–113. [PMID: 18721654]

6. Bacteremia & Endocarditis

Anaerobic bacteremia usually originates from the gastrointestinal tract, the oropharynx, decubitus ulcers, or the female genital tract. Endocarditis due to anaerobic and microaerophilic streptococci and bacteroides originates from the same sites. Most cases of anaerobic or microaerophilic streptococcal endocarditis can be effectively treated with 12–20 million units of penicillin G daily for 4–6 weeks, but optimal therapy of other types of anaerobic bacterial endocarditis must rely on laboratory guidance. Anaerobic corynebacteria (propionibacteria), clostridia, and bacteroides occasionally cause endocarditis.

7. Skin & Soft Tissue Infections

Anaerobic infections in the skin and soft tissue usually follow trauma, inadequate blood supply, or surgery and are most common in areas that are contaminated by oral or fecal flora. These infections also occur in injection drug users and persons sustaining animal to human bites. There may be progressive tissue necrosis (Plate 104) and a putrid odor.

Several terms, such as bacterial synergistic gangrene, synergistic necrotizing cellulitis, necrotizing fasciitis, and nonclostridial crepitant cellulitis, have been used to classify these infections. Although there are some differences in microbiology among them, their differentiation on clinical grounds alone is difficult. All are mixed infections caused by aerobic and anaerobic organisms and require aggressive surgical debridement of necrotic tissue for cure. Surgical consultation is obligatory to assist in diagnosis and treatment.

Broad-spectrum antibiotics active against both anaerobes and gram-positive and gram-negative aerobes (eg, vancomycin plus piperacillin-tazobactam) should be instituted empirically and modified by culture results (see

Table 30–9). They are given for about a week after progressive tissue destruction has been controlled and the margins of the wound remain free of inflammation.

Anaya DA et al. Necrotizing soft-tissue infection: diagnosis and management. *Clin Infect Dis.* 2007 Mar 1;44(5):705–10. [PMID: 17278065]

ACTINOMYCOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ History of recent dental infection or abdominal trauma.
- ▶ Chronic pneumonia or indolent intra-abdominal or cervicofacial abscess.
- ▶ Sinus tract formation.

▶ General Considerations

Actinomyces israelii and other species of *Actinomyces* occur in the normal flora of the mouth and tonsillar crypts. They are anaerobic, gram-positive, branching filamentous bacteria (1 μm in diameter) that may fragment into bacillary forms. When introduced into traumatized tissue and associated with other anaerobic bacteria, these actinomycetes become pathogens.

The most common site of infection is the cervicofacial area (about 60% of cases). Infection typically follows extraction of a tooth or other trauma. Lesions may develop in the gastrointestinal tract or lungs following ingestion or aspiration of the organism from its endogenous source in the mouth. Interestingly, *T whippelii*, the causative agent of Whipple disease, is an actinomycete and therefore is related to the species that cause actinomycosis.

▶ Clinical Findings

A. Symptoms and Signs

1. Cervicofacial actinomycosis—Cervicofacial actinomycosis develops slowly. The area becomes markedly indurated, and the overlying skin becomes reddish or cyanotic. Abscesses eventually draining to the surface persist for long periods. Sulfur granules—masses of filamentous organisms—may be found in the pus. There is usually little pain unless there is secondary infection. Trismus indicates that the muscles of mastication are involved. Radiography may reveal bony involvement.

2. Thoracic actinomycosis—Thoracic involvement begins with fever, cough, and sputum production with night sweats and weight loss. Pleuritic pain may be present. Multiple sinuses may extend through the chest wall, to the heart, or into the abdominal cavity. Ribs may be involved. Radiography shows areas of consolidation and in many cases pleural effusion. Cervicofacial or thoracic disease may occasionally involve the central nervous system, most commonly brain abscess or meningitis.

3. Abdominal actinomycosis—Abdominal actinomycosis usually causes pain in the ileocecal region, spiking fever and chills, vomiting, and weight loss; it may be confused with Crohn disease. Irregular abdominal masses may be palpated. Pelvic inflammatory disease caused by actinomycetes has been associated with prolonged use of an intrauterine contraceptive device. Sinuses draining to the exterior may develop. CT scanning reveals an inflammatory mass extended to involve bone.

B. Laboratory Findings

The anaerobic, gram-positive organism may be demonstrated as a granule or as scattered branching gram-positive filaments in the pus. Anaerobic culture is necessary to distinguish actinomycetes from nocardiae because specific therapy differs for the two infections.

▶ Treatment

Penicillin G is the drug of choice. Ten to 20 million units are given via a parenteral route for 4–6 weeks, followed by oral penicillin V, 500 mg four times daily. Alternatives include ampicillin, 12 g/d intravenously for 4–6 weeks followed by oral amoxicillin 500 mg three times daily or doxycycline 100 mg twice daily intravenously or orally. Response to therapy is slow. Therapy should be continued for weeks to months after clinical manifestations have disappeared in order to ensure cure. Surgical procedures such as drainage and resection may be beneficial.

With penicillin and surgery, the prognosis is good. The difficulties of diagnosis, however, may permit extensive destruction of tissue before the diagnosis is identified and therapy is started.

Sharkawy AA. Cervicofacial actinomycosis and mandibular osteomyelitis. *Infect Dis Clin North Am.* 2007 Jun;21(2):543–56. [PMID: 17561082]

NOCARDIOSIS

Nocardia asteroides, an aerobic filamentous soil bacterium, causes pulmonary and systemic nocardiosis. Bronchopulmonary abnormalities (eg, alveolar proteinosis) predispose to colonization, but infection is unusual unless the patient is also receiving systemic corticosteroids or is otherwise immunosuppressed.

Pulmonary involvement usually begins with malaise, loss of weight, fever, and night sweats. Cough and production of purulent sputum are the chief complaints. Radiography may show infiltrates accompanied by pleural effusion. The lesions may penetrate to the exterior through the chest wall, invading the ribs.

Dissemination involves any organ. Brain abscesses and subcutaneous nodules are most frequent. This is seen exclusively in immunocompromised patients.

N asteroides is usually found as delicate, branching, gram-positive filaments. It may be weakly acid-fast, occasionally causing diagnostic confusion with tuberculosis. Identification is made by culture.

For cutaneous infections, therapy is initiated with intravenous trimethoprim-sulfamethoxazole administered at a dosage of 5–10 mg/kg/d (based on trimethoprim) and continued with oral trimethoprim-sulfamethoxazole, one double-strength tablet twice a day. Surgical procedures such as drainage and resection may be needed as adjunctive therapy. A higher dose of 15 mg/kg/d (based on trimethoprim) should be used for disseminated or pulmonary infections. Imipenem 500 mg intravenously every 6 hours is an alternative.

Response may be slow, and therapy must be continued for at least 6 months. The prognosis in systemic nocardiosis is poor when diagnosis and therapy are delayed.

Nocardia brasiliensis typically causes a digital lesion—resembling herpetic whitlow—and ascending lymphangitis in normal hosts. Antimicrobial treatment is as for *N asteroides* infection, and the prognosis is excellent.

INFECTIONS CAUSED BY MYCOBACTERIA

NONTUBERCULOUS ATYPICAL MYCOBACTERIAL DISEASES

About 10% of mycobacterial infections are caused by atypical mycobacteria. Atypical mycobacterial infections are among the most common opportunistic infections in advanced HIV disease. These organisms have distinctive laboratory characteristics, occur ubiquitously in the environment, are not communicable from person to person, and are often resistant to standard antituberculous drugs.

1. Disseminated *Mycobacterium avium* Infection

Mycobacterium avium complex (MAC) produces asymptomatic colonization or a wide spectrum of diseases, including coin lesions, bronchitis in patients with chronic lung disease, and invasive pulmonary disease that is often cavitory and occurs in patients with underlying lung disease. MAC causes disseminated disease in the late stages of HIV infection, when the CD4 cell count is less than 50/mcL. Persistent fever and weight loss are the most common symptoms. The organism can usually be cultured from multiple sites, including blood, liver, lymph node, or bone marrow. Blood culture is the preferred means of establishing the diagnosis and has a sensitivity of 98%.

Agents with proved activity against MAC are rifabutin, azithromycin, clarithromycin, and ethambutol. Amikacin and ciprofloxacin work in vitro, but clinical results are inconsistent. A combination of two or more active agents should be used to prevent rapid emergence of secondary resistance. Clarithromycin, 500 mg orally twice daily, plus

ethambutol, 15 mg/kg/d orally as a single dose, with or without rifabutin, 300 mg/d orally, is the treatment of choice. Azithromycin, 500 mg orally once daily, may be used instead of clarithromycin. Insufficient data are available to permit specific recommendations about second-line regimens for patients intolerant of macrolides or those with macrolide-resistant organisms. MAC therapy may be discontinued in patients who have been treated with 12 months of therapy for disseminated MAC, who have no evidence of active disease, and whose CD4 counts exceed 100 cells/mL while receiving highly active antiretroviral therapy (HAART). Antimicrobial prophylaxis of MAC prevents disseminated disease and prolongs survival. It is the standard of care to offer it to all HIV-infected patients with CD4 counts \leq 50/mL. In contrast to active infection, single-drug oral regimens of clarithromycin, 500 mg twice daily, azithromycin, 1200 mg once weekly, or rifabutin, 300 mg once daily, are appropriate. Clarithromycin or azithromycin is more effective and better tolerated than rifabutin, and therefore preferred. Primary prophylaxis for MAC infection can be stopped in patients who have responded to antiretroviral combination therapy with elevation of CD4 counts above 100 cells/mL for 3 months.

2. Pulmonary Infections

MAC causes a chronic, slowly progressive pulmonary infection resembling tuberculosis in immunocompetent patients, who typically have underlying pulmonary disease.

Treatment of immunocompetent patients with pulmonary infection is empiric and based entirely on anecdotal data. A combination of agents is probably best. Rifampin, 600 mg orally once daily, plus ethambutol, 15–25 mg/kg/d orally, plus streptomycin, 1 g intramuscularly three to five times a week for the first 4–6 months, have been used. The role of rifabutin, fluoroquinolones, and the macrolides is not known, but based on their excellent efficacy in immunocompromised AIDS patients, they may actually be more effective than the relatively weak agents traditionally used in immunocompetent patients. Clarithromycin is a very potent drug in the treatment of MAC in AIDS patients. Based on this, inclusion of clarithromycin in the initial treatment regimen of immunocompetent patients is prudent. Therapy is continued for a total of 18–24 months.

Mycobacterium kansasii can produce clinical disease resembling tuberculosis, but the illness progresses more slowly. Most such infections occur in patients with pre-existing lung disease, though 40% of patients have no known pulmonary disease. Microbiologically, *M kansasii* is similar to *Mycobacterium tuberculosis* and is sensitive to the same drugs except pyrazinamide, to which it is resistant. Therapy with isoniazid, ethambutol, and rifampin for 2 years (or 1 year after sputum conversion) has been successful.

Less common causes of pulmonary disease include *Mycobacterium xenopi*, *Mycobacterium szulgai*, and *Mycobacterium goodii*. These organisms have variable sensitivities, and treatment is based on results of sensitivity tests. The rapid growing mycobacteria, *Mycobacterium abscessus*, *Mycobacterium chelonae*, and *Mycobacterium fortuitum* also can cause pneumonia in the occasional patient.

3. Lymphadenitis

Most cases of lymphadenitis (scrofula) in adults are caused by *M tuberculosis* and can be a manifestation of disseminated disease. In children, the majority of cases are due to nontuberculous mycobacterial species, with MAC being the most common followed by *Mycobacterium scrofulaceum* in the United States and *Mycobacterium malmoense* and *Mycobacterium haemophilum* in Northern Europe. *M kansasii*, *Mycobacterium bovis*, *M chelonae*, and *M fortuitum* are less commonly observed. Unlike disease caused by *M tuberculosis*, which requires systemic therapy for 6 months, infection with nontuberculous mycobacteria can be successfully treated by surgical excision without antituberculous therapy.

4. Skin & Soft Tissue Infections

Skin and soft tissue infections such as abscesses, septic arthritis, and osteomyelitis can result from direct inoculation or hematogenous dissemination or may occur as a complication of surgery.

M abscessus, *M chelonae*, and *M fortuitum* are frequent causes of this type of infection. Most cases occur in the extremities and initially present as nodules. Ulceration with abscess formation often follows. The organisms are resistant to the usual antituberculous drugs but may be sensitive to a variety of antibiotics, including erythromycin, doxycycline, amikacin, cefoxitin, sulfonamides, imipenem, and ciprofloxacin. Therapy includes surgical debridement along with drug therapy. Initially, parenteral drugs are given for several weeks, and this is followed by an oral regimen to which the organism is sensitive. The duration of therapy is variable but usually continues for several months after the soft tissue lesions have healed.

Mycobacterium marinum infection (“swimming pool granuloma”) presents as a nodular skin lesion following exposure to nonchlorinated water. The lesions respond to therapy with clarithromycin, doxycycline, minocycline, or trimethoprim-sulfamethoxazole.

Mycobacterium ulcerans infection (Buruli ulcer) is seen mainly in Africa and Australia and produces a large ulcerative lesion. Therapy consists of surgical excision and skin grafting.

MYCOBACTERIUM TUBERCULOSIS INFECTIONS

Tuberculosis is discussed in Chapter 9. Further information and expert consultation can be obtained from the Francis J. Curry National Tuberculosis Center at the Web

site <http://www.nationaltbcenter.edu> or, by phone, 415-502-4600, or fax, 415-502-4620.

TUBERCULOUS MENINGITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Gradual onset of listlessness, irritability, and anorexia.
- ▶ Headache, vomiting, and seizures common.
- ▶ Cranial nerve abnormalities typical.
- ▶ Tuberculosis focus may be evident elsewhere.
- ▶ Cerebrospinal fluid shows several hundred lymphocytes, low glucose, and high protein.

▶ General Considerations

Tuberculous meningitis is caused by rupture of a meningeal tuberculoma resulting from earlier hematogenous seeding of tubercle bacilli from a pulmonary focus, or it may be a consequence of miliary spread.

▶ Clinical Findings

A. Symptoms and Signs

The onset is usually gradual, with listlessness, irritability, anorexia, and fever, followed by headache, vomiting, convulsions, and coma. In older patients, headache and behavioral changes are prominent early symptoms. Nuchal rigidity and cranial nerve palsies occur as the meningitis progresses. Evidence of active tuberculosis elsewhere or a history of prior tuberculosis is present in up to 75% of patients.

B. Laboratory Findings

The spinal fluid is frequently yellowish, with increased pressure, 100–500 cells/mcL (predominantly lymphocytes, though neutrophils may be present early during infection), increased protein, and decreased glucose. Acid-fast stains of cerebrospinal fluid usually are negative, and cultures also may be negative in 15–25% of cases. Nucleic acid amplification tests for rapid diagnosis of tuberculosis have variable sensitivity and specificity and none are FDA-approved for use in meningitis. Chest x-ray often reveals abnormalities compatible with tuberculosis but may be normal.

▶ Differential Diagnosis

Tuberculous meningitis may be confused with any other type of meningitis, but the gradual onset, the predominantly lymphocytic pleocytosis of the spinal fluid, and evidence of tuberculosis elsewhere often point to the diagnosis. The tuberculin skin test is usually (not always) positive. Fungal and other granulomatous meningitides, syphilis, and carcinomatous meningitis are in the differential diagnosis.

▶ Complications

Complications of tuberculous meningitis include seizure disorders, cranial nerve palsies, stroke, and obstructive hydrocephalus with impaired cognitive function. These result from inflammatory exudate primarily involving the basilar meninges and arteries.

▶ Treatment

Presumptive diagnosis followed by early, empiric antituberculous therapy is essential for survival and to minimize sequelae. Even if cultures are not positive, a full course of therapy is warranted if the clinical setting is suggestive of tuberculous meningitis.

Regimens that are effective for pulmonary tuberculosis are effective also for tuberculous meningitis (see Table 9–13). Rifampin, isoniazid, and pyrazinamide all penetrate into cerebrospinal fluid well. The penetration of ethambutol is more variable, but therapeutic concentrations can be achieved, and the drug has been successfully used for meningitis. Aminoglycosides penetrate less well. Regimens that do not include both isoniazid and rifampin may be effective but are less reliable and generally must be given for longer periods.

Many authorities recommend the addition of corticosteroids for patients with focal deficits or altered mental status. Dexamethasone, 0.15 mg/kg intravenously or orally four times daily for 1–2 weeks, then discontinued in a tapering regimen over 4 weeks, may be used.

LEPROSY (Hansen Disease)

ESSENTIALS OF DIAGNOSIS

- ▶ Pale, anesthetic macular—or nodular and erythematous—skin lesions.
- ▶ Superficial nerve thickening with associated anesthesia.
- ▶ History of residence in endemic area in childhood.
- ▶ Acid-fast bacilli in skin lesions or nasal scrapings, or characteristic histologic nerve changes.

▶ General Considerations

Leprosy (Hansen disease) is a chronic infectious disease caused by the acid-fast rod *Mycobacterium leprae*. The mode of transmission probably is respiratory and involves prolonged exposure in childhood. The disease is endemic in tropical and subtropical Asia, Africa, Central and South

America, and the Pacific regions, and rarely seen sporadically in the southern United States.

► Clinical Findings

A. Symptoms and Signs

The onset is insidious. The lesions involve the cooler body tissues: skin, superficial nerves, nose, pharynx, larynx, eyes, and testicles. Skin lesions may occur as pale, anesthetic macular lesions 1–10 cm in diameter; discrete erythematous, infiltrated nodules 1–5 cm in diameter; or diffuse skin infiltration. Neurologic disturbances are caused by nerve infiltration and thickening, with resultant anesthesia, and motor abnormalities. Bilateral ulnar neuropathy is highly suggestive. In untreated cases, disfigurement due to the skin infiltration and nerve involvement may be extreme, leading to trophic ulcers, bone resorption, and loss of digits.

The disease is divided clinically and by laboratory tests into two distinct types: lepromatous and tuberculoid. The **lepromatous** type (also referred to as multibacillary leprosy) occurs in persons with defective cellular immunity. The course is progressive and malignant, with nodular skin lesions; slow, symmetric nerve involvement; abundant acid-fast bacilli in the skin lesions; and a negative lepromin skin test. In the **tuberculoid** type (paucibacillary leprosy), cellular immunity is intact and the course is more benign and less progressive, with macular skin lesions, severe asymmetric nerve involvement of sudden onset with few bacilli present in the lesions, and a positive lepromin skin test. Intermediate (“borderline”) cases are frequent. Eye involvement (keratitis and iridocyclitis), nasal ulcers, epistaxis, anemia, and lymphadenopathy may occur.

B. Laboratory Findings

Laboratory confirmation of leprosy requires the demonstration of acid-fast bacilli in a skin biopsy. Biopsy of skin or of a thickened involved nerve also gives a typical histologic picture. *M leprae* does not grow in artificial media but does grow in the foot pads of armadillos.

► Differential Diagnosis

The skin lesions of leprosy often resemble those of lupus erythematosus, sarcoidosis, syphilis, erythema nodosum, erythema multiforme, cutaneous tuberculosis, and vitiligo.

► Complications

Kidney failure and hepatomegaly from secondary amyloidosis may occur with long-standing disease.

► Treatment

Combination therapy is recommended for treatment of all types of leprosy. Single-drug treatment is accompanied by emergence of resistance, and primary resistance to dapsone also occurs. For borderline and lepromatous cases (ie, multibacillary disease), the World Health Organization recommends a triple drug-regimen of rifampin, 600 mg once a month; dapsone, 100 mg daily; and clofazimine, 300 mg once a month and 50 mg daily for 12 months. For

indeterminate and tuberculoid leprosy (paucibacillary disease), the recommendation is rifampin, 600 mg once a month, plus dapsone, 100 mg daily for 6 months.

Two reactional states—erythema nodosum leprosum and reversal reactions—may occur as a consequence of therapy. The reversal reaction, typical of borderline lepromatous leprosy, probably results from enhanced host immunity. Skin lesions and nerves become swollen and tender, but systemic manifestations are not seen. Erythema nodosum leprosum, typical of lepromatous leprosy, is a consequence of immune injury from antigen-antibody complex deposition in skin and other tissues; in addition to skin and nerve manifestations, fever and systemic involvement may be seen. Prednisone, 60 mg/d orally, or thalidomide, 300 mg/d orally (in the nonpregnant patient only), is effective for erythema nodosum leprosum. Improvement is expected within a few days after initiating prednisone, and thereafter the dose may be tapered over several weeks to avoid recurrence. Thalidomide is also tapered over several weeks to a 100-mg bedtime dose. Erythema nodosum leprosum is usually confined to the first year of therapy, and prednisone or thalidomide can be discontinued. Thalidomide is ineffective for reversal reactions, and prednisone, 60 mg/d, is indicated. Reversal reactions tend to recur, and the dose of prednisone should be slowly tapered over weeks to months. Therapy for leprosy should not be discontinued during treatment of reactional states.

Walker SL et al. Leprosy. Clin Dermatol. 2007 Mar-Apr;25(2):165–72. [PMID: 17350495]

INFECTIONS CAUSED BY CHLAMYDIAE

Chlamydiae is a family of obligate intracellular parasites closely related to gram-negative bacteria. They include two important genera of human pathogens—*Chlamydia*, which includes the species *Chlamydia trachomatis*, and *Chlamydia pneumoniae*, which include the species *Chlamydia pneumoniae* (formerly known as *Chlamydia psittaci*) and *Chlamydia pneumoniae* (formerly known as *Chlamydia pneumoniae*). The differentiation of genera is based on differences in intracellular inclusions, sulfonamide susceptibility, antigenic composition, and disease production. *C trachomatis* causes many different human infections involving the eye (trachoma, inclusion conjunctivitis), the genital tract (lymphogranuloma venereum, nongonococcal urethritis, cervicitis, salpingitis), or the respiratory tract in infants (pneumonitis). *C psittaci* causes psittacosis and *C pneumoniae* is a cause of respiratory tract infections.

CHLAMYDIA TRACHOMATIS INFECTIONS

1. Lymphogranuloma Venereum

ESSENTIALS OF DIAGNOSIS

► Evanescent primary genital lesion.

- ▶ Lymph node enlargement, softening, and suppuration, with draining sinuses.
- ▶ Proctitis and rectal stricture in women or homosexual men.
- ▶ Positive complement fixation test.

▶ General Considerations

Lymphogranuloma venereum (LGV) is an acute and chronic sexually transmitted disease caused by *C trachomatis* types L1–L3. The disease is acquired during intercourse or through contact with contaminated exudate from active lesions. The incubation period is 5–21 days. After the genital lesion disappears, the infection spreads to lymph channels and lymph nodes of the genital and rectal areas. Inapparent infections and latent disease are not uncommon.

▶ Clinical Findings

A. Symptoms and Signs

In men, the initial vesicular or ulcerative lesion (on the external genitalia) is evanescent and often goes unnoticed. Inguinal buboes appear 1–4 weeks after exposure, are often bilateral, and have a tendency to fuse, soften, and break down to form multiple draining sinuses, with extensive scarring. In women, the genital lymph drainage is to the perirectal glands. Early anorectal manifestations are proctitis with tenesmus and bloody purulent discharge; late manifestations are chronic cicatrizing inflammation of the rectal and perirectal tissue. These changes lead to obstipation and rectal stricture and, occasionally, rectovaginal and perianal fistulas. They are also seen in homosexual men.

B. Laboratory Findings

The complement fixation test may be positive (titers > 1:64), but cross-reaction with other chlamydiae occurs. Although a positive reaction may reflect remote infection, high titers usually indicate active disease. Nucleic acid detection tests are sensitive, but not FDA-approved for rectal specimens and cannot differentiate LGV from non-LGV strains.

▶ Differential Diagnosis

The early lesion of LGV must be differentiated from the lesions of syphilis, genital herpes, and chancroid; lymph node involvement must be distinguished from that due to tularemia, tuberculosis, plague, neoplasm, or pyogenic infection; and rectal stricture must be distinguished from that due to neoplasm and ulcerative colitis.

▶ Treatment

If diagnostic testing for LGV is not available, patients with a clinical presentation suggestive of LGV should be treated empirically. The antibiotic of choice is doxycycline (contraindicated in pregnancy), 100 mg orally twice daily for 21 days. Erythromycin, 500 mg orally four times a day for 21 days, is also effective. Azithromycin, 1 g orally once weekly for 3 weeks, may also be effective.

McLean CA et al. Treatment of lymphogranuloma venereum. *Clin Infect Dis.* 2007 Apr 1;44 (Suppl 3):S147–52. [PMID: 17342667]

2. Chlamydial Urethritis & Cervicitis

C trachomatis immunotypes D–K are isolated in about 50% of cases of nongonococcal urethritis and cervicitis by appropriate techniques. In other cases, *Ureaplasma urealyticum* or *Mycoplasma genitalium* can be grown as a possible etiologic agent. *C trachomatis* is an important cause of postgonococcal urethritis. Coinfection with gonococci and chlamydiae is common, and postgonococcal (ie, chlamydial) urethritis may persist after successful treatment of the gonococcal component. Occasionally, epididymitis, prostatitis, or proctitis is caused by chlamydial infection.

Females infected with chlamydiae may be asymptomatic or may have symptoms and signs of cervicitis, salpingitis, or pelvic inflammatory disease. Chlamydiae are a leading cause of infertility in females in the United States. Active screening for chlamydial infection is recommended in certain settings: pregnant women; all sexually active women 25 years of age and under; older women with risk factors for sexually transmitted diseases; and men with risk factors for sexually transmitted diseases, such as HIV-positive men or men who have sex with men.

The urethral or cervical discharge due to *C trachomatis* tends to be less painful, less purulent, and watery compared with gonococcal infection. A patient with urethritis or cervicitis and absence of gram-negative diplococci on Gram stain and of *N gonorrhoeae* on culture is assumed to have chlamydial infection until proven otherwise. In the past, the diagnosis of chlamydial infection has been clinical because *C trachomatis* is difficult and expensive to culture; therefore, therapy often was given presumptively. The advent of FDA-approved, highly sensitive nucleic acid amplification tests for use with urine or vaginal swabs has simplified matters, and the diagnosis should be confirmed whenever possible. A negative nucleic acid amplification test for chlamydia reliably excludes the diagnosis of chlamydial urethritis or cervicitis and therapy need not be administered. Presumptively administered therapy still may be indicated in some cases (such as for an individual with gonococcal infection in whom no chlamydial testing was performed or a test other than a nucleic acid amplification test was used to exclude the diagnosis, an individual for whom a test result is pending but is considered unlikely to follow-up, and for sexual contacts of documented cases).

Recommended regimens are a single oral 1-g dose of azithromycin (preferred and safe in pregnancy), 100 mg of doxycycline orally for 7 days (contraindicated in pregnancy), or 500 mg of levofloxacin once daily for 7 days (also contraindicated in pregnancy). As for all sexually transmitted diseases, studies for HIV and syphilis should be performed.

CHLAMYDOPHILA PSITTACI & PSITTACOSIS (Ornithosis)

ESSENTIALS OF DIAGNOSIS

- ▶ Fever, chills, and cough; headache common.
- ▶ Atypical pneumonia with slightly delayed appearance of signs of pneumonitis.
- ▶ Contact with infected bird (psittacine, pigeons, many others) 7–15 days previously.
- ▶ Isolation of chlamydiae or rising titer of complement-fixing antibodies.

▶ General Considerations

Psittacosis is acquired from contact with birds (parrots, parakeets, pigeons, chickens, ducks, and many others), which may or may not be ill. The history may be difficult to obtain if the patient acquired infection from an illegally imported bird.

▶ Clinical Findings

The onset is usually rapid, with fever, chills, myalgia, dry cough, and headache. Signs include temperature-pulse dissociation, dullness to percussion, and rales. Pulmonary findings may be absent early. Dyspnea and cyanosis may occur later. Endocarditis, which is culture-negative, may occur. The radiographic findings in typical psittacosis are those of atypical pneumonia, which tends to be interstitial and diffuse in appearance, though consolidation can occur. Psittacosis is indistinguishable from other bacterial or viral pneumonias by radiography.

The organism is rarely isolated from cultures. The diagnosis is usually made serologically; antibodies appear during the second week and can be demonstrated by

complement fixation or immunofluorescence. Antibody response may be suppressed by early chemotherapy.

▶ Differential Diagnosis

The illness is indistinguishable from viral, mycoplasmal, or other atypical pneumonias except for the history of contact with birds. Psittacosis is in the differential diagnosis of culture-negative endocarditis.

▶ Treatment

Treatment consists of giving tetracycline, 0.5 g orally every 6 hours or 0.5 g intravenously every 12 hours, for 14–21 days. Erythromycin, 500 mg orally every 6 hours, may be effective as well.

CHLAMYDOPHILA PNEUMONIAE INFECTION

C pneumoniae causes pneumonia and bronchitis. The clinical presentation of pneumonia is that of an atypical pneumonia. The organism accounts for approximately 10% of community-acquired pneumonias, ranking second to mycoplasma as an agent of atypical pneumonia. A putative role in coronary artery disease has not held up to close scientific scrutiny.

Like *C psittaci*, strains of *C pneumoniae* are resistant to sulfonamides. Erythromycin or tetracycline, 500 mg orally four times a day for 10–14 days, appears to be effective therapy. Fluoroquinolones, such as levofloxacin (500 mg once daily for 7–14 days) or moxifloxacin (400 mg once daily for 7–14 days), are active in vitro against *C pneumoniae* and probably are effective. It is unclear if empiric coverage for atypical pathogens in hospitalized patients with community-acquired pneumonia provides a survival benefit or improves clinical outcome.

Spirochetal Infections

Susan S. Philip, MD, MPH

SYPHILIS

NATURAL HISTORY & PRINCIPLES OF DIAGNOSIS & TREATMENT

Syphilis is a complex infectious disease caused by *Treponema pallidum*, a spirochete capable of infecting almost any organ or tissue in the body and causing protean clinical manifestations (Table 34–1). Transmission occurs most frequently during sexual contact (including oral sex), through minor skin or mucosal lesions; sites of inoculation are usually genital but may be extragenital. The risk of developing syphilis after unprotected sex with an individual with infectious syphilis is approximately 30–50%. Rarely, it can also be transmitted through nonsexual contact, blood transfusion, or via the placenta from mother to fetus (congenital syphilis).

The natural history of acquired syphilis is generally divided into two major clinical stages: **early (infectious) syphilis** and **late syphilis**. The two stages are separated by a symptom-free latent phase during the first part of which (early latency) infectious lesions are liable to recur. Infectious syphilis includes the primary lesions (chancre and regional lymphadenopathy), the secondary lesions (commonly involving skin and mucous membranes, occasionally bone, central nervous system, or liver), relapsing lesions during early latency, and congenital lesions. The hallmark of these lesions is an abundance of spirochetes; tissue reaction is usually minimal. Late syphilis consists of so-called benign (gummatous) lesions involving skin, bones, and viscera; cardiovascular disease (principally aortitis); and a variety of central nervous system and ocular syndromes. These forms of syphilis are not contagious. The lesions contain few demonstrable spirochetes, but tissue reactivity (vasculitis, necrosis) is severe and suggestive of hypersensitivity phenomena.

COURSE & PROGNOSIS

The lesions associated with primary and secondary syphilis are self-limiting, even without treatment, and resolve with few or no residua. Late syphilis may be highly destructive and permanently disabling and may lead to death. Many experts now believe that while infection is almost never completely eradicated in the absence of treatment, most

infections remain latent without sequelae, and only a small number of latent infections progress to further disease.

CLINICAL STAGES OF SYPHILIS

1. Primary Syphilis

ESSENTIALS OF DIAGNOSIS

- ▶ History of sexual contact (often unreliable).
- ▶ Painless ulcer on genitalia, perianal area, rectum, pharynx, tongue, lip, or elsewhere 2–6 weeks after exposure.
- ▶ Nontender enlargement of regional lymph nodes.
- ▶ Fluid expressed from lesion contains *T pallidum* by immunofluorescence or darkfield microscopy.
- ▶ Serologic test for syphilis may be positive.

▶ Clinical Findings

A. Symptoms and Signs

This is the stage of invasion and may pass unrecognized. The typical lesion is the chancre at the site or sites of inoculation, most frequently located on the penis, labia, cervix, or anorectal region (Plate 105). Anorectal lesions are especially common among men who have sex with men. Chancres also occur occasionally in the oropharynx (lip, tongue, or tonsil) and rarely on the breast or finger. An initial small erosion 10–90 days (average, 3–4 weeks) after inoculation then rapidly develops into a painless superficial ulcer with a clean base and firm, indurated margins, which is associated with enlargement of regional lymph nodes, which are rubbery, discrete, and nontender. Bacterial infection of the chancre may occur and may lead to pain. Healing occurs without treatment, but a scar may form, especially with secondary bacterial infection. Multiple chancres may be present, particularly in HIV-positive patients. Although the “classic” ulcer of syphilis has been described as nontender, nonpurulent, and indurated, only 31% of patients have this triad.

Table 34–1. Stages of syphilis and common clinical manifestations.

| |
|---|
| Primary syphilis |
| Genital ulcer: painless ulcer with clean base and firm indurated borders |
| Regional lymphadenopathy |
| Secondary syphilis |
| Skin and mucous membranes |
| Rash: diffuse (including palms and soles), macular, papular, pustular, and combinations |
| Condylomata lata |
| Mucous patches: painless, silvery ulcerations of mucous membrane with surrounding erythema |
| Generalized lymphadenopathy |
| Constitutional symptoms |
| Fever, usually low-grade |
| Malaise |
| Anorexia |
| Arthralgias and myalgias |
| Central nervous system |
| Asymptomatic |
| Symptomatic |
| Headache |
| Meningitis |
| Cranial neuropathies (II–VIII) |
| Ocular |
| Iritis |
| Iridocyclitis |
| Other |
| Renal: glomerulonephritis, nephrotic syndrome |
| Liver: hepatitis |
| Bone and joint: arthritis, periostitis |
| Late syphilis |
| Late benign (gummatous): granulomatous lesion usually involving skin, mucous membranes and bones, but any organ can be involved |
| Cardiovascular |
| Aortic regurgitation |
| Coronary ostial stenosis |
| Aortic aneurysm |
| Neurosyphilis |
| Asymptomatic |
| Meningovascular |
| Seizures |
| Hemiparesis or hemiplegia |
| Tabes dorsalis |
| Impaired proprioception and vibratory sensation |
| Argyll Robertson pupil |
| Shooting pains |
| Ataxia |
| Romberg sign |
| Urinary and fecal incontinence |
| Charcot joint |
| Cranial nerve involvement (II–VIII) |
| General paresis |
| Personality changes |
| Hyperactive reflexes |
| Argyll Robertson pupil |
| Decreased memory |
| Slurred speech |
| Optic atrophy |

B. Laboratory Findings

1. Microscopic examination—In early (infectious) syphilis, darkfield microscopic examination by a skilled observer

Table 34–2. Percentage of patients with positive serologic tests for syphilis.¹

| Test | Stage | | |
|---------|---------|-----------|----------|
| | Primary | Secondary | Tertiary |
| VDRL | 75–85% | 99% | 95% |
| FTA-ABS | 85–95% | 100% | 98% |

¹Based on untreated cases.

FTA-ABS, fluorescent treponemal antibody absorption test; VDRL, Venereal Disease Research Laboratory test.

of fresh exudate from lesions or material aspirated from regional lymph nodes is up to 90% sensitive for diagnosis. The darkfield examination requires considerable experience for proper specimen collection and identification of characteristic features of morphology and motility of pathogenic spirochetes, and repeated examinations may be necessary. Therefore, this testing is usually only available in select sexually transmitted disease clinics. Darkfield examination of oral lesions is not recommended because of the presence of nonpathogenic treponemes in the mouth. Spirochetes usually are not found in late syphilitic lesions by this technique.

An immunofluorescent staining technique for demonstrating *T pallidum* in dried smears of fluid taken from early syphilitic lesions is available. Slides are fixed and treated with fluorescein-labeled antitreponemal antibody that has been preabsorbed with nonpathogenic treponemes. The slides are then examined for fluorescing spirochetes in an ultraviolet microscope. Because of its simplicity and convenience to clinicians (slides can be mailed), this technique has replaced darkfield microscopy in most health departments and medical center laboratories.

2. Serologic tests for syphilis—(Table 34–2.) There are two general categories of serologic tests for syphilis: (1) Nontreponemal tests detect antibodies to lipoidal antigens present in the host after modification by *T pallidum*. (2) Treponemal tests use live or killed *T pallidum* as antigen to detect antibodies specific for pathogenic treponemes.

A. NONTREPONEMAL ANTIGEN TESTS—The most commonly used nontreponemal antigen tests are the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR), which measure the ability of heated serum to flocculate a suspension of cardiolipin–cholesterol–lecithin. The flocculation tests are inexpensive, rapid, and easy to perform and are therefore used primarily for routine screening. Quantitative expression of the reactivity of the serum, based on titration of dilutions of serum, is valuable in establishing the diagnosis and in evaluating the efficacy of treatment, since titers usually correlate with disease activity.

Nontreponemal tests generally become positive 4–6 weeks after infection or 1–3 weeks after the appearance of a primary lesion; they are almost invariably positive in the secondary stage, with titers \geq 1:32. In the late stages, titers tend to be lower ($<$ 1:4). These serologic tests are not highly specific and must be closely correlated with other

clinical and laboratory findings. The tests are positive in patients with non-sexually transmitted treponematoses (see below). More important, false-positive serologic reactions are frequently encountered in a wide variety of nontreponemal states, including connective tissue diseases, infectious mononucleosis, malaria, febrile diseases, leprosy, injection drug use, infective endocarditis, old age, hepatitis C viral infection, and pregnancy. False-positive tests also occur more commonly in HIV-seropositive patients (4%) than in HIV-seronegative patients (0.8%). False-positive reactions are usually of low titer and transient and may be distinguished from true positives by specific treponemal antibody tests. False-negative results can be seen when very high antibody titers are present (the prozone phenomenon). If syphilis is strongly suspected and the nontreponemal test is negative, the laboratory should be instructed to dilute the specimen to detect a positive reaction. The RPR and VDRL tests are equally reliable, but titers of RPR tend to be higher than the VDRL. Thus, when these tests are used to follow disease activity, the same testing method should be used and preferably should be performed at the same laboratory.

Nontreponemal antibody titers are used to assess adequacy of therapy. The time required for the VDRL or RPR to become negative depends on the stage of the disease, the level of the initial titer, and whether the infection is an initial or repeat episode. In general, persons with repeat infections, higher initial titers, more advanced stages of disease, or those who are HIV positive at the time of treatment have a slower seroconversion rate and are more likely to remain serofast (ie, titers do not become negative). Data based on currently recommended treatment regimens (see below) suggest that in primary and secondary syphilis it may take 6 months to see a fourfold decrease in titer and 12 months to see an eightfold drop. In patients with early latent syphilis, response is even slower, with a fourfold drop in titer taking 12–24 months. Seronegativity was seen in 72% of patients with primary syphilis and only 56% of those with secondary syphilis after 3 years.

B. TREPONEMAL ANTIBODY TESTS—These tests measure antibodies capable of reacting with *T pallidum* antigens. The *T pallidum* hemagglutination (TPHA) test and the *T pallidum* particle agglutination (TPPA) test are comparable in specificity and sensitivity to the fluorescent treponemal antibody absorption test (FTA-ABS). The TPPA test, because of ease of performance, has supplanted the FTA-ABS test as the means of confirming the diagnosis of syphilis.

The treponemal tests are of value principally in determining whether a positive nontreponemal antigen test is false-positive or is indicative of syphilis. Because of their great sensitivity, particularly in the late stages of the disease, these tests are also of value when there is clinical evidence of syphilis but the nontreponemal serologic test for syphilis is negative. Treponemal tests are positive in most patients with primary syphilis and in almost all patients with secondary syphilis. Like nontreponemal antigen tests, the specific treponemal antibody test may revert to negative with adequate therapy. This is seen almost exclusively in initial infections in persons with primary

syphilis. In one study, 11% of individuals with a first episode of primary syphilis were seronegative by the FTA-ABS test at 1 year posttreatment and 24% were negative by 3 years. Immunologic status may also affect antibody titers. Seven percent of asymptomatic HIV-infected patients became seronegative after treatment, compared with 38% of symptomatic HIV-infected individuals. The long-held belief that a positive treponemal test persists indefinitely is clearly not valid, and this test therefore cannot be used as a reliable marker of previous infection. False-positive test results occur rarely in persons with systemic lupus erythematosus and in other disorders associated with increased levels of γ -globulins, malaria, leprosy, and other spirochetal infections. It is noteworthy that Lyme disease may cause a false-positive treponemal test but rarely causes a false-positive nontreponemal test. Final decisions about the significance of the results of serologic tests for syphilis must be based on a total clinical appraisal.

3. Polymerase chain reaction—There is increasing interest in the use of polymerase chain reaction (PCR) for the diagnosis of genital ulcer disease, including syphilis, but it is not yet widely available in the United States.

4. Cerebrospinal fluid examination—See Neurosyphilis (below).

► Differential Diagnosis

The syphilitic chancre may be confused with genital herpes, chancroid (usually painful and uncommon in the United States), lymphogranuloma venereum (also uncommon), or neoplasm. Any genital ulcer should be considered a possible primary syphilitic lesion. Simultaneous evaluation for herpes simplex virus types 1 and 2 using PCR or culture should also be done in these cases.

► Prevention & Screening

Avoidance of sexual contact is the only completely reliable method of prevention but is an impractical public health measure for obvious reasons. The standard latex condom is effective but protects covered areas only. Screening every 6–12 months for syphilis among men who have sex with men has been recommended based on preliminary data suggesting that this may decrease the rate of transmission. High-risk individuals (those who have multiple encounters with anonymous partners or who have sex in conjunction with the use of drugs) should be screened every 3–6 months. Patients treated for other sexually transmitted diseases should also be tested for syphilis, and persons who have known or suspected contact with patients who have syphilis should be evaluated and treated to abort development of infectious syphilis (see Treating Syphilis Contacts below).

► Treatment

A. Antibiotic Therapy

Penicillin remains the preferred treatment for syphilis, since there have been no documented cases of penicillin resistant *T pallidum* (Table 34–3). Although doxycycline is

Table 34-3. Recommended treatment for syphilis.¹

| Stage of Syphilis | Treatment | Alternative ² | Comment |
|-------------------------------------|---|--|--|
| Early | | | |
| Primary, secondary, or early latent | Benzathine penicillin G 2.4 million units IM once | Doxycycline 100 mg orally twice daily for 14 days or Tetracycline 500 mg orally four times daily for 28 days or Ceftriaxone 1 g IM daily for 8-10 days | |
| Late | | | |
| Late latent or uncertain duration | Benzathine penicillin G 2.4 million units IM weekly for 3 weeks | Doxycycline 100 mg orally twice daily for 28 days or Tetracycline 500 mg orally four times a day for 28 days | |
| Tertiary without neurosyphilis | Benzathine penicillin G 2.4 million units IM weekly for 3 weeks | Doxycycline 100 mg orally twice daily for 28 days or Tetracycline 500 mg orally four times a day for 28 days | Cerebrospinal fluid evaluation recommended in all patients |
| Neurosyphilis | Aqueous penicillin G 18-24 million units IV daily, given every 3-4 hours or as continuous infusion for 10-14 days | Procaine penicillin, 2.4 million units IM daily with probenidol 500 mg orally four times a day for 10-14 days or Ceftriaxone 2 g IM daily for 10-14 days | Follow treatment with benzathine penicillin G, 2.4 million units IM weekly for up to 3 weeks |

¹Penicillin is the only documented effective treatment in pregnancy, so pregnant patients with true allergy should be desensitized and treated with penicillin according to stage of disease as above.

²Patients treated with alternative therapies require close clinical and serologic monitoring.

an alternative for some patients, pregnant women must be treated with penicillin (see below).

There are limited data for ceftriaxone, although optimum dose and duration are not well defined. Azithromycin is no longer recommended due to increasing resistance. Patients treated for neurosyphilis should receive at least one dose of long-acting penicillin at the completion of therapy. All patients treated with a non-penicillin regimen must have close clinical and serologic follow up, as noted below.

B. Local Measures (Mucocutaneous Lesions)

Local treatment is usually not necessary. No local antiseptics or other chemicals should be applied to a suspected syphilitic lesion until specimens for microscopy have been obtained.

C. Public Health Measures

Patients with infectious syphilis must abstain from sexual activity for 7-10 days after treatment, or until lesions have resolved. All cases of syphilis must be reported to the appropriate local public health agency for assistance in identifying and treating contacts. In addition, all patients with syphilis should have an HIV test at the time of diagnosis. In areas of high HIV prevalence, a repeat HIV test should be performed in 3 months if the initial test result was negative.

D. Treating Syphilis Contacts

Patients who have been sexually exposed to infectious syphilis within the preceding 3 months may be infected but seronegative and thus should be treated as for early syphilis. Persons exposed more than 90 days previously should

be treated based on serologic results. If their partners are unavailable for testing or unreliable for follow-up, empiric therapy is indicated.

Persons at high risk for infection (ie, those with other sexually transmitted diseases and those infected with HIV) and pregnant women should undergo serologic tests for syphilis. Patients with gonorrhea and a known exposure to syphilis should be treated with separate regimens effective against both diseases.

► Complications of Specific Therapy

The Jarisch-Herxheimer reaction, manifested by fever and aggravation of the existing clinical picture in the hours following treatment, is ascribed to the sudden massive destruction of spirochetes. It is most common in early syphilis, particularly secondary syphilis where it can occur in 66% of cases. The reaction resolves spontaneously within 24 hours; treatment should not be discontinued unless the symptoms become severe or life-threatening or unless syphilitic laryngitis, auditory neuritis, or labyrinthitis is present, where the reaction may cause irreversible damage. It may prompt preterm labor in pregnant women.

The reaction may be prevented or modified by simultaneous administration of antipyretics, although no proved method of prevention exists. Patients should be reminded it does not represent an allergic reaction to penicillin.

► Follow-Up Care

Because treatment failures and reinfection may occur, patients treated for syphilis should be monitored clinically

and serologically at 3–6 month intervals. Response to therapy may be difficult to assess, and no definite criteria exist for cure in patients with primary or secondary syphilis. In primary and secondary syphilis, failure of nontreponemal antibody titers to decrease fourfold by 6 months may identify a group at high risk for treatment failure. Optimal management of these patients is unclear, but at a minimum, close clinical and serologic follow-up is indicated. If titers fail to decrease fourfold by 6 months, an HIV test should be repeated (all patients with syphilis should have an HIV test at the time of diagnosis); a lumbar puncture should be considered since unrecognized neurosyphilis can be a cause of treatment failure; and, if careful follow-up cannot be ensured (3-month intervals for HIV-positive individuals and 6-month intervals for HIV-negative patients), treatment should be repeated with 2.4 million units of benzathine penicillin intramuscularly weekly for 3 weeks. If symptoms or signs persist or recur after initial therapy or there is a fourfold or greater increase in nontreponemal titers, therapy has either failed or the patient has been reinfectured. In those individuals, an HIV test should be performed, a lumbar puncture done (unless reinfection is a certainty), and re-treatment given as indicated above.

2. Secondary Syphilis

ESSENTIALS OF DIAGNOSIS

- ▶ Generalized maculopapular skin rash.
- ▶ Mucous membrane lesions, including patches and ulcers.
- ▶ Weeping papules (condylomas) in moist skin areas.
- ▶ Generalized nontender lymphadenopathy.
- ▶ Fever.
- ▶ Meningitis, hepatitis, osteitis, arthritis, iritis.
- ▶ Many treponemes in scrapings of mucous membrane or skin lesions by immunofluorescence or darkfield microscopy.
- ▶ Serologic tests for syphilis always positive.

▶ General Considerations & Treatment

The secondary stage of syphilis usually appears a few weeks (or up to 6 months) after development of the chancre, when dissemination of *T pallidum* produces systemic signs (fever, lymphadenopathy) or infectious lesions at sites distant from the site of inoculation. The most common manifestations are skin and mucosal lesions. The skin lesions are nonpruritic, macular, papular, pustular, or follicular (or combinations of any of these types, but *not* vesicular), though the maculopapular rash is the most common. The skin lesions usually are generalized; involvement of the palms and soles occurs in 80% of cases (Plate 106). Annular lesions simulating ringworm may be observed in dark-skinned individuals. Mucous membrane lesions range from ulcers and papules of the lips, mouth,

throat, genitalia, and anus (“mucous patches”) to a diffuse redness of the pharynx. Both skin and mucous membrane lesions are highly infectious at this stage. Specific lesions—**condylomata lata**—are fused, weeping papules on the moist areas of the skin and mucous membranes and are sometimes mistaken for genital warts.

Meningeal (aseptic meningitis or acute basilar meningitis), hepatic, renal, bone, and joint invasion may occur, with resulting cranial nerve palsies, jaundice, nephrotic syndrome, and periostitis. Alopecia (moth-eaten appearance) and uveitis may also occur.

The serologic tests for syphilis are positive in almost all cases (see Primary Syphilis, above). The moist cutaneous and mucous membrane lesions often show *T pallidum* on darkfield microscopic examination. A transient cerebrospinal fluid (CSF) pleocytosis is seen in 30–70% of patients with secondary syphilis, though only 5% have positive serologic CSF reactions. There may be evidence of hepatitis or nephritis (immune complex type). Circulating immune complexes exist in the blood and are deposited in blood vessel walls.

Skin lesions may be confused with the infectious exanthems, pityriasis rosea, and drug eruptions (Plate 107). Visceral lesions may suggest nephritis or hepatitis due to other causes. The diffusely red throat may mimic other forms of pharyngitis.

Treatment is as for primary syphilis unless central nervous system or ocular disease is present, in which case a lumbar puncture should be performed and, if positive, treatment is as for neurosyphilis (Table 34–3). Isolation of the patient is important. See Primary Syphilis for follow-up care and treatment of contacts.

3. Early Latent Syphilis

ESSENTIALS OF DIAGNOSIS

- ▶ No physical signs.
- ▶ History of syphilis with inadequate treatment.
- ▶ Positive serologic tests for syphilis.

▶ General Considerations & Treatment

Latent syphilis is the clinically quiescent phase during the interval after the disappearance of secondary lesions and is defined as the first year after primary infection. Early latent syphilis may relapse to secondary syphilis if undiagnosed or inadequately treated (see above). Unlike the usual asymptomatic neurologic involvement of secondary syphilis, neurologic relapses may be fulminating, leading to death. Relapse is almost always accompanied by a rising titer in quantitative serologic tests; indeed, a rising titer may be the first or only evidence of relapse. About 90% of relapses occur during the first year after infection. If untreated, a small proportion of patients progress to tertiary syphilis.

Treatment and follow up is as for primary syphilis unless central nervous system disease is present (Table 34–3).

4. Late Latent (“Hidden”) Syphilis

ESSENTIALS OF DIAGNOSIS

- ▶ No physical signs.
- ▶ History of syphilis with inadequate treatment.
- ▶ Positive serologic tests for syphilis.

▶ General Considerations & Treatment

After the first year of latent syphilis, the patient is said to be in the late latent phase. Transmission to the fetus, however, can probably occur in any phase. There are (by definition) no clinical manifestations during the latent phase, and the only significant laboratory findings are positive serologic tests. A diagnosis of latent syphilis is justified only when the CSF is entirely negative, radiographic studies and physical examination show no evidence of cardiovascular involvement, and false-positive tests for syphilis have been ruled out. The latent phase may last from months to a lifetime.

Treatment of late latent syphilis is shown in Table 34–3. The treatment of this stage of the disease is intended to prevent the late sequelae. If there is evidence of central nervous system involvement, a lumbar puncture should be performed and, if positive, the patient should receive treatment as for neurosyphilis. Titers may not decline as rapidly following treatment as in early syphilis. Nontreponemal serologic tests should be repeated at 6, 12, and 24 months. If titers increase fourfold or if initially high titers ($\geq 1:32$) fail to decrease fourfold by 12–24 months or if symptoms or signs consistent with syphilis develop, an HIV test and lumbar puncture should be performed and re-treatment given according to the stage of the disease.

5. Late (Tertiary) Syphilis

ESSENTIALS OF DIAGNOSIS

- ▶ Infiltrative tumors of skin, bones, liver (gummas).
- ▶ Aortitis, aneurysms, aortic regurgitation.
- ▶ Central nervous system disorders, including meningovascular and degenerative changes, paresthesias, shooting pains, abnormal reflexes, dementia, or psychosis.

▶ General Considerations

This stage may occur at any time after secondary syphilis, even after years of latency, and is rarely seen in the modern antibiotic era. Late lesions probably represent, at least in part, a delayed hypersensitivity reaction of the tissue to the organism and are usually divided into two types: (1) a localized gummatous reaction, with a relatively rapid onset and generally prompt response to therapy (“benign late syphilis”) and (2) diffuse inflammation of a more insidious

onset that characteristically involves the central nervous system and large arteries, is often fatal if untreated, and is at best arrested by treatment. Gummas may involve any area or organ of the body but most often affect the skin or long bones. Cardiovascular disease is usually manifested by aortic aneurysm, aortic regurgitation, or aortitis. Various forms of diffuse or localized central nervous system involvement may occur.

Late syphilis must be differentiated from neoplasms of the skin, liver, lung, stomach, or brain; other forms of meningitis; and primary neurologic lesions.

Although almost any tissue and organ may be involved in late syphilis, the following are the most common types of involvement: skin, mucous membranes, skeletal system, eyes, respiratory system, gastrointestinal system, cardiovascular system, and nervous system.

▶ Clinical Findings

A. Symptoms and Signs

1. Skin—Cutaneous lesions of late syphilis are of two varieties: (1) multiple nodular lesions that eventually ulcerate (lues maligna) or resolve by forming atrophic, pigmented scars and (2) solitary gummas that start as painless subcutaneous nodules, then enlarge, attach to the overlying skin, and eventually ulcerate (Plate 108).

2. Mucous membranes—Late lesions of the mucous membranes are nodular gummas or leukoplakia, highly destructive to the involved tissue.

3. Skeletal system—Bone lesions are destructive, causing periostitis, osteitis, and arthritis with little or no associated redness or swelling but often marked myalgia and myositis of the neighboring muscles. The pain is especially severe at night.

4. Eyes—Late ocular lesions are gummatous iritis, chorioretinitis, optic atrophy, and cranial nerve palsies, in addition to the lesions of central nervous system syphilis.

5. Respiratory system—Respiratory involvement by late syphilis is caused by gummatous infiltrates into the larynx, trachea, and pulmonary parenchyma, producing discrete pulmonary densities. There may be hoarseness, respiratory distress, and wheezing secondary to the gummatous lesion itself or to subsequent stenosis occurring with healing.

6. Gastrointestinal system—Gummas involving the liver produce the usually benign, asymptomatic hepar lobatum. A picture resembling Laennec cirrhosis is occasionally produced by liver involvement. Gastric involvement can consist of diffuse infiltration into the stomach wall or focal lesions that endoscopically and microscopically can be confused with lymphoma or carcinoma. Epigastric pain, early satiety, regurgitation, belching, and weight loss are common symptoms.

7. Cardiovascular system—Cardiovascular lesions (10–15% of late syphilitic lesions) are often progressive, disabling, and life-threatening. Central nervous system lesions are often present concomitantly. Involvement usually starts as an arteritis in the supracardiac portion of the aorta and

progresses to one or more of the following: (1) narrowing of the coronary ostia, with resulting decreased coronary circulation, angina, and acute myocardial infarction; (2) scarring of the aortic valves, producing aortic regurgitation, and eventually congestive heart failure; and (3) weakness of the wall of the aorta, with saccular aneurysm formation (Plate 109) and associated pressure symptoms of dysphagia, hoarseness, brassy cough, back pain (vertebral erosion), and occasionally rupture of the aneurysm. Recurrent respiratory infections are common as a result of pressure on the trachea and bronchi.

8. Nervous system (neurosyphilis)—See following section.

► Treatment

Treatment of tertiary syphilis (excluding neurosyphilis) is the same as late latent syphilis (Table 34–3). Reversal of positive serologic tests does not usually occur. A second course of penicillin therapy may be given, but there is no known method for reliable eradication of the treponeme from humans in the late stages of syphilis. Viable spirochetes are occasionally found in the eyes, in CSF, and elsewhere in patients with “adequately” treated syphilis, but claims for their capacity to cause progressive disease are speculative.

In the presence of definite CSF or neurologic abnormalities, one should treat for neurosyphilis. The pretreatment clinical and laboratory evaluation should include neurologic, ocular, cardiovascular, psychiatric, and CSF examinations.

6. Neurosyphilis

ESSENTIALS OF DIAGNOSIS

- ▶ Can occur at any stage of disease.
- ▶ Consider both clinical presentation and laboratory data.
- ▶ Carefully evaluate HIV-positive patients and consider CSF evaluation for atypical symptoms or lack of decrease in nontreponemal serology titers.

► General Considerations

Neurosyphilis can occur at any stage of disease and can be a progressive, disabling, and life-threatening complication. CSF pleocytosis has been reported in 10–20% of patients with primary syphilis. Asymptomatic and meningovascular syphilis occur earlier (months to years after infection, sometimes coexisting with primary and secondary syphilis) than tabes dorsalis and general paresis (2–50 years after infection).

► Clinical Findings

A. Classification

There are four clinical types.

1. Asymptomatic neurosyphilis—This form is characterized by spinal fluid abnormalities (positive spinal fluid

serology, increased cell count, occasionally increased protein) without symptoms or signs of neurologic involvement.

2. Meningovascular syphilis—This form is characterized by meningeal involvement or changes in the vascular structures of the brain (or both), producing symptoms of chronic meningitis (headache, irritability); cranial nerve palsies (basilar meningitis); unequal reflexes; irregular pupils with poor light and accommodation reflexes; and when large vessels are involved, cerebrovascular accidents. The CSF shows increased cells (100–1000/mcL), elevated protein, and usually a positive serologic test for syphilis. The symptoms of acute meningitis are rare in late syphilis.

3. Tabes dorsalis—This form is a chronic progressive degeneration of the parenchyma of the posterior columns of the spinal cord and of the posterior sensory ganglia and nerve roots. The symptoms and signs are impairment of proprioception and vibration sense, Argyll Robertson pupils (which react poorly to light but well to accommodation), and muscular hypotonia and hyporeflexia. Impairment of proprioception results in a wide-based gait and inability to walk in the dark. Paresthesias, analgesia, or sharp recurrent pains in the muscles of the leg (“shooting” or “lightning” pains) may occur. Crises are also common in tabes: gastric crises, consisting of sharp abdominal pains with nausea and vomiting (simulating an acute abdomen); laryngeal crises, with paroxysmal cough and dyspnea; urethral crises, with painful bladder spasms; and rectal and anal crises. Crises may begin suddenly, last for hours to days, and cease abruptly. Neurogenic bladder with overflow incontinence is also seen. Painless trophic ulcers may develop over pressure points on the feet. Joint damage may occur as a result of lack of sensory innervation (Charcot joint, Plate 110). The CSF may have a normal or increased cell count (3–200/mcL), elevated protein, and variable results of serologic tests.

4. General paresis—This is generalized involvement of the cerebral cortex with insidious onset of symptoms. There is usually a decrease in concentrating power, memory loss, dysarthria, tremor of the fingers and lips, irritability, and mild headaches. Most striking is the change of personality; the patient becomes slovenly, irresponsible, confused, and psychotic. The CSF findings resemble those of tabes dorsalis. Combinations of the various forms of neurosyphilis (especially tabes and paresis) are not uncommon.

B. Laboratory Findings

See Serologic Tests for Syphilis, above; these tests should also be performed in cases of suspected neurosyphilis.

1. Indications for a lumbar puncture—It is most important to prevent neurosyphilis by prompt diagnosis, adequate treatment, and follow-up of early syphilis. Indications for lumbar puncture vary depending on the stage of the disease and the patient’s immune status. In early syphilis (primary and secondary syphilis and early latent syphilis of less than 1 year duration), invasion of the central nervous system by *T pallidum* with CSF abnormalities occurs commonly, but clinical neurosyphilis rarely develops in patients

who have received the standard therapy outlined above. Thus, unless clinical symptoms and signs of neurosyphilis or ophthalmologic involvement (uveitis, neuroretinitis, optic neuritis, iritis) are present, a lumbar puncture in early syphilis is not recommended as part of the routine evaluation. In latent syphilis, the decision to perform a lumbar puncture should be individualized. Routine lumbar puncture for all patients is not indicated since the yield is low and findings rarely influence therapeutic decisions. CSF evaluation is recommended, however, in the later stages of syphilis if neurologic or ophthalmologic symptoms and signs are present, if therapy other than with penicillin is to be given, if the patient is HIV positive (see next section), if there is evidence of treatment failure (see earlier discussion), or if there is evidence of active tertiary syphilis (eg, aortitis, iritis, optic atrophy, the presence of a gumma). Some experts also routinely recommend lumbar puncture for all persons with latent syphilis if the serum nontreponemal antibody titer is $\geq 1:32$ or the CD4 count is $< 350/\text{mL}$ in HIV-infected persons.

2. Spinal fluid examination—CSF findings in neurosyphilis are variable. In “classic” cases, there is an elevation of total protein, lymphocytic pleocytosis, and a positive CSF reagin test (VDRL). However, CSF may be completely normal in neurosyphilis, and the VDRL may be negative. In one study, 25% of patients with primary or secondary syphilis in whom *T pallidum* was isolated from CSF had normal findings. In later stages of syphilis, normal CSF analysis in the presence of infection can occur, but it is unusual. Because false-positive reagin tests rarely occur in the CSF, a positive test confirms the presence of neurosyphilis. Because the CSF VDRL may be negative in 30–70% of cases of neurosyphilis, *a negative test does not exclude neurosyphilis*. The CSF FTA-ABS is sometimes used; it is a highly sensitive test but lacks specificity, and a high serum titer of FTA-ABS may result in a positive CSF titer in the absence of neurosyphilis.

▶ Treatment

Current recommendations for the therapy of neurosyphilis include higher doses of short-acting penicillin to achieve better penetration and higher levels of drug in the CSF than is possible with benzathine penicillin (Table 34–3). Because of concerns about slowly dividing organisms that may persist after only 10–14 days of therapy, many experts recommend subsequent administration of 2.4 million units of benzathine penicillin intramuscularly once weekly for up to 3 weeks as additional therapy. There are some data for using ceftriaxone as well, but because other regimens for neurosyphilis have not been adequately studied, patients with a history of an IgE-mediated reaction to penicillin should be skin tested for allergy to penicillin and, if positive, desensitized.

All patients should have nontreponemal serologic tests done every 3 months. Guidelines established by the Centers for Disease Control and Prevention (CDC) recommend spinal fluid examinations at 6-month intervals until the CSF cell count is normal; however, a recent study suggested that in certain patients normalization of serum titers are an

acceptable surrogate for CSF response. In general, CSF white blood cell count and CSF VDRL normalize more quickly (usually in 12 months) than CSF protein concentration, which can remain abnormal for extended periods. If the serum nontreponemal titers do not normalize, the CSF analysis should be repeated. A second course of penicillin therapy may be given if the CSF cell count has not decreased at 6 months or is not normal at 2 years.

7. Syphilis in HIV-Infected Patients

Interpretation of serologic tests should be the same for HIV-positive and HIV-negative persons. Although unusual serologic responses have been reported in HIV-positive patients, including high titers of nontreponemal tests, delayed appearance of positive titers, and false-negative tests, most HIV-positive patients respond serologically in largely the same way as noninfected patients. All HIV-positive patients in care should be screened at least twice a year by RPR or VDRL to identify latent disease because by establishing a serologic history, unnecessary lumbar punctures and prolonged treatment for latent syphilis of uncertain duration can be avoided. If the diagnosis of syphilis is suggested on clinical grounds but reagin tests are negative, alternative tests should be performed. These tests include darkfield examination of lesions and direct fluorescent antibody staining for *T pallidum* of lesion exudate or biopsy specimens.

Treatment of HIV-positive patients with primary and secondary syphilis is the same as for HIV-negative patients. Because of concerns about the adequacy of this therapy, some experts recommend additional therapy with 2.4 million units of benzathine penicillin intramuscularly weekly for 3 weeks instead of single-dose therapy. However, despite occasional reports of neurosyphilis developing in HIV-infected patients despite appropriate therapy for early disease, most HIV-infected patients with primary or secondary syphilis respond appropriately to currently recommended regimens. In all cases, careful clinical and serologic follow-up should be done at 3, 6, 9, 12, and 24 months. HIV-infected patients with late latent syphilis, syphilis of uncertain duration, and neurosyphilis should be treated like HIV-negative individuals, with follow-up at 6, 12, 18, and 24 months. A study among HIV-clinic patients in Baltimore found that the use of antiretroviral therapy was associated with reduced serologic failure rates after syphilis treatment.

The diagnosis of neurosyphilis in HIV-infected patients is complicated by the fact that CSF abnormalities are frequently seen and may be due to neurosyphilis or HIV infection itself. The significance of these abnormalities is unknown, and similar abnormalities are frequently seen in non-HIV-infected patients with primary or secondary syphilis. Thus, although some experts recommend a CSF examination for all HIV-positive patients with syphilis, such testing is probably not needed in those with early disease. In contrast, a lumbar puncture should be performed in HIV-positive patients if they have late latent syphilis or syphilis of uncertain duration, if neurologic signs are present, or if therapy has failed. A recent study found that HIV-positive patients with a nontreponemal antibody titer $\geq 1:32$ had a

sixfold increased risk of having neurosyphilis, and if the CD4 count was $\leq 350/\text{mL}$, there was a threefold increased risk of neurosyphilis, suggesting that these subgroups should also undergo lumbar puncture. Following treatment, CSF white blood cell counts normalize within 12 months regardless of HIV status, while the CSF VDRL is slower to normalize in HIV-infected individuals, especially those with CD4 counts < 200 cells/ mL . As discussed above, the same criteria for failure apply to HIV-positive and HIV-negative patients, and re-treatment regimens are the same.

Because clinical experience in treating HIV-infected patients with syphilis is based on penicillin regimens, few options exist for treating the penicillin-allergic patient. Doxycycline or tetracycline regimens can be used for primary, secondary, and early latent syphilis as well as for late latent syphilis and latent syphilis of unknown duration though with caution and close follow-up. For neurosyphilis, penicillin regimens are optimal even if this requires skin testing and desensitization; limited data exist for ceftriaxone.

8. Syphilis in Pregnancy

All pregnant women should have a nontreponemal serologic test for syphilis at the time of the first prenatal visit. In women who may be at increased risk for syphilis or for populations in which there is a high prevalence of syphilis, additional nontreponemal tests should be performed during the third trimester at 28 weeks and again at delivery. The serologic status of all women who have delivered should be known before discharge from the hospital. Seropositive women should be considered infected and should be treated unless prior treatment with fall in antibody titer is medically documented.

The only acceptable treatment for syphilis in pregnancy is penicillin in dosage schedules appropriate for the stage of disease (see above). Penicillin prevents congenital syphilis in 90% of cases, even when treatment is given late in pregnancy. Tetracycline and doxycycline are contraindicated in pregnancy. Erythromycin should not be used because of failure to eradicate infection in the fetus, and insufficient data are available to justify a recommendation for ceftriaxone or azithromycin. Thus, women with a history of penicillin allergy should be skin tested and desensitized if necessary.

The infant should be evaluated immediately, as noted below, and at 6–8 weeks of age.

9. Congenital Syphilis

Congenital syphilis is a transplacentally transmitted infection that occurs in infants of untreated or inadequately treated mothers. The physical findings at birth are quite variable: The infant may have many or minimal signs or even no signs until 6–8 weeks of life (delayed form). The most common findings are on the mucous membranes and skin—maculopapular rash, condylomas, mucous membrane patches, and serous nasal discharge (snuffles). These lesions are infectious; *T pallidum* can easily be found microscopically, and the infant must be isolated. Other common findings are hepatosplenomegaly, anemia, or osteochondritis. These early active lesions subsequently

heal, and if the disease is left untreated it produces the characteristic stigmas of syphilis—interstitial keratitis, Hutchinson teeth, saddle nose, saber shins, deafness, and central nervous system involvement.

The presence of negative serologic tests at birth in both the mother and the infant usually means that the newborn is free of infection. However, recent infection near the time of delivery may result in negative tests because there has been insufficient time to develop a serologic response. Thus, it is necessary to maintain a high index of suspicion in infants with delayed onset of symptoms despite negative serologic tests at birth, especially in infants born to high-risk mothers (HIV-positive, illicit drug users). All infants born to mothers with positive nontreponemal and treponemal antibody titers should have blood drawn for an RPR or VDRL test and, if positive, be referred to a pediatrician for further evaluation and therapy.

► When to Refer

Consultation with the local public health department may help obtain all prior positive syphilis serologic results and may be helpful in complicated or atypical cases.

► When to Admit

- Pregnant women with syphilis and true penicillin allergy should be admitted for desensitization and treatment.
- Women in late pregnancy treated for early syphilis should have close outpatient monitoring or be admitted because the Jarisch-Herxheimer reaction can induce premature labor.
- Patients with neurosyphilis usually require admission for treatment with aqueous penicillin.

NON-SEXUALLY TRANSMITTED TREPONEMATOSES

A variety of treponemal diseases other than syphilis occur endemically in many tropical areas of the world. They are distinguished from disease caused by *T pallidum* by their nonsexual transmission, their relatively high incidence in certain geographic areas and among children, and their tendency to produce less severe visceral manifestations. As in syphilis, organisms can be demonstrated in infectious

lesions with darkfield microscopy or immunofluorescence but cannot be cultured in artificial media; the serologic tests for syphilis are positive; the diseases have primary, secondary, and sometimes tertiary stages; and penicillin is the drug of choice. There is evidence that infection with these agents may provide partial resistance to syphilis and vice versa. Treatment with penicillin in doses appropriate to primary syphilis (eg, 2.4 million units of benzathine penicillin G intramuscularly) is generally curative in any stage of the non-sexually transmitted treponematoses. In cases of penicillin hypersensitivity, tetracycline, 500 mg orally four times a day for 10–14 days, is usually the recommended alternative.

YAWS (Frambesia)

Yaws is a contagious disease largely limited to tropical regions that is caused by *T pallidum* subspecies *pertenue*. It is characterized by granulomatous lesions of the skin, mucous membranes, and bone. Yaws is rarely fatal, though if untreated it may lead to chronic disability and disfigurement. Yaws is acquired by direct nonsexual contact, usually in childhood, although it may occur at any age. The “mother yaw,” a painless papule that later ulcerates, appears 3–4 weeks after exposure. There is usually associated regional lymphadenopathy. Six to 12 weeks later, secondary lesions that are raised papillomas and papules that weep highly infectious material appear and last for several months or years. Painful ulcerated lesions on the soles are called “crab yaws” because of the resulting gait. Late gummatous lesions may occur, with associated tissue destruction involving large areas of skin and subcutaneous tissues. The late effects of yaws, with bone change, shortening of digits, and contractions, may be confused with similar changes occurring in leprosy. Central nervous system, cardiac, or other visceral involvement is rare. See above for therapy.

PINTA

Pinta is a non-sexually transmitted spirochetal infection caused by *Treponema carateum*. It occurs endemically in rural areas of Latin America, especially in Mexico, Colombia, and Cuba, and in some areas of the Pacific. A nonulcerative, erythematous primary papule spreads slowly into a papulosquamous plaque showing a variety of color changes (slate, lilac, black). Secondary lesions resemble the primary one and appear within a year after it. These appear successively, new lesions together with older ones; are most common on the extremities; and later show atrophy and depigmentation. Some cases show pigmentary changes and atrophic patches on the soles and palms, with or without hyperkeratosis, that are indistinguishable from “crab yaws.” Very rarely, central nervous system or cardiovascular disease is observed late in the course of infection. See above for therapy.

ENDEMIC SYPHILIS

Endemic syphilis is an acute or chronic infection caused by *T pallidum* subspecies *endemicum*. It has been reported in a

number of countries, particularly in the eastern Mediterranean area, often with local names: bejel in Syria, Saudi Arabia, and Iraq, and dichuchwa, njovera, and siti in Africa. It also occurs in Southeast Asia. The local forms have distinctive features. Moist ulcerated lesions of the skin or oral or nasopharyngeal mucosa are the most common manifestations. Generalized lymphadenopathy and secondary and tertiary bone and skin lesions are also common. Deep leg pain points to periostitis or osteomyelitis. In the late stages of disease, destructive gummatous lesions similar to those seen in yaws can develop, resulting in loss of cartilage and saber shin deformity. Cardiovascular and central nervous system involvement are rare. See above for therapy.

SELECTED SPIROCHETAL DISEASES

RELAPSING FEVER

Relapsing fever is endemic in many parts of the world. The main reservoir is rodents, which serve as the source of infection for ticks (eg, ornithodoros). The distribution and seasonal incidence of the disease are determined by the ecology of the ticks in different areas. In the United States, infected ticks are found throughout the West, especially in mountainous areas, but clinical cases are uncommon in humans.

The infectious organisms are spirochetes of the genus *Borrelia*. The infection has two forms: tick-borne and louse-borne. Tick-borne relapsing fever may be transmitted transovarially from one generation of ticks to the next. Humans can be infected by tick bites or by rubbing crushed tick tissues or feces into the bite wound. Tick-borne relapsing fever is endemic but is not transmitted from person to person. Different species (or strain) names have been given to *Borrelia* in different parts of the world where the organisms are transmitted by different ticks.

The louse-borne form is primarily seen in the developing world. Large epidemics may occur in louse-infested populations, and transmission is favored by crowding, malnutrition, and cold climate.

► Clinical Findings

A. Symptoms and Signs

There is an abrupt onset of fever, chills, tachycardia, nausea and vomiting, arthralgia, and severe headache. Hepatomegaly and splenomegaly may develop, as well as various types of rashes (macular, popular, petechial) that usually occur at the end of a febrile episode. Delirium occurs with high fever, and there may be various neurologic and psychic abnormalities. The attack terminates, usually abruptly, after 3–10 days. After an interval of 1–2 weeks, relapse occurs, but often it is somewhat milder. Three to ten relapses may

occur before recovery in tick-borne disease, whereas louse-borne disease is associated with only one or two relapses.

B. Laboratory Findings

During episodes of fever, large spirochetes are seen in blood smears stained with Wright or Giemsa stain. The organisms can be cultured in special media but rapidly lose pathogenicity. The spirochetes can multiply in injected rats or mice and can be seen in their blood.

A variety of anti-borrelia antibodies develop during the illness; sometimes the Weil–Felix test for rickettsioses and nontreponemal serologic tests for syphilis may also be falsely positive. Infection with *B recurrentis* can cause false-positive indirect fluorescent antibody and Western blot tests for *Borrelia burgdorferi*, and some cases may be misdiagnosed as Lyme disease. CSF abnormalities occur in patients with meningeal involvement. Mild anemia and thrombocytopenia are common, but the white blood cell count tends to be normal.

► Differential Diagnosis

The manifestations of relapsing fever may be confused with malaria, leptospirosis, meningococcemia, yellow fever, typhus, or rat-bite fever.

► Prevention

Prevention of tick bites (as described for rickettsial diseases) and delousing procedures applicable to large groups can prevent illness. Arthropod vectors should be controlled if possible.

Doxycycline 200 mg orally on day 1 and 100 mg daily for 4 days has been shown to prevent recurrent fever following tick bites in highly endemic areas.

► Treatment

A single dose of tetracycline or erythromycin, 0.5 g orally, or a single dose of procaine penicillin G, 400,000–600,000 units intramuscularly, probably constitutes adequate treatment for louse-borne relapsing fevers. Because of higher relapse rates, tick-borne disease is treated with 0.5 g of tetracycline or erythromycin given orally four times daily for 5–10 days. Jarisch–Herxheimer reactions occur commonly following treatment and may be life-threatening, so patients should be closely monitored. There is evidence that administration of anti-TNF antibodies prior to antibiotic therapy can be effective in preventing the reaction.

► Prognosis

The overall mortality rate is usually about 5%. Fatalities are most common in old, debilitated, or very young patients. With treatment, the initial attack is shortened and relapses are largely prevented.

 Hasin T et al. Postexposure treatment with doxycycline for prevention of tick-borne relapsing fever. *N Engl J Med.* 2006 Jul 13;355(2):148–55. [PMID: 16837678]

RAT-BITE FEVER

Rat-bite fever is an uncommon acute infectious disease caused by the treponeme *Spirillum minus* (Asia), covered in this section, or the bacteria *Streptobacillus moniliformis* (North America). It is transmitted to humans by the bite of a rat. Inhabitants of rat-infested dwellings and laboratory workers are at greatest risk.

► Clinical Findings

A. Symptoms and Signs

In *Spirillum* infections, the original rat bite, unless secondarily infected, heals promptly, but 1 to several weeks later the site becomes swollen, indurated, and painful; assumes a dusky purplish hue; and may ulcerate. Regional lymphangitis and lymphadenitis, fever, chills, malaise, myalgia, arthralgia, and headache are present. Splenomegaly may occur. A sparse, dusky-red maculopapular rash appears on the trunk and extremities in many cases, and there may be frank arthritis.

After a few days, both the local and systemic symptoms subside, only to reappear several days later. This relapsing pattern of fever for 3–4 days alternating with afebrile periods lasting 3–9 days may persist for weeks. The other features, however, usually recur only during the first few relapses. Endocarditis is a rare complication of infection.

B. Laboratory Findings

Leukocytosis is often present, and the nontreponemal test for syphilis is often falsely positive. The organism may be identified in darkfield examination of the ulcer exudate or aspirated lymph node material; more commonly, it is observed after inoculation of a laboratory animal with the patient's exudate or blood. It has not been cultured in artificial media.

► Differential Diagnosis

Rat-bite fever must be distinguished from the rat-bite-induced lymphadenitis and rash of streptobacillary fever. Clinically, the severe arthritis and myalgias seen in streptobacillary disease are rarely seen in disease caused by *S minus*. Reliable differentiation requires an increasing titer of agglutinins against *S moniliformis* or isolation of the causative organism. Other diseases in the differential include tularemia, rickettsial disease, *Pasteurella multocida* infections, and relapsing fever.

► Treatment

Penicillin is given for 10–14 days. During the acute phase of illness, the intravenous route is used (1–2 million units every 4–6 hours) and once improvement has occurred, therapy is completed with oral medication, penicillin V 500 mg four times daily to complete 10–14 days of therapy. For the penicillin-allergic patient, tetracycline 500 mg orally four times daily or doxycycline 100 mg twice a day can be used.

► Prognosis

The reported mortality rate of about 10% should be markedly reduced by prompt diagnosis and antimicrobial treatment.

Elliot SP. Rat bite fever and *Streptobacillus moniliformis*. Clin Microbiol Rev. 2007 Jan;20(1):13–22. [PMID: 17223620]

LEPTOSPIROSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Clinical illness can vary from asymptomatic to fatal liver and kidney disease.
- ▶ Anicteric leptospirosis is the more common and milder form of the disease.
- ▶ Icteric leptospirosis (Weil syndrome) is characterized by impaired kidney and liver function, abnormal mental status, and hemorrhagic pneumonia and has a 5–40% mortality rate.

▶ General Considerations

Leptospirosis is an acute and often severe treponemal infection that frequently affects the liver or other organs and is caused by multiple species within the genus *Leptospira*. The disease is worldwide in distribution, and it is among the most common zoonotic diseases. The leptospires are often transmitted to humans by the ingestion of food and drink contaminated by the urine of the reservoir animal. The organism may also enter through minor skin lesions and probably via the conjunctiva. Recreational cases have followed swimming or rafting in contaminated water, and occupational cases occur among sewer workers, rice planters, abattoir workers, and farmers. Sporadic urban cases have been seen in the homeless exposed to rat urine. The incubation period is 2–20 days.

▶ Clinical Findings

A. Symptoms and Signs

Anicteric leptospirosis, the more common and milder form of the disease, is often biphasic. The initial or “septicemic” phase begins with abrupt fever to 39–40 °C, chills, abdominal pain, severe headache, and myalgias, especially of the calf muscles. There may be marked conjunctival suffusion. Leptospire can be isolated from blood, CSF, and tissues. Following a 1- to 3-day period of improvement in symptoms and absence of fever, the second or “immune” phase begins. Leptospire are absent from blood and CSF but are still present in the kidney, and specific antibodies appear. A recurrence of symptoms is seen as in the first phase of disease with the onset of meningitis. Uveitis (which can be unilateral or bilateral and usually involves the entire uveal tract), rash, and adenopathy may occur. A rare but severe manifestation is hemorrhagic pneumonia. The illness is usually self-limited, lasting 4–30 days, and complete recovery is the rule.

Icteric leptospirosis (Weil syndrome) is the most severe form of the disease, characterized by impaired kidney and liver function, abnormal mental status, hemorrhagic pneumonia, hypotension, and a 5–40% mortality rate. Symptoms and signs often are continuous and not biphasic.

Leptospirosis with jaundice must be distinguished from hepatitis, yellow fever, and relapsing fever.

B. Laboratory Findings

The leukocyte count may be normal or as high as 50,000/mcL, with neutrophils predominating. The urine may contain bile, protein, casts, and red cells. Oliguria is common, and in severe cases uremia may occur. Elevated bilirubin and aminotransferases are seen in 75%, and elevated creatinine (> 1.5 mg/dL) is seen in 50% of cases. In cases with meningeal involvement, organisms may be found in the CSF during the first 10 days of illness. Early in the disease, the organism may be identified by darkfield examination of the patient’s blood (a test requiring expertise since false-positives are frequent in inexperienced hands) or by culture on a semisolid medium (eg, Fletcher EMJH). Cultures take 1–6 weeks to become positive. The organism may also be grown from the urine from the tenth day to the sixth week. Diagnosis is usually made by means of serologic tests, of which several are available. Agglutination tests (microscopic, using live organisms, and macroscopic, using killed antigen) become positive after 7–10 days of illness, peak at 3–4 weeks, and may persist at high levels for many years. Thus, to make a diagnosis, a fourfold or greater rise in titer must be documented. The agglutination tests are cumbersome to perform and require trained personnel. Indirect hemagglutination and enzyme-linked immunosorbent assay (ELISA) tests are also available. The IgM EIA is particularly useful in making an early diagnosis, since it is positive as early as 2 days into illness, a time when the clinical manifestations may be nonspecific, and it is extremely sensitive and specific (93%). PCR methods (presently investigational) appear to be sensitive, specific, positive early in disease, and able to detect leptospiral DNA in blood, urine, CSF, and aqueous humor. Serum creatine kinase (CK) is usually elevated in persons with leptospirosis and normal in persons with hepatitis.

▶ Complications

Myocarditis, aseptic meningitis, acute kidney injury, and pulmonary infiltrates with hemorrhage are not common but are the usual causes of death. Iridocyclitis may occur.

▶ Prevention

The mainstay of prevention is avoidance of potentially contaminated food and water.

Prophylaxis with doxycycline, 200 mg orally once weekly, can be given during periods of possible exposure. Human vaccine is used in some limited settings but is not widely available.

▶ Treatment

Various antimicrobial drugs, including penicillin, ceftriaxone, and tetracyclines, show antileptospiral activity. Penicillin (eg, 1.5 million units every 6 hours intravenously) or ceftriaxone (1 g daily intravenously) is the drug of choice in severe leptospirosis and is especially effective if started within the first 4 days of illness. Jarisch–Herxheimer reactions may

occur. Doxycycline, 100 mg orally twice daily for 7 days, is also effective as therapy if started early, but this agent is most often used in mild to moderate disease. Although therapy for mild disease is controversial, most clinicians treat with oral penicillin, 500 mg four times daily, or doxycycline, 100 mg orally twice daily, for 7 days. Azithromycin is also active, but clinical experience is limited.

► Prognosis

Without jaundice, the disease is almost never fatal. With jaundice, the mortality rate is 5% for those under age 30 years and 30% for those over age 60 years.

LYME DISEASE (Lyme Borreliosis)

ESSENTIALS OF DIAGNOSIS

- Erythema migrans, a flat or slightly raised red lesion that expands with central clearing.
- Headache or stiff neck.
- Arthralgias, arthritis, and myalgias; arthritis is often chronic and recurrent.
- Wide geographic distribution, with most United States cases in the Northeast, mid-Atlantic, upper Midwest, and Pacific coastal regions.

► General Considerations

This illness, named after the town of Old Lyme, Connecticut, is the most common tickborne disease in the United States and Europe. In the United States, the causative organism is the spirochete *B burgdorferi*, whereas in Europe and Asia the predominant organisms are *Borrelia garinii* and *Borrelia afzelii*. Most cases (90%) are reported from the mid-Atlantic, northeastern, and north central regions of the country, whereas far fewer cases are reported from the West Coast. The true incidence of Lyme disease is not known and overreporting continues to be a problem for a number of reasons: (1) serologic tests are not standardized (see below); (2) clinical manifestations are nonspecific; (3) even with reliable testing, serology is insensitive in early disease; and (4) other as yet unidentified organisms may cause illnesses similar to Lyme disease, eg, the Lone Star tick (*Amblyomma americanum*) found in the midwestern and southern regions of the United States can carry a spirochete that produces skin lesions indistinguishable from erythema migrans.

The vector of Lyme disease varies geographically and is *Ixodes scapularis* in the northeastern, north central, and mid-

Atlantic regions of the United States; *Ixodes pacificus* on the West Coast; *Ixodes ricinus* in Europe; and *Ixodes persulcatus* in Asia. The disease also occurs in Australia. Mice and deer make up the major animal reservoir of *B burgdorferi*, but other rodents and birds may also be infected. Domestic animals such as dogs, cattle, and horses can also develop clinical illness, usually manifested as arthritis.

Ticks feed once during each of their three stages of life. Larval ticks feed in late summer, nymphs in the following spring and early summer, and adults during the fall. In the northeastern United States and the mid-Atlantic states, the preferred host for the nymphs and larvae is the white-footed mouse (the black-striped mouse in Europe). This animal is tolerant of infection—a fact that is critical in maintaining infection, since the mouse can remain spirochetemic and transmit the agent to the larvae the following spring after being infected by the nymphal form in early summer. Adult ticks prefer the white-tailed deer as host. Although only 20–25% of nymphs harbor spirochetes compared with 50–65% of adults, most infections occur in the spring and summer (when nymphs are active), and fewer cases occur in the cooler months (October to April), when adults feed. This is probably due to the greater abundance of nymphs; greater human outdoor activity in spring and summer, when nymphs feed; and the fact that adult ticks are larger, easier to detect by the human host, and thus can be removed before disease is transmitted. Less than 1% of larvae are infected with spirochetes, and transmission of the disease through contact with larvae is unlikely. In the western United States, the *I pacificus* nymph prefers to feed on lizards, which are not susceptible to infection. It is only the few nymph and larval ticks that feed on wood rats, which can be infected, that are capable of transmitting disease.

Under experimental conditions, ticks must feed for 24–36 hours or longer to transmit infections. Human epidemiologic studies have indicated that the incidence of disease is significantly higher when tick attachment is for longer than 72 hours than if it is less than 72 hours, though rare cases have been documented with attachment of less than 24 hours. In addition, the percentage of ticks infected varies on a regional basis. In the northeastern and midwestern regions, 15–65% of *I scapularis* ticks are infected with the spirochete; in the western United States, only 2% of *I pacificus* are infected. These are important epidemiologic features in assessing the likelihood that tick exposure will result in disease. Exposure to *I pacificus* is unlikely to result in disease, since so few ticks are infected, but this is not true of exposure to *I scapularis*. Eliciting a history of brushing a tick off the skin (ie, the tick was not feeding) or removing a tick on the same day as exposure (ie, the tick did not feed long enough) decreases the likelihood that infection will develop.

Ixodes ticks are smaller than the more common dog ticks (*Dermacentor variabilis*). Larvae are less than 1 mm in size, and the adult female is 2–3 mm in size, with a red body and black legs. After a blood meal, ticks can reach two to three times their unengorged size. Because the tick is so small, the bite is usually painless and goes unnoticed. After feeding, the tick drops off in 2–4 days. If a tick is found, it should be removed immediately. The best way to accomplish this is to use a fine-tipped tweezers to pull firmly and

repeatedly on the tick's mouth part—not the tick's body—until the tick releases its hold. Saving the tick in a bottle of alcohol for future identification may be useful, especially if symptoms develop.

Congenital infection has been documented, but the exact frequency and manifestations have not been clearly defined. Similarly, because the organism can be latent, it is not known if women infected prior to becoming pregnant can activate the disease and transmit infection to the fetus. In one retrospective study, 5 of 19 pregnancies complicated by Lyme disease resulted in an adverse outcome, but all of the outcomes were different and could not be conclusively linked to infection. Several serosurveys involving over 2000 pregnant women in endemic areas have not found any association between seropositivity in prospective mothers and the prevalence of congenital malformations, fetal death, and prematurity. Thus, if *B burgdorferi* causes a congenital syndrome like some other spirochetal illnesses, it must be extremely uncommon.

► Clinical Findings

The typical clinical description of Lyme disease divides the illness into three stages: stage 1, flu-like symptoms and a typical skin rash (**erythema migrans**, Plate 32); stage 2, weeks to months later, Bell palsy or meningitis; and stage 3, months to years later, arthritis. The problem with this simplified scheme is that there is a great deal of overlap, and the skin, central nervous system, and musculoskeletal system can be involved early or late. A more accurate classification divides disease into early and late manifestations and specifies whether disease is localized or disseminated.

A. Symptoms and Signs

1. Stage 1, early localized infection—Stage 1 infection is characterized by erythema migrans. About 1 week after the tick bite (range, 3–30 days; median 7–10 days), a flat or slightly raised red lesion appears at the site, which is commonly seen in areas of tight clothing such as the groin, thigh, or axilla. This lesion expands over several days. Although originally described as a lesion that progresses with central clearing (“bull's-eye” lesion), often there is a more homogeneous appearance or even central intensification. About 10–20% of patients either do not have typical skin lesions or the lesions go unnoticed. Most patients with erythema migrans will have a concomitant viral-like illness (the “summer flu”) characterized by myalgias, arthralgias, headache, and fatigue. Fever may or may not be present. Even without treatment, the symptoms and signs of erythema migrans resolve in 3–4 weeks. Although the classic lesion of erythema migrans is not difficult to recognize, atypical forms can occur that may lead to misdiagnosis. Vesicular, urticarial, and evanescent erythema migrans have all been reported. Similarly, chemical reactions to tick and spider bites (these usually recede in 24–48 hours whereas erythema migrans increases in size in this time period), drug eruptions, urticaria, and staphylococcal and streptococcal cellulitis have been mistaken for erythema migrans.

Completely asymptomatic disease, without erythema migrans or flu-like symptoms, can occur but is very

uncommon in the United States. Serosurveys done as part of vaccination trials found asymptomatic seroconversion in 7% or less of the population.

2. Stage 2, early disseminated infection—Up to 50–60% of patients with erythema migrans are bacteremic (especially if multiple lesions are present) leading to dissemination of the spirochete resulting in a wide variety of symptoms and signs. Within days to weeks of the original infection, secondary skin lesions that are not associated with a tick bite develop in about 50% of patients. These lesions are similar in appearance to the primary lesion but are usually smaller. Malaise, fatigue, fever, headache (sometimes severe), neck pain, and generalized aches are common with the skin lesions. Most symptoms are transient, although fatigue may persist for months. After hematogenous spread, the organism may sequester itself in certain areas and produces focal symptoms. Some patients experience cardiac (4–10% of patients) or neurologic (10–15% of patients) manifestations. Involvement of the heart includes myopericarditis, with atrial or ventricular arrhythmias and heart block. Neurologic manifestations include both the central and peripheral nervous systems. The most common central nervous system manifestation is an aseptic meningitis with mild headache and neck stiffness. The most common peripheral manifestation is a cranial neuropathy, ie, Bell palsy (usually unilateral but can be bilateral, Plate 90). A sensory or motor radiculopathy and mononeuritis multiplex occur less frequently. Conjunctivitis, keratitis and, rarely, panophthalmitis can also occur.

3. Stage 3, late persistent infection—Stage 3 infection occurs months to years after the initial infection and again primarily manifests itself as musculoskeletal, neurologic, and skin disease. In early reports, musculoskeletal complaints developed in up to 60% of patients. With early recognition and treatment of disease, joint complaints develop in less than 10% of patients. The classic manifestation of late disease is a monoarticular or oligoarticular arthritis most commonly affecting the knee or other large weight bearing joints. Knees are swollen out of proportion to the pain experienced by the patient. Even if untreated, the arthritis is self-limited, resolving in a few weeks to months. Multiple recurrences are common but are usually less severe than the original disease. Joint fluid reflects an inflammatory arthritis with a mean white blood cell count of 25,000/mcL with a predominance of neutrophils. Chronic arthritis develops in about 10% of patients. The pathogenesis of chronic Lyme arthritis may be an immunologic phenomenon rather than persistence of infection. The observations that persons with chronic arthritis have an increased frequency of HLA-DR4 gene expression, antibodies to OspA and OspB protein in joint fluid (major outer surface proteins of *B burgdorferi*), lack *B burgdorferi* DNA in synovial fluid as detected by PCR, and often do not respond to antibiotics—all support the inference of an immunologic mechanism.

Rarely, the nervous system (both central and peripheral) can be involved in late Lyme disease. In the United States, a subacute encephalopathy, characterized by memory loss, mood changes, and sleep disturbance, is seen. In Europe, a

more severe encephalomyelitis caused by *B garinii* is seen and presents with cognitive dysfunction, spastic paraparesis, ataxia, and bladder dysfunction. Peripheral nervous system involvement includes intermittent paresthesias, often in a stocking glove distribution, or radicular pain.

The cutaneous manifestation of late infection, which can occur up to 10 years after infection, is **acrodermatitis chronicum atrophicans**. It has been described mainly in Europe and is due to infection with *B afzelii*, a species that commonly causes disease in Europe but not the United States. There is usually bluish-red discoloration of a distal extremity with associated swelling. These lesions become atrophic and sclerotic with time and eventually resemble localized scleroderma. At least two cases of diffuse fasciitis with eosinophilia, a rare entity that resembles scleroderma, have been associated with infection with *B burgdorferi*.

B. Laboratory Findings

The diagnosis of Lyme disease is based on both clinical manifestations and laboratory findings. The National Surveillance Case Definition specifies a person with exposure to a potential tick habitat (within the 30 days just prior to developing erythema migrans) with (1) erythema migrans diagnosed by a physician or (2) at least one late manifestation of the disease and (3) laboratory confirmation as fulfilling the criteria for Lyme disease.

Laboratory confirmation requires detection of specific antibodies to *B burgdorferi* in serum, either by indirect immunofluorescence assay (IFA) or ELISA; the latter is preferred because it is more sensitive and specific. A Western blot assay that can detect both IgM and IgG antibodies is used as a confirmatory test. IgM antibody appears first 2–4 weeks after onset of erythema migrans, peaks at 6–8 weeks, and then declines to low levels after 4–6 months of illness. The presence of IgM antibody in patients with prolonged symptoms persisting for several months is likely to be a false-positive result. IgG occurs later (6–8 weeks after onset of disease), peaks at 4–6 months, and may remain elevated at low levels indefinitely despite appropriate therapy and resolution of symptoms. A two-test approach is recommended for the diagnosis of active Lyme disease. All specimens positive or equivocal by ELISA or IFA should be tested by Western immunoblot. When Western immunoblot is done during the first 4 weeks of illness, both IgM and IgG should be tested. If a patient with suspected early Lyme disease has negative serologic studies, acute and convalescent titers should be obtained since up to 50% of patients with early disease can be antibody negative in the first several weeks of illness. A fourfold rise in antibody titer would be diagnostic of recent infection. In patients with later stages of disease, almost all are antibody positive. False-positive reactions in the ELISA and IFA have been reported in juvenile rheumatoid arthritis, rheumatoid arthritis, systemic lupus erythematosus, infectious mononucleosis, subacute infective endocarditis, syphilis, relapsing fever, leptospirosis, enteroviral and other viral illnesses, and patients with gingival disease (presumably because of cross-reactivity with oral treponemes). False-negative serologic reactions occur early in

illness, and antibiotic therapy early in disease can abort subsequent seroconversion.

An ELISA test measures antibodies against a peptide in the invariant region of VlsE, an outer surface lipoprotein of *B burgdorferi*. The test is done in a single step (as opposed to the current two-step test recommended by the Centers for Disease Control and Prevention), is easy to standardize, and is less expensive than two-step testing. The ELISA appears to be as sensitive and specific as the current two-step test in the diagnosis of late stage disease and it is more sensitive for early disease.

Cautions should be exercised in interpreting serologic tests because they are not subject to national standards, and inter-laboratory variation is a major problem. In addition, some laboratories perform tests that are entirely unreliable and should never be used to support the diagnosis of Lyme disease (eg, the Lyme urinary antigen test, immunofluorescent staining for cell wall-deficient forms of *B burgdorferi*, lymphocyte transformation tests, using PCR on inappropriate specimens such as blood or urine). Finally, testing is often done in patients with nonspecific symptoms such as headache, arthralgia, myalgia, fatigue, and palpitations. Even in endemic areas, the pretest probability of having Lyme disease is low in these patients, and the probability of a false-positive test result is greater than that of a true-positive result. For these reasons, the American College of Physicians has established guidelines for laboratory evaluation of patients with suspected Lyme disease:

1. The diagnosis of early Lyme disease is clinical (ie, exposure in an endemic area, with physician-documented erythema migrans), and does *not* require laboratory confirmation. (Tests are often negative at this stage.)

2. Late disease requires objective evidence of clinical manifestations (recurrent brief attacks of monoarticular or oligoarticular arthritis of the large joints; lymphocytic meningitis, cranial neuritis [Bell palsy], peripheral neuropathy or, rarely, encephalomyelitis—but *not* headache, fatigue, paresthesias, or stiff neck alone; atrioventricular conduction defects with or without myocarditis) and laboratory evidence of disease (two-stage testing with ELISA and Western blot, as described above).

3. Patients with nonspecific symptoms without objective signs of Lyme disease should *not* have serologic testing done. It is in this setting that false-positive tests occur more commonly than true-positive tests.

4. The role of serologic testing in neuroborreliosis is unclear, as sensitivity and specificity of CSF serologic tests have not been determined. However, it is rare for a patient with neuroborreliosis to have positive serologic tests on CSF without positive tests on serum (see below).

5. Other tests such as the T cell proliferative assay, PCR testing, and urinary antigen detection have not yet been studied well enough to be routinely used (see discussion below).

Cultures for *B burgdorferi* can be performed but are not routine and are usually reserved for clinical studies. Aspiration of erythema migrans lesions has yielded positive cultures in up to 30% of cases, whereas culture of a 2-mm punch biopsy is positive in 50–70%. PCR of a skin biopsy is even more sensitive, with positivity rates of 80%. In early

disease, blood cultures are positive in up to 50% if large volumes (9 mL) are used, but CSF is rarely culture positive. The ability to culture organisms from skin lesions is greatly influenced by antibiotic therapy. Even a brief course of several days will result in negative cultures. Special silver staining of chronically inflamed synovial tissue demonstrates spirochetes in one-third of patients.

PCR is very specific for detecting the presence of *Borrelia* DNA, but sensitivity is variable and depends on which body fluid is tested and the stage of the disease. In general, PCR is more sensitive than culture, especially in chronic disease. Up to 85% of synovial fluid samples are positive in active arthritis. In contrast, 38% of CSF samples in acute neuroborreliosis are PCR positive, and only 25% are positive in chronic neuroborreliosis. The significance of a positive reaction is unclear. Whether a positive PCR indicates persistence of viable organisms that will respond to further treatment or is a marker for residual DNA (not active infection) has not been clarified. In chronic Lyme arthritis, some have suggested that a positive PCR indicates active infection that requires further therapy, while others have found a positive reaction despite months of therapy, suggesting that the presence of DNA is indicative of an autoimmune arthritis.

The diagnosis of late **neuroborreliosis** is often difficult since clinical manifestations, such as subtle memory impairment, may be difficult to document. Most patients with neuroborreliosis have a history of previous erythema migrans or monarticular or polyarticular arthritis, and the vast majority have antibody present in serum. When CSF is sampled from patients with encephalopathy, there may be evidence of inflammation (pleocytosis or elevated protein, or both), and localized antibody production, ie, a ratio of CSF to serum antibody of > 1.0 . The role of other tests such as PCR in detection of DNA or ELISA in detecting the presence of outer surface protein A (OspA) antigen is unclear, but in difficult cases these tests can be performed and, if positive, help establish the diagnosis. Patients with late disease and peripheral neuropathy almost always have positive serum antibody tests, usually have abnormal electrophysiology tests, and may have abnormal nerve biopsies showing perivascular collections of lymphocytes. Because disease involves peripheral nerves, the cerebral spinal fluid is usually normal and does not demonstrate local antibody production.

Nonspecific laboratory abnormalities can be seen, particularly in early disease. The most common are an elevated sedimentation rate of > 20 mm/h seen in 50% of cases and mildly abnormal liver function tests present in 30%. The abnormal liver function tests are transient and return to normal within a few weeks of treatment. A mild anemia, leukocytosis (11,000–18,000/mcL), and microscopic hematuria have been reported in 10% or less of patients.

► Prevention

Simple preventive measures such as avoiding tick-infested areas, covering exposed skin with long-sleeved shirts and wearing long trousers tucked into socks, wearing light-colored clothing, using repellents, and inspecting for ticks

after exposure will greatly reduce the number of tick bites. Environmental controls directed at limiting ticks on residential property would be helpful, but trying to limit the deer, tick, or white-footed mouse populations over large areas is not feasible.

Prophylactic antibiotics following tick bites is recommended in certain high risk situations if all of the following criteria are met: (1) a tick identified as an adult or nymphal *I scapularis* has been attached for at least 36 hours; (2) prophylaxis can be started within 72 hours of the time the tick was removed; (3) more than 20% of ticks in the area are known to be infected with *B burgdorferi*; and (4) there is no contraindication to the use of doxycycline (not pregnant, age greater than 8 years, not allergic). As noted above, *I scapularis* ticks in the northeastern, mid-Atlantic, and upper midwestern states are infected with *B burgdorferi* at a high rate ($> 20\%$) whereas *I pacificus* ticks on the West Coast are not (about 2%). The drug of choice for prophylaxis is a single 200 mg dose of doxycycline. If doxycycline is contraindicated, no prophylaxis should be given, since short course prophylactic therapy with other agents has not been studied and if early disease does develop appropriate therapy is very effective in preventing long-term sequelae. Individuals who have removed ticks (including those who have had prophylaxis) should be monitored carefully for 30 days. If skin lesions or a viral-like illness develop, they should be evaluated for possible Lyme disease, human granulocytic anaplasmosis, and babesiosis. There is no human vaccine currently available.

► Treatment

Present recommendations for therapy are outlined in Table 34–4. For erythema migrans, antibiotic therapy shortens the duration of rash and prevents late sequelae. Doxycycline is most commonly used and has the advantage of being active against *Anaplasma phagocytophilum* (formerly *Ehrlichia*). Amoxicillin is also effective and is recommended for pregnant or lactating women and for those who cannot tolerate doxycycline. Cefuroxime axetil, is as effective as doxycycline, but because of its cost it should be considered an alternative choice for those who cannot tolerate doxycycline or amoxicillin or for those in whom the drugs are contraindicated. Erythromycin and azithromycin are less effective, associated with higher rates of relapse, and are not recommended as first-line therapy.

Isolated Bell palsy (without meningitis or peripheral neuropathy) can be treated with doxycycline, amoxicillin, or cefuroxime axetil for 2–3 weeks. Although therapy does not affect the rate of resolution of the cranial neuropathy, it does prevent development of late manifestations of disease.

The need for a lumbar puncture in patients with seventh nerve palsy is controversial. Some clinicians perform lumbar puncture on all patients with Bell palsy and others only if there are symptoms or signs of meningitis. If meningitis is present, therapy with a parenteral antibiotic is indicated. Ceftriaxone is most commonly used, but penicillin is equally efficacious. In European countries, doxycycline 400 mg/d for 14 days is frequently used and is comparable in efficacy to ceftriaxone.

Table 34–4. Treatment of Lyme disease.

| Manifestations | Drug and Dosage |
|---|--|
| Tick bite | No treatment in most circumstances (see text); observe |
| Erythema migrans | Doxycycline, 100 mg orally twice daily, or amoxicillin, 500 mg orally three times daily, or cefuroxime axetil, 500 mg orally twice daily—all for 2–3 weeks |
| Neurologic disease | |
| Bell palsy (without meningitis) | Doxycycline, amoxicillin, or cefuroxime axetil as above for 2–3 weeks |
| Other central nervous system disease | Ceftriaxone, 2 g intravenously once daily, or penicillin G, 18–24 million units daily intravenously in six divided doses, or cefotaxime, 2 g intravenously every 8 hours—all for 2–4 weeks |
| Cardiac disease | |
| Atrioventricular block and myopericarditis ¹ | An oral or parenteral regimen as described above can be used Ceftriaxone or penicillin G as above for 30–60 days (see text) |
| Arthritis | |
| Oral dosage | Doxycycline, amoxicillin, or cefuroxime axetil as above for 28 days (see text) |
| Parenteral dosage | Ceftriaxone, cefotaxime, or penicillin G as above for 2–4 weeks |
| Acrodermatitis chroni-cum atrophicans | Doxycycline, amoxicillin, or cefuroxime axetil as above for 3 weeks |
| “Chronic Lyme disease” or “post-Lyme disease syndrome” | Symptomatic therapy |

¹Symptomatic patients, those with second- or third-degree block and those with first-degree block with a PR interval \geq 30 milliseconds should be hospitalized for observation.

Patients with atrioventricular block or myopericarditis (or both) can be treated with either oral or parenteral agents for 2–3 weeks. Hospitalization and observation is indicated for symptomatic patients, those with second- or third-degree block, and those with first-degree block with a PR interval \geq 30 milliseconds. Once stabilized, hospitalized patients can be transitioned to one of the oral regimens to complete therapy.

Therapy of arthritis is difficult because some patients do not respond to any therapy, and those who do respond may do so slowly. Oral agents (doxycycline, amoxicillin, or cefuroxime axetil) are as effective as intravenous regimens (ceftriaxone, cefotaxime, or penicillin). A reasonable approach to the patient with Lyme arthritis is to start with oral therapy for 28 days, and if this fails (persistent or recurrent joint swelling), to re-treat with an oral regimen for 28 days or switch to an intravenous regimen for 2–4 weeks. If some improvement has occurred with initial treatment with an oral regimen, another course of oral therapy is

reasonable. If there has been no response or worsening with initial oral therapy, a parenteral regimen should be used. Re-treatment should be delayed for several months because of the slow resolution of joint symptoms. If arthritis persists after re-treatment, symptomatic therapy with nonsteroidal anti-inflammatory drugs is recommended. For severe refractory pain, synovectomy may be required.

Based on the limited published data, therapy of Lyme disease in pregnancy should be the same as therapy in other patients with the exception that doxycycline should not be used.

Clinicians are often confronted with patients with non-specific symptoms (such as fatigue and myalgias) and positive serologic tests for Lyme disease who request (or demand) therapy for their illness. It is important in managing these patients to remember (1) that the diagnosis of Lyme disease is primarily a clinical one, and nonspecific symptoms alone are not diagnostic; (2) that serologic tests are fraught with difficulty (as noted above), and in areas where disease prevalence is low, false-positive serologic tests are much more common than true-positive tests; and (3) that parenteral therapy with ceftriaxone for 2–4 weeks is costly (approximately \$5000) and has been associated with significant adverse effects (cholelithiasis). Parenteral therapy should be reserved for those most likely to benefit, ie, those with cutaneous, neurologic, cardiac, or rheumatic manifestations that are characteristic of Lyme disease.

► Coinfections

Lyme disease, babesiosis (see Chapter 35), and human granulocytic anaplasmosis (formerly human granulocytic ehrlichiosis) (see Chapter 32) are endemic in similar areas of the country and are transmitted by the same tick, *I scapularis*. Coinfection with two or even all three of these organisms can occur, causing a clinical picture that is not “classic” for any of these diseases. The presence of erythema migrans is highly suggestive of Lyme disease, whereas flu-like symptoms without rash are more suggestive of babesiosis or anaplasmosis. The complete blood count is usually normal in Lyme disease, but in patients with Lyme disease and babesiosis, anemia and thrombocytopenia are more common. Patients with Lyme disease and anaplasmosis are more likely to have leukopenia. Coinfection should be considered and excluded in patients who have persistent high fevers 48 hours after starting appropriate therapy for Lyme disease; in patients with persistent symptoms despite resolution of rash; and in those with anemia, leukopenia, or thrombocytopenia.

Even in patients with documented Lyme disease, immunity is not complete. Reinfection, although uncommon, is predominantly seen in patients successfully treated for early disease (erythema migrans) who do not develop antibody titers. Clinical manifestations and serologic response is similar to an initial infection.

► Prognosis

Most patients respond to appropriate therapy with prompt resolution of symptoms within 4 weeks. True treatment failures are thus uncommon, and in most cases re-treatment or prolonged treatment of Lyme disease is instituted because

of misdiagnosis or misinterpretation of serologic results (both IgG and IgM antibodies can persist for prolonged periods despite adequate therapy) rather than inadequate therapy or response. The terms “chronic Lyme disease” or “post-Lyme disease syndrome” have been applied to a heterogeneous group of patients with documented Lyme disease who have been adequately treated but have persistent poorly defined, nonspecific symptoms such as fatigue, arthralgias, myalgias, and neurocognitive complaints. Although some providers treat these patients with multiple or prolonged courses of oral or intravenous antibiotics, there are no data suggesting that this is efficacious, and the prolonged use of antibiotics in this setting is emphatically discouraged.

The long-term outcome of adult patients with Lyme disease is generally favorable, but some patients have chronic complaints. Joint pain, memory impairment, and poor functional status secondary to pain are common subjective complaints in patients with Lyme disease, but physical examination and neurocognitive testing fail to document the presence of these symptoms as objective sequelae. Similarly, in highly endemic areas, patients with a diagnosis of Lyme disease commonly complain of pain, fatigue, and an inability to perform certain physical activities when followed for several years. However, these complaints occur just as commonly in age-matched controls without a history of Lyme disease. Attempts to document chronic cardiac disease in patients treated for Lyme disease also have been unsuccessful. The long-term outcome of treated neuroborreliosis is favorable, with complete recovery in 75% of patients. Of

the remaining individuals, only 12% had sequelae that affected their daily activities.

▶ When to Refer

Consultation with an infectious diseases specialist with experience in treating Lyme disease can be helpful in atypical or prolonged cases.

▶ When to Admit

Admission for parenteral antibiotics is indicated for any patient with symptomatic CNS or cardiac disease as well as those with second- or third-degree atrioventricular block, or first-degree block with a PR interval ≥ 30 milliseconds.

Protozoal & Helminthic Infections

Philip J. Rosenthal, MD

PROTOZOAL INFECTIONS

AFRICAN TRYPANOSOMIASIS (Sleeping Sickness)

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure to tsetse flies, with subsequent bite lesion.
- ▶ Irregular fever, headache, joint pain, rash, edema, lymphadenopathy progressing to somnolence, and neurologic abnormalities.
- ▶ Trypanosomes in blood or lymph node aspirates; positive serologic tests.
- ▶ Trypanosomes and increased white cells and protein in cerebrospinal fluid.

▶ General Considerations

African trypanosomiasis is caused by the hemoflagellates *Trypanosoma brucei rhodesiense* and *Trypanosoma brucei gambiense*. The organisms are transmitted by bites of tsetse flies (genus *Glossina*), which inhabit shaded areas along streams and rivers. Trypanosomes ingested in a blood meal develop over 18–35 days in the fly; when the fly feeds again on a mammalian host, the infective stage is injected. Human disease occurs in rural areas of sub-Saharan Africa from south of the Sahara to about 15 degrees south latitude. *T b gambiense* causes West African trypanosomiasis, and is transmitted in the moist sub-Saharan savannas and forests of west and central Africa. *T b rhodesiense* causes East African trypanosomiasis, and is transmitted in the savannas of east and southeast Africa.

T b rhodesiense infection is primarily a zoonosis of game animals and cattle; humans are infected sporadically. Humans are the principal mammalian host for *T b gambiense*, but domestic animals can be infected. African trypanosomiasis is an increasing threat, especially where control has been disrupted by civil strife. The largest number of cases is in the Democratic Republic of the Congo. Annual incidence estimates are about 100,000 cases and 48,000 deaths, mostly due to *T b gambiense*, leading to the loss of 1.5 million disability-

adjusted life years. Infections are rare among travelers, including visitors to game parks.

▶ Clinical Findings

A. Symptoms and Signs

1. West African trypanosomiasis—Chancres at the site of the bite are uncommon. After an asymptomatic period that may last for months, hemolympathic disease presents with fever, headache, myalgias, arthralgias, weight loss, and lymphadenopathy, with discrete, nontender, rubbery nodes, referred to as Winterbottom sign when in a posterior cervical distribution. Other common signs are mild splenomegaly, transient edema, and a pruritic erythematous rash. Febrile episodes may be broken by afebrile periods of up to several weeks. The hemolympathic stage progresses over months to meningoencephalitic disease, with somnolence, irritability, personality changes, severe headache, and parkinsonian symptoms progressing to coma and death.

2. East African trypanosomiasis—Chancres are more commonly recognized with *T b rhodesiense* infection, with a painful lesion of 3–10 cm and regional lymphadenopathy that appears about 48 hours after the tsetse fly bite and lasts 2–4 weeks. East African disease follows a much more acute course, with the onset of symptoms usually within a few days of the insect bite. The hemolympathic stage includes intermittent fever and rash, but lymphadenopathy is less common than with West African disease. Myocarditis can cause tachycardia and death due to arrhythmias or heart failure. If untreated, East African trypanosomiasis progresses over weeks to months to meningoencephalitic disease, somnolence, coma, and death.

B. Laboratory Findings

Definitive diagnosis requires identification of trypanosomes. Microscopic examination of fluid expressed from a chancre or lymph node may show motile trypanosomes or, in fixed specimens, parasites stained with Giemsa. During the hemolympathic stage, detection of parasites in Giemsa-stained blood smears is common in East African disease but difficult in West African disease. Serial specimens should be examined, since parasitemias vary greatly over time. With meningoencephalitic disease, cerebrospinal fluid (CSF)

shows increased mononuclear cells and protein as well as trypanosomes. Concentration techniques can aid identification of parasites in blood or CSF. Serologic tests are also available. The simple card agglutination test for trypanosomes (CATT) has excellent sensitivity and specificity and can be performed in the field; however, the diagnosis should be confirmed by identification of the parasites.

▶ Treatment

Detection of trypanosomes is a prerequisite for treatment of African trypanosomiasis because of the significant toxicity of most available therapies. Treatment recommendations depend on the type of trypanosomiasis, which is determined by geography, and stage of disease, which requires examination of CSF (Table 35–1).

A. West African Trypanosomiasis

1. Early stage infection—Pentamidine (4 mg/kg intramuscularly or intravenously every day or every other day for 7 days) is used to treat infection that does not involve the central nervous system (CNS). The side effects of pentamidine include immediate hypotension; tachycardia; gastrointestinal symptoms during administration; sterile abscesses; and pancreatic, liver, and kidney abnormalities. An alternate drug is eflornithine (100 mg/kg/d intravenously every 6 hours for 14 days).

2. Late stage infection—Eflornithine is the drug of choice for infection that involves the CNS; the dosage is the same as that used to treat early disease. Eflornithine has less toxicity than older trypanocidal drugs, but it can cause gastrointestinal symptoms and bone marrow suppression and is limited by lack of availability and the need for frequent infusions. Alternative therapies are melarsoprol (see below) or nifurtimox (5 mg/kg orally three times per day for 14 days), and drug combinations may offer improved efficacy over monotherapies, with simplified regimens and decreased doses of toxic drugs.

B. East African Trypanosomiasis

Pentamidine and eflornithine are not reliably effective, and early disease is treated with suramin. The dosing regimens

of suramin vary (eg, 100–200 mg test dose, then 20 mg/kg [maximum 1 g] intravenously on days 1, 3, 7, 14, and 21 or weekly for 5 doses). Suramin toxicities include vomiting and, rarely, seizures and shock during infusions as well as subsequent fever, rash, headache, neuropathy, and kidney and bone marrow dysfunction.

Suramin does not enter the CNS, so East African trypanosomiasis involving the CNS is treated with melarsoprol (three series of 3.6 mg/kg/d intravenously for 3 days, with 7-day breaks between the series or a 10-day intravenous course with 0.6 mg/kg on day 1, 1.2 mg/kg on day 2, and 1.8 mg/kg on days 3–10). Although melarsoprol acts against both early West and East African disease, it is very toxic. Immediate side effects of melarsoprol include fever and gastrointestinal symptoms. The most important side effect is a reactive encephalopathy that can progress to seizures, coma, and death. To help avoid this side effect, corticosteroids are coadministered (recommended regimens include dexamethasone 1 mg/kg/d intravenously for 2–3 days or oral prednisolone 1 mg/kg/d for 5 days, and then 0.5 mg/kg/d until treatment completion). In addition, increasing resistance to melarsoprol is a serious concern. Suramin and melarsoprol are available in the United States from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333; telephone: 404-639-3670.

▶ Prevention & Control

Individual prevention in endemic areas should include long sleeves and pants, insect repellents, and mosquito nets. Control programs focusing on vector elimination and treatment of infected persons and animals have shown good success in many areas but suffer from limited resources.

CNS, central nervous system.

AMERICAN TRYPANOSOMIASIS (Chagas Disease)

ESSENTIALS OF DIAGNOSIS

Acute stage

- ▶ Inflammatory lesion at inoculation site.
- ▶ Fever.

- ▶ Hepatosplenomegaly.
- ▶ Lymphadenopathy.
- ▶ Myocarditis.
- ▶ Parasites in blood is diagnostic.

Chronic stage

- ▶ Heart failure, cardiac arrhythmias.
- ▶ Thromboembolism.
- ▶ Megaesophagus.
- ▶ Megacolon.
- ▶ Serologic tests are usually diagnostic.

▶ General Considerations

Chagas disease is caused by *Trypanosoma cruzi*, a protozoan parasite found only in the Americas; it infects wild animals and to a lesser extent humans from southern South America to the southern United States. An estimated 10–12 million people are infected, mostly in rural areas, resulting in about 45,000 deaths annually. The disease is often acquired in childhood. In many countries in South America, Chagas disease is the most important cause of heart disease. In the United States, the vector is found and some animals are infected, but only a few instances of local transmission have been reported.

T. cruzi is transmitted by reduviid (triatomine) bugs infected by ingesting blood from animals or humans who have circulating trypanosomes. Multiplication occurs in the digestive tract of the bug and infective forms are eliminated in feces. Infection in humans occurs when the parasite penetrates the skin through the bite wound, mucous membranes, or the conjunctiva. Transmission can also occur by blood transfusion or in utero. From the bloodstream, *T. cruzi* invades many cell types but has a predilection for myocardium, smooth muscle, and CNS glial cells. Multiplication causes cellular destruction, inflammation, and fibrosis, with progressive disease over decades.

▶ Clinical Findings

A. Symptoms and Signs

As many as 70% of infected persons remain asymptomatic. The **acute stage** is seen principally in children and lasts 1–2 months. The earliest findings are at the site of inoculation either in the eye—Romaña sign (unilateral edema, conjunctivitis, and lymphadenopathy)—or in the skin—a chagoma (swelling with local lymphadenopathy). Subsequent findings include fever, malaise, headache, mild hepatosplenomegaly, and generalized lymphadenopathy. Acute myocarditis and meningoencephalitis are rare but can be fatal.

An asymptomatic latent period (indeterminate phase) may last for life, but symptomatic disease develops in 10–30% of infected individuals, commonly many years after infection.

Chronic Chagas disease generally manifests as abnormalities in cardiac and smooth muscle. Cardiac disease includes arrhythmias, congestive heart failure, and embolic

disease. Smooth muscle abnormalities lead to megaesophagus and megacolon, with dysphagia, regurgitation, aspiration, constipation, and abdominal pain. These findings can be complicated by superinfections. In immunosuppressed persons, including AIDS patients and transplant recipients, latent Chagas disease may reactivate; findings have included brain abscesses.

B. Diagnostic Testing

Diagnosis should be considered in persons with suggestive findings who have resided in an endemic area. Transmission by blood transfusion and congenital transmission should also be considered. The diagnosis is made by detecting parasites. With **acute** infection, evaluation of fresh blood or buffy coats may show motile trypanosomes, and fixed preparations may show Giemsa-stained parasites. Trypanosomes may be identified in lymph nodes, bone marrow, or pericardial or spinal fluid. When initial tests are unrevealing in a suspicious case, xenodiagnosis using laboratory vectors, laboratory culture, or animal inoculation may provide a diagnosis, but these methods are expensive and slow.

Chronic Chagas disease is usually diagnosed serologically. Many different serologic assays are available, but sensitivity and specificity are not ideal, so confirmatory assays are advised after an initial positive test, as is standard for blood bank testing in South America. Polymerase chain reaction (PCR) may offer an important new modality for diagnosis, but sensitivity of PCR assays has been disappointing.

▶ Treatment

Treatment is inadequate because the two drugs used, nifurtimox and benznidazole, often cause severe side effects, must be used for long periods, and are ineffective against chronic infection. In acute and congenital infections, the drugs can reduce the duration and severity of infection, but cure is achieved in only about 70% of patients. During the chronic phase of infection, although parasitemia may disappear in up to 70% of patients, treatment does not clearly alter the progression of the disease. Nevertheless, there is general consensus that treatment should be considered in all *T. cruzi*-infected persons regardless of clinical status or time since infection.

Nifurtimox is given orally in daily doses of 8–10 mg/kg in four divided doses after meals for 90–120 days. Side effects include gastrointestinal and neurologic symptoms, which appear to be reversible and to lessen with dosage reduction. Benznidazole is an alternative therapy that is given orally at a dosage of 5 mg/kg/d in divided doses for 60 days. Its side effects include granulocytopenia, rash, and peripheral neuropathy. In the United States, nifurtimox and benznidazole are available only from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333; telephone: 404-639-3670. Patients with chronic Chagas disease may also benefit from antiarrhythmic therapy, standard therapy for congestive heart failure, and conservative and surgical management of megaesophagus and megacolon.

► **Prevention & Control**

In South America, a major eradication program based on improved housing, use of residual pyrethroid insecticides and pyrethroid-impregnated bed curtains, and screening of blood donors has achieved striking reductions in new infections. In endemic areas and ideally in donors from endemic areas, blood should not be used for transfusion unless at least two serologic tests are negative.

LEISHMANIASIS

ESSENTIALS OF DIAGNOSIS

- Sand fly bite in an endemic area.
- Visceral leishmaniasis: irregular fever, progressive hepatosplenomegaly, pancytopenia, wasting.
- Cutaneous leishmaniasis: chronic, painless, moist ulcers or dry nodules.
- Mucocutaneous leishmaniasis: destructive nasopharyngeal lesions.
- Amastigotes in macrophages in aspirates, touch preparations, or biopsies.
- Positive culture, serologic tests, PCR, or skin test.

► **General Considerations**

Leishmaniasis is a zoonosis transmitted by bites of sand flies of the genus *Lutzomyia* in the Americas and *Phlebotomus* elsewhere. When sand flies feed on an infected host, the parasitized cells are ingested with the blood meal. Leishmaniasis is caused by about 20 species of *Leishmania*; taxonomy is complex. Clinical syndromes are generally dictated by the infecting species, but some species can cause more than one syndrome.

An estimated 350 million persons are at risk for leishmaniasis. The estimated annual incidence of disease is 1–1.5 million new cases of cutaneous and 500,000 cases of visceral disease, leading to an estimated 50,000–60,000 deaths. The incidence of disease is increasing in many areas.

Visceral leishmaniasis (kala azar) is caused mainly by *Leishmania donovani* in the Indian subcontinent and East Africa; *Leishmania infantum* in the Mediterranean, Middle East, China, parts of Asia, and Horn of Africa; and *Leishmania chagasi* in South and Central America. Other species may occasionally cause visceral disease. Over 90% of cases occur in five countries: India, Bangladesh, Nepal, Sudan,

and Brazil. In each locale, the disease has particular clinical and epidemiologic features. The incubation period is usually 4–6 months (range: 10 days to 24 months). Without treatment, the fatality rate reaches 90%. Early diagnosis and treatment reduces mortality to 2–5%.

Old World cutaneous leishmaniasis is caused mainly by *Leishmania tropica*, *Leishmania major*, and *Leishmania aethiops* in the Mediterranean, Middle East, Africa, Central Asia, and Indian subcontinent. New World cutaneous leishmaniasis is caused by *Leishmania mexicana* and *Leishmania amazonensis* in Central and South America. Mucocutaneous leishmaniasis (espundia) occurs in lowland forest areas of the Americas and is caused by *Leishmania braziliensis*, *Leishmania panamensis*, and *Leishmania peruviana*.

► **Clinical Findings**

A. Symptoms and Signs

1. Visceral leishmaniasis (kala azar)—Most infections are subclinical, but a small number progress to full-blown disease. A local nonulcerating nodule at the site of the sand fly bite may precede systemic manifestations but usually is inapparent. The onset of illness may be acute, within 2 weeks of infection, or insidious. Symptoms and signs include fever, chills, sweats, weakness, anorexia, weight loss, cough, and diarrhea. The spleen progressively becomes greatly enlarged, firm, and nontender. The liver is somewhat enlarged, and generalized lymphadenopathy may occur. Hyperpigmentation of skin can be seen, leading to the name kala azar (“black fever”). Other signs include skin lesions, petechiae, gingival bleeding, jaundice, edema, and ascites. As the disease progresses, severe wasting and malnutrition are seen; death eventually occurs often due to secondary infections, within months to a few years. Post-kala azar dermal leishmaniasis may appear after apparent cure in the Indian subcontinent and Sudan. It may simulate leprosy, with hypopigmented macules or nodules developing on preexisting lesions. Viscerotropic leishmaniasis has been reported in small numbers of American military personnel in the Middle East, with mild systemic febrile illnesses after *L. tropica* infections.

2. Cutaneous leishmaniasis—Cutaneous swellings appear 2 weeks to several months after sand fly bites and can be single or multiple. Characteristics of lesions and courses of disease vary depending on the leishmanial species and host immune response. Lesions begin as small papules and develop into nonulcerated dry plaques or large encrusted ulcers with well-demarcated raised and indurated margins (Plate 111). Satellite lesions may be present. The lesions are painless unless secondarily infected. Local lymph nodes may be enlarged. Systemic symptoms are uncommon, but fever, constitutional symptoms, and regional lymphadenopathy may be seen. For most species, healing occurs spontaneously in months to a few years, but scarring is commonly seen.

Leishmaniasis recidivans is a relapsing form of *L. tropica* infection associated with hypersensitivity, in which the primary lesion heals centrally, but spreads laterally, with extensive scarring. Diffuse cutaneous leishmaniasis

involves spread from a central lesion to local dissemination of nodules and a protracted course. Disseminated cutaneous leishmaniasis involves multiple nodular or ulcerated lesions, often with mucosal involvement.

3. Mucocutaneous leishmaniasis (espundia)—In Latin America, mucosal lesions develop in a small percentage of persons infected with *L. braziliensis* and some other species, usually months to years after resolution of a cutaneous lesion. Nasal congestion is followed by ulceration of the nasal mucosa and septum, progressing to involvement of the mouth, lips, palate, pharynx, and larynx. Extensive destruction can occur, and secondary bacterial infection is common. Similar syndromes have been reported with some other species in other areas.

4. Infections in patients with AIDS—Leishmaniasis is an opportunistic infection in persons with AIDS seen in southern Europe and other areas. Visceral leishmaniasis can present late in the course of HIV infection, with fever, hepatosplenomegaly, and pancytopenia. The gastrointestinal tract, respiratory tract, and skin may also be involved.

B. Laboratory Findings

Identifying parasites in tissue samples or culture material provides a definitive diagnosis. In **visceral leishmaniasis**, fine-needle aspiration of the spleen for culture and tissue evaluation is generally safe, and yields a diagnosis in over 95% of cases. Bone marrow aspiration is less sensitive but safer and diagnostic in most cases. Giemsa-stained buffy coat of peripheral blood may occasionally show organisms. For all tissue biopsies and touch preparations, Giemsa staining will show amastigotes within macrophages. Cultures with media available from the CDC will grow promastigotes within a few days to weeks. PCR can also identify the infection. Inoculation of laboratory animals can also be used but is time consuming. Species are identified by molecular, isoenzyme, and monoclonal antibody methods. Serologic tests may facilitate diagnosis, but none are sufficiently sensitive or specific to be used alone. Antibody levels are typically high with visceral leishmaniasis but not cutaneous disease. For **cutaneous lesions**, biopsies should be taken from the raised border of a skin lesion, with samples for histopathology, touch preparation, and culture. The histopathology shows inflammation with mononuclear cells. Macrophages filled with amastigotes may be present, especially early in infection. An intradermal leishmanin (Montenegro) skin test is positive in most individuals with cutaneous disease but negative in those with progressive visceral or diffuse cutaneous disease; this test is not approved in the United States. In **mucocutaneous leishmaniasis**, diagnosis is established by detecting amastigotes in scrapings, biopsy preparations, or aspirated tissue fluid, but organisms may be rare. Cultures from these samples may grow organisms. Serologic studies are often negative, but the leishmanin skin test is usually positive.

► Treatment

Treatment is not adequate because most drugs are quite toxic, require long courses, and are mostly administered

parenterally. The drugs of choice have been pentavalent antimonials, but they are quite toxic, and failures are increasing due to drug resistance. Important newer therapies are amphotericin B, miltefosine, and paromomycin.

A. Visceral Leishmaniasis

The treatment of choice for visceral leishmaniasis is liposomal amphotericin B, which is generally effective and well tolerated but very expensive. Liposomal amphotericin B is approved for this use in the United States; other lipid formulations have been less studied. Standard dosing is 3 mg/kg/d intravenously on days 1–5, 14, and 21, but simpler regimens may be equally effective. Infusion-related side effects include gastrointestinal symptoms, fever, chills, dyspnea, hypotension, and hepatic and renal toxicity. Conventional amphotericin B deoxycholate, which is much less expensive, is also highly effective but with more toxicity. It is administered as a slow infusion of 1 mg/kg/d for 20 days or 0.5–1 mg/kg every second day for up to 8 weeks.

Pentavalent antimonials remain the most commonly used drugs to treat leishmaniasis in most areas. Response rates are good outside India, but in India, resistance is a major problem. Two preparations are available, sodium stibogluconate in the United States and many other areas and meglumine antimonate in Latin America and francophone countries; the compounds appear to have comparable activities. In the United States, sodium stibogluconate can be obtained from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333; telephone: 404-639-3670.

Treatment is given once daily at a dose of 20 mg/kg/d intravenously (preferred) or intramuscularly for 20 days for cutaneous leishmaniasis and 28 days for visceral or mucocutaneous disease. Toxicity increases over time, with development of gastrointestinal symptoms, fever, headache, myalgias, arthralgias, pancreatitis, and rash. Intramuscular injections can cause sterile abscesses. Monitoring should include serial ECGs, and changes are indications for discontinuation to avoid progression to serious arrhythmias.

Miltefosine is the first oral drug for the treatment of leishmaniasis, and it provides excellent results in India, where resistance to antimonials is increasing. It can be administered at a daily oral dose of 2.5 mg/kg in two divided doses for 28 days and was also effective in regimens including a single dose of liposomal amphotericin followed by 7–14 days of miltefosine. A 28-day course of miltefosine (2.5 mg/kg/d) was also effective for the treatment of New World cutaneous leishmaniasis. Vomiting, diarrhea, and elevations in transaminases and kidney function studies are common, but generally short-lived, side effects. Miltefosine is registered for the treatment of visceral leishmaniasis in India and may become the standard of care in that country, although additional study is needed.

Pentamidine isethionate is an alternative therapy for visceral leishmaniasis, given daily or on alternate days for 15 doses of 2–4 mg/kg intramuscularly or intravenously. Side effects include immediate hypotension; tachycardia; and gastrointestinal symptoms during administration; sterile abscesses; and pancreatic, liver, and kidney abnormalities.

Paromomycin showed some success when applied topically to treat cutaneous leishmaniasis and has recently been developed as a parenteral therapy for visceral disease. The drug was shown to be similarly efficacious to amphotericin B in India. It is much less expensive than liposomal amphotericin B or miltefosine. Approval of an intramuscular preparation for visceral leishmaniasis was received in India in 2006. The drug is well tolerated; side effects include ototoxicity and reversible elevations in liver enzymes.

B. Cutaneous Leishmaniasis

In the Old World, cutaneous leishmaniasis is generally self-healing over some months and does not metastasize to the mucosa, so it may be justified to withhold treatment in regions without mucocutaneous disease if lesions are small and cosmetically unimportant. Lesions on the face or hands are generally treated. New World leishmaniasis has a greater risk of progression to mucocutaneous disease, so treatment is more often warranted. Standard therapy is with pentavalent antimonials for 20 days, as described above. Other treatments include those discussed above for visceral disease, azole antifungals, and allopurinol. Topical therapy has included intralesional antimony, paromomycin ointment, cryotherapy, local heat, and surgical removal. Diffuse cutaneous leishmaniasis and related chronic skin processes generally respond poorly to therapy.

C. Mucocutaneous Leishmaniasis

Cutaneous infections from regions where parasites include those that cause mucocutaneous disease (eg, *L. braziliensis* in parts of Latin America) should all be treated to help prevent disease progression. Treatment of mucocutaneous disease with antimonials is disappointing, with responses in only about 60% in Brazil. Other therapies listed above for visceral leishmaniasis may also be used, although they have not been well studied for this indication.

► Prevention & Control

Personal protection measures for avoidance of sand fly bites include use of insect repellants, fine-mesh insect netting, long sleeves and pants, and avoidance of warm shaded areas where flies are common. Disease control measures include destruction of animal reservoir hosts, mass treatment of humans in disease-prevalent areas, residual insecticide spraying in dwellings, limiting contact with dogs and other domesticated animals, and use of permethrin-impregnated collars for dogs.

MALARIA

ESSENTIALS OF DIAGNOSIS

- Residence or exposure in a malaria-endemic area.
- Intermittent attacks of chills, fever, and sweating.
- Headache, malaise, myalgia, nausea, vomiting, splenomegaly; anemia, thrombocytopenia.
- Intraerythrocytic parasites identified in thick or thin blood smears.
- Severe complications of falciparum malaria: cerebral malaria, severe anemia, hypotension, noncardiogenic pulmonary edema, acute kidney injury, hypoglycemia, acidosis, and hemolysis.

► General Considerations

Malaria is the most important parasitic disease of humans, causing hundreds of millions of illnesses and probably over a million deaths each year. The disease is endemic in most of the tropics, including much of South and Central America, Africa, the Middle East, the Indian subcontinent, Southeast Asia, and Oceania. Transmission, morbidity, and mortality are greatest in Africa, where most deaths from malaria are in young children. Malaria is also common in travelers from nonendemic areas to the tropics.

Four species of the genus *Plasmodium* classically cause human malaria. *Plasmodium falciparum* is responsible for nearly all severe disease. It is endemic in most malarious areas and is by far the predominant species in Africa. *Plasmodium vivax* is about as common as *P falciparum*, except in Africa. *P vivax* uncommonly causes severe disease, although this outcome may be more common than previously appreciated. *Plasmodium ovale* and *Plasmodium malariae* are much less common causes of disease, and generally do not cause severe illness. *Plasmodium knowlesi*, a parasite of macaque monkeys, is now recognized to cause occasional illnesses, including some severe disease, in humans in Southeast Asia.

Malaria is transmitted by the bite of infected female anopheline mosquitoes. During feeding, mosquitoes inject sporozoites, which circulate to the liver, and rapidly infect hepatocytes, causing asymptomatic liver infection. Merozoites are subsequently released from the liver, and they rapidly infect erythrocytes to begin the asexual erythrocytic stage of infection that is responsible for human disease. Multiple rounds of erythrocytic development, with production of merozoites that invade additional erythrocytes, lead to large numbers of circulating parasites and clinical illness. Some erythrocytic parasites also develop into sexual

gametocytes, which are infectious to mosquitoes, allowing completion of the life cycle and infection of others.

Malaria may uncommonly be transmitted from mother-to-infant (congenital malaria), by blood transfusion, and in nonendemic areas by mosquitoes infected after biting infected immigrants or travelers. In *P vivax* and *P ovale*, parasites also form dormant liver hypnozoites, which are not killed by most drugs, allowing subsequent relapses of illness after initial elimination of erythrocytic infections. For all plasmodial species, parasites may recrudesce following initial clinical improvement after suboptimal therapy.

In highly endemic regions, where people are infected repeatedly, antimalarial immunity prevents severe disease in most older children and adults. However, young children, who are relatively nonimmune, are at high risk for severe disease from *P falciparum* infection, and this population is responsible for most deaths from malaria. Pregnant women are also at increased risk for severe falciparum malaria. In areas with lower endemicity, individuals of all ages commonly present with uncomplicated or severe malaria. Travelers, who are generally nonimmune, are at high risk for severe disease from falciparum malaria at any age.

► Clinical Findings

A. Symptoms and Signs

An acute attack of malaria typically begins with a prodrome of headache and fatigue, followed by fever. A classic malarial paroxysm includes chills, high fever, and then sweats. Patients may appear to be remarkably well between febrile episodes. Fevers are usually irregular, especially early in the illness, but without therapy may become regular, with 48-hour cycles (*P vivax* and *P ovale*) or 72-hour cycles (*P malariae*), especially with non-falciparum disease. Headache, malaise, myalgias, arthralgias, cough, chest pain, abdominal pain, anorexia, nausea, vomiting, and diarrhea are common. Seizures may represent simple febrile convulsions or evidence of severe neurologic disease. Physical findings may be absent or include signs of anemia, jaundice, splenomegaly, and mild hepatomegaly. Rash and lymphadenopathy are not typical in malaria, and thus suggestive of another cause of fever. When treated appropriately, uncomplicated malaria generally responds well, with a mortality of about 0.1%.

In the developed world, it is imperative that all persons with suggestive symptoms, in particular fever, who have traveled in an endemic area be evaluated for malaria. The risk for falciparum malaria is greatest within 2 months of return from travel; other species may cause disease many months—and occasionally more than a year—after return from an endemic area.

Severe malaria is principally a result of *P falciparum* infection because this species uniquely infects erythrocytes of all ages and mediates the sequestration of infected erythrocytes in small blood vessels, thereby evading clearance of infected erythrocytes by the spleen. Severe falciparum malaria can include dysfunction of any organ system, including neurologic abnormalities progressing to alterations in consciousness, repeated seizures, and coma (cerebral malaria); severe anemia; hypotension and shock;

noncardiogenic pulmonary edema and the acute respiratory distress syndrome; acute kidney injury due to acute tubular necrosis or, less commonly, severe hemolysis); hypoglycemia; acidosis; hemolysis with jaundice; hepatic dysfunction; retinal hemorrhages and other fundoscopic abnormalities; bleeding abnormalities, including disseminated intravascular coagulation; and secondary bacterial infections, including pneumonia and *Salmonella* bacteremia. The most common causes of death in children are cerebral malaria and severe anemia; the former a consequence of a single severe infection and the latter often of multiple malarial infections, intestinal helminths, and nutritional deficiencies. Pregnant women are at particular risk during their first pregnancy, probably due to the selection of *P falciparum* strains that preferentially sequester in the placenta; multiparous women are more likely to have antibodies against these strains and thus avoid severe disease. Malaria in pregnancy also increases the likelihood of poor pregnancy outcomes, with increased prematurity, low birth weight, and mortality.

Uncommon disorders resulting from immunologic responses to chronic infection are massive splenomegaly and, with *P malariae* infection, immune complex glomerulopathy with nephrotic syndrome. Although the presentation of malaria is not as markedly affected by HIV infection as are classic opportunistic infections, HIV-infected individuals are at increased risk for malaria and for severe disease, in particular with advanced immunodeficiency.

B. Laboratory Findings

Giemsa-stained blood smears remain the mainstay of diagnosis (Plates 112, 113, 114, and 115), although other routine stains (eg, Wright stain) will also demonstrate parasites. Thick smears provide efficient evaluation of large volumes of blood, but thin smears are simpler for inexperienced personnel and better for discrimination of parasite species. Single smears are usually positive in infected individuals, although parasitemias may be very low in nonimmune individuals. If illness is suspected, repeating smears in 8- to 24-hour intervals is appropriate. The severity of malaria correlates only loosely with the quantity of infecting parasites, but high parasitemias (especially > 10–20% of erythrocytes infected or > 200,000–500,000 parasites/mL) or the presence of malarial pigment (a breakdown product of hemoglobin) in > 5% of neutrophils are associated with a particularly poor prognosis.

A second means of diagnosis is rapid diagnostic tests to identify circulating plasmodial antigens with a simple “dipstick” format. These tests are not yet well standardized but are increasingly available around the world, including in the United States. At best, they offer sensitivity and specificity near that of high-quality blood smear analysis and are simpler to perform.

Serologic tests indicate history of disease but are not useful for diagnosis of acute infection. PCR is highly sensitive but not available for routine diagnosis. In immune populations, highly sensitive tests, such as PCR, have limited value because subclinical infections, which are of uncertain significance and not routinely treated, are common.

Table 35–2. Major antimalarial drugs.

| Drug | Class | Use |
|---|---------------------------------------|---|
| Chloroquine | 4-Aminoquinoline | Treatment and chemoprophylaxis of infection with sensitive parasites |
| Amodiaquine ¹ | 4-Aminoquinoline | Treatment of <i>Plasmodium falciparum</i> , optimally in fixed combination with artesunate |
| Piperaquine ¹ | 4-Aminoquinoline | Treatment of <i>P falciparum</i> in fixed combination with dihydroartemisinin |
| Quinine | Quinoline methanol | Oral and intravenous ¹ (for severe infections) treatment of <i>P falciparum</i> |
| Quinidine | Quinoline methanol | Intravenous therapy of severe infections with <i>P falciparum</i> |
| Mefloquine | Quinoline methanol | Chemoprophylaxis and treatment of infections with <i>P falciparum</i> |
| Primaquine | 8-Aminoquinoline | Radical cure and terminal prophylaxis of infections with <i>Plasmodium vivax</i> and <i>Plasmodium ovale</i> ; alternative for malaria chemoprophylaxis |
| Sulfadoxine-pyrimethamine (Fansidar) | Folate antagonist combination | Treatment of <i>P falciparum</i> , optimally in combination with artesunate |
| Atovaquone-proguanil (Malarone) | Quinone-folate antagonist combination | Treatment and chemoprophylaxis of <i>P falciparum</i> infection |
| Doxycycline | Tetracycline | Treatment (with quinine) of infections with <i>P falciparum</i> ; chemoprophylaxis |
| Halofantrine ¹ | Phenanthrene methanol | Treatment of infections with some chloroquine-resistant <i>P falciparum</i> |
| Lumefantrine | Amyl alcohol | Treatment of <i>P falciparum</i> malaria in fixed combination with artemether (Coartem) |
| Artemisinins (Artesunate, artemether, dihydroartemisinin) | Sesquiterpene lactone endoperoxides | Treatment of <i>P falciparum</i> in oral combination regimens for uncomplicated disease and parenterally for severe malaria |

¹Not available in the United States.

Modified, with permission, from Katzung BG. *Basic & Clinical Pharmacology*. 11th edition. McGraw-Hill, 2009.

Other diagnostic findings with uncomplicated malaria include thrombocytopenia, anemia, leukocytosis or leukopenia, liver function abnormalities, and hepatosplenomegaly. Severe malaria can present with the laboratory abnormalities expected for the advanced organ dysfunction discussed above.

► Treatment

Malaria is the most common cause of fever in much of the tropics and in travelers seeking medical attention after return from endemic areas. Fevers are often treated presumptively in endemic areas, but ideally, treatment should follow definitive diagnosis, especially in nonimmune individuals.

Symptomatic malaria is caused only by the erythrocytic stage of infection. Available antimalarial drugs (Table 35–2) act against this stage, except for primaquine, which acts principally against hepatic parasites.

A. Uncomplicated Falciparum Malaria

Decisions about how to treat malaria are affected by the potential for drug resistance, especially with *P falciparum*; the high cost and limited availability of newer agents for developing world populations; and potential toxicity. The drug sensitivity of individual strains can be determined, but such testing is slow and not useful clinically. Rather, therapeutic decisions are made based on the infecting species and geography. *P falciparum* is now commonly resistant to chloroquine and sulfadoxine-pyrimethamine in most areas, with the principal exceptions of Central America west of the

Panama Canal and Hispaniola. Falciparum malaria from other areas should not be treated with these older drugs, and decisions regarding appropriate chemoprophylaxis should follow the same geographic considerations.

In the developing world, malaria is often treated with suboptimal regimens due to the high cost and limited supplies of newer agents. Chloroquine is still widely used in Africa, and its poor efficacy may be underappreciated due to its antipyretic properties, the ability of some immune individuals to recover from acute malaria without effective therapy, and the fact that recrudescences may not lead to symptoms until weeks after partially effective therapy. Sulfadoxine-pyrimethamine is slower acting than most other agents, and suffers from increasing resistance in most areas. Antimalarial therapy in the developing world has undergone major change in recent years, with increasing advocacy of combination regimens as first-line therapies. Most of these regimens are combinations of highly potent but short-acting artemisinin derivatives with longer-acting partner drugs. The World Health Organization (WHO) currently lists five combination therapies as desirable treatments for falciparum malaria in most areas (Table 35–3), but the efficacy of these regimens varies. Other combination therapies are under development. Another drug that remains generally effective for falciparum malaria is quinine, but it must be taken for an extended period to cure disease and is quite poorly tolerated. Thus, in the developing world, quinine is generally reserved for the treatment of severe malaria and for treatment after another regimen has failed.

Table 35–3. Modified WHO recommendations for the treatment of malaria.

| Regimen | Notes |
|---|---|
| Artemether-lumefantrine (Coartem, Riamet) | Coformulated, first-line therapy in multiple African countries. Approved in the United States. |
| Artesunate-amodiaquine (ASAQ) | Coformulated, first-line therapy in multiple African countries. |
| Artesunate-mefloquine | Standard therapy in parts of Southeast Asia. |
| Artesunate-sulfadoxine-pyrimethamine | Efficacy low compared with other regimens in most areas. |
| Amodiaquine-sulfadoxine-pyrimethamine | Less expensive; efficacy varies, but remains good in some areas; recommended as an interim option when efficacy established and other regimens are not available. |
| Dihydroartemisinin-piperaquine | Newer coformulated combination. Highly effective in most areas, but not yet part of WHO recommendations. |

World Health Organization: Guidelines for the Treatment of Malaria. World Health Organization. Geneva 2006. *ISBM* 924 1546948.

In developed countries, malaria is an uncommon but potentially life-threatening infection of travelers and immigrants, many of whom are nonimmune, so they are at risk for rapid progression to severe disease. Nonimmune individuals with falciparum malaria should generally be admitted to the hospital due to risks of rapid progression of disease. Options for the treatment of uncomplicated falciparum malaria in the United States have increased with the approval of artemether-lumefantrine in 2008; this drug will likely become the standard for this indication (Table 35–4).

B. Treatment of Non-Falciparum Malaria

The first-line drug for non-falciparum malaria remains chloroquine. Resistance of *P vivax* to chloroquine has increased, but the drug remains generally effective, and since non-falciparum malaria is uncommonly severe, it is reasonable to accept a small risk of treatment failure. For *P vivax* or *P ovale*, eradication of erythrocytic parasites with chloroquine should be accompanied by treatment with primaquine (after evaluating for glucose-6-phosphate dehydrogenase (G6PD) deficiency; see below) to eradicate dormant liver stages (hypnozoites), which may lead to relapses with recurrent erythrocytic infection and malaria symptoms after weeks to months if left untreated. *P malariae* infections need only be treated with chloroquine.

C. Treatment of Severe Malaria

Severe malaria can be defined as presentation with any signs of severe illness or organ dysfunction (including prostration, impaired consciousness, convulsions, respiratory distress, shock, acidosis, severe anemia, excessive bleeding, hypogly-

cemia, jaundice, hemoglobinuria, or kidney impairment) or a high parasite load (generally peripheral parasitemia > 5% or > 200,000 parasites/mL). It is a medical emergency. Indications for parenteral treatment include severe malaria, as defined above, and inability to take oral drugs. With appropriate prompt therapy and supportive care, rapid recoveries may be seen in even very ill individuals.

In the developing world, severe malaria and deaths from the disease are mostly in young children, in particular from cerebral malaria, severe anemia, and pulmonary disease. In the developed world, mortality from malaria is mostly in adults, and often follows extended illnesses and secondary complications long after eradication of the malarial infection. Standard therapy for severe malaria has been intravenous quinine in most areas and, in the United States, intravenous quinidine, which is equally effective. However, the standard of care is now changing, since intravenous artesunate has shown superiority over quinine.

Patients receiving intravenous quinine or quinidine should receive continuous cardiac monitoring; if QTc prolongation exceeds 25% of baseline, the infusion rate should be reduced. Blood glucose should be monitored every 4–6 hours, and 5–10% dextrose may be coadministered to decrease the likelihood of hypoglycemia. Appropriate care of severe malaria includes maintenance of fluids and electrolytes; respiratory and hemodynamic support; and consideration of blood transfusions, anticonvulsants, antibiotics for bacterial infections, and dialysis. With high parasitemia (> 5–10%), exchange transfusion has been used, but beneficial effects have not clearly been demonstrated, and its role remains uncertain.

Recent studies indicate that intravenous artesunate has superior efficacy and better tolerability than intravenous quinine for severe malaria. Intravenous artesunate became available in the United States in 2007 on an investigational basis through the CDC (for enrollment call 770-488-7788); if approved, the drug is provided emergently from CDC Quarantine Stations. The drug is administered in four doses of 2.4 mg/kg over 3 days, every 12 hours on day 1, and then daily. If artesunate cannot be obtained promptly, severe malaria should be treated with intravenous quinidine. In endemic regions, if parenteral therapy is not available, intrarectal administration of artemether or artesunate is also effective.

D. Antimalarial Drugs

1. Chloroquine—Chloroquine remains the drug of choice for the treatment of sensitive *P falciparum* and other species of malaria parasites. Chloroquine is active against erythrocytic parasites of all human malaria species. It does not eradicate hepatic stages, so must be used with primaquine to eradicate *P vivax* and *P ovale* infections. Chloroquine-resistant *P falciparum* is widespread in nearly all areas of the world with falciparum malaria, with the exceptions of Central America west of the Panama Canal, Mexico, and Hispaniola. Chloroquine-resistant *P vivax* has been reported from a number of areas, most notably Southeast Asia.

Chloroquine is the drug of choice for the treatment of non-falciparum and sensitive falciparum malaria. It rapidly

Table 35–4. Treatment of malaria.

| Clinical Setting | Drug Therapy ¹ | Alternative Drugs |
|--|---|---|
| Chloroquine-sensitive <i>Plasmodium falciparum</i> and <i>Plasmodium malariae</i> infections | Chloroquine phosphate, 1 g, followed by 500 mg at 6, 24, and 48 hours or- Chloroquine phosphate, 1 g at 0 and 24 hours, then 0.5 g at 48 hours | |
| <i>Plasmodium vivax</i> and <i>Plasmodium ovale</i> infections | Chloroquine (as above), then (if G6PD normal) primaquine, 30 mg base daily for 14 days | |
| Uncomplicated infections with chloroquine-resistant <i>P falciparum</i> | Coartem (artemether 20 mg, lumefantrine 120 mg, four tablets twice daily for 3 days Malarone, four tablets (total of 1 g atovaquone, 400 mg proguanil) daily for 3 days Quinine sulfate, 650 mg three times daily for 3–7 days Plus one of the following (when quinine given for < 7 days)- Doxycycline, 100 mg twice daily for 7 days or- Clindamycin, 600 mg twice daily for 7 days | Mefloquine, 15 mg/kg once or 750 mg, then 500 mg in 6–8 hours or- ASAQ ² (artesunate 100 mg, amodiaquine 270 mg), two tablets daily for 3 days |
| Severe or complicated infections with <i>P falciparum</i> ³ | Artesunate 2.4 mg/kg IV every 12 hours for 1 day, then daily ^{3,6} | Quinidine gluconate, ^{4,6} 10 mg/kg IV over 1–2 hours, then 0.02 mg/kg IV/min or- Quinidine gluconate, ^{4,6} 15 mg/kg IV over 4 hours, then 7.5 mg/kg IV over 4 hours every 8 hours or- Quinine dihydrochloride, ^{2,4,6} 20 mg/kg IV over 4 hours, then 10 mg/kg IV every 8 hours or- Artemether, ^{2,6} 3.2 mg/kg IM, then 1.6 mg/kg/d IM |

¹All dosages are oral and refer to salts unless otherwise indicated. See text for additional information on all agents, including toxicities and cautions. See Centers for Disease Control and Prevention’s guidelines (phone: 877-FYI-TRIP; <http://www.cdc.gov>) for additional information and pediatric dosing.

²Not available in the United States.

³Available in the United States only on an investigational basis through the CDC (phone: 770-488-7788).

⁴Cardiac monitoring should be in place during intravenous administration of quinidine or quinine.

⁵Avoid loading doses in persons who have received quinine, quinidine, or mefloquine in the prior 24 hours.

⁶With all parenteral regimens, change to an oral regimen (most commonly doxycycline in adults or clindamycin in children) as soon as the patient can tolerate it.

G6PD, glucose-6-phosphate dehydrogenase.

Modified, with permission, from Katzung BG. *Basic & Clinical Pharmacology*. 11th edition. McGraw-Hill, 2009.

terminates fever (in 24–48 hours) and clears parasitemia (in 48–72 hours) caused by sensitive parasites. Chloroquine is also the preferred chemoprophylactic agent in malarious regions without resistant falciparum malaria. Eradication of *P vivax* and *P ovale* requires a course of primaquine.

Chloroquine is usually well tolerated, even with prolonged use. Pruritus is common, primarily in Africans. Nausea, vomiting, abdominal pain, headache, anorexia, malaise, blurring of vision, and urticaria are uncommon. Dosing after meals may reduce some adverse events.

2. Amodiaquine and piperazine—Amodiaquine is a 4-aminoquinoline that is closely related to chloroquine. Amodiaquine has been widely used to treat malaria because of its low cost, limited toxicity and, in some areas, effectiveness against chloroquine-resistant strains of *P falciparum*. Use of amodiaquine decreased after recognition of rare but

serious side effects, notably agranulocytosis, aplastic anemia, and hepatotoxicity. However, serious side effects are rare with short-term use, and amodiaquine is increasingly advocated as a replacement for chloroquine, particularly in combination regimens (Table 35–3). Chemoprophylaxis with amodiaquine is best avoided because of its apparent increased toxicity with long-term use.

Piperazine is another 4-aminoquinoline that was previously heavily used in China and has been coformulated with dihydroartemisinin in a new artemisinin-based therapy. Piperazine appears to be well tolerated, to have minimal problems with resistance (despite prior reports of resistance in China), and in combination with dihydroartemisinin to offer a highly efficacious therapy for falciparum malaria.

3. Mefloquine—Mefloquine is effective therapy for many chloroquine-resistant strains of *P falciparum* and against

other malarial species. Although toxicity is a concern, mefloquine is also a recommended chemoprophylactic drug. Resistance to mefloquine has been reported sporadically from many areas, but it appears to be uncommon except in regions of Southeast Asia with high rates of multidrug resistance (especially border areas of Thailand).

For treatment of uncomplicated malaria, mefloquine is rapidly active and can be administered as a single dose or in two doses over 1 day. It is used in combination with artesunate in Southeast Asia, where resistance to mefloquine has been seen but the combination remains effective in most areas. It should be taken with meals and swallowed with a large amount of water. For chemoprophylaxis, mefloquine is effective against most strains of *P falciparum* and probably all other malarial species. It is recommended by the CDC for chemoprophylaxis in all malarious areas except those with no chloroquine resistance (where chloroquine is preferred) and some rural areas of Southeast Asia with a high prevalence of mefloquine resistance. As with chloroquine, eradication of *P vivax* and *P ovale* requires a course of primaquine.

Adverse effects with weekly dosing of mefloquine for chemoprophylaxis include nausea, vomiting, dizziness, sleep and behavioral disturbances, epigastric pain, diarrhea, abdominal pain, headache, and rash. Despite anecdotal reports of seizures and psychosis, a number of controlled studies have found the frequency of serious adverse effects from mefloquine to be no higher than that with other common chemoprophylactic regimens. Nonetheless, mefloquine should be avoided in persons with histories of psychiatric disease or seizures.

Adverse effects are much more common (up to 50% of treatments) with the higher dosages of mefloquine required for treatment. These effects may be lessened by splitting administration of the drug into two doses separated by 6–8 hours. Serious neuropsychiatric toxicities (depression, confusion, acute psychosis, or seizures) have been reported in less than 1 in 1000 treatments, but some authorities believe that these are more common. Mefloquine can also alter cardiac conduction, and so it should not be coadministered with quinine, quinidine, or halofantrine, and caution is required if quinine or quinidine is used to treat malaria after mefloquine chemoprophylaxis. Mefloquine is generally considered safe in young children and pregnant women.

4. Quinine and quinidine—Quinine dihydrochloride and quinidine gluconate remain first-line therapies for falciparum malaria, especially severe disease, although toxicity concerns complicate therapy. Quinine acts rapidly against the four species of human malaria parasites. Quinidine, the dextrorotatory stereoisomer of quinine, is at least as effective as quinine in the treatment of severe falciparum malaria.

Resistance of *P falciparum* to quinine is common in some areas of Southeast Asia, where the drug may fail if used alone to treat falciparum malaria. However, quinine still provides at least a partial therapeutic effect in most patients.

Quinine and quinidine are effective treatments for severe falciparum malaria, although intravenous artesunate is becoming the standard of care (see Artemisinins section below). Quinine can be administered slowly intravenously

or, in a dilute solution, intramuscularly, but parenteral quinine is not available in the United States, where quinidine is used. The drugs can be administered in divided doses or by continuous intravenous infusion; treatment should begin with a loading dose to rapidly achieve effective plasma concentrations. Intravenous quinine and quinidine should be administered with cardiac monitoring because of their cardiac toxicity and the relative unpredictability of their pharmacokinetics. Therapy should be changed to oral quinine as soon as the patient has improved and can tolerate oral medications.

In areas without newer combination regimens, oral quinine sulfate is appropriate first-line therapy for uncomplicated falciparum malaria, although poor tolerance may limit compliance. Quinine is commonly used with a second drug (most often doxycycline) to shorten the duration of use (usually to 3 days) and to limit toxicity. Therapeutic dosages of quinine and quinidine commonly cause tinnitus, headache, nausea, dizziness, flushing, and visual disturbances, a constellation of symptoms termed “cinchonism.” Mild symptoms of cinchonism do not warrant the discontinuation of therapy. Hypersensitivity reactions include rash, urticaria, angioedema, and bronchospasm. Hematologic abnormalities include hemolysis (especially with G6PD deficiency), leukopenia, agranulocytosis, and thrombocytopenia. Therapeutic doses may cause hypoglycemia; this is a particular problem in severe infections and in pregnant patients. Quinine can stimulate uterine contractions, especially in the third trimester, but this effect is mild, and quinine and quinidine are considered safe in pregnancy. Intravenous infusions of the drugs may cause thrombophlebitis. Overly rapid infusions can cause severe hypotension. ECG abnormalities (QT prolongation) are fairly common, especially with quinidine, but dangerous arrhythmias are uncommon when the drugs are administered appropriately in a monitored setting. Blackwater fever is a rare severe illness, probably due to hypersensitivity, that includes marked hemolysis and hemoglobinuria in the setting of quinine therapy for malaria. Quinine should not be given concurrently with mefloquine and should be used with caution in a patient who has previously received mefloquine. Absorption may be blocked by aluminum-containing antacids. Quinine can raise plasma levels of warfarin and digoxin. Dosage must be reduced in renal insufficiency.

5. Primaquine—Primaquine phosphate, a synthetic 8-aminoquinoline, is the drug of choice for the eradication of dormant liver forms of *P vivax* and *P ovale*. Primaquine is active against hepatic stages of all human malaria parasites. This action is optimal soon after therapy with chloroquine or quinine. Primaquine also acts against erythrocytic stage parasites, although this activity is too weak for the treatment of active disease, and against gametocytes.

For *P vivax* and *P ovale* infections, chloroquine is used to eradicate erythrocytic forms, and if the G6PD level is normal, a 14-day course of primaquine is initiated to eradicate liver hypnozoites and prevent a subsequent relapse. Some strains of *P vivax*, particularly in New Guinea and Southeast Asia, are relatively resistant to prim-

primaquine. For this reason, the CDC has recently doubled the recommended dosage for primaquine to eradicate liver forms (to 52.6 mg primaquine phosphate, or 30 mg base/day), but it remains possible that liver forms may not be eradicated by a single treatment.

Standard chemoprophylaxis does not prevent a relapse of *P vivax* or *P ovale* infections, since the hypnozoite forms of these parasites are not eradicated by chloroquine or other standard treatments. To diminish the likelihood of relapse, some authorities advocate the use of a treatment course of primaquine after the completion of travel to an endemic area.

Primaquine has also been studied as a daily chemoprophylactic agent. Daily treatment with 0.5 mg/kg of base (to a maximum of 30 mg/day) provides protection against malaria caused by *P falciparum* and *P vivax*, but should only be used in persons with documented normal levels of G6PD. In addition, potential toxicities of long-term use remain a concern, and primaquine is not a first-line choice for this purpose.

Primaquine in recommended doses is generally well tolerated. It infrequently causes nausea, epigastric pain, abdominal cramps, and headache, especially when taken on an empty stomach. Rare adverse effects include leukopenia, agranulocytosis, leukocytosis, and cardiac arrhythmias. Standard doses of primaquine may cause hemolysis or methemoglobinemia (manifested by cyanosis), especially in persons with G6PD deficiency or other hereditary metabolic defects. Patients should be tested for G6PD deficiency before primaquine is prescribed. When a patient is deficient in G6PD, treatment strategies may consist of (1) withholding therapy and treating subsequent relapses, if they occur, with chloroquine; (2) treating patients with standard dosing, paying close attention to their hematologic status; or (3) treating with weekly primaquine (45 mg base) for 8 weeks. G6PD-deficient individuals of Mediterranean and Asian ancestry are most likely to have severe deficiency, while those of African ancestry usually have a milder biochemical defect. This difference can be taken into consideration in choosing a treatment strategy. Primaquine should be discontinued if there is evidence of hemolysis or anemia and should be avoided in pregnancy.

6. Inhibitors of folate synthesis—Inhibitors of two parasite enzymes involved in folate metabolism, dihydrofolate reductase (DHFR) and dihydropteroate synthase (DHPS), are used, generally in combination regimens, for the treatment and prevention of malaria. These include the DHFR inhibitors pyrimethamine, proguanil, and chlorproguanil, and the DHPS inhibitors sulfadoxine and dapsone. All described antifolates act relatively slowly against erythrocytic forms of susceptible strains of all four human malaria species. They are not reliably effective against hepatic stages or gametocytes. Fixed-dosed antifolate combinations to treat malaria are sulfadoxine-pyrimethamine (Fansidar) and chlorproguanil/dapsone (Lapdap). These drugs will be discussed only as combinations, as they are not otherwise used to treat or prevent malaria. Malarone, a combination of proguanil with atovaquone, is discussed below.

Fansidar is a fixed combination of sulfadoxine (500 mg) and pyrimethamine (25 mg). The long half-lives of its

components allow weekly dosing for chemoprophylaxis, but due to rare serious side effects with long-term dosing, this drug is no longer recommended for this purpose. Sulfadoxine-pyrimethamine became a common back-up drug after chloroquine in many malaria-endemic areas, and replaced chloroquine as the first-line therapy in a number of countries. Advantages of sulfadoxine-pyrimethamine include ease of administration (a single oral dose) and low cost. However, resistance to sulfadoxine-pyrimethamine is rapidly limiting its efficacy. In addition, it is not reliably effective in *P vivax* infections, and its usefulness against *P ovale* and *P malariae* infections has not been adequately studied, limiting its utility outside of Africa.

Sulfadoxine-pyrimethamine is a component of two combination regimens for uncomplicated malaria recommended by the WHO (Table 35–3). Sulfadoxine-pyrimethamine plus artesunate has shown efficacy in some areas but is best replaced by more effective combination regimens in most areas. Amodiaquine plus sulfadoxine-pyrimethamine has shown surprisingly good efficacy in many parts of Africa, despite increasing resistance to both components, and probably offers the most practical treatment for uncomplicated malaria in many endemic areas without access to artemisinin-based therapies.

Lapdap, a fixed combination of chlorproguanil (80 mg) and dapsone (100 mg), was developed as an inexpensive treatment of falciparum malaria for Africa, and a combination with artesunate was under development. However, the drug was withdrawn in 2008 due to unacceptable rates of hematologic toxicity.

7. Artemisinins—Artemisinin (qinghaosu) is a sesquiterpene lactone endoperoxide, the active component of an herbal medicine that has been used as an antipyretic in China for over 2000 years. Analogs have been synthesized to increase solubility and improve antimalarial efficacy. The most important of these analogs are artesunate, artemether, and dihydroartemisinin. A number of artemisinins are available in many countries, although they are more expensive than older therapies. The WHO is encouraging availability of oral artemisinins only in coformulated combination regimens.

Artemisinins act very rapidly against all erythrocytic-stage human malaria parasites. Artemisinin resistance is not yet an important problem, but *P falciparum* isolates with diminished in vitro susceptibility to artemether have been described from South America, and delayed clearance of parasites has been seen after treatment with artesunate in parts of Cambodia.

Artemisinins are playing an increasing role in the treatment of malaria, including multidrug-resistant *P falciparum* malaria. However, due to their short plasma half-lives, recrudescence rates are unacceptably high after short-course therapy, and they are best used in conjunction with another agent. Also because of their short-half lives, they are not useful in chemoprophylaxis.

Artemisinins should be used for uncomplicated malaria in combination regimens including a longer-acting partner drug, known as artemisinin-based combination therapy. Artesunate plus mefloquine has demonstrated excellent

efficacy against multidrug resistant parasites in Thailand, but this regimen is too expensive for widespread use in Africa and other areas. The artemisinin-based combination regimens that are currently most advocated in Africa are artesunate plus amodiaquine (ASAQ) and artemether plus lumefantrine (Coartem), each of which is available as a coformulated product and is the recommended therapy for uncomplicated malaria in a number of countries in Africa. However, implementation of treatment guidelines has been slowed due to the high cost of the new therapies, limited drug availability, and other factors. A third available coformulated regimen that has performed well in clinical trials is dihydroartemisinin plus piperaquine.

In studies of severe malaria, intramuscular artemether was at least as effective as intramuscular quinine, and intravenous artesunate was superior to intravenous quinine in terms of efficacy and tolerability. Thus, the standard of care for severe malaria is intravenous artesunate, when it is available, although parenteral quinine remains an acceptable alternative. Artesunate and artemether have also been effective in the treatment of severe malaria when administered rectally, offering a valuable treatment modality when parenteral therapy is not available.

Artemisinins appear to be very well tolerated. The most commonly reported adverse effects have been nausea, vomiting, and diarrhea, which may often be due to acute malaria, rather than drug toxicity. Irreversible neurotoxicity has been seen in animals after very high doses, but this problem has not been recognized in humans after widespread use. Artemisinins are teratogenic in animals, and they should be avoided in the first trimester of pregnancy for uncomplicated malaria. However, for severe malaria, for which all available treatments entail some risk, the WHO endorses the use of intravenous artesunate or quinine while additional data are gathered on artesunate safety.

8. Atovaquone plus proguanil (Malarone)—Atovaquone, a hydroxynaphthoquinone, is not effective when used alone, due to rapid development of drug resistance. However, Malarone, a fixed combination of atovaquone (250 mg) and proguanil (100 mg), is highly effective for both the treatment and chemoprophylaxis of falciparum malaria, and it is approved for both indications in the United States. It also appears to be active against other species of malaria parasites. Unlike most other antimalarials, Malarone provides activity against both erythrocytic and hepatic stage parasites.

For treatment, Malarone is given at an adult dose of four tablets daily for 3 days. For chemoprophylaxis, Malarone must be taken daily. It has an advantage over mefloquine and doxycycline in requiring shorter periods of treatment before and after the period at risk for malaria transmission, due to activity against liver-stage parasites, but it is more expensive than the other agents. It should be taken with food.

Malarone is generally well tolerated. Adverse effects include abdominal pain, nausea, vomiting, diarrhea, headache, and rash, and these are more common with the higher dose required for treatment. Reversible elevations in liver enzymes have been reported. The safety of atovaquone in pregnancy is unknown.

9. Antibiotics—A number of antibacterials in addition to the folate antagonists and sulfonamides are slow-acting antimalarials. None of the antibiotics should be used as single agents for the treatment of malaria due to their slow rate of action.

Tetracycline and doxycycline are active against asexual erythrocytic forms of all human malaria parasites. Doxycycline is commonly used in the treatment of falciparum malaria in conjunction with quinidine or quinine, allowing a shorter and better-tolerated course of those drugs. Doxycycline is also a standard chemoprophylactic drug, especially for use in areas of Southeast Asia with high rates of resistance to other antimalarials, including mefloquine. Doxycycline side effects include gastrointestinal symptoms, candidal vaginitis, and photosensitivity. The drug should be taken while upright with a large amount of water to avoid esophageal irritation. Its safety in long-term chemoprophylaxis has not been extensively evaluated.

Clindamycin can be used in conjunction with quinine or quinidine in those for whom doxycycline is not recommended, such as children and pregnant women. The most common toxicities with clindamycin are gastrointestinal. Azithromycin also has antimalarial activity and is now under study for treatment and chemoprophylaxis.

10. Halofantrine and lumefantrine—Halofantrine hydrochloride, a phenanthrene-methanol related to quinine, is effective against erythrocytic stages of all four human malaria species. Oral absorption is variable and is enhanced with food. Because of toxicity concerns, it should not be taken with meals. Halofantrine is rapidly effective against most chloroquine-resistant strains of *P. falciparum*, but its use is limited by irregular absorption and cardiac toxicity. As treatment for falciparum malaria, halofantrine is given orally in three 500-mg doses at 6-hour intervals, and this course is repeated in 1 week for nonimmune individuals. Halofantrine is generally well tolerated. The most common adverse effects are abdominal pain, diarrhea, vomiting, cough, rash, headache, pruritus, and elevated liver enzymes. Of greater concern, the drug alters cardiac conduction, with dose-related prolongation of QT and PR intervals. This effect is worsened by prior mefloquine therapy. Rare instances of dangerous arrhythmias and some deaths have been reported. The drug is contraindicated in patients with cardiac conduction defects and should not be used in those who have recently taken mefloquine. It is also contraindicated in pregnancy.

Lumefantrine, an aryl alcohol related to halofantrine, is available only as a fixed-dose combination with artemether (Coartem or Riamet). As with halofantrine, oral absorption is highly variable and improved when the drug is taken with food. Use of Coartem with a fatty meal is recommended. Coartem is highly effective for the treatment of falciparum malaria, but it is expensive and requires twice-daily dosing. Despite these limitations, due to its reliable efficacy against falciparum malaria, Coartem has recently been selected as the first-line therapy for malaria in many African countries. Coartem is well tolerated; side effects include headache, dizziness, loss of appetite, gastrointestinal symptoms, and palpitations. Importantly, Coartem does not appear to cause the cardiac toxicity seen with halofantrine.

► Prevention

Malaria is transmitted by night-biting anopheline mosquitoes. Measures to prevent malaria include control of mosquitoes using ecologic measures and insecticides, and optimal use of these modalities is now under study. Bed nets, in particular nets treated with permethrin insecticides, are heavily promoted as inexpensive means of antimalarial protection, and improvement in mortality rates has been demonstrated. Extensive efforts are also underway to develop a malaria vaccine, and partial protection of African children has been demonstrated, but a vaccine offering complete protection is not anticipated in the near future.

When travelers from nonendemic to endemic countries are counseled on the prevention of malaria, it is imperative to emphasize measures to prevent mosquito bites (insect repellents, insecticides, and bed nets), since parasites are increasingly resistant to multiple drugs and no chemoprophylactic regimen is fully protective. Chemoprophylaxis is recommended for all travelers from nonendemic regions to endemic areas, although risks vary greatly for different locations, and some tropical areas entail no risk; specific recommendations for travel to different locales are available from the CDC (www.cdc.gov). Current recommendations from the CDC include the use of chloroquine for chemoprophylaxis in the few areas with only chloroquine-sensitive malaria parasites (principally the Caribbean and Central America west of the Panama Canal), mefloquine or Malarone for most other malarious areas, and doxycycline for areas with a high prevalence of multidrug-resistant falciparum malaria (principally parts of Southeast Asia) (Table 35-5). Recommendations should be checked regularly (Phone: 877-FYI-TRIP; Internet: www.cdc.gov/travel/) because they may change in response to changing resistance patterns and increasing experience with new drugs. In some circumstances, it may be appropriate for travelers

to not use chemoprophylaxis but to carry supplies of drugs with them in case a febrile illness develops and medical attention is unavailable. Regimens for self-treatment include artemisinin-based combinations, Malarone, and quinine. Most authorities do not recommend routine terminal chemoprophylaxis with primaquine to eradicate dormant hepatic stages of *P vivax* and *P ovale* after travel, but this may be appropriate in some circumstances, especially for travelers with major exposure to these parasites.

Regular chemoprophylaxis is not a standard management practice in developing world populations due to the expense and potential toxicities of long-term therapy. However, there is increasing interest in intermittent preventive therapy, whereby at-risk populations receive antimalarial therapy at certain intervals. This strategy may decrease the incidence of malarial morbidity and mortality while allowing antimalarial immunity to develop. Intermittent preventive therapy has been best studied with sulfadoxine-pyrimethamine, a long-acting drug that is administered in a single dose. The two high-risk populations that have been studied are pregnant women and infants. During pregnancy, sulfadoxine-pyrimethamine provided once during both the second and third trimesters has improved pregnancy outcomes. In infants, intermittent therapy with sulfadoxine-pyrimethamine has offered benefits, but dosing schedules are not standardized. With increasing resistance to sulfadoxine-pyrimethamine, it is not clear if the drug will retain prophylactic efficacy or if other drugs with shorter half-lives will be effective for intermittent preventive therapy.

► When to Refer

Referral to an expert on infectious diseases or travel medicine is important with all cases of malaria in the United States, and in particular for falciparum malaria, as management can be complex, but referral should not lead to a

Table 35-5. Drugs for the prevention of malaria in travelers.¹

| Drug | Use ² | Adult Dosage (all oral) ³ |
|-------------------------|---|---|
| Chloroquine | Areas without resistant <i>Plasmodium falciparum</i> | 500 mg weekly |
| Malarone | Areas with multidrug-resistant <i>P falciparum</i> | 1 tablet (250 mg atovaquone/100 mg proguanil) daily |
| Mefloquine | Areas with chloroquine-resistant <i>P falciparum</i> | 250 mg weekly |
| Doxycycline | Areas with multidrug-resistant <i>P falciparum</i> | 100 mg daily |
| Primaquine ⁴ | Terminal prophylaxis of <i>Plasmodium vivax</i> and <i>Plasmodium ovale</i> infections; alternative for <i>P falciparum</i> prophylaxis | 30 mg base daily for 14 days after travel |

¹Recommendations may change, as resistance to all available drugs is increasing. See text for additional information on toxicities and cautions. For additional details and pediatric dosing, see Centers for Disease Control and Prevention’s guidelines (phone: 800-CDC-INFO; <http://www.cdc.gov>). Travelers to remote areas should consider carrying effective therapy (see text) for use if a febrile illness develops, and they cannot reach medical attention quickly.

²Areas without known chloroquine-resistant *P falciparum* are Central America west of the Panama Canal, Haiti, Dominican Republic, Egypt, and most malarious countries of the Middle East. Malarone or mefloquine is currently recommended for other malarious areas except for border areas of Thailand, where doxycycline is recommended.

³For drugs other than primaquine, begin 1–2 weeks before departure (except 2 days before for doxycycline and Malarone) and continue for 4 weeks after leaving the endemic area (except 1 week for Malarone). All dosages refer to salts unless otherwise indicated.

⁴Screen for glucose-6-phosphate dehydrogenase deficiency before using primaquine.

delay in initial diagnosis and therapy, since delays in therapy can lead to severe illness or death.

▶ When to Admit

- Non-falciparum malaria generally does not cause severe disease and responds well to therapy, and so admission is only warranted if a patient presents with specific problems that require hospital management.
- Patients with falciparum malaria are generally admitted because the disease can progress rapidly to severe illness; exceptions may be made with individuals who are from malaria-endemic areas, and thus expected to have a degree of immunity, who are without evidence of severe disease, and who are judged able to return promptly for medical attention if their disease progresses.

BABESIOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ History of tick bite or exposure to ticks.
- ▶ Fever, flu-like symptoms, anemia.
- ▶ Intraerythrocytic parasites on Giemsa-stained blood smears.
- ▶ Positive serologic tests.

▶ General Considerations

Babesiosis is an uncommon intraerythrocytic infection caused mainly by two *Babesia* species and transmitted by *Ixodes* ticks. In Europe, where only 31 cases of babesiosis have been reported, infection is caused by *Babesia divergens*, which also infects cattle. In the United States, hundreds of cases of babesiosis have been reported, and infection is caused by *Babesia microti*, which also infects wild

mammals. Most babesiosis in the United States occurs in the coastal northeast, with some cases also in the upper midwest, following the geographic range of the vector *Ixodes scapularis*, and Lyme disease and anaplasmosis, which are spread by the same vector. Rare episodes of illnesses caused by *B microti*, *B divergens*, and other *Babesia*-like organisms have been reported from other areas. Babesiosis can also be transmitted by blood transfusion.

▶ Clinical Findings

A. Symptoms and Signs

With *B microti* infections, symptoms appear 1 week to several weeks after a tick bite; parasitemia is evident after 2–4 weeks. Patients usually do not recall the tick bite. The typical flu-like illness develops gradually and is characterized by fever, fatigue, headache, arthralgia, and myalgia. Other findings may include nausea, vomiting, abdominal pain, sore throat, depression, emotional lability, anemia, thrombocytopenia, and splenomegaly. Parasitemia may continue for months to years, with or without symptoms, and the disease is usually self-limited. Severe complications are most likely to occur in older persons or in those who have had splenectomy. Serious complications include respiratory failure, hemolytic anemia, disseminated intravascular coagulation, congestive heart failure, and acute kidney injury. In a study of hospitalized patients, the mortality rate was 6.5%. Most recognized *B divergens* infections in Europe have been in patients who have had splenectomy. These infections progress rapidly with high fever, severe hemolytic anemia, jaundice, hemoglobinuria, and acute kidney injury, with death rates over 40%.

B. Laboratory Findings

Identification of the intraerythrocytic parasite on Giemsa-stained blood smears establishes the diagnosis (Plate 116). These can be confused with malaria parasites, but the morphology is distinctive. Repeated smears are often necessary because well under 1% of erythrocytes may be infected, especially early in infection, although parasitemias can exceed 10%. An indirect immunofluorescent antibody test for *B microti* is available from the CDC; antibody is detectable within 2–4 weeks after the onset of symptoms and persists for months. Diagnosis can also be made by PCR or by inoculation of hamsters or gerbils.

▶ Treatment

Most patients have a mild illness and recover without therapy. Standard therapy is a 7-day course of quinine (650 mg orally three times daily) plus clindamycin (600 mg orally three times daily). An alternative is a 7-day course of atovaquone (750 mg orally every 12 hours) plus azithromycin (600 mg orally once daily). Exchange transfusion has been used successfully in severely ill asplenic patients and those with parasitemia greater than 10%.

TOXOPLASMOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Infection confirmed by isolation of *Toxoplasma gondii* or identification of tachyzoites in tissue or body fluids.

Primary infection

- ▶ Fever, malaise, headache, sore throat.
- ▶ Lymphadenopathy.
- ▶ Positive IgG and IgM serologic tests.

Congenital infection

- ▶ Follows acute infection of seronegative women and leads to CNS abnormalities and retinochoroiditis.

Infection in immunocompromised persons

- ▶ Reactivation leads to encephalitis, retinochoroiditis, pneumonitis, myocarditis.
- ▶ Positive IgG but negative IgM serologic tests.

General Considerations

T gondii, an obligate intracellular protozoan, is found worldwide in humans and in many species of animals and birds. The definitive hosts are cats. Humans are infected after ingestion of cysts in raw or undercooked meat, ingestion of oocysts in food or water contaminated by cats, transplacental transmission of trophozoites or, rarely, direct inoculation of trophozoites via blood transfusion or organ transplantation. *Toxoplasma* seroprevalence varies widely. It has decreased in the United States to about 20–30%, but it is much higher in other countries in both the developed and developing worlds, where it may exceed 80%.

Clinical Findings

A. Symptoms and Signs

The clinical manifestations of toxoplasmosis may be grouped into four syndromes.

1. Primary infection in the immunocompetent person—After ingestion, *T gondii* infection progresses from the gastrointestinal tract to lymphatics, and then dissemination. Most acute infections are asymptomatic. About 10–20% are symptomatic after an incubation period of 1–2 weeks. Acute infections in immunocompetent persons typically present as mild, febrile illnesses that resemble infectious mononucleosis. Nontender cervical or diffuse lymphadenopathy may persist for weeks to months. Sys-

tem findings may include fever, malaise, headache, sore throat, rash, myalgias, hepatosplenomegaly, and atypical lymphocytosis. Rare severe manifestations are pneumonitis, meningoencephalitis, hepatitis, myocarditis, polymyositis, and retinochoroiditis. Symptoms may fluctuate, but most patients recover spontaneously within at most a few months.

2. Congenital infection—Congenital transmission occurs as a result of infection, which may be symptomatic or asymptomatic, in a nonimmune woman during pregnancy. Fetal infection follows maternal infection in 30–50% of cases, but this risk varies by trimester: 10–25% during the first, 30–50% during the second, and 60% or higher during the third trimester. In the United States, an estimated 400 to 4000 congenital infections occur yearly. While the risk of fetal infection increases, the risk of severe fetal disease decreases over the course of pregnancy. Early fetal infections commonly lead to spontaneous abortion, stillbirths, or severe neonatal disease, including neurologic manifestations. Neurologic findings can include seizures, psychomotor retardation, deafness, and hydrocephalus. Retinochoroiditis and other sight-threatening eye lesions may develop. Systemic findings include fever or hypothermia, jaundice, vomiting, diarrhea, hepatosplenomegaly, pneumonitis, myocarditis, and rash. Infections later in pregnancy less commonly lead to major fetal problems. Most infants appear normal at birth, but they may have subtle abnormalities and progress to symptoms and signs of congenital toxoplasmosis later in life. Hepatosplenomegaly and lymphadenopathy may develop in the first few months of life; CNS and eye disease often present later. The most common late presentation of congenital toxoplasmosis is retinochoroiditis.

3. Retinochoroiditis—This manifestation of congenital toxoplasmosis presents weeks to years after congenital infection, commonly in teenagers or young adults. Retinochoroiditis also is seen in persons who acquire infection early in life, and these patients more often present with unilateral disease. Uveitis is also seen. Disease presents with pain, photophobia, and visual changes, usually without systemic symptoms. Signs and symptoms eventually improve, but visual defects may persist. Rarely, progression may result in glaucoma and blindness.

4. Reactivated disease in the immunocompromised person—Reactivated toxoplasmosis occurs in patients with AIDS, cancer, or those given immunosuppressive drugs. In patients with advanced AIDS, the most common manifestation is encephalitis, with multiple necrotizing brain lesions. The encephalitis usually presents subacutely, with fever, headache, altered mental status, focal neurologic findings, and other evidence of brain lesions. Less common manifestations of toxoplasmosis in patients with AIDS are chorioretinitis and pneumonitis. Chorioretinitis presents with ocular pain and alterations in vision. Pneumonitis presents with fever, cough, and dyspnea. Toxoplasmosis can develop in seronegative recipients of solid organ or bone marrow transplants due to reactivation or transmission of infection. Reactivation also can occur in

those with hematologic malignancies or treated with immunosuppressive drugs. Toxoplasmosis is similar to that in individuals with AIDS, but with immunodeficiency due to malignancy or immunosuppressive drugs, pneumonitis and myocarditis are more common. Less commonly, generalized toxoplasmosis in immunocompromised individuals can involve other organ systems.

B. Diagnostic Testing

1. Identification of parasites—Organisms can be seen in tissue or body fluids, although they may be difficult to identify; special staining techniques can facilitate identification. The demonstration of tachyzoites indicates acute infection; cysts may represent either acute or chronic infection. With lymphadenopathy due to toxoplasmosis, examination of lymph nodes usually does not show organisms. Parasite identification can also be made by inoculation of tissue culture or mice. PCR can be used for sensitive identification of organisms in amniotic fluid, blood, CSF, aqueous humor, and bronchoalveolar lavage fluid.

2. Serologic diagnosis—Multiple serologic methods are used, including the Sabin-Feldman dye test, enzyme-linked immunosorbent assay (ELISA), indirect fluorescent antibody test, and agglutination tests. IgG antibodies are seen within 1–2 weeks of infection, and usually persist for life. IgM antibodies peak earlier than IgG and decline more rapidly, although they may persist for years. In immunocompromised individuals in whom reactivation is suspected, a positive IgG assay indicates distant infection, and thus the potential for reactivated disease; a negative IgG argues strongly against reactivation toxoplasmosis. With reactivation in immunocompromised persons, IgM tests are generally negative.

3. During pregnancy and in newborns—Conversion from a negative to positive serologic test or rising titers are suggestive of acute infection, but tests are not routinely performed during pregnancy. When pregnant women are screened, negative IgG and IgM assays exclude active infection, but indicate the risk of infection during the pregnancy. The pattern of positive IgG with negative IgM is highly suggestive of chronic infection, with no risk of congenital disease unless the mother is severely immunocompromised. A positive IgM test is concerning for new infection because of the risk of congenital disease. Confirmatory testing should be performed before consideration of treatment or possible termination of pregnancy due to the limitations of available tests. Tests of the avidity of anti-IgG antibodies can be helpful, but a battery of tests is needed for confirmation of acute infection during pregnancy. When acute infection during pregnancy is suspected, PCR of amniotic fluid offers a sensitive assessment for congenital disease; this test should optimally be performed at 18 weeks of gestation. In newborns, positive IgM or IgA antibody tests are indicative of congenital infection, although the diagnosis is not ruled out by a negative test. Positive IgG assays may represent transfer of maternal antibodies without infection of the infant. Organisms may be identified by PCR; smears; or culture of blood, CSF, or tissue.

4. In immunocompetent individuals—Individuals with a suggestive clinical syndrome should be tested for IgG and IgM antibodies. Seroconversion, a 16-fold rise in antibody titer, or an IgM titer $> 1:64$ are suggestive of acute infection, although false-positive results may occur. Acute infection can also be diagnosed by detection of tachyzoites in tissue, culture of organisms, or PCR of blood or body fluids. Histologic evaluation of lymph nodes can show characteristic morphology, with or without organisms.

5. In immunodeficient individuals—A presentation consistent with toxoplasmic encephalitis warrants imaging of the brain. CT and MRI scans typically show multiple ring-enhancing cerebral lesions, most commonly involving the corticomedullary junction and basal ganglia. MRI is the more sensitive imaging modality. In AIDS patients with a positive IgG serologic test and no recent antitoxoplasma or antiviral therapy, the predictive value of a typical imaging study is about 80%. The other common diagnosis in this setting is CNS lymphoma, which more typically causes a single brain lesion. The differential diagnosis also includes tuberculoma, bacterial brain abscess, fungal abscess, and carcinoma. Diagnosis of CNS toxoplasmosis is most typically made after a therapeutic trial, with clinical and radiologic improvement expected within 2–3 weeks. Definitive diagnosis requires brain biopsy and search for organisms and typical histology. In retinochoroiditis, fundoscopic examination shows vitreous inflammatory reaction, white retinal lesions, and pigmented scars. Diagnosis of other clinical entities in immunocompromised individuals is generally based on histology.

▶ Treatment

A. Approach to Treatment

Therapy is generally not necessary in immunocompetent persons, since primary illness is self-limited. However, for severe, persistent, or visceral disease, treatment for 2–4 weeks may be considered. Treatment is appropriate for primary infection during pregnancy because the risk of fetal transmission or the severity of congenital disease may be reduced. For retinochoroiditis, most episodes are self-limited, and opinions vary on indications for treatment. Treatment is often advocated for episodes with decreases in visual acuity, multiple or large lesions, macular lesions, significant inflammation, or persistence for over a month. Immunocompromised patients with active infection must be treated. For those with transient immunodeficiency, therapy can be continued for 4–6 weeks after cessation of symptoms. For those with persistent immunodeficiency, such as AIDS patients, full therapy for 4–6 weeks is followed by maintenance therapy with lower doses of drugs. Immunodeficient patients who are asymptomatic but have a positive IgG serologic test should receive long-term chemoprophylaxis.

B. Choice of Drugs

Drugs for toxoplasmosis are active only against tachyzoites, so they do not eradicate infection. Standard therapy is the combination of pyrimethamine (200 mg loading dose, then

50–75 mg (1 mg/kg) orally once daily) plus sulfadiazine (1–1.5 g orally four times daily), with folinic acid (10–20 mg orally once daily) to prevent bone marrow suppression. Patients should be screened for a history of sulfonamide sensitivity (skin rashes, gastrointestinal symptoms, hepatotoxicity). To prevent crystal-induced nephrotoxicity, good urinary output should be maintained; alkalinization with sodium bicarbonate may also be useful. Pyrimethamine side effects include headache and gastrointestinal symptoms. Even with folinic acid therapy, bone marrow suppression may occur; platelet and white blood cell counts should be monitored at least weekly. A first-line alternative to sulfadiazine is clindamycin (600 mg orally four times daily). Other possible alternatives are trimethoprim-sulfamethoxazole or combining pyrimethamine with atovaquone, clarithromycin, azithromycin, or dapsone. Pyrimethamine is not used during the first trimester of pregnancy due to its teratogenicity. Standard therapy for the treatment of acute toxoplasmosis during pregnancy is with spiramycin (1 g orally three times daily until delivery). This therapy is used only to decrease the risk of fetal infection; it reduces the frequency of transmission to the fetus by about 60%. Spiramycin does not cross the placenta, so when fetal infection is documented or for acute infections late in pregnancy (which commonly lead to fetal transmission) treatment with combination regimens as described above is indicated.

▶ Prevention

Prevention of primary infection centers on avoidance of undercooked meat or contact with material contaminated by cat feces, particularly for seronegative pregnant women and immunocompromised persons. For meat, irradiation, cooking to 66 °C kills tissue cysts. Thorough cleaning of hands and surfaces is needed after contact with raw meat or areas contaminated by cats. Oocysts passed in cat feces can remain infective for a year or more, but fresh oocysts are not infective for 48 hours. For best protection, litter boxes should be changed daily and soaked in boiling water for 5 minutes. In addition, gloves should be worn when gardening, fruits and vegetables should be thoroughly washed, and ingestion of dried meat should be avoided.

Universal screening of pregnant women for *T gondii* antibodies is conducted in some countries but not the United States. Pregnant women should ideally have their serum examined for IgG and IgM antibody, and those with negative titers should adhere to the prevention measures described above. Seronegative women who continue to have environmental exposure should undergo repeat serologic screening several times during pregnancy.

For immunocompromised individuals, chemoprophylaxis to prevent primary or reactivated infection is warranted. For transplant recipients, pyrimethamine (25 mg daily for 6 weeks) has been used. For advanced AIDS patients and others, chemoprophylaxis with trimethoprim-sulfamethoxazole (one double-strength tablet daily or two tablets three times weekly), used primarily for protection against *Pneumocystis*, is also effective against *T gondii*. Alternatives are pyrimethamine plus either sulfadoxine or dapsone (various regimens). In AIDS patients,

chemoprophylaxis can be discontinued if antiretroviral therapy leads to immune reconstitution.

AMEBIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Organisms or antigen present in stools or abscess aspirate.
- ▶ Positive serologic tests with colitis or hepatic abscess but may represent prior infections.

Mild to moderate colitis

- ▶ Recurrent diarrhea.

Severe colitis

- ▶ Severe bloody diarrhea with fever, abdominal pain, and tenderness.
- ▶ Prostration.
- ▶ Progression to hemorrhage or perforation.

Hepatic abscess

- ▶ Fever, abdominal pain.
- ▶ Hepatomegaly, hepatic abscess on imaging studies.

▶ General Considerations

The *Entamoeba* complex contains two morphologically identical species: *Entamoeba dispar*, which is avirulent, and *Entamoeba histolytica*, which may be an avirulent intestinal commensal or lead to serious disease. Disease follows penetration of the intestinal wall, resulting in diarrhea, and with severe involvement, dysentery or extraintestinal disease, most commonly liver abscess.

E histolytica infections are present worldwide but are most prevalent in subtropical and tropical areas under conditions of crowding, poor sanitation, and poor nutrition. Of the estimated 500 million persons worldwide infected with *Entamoeba*, most are infected with *E dispar* and an estimated 10% with *E histolytica*. Mortality from invasive *E histolytica* infections is estimated at 100,000 per year.

Humans are the only established *E histolytica* host. Transmission occurs through ingestion of cysts from fecally contaminated food or water, facilitated by person-to-person spread, flies and other arthropods as mechanical vectors, and

use of human excrement as fertilizer. Urban outbreaks have occurred because of common-source water contamination.

► Clinical Findings

A. Symptoms and Signs

1. Intestinal amebiasis—In most infected persons, the organism lives as a commensal, and the carrier is without symptoms. With symptomatic disease, diarrhea may begin within a week of infection, although an incubation period of 2–4 weeks is more common, with gradual onset of abdominal pain and diarrhea. Fever is uncommon. Periods of remission and recurrence may last days to weeks or longer. Abdominal examination may show distention, tenderness, hyperperistalsis, and hepatomegaly. Microscopic hematochezia is common. More severe presentations include colitis and dysentery, with more extensive diarrhea (10–20 stools per day) and bloody stools. With dysentery, physical findings include high fevers, prostration, vomiting, abdominal pain and tenderness, hepatic enlargement, and hypotension. Severe presentations are more common in young children, pregnant women, those who are malnourished, and those receiving corticosteroids. Thus, in endemic regions, corticosteroids should not be started for presumed inflammatory bowel disease without first ruling out amebiasis. Fulminant amebic colitis can progress to necrotizing colitis, intestinal perforation, mucosal sloughing, and severe hemorrhage, with mortality rates over 40%. More chronic complications of intestinal amebiasis include chronic diarrhea with weight loss, which may last for months to years; bowel ulcerations; and amebic appendicitis. Localized granulomatous lesions (amebomas) can present after either dysentery or chronic intestinal infection. Clinical findings include pain, obstructive symptoms, and hemorrhage and may suggest intestinal carcinoma.

2. Extraintestinal amebiasis—The most common extraintestinal manifestation is amebic liver abscess. This can occur with colitis, but more frequently presents without history of prior intestinal symptoms. Patients present with the acute or gradual onset of abdominal pain, fever, an enlarged and tender liver, anorexia, and weight loss. Diarrhea is present in a small number of patients. Physical examination may show intercostal tenderness. Abscesses are most commonly single and in the right lobe of the liver, and they are much more common in men. Without prompt treatment, amebic abscesses may rupture into the pleural, peritoneal, or pericardial space, which is often fatal. Amebic infections may rarely occur throughout the body, including the lungs, brain, and genitourinary system.

B. Laboratory Findings

Laboratory studies with intestinal amebiasis show leukocytosis and hematochezia, with fecal leukocytes not present in all cases. With extraintestinal amebiasis, leukocytosis and elevated liver function studies are seen.

C. Diagnostic Testing

Diagnosis is by finding *E histolytica* or its antigen or by serologic tests. However, each method has limitations.

1. Intestinal amebiasis—Diagnosis is most commonly made by identifying organisms in the stool. *E histolytica* and *E dispar* cannot be distinguished, but the identification of amebic trophozoites or cysts in a symptomatic patient is highly suggestive of amebiasis. Stool evaluation for organisms is not highly sensitive (~30–50% for amebic colitis), and at least three stool specimens should be evaluated after concentration and staining. Multiple serologic assays are available; these tests are fairly sensitive, although sensitivity is lower (~70% in colitis) early in illness, and they cannot distinguish recent and old disease, as they remain positive for years after infection. A commercially available stool antigen test (TechLab II) offers improved sensitivity (> 90% for colitis); it requires fresh or frozen (not preserved) stool specimens. PCR-based tests are available but not used routinely. Colonoscopy of uncleaned bowel typically shows no specific findings in mild intestinal disease; in severe disease, ulcers may be found with intact intervening friable mucosa, resembling inflammatory bowel disease (Plate 117). Examination of fresh ulcer exudate for motile trophozoites and for *E histolytica* antigen may yield a diagnosis.

2. Hepatic abscess—Serologic tests for anti-amebic antibodies are almost always positive, except very early in the infection. Thus, a negative test in a suspicious case should be repeated in about a week. The stool *E histolytica* antigen test is positive in ~40% of cases. The TechLab II test can also be used to test serum, with good sensitivity if used before the initiation of therapy. Examination of stools for organisms or antigen is frequently negative. As imaging studies cannot distinguish amebic and pyogenic abscesses, when a diagnosis is not available from serologic studies, percutaneous aspiration may be indicated, ideally with an image-guided needle. Aspiration typically yields brown or yellow fluid. Detection of organisms in the aspirate is uncommon, but detection of *E histolytica* antigen is very sensitive and diagnostic. The key risk of aspiration is peritoneal spillage leading to peritonitis from amebas or other (pyogenic or echinococcal) organisms.

D. Imaging

Liver abscesses can be identified by ultrasonography, CT, or MRI, typically with round or oval low-density nonhomogeneous lesions, with abrupt transition from normal liver to the lesion, and hypoechoic centers. Abscesses are most commonly single, but more than one may be present. The right lobe is usually involved.

► Treatment

Treatment of amebiasis generally entails the use of metronidazole or tinidazole to eradicate tissue trophozoites and a luminal amebicide to eradicate intestinal cysts (Table 35–6). Asymptomatic infection with *E dispar* does not require therapy. This organism cannot be differentiated morphologically from *E histolytica*, but with negative serology *E dispar* colonization is likely, and treatment is not indicated. Colonization with *E histolytica* is generally treated with a luminal agent. Effective luminal agents are diloxanide furoate (500 mg orally three times daily with meals for 10 days), iodoquinol (diiodohydroxyquin; 650 mg orally three times daily for 21

Table 35–6. Treatment of amebiasis.¹

| Clinical Setting | Drugs of Choice and Adult Dosage | Alternative Drugs and Adult Dosage |
|---|---|--|
| Asymptomatic intestinal infection | Luminal agent: Diloxanide furoate, ² 500 mg orally three times daily for 10 days or- Iodoquinol, 650 mg orally three times daily for 21 days or- Paromomycin, 10 mg/kg orally three times daily for 7 days | |
| Mild to moderate intestinal infection | Metronidazole, 750 mg orally three times daily (or 500 mg IV every 6 hours) for 10 days or- Tinidazole, 2 g orally daily for 3 days plus- Luminal agent (see above) | Luminal agent (see above) plus either- Tetracycline, 250 mg orally three times daily for 10 days or- Erythromycin, 500 mg orally four times daily for 10 days |
| Severe intestinal infection | Metronidazole, 750 mg orally three times daily (or 500 mg IV every 6 hours) for 10 days or- Tinidazole, 2 g orally daily for 3 days plus- Luminal agent (see above) | Luminal agent (see above) plus either- Tetracycline, 250 mg orally three times daily for 10 days or- Dehydroemetine ³ or emetine, ² 1 mg/kg SC or IM for 3–5 days |
| Hepatic abscess, ameboma, and other extraintestinal disease | Metronidazole, 750 mg orally three times daily (or 500 mg IV every 6 hours) for 10 days or- Tinidazole, 2 g orally daily for 3 days plus- Luminal agent (see above) | Dehydroemetine ³ or emetine, ² 1 mg/kg SC or IM for 8–10 days, followed by (liver abscess only) chloroquine, 500 mg orally twice daily for 2 days, then 500 mg daily for 21 days plus- Luminal agent (see above) |

¹See text for additional details and cautions.

²Not available in the United States.

³Available in the United States only from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta (404-639-3670).

days), and paromomycin (30 mg/kg base orally, maximum 3 g, in three divided doses after meals daily for 7 days). Side effects associated with luminal agents are flatulence with diloxanide furoate, mild diarrhea with iodoquinol, and gastrointestinal symptoms with paromomycin. Relative contraindications are thyroid disease for iodoquinol and kidney disease for iodoquinol or paromomycin.

Treatment of intestinal amebiasis requires metronidazole (750 mg orally three times daily for 10 days) or tinidazole (2 g orally once daily for 3 days for mild disease and 5 days for serious disease) plus a luminal agent (Table 35–6). Metronidazole has most commonly been used in the United States, but tinidazole, which is now available, offers simpler dosing and less side effects. Metronidazole often induces transient nausea, vomiting, epigastric discomfort, headache, or a metallic taste. A disulfiram-like reaction may occur if alcohol is coingested. Metronidazole should be avoided in pregnant or nursing mothers if possible. The same toxicities and concerns probably apply for tinidazole, although it appears to be better tolerated. Fluid and electrolyte replacement is also important for patients with significant diarrhea. Surgical management of acute complications of intestinal amebiasis is

best avoided whenever possible. Successful therapy of severe amebic colitis may be followed by postdysenteric colitis, with continued diarrhea without persistent infection; this syndrome generally resolves in weeks to months.

Alternatives for the treatment of intestinal amebiasis are tetracycline (250–500 mg orally four times daily for 10 days) plus chloroquine (500 mg orally daily for 7 days). Emetine or dehydroemetine can be given subcutaneously (preferred) or intravenously in a dose of 1–1.5 mg/kg/d; the maximum daily dose is 90 mg for dehydroemetine and 65 mg for emetine). These agents are effective but cardiotoxic with a narrow therapeutic range and should be used only until severe disease is controlled. They cause nausea, vomiting, and pain at the injection site. Emetine is not available in the United States and dehydroemetine is only available from the Centers for Disease Control and Prevention Drug Service.

Amebic liver abscess is also treated with metronidazole or tinidazole plus a luminal agent (even if intestinal infection is not documented; Table 35–6). Metronidazole can be used intravenously when necessary. With failure of initial response to metronidazole or tinidazole, chloroquine, emetine or dehydroemetine may be added. Needle

aspiration may be helpful for large abscesses (over 5–10 cm), in particular if the diagnosis remains uncertain, if there is an initial lack of response, or if a patient is very ill, suggesting imminent abscess rupture. With successful therapy, abscesses disappear slowly (over months).

► Prevention & Control

Prevention requires safe water supplies; sanitary disposal of human feces; adequate cooking of foods; protection of foods from fly contamination; handwashing; and, in endemic areas, avoidance of foods that cannot be cooked or peeled. Water supplies can be boiled, treated with iodine (0.5 mL tincture of iodine per liter for 20 minutes; cysts are resistant to standard concentrations of chlorine), or filtered.

INFECTIONS WITH PATHOGENIC FREE-LIVING AMEBAS

ESSENTIALS OF DIAGNOSIS

- Acute meningoencephalitis or chronic granulomatous encephalitis after contact with warm fresh water.
- Keratitis, particularly in contact lens users.

The free-living amebas that cause disease in humans are of the genera *Acanthamoeba*, *Naegleria*, and *Balamuthia*. The organisms are widely distributed in soil and fresh and brackish water. *Acanthamoeba* and *Naegleria* species have been found to harbor *Legionella*, *Vibrio cholerae*, and other endosymbiotic bacteria and may serve as a reservoir for these organisms.

1. Primary Amebic Meningoencephalitis

Primary amebic meningoencephalitis is a fulminating, hemorrhagic, necrotizing meningoencephalitis that occurs in healthy children and young adults and is rapidly fatal. It is caused by free-living amebas, most commonly *Naegleria fowleri*, but also *Balamuthia mandrillaris* and *Acanthamoeba* species. *N fowleri* is a thermophilic organism found in fresh and polluted warm lake water, domestic water supplies, swimming pools, thermal water, and sewers. Most patients give a history of exposure to warm fresh water. The incubation period varies from 2 to 15 days. Early symptoms include headache, fever, stiff neck, and lethargy, often associated with rhinitis and pharyngitis. Vomiting, disorientation, and other signs of meningoencephalitis develop within 1 or 2

days, followed by coma and then death within 7–10 days. No distinctive clinical features distinguish the infection from acute bacterial meningoencephalitis. CSF shows hundred to thousands of leukocytes and erythrocytes per cubic millimeter. Protein is usually elevated, and glucose is normal or moderately reduced. A fresh wet mount of the CSF may show motile trophozoites. Staining with Giemsa or Wright stain will identify the trophozoites. Species identification is based on morphology and immunologic methods. Primary amebic meningoencephalitis is nearly always fatal. Amphotericin B appears to be the drug of choice; one survivor was treated with intravenous and intrathecal amphotericin B, intravenous miconazole, and oral rifampin.

2. Granulomatous Amebic Encephalitis

Acanthamoeba species and *B mandrillaris* can cause an encephalitis that is more chronic in nature than primary amebic meningoencephalitis. Neurologic disease may be preceded by skin lesions, including ulcers and nodules. After an uncertain incubation period neurologic symptoms develop slowly, with headache, meningismus, nausea, vomiting, lethargy, and low-grade fevers progressing over weeks to months to focal neurologic findings, mental status abnormalities, and eventually coma and death. CT and MRI show single or multiple nonspecific lesions. Lumbar puncture is dangerous due to increased intracranial pressure. CSF shows a lymphocytic pleocytosis with elevated protein; amebas are not typically seen. Diagnosis can be made by biopsy of skin or brain lesions. Information on the treatment of granulomatous amebic encephalitis is limited. Some patients have been successfully treated with various combinations of flucytosine, pentamidine, fluconazole or itraconazole, sulfadiazine, trimethoprim-sulfamethoxazole, and azithromycin.

3. Acanthamoeba Keratitis

Acanthamoeba keratitis is a painful, sight-threatening corneal infection. It is associated with corneal trauma, most commonly after use of contact lenses and contaminated saline solution. Symptoms include severe eye pain, photophobia, tearing, and blurred vision. The keratitis progresses slowly, with waxing and waning clinical findings over months, and can progress to blindness. Lack of response to antibacterial, antifungal, and antiviral topical treatments and potential use of contaminated contact lens solution are suggestive of the diagnosis. Ocular examination shows corneal ring infiltrates, but these can also be caused by other pathogens. The diagnosis can be made by examination or culture of corneal scrapings. Available diagnostic techniques include examination of a wet preparation for cysts and motile trophozoites, examination of stained specimens, evaluation with immunofluorescent reagents, culture of organisms, and PCR.

Acanthamoeba keratitis can be cured with local therapy. Topical propamidine isethionate (0.1%), chlorhexidine digluconate (0.02%), polyhexamethylene biguanide, neomycin-polymyxin B-gramicidin, miconazole, and combinations of these agents have been used successfully. Oral itraconazole or ketoconazole can be added for deep kerati-

tis. Drug resistance has been reported. Use of corticosteroid therapy is controversial. In some cases, debridement and penetrating keratoplasty have been performed in addition to medical therapy. Corneal grafting can be done after the amebic infection has been eradicated.

COCCIDIOSIS (Cryptosporidiosis, Isosporiasis, Cyclosporiasis, Sarcocystosis) & MICROSPORIDIOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Acute diarrhea, especially in children in developing countries.
- ▶ Outbreaks of diarrhea secondary to contaminated water or food.
- ▶ Prolonged diarrhea in immunocompromised persons.
- ▶ Diagnosis mostly by identifying organisms in specially stained stool specimens.

▶ General Considerations

The causes of coccidiosis are *Cryptosporidium* species (*C parvum*, *C hominis*, and others); *Isospora belli*; *Cyclospora cayetanensis*; and *Sarcocystis* species. Microsporidiosis is caused by at least 14 species, most commonly *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*. These infections occur worldwide, particularly in the tropics and in regions where hygiene is poor. They are causes of endemic childhood gastroenteritis (particularly in malnourished children in developing countries); institutional and community outbreaks of diarrhea; traveler’s diarrhea; and acute and chronic diarrhea in immunosuppressed patients, in particular those with AIDS. They are all notable for the potential to cause prolonged diarrhea, often lasting for a number of weeks. Clustering occurs in households, day care centers, and among sexual partners.

The infectious agents are oocysts (coccidiosis) or spores (microsporidiosis) transmitted from person to person or by contaminated drinking or swimming water or food. Ingested oocysts release sporozoites that invade and multiply in enterocytes, primarily in the small bowel. Coccidian oocysts and microsporidian cysts can remain viable in the environment for years.

I belli and *C cayetanensis* appear to infect only humans. *C cayetanensis* has caused a number of food-borne outbreaks in the United States in recent years, most commonly associated with imported fresh produce. *Sarcocystis* infects many species; humans are intermediate hosts (infected by ingestion of fecal sporocysts) for some species but definitive hosts for *Sarcocystis bovihominis* and *Sarcocystis suihominis* (infected by ingestion of tissue cysts in undercooked beef and pork, respectively).

Cryptosporidiosis is a zoonosis (*C parvum* principally infects cattle), but most human infections are acquired from humans, in particular with *C hominus*. Cryptosporidia are highly infectious and readily transmitted in day care settings and households. They have caused large community outbreaks due to contaminated water supplies (causing ~400,000 illnesses in Milwaukee in 1993) and are the leading cause of recreational water-associated outbreaks of gastroenteritis. Of note, coccidia and microsporidians will generally be missed on routine evaluations of stool for ova and parasites, as they require special staining techniques for identification.

▶ Clinical Findings

A. Symptoms and Signs

1. Cryptosporidiosis—The incubation period appears to be about 1–14 days. In developing countries, disease is seen primarily in children under 5 years of age, where cryptosporidiosis causes 5–10% of cases of childhood diarrhea. Presenting symptoms in children include acute watery diarrhea, abdominal pain, and cramps, with rapid resolution in most patients; however, symptoms quite commonly persist for 2 weeks or more. In developed countries, most patients are adults. Diarrhea in immunocompetent individuals typically lasts from 5 to 10 days. It is usually watery, with accompanying abdominal pain and cramps, nausea, vomiting, and fever. Relapses may follow initial resolution of symptoms. Mild illness and asymptomatic infection may also be common.

Cryptosporidiosis is a well-characterized cause of diarrhea in those with AIDS. It was common in this population before the advent of highly active antiretroviral therapy, particularly in those with advanced immunosuppression. Clinical manifestations are variable, but patients commonly have chronic diarrhea with frequent foul smelling stools, malabsorption, and weight loss. Severe, life-threatening watery diarrhea may be seen. Cryptosporidiosis also causes extraintestinal disease with AIDS, including pulmonary infiltrates with dyspnea and biliary tract infection with sclerosing cholangitis and AIDS cholangiopathy.

2. Isosporiasis—The incubation period for *I belli* is about 1 week. In immunocompetent persons, it usually causes a self-limited watery diarrhea lasting 2–3 weeks, with abdominal cramps, anorexia, malaise, and weight loss. Fever is unusual. Chronic symptoms may persist for months in some patients. In immunocompromised patients, isosporiasis more commonly causes severe and chronic diarrhea, with complications including marked dehydration, malnutrition, and hemorrhagic colitis. Extraintestinal disease has been reported rarely.

3. Cyclosporiasis—*C. cayetanensis* oocysts must undergo a period of sporulation of 7 days or more after shedding before they become infectious. Therefore, person-to-person spread is unlikely, and spread has typically been due to contaminated food (especially fresh produce) and water. The incubation period is 1–11 days. Infections can be asymptomatic. Cyclosporiasis causes an illness similar to that described for the other pathogens described in this section, with watery diarrhea, abdominal cramps, nausea, fatigue, and anorexia. Fever is seen in 25% of cases. Symptoms typically continue for 2 weeks or longer and may persist for months. Relapses of diarrhea are common. Diarrhea may be preceded by a flu-like prodrome and followed by persistent fatigue. In immunocompromised patients, cyclosporiasis is typically more severe and prolonged, with chronic fulminant watery diarrhea and weight loss.

4. Sarcocystosis—*Sarcocystis* infection may be common in some developing countries, but it is usually asymptomatic. Infection appears to most commonly follow the ingestion of undercooked beef or pork, leading to the development of cysts in muscle, with myalgias, fever, bronchospasm, pruritic rash, lymphadenopathy, and subcutaneous nodules. Ingestion of fecal sporocysts may lead to gastrointestinal symptoms.

5. Microsporidiosis—Microsporidia are obligate intracellular protozoans that cause a wide spectrum of diseases. Many infections are of zoonotic origin, but human-to-human transmission has been documented. Infection is mainly by ingestion of spores, but also by direct inoculation of the eyes. In immunocompetent hosts, microsporidian infections most commonly present as self-limited diarrhea. Ocular infections have also been described. Disease from microsporidia is seen mainly in immunocompromised persons, particularly those with AIDS. Infections in AIDS patients are most commonly with *E. bienewisi* and *E. intestinalis*. They cause chronic diarrhea, with anorexia, bloating, weight loss, and wasting, especially in those with advanced immunodeficiency. Fever is usually not seen. Other illnesses in immunocompromised persons associated with microsporidians (including the genera *Enterocytozoon*, *Encephalitozoon*, *Brachiola*, *Vittaforma*, *Pleistophora*, *Trachipleistophora*, and *Microsporidium*) include biliary tract disease (AIDS cholangiopathy), genitourinary infection with cystitis, kidney disease, hepatitis, peritonitis, myositis, respiratory infections including sinusitis, central nervous system infections including granulomatous encephalitis, and disseminated infections. Ocular infections with *Encephalitozoon* species cause conjunctivitis and keratitis, presenting as redness, photophobia, and loss of visual acuity.

B. Laboratory Findings

1. Cryptosporidiosis—Typically, stool is without blood or leukocytes. Diagnosis is traditionally made by detecting the organism in stool using a modified acid-fast stain; this technique is relatively insensitive, and multiple specimens should be evaluated before ruling out the diagnosis. Of note, routine evaluation for ova and parasites typically does not include a modified acid-fast stain, so this must be

specifically requested in many laboratories. Antigen detection offers improved sensitivity and specificity, both of which are well over 90% with a number of available assays, and these methods may now be considered the optimal means of diagnosis.

2. Isosporiasis—Diagnosis of isosporiasis is by examination of stool wet mounts or after modified acid-fast staining, in which the organism is clearly distinguishable from other parasites. Other stains also show the organism. Shedding of oocysts may be intermittent, so the sensitivity of stool evaluation is not high, and multiple samples should be examined. The organism may also be identified in duodenal aspirates or small bowel biopsies.

3. Cyclosporiasis—Diagnosis is made by examination of stool wet mounts or after modified acid-fast staining. Multiple specimens may need to be examined to make a diagnosis. The organism can also be identified in small bowel aspirates or biopsy specimens.

4. Sarcocystosis—Eosinophilia and elevated creatine kinase may be seen. Diagnosis is by identification of the acid-fast organisms in stool or by identification of trophozoites or bradyzoites in tissue biopsies.

5. Microsporidiosis—Diagnosis can be made by identification of organisms in specially stained stool, fluid, or tissue specimens, for example with Weber chromotrope-based stain. Electron microscopy is helpful for confirmation of the diagnosis and speciation. PCR and culture techniques are available but not used routinely.

▶ Treatment

Most acute infections with these pathogens in immunocompetent persons are self-limited and do not require treatment. Supportive treatment for severe or chronic diarrhea includes fluid and electrolyte replacement and, in some cases, parenteral nutrition.

1. Cryptosporidiosis—Treatment of cryptosporidiosis is challenging. No agent is clearly effective. Modest benefits have been seen in some (but not other) studies with paromomycin, a non-absorbed aminoglycoside (25–35 mg/kg orally for 14 days has been used), and nitazoxanide (500 mg–1 g orally twice daily for 3 days in nonimmunocompromised and 2–8 weeks in advanced AIDS patients), which is approved in the United States for this indication. It can cause mild gastrointestinal toxicity. Other agents that have been used with mixed success in AIDS patients with cryptosporidiosis include azithromycin, spiramycin, bovine hyperimmune colostrum, and octreotide. Reversing immunodeficiency with effective antiretroviral therapy is of greatest importance.

2. Isosporiasis—Isosporiasis is effectively treated in immunocompetent and immunosuppressed persons with trimethoprim-sulfamethoxazole (160 mg/800 mg orally 2–4 times daily for 10 days, with higher doses for patients with AIDS). An alternative therapy is pyrimethamine (75 mg orally in four divided doses) with folinic acid (10–25 mg/d orally). Maintenance therapy with low-dose trimeth-

oprim-sulfamethoxazole (daily or three times per week) or Fansidar (weekly) prevents relapse in those with persistent immunosuppression.

3. Cyclosporiasis—Cyclosporiasis is also treated with trimethoprim-sulfamethoxazole (dosing as for isosporiasis). With AIDS, long-term maintenance therapy (three times weekly) helps prevent relapse. For patients intolerant of trimethoprim-sulfamethoxazole, ciprofloxacin (500 mg orally twice daily for 7 days) showed efficacy, albeit with less ability to clear the organism than trimethoprim-sulfamethoxazole.

4. Sarcocystosis—For sarcocystosis, no specific treatment is established, but sulfadiazine cleared intestinal cysts in one study.

5. Microsporidiosis—Treatment of microsporidiosis is complex. Infections with most species, including those causing gastrointestinal and other manifestations, should be treated with albendazole (400 mg orally twice daily for 2–4 weeks), which has activity against a number of species, but relatively poor efficacy (about 50%) against *E bienewisi*, the most common microsporidial cause of diarrhea in AIDS patients. Fumagillin, which is used to treat honeybees and fish with microsporidian infections, has shown benefit in clinical trials at a dose of 20 mg three times per day for 14 days; treatment was accompanied by reversible thrombocytopenia. As with cryptosporidiosis, the best means of controlling microsporidiosis in AIDS patients is to restore immune function with effective antiretroviral therapy. Ocular microsporidiosis can be treated with fumagillin solution (3 mg/mL); this probably should be given with concurrent systemic therapy with albendazole. Adjunctive management may include corticosteroids to decrease inflammation and keratoplasty.

► Prevention

Water purification is important for control of these infections. Chlorine disinfection is not effective against cryptosporidial oocysts, so other purification measures are needed. Immunocompromised patients should boil or filter drinking water and should consider avoidance of lakes and swimming pools. Routine precautions (hand-washing, gloves, disinfection) should prevent institutional patient-to-patient spread. Optimal means of preventing microsporidial infections are not well understood, but water purification as discussed above and body substance precautions for immunocompromised and hospitalized individuals are likely effective.

GIARDIASIS

ESSENTIALS OF DIAGNOSIS

- Acute diarrhea, which may be profuse and watery.
- Chronic diarrhea with greasy, malodorous stools.
- Abdominal cramps, distention, flatulence, and malaise.
- Cysts or trophozoites in stools.

► General Considerations

Giardiasis is a protozoal infection of the upper small intestine caused by the flagellate *Giardia lamblia* (also called *Giardia intestinalis* and *Giardia duodenalis*). The parasite occurs worldwide, most abundantly in areas with poor sanitation. In developing countries, young children are very commonly infected. In the United States and Europe, the infection is the most common intestinal protozoal pathogen; the US estimate is of 100,000 to 2.5 million new infections leading to 5000 hospital admissions yearly. Groups at special risk include travelers to *Giardia*-endemic areas, those who swallow contaminated water during recreation or wilderness travel, men who have sex with men, and persons with impaired immunity. Outbreaks are common in households, children's day care centers, and residential facilities, and may occur as a result of contamination of water supplies.

The organism occurs in feces as a flagellated trophozoite and as a cyst. Only the cyst form is infectious by the oral route; trophozoites are destroyed by gastric acidity. Humans are a reservoir for the pathogen; dogs, cats, beavers, and other mammals have been implicated but not confirmed as reservoirs. Under suitable moist, cool conditions, cysts can survive in the environment for weeks to months. Cysts are transmitted as a result of fecal contamination of water or food, by person-to-person contact, or by anal-oral sexual contact. The infectious dose is low, requiring as few as ten cysts. After the cysts are ingested, trophozoites emerge in the duodenum and jejunum. Epithelial damage and mucosal invasion are uncommon. Hypogammaglobulinemia, low secretory IgA levels in the gut, achlorhydria, and malnutrition favor the development of infection.

► Clinical Findings

A. Symptoms and Signs

It is estimated that about 50% of infected persons have no discernable infection, about 10% become asymptomatic cyst passers, and 25–50% develop an acute diarrheal syndrome. Acute diarrhea may clear spontaneously but is commonly followed by chronic diarrhea. The incubation period is usually 1–3 weeks but may be longer. The illness may begin gradually or suddenly. Cysts may not be detected

in the stool at the onset of the illness. The acute phase may last days or weeks, and is usually self-limited, although cyst excretion may be prolonged. The initial illness may include profuse watery diarrhea, and hospitalization may be required due to dehydration, particularly in young children. Typical symptoms of chronic disease are abdominal cramps, bloating, flatulence, nausea, malaise, and anorexia. Fever and vomiting are uncommon. Diarrhea is usually not severe in the chronic stage of infection; stools are greasy or frothy and foul smelling, without blood, pus, or mucus. The diarrhea may be daily or recurrent; intervening periods may include constipation. Symptoms can persist for weeks to months. Weight loss is frequent. Chronic disease can include malabsorption, including fat- and protein-losing enteropathy and vitamin deficiencies.

B. Laboratory Findings

Most patients seek medical attention after having been ill for over a week, commonly with weight loss of 5 kg or more. Stool is generally without blood or leukocytes. Diagnosis is traditionally made by the identification of trophozoites or cysts in stool. A wet mount of liquid stool may identify motile trophozoites. Stained fixed specimens may show cysts or trophozoites. Sensitivity of stool analysis is not ideal, estimated at 50–80% for a single specimen and over 90% for three specimens. Sampling of duodenal contents with a string test or biopsy is no longer generally recommended, but biopsies may be helpful in very ill or immunocompromised patients. When giardiasis is highly suspected, antigen assays may be simpler and cheaper than repeated stool examinations, but these tests will not identify other stool pathogens. Multiple tests, which identify antigens of trophozoites or cysts, are available. They are generally quite sensitive (85–98%) and specific (90–100%).

► Treatment

The treatments of choice for giardiasis are metronidazole (250 mg orally three times daily for 5–7 days) or tinidazole (2 g orally once). The drugs are not universally effective; cure rates for single courses are typically about 80–95%. Toxicities are as described for treatment of amebiasis, but the lower dosages used for giardiasis limit side effects. Nitazoxanide (500 mg orally twice daily for 3 days) is generally well tolerated but may cause mild gastrointestinal side effects. Other drugs with activity against *Giardia* include furazolidone (100 mg orally four times a day for 7 days), which is about as effective as the other named drugs but causes gastrointestinal side effects; albendazole (400 mg orally daily for 5 days), which appears to have similar efficacy but has been less studied; and paromomycin (500 mg orally three times a day for 7 days), which appears to have somewhat lower efficacy but may be the safest drug (considering potential mutagenicity of metronidazole, tinidazole, and furazolidone) in pregnant women. Symptomatic giardiasis should always be treated. Treatment of asymptomatic patients should be considered, since they can transmit the infection to others. With a presumptive diagnosis but negative diagnostic studies, an empiric

course of treatment is sometimes appropriate. Household or day care contacts with an index case should be tested and treated if infected.

► Prevention

Community chlorination (0.4 mg/L) of water is relatively ineffective for inactivating cysts, so filtration is required. For wilderness or international travelers, bringing water to a boil for 1 minute or filtration with a pore size less than 1 µm are adequate. In day care centers, appropriate disposal of diapers and frequent hand washing are essential.

Huang DB et al. An updated review on *Cryptosporidium* and *Giardia*. *Gastroenterol Clin North Am.* 2006 Jun;35(2):291–314. [PMID: 16880067]

OTHER INTESTINAL FLAGELLATE INFECTIONS

Balantidium coli is a large ciliated intestinal protozoan found worldwide, but particularly in the tropics. Pigs are the main reservoir. The infection is rare in humans, and results from ingestion of cysts passed in stools of humans or swine. In the new host, the cyst wall dissolves and the trophozoite may invade intestinal mucosa, causing abscesses and ulcerations. Many infections are asymptomatic. Chronic infections may cause recurrent diarrhea or dysentery. Deaths have occurred from intestinal perforation and hemorrhage.

Dientamoeba fragilis is a protozoan that commonly causes infection without symptoms, so its role in human disease remains somewhat controversial. Symptoms attributed to the pathogen include diarrhea, abdominal pain, and anorexia. Other flagellates may infect humans, are generally considered nonpathogens, but may be markers for fecal-oral contamination.

Diagnosis of balantidiasis is established by finding trophozoites or cysts in stool, or in ulcer scrapings of the large bowel. *D fragilis* infection can be hard to diagnose because it only exists in the trophozoite form; the sensitivity of evaluation of three stools is 70–90%. The treatment of choice for balantidiasis is tetracycline, 500 mg orally four times daily for 10 days. The alternative is iodoquinol (diiodohydroxyquin), 650 mg orally three times daily for 21 days, and metronidazole, paromomycin, and nitazoxanide have also been used successfully. *D fragilis* infections have been successfully treated with metronidazole, iodoquinol, and tetracycline; all the regimens are the same as for balantidiasis.

TRICHOMONIASIS

ESSENTIALS OF DIAGNOSIS

- Copious vaginal discharge in women.

- ▶ Nongonococcal urethritis in men.
- ▶ Motile trichomonads on wet mounts.

▶ General Considerations

Trichomoniasis is caused by the protozoan *Trichomonas vaginalis* and is among the most common sexually transmitted diseases, causing vaginitis in women and nongonococcal urethritis in men. It can also occasionally be acquired by other means, since it can survive in moist environments for several hours.

▶ Clinical Findings

A. Symptoms and Signs

T vaginalis is often harbored asymptotically. For women with symptomatic disease, after an incubation period of 5 days to 4 weeks, a vaginal discharge develops, often with vulvovaginal discomfort, pruritus, dysuria, dyspareunia, or abdominal pain. Examination shows a copious discharge, which is usually not foul smelling but is often frothy and yellow or green in color. Inflammation of the vaginal walls and cervix with punctate hemorrhages are common. Most men infected with *T vaginalis* are asymptomatic, but it can be isolated from about 10% of men with nongonococcal urethritis. In men with trichomonal urethritis, the urethral discharge is generally more scanty than with other causes of urethritis.

B. Diagnostic Testing

Diagnosis is typically made by identifying the organism in vaginal or urethral secretions. Examination of wet mounts will show motile organisms. Tests for bacterial vaginosis (pH > 4.5, fishy odor after addition of potassium hydroxide) are often positive with trichomoniasis. Rapid antigen and nucleic acid amplification tests that are highly specific and much more sensitive than wet mounts are available but are not yet widely used.

▶ Treatment

The treatment of choice is metronidazole (2 g single oral dose). Tinidazole is also approved for this indication at the same dose, and it may be better tolerated and active against some resistant parasites. Toxicities of these drugs are discussed in the section on amebiasis. If the large single dose cannot be tolerated, an alternative metronidazole dosage is 500 mg orally twice daily for 1 week. All infected persons should be treated, even if asymptomatic, to prevent subsequent symptomatic disease and limit spread. Treatment failure suggests reinfection, but metronidazole-resistant organisms have been reported. These may be treated with tinidazole, longer courses of metronidazole, or some experimental therapies.

HELMINTHIC INFECTIONS

TREMATODE (FLUKE) INFECTIONS

SCHISTOSOMIASIS (Bilharziasis)

ESSENTIALS OF DIAGNOSIS

- ▶ History of fresh water exposure in an endemic area.
- ▶ Acute schistosomiasis: fever, headache, myalgias, cough, malaise, urticaria, diarrhea, and eosinophilia.
- ▶ Intestinal schistosomiasis: abdominal pain, fatigue, diarrhea, and hepatomegaly, progressing to anorexia, weight loss, and features of portal hypertension.
- ▶ Urinary schistosomiasis: hematuria and dysuria, progressing to hydroureter, hydronephrosis, urinary infections, and kidney injury.
- ▶ Diagnosis based on characteristic eggs in feces or urine; biopsy of rectal or bladder mucosa; positive serology.

▶ General Considerations

Schistosomiasis, which affects more than 200 million persons worldwide, leads to severe consequences in 20 million persons and about 100,000 deaths annually. The disease is caused by five species of trematode blood flukes. Four species cause intestinal schistosomiasis, with infection of mesenteric venules: *Schistosoma mansoni*, which is present in Africa, the Arabian peninsula, South America, and the Caribbean; *Schistosoma japonicum*, which is endemic in China and Southeast Asia; *Schistosoma mekongi*, which is endemic near the Mekong River in Southeast Asia; and *Schistosoma intercalatum*, which occurs in parts of Africa. *Schistosoma haematobium* causes urinary schistosomiasis, with infection of venules of the urinary tract, and is endemic in Africa and the Middle East. Transmission of schistosomiasis is focal, with greatest prevalence in poor rural areas. Control efforts have diminished transmission significantly in many areas, but high level transmission remains common in sub-Saharan Africa and some other areas. Prevalence of infection and illness typically peaks at about 15–20 years of age.

Humans are infected with schistosomes after contact with fresh water containing cercariae released by infected snails. Infection is initiated by penetration of skin or mucous membranes. After penetration, schistosomulae migrate to the portal circulation, where they rapidly mature. After about 6 weeks, adult worms mate, and migrate to terminal mesenteric or bladder venules, where females deposit their eggs. Some eggs reach the lumen of the bowel or bladder and are passed with feces or urine, while others are retained in the bowel or bladder wall or transported in the circulation to other tissues, in particular the liver. Disease in endemic areas is primarily due to a host response to eggs, with granuloma formation and inflammation, eventually leading to fibrosis.

Chronic infection can result in scarring of mesenteric or vesicular blood vessels, leading to portal hypertension and alterations in the urinary tract. In previously uninfected individuals, such as travelers with fresh water contact in endemic regions, acute schistosomiasis may occur, with a febrile illness 2–8 weeks after infection.

► Clinical Findings

A. Symptoms and Signs

1. Cercarial dermatitis—Following cercarial penetration, localized erythema develops in some individuals, which can progress to a pruritic maculopapular rash that persists for some days. Dermatitis can be caused by human schistosomes and, in non-tropical areas, by bird schistosomes that cannot complete their life cycle in humans (swimmer's itch).

2. Acute schistosomiasis (Katayama syndrome)—A febrile illness may develop 2–8 weeks after exposure in persons without prior infection, most commonly after heavy infection with *S mansoni* or *S japonicum*. Presenting symptoms and signs include acute onset of fever; headache; myalgias; cough; malaise; urticaria; diarrhea, which may be bloody; hepatosplenomegaly; lymphadenopathy; and pulmonary infiltrates. Localized lesions may occasionally cause severe manifestations, including CNS abnormalities and death. Acute schistosomiasis usually resolves in 2–8 weeks.

3. Chronic schistosomiasis—Many infected persons have light infections and are asymptomatic, but an estimated 50–60% have symptoms and 5–10% have advanced organ damage. Asymptomatic infected children may suffer from anemia and growth retardation. Symptomatic patients with intestinal schistosomiasis typically experience abdominal pain, fatigue, diarrhea, and hepatomegaly. Over years, anorexia, weight loss, weakness, colonic polyps, and features of portal hypertension develop. Late manifestations include hematemesis from esophageal varices, hepatic failure, and pulmonary hypertension. Urinary schistosomiasis may present within months of infection with hematuria and dysuria, most commonly in children and young adults. Fibrotic changes in the urinary tract can lead to hydronephrosis, bacterial urinary infections and, ultimately, kidney disease or bladder cancer.

B. Laboratory Findings

Microscopic examination of stool or urine for eggs, evaluation of tissue, or serologic tests establish the diagnosis. Characteristic eggs can be identified on smears of stool or urine, but filtration or concentration techniques can improve yields. Quantitative tests that yield > 400 eggs per gram of feces or 10 mL of urine are indicative of heavy infections with increased risk of complications. Diagnosis can also be made by biopsy of the rectum, colon, liver, or bladder. Serologic tests include an ELISA available from the CDC that is 99% specific for all species. The test is 99% sensitive for *S mansoni*, 95% sensitive for *S haematobium*, but < 50% sensitive for *S japonicum*. Species-specific immunoblots can increase sensitivity. In acute schistosomiasis, leukocytosis, and marked eosinophilia may occur; serologic

tests may become positive before eggs are seen in stool or urine. After therapy, eggs may be shed in stool or urine for months, and so the identification of eggs in fluids or tissue or positive serologic tests cannot distinguish past or active disease. Tests for egg viability are available. With a diagnosis of schistosomiasis, evaluation for the extent of disease is warranted, including liver function studies and imaging of the liver with intestinal disease and ultrasound or other imaging studies of the urinary system in urinary disease.

► Treatment

Treatment is indicated for all schistosome infections. In areas where recurrent infection is common, treatment is valuable in reducing worm burdens and limiting clinical complications. The drug of choice for schistosomiasis is praziquantel. The drug is administered for 1 day at an oral dose of 40 mg/kg (in one or two doses) for *S mansoni*, *S haematobium*, and *S intercalatum* infections and a dose of 60 mg/kg (in two or three doses) for *S japonicum* and *S mekongi*. Cure rates are generally > 80% after a single treatment, and those not cured have marked reduction in the intensity of infection. Praziquantel is active against invading cercariae but not developing schistosomulae. Therefore, the drug may not prevent illness when given after exposure and, for recent infections, a repeat course after a few weeks may be appropriate. Praziquantel may be used during pregnancy. Resistance to praziquantel has been reported. Toxicities include abdominal pain, diarrhea, urticaria, headache, nausea, vomiting, and fever, and may be due both to direct effects of the drug and responses to dying worms. Alternative therapies are oxamniquine for *S mansoni* infection and metrifonate for *S haematobium* infection. Both of these drugs currently have limited availability (they are not available in the United States), and resistance may be a problem. No second-line drug is available for *S japonicum* infections. The antimalarial drug artemether has activity against schistosomulae and adult worms and may be effective in chemoprophylaxis; however, it is expensive, and long-term use in malarious areas might select for resistant malaria parasites. With severe disease, use of corticosteroids in conjunction with praziquantel may decrease complications. Treatment should be followed by repeat examinations for eggs about every 3 months for 1 year after therapy, with re-treatment if eggs are seen.

► Prevention

Travelers to endemic areas should avoid fresh water exposure. Vigorous toweling after exposure may limit cercarial penetration. Chemoprophylaxis with artemether has shown efficacy but is not standard practice. Community control of schistosomiasis includes improved sanitation and water supplies, elimination of snail habitats, and intermittent administration of treatment to limit worm burdens.

LIVER, LUNG, AND INTESTINAL FLUKES

FASCIOLIASIS

Infection by *Fasciola hepatica*, the sheep liver fluke, results from ingestion of encysted metacercariae on watercress or other aquatic vegetables. Infection is prevalent in sheep-raising areas in many countries, especially parts of South America, the Middle East, and southern Europe. *Fasciola gigantica* has a more restricted distribution in Asia and Africa and causes similar findings. Eggs are passed from host feces into fresh water, leading to infection of snails, and then deposition of metacercariae on vegetation. In humans, metacercariae excyst, penetrate into the peritoneum, migrate through the liver, and mature in the bile ducts, where they cause local necrosis and abscess formation.

Two clinical syndromes are seen, related to acute migration of worms and chronic infection of the biliary tract. Symptoms related to migration of larvae present 6–12 weeks after ingestion. Typical findings are abdominal pain, fever, malaise, weight loss, urticaria, eosinophilia, and leukocytosis. Tender hepatomegaly and elevated liver function tests may be seen. Rarely, migration to other organs may lead to localized disease. The symptoms of worm migration subside after 2–4 months, followed by asymptomatic infection by adult worms or intermittent symptoms of biliary obstruction, with biliary colic and, at times, findings of cholangitis. Early diagnosis is difficult, as eggs are not found in the feces during the acute migratory phase of infection. Clinical suspicion should be based on clinical findings and marked eosinophilia in at risk individuals. CT and other imaging studies show hypodense migratory lesions of the liver. Serologic assays may be positive about 1 month before eggs are seen in stool, but specificities of available tests are not ideal. Definitive diagnosis is made by the identification of characteristic eggs in stool. Repeated examinations may be necessary. In chronic infection, imaging studies show masses obstructing the extrahepatic biliary tract.

Fascioliasis is unusual among fluke infections, in that it does not respond well to treatment with praziquantel. The treatment of choice is triclabendazole, which is also used in veterinary medicine, but is not available in the United States. Standard dosing of 10 mg/kg orally in a single dose or two doses over 12 hours achieves a cure rate of about 80%, but repeat dosing is indicated if abnormal radiologic findings or eosinophilia do not resolve. The second-line drug for fascioliasis is bithionol (30–50 mg/kg/d orally in three divided doses on alternate days for 10–15 days; available in the United States from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333; telephone: 404-639-3670). Treatment with either drug can be accompanied by abdominal pain and other gastrointestinal symptoms. Prevention of fascioliasis involves avoidance of ingestion of raw aquatic plants.

CLONORCHIASIS & OPISTHORCHIASIS

Infection by *Clonorchis sinensis*, the Chinese liver fluke, is endemic in areas of Japan, Korea, China, Taiwan, Southeast Asia, and the far eastern part of Russia. Millions of people are affected and, in some communities, prevalence can reach over 80%. Opisthorchiasis is principally caused by *Opisthorchis felineus* (regions of the former Soviet Union) or *Opisthorchis viverrini* (Thailand, Laos, Vietnam). Clonorchiasis and opisthorchiasis are clinically indistinguishable. Parasite eggs are shed into water in human or animal feces, where they infect snails, which release cercariae, which infect fish. Human infection follows ingestion of raw, undercooked, or pickled freshwater fish containing metacercariae. These parasites excyst in the duodenum and ascend into the biliary tract, where they mature and remain for many years, shedding eggs in the bile.

Most patients harbor few parasites and are asymptomatic. An acute illness can occur 2–3 weeks after initial infection, with fever, abdominal pain, tender hepatomegaly, urticaria, and eosinophilia. The acute syndrome is difficult to diagnose, since ova may not appear in the feces until 3–4 weeks after onset of symptoms. In chronic heavy infections, findings include abdominal pain, anorexia, weight loss, and tender hepatomegaly. More serious findings can include recurrent bacterial cholangitis and sepsis, cholecystitis, liver abscess, and pancreatitis. An increased risk of cholangiocarcinoma has been documented.

Early diagnosis is presumptive, based on clinical findings and epidemiology. Subsequent diagnosis is made by finding characteristic eggs in stool or duodenal or biliary contents. Repeated concentration tests of stool may be necessary. Imaging studies show characteristic biliary tract dilatations with filling defects due to flukes. Serologic tests can be helpful but are limited by suboptimal specificity.

The drug of choice is praziquantel. A dosage of 25 mg/kg orally three times daily for 2 days provides cure rates over 95%. One day of treatment may be sufficient. Re-treatment may be required, especially in some areas with known decreased praziquantel efficacy. The second-line drug is albendazole (400 mg orally twice daily for 7 days), which appears to be somewhat less effective.

PARAGONIMIASIS

Eight species of *Paragonimus* lung flukes cause human disease. The most important is *Paragonimus westermani*. *Paragonimus* species are endemic in East Asia, Oceania, West Africa, and South America, where millions of persons are infected. Eggs are released into fresh water, where parasites infect snails, and then cercariae infect crabs and crayfish. Human infection follows consumption of raw, undercooked, or pickled freshwater shellfish. Metacercariae then excyst, penetrate into the peritoneum, and pass into the lungs, where they mature into adult worms over about 2 months.

Most persons have moderate worm burdens and are asymptomatic. In symptomatic cases, abdominal pain and diarrhea develop 2 days to 2 weeks after infection, followed by fever, cough, chest pain, urticaria, and eosinophilia. Acute

symptoms may last for several weeks. Chronic infection can cause cough productive of brown sputum, hemoptysis, dyspnea, and chest pain, with progression to chronic bronchitis, bronchiectasis, bronchopneumonia, lung abscess, and pleural disease. Ectopic infections can cause disease in other organs, most commonly the CNS, where disease can present with seizures, headaches, and focal neurologic findings due to parasite meningitis, and intracerebral lesions.

The diagnosis of paragonimiasis is made by identifying characteristic eggs in sputum or stool or identifying worms in biopsied tissue. Multiple examinations and concentration techniques may be needed. Serologic tests may be helpful; an ELISA available from the CDC has sensitivity and specificity > 95%. Chest radiographs may show varied abnormalities of the lungs or pleura, including infiltrates, nodules, cavities, and fibrosis, and the findings can be confused with those of tuberculosis. With CNS disease, skull radiographs can show clusters of calcified cysts, and CT or MRI can show clusters of ring-enhancing lesions.

Treatment is with praziquantel (25 mg/kg orally three times daily for 2 days), which provides efficacy of at least 90%. Alternative therapies are bithionol and triclabendazole. As with cysticercosis, for cerebral paragonimiasis, praziquantel should generally be used with corticosteroids. Chronic infection may lead to permanent lung dysfunction and pleural disease requiring drainage procedures.

INTESTINAL FLUKES

The large intestinal fluke, *Fasciolopsis buski*, is a common parasite of pigs and humans in eastern and southern Asia. Eggs shed in stools hatch in fresh water, followed by infection of snails, and release of cercariae that encyst on aquatic plants. Humans are infected by eating uncooked plants, including water chestnuts, bamboo shoots, and watercress. Adult flukes mature in about 3 months and live in the small intestine attached to the mucosa, leading to local inflammation and ulceration. Other intestinal flukes that cause similar syndromes include *Heterophyes* (North Africa and Turkey) and *Metagonimus* (East Asia) species; these species are transmitted by undercooked freshwater fish.

Infections with intestinal flukes are often asymptomatic, although eosinophilia may be marked. In symptomatic cases, after an incubation period of 1–2 months, manifestations include epigastric pain and diarrhea. Other gastrointestinal symptoms, ileus, edema, and ascites may be seen uncommonly. Diagnosis is based on identification of characteristic eggs or adult flukes in the stool. In contrast to other fluke infections, illness more than 6 months after travel in an endemic area is unlikely. The drug of choice is praziquantel, 25 mg/kg orally as a single dose. Alternative therapies are triclabendazole and niclosamide (for most species).

CESTODE INFECTIONS

The four major tapeworms that cause noninvasive infections in humans are the beef tapeworm *Taenia saginata*, the pork tapeworm *Taenia solium*, the fish tapeworm *Diphyllobothrium latum*, each of which can reach many meters in length, and the dwarf tapeworm *Hymenolepis nana*. *Taenia* and *Hymenolepis* species are broadly distributed, especially in the tropics; *D latum* is most prevalent in temperate regions. Other tapeworms that can cause noninvasive human disease include the rodent tapeworm *Hymenolepis diminuta*, the dog tapeworm *Dipylidium caninum*, and other *Taenia* and *Diphyllobothrium* species. Invasive tapeworm infections, including *T solium* (when infective eggs, rather than cysticerci are ingested) and *Echinococcus* species, will be discussed separately.

NONINVASIVE TAPEWORM INFECTIONS

1. Beef Tapeworm

Infection is most common in cattle breeding areas. Humans are the definitive host. Gravid segments of *T saginata* are passed in human feces to soil, where they are ingested by grazing animals, especially cattle. The eggs then hatch to release embryos that encyst in muscle as cysticerci. Humans are infected by eating raw or undercooked infected beef. Most individuals infected with *T saginata* are asymptomatic, but abdominal pain and other gastrointestinal symptoms may be present. Eosinophilia is common. The most common presenting finding is the passage of proglottids in the stool.

2. Pork Tapeworm

T solium is transmitted to pigs that ingest human feces. Humans can be either the definitive host (after consuming undercooked pork, leading to tapeworm infection) or the intermediate host (after consuming food contaminated with human feces containing *T solium* eggs, leading to cysticercosis, which is discussed under invasive tapeworm infections). As with the beef tapeworm, infection with *T solium* adult worms is generally asymptomatic, but gastrointestinal symptoms may occur. Infection is generally recognized after passage of proglottids. Autoinfection with eggs can progress to cysticercosis.

3. Fish Tapeworm

Infection with *D latum* follows ingestion of undercooked freshwater fish, most commonly in temperate regions. Eggs from human feces are taken up by crustaceans, these are eaten by fish, which are then infectious to humans. Infection with multiple worms over many years can occur. Infections are most commonly asymptomatic, but nonspecific gastrointestinal symptoms, including diarrhea, may occur. Diagnosis usually follows passage of proglottids. Prolonged heavy infection can lead to megaloblastic anemia and neuropathy from vitamin B₁₂ deficiency, which is due to infection-induced dissociation of the vitamin from intrinsic factor and to utilization of the vitamin by worms.

4. Dwarf Tapeworm

H nana is the only tapeworm that can be transmitted between humans. Infections are common in warm areas, especially with poor hygiene and institutionalized populations. Infection follows ingestion of food contaminated with human feces. Eggs hatch in the intestines, where oncospheres penetrate the mucosa, encyst as cysticercoid larvae, and then rupture after about 4 days to release adult worms. Autoinfection can lead to amplification of infection. Infection with *H nana*, the related rodent tapeworm *H diminuta*, or the dog tapeworm *D caninum* can also follow accidental ingestion of infected insects. *H nana* are dwarf in size relative to other tapeworms but can reach 5 cm in length. Heavy infection is common, especially in children, and can be accompanied by abdominal discomfort, anorexia, and diarrhea.

▶ Laboratory Findings

Diagnosis is usually made based on the identification of characteristic eggs or proglottids in stool. Egg release may be irregular, so examination of multiple specimens or concentration techniques may be needed.

▶ Treatment

The treatment of choice for noninvasive tapeworm infections is praziquantel. A single dose of praziquantel (5–10 mg/kg orally) is highly effective, except for *H nana*, for which the dosage is 25 mg/kg. Treatment of *H nana* is more difficult, as the drug is not effective against maturing cysts. Therefore, with heavy infections with this parasite a repeat treatment after 1 week, and screening after therapy to document cure are appropriate. Therapy can be accompanied by headache, malaise, dizziness, abdominal pain, and nausea.

The alternative therapy for these infections is niclosamide. A single dose of niclosamide (2 g chewed) is effective against *D latum*, *Taenia*, and *D caninum* infections. For *H nana*, therapy is continued daily for 1 week. Niclosamide may cause nausea, malaise, and abdominal pain.

Willingham AL et al. Control of *Taenia solium* cysticercosis/taeniosis. *Adv Parasitol.* 2006;61:509–66. [PMID: 16735172]

INVASIVE CESTODE INFECTIONS

1. Cysticercosis

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure to *T solium* through fecal contamination of food.
- ▶ Seizures, headache, and other findings of a focal CNS lesion.
- ▶ Brain imaging shows cysts; positive serologic tests.

▶ General Considerations

Cysticercosis is due to tissue infection with cysts of *T solium* that develop after humans ingest food contaminated with eggs from human feces, thus acting as an intermediate host for the parasite. Prevalence is high where the parasite is endemic, in particular Mexico, Central and South America, the Philippines, and Southeast Asia. An estimated 20 million persons are infected with cysticerci yearly, leading to about 400,000 persons with neurologic symptoms and 50,000 deaths. Antibody prevalence rates up to 10% are recognized in some endemic areas, and the infection is one of the most important causes of seizures in the developing world and in immigrants to the United States from endemic countries.

▶ Clinical Findings

A. Symptoms and Signs

Neurocysticercosis can cause intracerebral, subarachnoid, and spinal cord lesions and intraventricular cysts. Single or multiple lesions may be present. Lesions may persist for years before symptoms develop, generally due to local inflammation or ventricular obstruction. Presenting symptoms include seizures, focal neurologic deficits, altered cognition, and psychiatric disease. Symptoms develop more quickly with intraventricular cysts, with findings of hydrocephalus and meningeal irritation, including severe headache, vomiting, papilledema, and visual loss. A particularly aggressive form of the disease, racemose cysticercosis, involves proliferation of cysts at the base of the brain, leading to alterations of consciousness and death. Spinal cord lesions can present with progressive focal findings.

Cysticercosis of other organ systems is usually clinically benign. Involvement of muscles can uncommonly cause discomfort and is identified by radiographs of muscle showing multiple calcified lesions. Subcutaneous involvement presents with multiple painless palpable skin lesions. Involvement of the eyes can present with ptosis due to extraocular muscle involvement or intraocular abnormalities.

B. Laboratory Findings

CSF examination may show lymphocytic or eosinophilic pleocytosis, decreased glucose, and elevated protein. Serologic tests can indicate prior exposure to *T solium*, but both sensitivity and specificity are limited.

C. Imaging

The diagnosis of neurocysticercosis can be difficult. With neuroimaging by CT or MRI, multiple parenchymal cysts are most typically seen. Parenchymal calcification is also common. Ventricular cysts may be difficult to visualize, with MRI offering better sensitivity than CT.

▶ Treatment

The medical management of neurocysticercosis is controversial, as the benefits of cyst clearance must be weighed against potential harm of an inflammatory response to dying worms. Antihelminthic therapy hastens radiologic improvement in parenchymal cysticercosis. However, some randomized trials

have shown that corticosteroids alone are as effective as specific therapy plus corticosteroids for controlling seizures, and some reports have shown exacerbation of disease after antihelminthic therapy. Considering active lesions, disease with a high likelihood of progression, such as intraventricular cysts, may benefit from therapy. At the other end of the spectrum, inactive calcified lesions probably do not benefit from therapy. Overall, it remains difficult to determine when treatment is indicated. When treatment is deemed appropriate, standard therapy consists of albendazole (10–15 mg/kg/d orally for 8 days) or praziquantel (50 mg/kg/d orally for 15–30 days). Albendazole is probably preferred, since it has shown better efficacy in some comparisons and since corticosteroids appear to lower circulating praziquantel levels but increase albendazole levels. Increasing the dosage of albendazole to 30 mg/kg/d orally may improve outcomes. Corticosteroids are usually administered concurrently but dosing is not standardized. Patients should be observed for evidence of localized inflammatory responses. Anticonvulsant therapy is provided if needed, and shunting is performed if required for elevated intracranial pressure. Surgical removal of cysts may be helpful for some difficult cases of neurocysticercosis and for symptomatic non-neurologic disease.

2. Echinococcosis

ESSENTIALS OF DIAGNOSIS

- ▶ History of exposure to dogs or wild canines in an endemic area.
- ▶ Large cystic lesions, most commonly of the liver or lung.
- ▶ Positive serologic tests.

▶ General Considerations

Echinococcosis occurs when humans are intermediate hosts for canine tapeworms. Infection is acquired by ingesting food contaminated with canine feces containing parasite eggs. The principal species that infect humans are *Echinococcus granulosus*, which causes cystic hydatid disease, and *Echinococcus multilocularis*, which causes alveolar hydatid disease. *E granulosus* is transmitted by domestic dogs in areas with livestock (sheep, goats, camels, and horses) as

intermediate hosts, including Africa, the Middle East, southern Europe, South America, Central Asia, Australia, New Zealand, and the southwestern United States. *E multilocularis*, which much less commonly causes human disease, is transmitted by wild canines, and endemic in northern forest areas of the northern hemisphere, including central Europe, Siberia, northern Japan, northwestern Canada, and western Alaska. An increase in the fox population in Europe has been associated with an increase in human cases. The disease range has also extended southward in Central Asia and China. Other species that cause limited disease in humans are endemic in South America and China.

After humans ingest parasite eggs, the eggs hatch in the intestines to form oncospheres, which penetrate the mucosa, enter the circulation, and encyst in specific organs as hydatid cysts. *E granulosus* forms cysts most commonly in the liver (65%) and lungs (25%), but the cysts may develop in any organ, including the brain, bones, skeletal muscles, kidneys, and spleen. Cysts are most commonly single. The cysts can persist and slowly grow for many years.

▶ Clinical Findings

A. Symptoms and Signs

Infections are commonly asymptomatic and may be noted incidentally on imaging studies or present with symptoms caused by an enlarging or superinfected mass. Findings may include abdominal or chest pain, biliary obstruction, cholangitis, portal hypertension, cirrhosis, bronchial obstruction leading to segmental lung collapse, and abscesses. Cyst leakage or rupture may be accompanied by a severe allergic reaction, including fever and hypotension. Seeding of cysts after rupture may extend the infection to new areas.

E multilocularis generally causes a more aggressive disease than *E granulosus*, with initial infection of the liver, but then local and distant spread commonly suggesting a malignancy. Symptoms based on the areas of involvement gradually worsen over years, with the development of obstructive findings in the liver and elsewhere.

B. Laboratory Findings

Serologic tests, including ELISA and immunoblot, offer sensitivity and specificity over 80% for *E granulosus* liver infections, but lower sensitivity for involvement of other organs. Serologic tests may also distinguish the two major echinococcal infections.

C. Imaging

Diagnosis is usually based on imaging studies, including ultrasonography, CT, and MRI. In *E granulosus* infection, a large cyst containing daughter cysts is highly suggestive of the diagnosis. In *E multilocularis* infection, imaging shows an irregular mass, often with areas of calcification.

▶ Treatment

Treatment of cystic hydatid disease has traditionally involved cautious surgical resection of cysts, with care not to rupture cysts during removal. Injection of a cysticidal agent was used

to limit spread in the case of rupture. Recently, new management algorithms include treatment with albendazole, often in conjunction with surgery. When used alone, as in cases where surgery is not possible, albendazole (10–15 mg/kg/d orally) has demonstrated efficacy, with courses of 3 months or longer duration, in some cases with alternating cycles of treatment and rest. Mebendazole (40–50 mg/kg/d orally) is an alternative drug, and praziquantel may also be effective. In some cases, medical therapy is begun, with surgery performed if disease persists after some months of therapy. Another approach, in particular with inoperable cysts, is percutaneous aspiration, injection, and reaspiration (PAIR). In this approach (which should not be used if cysts communicate with the biliary tract), patients receive antihelminthic therapy, and the cyst is partially aspirated. After diagnostic confirmation by examination for parasite protoscolices, a scolicalid agent (such as 95% ethanol or 0.5% cetrimide) is injected. Treatment of alveolar cyst disease is challenging, generally relying on wide surgical resection of lesions. Therapy with albendazole before or during surgery may be beneficial and may also provide improvement or even cure in inoperable cases.

3. Other Invasive Cestode Infections

Ingestion of aquatic copepods infected with larvae of *Spirometra* canine or feline tapeworms can lead to sparganosis, especially in South America and East Asia. Infection can also come from ingestion of undercooked infected meat (including mammals, birds, reptiles, and amphibians) or from use of frog or snake-meat poultices. The worms penetrate the intestinal wall or skin and migrate to various tissues. Inflammatory lesions, most commonly of the skin or eyes, are typically present. In cerebral sparganosis, an intense inflammatory response to worms can lead to severe neurologic disease. Diagnosis is by biopsy or visualization of the parasite. Treatment consists of surgical resection or local injection of ethanol. Antihelminthics do not appear to be helpful. Other non-human tapeworms can also cause localized and CNS inflammatory lesions. These are also managed with surgical resection.

INTESTINAL NEMATODE (ROUNDWORM) INFECTIONS

ASCARIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Transient cough, urticaria, pulmonary infiltrates, eosinophilia.

- ▶ Nonspecific abdominal symptoms.
- ▶ Eggs in stool; adult worms occasionally passed.

Ascaris lumbricoides is the most common of the intestinal helminths, infecting about a quarter of the world's population, with estimates of over a billion infections, 12 million acute cases, and 10,000 or more deaths annually. Prevalence is high wherever there is poor hygiene and sanitation or where human feces are used as fertilizer. Heavy infections are most common in children.

Infection follows ingestion of eggs in contaminated food. Larvae hatch in the small intestine, penetrate into the bloodstream, migrate to the lungs, and then travel via airways back to the gastrointestinal tract, where they develop to adult worms, which can be up to 40 cm in length, and live for 1–2 years.

Clinical Findings

Most persons with *Ascaris* infection are asymptomatic. A small proportion develop symptoms during migration of worms through the lungs, with fever, nonproductive cough, chest pain, dyspnea, and eosinophilia, occasionally with eosinophilic pneumonia. Rarely, larvae lodge ectopically in the brain, kidney, eye, spinal cord, and other sites and may cause local symptoms.

Light intestinal infections usually produce no symptoms. With heavy infection, abdominal discomfort may be seen. Adult worms may also migrate and be coughed up, be vomited, or may emerge through the nose or anus. They may also migrate into the common bile duct, pancreatic duct, appendix, and other sites, which may lead to cholangitis, cholecystitis, pyogenic liver abscess, pancreatitis, obstructive jaundice, or appendicitis. With very heavy infestations, masses of worms may cause intestinal obstruction, volvulus, intussusception, or death. Although severe manifestations of infection are uncommon, the very high prevalence of ascariasis leads to large numbers of individuals, especially children, with important sequelae. Moderate to high worm loads in children are also associated with nutritional abnormalities due to decreased appetite and food intake, and also decreased absorption of nutrients.

The diagnosis of ascariasis is made after adult worms emerge from the mouth, nose, or anus, or by identifying characteristic eggs in the feces. Due to the very high egg burden, concentration techniques are generally not needed. Imaging studies demonstrate worms, with filling defects in contrast studies and at times evidence of intestinal or biliary obstruction. Eosinophilia is marked during worm migration but may be absent during intestinal infection.

Treatment

All infections should ideally be treated. Treatments of choice are albendazole (single 400 mg oral dose), mebendazole (single 500 mg oral dose or 100 mg twice daily for 3 days), or pyrantel pamoate (single 11 mg/kg oral dose, maximum 1 g). These drugs are all well tolerated but may cause mild gastrointestinal toxicity. They are now considered safe for children above 1 year of age and in pregnancy, although use in the first trimester is best avoided. Intestinal obstruction

usually responds to conservative management and antihelminthic therapy. Surgery may be required for appendicitis and other gastrointestinal complications.

TRICHURIASIS

Trichuris trichiura, the whipworm, infects about a billion persons throughout the world, particularly in humid tropical and subtropical environments. Infection is heaviest and most frequent in children. Infections are acquired by ingestion of eggs. The larvae hatch in the small intestine and mature in the large bowel to adult worms of about 4 cm in length. The worms do not migrate through tissues.

Most infected persons are asymptomatic. Heavy infections may be accompanied by abdominal cramps, tenesmus, diarrhea, distention, nausea, and vomiting. The *Trichuris* dysentery syndrome may develop, particularly in malnourished young children, with findings resembling inflammatory bowel disease including bloody diarrhea and rectal prolapse. Chronic infections in children can lead to iron deficiency anemia, growth retardation, and clubbing of the fingers.

Trichuriasis is diagnosed by identification of characteristic eggs and sometimes adult worms in stools. Concentration techniques are not needed. Eosinophilia is common. Treatment is with albendazole (400 mg/d orally) or mebendazole (200 mg/d orally), for 1–3 days for light infections or 3–7 days for heavy infections.

HOOKWORM DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Transient pruritic skin rash and pulmonary symptoms.
- ▶ Anorexia, diarrhea, abdominal discomfort.
- ▶ Iron deficiency anemia.
- ▶ Characteristic eggs and occult blood in the stool.

▶ General Considerations

Infection with the hookworms *Ancylostoma duodenale* and *Necator americanus* is very common, especially in most tropical and subtropical regions. Both worms are broadly distributed. Prevalence is estimated at about 1 billion, causing approximately 65,000 deaths each year. When eggs are deposited on warm moist soil they hatch, releasing larvae that remain infective for up to a week. With contact, the larvae penetrate skin and migrate in the bloodstream to the pulmonary capillaries. In the lungs, the larvae penetrate into alveoli and then are carried by ciliary action upward to the bronchi, trachea, and mouth. After being swallowed, they reach and attach to the mucosa of the upper small bowel, where they mature to adult worms. *Ancylostoma* infection can also be acquired by ingestion of the larvae in food or water. Hookworms attach to the intestinal mucosa and suck blood. Blood loss is proportionate to the worm burden.

▶ Clinical Findings

A. Symptoms and Signs

Most infected persons are asymptomatic. A pruritic maculopapular rash (ground itch) may occur at the site of larval penetration, usually in previously sensitized persons. Pulmonary symptoms may be seen during larval migration through the lungs, with dry cough, wheezing, and low-grade fever, but these symptoms are less common than with ascariasis. Eosinophilia is common, especially during worm migration. About 1 month after infection, as maturing worms attach to the small intestinal mucosa, gastrointestinal symptoms may develop, with epigastric pain, anorexia, and diarrhea, especially in previously unexposed individuals. Persons chronically infected with large worm burdens may have abdominal pain, anorexia, diarrhea, and findings of marked iron-deficiency anemia and protein malnutrition. Anemia can lead to pallor, weakness, dyspnea, and congestive heart failure, and protein loss can lead to hypoalbuminemia, edema, and ascites. These findings may be accompanied by impairment in growth and cognitive development in children. Infection with the dog hookworm *Ancylostoma caninum* can uncommonly lead to abdominal pain, diarrhea, and eosinophilia, with intestinal ulcerations and regional lymphadenitis.

B. Laboratory Findings

Diagnosis is based on the demonstration of characteristic eggs in feces; concentration techniques are usually not needed. Microcytic anemia, occult blood in the stool, hypoalbuminemia, and eosinophilia are common.

▶ Treatment

Treatment is with albendazole (single 400 mg oral dose) or mebendazole (100 mg orally twice daily for 3 days). These drugs are teratogenic, but experience suggests that they are safe in children over 1 year of age and during the second and third trimesters of pregnancy. Occasional adverse effects are diarrhea and abdominal pain. Pyrantel pamoate and levamisole are also effective. Anemia should be managed with iron replacement and, for severe symptomatic anemia, blood transfusion. Mass treatment of children with single doses of albendazole or mebendazole at regular intervals limits worm burdens and the extent of disease and is advocated by the WHO.

STRONGYLOIDIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Transient pruritic skin rash and pulmonary symptoms.
- ▶ Anorexia, diarrhea, abdominal discomfort.
- ▶ Hyperinfection syndrome with varied severe presentations in the immunocompromised.
- ▶ Larvae detected in stool.

- ▶ With hyperinfection, larvae detected in sputum or other fluids.
- ▶ Eosinophilia.

▶ General Considerations

Strongyloidiasis is caused by infection with *Strongyloides stercoralis*. Although much less prevalent than ascariasis, trichuriasis, or hookworm infections, strongyloidiasis is nonetheless a significant problem, infecting tens of millions of individuals in tropical and subtropical regions. Infection is also endemic in some temperate regions of North America, Europe, Japan, and Australia. Of particular importance is the predilection of the parasite to cause severe infections in immunocompromised individuals due to its ability to replicate in humans. A related parasite, *Strongyloides fuelleborni*, infects humans in parts of Africa and New Guinea.

Among nematodes, *S stercoralis* is uniquely capable of maintaining its full life cycle both within the human host and in soil. Infection occurs when filariform larvae in soil penetrate the skin, enter the bloodstream, and are carried to the lungs, where they escape from capillaries into alveoli, ascend the bronchial tree, and are then swallowed and carried to the duodenum and upper jejunum, where maturation to the adult stage takes place. Females live embedded in the mucosa for up to 5 years, releasing eggs that hatch in the intestines as free rhabditiform larvae that pass to the ground via the feces. In moist soil, these larvae metamorphose into infective filariform larvae. Autoinfection can occur in humans, when some rhabditiform larvae develop into filariform larvae that penetrate the intestinal mucosa or perianal skin, and enter the circulation.

▶ Clinical Findings

A. Symptoms and Signs

As with other intestinal nematodes, most infected persons are asymptomatic. An acute syndrome can be seen at the time of infection, with a pruritic, erythematous, maculopapular rash, usually of the feet. These symptoms may be followed by pulmonary symptoms (including dry cough, dyspnea, and wheezing) and eosinophilia after a number of days, followed by gastrointestinal symptoms after some weeks, as with hookworm infections. Chronic infection may be accompanied by epigastric pain, nausea, diarrhea, and anemia. Maculopapular or urticarial rashes of the buttocks, perineum, and thighs, due to migrating larvae, may be seen. Large worm burdens can lead to malabsorption or intestinal obstruction. Eosinophilia is common but may fluctuate.

The most dangerous manifestation of *S stercoralis* infection is the **hyperinfection syndrome**, with dissemination of large numbers of filariform larvae to the lungs and other tissues in immunocompromised individuals. Mortality with this syndrome approaches 100% without treatment and has been about 25% with treatment. The hyperinfection syndrome is seen in those receiving corticosteroids and other immunosuppressive medications, those with hematologic malignancies, malnutrition, or alcoholism, or

those with AIDS. The risk seems greatest for those receiving corticosteroids, and considering the large number of at risk individuals, the risk in those with AIDS seems relatively low. With hyperinfection large numbers of larvae can migrate to many tissues, including the lungs, CNS, kidneys, and liver. Gastrointestinal symptoms can include abdominal pain, nausea, vomiting, diarrhea, and more severe findings related to intestinal obstruction, perforation, or hemorrhage. Bacterial sepsis, probably secondary to intestinal ulcerations, is a common presenting finding. Pulmonary findings include pneumonitis, cough, hemoptysis, and respiratory failure. Sputum may contain adult worms, larvae, and eggs. CNS disease includes meningitis and brain abscesses; the CSF may contain larvae. Various presentations can progress to shock and death.

B. Laboratory Findings

The diagnosis of strongyloidiasis can be difficult, as eggs are seldom found in feces. Diagnosis is usually based on the identification of rhabditiform larvae in the stool or duodenal contents. These larvae must be distinguished from hookworm larvae, which may hatch after stool collection. Repeated examinations of stool or examination of duodenal fluid may be required for diagnosis because the sensitivity of individual tests is only about 30%. Hyperinfection is diagnosed by the identification of large numbers of larvae in stool, sputum, or other body fluids. An ELISA from the CDC offers about 90% sensitivity and specificity, but cross-reactions with other helminths may occur. Eosinophilia and mild anemia are common, but eosinophilia may be absent with hyperinfection. Hyperinfection may include extensive pulmonary infiltrates, hypoproteinemia, and abnormal liver function studies.

▶ Treatment

Full eradication of *S stercoralis* is more important than with other intestinal helminths due to the ability of the parasite to replicate in humans. The treatment of choice for routine infection is ivermectin (200 mcg orally daily for 1–2 days). This treatment has replaced thiabendazole (25 mg/kg orally twice daily for 3 days), which is relatively poorly tolerated, and albendazole (400 mg orally twice daily for 3 days), which is less effective. For hyperinfection, ivermectin should be administered daily until the clinical syndrome has resolved and larvae have not been identified for at least 2 weeks. Follow-up examinations for larvae in stool or sputum are necessary, with repeat dosing if the infection persists. With continued immunosuppression, eradication may be difficult, and regular repeated doses of antihelminthic therapy (eg, monthly ivermectin) may be required. It is important to be aware of the possibility of strongyloidiasis in those with even a distant history of residence in an endemic area, since the infection can be maintained for decades. Screening of at-risk individuals for infection is appropriate before institution of immunosuppressive therapy. Screening can consist of serologic tests, with stool examinations in those with positive serologic tests, but consideration of presumptive treatment even if the stool evaluations are negative.

ENTEROBIOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Nocturnal perianal pruritus.
- ▶ Identification of eggs or adult worms on perianal skin or in stool.

▶ General Considerations

Enterobius vermicularis, the pinworm, is a common cause of intestinal infections worldwide, with maximal prevalence in school-age children. Enterobiasis is transmitted person-to-person via ingestion of eggs after contact with the hands or perianal region of an infected individual, food or fomites that have been contaminated by an infected individual, or infected bedding or clothing. Autoinfection also occurs. Eggs hatch in the duodenum and larvae migrate to the cecum. Females mature in about a month, and remain viable for about another month. During this time they migrate through the anus to deposit large numbers of eggs on the perianal skin. Due to the relatively short lifespan of these helminths, continuous reinfection, as in institutional settings, is required, for long-standing infection.

▶ Clinical Findings

A. Symptoms and Signs

Most individuals with pinworm infection are asymptomatic. The most common symptom is perianal pruritus, particularly at night, due to the presence of the female worms or deposited eggs. Insomnia, restlessness, and enuresis are common in children. Perianal scratching may result in excoriation and impetigo. Many mild gastrointestinal symptoms have also been attributed to enterobiasis, but associations are not proven. Serious sequelae are uncommon. Rarely, worm migration results in inflammation or granulomatous reactions of the gastrointestinal or genitourinary tracts. Colonic ulceration and eosinophilic colitis have been reported.

B. Laboratory Findings

Pinworm eggs are usually not found in stool. Diagnosis is made by finding adult worms or eggs on the perianal skin. A common test is to apply clear cellophane tape to the perianal skin, ideally in the early morning, followed by microscopic examination for eggs. The sensitivity of the tape test is reported to be about 50% for a single test and 90% for three tests. Nocturnal examination of the perianal area or gross examination of stools may reveal adult worms, which are about 1 cm in length. Eosinophilia is rare.

▶ Treatment

Treatment is with single oral doses of albendazole (400 mg), mebendazole (100 mg) or pyrantel pamoate (11 mg/kg, to a maximum of 1 g). The dose is repeated in 2 weeks

due to frequent reinfection. Other infected family members should be treated concurrently, and treatment of all close contacts may be appropriate when rates of reinfection are high in family, school, or institutional settings. Standard handwashing and hygiene practices are helpful in limiting spread. Perianal scratching should be discouraged. Washing of clothes and bedding should kill pinworm eggs.

INVASIVE NEMATODE (ROUNDWORM) INFECTIONS

DRACUNCULIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Tender cutaneous ulcer and worm protruding from the skin of an individual who has ingested untreated water in rural Africa.

▶ General Considerations

Dracunculiasis is caused by the nematode *Dracunculus medinensis*, or Guinea worm. It causes chronic cutaneous ulcers with protruding worms in rural Africa. It occurs only in humans and is a major cause of disability, although recent control efforts have been remarkably successful, with decreased annual incidence from about 3.5 million cases in the late 1980s to under 10,000 reported cases in 2007. Dracunculiasis has been eradicated from Asia, but remains endemic in 11 countries in West and Northeast Africa, most notably in southern Sudan. The disease occurs almost exclusively in isolated rural areas; all ages are affected, and prevalence may reach 60%.

Infection occurs after swallowing water containing the infected intermediate host, the crustacean *Cyclops* (known as copepods or water fleas). In the stomach, larvae escape from the copepods, and migrate through the intestinal mucosa to the retroperitoneum, where mating occurs. Females then migrate to subcutaneous tissue, usually of the legs, over about a year. A subcutaneous ulcer then forms. Upon contact with water, the parasite discharges large numbers of larvae, which are ingested by copepods. Adult worms, which can be up to a meter in length, are gradually extruded. Worm death and disintegration in tissue may provoke a severe inflammatory reaction.

► **Clinical Findings**

Patients are usually asymptomatic until the time of worm extrusion. At that time a painful papule develops, with erythema, pruritus, and burning, usually on the lower leg. Multiple lesions may be present. At this time, some patients may also develop a short-lived systemic reaction, which may include fever, urticaria, nausea, vomiting, diarrhea, and dyspnea. The skin lesion vesiculates over a few days, followed by ulceration. The ulcer is tender, often with a visible worm. The worm is then extruded or absorbed over a few weeks, followed by ulcer healing. Secondary infections, including infectious arthritis and tetanus, are common. The disease causes significant disability; lesions commonly prevent walking for a month or more.

Diagnosis follows identification of a typical skin ulcer with a protruding worm. When the worm is not visible, larvae may be identified on smears or seen after immersion in cold water. Eosinophilia is usually present.

► **Treatment**

No drug cures the infection, but metronidazole and mebendazole are sometimes used to limit inflammation and facilitate worm removal. Wet compresses may relieve discomfort. Occlusive dressings improve hygiene and limit shedding of infectious larvae. Worms are typically removed by sequentially rolling them out over a small stick. When available, simple surgical procedures can be used to remove worms. Corticosteroid ointments may hasten healing. Topical antibiotics may limit bacterial superinfection.

► **Prevention**

Dracunculiasis has proven to be easier to control than most parasitic infections. The disease is prevented by avoidance of contaminated drinking water. This can be accomplished by boiling, chlorination, or filtration through finely woven cloth. A WHO dracunculiasis eradication program, initiated in 1986, has been highly successful.

TRICHINOSIS

ESSENTIALS OF DIAGNOSIS

- Ingestion of inadequately cooked pork or game.
- Transient intestinal symptoms followed by fever, myalgias, and periorbital edema.
- Eosinophilia and elevated serum muscle enzymes.

► **General Considerations**

Trichinosis (or trichinellosis) is caused worldwide by *Trichinella spiralis* and related *Trichinella* species. The disease is

spread by ingestion of undercooked meat, most commonly pork in areas where pigs feed on garbage. When infected raw meat is ingested, *Trichinella* larvae are freed from cyst walls by gastric acid and pass into the small intestine. The larvae then invade intestinal epithelial cells, develop into adults, and the adults release infective larvae. These parasites travel to skeletal muscle via the bloodstream. They invade muscle cells, enlarge, and form cysts. These larvae may be viable for years. Pigs and other animals become infected by eating infected uncooked food scraps or other animals, such as rats.

The worldwide incidence of trichinosis has decreased, but human infections continue to occur sporadically or in outbreaks. In addition to undercooked pork, infections have been transmitted by ingestion of game and other animals, including bear and walrus in North America and wild boar and horse in Europe. In the United States, about 100 infections are reported annually, about three-fourths from pork and the remainder from game animals.

► **Clinical Findings**

A. Symptoms and Signs

Most infections are asymptomatic. In symptomatic cases, gastrointestinal symptoms, including diarrhea, vomiting, and abdominal pain, develop within the week after ingestion of contaminated meat. These symptoms usually last for less than a week but can occasionally persist for much longer. During the following week, symptoms and signs related to migrating larvae are seen. These findings include, most notably, fever, myalgias, periorbital edema, and eosinophilia. Additional findings may include headache, cough, dyspnea, hoarseness, dysphagia, macular or petechial rash, and subconjunctival and retinal hemorrhages. Systemic symptoms usually peak within 2–3 weeks, and commonly persist for about 2 months. In severe cases, generally with large parasite burdens, muscle involvement can be pronounced, with severe muscle pain, edema, and weakness, especially in the head and neck. Muscle pain may persist for months. Uncommon severe findings include myocarditis, pneumonitis, and meningoencephalitis, sometimes leading to death.

B. Laboratory Findings

The clinical diagnosis is supported by findings of elevated serum muscle enzymes (creatinine kinase, lactate dehydrogenase, aspartate aminotransferase). Serologic tests become positive 3 or more weeks after infection; a variety of techniques are used, including ELISA, immunofluorescence, indirect hemagglutinin, precipitin, and bentonite flocculation assays. Rising antibody titers are highly suggestive of the diagnosis. Muscle biopsy can usually be avoided, but if the diagnosis is uncertain, biopsy of a tender, swollen muscle may identify *Trichinella* larvae. For maximal yield, biopsy material should be examined histologically, and a portion should be enzymatically digested to release larvae, but evaluation before about 3 weeks after infection may not show muscle larvae.

► **Treatment**

No effective specific therapy for full-blown trichinosis has been identified. However, if infection is suspected early in

the course of illness, treatment with mebendazole (2.5 mg/kg orally twice daily) or albendazole (5–7.5 mg/kg orally twice daily) will kill intestinal worms and may limit progression to tissue invasion. Supportive therapy for systemic disease consists of analgesics, antipyretics, bed rest and, in severe illness, corticosteroids. Disease is prevented by adequate cooking or long-term freezing of pork and game. Irradiation of meat is also effective in eliminating *Trichinella* larvae.

ANGIOSTRONGYLIASIS

Nematodes of rats of the genus *Angiostrongylus* cause two distinct syndromes in humans. *Angiostrongylus cantonensis*, the rat lungworm, causes eosinophilic meningoencephalitis, primarily in Southeast Asia and some Pacific islands. *Angiostrongylus costaricensis* causes gastrointestinal inflammation. In both diseases, human infection follows ingestion of larvae within slugs or snails (and also crabs or prawns for *A cantonensis*) or on material contaminated by these organisms. Since the parasites are not in their natural hosts, they cannot complete their life cycles, but they can cause disease after migrating to the brain or gastrointestinal tract.

In *A cantonensis* infection, disease appears to be caused primarily by worm larvae migrating through the CNS and an inflammatory response to dying worms. After an incubation period of 1 day to 2 weeks, presenting symptoms and signs include headache, stiff neck, nausea, vomiting, cranial nerve abnormalities, and paresthesias. Most cases resolve spontaneously after 2–8 weeks, but serious sequelae and death have been reported. The diagnosis is strongly suggested by the finding of eosinophilic CSF pleocytosis (leukocytosis with over 10% eosinophils) in a patient with a history of travel to an endemic area. Peripheral eosinophilia may not be present. A *cantonensis* larvae have rarely been recovered from the CSF and the eyes. There is no specific treatment. Antihelminthic therapy is probably not indicated, since responses to dying worms may worsen with therapy. Corticosteroids have been used in severe cases.

In *A costaricensis* infection, parasites penetrate ileocecal vasculature and develop into adults, which lay eggs, but do not complete their life cycle. Disease is due to an inflammatory response to dying worms in the intestinal tract, with an eosinophilic granulomatous response, at times including vasculitis and ischemic necrosis. Common findings are abdominal pain, vomiting, and fever. Pain is most commonly localized to the right lower quadrant, and a mass may be appreciated, all mimicking appendicitis. Symptoms may recur over months. Uncommon findings are intestinal perforation or obstruction, or disease due to migration of worms to other sites. Many cases are managed surgically, usually for suspected appendicitis. Biopsy of inflamed intes-

tinal tissue may show worms localized to mesenteric arteries and eosinophilic granulomas. It is not known if antihelminthic therapy is helpful, but diethylcarbamazine, thiabendazole, and mebendazole have been used.

Wang QP et al. Human angiostrongyliasis. *Lancet Infect Dis*. 2008 Oct;8(10):621–30. [PMID: 18922484]

GNATHOSTOMIASIS

A number of species of *Gnathostoma*, which are parasites of carnivores, can occasionally infect humans. Most cases have been seen in Southeast Asia, but the disease has also been described in many other areas. Eggs shed in the feces of mammals are ingested by marine crustaceans, which are then ingested by fish, frogs, snakes, or mammals. Larvae then encyst in muscles. Human infection follows eating undercooked fish, shellfish, chicken, or pork and can also be transmitted by ingesting copepods in contaminated water. After ingestion, larvae cannot complete development in humans, but rather migrate through tissues.

Acute gastrointestinal symptoms, including nausea, vomiting, abdominal pain, and fever, may develop soon after infection and persist for 2–3 weeks. The disease may then progress to findings consistent with cutaneous or visceral larva migrans. Migratory subcutaneous erythematous swellings may be painful or pruritic. Migrating larvae may also invade other tissues, leading to findings in the eyes, lungs, intestines, and elsewhere. The most serious complications are due to invasion of the CNS, leading to eosinophilic meningoencephalitis and other serious findings. Although a less common cause of eosinophilic meningitis than *A cantonensis* infection, gnathostomiasis tends to be more severe. Severe pain due to migration through spinal roots and focal neurologic findings may be seen. Symptoms are highly variable over time. CSF eosinophilic pleocytosis and peripheral eosinophilia are seen.

The diagnosis of gnathostomiasis is suggested by the history of intermittent subcutaneous swellings and typical CNS findings. Worms can occasionally be identified in skin lesions. Serologic tests may be helpful in establishing a diagnosis. Treatment is with ivermectin (200 mcg/kg orally single dose) or albendazole (400 mg/kg orally daily for 21 days); both treatments have reported cure rates over 90%.

TOXOCARIASIS

▶ General Considerations

The dog roundworm *Toxocara canis*, the cat roundworm *Toxocara cati*, and less commonly other helminths may cause visceral larva migrans. *T canis* is highly prevalent in

dogs. Humans are infected after ingestion of eggs in material contaminated by dog or other feces. With *T canis*, infection is spread principally by puppies and lactating females, and the eggs must be on the ground for several weeks before they are infectious. After ingestion by humans, larvae migrate to various tissues but cannot complete their life cycle.

► Clinical Findings

Visceral larva migrans is seen principally in young children. Most infections are asymptomatic. The most commonly involved organs are the liver and lungs. Presentations include cough, fever, wheezing, hepatomegaly, splenomegaly, lymphadenopathy, pulmonary infiltrates, and eosinophilia. Involvement of the CNS can occur rarely, leading to eosinophilic meningitis and other abnormalities. Ocular larva migrans is a distinct syndrome, usually in children older than is typical for visceral larva migrans. Children present with visual deficits, pain, and a retinal mass, which can be confused with retinoblastoma. *Baylisascaris procyonis*, a roundworm of raccoons, can rarely cause visceral larva migrans in humans, with typically more severe manifestations than those with *T canis*, including eosinophilic meningitis and eye disease.

The diagnosis of visceral larva migrans is suggested by the finding of eosinophilia in a child with hepatomegaly or other signs of the disease, especially with a history of exposure to puppies. The diagnosis is confirmed by the identification of larvae in a biopsy of infected tissue, usually performed when other diseases are suspected. Serologic tests may be helpful; an available ELISA was estimated to have 78% sensitivity and 92% specificity. Most patients recover without specific therapy, although symptoms may persist for months.

► Treatment

Treatment with antihelminthics or corticosteroids may be considered in severe cases. No drugs have been proven to be effective, but albendazole (400 mg twice daily for 5 days), mebendazole, thiabendazole, diethylcarbamazine, and ivermectin have been used, and albendazole has been recommended as the treatment of choice.

Good B et al. Ocular toxocariasis in schoolchildren. *Clin Infect Dis.* 2004 Jul 15;39(2):173–8. [PMID: 15307025]

CUTANEOUS LARVA MIGRANS (Creeping Eruption)

Cutaneous larva migrans is caused principally by larvae of the dog and cat hookworms, *Ancylostoma braziliense* and *A caninum*. Other animal hookworms, gnathostomiasis, and strongyloidiasis may also cause this syndrome. Infections are common in warm areas, including the southeastern United States. They are most common in children. The disease is caused by the migration of worms through skin;

the non-human parasites cannot complete their life cycles, so only cause cutaneous disease.

► Clinical Findings

Intensely pruritic erythematous papules develop, usually on the feet or hands, followed within a few days by serpiginous tracks marking the course of the parasite, which may travel several millimeters per day (Plate 118). Several tracks may be present. The process may continue for weeks, with lesions becoming vesiculated, encrusted, or secondarily infected. Systemic symptoms or eosinophilia are uncommon.

The diagnosis is based on the characteristic appearance of the lesions. Biopsy is usually not indicated.

► Treatment

Without treatment, the larvae eventually die and are absorbed. Mild cases do not require treatment. Thiabendazole (10% aqueous suspension) can be applied topically three times daily for 5 or more days. Systemic therapy with albendazole (400 mg orally once or twice daily for 3–5 days) or ivermectin (200 mcg/kg orally single dose) is highly effective.

Heukelbach J et al. Epidemiological and clinical characteristics of hookworm-related cutaneous larva migrans. *Lancet Infect Dis.* 2008 May;8(5):302–9. [PMID: 18471775]

ANISAKIASIS

Anisakiasis is caused by infection with larvae of saltwater fish and squid. Multiple species of the family *Anisakidae* may occasionally infect humans. Definitive hosts for these parasites are marine mammals. Eggs are passed in the feces and ingested by crustaceans, which are then eaten by fish and squid. When ingested by humans in undercooked seafood, larvae penetrate the stomach or intestinal wall but cannot complete their life cycle. The disease is most common in Japan.

► Clinical Findings

Clinical manifestations of anisakiasis follow burrowing of worms into the stomach or intestinal wall, leading to localized ulceration, edema, and eosinophilic granuloma formation. Symptoms usually occur within 2 days of parasite ingestion and include severe epigastric or abdominal pain, nausea, and vomiting. Intestinal involvement can mimic appendicitis. Allergic symptoms, including urticaria, angioedema, and anaphylaxis, have also been attributed to acute infection. Acute symptoms generally resolve within 2 weeks, but chronic symptoms may also be seen, suggesting chronic intestinal diseases such as inflammatory bowel disease, diverticulitis, or carcinoma. Rarely, worms may migrate to other sites or be coughed up. Eosinophilia is usually not seen.

The diagnosis of anisakiasis is suggested in those with acute abdominal symptoms after ingestion of raw fish. Radiographic studies may identify stomach or intestinal lesions, and endoscopy may allow visualization and removal of the worm. When surgery is performed due to

consideration of other diagnoses, eosinophilic inflammatory lesions and the invading worms are found.

► Treatment

Specific therapy is not indicated, but endoscopic worm removal hastens recovery. The parasites are killed by cooking or deep freezing fish.

FILARIASIS

LYMPHATIC FILIASIS

ESSENTIALS OF DIAGNOSIS

- Episodic attacks of lymphangitis, lymphadenitis, and fever.
- Chronic progressive swelling of extremities and genitals; hydrocele; chyluria; lymphedema.
- Microfilariae in blood, chyluria, or hydrocele fluid; positive serologic tests.

Lymphatic filariasis is caused by three filarial nematodes: *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*, and is among the most important parasitic diseases of man. Approximately 120 million people are infected with these organisms in tropical and subtropical countries, about a third of these suffer clinical consequences of the infections, and many are seriously disfigured. *W bancrofti* causes about 90% of episodes of lymphatic filariasis. It is transmitted by *Culex*, *Aedes*, and *Anopheles* mosquitoes and is widely distributed in the tropics and subtropics, including subsaharan Africa, Southeast Asia, the western Pacific, India, South America, and the Caribbean. *B malayi* is transmitted by *Mansonia* and *Anopheles* mosquitoes and is endemic in parts of China, India, Southeast Asia, and the Pacific. *B timori* is found only in islands of southeastern Indonesia.

Humans are infected by the bites of infected mosquitoes. Larvae then move to the lymphatics and lymph nodes, where they mature over months to thread-like adult worms, and then can persist for many years. The adult worms produce large numbers of microfilariae, which are released into the circulation, and infective to mosquitoes, particularly at night (except for the South Pacific, where microfilaremia peaks during daylight hours).

► Clinical Findings

A. Symptoms and Signs

Many infections remain asymptomatic despite circulating microfilariae. Clinical consequences of filarial infection are principally due to inflammatory responses to developing,

mature, and dying worms. The initial manifestation of infection is often acute lymphangitis, with fever, painful lymph nodes, edema, and inflammation spreading peripherally from involved lymph nodes (in contrast to bacterial lymphangitis, which spreads centrally). Lymphangitis and lymphadenitis of the upper and lower extremities is common (Plate 119); genital involvement, including epididymitis and orchitis, with scrotal pain and tenderness, occurs principally only with *W bancrofti* infection. Acute attacks of lymphangitis last for a few days to a week and may recur a few times per year. Filarial fevers may also occur without lymphatic inflammation.

The most common chronic manifestation of lymphatic filariasis is swelling of the extremities or genitals due to chronic lymphatic inflammation and obstruction. Extremities become increasingly swollen, with a progression over time from pitting edema, to nonpitting edema, to sclerotic changes of the skin that are referred to as elephantiasis. Genital involvement, particularly with *W bancrofti*, occurs more commonly in men, progressing from painful epididymitis to hydroceles that are usually painless but can become very large, with inguinal lymphadenopathy, thickening of the spermatic cord, scrotal lymphedema, thickening and fissuring of the scrotal skin, and occasionally chyluria. Lymphedema of the female genitalia and breasts may also occur.

Tropical pulmonary eosinophilia is a distinct syndrome principally affecting young adult males with either *W bancrofti* or *B malayi* infection but typically without microfilaremia. This syndrome is characterized by asthma-like symptoms, with cough, wheezing, dyspnea, and low-grade fevers, usually at night. Without treatment, tropical pulmonary eosinophilia can progress to interstitial fibrosis and chronic restrictive lung disease.

B. Laboratory Findings

The diagnosis of lymphatic filariasis is strongly suggested by characteristic findings of lymphangitis or lymphatic obstruction in persons with risk factors for the disease. The diagnosis is confirmed by finding microfilariae, usually in blood, but this may be difficult. In addition, microfilariae may be absent, especially early in the disease progression (first 2–3 years) or with chronic obstructive disease. To increase yields, blood samples are obtained at about midnight in most areas, but not in the South Pacific, where microfilaremia is diurnal. Smears are evaluated by wet mount to identify motile parasites and by Giemsa staining; these examinations can be delayed until the following morning, with storage of samples at room temperature. Of note, the periodicity of microfilaremia is variable, and daytime samples may yield positive results. Microfilariae may also be identified in hydrocele fluid or chylous urine. Eosinophilia is usually absent, except during acute inflammatory syndromes. Available serologic tests, including bentonite flocculation, indirect hemagglutination, ELISA, and indirect fluorescent antibody tests, may be helpful but cannot distinguish between past and active infections. Rapid antigen tests with sensitivity and specificity over 90% are available. Adult worms may also be found in

lymph node biopsy specimens (although biopsy is not usually clinically indicated) or by ultrasound of a scrotal hydrocele or lymphedematous breast. When microfilariaemia is lacking, especially if sophisticated techniques are not available, diagnoses may need to be made on clinical grounds alone.

► Treatment & Control

A. Drug Treatment

Treatment is somewhat controversial, as no drug can fully control or reverse the disease, and treatment may cause serious acute inflammatory symptoms. Diethylcarbamazine is the drug of choice, but it cannot cure infections due to its limited action against adult worms. Asymptomatic infection and acute lymphangitis are treated with this drug (2 mg/kg orally three times daily) for 10–14 days, leading to a marked decrease in microfilaraemia. Therapy may be accompanied by allergic symptoms, including fever, headache, malaise, hypotension, and bronchospasm, probably due to release of antigens from dying worms. For this reason, treatment courses may begin with a lower dosage, with escalation over the first 4 days of treatment. Single annual doses of diethylcarbamazine (6 mg/kg orally), alone or with ivermectin (400 mcg/kg orally) or albendazole (400 mg orally) may be as effective as longer courses of diethylcarbamazine. When onchocerciasis or loiasis is suspected, it may be appropriate to withhold diethylcarbamazine to avoid severe reactions to dying microfilariae; rather, ivermectin plus albendazole may be given, although these drugs are less active than diethylcarbamazine against adult worms. Appropriate management of advanced obstructive disease is uncertain. Drainage of hydroceles provides symptomatic relief, although they will recur. Therapy with diethylcarbamazine cannot reverse chronic lymphatic changes but is typically provided to lower worm burdens. An interesting approach under study is to treat with doxycycline (100–200 mg/d orally for 4–6 weeks), which kills obligate intracellular *Wolbachia* bacteria, leading to death of adult filarial worms. Secondary bacterial infections must be treated. Surgical correction may be helpful in some cases.

B. Disease Control

Avoidance of mosquitoes is a key measure; preventive measures include the use of screens, bed nets (ideally treated with insecticide), and insect repellents. Community-based treatment with single annual doses of effective drugs offers a highly effective means of control. The current WHO strategy for control includes mass treatment of at risk communities with single annual doses of diethylcarbamazine plus albendazole or, for areas with onchocerciasis, albendazole plus ivermectin.

ONCHOCERCIASIS

ESSENTIALS OF DIAGNOSIS

- Severe pruritus, skin excoriations, pigment changes, nodules, and thickening.
- Conjunctivitis progressing to severe eye disease and blindness.
- Microfilariae in skin snips and on slit-lamp examination; adult worms in subcutaneous nodules.

► General Considerations

Onchocerciasis, or river blindness is caused by *Onchocerca volvulus*. An estimated 18 million persons are infected, of whom 3–4 million have skin disease, 500,000 have severe visual impairment, and 300,000 are blinded. Over 99% of infections are in subsaharan Africa, especially the West African savanna, with about half of cases in Nigeria and Congo. In some hyperendemic African villages, close to 100% of individuals are infected, and 10% or more of the population is blind. The disease is also prevalent in the southwestern Arabian peninsula and Latin America, including southern Mexico, Guatemala, Venezuela, Colombia, Ecuador, and northwestern Brazil. Onchocerciasis is transmitted by simulium flies (blackflies). These insects breed in fast-flowing streams and bite during the day.

After the bite of an infected blackfly, larvae are deposited in the skin, where adults develop over 6–12 months. Adult worms live in subcutaneous connective tissue or muscle nodules for a decade or more. Microfilariae are released from the nodules and migrate through subcutaneous and ocular tissues. Disease is due to responses to worms and to intracellular *Wolbachia* bacteria.

► Clinical Findings

A. Symptoms and Signs

After an incubation period of up to 1–3 years, the disease typically produces an erythematous, papular, pruritic rash, which may progress to chronic skin thickening and depigmentation. Itching may be severe and unresponsive to medications, such that more disability-adjusted life years are lost to onchocercal skin problems than to blindness. Numerous firm, nontender, movable subcutaneous nodules of about 0.5–3 cm, which contain adult worms, may be present. Due to differences in vector habits, these nodules are more com-

monly on the lower body in Africa but on the head and upper body in Latin America. Inguinal and femoral lymphadenopathy is common, at times resulting in a “hanging groin,” with lymph nodes hanging within a sling of atrophic skin. Patients may also have systemic symptoms, with weight loss and musculoskeletal pain.

The most serious manifestations of onchocerciasis involve the eyes. Microfilariae migrating through the eyes elicit host responses that lead to pathology. Findings include punctate keratitis and corneal opacities, progressing to sclerosing keratitis and blindness. Iridocyclitis, glaucoma, choroiditis, and optic atrophy may also lead to vision loss. The likelihood of blindness after infection varies greatly based on geography, with the risk greatest in savanna regions of West Africa.

B. Diagnostic Testing

The diagnosis is made by identifying microfilariae in skin snips, by visualizing microfilariae in the cornea or anterior chamber by slit-lamp examination, by identification of adult worms in a biopsy or aspirate of a nodule or, uncommonly, by identification of microfilariae in urine. Skin snips from the iliac crest (Africa) or scapula (Americas) are allowed to stand in saline for 2–4 hours or longer, and then examined microscopically for microfilariae. Deep punch biopsies are not needed, and if suspicion persists after a skin snip is negative, the procedure should be repeated. Ultrasound may identify characteristic findings suggestive of adult worms in skin nodules. When the diagnosis remains difficult, the Mazzoti test can be used. In this test, a 50-mg dose of diethylcarbamazine is given. A positive test, with exacerbation of skin rash and pruritus, usually within 3 hours, is highly suggestive of the diagnosis. This test should only be used in suspected lightly infected patients (after other tests are negative), as this treatment can elicit severe skin and eye reactions in heavily infected individuals. A related and safer test using topical diethylcarbamazine is available in some areas. Eosinophilia is a common, but inconsistent finding. Serologic tests are poorly standardized, nonspecific, and generally unhelpful, as in endemic areas positivity is not indicative of acute disease.

▶ Treatment & Control

The treatment of choice is ivermectin, which has replaced diethylcarbamazine due to a much lower risk of severe reactions to therapy. Ivermectin kills microfilariae, but not adult worms, so disease control requires repeat administrations. Treatment is with a single oral dose of 150 mcg/mL, but schedules for re-treatment have not been standardized. One regimen is to treat every 3 months for 1 year, followed by treatment every 6–12 months for the suspected lifespan of adult worms (about 15 years). Treatment results in marked reduction in numbers of microfilariae in the skin and eyes, although its impact on the progression of visual loss remains uncertain. Toxicities of ivermectin are generally mild; fever, pruritus, urticaria, myalgias, edema, hypotension, and tender lymphadenopathy may be seen, presumably due to reactions to dying worms. Ivermectin should be used with caution in patients also at risk for

loiasis, since it can elicit severe reactions including encephalopathy. In patients with severe skin findings not controlled by ivermectin, therapy with suramin may be considered. This is the only drug known to kill adult worms, but it is very toxic. As with other filarial infections, doxycycline acts against *O. volvulus* by killing intracellular *Wolbachia* bacteria. A course of 100 mg/day for 6 weeks kills the bacteria and prevents parasite embryogenesis for at least 18 months. Doxycycline is under study for onchocerciasis control but has no clear role in treatment of individual affected patients.

Protection against onchocerciasis includes avoidance of biting flies. Major efforts are underway to control insect vectors in Africa. In addition, mass distribution of ivermectin for intermittent administration at the community level is ongoing, and the prevalence of severe skin and eye disease is decreasing.

Udall DN. Recent updates on onchocerciasis: diagnosis and treatment. *Clin Infect Dis.* 2007 Jan 1;44(1):53–60. [PMID: 17143815]

LOIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Subcutaneous swellings; adult worms migrating across the eye.
- ▶ Encephalitis, which may be brought on by treatment.
- ▶ Microfilariae in the blood.

▶ General Considerations

Loiasis is a chronic filarial disease caused by infection with *Loa loa*. The infection occurs in humans and monkeys in rainforest areas of West and central Africa. An estimated 3–13 million persons are infected. The disease is transmitted by chrysops flies, which bite during the day. Over 6–12 months after infection, larvae develop into adult worms, which migrate through subcutaneous tissues, including the subconjunctiva (leading to the term “eye worm”). Adults can live for up to 17 years.

▶ Clinical Findings

A. Symptoms and Signs

Many infected persons are asymptomatic, although they may have high levels of microfilaremia and eosinophilia. Transient subcutaneous swellings (Calabar swellings)

develop in symptomatic persons. The swellings are non-erythematous, up to 20 cm in diameter, and may be preceded by local pain or pruritus. They usually resolve after 2–4 days but occasionally persist for several weeks. Calabar swellings are commonly seen around joints and may recur at the same or different sites. Visitors from nonendemic areas are more likely to have allergic-type reactions, including pruritus, urticaria, and angioedema. Adult worms may be seen to migrate across the eye, with either no symptoms or conjunctivitis, with pain and edema. The most serious complication of loiasis is encephalitis, which is most common in those with high level microfilaremia and microfilariae in the CSF. Symptoms may range from headache and insomnia to coma and death. Encephalitis may be brought on by treatment with diethylcarbamazine or ivermectin. Other complications of loiasis include kidney disease, with hematuria and proteinuria; endomyocardial fibrosis; and peripheral neuropathy.

B. Laboratory Findings

The diagnosis is established by identifying microfilariae in blood. Blood is evaluated as for lymphatic filariasis, but for loiasis blood should be obtained during the day. The failure to find microfilariae does not rule out the diagnosis. Identification of a migrating eye worm is also diagnostic. Serologic tests may be helpful in persons from nonendemic areas who may be acutely ill without detectable microfilaremia, but such tests have limited utility for residents of endemic areas because most of them will have positive test results. Diagnostic PCR methods have been described.

▶ Treatment

The treatment of choice is diethylcarbamazine, which eliminates microfilariae and has some activity against adult worms. Treatment with 8–10 mg/kg/d orally for 21 days is curative in about 50% of amicrofilaremic patients, and repeat courses increase efficacy. Mild side effects are common with therapy, including fever, pruritus, arthralgias, nausea, diarrhea, and Calabar swellings. These symptoms may be lessened by administration of antihistamines or corticosteroids. Patients with large worm burdens are at greater risk for serious complications of therapy, including kidney injury, shock, encephalitis, coma, and death. Treatment with ivermectin, which is highly active against microfilariae, but not adult worms, also entails a high risk of severe reactions. To attempt to avoid these sequelae, pretreatment with corticosteroids and antihistamines, and escalating dosage of diethylcarbamazine have been used, but this strategy does not prevent encephalitis. The circulating parasite load that indicates particular risk for severe complications with therapy has been estimated at 2500/mL or greater. Strategies to treat patients with high parasite loads include (1) no treatment; (2) apheresis, if available, to remove microfilariae prior to therapy with diethylcarbamazine; or (3) therapy with albendazole, which appears to be well tolerated due to its slow antiparasitic effects, prior to therapy with diethylcarbamazine or ivermectin.

36

Mycotic Infections

Samuel A. Shelburne, MD
Richard J. Hamill, MD

Fungal infections have assumed an increasingly important role as use of broad-spectrum antimicrobial agents has increased and the number of immunodeficient patients has risen. Some pathogens (eg, *Cryptococcus*, *Candida*, *Pneumocystis*, *Fusarium*) rarely cause serious disease in normal hosts. Other endemic fungi (eg, *Histoplasma*, *Coccidioides*, *Paracoccidioides*) commonly cause disease in normal hosts but tend to be more aggressive in immunocompromised ones. Superficial mycoses are discussed in Chapter 6.

Successful management of most systemic fungal infections requires knowledge of the natural history of these diseases as well as familiarity with the unique pharmacokinetics, adverse effects, and drug interactions of the various therapeutic agents. Furthermore, most affected individuals usually have significant underlying illnesses. Consequently, clinicians with extensive experience in the management of these disorders should be consulted.

CANDIDIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Common normal flora but opportunistic pathogen.
- ▶ Gastrointestinal mucosal disease, particularly esophagitis, most common.
- ▶ Catheter-associated fungemia occurs in patients who have sustained mucosal injury or received broad-spectrum antibiotics.

▶ General Considerations

Candida albicans can be cultured from the mouth, vagina, and feces of most people. Cutaneous and oral lesions are discussed in Chapters 6 and 8, respectively. The risk factors for invasive candidiasis include prolonged neutropenia, recent abdominal surgery, broad-spectrum antibiotic therapy, advanced chronic kidney disease, the presence of intravascular catheters (especially when providing total parenteral nutrition), and injection drug use. Cellular immunodeficiency predisposes to mucocutaneous disease.

When no other underlying cause is found, persistent oral or vaginal candidiasis should arouse a suspicion of HIV infection.

▶ Clinical Findings & Treatment

A. Mucosal Candidiasis

Esophageal involvement is the most frequent type of significant mucosal disease. Presenting symptoms include substernal odynophagia, gastroesophageal reflux, or nausea without substernal pain. Oral candidiasis, though often associated, is not invariably present. Diagnosis is best confirmed by endoscopy with biopsy and culture. Therapy depends on the severity of disease. If patients are able to swallow and take adequate amounts of fluid orally, fluconazole, 100 mg/d (or itraconazole solution, 10 mg/mL, 200 mg/d), for 10–14 days will usually suffice. In the individual who is more ill or in whom esophagitis has developed while taking fluconazole, options include oral or intravenous voriconazole, 200 mg twice daily; intravenous amphotericin B, 0.3 mg/kg/d; intravenous caspofungin, 50 mg/d; intravenous anidulafungin, 100 mg on day 1, then 50 mg/d; or intravenous micafungin, 150 mg/d. Relapse is common with all agents when there is underlying HIV infection without adequate immune reconstitution.

Vulvovaginal candidiasis occurs in an estimated 75% of women during their lifetime. Risk factors include pregnancy, uncontrolled diabetes mellitus, broad-spectrum antimicrobial treatment, corticosteroid use, and HIV infection. Symptoms include acute vulvar pruritus, burning vaginal discharge, and dyspareunia. Various topical azole preparations (eg, clotrimazole, 100 mg vaginal tablet for 7 days, or miconazole, 200 mg vaginal suppository for 3 days) are effective. One 150 mg oral dose of fluconazole has been shown to have equivalent efficacy with better patient acceptance. Disease recurrence is common but can be decreased with weekly fluconazole therapy (150 mg weekly).

B. Candidal Funguria

Candidal funguria frequently resolves with discontinuance of antibiotics or removal of bladder catheters. Clinical benefit from treatment of asymptomatic candiduria has not

been demonstrated, but persistent funguria should raise the suspicion of disseminated infection. When symptomatic funguria persists, oral fluconazole, 200 mg/d for 7–14 days, can be used. Rare complications of candidal urinary tract infections are ureteral obstruction and dissemination.

C. Disseminated Candidiasis

The diagnosis of disseminated *Candida* infection is problematic because *Candida* species are often isolated from mucosal sites in the absence of invasive disease while blood cultures are positive only 50% of the time in disseminated infection. Serologic tests have not proved useful for distinguishing colonization from invasive disease. Thus, the decision to treat for *Candida* when organisms are isolated from urine or sputum (or both) needs to be individualized for each patient. A randomized trial of empiric fluconazole for patients at high risk for, but not proven to have, disseminated candidiasis showed no clinical benefit compared with placebo. Disseminated candidiasis may represent a benign, self-limited process, but until proven otherwise it should be considered a sign of serious, complicated disease.

Organ system involvement in invasive disease may include the eyes, skin, brain, meninges, and myocardium. Antifungal therapy for invasive candidiasis is rapidly evolving with the addition of new agents and the emergence of non-*albicans* species causing significant disease. Options for treatment include fluconazole, 400–800 mg daily; amphotericin B, 0.7 mg/kg/d; liposomal amphotericin B, 3 mg/kg/d; voriconazole, 200 mg twice a day; caspofungin, 50 mg/d; micafungin, 100 mg daily; or anidulafungin, 100 mg/d after 200 mg intravenously once. Therapy for disseminated candidiasis should be continued for 2 weeks after the last positive blood culture and resolution of symptoms and signs of infection. Once patients have become clinically stable, parenteral therapy can be discontinued and oral fluconazole, 200–800 mg orally given as one or two doses daily, is used to complete treatment. Removal or exchange of intravascular catheters is generally recommended and substantially decreases the duration of candidemia and overall mortality, which approaches 30%.

Another form of invasive disease is hepatosplenic candidiasis. This results from aggressive chemotherapy and prolonged neutropenia in patients with underlying hematologic cancers. Typically, fever and variable abdominal pain present weeks after chemotherapy, when neutrophil counts have recovered. Blood cultures are generally negative. Hepatic enzymes reveal an alkaline phosphatase elevation that may be marked. Fluconazole, 400 mg daily, or a lipid formulation of amphotericin B should be given until clinical and radiographic improvement occurs.

D. Candidal Endocarditis

Candidal endocarditis rarely is a complication of transient fungemia. It usually results from direct inoculation at the time of valvular heart surgery or repeated inoculation with injection drug use. Candidal endocarditis occurs with increased frequency on prosthetic valves in the first few months following surgery. Splenomegaly and petechiae are common, and there is a predilection for large-vessel embolization.

The diagnosis is established definitively by culturing *Candida* from emboli or from vegetations at the time of valve replacement. Valve destruction (usually aortic or mitral), myocardial ring abscess, and systemic embolization are common. Amphotericin has long been considered the optimal therapy, given in a dosage of 0.5–1 mg/kg/d intravenously, although there are now more and more data regarding the utility of echinocandin and imidazole.

Non-*albicans* species of *Candida* now account for over 50% of clinical bloodstream isolates and are often resistant to imidazole antibiotics such as fluconazole. The widespread use of these agents for prophylaxis in immunocompromised patients can lead to the emergence of pathogens such as *Candida krusei*. Azole-resistant *C. albicans* has increased in frequency in immunocompromised patients, particularly in patients with late-stage AIDS receiving long-term suppressive fluconazole.

In all forms of invasive candidiasis, an important element of therapy is reversal of the underlying predisposing factor when possible. In high-risk patients undergoing induction chemotherapy, bone marrow transplantation, or liver transplantation, prophylaxis with antifungal agents has been shown to prevent invasive fungal infections although the effect on mortality and the preferred agent remain debated.

HISTOPLASMOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Epidemiologically linked to bird droppings and bat exposure; common along river valleys (especially the Ohio River and the Mississippi River valleys).
- ▶ Most patients asymptomatic; respiratory illness most common clinical problem.
- ▶ Widespread disease especially common in AIDS or other immunosuppressed states, with poor prognosis.
- ▶ Biopsy of affected organs with culture or urinary polysaccharide antigen most useful in disseminated disease.

▶ General Considerations

Histoplasmosis is caused by *Histoplasma capsulatum*, a dimorphic fungus that has been isolated from soil contaminated with bird or bat droppings in endemic areas (central

and eastern United States, eastern Canada, Mexico, Central America, South America, Africa, and southeast Asia). Infection presumably takes place by inhalation of conidia. These convert into small budding cells that are engulfed by phagocytes in the lungs. The organism proliferates and is carried hematogenously to other organs.

► Clinical Findings

A. Symptoms and Signs

Most cases of histoplasmosis are asymptomatic or mild and thus go unrecognized. Past infection is recognized by pulmonary and splenic calcification noted on incidental radiographs. Symptoms and signs of pulmonary involvement are usually absent even in patients who subsequently show areas of calcification on chest radiographs. Symptomatic infection may present with mild influenza-like illness, often lasting 1–4 days. Moderately severe infections are frequently diagnosed as atypical pneumonia. These patients have fever, cough, and mild central chest pain lasting 5–15 days.

Clinically evident infections occur in several forms:

(1) **Acute histoplasmosis** frequently occurs in epidemics, often when soil containing infected bird or bat droppings is disturbed. It is a severe disease manifested by marked prostration, fever, and relatively few pulmonary complaints even when radiographs show diffuse pneumonia. The illness may last from 1 week to 6 months but is almost never fatal. (2) **Progressive disseminated histoplasmosis** is usually fatal within 6 weeks or less. Symptoms usually consist of fever, dyspnea, cough, loss of weight, and prostration. Ulcers of the mucous membranes of the oropharynx may be present. The liver and spleen are nearly always enlarged, and all the organs of the body are involved, particularly the adrenal glands, though this infrequently results in adrenal insufficiency. Gastrointestinal involvement may mimic inflammatory bowel disease. (3) **Chronic progressive pulmonary histoplasmosis** is usually seen in older patients with various lesions including apical cavities, infiltrates, and nodules found on radiographs. (4) **Disseminated disease** usually occurs in the profoundly immunocompromised person but can affect immunocompetent persons as well. This form is commonly seen in patients with underlying HIV infection—with CD4 cell counts usually < 100 cells/mL—and is characterized by fever and multiple organ system involvement. Chest radiographs may show a miliary pattern. Presentation may be fulminant, simulating septic shock, with death ensuing rapidly unless treatment is provided.

B. Laboratory Findings

Most patients with progressive pulmonary disease show anemia of chronic disease. Bone marrow involvement may be prominent in disseminated forms with occurrence of pancytopenia. Alkaline phosphatase and marked lactate dehydrogenase (LDH) and ferritin elevations are also common as are mild elevations of serum aspartate aminotransferase, although alanine aminotransferase is often normal.

In pulmonary disease, sputum culture is rarely positive except in chronic disease; antigen testing of bronchoalveolar lavage fluid may be helpful in acute disease. Blood or bone

marrow cultures from immunocompromised patients with acute disseminated disease are positive more than 80% of the time but may take several weeks. A urine antigen assay has a sensitivity of greater than 90% for disseminated disease in AIDS patients and can be used to follow response to therapy. The sensitivity of screening immunodiffusion is 70% in acute pulmonary histoplasmosis, and complement fixation titers are positive in about 80% of cases. Patients with disseminated histoplasmosis may have a false-positive *Aspergillus* galactomannan assay.

► Treatment

For progressive localized disease and for mild to moderately severe nonmeningeal disseminated disease in immunocompetent or immunocompromised patients, itraconazole, 200–400 mg/d orally divided into two doses, is the treatment of choice with an overall response rate of approximately 80%. The oral solution is better absorbed than the capsule formulation. Duration of therapy ranges from weeks to several months depending on the severity of illness. Amphotericin B is reserved for individuals who cannot take oral medications; for those who have not responded to itraconazole therapy; for those with meningitis; and for management of severe disseminated disease in an immunocompromised person. Up to 2.5 g total may need to be given in the latter two situations, though this course of treatment can be abbreviated and oral itraconazole instituted once clinical stabilization has occurred. Liposomal amphotericin B in a dosage of 3 mg/kg/d intravenously may be more effective and safer than conventional amphotericin B in seriously ill individuals. Patients with AIDS-related histoplasmosis require life-long suppressive therapy with itraconazole, 200–400 mg/d orally, although secondary prophylaxis may be discontinued if immune reconstitution occurs in response to antiretroviral therapy.

COCCIDIOIDOMYCOSIS

ESSENTIALS OF DIAGNOSIS

- Influenza-like illness with malaise, fever, backache, headache, and cough.
- Erythema nodosum common with acute infection.
- Dissemination may result in meningitis, bony lesions, or skin and soft tissue abscesses.
- Chest radiograph findings vary widely from pneumonitis to cavitation.
- Serologic tests useful; spherules containing endospores demonstrable in sputum or tissues.

► General Considerations

Coccidioidomycosis should be considered in the diagnosis of any obscure illness in a patient who has lived in or visited an endemic area.

Infection results from the inhalation of arthroconidia of *Coccidioides immitis* or *Coccidioides posadasii*; both organisms are molds that grow in soil in certain arid regions of the southwestern United States, in Mexico, and in Central and South America.

Less than 1% of immunocompetent persons show dissemination, but among these patients, the mortality rate is high.

In HIV-infected people in endemic areas, coccidioidomycosis is a common opportunistic infection. In these patients, disease manifestations range from focal pulmonary infiltrates to widespread miliary disease with multiple organ involvement and meningitis.

► Clinical Findings

A. Symptoms and Signs

Symptoms of primary coccidioidomycosis occur in about 40% of infections. Symptom onset (after an incubation period of 10–30 days) is usually that of a respiratory tract illness with fever and occasionally chills, and coccidioidomycosis is a common etiology of community-acquired pneumonia in endemic areas.

Arthralgia accompanied by periarticular swelling, often of the knees and ankles, is common. Erythema nodosum may appear 2–20 days after onset of symptoms. Persistent pulmonary lesions, varying from cavities and abscesses to parenchymal nodular densities or bronchiectasis, occur in about 5% of diagnosed cases.

Disseminated disease occurs in about 0.1% of white and 1% of nonwhite patients. Filipinos and blacks are especially susceptible, as are pregnant women of all races. Any organ may be involved. Pulmonary findings usually become more pronounced, with mediastinal lymph node enlargement, cough, and increased sputum production. Lung abscesses may rupture into the pleural space, producing an empyema. These may also extend to bones and skin, and pericardial and myocardial involvement has been occasionally observed. Fungemia may occur and is characterized clinically by a diffuse miliary pattern on chest radiograph and by early death. The course may be particularly rapid in immunosuppressed patients. Physicians caring for immunosuppressed patients in endemic areas need to consider that patients may be latently infected.

Bone lesions most often occur at bony prominences. Meningitis occurs in 30–50% of cases of dissemination. Subcutaneous abscesses and verrucous skin lesions are especially common in fulminating cases. Lymphadenitis may occur and may progress to suppuration. HIV-infected persons with disseminated disease have a higher incidence of miliary infiltrates, lymphadenopathy, and meningitis, but skin lesions are uncommon.

B. Laboratory Findings

In primary coccidioidomycosis, there may be moderate leukocytosis and eosinophilia. Serologic testing is useful

for both diagnosis and prognosis. The immunodiffusion tube precipitin test detects IgM antibodies and is useful for diagnosis early in the disease process. Historically, a persistent rising IgG complement fixation titer ($\geq 1:16$) has been considered suggestive of disseminated disease; in addition, complement fixation titers can be used to assess the adequacy of therapy. Serum complement fixation titer may be low when there is meningitis but no other disseminated disease. In patients with HIV-related coccidioidomycosis, the false-negative rate may be as high as 30%.

Demonstrable complement-fixing antibodies in spinal fluid are diagnostic of coccidioidal meningitis. These are found in over 90% of cases. Spinal fluid findings include increased cell count with lymphocytosis and reduced glucose. Spinal fluid culture is positive in approximately 30% of meningitis cases. Spherules filled with endospores may be found in biopsy specimens; though they are not infectious, they convert to the highly contagious arthroconidia when grown in culture media. Blood cultures are rarely positive. A urine antigen test similar to that for histoplasmosis has been developed for coccidioidomycosis; however, there is cross-reactivity of this test for the two diseases.

C. Imaging

Radiographic findings vary, but patchy, nodular pulmonary infiltrates and thin-walled cavities are most common. Hilar lymphadenopathy may be visible and is seen in localized disease; mediastinal lymphadenopathy suggests dissemination. There may be pleural effusions and lytic lesions in bone with accompanying complicated soft-tissue collections.

► Treatment

General symptomatic therapy is given as needed for disease limited to the chest with no evidence of progression. For progressive pulmonary or extrapulmonary disease, amphotericin B intravenously is used although oral azoles may be used for mild cases (see Chapter 30). Therapy should be continued, with duration of therapy determined by a declining complement fixation titer and a favorable clinical response. For meningitis, treatment usually is with high-dose oral fluconazole (400–800 mg/d) although lumbar or cisternal intrathecal administration of amphotericin B daily in increasing doses up to 1–1.5 mg/d is used initially by some physicians or in cases refractory to fluconazole. Systemic therapy with amphotericin B, 0.6 mg/kg/d intravenously, is generally given concurrently with intrathecal therapy but is not sufficient alone for the treatment of meningeal disease. Voriconazole or posaconazole may be alternatives to intrathecal amphotericin B in patients who do not respond to fluconazole. Once the patient is clinically stable, oral therapy with an azole, usually lifelong, is the recommended alternative to intrathecal amphotericin B therapy.

Fluconazole, 200–400 mg orally once daily, or itraconazole, 400 mg orally daily divided into two doses, may be given for disease in the chest, bones, and soft tissues; however, therapy must be continued for 6 months or longer after the disease is inactive to prevent relapse. Response to

therapy should be monitored by following the progressive decrease in serum complement fixation titers.

Thoracic surgery is occasionally indicated for giant, infected, or ruptured cavities. Surgical drainage is necessary for management of soft tissue abscesses and bone disease. Amphotericin B, 1 mg/kg/d intravenously, is advisable following extensive surgical manipulation of infected tissue until the disease is inactive, whereupon therapy may be continued with an azole.

► Prognosis

The prognosis for patients with limited disease is good, but persistent pulmonary cavities may cause complications such as hemoptysis or rupture producing pyopneumothorax. Nodules, cavities, and fibrotic residuals may rarely progress after long periods of stability or regression. Serial complement fixation titers should be performed after therapy for patients with coccidioidomycosis; rising titers warrant reinstitution of therapy because relapse is likely. Late central nervous system complications of adequately treated meningitis include cerebral vasculitis and hydrocephalus that may require shunting. Disseminated and meningeal forms still have mortality rates exceeding 50% in the absence of therapy.

 Durkin M et al. Diagnosis of coccidioidomycosis with use of the *Coccidioides* antigen enzyme immunoassay. *Clin Infect Dis*. 2008 Oct 15;47(8):e69–73. [PMID: 18781884]

PNEUMOCYSTOSIS (*Pneumocystis jiroveci* Pneumonia)

ESSENTIALS OF DIAGNOSIS

- Fever, dyspnea, nonproductive cough.
- Bilateral diffuse interstitial disease without hilar adenopathy by chest radiograph.
- Bibasilar crackles on auscultation in many cases; others have no findings.
- Reduced partial pressure of oxygen.
- *P jiroveci* in sputum, bronchoalveolar lavage fluid, or lung tissue.

► General Considerations

Pneumocystis jiroveci, the *Pneumocystis* species that affects humans, is distributed worldwide. Although symptomatic *P jiroveci* disease is rare in the general population, serologic evidence indicates that asymptomatic infections have occurred in most persons by a young age. The overt infection is an acute interstitial plasma cell pneumonia that occurs with high frequency among two groups: (1) as epidemics of primary infections among premature or debilitated or marasmic infants on hospital wards in underdevel-

oped parts of the world, and (2) as sporadic cases among older children and adults who have an abnormal or altered cellular immune status. Cases occur most commonly in patients with cancer or severe malnutrition and debility, in patients treated with immunosuppressive or cytotoxic drugs or irradiation for the management of organ transplants and cancer and, most frequently, in patients with AIDS (see Chapter 31).

The mode of transmission in primary infection is unknown, but the evidence suggests airborne transmission. Following asymptomatic primary infection, latent and presumably inactive organisms are sparsely distributed in the alveoli. Whether acute infection in older children and adults results from de novo infection or from reactivation of latent infection is not entirely clear, although both mechanisms probably contribute.

Pneumocystis pneumonia occurs in up to 80% of AIDS patients not receiving prophylaxis and is a major cause of death. Its incidence increases in direct proportion to the fall in CD4 cells, with most cases occurring at CD4 cell counts below 200/mcL. Dissemination of the infection to tissues other than the lung is rare. In non-AIDS patients receiving immunosuppressive therapy, symptoms frequently begin after corticosteroids have been tapered or discontinued.

► Clinical Findings

A. Symptoms and Signs

Findings are usually limited to the pulmonary parenchyma; extrapulmonary disease is reported rarely. In the sporadic form of the disease associated with deficient cell-mediated immunity, the onset is abrupt, with fever, tachypnea, shortness of breath, and usually nonproductive cough. Pulmonary physical findings may be slight and disproportionate to the degree of illness and the radiologic findings; many patients have bibasilar crackles, but others do not. Without treatment, the course is usually one of rapid deterioration and death. Adult patients may present with spontaneous pneumothorax, usually in patients with previous episodes or those receiving aerosolized pentamidine prophylaxis. Patients with AIDS will usually have other evidence of HIV-associated disease, including fever, fatigue, and weight loss, for weeks or months preceding the illness.

B. Laboratory Findings

Chest radiographs most often show diffuse “interstitial” infiltration, which may be heterogeneous, miliary, or patchy early in infection. There may also be diffuse or focal consolidation, cystic changes, nodules, or cavitation within nodules. Pleural effusions are not seen. About 5–10% of patients with *Pneumocystis* pneumonia have normal chest films. High-resolution chest CT scans may be quite suggestive of *P jiroveci* pneumonia, helping distinguish it from other causes of pneumonia.

Arterial blood gas determinations usually show hypoxemia with hypocapnia but may be normal; however, rapid desaturation occurs if patients are exercised before samples are drawn. Isolated elevation or rising levels of serum LDH are very sensitive but not specific findings for *P jiroveci*.

Lymphopenia with depleted CD4 lymphocytes is common. Serologic tests, including tests to detect antigenemia, are not helpful in diagnosis.

Specific diagnosis depends on morphologic demonstration of the organisms in clinical specimens using specific stains. The organism cannot be cultured. Adequate specimens can sometimes be obtained with induced sputum by having patients inhale an aerosol of hypertonic saline (3%) produced by an ultrasonic nebulizer. Specimens are then stained with Giemsa stain or methenamine silver, either of which allows detection of cysts. The use of monoclonal antibody with immunofluorescence has increased the sensitivity of diagnosis. Alternative techniques for obtaining specimens include bronchoalveolar lavage (sensitivity 86–97%) followed by transbronchial lung biopsy (85–97%), if necessary. Open lung biopsy and needle lung biopsy are infrequently done but may need to be performed to diagnose a granulomatous form of *Pneumocystis* pneumonia. The polymerase chain reaction (PCR) test for the detection of *P. jiroveci* appears to be overly sensitive in that many patients without *Pneumocystis* pneumonia will have a positive PCR on respiratory samples.

► Treatment

See Table 31–5. It is appropriate to start empiric therapy for *P. jiroveci* pneumonia if the disease is suspected clinically; however, in both AIDS patients and non-AIDS patients with mild to moderately severe disease, continued treatment should be based on a proved diagnosis because of clinical overlap with other infections, the toxicity of therapy, and the possible coexistence of other infectious organisms. Oral trimethoprim-sulfamethoxazole (TMP-SMZ) is the preferred agent because of its low cost and excellent bioavailability in both AIDS patients and non-AIDS patients with mild to moderately severe disease. Patients suffering from nausea and vomiting or intractable diarrhea should be given intravenous TMP-SMZ until they can tolerate the oral formulation. The best-studied second-line option is a combination of clindamycin and primaquine, although dapsone/trimethoprim, pentamidine, and atovaquone have also been used. Therapy should be continued with the selected drug for at least 5–10 days before considering changing agents, as fever, tachypnea, and pulmonary infiltrates persist for 4–6 days after starting treatment. Some patients have a transient worsening of their disease during the first 3–5 days, which may be related to an inflammatory response secondary to the presence of dead or dying organisms. Early addition of corticosteroids may attenuate this response (see Chapter 31). Some clinicians prefer to treat episodes of AIDS-associated *Pneumocystis* pneumonia for 21 days rather than the usual 14 days recommended for non-AIDS cases.

A. Trimethoprim-Sulfamethoxazole

The dosage is TMP 20 mg/kg (12–15 mg/kg may decrease side effects without decreasing efficacy) and SMZ 100 mg/kg given orally or intravenously daily in three or four divided doses for 14–21 days. Adverse reactions are generally those of the sulfonamide component. Patients with AIDS have a

high frequency of hypersensitivity reactions (approaching 50%), which may include fever, rashes (sometimes severe), malaise, neutropenia, hepatitis, nephritis, thrombocytopenia, hyperkalemia, and hyperbilirubinemia.

B. Clindamycin/Primaquine

Although there are strong data indicating that trimethoprim-sulfamethoxazole is optimal first-line therapy for *Pneumocystis* pneumonia, the data on alternative agents is less clear. A meta-analysis suggested that clindamycin, 600 mg three times daily, plus primaquine, 15 mg/d, is the best second-line therapy with superior results when compared with pentamidine. Primaquine may cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD)-deficiency.

C. Pentamidine Isethionate

The use of pentamidine has decreased as alternative agents have been studied. This drug is administered intravenously (preferred) or intramuscularly as a single dose of 3 mg (salt)/kg/d for 14–21 days. Pentamidine causes side effects in nearly 50% of patients. Hypoglycemia (often clinically inapparent), hyperglycemia, hyponatremia, and delayed nephrotoxicity with azotemia may occur. Rarely, a variety of other severe adverse reactions may occur, including anemia, thrombocytopenia, ventricular arrhythmias, and fatal pancreatitis. Blood glucose levels should be monitored. Inadvertent rapid intravenous infusion may cause precipitous hypotension.

D. Atovaquone

Atovaquone has been approved by the US Food and Drug Administration (FDA) for patients with mild to moderate disease who cannot tolerate TMP-SMZ or pentamidine, but failure is reported in 15–30% of cases. Mild side effects are common, but no serious reactions have been reported. The dosage is 750 mg three times daily for 21 days.

E. Other Drugs

Dapsone, 100 mg/d, plus trimethoprim 15 mg/kg/d, in three divided doses daily, is an alternative oral regimen for mild to moderate disease or for continuation of therapy after intravenous therapy is no longer needed.

F. Prednisone

Prednisone is given for moderate to severe pneumonia (when PaO₂ on admission is < 70 mm Hg or oxygen saturation is < 90%) in conjunction with antimicrobials; its use during the first 72 hours of therapy for severe *Pneumocystis* pneumonia prevents deterioration in oxygenation and improves survival. The dosage of prednisone is 40 mg twice daily for 5 days, then 40 mg daily for 5 days, and then 20 mg daily until therapy is completed.

G. Supportive Care

Oxygen therapy is indicated to maintain the oxygen saturation over 90% by pulse oximetry.

► Prevention

Primary prophylaxis for *Pneumocystis pneumonia* in HIV-infected patients should be given to persons with CD4 counts < 200 cells/mL, a CD4 percentage below 14%, or weight loss or oral candidiasis (see Table 31–4). Primary prophylaxis is often used in patients with hematologic malignancy and transplant recipients. The occurrence of *P jirovecii* pneumonia while on prophylaxis may be associated with development of resistance to TMP-SMZ. Patients with a history of *Pneumocystis pneumonia* should receive secondary prophylaxis until they have had a durable virologic response to antiretroviral therapy for at least 3–6 months and maintain a CD4 count of > 250 cells/mL.

► Prognosis

In the absence of early and adequate treatment, the fatality rate for the endemic infantile form of *Pneumocystis pneumonia* is 20–50%; for the sporadic form in immunodeficient persons, the fatality rate is nearly 100%. Early treatment reduces the mortality rate to about 3% in the former and 10–20% in AIDS patients. The mortality rate in other immunodeficient patients is still 30–50%, probably because of failure to make a timely diagnosis. In immunodeficient patients who do not receive prophylaxis, recurrences are common (30% in AIDS).

Davis JL et al. *Pneumocystis* colonisation is common among hospitalised HIV-infected patients with non-*Pneumocystis pneumonia*. *Thorax*. 2008 Apr;63(4):329–34. [PMID: 18024536]

CRYPTOCOCCOSIS

ESSENTIALS OF DIAGNOSIS

- Most common cause of fungal meningitis.
- Predisposing factors: Hodgkin disease, corticosteroid therapy, HIV infection, transplant recipients.
- Symptoms of headache, abnormal mental status; meningismus seen occasionally, though rarely in HIV-infected patients.
- Demonstration of capsular polysaccharide antigen in cerebrospinal fluid diagnostic; 95% of HIV-infected and solid-organ transplant patients also have a positive serum antigen.

► General Considerations

Cryptococcosis is mainly caused by *Cryptococcus neoformans*, an encapsulated budding yeast that has been found worldwide in soil and on dried pigeon dung. *Cryptococcus gattii* is a closely related species that also causes disease in humans although *C gattii* may affect more immunocompetent persons.

Infections are acquired by inhalation. In the lung, the infection may remain localized, heal, or disseminate. Clinically apparent cryptococcal pneumonia rarely develops in immunocompetent persons. Progressive lung disease and dissemination most often occur in the setting of cellular immunodeficiency, including underlying hematologic cancer under treatment, Hodgkin disease, long-term corticosteroid therapy, solid-organ transplant, or HIV infection.

► Clinical Findings

A. Symptoms and Signs

Pulmonary disease ranges from simple nodules to widespread infiltrates leading to respiratory failure. Disseminated disease may involve any organ, but central nervous system disease predominates. Headache is usually the first symptom of meningitis. Confusion and other mental status changes as well as cranial nerve abnormalities, nausea, and vomiting may be seen as the disease progresses. Nuchal rigidity and meningeal signs occur about 50% of the time but are uncommon in HIV-infected patients. Communicating hydrocephalus may complicate the course. Primary *C neoformans* infection of the skin may mimic bacterial cellulitis, especially in immunocompromised persons. Clinical worsening associated with improved immunologic status has been reported in HIV-positive and transplant patients with cryptococcosis; this entity has been labeled the immune reconstitution inflammatory syndrome (IRIS).

B. Laboratory Findings

Respiratory tract disease is diagnosed by culture of respiratory secretions or pleural fluid. For suspected meningitis, lumbar puncture is the preferred diagnostic procedure. Spinal fluid findings include increased opening pressure, variable pleocytosis, increased protein, and decreased glucose, though as many as 50% of AIDS patients have no pleocytosis. Gram stain of the cerebrospinal fluid usually reveals budding, encapsulated fungal cells. Cryptococcal capsular antigen in cerebrospinal fluid and culture together establish the diagnosis over 90% of the time. Patients with AIDS often have the antigen in both cerebrospinal fluid and serum, and extrameningeal disease (lungs, blood, urinary tract) is common. In patients with AIDS, the serum cryptococcal antigen is also a sensitive screening test for meningitis, being positive in over 95% of cases. MRI is more sensitive than CT in finding central nervous system abnormalities such as cryptococcomas.

► Treatment

Because of decreased efficacy and development of resistance, initial therapy with an azole is not recommended for treatment of acute cryptococcal meningitis. Consequently, treatment regimens using amphotericin B should be started. However, there has been a trend away from prolonged amphotericin B therapy regimens, particularly in HIV-infected patients. Thus, amphotericin B, 0.7–1 mg/kg/d intravenously is used for 14 days, followed by an additional 8 weeks of fluconazole, 400 mg/d orally. This regimen has been quite effective, achieving clinical

responses and cerebrospinal fluid sterilization in about 70% of patients. The addition of flucytosine has been associated with improved survival, but toxicity is common. Flucytosine is administered orally at a dose of 100 mg/kg/d divided into four equal doses and given every 6 hours. Hematologic parameters should be closely monitored during flucytosine therapy. Repeated lumbar punctures or ventricular shunting should be performed to relieve high cerebrospinal fluid pressures or if hydrocephalus is a complication. Failure to adequately relieve raised intracranial pressure is a major cause of morbidity and mortality. The end points for amphotericin B therapy and for switching to oral fluconazole are a favorable clinical response (decrease in temperature; improvement in headache, nausea, vomiting, and mini-mental status scores), improvement in cerebrospinal fluid biochemical parameters and, most importantly, conversion of cerebrospinal fluid culture to negative.

A similar approach is reasonable for patients with cryptococcal meningitis in the absence of AIDS, though the mortality rate is considerably higher. Lipid amphotericin B preparations appear to have equivalent efficacy with reduced nephrotoxicity. Therapy is generally continued until cerebrospinal fluid cultures become negative and cerebrospinal fluid antigen titers are below 1:8.

Maintenance antifungal therapy is important after treatment of an acute episode in HIV-related cases, since otherwise the rate of relapse is greater than 50%. Fluconazole, 200 mg/d, is the maintenance therapy of choice, decreasing the relapse rate approximately tenfold compared with placebo and threefold compared with weekly amphotericin B in patients whose cerebrospinal fluid has been sterilized by the induction therapy. After successful therapy of cryptococcal meningitis, it is possible to discontinue secondary prophylaxis with fluconazole in individuals with AIDS who have had a satisfactory response to antiretroviral therapy (eg, CD4 cell count > 100–200 cells/mL for at least 6 months). Among practitioners treating patients without AIDS, there has been a trend in recent years to prescribe a course (eg, 6–12 months) of fluconazole as maintenance therapy following successful treatment of the acute illness; recently published guidelines suggest this as an option.

▶ Prognosis

Factors that indicate a poor prognosis include the activity of the predisposing conditions, older age, organ failure, lack of spinal fluid pleocytosis, high initial antigen titer in either serum or cerebrospinal fluid, decreased mental status, increased intracranial pressure, and the presence of disease outside the nervous system.

ASPERGILLOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Most common cause of invasive fungal infection in stem cell or organ transplant patients.
- ▶ Predisposing factors: leukemia, bone marrow or organ transplant, late HIV infection.
- ▶ Pulmonary, sinus, and CNS are most common disease sites.
- ▶ Demonstration of galactomannan or β -D-glucan in serum or other body fluid samples contributes to early diagnosis and treatment.

▶ General Considerations

Aspergillus fumigatus is the usual cause of aspergillosis, though many species of *Aspergillus* may cause a wide spectrum of disease. The lungs, sinuses, and brain are the organs most often involved. Clinical illness results either from an aberrant immunologic response or tissue invasion.

▶ Clinical Findings

A. Allergic Bronchopulmonary Aspergillosis

This form of aspergillosis occurs in patients with preexisting asthma who develop worsening bronchospasm and fleeting pulmonary infiltrates accompanied by eosinophilia, high levels of IgE, and IgG *Aspergillus* precipitins in the blood. It also may complicate cystic fibrosis.

B. Invasive Aspergillosis

Invasive manifestations may be seen in immunocompetent or only mildly immunocompromised adults. These include chronic **sinusitis**, colonization of preexisting pulmonary cavities (**aspergilloma**), and chronic necrotizing pulmonary aspergillosis.

1. Sinusitis—Sinus involvement is usually diagnosed histologically after patients with chronic sinus disease undergo surgery.

2. Aspergillomas—Aspergillomas of the lung occur when preexisting lung lesions become secondarily colonized with *Aspergillus* species. These may be found by incidental radiographic studies but may also present with significant hemoptysis.

3. Chronic necrotizing aspergillosis—This invasive manifestation is a relatively rare disease seen in patients with some degree of immunocompromise and presents with a protracted course compared with the more common acute invasive form of the disease. Fibrosis and cavity formation may be prominent.

4. Life-threatening invasive aspergillosis—Severe invasive aspergillosis most commonly occurs in profoundly immunodeficient patients, particularly in patients who have undergone hematopoietic stem cell transplants and in those

with prolonged, severe neutropenia. Specific risk factors in patients who have undergone a hematopoietic stem cell transplant include cytopenias, corticosteroid use, iron overload, cytomegalovirus disease, and graft-versus-host disease. Pulmonary disease is most common, with patchy infiltration leading to a severe necrotizing pneumonia. Invasive sinus disease also occurs. There is often tissue infarction as the organism grows into blood vessels; clues to this are the development of pleuritic chest pain and elevation of serum LDH. At any time, there may be hematogenous dissemination to the central nervous system, skin, and other organs. Early diagnosis and reversal of any correctable immunosuppression are essential. Blood cultures have very low yield. Detection of galactomannan by enzyme-linked immunosorbent assay (ELISA) or β -D-glucan, or both, has been used for the early diagnosis of invasive disease, though multiple determinations should be done. Higher galactomannan levels are correlated with increased mortality. False-positive galactomannan tests have been reported in patients receiving β -lactam antibiotics. Isolation of *Aspergillus* from pulmonary secretions does not necessarily imply invasive disease, although its positive predictive value increases with more advanced immunosuppression. Therefore, a definitive diagnosis requires demonstration of *Aspergillus* in tissue or culture from a sterile site. CT scan of the chest may show characteristics quite suggestive of invasive aspergillosis (eg, “halo sign”).

► Prevention

The high mortality rate and difficulty in diagnosis of invasive aspergillosis often leads clinicians to institute prophylactic therapy for patients with profound immunosuppression. The best-studied agents include fluconazole, itraconazole, voriconazole, and posaconazole, although patient and agent selection criteria remain undefined. Widespread use of broad-spectrum azoles raises concern for development of invasive disease by highly resistant fungi.

► Treatment

A. Allergic Bronchopulmonary Aspergillosis

For acute exacerbations, oral prednisone is begun at a dose of 1 mg/kg/d and then tapered slowly over several months. Itraconazole at a dose of 200 mg daily for 16 weeks appears to improve pulmonary function and decrease corticosteroid requirements in these patients, although voriconazole may become the preferred oral agent.

B. Invasive Aspergillosis

1. Sinusitis—These patients may require protracted courses of antifungals (itraconazole, 200 mg twice daily, for weeks to months) in addition to the surgical debridement.

2. Aspergilloma—The most effective therapy for symptomatic aspergilloma remains surgical resection.

3. Chronic necrotizing aspergillosis—Although it would be reasonable to institute therapy targeting *Aspergillus*, response to such therapy is not clear.

4. Life-threatening invasive aspergillosis—When severe invasive aspergillosis is considered clinically likely or is demonstrable by laboratory testing, rapid institution of voriconazole, high doses of amphotericin B, or caspofungin may be life-saving. Voriconazole (6 mg/kg intravenously twice on day 1, then 4 mg/kg/d thereafter) has been shown to be more effective, improve survival, and be associated with fewer severe side effects than conventional amphotericin B when used as initial therapy in invasive aspergillosis. Oral dosing of voriconazole at 4 mg/kg twice daily can be used for less serious infections or as a step-down strategy after intravenous therapy. Some experts believe that intravenous lipid preparations of amphotericin B (3–5 mg/kg/d) should be used preferentially in this setting because they are better tolerated and can be given at higher doses.

Caspofungin (70 mg intravenously on day 1, then 50 mg/d thereafter) is approved for the treatment of invasive aspergillosis in patients who do not respond to or are intolerant of other treatments. Other options include micafungin (100–150 mg/d intravenously) and posaconazole (200 mg orally four times daily). In critically ill patients who are not responding to conventional antifungal treatment, there may be a role for the addition of caspofungin to amphotericin B or voriconazole therapy, although randomized trials are lacking. Based on promising results in neutropenic patients with invasive pulmonary aspergillosis, surgical resection warrants further study. The mortality rate of pulmonary or disseminated disease in the immunocompromised patient remains well above 50%, particularly in patients with refractory neutropenia.

MUCORMYCOSIS

The term “mucormycosis” (zygomycosis, phycomycosis) is applied to opportunistic infections caused by members of the genera *Rhizopus*, *Mucor*, *Absidia*, and *Cunninghamella*. Predisposing conditions include diabetic ketoacidosis, chronic kidney disease, desferoxamine therapy, and treatment with corticosteroids or cytotoxic drugs. These organisms appear in tissues as broad, branching nonseptate hyphae. Biopsy with histologic examination is almost always required for diagnosis; cultures are frequently negative. Invasive disease of the sinuses, orbits, and the lungs may occur. Widely disseminated disease is seen in patients who have received aggressive chemotherapy and broad-spectrum antifungal prophylaxis. A prolonged course of high-dosage amphotericin B (1–1.5 mg/kg/d intravenously) or a lipid preparation of amphotericin B should be

started early. Based on in vitro susceptibility and reports of successful salvage therapy, there may be a role for posaconazole in the treatment of these infections, but other azoles are likely to be ineffective. There are limited data suggesting beneficial synergistic activity when amphotericin and caspofungin are used in combination for mucormycosis. Ongoing studies are assessing whether iron chelation therapy with deferasirox may also be helpful. Control of diabetes and other underlying conditions, along with extensive repeated surgical removal of necrotic, nonperfused tissue, is essential. Even when these measures are introduced in a timely fashion, the prognosis is poor, with a 30–50% mortality rate for localized disease and higher rates in disseminated cases.

BLASTOMYCOSIS

Blastomycosis occurs most often in men infected during occupational or recreational activities out of doors and in a geographically limited area of the south central and midwestern United States and Canada. Disease usually occurs in immunocompetent individuals.

Pulmonary infection is most common and may be asymptomatic. When dissemination takes place, lesions are most frequently seen in the skin, bones, and urogenital system.

Cough, moderate fever, dyspnea, and chest pain are common. These may resolve or progress, with bloody and purulent sputum production, pleurisy, fever, chills, loss of weight, and prostration. Radiologic studies, either chest radiographs or CT scans, usually reveal airspace consolidations or masses.

Raised, verrucous cutaneous lesions are commonly present in disseminated blastomycosis. Bones—often the ribs and vertebrae—are frequently involved. Lesions appear to be both destructive and proliferative on radiography. Epididymitis, prostatitis, and other involvement of the male urogenital system may occur. Although they do not appear to be at greater risk for acquisition of disease, infection in HIV-infected persons may progress rapidly, with dissemination common.

Laboratory findings usually include leukocytosis and anemia, though these are not specific. The organism is found in clinical specimens, such as expectorated sputum or tissue, as a thick-walled cell 5–20 μm in diameter that may have a single broad-based bud. It grows readily on culture. Serologic tests are not well standardized. A urinary antigen test is available, but it has some cross reactivity with *Histoplasma*; consequently, its usefulness in diagnosis and in assessing response to therapy is unclear.

Itraconazole, 200–400 mg/d orally for at least 2–3 months, is the therapy of choice for nonmeningeal disease, with a response rate of over 80%. Amphotericin B, 0.7–1.0 mg/kg/d intravenously (or lipid formulation amphotericin

B), is given for severe disease, treatment failures, or central nervous system involvement.

Clinical follow-up for relapse should be made regularly for several years so that therapy may be resumed or another drug instituted.

Chapman SW et al. Clinical practice guidelines for the management of blastomycosis: 2008 update by the Infectious Diseases Society of America. *Clin Infect Dis.* 2008 Jun 15;46(12):1801–12. [PMID: 18462107]

Hussein R et al. Blastomycosis in the mountainous region of Northeast Tennessee. *Chest.* 2008 Nov 18 2009 April;135(4):1019–23. [PMID: 19017881]

PARACOCCIDIOIDOMYCOSIS (South American Blastomycosis)

Paracoccidioides brasiliensis infections have been found only in patients who have resided in South or Central America or Mexico. Long asymptomatic periods enable patients to travel far from the endemic areas before developing clinical problems. Weight loss, pulmonary complaints, or mucosal ulcerations are the most common symptoms. Cutaneous papules may ulcerate and enlarge both peripherally and deeper into the subcutaneous tissue. Differential diagnosis includes mucocutaneous leishmaniasis and syphilis. Extensive coalescent ulcerations may eventually result in destruction of the epiglottis, vocal cords, and uvula. Extension to the lips and face may occur. Eating and drinking are extremely painful. Skin lesions may occur, usually on the face. Variable in appearance, they may have a necrotic central crater with a hard hyperkeratotic border. Lymph node enlargement may follow mucocutaneous lesions, eventually ulcerating and forming draining sinuses; in some patients, it is the presenting symptom. Hepatosplenomegaly may be present as well. The extensive ulceration of the upper gastrointestinal tract may prevent caloric intake and result in cachexia.

Laboratory findings are nonspecific. Serology by immunodiffusion is positive in 98% of cases. Complement fixation titers correlate with progressive disease and fall with effective therapy. The fungus is found in clinical specimens as a spherical cell that may have many buds arising from it. If direct examination does not reveal the organism, biopsy with Gomori staining may be helpful.

Itraconazole, 100 mg twice daily, is the treatment of choice and generally results in a clinical response within 1 month and effective control after 2–6 months. Voriconazole, 200 mg twice daily, appears to be as effective as itraconazole.

de Camargo ZP. Serology of paracoccidioidomycosis. *Mycopathologia.* 2008 Apr–May;165(4–5):289–302. [PMID: 18777635]

SPOROTRICHOSIS

Sporotrichosis is a chronic fungal infection caused by *Sporothrix schenckii*. It is worldwide in distribution; most patients have had contact with soil, sphagnum moss, or decaying wood. Transmission from animals to humans has also been reported. Infection takes place when the organism is inoculated into the skin—usually on the hand, arm, or foot, especially during gardening.

The most common form of sporotrichosis begins with a hard, nontender subcutaneous nodule. This later becomes adherent to the overlying skin and ulcerates. Within a few days to weeks, similar nodules develop along the lymphatics draining this area, and these may ulcerate as well.

Disseminated sporotrichosis is rare in the immunocompetent person but may present with widespread cutaneous, lung, bone, joint, and central nervous system involvement in immunocompromised patients, especially those with AIDS and alcohol abuse.

Cultures are needed to establish diagnosis. Antibody tests may be useful for diagnosis of disseminated disease, especially meningitis.

Itraconazole, 200–400 mg orally daily for several months, is now the treatment of choice for localized disease and some milder cases of disseminated disease. Terbinafine, 500 mg twice daily, also appears to have good efficacy in lymphocutaneous disease. Amphotericin B intravenously, 1–2 g, is used for severe systemic infection. Surgery is usually contraindicated except for simple aspiration of secondary nodules. Joint involvement may require arthrodesis.

The prognosis is good for lymphocutaneous sporotrichosis; pulmonary, joint, and disseminated disease respond less favorably.

Schubach A. Epidemic sporotrichosis. *Curr Opin Infect Dis.* 2008 Apr;21(2):129–33. [PMID: 18317034]

PENICILLIUM MARNEFFEI INFECTIONS

Penicillium marneffeii is a dimorphic fungus, endemic in southeast Asia, that causes systemic infection in both healthy and immunocompromised hosts. There have been reports of travelers with advanced AIDS returning from southeast Asia with disseminated infection. Clinical manifestations include fever, generalized umbilicated papular rash, lymphadenopathy, cough, and diarrhea. Diagnosis is made by identification of the organism on smears or histopathologic specimens or by culture, where the fungus produces a characteristic red pigment. The best sites for isolation of the fungus include the skin, blood, bone marrow, respiratory tract, and lymph nodes. Antigen and antibody tests have been developed in endemic regions. Patients with mild to moderate infection can be treated with itraconazole, 400 mg divided into two doses daily by mouth for 8 weeks. Amphotericin B, 0.5–0.7 mg/kg/d, is the drug of choice for severe disease and should be continued until patients have had a satisfactory clinical response, at which time they can be switched to itraconazole. Because the relapse rate after successful treatment is 30%, maintenance therapy with itraconazole, 200–400 mg daily, is indicated indefinitely.

Ustianowski AP et al. *Penicillium marneffeii* infection in HIV. *Curr Opin Infect Dis.* 2008 Feb;21(1):31–6. [PMID: 18192783]

CHROMOBLASTOMYCOSIS (Chromomycosis)

Chromoblastomycosis is a chronic, principally tropical cutaneous infection usually affecting young men who are

agricultural workers and caused by several species of closely related black molds; *Cladophialophora carrionii* and *Fonsecaea pedrosoi* are the most common etiologic agents.

Lesions usually follow puncture wounds and are slowly progressive, occurring most frequently on a lower extremity. The lesion begins as a papule or ulcer. Over months to years, papules enlarge to become vegetating, papillomatous, verrucous elevated nodules. Satellite lesions may appear along the lymphatics. There may be secondary bacterial infection. Elephantiasis may result.

The fungus is seen as brown, thick-walled, spherical, sometimes septate cells in potassium hydroxide preparations of pus or skin scrapings, which are quite sensitive for diagnosis. The type of reproduction found in culture determines the species.

Itraconazole, 200–400 mg/d orally for 6–18 months, achieves a response rate of 65%. Response rates may be improved by the addition to itraconazole of flucytosine, 100–150 mg/kg/d by mouth divided into four doses. Terbinafine at 500 mg/d may have similar efficacy to itraconazole. Cryosurgery alone for smaller lesions or combined with itraconazole for larger lesions is beneficial.

Queiroz-Telles F et al. Chromoblastomycosis: an overview of clinical manifestations, diagnosis and treatment. *Med Mycol.* 2009 Feb;47(1):3–15. [PMID: 19085206]

MYCETOMA (Maduromycosis & Actinomycetoma)

Mycetoma is a chronic local, slowly progressive destructive infection, usually involving the foot, that begins in subcutaneous tissues, frequently after localized trauma, and then spreads to contiguous structures. Maduromycosis (also known as eumycetoma) is the term used to describe mycetoma caused by the true fungi and by phylogenetically diverse organisms. Actinomycotic mycetoma is caused by *Nocardia* and *Actinomadura* species. The disease begins as a papule, nodule, or abscess that over months to years progresses slowly to form multiple abscesses and sinus tracts ramifying deep into the tissue. Secondary bacterial infection may result in large open ulcers. Radiographs may show destructive changes in the underlying bone. Tissue Gram stain reveals fine branching hyphae with actinomycotic mycetoma. Larger hyphae are seen with fungal mycetoma; the causative species can often be identified by the color of the characteristic grains within the infected tissues.

The prognosis is good for patients with actinomycetoma, since they usually respond well to sulfonamides and sulfones, especially if treated early. TMP-SMZ, 160/800 mg orally twice a day, or dapson, 100 mg twice daily after meals, has been reported to be effective. Streptomycin, 14 mg/kg/d intramuscularly, may be useful during the first month of therapy. All oral medications must be taken for months and continued for several months after clinical cure to prevent relapse. Debridement assists healing.

The prognosis for maduromycosis is poor, though surgical debridement along with prolonged itraconazole therapy may result in a response rate of 70%. The various etiologic agents may respond differently to antifungal

Table 36–1. Agents for systemic mycoses.

| Drug | Dosing | Renal Clearance? | CSF Penetration? | Toxicities | Spectrum of Activity |
|------------------------------|---|--------------------|------------------|--|---|
| Amphotericin B | 0.3–1.5 mg/kg/d intravenously | No | Poor | Rigors, fever, azotemia, hypokalemia, hypomagnesemia, renal tubular acidosis, anemia | All major pathogens except <i>Scedosporium</i> |
| Amphotericin B lipid complex | 5 mg/kg/d intravenously | No | Poor | Fever, rigors, nausea, hypotension, anemia, azotemia, tachypnea | Same as amphotericin B, above |
| Liposomal amphotericin B | 3–6 mg/kg/d intravenously | No | Poor | Fever, rigors, nausea, hypotension, azotemia, anemia, tachypnea, chest tightness | Same as amphotericin B, above |
| Anidulafungin | 100 mg intravenous loading dose, followed by 50 mg/d intravenously in one dose | < 1% | Poor | Diarrhea, hepatic enzyme elevations, histamine-mediated reactions | Mucosal and invasive candidiasis |
| Caspofungin acetate | 70 mg intravenous loading dose, followed by 50 mg/d intravenously in one dose | < 50% ¹ | Poor | Transient neutropenia; hepatic enzyme elevations when used with cyclosporine | Aspergillosis, mucosal and invasive candidiasis, empiric antifungal therapy in febrile neutropenia |
| Micafungin sodium | 150 mg intravenously in one dose (treatment) 50 mg (prophylaxis) | No | Poor | Rash, rigors, headache, phlebitis | Mucosal and invasive candidiasis, prophylaxis in hematopoietic stem cell transplantation |
| Fluconazole | 100–800 mg/d in one or two doses intravenously or orally | Yes | Yes | Nausea, rash, alopecia, headache, hepatic enzyme elevations | Mucosal candidiasis (including urinary tract), cryptococcosis, histoplasmosis, coccidioidomycosis |
| Flucytosine (5-FC) | 100–150 mg/kg/d orally in four divided doses | Yes | Yes | Leukopenia, ² rash, diarrhea, hepatitis, nausea, vomiting | Cryptococcosis, ³ candidiasis, ³ chromomycosis |
| Itraconazole | 100–400 mg/d orally in one or two doses | No | Variable | Nausea, hypokalemia, edema, hypertension | Histoplasmosis, coccidioidomycosis, blastomycosis, paracoccidioidomycosis, mucosal candidiasis (except urinary), sporotrichosis, aspergillosis, chromomycosis |
| Ketoconazole | 200–800 mg/d orally in one or two doses | No | Poor | Anorexia, nausea, suppression of testosterone and cortisol, rash, headache, hepatic enzyme elevations, hepatic failure | Nonmeningeal histoplasmosis and coccidioidomycosis, blastomycosis, paracoccidioidomycosis, mucosal candidiasis (except urinary) |
| Posaconazole | 400–800 mg/d orally in one or two doses | No | Yes | Nausea, vomiting, abdominal pain, diarrhea, and headache | Broad range of activity including zygomycosis |
| Terbinafine | 250 mg/d orally in one dose | Yes | Poor | Nausea, abdominal pain, taste disturbance, rash, diarrhea, and hepatic enzyme elevations | Dermatophytes, sporotrichosis |
| Voriconazole | 200–400 mg/d orally in two doses or 12 mg/kg intravenously as loading dose for 2 days followed by 6 mg/kg/d intravenously in two doses ⁵ | Yes | Yes | Transient visual disturbances, rash, hepatic enzyme elevations ⁴ | All major pathogens except zygomycetes and sporotrichosis |

¹No dosage adjustment required for chronic kidney disease; dosage adjustment necessary with moderate to severe hepatic dysfunction.²Use should be monitored with blood levels to prevent this or the dose adjusted according to creatinine clearance.³In combination with amphotericin B.⁴Administration with drugs that are metabolized by the cytochrome P450 system is contraindicated or requires careful monitoring.⁵Because of polymorphisms affecting metabolism, some authorities advocate therapeutic drug monitoring in patients who are not responding to therapy.

agents, so culture results are invaluable. Amputation is necessary in far advanced cases.

Ameen M et al. Developments in the management of mycetomas. *Clin Exp Dermatol*. 2009 Jan;34(1):1–7. [PMID: 19076788]

OTHER OPPORTUNISTIC MOLD INFECTIONS

Fungi previously considered to be harmless colonizers, including *Pseudallescheria boydii* (*Scedosporium apiospermum*), *Scedosporium prolificans*, *Fusarium*, *Paecilomyces*, *Trichoderma longibrachiatum*, and *Trichosporon*, are emerging as significant pathogens in immunocompromised patients. This occurs most often in patients being treated for hematopoietic malignancies and in those receiving broad-spectrum antifungal prophylaxis. Infection may be localized in the skin, lungs, or sinuses, or widespread disease may appear with lesions in multiple organs. Colonization of old cavitory disease may cause minimal symptoms or may precede dissemination with meningitis or brain abscesses. Endocarditis occurs more commonly in injection drug users. Sinus infection may cause bony erosion. Infection in subcutaneous tissues following traumatic implantation may develop as a well-circumscribed cyst or as an ulcer.

Nonpigmented septate hyphae are seen in tissue and are indistinguishable from those of *Aspergillus* when infections are due to *S apiospermum* or species of *Fusarium*, *Paecilomyces*, *Penicillium*, or other hyaline molds. Spores or mycetoma-like granules are rarely present in tissue.

Infection by any of a number of black molds is designated as phaeohyphomycosis. These black molds (eg, *Exophiala*, *Bipolaris*, *Cladophialophora*, *Curvularia*, *Alternaria*) are common in the environment, especially on decaying vegetation. Human disease due to these agents is rarely encountered but may result in soft tissue abscesses due to traumatic inoculation or may occur as a sequela of chronic sinusitis or profound immunosuppression. In tissues of patients with phaeohyphomycosis, the mold is seen as black or faintly brown hyphae, yeast cells, or both. Culture on appropriate medium is needed to identify the agent. Histologic demonstration of these organisms is definitive evidence of invasive infection; positive cultures must be interpreted cautiously and not assumed to be contaminants in immunocompromised hosts. Some isolates are sensitive to antifungal agents. The differentiation of *S apiospermum* and *Aspergillus* is particularly important, since the former is

uniformly resistant to amphotericin B but may be sensitive to azole antifungals (eg, voriconazole).

Troke P et al; Global Scedosporium Study Group. Treatment of scedosporiosis with voriconazole: clinical experience with 107 patients. *Antimicrob Agents Chemother*. 2008 May;52(5):1743–50. [PMID: 18212110]

ANTIFUNGAL THERAPY

Table 36–1 summarizes the major properties of currently available antifungal agents. Several different lipid-based amphotericin B formulations are used to treat systemic candidiasis, invasive aspergillosis and other disseminated mold infections, disseminated histoplasmosis, and cryptococcal meningitis. Their principal advantage appears to be substantially reduced nephrotoxicity, allowing administration of much higher doses. Because of their expense, use of these agents is often reserved for individuals in whom significant nephrotoxicity develops during amphotericin B therapy. Three agents of the echinocandin class, caspofungin acetate, anidulafungin, and micafungin sodium, are currently approved. The echinocandins have relatively few adverse effects and are useful for the treatment of invasive *Candida* infections. Caspofungin acetate is also approved for use in refractory cases of invasive aspergillosis. Voriconazole has excellent activity against a broad range of fungal pathogens and has been FDA approved for use in invasive *Aspergillus* cases, *Fusarium* and *Scedosporium* infections, *Candida* esophagitis, deep *Candida* infections, and candidemia. Posaconazole has good activity against a broad range of filamentous fungi, including some of the zygomycetes. Cytokine therapy (such as with interferon- γ) and use of growth factors such as granulocyte macrophage-colony-stimulating factor (GM-CSF) (sargramostim or molgramostim) have been shown in animal models to increase clearance of fungi and result in better clinical outcomes and are being evaluated in human disease.

Disorders Due to Physical Agents

Jacqueline A. Nemer, MD, FACEP
Brent R.W. Moelleken, MD, FACS

37

COLD & HEAT

The human body maintains a steady temperature through the balance of internal heat production and environmental heat loss. In extreme temperatures, the body's thermoregulation may fail. This results in the body's internal temperature moving toward the temperature of the external environment. Heat exchange between the body and environment occurs via four common processes: radiation, evaporation, conduction, and convection. Cold and heat tolerance vary considerably among individuals, depending on physiological and environmental factors.

Cold- and heat-related conditions may arise in any individual, regardless of sex, race, age, or underlying health status. Exposure to cold or heat may cause a wide spectrum of conditions. Factors that increase the likelihood of extreme temperature-related conditions include underlying cardiopulmonary, vascular, neurologic or musculoskeletal diseases; poor physical conditioning; nonacclimatization; advanced age; altered mental status; poor tissue perfusion; inappropriate clothing; concurrent injury; poor peripheral vascular function; inadequate thermoregulation; systemic illness; pharmacologic effects of tobacco, alcohol, and drugs (ie, recreational drugs, sedatives, or drugs that affect sweating).

ACCIDENTAL SYSTEMIC HYPOTHERMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Hypothermia is a reduction of core body temperature below 35 °C.
- ▶ An esophageal or rectal probe that measures as low as 25 °C is required; oral, axillary, and otic temperatures are inaccurate.
- ▶ Resuscitative measures must be continued until the core temperature is over 32 °C.

General Considerations

Systemic hypothermia is defined as core body temperature less than 35 °C. This may be primary (from exposure to prolonged ambient extremely low temperature) or secondary (due to thermoregulatory dysfunction). Primary and secondary hypothermia may be present at the same time. Hypothermia risk factors include malnutrition, hypothyroidism, adrenal insufficiency, hypopituitarism, diabetes mellitus, uremia, sedentary lifestyle, homelessness, inadequately heated housing, inadequate clothing, occupational or recreational exposure, prior cold weather injury, substance use or overdose, antipsychotic drug use, sepsis, infection, hypoglycemia, as well as the factors listed above. Heat loss occurs more rapidly with high wind velocity ("windchill factor"); water immersion or wet clothing; or direct contact with a cold surface (ie, stone, concrete, soil or the ground).

Accidental hypothermia may occur in the hospital setting due to prolonged postoperative hypothermia or administration of large amounts of refrigerated stored blood products (without rewarming), rapid infusion of intravenous fluids, or prolonged exposure of an undressed patient during resuscitation or procedures.

The human body generates internal heat through muscle activity (ie, shivering or increased physical exertion) and preserves heat loss via peripheral vasoconstriction. In prolonged or repetitive cold exposure, these thermoregulatory responses can become impaired; hypothermia ensues. Hypothermia diagnosis can be easily overlooked and delayed in a critically ill or injured patient. Hypothermia should be considered in any patient with prolonged exposure to ambient or cold environment, trauma, or inadequate clothing.

Systemic hypothermia alters physiologic function. This results in decreased respiratory drive, oxygen consumption, peripheral nerve conduction, gastrointestinal motility, myocardial repolarization, and coagulation cascade.

Clinical Findings

Symptoms and signs of hypothermia are typically nonspecific and markedly variable based on the patient's underlying

▲ **Figure 37-1.** Electrocardiogram shows leads II and V5 in a patient whose body temperature is 24 °C. Note the bradycardia and Osborn waves. These findings become more prominent as the body temperature lowers, and gradually resolve with rewarming. Osborn waves have an extra deflection at the end of the QRS complex. These are best seen in the inferior and lateral precordial leads.

ing health and circumstances of hypothermia. In mild cases with core temperature between 32 °C and 35 °C, symptoms include tachypnea, tachycardia, hypertension, shivering, impaired coordination, poor judgment, and apathy. With core temperature between 28 °C and 32 °C, the body slows down. Shivering stops; bradycardia, dilated pupils, slowed reflexes, cold diuresis, and confusion and lethargy ensue. Electrocardiogram (ECG) may reveal J wave or Osborn wave (positive deflection in the terminal portion of the QRS complex, most notable in leads II, V₅, and V₆) (Figure 37-1). Below 28 °C, the skin may appear blue or puffy; coma, apnea, loss of reflexes, asystole, or ventricular fibrillation may lead the clinician to assume that patient is dead. Prolonged hypothermia may lead to dysrhythmias and conduction abnormalities, acidemia, hyperkalemia, rhabdomyolysis, pulmonary edema, chronic kidney disease, pneumonia, pancreatitis, hypoglycemia or hyperglycemia, and coagulopathy. Death in systemic hypothermia is usually due to ventricular fibrillation, asystole, or chronic kidney disease.

► Treatment

Resuscitation begins with assessment and support of airway, breathing and circulation, initiation of rewarming, and prevention of further heat loss. Rewarming is the initial, imperative treatment. The patient should be evaluated for secondary causes of hypothermia, trauma, and peripheral cold injury. Rewarming methods are determined by the degree of hypothermia and the resources available.

During rewarming, continuous monitoring of temperature and other vital signs, cardiac rhythm, and blood sugar must be done. Common complications of rewarming occur as colder peripheral blood returns to central circulation. This may result in core temperature afterdrop, rewarming acidosis from shunting lactate into the circulation, rewarming shock from peripheral vasodilation and

hypovolemia, ventricular fibrillation and other cardiac arrhythmias. Extreme caution must be taken when handling the hypothermic patient to avoid triggering arrhythmias. During the rewarming process, essential testing includes ECG, chest radiograph, arterial blood gases, and bedside glucose. Laboratory evaluation should assess for potential complications of lactic acidosis; rhabdomyolysis; electrolyte abnormalities; infection; and dysfunction of the pancreas, liver, kidneys, and coagulation. False laboratory values will occur if the blood sample is warmed to 37 °C for the testing. Antibiotics are not routinely given. Comatose patients have a high risk of aspiration pneumonia.

A. Passive and Active External Rewarming Methods

Patients with mild hypothermia (rectal temperature > 33 °C) who have been otherwise healthy usually respond well to passive and active external warming. **Passive external rewarming** involves removal of cold wet clothing and covering the patient with blankets to prevent further heat loss. The patient will rewarm due to the body's internal heat production through shivering and increased metabolism. **Active external rewarming** is highly effective and safe for mild hypothermia. This is a noninvasive method of applying external heat to the patient's skin. Examples include warm bedding, heated blankets, heat packs, and immersion into a 40 °C bath. Afterdrop can be lessened by active external rewarming of the trunk but not the extremities and by avoiding any muscle movement by the patient.

B. Active Internal (Core) Rewarming Methods

Active internal core rewarming methods are required for patients with core temperatures of < 33 °C. Patients with milder degrees of hypothermia may also benefit from these methods. Warm humidified oxygen (43–46 °C) is an easy, safe, and highly effective method. Warmed intravenous saline infusions (43 °C) should be used instead of lactated Ringer solution. Volume resuscitation is needed to prevent shock as vasodilation occurs during rewarming. Other methods (including warm solution lavage of the stomach, colon, thoracic cavity, peritoneum, or bladder; extracorporeal blood rewarming by cardiopulmonary, arteriovenous femorofemoral, or venovenous bypass; and hemodialysis) are based on the availability of equipment and skilled personnel. Esophageal rewarming tubes are used abroad and may soon become available in the United States. Endovascular warming devices are a less invasive alternative than extracorporeal methods but are not widely available in hospitals.

For patients with core temperature < 30 °C, treatment includes active rewarming, cardiopulmonary resuscitation (CPR), one shock attempt for dysrhythmia, and withholding of intravenous medications. Once the core temperature reaches 30 °C, cardiac medications can be given but at longer than standard intervals because metabolism is slowed and there is a risk of toxic accumulation as circulation is restored. Defibrillation may be performed as needed. Resuscitative efforts should be continued until the patient's core temperature increases to at least 32 °C.

► Prognosis

Prognosis is directly related to the patient's underlying health and comorbidities, the severity of associated conditions, circumstances surrounding the hypothermia, and degree of metabolic acidosis. Prognosis is poor with low pH (≤ 6.6), elevated potassium (≥ 4.0 mEq/L), serious underlying condition, or treatment delay. If treated early, most otherwise healthy patients may survive moderate or severe hypothermia.

HYPOTHERMIA OF THE EXTREMITIES

ESSENTIALS OF DIAGNOSIS

- Cold-induced injuries should not be rubbed or massaged during rewarming.
- Rewarming of cold-induced injuries must be performed as soon as possible after there is no risk of refreezing.

► Clinical Findings

Cold exposure of the extremities produces immediate localized vasoconstriction followed by generalized vasoconstriction. When the skin temperature falls to 25 °C, tissue demand for oxygen is greater than what is supplied by the slowed circulation: the area becomes cyanotic. At 15 °C, tissue damage occurs due to marked reduction in tissue metabolism and in oxyhemoglobin dissociation. This gives a deceptive pink, well-oxygenated appearance to the skin. Tissue death may result from ischemia and thromboses in the smaller vessels or by actual freezing. Freezing (frostbite) may occur when the skin temperature drops below -4 to -10 °C or at higher temperatures in the presence of wind, immobility, malnutrition, or vascular disease. Cold-induced injuries to the extremities (frostnip, chilblain, trench foot, and frostbite) range from mild to severe.

► Prevention

“Keep warm, keep dry, and keep moving.” Individuals should wear warm, dry clothing, preferably several layers, with a windproof outer garment. Arms, legs, fingers, and toes should be exercised to maintain circulation. Wet clothing, socks, and shoes should be replaced with dry ones. Extra socks, mittens, and insoles should always be carried in a pack during travel in cold or icy areas. Caution must be taken to avoid cramped positions; constrictive clothing; prolonged dependency of the feet; use of tobacco, alcohol, and sedative medications; and exposure to wet muddy ground and windy conditions.

FROSTNIP & CHILBLAIN (Erythema Pernio)

Frostnip is a mild temporary form of cold-induced injury. The involved area has local paresthesias that completely resolve with passive external rewarming.

Chilblains or **erythema pernio** are inflammatory skin changes caused by exposure to cold without actual freezing of the tissues. These skin lesions may be red or purple, painful or pruritic, with burning or paresthesias; they may be associated with edema or blistering and aggravated by warmth. With continued exposure, ulcerative or hemorrhagic lesions may appear and progress to scarring, fibrosis, and atrophy.

Treatment consists of elevating and passively externally rewarming the affected part. Caution must be taken to avoid rubbing or massaging injured tissues and to avoid applying ice or heat. The area must be protected from trauma and secondary infection.

IMMERSION FOOT OR TRENCH FOOT

Immersion foot (or hand) is caused by prolonged immersion in cool or cold water or mud, usually less than 10 °C. Early symptoms include cold and anesthesia of the affected area (prehyperemic stage). This is followed by hot sensation, intense burning, shooting pains (hyperemic stage). With ongoing cold exposure, the affected part becomes pale or cyanotic with diminished pulsations due to vasospasm (posthyperemic stage). This may result in blistering, swelling, redness, ecchymoses, hemorrhage, necrosis, peripheral nerve injury, or gangrene and secondary complications such as lymphangitis, cellulitis, and thrombophlebitis.

Treatment is best instituted during the hyperemic stage. Treatment consists of air drying, protecting the extremities from trauma and secondary infection, and gradual rewarming by exposure to air at room temperature (not ice or heat). Caution must be taken to avoid massaging or moistening the skin and to avoid water immersion. Bed rest is required until all ulcers have healed. Affected parts are elevated to aid in removal of edema fluid, and pressure sites (eg, heels) are protected with pillows. Prevention involves properly fitting footwear, improved foot hygiene, and sock changes to keep feet clean and dry.

FROSTBITE

Frostbite is injury from tissue freezing and formation of ice crystals in the tissue. In mild cases, only the skin and subcutaneous tissues are involved; the symptoms are numbness, pricking, itching, and pallor. With increasing severity, deep frostbite involves deeper structures. The skin appears white or yellow, loses its elasticity, and becomes immobile. Edema, hemorrhagic blisters, necrosis, and gangrene may appear. This may cause paresthesias and stiffness.

► Treatment

A. Immediate Treatment

Evaluate and treat the patient for associated systemic hypothermia and injury. Fluids and electrolytes should be monitored.

1. Rewarming—Rapid rewarming at temperatures slightly above body heat may significantly decrease tissue necrosis. If there is any possibility of refreezing, the frostbitten part

should not be thawed. Refreezing results in increased tissue necrosis. Rewarming is best accomplished by warm bath immersion. The frozen extremity is immersed for several minutes in a moving water bath heated to 40–42 °C until the distal tip of the part being thawed flushes. Dry heat (eg, stove or open fire) is more difficult to regulate, increases likelihood of accidental burns and is not recommended. Thawing may cause tenderness and burning pain. Once the frozen part has thawed and returned to normal temperature (usually in about 30 minutes), discontinue external heat. Rewarming by exercise, rubbing, or friction is contraindicated in the early stage. The patient is kept at bed rest with the affected parts elevated and uncovered at room temperature. Casts, occlusive dressings, or bandages are not applied. Blisters should be left intact unless signs of infection supervene.

2. Anti-infective measures and wound care—Frostbite increases susceptibility to tetanus and infection. Tetanus prophylaxis must be considered. Infection risk may be reduced by aseptic wound care and protection of skin blebs from physical contact. Wounds should be kept open and allowed to dry before applying dressings. Nonadherent sterile gauze and fluffy dressing should be loosely applied to wounds and cushions used for all areas of pressure. Antibiotics should not be administered empirically. Systemic antibiotics are reserved for deep infections not responding to local wound care.

B. Medical and Surgical Treatment Options

Debridement and amputation should be considered only after it is established that the tissues are necrotic. Magnetic resonance imaging with angiography and technetium scintigraphy have been used to assess the extent of frostbite and to distinguish viable from nonviable tissue. Eschar formation without evidence of infection may be conservatively treated. The underlying skin may heal spontaneously with the eschar acting as a biologic dressing. Intra-arterial thrombolytic administration within 24 hours of exposure has resulted in improved tissue perfusion and has reduced amputation.

C. Follow-Up Care

Gentle, progressive physical therapy to promote circulation should be instituted as tolerated.

► Prognosis

Recovery from frostbite depends on the extent of initial tissue damage, the rewarming reperfusion injury, and the late sequelae (such as chronic kidney disease or postinjury infections) and underlying comorbidities. There may be increased susceptibility to discomfort and injury in the involved extremity upon reexposure to cold. Neuropathic sequelae such as pain, numbness, tingling, hyperhidrosis, and cold sensitivity of the extremities, and nerve conduction abnormalities may persist for many years after the cold injury.

DISORDERS DUE TO HEAT

ESSENTIALS OF DIAGNOSIS

- There is a spectrum of heat-related illnesses: heat cramps, heat exhaustion, heat syncope, and heat stroke.

► General Considerations

Hyperthermia results from the body's inability to maintain normal internal temperature through heat loss. The body's heat source is a result of internal metabolic function and environmental conditions. Heat loss occurs through sweating and peripheral vasodilation. The common comorbidities and risk factors leading to heat-related conditions are listed in the chapter's introduction. Additional risk factors include inhibition of sweat production or evaporation, obesity, skin disorders (miliaria), reduced cutaneous blood flow, dehydration, hypotension, reduced cardiac output, and use of drugs that increase metabolism or muscle activity or impair sweating, prolonged seizures, and withdrawal syndromes.

► Prevention

Public education is necessary to improve prevention and early recognition of heat-related disorders. Individuals should take steps to reduce personal risk factors (ie, physical inactivity, obesity, tobacco and drug use) and to acclimatize to the hot environment. Proper acclimatization must be achieved before heavy physical exertion (ie, occupational or exercise) is performed in hot environments.

Medical evaluation and monitoring should be used to identify the individuals and the weather conditions that increase risk of heat-related disorders. Athletic events should be organized with attention to thermoregulation: the wet

bulb globe temperature (WBGT) index should be monitored. Competition is not recommended when the WBGT exceeds 26–28 °C. Guidance regarding heat hazard is found in the National Weather Service's Heat Index that rates weather conditions based on humidity and temperature measurements (www.weather.gov/om/heat/index.shtml). The US Army provides guidance regarding activity levels according to WBGT levels (www.usariem.army.mil/heatill/appendc.htm).

Those who are physically active in a hot environment should increase fluid consumption. Fluid consumption should include balanced electrolyte fluids and water. Water consumption alone may lead to electrolyte imbalance, particularly hyponatremia. It is not recommended to have salt tablets available for use without medical supervision. Close monitoring of fluid and electrolyte intake and early intervention are recommended in situations necessitating exertion or activity in hot environments. Exertional heat-related disorders are common in unconditioned participants in strenuous activities in hot humid conditions (ie, military drills, marathons, triathlon competitions, or exercise during heat waves).

SPECIFIC SYNDROMES DUE TO HEAT EXPOSURE

1. Heat Syncope or Collapse

Sudden collapse or unconsciousness may result from volume depletion and cutaneous vasodilation with consequent systemic and cerebral hypotension. Exercise-associated postural hypotension is usually the cause of this: it may occur during or immediately following exercise. There is usually a history of prolonged vigorous physical activity. Typically, the skin is cool and moist, the pulse is weak, and the systolic blood pressure is low.

Treatment consists of rest and recumbency in a cool place and fluid and electrolyte rehydration by mouth (or intravenously if necessary).

2. Heat Cramps

Fluid and electrolyte depletion may result in slow, painful skeletal muscle contractions ("cramps") and severe muscle spasms lasting 1–3 minutes, usually of the muscles most heavily used. The skin is moist and cool. The muscles are tender, hard and lumpy, and muscle twitching may be present. The patient is alert, with stable vital signs, and may be agitated and complaining of pain. The body temperature may be normal or slightly increased. There is almost always a history of vigorous activity just preceding the onset of symptoms. Laboratory evaluation may show low serum sodium, hemoconcentration, and elevated urea and creatinine.

The patient should be moved to a cool environment and given oral saline solution (4 tsp of salt per gallon of water) to replace both salt and water. *Oral salt tablets are not recommended.* The patient may have to rest for 1–3 days with continued dietary salt supplementation before returning to work or resuming strenuous activity in the heat.

3. Heat Exhaustion

Heat exhaustion results from prolonged strenuous activity with inadequate water or salt intake in a hot environment. It is characterized by dehydration, sodium depletion, or isotonic fluid loss with accompanying cardiovascular changes.

The diagnosis is based on prolonged symptoms and a rectal temperature over 37.8 °C, increased pulse (> 150% of the patient's normal) and moist skin. Symptoms are similar to those associated with heat syncope and heat cramps. Additional symptoms include nausea, vomiting, malaise, myalgias, hyperventilation, thirst, and weakness. Central nervous system symptoms include headache, dizziness, fatigue, anxiety, paresthesias, impaired judgment, hysteria, and occasionally psychosis. Hyperventilation secondary to heat exhaustion can cause respiratory alkalosis; lactic acidosis may also occur due to poor tissue perfusion. Heat exhaustion may progress to heat stroke if sweating ceases and mental status declines.

Treatment consists of moving patient to a shaded, cool environment, providing adequate hydration (1–2 L over 2–4 hours), oral salt replenishment, and active cooling (ie, fans, cool packs) if necessary. Physiologic saline or isotonic glucose solution should be administered intravenously when oral administration is not appropriate. At least 24 hours of rest and rehydration are recommended.

4. Heat Stroke

Heat stroke is a life-threatening medical emergency. The hallmarks of heat stroke are cerebral dysfunction with core temperature over 40 °C and absence of sweating. It presents in one of two forms: classic and exertional. **Classic heat stroke** occurs in patients with impaired thermoregulatory mechanisms; **exertional heat stroke** occurs in healthy persons undergoing strenuous exertion in a hot or humid environment. Persons at greatest risk are the very young, the elderly, the chronically debilitated, and those taking medications that interfere with heat-dissipating mechanisms (ie, anticholinergics, antihistamines, phenothiazines).

Heat stroke is associated with high morbidity and mortality from cerebral, cardiovascular, liver, or kidney damage. A high Simplified Acute Physiology Score II, high body temperature, prolonged prothrombin time, use of vasoactive drugs within the first day in the intensive care unit (ICU), and an ICU without air conditioning all were associated with increased mortality.

▶ Clinical Findings

A. Symptoms and Signs

Heat stroke may present with dizziness, weakness, emotional lability, nausea and vomiting, diarrhea, confusion, delirium, blurred vision, convulsions, collapse, and unconsciousness. The skin is hot, initially covered with perspiration; later it dries. The pulse is strong initially. Widened pulse pressure is present. Blood pressure may be slightly elevated at first, but hypotension develops later. Tachycardia and hyperventilation (with subsequent respiratory alkalosis) occur. The core temperature is usually over 40 °C.

Exertional heat stroke may present with sudden collapse and loss of consciousness followed by irrational behavior. Anhidrosis may not be present. Multiorgan dysfunction or injury is a common and serious complication.

B. Laboratory Findings

Laboratory evaluation may reveal dehydration; leukocytosis; elevated blood urea nitrogen (BUN); hyperuricemia; hemoconcentration; acid-base abnormalities (eg, lactic acidosis, respiratory alkalosis); decreased serum potassium, sodium, calcium, and phosphorus; thrombocytopenia, fibrinolysis, and coagulopathy; elevated creatine kinase (CK); elevated aminotransferase levels and liver dysfunction; and elevated cardiac markers. Urine is concentrated, with proteinuria, hematuria, tubular casts, and myoglobinuria. ECG findings may include ST-T changes consistent with myocardial ischemia. P_{CO_2} may be less than 20 mm Hg.

► Treatment

Treatment is aimed at reducing the core temperature rapidly (within 1 hour) while supporting organ system function. Care must be taken to avoid shivering, which will increase internal heat production and inhibit effectiveness of cooling. Benzodiazepines may be used to suppress shivering. Evaporative cooling is a noninvasive, effective, quick and easy way to reduce temperature. The patient is undressed and the entire body sprayed with lukewarm water (20 °C) while large fans circulate the room air. The patient should be in the lateral recumbent position or supported in a hands-and-knees position to expose as maximum skin surface to the air. Alternatively, the use of cold wet sheets accompanied by fanning may be used. Inhalation of cool air or oxygen, and infusion of cool intravenous fluids are also effective.

Immersion in an ice-water bath (1–5 °C) is effective but impractical method due to its physical requirements and limitations to patient access and monitoring. Other cooling alternatives include hand and forearm immersion in cold water, localized ice or ice slush application (groin, axillas, neck), and iced gastric lavage. These are much less effective than evaporative cooling and usually less tolerated in the awake patient. Skin massage is recommended to prevent cutaneous vasoconstriction. Intravascular heat exchange catheter systems as well as hemodialysis using cold dialysate (30–35 °C) have been successful in reducing core temperature. Research suggests that brain cooling may lessen cerebrovascular injury from heat stroke. *Antipyretics (aspirin, acetaminophen) have no effect on environmentally induced hyperthermia and are contraindicated.* Treatment should be continued until the rectal temperature drops to 39 °C.

All patients with suspected heat stroke must be admitted to the hospital for close monitoring, including vital signs, temperature, and cardiac rhythm, and observation for 24 hours. The patient should also be monitored for potential complications of electrolyte abnormalities, acute kidney injury due to rhabdomyolysis, cardiac arrhythmias, coagulopathy, hepatic failure, acute respiratory distress syndrome (ARDS), hypoglycemia, seizures, and infection. Intravascular volume status should be assessed and man-

aged. Hypovolemic and cardiogenic shock must be carefully distinguished, since either or both may occur. Oral or intravenous fluid administration must be provided to ensure a high urinary output (> 50 mL/h). Fluid output should be monitored through the use of an indwelling urinary catheter. Mannitol administration (0.25 mg/kg), and alkalinizing the urine (intravenous administration of 250 mL of 4% bicarbonate administration) may be needed.

Multiorgan dysfunction is the usual cause of heat stroke–related death, and it can be predicted by CK > 1000 units/L, metabolic acidosis, and elevated liver enzymes. Multiorgan dysfunction and inflammation may continue after temperature is normalized. Hypokalemia frequently accompanies heat stroke but may not appear until rehydration. Maintenance of extracellular hydration and electrolyte balance should reduce the risk of chronic kidney disease due to rhabdomyolysis.

Because sensitivity to high environmental temperature may persist for prolonged periods following an episode of heat stroke, immediate reexposure should be avoided.

BURNS

The incidence and severity of burn injuries has been declining, with both deaths and acute hospitalizations attributable to burns down about 50%. Over three-fourths of burns involve less than 10% of total body surface area. Aggressive, early excision (24–72 hours postburn) of deeply burned tissues and skin grafting, early enteral feeding, and improved infection control have contributed to significantly lower mortality rates and shorter hospitalizations. Nonetheless, an estimated 1.25 million burn injuries and 51,000 acute hospitalizations of burn victims occur each year in the United States. Approximately 12,500 patients per year are admitted

to dedicated burn units. Overall, 62% of all patients with burns seen in burn centers had minor burns that affected less than 10% of the total body surface area, and 6.5% of patients admitted had inhalation injury. Among burn patients, 70% were male and had a mean age of 33 years. Flame and scald burns accounted for 78% of injuries.

The first 48 hours of hemodynamic shifts offer the greatest opportunity to impact the survival of the multiply injured patient with burn injuries. Related injuries include smoke inhalation, fractures, and blast injuries. Subsequent problems include bacterial superinfection, sepsis, and multiorgan failure. Finally, scar contractures and disfigurement occur during the later stages of burn injury.

CLASSIFICATION

Burns are classified by extent, depth, patient age, and associated illness or injury. Accurate estimation of burn size and depth is important since this figure will quantify the parameters of resuscitation.

A. Extent

The “rule of nines” (Figure 37–2) is useful for rapidly assessing the extent of a burn. More detailed charts based on age are available when the patient reaches the burn unit. Therefore, it is important to view the entire patient after cleaning soot to make an accurate assessment, both initially and on subsequent examinations. On average, the degree of burn is overestimated by 75% by referring doctors. This becomes important when air transport is instituted to a burn center for minor injuries. One rule of thumb is that the palm of the hand, open, constitutes 1% total body surface area in

▲ **Figure 37-2.** Estimation of body surface area in burns.

adults. Only second- and third-degree burns are included in calculating the total burn surface area, since first-degree burns usually do not represent significant injury in terms of prognosis or fluid and electrolyte management. However, first- or second-degree burns may convert to deeper burns, especially if treatment is delayed or bacterial colonization or superinfection occurs.

B. Depth

Judgment of depth of injury is difficult. The **first-degree burn** may be red or gray but will demonstrate excellent capillary refill. First-degree burns are not blistered initially. If the wound is blistered, this represents a partial-thickness injury to the dermis, or a **second-degree burn**. As the degree of burn is progressively deeper, there is a progressive loss of adnexal structures. Hairs can be easily extracted or are absent, sweat glands become less visible, and the skin appears smoother.

Deep second- and third-degree burns are treated in a similar fashion, since neither will heal appropriately without early debridement and grafting; the resultant skin is thin and scarred.

The benefits of hyperbaric oxygen for treatment of acute burns remain unproven and anecdotal.

C. Survival after Burn Injury

The Prognostic Burn Index is the sum of the patient’s age and percentage of full thickness or deep partial thickness burn. An additional 20% mortality is added if inhalation injury is present. Recently, patients with a 90–100% predicted mortality rate now have an estimated mortality rate of 50–70%. The Prognostic Burn Index is most useful at the extremes of age. Recent treatment advances have significantly reduced mortality rates, including early burn excision, skin substitute usage, and early enteral feeding. Transfer to a burn unit with its support staff is indicated when burns are large, when there are comorbidities, and when smaller burns occur in high risk areas. According to the 2005 Burn Repository Statistics, mortality rates among all burn victims have decreased from 6.2% in 1995 to 4.7% in 2005.

D. Associated Injuries or Illnesses

An injury commonly associated with burns is smoke inhalation (see Chapter 9). Suspicion of inhalation injury is aroused when the nasal hairs are singed, the mechanism of burn involves closed spaces, the sputum is carbonaceous, or the carboxyhemoglobin level exceeds 5% in nonsmokers. This suspicion should lead the clinician to institute early intubation before airway edema occurs. The products of combustion, not heat, are responsible for lower airway injury. When carbon monoxide poisoning is suspected, pure oxygen is administered for 45 minutes. Early extubation is avoided for the first 48–72 hours since there is a risk of continued airway edema during the dynamic fluid shift period of early resuscitation. Electrical injury that causes burns may also produce cardiac arrhythmias that require immediate attention. Pancreatitis occurs in severe burns. Prior alcohol exposure may exacerbate the pulmonary components of burn injury.

Toxic epidermal necrolysis (TEN) occasionally occurs following sulfonamide or phenytoin administration (see Chapter 6). If TEN is severe, patients are best transferred to a burn unit and treated as having severe burn injury. Corticosteroid therapy should be avoided.

SYSTEMIC REACTIONS TO BURN INJURY

The actual burn injury is only the incipient event in a cascade of deleterious local tissue and systemic inflammatory reactions leading to multiorgan system failure in the severely burned patient. When burns greater than approximately 20% of total body surface area are present, systemic metabolic alterations occur and require intensive support. The inflammatory cascade can result in shock.

INITIAL MANAGEMENT

A. Airway

The practitioner or emergency medical technician should proceed as with any other trauma using standard Advanced Trauma Life Support (ATLS) guidelines. The priorities are first to establish an airway, recognizing the frequent necessity to intubate a patient who may appear to be breathing normally but who has sustained an inhalation injury; next, to evaluate the cervical spine and head injuries; and finally, to stabilize fractures. Fluid resuscitation by the Parkland formula (see below) may be instituted simultaneously with initial resuscitation. Endotracheal intubation or tracheotomy should be considered for major burn cases regardless of the area of the body involved, because as fluid resuscitation proceeds generalized edema develops, including edema of the soft tissues of the upper airway and perhaps the lungs as well. Chest radiographs are typically normal initially but may develop an ARDS picture in 24–48 hours with severe inhalation injury. Supplemental oxygen should be administered. Inhalation injuries should be monitored with serial blood gas determination and bronchoscopy. The use of corticosteroids or routine use of antibiotic therapy is not indicated.

B. Vascular Access

A thorough examination is performed to assess the extent of burn and associated injuries. Large bore venous catheter access is established. Subclavian lines are avoided in the emergency setting because of the risk of pneumothorax and subclavian vein laceration when such a line is placed in a volume-depleted patient. Femoral lines provide good temporary access during resuscitation. *Venous access catheters placed in the emergency department should be changed within 24 hours because of the high risk of nonsterile placement.* An arterial line is useful for monitoring mean arterial pressure and for drawing blood in critically ill patients.

FLUID RESUSCITATION

A. Crystalloids

Generalized capillary leak results from burn injury over more than 20% of total body surface area. This often necessitates replacement of a large volume of fluid.

There are many guidelines for fluid resuscitation. The **Parkland formula** relies on the use of lactated Ringer injection. The fluid requirement in the first 24 hours is estimated as 4 mL/kg body weight per percent of body surface area burned. Half the calculated fluid is given in the first 8-hour period. The remaining fluid, divided into two equal parts, is delivered over the next 16 hours. An extremely large volume of fluid may be required. For example, an injury over 40% of the total body surface area in a 70-kg victim may require 11.2 L in the first 24 hours [$4 \text{ mL} \times 40(\%) \times 70 \text{ (kg)} = 11,200 \text{ mL}$]. The first 8-hour period is measured from the hour of injury. These guidelines may be inadequate, since crystalloid solutions alone may be insufficient to restore cardiac preload during the period of burn shock.

Deep electrical burns and inhalation injury increase the fluid requirement. Adequacy of resuscitation is determined by clinical parameters, including urinary output and specific gravity, blood pressure, pulse, temperature, and central venous pressure. The need for fluid replacement of more than 150% of calculated values indicates possible unrecognized injury, possible comorbidities, and a worse prognosis and may indicate the need for a Swan-Ganz catheter to assist in management.

B. Colloids

Overly aggressive crystalloid administration must be avoided in patients with pulmonary injury, since significant pulmonary edema can develop in patients with normal pulmonary capillary wedge and central venous pressures. In addition, routine colloid administration, previously commonplace, is no longer warranted in routine burn resuscitation in view of its deleterious effect on glomerular filtration and its association with pulmonary edema.

C. Monitoring Fluid Resuscitation

A Foley catheter is essential for monitoring urinary output. Diuretics have no role in this phase of patient management unless fluid overload has occurred or mannitol diuresis is performed in the case of rhabdomyolysis.

D. Abdominal Compartment Syndrome

Abdominal compartment syndrome is emerging as a potentially lethal condition in severely burned patients, even if abdominal decompression is performed. Markedly increased intra-abdominal pressures can cause pulmonary damage and multisystem organ failure. Only 40% of patients with this complication survive. Bladder pressures over 30 mm Hg establish the diagnosis in at-risk patients. Surgical abdominal decompression may be indicated to improve ventilation and oxygen delivery, but even after this, surgery survival remains low.

E. Escharotomy

As edema fluid accumulates, ischemia may develop under any constricting eschar of an extremity, neck, or trunk if the full-thickness burn is circumferential. Escharotomy incisions through the anesthetic eschar can save life and limb

and can be performed in the emergency department or operating room.

F. Fasciotomy in Electrical Burns or Crush Injuries

When high-voltage electrical injury occurs, extensive deep tissue necrosis should be suspected. Deep tissue necrosis leads to profound tissue swelling. Because deep tissue compartments in the arms and legs are contained by unyielding fascia, these compartments must be opened by surgical fasciotomy to prevent further soft tissue, vascular, and nerve death.

Electrical burn injuries remain the most devastating and underrecognized burn injuries, causing amputations (often because of unrecognized compartment syndromes) and acute kidney injury, resulting in part from rhabdomyolysis.

THE BURN WOUND

Minor burn wounds should be debrided at bedside to determine the depth of the burn and then thoroughly cleansed. Thereafter, the wound should be debrided daily and dressed with a topical antibiotic such as silver sulfadiazine (Silvadene) or bacitracin ointment. Patient compliance and adequate pain treatment is essential for successful outpatient treatment. The wound should be reevaluated by the treating surgeon if possible within 72 hours to evaluate for signs of infection.

Biobrane and Tegaderm should be reserved for clean scald burns. Acute burns caused by hydrofluoric acid should be treated by water rinsing followed by application of topical calcium. Treatment of the burn wound is based on protecting the wound from desiccation and avoiding further injury of those burned areas that will spontaneously reepithelialize in 7–10 days by application of topical antibiotic such as silver sulfadiazine (Silvadene). It is painless, easy to apply, and effective against most strains of *Pseudomonas*. For severely burned patients, Integra, a temporary skin substitute that can create a thin neodermis, may provide temporary coverage (and may even reduce hospitalization) but it is very expensive. Regular and thorough cleansing of burned areas is a critically important intervention in burn units. Early excision and grafting of burned areas may be performed as soon as 24 hours after burn injury or when the patient can hemodynamically tolerate the excision and grafting procedure. Meticulous prevention of seromas, hypergranulation tissue formation, and malnutrition all decrease time to complete wound healing in skin-grafted patients.

Systemic infection remains a leading cause of morbidity among patients with major burn injuries, with nearly all severely burned patients having one or more septicemic episodes during the hospital course. Antibiotic usage should be targeted to specific organisms obtained by culture. Healthcare-associated infections are increasingly common. Obtaining pharmacologic expertise is useful in choosing appropriate antibiotic therapy, interpreting varying drug levels, and assessing drug-drug interactions. Coagulase-negative staphylococci (63%) and *Staphylococcus*

aureus (20%) are commonly cultured from burn wounds. Methicillin-resistant *S aureus*, vancomycin-resistant *Enterococcus*, and *Pseudomonas aeruginosa* are also commonly cultured but usually later in the hospital course. *P aeruginosa* infections are associated with the highest mortality rate (33% vs 9% in nonpseudomonal infections), with aminoglycoside-resistant *Pseudomonas* infections particularly morbid. Routine use of blood culture in the severely burned population is indicated to elucidate systemic blood infections that do not manifest these clinical predictors of sepsis.

Wound Closure

The goal of therapy after fluid resuscitation is rapid and stable closure of the wound. Wounds that will not heal spontaneously in 7–10 days (ie, deep second-degree or third-degree burns) are best treated by excision and autograft; otherwise, granulation and infection may develop, and the quality of the skin in regenerated deep partial thickness burns is marginal because of the very thin dermis that emerges.

Cultured allogeneic keratinocyte grafts can provide rapid early coverage for superficial burn injuries. With severe burns, skin substitution with such cultured grafts can be lifesaving. However, although the replaced dermis does have nearly normal histologic dermal elements, there are no adnexal structures present and very few, if any, elastic fibers. Intraoperative use of topical fibrin sealants may reduce blood loss, improve cosmetic results, and improve postoperative graft adherence.

PATIENT SUPPORT

Burn patients require extensive support. An attempt must be made to maintain normal core body temperature (by maintaining environmental temperature at or above 30 °C) in patients with burns over more than 20% of total body surface area, since the hypermetabolic state of burns is exacerbated by subnormal temperatures. Respiratory injury, sepsis, and multiorgan failure are common. Enteral feedings may be started once the ileus of the resuscitation period has resolved, usually the day after the injury. There is often a markedly increased metabolic rate after burn injury, due in large part to whole body synthesis and increased fatty acid substrate cycles. If the patient does not tolerate low-residue tube feedings, total parenteral nutrition should be started without delay through a central venous catheter. Contrary to conventional teachings, data indicate that most patients can be fed adequately with energy equal to 100% to 120% of estimated basal energy expenditure (BEE). A useful guide is to provide 25 kcal/kg body weight plus 40 kcal per percent of burn surface area. Early aggressive enteral nutrition reduces infections, noninfectious complications, length of hospital stay, impaired healing, and mortality. Anticatabolic treatments such as β -blockade, growth hormone, insulin, oxandrolone, and synthetic testosterone have been advocated. Melatonin, which appears to possess multifaceted antioxidant properties, may reduce proinflammatory cytokines and have beneficial chronobiotic effects in severely burned patients.

Careful control of the postinjury blood glucose has been associated with improved hepatic function and

better survival after severe burns. Occasionally, ARDS or respiratory failure unresponsive to maximal ventilatory support may develop in burn patients. In addition, the incidence of venous thromboembolism in the lower extremities is high among burn patients. Duplex ultrasonography is the best method for identifying venous thromboembolism.

Prevention of long-term scars remains a formidable problem in seriously burned patients. The V-beam pulsed dye laser and intense pulsed light are emerging as adjunctive treatments to the usual regimen of corticosteroid injections, silicone patches, compression, and scar revision. Permanent sequelae can be avoided by prevention of infection, early aggressive rehabilitation, compressive garments, and early psychological support. Facial transplantation has become a controversial but potential treatment for those patients with devastating unreconstructable facial burns.

Complex microsurgical reconstructions, including prefabricated reconstructive flaps, now benefit severely burned patients with injuries to neck, hand, and arm.

ELECTRICAL INJURY

ESSENTIALS OF DIAGNOSIS

- ▶ Extent of injury is determined by the type, amount, duration, and pathway of electrical current.
- ▶ Resuscitation must be attempted on an electrical injury victim before assuming the patient is dead; clinical findings are unreliable.
- ▶ Skin findings may be misleading, and not indicative of the degree of deeper injury.

▶ General Considerations

Electricity-induced injury occurs by exposure to electrical current of low voltage, high voltage, or lightning. Direct current (DC) is unidirectional electrical flow. It is more likely to cause a single intense muscle contraction and asystole. Alternating current (AC) is bidirectional electrical flow that reverses direction in a sine wave pattern. This may cause muscle tetany, which prolongs the duration and amount of current exposure. If AC current passes through the thoracic area, it may lead to respiratory arrest or ventricular fibrillation. Low voltage is less than 1000 volts, and high voltage is more than 1000 volts. High voltage is most often related to occupational exposure and associated with higher morbidity and mortality. Fatal injury and significant damage may also occur with exposure to low voltage of household AC current. Lightning differs from high-voltage electrical shock in that lightning is massive high voltage (millions of volts) lasting a very brief duration (a small fraction of a second).

Electricity causes damage by various means: direct tissue damage, muscle tetany, direct thermal injury and coagulation necrosis, and trauma from associated falls or violent muscle contractions. The degree of injury depends on the following factors: current type, voltage, and pathway; duration of exposure; tissue resistance; associated trauma; and comorbidities. Tissue resistance varies through the body. Nerve cells are the most vulnerable and bone is the most resistant to electrical current. Skin resistance depends on thickness and condition of skin.

▶ Clinical Findings

The type and degree of injury is highly dependent on the current pathway. Symptoms and signs may range from tingling, superficial skin burns, and myalgias to paralysis, massive tissue damage, or death. Skin damage does not correlate with the degree of injury. Not all electrical injuries

cause skin damage; only very minor skin damage may be present with massive internal injuries. Electrical burns are of three distinct types: flash (arcing) burns, flame (clothing) burns, and the direct heating effect of tissues by the electrical current. The latter lesions are usually sharply demarcated, round or oval, painless yellow-brown areas (Joule burn) with inflammatory reaction. Significant subcutaneous damage can be accompanied by little skin injury, particularly with larger skin surface area electrical contact.

A victim of electrical current injury may appear dead due to dysrhythmia, respiratory arrest, or autonomic dysfunction resulting in pupils that are fixed, dilated, or asymmetric. Resuscitation must be initiated on all victims of electrical injury since clinical findings are deceptive.

► Complications

Complications include seizures, paralysis, headache, dysrhythmias, pneumothorax, tissue edema and necrosis, compartment syndrome, fractures from falls or muscle contractions, rhabdomyolysis, acute kidney injury, hypovolemia from third spacing, ruptured ear drums, and acute or delayed cataract formation.

► Treatment

A. Emergency Measures

The victim must be separated from the electrical current prior to initiation of CPR or other treatment. The rescuer must be protected. Turn off the power, or separate the victim using nonconductive implements such as dry clothing. Resuscitation must then be initiated since clinical findings of death are unreliable.

B. Hospital Measures

The initial assessment involves airway, breathing, and circulation followed by trauma protocol. Fluid resuscitation is important to maintain adequate urinary output (0.5 mL/kg/h if no myoglobinuria is present, 1.0 mL/kg/h if myoglobinuria is present). Initial evaluation includes cardiac monitoring and ECG, complete blood count, electrolytes, renal function tests, liver biochemical tests, urinalysis, urine myoglobin, serum CK, and CK-MB. Victims must be evaluated for hidden injury (eg, ophthalmic, otologic, muscular, compartment syndromes), organ injury (myocardium, liver, kidney, pancreas), blunt trauma, dehydration, skin burns, hypertension, posttraumatic stress, acid-base disturbances, and neurologic damage.

► Prognosis

Prognosis depends on the degree and location of electrical injury, initial damage, and complications. Psychiatric support may be necessary following lightning or severe electroshock exposures.

► When to Refer

Fasciotomy may be needed for compartment syndrome. Research suggests some benefit from microvascular reconstruction.

► When to Admit

Indications for hospitalization include arrhythmia or ECG changes; high voltage exposure; large burn; neurologic, pulmonary, or cardiac symptoms; suspicion of significant deep tissue or organ damage; transthoracic current pathway; history of cardiac disease; and need for surgery.

RADIATION EXPOSURE

Radiation exposures occur from both nonionizing and ionizing radiation sources. Nonionizing radiation is low energy, resulting in injuries related to local thermal damage (ie, microwave and radiowave). Ionizing radiation is high energy, causing cellular disruption, DNA damage, and mutations. Ionizing radiation is either electromagnetic (ie, x-rays and gamma rays) or particulate, (ie, alpha or beta particles, neutrons, and protons).

Exposure to radiation may occur from environmental, occupational, medical care, accidental, or intentional (ie, terrorism) exposure. The extent of damage due to radiation exposure depends on the type, quantity, and duration of radiation exposure, the organs exposed, the degree of disruption to DNA, metabolic and cellular function, and the age and underlying condition of the victim.

In 2008, the International Commission on Radiological Protection (ICRP) issued new recommendations for radiologic protection, justification for radiation use, and optimization of protection, and application of dose limits. ICRP uses the term “tissue reaction” to describe the biologic effects of radiation exposure.

In **acute radiation exposure**, medical care includes close monitoring of the gastrointestinal, cutaneous, hematologic, and cerebrovascular symptoms and signs from initial exposure and over time. Radiation dose may be estimated by the timing of symptom onset and severity of symptoms, (particularly nausea and vomiting), decrease in absolute lymphocyte count over hours and days after exposure, and chromosomal abnormalities in circulating lymphocytes.

Radiation exposure results in early and delayed effects. Early effects involve damage of the rapidly dividing cells

(ie, the mucosa, skin, and bone marrow). Delayed effects include malignancy, reproduction abnormalities, liver, kidney, and central nervous system and immune system dysfunction. The short-term and long-term outcomes of Chernobyl, Hiroshima, and Nagasaki illustrate these various radiation effects.

IMMEDIATE & DELAYED EFFECTS OF RADIATION EXPOSURE ON NORMAL TISSUES

► Clinical Findings

A. Injury to Superficial Structures

Radiation exposure to the skin and mucous membranes may cause erythema, epilation, destruction of fingernails, or epidermolysis, and burns that appear similar to thermal burns usually have a slower onset and course. Chronic damage includes skin scarring, atrophy, telangiectasis, and xerostomia. Radiation effects on the eyes include cataracts, dry eye syndrome, and retinopathy.

B. Injury to Deep Structures

1. Hematopoietic system—Injury to the bone marrow may vary from transient decreases to complete destruction of blood elements. Lymphocytes are most sensitive, followed by polymorphonuclear leukocytes; erythrocytes are the least sensitive. Hematopoietic effects consisting of anemia, thrombocytopenia, and bone marrow suppression can occur 1–3 weeks after radiation exposures exceeding 100 cGy. Bone marrow failure is the main cause of death within the first few months following exposure.

2. Nervous system—The brain and spinal cord are much more sensitive than the peripheral nerves to the acute and delayed effects of radiation. Effects include neuropathy, myelopathy, and cerebral injury. Radiofrequency fields emitted by mobile telephones have been linked to the formation of benign and malignant brain tumors.

3. Cardiovascular system—Ionizing radiation damages the heart and coronary arteries. Smaller vessels (the capillaries and arterioles) are more susceptible to damage than larger blood vessels. Delayed effects from radiation include obliterative endarteritis; coronary artery disease; pericarditis with effusion; or constrictive pericarditis, which may occur months or years later. Myocarditis is less common.

4. Pulmonary system—High or repeated moderate doses of radiation may cause pneumonitis or pulmonary fibrosis, which is often delayed for weeks or months.

5. Gastrointestinal system—Mucositis and mucosal edema may occur within hours or days after exposure. Symptoms include odynophagia, anorexia, nausea, vomiting, dehydration, and weakness. High doses of radiation inhibit gastric secretion and cause inflammation and ulceration of the bowels. Hepatitis, liver dysfunction, and intestinal stenosis may occur as delayed effects.

6. Genitourinary and reproductive systems—Genitourinary radiation effects are dose-dependent, varying from transient decrease in fertility to permanent sterility, chromoso-

mal aberrations, fetal damage, or demise. Nephritis and kidney dysfunction may occur as immediate or delayed effects. In men, small single doses of radiation (200–300 cGy) cause temporary aspermatogenesis, and larger doses (600–800 cGy) may cause permanent sterility. In women, single doses of 200 cGy may cause temporary cessation of menses, and 500–800 cGy may cause permanent castration. Moderate to heavy irradiation of the embryo results in injury to the fetus (eg, mental retardation) or in embryonic death and spontaneous abortion. Microcephaly and other congenital abnormalities may occur in children exposed in utero, especially if the fetus was exposed during early pregnancy.

7. Endocrine system—The endocrine system is relatively resistant to low or moderate doses of radiation. Delayed effects of exposure include thyroid dysfunction.

C. Systemic Reaction (Radiation Sickness)

The basic mechanisms of radiation sickness are not known. Symptoms include anorexia, nausea, vomiting, weakness, exhaustion, lassitude and, in some cases prostration; these symptoms may occur singly or in combination. Dehydration, anemia, and infection may follow.

► Prevention

Persons handling radiation sources must minimize exposure to radiation by recognizing the importance of time, distance, and shielding. Occupational safety policies and procedures must be followed. This will reduce occupational risk of radiation exposure and improve the emergency response to accidental exposure.

► Accidental or Intentional Radiation Exposure

There is an increase in likelihood of accidental or intentional radiation exposure due to the increased use of radiation equipment, radioactive materials, and threat of nuclear terrorism. Prehospital and hospital disaster plans are required for optimal management of radiation exposure. The Radiation Assistance Center (1-865-576-1005) provides 24-hour access to expert information. The Centers for Disease Control and Prevention “Radiation Emergency” website (www.bt.cdc.gov/radiation/index.asp) is also helpful.

► Treatment

Treatment is focused on decontamination, symptomatic relief, supportive care, and psychosocial support. Specific treatment options focus on the dose, route, and effects of exposure. Options include administration of fluids and electrolytes, blood product transfusion, antimicrobials, prophylaxis against malignancy, blood stem cell transplantation, and bone marrow transplantation.

► Prognosis

Prognosis is determined by the radiation dose, duration, and frequency as well as by the underlying condition of the victim. Approximate dose of exposure correlates with the early onset and severity of symptoms (ie, nausea, vomiting, anorexia,

abdominal pain, bloody diarrhea, weight loss) and laboratory findings, particularly the decline in lymphocyte count on the complete blood count. Death is usually due to hematopoietic failure (ie, hemorrhage, anemia, and immunosuppression), gastrointestinal mucosal damage, central nervous system damage, widespread vascular injury, or secondary infection.

The International Agency for Research on Cancer (IARC) reviews the increasing evidence linking radiation exposure to increased cancer risk. Carcinogenesis is related to the total dose, duration, frequency of exposure and to the susceptibility of the victim. There are age-related sensitivities to radiation; prenatal and younger age victims are more susceptible to carcinogenesis.

▶ When to Admit

Most patients with significant ionizing radiation exposure require admission for close monitoring and care.

▶ Clinical manifestations are hypoxemia, pulmonary edema, and hypoventilation.

▶ General Considerations

Near drowning describes a submersion event leading to injury. Submersion injury may result in aspiration, laryngospasm, hypoxemia, and acidemia. Drowning describes submersion resulting in death. “Wet” drowning is due to aspiration of fluid or foreign material. “Dry” drowning is due to laryngospasm or airway obstruction. The primary effect is hypoxemia due to perfusion of poorly ventilated alveoli, intrapulmonary shunting, and decreased compliance.

Conditions that increase risk of submersion injury include the following: (1) use of alcohol or other drugs, (2) extreme fatigue, (3) poor physical health, (4) hyperventilation, (5) sudden acute illness (eg, hypoglycemia, seizure, dysrhythmia, myocardial infarction), (6) acute brain or spinal cord injury (or both), (7) venomous stings, bites, or injury in the water, and (8) decompression sickness.

A patient may be deceptively asymptomatic during the initial recovery period only to deteriorate or die as a result of acute respiratory failure within the following 12–24 hours.

▶ Clinical Findings

A. Symptoms and Signs

The patient’s appearance may vary from asymptomatic, to abnormal vital signs, anxiety, dyspnea, cough, wheezing, trismus, cyanosis, chest pain, dysrhythmia, hypotension, vomiting, diarrhea, headache, altered level of consciousness, neurologic deficit, and apnea. With cold water or prolonged submersion, hypothermia is likely.

B. Laboratory Findings

Arterial blood gas results are helpful in determining the degree of injury since initial clinical findings may appear benign. P_{aO_2} is usually decreased; P_{aCO_2} may be increased or decreased; pH is decreased. Bedside blood sugar must be checked rapidly. Other testing is based on clinical scenario and may include kidney function, electrolytes, urinalysis, blood count, lactate, cardiac markers, coagulation studies, and alcohol and toxicology levels. Metabolic acidosis is common.

▶ Prevention

Prevention is multi-faceted. Physical barriers (ie, fences) should be placed around pools and other accessible bodies of water. Safety flotation devices and rescue supplies must be immediately available. Use of alcohol or sedative drugs must be avoided during swimming, boating, or other water-based activities. There must be close supervision of those who cannot swim, and personal flotation devices must be worn when boating or water skiing. Swimming lessons, water safety, and basic life support education is necessary for anyone involved in water-based activities.

NEAR DROWNING

ESSENTIALS OF DIAGNOSIS

▶ The first requirement of rescue is immediate CPR.

► Treatment

A. First Aid

The first requirement of rescue is immediate basic life support (BLS) treatment and CPR. At the scene, immediate measures to combat hypoxemia are critical to improve outcome. BLS care includes sustained ventilation, oxygenation, and circulatory support. Hypothermia and cervical spine injury should always be suspected.

1. Standard BLS is initiated. CPR is provided if pulse and respirations are absent.
2. Rescuer should not attempt to drain water from the victim's lungs. The Heimlich maneuver (subdiaphragmatic pressure) should be used only if foreign material airway obstruction is suspected. The cervical spine must be immobilized if neck injury is possible.
3. Resuscitation and BLS efforts must be continued until core temperature reaches 32 °C even for seemingly "hopeless" patients. Complete recovery has been reported after prolonged resuscitation of hypothermic patients.

B. Subsequent Management

Careful inpatient monitoring of the patient's condition must occur for 24 hours following near drowning. This includes continuous monitoring of cardiorespiratory and neurologic function; maintenance of oxygenation, serial determination of arterial blood gases, pH, kidney function (serum creatinine), and electrolytes; and measurement of urinary output. Pulmonary edema may not appear for 24 hours.

1. Ensure optimal ventilation and oxygenation—The danger of hypoxemia exists even in the alert, conscious patient who appears to be breathing normally. Oxygen should be administered immediately at the highest available concentration. Oxygen saturation should be maintained at 90% or higher. Endotracheal intubation and mechanical ventilation are necessary for patients unable to maintain an open airway, adequate oxygenation, or ventilation. Nasogastric suctioning can decompress the stomach, aid in removal of swallowed water and reduce the risk of aspiration. Continuous positive airway pressure (CPAP) is an effective noninvasive way of reversing hypoxia and hypercarbia in patients with spontaneous respirations and a patent airway. Positive end-expiratory pressure (PEEP) is also effective for treating respiratory insufficiency. Serial physical examinations and chest radiographs should be carried out to detect possible pneumonitis, atelectasis, and pulmonary edema. Bronchodilators may be used to treat wheezing and bronchospasms due to aspiration. Antibiotics are reserved for clinical evidence of infection and should not be given prophylactically.

2. Cardiovascular support—Intravascular volume status must be monitored to determine whether vascular fluid replacement and pressors or diuretics are needed. Standard therapy for hypotension and pulmonary edema is administered.

3. Correction of blood pH and electrolyte abnormalities—Metabolic acidosis is present in 70% of near-drowning victims, but it is usually corrected through adequate

ventilation and oxygenation. Glycemic control improves outcome.

4. Cerebral injury—Central nervous system damage may progress despite apparently adequate treatment of hypoxia and shock. Standard treatment for brain and spinal cord injury must be followed.

5. Hypothermia—Core temperature should be measured and managed as appropriate (see Systemic Hypothermia, above).

► Course & Prognosis

Victims of near drowning who have had prolonged hypoxemia should remain under close hospital observation for 2–3 days after all supportive measures have been withdrawn and clinical and laboratory findings have been stable. Long-term complications of near drowning may include neurologic impairment, seizure disorder, and pulmonary or cardiac damage.

DISORDERS DUE TO ENVIRONMENTAL FACTORS

DYSBARISM & DECOMPRESSION SICKNESS

ESSENTIALS OF DIAGNOSIS

- Symptoms temporally related to recent diving, altitude or pressure changes.
- Early recognition and prompt treatment of decompression sickness are extremely important.
- Consultation with diving medicine or hyperbaric oxygen specialist is indicated.

► General Considerations

Dysbarism and decompression sickness (DCS) are physiologic problems that result from environmental pressure effects in gases in the body during underwater descent and ascent. These are hazards for fliers and for divers who are involved in recreational diving (eg, scuba diving), deep-water exploration, rescue or salvage operations, or construction. These may also occur in an air traveler when the aircraft cabin is not adequately pressurized during rapid ascent or descent between sea level and high altitudes.

Physics laws describe the mechanisms involved in dysbarism and DCS. As a diver descends, the gases in the body compress; gases dissolve in blood and tissues. During the ascent, gases in the body expand. If the ascent is too rapid, gas bubbles will form and cause damage depending on their

location. DCS symptoms depends on the size and number and location of gas bubbles released (notably nitrogen).

Risk of DCS depends on the dive details (depth, duration, number of dives, and interval surface time between dives, water conditions) as well as the diver's age, weight, physical condition, physical exertion, and the rate of ascent. Predisposing factors for DCS include obesity, injury, hypoxia, lung or cardiac disease, right to left cardiac shunt, diver's overall health, dehydration, alcohol and medication effects, and panic attacks. DCS also occurs in those who take hot showers after cold dives, or take air travel too soon.

► Clinical Findings

The range of clinical manifestations varies depending on the location of the gas bubble formation or the compressibility of gases in the body. Symptom onset may be immediate, within minutes or hours (in the majority), or present up to 36 hours later. DCS symptoms include pain in the joints ("the bends"); skin pruritus or burning (skin bends); rashes; spinal cord or cerebral symptoms ("dissociation" symptoms that do not follow typical distribution patterns); labyrinthine DCS ("the staggers," central vertigo); pulmonary DCS ("the chokes," inspiratory pain, cough, and respiratory distress); arterial gas embolism (cerebral, pulmonary); barotrauma of the lungs, ear and sinus; dysbaric osteonecrosis; and coma.

► Treatment

Early recognition and prompt treatment are extremely important. DCS must be considered if symptoms are temporally related to recent diving or altitude or pressure changes. Immediate consultation with diving medicine or hyperbaric oxygen specialist is indicated even if mild symptoms resolved, since relapses with worse outcomes have occurred. Continuous administration of 100% oxygen is indicated and beneficial for all patients. Aspirin may be given for pain. Opioids should be used very cautiously, since these may obscure the response to recompression. Rapid transportation to a hyperbaric treatment facility for recompression is imperative for DCS. If air transportation is chosen, the aircraft must maintain pressurization near sea level to avoid worsening DCS. The clinician should be familiar with the nearest hyperbaric facility. The Divers Alert Network (DAN) is an excellent worldwide resource for emergency advice 24 hours daily for the management of diving-related conditions (www.diversalertnetwork.org, DAN USA 1-919-684-8111, see website for other international phone numbers).

ALTITUDE-RELATED ILLNESS

ESSENTIALS OF DIAGNOSIS

- The severity of the altitude illness correlates with the rate and height of ascent, and the individual's susceptibility.
- Prompt recognition and medical attention of early symptoms of altitude illness should prevent progression.

► General Considerations

High altitude medical problems are due to hypobaric hypoxia at high altitudes (greater than 2000 meters or 6560 feet). This usually results from increased physical activity with insufficient acclimatization, inadequate education and preparation, and individual susceptibility (preexisting medical conditions and medication use). Individual susceptibility is a key determinant of the risk of high altitude illness.

The severity of the altitude-related illness correlates with the rapid rate and height of ascent and the individual's susceptibility. High altitude illness comprises a spectrum of conditions based on end-organ effects. Manifestations of altitude illness are: (1) acute mountain sickness (AMS), (2) high-altitude pulmonary edema (HAPE), (3) high-altitude cerebral edema (HACE), (4) subacute mountain sickness, and (5) chronic mountain sickness (Monge disease).

Preventive measures include participant education, medical prescreening, pre-trip planning, and optimal physical conditioning before travel; adequate rest and sleep the day before travel; reduced food intake; and avoidance of alcohol, tobacco, and unnecessary physical activity during travel; slow ascent to allow acclimatization; and a period of rest and inactivity for 1-2 days after arrival at high altitudes. Prophylactic medications may be prescribed if no contraindications exist. Acetazolamide, 250 mg orally every 8-12 hours, may be started on the day before ascent and continued for 48-72 hours at high altitude. Dexamethasone, 4 mg orally every 12 hours beginning on the day of ascent, continuing for 3 days at the higher altitude, and then tapering over 5 days, is an alternative.

1. Acute Mountain Sickness (AMS)

Initial manifestations of AMS include headache (most severe and persistent symptom), lassitude, drowsiness, dizziness, chilliness, nausea and vomiting, facial pallor, dyspnea, and cyanosis. Later symptoms include facial flushing, irritability, difficulty concentrating, vertigo, tinnitus, visual and auditory disturbances, anorexia, insomnia, increased dyspnea and weakness on exertion, increased headaches (due to cerebral edema), palpitations, tachycardia, Cheyne-Stokes breathing, and weight loss. More severe manifesta-

tions include pulmonary and cerebral edema (HAPE and HACE; see below).

Initial treatment involves oxygen administration, voluntary periodic hyperventilation, which will often relieve acute symptoms. If immediate descent is not possible, portable hyperbaric chambers can provide symptomatic relief.

Acetazolamide (250 mg orally every 8–12 hours) remains the most effective medication for treatment of AMS and for more severe forms of altitude-related conditions. Dexamethasone (8 mg orally initially followed by 4 mg every 6 hours) is effective for treatment of AMS and acute cerebral edema. Both are recommended therapy for as long as symptoms persist and may be used together in severe cases. In most individuals, symptoms clear within 24–48 hours.

Definitive treatment is immediate descent. Descent is essential if the symptoms are persistent, severe, or worsening or if HAPE or HACE are present.

2. Acute High-Altitude Pulmonary Edema (HAPE)

HAPE is a serious complication and the leading cause of death from altitude illness. The hallmark is markedly elevated pulmonary artery pressure followed by pulmonary edema. It usually occurs at levels above 3000 meters (9840 feet). Early symptoms may appear within 6–36 hours after arrival at a high-altitude area. These include incessant dry cough, shortness of breath disproportionate to exertion, headache, decreased exercise performance, fatigue, dyspnea at rest, and chest tightness. Recognition of the early symptoms may enable the patient to descend before incapacitating pulmonary edema develops. Strenuous exertion should be avoided. An early descent of even 500 or 1000 meters may result in improvement of symptoms. Later, wheezing, orthopnea, and hemoptysis may occur as pulmonary edema worsens. Physical findings include tachycardia, mild fever, tachypnea, cyanosis, prolonged respiration, and rales and rhonchi. The clinical picture may resemble severe pneumonia. The patient may become confused or comatose. Diagnosis is usually clinical; ancillary tests are nonspecific or unavailable on site.

Treatment must often be initiated under field conditions. Prompt recognition and medical attention of early symptoms prevent progression. The patient must rest in the semi-Fowler position (head raised), and 100% oxygen must be administered. *Immediate descent (at least 610 meters [2000 feet]) is essential.* Recompression in a portable hyperbaric bag will temporarily reduce symptoms if rapid or immediate descent is not possible. To conserve oxygen, lower flow rates (2–4 L/min) may be used until the victim recovers or is evacuated to a lower altitude and $\text{SaO}_2 \geq 90\%$. Treatment for ARDS (see Chapter 9) may be required for some patients. Calcium channel blockers and selective phosphodiesterase type 5 (PDE5) inhibitors are effective for symptomatic relief. Nifedipine, 10 mg initially followed by 30 mg slow-release tablets every 12 hours is recommended. Dexamethasone, 4 mg every 6 hours, has been recommended if central nervous system symptoms are present. Acetazolamide, 250 mg every 8–12 hours, should be administered if AMS is suspected.

3. Acute High-Altitude Cerebral Edema (HACE)

HACE appears to be an extension of the central nervous system symptoms of AMS and results from cerebral vasogenic edema and hypoxia. It usually occurs at elevations above 2500 meters (8250 feet) and is more common in unacclimatized individuals. Hallmarks are altered consciousness and ataxic gait. Severe headaches, confusion, truncal ataxia, urinary retention or incontinence, focal deficits, papilledema, nausea, vomiting, and seizures may also occur and progress to obtundation and coma.

Treatment is immediate descent for at least 610 meters (2000 feet), continuing until symptoms improve. Oxygen (100% 2–4 L/min) should be administered by mask. Dexamethasone, 4–8 mg orally every 6 hours, is recommended thereafter. If immediate descent is impossible, a portable hyperbaric chamber should be used until symptomatic improvement occurs.

4. Subacute Mountain Sickness

This occurs most frequently in unacclimatized individuals and at altitudes above 4500 meters (14,764 feet). Symptoms of dyspnea and cough are probably due to hypoxic pulmonary hypertension and secondary congestive heart failure. Dehydration, skin dryness, and pruritus also can occur. Treatment consists of rest, oxygen administration, diuretics, and return to lower altitudes.

5. Chronic Mountain Sickness (Monge Disease)

This uncommon condition is seen in residents of high-altitude communities who have lost their acclimatization to such an environment. The disorder is characterized by somnolence, mental depression, cyanosis, clubbing of fingers, chronic hypoxia, hemoglobin > 22 g/dL, polycythemia (hematocrit often $> 75\%$), signs of right ventricular failure, ECG evidence of right axis deviation and right atrial and ventricular hypertrophy, and radiographic evidence of right heart enlargement and central pulmonary vessel prominence, and pulmonary hypertension in some cases. There is no radiographic evidence of structural pulmonary disease. Pulmonary function tests usually disclose alveolar hypoventilation and elevated PaCO_2 but fail to reveal defective oxygen transport. There is a diminished respiratory response to CO_2 .

Almost complete disappearance of all abnormalities eventually occurs when the patient returns to sea level. Recommended treatments include phlebotomy, oxygen supplementation, respiratory training, medroxyprogesterone (20–60 mg/d orally for 10 weeks), acetazolamide (250 mg/d orally for 3 weeks) and enalapril (5 mg orally daily).

▶ When to Admit

- All patients with HAPE or HACE should be hospitalized for further observation.
- Hospitalization should also be considered for any patient who remains symptomatic after treatment and

descent. Pulmonary symptoms and hypoxia may be worsened by pulmonary embolism, bacterial pneumonia, or bronchitis.

SAFETY OF AIR TRAVEL & SELECTION OF PATIENTS FOR AIR TRAVEL

The medical safety of air travel depends not only on the nature and severity of the traveler's condition but also on other factors such as the duration and frequency of traveler's air travel, cabin pressurization, availability of medical supplies, presence of health care professionals on board, and traveler's preflight condition. Air travel passengers are susceptible to a wide range of problems: pulmonary (eg, thromboembolism), cardiovascular, gastrointestinal, ocular, immunologic, syncope, neuropsychiatric, metabolic, and substance related. Occupational and frequent flyers are at risk for these as well as radiation, infection, circadian disturbance, and pressurization problems.

Hypobaric hypoxia is the underlying etiology of most serious medical emergencies in flight. Despite commercial aircraft pressurization requirements, there is significant hypoxemia, dyspnea, and stress in travelers with underlying serious cardiopulmonary and other conditions.

Research also demonstrates an association between venous thrombosis and air travel. The risk of severe pulmonary embolism occurring after air travel increases proportionally with the flight duration. Travelers can take preventive measures by wearing support hose and engaging in in-flight leg exercises and walking. Air travel complications may be reduced by the following preventive measures: passenger education, passenger prescreening (especially those who have had recent surgery or an emergency condition, and those with chronic serious medical conditions). Travelers with pulmonary disease must have preflight medical assessment to determine whether supplemental oxygen is required. This is determined by an arterial oxygen tension of less than 70 mm Hg or pulse oximetry less than 92%.

The Air Transport Association of America defines an incapacitated passenger as "one who is suffering from a physical or mental disability and who, because of such disability or the effect of the flight on the disability, is incapable of self-care; would endanger the health or safety of such person or other passengers or airline employees; or would cause discomfort or annoyance of other passengers." Air travel is not advised for anyone with an active pneumothorax, class III and IV pulmonary hypertension, acute worsening of an underlying lung disease, or any unstable conditions. Unstable conditions include poorly controlled hypertension, dysrhythmias, angina, valvular disease, congestive heart failure, or psychiatric condition; severe anemia or sickle cell disease; recent myocardial infarction, cerebrovascular accident, or deep venous thrombosis; postsurgery, especially heart surgery (unless approved by surgeon); and any active communicable disease (tuberculosis, measles, chickenpox, or other communicable virulent infections). Small meals of easily digested food and avoidance of carbonated beverages before and during the flight may reduce the tendency to nausea and vomiting.

Pregnancy and Infancy

Pregnant women may be permitted to fly during the first 8 months of pregnancy unless there is a history of pregnancy complications or premature birth. Infants less than 1 week old should not be flown at high altitudes or for long distances.

Poisoning

Kent R. Olson, MD

INITIAL EVALUATION: POISONING OR OVERDOSE

Patients with drug overdoses or poisoning may initially have no symptoms or they may have varying degrees of overt intoxication. The asymptomatic patient may have been exposed to or may have ingested a lethal dose of a poison but not yet exhibit any manifestations of toxicity. It is important to: (1) quickly assess the potential danger, (2) consider gut decontamination to prevent absorption, and (3) observe the patient for an appropriate interval.

▶ Assess the Danger

If the drug or poison is known, its danger can be assessed by consulting a text or computerized information resource (eg, Poisindex) or by calling a regional poison control center. (In the United States, dialing 800-222-1222 will direct the call to the regional poison control center.) Assessment will usually take into account the dose ingested; the time interval since ingestion; the presence of any symptoms or clinical signs; preexisting cardiac, respiratory, kidney, or liver disease; and, occasionally, specific serum drug or toxin levels. Be aware that the history given by the patient or family may be incomplete or unreliable.

The manufacturer or its local representative may be able to provide information over the phone concerning the toxic ingredients in question and can be contacted directly or via the regional poison control center.

▶ Gut Decontamination

The choice of gut decontamination procedure depends on the toxin and the circumstances. (See below for a more detailed discussion of methods.)

IMMEDIATE 24-HOUR TOXICOLOGY CONSULTATION

Call your regional poison control center
U.S. toll-free 1-800-222-1222

▶ Observation of the Patient

Asymptomatic or mildly symptomatic patients should be observed for at least 4–6 hours. Longer observation is indicated if the ingested substance is a sustained-release preparation or is known to slow gastrointestinal motility or if there may have been exposure to a poison with delayed onset of symptoms (such as acetaminophen, colchicine, or hepatotoxic mushrooms). After that time, the patient may be discharged if no symptoms have developed and adequate gastric decontamination has been provided. Before discharge, psychiatric evaluation should be performed to assess suicidal risk. Intentional ingestions in adolescents should raise the possibility of unwanted pregnancy or sexual abuse.

THE SYMPTOMATIC PATIENT

In symptomatic patients, treatment of life-threatening complications takes precedence over in-depth diagnostic evaluation. Patients with mild symptoms may deteriorate rapidly, which is why all potentially significant exposures should be observed in an acute care facility. The following complications may occur, depending on the type of poisoning.

COMA

▶ Assessment & Complications

Coma is commonly associated with ingestion of large doses of antihistamines, benzodiazepines and other sedative-hypnotic drugs, γ -hydroxybutyrate (GHB), ethanol, opioids, antipsychotic drugs, or antidepressants. The most common cause of death in comatose patients is respiratory failure, which may occur abruptly. Pulmonary aspiration of gastric contents may also occur, especially in victims who are deeply obtunded or convulsing. Hypoxia and hypoventilation may cause or aggravate hypotension, arrhythmias, and seizures. Thus, protection of the airway and assisted ventilation are the most important treatment measures for any poisoned patient.

► Treatment

A. Emergency Management

The initial emergency management of coma can be remembered by the mnemonic *ABCD*, for *Airway, Breathing, Circulation, and Drugs* (dextrose, thiamine, and naloxone or flumazenil), respectively.

1. Airway—Establish a patent airway by positioning, suction, or insertion of an artificial nasal or oropharyngeal airway. If the patient is deeply comatose or if there is no gag or cough reflex, perform endotracheal intubation. These airway interventions may not be necessary if the patient is intoxicated by an opioid or a benzodiazepine and responds rapidly to intravenous naloxone or flumazenil (see below).

2. Breathing—Clinically assess the quality and depth of respiration, and provide assistance if necessary with a bag-valve-mask device or mechanical ventilator. Provide supplemental oxygen. The arterial blood CO₂ tension is useful in determining the adequacy of ventilation. The arterial blood PO₂ determination may reveal hypoxemia, which may be caused by respiratory arrest, bronchospasm, pulmonary aspiration, or noncardiogenic pulmonary edema. Pulse oximetry provides an assessment of oxygenation but is not reliable in patients with methemoglobinemia or carbon monoxide poisoning, unless a newer oximetry device capable of detecting these forms of hemoglobin is used (eg, the Masimo Rad-57 pulse CO-oximeter).

3. Circulation—Measure the pulse and blood pressure and estimate tissue perfusion (eg, by measurement of urinary output, skin signs, arterial blood pH). Place the patient on continuous ECG monitoring. Insert an intravenous line, and draw blood for glucose, electrolytes, serum creatinine and liver tests, and possible quantitative toxicologic testing.

4. Drugs

A. DEXTROSE AND THIAMINE—Unless promptly treated, severe hypoglycemia can cause irreversible brain damage. Therefore, in all comatose or convulsing patients, give 50% dextrose, 50–100 mL by intravenous bolus, unless a rapid bedside blood sugar test is available and rules out hypoglycemia. In alcoholic or very malnourished patients who may have marginal thiamine stores, give thiamine, 100 mg intramuscularly or over 2–3 minutes intravenously.

B. NARCOTIC ANTAGONISTS—Naloxone, 0.4–2 mg intravenously, may reverse opioid-induced respiratory depression and coma. It is often given empirically to any comatose patient with depressed respirations. If opioid overdose is strongly suspected, give additional doses of naloxone (up to 5–10 mg may be required to reverse the effects of potent opioids or propoxyphene). **Note:** Naloxone has a much shorter duration of action (2–3 hours) than most common opioids; repeated doses may be required, and continuous observation for at least 3–4 hours after the last dose is mandatory. Nalmefene, a newer opioid antagonist, has a duration of effect longer than that of naloxone but still shorter than that of the opioid methadone.

C. FLUMAZENIL—Flumazenil, 0.2–0.5 mg intravenously, repeated every 30 seconds as needed up to a maximum of 3 mg, may reverse benzodiazepine-induced coma. **Caution:** Flumazenil should **not** be given if the patient has coingested a tricyclic antidepressant, is a user of high-dose benzodiazepines, or has a seizure disorder because its use in these circumstances may precipitate seizures. *In most circumstances, use of flumazenil is not advised as the potential risks outweigh its benefits.* **Note:** Flumazenil has a short duration of effect (2–3 hours), and resedation requiring additional doses is common.

HYPOTHERMIA

► Assessment & Complications

Hypothermia commonly accompanies coma due to opioids, ethanol, hypoglycemic agents, phenothiazines, barbiturates, benzodiazepines, and other sedative-hypnotics and central nervous system depressants. Hypothermic patients may have a barely perceptible pulse and blood pressure. Hypothermia may cause or aggravate hypotension, which will not reverse until the temperature is normalized.

► Treatment

Treatment of hypothermia is discussed in Chapter 37. Gradual rewarming is preferred unless the patient is in cardiac arrest.

HYPOTENSION

► Assessment & Complications

Hypotension may be due to poisoning by many different drugs and poisons, including antihypertensive drugs, β -blockers, calcium channel blockers, disulfiram (ethanol interaction), iron, trazodone, quetiapine, and other antipsychotic agents and antidepressants. Poisons causing hypotension include cyanide, carbon monoxide, hydrogen sulfide, arsenic, and certain mushrooms.

Hypotension in the poisoned or drug-overdosed patient may be caused by venous or arteriolar vasodilation, hypovolemia, depressed cardiac contractility, or a combination of these effects. The only certain way to determine the cause of hypotension in any individual patient is to insert a pulmonary artery catheter and calculate the cardiac output and peripheral vascular resistance. Alternatively, a central venous pressure (CVP) monitor may indicate a need for further fluid therapy.

► Treatment

Most patients respond to empiric treatment with repeated 200 mL intravenous boluses of 0.9% saline or other isotonic crystalloid up to a total of 1–2 L; much larger amounts may be needed if the victim is profoundly volume depleted. If fluid therapy is not successful, give dopamine, 5–15 mcg/kg/min by intravenous infusion. Consider pulmonary artery catheterization if hypotension persists.

Hypotension caused by certain toxins may respond to specific treatment. For hypotension caused by overdoses of

tricyclic antidepressants or related drugs, administer sodium bicarbonate, 50–100 mEq by intravenous bolus injection. Norepinephrine 4–8 mcg/min by intravenous infusion is more effective than dopamine in some patients with overdoses of tricyclic antidepressants or of drugs with predominantly vasodilating effects. For β -blocker overdose, glucagon (5–10 mg intravenously) may be of value. For calcium channel blocker overdose, administer calcium chloride, 1–2 g intravenously (repeated doses may be necessary; doses of 5–10 g and more have been given in some cases). High-dose insulin euglycemic therapy may also be used (see Calcium Channel Blockers, below). Intralipid 20% lipid emulsion has been reported to improve hemodynamics in human case reports or animal studies of intoxication by highly lipid-soluble drugs such as bupivacaine, bupropion, clomipramine, and verapamil.

Sirianni AJ et al. Use of lipid emulsion in the resuscitation of a patient with prolonged cardiovascular collapse after overdose of bupropion and lamotrigine. *Ann Emerg Med.* 2008 Apr;51(4):412–5. [PMID: 1776009]

HYPERTENSION

► Assessment & Complications

Hypertension may be due to poisoning with amphetamines, anticholinergics, cocaine, yohimbine-containing performance-enhancing products, monoamine oxidase (MAO) inhibitors, and other drugs.

Severe hypertension (eg, diastolic blood pressure > 105–110 mm Hg in a person who does not have chronic hypertension) can result in acute intracranial hemorrhage, myocardial infarction, or aortic dissection.

► Treatment

Treat hypertension if the patient is symptomatic or if the diastolic pressure is greater than 105–110 mm Hg—especially if there is no prior history of hypertension.

Hypertensive patients who are agitated or anxious may benefit from a sedative such as lorazepam, 2–3 mg intravenously. For persistent hypertension, administer phentolamine, 2–5 mg intravenously, or nitroprusside sodium, 0.25–8 mcg/kg/min intravenously. If excessive tachycardia is present, add propranolol, 1–5 mg intravenously, or esmolol, 25–100 mcg/kg/min intravenously, or labetalol 0.2–0.3 mg/kg intravenously. **Caution:** Do not give β -blockers alone, since doing so may paradoxically worsen hypertension as a result of unopposed α -adrenergic stimulation.

Wang NE et al. Hypertensive crisis and NSTEMI after accidental overdose of sustained release pseudoephedrine: a case report. *Clin Toxicol (Phila).* 2008 Nov;46(9):922–3. [PMID: 18608273]

ARRHYTHMIAS

► Assessment & Complications

Arrhythmias may occur with a variety of drugs or toxins (Table 38–1). They may also occur as a result of hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyperkale-

Table 38–1. Common toxins or drugs causing arrhythmias.¹

| Arrhythmia | Common Causes |
|---|---|
| Sinus bradycardia | β -Blockers, calcium channel blockers, clonidine, digitalis glycosides, organophosphates |
| Atrioventricular block | β -Blockers, calcium channel blockers, class Ia antiarrhythmics (including quinidine), carbamazepine, clonidine, digitalis glycosides, lithium |
| Sinus tachycardia | β -Agonists (eg, albuterol), amphetamines, anticholinergics, antihistamines, caffeine, cocaine, pseudoephedrine, tricyclic and other antidepressants |
| Wide QRS complex | Class Ia and class Ic antiarrhythmics, phenothiazines (eg, thioridazine), potassium (hyperkalemia), propranolol, tricyclic antidepressants, diphenhydramine (severe overdose) |
| QT interval prolongation and torsades de pointes | Arsenic, class Ia and class III antiarrhythmics, droperidol, lithium, methadone, pentamidine, sotalol, thioridazine, venlafaxine, and many other drugs (see http://www.azcert.org/medical-pros/drug-lists/drug-lists.cfm) |
| Ventricular premature beats and ventricular tachycardia | Amphetamines, cocaine, ephedrine, caffeine, chlorinated or fluorinated hydrocarbons, digoxin, aconite (found in some Chinese herbal preparations), fluoride, theophylline. QT prolongation can lead to atypical ventricular tachycardia (torsades de pointes) |

¹Arrhythmias may also occur as a result of hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyperkalemia or hypokalemia, hypocalcemia).

mia, hypokalemia, hypomagnesemia or hypocalcemia), or following exposure to chlorinated solvents or chloral hydrate overdose. Atypical ventricular tachycardia (torsades de pointes) is often associated with drugs that prolong the QT interval.

► Treatment

Arrhythmias are often caused by hypoxia or electrolyte imbalance, and these conditions should be sought and treated. If ventricular arrhythmias persist, administer lidocaine or amiodarone at usual antiarrhythmic doses. **Note:** Wide QRS complex tachycardia in the setting of tricyclic antidepressant overdose (or quinidine and other class Ia drugs) should be treated with sodium bicarbonate, 50–100 mEq intravenously by bolus injection. (See discussion of tricyclic antidepressant poisoning.) **Caution:** Avoid class Ia agents (quinidine, procainamide, disopyramide), which may aggravate arrhythmias caused by tricyclic antidepressants. Torsades de pointes associated with prolonged QT interval may respond to intravenous magnesium (2 g intravenously over 2 minutes) or overdrive pacing. Treat digitalis-induced arrhythmias with digoxin-specific antibodies (see discussion of cardiac glycoside poisoning).

For tachyarrhythmias induced by chlorinated solvents, chloral hydrate, Freons, or sympathomimetic agents, use propranolol or esmolol (see doses given above in Hypertension section).

Tarabar AF et al. Citalopram overdose: late presentation of torsades de pointes (TdP) with cardiac arrest. *J Med Toxicol.* 2008 Jun;4(2):101–5. [PMID: 18570170]

SEIZURES

▶ Assessment & Complications

Seizures may be due to poisoning with many poisons and drugs, including amphetamines, antidepressants (especially tricyclic antidepressants, bupropion, and venlafaxine), antihistamines (especially diphenhydramine), antipsychotics, cocaine, isoniazid (INH), and theophylline.

Seizures may also be caused by hypoxia, hypoglycemia, hypocalcemia, hyponatremia, withdrawal from alcohol or sedative-hypnotics, head trauma, central nervous system infection, or idiopathic epilepsy.

Prolonged or repeated seizures may lead to hypoxia, metabolic acidosis, hyperthermia, and rhabdomyolysis.

▶ Treatment

Administer lorazepam, 2–3 mg, or diazepam, 5–10 mg, intravenously over 1–2 minutes, or—if intravenous access is not immediately available—midazolam, 5–10 mg intramuscularly. If convulsions continue, administer phenobarbital, 15–20 mg/kg slowly intravenously over no less than 30 minutes; or phenytoin, 15 mg/kg intravenously over no less than 30 minutes (maximum infusion rate, 50 mg/min). For drug-induced seizures, phenobarbital is generally preferred over phenytoin. Propofol infusion has also been reported effective for some resistant drug-induced seizures.

Seizures due to a few drugs and toxins may require antidotes or other specific therapies (as listed in Table 38–2).

Thundiyil JG et al. Evolving epidemiology of drug-induced seizures reported to a Poison Control Center System. *J Med Toxicol.* 2007 Mar;3(1):15–9. [PMID: 18072153]

HYPERTHERMIA

▶ Assessment & Complications

Hyperthermia may be associated with poisoning by amphetamines (especially methylenedioxymethamphetamine [MDMA; “Ecstasy”]), atropine and other anticholinergic drugs, cocaine, salicylates, strychnine, tricyclic antidepressants, and various other medications. Overdoses of serotonin reuptake inhibitors (eg, fluoxetine, paroxetine, sertraline) or their use in a patient taking an MAO inhibitor may cause agitation, hyperactivity, myoclonus, and hyperthermia (“serotonin syndrome”). Antipsychotic agents can cause rigidity and hyperthermia (neuroleptic malignant syndrome [NMS]). (See section on schizophrenia and other psychotic disorders in Chapter 25.) Malignant hyperthermia is a rare disorder associated with general anesthetic agents.

Hyperthermia is a rapidly life-threatening complication. Severe hyperthermia (temperature > 40–41 °C) may

Table 38–2. Seizures related to toxins or drugs requiring special consideration.¹

| Toxin or Drug | Comments |
|---|---|
| Methylenedioxymethamphetamine (MDMA; “Ecstasy”) | Seizures may be due to hyponatremia. |
| Isoniazid | Administer pyridoxine. |
| Lithium | May indicate need for hemodialysis. |
| Organophosphates | Administer pralidoxime (2-PAM) and atropine. |
| Strychnine | “Seizures” are actually spinally mediated muscle spasms and usually require neuromuscular paralysis. |
| Theophylline | Seizures indicate need for hemodialysis. |
| Tricyclic antidepressants | Hyperthermia and cardiotoxicity are common complications of repeated seizures; paralyze early with neuromuscular blockers to reduce muscular hyperactivity. |

¹See text for dosages.

rapidly cause brain damage and multiorgan failure, including rhabdomyolysis, advanced chronic kidney disease, and coagulopathy (see Chapter 37).

▶ Treatment

Treat hyperthermia aggressively by removing all clothing, spraying the patient with tepid water, and fanning the patient. If this is not rapidly effective, as shown by a normal rectal temperature within 30–60 minutes, or if there is significant muscle rigidity or hyperactivity, induce neuromuscular paralysis with a nondepolarizing neuromuscular blocker (eg, rocuronium, vecuronium). Once paralyzed, the patient must be intubated and mechanically ventilated. In patients with seizures, absence of visible muscular convulsive movements may give the false impression that brain seizure activity has ceased; however, this must be confirmed by electroencephalography.

Dantrolene (2–5 mg/kg intravenously) may be effective for hyperthermia associated with muscle rigidity that does not respond to neuromuscular blockade (ie, malignant hyperthermia). Bromocriptine, 2.5–7.5 mg orally daily, has been recommended for neuroleptic malignant syndrome. Cyproheptadine, 4 mg orally every hour for three or four doses, has been used to treat serotonin syndrome.

Dvir Y et al. Serotonin syndrome: a complex but easily avoidable condition. *Gen Hosp Psychiatry.* 2008 May–Jun;30(3):284–7. [PMID: 18433663]

ANTIDOTES & OTHER TREATMENT

ANTIDOTES

Give an antidote (if available) when there is reasonable certainty of a specific diagnosis (Table 38–3). Antidotes

Table 38–3. Some toxic agents for which there are specific antidotes.¹

| Toxic Agent | Specific Antidote |
|--|--|
| Acetaminophen | <i>N</i> -Acetylcysteine |
| Anticholinergics (eg, atropine) | Physostigmine |
| Anticholinesterases (eg, organophosphate pesticides) | Atropine and pralidoxime (2-PAM) |
| Benzodiazepines | Flumazenil (rarely used; see warning in text) |
| Carbon monoxide | Oxygen, hyperbaric oxygen |
| Cyanide | Sodium nitrite, sodium thiosulfate; hydroxocobalamin |
| Digitalis glycosides | Digoxin-specific Fab antibodies |
| Heavy metals (eg, lead, mercury, iron) and arsenic | Specific chelating agents |
| Isoniazid | Pyridoxine (vitamin B ₆) |
| Methanol, ethylene glycol | Ethanol (ethyl alcohol) or fomepizole (4-methylpyrazole) |
| Opioids | Naloxone, nalmefene |
| Snake venom | Specific antivenin |

¹See text for indications and dosages.

themselves may have serious side effects. The indications and dosages for specific antidotes are discussed in the respective sections for specific toxins.

DECONTAMINATION OF THE SKIN

Corrosive agents rapidly injure the skin and eyes and must be removed immediately. In addition, many toxins are readily absorbed through the skin, and systemic absorption can be prevented only by rapid action.

Wash the affected areas with copious quantities of lukewarm water or saline. Wash carefully behind the ears, under the nails, and in skin folds. For oily substances (eg, pesticides), wash the skin at least twice with plain soap and shampoo the hair. Specific decontaminating solutions or solvents (eg, alcohol) are rarely indicated and in some cases may paradoxically enhance absorption. For exposure to chemical warfare poisons such as nerve agents or vesicants, some authorities recommend use of a dilute hypochlorite solution (household bleach diluted 1:10 with water).

DECONTAMINATION OF THE EYES

Act quickly to prevent serious damage. Flush the eyes with copious amounts of saline (preferred) or water. (If available, instill local anesthetic drops in the eye before beginning irrigation.) Remove contact lenses if present. Direct the irrigating stream so that it will flow across the eyes after running off the nasal bridge. Lift the tarsal conjunctiva to look for undissolved particles and to facilitate irrigation. Continue irrigation for 15 minutes or until each eye has been irrigated with at least 1 L of solution. If the toxin is an

acid or a base, check the pH of the tears after irrigation, and continue irrigation until the pH is between 6.5 and 7.5.

After irrigation is complete, perform a careful examination of the eye, using fluorescein and a slit lamp or Wood lamp to identify areas of corneal injury. Patients with serious conjunctival or corneal injury should be immediately referred to an ophthalmologist.

GASTROINTESTINAL DECONTAMINATION

Removal of ingested poisons was a routine part of emergency treatment for decades. However, prospective clinical studies have failed to demonstrate improved outcome after gastric emptying. For small or moderate ingestions of most substances, toxicologists generally recommend oral activated charcoal alone without prior gastric emptying. Exceptions are large ingestions of anticholinergic compounds and salicylates, which often delay gastric emptying, and ingestion of sustained-release or enteric-coated tablets, which may remain intact for several hours.

Gastric emptying is not generally used for ingestion of corrosive agents or petroleum distillates, because further esophageal injury or pulmonary aspiration may result. However, in certain cases, removal of the toxin may be more important than concern over possible complications. Consult a medical toxicologist or regional poison control center (800-222-1222) for advice.

▶ Emesis

Emesis using syrup of ipecac can partially evacuate gastric contents if given very soon after ingestion (eg, at work or at home). However, it may increase the risk of pulmonary aspiration and delay or prevent the use of oral activated charcoal. Therefore, it is no longer used in the routine management of ingestions.

A. Gastric Lavage

Gastric lavage is more effective for liquid poisons or small pill fragments than for intact tablets or pieces of mushroom. It is most useful when started within 60 minutes after ingestion. However, the lavage procedure may delay administration of activated charcoal and may stimulate vomiting and pulmonary aspiration in an obtunded patient.

1. Indications—Gastric lavage is sometimes used after very large ingestions (eg, massive aspirin overdose), for collection and examination of gastric contents for identification of poison, and for convenient administration of charcoal and antidotes.

2. Contraindications—Do *not* use lavage for stuporous or comatose patients with absent gag reflexes unless they are endotracheally intubated beforehand. Some authorities advise against lavage when caustic material has been ingested; others regard it as essential to remove liquid corrosives from the stomach.

3. Technique—In obtunded or comatose patients, the danger of aspiration pneumonia is reduced by performing endotracheal intubation with a cuffed tube before the proce-

sure. Gently insert a lubricated, soft but noncollapsible stomach tube (at least 37–40 F) through the mouth or nose into the stomach. Aspirate and save the contents, and then lavage repeatedly with 50- to 100-mL aliquots of fluid until the return fluid is clear. Use lukewarm tap water or saline.

B. Activated Charcoal

Activated charcoal effectively adsorbs almost all drugs and poisons. Poorly adsorbed substances include iron, lithium, potassium, sodium, mineral acids, and alcohols.

1. Indications—Activated charcoal should be used for prompt adsorption of drugs or toxins in the stomach and intestine. Studies in volunteers show that activated charcoal given alone may be as effective as or more effective than ipecac-induced emesis or gastric lavage. However, evidence of benefit in clinical studies is lacking. Administration of charcoal, especially if mixed with sorbitol, can provoke vomiting, which could lead to pulmonary aspiration in an obtunded patient.

2. Contraindications—Activated charcoal should not be used for comatose or convulsing patients unless it can be given by gastric tube and the airway is first protected by a cuffed endotracheal tube. It is also contraindicated for patients with ileus or intestinal obstruction or those who have ingested corrosives for whom endoscopy is planned.

3. Technique—Administer activated charcoal, 60–100 g orally or via gastric tube, mixed in aqueous slurry. Repeated doses may be given to ensure gastrointestinal adsorption or to enhance elimination of some drugs (see below).

C. Catharsis

1. Indications—Cathartics are used by some toxicologists for stimulation of peristalsis to hasten the elimination of unabsorbed drugs and poisons and the activated charcoal slurry. There is no clinical evidence to support their use, and some agents (eg, sorbitol) can provoke vomiting, increasing the risk of pulmonary aspiration.

2. Contraindications and cautions—Do not give a cathartic to patients with suspected intestinal obstruction. Avoid sodium-based cathartics in patients with hypertension, advanced chronic kidney disease, and congestive heart failure and magnesium-based cathartics in patients with advanced chronic kidney disease. Sorbitol (an osmotic cathartic found in some prepackaged activated charcoal slurry products) can cause hypotension and dehydration due to third-spacing and also causes intestinal cramping and vomiting.

D. Whole Bowel Irrigation

Whole bowel irrigation uses large volumes of balanced polyethylene glycol-electrolyte solution to mechanically cleanse the entire intestinal tract. Because of the composition of the irrigating solution, there is no significant gain or loss of systemic fluids or electrolytes.

1. Indications—Whole bowel irrigation is particularly effective for massive iron ingestion in which intact tablets are visible on abdominal radiographs. It has also been used

for ingestions of lithium, sustained-release and enteric-coated tablets, and swallowed drug-filled packets.

2. Contraindications—Do not use in patients with suspected intestinal obstruction. Use with caution in patients who are obtunded or have depressed airway protective reflexes.

3. Technique—Administer a balanced polyethylene glycol-electrolyte solution (CoLyte, GoLYTELY) into the stomach via gastric tube at a rate of 1–2 L/h until the rectal effluent is clear. This may take several hours. It is most effective when patients are able to sit on a commode to pass the intestinal contents.

E. Increased Drug Removal

1. Urinary manipulation—Forced diuresis is hazardous; the risk of complications (pulmonary edema, electrolyte imbalance) usually outweighs its benefits. Acidic drugs (eg, salicylates, phenobarbital) are more rapidly excreted with an alkaline urine. Acidification (sometimes promoted for amphetamines, phencyclidine) is *not* very effective and is contraindicated in the presence of rhabdomyolysis or myoglobinuria.

2. Hemodialysis—The indications for dialysis are as follows: (1) Known or suspected potentially lethal amounts of a dialyzable drug (Table 38–4). (2) Poisoning with deep coma, apnea, severe hypotension, fluid and electrolyte or acid-base disturbance, or extreme body temperature changes that cannot be corrected by conventional measures. (3) Poisoning in patients with severe kidney, cardiac, pulmonary, or hepatic disease who will not be able to eliminate toxin by the usual mechanisms.

Continuous renal replacement therapy (also known as continuous venovenous hemodiafiltration) is of uncertain

Table 38–4. Recommended use of hemodialysis in poisoning.

| Poison | Indications ¹ |
|-----------------|--|
| Carbamazepine | Seizures, severe cardiotoxicity; serum level > 60 mg/L |
| Ethylene glycol | Acidosis, serum level > 50 mg/dL |
| Lithium | Severe symptoms; level > 4 mEq/L more than 12 hours after last dose |
| Methanol | Acidosis, serum level > 50 mg/dL |
| Phenobarbital | Intractable hypotension, acidosis despite maximal supportive care |
| Salicylate | Severe acidosis, CNS symptoms, level > 100 mg/dL (acute overdose) or > 60 mg/dL (chronic intoxication) |
| Theophylline | Serum level > 90–100 mg/L (acute) or seizures and serum level > 40–60 mg/L (chronic) |
| Valproic acid | Serum level > 900–1000 mg/L or deep coma, severe acidosis |

¹See text for further discussion of indications. CNS, central nervous system.

benefit for elimination of most poisons but has been used successfully in the management of lithium intoxication.

3. Repeat-dose charcoal—Repeated doses of activated charcoal, 20–30 g orally or via gastric tube every 3–4 hours, may hasten elimination of some drugs (eg, phenytoin, carbamazepine, dapsone) by absorbing drugs excreted into the gut lumen (“gut dialysis”). However, clinical studies have failed to prove better outcome using multiple-dose charcoal. Sorbitol or other cathartics should *not* be used with each dose, or resulting large stool volumes may lead to dehydration or hypernatremia.

DIAGNOSIS OF POISONING

The identity of the ingested substance or substances is usually known, but occasionally a comatose patient is found with an unlabeled container or the patient is unable or unwilling to give a coherent history. By performing a directed physical examination and ordering common clinical laboratory tests, the clinician can often make a tentative diagnosis that may allow empiric interventions or may suggest specific toxicologic tests.

► Physical Examination

Important diagnostic variables in the physical examination include blood pressure, pulse rate, temperature, pupil size, sweating, and the presence or absence of peristaltic activity. Poisonings with many drugs fit into one of four common syndromes.

A. Sympathomimetic Syndrome

The blood pressure and pulse rate are elevated, though with severe hypertension reflex bradycardia may occur. The temperature is often elevated, pupils are dilated, and the skin is sweaty, though mucous membranes are dry. Patients are usually agitated, anxious, or frankly psychotic.

Examples: Amphetamines, cocaine, ephedrine and pseudoephedrine.

B. Sympatholytic Syndrome

The blood pressure and pulse rate are decreased and body temperature is low. The pupils are small or even pinpoint. Peristalsis is usually decreased. Patients are usually obtunded or comatose.

Examples: Barbiturates, benzodiazepines and other sedative hypnotics, GHB, clonidine and related antihypertensives, ethanol, opioids.

C. Cholinergic Syndrome

Stimulation of muscarinic receptors causes bradycardia, miosis, sweating, and hyperperistalsis as well as bronchorrhea, wheezing, excessive salivation, and urinary incontinence. Nicotinic receptor stimulation may produce initial hypertension and tachycardia as well as fasciculations and muscle weakness. Patients are usually agitated and anxious.

Examples: Carbamates, nicotine, organophosphates (including nerve agents), physostigmine.

D. Anticholinergic Syndrome

Tachycardia with mild hypertension is common, and the body temperature is often elevated. Pupils are widely dilated. The skin is flushed, hot, and dry. Peristalsis is decreased, and urinary retention is common. Patients may have myoclonic jerking or choreoathetoid movements. Agitated delirium is frequently seen, and severe hyperthermia may occur.

Examples: Atropine, scopolamine, other naturally occurring and pharmaceutical anticholinergics, antihistamines, tricyclic antidepressants.

► Laboratory Tests

The following clinical laboratory tests are recommended for screening of the overdosed patient: measured serum osmolality and osmol gap, electrolytes, glucose, creatinine, blood urea nitrogen (BUN), urinalysis (eg, oxalate crystals with ethylene glycol poisoning, myoglobinuria with rhabdomyolysis), and electrocardiography. Serum acetaminophen and ethanol quantitative levels should be determined in all patients with drug overdoses.

A. Osmol Gap

The osmol gap is defined and calculation of the gap is described in Table 38–5. It is increased in the presence of large quantities of low-molecular-weight substances, most commonly ethanol. Common poisons associated with increased osmol gap are acetone, ethanol, ethylene glycol, isopropyl alcohol, methanol, and propylene glycol. **Note:** Severe alcoholic ketoacidosis and diabetic ketoacidosis can also cause an elevated osmol gap resulting from the production of ketones and other low-molecular-weight substances.

B. Anion Gap

Metabolic acidosis associated with an elevated anion gap is usually due to an accumulation of lactic acid or other acids (see Chapter 21). Common causes of elevated anion gap in poisoning include carbon monoxide, cyanide, ethylene glycol, medicinal iron, INH, methanol, metformin, ibuprofen and salicylates.

The osmol gap should also be checked; combined elevated anion and osmol gaps suggests poisoning by methanol or ethylene glycol, though this may also occur in patients with diabetic ketoacidosis and alcoholic ketoacidosis.

C. Toxicology Laboratory Examination

A comprehensive toxicology screen is of little value in the initial care of the poisoned patient—on the contrary, it is

Table 38–5. Use of the osmol gap in toxicology.

The osmol gap (Δosm) is determined by subtracting the calculated serum osmolality from the measured serum osmolality.

$$\text{Calculated osmolality (osm)} = 2[\text{Na}^+ (\text{mEq/L})] + \frac{\text{Glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8}$$

$\Delta\text{osm} = \text{Measured osmolality} - \text{Calculated osmolality}$

Serum osmolality may be increased by contributions of circulating alcohols and other low-molecular-weight substances. Since these substances are not included in the calculated osmolality, there will be a gap proportionate to their serum concentration and inversely proportionate to their molecular weight:

$$\text{Serum concentration (mg/dL)} = \Delta\text{osm} \times \frac{\text{Molecular weight}}{10}$$

| | Molecular Weight | Toxic Concentration | Approximate Corresponding Δosm (mosm/L) |
|-----------------|------------------|---------------------|---|
| Ethanol | 46 | 300 | 65 |
| Methanol | 32 | 50 | 16 |
| Ethylene glycol | 60 | 100 | 16 |
| Isopropanol | 60 | 150 | 25 |

Note: The normal osmol gap may vary by as much as ± 10 mosm/L; thus, small osmol gaps may be unreliable in the diagnosis of poisoning.

Adapted, with permission, from Stone CK, Humphries RL (editors): *Current Emergency Diagnosis & Treatment*, 5th ed. McGraw-Hill, 2004.

time-consuming and expensive. Specific quantitative levels of certain drugs may be extremely helpful (Table 38–6), however, especially if specific antidotes or interventions (eg, dialysis) would be indicated based on the results.

If a toxicology screen is required, urine is the best specimen. Many hospitals can perform a quick but limited screen for “drugs of abuse” (typically these screens include only opiates, amphetamines, and cocaine, and some add benzodiazepines, barbiturates, and tetrahydrocannabinol [marijuana]). There are numerous false-positive and false-negative results. For example, synthetic opioids, such as fentanyl, oxycodone, and methadone are usually not detected by routine opiate screening. Blood samples may be saved for possible quantitative testing, but blood is not generally used for screening purposes since it is relatively insensitive for many common drugs, including psychotropic agents, opioids, and stimulants.

► Abdominal Radiographs

A plain film of the abdomen may reveal radiopaque iron tablets, drug-filled condoms, or other toxic material. Studies suggest that few tablets are predictably visible (eg, ferrous sulfate, sodium chloride, calcium carbonate, and potassium chloride). Thus, the radiograph is useful only if abnormal.

Table 38–6. Specific quantitative levels and potential therapeutic interventions.¹

| Drug or Toxin | Treatment |
|---------------------------|---|
| Acetaminophen | Specific antidote (<i>N</i> -acetylcysteine) based on serum level |
| Carbon monoxide | High carboxyhemoglobin level indicates need for 100% oxygen, consideration of hyperbaric oxygen |
| Carbamazepine | High level may indicate need for hemodialysis |
| Digoxin | On basis of serum digoxin level and severity of clinical presentation, treatment with Fab antibody fragments (Digibind) may be indicated |
| Ethanol | Low serum level may suggest nonalcoholic cause of coma (eg, trauma, other drugs, other alcohols). Serum ethanol may also be useful in monitoring ethanol therapy for methanol or ethylene glycol poisoning. |
| Iron | Level may indicate need for chelation with deferoxamine |
| Lithium | Serum levels can guide decision to institute hemodialysis |
| Methanol, ethylene glycol | Acidosis, high levels indicate need for hemodialysis, therapy with ethanol or fomepizole |
| Methemoglobin | Methemoglobinemia can be treated with methylene blue intravenously |
| Salicylates | High level may indicate need for hemodialysis, alkaline diuresis |
| Theophylline | Immediate hemodialysis or hemoperfusion may be indicated based on serum level |
| Valproic acid | Elevated levels may indicate need to consider hemodialysis or L-carnitine therapy, or both |

¹Some drugs or toxins may have profound and irreversible toxicity unless rapid and specific management is provided outside of routine supportive care. For these agents, laboratory testing may provide the serum level or other evidence required for administering a specific antidote or arranging for hemodialysis.

► When to Refer

Consultation with a regional poison control center (1-800-222-1222) or medical toxicologist is recommended when the diagnosis is uncertain; there are questions about what laboratory tests to order; dialysis is being considered to remove the drug or poison; or advice is needed regarding the indications, dose, and side effects of antidotes.

► When to Admit

- The patient has symptoms and signs of intoxication that are not expected to clear within a 6–8 hour observation period.
- Delayed absorption of the drug might be predicted to cause a later onset of serious symptoms (eg, after ingestion of a sustained-release product).

- Continued administration of an antidote is required (eg, *N*-acetylcysteine for acetaminophen overdose).
- Psychiatric or social services evaluation is needed for suicide attempt or suspected drug abuse.

SELECTED POISONINGS

ACETAMINOPHEN

Acetaminophen (paracetamol in the United Kingdom, Europe) is a common analgesic found in many nonprescription and prescription products. After absorption, it is metabolized mainly by glucuronidation and sulfation, with a small fraction metabolized via the P450 mixed-function oxidase system (2E1) to a highly toxic reactive intermediate. This toxic intermediate is normally detoxified by cellular glutathione. With acute acetaminophen overdose (> 150–200 mg/kg, or 8–10 g in an average adult), hepatocellular glutathione is depleted and the reactive intermediate attacks other cell proteins, causing necrosis. Patients with enhanced P450 2E1 activity, such as chronic alcoholics and patients taking INH, are at increased risk of developing hepatotoxicity. Hepatic toxicity may also occur after long-term overuse of acetaminophen—eg, as a result of taking two or three acetaminophen-containing products concurrently or exceeding the recommended maximum dose of 4 g/d for several days.

Clinical Findings

Shortly after ingestion, patients may have nausea or vomiting, but there are usually no other signs of toxicity until 24–48 hours after ingestion, when hepatic aminotransferase levels begin to increase. With severe poisoning, fulminant hepatic necrosis may occur, resulting in jaundice, hepatic encephalopathy, advanced chronic kidney disease, and death. Rarely, massive ingestion (eg, serum levels over 500–1000 mg/L) can cause early onset of acute coma, hypotension, and metabolic acidosis unrelated to hepatic injury.

The diagnosis after acute overdose is based on measurement of the serum acetaminophen level. Plot the serum level versus the time since ingestion on the acetaminophen nomogram shown in Figure 38–1. Ingestion of sustained-release products or coingestion of an anticholinergic agent, salicylate, or opioid drug may cause delayed elevation of serum levels and may render the nomogram useless. The nomogram is not useful after chronic overdose.

▲ **Figure 38–1.** Nomogram for prediction of acetaminophen hepatotoxicity following acute overdosage. The upper line defines serum acetaminophen concentrations associated with a risk of hepatotoxicity; the lower line defines serum levels 25% below those expected to cause hepatotoxicity. In uncomplicated cases, the upper line can be used as an indication for therapy with *N*-acetylcysteine. However, to provide a margin for error in the estimation of the time of ingestion and for patients at higher risk for hepatotoxicity, the lower line is often used as a guide to treatment. (Adapted, with permission, from Rumack BH et al. Acetaminophen poisoning and toxicity. *Pediatrics*. 1975 Jun;55(6):871–6.)

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p 1425) if it can be given within 1–2 hours of the ingestion. Although charcoal may interfere with absorption of the oral antidote acetylcysteine, this is not considered clinically significant.

B. Specific Treatment

Although the general recommendation is to treat if the serum acetaminophen level is above the toxic line on the nomogram (Figure 38–1), many clinicians and published guidelines prefer to use the lower line as a guide to treatment, as it provides a 25% safety margin. If the precise time of ingestion is unknown or if the patient is at higher risk for hepatotoxicity (eg, alcoholic, liver disease, long-term use of P450-inducing drugs), then use a lower threshold for initiation of *N*-acetylcysteine (in some case reports, a level of 100 mg/L at 4 hours was suggested in very high-risk patients).

The antidote *N*-acetylcysteine can be given orally or intravenously. Oral treatment begins with a loading dose of *N*-acetylcysteine, 140 mg/kg, followed by 70 mg/kg every 4 hours. Dilute the solution to 5% with water, juice, or soda.

If vomiting interferes with oral *N*-acetylcysteine administration, consider giving the antidote intravenously (see below). The most widely used oral *N*-acetylcysteine protocol in the United States calls for 72 hours of treatment. However, other regimens have demonstrated equivalent success with 20–48 hours of treatment.

A 20-hour intravenous regimen was recently approved by the FDA (Acetadote). It calls for a loading dose of 150 mg/kg given intravenously over 60 minutes, followed by a 4-hour infusion of 50 mg/kg, and a 16-hour infusion of 100 mg/kg. (If Acetadote is not available, the conventional oral formulation may also be given intravenously using a micropore filter and a slow rate of infusion. Call a regional poison control center or medical toxicologist for assistance.)

Treatment with *N*-acetylcysteine is most effective if it is started within 8–10 hours after ingestion.

ACIDS, CORROSIVE

The strong mineral acids exert primarily a local corrosive effect on the skin and mucous membranes. Symptoms include severe pain in the throat and upper gastrointestinal tract; bloody vomitus; difficulty in swallowing, breathing, and speaking; discoloration and destruction of skin and mucous membranes in and around the mouth; and shock. Severe systemic metabolic acidosis may occur both as a result of cellular injury and from systemic absorption of the acid.

Severe deep destructive tissue damage may occur after exposure to hydrofluoric acid because of the penetrating and highly toxic fluoride ion. Systemic hypocalcemia and hyperkalemia may also occur after fluoride absorption, even following skin exposure.

Inhalation of volatile acids, fumes, or gases such as chlorine, fluorine, bromine, or iodine causes severe irritation of the throat and larynx and may cause upper airway obstruction and noncardiogenic pulmonary edema.

► Treatment

A. Ingestion

Dilute immediately by giving a glass (4–8 oz) of water to drink. Do *not* give bicarbonate or other neutralizing agents, and do *not* induce vomiting. Some experts recommend immediate placement of a small flexible gastric tube and removal of stomach contents followed by lavage, particularly if the corrosive is a liquid or has important systemic toxicity.

In symptomatic patients, perform flexible endoscopic esophagoscopy to determine the presence and extent of injury. CT scan or plain radiographs of the chest and abdomen may reveal esophageal or gastric perforation.

Perforation, peritonitis, and major bleeding are indications for surgery.

B. Skin Contact

Flood with water for 15 minutes. Use no chemical antidotes; the heat of the reaction may cause additional injury.

For hydrofluoric acid burns, soak the affected area in benzalkonium chloride solution or apply 2.5% calcium gluconate gel (prepared by adding 3.5 g calcium gluconate to 5 oz of water-soluble surgical lubricant, eg, K-Y Jelly); then arrange immediate consultation with a plastic surgeon or other specialist. Binding of the fluoride ion may be achieved by injecting 0.5 mL of 5% calcium gluconate per square centimeter under the burned area. (**Caution:** Do not use calcium chloride.) Intra-arterial infusion of calcium is sometimes required for extensive burns or those involving the nail bed; consult with a hand surgeon or poison control center (1-800-222-1222).

C. Eye Contact

Anesthetize the conjunctiva and corneal surfaces with topical local anesthetic drops (eg, proparacaine). Flood with water for 15 minutes, holding the eyelids open. Check pH with pH 6.0–8.0 test paper, and repeat irrigation, using 0.9% saline, until pH is near 7.0. Check for corneal damage with fluorescein and slit lamp examination; consult an ophthalmologist about further treatment.

D. Inhalation

Remove from further exposure to fumes or gas. Check skin and clothing. Treat pulmonary edema.

Flammiger A et al. Sulfuric acid burns (corrosion and acute irritation): evidence-based overview to management. *Cutan Ocul Toxicol.* 2006;25(1):55–61. [PMID: 16702054]

Vohra R et al. Recurrent life-threatening ventricular dysrhythmias associated with acute hydrofluoric acid ingestion: observations in one case and implications for mechanism of toxicity. *Clin Toxicol (Phila).* 2008 Jan;46(1):79–84. [PMID: 17906993]

ALKALIES

The strong alkalis are common ingredients of some household cleaning compounds and may be suspected by their “soapy” texture. Those with alkalinity above pH 12.0 are particularly corrosive. Disk (or “button”) batteries are also a source. Alkalis cause liquefactive necrosis, which is deeply penetrating. Symptoms include burning pain in the upper gastrointestinal tract, nausea, vomiting, and difficulty in swallowing and breathing. Examination reveals destruction and edema of the affected skin and mucous membranes and bloody vomitus and stools. Radiographs may reveal evidence of perforation or the presence of radiopaque disk batteries in the esophagus or lower gastrointestinal tract.

► Treatment

A. Ingestion

Dilute immediately with a glass of water. Do *not* induce emesis. Some gastroenterologists recommend immediate

placement of a small flexible gastric tube and removal of stomach contents followed by gastric lavage after ingestion of liquid caustic substances to remove residual material.

Prompt endoscopy is recommended in symptomatic patients to evaluate the extent of damage. If radiograph reveals the location of ingested disk batteries in the esophagus, immediate endoscopic removal is mandatory.

The use of corticosteroids to prevent stricture formation is of no proved benefit and is definitely contraindicated if there is evidence of esophageal perforation.

B. Skin Contact

Wash with running water until the skin no longer feels soapy. Relieve pain and treat shock.

C. Eye Contact

Anesthetize the conjunctival and corneal surfaces with topical anesthetic (eg, proparacaine). Irrigate with water or saline continuously for 20–30 minutes, holding the lids open. Check pH with pH test paper, and repeat irrigation, using 0.9% saline, for additional 30-minute periods until the pH is near 7.0. Check for corneal damage with fluorescein and slit lamp examination; consult an ophthalmologist for further treatment.

AMPHETAMINES & COCAINE

Amphetamines and cocaine are widely abused for their euphorogenic and stimulant properties. Both drugs may be smoked, snorted, ingested, or injected. Amphetamines and cocaine produce central nervous system stimulation and a generalized increase in central and peripheral sympathetic activity. The toxic dose of each drug is highly variable and depends on the route of administration and individual tolerance. The onset of effects is most rapid after intravenous injection or smoking. Amphetamine derivatives and related drugs include methamphetamine (“crystal meth,” “crank”), MDMA (“Ecstasy”), ephedrine (“herbal ecstasy”), and methcathinone (“cat”). Nonprescription medications and nutritional supplements may contain stimulant or sympathomimetic drugs such as ephedrine, yohimbine, or caffeine (see Theophylline, below).

► Clinical Findings

Presenting symptoms may include anxiety, tremulousness, tachycardia, hypertension, diaphoresis, dilated pupils, agitation, muscular hyperactivity, and psychosis. Muscle hyperactivity may lead to metabolic acidosis and rhabdomyolysis. In severe intoxication, seizures and hyperthermia may occur. Sustained or severe hypertension may result in intracranial hemorrhage, aortic dissection, or myocardial infarction. Hyponatremia has been reported after MDMA use; the mechanism is not known but may involve exces-

sive water intake, syndrome of inappropriate antidiuretic hormone (SIADH), or both.

The diagnosis is supported by finding amphetamines, cocaine, or the cocaine metabolite benzoylecgonine in the urine. Blood screening is generally not sensitive enough to detect these drugs.

► Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Treat coma or seizures as described at the beginning of this chapter. Rapidly lower the body temperature (see hyperthermia, p 1423) in patients who are hyperthermic (temperature > 39–40 °C).

B. Specific Treatment

Treat agitation, psychosis, or seizures with a benzodiazepine such as lorazepam, 2–3 mg intravenously. Add phenobarbital 15 mg/kg intravenously for persistent seizures. Treat hypertension with a vasodilator drug such as phentolamine (1–5 mg intravenously) or a combined α - and β -adrenergic blocker such as labetalol (10–20 mg intravenously). Do *not* administer a pure β -blocker such as propranolol alone, as this may result in paradoxical worsening of the hypertension as a result of unopposed α -adrenergic effects.

Treat tachycardia or tachyarrhythmias with a short-acting β -blocker such as esmolol (25–100 mcg/kg/min by intravenous infusion). Treat hyperthermia as described above. Treat hyponatremia as outlined in Chapter 21.

ANTICOAGULANTS

Warfarin and related compounds (including ingredients of many commercial rodenticides) inhibit the clotting mechanism by blocking hepatic synthesis of vitamin K–dependent clotting factors.

Anticoagulants may cause hemoptysis, gross hematuria, bloody stools, hemorrhages into organs, widespread bruising, and bleeding into joint spaces. The prothrombin time is increased within 12–24 hours (peak 36–48 hours) after a single overdose. After ingestion of brodifacoum, difenacoum, and related rodenticides (so-called “super-warfarins”), inhibition of clotting factor synthesis may persist for several weeks or even months after a single dose.

► Treatment

A. Emergency and Supportive Measures

Discontinue the drug at the first sign of gross bleeding, and determine the prothrombin time (international normal-

ized ratio, INR). If the patient has ingested an acute overdose, administer activated charcoal (see p 1425).

B. Specific Treatment

Do *not* treat prophylactically with vitamin K—wait for evidence of anticoagulation (elevated prothrombin time). If the INR is elevated, give phytonadione (vitamin K₁), 10–25 mg orally, and additional doses as needed to restore the prothrombin time to normal. Doses as high as 200 mg/d have been required after ingestion of “superwarfarins.” Give fresh-frozen plasma or activated Factor VII as needed to rapidly correct the coagulation factor deficit if there is serious bleeding. If the patient is chronically anticoagulated and has strong medical indications for being maintained in that status (eg, prosthetic heart valve), give much smaller doses of vitamin K (1 mg orally) and fresh-frozen plasma (or both) to titrate to the desired prothrombin time.

If the patient has ingested brodifacoum or a related superwarfarin, prolonged observation (over weeks) and repeated administration of large doses of vitamin K may be required.

ANTICONSULSANTS

Anticonvulsants (carbamazepine, phenytoin, valproic acid, and many newer agents) are widely used in the management of seizure disorders. In addition, carbamazepine and valproic acid are increasingly used for treatment of mood disorders.

Phenytoin can be given orally or intravenously. Rapid intravenous injection of phenytoin can cause acute myocardial depression and cardiac arrest owing to the solvent propylene glycol (fosphenytoin does not contain this diluent). Chronic phenytoin intoxication can occur following only slightly increased doses because of zero-order kinetics and a small toxic-therapeutic window. Phenytoin intoxication can also occur following acute intentional or accidental overdose. The overdose syndrome is usually mild even with high serum levels. The most common manifestations are ataxia, nystagmus, and drowsiness. Choreoathetoid movements have been described.

Carbamazepine is used for treatment of trigeminal neuralgia, temporal lobe epilepsy, and other seizure disorders. Intoxication causes drowsiness, stupor and, with high levels, coma and seizures. Dilated pupils and tachycardia are common. Toxicity may be seen with serum levels greater than 20 mg/L, though severe poisoning is usually associated with concentrations greater than 30–40 mg/L. Because of erratic and slow absorption, intoxication may progress over several hours to days.

Valproic acid intoxication produces a unique syndrome consisting of hypernatremia (from the sodium component of the salt), metabolic acidosis, hypocalcemia, elevated serum ammonia, and mild liver aminotransferase elevation. Hypoglycemia may occur as a result of hepatic metabolic dysfunction. Coma with small pupils may be seen and can mimic opioid poisoning. Encephalopathy and cerebral edema can occur.

The newer anticonvulsants **gabapentin**, **levetiracetam**, **vigabatrin**, and **zonisamide** generally cause somnolence, confusion and dizziness; **felbamate** can cause crystalluria and kidney dysfunction after overdose, and may cause idiosyncratic aplastic anemia with therapeutic use; **lamotrigine**, **topiramate**, and **tiagabine** have been reported to cause seizures after overdose.

▶ Treatment

A. Emergency and Supportive Measures

For recent ingestions, give activated charcoal orally or by gastric tube. For large ingestions of carbamazepine or valproic acid—especially of sustained-release formulations—consider whole bowel irrigation (see p 1425). Multiple-dose activated charcoal and whole-bowel irrigation may be beneficial in ensuring gut decontamination for selected large ingestions.

B. Specific Treatment

There are no specific antidotes. Naloxone was reported to have reversed valproic acid overdose in one anecdotal case. Carnitine may be useful in patients with valproic acid-induced hyperammonemia. Consider hemodialysis for massive intoxication with valproic acid or carbamazepine (eg, carbamazepine levels > 60 mg/L or valproic acid levels > 800 mg/L).

ARSENIC

Arsenic is found in some pesticides and industrial chemicals, and arsenic trioxide has recently been reintroduced as a chemotherapeutic agent. A massive epidemic of chronic arsenic poisoning has occurred in Bangladesh due to naturally occurring arsenic in deep aquifers. Symptoms of acute poisoning usually appear within 1 hour after ingestion but may be delayed as long as 12 hours. They include abdominal pain, vomiting, watery diarrhea, and skeletal muscle cramps. Profound dehydration and shock may occur. In chronic poisoning, symptoms can be vague but often

include pancytopenia, painful peripheral sensory neuropathy, and skin changes including melanosis, keratosis, and desquamating rash. Urinary arsenic levels may be falsely elevated after certain meals (eg, seafood) that contain large quantities of a nontoxic form of organic arsenic.

► Treatment

A. Emergency Measures

After recent ingestion (within 1–2 hours), perform gastric lavage and administer 60–100 g of activated charcoal (see p 1425). Administer intravenous fluids to replace losses due to vomiting and diarrhea.

B. Antidote

For patients with severe acute intoxication, give dimercaprol injection (British anti-Lewisite, BAL), 10% solution in oil, 3–5 mg/kg intramuscularly every 4–6 hours for 2 days. The side effects include nausea, vomiting, headache, and hypertension. Follow dimercaprol with oral succimer (dimercaptosuccinic acid, DMSA), 10 mg/kg every 8 hours, for 1 week. Consult a medical toxicologist or regional poison control center (800-222-1222) for advice regarding chelation.

Kapaj S et al. Human health effects from chronic arsenic poisoning—a review. *J Environ Sci Health A Tox Hazard Subst Environ Eng.* 2006;41(10):2399–428. [PMID: 17018421]

ATROPINE & ANTICHOLINERGICS

Atropine, scopolamine, belladonna, diphenoxylate with atropine, *Datura stramonium*, *Hyoscyamus niger*, some mushrooms, tricyclic antidepressants, and antihistamines are antimuscarinic agents with variable central nervous system effects. The patient complains of dryness of the mouth, thirst, difficulty in swallowing, and blurring of vision. The physical signs include dilated pupils, flushed skin, tachycardia, fever, delirium, myoclonus, ileus, and flushed appearance. Antidepressants and antihistamines may induce convulsions.

Antihistamines are commonly available with or without prescription. Diphenhydramine commonly causes delirium, tachycardia, and seizures. Massive overdose may mimic tricyclic antidepressant poisoning.

► Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p 1425). Tepid sponge baths and sedation, or neuromuscular paralysis in rare cases, are indicated to control high temperatures (see p 1423).

B. Specific Treatment

For pure atropine or related anticholinergic syndrome, if symptoms are severe (eg, agitated delirium or excessively

rapid tachycardia), give physostigmine salicylate, 0.5–1 mg slowly intravenously over 5 minutes, with ECG monitoring; repeat as needed to a total dose of 2 mg. Bradyarrhythmias and convulsions are a hazard with physostigmine administration, and it should be avoided in patients with tricyclic antidepressant overdose.

Pragat F et al. Poisonings with diphenhydramine—a survey of 68 clinical and 55 death cases. *Forensic Sci Int.* 2006 Sep 12;161(2–3):189–97. [PMID: 16857332]

Spina SP et al. Teenagers with Jimson weed (*Datura stramonium*) poisoning. *CJEM.* 2007 Nov;9(6):467–8. [PMID: 18072995]

β-ADRENERGIC BLOCKERS

There are a wide variety of β-adrenergic blocking drugs, with varying pharmacologic and pharmacokinetic properties (see Table 11–7). The most toxic β-blocker is propranolol. Propranolol competitively blocks β₁ and β₂ adrenoceptors and also has direct membrane-depressant and central nervous system effects.

► Clinical Findings

The most common findings with mild or moderate intoxication are hypotension and bradycardia. Cardiac depression from more severe poisoning is often unresponsive to conventional therapy with β-adrenergic stimulants such as dopamine and norepinephrine. In addition, with propranolol and other lipid-soluble drugs, seizures and coma may occur. Propranolol, oxprenolol, acebutolol, and alprenolol also have membrane-depressant effects and can cause conduction disturbance (wide QRS interval) similar to tricyclic antidepressant overdose.

The diagnosis is based on typical clinical findings. Routine toxicology screening does not usually include β-blockers.

► Treatment

A. Emergency and Supportive Measures

Initially, treat bradycardia or heart block with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion, titrated to the desired heart rate), or an external transcutaneous cardiac pacemaker. However, these measures are often ineffective, and specific antidotal treatment may be necessary (see below).

For ingested drugs, administer activated charcoal (see p 1425).

B. Specific Treatment

If the above measures are not successful in reversing bradycardia and hypotension, give glucagon, 5–10 mg intravenously, followed by an infusion of 1–5 mg/h. Glucagon is an inotropic agent that acts at a different receptor site and is therefore not affected by β-blockade. Membrane-depressant effects (wide QRS interval) may respond to boluses of sodium bicarbonate (50–100 mEq intravenously) as for tricyclic antidepressant poisoning.

Kerns W 2nd. Management of beta-adrenergic blocker and calcium channel antagonist toxicity. *Emerg Med Clin North Am.* 2007 May;25(2):309–31. [PMID: 17482022]
Shepherd G. Treatment of poisoning caused by beta-adrenergic and calcium-channel blockers. *Am J Health Syst Pharm.* 2006 Oct 1;63(19):1828–35. [PMID: 16990629]

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers are used to treat angina pectoris, hypertension, supraventricular tachycardia, migraine, and other disorders. In therapeutic doses, nifedipine, nifedipine, amlodipine, felodipine, isradipine, nisoldipine, and nimodipine act mainly on blood vessels, while verapamil and diltiazem act mainly on cardiac contractility and conduction. However, these selective effects are lost after acute overdose. Patients may present with bradycardia, atrioventricular (AV) nodal block, hypotension, or a combination of these effects. Hyperglycemia is common due to blockade of insulin release. With severe poisoning, cardiac arrest may occur.

► Treatment

A. Emergency and Supportive Measures

For ingested drugs, administer activated charcoal (see p 1425). In addition, whole bowel irrigation should be initiated as soon as possible if the patient has ingested a sustained-release product.

B. Specific Treatment

If bradycardia and hypotension are not reversed with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion), or a transcutaneous cardiac pacemaker, administer calcium chloride intravenously. Start with calcium chloride 10%, 10 mL, or calcium gluconate 10%, 20 mL. Repeat the dose every 3–5 minutes. The optimum (or maximum) dose has not been established, but there are reports of success after as much as 10–12 g of calcium chloride. Calcium is most useful in reversing negative inotropic effects and is less effective for AV nodal blockade and bradycardia. Epinephrine infusion (1–4 mcg/min initially) and glucagon (5–10 mg intravenously) have also been recommended. In addition, high doses of insulin (0.5–1 units/kg intravenous bolus followed by 0.5–1 units/kg/h infusion) along with sufficient dextrose to maintain euglycemia have been reported to be beneficial but there are no controlled studies. Infusion of Intralipid 20% lipid emulsion has been reported to improve hemodynamics in an animal model of verapamil poisoning.

Bania TC et al. Hemodynamic effects of intravenous fat emulsion in an animal model of severe verapamil toxicity resuscitated with atropine, calcium, and saline. *Acad Emerg Med.* 2007 Feb;14(2):105–11. [PMID: 17267527]

CARBON MONOXIDE

Carbon monoxide is a colorless, odorless gas produced by the combustion of carbon-containing materials. Poisoning may occur as a result of suicidal or accidental exposure to automobile exhaust, smoke inhalation in a fire, or accidental exposure to an improperly vented gas heater or other appliance. Carbon monoxide avidly binds to hemoglobin, with an affinity approximately 250 times that of oxygen. This results in reduced oxygen-carrying capacity and altered delivery of oxygen to cells (see also Smoke Inhalation in Chapter 9).

► Clinical Findings

At low carbon monoxide levels (carboxyhemoglobin saturation 10–20%), victims may have headache, dizziness, abdominal pain, and nausea. With higher levels, confusion, dyspnea, and syncope may occur. Hypotension, coma, and seizures are common with levels greater than 50–60%. Survivors of acute severe poisoning may develop permanent obvious or subtle neurologic and neuropsychiatric deficits. The fetus and newborn may be more susceptible because of high carbon monoxide affinity for fetal hemoglobin.

Carbon monoxide poisoning should be suspected in any person with severe headache or acutely altered mental status, especially during cold weather, when improperly vented heating systems may have been used. Diagnosis depends on specific measurement of the arterial or venous carboxyhemoglobin saturation, although the level may have declined if high-flow oxygen therapy has already been administered, and levels do not always correlate with clinical symptoms. Routine arterial blood gas testing and pulse oximetry are not useful because they give falsely normal PaO₂ and oxyhemoglobin saturation determinations, respectively. (A newer pulse oximetry device, the pulse CO-oximeter [Masimo Rad-57] is capable of distinguishing oxyhemoglobin from carboxyhemoglobin.)

► Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Remove the victim from exposure. Treat patients with coma, hypotension, or seizures as described at the beginning of this chapter.

B. Specific Treatment

The half-life of the carboxyhemoglobin (CoHb) complex is about 4–5 hours in room air but is reduced dramatically by high concentrations of oxygen. Administer 100% oxygen by tight-fitting high-flow reservoir face mask or endotracheal tube. Hyperbaric oxygen (HBO) can provide 100% oxygen under higher than atmospheric pressures, further shortening the half-life; it may also reduce the incidence of subtle neuropsychiatric sequelae. Recent studies disagree

about the benefit of HBO, but generally recommended indications for HBO in patients with carbon monoxide poisoning include a history of loss of consciousness, CoHb greater than 25%, metabolic acidosis, age over 50 years, and cerebellar findings on neurologic examination.

CHEMICAL WARFARE: NERVE AGENTS

Nerve agents used in chemical warfare work by cholinesterase inhibition and are most commonly organophosphorus compounds. Agents such as **tabun** (GA), **sarin** (GB), **soman** (GD), and **VX** are similar to insecticides such as malathion but are vastly more potent. They may be inhaled or absorbed through the skin. Systemic effects due to unopposed action of acetylcholine include miosis, salivation, abdominal cramps, diarrhea, and muscle paralysis producing respiratory arrest. Inhalation also produces severe bronchoconstriction and copious nasal and tracheobronchial secretions.

▶ Treatment

A. Emergency and Supportive Measures

Perform thorough decontamination of exposed areas with repeated soap and shampoo washing. Personnel caring for such patients must wear protective clothing and gloves, since cutaneous absorption may occur through normal skin.

B. Specific Treatment

Give atropine in an initial dose of 2 mg intravenously, and repeat as needed to reverse signs of acetylcholine excess. (Some victims have required several hundred milligrams.) Treat also with the cholinesterase-reactivating agent pralidoxime, 1–2 g intravenously initially followed by an infusion at a rate of 200–400 mg/h. United States military personnel in the Iraq invasion were equipped with autoinjectable units containing 2 mg of atropine plus 600 mg of the cholinesterase-reactivating agent pralidoxime.

Barelli A et al. The comprehensive medical preparedness in chemical emergencies: 'the chain of chemical survival'. *Eur J Emerg Med.* 2008 Apr;15(2):110–8. [PMID: 18446078]
 Yoshida T. Preparedness response to hazard and toxic incidents and food terrorism. *Yakugaku Zasshi.* 2008 Jun;128(6):851–7. [PMID: 18520132]

CHEMICAL WARFARE: RICIN

Ricin is a naturally occurring toxin found in minute quantities in the castor bean (*Ricinus communis*). It can cause toxicity if castor beans are thoroughly chewed or blenderized, although the quantity of ricin is small and it is poorly absorbed from the

gastrointestinal tract, so symptoms following castor bean ingestion are usually limited to diarrhea and abdominal pain. Less commonly, severe gastroenteritis can lead to volume depletion and advanced chronic kidney disease. On the other hand, purified ricin is extremely toxic if administered parenterally: the LD₅₀ for injected ricin in animals is as low as 0.1 mcg/kg. A fatal case of suspected ricin poisoning by homicidal injection of an estimated 0.28 mg of ricin was associated with diffuse organ damage and death from cardiac failure after 2 days. Inhalation of ricin powder has not been reported in humans, but animal studies suggest it could cause hemorrhagic tracheobronchitis and pneumonia.

▶ Treatment

A. Emergency and Supportive Measures

After suspected ricin inhalation or exposure to powdered ricin, remove clothing and wash skin with water. Personnel caring for such patients should wear protective respiratory gear, clothing, and gloves.

B. Specific Treatment

There is no known antidote or other specific treatment. A vaccine has been developed and is undergoing clinical trials. Provide supportive care for volume loss due to gastroenteritis and cardiac and respiratory support as needed.

Schier JG et al. Public health investigation after the discovery of ricin in a South Carolina postal facility. *Am J Public Health.* 2007 Apr;97(Suppl 1):S152–7. [PMID: 17413057]

CLONIDINE & OTHER SYMPATHOLYTIC ANTIHYPERTENSIVES

Overdosage with these agents (clonidine, guanabenz, guanfacine, methyl dopa) causes bradycardia, hypotension, miosis, respiratory depression, and coma. (Transient hypertension occasionally occurs after acute overdosage, a result of peripheral α -adrenergic effects in high doses.) Symptoms are usually resolved in less than 24 hours, and deaths are rare. Similar symptoms may occur after ingestion of topical nasal decongestants chemically similar to clonidine (oxymetazoline, tetrahydrozoline, naphazoline). Brimonidine is used as an ophthalmic preparation for glaucoma. Tizanidine is a centrally acting muscle relaxant structurally related to clonidine; it produces similar toxicity in overdose.

▶ Treatment

A. Emergency and Supportive Measures

Give activated charcoal (see p 1425). Maintain the airway and support respiration if necessary. Symptomatic treatment is usually sufficient even in massive overdose. Maintain blood pressure with intravenous fluids. Dopamine can also be used. Atropine is usually effective for bradycardia.

B. Specific Treatment

There is no specific antidote. Although tolazoline has been recommended for clonidine overdose, its effects are unre-

dictable and it should not be used. Naloxone has been reported to be successful in a few anecdotal and poorly substantiated cases.

COCAINE

See Amphetamines & Cocaine.

CYANIDE

Cyanide is a highly toxic chemical used widely in research and commercial laboratories and many industries. Its gaseous form, hydrogen cyanide, is an important component of smoke in fires. Cyanide-generating glycosides are also found in the pits of apricots and other related plants. Cyanide is generated by the breakdown of nitroprusside, and poisoning can result from rapid high-dose infusions. Cyanide is also formed by metabolism of acetonitrile, a solvent found in some over-the-counter fingernail glue removers. Cyanide is rapidly absorbed by inhalation, skin absorption, or ingestion. It disrupts cellular function by inhibiting cytochrome oxidase and preventing cellular oxygen utilization.

Clinical Findings

The onset of toxicity is nearly instantaneous after inhalation of hydrogen cyanide gas but may be delayed for minutes to hours after ingestion of cyanide salts or cyanogenic plants or chemicals. Effects include headache, dizziness, nausea, abdominal pain, and anxiety, followed by confusion, syncope, shock, seizures, coma, and death. The odor of “bitter almonds” may be detected on the victim’s breath or in vomitus, though this is not a reliable finding. The venous oxygen saturation may be elevated (> 90%) in severe poisonings because tissues have failed to take up arterial oxygen.

Treatment

A. Emergency and Supportive Measures

Remove the victim from exposure, taking care to avoid exposure to rescuers. For suspected cyanide poisoning due to nitroprusside infusion, stop or slow the rate of infusion. (Metabolic acidosis and other signs of cyanide poisoning usually clear rapidly.)

For cyanide ingestion, administer activated charcoal (see p 1425). Although charcoal has a low affinity for cyanide, the usual doses of 60–100 g are adequate to bind typically ingested lethal doses (100–200 mg).

B. Specific Treatment

In the United States, the conventional cyanide antidote package (Taylor Pharmaceuticals) (Table 38–7) contains nitrites (to induce methemoglobinemia, which binds free cyanide) and thiosulfate (to promote conversion of cyanide to the less toxic thiocyanate). Administer amyl nitrite by crushing an ampule under the victim’s nose or at the end of the endotracheal tube, and administer 3% sodium nitrite solution, 10 mL intravenously. **Caution:** Nitrites may induce hypotension and dangerous levels of methemoglobin. Also administer 25% sodium thiosulfate solution, 50 mL intravenously (12.5 g). Hydroxocobalamin, a newer and potentially safer alternative antidote, was approved by the FDA in December 2006. The dose of hydroxocobalamin (Cyanokit, EMD Pharmaceuticals) is 5 g intravenously (children, 70 mg/kg).

DIGITALIS & OTHER CARDIAC GLYCOSIDES

Cardiac glycosides are derived from a variety of plants and are widely used to treat heart failure and supraventricular arrhythmias. These drugs paralyze the Na⁺-K⁺-ATPase pump and have potent vagotonic effects. Intracellular effects include enhancement of calcium-dependent contractility and shortening of the action potential duration. Digoxin and ouabain are highly tissue-bound, but digitoxin has a volume of distribution of just 0.6 L/kg, making it potentially accessible to enhanced removal procedures such as hemoperfusion or repeated doses of activated charcoal. There are a number of plants (eg, oleander, foxglove, lily-of-the-valley) that contain cardiac glycosides. Bufotenin, a cardiotoxic steroid found in certain toad secretions and used as an herbal medicine and a purported aphrodisiac, has pharmacologic properties similar to cardiac glycosides.

Table 38–7. Currently available cyanide (CN) antidote kits.

| Antidote | Contents | Action |
|--|---|--|
| Conventional cyanide antidote kit ¹ | Amyl nitrite, 0.3 mL aspirol for inhalation; sodium nitrite 300 mg in a 10-mL vial; sodium thiosulfate 12.5 g in a 50-mL vial | Nitrites induce methemoglobinemia, which binds CN; thiosulfate hastens CN conversion to less toxic thiocyanate |
| Cyanokit ² | Hydroxocobalamin 5 g in two 2.5-g vials | Converts CN to cyanocobalamin (vitamin B ₁₂) |

¹In the United States, manufactured by Taylor Pharmaceuticals.

²Manufactured by EMD Pharmaceuticals.

► Clinical Findings

Intoxication may result from acute single exposure or chronic accidental overmedication. After acute overdosage, nausea and vomiting, bradycardia, hyperkalemia, and AV block frequently occur. Patients in whom toxicity develops gradually during long-term therapy may be hypokalemic and hypomagnesemic owing to concurrent diuretic treatment and more commonly present with ventricular arrhythmias (eg, ectopy, bidirectional ventricular tachycardia, or ventricular fibrillation). Digoxin levels may be only slightly elevated in patients with intoxication from cardiac glycosides other than digoxin because of limited cross-reactivity of immunologic tests.

► Treatment

A. Emergency and Supportive Measures

After acute ingestion, administer activated charcoal (see p 1425). Monitor potassium levels and cardiac rhythm closely. Treat bradycardia initially with atropine (0.5–2 mg intravenously) or a transcutaneous external cardiac pacemaker.

B. Specific Treatment

For patients with significant intoxication, administer digoxin-specific antibodies (digoxin immune Fab [ovine]; Digibind or DigiFab). Estimation of the Digibind dose is based on the body burden of digoxin calculated from the ingested dose or the steady-state serum digoxin concentration:

1. From the ingested dose—Number of vials = approximately $1.5\text{--}2 \times$ ingested dose (mg).

2. From the serum concentration—Number of vials = serum digoxin (ng/mL) \times body weight (kg) $\times 10^{-2}$. **Note:** This is based on the equilibrium digoxin level; after acute overdose, serum levels are falsely high before tissue distribution is complete, and overestimation of the Digibind or DigiFab dose is likely.

3. Empiric dosing—Empiric dosing of Digibind or DigiFab may be used if the patient's condition is relatively stable and an underlying condition (eg, atrial fibrillation) suggests a residual level of digitalis activity. Start with one or two vials and reassess the clinical condition after 20–30 minutes. For cardiac glycosides other than digoxin or digitoxin, there is no formula for estimation of vials needed and treatment is empiric.

Note: After administration of digoxin-specific Fab antibody fragment, serum digoxin levels may be falsely elevated depending on the assay technique.

ETHANOL, BENZODIAZEPINES, & OTHER SEDATIVE-HYPNOTIC AGENTS

The group of agents known as sedative-hypnotic drugs includes a variety of products used for the treatment of anxiety, depression, insomnia, and epilepsy. Ethanol and other selected agents are also popular recreational drugs. All of these drugs depress the central nervous system reticular activating system, cerebral cortex, and cerebellum.

► Clinical Findings

Mild intoxication produces euphoria, slurred speech, and ataxia. Ethanol intoxication may produce hypoglycemia, even at relatively low concentrations. With more severe intoxication, stupor, coma, and respiratory arrest may occur. Carisoprodol (Soma) commonly causes muscle jerking or myoclonus. Death or serious morbidity is usually the result of pulmonary aspiration of gastric contents. Bradycardia, hypotension, and hypothermia are common. Patients with massive intoxication may appear to be dead, with no reflex responses and even absent electroencephalographic activity. Diagnosis and assessment of severity of intoxication are usually based on clinical findings. Ethanol serum levels greater than 300 mg/dL (0.3 g/dL; 65 mmol/L) can produce coma in persons who are not chronically abusing the drug, but regular users may remain awake at much higher levels. Phenobarbital levels greater than 100 mg/L usually cause coma.

► Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p 1425). Repeat-dose charcoal may enhance elimination of phenobarbital, but it has not been proved to improve clinical outcome. Hemodialysis may be necessary for patients with severe phenobarbital intoxication.

B. Specific Treatment

Flumazenil is a benzodiazepine receptor-specific antagonist; it has no effect on ethanol, barbiturates, or other sedative-hypnotic agents. If used, flumazenil is given slowly intravenously, 0.2 mg over 30–60 seconds, repeated in 0.5 mg increments as needed up to a total dose of 3–5 mg. **Caution:** Flumazenil may induce seizures in patients with preexisting seizure disorder, benzodiazepine addiction, or concomitant tricyclic antidepressant overdose. If seizures occur, diazepam and other benzodiazepine anticonvulsants will not be effective. As with naloxone, the duration of action of flumazenil is short (2–3 hours) and re sedation may occur, requiring repeated doses.

Chudnofsky CR. Safety and efficacy of flumazenil in reversing conscious sedation in the emergency department. *Emergency Medicine Conscious Sedation Study Group.* *Acad Emerg Med.* 1997 Oct;4(10):944–50. [PMID: 9332625]

Thomson JS et al. Use of flumazenil in benzodiazepine overdose. *Emerg Med J.* 2006 Feb;23(2):162. [PMID: 16439763]

γ-HYDROXYBUTYRATE (GHB)

GHB has become a popular drug of abuse. It originated as a short-acting general anesthetic and is occasionally used in the treatment of narcolepsy. It gained popularity among bodybuilders for its alleged growth hormone stimulation and found its way into social settings, where it is consumed as a liquid. It has been used to facilitate sexual assault (“date-rape” drug). Symptoms after ingestion include drowsiness and lethargy followed by coma with respiratory depression. Muscle twitching and seizures are sometimes observed. Recovery is usually rapid, with patients awakening within a few hours. Other related chemicals with similar effects include butanediol and γ-butyrolactone (GBL). A prolonged withdrawal syndrome has been described in some heavy users.

▶ Treatment

Monitor the airway and assist breathing if needed. There is no specific treatment. Most patients recover rapidly with supportive care. GHB withdrawal syndrome may require very large doses of benzodiazepines.

Abanades S et al. Relative abuse liability of gamma-hydroxybutyric acid, flunitrazepam, and ethanol in club drug users. *J Clin Psychopharmacol*. 2007 Dec;27(6):625–38. [PMID: 18004131]

Anderson IB et al. Trends in gamma-hydroxybutyrate (GHB) intoxication: 1999–2003. *Ann Emerg Med*. 2006 Feb;47(2):177–83. [PMID: 16431231]

IRON

Iron is widely used therapeutically for the treatment of anemia and as a daily supplement in multiple vitamin preparations. Most children’s preparations contain about 12–15 mg of elemental iron (as sulfate, gluconate, or fumarate salt) per dose, compared with 60–90 mg in most adult-strength preparations. Iron is corrosive to the gastrointestinal tract and, once absorbed, has depressant effects on the myocardium and on peripheral vascular resistance. Intracellular toxic effects of iron include disruption of Krebs cycle enzymes.

▶ Clinical Findings

Ingestion of less than 30 mg/kg of elemental iron usually produces only mild gastrointestinal upset. Ingestion of more than 40–60 mg/kg may cause vomiting (sometimes with hematemesis), diarrhea, hypotension, and acidosis. Death may occur as a result of profound hypotension due to massive fluid losses and bleeding, metabolic acidosis, peritonitis from intestinal perforation, or sepsis. Fulminant hepatic failure may occur. Survivors of the acute ingestion may suffer permanent gastrointestinal scarring.

Serum iron levels greater than 350–500 mcg/dL are considered potentially toxic, and levels over 1000 mcg/dL are usually associated with severe poisoning. A plain abdominal radiograph may reveal radiopaque tablets.

▶ Treatment

A. Emergency and Supportive Measures

Treat hypotension aggressively with intravenous crystalloid solutions (0.9% saline or lactated Ringer solution). Fluid losses may be massive owing to vomiting and diarrhea as well as third-spacing into injured intestine.

Perform whole bowel irrigation to remove unabsorbed pills from the intestinal tract (see p 1425). Activated charcoal is not effective but may be appropriate if other ingestants are suspected.

B. Specific Treatment

Deferoxamine is a selective iron chelator. It is not useful as an oral binding agent. For patients with established manifestations of toxicity—and particularly those with markedly elevated serum iron levels (eg, greater than 800–1000 mcg/dL)—administer 10–15 mg/kg/h by constant intravenous infusion; higher doses (up to 40–50 mg/kg/h) have been used in massive poisonings. Hypotension may occur. The presence of an iron-deferoxamine complex in the urine may give it a “vin rosé” appearance. Deferoxamine is safe for use in pregnant women with acute iron overdose. **Caution:** Prolonged infusion of deferoxamine (> 36–48 hours) has been associated with development of acute respiratory distress syndrome (ARDS)—the mechanism is not known.

ISONIAZID

INH is an antibacterial drug used mainly in the treatment and prevention of tuberculosis. It may cause hepatitis with long-term use, especially in alcoholic patients and elderly persons. It produces acute toxic effects by competing with pyridoxal 5-phosphate, resulting in lowered brain γ-aminobutyric acid (GABA) levels. Acute ingestion of as little as 1.5–2 g of INH can cause toxicity, and severe poisoning is likely to occur after ingestion of more than 80–100 mg/kg.

▶ Clinical Findings

Confusion, slurred speech, and seizures may occur abruptly after acute overdose. Severe lactic acidosis—out of proportion to the severity of seizures—is probably due to inhibited metabolism of lactate. Peripheral neuropathy and acute hepatitis may occur with long-term use.

Diagnosis is based on a history of ingestion and the presence of severe acidosis associated with seizures. INH is not usually included in routine toxicologic screening, and serum levels are not readily available.

▶ Treatment

A. Emergency and Supportive Measures

Seizures may require higher than usual doses of benzodiazepines (eg, lorazepam, 3–5 mg intravenously) or administration of pyridoxine as an antidote (see below).

Administer activated charcoal (see p 1425). Do *not* induce emesis, because of the risk of abrupt onset of seizures.

B. Specific Treatment

Pyridoxine (vitamin B₆) is a specific antagonist of the acute toxic effects of INH and is usually successful in controlling convulsions that do not respond to benzodiazepines. Give 5 g intravenously over 1–2 minutes or, if the amount ingested is known, give a gram-for-gram equivalent amount of pyridoxine. Patients taking INH are usually given 25–50 mg of pyridoxine orally daily to help prevent neuropathy.

LEAD

Lead is used in a variety of industrial and commercial products, such as storage batteries, solders, paints, pottery, plumbing, and gasoline and is found in some traditional Hispanic and Ayurvedic ethnic medicines. Lead toxicity usually results from chronic repeated exposure and is rare after a single ingestion. Lead produces a variety of adverse effects on cellular function and primarily affects the nervous system, gastrointestinal tract, and hematopoietic system.

▶ Clinical Findings

Lead poisoning often goes undiagnosed initially because presenting symptoms and signs are nonspecific and exposure is not suspected. Common symptoms include colicky abdominal pain, constipation, headache, and irritability. Severe poisoning may cause coma and convulsions. Chronic intoxication can cause learning disorders (in children) and motor neuropathy (eg, wrist drop). Lead-containing bullet fragments in or near joint spaces can result in chronic lead toxicity.

Diagnosis is based on measurement of the blood lead level. Whole blood lead levels less than 10 mcg/dL are usually considered nontoxic. Levels between 10 and 25 mcg/dL have been associated with impaired neurobehavioral development in children. Levels of 25–50 mcg/dL may be associated with headache, irritability, and subclinical neuropathy. Levels of 50–70 mcg/dL are associated with moderate toxicity, and levels greater than 70–100 mcg/dL are often associated with severe poisoning. Other laboratory findings of lead poisoning include microcytic anemia with basophilic stippling and elevated free erythrocyte protoporphyrin.

▶ Treatment

A. Emergency and Supportive Measures

For patients with encephalopathy, maintain a patent airway and treat coma and convulsions as described at the beginning of this chapter.

For recent acute ingestion, if a large lead-containing object (eg, fishing weight) is still visible in the stomach on abdominal radiograph, whole bowel irrigation (see p 1425), endoscopy, or even surgical removal may be necessary to prevent subacute lead poisoning. (The acidic gastric contents may corrode the metal surface, enhancing lead absorption. Once the object passes into the small intestine, the risk of toxicity declines.)

Conduct an investigation into the source of the lead exposure.

Workers with a single lead level greater than 60 mcg/dL (or three successive monthly levels greater than 50 mcg/dL) or construction workers with any single blood lead level greater than 50 mcg/dL must by federal law be removed from the site of exposure. Contact the regional office of the United States Occupational Safety and Health Administration (OSHA) for more information. Several states mandate reporting of cases of confirmed lead poisoning.

B. Specific Treatment

The indications for chelation depend on the blood lead level and the patient's clinical state. A medical toxicologist or regional poison control center (800-222-1222) should be consulted for advice about selection and use of these antidotes.

Note: It is impermissible under the law to treat asymptomatic workers with elevated blood lead levels in order to keep their levels under 50 mcg/dL rather than remove them from the exposure.

1. Severe toxicity—Patients with severe intoxication (encephalopathy or levels greater than 70–100 mcg/dL) should receive edetate calcium disodium (ethylenediaminetetraacetic acid, EDTA), 1500 mg/m²/kg/d (approximately 50 mg/kg/d) in four to six divided doses or as a continuous intravenous infusion. Some clinicians also add dimercaprol (BAL), 4–5 mg/kg intramuscularly every 4 hours for 5 days.

2. Less severe toxicity—Patients with less severe symptoms and asymptomatic patients with blood lead levels between 55 and 69 mcg/dL may be treated with edetate calcium disodium alone in dosages as above. An oral chelator, succimer (DMSA), is available for use in patients with mild to moderate intoxication. The usual dose is 10 mg/kg orally every 8 hours for 5 days, then every 12 hours for 2 weeks.

LSD & OTHER HALLUCINOGENS

A variety of substances—ranging from naturally occurring plants and mushrooms to synthetic substances such as phencyclidine (PCP), toluene and other solvents, dextromethorphan, and lysergic acid diethylamide (LSD)—are abused for their hallucinogenic properties. The mechanism of toxicity and the clinical effects vary for each substance.

Many hallucinogenic plants and mushrooms produce anticholinergic delirium, characterized by flushed skin, dry mucous membranes, dilated pupils, tachycardia, and urinary retention. Other plants and mushrooms may contain hallucinogenic indoles such as mescaline and LSD, which typically cause marked visual hallucinations and perceptual distortion, widely dilated pupils, and mild tachycardia. PCP, a dissociative anesthetic agent similar to ketamine, can produce fluctuating delirium and coma, often associated with vertical and horizontal nystagmus. Toluene and other hydrocarbon solvents (butane, trichloroethylene, “chemo,” etc) cause euphoria and delirium and may sensitize the myocardium to the effects of catecholamines, leading to fatal dysrhythmias.

▶ Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist respirations if necessary. Treat coma, hyperthermia, and seizures as outlined at the beginning of this chapter. For recent large ingestions, consider giving activated charcoal orally or by gastric tube.

B. Specific Treatment

Patients with anticholinergic delirium may benefit from a dose of physostigmine, 0.5–1 mg intravenously, not to exceed 1 mg/min. Dysphoria, agitation, and psychosis associated with LSD or mescaline intoxication may respond to benzodiazepines (eg, lorazepam, 1–2 mg orally or intravenously) or haloperidol (2–5 mg intramuscularly or intravenously). Monitor patients who have sniffed solvents for cardiac dysrhythmias (most commonly premature ventricular contractions, ventricular tachycardia, ventricular fibrillation); treatment with β -blockers such as propranolol (1–5 mg intravenously) or esmolol (250–500 mcg/kg intravenously, then 50 mcg/kg/min by infusion) may be more effective than lidocaine.

Jamison SC et al. A 60-year-old woman with agitation and psychosis following ingestion of dextromethorphan and opioid analgesics. *J Psychopharmacol*. 2008 Jun 26 [Epub ahead of print]. [PMID: 18583439]

MERCURY

Acute mercury poisoning usually occurs by ingestion of inorganic mercuric salts or inhalation of metallic mercury vapor. Ingestion of the mercuric salts causes a burning sensation in the throat, discoloration and edema of oral mucous membranes, abdominal pain, vomiting, bloody

diarrhea, and shock. Direct nephrotoxicity causes acute kidney injury. Inhalation of high concentrations of metallic mercury vapor may cause acute fulminant chemical pneumonia. Chronic mercury poisoning causes weakness, ataxia, intention tremors, irritability, and depression. Exposure to alkyl (organic) mercury derivatives from contaminated fish or fungicides used on seeds has caused ataxia, tremors, convulsions, and catastrophic birth defects.

▶ Treatment

A. Acute Poisoning

There is no effective specific treatment for mercury vapor pneumonitis. Remove ingested mercuric salts by lavage, and administer activated charcoal (see p 1425). For acute ingestion of mercuric salts, give dimercaprol (BAL) at once, as for arsenic poisoning. Unless the patient has severe gastroenteritis, consider succimer (DMSA), 10 mg/kg orally every 8 hours for 5 days and then every 12 hours for 2 weeks. Unithiol is a chelator that can be given orally or parenterally, but is not commonly available in the United States. Maintain urinary output. Treat oliguria and anuria if they occur.

B. Chronic Poisoning

Remove from exposure. Neurologic toxicity is not considered reversible with chelation, although some authors recommend a trial of succimer or unithiol (contact a regional poison center or medical toxicologist for advice).

Mozaffarian D et al. Fish intake, contaminants, and human health: evaluating the risks and the benefits. *JAMA*. 2006 Oct 18;296(15):1885–99. [PMID: 17047219]

METHANOL & ETHYLENE GLYCOL

Methanol (wood alcohol) is commonly found in a variety of products, including solvents, duplicating fluids, record cleaning solutions, and paint removers. It is sometimes ingested intentionally by alcoholic patients as a substitute for ethanol and may also be found as a contaminant in bootleg whiskey. Ethylene glycol is the major constituent in most antifreeze compounds. The toxicity of both agents is caused by metabolism to highly toxic organic acids—methanol to formic acid; ethylene glycol to glycolic and oxalic acids.

▶ Clinical Findings

Shortly after ingestion of either of these agents, patients usually appear “drunk.” The serum osmolality (measured with the freezing point device) is usually increased, but acidosis is often absent early. After several hours, metabolism to toxic organic acids leads to a severe anion gap metabolic acidosis, tachypnea, confusion, convulsions, and coma. Methanol intoxication frequently causes visual disturbances, while ethylene glycol often produces oxalate crystalluria and advanced chronic kidney disease.

▶ Treatment

A. Emergency and Supportive Measures

For patients presenting within 30–60 minutes after ingestion, empty the stomach by gastric lavage (see p 1424). Charcoal is not very effective but should be administered if other poisons or drugs have also been ingested.

B. Specific Treatment

Patients with significant toxicity (manifested by severe metabolic acidosis, altered mental status, and markedly elevated osmol gap) should undergo hemodialysis as soon as possible to remove the parent compound and the toxic metabolites. Treatment with folic acid, thiamine, and pyridoxine may enhance the breakdown of toxic metabolites.

Ethanol blocks metabolism of the parent compounds by competing for the enzyme alcohol dehydrogenase. Fomepizole (4-methylpyrazole; Antizol) blocks alcohol dehydrogenase and is easier to use than ethanol. A regional poison control center (800-222-1222) should be contacted for indications and dosing.

METHEMOGLOBINEMIA-INDUCING AGENTS

A large number of chemical agents are capable of oxidizing ferrous hemoglobin to its ferric state (methemoglobin), a form that cannot carry oxygen. Drugs and chemicals known to cause methemoglobinemia include benzocaine (a local anesthetic found in some topical anesthetic sprays and a variety of nonprescription products), aniline, propylamine, nitrites, nitrogen oxide gases, nitrobenzene, dapsone, phenazopyridine (Pyridium), and many others. Dapsone has a long elimination half-life and may produce prolonged or recurrent methemoglobinemia.

▶ Clinical Findings

Methemoglobinemia reduces oxygen-carrying capacity and may cause dizziness, nausea, headache, dyspnea, confusion, seizures, and coma. The severity of symptoms depends on the percentage of hemoglobin oxidized to methemoglobin; severe poisoning is usually present when methemoglobin fractions are greater than 40–50%. Even at low levels (15–20%), victims appear cyanotic because of the “chocolate brown” color of methemoglobin, but they have normal PO₂ results on arterial blood gas determinations. Pulse oximetry gives inaccurate oxygen saturation measurements; the reading is often between 85% and 90%. Severe metabolic

acidosis may be present. Hemolysis may occur, especially in patients susceptible to oxidant stress (ie, those with glucose-6-phosphate dehydrogenase deficiency).

▶ Treatment

A. Emergency and Supportive Measures

Administer high-flow oxygen. If the causative agent was recently ingested, administer activated charcoal (see p 1425). Repeat-dose activated charcoal may enhance dapsone elimination (see p 1425).

B. Specific Treatment

Methylene blue enhances the conversion of methemoglobin to hemoglobin by increasing the activity of the enzyme methemoglobin reductase. For symptomatic patients, administer 1–2 mg/kg (0.1–0.2 mL/kg of 1% solution) intravenously. The dose may be repeated once in 15–20 minutes if necessary. Patients with hereditary methemoglobin reductase deficiency or glucose-6-phosphate dehydrogenase deficiency may not respond to methylene blue treatment.

MONOAMINE OXIDASE INHIBITORS

Overdoses of MAO inhibitors (isocarboxazid, phenelzine, selegiline, moclobemide) cause ataxia, excitement, hypertension, and tachycardia, followed several hours later by hypotension, convulsions, and hyperthermia.

Ingestion of tyramine-containing foods may cause a severe hypertensive reaction in patients taking MAO inhibitors. Foods containing tyramine include aged cheese and red wines. Hypertensive reactions may also occur with any sympathomimetic drug. Severe or fatal hyperthermia (serotonin syndrome) may occur if patients receiving MAO inhibitors are given meperidine, fluoxetine, paroxetine, fluvoxamine, venlafaxine, tryptophan, dextromethorphan, tramadol, or other serotonin-enhancing drugs. This reaction can also occur with the newer selective MAO inhibitor moclobemide, and the antibiotic linezolid, which has MAO-inhibiting properties. The serotonin syndrome has also been reported in patients taking selective serotonin reuptake inhibitors (SSRIs) in large doses or in combination with other SSRIs, even in the absence of an MAO inhibitor or meperidine.

▶ Treatment

Administer activated charcoal (see p 1425). Treat severe hypertension with nitroprusside, phentolamine, or other rapid-acting vasodilators (see p 1422). Treat hypotension

with fluids and positioning, but avoid use of pressor agents if possible. Observe patients for at least 24 hours, since hyperthermic reactions may be delayed. Treat hyperthermia with aggressive cooling; neuromuscular paralysis may be required (see p 1423). Cyproheptadine, 4 mg orally (or by gastric tube) every hour for three or four doses, has been reported to be effective against serotonin syndrome.

Sun-Edelstein C et al. Drug-induced serotonin syndrome. *Expert Opin Drug Saf.* 2008 Sep;7(5):587–96. [PMID: 18759711]

MUSHROOMS

There are thousands of mushroom species that cause a variety of toxic effects. The most dangerous species of mushrooms are *Amanita phalloides*, *Amanita verna*, *Amanita virosa*, *Gyromitra esculenta*, and the *Galerina* species, all of which contain amatoxin, a potent cytotoxin. Ingestion of even a portion of one mushroom of a dangerous species may be sufficient to cause death.

The characteristic pathologic finding in fatalities from amatoxin-containing mushroom poisoning is acute massive necrosis of the liver.

► Clinical Findings (Table 38-8)

A. Symptoms and Signs

1. Amatoxin-type cyclopeptides—(*A phalloides*, *A verna*, *A virosa*, and *Galerina* species.) After a latent interval of 8–12 hours, severe abdominal cramps and vomiting begin and progress to profuse diarrhea, followed in 1–2 days by hepatic necrosis, hepatic encephalopathy, and frequently

acute kidney injury. The fatality rate is about 20%. Cooking the mushrooms does not prevent poisoning.

2. Gyromitrin type—(*Gyromitra* and *Helvella* species.) Toxicity is more common following ingestion of uncooked mushrooms. Vomiting, diarrhea, hepatic necrosis, convulsions, coma, and hemolysis may occur after a latent period of 8–12 hours. The fatality rate is probably less than 10%.

3. Muscarinic type—(*Inocybe* and *Clitocybe* species.) Vomiting, diarrhea, bradycardia, hypotension, salivation, miosis, bronchospasm, and lacrimation occur shortly after ingestion. Cardiac arrhythmias may occur. Fatalities are rare.

4. Anticholinergic type—(Eg, *Amanita muscaria*, *Amanita pantherina*.) This type causes a variety of symptoms that may be atropine-like, including excitement, delirium, flushed skin, dilated pupils, and muscular jerking tremors, beginning 1–2 hours after ingestion. Fatalities are rare.

5. Gastrointestinal irritant type—(Eg, *Boletus*, *Cantharellus*.) Nausea, vomiting, and diarrhea occur shortly after ingestion. Fatalities are rare.

6. Disulfiram type—(*Coprinus* species.) Disulfiram-like sensitivity to alcohol may persist for several days. Toxicity is characterized by flushing, hypotension, and vomiting after coingestion of alcohol.

7. Hallucinogenic—(*Psilocybe* and *Panaeolus* species.) Mydriasis, nausea and vomiting, and intense visual hallucinations occur 1–2 hours after ingestion. Fatalities are rare.

8. Cortinarius orellanus—This mushroom may cause acute kidney injury due to tubulointerstitial nephritis. *Amanita smithiana* has also been reported to cause acute kidney injury.

Table 38-8. Poisonous mushrooms.

| Toxin | Genus | Symptoms and Signs | Onset | Treatment |
|----------------------------|---|--|---------------|---|
| Amanitin | <i>Amanita</i> (<i>A phalloides</i> , <i>A verna</i> , <i>A virosa</i>) | Severe gastroenteritis followed by delayed hepatic failure and acute kidney injury after 48–72 hours | 6–24 hours | Supportive. Correct dehydration. Give repeated doses of activated charcoal orally. Consider silymarin (silibinin) (see text). |
| Muscarine | <i>Inocybe</i> , <i>Clitocybe</i> | Muscarinic (salivation, miosis, bradycardia, diarrhea) | 30–60 minutes | Supportive. Give atropine, 0.5–2 mg intravenously, for severe cholinergic symptoms and signs. |
| Ibotenic acid, muscimol | <i>Amanita muscaria</i> (“fly agaric”) | Anticholinergic (mydriasis, tachycardia, hyperpyrexia, delirium) | 30–60 minutes | Supportive. Give physostigmine, 0.5–2 mg intravenously, for severe anticholinergic symptoms and signs. |
| Coprine | <i>Coprinus</i> | Disulfiram-like effect occurs with ingestion of ethanol | 30–60 minutes | Supportive. Abstain from ethanol for 3–4 days. |
| Monomethylhydrazine | <i>Gyromitra</i> | Gastroenteritis; occasionally hemolysis, hepatic failure, and acute kidney injury | 6–12 hours | Supportive. Correct dehydration. Pyridoxine, 2.5 mg/kg intravenously, may be helpful. |
| Orellanine | <i>Cortinarius</i> | Nausea, vomiting; acute kidney injury after 1–3 weeks | 2–14 days | Supportive. |
| Psilocybin | <i>Psilocybe</i> | Hallucinations | 15–30 minutes | Supportive. |
| Gastrointestinal irritants | Many species | Nausea and vomiting, diarrhea | ½–2 hours | Supportive. Correct dehydration. |

▶ Treatment

A. Emergency Measures

After the onset of symptoms, efforts to remove the toxic agent are probably useless, especially in cases of amatoxin or gyromitrin poisoning, where there is usually a delay of 12 hours or more before symptoms occur and patients seek medical attention. However, induction of vomiting or administration of activated charcoal is recommended for any recent ingestion of an unidentified or potentially toxic mushroom (see p 1425).

B. General Measures

1. Amatoxin-type cyclopeptides—A variety of antidotes (eg, thioctic acid, penicillin, corticosteroids) have been suggested for amatoxin-type mushroom poisoning, but controlled studies are lacking and experimental data in animals are equivocal. Aggressive fluid replacement for diarrhea and intensive supportive care for hepatic failure are the mainstays of treatment. Silymarin (silibinin), a derivative of milk thistle, is commonly used in Europe but is not available in the United States as a pharmaceutical grade intravenous preparation.

Interruption of enterohepatic circulation of the amatoxin by the administration of activated charcoal or by cannulation and drainage of the bile duct may be of value.

Liver transplant may be the only hope for survival in gravely ill patients—contact a liver transplant center early.

2. Gyromitrin type—For gyromitrin poisoning, give pyridoxine, 25 mg/kg intravenously.

3. Muscarinic type—For mushrooms producing predominantly muscarinic-cholinergic symptoms, give atropine, 0.005–0.01 mg/kg intravenously, and repeat as needed.

4. Anticholinergic type—For anticholinergic type, physostigmine, 0.5–1 mg intravenously, may calm extremely agitated patients and reverse peripheral anticholinergic manifestations, but it may also cause bradycardia, asystole, and seizures. Alternately, use a benzodiazepine such as lorazepam, 1–2 mg intravenously.

5. Gastrointestinal irritant type—Treat with antiemetics and intravenous or oral fluids.

6. Disulfiram type—For *Coprinus* ingestion, avoid alcohol. Treat alcohol reaction with fluids and supine position.

7. Hallucinogenic type—Provide a quiet, supportive atmosphere. Diazepam or haloperidol may be used for sedation.

8. Cortinari—Provide supportive care and hemodialysis as needed for acute kidney injury.

Yang WS et al. Acute renal failure caused by mushroom poisoning. *J Formos Med Assoc*. 2006 Mar;105(3):263–7. [PMID: 16520846]

OPIOIDS

Prescription and illicit opioids (morphine, heroin, codeine, oxycodone, fentanyl, hydromorphone, etc) are popular drugs of abuse and the cause of frequent hospitalizations for overdose. These drugs have widely varying potencies and durations of action; for example, some of the illicit fentanyl derivatives are up to 2000 times more potent than morphine. All of these agents decrease central nervous system activity and sympathetic outflow by acting on opiate receptors in the brain. Tramadol is an analgesic that is unrelated chemically to the opioids but acts on opioid receptors. Buprenorphine is a partial agonist-antagonist opioid used for the outpatient treatment of opioid addiction.

▶ Clinical Findings

Mild intoxication is characterized by euphoria, drowsiness, and constricted pupils. More severe intoxication may cause hypotension, bradycardia, hypothermia, coma, and respiratory arrest. Pulmonary edema may occur. Death is usually due to apnea or pulmonary aspiration of gastric contents. Propoxyphene may cause seizures and prolongation of the QRS interval. Methadone has been associated with QT interval prolongation and torsades de pointes. Tramadol, dextromethorphan, and meperidine also occasionally cause seizures. With meperidine, the metabolite normeperidine is probably the cause of seizures and is most likely to accumulate with repeated dosing in patients with chronic kidney disease. While the duration of effect for heroin is usually 3–5 hours, methadone intoxication may last for 48–72 hours or longer. Many opioids, including fentanyl, tramadol, oxycodone, and methadone, are not detected on routine urine toxicology “opiate” screening. Wound botulism has been associated with skin-popping, especially involving “black tar” heroin. Buprenorphine added to an opioid regimen may produce acute narcotic withdrawal symptoms.

▶ Treatment

A. Emergency and Supportive Measures

Protect the airway and assist ventilation. Administer activated charcoal (see p 1425).

B. Specific Treatment

Naloxone is a specific opioid antagonist that can rapidly reverse signs of narcotic intoxication. Although it is structurally related to the opioids, it has no agonist effects of its own. Administer 0.4–2 mg intravenously, and repeat as needed to awaken the patient and maintain airway protective reflexes and spontaneous breathing. Very large doses (10–20 mg) may be required for patients intoxicated by some opioids (eg, propoxyphene, codeine, fentanyl deriva-

tives). **Caution:** The duration of effect of naloxone is only about 2–3 hours; repeated doses may be necessary for patients intoxicated by long-acting drugs such as methadone. Continuous observation for at least 3 hours after the last naloxone dose is mandatory.

PARAQUAT

Paraquat is used as a herbicide. Concentrated solutions of paraquat are highly corrosive to the oropharynx, esophagus, and stomach. The fatal dose after absorption may be as small as 4 mg/kg. If ingestion of paraquat is not rapidly fatal because of its corrosive effects, the herbicide may cause progressive pulmonary fibrosis, with death ensuing after 2–3 weeks. Patients with plasma paraquat levels above 2 mg/L at 6 hours or 0.2 mg/L at 24 hours are likely to die.

▶ Treatment

Remove ingested paraquat by immediate induced emesis, or by gastric lavage if the patient is already in a health care facility (see p 1424). Clay (bentonite or fuller's earth) and activated charcoal are effective adsorbents. Administer repeated doses of 60 g of activated charcoal by gastric tube every 2 hours for at least three or four doses. Charcoal hemoperfusion, 8 hours per day for 2–3 weeks, has been anecdotally reported to be lifesaving, but clinical and animal studies are equivocal. Supplemental oxygen should be withheld unless the P_{aO_2} is less than 70 mm Hg because oxygen may contribute to the pulmonary damage, which is mediated through lipid peroxidation. Immunosuppressive therapy (cyclophosphamide with dexamethasone) has shown possible benefit in anecdotal reports.

PESTICIDES: CHOLINESTERASE INHIBITORS

Organophosphorus and carbamate insecticides (organophosphates: parathion, malathion, etc; carbamates: carbaryl, aldicarb, etc) are widely used in commercial agriculture and

home gardening and have largely replaced older, more environmentally persistent organochlorine compounds such as DDT and chlordane. The organophosphates and carbamates—also called anticholinesterases because they inhibit the enzyme acetylcholinesterase—cause an increase in acetylcholine activity at nicotinic and muscarinic receptors and in the central nervous system. There are a variety of chemical agents in this group, with widely varying potencies. Most of them are poorly water-soluble, are formulated with an aromatic hydrocarbon solvent such as xylene, and are well absorbed through intact skin. Most chemical warfare “nerve agents” (see above) are organophosphates.

▶ Clinical Findings

Inhibition of cholinesterase results in abdominal cramps, diarrhea, vomiting, excessive salivation, sweating, lacrimation, miosis (constricted pupils), wheezing and bronchorrhea, seizures, and skeletal muscle weakness. Initial tachycardia is usually followed by bradycardia. Profound skeletal muscle weakness, aggravated by excessive bronchial secretions and wheezing, may result in respiratory arrest and death. Symptoms and signs of poisoning may persist or recur over several days, especially with highly lipid-soluble agents such as fenthion or dimethoate.

The diagnosis should be suspected in patients who present with miosis, sweating, and hyperperistalsis. Serum and red blood cell cholinesterase activity is usually depressed at least 50% below baseline in those victims who have severe intoxication.

▶ Treatment

A. Emergency and Supportive Measures

If the agent was recently ingested, empty the stomach by gastric lavage and administer activated charcoal (see p 1424–5). If the agent is on the victim's skin or hair, wash repeatedly with soap or shampoo and water. Providers must take care to avoid skin exposure by wearing gloves and waterproof aprons. Dilute hypochlorite solution (eg, household bleach diluted 1:10) is reported to help break down organophosphate pesticides and nerve agents on equipment or clothing.

B. Specific Treatment

Atropine reverses excessive muscarinic stimulation and is effective for treatment of salivation, bronchial hypersecretion, wheezing, abdominal cramping, and sweating. However, it does not interact with nicotinic receptors at autonomic ganglia and at the neuromuscular junction and has no effect on muscle weakness. Administer 2 mg intravenously, and if there is no response after 5 minutes, give repeated boluses in rapidly escalating doses as needed to dry bronchial secretions and decrease wheezing; as much as several hundred milligrams of atropine has been given to treat severe poisoning.

Pralidoxime (2-PAM, Protopam) is a specific antidote that reverses organophosphate binding to the cholinesterase enzyme; therefore, it is effective at the neuromuscular

junction as well as other nicotinic and muscarinic sites. It is most likely to be effective if started very soon after poisoning, to prevent permanent binding of the organophosphate to cholinesterase. Clinical studies are conflicting regarding the effectiveness of pralidoxime in reducing mortality. It appears to be more effective for chlorpyrifos compared with dimethoate poisoning. Administer 1–2 g intravenously as a loading dose, and begin a continuous infusion (200–500 mg/h, titrated to clinical response). Continue to give pralidoxime as long as there is any evidence of acetylcholine excess. Pralidoxime is of questionable benefit for carbamate poisoning, because carbamates have only a transitory effect on the cholinesterase enzyme. High-dose sodium bicarbonate (5 mEq/kg intravenously over 5 minutes) has been reported effective although the mechanism is unclear and the treatment has not been widely adopted.

PETROLEUM DISTILLATES & SOLVENTS

Petroleum distillate toxicity may occur from inhalation of the vapor or as a result of pulmonary aspiration of the liquid during or after ingestion. Acute manifestations of aspiration pneumonitis are vomiting, coughing, and bronchopneumonia. Some hydrocarbons—ie, those with aromatic or halogenated subunits—can also cause severe systemic poisoning after oral ingestion. Hydrocarbons can also cause systemic intoxication by inhalation. Vertigo, muscular incoordination, irregular pulse, myoclonus, and seizures occur with serious poisoning and may be due to hypoxemia or the systemic effects of the agents. Chlorinated and fluorinated hydrocarbons (trichloroethylene, Freons, etc) and many other hydrocarbons can cause ventricular arrhythmias due to increased sensitivity of the myocardium to the effects of endogenous catecholamines.

► Treatment

Remove the patient to fresh air. For simple aliphatic hydrocarbon ingestion, gastric emptying and activated charcoal are not recommended, but these procedures may be indicated if the preparation contains toxic solutes (eg, an insecticide) or is an aromatic or halogenated product. Observe the victim for 6–8 hours for signs of aspiration pneumonitis (cough, localized rales or rhonchi, tachypnea, and infiltrates on chest radiograph). Corticosteroids are not recommended. If fever occurs, give a specific antibiotic only after identification of bacterial pathogens by laboratory studies. Because of the risk of arrhythmias, use bronchodilators with caution in patients with chlorinated or

fluorinated solvent intoxication. If tachyarrhythmias occur, use esmolol intravenously 25–100 mcg/kg/min.

PHENOTHIAZINES & OTHER ANTIPSYCHOTIC AGENTS

Promethazine, prochlorperazine, chlorpromazine, haloperidol, droperidol, risperidone, olanzapine, ziprasidone, quetiapine, and aripiprazole are used as antiemetics and antipsychotic agents and as potentiators of analgesic and hypnotic drugs.

Phenothiazines (particularly chlorpromazine) induce drowsiness and mild orthostatic hypotension in as many as 50% of patients. Larger doses can cause obtundation, miosis, severe hypotension, tachycardia, convulsions, and coma. Abnormal cardiac conduction may occur, resulting in prolongation of QRS or QT intervals (or both) and ventricular arrhythmias. (Droperidol now has a “black box” warning about prolonged QT interval and the risk of torsades de pointes.) Among the newer agents, quetiapine is more likely to cause coma and hypotension.

With therapeutic or toxic doses, an acute extrapyramidal dystonic reaction may develop in some patients, with spasmodic contractions of the face and neck muscles, extensor rigidity of the back muscles, carpopedal spasm, and motor restlessness. This reaction is more common with haloperidol and the butyrophenones and less common with newer atypical antipsychotics such as ziprasidone, olanzapine, aripiprazole, and quetiapine. Severe rigidity accompanied by hyperthermia and metabolic acidosis (“neuroleptic malignant syndrome”) may occasionally occur and is life-threatening (see Chapter 25).

► Treatment

A. Emergency and Supportive Measures

Administer activated charcoal. For severe hypotension, treatment with intravenous fluids and pressor agents may be necessary. Treat hyperthermia as outlined on p 1423. Maintain cardiac monitoring.

B. Specific Treatment

Hypotension and cardiac arrhythmias associated with widened QRS intervals on the ECG in a patient with thioridazine poisoning may respond to intravenous sodium bicarbonate as used for tricyclic antidepressants. Prolongation of the QT interval and torsades de pointes is usually treated with intravenous magnesium or overdrive pacing.

For extrapyramidal signs, give diphenhydramine, 0.5–1 mg/kg intravenously, or benztropine mesylate, 0.01–

0.02 mg/kg intramuscularly. Treatment with oral doses of these agents should be continued for 24–48 hours.

Bromocriptine (2.5–7.5 mg orally daily) may be effective for mild or moderate neuroleptic malignant syndrome. Dantrolene (2–5 mg/kg intravenously) has also been used for muscle contractions but is not a true antidote.

QUINIDINE & RELATED ANTIARRHYTHMICS

Quinidine, procainamide, and disopyramide are class Ia antiarrhythmic agents, and flecainide and propafenone are class Ic agents. These drugs have membrane-depressant effects on the sodium-dependent channel responsible for cardiac cell depolarization. Manifestations of cardiotoxicity include arrhythmias, syncope, hypotension, and widening of the QRS complex on the ECG (> 100–120 ms). With type Ia drugs, a lengthened QT interval and atypical or polymorphous ventricular tachycardia (torsades de pointes) may occur. The antimalarials chloroquine and hydroxychloroquine have similar effects in overdose.

► Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p 1425); consider gastric lavage after large recent overdose. Assist ventilation if needed. Perform continuous cardiac monitoring.

B. Specific Treatment

Treat cardiotoxicity (hypotension, QRS interval widening) with intravenous boluses of sodium bicarbonate, 50–100 mEq. Torsades de pointes may be treated with intravenous magnesium or overdrive pacing.

SALICYLATES

Salicylates (aspirin, methyl salicylate, etc) are found in a variety of over-the-counter and prescription medications. Salicylates uncouple cellular oxidative phosphorylation, resulting in anaerobic metabolism and excessive production of lactic acid and heat, and they also interfere with several Krebs cycle enzymes. A single ingestion of more than 200 mg/kg of salicylate is likely to produce significant

acute intoxication. Poisoning may also occur as a result of chronic excessive dosing over several days. Although the half-life of salicylate is 2–3 hours after small doses, it may increase to 20 hours or more in patients with intoxication.

► Clinical Findings

Acute ingestion often causes nausea and vomiting, occasionally with gastritis. Moderate intoxication is characterized by hyperpnea (deep and rapid breathing), tachycardia, tinnitus, and elevated anion gap metabolic acidosis. Serious intoxication may result in agitation, confusion, coma, seizures, cardiovascular collapse, pulmonary edema, hyperthermia, and death. The prothrombin time is often elevated owing to salicylate-induced hypoprothrombinemia.

Diagnosis is suspected in any patient with metabolic acidosis and is confirmed by measuring the serum salicylate level. Patients with levels greater than 100 mg/dL (1000 mg/L) after an acute overdose are more likely to have severe poisoning. On the other hand, patients with subacute or chronic intoxication may suffer severe symptoms with levels of only 60–70 mg/dL. The arterial blood gas typically reveals a respiratory alkalosis with an underlying metabolic acidosis.

► Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p 1425). Gastric lavage followed by administration of extra doses of activated charcoal may be needed in patients who ingest more than 10 g of aspirin (see p 1424). The desired ratio of charcoal to aspirin is about 10:1 by weight; while this cannot always be given as a single dose, it may be administered over the first 24 hours in divided doses every 2–4 hours. Treat metabolic acidosis with intravenous sodium bicarbonate. This is critical because acidosis (especially acidemia, pH < 7.40) promotes greater entry of salicylate into cells, worsening toxicity. Brief hypoventilation during rapid sequence intubation may cause sudden and severe deterioration if the pH is allowed to fall.

B. Specific Treatment

Alkalinization of the urine enhances renal salicylate excretion by trapping the salicylate anion in the urine. Add 100 mEq (two ampules) of sodium bicarbonate to 1 L of 5% dextrose in 0.2% saline, and infuse this solution intravenously at a rate of about 150–200 mL/h. Unless the patient is oliguric or hyperkalemic, add 20–30 mEq of potassium chloride to each liter of intravenous fluid. Patients who are volume-depleted often fail to produce an alkaline urine (paradoxical aciduria) unless potassium is given.

Hemodialysis may be lifesaving and is indicated for patients with severe metabolic acidosis, markedly altered mental status, or significantly elevated salicylate levels (eg, > 100–120 mg/dL [1000–1200 mg/L] after acute overdose or > 60–70 mg/dL [600–700 mg/L] with subacute or chronic intoxication).

Kuzak N et al. Reversal of salicylate-induced euglycemic delirium with dextrose. *Clin Toxicol (Phila).* 2007 Jun–Aug;45(5):526–9. [PMID: 17503260]

Table 38–9. Common seafood poisonings.

| Type of Poisoning | Mechanism | Clinical Presentation |
|-------------------------------|--|--|
| Ciguatera | Reef fish ingest toxic dinoflagellates, whose toxins accumulate in fish meat. Commonly implicated fish in the United States are barracuda, jack, snapper, and grouper. | 1–6 hours after ingestion, victims develop abdominal pain, vomiting, and diarrhea accompanied by a variety of neurologic symptoms, including paresthesias, reversal of hot and cold sensation, vertigo, headache, and intense itching. Autonomic disturbances, including hypotension and bradycardia, may occur. |
| Scombroid | Improper preservation of large fish results in bacterial degradation of histidine to histamine. Commonly implicated fish include tuna, mahimahi, bonito, mackerel, and kingfish. | Allergic-like (anaphylactoid) symptoms are due to histamine, usually begin within 15–90 minutes, and include skin flushing, itching, urticaria, angioedema, bronchospasm, and hypotension as well as abdominal pain, vomiting, and diarrhea. |
| Paralytic shellfish poisoning | Dinoflagellates produce saxitoxin, which is concentrated by filter-feeding mussels and clams. Saxitoxin blocks sodium conductance and neuronal transmission in skeletal muscles. | Onset is usually within 30–60 minutes. Initial symptoms include perioral and intraoral paresthesias. Other symptoms include nausea and vomiting, headache, dizziness, dysphagia, dysarthria, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest. |
| Puffer fish poisoning | Tetrodotoxin is concentrated in liver, gonads, intestine, and skin. Toxic effects are similar to those of saxitoxin. Tetrodotoxin is also found in some North American newts and Central American frogs. | Onset is usually within 30–40 minutes but may be as short as 10 minutes. Initial perioral paresthesias are followed by headache, diaphoresis, nausea, vomiting, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest. |

SEAFOOD POISONINGS

A variety of intoxications may occur after eating certain types of fish or other seafood. These include scombroid, ciguatera, paralytic shellfish, and puffer fish poisoning. The mechanisms of toxicity and clinical presentations are described in Table 38–9. In the majority of cases, the seafood has a normal appearance and taste (scombroid may have a peppery taste).

► Treatment

A. Emergency and Supportive Measures

Caution: Abrupt respiratory arrest may occur in patients with acute paralytic shellfish and puffer fish poisoning. Observe patients for at least 4–6 hours. Replace fluid and electrolyte losses from gastroenteritis with intravenous saline or other crystalloid solution.

For recent ingestions, it may be possible to adsorb residual toxin in the gut with activated charcoal, 50–60 g orally (see p 1425).

B. Specific Treatment

There is no specific antidote for paralytic shellfish or puffer fish poisoning.

1. Ciguatera—There are anecdotal reports of successful treatment of acute neurologic symptoms with mannitol, 1 g/kg intravenously, but this approach is not widely accepted.

2. Scombroid—Antihistamines such as diphenhydramine, 25–50 mg intravenously, and the H₂-blocker cimetidine, 300 mg intravenously, are usually effective. For severe reactions, give also epinephrine, 0.3–0.5 mL of a 1:1000 solution subcutaneously.

Noguchi T et al. Tetrodotoxin—distribution and accumulation in aquatic organisms, and cases of human intoxication. *Mar Drugs.* 2008 May 28;6(2):220–42. [PMID: 18728726]

SNAKE BITES

The venom of poisonous snakes and lizards may be predominantly neurotoxic (coral snake) or predominantly cytolytic (rattlesnakes, other pit vipers). Neurotoxins cause respiratory paralysis; cytolytic venoms cause tissue destruction by digestion and hemorrhage due to hemolysis and destruction of the endothelial lining of the blood vessels. The manifestations of rattlesnake envenomation are mostly local pain, redness, swelling, and extravasation of blood. Perioral tingling, metallic taste, nausea and vomiting, hypotension, and coagulopathy may also occur. Neurotoxic envenomation may cause ptosis, dysphagia, diplopia, and respiratory arrest.

► Treatment

A. Emergency Measures

Immobilize the patient and the bitten part in a neutral position. Avoid manipulation of the bitten area. Transport the patient to a medical facility for definitive treatment. Do *not* give alcoholic beverages or stimulants; do *not* apply ice;

do *not* apply a tourniquet. The trauma to underlying structures resulting from incision and suction performed by unskilled people is probably not justified in view of the small amount of venom that can be recovered.

B. Specific Antidote and General Measures

1. Pit viper (eg, rattlesnake) envenomation—For local signs such as swelling, pain, and ecchymosis but no systemic symptoms, give 4–6 vials of crotalid antivenin (CroFab) by slow intravenous drip in 250–500 mL saline. Repeated doses of 2 vials every 6 hours for up to 18 hours has been recommended. For more serious envenomation with marked local effects and systemic toxicity (eg, hypotension, coagulopathy), higher doses and additional vials may be required. Monitor vital signs and the blood coagulation profile. Type and cross-match blood. The adequacy of venom neutralization is indicated by improvement in symptoms and signs, and the rate that swelling slows. Prophylactic antibiotics are not indicated after a rattlesnake bite.

2. Elapid (coral snake) envenomation—Give 1–2 vials of specific antivenom as soon as possible. To locate antisera for exotic snakes, call a regional poison control center (800-222-1222).

SPIDER BITES & SCORPION STINGS

The toxin of most species of spiders in the United States causes only local pain, redness, and swelling. That of the more venomous black widow spiders (*Latrodectus mactans*) causes generalized muscular pains, muscle spasms, and rigidity. The brown recluse spider (*Loxosceles reclusa*) causes progressive local necrosis as well as hemolytic reactions (rare). Stings by most scorpions in the United States cause only local pain. Stings by the more toxic *Centruroides* species (found in the southwestern United States) may cause muscle cramps, twitching and jerking, and occasionally hypertension, convulsions, and pulmonary edema. Stings by scorpions from other parts of the world are not discussed here.

▶ Treatment

A. Black Widow Spider Bites

Pain may be relieved with parenteral narcotics or muscle relaxants (eg, methocarbamol, 15 mg/kg). Calcium gluconate 10%, 0.1–0.2 mL/kg intravenously, may relieve muscle rigidity, though its effectiveness is questionable. Antivenin is available, but because of concerns about acute hypersensitivity reactions (horse serum-derived), it is often reserved for very young or elderly patients or those who do

not respond to the above measures. Horse serum sensitivity testing is required. (Instruction and testing materials are included in the antivenin kit.)

B. Brown Recluse Spider Bites

Because bites occasionally progress to extensive local necrosis, some authorities recommend early excision of the bite site, whereas others use oral corticosteroids. Anecdotal reports have claimed success with dapsone and colchicine. All of these treatments remain of unproved value.

C. Scorpion Stings

No specific treatment is available for envenomations by scorpions found in the United States. For *Centruroides* stings, some toxicologists use a specific antivenom developed in Arizona, but this is neither FDA-approved nor widely available.

THEOPHYLLINE & CAFFEINE

Theophylline may cause intoxication after an acute single overdose, or intoxication may occur as a result of chronic accidental repeated overmedication or reduced elimination resulting from hepatic dysfunction or interacting drug (eg, cimetidine, erythromycin). The usual serum half-life of theophylline is 4–6 hours, but this may increase to more than 20 hours after overdose. Caffeine and caffeine-containing herbal products can produce similar toxicity.

▶ Clinical Findings

Mild intoxication causes nausea, vomiting, tachycardia, and tremulousness. Severe intoxication is characterized by ventricular and supraventricular tachyarrhythmias, hypotension, and seizures. Status epilepticus is common and often intractable to the usual anticonvulsants. After acute overdose (but not chronic intoxication), hypokalemia, hyperglycemia, and metabolic acidosis are common. Seizures and other manifestations of toxicity may be delayed for several hours after acute ingestion, especially if a sustained-release preparation such as Theo-Dur was taken.

Diagnosis is based on measurement of the serum theophylline concentration. Seizures and hypotension are likely to develop in acute overdose patients with serum levels greater than 100 mg/L. Serious toxicity may develop at lower levels (ie, 40–60 mg/L) in patients with chronic intoxication.

▶ Treatment

A. Emergency and Supportive Measures

After acute ingestion, administer activated charcoal (see p 1425). Repeated doses of activated charcoal may enhance theophylline elimination by “gut dialysis.” Addition of whole bowel irrigation should be considered for large ingestions involving sustained-release preparations (see p 1425).

Hemodialysis is effective in removing theophylline and is indicated for patients with status epilepticus or markedly elevated serum theophylline levels (eg, > 100 mg/L after acute overdose or > 60 mg/L with chronic intoxication).

B. Specific Treatment

Treat seizures with benzodiazepines (lorazepam, 2–3 mg intravenously, or diazepam, 5–10 mg intravenously) or phenobarbital (10–15 mg/kg intravenously). Phenytoin is not effective. Hypotension and tachycardia—which are mediated through excessive β -adrenergic stimulation—may respond to β -blocker therapy even in low doses. Administer esmolol, 25–50 mcg/kg/min by intravenous infusion, or propranolol, 0.5–1 mg intravenously.

TRICYCLIC & OTHER ANTIDEPRESSANTS

Tricyclic and related cyclic antidepressants are among the most dangerous drugs involved in suicidal overdose. These drugs have anticholinergic and cardiac depressant properties (“quinidine-like” sodium channel blockade). Tricyclic antidepressants produce more marked membrane-depressant cardiotoxic effects than the phenothiazines.

Newer antidepressants such as trazodone, fluoxetine, citalopram, paroxetine, sertraline, bupropion, venlafaxine, and fluvoxamine are not chemically related to the tricyclic antidepressant agents and do not generally produce quinidine-like cardiotoxic effects. However, they may cause seizures in overdoses and they may cause serotonin syndrome (see Monoamine Oxidase Inhibitors, above).

▶ Clinical Findings

Signs of severe intoxication may occur abruptly and without warning within 30–60 minutes after acute tricyclic overdose. Anticholinergic effects include dilated pupils, tachycardia, dry mouth, flushed skin, muscle twitching, and decreased peristalsis. Quinidine-like cardiotoxic effects include QRS interval widening (> 0.12 s; see Figure 38–2), ventricular arrhythmias, AV block, and hypotension. Rightward-axis deviation of the terminal 40 ms of the QRS has also been described. Prolongation of the QT interval has been reported with citalopram and venlafaxine. Seizures and

▲ **Figure 38–2.** Cardiac arrhythmias resulting from tricyclic antidepressant overdose. **A:** Delayed intraventricular conduction results in prolonged QRS interval (0.18 s). **B and C:** Supraventricular tachycardia with progressive widening of QRS complexes mimics ventricular tachycardia. (Reproduced, with permission, from Benowitz NL, Goldschlager N. Cardiac disturbances in the toxicologic patient. In: Haddad LM, Winchester JF [editors], *Clinical Management of Poisoning and Drug Overdose*, 3rd edition. Saunders/Elsevier, 1998.)

coma are common with severe intoxication. Life-threatening hyperthermia may result from status epilepticus and anticholinergic-induced impairment of sweating. Among newer agents, bupropion and venlafaxine have been associated with a greater risk of seizures.

The diagnosis should be suspected in any overdose patient with anticholinergic side effects, especially if there is widening of the QRS interval or seizures. For intoxication by most tricyclic antidepressants, the QRS interval correlates with the severity of intoxication more reliably than the serum drug level.

Serotonin syndrome should be suspected if agitation, delirium, muscular hyperactivity, and fever develop in a patient taking serotonin reuptake inhibitors.

▶ Treatment

A. Emergency and Supportive Measures

Observe patients for at least 6 hours, and admit all patients with evidence of anticholinergic effects (eg, delirium, dilated pupils, tachycardia) or signs of cardiotoxicity (see above).

Administer activated charcoal, and consider gastric lavage after recent large ingestions (see p 1424–5). All of these drugs are highly tissue-bound and are not effectively removed by hemodialysis procedures.

B. Specific Treatment

Cardiotoxic sodium channel-depressant effects of tricyclic antidepressants may respond to boluses of sodium bicarbonate (50–100 mEq intravenously). Sodium bicarbonate provides a large sodium load that alleviates depression of

the sodium-dependent channel. Reversal of acidosis may also have beneficial effects at this site. Maintain the pH between 7.45 and 7.50. Alkalinization does not promote excretion of tricyclic antidepressants. Prolongation of the QT interval or torsades de pointes is usually treated with intravenous magnesium or overdrive pacing. Fab antibodies have been developed for some tricyclic antidepressants, but they remain experimental.

Mild serotonin syndrome may be treated with benzodiazepines and withdrawal of the antidepressant. Moderate cases may respond to cyproheptadine (4 mg orally or via gastric tube hourly for three or four doses). Severe hyperthermia should be treated with neuromuscular paralysis

and endotracheal intubation in addition to external cooling measures.

Cancer

Patricia A. Cornett, MD
Tiffany O. Dea, PharmD

The major features of this chapter are the clinical aspects of cancer, including etiology and prevention; staging; diagnosis and treatment of common cancers; and recognition and management of complications from cancer. Additional information may be obtained from the National Cancer Institute (NCI) website at www.cancer.gov/cancerinformation, the American Society of Clinical Oncology website at www.asco.org, and the National Comprehensive Cancer Network (NCCN) website at www.nccn.org. The NCCN website provides detailed, evidence-based recommendations for management of specific cancers as well as guidelines for cancer screening and for supportive care. General reviews in oncology can be obtained from Medscape Hematology/Oncology (www.medscape.com).

▶ Etiology

Cancer is the second most common cause of death in the United States. In 2008, an estimated 1,437,180 cases of cancer were diagnosed, and 565,650 persons died as a result of cancer. Based on cancer rates determined in 2003–2005, more than 40% of people born today will have cancer diagnosed at some point in their lifetime. Table 39–1 lists the 10 leading cancer types in men and women by site.

However, the incidence of cancer in both men and women is decreasing. In 2008, the American Cancer Society, NCI, and the Centers for Disease Control and Prevention reported that the incidence of all cancers for both sexes decreased 0.8% per year from 1999 through 2005. In men, the rate decreased 1.8% per year from 2001 through 2005, largely because the incidence of the three most common cancers (prostate, lung, colorectum) decreased. In women, the rate decreased 0.6% per year from 1998 through 2005 due to the decline in incidence of two of the top three cancers (breast, colorectum); the incidence of the third cancer (lung) was steady.

Over the last two decades, the decreasing incidence of cancer has translated into a decrease in cancer death rates. Ten of the top 15 cancer sites have shown a decrease in mortality events. Only esophageal cancer in men, pancreatic cancer in women, and hepatocellular in both men and women have increased in mortality numbers. This decline

in mortality has been seen in all ethnic and racial groups except for American Indians and Alaskan Natives.

Reductions in cancer incidence and mortality reflect a successful implementation of a broad strategy of prevention, detection, and treatment.

▶ Modifiable Risk Factors

Tobacco is the most common preventable cause of cancer death; it is estimated that at least 30% of all cancer deaths in the United States are directly linked to tobacco. A total of 440,000 cancer deaths in the United States and 4.8 million cancer deaths worldwide can be directly attributed to tobacco abuse. Clear evidence links at least 15 cancers to tobacco use. The most dramatic link is with lung cancer, the most common non-dermatologic malignancy; over 90% of lung cancer cases occur in smokers. Any strategy for cancer control must start with the goal of markedly reducing if not eliminating tobacco use.

Strategies for tobacco control should involve a focus on the individual as well as society as a whole. Tobacco cessation directed toward the individual should start with the clinician providing counseling. Simple, concise advice from a clinician can yield cessation rates of 10–20%. Additive strategies include more intensive counseling; nicotine replacement therapy with patches, gum, or lozenges; and prescription medication with bupropion or varenicline. Perhaps a more intriguing phenomenon, with potential for significant impact on cessation rates, is the influence of social contact behavior on an individual smoker's abstinence decision. For instance, analysis of the Framingham Heart Study demonstrated that smoking cessation by a spouse resulted in a 67% decrease in the subject's likelihood of continuing to smoke, and smoking cessation by a friend resulted in a 36% decrease in the subject's likelihood of smoking.

On a societal level, many initiatives have been put into place to actively discourage tobacco use. State or local laws regulating tobacco use in restaurants, the workplace, and other public places have resulted in declines in tobacco use. Countermarketing with aggressive anti-tobacco advertisements has also contributed to tobacco cessation and abstinence. The key recipients of these messages are children; 80%

Table 39–1. Estimated 10 most common cancer cases in the United States in males and females (all races).

| Rank | Males (745,180 Total Cases) | Percent | Females (692,000 Total Cases) | Percent |
|------|-----------------------------------|---------|-------------------------------------|---------|

of smokers will start by age 18. Preventing the start of addiction in this vulnerable population should be a top priority.

In fact, there are encouraging signs of success with tobacco control. The prevalence of smoking for United States adults has hit a modern day nadir of 19%, which is a remarkable reduction from the 1955 peak of 57% for males and the 1965 peak of 34% for females. See Chapter 1 for additional material on smoking cessation techniques.

For those Americans who do not abuse tobacco, the most modifiable risk factors would be nutrition and physical activity. Epidemiologic studies suggest that fruit- and vegetable-rich diets lower risks of several gastrointestinal malignancies, including esophageal, stomach, and colon cancers. Excessive consumption of alcohol is linked to increased risks of head and neck cancers as well as cancers of the esophagus and liver. Lastly, being overweight is linked to several malignancies, including breast and uterine cancers in women and colorectal, esophageal, and kidney cancers in both men and women. More importantly, weight reduction can decrease the risks of these cancers.

▶ Staging

The most commonly used staging system at the time of diagnosis is the TNM (Tumor, Nodes, Metastasis) system (see www.cancerstaging.org). Rules for staging for individual cancers are established and published by the American Joint Committee on Cancer (AJCC). Elements used for staging include tumor size and level of tumor invasion (T), absence or presence and extent of nodal metastases (N), and presence or absence of systemic metastases (M). Once the TNM designations have been determined, an overall stage is assigned, stage I, II, III, or IV. Clinical staging utilizes physical examination,

laboratory and imaging tests as well as results from biopsies; pathologic staging relies on the results from surgery. In some instances, other classifications may be used for certain cancers such as the Ann Arbor staging system for lymphomas or the International Federation of Gynecologists and Obstetricians (FIGO) staging systems for gynecologic malignancies.

Other characteristics of cancers, not reflected in the TNM stage, may be used as another indicator of prognosis. Pathologic features seen on routine histologic examination for some cancers are very important; examples include the Gleason score for prostate cancer and the grade of sarcomas. Special tests done on cancer specimens can also be used to determine prognosis as well as treatment; examples include estrogen and progesterone status and the presence or absence of *HER-2/neu* for breast cancers. Chromosome analysis, now routinely done for patients with hematologic disorders and important in determining prognosis, can occasionally be useful for patients with solid tumors. For example, in patients with carcinoma of unknown primary origin, abnormal findings on chromosome 12 predict a response to chemotherapy and a better prognosis. In the future, as the pathways for oncogenesis and relationships of mutations to treatment and prognosis are better delineated, analysis for detection of chromosomal alterations and oncogene products will be increasingly incorporated into routine practice.

THE PARANEOPLASTIC SYNDROMES

The clinical manifestations of cancer are usually due to pressure effects of local tumor growth, infiltration or metastatic deposition of tumor cells in a variety of organs in the body, or certain systemic symptoms. General problems observed in many patients with advanced or widespread metastatic cancer include anorexia, malaise, weight loss, and sometimes fever. These characteristics must be considered when evaluating a patient with an undiagnosed illness. Except in the case of functioning tumors such as those of the endocrine glands, systemic symptoms of cancer usually are not specific, often consisting of weakness, anorexia, and weight loss. The term paraneoplastic refers to features of disease considered to be due to the remote effects of a cancer that cannot be attributed either to a cancer's direct invasive or metastatic properties and are often considered to be due to aberrant hormonal or metabolic effects not observed in a cancer's normal tissue equivalent. In the paraneoplastic syndromes, clinical findings may resemble those of primary endocrine, metabolic, hematologic, or neuromuscular disorders. At present, the mechanisms for such remote effects can be classified into three groups: (1) effects initiated by a tumor product (eg, carcinoid syndrome, ectopic hormone production), (2) effects of destruction of normal tissues by tumor (eg, hypercalcemia with osteolytic skeletal metastases), and (3) effects due to unknown mechanisms. In paraneoplastic syndromes associated with ectopic hormone production, tumor tissue itself secretes the hormone that produces the syndrome. Ectopic hormones secreted by neoplasms are often pro-hormones of higher molecular weight than those secreted by the more differentiated normal endocrine cell. Such ectopic hormone production by cancer cells is believed to result from activation of genes in the malig-

nant cells that are suppressed in the normal tissue equivalent and in most somatic cells. Autocrine growth factors secreted by neoplastic cells may also result in paraneoplastic syndromes. Small cell lung cancer is the one type of cancer most likely to be associated with paraneoplastic syndromes.

The paraneoplastic syndromes are clinically important for the following reasons:

(1) They sometimes accompany relatively limited neoplastic growth and may provide the clinician with an early clue to the presence of certain types of cancer.

(2) The metabolic or toxic effects of the syndrome may constitute a more urgent hazard to the patient's life than the underlying cancer (eg, hypercalcemia, hyponatremia).

(3) Effective treatment of the tumor should be accompanied by resolution of the paraneoplastic syndrome and, conversely, recurrence of the cancer may be heralded by return of the systemic symptoms. In some instances, rapid response to cytotoxic chemotherapy may briefly increase the severity of the paraneoplastic syndrome in association with tumor lysis (eg, hyponatremia with inappropriate antidiuretic hormone excretion). In some instances the identical symptom complex (eg, hypercalcemia) may be induced by entirely different mechanisms. A single syndrome such as hypercalcemia may be due to any one of a variety of humoral factors, such as secretion of parathyroid hormone precursors or homologs, an osteoclast-activating factor (lymphotoxin), transforming growth factor- α , or prostaglandins. Effective antitumor treatment usually results in return of serum calcium to normal.

Common paraneoplastic syndromes and endocrine secretions associated with functional cancers are summarized in Table 39-2.

TYPES OF CANCER

LUNG CANCER

Sunny Wang, MD; Mark S. Chesnutt, MD;
James A. Murray, DO & Thomas J. Prendergast, MD

BRONCHOGENIC CARCINOMA

ESSENTIALS OF DIAGNOSIS

- ▶ New cough, or change in chronic cough.
- ▶ Dyspnea, hemoptysis, anorexia, weight loss.
- ▶ Enlarging nodule or mass; persistent opacity, atelectasis, or pleural effusion on chest radiograph or CT scan.
- ▶ Cytologic or histologic findings of lung cancer in sputum, pleural fluid, or biopsy specimen.

▶ General Considerations

Lung cancer is the leading cause of cancer deaths in both men and women. The American Cancer Society estimated

that there were 215,020 new diagnoses and 161,840 deaths from lung cancer in the United States in 2008, accounting for approximately 15% of new cancer diagnoses and 29% of all cancer deaths. More Americans die of lung cancer than of colorectal, breast, and prostate cancers combined. Lung cancer was a previously reportable disease until the widespread use of manufactured cigarettes in the 20th century. The causal connection between cigarettes and lung cancer is now established not only epidemiologically but also through identification of carcinogens in tobacco smoke and analysis of the effect of these carcinogens on specific oncogenes expressed in lung cancer. Even cigarette manufacturers no longer dispute the role of tobacco in this epidemic.

Cigarette smoking causes more than 90% of cases of lung cancer. Since the early 1990s, mortality from lung cancer fell among men while it increased among women and is only now peaking among women, reflecting changing patterns of tobacco use over the past 30 years (see Chapter 1). Other environmental risk factors for the development of lung cancer include exposure to environmental tobacco smoke, radon gas (among uranium miners and in areas where radium in the soil causes significant indoor air contamination), asbestos (60- to 100-fold increased risk in smokers with asbestos exposure), metals (arsenic, chromium, nickel, iron oxide), and industrial carcinogens (bis-chloromethyl ether). A familial predisposition to lung cancer is recognized. Certain diseases are associated with an increased risk of lung cancer, including pulmonary fibrosis, chronic obstructive pulmonary disease, and sarcoidosis. Second primary lung cancers are more frequent in patients who survive their initial lung cancer.

The median age at diagnosis of lung cancer is 71; it is unusual under the age of 40. After the diagnosis of lung cancer is made, approximately 41% of patients survive 1 year. The combined 5-year survival rate for all stages of lung cancer is now approximately 15%, improved from 12% in 1974-1976.

Five histologic categories of bronchogenic carcinoma account for more than 90% of cases of primary lung cancer. **Squamous cell carcinoma** (20% of cases) arises from the bronchial epithelium, typically as a centrally located, intraluminal sessile or polypoid mass. Squamous cell tumors are more likely to present with hemoptysis and more frequently are diagnosed by sputum cytology. They spread locally and may be associated with hilar adenopathy and mediastinal widening on chest radiography. **Adenocarcinoma** (35-40% of cases) arises from mucus glands or, in the case of **bronchioloalveolar cell carcinoma** (2% of cases), from any epithelial cell within or distal to the terminal bronchioles. Adenocarcinomas usually present as peripheral nodules or masses. Bronchioloalveolar cell carcinoma spreads intralveolarly and may present as an infiltrate or as single or multiple pulmonary nodules. **Large cell carcinoma** (3-5% of cases) is a heterogeneous group of relatively undifferentiated tumors that share large cells and do not fit into other categories. Large cell carcinomas typically have rapid doubling times and an aggressive clinical course. They present as central or peripheral masses. Tumors that are not better differentiated on pathologic review other than carcinoma unspecified make up about 20-25% of cases. **Small cell**

SIADH, syndrome of inappropriate antidiuretic hormone.

carcinoma (10–15% of cases) is a tumor of bronchial origin that typically begins centrally, infiltrating submucosally to cause narrowing or obstruction of the bronchus without a discrete luminal mass. Hilar and mediastinal abnormalities are common on chest radiography.

For purposes of staging and treatment, bronchogenic carcinoma is divided into small cell lung cancer (SCLC) and the other four types, conveniently labeled non–small cell lung cancer (NSCLC). This practical classification reflects different natural histories and different treatment. SCLC is prone to early hematogenous spread. It is rarely amenable to surgical resection and has a very aggressive course with a median survival (untreated) of 6–18 weeks. The four histologic categories comprising NSCLC spread more slowly. They may be cured in the early stages following resection, and they respond similarly to chemotherapy.

► Clinical Findings

Lung cancer is symptomatic at diagnosis in 75–90% of patients. The clinical presentation depends on the type and location of the primary tumor, the extent of local spread, and the presence of distant metastases and any paraneoplastic syndromes.

A. Symptoms and Signs

Anorexia, weight loss, or asthenia occurs in 55–90% of patients presenting with a new diagnosis of lung cancer. Up to 60% of patients have a new cough or a change in a chronic cough; 6–31% have hemoptysis; and 25–40% complain of pain, sometimes nonspecific chest pain but often referable to bony metastases to the vertebrae, ribs, or pelvis. Local spread may cause endobronchial obstruction with atelectasis and postobstructive pneumonia, pleural effusion (12–33%), change in voice (compromise of the recurrent laryngeal nerve), superior vena cava syndrome (obstruction of the superior vena cava with supraclavicular venous engorgement), and Horner syndrome (ipsilateral ptosis, miosis, and anhidrosis from involvement of the inferior cervical ganglion and the paravertebral sympathetic chain). Distant metastases to the liver are associated with asthenia and weight loss. Brain metastases (10% in NSCLC, more common in adenocarcinoma, and 20–30% in SCLC) may present with headache, nausea, vomiting, seizures, or altered mental status.

Paraneoplastic syndromes are incompletely understood patterns of organ dysfunction related to immune-mediated or secretory effects of neoplasms. These syndromes occur in 10–20% of lung cancer patients. They may precede, accompany, or follow the diagnosis of lung cancer. They do not necessarily indicate metastatic disease. In patients with small cell carcinoma, the syndrome of inappropriate antidiuretic hormone (SIADH) will develop in 10–15%; in those with squamous cell carcinoma, hypercalcemia will develop in 10%. Digital clubbing is seen in up to 20% of patients at diagnosis (Plate 47). Other common paraneoplastic syndromes include increased ACTH production, anemia, hypercoagulability, peripheral neuropathy, and the Eaton-Lambert myasthenia syndrome. Their recognition is important because treatment of the primary

tumor may improve or resolve symptoms even when the cancer is not curable.

B. Laboratory Findings

The diagnosis of lung cancer rests on examination of a tissue or cytology specimen. Sputum cytology is highly specific but insensitive; the yield is highest when there are lesions in the central airways. Thoracentesis (sensitivity 50–65%) can be used to establish a diagnosis of lung cancer in patients with malignant pleural effusions. If cytologic examination of an adequate sample (50–100 mL) of pleural fluid is nondiagnostic, the procedure should be repeated once; approximately 30% of the second samples are positive when the first sample is negative. If results remain negative, thoracoscopy is preferred to blind pleural biopsy. Fine-needle aspiration (FNA) of palpable supraclavicular or cervical lymph nodes is frequently diagnostic. Serum tumor markers are neither sensitive nor specific enough to aid in diagnosis.

Fiberoptic bronchoscopy allows visualization of the major airways, cytology brushing of visible lesions or lavage of lung segments with cytologic evaluation of specimens, direct biopsy of endobronchial abnormalities, blind transbronchial biopsy of the pulmonary parenchyma or peripheral nodules, and FNA biopsy of mediastinal lymph nodes. Diagnostic yield varies widely (10–90%) depending on the size of the lesion and its location. Recent advances include fluorescence bronchoscopy, which improves the ability to identify early endobronchial lesions; and endobronchial and transesophageal endoscopic ultrasound, both of which permit more accurate direction of FNA of mediastinal nodes. Transthoracic needle aspiration (TTNA) has a sensitivity between 50% and 97%. Mediastinoscopy, video-assisted thoracoscopic surgery (VATS), and thoracotomy are necessary in cases where less invasive techniques fail to yield a diagnosis.

C. Imaging

Nearly all patients with lung cancer have abnormal findings on chest radiography or CT scan. These findings are rarely specific for a particular diagnosis. Interpretation of characteristic findings in isolated nodules is described in Chapter 9.

D. Special Examinations

1. Staging—Accurate staging is crucial (1) to provide the clinician with information to guide treatment, (2) to provide the patient with accurate information regarding prognosis, and (3) to standardize entry criteria for clinical trials to allow interpretation of results.

There are two essential principles of staging NSCLC. First, the more extensive the disease, the worse the prognosis; second, surgical resection offers the best hope for cure. Staging of NSCLC uses two integrated systems. The **TNM international staging system** attempts a physical description of the neoplasm: T describes the size and location of the primary tumor; N describes the presence and location of nodal metastases; and M refers to the presence or

Table 39–3. Approximate survival rates following treatment for lung cancer.

| Non-Small Cell Lung Cancer: Mean 5-Year Survival Following Resection | | |
|---|----------------------|------------------|
| Stage | Clinical Staging | Surgical Staging |

absence of distant metastases. These TNM stages are grouped into prognostic categories (stages I–IV) using the results of clinical trials. This classification is used to guide therapy. Many patients with stage I and stage II disease are cured through surgery. Patients with stage IIB and stage IV disease do not benefit from surgery (Table 39–3). Patients with stage IIIA disease have locally invasive disease that may benefit from surgery in certain circumstances.

SCLC is not staged using the TNM system because micrometastases are assumed to be present on diagnosis. SCLC is divided into two categories: **limited disease** (30%), when the tumor is limited to the unilateral hemithorax (including contralateral mediastinal nodes); or **extensive disease** (70%), when the tumor extends beyond the hemithorax (including pleural effusion). This scheme also guides therapy. Patients with limited SCLC benefit from thoracic radiation therapy in addition to chemotherapy as well as prophylactic cranial radiation therapy.

For both SCLC and NSCLC, staging begins with a thorough history and physical examination. A complete examination is essential to exclude obvious metastatic disease to lymph nodes, skin, and bone. A detailed history is essential because the patient's performance status is a powerful predictor of disease course. All patients should have measurement of a complete blood count, electrolytes including calcium, creatinine, liver tests including lactate dehydrogenase (LD) and alkaline phosphatase, and a chest radiograph. Further evaluation will follow the results of these tests. In general, screening asymptomatic lung cancer patients with MRI of the brain, radionuclide bone imaging, and abdominal CT imaging does not change patient outcomes. These tests should be targeted to specific symptoms and signs.

NSCLC patients being considered for surgery require meticulous evaluation to identify those with resectable disease. CT imaging is the most important modality for staging candidates for resection. A chest CT scan precisely defines the size of parenchymal lesions and identifies atelectatic lung or pleural effusions. However, CT imaging is less accurate at determining invasion of the chest wall (sensitivity 62%) or mediastinum (sensitivity 60–75%). The sensitivity and specificity of CT imaging for identifying lung cancer metastatic to the mediastinal lymph nodes are 57% (49–66%) and 82% (77–86%), respectively. Therefore, chest CT imaging does not provide definitive information on staging. CT imaging does help in making the decision about whether to proceed to resection of the primary tumor and sample the mediastinum at thoracotomy (common if there are no lymph nodes > 1 cm) or to use TTNA, mediastinoscopy, esophageal ultrasound with transesophageal needle aspiration, or limited thoracotomy to biopsy suspected metastatic disease (common where there are lymph nodes > 1–2 cm).

Positron emission tomography (PET) using 2-[¹⁸F]fluoro-2-deoxyglucose (FDG) is a noninvasive alternative for identifying metastatic foci in the mediastinum or distant sites. The sensitivity and specificity of PET for detecting mediastinal spread of primary lung cancer depend on the size of mediastinal nodes or masses. When only normal-sized (< 1 cm) mediastinal lymph nodes are present, the sensitivity and specificity of PET for tumor involvement of nodes are 74% and 96%, respectively. When CT shows enlarged (> 1 cm) lymph nodes, the sensitivity and specificity are 95% and 76%, respectively.

PET imaging is being incorporated into diagnostic algorithms that take advantage of both its positive and negative predictive values. Many lung cancer specialists find PET most useful to confirm lack of metastatic disease in NSCLC patients who are candidates for surgical resection. There is also evidence that PET imaging reduces futile thoracotomies by identifying mediastinal and distant metastases in patients with NSCLC. Disadvantages of PET imaging include limited resolution below 1 cm; the expense of FDG; limited availability; and false-positive scans due to sarcoidosis, tuberculosis, or fungal infections.

2. Preoperative assessment—See Chapter 3.

3. Pulmonary function testing—

Many patients with NSCLC have moderate to severe chronic lung disease that increases the risk of perioperative complications as well as long-term pulmonary insufficiency following lung resection. All patients considered for surgery require spirometry. In the absence of other comorbidities, patients with good lung function (preoperative FEV₁ ≥ 2 L) are at low risk for complications from lobectomy or pneumonectomy. If the FEV₁ is less than 2 L, then an estimated postoperative FEV₁ should be calculated. The postresection FEV₁ may be estimated from considering preoperative spirometry and the amount of lung to be resected; in severe obstructive disease, a quantitative lung perfusion scan may improve the estimate. A predicted post-lung resection FEV₁ > 800 mL (or > 40% of predicted FEV₁) is associated with a low incidence of perioperative complications. High-risk patients include those with a predicted postoperative FEV₁ < 700 mL (or < 40%

of predicted FEV₁). In these patients and in those with borderline spirometry, cardiopulmonary exercise testing may be helpful. A maximal oxygen uptake ($\dot{V}O_2$) of > 15 mL/kg/min identifies patients with an acceptable incidence of complications and mortality. Patients with a $\dot{V}O_2$ of < 10 mL/kg/min have a very high mortality rate at thoracotomy. Hypoxemia and hypercapnia are not independent predictors of outcome.

4. Screening—The optimal screening of smokers for lung cancer is unclear. Both chest radiographs and analysis of expectorated sputum is ineffective. Recent studies have tried to assess the role of chest CT scans. A study by Bach et al showed that CT screening of populations increases the diagnosis of lung cancer but does not reduce the risk of advanced lung cancer or reduce mortality. The investigators of the International Early Lung Cancer Action Program, however, suggested that there is a role for screening with chest CT. These studies highlight how complex and confusing the analysis of screening for lung cancer can be. At the present time, there are inadequate data to recommend the use of chest CT to screen smokers for lung cancer. The National Lung Screening Trial is an ongoing National Cancer Institute funded multicenter trial to determine whether using low-dose helical CT to screen current or former heavy smokers for lung cancer will improve mortality in this population. Information is available at <http://www.cancer.gov/NLST/>.

► Treatment

A. Non-Small Cell Carcinoma

Cure of NSCLC is unlikely without resection. Therefore, the initial approach to the patient is determined by the answers to two questions: (1) Is complete surgical resection technically feasible? (2) If yes, is the patient able to tolerate the surgery with acceptable morbidity and mortality? Clinical features that preclude complete resection include extrathoracic metastases or a malignant pleural effusion; or tumor involving the heart, pericardium, great vessels, esophagus, recurrent laryngeal or phrenic nerves, trachea, main carina, or contralateral mediastinal lymph nodes. Accordingly, stage I and stage II patients are treated with surgical resection where possible. Stage II, and possibly a subset of stage IB, are additionally recommended to receive adjuvant chemotherapy. Stage IIIA patients have poor outcomes when treated with resection alone. They should be referred to multimodality protocols, including chemotherapy and radiotherapy. Stage IIIB patients treated with concurrent chemotherapy and radiation therapy have improved survival. Selected stage IIIB patients who undergo resection after multimodality therapy have shown long-term survival and may be cured. Stage IV patients are treated with chemotherapy or symptom-based palliative therapy, or both (see below).

Surgical approach affects outcome. The North American Lung Cancer Study Group conducted a prospective trial of stage IA patients randomized to lobectomy versus limited resection. They reported a threefold increased rate of local recurrence in the limited resection group ($P = 0.008$) and a

trend toward an increase in overall death rate (increase of 30%, $P = 0.08$) and increase in death rate due to cancer (increase of 50%, $P = 0.09$), compared with patients receiving lobectomy. There are inadequate outcome data on which to base a comparison of VATS with standard thoracotomy. Radiation therapy following surgery improves local control but does not improve survival.

Patients with small early-stage primary lung cancers who are not candidates for surgery because of significant comorbidity or other surgical contraindication may be candidates for stereotactic radiosurgery or radiotherapy. This technology, which is composed of multiple non-parallel radiation beams that converge, allows the delivery of a relatively large dose of radiation to a small, well-defined target. Referral to a radiation oncologist is appropriate in such cases. Patients with locally advanced disease (stages IIIA and IIIB) who are not surgical candidates have improved survival when treated with concurrent chemotherapy and radiation therapy compared with no therapy, radiation alone, or even sequential chemotherapy and radiation.

Neoadjuvant chemotherapy consists of giving antineoplastic drugs in advance of surgery or radiation therapy. There is no consensus on the impact of neoadjuvant therapy on survival in stage I and stage II NSCLC. Such therapy is not recommended outside of ongoing clinical trials. Neoadjuvant therapy is more widely used in selected patients with stage IIIA or stage IIIB disease. Some studies suggest a survival advantage. This remains an area of active research.

Adjuvant chemotherapy consists of administering antineoplastic drugs following surgery or radiation therapy. Cisplatin-containing regimens have been shown to confer an overall survival benefit in at least stage II disease and possibly a subset of stage IB disease. The Lung Adjuvant Cisplatin Evaluation Collaborative Group just published a meta-analysis of the five largest cisplatin-based adjuvant trials. They reported a 5% absolute benefit in 5-year overall survival with a cisplatin-containing doublet regimen following surgery ($P = 0.005$) in patients with at least stage II disease. There is no evidence of a survival benefit, and it may even be detrimental in patients with poor performance status (Eastern Cooperative Oncology Group Score ≤ 2). Novel targeted agents with less toxicity are in clinical trials, and gene expression profiling has shown promise in defining a subset of patients with stage IA disease who may benefit from adjuvant therapy.

Although not curative, chemotherapy has been shown in multiple clinical trials to provide a modest increase in overall survival in patients with stage IIIB and stage IV NSCLC and good performance status compared with supportive care alone, with median survival increased from 5 months to a range of 7–11 months. Palliative chemotherapy also leads to improved quality of life and symptom control. A platinum-based regimen is most often used to treat such cases, with a multitude of active agents from which to choose. A recent randomized trial has now shown a survival benefit of adding bevacizumab (a monoclonal antibody to vascular endothelial growth factor [VEGF]) to a traditional platinum doublet regimen. Another targeted agent, erlotinib (an epidermal growth factor receptor [EGFR] tyrosine kinase inhibitor) has been shown to improve survival as

second-line treatment for advanced NSCLC and is especially effective in cases affecting women, nonsmokers, and persons of Asian ethnicity as well as cases involving adenocarcinoma and bronchioalveolar carcinoma histology.

B. Small Cell Carcinoma

Response rates of SCLC to cisplatin and etoposide are excellent: 80–90% response in limited-stage disease (50–60% complete response), and 60–80% response in extensive stage disease (15–20% complete response). However, remissions tend to be short-lived with a median duration of 6–8 months. Once the disease has recurred, median survival is 3–4 months. Overall 2-year survival is 20–40% in limited-stage disease and less than 5% in extensive-stage disease. Thoracic radiation therapy improves survival in patients with limited SCLC but not those with extensive disease. There is a high rate brain metastasis in patients with SCLC, even following a good response to chemotherapy, because chemotherapy does not adequately penetrate the blood-brain barrier. Prophylactic cranial irradiation has been shown to decrease the incidence of central nervous system disease and improve survival in patients with limited stage disease who respond to chemotherapy and possibly in a subset of patients with extensive stage disease who have had an excellent response to chemotherapy.

Occasionally, a patient may have a peripheral nodule resected that turns out to be SCLC. Five-year survival following resection of the equivalent of stage I and stage II SCLC is higher than in patients treated with chemotherapy.

C. Palliative Therapy

Photoresection with the Nd:YAG laser is sometimes performed on central tumors to relieve endobronchial obstruction, improve dyspnea, and control hemoptysis. External beam radiation therapy is also used to control dyspnea and hemoptysis, pain from bony metastases, obstruction from superior vena cava syndrome, and symptomatic brain metastases. Resection of a *solitary* brain metastasis improves quality of life when combined with radiation therapy, and if there is no evidence of other metastatic disease, it may improve survival. Intraluminal radiation (brachytherapy) is an alternative approach to endobronchial disease. Pain syndromes are very common in advanced disease. As patients approach the end of life, meticulous efforts at pain control are essential (see Chapter 5). Consultation with or referral to a palliative care specialist is recommended in advanced disease to aid in symptom management and to facilitate referrals to hospice programs.

► Prognosis

The overall 5-year survival rate for lung cancer is 15%. Predictors of survival are the type of tumor (SCLC versus NSCLC), the stage of the tumor, and the patient's performance status, including weight loss in the past 6 months. These are independent predictors in both early and late stage disease. Most data suggest that there is no difference among non-small cell carcinomas when adjusted for stage and performance status.

PULMONARY METASTASES

Pulmonary metastasis results from the spread of an extrapulmonary malignant tumor through vascular or lymphatic channels or by direct extension. Almost any cancer can metastasize to the lung. Metastases usually occur via the pulmonary artery and typically present as multiple nodules or masses on chest radiography. The radiographic differential diagnosis of multiple pulmonary nodules also includes pulmonary arteriovenous malformation, pulmonary abscesses, granulomatous infection, sarcoidosis, rheumatoid nodules, and Wegener granulomatosis. Metastases to the lungs are found in 20–55% of patients dying of various malignancies. Most are intraparenchymal. Endobronchial metastases occur in less than 5% of patients dying of nonpulmonary cancer; carcinoma of the kidney, breast, colon, and cervix and malignant melanoma are the most likely primary tumors.

Lymphangitic carcinomatosis denotes diffuse involvement of the pulmonary lymphatic network by primary or metastatic lung cancer, probably a result of extension of tumor from lung capillaries to the lymphatics. **Tumor embolization** from extrapulmonary cancer (renal cell car-

cinoma, hepatocellular carcinoma, choriocarcinoma) is an uncommon route for tumor spread to the lungs. Metastatic cancer may also present as a malignant pleural effusion.

► Clinical Findings

A. Symptoms and Signs

Symptoms are uncommon but include cough, hemoptysis and, in advanced cases, dyspnea and hypoxemia. Symptoms are more often referable to the site of the primary tumor.

B. Laboratory Findings

The diagnosis of metastatic cancer involving the lungs is usually established by identifying a primary tumor. Appropriate studies should be ordered if there is a suspicion of any primary cancer, such as breast, thyroid, testis, colorectal, or prostate, for which specific treatment is available. For example, an elevated prostate-specific antigen (PSA) may indicate prostate cancer, carcinoembryonic antigen (CEA) tests for colorectal or pancreatic cancer, and β -human chorionic gonadotropin (β HCG) and α -fetoprotein (AFP) test for testicular cancer. Based on the clinical setting, certain imaging studies should be ordered (see below). If the history, physical examination, and initial studies fail to reveal the site of the primary tumor, attention is better focused on the lung, where tissue samples obtained by bronchoscopy, percutaneous needle biopsy, or thoracotomy may establish the histologic diagnosis and suggest the most likely primary cancer. Occasionally, cytologic studies of pleural fluid or pleural biopsy reveal the diagnosis. Sputum cytology is rarely helpful.

If the initial histologic review does not reveal a primary diagnosis, immunohistochemical staining should be done on the biopsy specimen. For example, PSA and thyroglobulin staining are highly specific for prostate and thyroid cancer, respectively. Thyroid transcription factor-1 (TTF-1) is relatively specific for primary lung adenocarcinoma, while also positive for small cell carcinoma and thyroid carcinoma. An adenocarcinoma that demonstrates negative TTF-1 staining strongly suggests a nonpulmonary primary cancer. Positive estrogen receptor (ER) and progesterone receptor (PR) stains suggest primary breast cancer. Finally, the pattern of cytokeratin 7 and 20 staining can also help point toward a primary diagnosis.

C. Imaging

Chest radiographs usually show multiple spherical densities with sharp margins. The size of metastatic lesions varies from a few millimeters (miliary densities) to large masses. Nearly all are less than 5 cm in diameter. The lesions are usually bilateral, pleural or subpleural in location, and more common in lower lung zones. Cavitation suggests primary squamous cell tumor; calcification suggests osteosarcoma. Lymphangitic spread and solitary pulmonary nodule are less common radiographic presentations of pulmonary metastasis. Conventional chest radiography is less sensitive than CT scan in detecting pulmonary metastases. Mammography should be considered in women unless one has been performed recently to search for possible primary breast cancer. CT imaging of the chest, abdomen, and pelvis may reveal the

site of a primary tumor and will help determine feasibility of surgical resection of the metastatic lung tumors. PET scan may also help in identifying the site of a primary cancer or identifying other areas of extrathoracic metastasis.

► Treatment

Once the diagnosis has been established, management consists of treatment of the primary neoplasm and any pulmonary complications. Surgical resection of a *solitary* pulmonary nodule is often prudent in the patient with known current or previous extrapulmonary cancer. Local resection of one or more pulmonary metastases is feasible in a few carefully selected patients with various sarcomas and carcinomas (breast, testis, colon, kidney, and head and neck). Surgical resection should be considered only if the primary tumor is under control, if the patient is a good surgical risk, if all of the metastatic tumor can be resected, if nonsurgical approaches are not available, and if there are no metastases elsewhere in the body. Relative contraindications to resection of pulmonary metastases include (1) malignant melanoma primary, (2) requirement for pneumonectomy, and (3) pleural involvement. Data from the International Registry of Lung Metastases report an overall 5-year survival rate of 36% and 10-year survival rate of 26% after complete resection of pulmonary metastases. For patients with progressive disease, diligent attention to palliative care is essential (see Chapter 5).

MESOTHELIOMA

ESSENTIALS OF DIAGNOSIS

- Unilateral, nonpleuritic chest pain and dyspnea.
- Distant (> 20 years earlier) history of exposure to asbestos.
- Pleural effusion or pleural thickening or both on chest radiographs.
- Malignant cells in pleural fluid or tissue biopsy.

► General Considerations

Mesotheliomas are primary tumors arising from the surface lining of the pleura (80% of cases) or peritoneum (20% of cases). About three-fourths of pleural mesotheliomas are diffuse (usually malignant) tumors, and the remaining one-fourth are localized (usually benign). Men outnumber women by a 3:1 ratio. Numerous studies have confirmed the association of **malignant pleural mesothelioma** with expo-

sure to asbestos (particularly the crocidolite form). The lifetime risk to asbestos workers of developing malignant pleural mesothelioma is as high as 10%. Sixty to 80 percent of patients with malignant mesothelioma report a history of asbestos exposure. The latent period between exposure and onset of symptoms ranges from 20 to 40 years. The clinician should inquire about asbestos exposure through mining, milling, manufacturing, shipyard work, insulation, brake linings, building construction and demolition, roofing materials, and a variety of asbestos products (pipe, textiles, paint, tile, gaskets, panels). Although cigarette smoking significantly increases the risk of bronchogenic carcinoma in asbestos workers and aggravates asbestosis, there is no association between smoking and mesothelioma.

► Clinical Findings

A. Symptoms and Signs

The mean age at onset of symptoms of malignant pleural mesothelioma is about 60 years. Symptoms include the insidious onset of shortness of breath, nonpleuritic chest pain, and weight loss. Physical findings include dullness to percussion, diminished breath sounds and, in some cases, digital clubbing.

B. Laboratory Findings

Pleural fluid is exudative and often hemorrhagic. Cytologic tests of pleural fluid are often negative. VATS biopsy is usually necessary to obtain an adequate specimen for histologic diagnosis; even then, distinction from benign inflammatory conditions and from metastatic adenocarcinoma may be difficult. The histologic variants of malignant pleural mesothelioma are epithelial and fibrous (sarcomatous). Special stains and electron microscopy may be needed to confirm the diagnosis.

C. Imaging

Radiographic abnormalities consist of nodular, irregular, unilateral pleural thickening and varying degrees of unilateral pleural effusion. Sixty percent of patients have right-sided disease, while only 5% have bilateral involvement. There may be scoliosis toward the side of the lesion. CT scan helps demonstrate the extent of pleural involvement.

► Complications

Malignant pleural mesothelioma progresses rapidly as the tumor spreads along the pleural surface to involve the pericardium, mediastinum, and contralateral pleura. The tumor may eventually extend beyond the thorax to involve abdominal lymph nodes and organs. Progressive pain and dyspnea are characteristic. Local invasion of thoracic structures may cause superior vena cava syndrome, hoarseness, Horner syndrome, and dysphagia. Paraneoplastic syndromes associated with mesothelioma include thrombocytosis, hemolytic anemia, disseminated intravascular coagulopathy, hypercalcemia, and migratory thrombophlebitis.

► Treatment

Surgery, radiotherapy, chemotherapy, and a combination of methods are attempted, but treatments are generally un-

successful. Pleurectomy and decortication (surgical stripping of the pleura and pericardium from apex of the lung to diaphragm) is one surgical approach but does not improve survival outcome even with adjuvant therapy. Some surgeons favor a trimodality approach with extrapleural pneumonectomy, adjuvant radiation, and chemotherapy, arguing that it prolongs survival in highly selected patients. Extrapleural pneumonectomy is a radical surgical procedure involving removal of the ipsilateral lung, parietal and visceral pleura, pericardium, and most of the hemi-diaphragm. However, the limited data for extrapleural pneumonectomy comes from retrospective studies and case series, where the patients are younger, have early-stage disease, have epithelial histology, and lack extrapleural nodal disease. In advanced unresectable cases, palliative chemotherapy with cisplatin and pemetrexed can extend survival as well as improve quality of life. Drainage of pleural effusions, pleurodesis, radiation therapy, and even surgical resection may offer palliative benefit in some patients.

► Prognosis

Most patients die of respiratory failure and complications of local extension. Median survival time from onset of symptoms ranges from 4 months in extensive disease to 16 months in localized disease. Five-year survival is less than 5%.

HEPATOBIILIARY CANCERS

Lawrence S. Friedman, MD

HEPATOCELLULAR CARCINOMA

ESSENTIALS OF DIAGNOSIS

- In Western countries, usually a complication of cirrhosis.
- Characteristic CT and MRI features and elevated serum α -fetoprotein may obviate the need for a confirmatory biopsy.

► General Considerations

Malignant neoplasms of the liver that arise from parenchymal cells are called hepatocellular carcinomas; those that originate in the ductular cells are called cholangiocarcinomas.

Hepatocellular carcinomas are associated with cirrhosis in 80% of cases. Incidence rates are rising rapidly (twofold since 1978) in the United States and other Western countries, presumably because of the increasing prevalence of cirrhosis caused by chronic hepatitis C infection and nonalcoholic fatty liver disease. In Western countries, risk factors for hepatocellular carcinoma in patients known to have cirrhosis are male gender, age > 55 years (although there has been an increase in the number of younger cases), Asian or Hispanic ethnicity, family history in a first-degree relative, overweight, obesity, diabetes mellitus, hypothyroidism, HCV infection, HBsAg and anti-HBc positivity, prothrombin time < 75% of control, low platelet count, and an elevated serum transferrin saturation. In Africa and most of Asia, hepatitis B is of major etiologic significance, whereas in Western countries and Japan, hepatitis C (particularly genotype 1b and sometimes in combination with “occult” HBV infection) and alcoholic cirrhosis are the most common risk factors. Other associations include hemochromatosis (and possibly the C282Y carrier state), aflatoxin exposure (associated with mutation of the *TP53* gene), α_1 -antitrypsin (α_1 -antitrypsin) deficiency, and tyrosinemia. Evidence for an association with long-term use of oral contraceptives is inconclusive. Coffee consumption appears to be protective. The fibrolamellar variant of hepatocellular carcinoma occurs in young women and is characterized by a distinctive histologic picture, absence of risk factors, and indolent course. Vinyl chloride exposure is associated with angiosarcoma of the liver.

► Clinical Findings

A. Symptoms and Signs

The presence of a hepatocellular carcinoma may be unsuspected until there is deterioration in the condition of a cirrhotic patient who was formerly stable. Cachexia, weakness, and weight loss are associated symptoms. The sudden appearance of ascites, which may be bloody, suggests portal or hepatic vein thrombosis by tumor or bleeding from the necrotic tumor.

Physical examination may show tender enlargement of the liver, occasionally with a palpable mass. In Africa, the typical presentation in young patients is a rapidly expanding abdominal mass. Auscultation may reveal a bruit over the tumor or a friction rub when the process has extended to the surface of the liver.

B. Laboratory Findings

Laboratory tests may reveal leukocytosis, as opposed to the leukopenia that is frequently encountered in cirrhotic patients. Anemia is common, but a normal or elevated hematocrit may be found in up to one-third of patients owing to elaboration of erythropoietin by the tumor. Sudden and sustained elevation of the serum alkaline

phosphatase in a patient who was formerly stable is a common finding. HBsAg is present in a majority of cases in endemic areas, whereas in the United States anti-HCV is found in up to 40% of cases. α -Fetoprotein levels are elevated in up to 70% of patients with hepatocellular carcinoma in Western countries (although the sensitivity is lower in blacks); however, mild elevations are also often seen in patients with chronic hepatitis. Serum levels of des-gamma-carboxy prothrombin are elevated in up to 90% of patients with hepatocellular carcinoma, but they may also be elevated in patients with vitamin K deficiency, chronic hepatitis, and metastatic cancer. The L3 glycoform of α -fetoprotein (AFP-L3) is under study. Cytologic study of ascitic fluid rarely reveals malignant cells.

C. Imaging

Multiphasic helical CT scanning and MRI with contrast enhancement are the preferred imaging studies for determining the location and vascularity of the tumor. Lesions smaller than 2 cm may be difficult to characterize. Arterial phase enhancement of the lesion followed by delayed hypointensity (“washout”) is most specific for hepatocellular carcinoma. Ultrasound is less sensitive and operator dependent but is used to screen for hepatic nodules in high-risk patients. Contrast-enhanced ultrasound has a sensitivity and specificity approaching those of arterial phase helical CT but, unlike CT and MRI, cannot image the entire liver during the short duration of the arterial phase. In selected cases, endoscopic ultrasonography may be useful. PET is under study.

D. Liver Biopsy and Staging

Liver biopsy is diagnostic, although seeding of the needle tract by tumor is a potential risk (1–3%). Biopsy can be deferred if imaging studies and α -fetoprotein levels are diagnostic (eg, serum α -fetoprotein > 200 ng/mL and a hypervascular mass lesion > 2 cm on imaging of a cirrhotic liver) or if surgical resection is planned. Staging in the TNM classification includes the following definitions: T0: no evidence of primary tumor; T1: solitary tumor without vascular invasion; T2: solitary tumor with vascular invasion or multiple tumors none more than 5 cm; T3: multiple tumors more than 5 cm or tumor involving a major branch of the portal or hepatic vein; and T4: tumors with direct invasion of adjacent organs other than the gallbladder or with perforation of the visceral peritoneum. Alternative staging systems also incorporate liver function, tumor aggressiveness and growth rate, general health of the patient, and treatment. The BCLC (Barcelona Clinic Liver Cancer) staging system is now preferred and includes the Child-Turcotte-Pugh stage, tumor stage, and liver function and has the advantage of linking overall stage with preferred treatment modalities and with an estimation of life expectancy.

► Screening & Prevention

In the patient with chronic hepatitis B or cirrhosis caused by HCV or alcohol, surveillance for the development of hepatocellular carcinoma is recommended. Although the

standard approach is α -fetoprotein testing and ultrasonography every 6 months, the value of α -fetoprotein screening has been questioned because of its low sensitivity. The risk of hepatocellular carcinoma in a patient with cirrhosis is 3–5% a year. The diagnosis of hepatocellular carcinoma is established (without the need for biopsy) for lesions > 2 cm when characteristic arterial hypervascularity is demonstrated on both helical CT and MRI (or on either CT or MRI if the serum α -fetoprotein level is higher than 200 mg/L). In a population of patients with cirrhosis, over 60% of nodules < 2 cm in diameter detected on a screening ultrasound prove to be hepatocellular carcinoma. Mass vaccination programs against HBV in developing countries are leading to reduced rates of hepatocellular carcinoma. Successful treatment of hepatitis C in patients with cirrhosis reduces the subsequent risk of hepatocellular carcinoma.

▶ Treatment

Surgical resection of solitary hepatocellular carcinomas may result in cure if liver function is preserved (Child-Turcotte-Pugh class A or possibly B) and portal vein thrombosis is not present. Laparoscopic liver resection has been performed in selected cases. Treatment of underlying chronic viral hepatitis, adjuvant chemotherapy, and adaptive immunotherapy may lower postsurgical recurrence rates. Liver transplantation may be appropriate for small unresectable tumors in a patient with advanced cirrhosis, with reported 5-year survival rates of up to 75%. The recurrence-free survival may be better for liver transplantation than for resection in patients with well-compensated cirrhosis and small tumors (one tumor < 5 cm or three or fewer tumors each < 3 cm in diameter [Milan criteria]). Patients with stage 2 hepatocellular carcinoma receive an additional 22 points on their Model for End-Stage Liver Disease (MELD) score (see Chapter 16), markedly increasing their chances of a transplant. However, liver transplantation is often impractical because of the donor organ shortage and living donor liver transplantation may be considered in these cases. Patients with larger tumors (3–5 cm), a serum α -fetoprotein level \geq 455 ng/mL, or a MELD score \geq 20 have poor posttransplantation survival. Chemotherapy, hormonal therapy with tamoxifen, and long-acting octreotide have not been shown to prolong life, but transarterial chemoembolization (TACE), transarterial chemoinfusion (TACI), and transarterial radioembolization (TARE) via the hepatic artery are palliative and may prolong survival in patients with a large or multifocal tumor in the absence of extrahepatic spread. TACI and TARE are suitable for patients with portal vein thrombosis. Injection of absolute ethanol into, radiofrequency ablation of, cryotherapy of, or microwave ablation of small tumors (< 2 cm) may prolong survival in patients who are not candidates for resection; these interventions may provide a “bridge” to liver transplantation. Radiofrequency ablation is superior to ethanol injection for tumors > 2 cm in diameter and can be performed after TACE in select cases. Sorafenib (an oral multikinase inhibitor of Raf kinase, the VEGF, and the platelet-derived growth factor receptor [and others]), prolongs median survival as well as the time to radiologic progression by 3 months in patients with advanced hepa-

tocellular carcinoma; sorafenib is the standard of care in these patients. New chemotherapy and radiation therapy techniques (“radioembolization”) and novel biologic approaches (eg, bortezomib, a proteasome inhibitor; antiangiogenesis agents; other inhibitors of growth-factor signaling; and gene therapy) are under study. For patients whose disease progresses despite treatment or who present with advanced tumors, vascular invasion, or extrahepatic spread, meticulous efforts at palliative care are essential (see Chapter 5). Severe pain may develop in such patients due to expansion of the liver capsule by the tumor and requires concerted efforts at pain management, including the use of opioids (see Chapter 5).

▶ Prognosis

In the United States, overall 1- and 5-year survival rates for patients with hepatocellular carcinoma are 23% and 5%, respectively. Five-year survival rates rise to 56% for patients with localized resectable disease (T1, T2, selected T3 and T4; N0; M0) but are virtually nil for those with localized unresectable or advanced disease. The fibrolamellar variant has a better prognosis than conventional hepatocellular carcinoma, with a 5-year survival rate of up to 75% following resection.

▶ When to Refer

All patients with hepatocellular carcinoma should be referred to a specialist.

▶ When to Admit

CARCINOMA OF THE BILIARY TRACT

ESSENTIALS OF DIAGNOSIS

- ▶ Presents with obstructive jaundice, usually painless, often with dilated biliary tree.

- ▶ Pain is more common in gallbladder carcinoma than cholangiocarcinoma.
- ▶ A Courvoisier (dilated) gallbladder may be detected.
- ▶ Diagnosis by cholangiography with biopsy and brushings for cytology.

▶ General Considerations

Carcinoma of the gallbladder occurs in approximately 2% of all people operated on for biliary tract disease. It is notoriously insidious, and the diagnosis is often made unexpectedly at surgery. Cholelithiasis (often large, symptomatic stones) is usually present. Other risk factors are chronic infection of the gallbladder with *Salmonella typhi*, gallbladder polyps over 1 cm in diameter, mucosal calcification of the gallbladder (porcelain gallbladder), and anomalous pancreaticobiliary ductal junction. Genetic factors include *K-ras* and *TP53* mutations. Spread of the cancer—by direct extension into the liver or to the peritoneal surface—may be the initial manifestation. The TNM classification includes the following stages: Tis, carcinoma in situ; T1a, tumor invades lamina propria, and T1b, tumor invades muscle layer; T2, tumor invades perimuscular connective tissue, no extension beyond serosa (visceral peritoneum) or into liver; T3, tumor perforates the serosa or directly invades the liver or adjacent organ or structure; T4, tumor invades the main portal vein or hepatic artery or invades multiple extrahepatic organs or structures; N1, regional lymph node metastasis; and M1, distant metastasis.

Carcinoma of the bile ducts (cholangiocarcinoma) accounts for 3% of all cancer deaths in the United States. It is more prevalent in persons aged 50–70, with a slight male predominance. Two-thirds arise at the confluence of the hepatic ducts (Klatskin tumors), and one-fourth arise in the distal extrahepatic bile duct; the remainder are intrahepatic (peripheral), the incidence of which has risen dramatically since the 1970s. Staging is as follows: T1, solitary tumor without vascular invasion; T2, solitary tumor with vascular invasion or multiple tumors ≤ 5 cm; T3, multiple tumors > 5 cm or involving major branch of portal or hepatic veins; T4, tumor invading adjacent organ (except gallbladder) or perforation of visceral peritoneum; N1, regional lymph node metastasis; and M1, distant metastasis. Other staging systems consider tumor extent, vascular encasement, and hepatic lobe atrophy. The frequency of carcinoma in persons with choledochal cysts has been reported to be over 14% at 20 years, and surgical excision is recommended. There is an increased incidence in patients with bile duct adenoma; biliary papillomatosis; Caroli disease; a biliary-enteric anastomosis; ulcerative colitis, especially those with primary sclerosing cholangitis; biliary cirrhosis; diabetes mellitus; hyperthyroidism; chronic pancreatitis; heavy alcohol consumption; and past exposure to thorotrast, a contrast agent. In southeast Asia, hepatolithiasis and infection of the bile ducts with helminths (*Clonorchis sinensis*, *Opisthorchis viverrini*) are associated with chronic cholangitis and an increased risk of cholangiocarcinoma. Hepatitis C virus infection, cirrhosis, HIV infection, nonalcoholic fatty liver disease, diabetes

mellitus, obesity, and tobacco smoking are additional risk factors for intrahepatic cholangiocarcinoma.

▶ Clinical Findings

A. Symptoms and Signs

Progressive jaundice is the most common and usually the first sign of obstruction of the extrahepatic biliary system. Pain in the right upper abdomen with radiation into the back is usually present early in the course of gallbladder carcinoma but occurs later in the course of bile duct carcinoma. Anorexia and weight loss are common and may be associated with fever and chills due to cholangitis. Rarely, hematemesis or melena results from erosion of tumor into a blood vessel (hemobilia). Fistula formation between the biliary system and adjacent organs may also occur. The course is usually one of rapid deterioration, with death occurring within a few months.

Physical examination reveals profound jaundice. A palpable gallbladder with obstructive jaundice usually is said to signify malignant disease (Courvoisier law); however, this clinical generalization has been proved to be accurate only about 50% of the time. Hepatomegaly due to hypertrophy of the unobstructed liver lobe is usually present and is associated with liver tenderness. Ascites may occur with peritoneal implants. Pruritus and skin excoriations are common.

B. Laboratory Findings

With biliary obstruction, laboratory examination reveals predominantly conjugated hyperbilirubinemia, with total serum bilirubin values ranging from 5 to 30 mg/dL. There is usually concomitant elevation of the alkaline phosphatase and serum cholesterol. AST is normal or minimally elevated. An elevated CA 19-9 level may help distinguish cholangiocarcinoma from a benign biliary stricture (in the absence of cholangitis).

C. Imaging

Ultrasonography and contrast-enhanced, triple-phase, helical CT may show a gallbladder mass in gallbladder carcinoma and intrahepatic mass or biliary dilation in carcinoma of the bile ducts. CT may also show involved regional lymph nodes and atrophy of a hepatic lobe because of vascular encasement with compensatory hypertrophy of the unaffected lobe. MRI with magnetic resonance cholangiopancreatography (MRCP) and gadolinium enhancement permits visualization of the entire biliary tree and detection of vascular invasion and obviates the need for angiography and, in some cases, direct cholangiography; it has become the imaging procedure of choice but may understage malignant hilar strictures. The sensitivity and image quality can be increased with use of ferumoxide enhancement. In indeterminate cases, PET can detect cholangiocarcinomas as small as 1 cm and lymph node and distant metastases, but false-positive results occur. The most helpful diagnostic studies before surgery are either percutaneous transhepatic or endoscopic retrograde cholangiography with biopsy and cytologic specimens, although false-negative biopsy and cytology results are common. Digital image analysis and

fluorescent in situ hybridization of cytologic specimens improve sensitivity. Endoscopic ultrasound (EUS) with FNA of tumors, choledochoscopy, and intraductal ultrasonography may confirm a diagnosis of cholangiocarcinoma in a patient with bile duct stricture and an otherwise indeterminate evaluation.

► Treatment

In young and fit patients, curative surgery may be attempted if the tumor is well localized. The 5-year survival rate for carcinoma of the gallbladder invading the lamina propria or muscularis (stage 1, T1a or 1b, N0, M0) is as high as 85% with laparoscopic cholecystectomy but drops to 60%, even with a more extended open resection, if there is perimuscular invasion (T2). The role of radical surgery for T3 and T4 tumors is debatable. If the tumor is unresectable at laparotomy, biliary-enteric bypass (eg, Roux-en-Y hepaticojejunostomy) can be performed. Carcinoma of the bile ducts is curable by surgery in less than 10% of cases. If resection margins are negative, the 5-year survival rate may be as high as 47% for intrahepatic cholangiocarcinomas, 41% for hilar cholangiocarcinoma, and 37% for distal cholangiocarcinomas, but the perioperative mortality rate may be as high as 10%. Palliation can be achieved by placement of a self-expandable metal stent via an endoscopic or percutaneous transhepatic route. Covered metal stents may be more cost-effective than uncovered metal stents because of a lower risk of stent occlusion, but they are not associated with longer survival. For hilar tumors, there is controversy as to whether unilateral or bilateral stents should be inserted. Plastic stents are less expensive but more prone to occlude than metal ones; they are suitable for patients expected to survive only a few months. Photodynamic therapy in combination with stent placement has been demonstrated to prolong survival when compared with stent placement alone in patients with nonresectable cholangiocarcinoma. Radiotherapy may relieve pain and contribute to biliary decompression. There is limited response to chemotherapy such as with gemcitabine. In general, the prognosis is poor, with few patients surviving for more than 12 months after surgery. Although cholangiocarcinoma is generally considered to be a contraindication to liver transplantation because of rapid tumor recurrence, a 75% 5-year survival rate has been reported in patients with stage I and II cholangiocarcinoma undergoing chemoradiation and exploratory laparotomy followed by liver transplantation.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).

► When to Refer

All patients with carcinoma of the biliary tract should be referred to a specialist.

► When to Admit

- Biliary obstruction.
- Cholangitis.

CARCINOMA OF THE PANCREAS & THE PERIAMPULLARY AREA

ESSENTIALS OF DIAGNOSIS

- Obstructive jaundice (may be painless).
- Enlarged gallbladder (may be painful).
- Upper abdominal pain with radiation to back, weight loss, and thrombophlebitis are usually late manifestations.

► General Considerations

Carcinomas involving the head of the pancreas, the ampulla of Vater, the distal common bile duct, and the duodenum are considered together, because they are usually indistinguishable clinically; of these, carcinomas of the pancreas constitute over 90%. Carcinoma is the most common neoplasm of the pancreas. About 75% are in the head and 25% in the body and tail of the organ. They comprise 2% of all cancers and 5% of cancer deaths. Risk factors include age, obesity, tobacco use, heavy alcohol use, chronic pancreatitis, prior abdominal radiation, and family history. New-onset diabetes mellitus after age 45 years occasionally heralds the onset of early pancreatic cancer. About 7–8% of patients with pancreatic cancer have a family history of pancreatic cancer in a first-degree relative, compared with 0.6% of control subjects. Point mutations in codon 12 of the *K-ras* oncogene are found in 70–100%, inactivation of the tumor suppressor genes *INK4A* on chromosome 9, *TP53* on chromosome 17, and *MADH4* on chromosome 18 is found in 95%, 75%, and 55% of pancreatic cancers, respectively, and mutation of the palladin gene is reported to be common. Pancreatic cancer can also occur as part of several hereditary syndromes, including familial breast cancer (carriers of *BRCA-2* have a 7% lifetime risk of pancreatic cancer), hereditary pancreatitis (*PSS1* mutation), familial cutaneous malignant melanoma (*CDKN2A* mutation), Peutz–Jeghers syndrome, ataxia-telangiectasia, and hereditary nonpolyposis colorectal cancer. Polymorphisms of the genes for methylene tetrahydrofolate reductase and thymidylate synthase have been reported to be associated with pancreatic cancer. Neuroendocrine tumors account for 1–2% of pancreatic neoplasms and may be functional (producing gastrin, insulin, glucagon, vasoactive intestinal peptide, somatostatin, growth hormone–releasing hormone, adrenocorticotrophic hormone, and others) or nonfunctional. Plasma chromogranin A levels are elevated in 88–100% of affected patients.

Cystic neoplasms account for only 1% of pancreatic cancers, but they are important because they are often mistaken for pseudocysts. A cystic neoplasm should be suspected when a cystic lesion in the pancreas is found in the absence of a history of pancreatitis. At least 15% of all pancreatic cysts are neoplasms. Whereas serous cystadenomas (which account for 32–39% of cystic pancreatic neoplasms and also occur in patients with von Hippel–Lindau disease) are benign, mucinous cystic neoplasms (defined by the presence of ovarian stroma) (10–45%), intraductal papillary mucinous neoplasms (21–33%), solid pseudopapillary neoplasms (< 5%), and cystic islet cell tumors (3–5%) may be malignant, although their prognoses are better than the prognosis of adenocarcinoma of the pancreas, unless the neoplasm is locally advanced.

► Clinical Findings

A. Symptoms and Signs

Pain is present in over 70% of cases and is often vague, diffuse, and located in the epigastrium or left upper quadrant when the lesion is in the tail. Radiation of pain into the back is common and sometimes predominates. Sitting up and leaning forward may afford some relief, and this usually indicates that the lesion has spread beyond the pancreas and is inoperable. Diarrhea, perhaps due to maldigestion, is an occasional early symptom. Migratory thrombophlebitis is a rare sign. Weight loss is a common but late finding and may be associated with depression. Occasionally a patient presents with acute pancreatitis in the absence of an alternative cause. Jaundice is usually due to biliary obstruction by a cancer in the pancreatic head. A palpable gallbladder is also indicative of obstruction by neoplasm (Courvoisier law), but there are frequent exceptions. A hard, fixed, occasionally tender mass may be present. In advanced cases, a hard periumbilical (Sister Joseph's) nodule may be palpable.

B. Laboratory Findings

There may be mild anemia. Glycosuria, hyperglycemia, and impaired glucose tolerance or true diabetes mellitus are found in 10–20% of cases. The serum amylase or lipase level is occasionally elevated. Liver biochemical tests may suggest obstructive jaundice. Steatorrhea in the absence of jaundice is uncommon. Occult blood in the stool is suggestive of carcinoma of the ampulla of Vater (the combination of biliary obstruction and bleeding may give the stools a distinctive silver appearance). CA 19-9, with a sensitivity of 70% and a specificity of 87%, has not proved sensitive enough for early detection of pancreatic cancer; increased values are also found in acute and chronic pancreatitis and cholangitis.

C. Imaging

With carcinoma of the head of the pancreas, an upper gastrointestinal series may show a widening of the duodenal loop, mucosal abnormalities in the duodenum ranging from edema to invasion or ulceration, spasm, or compression. Ultrasound is not reliable because of interference by intesti-

nal gas. Multiphase thin-cut helical CT scanning is generally the initial diagnostic procedure and detects a mass in over 80% of cases. CT scanning identifies metastases, delineates the extent of the tumor, and allows for percutaneous FNA for cytologic studies and tumor markers. MRI is an alternative to CT scanning. Preliminary experience suggests that PET is a sensitive technique for detecting pancreatic cancer and metastases. Selective celiac and superior mesenteric arteriography may demonstrate vessel invasion by tumor, a finding that would interdict attempts at surgical resection, but it is less widely used since the advent of multiphase helical CT. Endoscopic ultrasonography is more sensitive than CT scanning for detecting pancreatic cancer and equivalent to CT scanning for determining nodal involvement and resectability. A normal EUS excludes pancreatic cancer. Endoscopic ultrasonography may also be used to guide FNA for tissue diagnosis and tumor markers. Endoscopic retrograde cholangiopancreatography (ERCP) may clarify an ambiguous CT scan or MRI study by delineating the pancreatic duct system or confirming an ampullary or biliary neoplasm. MRCP appears to be at least as sensitive as ERCP in diagnosing pancreatic cancer. In some centers, pancreatoscopy or intraductal ultrasonography can be used to evaluate filling defects in the pancreatic duct and assess resectability of intraductal papillary mucinous tumors. With obstruction of the splenic vein, splenomegaly or gastric varices are present, the latter delineated by endoscopy, endoscopic ultrasonography, or angiography.

Cystic neoplasms can be distinguished by their appearance on CT, endoscopic ultrasonography, and ERCP and features of the cyst fluid on gross and cytologic analysis. For example, serous cystadenomas may have a central scar or honeycomb appearance; mucinous cystadenomas are unilocular or multilocular and contain mucin-rich fluid with high carcinoembryonic antigen levels (> 200 ng/mL); and intraductal papillary mucinous neoplasms are associated with a dilated pancreatic duct and extrusion of gelatinous material from the ampulla.

Staging of pancreatic cancer by the TNM classification includes the following definitions: Tis: carcinoma in situ; T1: tumor limited to the pancreas, 2 cm or less in greatest dimension; T2: tumor limited to the pancreas, more than 2 cm in greatest dimension; T3: tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery; T4, tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor).

► Treatment

Abdominal exploration is usually necessary when cytologic diagnosis cannot be made or if resection is to be attempted, which includes about 30% of patients. In a patient with a localized mass in the head of the pancreas and without jaundice, laparoscopy may detect tiny peritoneal or liver metastases and thereby avoid resection in 4–13% of patients. Radical pancreaticoduodenal (Whipple) resection is indicated for lesions strictly limited to the head of the pancreas, periampullary area, and duodenum (T1, N0, M0). Five-year survival rates are 20–25% in this group and

as high as 40% in those with negative resection margins and without lymph node involvement. Preoperative endoscopic decompression of an obstructed bile duct is often achieved with a plastic stent or short metal stent but does not reduce operative mortality or morbidity. The best surgical results are achieved at centers that specialize in the multidisciplinary treatment of pancreatic cancer. Adjuvant or neoadjuvant chemotherapy with gemcitabine and fluorouracil, possibly combined with irradiation, appears to be of benefit (Table 39–4). When resection is not feasible, endoscopic stenting of the bile duct is performed to relieve jaundice. A plastic stent is generally placed if the patient's anticipated survival is less than 6 months (or surgery is planned). A metal stent is preferred when anticipated survival is 6 months or greater. Surgical biliary bypass may be considered in patients expected to survive at least 6 months. Surgical duodenal bypass may be considered in patients in whom duodenal obstruction is expected to develop later; alternatively, endoscopic placement of a self-expandable duodenal stent may be feasible. Chemoradiation may be used for palliation of unresectable cancer confined to the pancreas. Chemotherapy has been disappointing in metastatic pancreatic cancer, although improved response rates have been reported with gemcitabine. Novel small molecules (eg, erlotinib), capecitabine (an oral fluoropyrimidine), nucleoside cytidine analogues, and topoisomerase inhibitors are under study. Celiac plexus nerve block or thoracoscopic splanchnicectomy may improve pain control. Photodynamic therapy is under study.

Surgical resection is the treatment of choice for neuroendocrine tumors, when feasible. Metastatic disease may be controlled with long-acting somatostatin analogs, interferon, peptide-receptor radionuclide therapy, and chemoembolization. There is a growing consensus that asymptomatic incidental pancreatic cysts of 2 cm or less are at low risk of invasive carcinoma and may be followed by imaging tests at 6-month intervals, with surgery performed if a cyst enlarges or exceeds 2.5 cm.

Surgical resection is indicated for mucinous cystic neoplasms, symptomatic serous cystadenomas, and cystic tumors larger than 2 cm in diameter that remain undefined after helical CT, EUS, and diagnostic aspiration. All intraductal papillary mucinous neoplasms of the main pancreatic duct should be resected, but those of branch ducts may be followed with serial imaging if they are asymptomatic and exhibit benign features (eg, diameter < 3 cm, absence of nodules or thick walls); most of the latter remain stable on follow-up, but the risk of pancreatic ductal carcinoma and of nonpancreatic cancers may also be increased in this group of patients. In the absence of locally advanced disease, survival is higher for malignant cystic neoplasms than for adenocarcinoma. Endoscopic resection or ablation, with temporary placement of a pancreatic duct stent, may be feasible for ampullary adenomas, but patients must be followed for recurrence.

► Prognosis

Carcinoma of the pancreas, especially in the body or tail, has a poor prognosis. Reported 5-year survival rates range

from 2% to 5%. Lesions of the ampulla have a better prognosis, with reported 5-year survival rates of 20–40% after resection; jaundice and lymph node involvement are adverse prognostic factors. In carefully selected patients, resection of cancer of the pancreatic head is feasible and results in reasonable survival. In persons with a strong family history of pancreatic cancer, screening with helical CT and endoscopic ultrasonography should be considered beginning 10 years before the age at which pancreatic cancer was diagnosed in a family member.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).

► When to Refer

All patients with carcinoma involving the pancreas and the periampullary area should be referred to a specialist.

► When to Admit

Patients who require surgery and other interventions should be hospitalized.

ALIMENTARY TRACT CANCERS

Kenneth R. McQuaid, MD

ESOPHAGEAL CANCER

ESSENTIALS OF DIAGNOSIS

- Progressive solid food dysphagia.
- Weight loss common.
- Endoscopy with biopsy establishes diagnosis.

► General Considerations

Esophageal cancer usually develops in persons between 50 and 70 years of age. The overall ratio of men to women is 3:1. There are two histologic types: squamous cell carcinoma and adenocarcinoma. In the United States, **squamous cell cancer** is much more common in blacks than in whites.

Table 39-4. Treatment choices for cancers responsive to systemic agents.

| Diagnosis | Current Treatment of Choice | Other Treatments |
|--|---|--|
| Acute lymphocytic leukemia (ALL) | Induction combination chemotherapy: Vincristine, prednisone, daunorubicin, asparaginase, intrathecal methotrexate Consolidation combination chemotherapy: Cyclophosphamide, vincristine, doxorubicin, dexamethasone (hyper-CVAD) alternated with cytarabine, methotrexate Maintenance: Methotrexate, 6-mercaptopurine | Imatinib mesylate (Ph positive ALL), autologous or allogeneic transplantation for high risk or at relapse |
| Acute myelogenous leukemia (AML) | Combination chemotherapy: Cytarabine plus daunorubin or idarubicin | Gemtuzumab ozogamicin, prednisone, doxorubicin |
| Chronic myelocytic leukemia (CML) | Imatinib mesylate | Dasatinib, nilotinib, allogeneic bone marrow transplantation, hydroxyurea, interferon- α , cytarabine, busulfan |
| Chronic lymphocytic leukemia (CLL) | Combination chemotherapy: Fludarabine, cyclophosphamide, rituximab (FCR); Fludarabine; or Chlorambucil | Alemtuzumab, bendamustine, pentostatin, cladribine, cyclophosphamide, vincristine, doxorubicin, prednisone |
| Hairy cell leukemia | Cladribine (2-chlorodeoxyadenosine) | Pentostatin, interferon- α |
| Hodgkin disease (stages III and IV) | Combination chemotherapy: Doxorubicin, bleomycin, vinblastine, dacarbazine (ABVD); Doxorubicin, vinblastine, mechlorethamine, etoposide, vincristine, bleomycin, prednisone (Stanford V) | Gemcitabine, vinorelbine, ifosfamide, cyclophosphamide, procarbazine, transplantation for relapse |
| Non-Hodgkin lymphoma (intermediate and high grade) | Combination chemotherapy: Cyclophosphamide, doxorubicin, vincristine, prednisone, rituximab (CHOP-R) | Combination chemotherapy second line: Dexamethasone, cisplatin, cytarabine (DHAP) Etoposide, methylprednisolone, cytarabine, cisplatin (ESHAP) Ifosfamide, carboplatin, etoposide (ICE) Mesna, ifosfamide, mitoxantrone, etoposide (MINE); transplantation for high risk or first relapse |
| Non-Hodgkin lymphoma (low grade) | Combination chemotherapy: Fludarabine, cyclophosphamide, rituximab (FCR) Cyclophosphamide, vincristine, doxorubicin, prednisone, rituximab (CHOP-R), or Cyclophosphamide, vincristine, prednisone, rituximab (CVP-R) or Chlorambucil | ¹³¹ I tositumomab, ⁹⁰ Y ibritumomab tiuxetan, bendamustine, autologous or allogeneic transplantation |
| Multiple myeloma | Combination chemotherapy (transplant candidates): Bortezomib, dexamethasone, thalidomide or lenalidomide Dexamethasone, thalidomide or lenalidomide Dexamethasone followed by autologous or miniallogeneic stem cell transplantation Combination chemotherapy (non-transplant candidates): Melphalan, prednisone, bortezomib Melphalan, prednisone | Bortezomib, lenalidomide, thalidomide, dexamethasone, cyclophosphamide |
| Waldenstrom macroglobulinemia | Combination therapy: Fludarabine, cyclophosphamide, rituximab (FCR), with or without plasmapheresis | Cladribine, thalidomide, bortezomib, chlorambucil, autologous bone marrow transplantation, prednisone |
| Polycythemia vera | Phlebotomy, hydroxyurea | Anagrelide, radiophosphorus ³² P, interferon- α , busulfan, chlorambucil, cyclophosphamide |
| Non-small cell lung cancer | Combination chemotherapy: Cisplatin, vinorelbine Cisplatin, gemcitabine Cisplatin, etoposide Paclitaxel, carboplatin; all regimens with or without bevacizumab | Docetaxel, vinorelbine, pemetrexed, erlotinib, cetuximab |
| Small cell lung cancer | Combination chemotherapy: Cisplatin, etoposide | Irinotecan, cyclophosphamide, doxorubicin, vincristine, topotecan |
| Mesothelioma | Combination chemotherapy: Cisplatin, pemetrexed | Doxorubicin |

| Diagnosis | Current Treatment of Choice | Other Treatments |
|---|--|--|
| Head and neck cancer | Combination chemotherapy: Cisplatin, fluorouracil Paclitaxel, carboplatin Docetaxel, cisplatin, fluorouracil Cisplatin or cetuximab with radiation therapy | Hydroxyurea, bleomycin, methotrexate, cetuximab |
| Esophageal cancer | Combination chemotherapy: Cisplatin, fluorouracil | Paclitaxel, irinotecan, oxaliplatin, capecitabine, docetaxel, epirubicin |
| Uterine cancer | Progestins, tamoxifen, aromatase inhibitors Combination chemotherapy: Cisplatin, doxorubicin, paclitaxel Cisplatin, doxorubicin Carboplatin, paclitaxel | Fluorouracil |
| Ovarian cancer | Combination chemotherapy: Paclitaxel, carboplatin Intraperitoneal cisplatin, paclitaxel Docetaxel, carboplatin Paclitaxel, cisplatin | Gemcitabine, liposomal doxorubicin, topotecan, cyclophosphamide, etoposide, docetaxel |
| Cervical cancer | With radiation: Cisplatin Combination chemotherapy: Cisplatin, paclitaxel Cisplatin, topotecan Carboplatin, paclitaxel Cisplatin, gemcitabine | Docetaxel, ifosfamide, vinorelbine, irinotecan, epirubicin, mitomycin, fluorouracil |
| Breast cancer | Adjuvant endocrine therapy: Premenopausal: Tamoxifen Postmenopausal: Aromatase inhibitors (anastrozole, letrozol, exemestane) Adjuvant chemotherapy (without trastuzumab): Doxorubicin, cyclophosphamide, docetaxel Doxorubicin, cyclophosphamide, paclitaxel Docetaxel, cyclophosphamide Doxorubicin, cyclophosphamide Adjuvant chemotherapy (with trastuzumab): Doxorubicin, cyclophosphamide, paclitaxel, trastuzumab Docetaxel, carboplatin, trastuzumab | Megestrol, aminoglutethimide, capecitabine, mitoxantrone, cisplatin, etoposide, vinblastine, fluorouracil, ixabepilone, gemcitabine |
| Choriocarcinoma (trophoblastic neoplasms) | Single agents: Methotrexate or dactinomycin for low risk disease Combination chemotherapy: Etoposide/methotrexate, dactinomycin, cyclophosphamide, vincristine (EMA-CO) for high-risk disease | Vinblastine, cisplatin, mercaptopurine, chlorambucil, doxorubicin |
| Testicular cancer | Combination chemotherapy: Bleomycin, etoposide, cisplatin (BEP) Cisplatin, etoposide (EP) | Vinblastine, ifosfamide, paclitaxel, mesna |
| Kidney cancer | Sunitinib, temsirolimus, bevacizumab, sorafenib, interleukin-2 | Interferon- α , vinblastine, capecitabine, fluorouracil |
| Bladder cancer | Combination chemotherapy: Gemcitabine, cisplatin | Carboplatin, paclitaxel, docetaxel, fluorouracil, pemetrexed, methotrexate |
| Prostate cancer | Luteinizing hormone-releasing agonist (leuprolide, goserelin, triptorelin) plus an antiandrogen (flutamide, bicalutamide, nilutamide) | Ketoconazole, docetaxel, mitoxantrone, estramustine, prednisone |
| Brain cancer (anaplastic astrocytoma and glioblastoma multiforme) | Temozolomide | Bevacizumab, irinotecan, procarbazine, carmustine, lomustine |
| Neuroblastoma | Combination chemotherapy: Cyclophosphamide, doxorubicin, cisplatin, etoposide | Vincristine, topotecan, irinotecan, ifosfamide, carboplatin, 13-cis-retinoic acid, ¹³¹ I-MIBG, autologous or allogeneic transplantation |
| Thyroid cancer | Radioiodine (¹³¹ I), sorafenib | Doxorubicin, dacarbazine |
| Adrenal cancer | Mitotane | Doxorubicin, etoposide, cisplatin |
| Stomach cancer | Combination chemotherapy: Epirubicin, cisplatin, fluorouracil Docetaxel, cisplatin, fluorouracil Fluorouracil, leucovorin, oxaliplatin | Capecitabine, sorafenib |

(continued)

Table 39–4. Treatment choices for cancers responsive to systemic agents. (continued)

| Diagnosis | Current Treatment of Choice | Other Treatments |
|-----------------------|--|--|
| Pancreatic cancer | Combination chemotherapy: Gemcitabine, cisplatin; Gemcitabine, erlotinib; Gemcitabine | Capecitabine, fluorouracil, oxaliplatin |
| Colon cancer | Combination chemotherapy: Fluorouracil, leucovorin, oxaliplatin (FOLFOX6) Capecitabine, oxaliplatin (CapeOx) Fluorouracil, leucovorin, irinotecan (FOLFIRI); each regimen with or without bevacizumab | Cetuximab, irinotecan, panitumumab |
| Rectal cancer | Chemotherapy with radiation: Fluorouracil; for advanced disease same regimens used with colon cancer | Cetuximab, irinotecan, panitumumab |
| Anal cancer | Combination chemotherapy with radiation: Fluorouracil, mitomycin | Cisplatin |
| Carcinoid | Combination chemotherapy: Streptozocin, fluorouracil; Cisplatin, etoposide | Doxorubicin, dacarbazine, octreotide, interferon- α |
| Insulinoma | Interferon, streptozocin | Doxorubicin, fluorouracil, mitomycin |
| Osteogenic sarcoma | Combination chemotherapy with two of these agents: Doxorubicin, cisplatin, ifosfamide, high-dose methotrexate | Cyclophosphamide, dacarbazine |
| Soft tissue sarcomas | Combination chemotherapy: Doxorubicin, dacarbazine (AD) Doxorubicin, ifosfamide, mesna (AIM) Mesna, doxorubicin, ifosfamide, dacarbazine (MAID) | Liposomal doxorubicin, methotrexate, gemcitabine, docetaxel |
| Melanoma | Dacarbazine, temozolomide, high-dose interleukin-2 | Paclitaxel, cisplatin, carboplatin, interferon- α , vinblastine |
| Hepatocellular cancer | Sorafenib | Doxorubicin |
| Kaposi sarcoma | Liposomal doxorubicin, liposomal daunorubicin | Paclitaxel, vinblastine, vincristine, etoposide, doxorubicin |

Chronic alcohol and tobacco use are strongly associated with an increased risk of squamous cell carcinoma. The risk of squamous cell cancer is also increased in patients with tylosis, achalasia, caustic-induced esophageal stricture, and other head and neck cancers. Squamous cell cancer has a high incidence in certain regions of China and Southeast Asia. Half of all cases occur in the distal third of the esophagus. **Adenocarcinoma** is more common in whites. It is increasing dramatically in incidence and now is as common as squamous carcinoma. The majority of adenocarcinomas develop as a complication of Barrett metaplasia due to chronic gastroesophageal reflux. Thus, most adenocarcinomas arise in the distal third of the esophagus. Obesity also is strongly associated with adenocarcinoma, even after controlling for gastroesophageal reflux; however, no causal relationship has been convincingly shown.

► Clinical Findings

A. Symptoms and Signs

Most patients with esophageal cancer present with advanced, incurable disease. Over 90% have solid food dysphagia, which progresses over weeks to months. Odynophagia is sometimes present. Significant weight loss is common. Local tumor extension into the tracheobronchial tree may result in a tracheoesophageal fistula, characterized by coughing on swallowing or pneumonia. Chest or back pain suggests mediastinal extension. Recurrent laryngeal involvement may pro-

duce hoarseness. Physical examination is often unrevealing. The presence of supraclavicular or cervical lymphadenopathy or of hepatomegaly implies metastatic disease.

B. Laboratory Findings

Laboratory findings are nonspecific. Anemia related to chronic disease or occult blood loss is common. Elevated aminotransferase or alkaline phosphatase concentrations suggest hepatic or bony metastases. Hypoalbuminemia may result from malnutrition.

C. Imaging

Chest radiographs may show adenopathy, a widened mediastinum, pulmonary or bony metastases, or signs of tracheoesophageal fistula such as pneumonia. A barium esophagogram may be the first study obtained to evaluate dysphagia. The appearance of a polypoid, infiltrative, or ulcerative lesion is suggestive of carcinoma and requires endoscopic evaluation. However, even lesions believed to be benign by radiography warrant endoscopic evaluation.

D. Upper Endoscopy

Endoscopy with biopsy establishes the diagnosis of esophageal carcinoma with a high degree of reliability. In some cases, significant submucosal spread of the tumor may yield nondiagnostic mucosal biopsies. Repeated biopsy may be necessary.

► Staging

After confirmation of the diagnosis of esophageal carcinoma, the stage of the disease should be determined since doing so influences the choice of therapy. Patients should undergo evaluation with CT of the chest and abdomen to look for evidence of pulmonary or hepatic metastases, lymphadenopathy, and local tumor extension. If there is no evidence of distant metastases or extensive local spread on CT, endoscopic ultrasonography with guided FNA biopsy of lymph nodes should be performed, which is superior to CT in demonstrating the level of local mediastinal extension and local lymph node involvement. PET with fluorodeoxyglucose or integrated PET-CT imaging is more sensitive (and expensive) than CT for detection of distant metastasis. It is increasingly used to look for regional or distant spread in patients thought to have localized disease after other diagnostic studies. Bronchoscopy is sometimes required in proximal esophageal cancer to exclude tracheobronchial extension. Apart from distant metastasis (M1b), the two most important predictors of poor survival are adjacent mediastinal spread (T4) and lymph node involvement. Whereas cure may be achieved in patients with regional lymph node involvement (stages IIB and III), involvement of nodes outside the chest (M1a) is indicative of metastatic disease (stage IV) that is incurable.

► Differential Diagnosis

Esophageal carcinoma must be distinguished from other causes of progressive dysphagia, including peptic stricture, achalasia, and adenocarcinoma of the gastric cardia with esophageal involvement. Benign-appearing peptic strictures should be biopsied at presentation to exclude occult malignancy.

► Treatment

The approach to esophageal cancer depends on the tumor stage, patient preference and functional status, and the expertise of the attending surgeons, oncologists, gastroenterologists, and radiotherapists. There is no consensus about the optimal treatment approach. It is helpful, however, to classify patients into two general categories.

A. Therapy for “Curable” Disease

Superficial esophageal cancers confined to the epithelium (high-grade dysplasia or carcinoma in situ [Tis]), lamina propria (T1a), or submucosal (T1b) are increasingly recognized in endoscopic screening and surveillance programs. Esophagectomy achieves high cure rates but is associated with mortality (2%) and morbidity. If performed by experienced physicians, endoscopic mucosal resection of superficial cancers (especially Tis and T1a) achieves equivalent long-term survival with less morbidity. For a full discussion of management options in superficial adenocarcinoma, see the section on Barrett Esophagus in Chapter 15. The management of other invasive but potentially “curable” esophageal cancers (stage I, II, or IIIA) is controversial and depends on institutional experience.

1. Surgery with or without neoadjuvant chemoradiation therapy

—There is debate over the optimal surgical approach. The procedure with the lowest morbidity is transhiatal esophagectomy with anastomosis of the stomach to the cervical esophagus; however, this approach does not involve sampling or removal of mediastinal lymph nodes. Alternatively, surgeons may perform en bloc trans-thoracic excision of the esophagus with extended dissection of lymph nodes in the mediastinum and upper abdomen. In a randomized controlled trial comparing these two approaches, en bloc resection was associated with higher perioperative morbidity but a nonsignificant trend toward improved 5-year survival (39% vs 27%). Transhiatal resection may be more appropriate for patients who are elderly or have comorbid illness, and en bloc resection more appropriate in younger or healthier patients with a better prognosis.

Patients without regional lymph node spread (stage I and stage IIA) have high cure rates with surgery alone and require no other radiation or chemotherapy. If regional lymph node metastases have occurred (stage IIB and stage IIIA), the rate of cure with surgery alone is reduced to less than 20%. Meta-analysis of trials comparing neoadjuvant therapy followed by surgery with surgery alone suggests a 13% absolute improvement in 2-year survival with combined therapy. Therefore, in many centers, preoperative (neoadjuvant) chemoradiation therapy is recommended. The most commonly used chemotherapeutic agents are cisplatin and 5-fluorouracil (5-FU), although the optimal regimen is unclear. Furthermore, the superiority of this combined approach compared with surgery alone, or surgery with postoperative adjuvant chemotherapy is unproven.

2. Chemotherapy plus radiation therapy without surgery

—Combined treatment with chemotherapy and radiation therapy is superior to radiation therapy alone and has achieved long-term survival rates in up to 25% of patients. In two randomized trials, there was no difference in long-term survival between patients treated with chemoradiation therapy alone versus chemoradiation therapy followed by surgery, although combination therapy achieves superior control of mediastinal disease with a reduced need for subsequent palliative therapies. Chemoradiation therapy alone should be considered in patients with localized disease (stage II or IIIA) who are poor surgical candidates due to serious medical illness or poor functional status (Eastern Cooperative Oncology Group score > 2).

B. Therapy for Incurable Disease

More than half of patients have either locally extensive tumor spread (T4) that is unresectable or distant metastases (M1) ie, stage IIIB and stage IV tumors. Surgery is not warranted in these patients. Since prolonged survival can be achieved in few patients, the primary goal is to provide relief from dysphagia and pain, optimize quality of life, and minimize treatment side effects. The optimal palliative approach depends on the presence or absence of metastatic disease, patient's expected survival, patient preference, and local institutional experience. Many patients with advanced

disease may prefer concerted efforts at pain relief and care directed at symptom management (see Chapter 5).

1. Radiation therapy, chemotherapy, and combined therapy—Combined radiation therapy and chemotherapy (5-FU and cisplatin) may achieve palliation in two-thirds of patients but is associated with significant side effects. It should be considered for patients with locally advanced tumors without distant metastases (stage IIIB) who have good functional status, no significant medical problems, in whom prolonged survival may be achieved. Improvement in dysphagia occurs within 2–4 weeks in almost 90% of patients.

Combination chemotherapy may be considered in patients with metastatic disease who still have good functional status and expected survival of several months. Although there is no consensus on optimal therapy, three drug combinations are commonly used: (1) epirubicin or a taxane (docetaxel or paclitaxel), (2) cisplatin or oxaliplatin, and (3) a fluoropyrimidine (5-FU or capecitabine). For patients with poor functional status, single-agent therapy with a fluoropyrimidine, a taxane, or irinotecan may be used. The role of biologic agents (anti-EGFR, anti-VEGF, kinase inhibitors) requires further study.

Radiation therapy alone may afford short-term relief of pain and dysphagia and may be suitable for patients with poor functional status or underlying medical problems. Because it takes up to 6 weeks to administer and may be complicated by temporary worsening of dysphagia and odynophagia, local antitumor therapies may be preferred.

2. Local antitumor therapy—Patients with advanced esophageal cancer often have a poor functional and nutritional status with an average survival of less than 12 weeks from diagnosis. Radiation or chemoradiation is poorly tolerated. Rapid palliation of dysphagia may be achieved by peroral placement of permanent expandable wire stents, application of endoscopic laser therapy, or photodynamic therapy. Although dysphagia and quality of life are improved significantly, patients can seldom eat normally. The choice of treatment depends on available expertise and equipment. Stents are most commonly used because of their relative ease of placement.

► Prognosis

The overall 5-year survival rate of esophageal carcinoma is less than 20%. For those patients whose disease progresses despite chemotherapy, meticulous efforts at palliative care are essential (see Chapter 5).

► When to Refer

- Patients should be referred to gastroenterologist for evaluation and staging (endoscopy with biopsy, EUS) and palliative endoscopic antitumor therapy (stent).
- Patients with curable and resectable disease (stage IIB or IIIA) and those with locally advanced or metastatic disease should be referred to an oncologist for consideration of neoadjuvant chemotherapy or consideration of chemoradiotherapy or palliative chemotherapy, respectively.

► When to Admit

Patients with high-grade esophageal obstruction with inability to manage oral secretions should be admitted.

GASTRIC ADENOCARCINOMA

ESSENTIALS OF DIAGNOSIS

- Dyspeptic symptoms with weight loss in patients over age 40 years.
- Iron deficiency anemia: occult blood in stools.
- Abnormality detected on upper gastrointestinal series or endoscopy.

► General Considerations

Gastric adenocarcinoma remains the second most common cause of cancer death worldwide. Its incidence however has declined rapidly over the last 70 years, especially in western countries, which may be attributable to changes in diet (more fruits and vegetables), food refrigeration (allowing more fresh foods and reduced salted, smoked, and preserved foods), reduced toxic environmental exposures, and a decline in *Helicobacter pylori*. The incidence of gastric cancer remains high (70/100,000) in Japan and many developing regions, including eastern Asia, Eastern Europe, Chile, Colombia, and Central America. In the United States, there were an estimated 21,500 new cases and 10,800 deaths in 2008. The incidence is higher in Latinos, African Americans, and Asian Americans.

There are two main histologic variants of gastric cancer: “intestinal-type” (which resembles intestinal cancers in forming glandular structures) and “diffuse” (which is poorly differentiated, has signet-ring cells, and lacks glandular formation). Although both types are declining in incidence, intestinal-type has had the most dramatic reduction. Intestinal-type is still more common (70–80%), occurs twice as often in men as women, primarily affects older people (mean age 63 years), and is more strongly associated with

environmental factors. It is believed to arise through a gradual, multi-step progression from inflammation (most commonly due to *H pylori*), to atrophic gastritis, to intestinal metaplasia, and finally dysplasia or cancer. Chronic *H pylori* gastritis is the strong risk factor for gastric carcinoma, increasing the relative risk 3.5- to 20-fold. It is estimated that 60–90% of cases of gastric carcinomas may be attributable to *H pylori*. Because of its unproven efficacy and cost-effectiveness, screening for *H pylori* infection and treating it to prevent gastric cancer is not recommended for asymptomatic adults in the general population but may be considered in patients who have immigrated from regions with a high incidence of gastric cancer or who have a family history of gastric cancer. Other risk factors for intestinal-type gastric cancer include pernicious anemia, a history of partial gastric resection more than 15 years previously, smoking, and diets that are high in nitrates or salt and low in vitamin C.

Diffuse gastric cancer accounts for 20–30% of gastric cancer. In contrast to intestinal-type cancer, it affects men and women equally, occurs more commonly in young people, is not as strongly related to *H pylori* infection, has a worse prognosis, and has not declined in incidence. Most diffuse gastric cancers are attributable to acquired or hereditary mutations in the genes regulating the E-cadherin cell adhesion protein. Familial diffuse gastric cancer accounts for 1–3% of gastric cancers. The cancer may arise at a young age, is often multifocal and infiltrating, and carries a poor prognosis. Many of these families have a germline mutation of E-cadherin *CDH1*, which is inherited in an autosomal dominant pattern and carries a greater than 60% lifetime risk of gastric cancer.

Most gastric cancers arise in the body and antrum. These may occur in a variety of morphologic types: (1) polypoid or fungating intraluminal masses; (2) ulcerating masses; (3) diffusely spreading (linitis plastica), in which the tumor spreads through the submucosa, resulting in a rigid, atonic stomach with thickened folds (prognosis dismal); and (4) superficially spreading or “early” gastric cancer—confined to the mucosa or submucosa (with or without lymph node metastases) and associated with an excellent prognosis.

In contrast to the dramatic decline in cancers of the distal stomach, a rise in incidence of tumors of the gastric cardia has been noted. These tumors have demographic and pathologic features that resemble Barrett-associated esophageal adenocarcinomas (see Esophageal Cancer).

► Clinical Findings

A. Symptoms and Signs

Gastric carcinoma is generally asymptomatic until the disease is quite advanced. Symptoms are nonspecific and are determined in part by the location of the tumor. Dyspepsia, vague epigastric pain, anorexia, early satiety, and weight loss are the presenting symptoms in most patients. Patients may derive initial symptomatic relief from over-the-counter remedies, further delaying diagnosis. Ulcerating lesions can lead to acute gastrointestinal bleeding with hematemesis or melena. Pyloric obstruction results in postprandial vomiting. Lower esophageal obstruction causes

progressive dysphagia. Physical examination is rarely helpful. A gastric mass is palpated in less than 20% of patients. Signs of metastatic spread include a left supraclavicular lymph node (Virchow node), an umbilical nodule (Sister Mary Joseph nodule), a rigid rectal shelf (Blumer shelf), and ovarian metastases (Krukenberg tumor). Guaiac-positive stools may be detectable.

B. Laboratory Findings

Iron deficiency anemia due to chronic blood loss or anemia of chronic disease is common. Liver function test abnormalities may be present if there is metastatic liver spread. Other tumor markers are of no value.

C. Endoscopy

Upper endoscopy should be obtained in all patients over age 55 years with new onset of epigastric symptoms (dyspepsia) and in anyone with dyspepsia that is persistent or fails to respond to a short trial of antisecretory therapy. Endoscopy with biopsies of suspicious lesions is highly sensitive for detecting gastric carcinoma. It can be difficult to obtain adequate biopsy specimens in linitis plastica lesions. Because of the high incidence of gastric carcinoma in Japan, screening upper endoscopy is performed to detect early gastric carcinoma. Approximately 40% of tumors detected by screening are early, with a 5-year survival rate of almost 90%. Screening programs are not recommended in the United States.

D. Imaging

A barium upper gastrointestinal series is an acceptable alternative when endoscopy is not readily available but may not detect small or superficial lesions and cannot reliably distinguish benign from malignant ulcerations. Any abnormalities detected with this procedure require endoscopic confirmation.

Once a gastric cancer is diagnosed, preoperative evaluation with abdominal and chest CT and EUS is indicated to delineate the local extent of the primary tumor as well as nodal or distant metastases. PET or combined PET-CT imaging may be more sensitive than CT for detection of distant metastasis. EUS imaging is superior to CT in determining the depth of tumor penetration and is useful for evaluation of early gastric cancers that may be removed by endoscopic mucosal resection.

► Staging

Staging is defined according to the TNM system, in which T1 tumors invade the lamina propria (T1a) or submucosa (T1b), T2 invade the muscularis propria, T3 penetrate the serosa, and T4 invade adjacent structures. Lymph nodes are graded as N0 if there is no involvement, and N1, N2, or N3 if there is involvement of 1–6, 7–15, or more than 15 regional nodes. M1 signifies the presence of metastatic disease.

► Differential Diagnosis

Ulcerating gastric adenocarcinomas are distinguished from benign gastric ulcers by biopsies. Approximately 3% of gastric

ulcers initially believed to be benign later prove to be malignant. To exclude malignancy, all gastric ulcers identified at endoscopy should be biopsied. Ulcers that are suspicious for malignancy to the endoscopist or that have atypia or dysplasia on histologic examination warrant repeat endoscopy in 2–3 months to verify healing and exclude malignancy. Nonhealing ulcers should be considered for resection. Infiltrative carcinoma with thickened gastric folds must be distinguished from lymphoma and other hypertrophic gastropathies.

► Treatment

A. Curative Surgical Resection

After preoperative staging, about two-thirds of patients will be found to have localized disease (ie, stages I–III). In Japan and in specialized centers in the United States, endoscopic mucosal resection is performed in selected patients with small (< 1–2 cm), early (intramucosal or T1aNO) gastric cancers after careful staging with EUS. For all other patients, surgical resection is the only therapy with curative potential. At surgery, approximately 25% of these patients will be found to have locally unresectable tumors or peritoneal, hepatic, or distant lymph node metastases for which “curative” surgical resection is not warranted (see below). The remaining patients with confirmed localized disease should undergo radical surgical resection with curative intent. For adenocarcinoma localized to the distal two-thirds of the stomach, a subtotal distal gastrectomy should be performed. For proximal gastric cancer or diffusely infiltrating disease, total gastrectomy is necessary. Although lymph node dissection should be performed for curative resections, there has been ongoing debate about whether an extended (perigastric; D1), regional (D2), or distant (porta hepatic and peri-aortic; D3) lymph node dissection is needed. A 2008 large Japanese trial found no difference in survival between patients treated with D2 and D3 (para-aortic) lymphadenectomy. Current NCCN treatment guidelines recommend regional (D2) node resection. The role of preoperative (neoadjuvant) or postoperative (adjuvant) chemotherapy or radiochemotherapy after curative resection is controversial. In the United States, adjuvant chemoradiotherapy (commonly 5-FU and leucovorin) is recommended, especially for patients with lymph node involvement. Outside of the United States, adjuvant chemotherapy alone (commonly, epirubicin, cisplatin, and 5-FU) is used. Tumors arising in the cardia are treated similar to esophageal cancer.

B. Palliative Modalities

Many patients will be found either preoperatively or at the time of surgical exploration to have advanced disease that is not amenable to “curative” surgery due to peritoneal or distant metastases or local invasion of other organs. In some of these cases, palliative resection of the tumor nonetheless may be indicated to alleviate pain, bleeding, or obstruction. For patients with unresectable disease, gastrojejunostomy may be indicated to prevent obstruction. Alternatively, unresected tumors may be treated with endoscopic laser or stent therapy, radiation therapy, or angiographic embolization to relieve bleeding or obstruction. Chemotherapy may

be considered in patients with metastatic disease who still have good functional status and expected survival of several months. Although there is no consensus on optimal therapy, a combination of epirubicin, cisplatin, and 5-FU commonly is used. A large 2008 trial assigned patients with advanced esophageal and gastric cancer to one of four triplet therapies: epirubicin and cisplatin plus either fluorouracil (ECF) or capecitabine (ECX) or epirubicin and oxaliplatin plus either fluorouracil (EOF) or capecitabine (EOX). No difference in median survival was found among the four regimens (9–11 months); however, toxicity in patients treated with oxaliplatin.

► Prognosis

The long-term survival of gastric carcinoma is less than 15%. However, 5-year survival in patients who undergo successful curative resection is over 45%. Survival is related to tumor stage, location, and histologic features. Stage I and stage II tumors resected for cure have a greater than 50% long-term survival. Patients with stage III tumors have a poor prognosis (< 20% long-term survival) and should be considered for enrollment in clinical trials. Tumors of the diffuse type have a worse prognosis than the intestinal type. Tumors of the proximal stomach (fundus and cardia) carry a far worse prognosis than distal lesions. Even with apparently localized disease, proximal tumors have a 5-year survival of less than 15%. For those whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see Chapter 5).

► When to Refer

- Patients with dysphagia, weight loss, protracted vomiting, iron-deficiency anemia, or new-onset of dyspepsia (especially if age 55 years or older or associated with other alarm symptoms) in whom gastric cancer is suspected should be referred to a gastroenterologist for endoscopic screening.
- Patients should be referred to a surgeon for attempt at curative resection in stage I, II, or III cancer.
- Patients with unresectable or metastatic disease should be referred to an oncologist for consideration of adjuvant chemotherapy or chemoradiotherapy after curative resection or palliative therapy.

► When to Admit

Patients with advanced gastric cancer causing protracted vomiting, inability to maintain oral intake, or acute bleeding should be admitted.

GASTRIC LYMPHOMA

ESSENTIALS OF DIAGNOSIS

- ▶ Symptoms of dyspepsia, weight loss, or anemia.
- ▶ Variable abnormalities on upper gastrointestinal series or endoscopy including thickened folds, ulcer, mass or infiltrating lesions; diagnosis established by endoscopic biopsy.
- ▶ Abdominal CT and EUS required for staging.

▶ General Considerations

Gastric lymphomas may be primary (arising from the gastric mucosa) or may represent a site of secondary involvement in patients with nodal lymphomas. Distinguishing advanced primary gastric lymphoma with adjacent nodal spread from advanced nodal lymphoma with secondary gastric spread can be problematic. Because the prognosis and treatment of primary and secondary gastric lymphomas are entirely different, the distinction is important. Primary lymphoma is the second most common gastric malignancy, accounting for 3% of cancers. More than 95% of these are non-Hodgkin B cell lymphomas. Most primary gastric lymphomas are believed to arise from mucosa-associated lymphoid tissue (MALT). Primary gastric lymphomas comprise two main types: 60% are diffuse large B-cell lymphomas (previously called “high-grade” MALT lymphomas) and 40% are marginal zone B-cell lymphomas of the MALT-type (previously call “low-grade” MALT lymphoma). B cells of nodal origin may be distinguished from those derived from MALT (CD19 and CD20 positive).

Infection with *H pylori* is an important risk factor for the development of primary gastric lymphoma. Chronic infection with *H pylori* causes an intense lymphocytic inflammatory response that may lead to the development of lymphoid follicles. Over 85% of low-grade primary gastric MALT-type lymphomas are associated with *H pylori* infection. It is hypothesized that chronic antigenic stimulation may result in a monoclonal lymphoproliferation that may culminate in low-grade or high-grade lymphoma.

▶ Clinical Findings

The clinical presentation and endoscopic appearance of gastric lymphoma are similar to those of adenocarcinoma.

Most patients have abdominal pain, weight loss, or bleeding. Patients with diffuse large B-cell lymphoma are more likely to have systemic symptoms and advanced tumor stage. At endoscopy, lymphoma may appear as an ulcer, mass, or diffusely infiltrating lesion. The diagnosis is established with endoscopic biopsy. All patients should undergo staging with abdominal and chest CT. EUS is the most sensitive test for determining the level of invasion and presence of perigastric lymphadenopathy.

▶ Treatment

Nodal lymphomas with secondary gastrointestinal involvement usually present at an advanced stage with widely disseminated disease and are seldom curable. Their treatment is addressed in Chapter 13. Treatment of primary gastric lymphomas depends on the tumor histology, grade, and stage. Marginal B-cell lymphomas of the MALT type may be low-grade and localized to the stomach wall (stage IE) and have an excellent prognosis. Where available, EUS should be performed to accurately determine tumor stage. Patients with primary gastric MALT-lymphoma should be tested for *H pylori* infection and treated if positive. Complete lymphoma regression after successful *H pylori* eradication occurs in 75% of cases of stage IE low-grade lymphoma. Remission may take as long as a year. Patients with localized (stage IE) marginal zone MALT-type lymphomas who either are not infected with *H pylori* or do not respond to eradication therapy may be treated with radiation therapy. Patients with diffuse large cell (high-grade) lymphomas and patients with MALT-type lymphomas that extend beyond the gastric wall should be treated with combination chemotherapy (eg, CHOP with rituximab). Because of a low risk of perforation with either radiation therapy or chemotherapy, surgical resection is no longer recommended. The long-term survival of primary gastric lymphoma for stage I is over 85% and for stage II is 35–65%.

GASTRIC CARCINOID TUMORS

Gastric carcinoids are rare neuroendocrine tumors that make up less than 1% of gastric neoplasms. They may occur sporadically or secondary to chronic hypergastrinemia that results in hyperplasia and transformation of enterochromaffin cells in the gastric fundus. Sporadic carcinoids account for 20% of gastric carcinoids. Most are solitary, over 2 cm in size, and have a strong propensity for metastatic spread. Most sporadic carcinoids already have carcinoid syndrome and hepatic or pulmonary metastatic

involvement at initial presentation. Localized sporadic carcinoids should be treated with radical gastrectomy.

The majority of carcinoids caused by hypergastrinemia occur in association with either pernicious anemia (75%) or Zollinger-Ellison syndrome (5%). Carcinoids associated with Zollinger-Ellison syndrome occur almost exclusively in patients with MEN 1, in which loss of 11q13 has been reported. Carcinoids caused by hypergastrinemia tend to be multicentric, less than 1 cm in size, and have a low potential for metastatic spread or development of carcinoid syndrome. Small lesions may be successfully treated with endoscopic resection followed by periodic endoscopic surveillance. Antrectomy reduces serum gastrin levels and may lead to regression of small tumors. Patients with large or multiple carcinoids should undergo surgical tumor resection (see Carcinoid Tumors, below).

Landry CS et al. A proposed staging system for gastric carcinoid tumors based on an analysis of 1,543 patients. *Ann Surg Oncol.* 2009 Jan;16(1):51–60. [PMID: 18953609]

GASTROINTESTINAL MESENCHYMAL TUMORS

Gastrointestinal mesenchymal tumors occur throughout the gastrointestinal tract, but approximately two-thirds occur in the stomach. These tumors (which include stromal tumors, leiomyomas, and schwannomas) derive from mesenchymal stem cells and have an epithelioid or spindle cell histologic pattern, resembling smooth muscle. The most common stromal tumors are gastrointestinal stromal tumors (“GISTs”), which appear to originate from interstitial cells of Cajal. GISTs occur throughout the gastrointestinal tract but most commonly in the stomach (50%) and small intestine (30%). About 85–90% of GISTs have mutations in KIT, a receptor tyrosine kinase that binds stem cell factor, or a homologous tyrosine kinase, platelet-derived growth factor alpha that lead to constitutive activation. Approximately 90% of stromal tumors stain positively for CD117 (part of the KIT protein). Other mesenchymal tumors such as leiomyomas, which derive from smooth muscle cells, stain negative for CD117. Mesenchymal tumors may be discovered incidentally on imaging studies or endoscopy or may cause symptoms, mainly obstruction by large tumors or acute or chronic bleeding due to central ulceration within the tumor. At endoscopy, they appear as a submucosal mass that may have central umbilication or ulceration. EUS (possibly with guided FNA biopsy) is the optimal study for diagnosing mesenchymal tumors and distinguishing them from other submucosal lesions. While almost all GISTs have malignant potential, the risk of developing metastasis is related to the tumor size and mitotic index (> 5 mitoses per high-powered field); however, mitotic index can only be assessed after resection. It is difficult to distinguish with certainty benign from malignant (sarcoma) tumors before resection by EUS appearance or FNA. In general, lesions that are smaller than 2 cm, have a smooth border, and have a homogeneous echo pattern on EUS are more likely benign.

Surgery is recommended for all patients with tumors that are symptomatic, ≥ 2 cm, are increasing in size, or have

an EUS appearance suspicious for malignancy. PET-CT scan should be obtained prior to surgery to look for metastatic disease. The management of asymptomatic benign-appearing lesions ≤ 2 cm in size is problematic. Because of a low risk of malignancy, surgical resection should be considered in younger, otherwise healthy patients; however, other patients may be followed up with serial EUS examinations or, in selected cases, endoscopic resections. There is a high risk of metastasis or recurrence when tumors are larger than 5 cm, have an irregular border or cystic spaces, and have increased mitotic activity (more than five mitoses per high-power field). These high-risk tumors have a 50% 5-year survival rate after complete surgical resection. Metastatic tumors are aggressive and carry a poor prognosis. The tyrosine kinase inhibitor imatinib induces disease control in up to 85% of patients with metastatic disease with a progression free-survival of 20–24 months. Resistant tumors may respond to another tyrosine kinase inhibitor, sunitinib.

MALIGNANCIES OF THE SMALL INTESTINE

1. Adenocarcinoma

These are aggressive tumors that occur most commonly in the duodenum or proximal jejunum. The ampulla of Vater is the most common site of small bowel carcinoma, and the incidence of ampullary carcinoma is increased more than 200-fold in patients with FAP. Ampullary carcinoma may present with jaundice due to bile duct obstruction or bleeding. Surgical resection of early lesions is curative in up to 40% of patients. Periodic endoscopic surveillance to detect early ampullary neoplasms therefore is recommended in patients with this disorder. Nonampullary adenocarcinoma of the small intestine accounts for < 3% of all gastrointestinal cancers but one-third of small bowel cancers. Peak incidence is in the sixth decade. Most cases present with symptoms of obstruction, acute or chronic bleeding, or weight loss. The majority of small bowel cancers have already metastasized at the time of diagnosis. Resection is recommended for control of symptoms. The role of adjuvant therapy is unclear. The prognosis is poor with a 5-year overall survival of 20–30%. Patients with Crohn disease have an increased risk of small intestine adenocarcinoma, most commonly in the ileum, which may be difficult to distinguish from disease-related fibrous strictures.

2. Lymphoma

Gastrointestinal lymphomas may arise in the gastrointestinal tract or involve it secondarily with disseminated disease. In Western countries, primary gastrointestinal lymphomas

account for 5% of lymphomas and 20% of small bowel malignancies. They occur most commonly in the distal small intestine. The majority are non-Hodgkin high-grade marginal zone B cell lymphomas. There is an increased incidence of small intestinal lymphomas in patients with AIDS, immunosuppressive therapy, and Crohn disease. T cell lymphomas may arise in patients with celiac sprue. In the Middle East, lymphomas may arise in the setting of immunoproliferative small intestinal disease. In this condition, there is diffuse lymphoplasmacytic infiltration with IgA-secreting B lymphocytes of the mucosa and submucosa that results in weight loss, diarrhea, and malabsorption, which may lead to lymphomatous transformation. A characteristic feature of the disease is the presence of α heavy chains in the serum in 70% produced by clones of IgA plasma cells. Other types of intestinal lymphomas include mantle cell and Burkitt.

Presenting symptoms or signs of primary lymphoma include abdominal pain, weight loss, nausea and vomiting, distention, anemia, and occult blood in the stool. Fevers are unusual. Protein-losing enteropathy may result in hypoalbuminemia, but other signs of malabsorption are unusual. Barium radiography or CT enterography helps localize the site of the lesion. The diagnosis requires endoscopic, percutaneous, or laparoscopic biopsy. To determine tumor stage, patients must undergo chest and abdominal CT, and bone marrow biopsy.

Treatment depends on the tumor histologic grade and stage of disease. Resection of primary intestinal lymphoma, if feasible, is usually recommended. Even in cases of stage III or stage IV disease, surgical debulking may improve survival. In patients with limited disease (stage IE) in whom resection is performed, the role of adjuvant chemotherapy is unclear. Most patients with more extensive disease are treated with combination chemotherapy (eg, CHOP with rituximab) with or without radiation therapy.

3. Carcinoid Tumors

ESSENTIALS OF DIAGNOSIS

- ▶ Majority are asymptomatic and discovered incidentally at endoscopy or surgery
- ▶ Carcinoid syndrome occurs in less than 10%; hepatic metastases are generally present.
- ▶ Risk of metastasis related to tumor size and location.

▶ General Considerations

Gastrointestinal carcinoids are slow growing neuroendocrine tumors that may arise anywhere in the gastrointestinal tract but most commonly occur in the small intestine (30%), rectum (12%), colon (8%), appendix (8%), and stomach (10–30%; see above). Carcinoids may contain a variety of hormones, including serotonin, somatostatin, gastrin, and substance P that may or may not be secreted, and usually display immunoreactivity to chromogranin A.

Although many carcinoids behave in an indolent fashion, the overall 5-year survival rate for patients with carcinoids is 50%, suggesting that most are malignant. The risk of metastatic spread is closely related to tumor size and tumor location. Many small carcinoids are detected incidentally at endoscopy or autopsy. It is not possible by histologic examination to distinguish benign from malignant disease. The best indicator of prognosis is evidence of invasive growth and the presence of regional or distant metastasis.

Carcinoids account for up to one-third of small intestinal tumors. Small intestinal carcinoids most commonly arise in the ileum. Up to one-third are multicentric. Although 60% are less than 2 cm in size, even these small carcinoids may metastasize. Almost all small intestinal carcinoids over 2 cm are associated with metastasis.

Appendiceal carcinoids are identified in 0.3% of appendectomies, usually as an incidental finding. Almost 80% of these tumors are less than 1 cm in size, and 90% are less than 2 cm. Rectal carcinoids are usually detected incidentally as submucosal nodules during proctoscopic examination. Rectal carcinoids less than 1 cm and appendiceal carcinoids less than 2 cm virtually never metastasize and are treated effectively with local excision or simple appendectomy. Tumors larger than 2 cm are associated with the development of metastasis in over 20% of appendiceal carcinoids and 10% of rectal carcinoids. Hence, in younger patients who are good candidates for surgery, a more extensive cancer resection operation is warranted.

▶ Clinical Findings

A. Symptoms and Signs

Most smaller lesions (less than 1-2 cm) are asymptomatic and difficult to detect by endoscopy or imaging studies. When carcinoids present with symptoms, most are at an advanced and incurable stage. Through local extension or metastasis to mesenteric lymph nodes, carcinoids engender a fibroblastic reaction with contraction and kinking of the bowel or encasement of mesenteric vessels. Small intestinal carcinoids may present with abdominal pain, bowel obstruction, or bowel infarction. Abdominal CT or enterography may reveal kinking, but because the lesion is extraluminal the diagnosis may be overlooked for several years. Appendiceal and rectal carcinoids usually are small and asymptomatic but large lesions can cause bleeding, obstruction, or altered bowel habits. Carcinoid involvement of the heart (resulting in right-sided valvular lesions) is a late manifestation of metastatic disease. **Carcinoid syndrome** occurs in less than 10% of patients. More than 90% of patients with carcinoid syndrome have hepatic metastases, usually from carcinoids of small bowel origin. About 10% of patients with carcinoid syndrome have primary bronchial or ovarian tumors without hepatic metastases. Carcinoid syndrome is caused by tumor secretion of hormonal mediators. The manifestations include facial flushing, edema of the head and neck (especially with bronchial carcinoid), abdominal cramps and diarrhea, bronchospasm, cardiac lesions (pulmonary or tricuspid stenosis or regurgitation), and telangiectases.

B. Laboratory Findings

Plasma chromogranin A (CgA) is the most sensitive screening test for small intestine carcinoids, although its sensitivity for small, localized tumors is unknown. CgA is elevated in almost 90% of patients with advanced small bowel carcinoid. Urinary 5-hydroxyindoleacetic acid (5-HIAA) or platelet serotonin levels are also elevated in patients with metastatic carcinoid; however, these tests are less sensitive than CgA. There is increased urinary 5-HIAA in carcinoid syndrome; symptomatic patients usually excrete more than 25 mg of 5-HIAA per day in the urine. Ideally, all drugs should be withheld for several days prior to the urine collection.

C. Imaging

Abdominal CT may demonstrate a mesenteric mass with tethering of the bowel, lymphadenopathy, and hepatic metastasis. Somatostatin receptor scintigraphy, which is positive in up to 90% of patients with metastatic carcinoid, is superior to all other imaging modalities for the diagnosis of primary and metastatic lesions. Almost all patients with carcinoid syndrome have obvious signs of cancer with liver metastasis on abdominal imaging.

▶ Treatment

Small intestinal carcinoids are extremely indolent tumors with slow spread. Patients with disease confined to the small intestine should have local excision, for which the cure rate exceeds 85%. In patients with resectable disease who have lymph node involvement, the 5-year disease-free survival is 80%; however, by 25 years, less than 25% remain disease free. Even patients with hepatic metastases may have an indolent course with a median survival of 3 years. In patients with advanced disease, therapy should be deferred until the patient is symptomatic. Surgery should be directed toward palliation of obstructive symptoms.

In patients with carcinoid syndrome, resection of hepatic metastases may provide dramatic improvement. The somatostatin analog octreotide (150–500 mcg subcutaneously three times daily) inhibits hormone secretion from the carcinoid tumor, resulting in dramatic relief of symptoms of carcinoid syndrome, including diarrhea or flushing, in 90% of patients for a median period of 1 year. Thereafter, many patients stop responding to octreotide. Hepatic artery occlusion and chemotherapy may provide symptomatic improvement in some patients with hepatic metastases. Emergency therapy for patients with symptomatic bronchial carcinoids consists of giving prednisone, 15–30 mg orally daily.

4. Small Intestine Sarcoma

Most small intestine sarcomas arise from stromal tumors that stain positive for CD117; a minority arise from smooth muscle tumors (leiomyosarcomas) (see Gastrointestinal Mesenchymal Tumors above).

Kaposi sarcoma was at one time a common complication in AIDS, but the incidence is declining with highly active antiretroviral therapy (HAART). It is strongly associ-

ated with infection with human herpesvirus 8. Lesions may be present anywhere in the intestinal tract. Visceral involvement usually is associated with cutaneous disease. Most lesions are clinically silent; however, large lesions may be symptomatic. Interferon- α induces regression in up to one-third of patients who have a CD4 cell count of > 200/mcL. Widespread involvement may be best treated by systemic chemotherapy using combinations of vincristine, bleomycin, or doxorubicin, to which the tumor is very responsive.

COLORECTAL CANCER

ESSENTIALS OF DIAGNOSIS

- ▶ Personal or family history of adenomatous polyps or colorectal cancer are important risk factors.
- ▶ Symptoms or signs depend on tumor location.
- ▶ Proximal colon: fecal occult blood, anemia.
- ▶ Distal colon: change in bowel habits, hematochezia.
- ▶ Diagnosis established with colonoscopy.

▶ General Considerations

Colorectal cancer is the second leading cause of death due to malignancy in the United States. Approximately 6% of Americans will develop colorectal cancer and 40% of those will die of the disease. In 2008, there were an estimated 149,000 new cases and 50,000 deaths. Colorectal cancers are almost all adenocarcinomas, which tend to form bulky exophytic masses or annular constricting lesions. Slightly less than 50% of cancers are located distal to the splenic flexure (within the descending colon or rectosigmoid region). It is currently believed that the majority of colorectal cancers arise from malignant transformation of an adenomatous polyp. Adenomatous polyps that are “advanced” (ie, adenomas at least 1 cm in size, adenomas with villous features, or adenomas with high-grade dysplasia) are associated with a greater risk of cancer.

Approximately 85% of sporadic colorectal cancers have loss of function of one or more tumor suppressor genes (eg, *p53*, *APC*, or *DCC*) due to a combination of spontaneous mutation of one allele combined with chromosomal

instability and aneuploidy (abnormal DNA content) that leads to deletion and loss of heterozygosity of the other allele (eg, 5q, 17q, or 18p deletion). Approximately 15% of colorectal cancers have microsatellite instability due to inactivation of DNA mismatch repair genes. This is most commonly an acquired defect caused by hypermethylation of the promoter region of the MLH1 gene, but may be an indicator of unrecognized HNPCC (see Chapter 15). Colon cancer with high microsatellite instability have distinct clinical and pathologic characteristics, including diploid DNA content, predominance in the proximal colon, poor differentiation, and more favorable prognosis.

► Risk Factors

A number of factors increase the risk of developing colorectal cancer. Recognition of these has impact on screening strategies. However, 75% of all cases occur in people with no known predisposing factors.

A. Age

The incidence of colorectal cancer rises sharply after age 45 years, and 90% of cases occur in persons over the age of 50 years.

B. Family History of Neoplasia

A family history of colorectal cancer is present in 20% of patients with colon cancer. Hereditary factors are believed to contribute to 20–30% of colorectal cancers; however, the genes responsible for most of these cases have not yet been identified. Up to 5% of colorectal cancers are caused by inherited germline mutations resulting in polyposis syndromes or hereditary nonpolyposis colorectal cancer (HNPCC) (see Chapter 15). Approximately 6% of the Ashkenazic Jewish population has a missense mutation in the APC gene (*APC I1307K*) that confers a modestly increased lifetime risk of developing colorectal cancer (OR 1.4–1.9) but phenotypically resembles sporadic colorectal cancer rather than FAP. Genetic screening is available, and patients harboring the mutation merit intensive screening.

A family history of colorectal cancer or adenomatous polyps is one of the most important risk factors for colorectal cancer. The risk of colon cancer is proportionate to the number and age of affected first-degree family members with colon neoplasia. People with one first-degree family member with colorectal cancer have an increased risk approximately two times that of the general population; however, the risk is almost four times if the family member's cancer was diagnosed at < 45 years of age. Patients with two first-degree relatives have a fourfold, or 25–30% lifetime, risk of developing colon cancer. First-degree relatives of patients with adenomatous polyps also have a twofold increased risk for colorectal neoplasia, especially if the polyp was large (≥ 10 mm) or detected before age 60 years.

C. Inflammatory Bowel Disease

The risk of adenocarcinoma of the colon begins to rise 7–10 years after disease onset in patients with ulcerative

colitis and Crohn colitis. The cumulative risk approaches 5–10% after 20 years and 20% after 30 years. Chronic treatment with 5-ASA agents and folate is associated with a lower risk of cancer in patients with ulcerative colitis.

D. Dietary Factors and Chemoprevention

In epidemiologic studies, diets rich in fats and red meat are associated with an increased risk of colorectal adenomas and cancer, whereas diets high in fruits, vegetables, and fiber are associated with a decreased risk. However, prospective, randomized controlled trials failed to demonstrate a risk reduction in the recurrence of adenomatous polyps after treatment with a diet low in fat and high in fiber, fruits, and vegetables, or with fiber supplementation. Calcium carbonate (3 g/d) has been shown in large cohort studies as well as small prospective trials to yield a modest reduction in the relative risk of developing colorectal neoplasia; however, a 2006 prospective study of 36,000 women did not show a protective benefit of calcium (500 mg) and vitamin D (200 international units twice daily) in preventing colon cancer. Similarly, the risk of colon cancer appears to be decreased in persons taking folic acid supplements, but a 2007 prospective trial conducted in patients with a history of adenomas found that folate supplementation did not reduce the incidence of adenoma recurrence compared with placebo. The antioxidant vitamins A, C, E, and beta carotene also have not been shown to be of benefit in prospective controlled studies.

A US Preventive Services Task Force meta-analysis of cohort and case-control studies suggest that prolonged (> 6 years) regular use of aspirin (at least 325 mg weekly) and NSAIDs is associated with a 22–33% relative risk reduction in the incidence of colorectal cancer. Two prospective, blinded clinical trials have shown that daily low-dose aspirin (80–325 mg) reduces the number of recurrent adenomas at 1–3 years in patients with a history of colorectal adenomas or cancer; however, two large randomized controlled trials in the United States did not demonstrate a reduction in colorectal cancer incidence in patients taking low-dose aspirin over a 5–10 years. Because long-term aspirin use is associated with a low incidence of serious complications (gastrointestinal hemorrhage, stroke), the US Preventive Services Task Force concluded that it should not be prescribed as a chemopreventive agent in people without polyps or with small adenomas unless there are other medical indications. Long-term administration of low-dose aspirin may be considered in patients with a personal or family history of colorectal cancer or advanced adenomas; however, they do not obviate the need for colonoscopy screening and surveillance.

E. Other Factors

The incidence of colon adenocarcinoma is higher in blacks than in whites. It is unclear whether this is due to genetic or socioeconomic factors (eg, diet or reduced access to screening). Diabetes, metabolic syndrome, obesity, and cigarette smoking are associated with a modest increase in cancer risk.

► Clinical Findings

A. Symptoms and Signs

Adenocarcinomas grow slowly and may be present for several years before symptoms appear. However, some asymptomatic tumors may be detected by the presence of fecal occult blood (see Colorectal Cancer Screening, below). Symptoms depend on the location of the carcinoma. Chronic blood loss from right-sided colonic cancers may cause iron deficiency anemia, manifested by fatigue and weakness. Obstruction, however, is uncommon because of the large diameter of the right colon and the liquid consistency of the fecal material. Lesions of the left colon often involve the bowel circumferentially. Because the left colon has a smaller diameter and the fecal matter is solid, obstructive symptoms may develop with colicky abdominal pain and a change in bowel habits. Constipation may alternate with periods of increased frequency and loose stools. The stool may be streaked with blood, though marked bleeding is unusual. With rectal cancers, patients note tenesmus, urgency, and recurrent hematochezia. Weight loss is uncommon. Physical examination is usually normal except in advanced disease. A mass may be palpable in the abdomen. The liver should be examined for hepatomegaly, suggesting metastatic spread. For cancers of the distal rectum, digital examination is necessary to determine whether there is extension into the anal sphincter or fixation, suggesting extension to the pelvic floor.

B. Laboratory Findings

A complete blood count is obtained to look for evidence of anemia. Elevated liver function tests are suspicious for metastatic disease. Carcinoembryonic antigen (CEA) should be measured in all patients with proved colorectal cancer. A preoperative CEA level > 5 ng/mL is a poor prognostic indicator. After complete surgical resection, CEA levels should normalize; persistently elevated levels suggest the presence of persistent disease and warrant further evaluation.

C. Colonoscopy

Colonoscopy is the diagnostic procedure of choice in patients with a clinical history suggestive of colon cancer or in patients with an abnormality suspicious for cancer detected on radiographic imaging. Colonoscopy permits biopsy for pathologic confirmation of malignancy (Plate 20). In patients in whom colonoscopy is unable to reach the cecum ($< 5\%$ of cases) or when a nearly obstructing tumor precludes passage of the colonoscope, barium enema or CT colonography examination should be performed.

D. Imaging

Clinicians obtain an abdominal and pelvic CT scan to assist in preoperative staging. CT scans may demonstrate distal metastases but are less accurate in the determination of the level of local tumor extension (T stage) or lymphatic spread (N stage). Intraoperative assessment of the liver by direct palpation and ultrasonography is more accurate
