Complex regional pain syndrome is a rare disorder of the extremities characterized by autonomic and vasomotor instability. The cardinal symptoms and signs are diffuse pain (characteristically localized to an arm or hand, leg or foot), swelling of the involved extremity, disturbances of color and temperature in the affected limb, dystrophic changes in the overlying skin and nails, and limited range of motion. Use of the former name of this entity, reflex sympathetic dystrophy, is now discouraged because the precise role of the sympathetic nervous system is unclear and dystrophy is not an inevitable sequela of the syndrome. Most cases are preceded by direct physical trauma, often of relatively minor nature, to the soft tissues, bone, or nerve. Early mobilization after injury or surgery reduces the likelihood of developing the syndrome. Any extremity can be involved, but the syndrome most commonly occurs in the hand and is associated with ipsilateral restriction of shoulder motion (shoulder-hand syndrome). The syndrome proceeds through phases: pain, swelling, and skin color and temperature changes develop early and, if untreated, lead to atrophy and dystrophy. The swelling in complex regional pain syndrome is diffuse (“catcher’s mitt hand”) and not restricted to joints. Pain is often burning in quality, intense, and often greatly worsened by minimal stimuli such as light touch. The shoulder-hand variant of this disorder sometimes complicates myocardial infarction or injuries to the neck or shoulder. Complex regional pain syndrome may occur after a knee injury or after arthroscopic knee surgery. There are no systemic symptoms. In the early phases of the syndrome, bone scans are sensitive,

showing diffuse increased uptake in the affected extremity. Radiographs eventually reveal severe generalized osteopenia. In the posttraumatic variant, this is known as Sudeck atrophy. Symptoms and findings are bilateral in some. This syndrome should be differentiated from other cervicobrachial pain syndromes, rheumatoid arthritis, thoracic outlet obstruction, and scleroderma, among others.

Early treatment offers the best prognosis for recovery. In the acute phase when edema is present, prednisone, 30–60 mg/d orally for 2 weeks and then tapered over 2 weeks, can be effective. Pain management is important and facilitates physical therapy, which plays a critical role in efforts to restore function. Some patients will also benefit from antidepressant agents (eg, nortriptyline initiated at a dosage of 10 mg orally at bedtime and gradually increased to 40–75 mg at bedtime). Regional nerve blocks and dorsal-column stimulation have also been demonstrated to be helpful. Patients who have restricted shoulder motion may benefit from the treatment described for scapulohumeral periarthritis. The prognosis partly depends on the stage in which the lesions are encountered and the extent and severity of associated organic disease.

Albazzaz R et al. Complex regional pain syndrome: a review. *Ann Vasc Surg*. 2008 Mar;22(2):297–306. [PMID: 18346583]

BURSITIS

Inflammation of bursae—the synovium-like cellular membranes overlying bony prominences—may be secondary to trauma, infection, or arthritic conditions such as gout, rheumatoid arthritis, or osteoarthritis. The most common locations are the subdeltoid, olecranon, ischial, trochanteric, semimembranosus-gastrocnemius (Baker cyst), and prepatellar bursae.

There are several ways to distinguish bursitis from arthritis. Bursitis is more likely than arthritis to cause focal tenderness and swelling and less likely to affect range of motion of the adjacent joint. Olecranon bursitis, for example, causes an oval (or, if chronic, bulbous) swelling at the tip of the elbow and does not affect elbow motion, whereas an elbow joint inflammation produces more diffuse swelling and reduces range of motion. Similarly, a patient with prepatellar bursitis has a small focus of swelling over the kneecap but no distention of the knee joint itself and preserved knee motion. A patient with trochanteric bursitis will have tenderness over the greater trochanter and normal internal rotation of the hip; a patient with hip arthritis usually will have reduced internal rotation. Bursitis caused by trauma responds to local heat, rest, NSAIDs, and local corticosteroid injections.

Bursitis can result from infection. The two most common sites are the olecranon and prepatellar bursae. Acute swelling and redness at either of these two sites calls for aspiration to rule out infection. The absence of fever does not exclude infection; one-third of those with septic olecranon bursitis are afebrile. A bursal fluid white blood cell count of greater than 1000/mcL indicates inflammation from infection, rheumatoid arthritis, or gout. In septic bursitis, the white cell count averages over 50,000/mcL.

Most cases are caused by *Staphylococcus aureus*; the Gram stain is positive in two-thirds. Treatment involves antibiotics and repeated aspiration for tense effusions.

Chronic, stable olecranon bursa swelling unaccompanied by erythema or other signs of inflammation does not suggest infection and does not require aspiration (Plate 81). Aspiration of the olecranon bursa in rheumatoid arthritis and in gout runs the risk of creating a chronic drainage site, which can be reduced by using a “zig-zag” approach with a small needle (25-gauge if possible) and pulling the skin over the bursa before introducing it. Applying a pressure bandage may also help prevent chronic drainage. Surgical removal of the bursa is indicated only for cases in which repeated infections occur. Repetitive minor trauma to the olecranon bursa should be eliminated by avoiding resting the elbow on a hard surface or by wearing an elbow pad.

A bursa can also become symptomatic when it ruptures. This is particularly true for Baker cyst, whose rupture can cause calf pain and swelling that mimic thrombophlebitis. Ruptured Baker cysts are imaged easily by sonography or MRI. In most cases, imaging is unnecessary because the cyst and an associated knee effusion are detectable on physical examination. It may be important to exclude a deep venous thrombosis, which can be mimicked by a ruptured Baker cyst. Treatment of a ruptured cyst includes rest, leg elevation, and injection of triamcinolone, 20–40 mg into the knee anteriorly (the knee compartment communicates with the cyst). Rarely, Baker cyst can compress vascular structures and cause leg edema and true thrombophlebitis.

SPORTS MEDICINE INJURIES

Musculoskeletal problems commonly occur as a result of both serious athletic pursuits and activities of daily living. For most such disorders, the diagnosis is made easily. Physical therapy is an increasingly important adjunct to the management of these disorders.

1. Rotator Cuff Disorders

Disorders of the rotator cuff, such as tendinitis, subacromial bursitis, and partial and complete tears, account for a substantial majority of shoulder problems. The tendons of the rotator cuff form a musculotendinous unit near their insertions into the proximal humerus. Years of cumulative irritation can lead to attenuation of these tendons, particularly the supraspinatus tendon. Distinguishing between the various soft tissue disorders that cause shoulder pain is difficult because these frequently cause similar symptoms and often occur together. Precise distinction is frequently unimportant for purposes of therapy.

► Clinical Findings

Patients usually present with nonspecific pain localized to the shoulder, often noticed more at night when lying on

the affected side. Locking sensations occur with motion of the shoulder, particularly through abduction. Because of the shared innervation, symptoms are frequently referred down the proximal lateral arm. With rotator cuff tears, the patient may be unable to abduct or flex the shoulder, depending on the site of the tear.

The rotator cuff may be palpated just lateral to the head of the acromion. Maximum tenderness is usually noted over the supraspinatus insertion. The acromioclavicular joint may also be tender if there is accompanying degenerative arthritis in that joint. There may be prominent crepitus. Pain with range of motion is most pronounced between 60 and 120 degrees of abduction, the site of greatest impingement of the rotator cuff tissues between the humerus and coracoacromial arch.

For patients with partial rotator cuff tendon ruptures, the findings are identical to those of chronic tendinitis and bursitis. Patients with partial ruptures often demonstrate mild abduction weakness. With complete ruptures, weakness of abduction (and, to a lesser extent, flexion) is substantial, even though full range of motion may be maintained by the shoulder’s accessory rotator muscles. Patients with complete tears usually have positive “drop arm” signs: inability to sustain passive abduction of the arm to 90 degrees.

► Treatment

For most rotator cuff disorders, rest and abstention from inciting activities are helpful. NSAIDs and moist heat afford some relief. Injections of a corticosteroid preparation (eg, 1 mL of triamcinolone, 40 mg/mL) mixed with 2–3 mL of lidocaine hydrochloride (1–2%) may be useful. Tears or partial tears of the rotator cuff tendons that are believed to be chronic do not preclude a corticosteroid injection. Most patients obtain significant relief with one injection, but the procedure—along with continued rest—may be repeated after 2–3 weeks. Physical therapy is valuable for refractory cases—if the patient does not maintain the shoulder’s normal range of motion, stiffness and impaired function from a “frozen shoulder” may ensue.

Aside from patients with complete rotator cuff tears, only those who do not improve after months of conservative therapy are candidates for operation. Persistent symptoms may be a sign of complete tear, which may be diagnosed by MRI. Patients with symptoms that continue in the absence of a complete tear, however, sometimes require surgery to excise the inferolateral portion of the acromion, release obstructed soft tissue, and repair partial tendon tears. Depending on the patient’s symptoms and functional status, complete tears may not always require surgical repair. Patients over 75 years of age rarely have symptoms or limitations that necessitate surgery. Moreover, surgical repairs are frequently less successful because of the attrition of the rotator cuff that occurs with aging.

Burbank KM et al. Chronic shoulder pain: part I. Evaluation and diagnosis. *Am Fam Physician.* 2008 Feb 15;77(4):453–60. [PMID: 18326164]

Burbank KM et al. Chronic shoulder pain: part II. Treatment. *Am Fam Physician.* 2008 Feb 15;77(4):493–7. [PMID: 18326169]

2. Lateral & Medial Epicondylitis

These disorders are better known by their sports associations: “tennis elbow” and “golf elbow,” respectively. Lateral epicondylitis is the more common of the two. The conditions are caused by overuse, and the pain results from minor tears in the tendons of the forearm’s extensor and flexor muscles.

► Clinical Findings

The patient complains of pain at the site of tendon insertion. Tasks that require grasping and squeezing, such as shaking hands or opening jars, cause pain.

The diagnoses are easily confirmed on physical examination by elicitation of point tenderness over the involved site. The characteristic pain may also be reproduced by extension or flexion of the wrist against pressure. Clenching the fist and extending the wrist against the pressure of the examiner’s palm is a useful maneuver for localizing lateral epicondylitis. Medial epicondylitis may be demonstrated by performing the same maneuver in flexion.

► Treatment

NSAIDs and rest are effective in mild cases. Symptoms that persist after 2 weeks of conservative therapy usually respond either to infiltration of triamcinolone, 10–20 mg mixed with 1–2 mL of 1% lidocaine, around the involved epicondyle—or to physiotherapy. Results are quicker with corticosteroid injections but longer-lasting with physiotherapy. Only experienced clinicians should inject the medial epicondyle because of the risk of injury to the ulnar nerve. After the pain and tenderness have subsided, patients may begin a physical therapy program involving daily stretching of the flexor and extensor tendons.

Calfee RP et al. Management of lateral epicondylitis: current concepts. *J Am Acad Orthop Surg.* 2008 Jan;16(1):19–29. [PMID: 18180389]

3. Patellofemoral Syndrome

Patellofemoral syndrome is among the most common causes of knee complaints in primary care medicine, particularly among adolescent and young adult patients. The syndrome frequently gives rise to the chief complaint of anterior knee pain. A variety of injuries or anatomic abnormalities predispose patients to irregular patellar movements, leading to the patellofemoral syndrome. Such predisposing conditions include imbalance of quadriceps strength, patella alta, recurrent patellar subluxation, direct trauma to the patella, and meniscal injuries. For most of these causes, the therapeutic approach is similar.

► Clinical Findings

Patients frequently have difficulty localizing the source of their complaint but generally confirm that the pain is in the front of the knee, around or underneath the patella. Questions regarding specific precipitants of the pain may be useful in establishing the diagnosis. For example,

because of the flexion load, patients have difficulty going up or down staircases (down is usually associated with greater symptoms). Another characteristic symptom is the positive “theater” sign: after remaining seated for a prolonged period, patients describe extreme discomfort with their first few steps after rising. The symptoms improve with further walking. Finally, patients with patellofemoral syndrome often complain of crepitus, joint locking, or sensations of joint instability, all of which lack readily confirmed anatomic explanations.

The physical examination is less useful than the history in establishing the diagnosis, but a significant number of patients have characteristic physical findings. In particular, when the knee is held in slight flexion, gentle pressure against the patella as the patient contracts the quadriceps muscles may reproduce the symptoms. In some cases, with the knee extended and the quadriceps relaxed, the typical pain may be reproduced by digital pressure under the medial or lateral border of the patella, with side-to-side movement of the bone. Inflammatory findings on examination are incompatible with the diagnosis of patellofemoral syndrome and suggest other disorders.

► Treatment

Therapy includes avoidance of flexion loads and strengthening of the quadriceps. Referral to a physical therapist is helpful in educating the patient about home exercises. Many patients learn that the most effective therapy is bicycling, with the seat high enough to permit nearly full knee extension with each cycle. Although most cases respond to these interventions and even resolve altogether, some persist for years. Even in the latter, conservative therapy remains the rule; operation is rarely indicated. There is only limited evidence for the effectiveness of NSAIDs in short-term pain reduction associated with the patellofemoral pain syndrome. The evidence supporting the use of glycosaminoglycan polysulfate is conflicting. Bracing is no more effective than a home exercise program.

Fredericson M et al. Physical examination and patellofemoral pain syndrome. *Am J Phys Med Rehabil.* 2006 Mar;85(3):234–43. [PMID: 16505640]

4. Overuse Syndromes of the Knee

Runners—particularly those who overtrain or do not attain the proper level of conditioning before starting a running program—may develop a variety of painful overuse syndromes of the knee. Most of these conditions are forms of tendinitis or bursitis that can be diagnosed on examination. The most common conditions include anserine bursitis, the iliotibial band syndrome, and popliteal and patellar tendinitis.

► Clinical Findings

Symptoms resulting from all of these conditions worsen as the patient continues to run and often require cessation of the activity. Anserine bursitis results in pain medial and inferior to the knee joint over the medial tibia. The iliotibial

ial band syndrome and popliteal tenosynovitis may be difficult to differentiate, because the popliteus tendon inserts into the lateral femoral condyle underneath the iliotibial band. Both conditions result in pain on the lateral side of the knee. Patellar tendinitis, a cause of anterior knee discomfort, typically occurs at the tendon's insertion into the patella rather than at its more inferior insertion.

All of these diagnoses are confirmed by palpation at the relevant sites around the knee. None is associated with joint effusions or other signs of synovitis.

► Treatment

Rest and abstention from the associated physical activities for a period of days to weeks are essential. Once pain has subsided, a program of gentle stretching (particularly prior to resuming exercise) may prevent recurrence. Corticosteroid injections with lidocaine may be useful when intense discomfort is present, but caution must be used when injecting corticosteroids into the region of a tendon to avoid rupture.

Brushøj C et al. Prevention of overuse injuries by a concurrent exercise program in subjects exposed to an increase in training load: a randomized controlled trial of 1020 army recruits. *Am J Sports Med.* 2008 Apr;36(4):663–70. [PMID: 18337359]

5. Medial Meniscus Injuries

Tears of the medial meniscus are the most common knee injuries encountered in primary care. Because the medial meniscus is tethered firmly to the underlying tibia, injuries to the medial meniscus occur ten times more commonly than injuries to the lateral meniscus. Both result from a twisting action exerted on the knee joint while the foot is in a weight-bearing position.

► Clinical Findings

The injury is heralded by a tearing or popping sensation followed by severe pain. Occasionally, meniscal tears result from seemingly minor trauma. In contrast to ligamentous injuries, in which hemorrhage causes immediate swelling, effusions associated with meniscal injuries accumulate over hours and are typically worse the day after the injury. Several days after resolution (full or partial), the patient may experience the sensation of joint locking or instability, recurrent swelling with activity, and pain. “Pseudolocking” caused by muscle spasm and swelling is more common than mechanical blockage caused by a fragment of torn meniscus.

A knee effusion is usually present. Tenderness may be localized to the medial joint line, and range of motion in the knee may be restricted. In patients without an acutely painful, swollen knee, McMurray test may suggest the diagnosis. This test is performed with the patient supine and the hip and knee in full flexion. The examiner has one hand on the involved knee and the other on the ipsilateral foot. As the foot is externally rotated, the examiner extends the patient's knee. The presence of a “snap” (palpable or audible) suggests a medial meniscus lesion. MRI is the optimal test for confirming the diagnosis if plain films exclude other conditions.

► Treatment

Initial management is conservative, with elevation of the joint and application of a compression dressing and ice. Weight bearing should be minimized for the first few days after the injury but may be resumed slowly thereafter. The patient should perform quadriceps-strengthening exercises under the instruction of a physical therapist. Surgery is reserved for patients with symptoms that recur upon resumption of normal activities or for patients with irreducible locking caused by mechanical problems.

6. Ankle Sprains

Ankle sprains are among the most common of all sports injuries. Most sprains involve the lateral ligament complex, particularly the anterior talofibular ligament. In more severe injuries, the calcaneofibular ligament may also be involved. If both of these ligaments are ruptured, the injury results in significant joint instability and is classified as a grade III (severe) sprain. (Grades I and II correspond to mild and moderate injuries, respectively.) This section reviews only the type of ankle sprain resulting from inversion (varus) injuries, which account for 85% of all sprains.

► Clinical Findings

Varus sprains include a spectrum of severity, ranging from slight loss of function to injuries in which the swelling is prompt, the pain prominent, and weight bearing impossible. A history of hearing a “pop” at the time of injury is frequently associated with the latter.

Hemorrhage resulting from torn ligaments and damaged peroneal muscle tendons may cause substantial ecchymosis. Tenderness is typically present at the site of injury, and the associated swelling may be considerable. Stability of the anterior talofibular and calcaneofibular ligaments should be assessed with the “anterior drawer” sign: With the foot held in slight plantar flexion, the examiner cups the patient's heel with one hand and the patient's shin with the other. The examiner then applies gentle anterior force in the plane of the patient's foot. Excessive anterior motion of the foot constitutes a positive test (grade III sprain). Plain radiographs exclude associated bony injury.

► Treatment

Most ankle sprains—even grade III—are treated identically. The acronym “RICE” (rest, ice, compression, elevation) applies more accurately to ankle sprains than to any other injury. Early application of a compression dressing is essential to control swelling and provide stability to the traumatized joint. An Aircast ankle brace may be more effective than an elastic support bandage. Weight bearing should be minimal, with liberal use of crutches. Elevation of the ankle for several days hastens functional recovery by diminishing pain and swelling, and ice is also helpful (alternating 30 minutes on, 30 minutes off). The ice should be applied on top of the compression dressing and not against the skin both because close apposition of the dressing to the skin is critical to control swelling and because direct application of ice is uncomfortable and even

deleterious to the skin. Referral to a physical therapist may expedite recovery. Patients should be informed that symptoms from lateral ankle sprains may take weeks or months to resolve, and that this period will be prolonged by premature attempts to bear weight on the injured ankle. Surgical repairs of ruptured lateral ligaments provide excellent outcomes but are usually necessary only in cases of chronically unstable joints.

van Rijn RM et al. What is the clinical course of acute ankle sprains? A systematic literature review. *Am J Med.* 2008 Apr;121(4):324–31. [PMID: 18374692]

7. Plantar Fasciitis

The most common cause of foot pain in outpatient medicine is plantar fasciitis, which results from constant strain on the plantar fascia at its insertion into the medial tubercle of the calcaneus. Although certain inflammatory disorders such as the seronegative spondyloarthropathies predispose patients to enthesopathies, the majority of cases occur in patients with no associated disease. Most occur as the result of excessive standing and improper footwear.

▶ Clinical Findings

Patients with plantar fasciitis report severe pain on the bottoms of their feet in the morning—the first steps out of bed in particular—but the pain subsides after a few minutes of ambulation.

The diagnosis may be confirmed by palpation over the plantar fascia's insertion on the medial heel. Radiographs have no role in the diagnosis of this condition—heel spurs frequently exist in patients without plantar fasciitis, and most symptomatic patients do not have heel spurs.

▶ Treatment

Treatment consists of restriction of prolonged standing for days and the use of arch supports. Arch supports give relief by requiring the arches to bear more of the patient's weight, thus unloading the plantar entheses. NSAIDs may provide some relief. In severe cases, a corticosteroid with lidocaine injection (small volume—no more than a total of 1.5 mL) directly into the most tender area on the sole of the foot is helpful. Rare patients require release of the plantar fascia from its attachment site at the os calcis.

Neufeld SK et al. Plantar fasciitis: evaluation and treatment. *J Am Acad Orthop Surg.* 2008 Jun;16(6):338–46. [PMID: 18524985]

AUTOIMMUNE DISEASES

RHEUMATOID ARTHRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Usually insidious onset with morning stiffness and pain in affected joints.

- ▶ Symmetric polyarthritis with predilection for small joints of the hands and feet; deformities common with progressive disease.
- ▶ Radiographic findings: juxta-articular osteoporosis, joint erosions, and joint space narrowing.
- ▶ Rheumatoid factor and antibodies to cyclic citrullinated peptides (anti-CCP) are present in 70–80%.
- ▶ Extra-articular manifestations: subcutaneous nodules, pleural effusion, pericarditis, lymphadenopathy, splenomegaly with leukopenia, and vasculitis.

▶ General Considerations

Rheumatoid arthritis is a chronic systemic inflammatory disease whose major manifestation is synovitis of multiple joints. It has a prevalence of 1% and is more common in women than men (female:male ratio of 3:1). Rheumatoid arthritis can begin at any age, but the peak onset is in the fourth or fifth decade for women and the sixth to eighth decades for men. The cause is not known. Susceptibility to rheumatoid arthritis is genetically determined with multiple genes contributing. Inheritance of class II HLA molecules with a distinctive five-amino-acid sequence known as the “shared epitope” is the best characterized genetic risk factor. Untreated, rheumatoid arthritis causes joint destruction with consequent disability and shortens life expectancy. Early, aggressive treatment is the standard of care.

The pathologic findings in the joint include chronic synovitis with formation of a pannus, which erodes cartilage, bone, ligaments, and tendons. In the acute phase, effusion and other manifestations of inflammation are common. In the late stage, organization may result in fibrous ankylosis; true bony ankylosis is rare.

▶ Clinical Findings

A. Symptoms and Signs

1. Joint symptoms—The clinical manifestations of rheumatoid disease are highly variable, but joint symptoms usually predominate. Although acute presentations may occur, the onset of articular signs of inflammation is usually insidious, with prodromal symptoms of vague periarticular pain or stiffness. Symmetric swelling of multiple joints with tenderness and pain is characteristic. Monarticular disease is occasionally seen initially. Stiffness persisting for more than 30 minutes (and usually many hours) is prominent in the morning. Stiffness may recur after daytime inactivity and be much more severe after strenuous activity. Although any diarthrodial joint may be affected, PIP joints of the fingers, MCP joints, wrists, knees, ankles, and MTP joints are most often involved (Plate 82). Synovial cysts and rupture of tendons may occur. Entrapment syndromes are not unusual—particularly of the median nerve at the carpal tunnel of the wrist. Rheumatoid arthritis can affect the neck but spares the other components of the spine and does not involve the sacroiliac joints.

2. Rheumatoid nodules—Twenty percent of patients have subcutaneous rheumatoid nodules, most commonly situated

over bony prominences but also observed in the bursae and tendon sheaths (Plate 83). Nodules are occasionally seen in the lungs, the sclerae, and other tissues. Nodules correlate with the presence of rheumatoid factor in serum (“seropositivity”), as do most other extra-articular manifestations.

3. Ocular symptoms—Dryness of the eyes, mouth, and other mucous membranes is found especially in advanced disease (see Sjögren syndrome). Other ocular manifestations include episcleritis, scleritis, and scleromalacia due to scleral nodules.

4. Other symptoms—Palmar erythema is common. Occasionally, a small vessel vasculitis develops and manifests as tiny hemorrhagic infarcts in the nail folds or finger pulps. Although necrotizing arteritis is well reported, it is rare. Pericarditis and pleural disease, when present, are usually silent clinically. Additional extra-articular manifestations of rheumatoid arthritis include pulmonary fibrosis, mononuclear cell infiltration of skeletal muscle and perineurium, and hyperplasia of lymph nodes. A small subset of patients with rheumatoid arthritis have Felty syndrome, the occurrence of splenomegaly and neutropenia, usually in the setting of severe, destructive arthritis. Felty syndrome must be distinguished from the large granular lymphocyte syndrome, with which it shares many features.

Aortitis is a rare late complication that can result in aortic regurgitation or rupture and is usually associated with evidence of rheumatoid vasculitis elsewhere in the body.

B. Laboratory Findings

Anti-CCP antibodies and rheumatoid factor, an IgM antibody directed against the Fc fragment of IgG, are present in 70–80% of patients with established rheumatoid arthritis but have sensitivities of only 50% in early disease. Anti-CCP antibodies are the most specific blood test for rheumatoid arthritis (specificity ~95%). Rheumatoid factor can occur in other autoimmune disease and in chronic infections, including hepatitis C, syphilis, subacute bacterial endocarditis, and tuberculosis. The prevalence of rheumatoid factor positivity also rises with age in healthy individuals. Approximately 20% of rheumatoid patients have antinuclear antibodies.

The ESR and levels of C-reactive protein are typically elevated in proportion to disease activity. A moderate hypochromic normocytic anemia is common. The white cell count is normal or slightly elevated, but leukopenia may occur, often in the presence of splenomegaly (eg, Felty syndrome). The platelet count is often elevated, roughly in proportion to the severity of overall joint inflammation. Initial joint fluid examination confirms the inflammatory nature of the arthritis. (See Table 20–2.) Arthrocentesis is needed to diagnose superimposed septic arthritis, which is a common complication of rheumatoid arthritis and should be considered whenever a patient with rheumatoid arthritis has one joint inflamed out of proportion to the rest.

C. Imaging

Of all the laboratory tests, radiographic changes are the most specific for rheumatoid arthritis. Radiographs

obtained during the first 6 months of symptoms, however, are usually normal. The earliest changes occur in the wrists or feet and consist of soft tissue swelling and juxta-articular demineralization. Later, diagnostic changes of uniform joint space narrowing and erosions develop. The erosions are often first evident at the ulnar styloid and at the juxta-articular margin, where the bony surface is not protected by cartilage. Diagnostic changes also occur in the cervical spine, with C1–2 subluxation, but these changes usually take many years to develop. Although both MRI and ultrasonography are more sensitive than radiographs in detecting bony and soft tissue changes in rheumatoid arthritis, their value in early diagnosis relative to that of plain radiographs has not been established.

► Differential Diagnosis

The differentiation of rheumatoid arthritis from other joint conditions and immune-mediated disorders can be difficult. In contrast to rheumatoid arthritis, osteoarthritis spares the wrist and the MCP joints. Osteoarthritis is not associated with constitutional manifestations, and the joint pain is characteristically relieved by rest, unlike the morning stiffness of rheumatoid arthritis. Signs of articular inflammation, prominent in rheumatoid arthritis, are usually minimal in degenerative joint disease. Although gouty arthritis is almost always intermittent and monoarticular in the early years, it may evolve with time into a chronic polyarticular process that mimics rheumatoid arthritis. Gouty tophi resemble rheumatoid nodules both in typical location and appearance. The early history of intermittent monoarthritis and the presence of synovial urate crystals are distinctive features of gout. Chronic Lyme arthritis typically involves only one joint, most commonly the knee, and is associated with positive serologic tests (see Chapter 34). Human parvovirus B19 infection in adults can mimic early rheumatoid arthritis. However, arthralgias are more prominent than arthritis, rash—on the cheeks, torso, or extremities—is common, IgM antibodies to parvovirus B19 are present, and the arthritis usually resolves within weeks. Infection with hepatitis C can cause a chronic nonerosive polyarthritis associated with rheumatoid factor; tests for anti-CCP antibodies are negative.

Malar rash, photosensitivity, discoid skin lesions, alopecia, high titer antibodies to double-stranded DNA, glomerulonephritis, and central nervous system abnormalities point to the diagnosis of SLE. Polymyalgia rheumatica occasionally causes polyarthralgias in patients over age 50, but these patients remain rheumatoid factor–negative and have chiefly proximal muscle pain and stiffness, centered on the shoulder and hip girdles. Rheumatic fever is characterized by the migratory nature of the arthritis, an elevated antistreptolysin titer, and a more dramatic and prompt response to aspirin; carditis and erythema marginatum may occur in adults, but chorea and subcutaneous nodules virtually never do. Finally, a variety of cancers produce paraneoplastic syndromes, including polyarthritis. One form is hypertrophic pulmonary osteoarthropathy most often produced by lung and gastrointestinal carcinomas, characterized by a rheumatoid-like arthritis associated with clubbing, perios-

teal new bone formation, and a negative rheumatoid factor. Diffuse swelling of the hands with palmar fasciitis occurs in a variety of cancers, especially ovarian carcinoma.

► Treatment

The primary objectives in treating rheumatoid arthritis are reduction of inflammation and pain, preservation of function, and prevention of deformity. Success requires early, effective pharmacologic intervention. Disease-modifying antirheumatic drugs (DMARDs) should be started as soon as the diagnosis of rheumatoid disease is certain and then adjusted with the aim of suppressing disease activity. The American College of Rheumatology recommends using standardized assessments, such as the Disease Activity Score 28 Joints (DAS28), to gauge therapeutic responses, with the target of mild disease activity or remission by these measures. In advanced disease, surgical intervention may help improve function of damaged joints and to relieve pain.

A. Nonsteroidal Anti-inflammatory Drugs

NSAIDs provide some symptomatic relief in rheumatoid arthritis but do not prevent erosions or alter disease progression. They are not appropriate for monotherapy and should only be used in conjunction with DMARDs. A large number of NSAIDs are available; all appear equivalent in terms of efficacy (see Table 5–3).

Celecoxib, a selective COX-2 inhibitor, is FDA-approved for the treatment of osteoarthritis and rheumatoid arthritis. Compared with traditional NSAIDs, COX-2 inhibitors are as effective for treating rheumatoid arthritis but less likely in some circumstances to cause upper gastrointestinal tract adverse events (eg, obstruction, perforation, hemorrhage, or ulceration). Long-term use of COX-2 inhibitors, particularly in the absence of concomitant aspirin use, has been associated with an increased risk of cardiovascular events, leading to the removal of some COX-2 inhibitors from the US market and intense scrutiny of all drugs in that class.

1. Gastrointestinal side effects—For traditional NSAIDs that inhibit both COX-1 and COX-2, gastrointestinal side effects, such as gastric ulceration, perforation, and gastrointestinal hemorrhage, are the most common serious side effects. The overall rate of bleeding with NSAID use in the general population is low (1:6000 users or less) but is increased by long-term use, higher NSAID dose, concomitant corticosteroids or anticoagulants, the presence of rheumatoid arthritis, history of peptic ulcer disease or alcoholism, and age over 70. Twenty-five percent of all hospitalizations and deaths from peptic ulcer disease result from traditional NSAID therapy. Each year, 1:1000 patients with rheumatoid arthritis will require hospitalization for NSAID-related gastrointestinal bleeding or perforation. Although all traditional NSAIDs can cause massive gastrointestinal bleeding, the risk may be higher with indomethacin and piroxicam, probably because these drugs preferentially inhibit COX-1 in the stomach.

One approach to reducing the gastrointestinal toxicity of traditional NSAIDs is to add a proton pump inhibitor (eg, omeprazole 20 mg orally daily). Sucralfate, antacids,

and H₂-blockers (such as ranitidine) either do not work or do not work as well as proton pump inhibitors. The expense of proton pump inhibitors and misoprostol dictates that their use should be reserved for patients with risk factors for NSAID-induced gastrointestinal toxicity (noted above). Patients who have recently recovered from an NSAID-induced bleeding gastric ulcer appear to be at high risk for rebleeding (about 5% in 6 months) when an NSAID is reintroduced, even if prophylactic measures such as proton pump inhibitors are used. NSAIDs can also affect the lower intestinal tract, causing perforation or aggravating inflammatory bowel disease.

Acute liver injury from NSAIDs is rare, occurring in about 1 of every 25,000 patients using these agents. Having rheumatoid arthritis or taking sulindac may increase the risk.

2. Renal side effects—All of the NSAIDs, including aspirin and the COX-2 inhibitors, can produce renal toxicity, including interstitial nephritis, nephrotic syndrome, prerenal azotemia, and aggravation of hypertension. Hyperkalemia due to hyporeninemic hypoaldosteronism may also be seen rarely. The risk of renal toxicity is low but is increased by age over 60, a history of kidney disease, congestive heart failure, ascites, and diuretic use. COX-2 inhibitors appear to cause as much nephrotoxicity as traditional NSAIDs.

3. Platelet effects—All NSAIDs except the nonacetylated salicylates and the COX-2 inhibitors interfere with platelet function and prolong bleeding time. For all older NSAIDs except aspirin, the effect on bleeding time resolves as the drug is cleared. Aspirin irreversibly inhibits platelet function, so the bleeding time effect resolves only as new platelets are made. COX-2 inhibitors, which differ from other NSAIDs in not inhibiting platelet function, do not increase the risk of bleeding with surgical procedures as most NSAIDs do. Unfortunately, this failure to inhibit platelets is now known to lead to increased risks of myocardial infarction and stroke, particularly when the medications are used in high doses for prolonged periods of time. Patients requiring low-dose aspirin who are not compliant have a greater risk of developing a thrombotic event while taking a COX-2 inhibitor than while taking a traditional NSAID. Whether combination therapy with low-dose aspirin and a COX-2 inhibitor maintains the gastrointestinal advantage of selective COX-2 inhibitors is not yet known.

Although groups of patients with rheumatoid arthritis respond similarly to NSAIDs, individuals may respond differently—an NSAID that works for one patient may not work for another. Thus, if the first NSAID chosen is not effective after 2–3 weeks of use, another should be tried.

B. Corticosteroids

Low-dose corticosteroids (eg, oral prednisone 5–10 mg daily) produce a prompt anti-inflammatory effect in rheumatoid arthritis and slow the rate of bony destruction. However, their multiple side effects limit their long-term use.

Low-dose corticosteroids often are used as a “bridge” to reduce disease activity until the slower acting DMARDs take effect or as adjunctive therapy for active disease that

persists despite treatment with DMARDs. No more than 10 mg of prednisone or equivalent per day is appropriate for articular disease. Many patients do reasonably well on 5–7.5 mg daily. (The use of 1 mg tablets, to facilitate doses of < 5 mg/d, is encouraged.) Higher doses are used to manage serious extra-articular manifestations (eg, pericarditis, necrotizing scleritis). When the corticosteroids are to be discontinued, they should be tapered gradually on a planned schedule appropriate to the duration of treatment. All patients receiving long-term corticosteroid therapy should take measures to prevent osteoporosis.

Intra-articular corticosteroids may be helpful if one or two joints are the chief source of difficulty. Intra-articular triamcinolone, 10–40 mg depending on the size of the joint to be injected, may be given for symptomatic relief but not more than four times a year.

C. Synthetic DMARDs

1. Methotrexate—Methotrexate is usually the initial synthetic DMARD of choice for patients with rheumatoid arthritis. It is generally well tolerated and often produces a beneficial effect in 2–6 weeks. The usual initial dose is 7.5 mg of methotrexate orally once weekly. If the patient has tolerated methotrexate but has not responded in 1 month, the dose can be increased to 15 mg orally once per week. The maximal dose is usually 20–25 mg/wk. The most frequent side effects are gastric irritation and stomatitis. Cytopenia, most commonly leukopenia or thrombocytopenia but rarely pancytopenia, due to bone marrow suppression is another important potential problem. The risk of developing pancytopenia is much higher in patients with elevation of the serum creatinine (≥ 2 mg/dL). Hepatotoxicity with fibrosis and cirrhosis is an important toxic effect that correlates with cumulative dose and is uncommon with appropriate monitoring of liver function tests. Methotrexate is contraindicated in a patient with any form of chronic hepatitis. Heavy alcohol use increases the hepatotoxicity, so patients should be advised to drink alcohol in extreme moderation, if at all. Diabetes, obesity, and kidney disease also increase the risk of hepatotoxicity. Liver function tests should be monitored at least every 12 weeks, along with a complete blood count. The dose of methotrexate should be reduced if aminotransferase levels are elevated, and the drug should be discontinued if abnormalities persist despite dosage reduction. Gastric irritation, stomatitis, cytopenias, and hepatotoxicity are reduced by prescribing either daily folate (1 mg) or weekly leucovorin calcium (2.5–5 mg taken 24 hours after the dose of methotrexate). Hypersensitivity to methotrexate can cause an acute or subacute interstitial pneumonitis that can be life-threatening but which usually responds to cessation of the drug and institution of corticosteroids. Methotrexate is associated with an increased risk of B cell lymphomas, some of which resolve following the discontinuation of the medication. The combination of methotrexate and other folate antagonists, such as trimethoprim-sulfamethoxazole, should be used cautiously, since pancytopenia can result. Probenecid should also be avoided since it increases methotrexate drug levels and toxicity.

2. Sulfasalazine—This drug is a second-line agent for rheumatoid arthritis. It is usually introduced at a dosage of 0.5 g orally twice daily and then increased each week by 0.5 g until the patient improves or the daily dose reaches 3 g. Side effects, particularly neutropenia and thrombocytopenia, occur in 10–25% and are serious in 2–5%. Sulfasalazine also causes hemolysis in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, so a G6PD level should be checked before initiating sulfasalazine. Patients taking sulfasalazine should have complete blood counts monitored every 2–4 weeks for the first 3 months, then every 3 months.

3. Leflunomide—Leflunomide, a pyrimidine synthesis inhibitor, is also FDA-approved for treatment of rheumatoid arthritis and is administered as a single daily dose of 20 mg. The most frequent side effects are diarrhea, rash, reversible alopecia, and hepatotoxicity. Some patients experience dramatic unexplained weight loss. The drug is carcinogenic, teratogenic, and has a half-life of 2 weeks. Thus, it is contraindicated in premenopausal women or in men who wish to father children.

4. Antimalarials—Hydroxychloroquine sulfate is the anti-malarial agent most often used against rheumatoid arthritis. Monotherapy with hydroxychloroquine should be reserved for patients with mild disease because only a small percentage will respond and in some of those cases only after 3–6 months of therapy. Hydroxychloroquine is often used in combination with other conventional DMARDs, particularly methotrexate and sulfasalazine. The advantage of hydroxychloroquine is its comparatively low toxicity, especially at a dosage of 200–400 mg/d orally (not to exceed 6.5 mg/kg/d). The most important reaction, pigmented retinitis causing visual loss, is rare at this dose. Ophthalmologic examinations every 12 months are required when this drug is used for long-term therapy. Other reactions include neuropathies and myopathies of both skeletal and cardiac muscle, which usually improve when the drug is withdrawn.

5. Minocycline—Minocycline is more effective than placebo for rheumatoid arthritis. It is reserved for early, mild cases, since its efficacy is modest, and it works better during the first year of rheumatoid arthritis. The mechanism of action is not clear, but tetracyclines do have anti-inflammatory properties, including the ability to inhibit destructive enzymes such as collagenase. The dosage of minocycline is 200 mg orally daily. Adverse effects are uncommon except for dizziness, which occurs in about 10%.

D. Biologic DMARDs

1. Tumor necrosis factor inhibitors—Inhibitors of tumor necrosis factor- α (TNF- α)—a pro-inflammatory cytokine—are fulfilling the aim of targeted therapy for rheumatoid arthritis. These medications are frequently added to the treatment of patients who have not responded adequately to methotrexate and are increasingly used as initial therapy in combination with methotrexate for patients with poor prognostic factors.

Three inhibitors are in use: etanercept, infliximab, and adalimumab. Etanercept, a soluble recombinant TNF receptor:Fc fusion protein, is usually administered at a dosage of 50 mg subcutaneously once per week. Infliximab, a chimeric monoclonal antibody, is administered at a dosage of 3–10 mg/kg intravenously; infusions are repeated after 2, 6, 10, and 14 weeks and then are administered every 8 weeks. Adalimumab, a human monoclonal antibody that binds to TNF, is given at a dosage of 40 mg subcutaneously every other week. Each drug produces substantial improvement in more than 60% of patients. Each is usually very well tolerated. Minor irritation at injection sites is the most common side effect of etanercept and adalimumab. Rarely, nonrecurrent leukopenia develops in patients.

TNF plays a physiologic role in combating many types of infection; TNF inhibitors have been associated with a several-fold increased risk of serious bacterial infections and a striking increase in granulomatous infections, particularly reactivation of tuberculosis. Screening for latent tuberculosis (see Chapter 9) is mandatory before the initiation of TNF blockers. It is prudent to suspend TNF blockers when a fever or other manifestations of a clinically important infection develops in a patient. Demyelinating neurologic complications that resemble multiple sclerosis have been reported rarely in patients taking etanercept, but the true magnitude of this risk—likely quite small—has not been determined with precision. There are conflicting data with respect to increased risk of malignancy. Contrary to expectation, TNF inhibitors were not effective in the treatment of congestive heart failure. The use of infliximab, in fact, was associated with increased morbidity in a congestive heart failure trial. Consequently, TNF inhibitors should be used with extreme caution in patients with congestive heart failure. Infliximab can rarely cause anaphylaxis and induce anti-DNA antibodies (but rarely clinically evident SLE). A final concern about TNF inhibitors is the expense, which is more than \$10,000 per year.

2. Abatacept—Abatacept, a recombinant protein made by fusing a fragment of the Fc domain of human IgG with the extracellular domain of a T cell inhibitory receptor (CTLA4), blocks T-cell costimulation. It is approved by the FDA for use in rheumatoid arthritis and produces clinically meaningful responses in approximately 50% of individuals whose disease is active despite the combination of methotrexate and a TNF inhibitor.

3. Rituximab—Rituximab is a humanized mouse monoclonal antibody that depletes B cells. It is approved by the FDA to be used in combination with methotrexate for patients whose disease has been refractory to treatment with a TNF inhibitor.

E. DMARD Combinations

As a general rule, DMARDs have greater efficacy when administered in combination than when used individually. Currently, the most commonly used combination is that of methotrexate with one of the TNF inhibitors, which clearly is superior to methotrexate alone. The urge to use combination therapies with TNF inhibitors as the initial treatment

for rheumatoid arthritis, however, has been tempered by concerns about their safety and cost. The American College of Rheumatology recently published detailed recommendations on the initiation of DMARD combinations.

► Course & Prognosis

After months or years, deformities may occur; the most common are ulnar deviation of the fingers, boutonnière deformity (hyperextension of the DIP joint with flexion of the PIP joint), “swan-neck” deformity (flexion of the DIP joint with extension of the PIP joint), valgus deformity of the knee, and volar subluxation of the MTP joints. The excess mortality associated with rheumatoid arthritis is largely due to cardiovascular disease that is unexplained by traditional risk factors and that appears to be a result of deleterious effects of chronic systemic inflammation on the vascular system.

► When to Refer

Early referral to a rheumatologist is essential for appropriate diagnosis and the timely introduction of effective pharmacologic and nonpharmacologic (physical and occupational) therapy.

ADULT STILL DISEASE

Still disease is a systemic form of juvenile chronic arthritis in which high spiking fevers are much more prominent, especially at the outset, than arthritis. This syndrome also occurs in adults. Most adults are in their 20s or 30s; onset after age 60 is rare. The fever is dramatic, often spiking to 40 °C, associated with sweats and chills, and then plunging to several degrees below normal in the absence of antipyretics. Many patients initially complain of sore throat. An evanescent salmon-colored nonpruritic rash, chiefly on the chest and abdomen, is a characteristic feature. The rash can easily be missed since it often appears only with the fever spike. Many patients also have lymphadenopathy and pericardial effusions. Joint symptoms are mild or absent in the beginning, but a destructive arthritis, especially of the wrists, may develop months later. Anemia and leukocytosis, with white blood counts sometimes exceeding 40,000/mcL, are the rule. Ferritin levels are exceptionally high (> 3000 mg/mL) in more than 70% of cases of adult Still disease—for reasons that are not clear. A low percentage (< 20%) of serum ferritin that is glycosylated may be even more specific for adult Still disease. Although there must be exclusion of

other causes of fever, the diagnosis of adult Still disease is strongly suggested by the fever pattern, sore throat, and the classic rash. About half of the patients respond to high-dose aspirin (eg, 1 g three times orally daily) or other NSAIDs, and half require prednisone, sometimes in doses greater than 60 mg/d orally. TNF inhibitors may be helpful for some patients with refractory adult Still disease, but most patients treated with these agents achieve only partial remissions. More complete and dramatic responses have been achieved with the IL-1 receptor antagonist anakinra.

SYSTEMIC LUPUS ERYTHEMATOSUS

ESSENTIALS OF DIAGNOSIS

- ▶ Occurs mainly in young women.
- ▶ Rash over areas exposed to sunlight.
- ▶ Joint symptoms in 90% of patients. Multiple system involvement.
- ▶ Anemia, leukopenia, thrombocytopenia.
- ▶ Glomerulonephritis, central nervous system disease, and complications of antiphospholipid antibodies are major sources of disease morbidity.
- ▶ Serologic findings: antinuclear antibodies (100%), anti-native DNA antibodies (approximately two-thirds), and low serum complement levels (particularly during disease flares).

▶ General Considerations

SLE is an inflammatory autoimmune disorder characterized by autoantibodies to nuclear antigens. It can affect multiple organ systems. Many of its clinical manifestations are secondary to the trapping of antigen-antibody complexes in capillaries of visceral structures or to autoantibody-mediated destruction of host cells (eg, thrombocytopenia). The clinical course is marked by spontaneous remission and relapses. The severity may vary from a mild episodic disorder to a rapidly fulminant, life-threatening illness.

The incidence of SLE is influenced by many factors, including gender, race, and genetic inheritance. About 85% of patients are women. Sex hormones appear to play some role; most cases develop after menarche and before menopause. Among older individuals, the gender distribution is more equal. Race is also a factor, as SLE occurs in 1:1000 white women but in 1:250 black women. Familial occurrence of SLE has been repeatedly documented, and the disorder is concordant in 25–70% of identical twins. If a mother has SLE, her daughters' risks of developing the disease are 1:40 and her sons' risks are 1:250. Aggregation of serologic abnormalities (positive antinuclear antibody) is seen in asymptomatic family members, and the prevalence

of other rheumatic diseases is increased among close relatives of patients. The importance of specific genes in SLE is emphasized by the high frequency of certain HLA haplotypes, especially DR2 and DR3, and null complement alleles.

Before making a diagnosis of SLE, it is imperative to ascertain that the condition has not been induced by a drug (Table 20–8). Procainamide, hydralazine, and isoniazid are the best-studied drugs. While antinuclear antibody tests and other serologic findings become positive in many persons receiving these agents, clinical manifestations occur in only a few.

Four features of drug-induced lupus separate it from SLE: (1) the sex ratio is nearly equal; (2) nephritis and central nervous system features are not ordinarily present; (3) hypocomplementemia and antibodies to native DNA are absent; and (4) the clinical features and most laboratory abnormalities usually revert toward normal when the offending drug is withdrawn.

The diagnosis of SLE should be suspected in patients having a multisystem disease with serologic positivity (eg, antinuclear antibody, false-positive serologic test for syphilis). Differential diagnosis includes rheumatoid arthritis, systemic vasculitis, scleroderma, inflammatory myopathies, viral hepatitis, sarcoidosis, acute drug reactions, and drug-induced lupus.

The diagnosis of SLE can be made with reasonable probability if 4 of the 11 criteria set forth in Table 20–9 are met. These criteria, developed as guidelines for the inclusion of patients in research studies, do not supplant clinical judgment in the diagnosis of SLE.

▶ Clinical Findings

A. Symptoms and Signs

The systemic features include fever, anorexia, malaise, and weight loss. Most patients have skin lesions at some time; the

11. Positive ANA

ANA, antinuclear antibody; SLE, systemic lupus erythematosus. Modified and reproduced, with permission, from Tan EM et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum.* 1982 Nov;25(11):1271–7.

characteristic “butterfly” (malar) rash affects less than half of patients. Other cutaneous manifestations are discoid lupus, typical fingertip lesions, periungual erythema, nail fold infarcts, and splinter hemorrhages. Alopecia is common. Mucous membrane lesions tend to occur during periods of exacerbation. Raynaud phenomenon, present in about 20% of patients, often antedates other features of the disease.

Joint symptoms, with or without active synovitis, occur in over 90% of patients and are often the earliest manifestation. The arthritis is seldom deforming; erosive changes are almost never noted on radiographs. Subcutaneous nodules are rare.

Ocular manifestations include conjunctivitis, photophobia, transient or permanent monocular blindness, and blurring of vision. Cotton-wool spots on the retina (cytoid bodies) represent degeneration of nerve fibers due to occlusion of retinal blood vessels.

Pleurisy, pleural effusion, bronchopneumonia, and pneumonitis are frequent. Restrictive lung disease can develop. Alveolar hemorrhage is rare but life-threatening.

The pericardium is affected in the majority of patients. Cardiac failure may result from myocarditis and hypertension. Cardiac arrhythmias are common. Atypical verrucous endocarditis of Libman-Sacks is usually clinically silent but occasionally can produce acute or chronic valvular incompetence—most commonly mitral regurgitation—and can serve as a source of emboli.

Mesenteric vasculitis occasionally occurs in SLE and may closely resemble polyarteritis nodosa, including the

presence of aneurysms in medium-sized blood vessels. Abdominal pain (particularly postprandial), ileus, peritonitis, and perforation may result.

Neurologic complications of SLE include psychosis, cognitive impairment, seizures, peripheral and cranial neuropathies, transverse myelitis, and strokes. Severe depression and psychosis are sometimes exacerbated by the administration of large doses of corticosteroids.

Several forms of glomerulonephritis may occur, including mesangial, focal proliferative, diffuse proliferative, and membranous (see Chapter 22). Some patients may also have interstitial nephritis. With appropriate therapy, the survival rate even for patients with serious chronic kidney disease (proliferative glomerulonephritis) is favorable, albeit a substantial portion of patients with severe lupus nephritis still eventually require renal replacement therapy.

B. Laboratory Findings

(Tables 20–10 and 20–11.) SLE is characterized by the production of many different autoantibodies. Antinuclear antibody tests are sensitive but not specific for SLE—ie, they are positive in virtually all patients with lupus but are positive also in many patients with nonlupus conditions such as rheumatoid arthritis, autoimmune thyroid disease, scleroderma, and Sjögren syndrome. Antibodies to double-stranded DNA and to Sm are specific for SLE but not sensitive, since they are present in only 60% and 30% of patients, respectively. Depressed serum complement—a finding suggestive of disease activity—often returns toward normal in remission. Anti-double-stranded DNA antibody levels also correlate with disease activity in some patients; anti-Sm levels do not.

Three types of antiphospholipid antibodies occur (Table 20–11). The first causes the biologic false-positive tests for syphilis; the second is the lupus anticoagulant, which despite its name is a risk factor for venous and arterial thrombosis and for miscarriage. It is most commonly identified by prolongation of the activated partial thromboplastin time, an in vitro phenomenon related to antibody reacting to phospholipid in the test materials. Anticardiolipin antibodies are the third type of antiphospholipid antibodies. In many cases, the “antiphospholipid antibody” appears to be directed at a serum cofactor (β_2 -glycoprotein-I) rather than at phospholipid itself. Abnormality of urinary sediment is almost always found in association with renal lesions. Showers of red blood cells, with or without casts, and proteinuria (varying from mild to nephrotic range) are frequent during exacerbation of the disease; these usually abate with remission.

► Treatment

Patient education and emotional support are especially important for patients with lupus. Since the various manifestations of SLE affect prognosis differently and since SLE activity often waxes and wanes, drug therapy—both the choice of agents and the intensity of their use—must be tailored to match disease severity. Patients with photosensitivity should be cautioned against sun exposure and should apply a protective lotion to the skin while out of

doors. Skin lesions often respond to the local administration of corticosteroids. Minor joint symptoms can usually be alleviated by rest and NSAIDs.

Antimalarials (hydroxychloroquine) may be helpful in treating lupus rashes or joint symptoms and appear to reduce the incidence of severe disease flares. The dose of hydroxychloroquine is 200 or 400 mg/d orally and should not exceed 6.5 mg/kg/d; annual monitoring for retinal

changes is recommended. Drug-induced neuropathy and myopathy may be erroneously ascribed to the underlying disease. The androgenic corticosteroid danazol may be effective therapy for thrombocytopenia not responsive to corticosteroids. Dehydroepiandrosterone (DHEA) has a therapeutic role comparable to that of the antimalarial agents in the treatment of SLE, but its side effects (particularly acne) are troubling to some patients.

Corticosteroids are required for the control of certain complications. (Systemic corticosteroids are not usually given for minor arthritis, skin rash, leukopenia, or the anemia associated with chronic disease.) Glomerulonephritis, hemolytic anemia, pericarditis or myocarditis, alveolar hemorrhage, central nervous system involvement, and thrombotic thrombocytopenic purpura all require corticosteroid treatment and often other interventions as well. Forty to 60 mg of oral prednisone is often needed initially; however, the lowest dose of corticosteroid that controls the condition should be used. Central nervous system lupus may require higher doses of corticosteroids than are usually given; however, corticosteroid psychosis may mimic lupus cerebritis, in which case reduced doses are appropriate. Immunosuppressive agents such as cyclophosphamide, mycophenolate mofetil, and azathioprine are used in cases resistant to corticosteroids. Treatment of severe lupus nephritis includes an induction phase and a maintenance phase. Cyclophosphamide, which improves renal survival but not patient survival, has been for many years the standard treatment for both phases of lupus nephritis. Mycophenolate mofetil appears to be an effective alternative treatment for many patients with lupus nephritis. Very close follow-up is needed to watch for potential side effects when immunosuppressants are given; these agents should be administered by clinicians experienced in their use. When cyclophosphamide is required, gonadotropin-releasing hormone analogs can be given to protect a woman against the risk of premature ovarian

failure. For patients with the **antiphospholipid syndrome**—the presence of antiphospholipid antibodies and compatible clinical events—anticoagulation is the treatment of choice (see Antiphospholipid Antibody Syndrome, below). Moderate intensive anticoagulation with warfarin to achieve an INR of 2.0–3.0 is as effective as more intensive regimens. Pregnant patients with recurrent fetal loss associated with antiphospholipid antibodies should be treated with low-molecular-weight heparin plus aspirin.

► Course & Prognosis

The prognosis for patients with systemic lupus appears to be considerably better than older reports implied. From both community settings and university centers, 10-year survival rates exceeding 85% are routine. In most patients, the illness pursues a relapsing and remitting course. Prednisone, often needed in doses of 40 mg/d orally or more during severe flares, can usually be tapered to low doses (5–10 mg/d) when the disease is inactive. However, there are some in whom the disease pursues a virulent course, leading to serious impairment of vital structures such as lung, heart, brain, or kidneys, and the disease may lead to death. With improved control of lupus activity and with increasing use of corticosteroids and immunosuppressive drugs, the mortality and morbidity patterns in lupus have changed. Mortality in SLE shows a bimodal pattern. In the early years after diagnosis, infections—especially with opportunistic organisms—are the leading cause of death, followed by active SLE, chiefly due to kidney or central nervous system disease. In later years, accelerated atherosclerosis, linked to chronic inflammation, becomes a major cause of death. Indeed, the incidence of myocardial infarction is five times higher in persons with SLE than in the general population. Therefore, it is especially important for SLE patients to avoid smoking and to minimize other conventional risk factors for atherosclerosis (eg, hypercholesterolemia, hypertension, obesity, and inactivity). Patients with SLE should receive influenza vaccination every year and pneumococcal vaccination every 5 years. Since some reports indicate that SLE patients have a higher risk of developing malignancy, preventive cancer screening recommendations should be followed assiduously. With more patients living longer, it has become evident that avascular necrosis of bone, affecting most commonly the hips and knees, is responsible for substantial morbidity. Still, the outlook for most patients with SLE has become increasingly favorable.

► When to Refer

- Appropriate management of SLE requires the active participation of a rheumatologist.
- The severity of organ involvement dictates referral to other subspecialists, such as nephrologists and pulmonologists.

► When to Admit

- Rapidly progressive glomerulonephritis, pulmonary hemorrhage, transverse myelitis, and other severe organ-

threatening manifestations of lupus usually require inpatient assessment and management.

- Severe infections, particularly in the setting of immunosuppressant therapy, should prompt admission.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

ESSENTIALS OF DIAGNOSIS

- Hypercoagulability, with recurrent thromboses in either the venous or arterial circulation.
- Thrombocytopenia is common.
- Pregnancy complications, specifically pregnancy losses after the first trimester.
- Lifelong anticoagulation with warfarin is recommended currently for patients with serious complications of this syndrome, as recurrent events are common.

► General Considerations

A primary **antiphospholipid antibody syndrome** (APS) is diagnosed in patients who have recurrent venous or arterial occlusions, recurrent fetal loss, or thrombocytopenia in the presence of antiphospholipid antibodies but not other features of SLE. In less than 1% of patients with antiphospholipid antibodies, a potentially devastating syndrome known as the “catastrophic antiphospholipid syndrome” occurs, leading to diffuse thromboses, thrombotic microangiopathy, and multiorgan system failure.

► Clinical Findings

A. Symptoms and Signs

Patients are often asymptomatic until suffering a thrombotic complication of this syndrome. Thrombotic events may occur in either the arterial or venous circulations. Thus, deep venous thromboses, pulmonary emboli, cerebrovascular accidents are typical clinical events among patients with the APS. Budd-Chiari syndrome, cerebral sinus vein thrombosis, myocardial or digital infarctions, and other thrombotic events also occur. A variety of other symptoms and signs are often attributed to the APS, including mental status changes, livedo reticularis, skin ulcers, microangiopathic nephropathy, and cardiac valvular dysfunction—typically mitral regurgitation that may mimic Libman-Sacks endocarditis. Livedo reticularis is strongly associated with the subset of patients with APS in whom arterial ischemic events develop.

B. Laboratory Findings

As noted in the discussion of SLE, three types of antiphospholipid antibody are believed to contribute to this syndrome: (1) anti-cardiolipin antibodies; (2) a “lupus anticoagulant” that prolongs certain coagulation tests (see below); and (3) an antibody associated with a biologic false-positive test for syphilis. Anti-cardiolipin antibodies are typically measured with enzyme immunoassays for either IgG or IgM. In general, IgG anti-cardiolipin antibodies are believed to be more pathologic than IgM. A clue to the presence of a lupus anticoagulant, which may occur in individuals who do not have SLE, may be detected by a prolongation of the partial thromboplastin time (which, paradoxically, is associated with a thrombotic tendency rather than a bleeding risk). A finding more sensitive for a lupus anticoagulant, however, is prolongation of a specialized coagulation assay known as the Russell viper venom time (RVVT). In the presence of a lupus anticoagulant, the RVVT is prolonged and does not correct with mixing studies. With the last type of antiphospholipid antibody, the patient has a positive rapid plasma reagin (RPR), but negative specific anti-treponemal assays.

► Differential Diagnosis

The exclusion of other autoimmune disorders, particularly those in the SLE spectrum, is essential, as such disorders may be associated with additional complications requiring alternative treatments. Other genetic or acquired conditions associated with hypercoagulability such as protein C, protein S, factor V Leiden, and antithrombin III deficiency should be excluded. The thrombocytopenia associated with APS must be distinguished from immune thrombocytopenic purpura. Catastrophic APS has a broad differential, including sepsis, pulmonary-renal syndromes, systemic vasculitis, disseminated intravascular coagulation, and thrombotic thrombocytopenic purpura.

► Treatment

Present recommendations for anticoagulation are to treat patients with warfarin to maintain an INR of 2.0–3.0. Patients who have recurrent thrombotic events on this level of anticoagulation may require higher INRs (> 3.0), but the bleeding risk increases substantially with this degree of anticoagulation. Guidelines indicate that patients with APS should be treated with anticoagulation for life. Because of the teratogenic effects of warfarin, subcutaneous heparin and baby aspirin is the usual approach to prevent pregnancy complications in women with APS. In patients with catastrophic APS, a three-pronged approach is taken in the acute setting: intravenous heparin, high doses of corticosteroids, and either intravenous immune globulin or plasmapheresis.

RAYNAUD PHENOMENON

ESSENTIALS OF DIAGNOSIS

- Paroxysmal bilateral symmetric pallor and cyanosis followed by rubor of the skin of the digits.
- Precipitated by cold or emotional stress; relieved by warmth.
- Primarily affects young women.
- Primary form benign; secondary form can cause digital ulceration or gangrene.

► General Considerations

Raynaud phenomenon (RP) is a syndrome of paroxysmal digital ischemia, most commonly caused by an exaggerated response of digital arterioles to cold or emotional stress. The initial phase of RP, mediated by excessive vasoconstriction, consists of well-demarcated digital pallor or cyanosis; the subsequent (recovery) phase of RP, caused by vasodilation, leads to intense hyperemia and rubor. Although RP chiefly affects fingers, it can also affect toes and other acral areas such as the nose and ears. RP is classified as primary (idiopathic or Raynaud disease) or secondary. Nearly one-third of the population reports being “sensitive to the cold” but does not experience the paroxysms of digital pallor, cyanosis, and erythema characteristic of RP. Primary RP occurs in 2–6% of adults, is especially common in young women, and poses more of a nuisance than a threat to good health. In contrast, secondary RP is less common, is chiefly associated with rheumatic diseases (especially scleroderma), and is frequently severe enough to cause digital ulceration or gangrene.

► Clinical Findings

In early attacks of RP, only one or two fingertips may be affected; as it progresses, all fingers down to the distal palm may be involved. The thumbs are rarely affected. During recovery there may be intense rubor, throbbing, paresthesia, pain, and slight swelling. Attacks usually terminate spontaneously or upon returning to a warm room or putting the extremity in warm water. The patient is usually asymptomatic between attacks. Sensory changes that often accompany vasomotor manifestations include numbness, stiffness, diminished sensation, and aching pain.

Primary RP appears first between ages 15 and 30, almost always in women. It tends to be mildly progressive and, unlike secondary RP (which may be unilateral and may involve only one or two fingers), symmetric involvement of the fingers of both hands is the rule. Spasm becomes more frequent and prolonged. Unlike secondary RP, primary RP does not cause digital pitting, ulceration, or gangrene.

Nailfold capillary abnormalities are among the earliest clues that a person has secondary rather than primary RP. The nailfold capillary pattern can be visualized by placing a drop of grade B immersion oil at the patient’s cuticle and

then viewing the area with an ophthalmoscope set to 20–40 diopters. Dilation or dropout of the capillary loops indicates the patient has a secondary form of RP, most commonly scleroderma (Table 20–12). While highly specific for secondary RP, nailfold capillary changes have a low sensitivity. Digital pitting or ulceration or other abnormal physical findings (eg, skin tightening, loss of extremity pulse, rash, swollen joints) can also provide evidence of secondary RP.

► Differential Diagnosis

Primary RP must be differentiated from the numerous causes of secondary RP (Table 20–12). The history and examination may suggest the diagnosis of systemic sclerosis (including its CREST variant), SLE, and mixed connective tissue disease; RP is occasionally the first manifestation of these disorders. The diagnosis of many of these rheumatic diseases can be confirmed with specific serologic tests (see Table 20–10).

The differentiation from Buerger disease (thromboangiitis obliterans) is usually not difficult, since thromboangiitis obliterans is generally a disease of men, particularly smokers; peripheral pulses are often diminished or absent; and, when RP occurs in association with thromboangiitis obliterans, it is usually in only one or two digits.

RP may occur in patients with the thoracic outlet syndromes. In these disorders, involvement is generally unilateral, and symptoms referable to brachial plexus compression tend to dominate the clinical picture. Carpal

tunnel syndrome should also be considered, and nerve conduction tests are appropriate in selected cases.

In acrocyanosis, cyanosis of the hands is permanent and diffuse; the sharp and paroxysmal line of demarcation with pallor does not occur with acrocyanosis. Frostbite may lead to chronic RP. Ergot poisoning, particularly due to prolonged or excessive use of ergotamine, must also be considered but is unusual.

A particularly severe form of RP occurs in up to one-third of patients receiving bleomycin and vincristine in combination, often for testicular cancer. Treatment is unsuccessful, and the problem persists even with discontinuation of the drugs.

Finally, RP may be mimicked by type I cryoglobulinemia, in which a monoclonal antibody cryoprecipitates in the cooler distal circulation. Type I cryoglobulinemia is usually associated with multiple myeloma or with lymphoproliferative disorders.

► Treatment

A. General Measures

Keeping the body warm is the cornerstone of initial therapy. Wearing warm shirts, coats, and hats will help prevent the exaggerated vasospasm that causes RP and that is not prevented by warming only the hands. The hands should be protected from injury at all times; wounds heal slowly, and infections are consequently hard to control. Softening and lubricating lotion to control the fissured dry skin should be applied to the hands frequently. Smoking should be stopped. For most patients with primary RP, general measures alone are sufficient to control symptoms. Medical or surgical therapy should be considered in patients who have severe symptoms or are experiencing tissue injury from digital ischemia.

B. Medications

Calcium channel blockers are first-line therapy for RP. Calcium channel blockers produce a modest benefit and are more effective in primary RP than secondary RP. Slow release nifedipine (30–180 mg/d orally), amlodipine (5–20 mg/d orally), felodipine, or nisoldipine are popular and more effective than verapamil and diltiazem. Other medications that are sometimes effective in treating RP include angiotensin-converting enzyme inhibitors, sympatholytic agents (eg, prazosin), topical nitrates, phosphodiesterase inhibitors (eg, sildenafil, tadalafil, and vardenafil), selective serotonin reuptake inhibitors (fluoxetine), and endothelin-receptor inhibitors (ie, bosentan).

C. Surgical Measures

Sympathectomy may be indicated when attacks have become frequent and severe, when they interfere with work and well being, and particularly when trophic changes have developed and medical measures have failed. Cervical sympathectomy is modestly effective for primary but not secondary RP. Digital sympathectomy may improve secondary RP.

► Prognosis

Primary PR is benign and largely a nuisance for affected individuals who are exposed to cold winters or excessive air conditioning. The prognosis of secondary RP depends on the severity of the underlying disease. Unfortunately, severe pain from ulceration and gangrene are not rare with scleroderma, especially the CREST variant.

Vinjar B et al. Oral vasodilators for primary Raynaud's phenomenon. *Cochrane Database Syst Rev.* 2008 Apr 16;(2):CD006687. [PMID: 18425964]

SCLERODERMA (Systemic Sclerosis)

ESSENTIALS OF DIAGNOSIS

- ▶ Limited disease (80% of patients): thickening of skin confined to the face, neck, and distal extremities.
- ▶ Diffuse disease (20%): widespread thickening of skin, including truncal involvement, with areas of increased pigmentation and depigmentation.
- ▶ Raynaud phenomenon and antinuclear antibodies are present in virtually all patients.
- ▶ Systemic features of gastroesophageal reflux, hypomotility of gastrointestinal tract, pulmonary fibrosis, pulmonary hypertension, and renal involvement.

► General Considerations

Scleroderma (systemic sclerosis) is a rare chronic disorder characterized by diffuse fibrosis of the skin and internal organs. Symptoms usually appear in the third to fifth decades, and women are affected two to three times as frequently as men.

Two forms of scleroderma are generally recognized: limited (80% of patients) and diffuse (20%). In limited scleroderma, which is also known as the CREST syndrome (representing calcinosis cutis, Raynaud phenomenon, esophageal motility disorder, sclerodactyly, and telangiectasia), the hardening of the skin (scleroderma) is limited to the face and hands. In contrast, in diffuse scleroderma, the skin changes also involve the trunk and proximal extremities. Tendon friction rubs over the forearms and shins occur uniquely (but not universally) in diffuse scleroderma. In general, patients with limited scleroderma have better outcomes than those with diffuse disease, largely because kidney disease or interstitial lung disease rarely develops in patients with limited disease. Cardiac disease is also more characteristic of diffuse scleroderma. Patients with limited disease, however, are more susceptible to digital ischemia, leading to finger loss, and to life-threatening pulmonary hypertension. Small and large bowel hypomotility, which may occur in either form of scleroderma, can cause constipation alternating with diarrhea, malabsorption due to bacterial overgrowth, pseudoobstruction, and severe bowel distension with rupture.

► Clinical Findings

A. Symptoms and Signs

Raynaud phenomenon is usually the initial manifestation and can precede other signs and symptoms by years in cases of limited scleroderma. Polyarthralgia, weight loss, and malaise are common early features of diffuse scleroderma but are infrequent in limited scleroderma. Cutaneous disease usually, but not always, develops before visceral involvement and can manifest initially as non-pitting subcutaneous edema associated with pruritus. With time the skin becomes thickened and hidebound, with loss of normal folds. Telangiectasia, pigmentation, and depigmentation are characteristic. Ulceration about the fingertips and subcutaneous calcification are seen. Dysphagia and symptoms of reflux due to esophageal dysfunction are common and result from abnormalities in motility and later from fibrosis. Fibrosis and atrophy of the gastrointestinal tract cause hypomotility. Large-mouthed diverticuli occur in the jejunum, ileum, and colon. Diffuse pulmonary fibrosis and pulmonary vascular disease are reflected in restrictive lung physiology and low diffusing capacities. Cardiac abnormalities include pericarditis, heart block, myocardial fibrosis, and right heart failure secondary to pulmonary hypertension. Scleroderma renal crisis, resulting from intimal proliferation of smaller renal arteries and usually associated with hypertension, is a marker for a poor outcome even though many cases can be treated effectively with angiotensin-converting enzyme inhibitors.

B. Laboratory Findings

Mild anemia is often present. In scleroderma renal crisis, the peripheral blood smear shows findings consistent with a microangiopathic hemolytic anemia (due to mechanical damage to red cells from diseased small vessels). Elevation of the ESR is unusual. Proteinuria and cylindruria appear in association with renal involvement. Antinuclear antibody tests are nearly always positive, frequently in high titers (Table 20–10). The scleroderma antibody (anti-SCL-70), directed against topoisomerase III, is found in one-third of patients with diffuse systemic sclerosis and in 20% of those with CREST syndrome. Although present in only a small number of patients with diffuse scleroderma, anti-SCL-70 antibodies may portend a poor prognosis, with a high likelihood of serious internal organ involvement (eg, interstitial lung disease). Anticentromere antibodies are seen in 50% of those with CREST syndrome and in 1% of individuals with diffuse scleroderma (Table 20–10). Anticentromere antibodies are highly specific for limited scleroderma, but they also occur occasionally in overlap syndromes.

► Differential Diagnosis

Early in its course, scleroderma can cause diagnostic confusion with other causes of Raynaud phenomenon, particularly SLE, mixed connective tissue disease, and the inflammatory myopathies. Scleroderma can be mistaken for other disorders characterized by skin hardening. Eosinophilic fasciitis is a rare disorder presenting with skin

changes that resemble diffuse scleroderma. The inflammatory abnormalities, however, are limited to the fascia rather than the dermis and epidermis. Moreover, patients with eosinophilic fasciitis are distinguished from those with scleroderma by the presence of peripheral blood eosinophilia, the absence of Raynaud phenomenon, the good response to prednisone, and an association (in some cases) with paraproteinemias. Diffuse skin thickening and visceral involvement are features of scleromyxedema; the presence of a paraprotein, the absence of Raynaud phenomenon, and distinct skin histology point to scleromyxedema. Diabetic cheiropathy typically develops in long-standing, poorly controlled diabetes and can mimic sclerodactyly. Nephrogenic fibrosing dermopathy produces thickening and hardening of the skin of the trunk and extremities in patients with chronic kidney disease; exposure to gadolinium may play a pathogenic role. Morphea and linear scleroderma cause sclerodermatous changes limited to circumscribed areas of the skin and usually have excellent outcomes.

▶ Treatment

Treatment of scleroderma is symptomatic and supportive and focuses on the organ systems involved. There is no effective therapy for the underlying disease process. However, interventions for management of specific organ manifestations of this disease have improved substantially. Severe Raynaud syndrome may respond to calcium channel blockers, eg, long-acting nifedipine, 30–120 mg/d orally, or to losartan, 50 mg/d orally, or to sildenafil 50 mg orally twice daily. Patients with esophageal disease should take medications in liquid or crushed form. Esophageal reflux can be reduced and the risk of scarring diminished by avoidance of late-night meals and by the use of proton pump inhibitors (eg, omeprazole, 20–40 mg/d orally), the only drugs that achieve near-complete inhibition of gastric acid production, are remarkably effective for refractory esophagitis. Patients with delayed gastric emptying maintain their weight better if they eat small, frequent meals and remain upright for at least 2 hours after eating. Long-term octreotide (0.1 mg subcutaneously twice daily), a somatostatin analog, helps some patients with bacterial overgrowth and pseudoobstruction. Malabsorption due to bacterial overgrowth also responds to antibiotics, eg, tetracycline, 500 mg four times orally daily, often prescribed cyclically. The hypertensive crises associated with systemic sclerosis renal crisis must be treated early and aggressively (in the hospital) with angiotensin-converting enzyme inhibitors, eg, captopril, initiated at 25 mg orally every 6 hours and titrated up as needed to a maximum of 100 mg every 6 hours. Apart from the patient with myositis, prednisone has little or no role in the treatment of scleroderma; high doses (> 15 mg daily) have been associated with scleroderma renal crisis. Cyclophosphamide improves dyspnea and pulmonary function tests modestly in patients with severe interstitial lung disease; this highly toxic drug should only be administered by physicians familiar with its use. Bosentan, an endothelin receptor antagonist, improves exercise capacity and cardiopulmonary hemodynamics in patients with pulmonary hypertension

and helps prevent digital ulceration. Sildenafil or prostaglandins (delivered by continuous intravenous infusion or intermittent inhalation) may also be useful in treating pulmonary hypertension. At an experimental level, immunoblastic therapy with or without stem cell rescue has achieved promising results for some patients with severe, rapidly progressive diffuse scleroderma.

The 9-year survival rate in scleroderma averages approximately 40%. The prognosis tends to be worse in those with diffuse scleroderma, in blacks, in males, and in older patients. Lung disease is now the number one cause of mortality. Death from advanced chronic kidney disease or heart failure is also common. Those persons in whom severe internal organ involvement does not develop in the first 3 years have a substantially better prognosis, with 72% surviving at least 9 years. Breast and lung cancer may be more common in patients with scleroderma.

▶ When to Refer

- Appropriate management of scleroderma requires frequent consultations with a rheumatologist.
- Severity of organ involvement dictates referral to other subspecialists, such as pulmonologists or gastroenterologists.

IDIOPATHIC INFLAMMATORY MYOPATHIES (Polymyositis & Dermatomyositis)

ESSENTIALS OF DIAGNOSIS

- ▶ Bilateral proximal muscle weakness.

- ▶ Characteristic cutaneous manifestations in dermatomyositis (Gottron papules, heliotrope rash).
- ▶ Diagnostic tests: elevated creatine kinase, muscle biopsy, electromyography, MRI.
- ▶ Increased risk of malignancy, particularly in dermatomyositis.
- ▶ Inclusion body myositis can mimic polymyositis but is less responsive to treatment.

▶ General Considerations

Polymyositis and dermatomyositis are systemic disorders of unknown cause whose principal manifestation is muscle weakness. Although their clinical presentations (aside from the presence of certain skin findings in dermatomyositis, some of which are pathognomonic) and treatments are similar, the two diseases are pathologically quite distinct. They affect persons of any age group, but the peak incidence is in the fifth and sixth decades of life. Women are affected twice as commonly as men, and the diseases (particularly polymyositis) also occur more often among blacks than whites. There is an increased risk of malignancy in adult patients with dermatomyositis. Indeed, up to one patient in four with dermatomyositis has an occult malignancy. Malignancies may be evident at the time of presentation with the muscle disease but may not be detected until months afterward in some cases. Rare patients with dermatomyositis have skin disease without overt muscle involvement, a condition termed “dermatomyositis sine myositis.” Myositis may also be associated with other connective tissue diseases, especially scleroderma, lupus, mixed connective tissue disease, and Sjögren syndrome.

▶ Clinical Findings

A. Symptoms and Signs

Polymyositis may begin abruptly, but the usual presentation is one of gradual and progressive muscle weakness. The weakness chiefly involves proximal muscle groups of the upper and lower extremities as well as the neck. Leg weakness (eg, difficulty in rising from a chair or climbing stairs) typically precedes arm symptoms. In contrast to myasthenia gravis, polymyositis and dermatomyositis do not cause facial or ocular muscle weakness. Pain and tenderness of affected muscles occur in one-fourth of cases, but these are rarely the chief complaints. About one-fourth of patients have dysphagia. In contrast to scleroderma, which affects the smooth muscle of the lower esophagus and can cause a “sticking” sensation below the sternum, polymyositis or dermatomyositis involves the striated muscles of the upper pharynx and can make initiation of swallowing difficult. Muscle atrophy and contractures occur as late complications of advanced disease. Clinically significant myocarditis is uncommon even though there is often creatine kinase-MB elevation. Patients who are bed-bound from myositis should be screened for respiratory muscle weakness that can be severe enough to cause CO₂ retention and can progress to require mechanical ventilation.

In **dermatomyositis**, the characteristic rash is dusky red and may appear in a malar distribution mimicking the classic rash of SLE. Facial erythema beyond the malar distribution is also characteristic of dermatomyositis. Erythema also occurs over other areas of the face, neck, shoulders, and upper chest and back (“shawl sign”). Periorbital edema and a purplish (heliotrope) suffusion over the eyelids are typical signs (Plate 84). Periungual erythema, dilations of nailbed capillaries, and scaly patches over the dorsum of PIP and MCP joints (Gottron sign) are highly suggestive. Scalp involvement by dermatomyositis may mimic psoriasis. Infrequently, the cutaneous findings of this disease precede the muscle inflammation by weeks or months. Diagnosing polymyositis in patients over age 70 years can be difficult because weakness may be overlooked or attributed erroneously to idiopathic frailty. Polymyositis can remain undiagnosed or will be misdiagnosed as hepatitis because of elevations in alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels. A subset of patients with polymyositis and dermatomyositis develop the “antisynthetase syndrome,” a group of findings including inflammatory arthritis, Raynaud phenomenon, interstitial lung disease, and often severe muscle disease associated with certain autoantibodies (eg, anti-Jo1 antibodies).

B. Laboratory Findings

Measurement of serum levels of muscle enzymes, especially creatine kinase and aldolase, is most useful in diagnosis and in assessment of disease activity. Anemia is uncommon. The ESR and C-reactive protein are often normal and are not reliable indicators of disease activity. Rheumatoid factor is found in a minority of patients. Antinuclear antibodies are present in many patients, especially those who have an associated connective tissue disease (Table 20-10). Three autoantibodies are seen exclusively in patients with myositis. The most common myositis-specific antibody, anti-Jo-1 antibody, is seen in the subset of patients who have associated interstitial lung disease (Table 20-10). The other myositis-specific autoantibodies are anti-Mi-2, associated with dermatomyositis, and anti-SRP (anti-signal recognition particle), associated with rapidly progressive, severe polymyositis. In the absence of the anti-synthetase syndrome, chest radiographs are usually normal. Electromyographic abnormalities consisting of polyphasic potentials, fibrillations, and high-frequency action potentials are helpful in establishing the diagnosis. None of the studies are specific. MRI can detect early and patchy muscle involvement, can guide biopsies, and may prove to be more useful than electromyography. The malignancies most commonly associated with dermatomyositis in descending order of frequency are ovarian, lung, pancreatic, stomach, colorectal, and non-Hodgkins lymphoma. The search for an occult malignancy should begin with a history and physical examination, supplemented with a complete blood count, comprehensive biochemical panel, serum protein electrophoresis, and urinalysis, and should include age- and risk-appropriate cancer screening tests. Given the especially strong association of ovarian carcinoma and dermatomyositis, pelvic ultrasonography and CT scanning and CA-125 levels may be useful in

women. No matter how extensive the initial screening, some malignancies will not become evident for months after the initial presentation.

C. Muscle Biopsy

Biopsy of clinically involved muscle is the only specific diagnostic test. The pathology findings in polymyositis and dermatomyositis are distinct. Although both include lymphoid inflammatory infiltrates, the findings in dermatomyositis are localized to perivascular regions and there is evidence of humoral and complement-mediated destruction of microvasculature associated with the muscle. In addition to its vascular orientation, the inflammatory infiltrate in dermatomyositis centers on the interfascicular septa and is located around, rather than in, muscle fascicles. A pathologic hallmark of dermatomyositis is perifascicular atrophy. In contrast, the pathology of polymyositis characteristically includes endomysial infiltration of the inflammatory infiltrate. Owing to the sometimes patchy distribution of pathologic abnormalities, however, false-negative biopsies sometimes occur in both disorders.

► Differential Diagnosis

Muscle inflammation may occur as a component of SLE, scleroderma, Sjögren syndrome, and overlap syndromes. In those cases, associated findings usually permit the precise diagnosis of the primary condition.

Inclusion body myositis, because of its tendency to mimic polymyositis, is a common cause of “treatment-resistant polymyositis.” In contrast to the epidemiologic features of polymyositis, however, the typical inclusion body myositis patient is white, male, and over the age of 50. The onset of inclusion body myositis is even more insidious than that of polymyositis or dermatomyositis (eg, occurring over years rather than months), and asymmetric distal motor weakness is common in inclusion body myositis. Creatine kinase levels in inclusion body myositis are often minimally elevated and are normal in 25%. Muscle biopsy shows characteristic intracellular vacuoles by light microscopy either tubular or filamentous inclusions in the nucleus or cytoplasm by electron microscopy. Inclusion body myositis is less likely to respond to therapy.

Hyperthyroidism and hypothyroidism may both be associated with proximal muscle weakness. Hypothyroidism is associated also with elevations of creatine kinase. Patients with polymyalgia rheumatica are over the age of 50 and—in contrast to patients with polymyositis—have pain but no objective weakness; creatine kinase levels are normal. Disorders of the peripheral and central nervous systems (eg, chronic inflammatory polyneuropathy, multiple sclerosis, myasthenia gravis, Eaton-Lambert disease, and amyotrophic lateral sclerosis) can produce weakness but are distinguished by characteristic symptoms and neurologic signs and often by distinctive electromyographic abnormalities. A number of systemic vasculitides (polyarteritis nodosa, microscopic polyangiitis, the Churg-Strauss syndrome, Wegener granulomatosis, and mixed cryoglobulinemia) can produce profound weakness through vasculitic neuropathy. The muscle weakness associated with

these disorders, however, is typically distal and asymmetric, at least in the early stages.

Many drugs, including corticosteroids, alcohol, clofibrate, penicillamine, tryptophan, and hydroxychloroquine, can produce proximal muscle weakness. Chronic use of colchicine at doses as low as 0.6 mg twice a day in patients with moderate chronic kidney disease can produce a mixed neuropathy-myopathy that mimics polymyositis. The weakness and muscle enzyme elevation reverse with cessation of the drug. HMG-CoA reductase inhibitors, which are frequently used to treat hypercholesterolemia, can cause myopathy and rhabdomyolysis. Although only about 0.1% of patients taking a statin drug alone develop myopathy, concomitant administration of other drugs (especially gemfibrozil, cyclosporine, niacin, macrolide antibiotics, azole antifungals, and protease inhibitors) increases the risk. Statin-induced muscle inflammation resolves after cessation of these medications. Polymyositis can occur as a complication of HIV or HTLV-I infection and with zidovudine therapy as well.

► Treatment

Most patients respond to corticosteroids. Often a daily dose of 40–60 mg or more of oral prednisone is required initially. The dose is then adjusted downward while monitoring muscle strength and serum levels of muscle enzymes. Long-term use of corticosteroids is often needed, and the disease may recur or reemerge when they are withdrawn. Patients with an associated neoplasm have a poor prognosis, although remission may follow treatment of the tumor; corticosteroids may or may not be effective in these patients. In patients resistant or intolerant to corticosteroids, therapy with methotrexate or azathioprine may be helpful. Intravenous immune globulin is effective for dermatomyositis resistant to prednisone. Mycophenolate mofetil (1.0–1.5 g orally twice daily) may be useful as a steroid-sparing agent. Since the rash of dermatomyositis is often photosensitive, patients should limit sun exposure. Hydroxychloroquine (200–400 mg/d orally not to exceed 6.5 mg/kg) can also help ameliorate the skin disease.

► When to Refer

- Appropriate management of myositis usually requires frequent consultations with a rheumatologist or neurologist.
- Severe lung disease may require consultation with a pulmonologist.

► When to Admit

- Signs of rhabdomyolysis.
- Respiratory insufficiency with hypoxia or carbon dioxide retention.

MIXED CONNECTIVE TISSUE DISEASE & OVERLAP SYNDROMES

Many patients with symptoms and signs compatible with a connective tissue disease have features consistent with more than one type of rheumatic disease. Special attention has been drawn to antinuclear antibody–positive patients who have overlapping features of SLE, scleroderma, and inflammatory myopathy together with autoantibodies to ribonuclear protein (RNP). Some consider these patients to have a distinct entity (“mixed connective tissue disease”), and others view this as a subset of SLE characterized by a higher prevalence of Raynaud phenomenon, polyarthritis, myositis, and pulmonary hypertension and a lower incidence of renal involvement. Other patients have features of more than one connective tissue disease (eg, rheumatoid arthritis and SLE, SLE and scleroderma) in the absence of anti-RNP antibodies and are referred to as having an “overlap syndrome.” Treatments are guided more by the distribution and severity of patients’ organ system involvement than by therapies specific to these overlap syndromes.

Vegh J et al. Clinical and immunoserological characteristics of mixed connective tissue disease associated with pulmonary arterial hypertension. *Scand J Immunol*. 2006 Jul;64(1):69–76. [PMID: 16784493]

SJÖGREN SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Women are 90% of patients; the average age is 50 years.
- ▶ Dryness of eyes and dry mouth (sicca components) are the most common features; they occur alone or in association with rheumatoid arthritis or other connective tissue disease.
- ▶ Rheumatoid factor and other autoantibodies common.
- ▶ Increased incidence of lymphoma.

▶ General Considerations

Sjögren syndrome is a systemic autoimmune disorder whose clinical presentation is usually dominated by dryness of the eyes and mouth due to immune-mediated dysfunction of the lacrimal and salivary glands. The disorder is predominantly seen in women, with a ratio of 9:1; most cases develop between the ages of 40 and 60 years. Sjögren syndrome can occur in isolation (“primary” Sjögren syndrome) or in association with another rheumatic disease. Sjögren syndrome is most frequently associated with rheumatoid arthri-

tis but also occurs with SLE, primary biliary cirrhosis, scleroderma, polymyositis, Hashimoto thyroiditis, polyarthritis, and interstitial pulmonary fibrosis.

▶ Clinical Findings

A. Symptoms and Signs

Keratoconjunctivitis sicca results from inadequate tear production caused by lymphocyte and plasma cell infiltration of the lacrimal glands. Ocular symptoms are usually mild. Burning, itching, and the sensation of having a foreign body or a grain of sand in the eye occur commonly. For some patients, the initial manifestation is the inability to tolerate wearing contact lenses. Many patients with more severe ocular dryness notice ropy secretions across their eyes, especially in the morning. Photophobia may signal corneal ulceration resulting from severe dryness. For most patients, symptoms of dryness of the mouth (xerostomia) dominate those of dry eyes. Patients frequently complain of a “cotton mouth” sensation and difficulty swallowing foods, especially dry foods like crackers, unless they are washed down with liquids. The persistent oral dryness causes most patients to carry water bottles or other liquid dispensers from which they sip constantly. A few patients have such severe xerostomia that they have difficulty speaking. Persistent xerostomia results often in rampant dental caries; caries at the gum line strongly suggest Sjögren syndrome. Some patients are most troubled by loss of taste and smell. Parotid enlargement, which may be chronic or relapsing, develops in one-third of patients. Desiccation may involve the nose, throat, larynx, bronchi, vagina, and skin.

Systemic manifestations include dysphagia, vasculitis, pleuritis, obstructive lung disease (in the absence of smoking), neuropsychiatric dysfunction (most commonly peripheral neuropathies), and pancreatitis; they may be related to the associated diseases noted above. Renal tubular acidosis (type I, distal) occurs in 20% of patients. Chronic interstitial nephritis, which may result in impaired kidney function, may be seen. A glomerular lesion is rarely observed but may occur secondary to associated cryoglobulinemia.

B. Laboratory Findings

Laboratory findings include mild anemia, leukopenia, and eosinophilia. Polyclonal hypergammaglobulinemia, rheumatoid factor positivity (70%), and antinuclear antibodies (95%) are all common findings. Antibodies against the cytoplasmic antigens SS-A and SS-B (also called Ro and La, respectively) are often present in primary Sjögren syndrome and tend to correlate with the presence of extraglandular manifestations (Table 20–10). Thyroid-associated autoimmunity is a common finding among patients with Sjögren syndrome.

Useful ocular diagnostic tests include the Schirmer test, which measures the quantity of tears secreted. Lip biopsy, a simple procedure, reveals characteristic lymphoid foci in accessory salivary glands. Biopsy of the parotid gland should be reserved for patients with atypical presentations such as unilateral gland enlargement that suggest a neoplastic process.

► Differential Diagnosis

Isolated complaints of dry mouth are most commonly due to medication side effects. Chronic hepatic C can cause sicca symptoms. Minor salivary gland biopsies reveal lymphocytic infiltrates but not to the extent of Sjögren syndrome, and tests for anti-SS-A and anti-SS-B are negative. Diffuse infiltration of CD8 T cells producing parotid gland enlargement can develop in HIV-infected individuals. Involvement of the lacrimal or salivary glands, or both in sarcoidosis can mimic Sjögren syndrome; biopsies reveal noncaseating granulomas. Rarely, amyloid deposits in the lacrimal and salivary glands produce sicca symptoms.

► Treatment & Prognosis

Treatment of sicca symptoms is symptomatic and supportive. Artificial tears applied frequently will relieve ocular symptoms and avert further desiccation. The mouth should be kept well lubricated. Sipping water frequently or using sugar-free gums and hard candies usually relieves dry mouth symptoms. Pilocarpine (5 mg orally four times daily) and the acetylcholine derivative cevimeline (30 mg orally three times daily) may improve xerostomia symptoms. Atropinic drugs and decongestants decrease salivary secretions and should be avoided. A program of oral hygiene, including fluoride treatment, is essential in order to preserve dentition. If there is an associated rheumatic disease, its systemic treatment is not altered by the presence of Sjögren syndrome.

Although Sjögren syndrome may compromise patients' quality of life significantly, the disease is usually consistent with a normal life span. Poor prognoses are influenced mainly by the presence of systemic features associated with underlying disorders, the development in some patients of lymphocytic vasculitis, the occurrence of a painful peripheral neuropathy, and the complication (in a minority of patients) of lymphoma. The patients (3–10% of the total Sjögren population) at greatest risk for developing lymphoma are those with severe exocrine dysfunction, marked parotid gland enlargement, splenomegaly, vasculitis, peripheral neuropathy, anemia, and mixed monoclonal cryoglobulinemia.

► When to Refer

- Presence of systemic symptoms or signs.
- Symptoms or signs of ocular dryness not responsive to artificial tears.

► When to Admit

Presence of severe systemic signs such as vasculitis unresponsive to outpatient management.

RHABDOMYOLYSIS

ESSENTIALS OF DIAGNOSIS

- Associated with crush injuries to muscle, prolonged immobility, drug toxicities, hypothermia, and other causes.
- Massive acute elevations of muscle enzymes that peak quickly and usually resolve within days once the inciting injury has been identified and removed.

► General Considerations

Defined strictly, rhabdomyolysis is necrosis of skeletal muscle and may be encountered in a wide variety of clinical settings, alone or in concert with other disorders of muscle. When the term “rhabdomyolysis” is used without being otherwise defined, healthcare providers ordinarily think of the syndrome of crush injury to muscle, associated with myoglobinuria, acute kidney injury, markedly elevated creatine kinase levels and, frequently, multiorgan failure as a consequence of other complications of the trauma. Acute kidney injury in myoglobinuria is caused by tubular injury resulting from excessive quantities of filtered myoglobin (See Acute Tubular Necrosis in Chapter 22). This complication is nearly always associated with hypovolemia. Experimental models of severe rhabdomyolysis in which blood volume and pressure are maintained ordinarily are not associated with acute tubular necrosis. From a practical point of view, however, many patients who suffer crush injuries are indeed volume-contracted, and oliguric renal failure is encountered routinely.

In addition to crush injuries, prolonged immobility, particularly after drug overdose or intoxication and commonly associated with exposure hypothermia, may be associated with rhabdomyolysis. Often there is little evidence for muscle injury on external examination of these patients—and specifically, neither myalgia nor myopathy presents. The clue to muscle necrosis in such individuals may be a urinary dipstick testing positive for blood in the absence of red cells in the sediment. This false-positive finding is due to myoglobinuria, which results in a positive reading for blood. Such an abnormality is investigated by serum creatine kinase determination. Other studies elevated in rhabdomyolysis include ALT and lactate dehydrogenase (LDH)—and once again, these studies may be obtained for other reasons, such as suspected liver disease or hemolysis. When disproportionately elevated, it is prudent to establish that they are not of muscle origin by confirming them with creatine kinase determination.

A number of other causes of rhabdomyolysis are encountered. Statins, agents used commonly to treat hyper-

lipidemia, are common offenders (see above). The presence of compromised kidney and liver function, diabetes, and hypothyroidism as well as concomitant use of other medications all increase the risk of rhabdomyolysis in those patients taking statins. Both acute alcohol intoxication and even intramuscular injections may cause some elevation of creatine kinase.

► Treatment

Vigorous fluid resuscitation (4–6 L/d, with careful monitoring for fluid overload), mannitol (100 mg/d), and urine alkalinization are suggested early in the course, but definitive evidence for the efficacy of these measures is lacking. On occasion, oliguric tubular necrosis may be converted to a nonoliguric variety, and—though the prognosis for recovery of kidney function and mortality is the same—many clinicians believe it is easier to care for nonoliguric disease because hyperkalemia and pulmonary edema are less important concerns. Myopathic complications of statins usually resolve within several weeks of discontinuing the drug.

VASCULITIS SYNDROMES

“Vasculitis” is a heterogeneous group of disorders characterized by inflammation within the walls of affected blood

Table 20–13. Classification scheme of primary vasculitides according to size of predominant blood vessels involved.

| |
|--|
| Predominantly large-vessel vasculitides |
| Takayasu arteritis |
| Giant cell arteritis (temporal arteritis) |
| Behçet disease ¹ |
| Predominantly medium-vessel vasculitides |
| Polyarteritis nodosa |
| Buergler disease |
| Predominantly small-vessel vasculitides |
| Immune-complex mediated |
| Cutaneous leukocytoclastic angitis (“hypersensitivity vasculitis”) |
| Henoch-Schönlein purpura |
| Essential cryoglobulinemia ² |
| “ANCA-associated” disorders ³ |
| Wegener granulomatosis ² |
| Microscopic polyangiitis ² |
| Churg-Strauss syndrome ² |

¹May involve small, medium, and large-sized blood vessels.

²Frequent overlap of small and medium-sized blood vessel involvement.

³Not all forms of these disorders are always associated with ANCA. ANCA, antineutrophil cytoplasmic antibodies.

Table 20–14. Typical clinical manifestations of large-, medium-, and small-vessel involvement by vasculitis.

| Large | Medium | Small |
|--|------------------------|--|
| Constitutional symptoms: fever, weight loss, malaise, arthralgias/arthritis | | |
| Limb claudication | Cutaneous nodules | Purpura |
| Asymmetric blood pressures | Ulcers | Vesiculobullous lesions |
| Absence of pulses | Livedo reticularis | Urticaria |
| Bruits | Digital gangrene | Glomerulonephritis |
| Aortic dilation | Mononeuritis multiplex | Alveolar hemorrhage |
| | Microaneurysms | Cutaneous extravascular necrotizing granulomas |
| | | Splinter hemorrhages |
| | | Uveitis |
| | | Episcleritis |
| | | Scleritis |

vessels. The major forms of primary systemic vasculitis are listed in Table 20–13. The first consideration in classifying cases of vasculitis is the size of the major vessels involved: large, medium, or small. The presence of the clinical signs and symptoms shown in Table 20–14 help distinguish among these three groups. After determining the size of the major vessels involved, other issues that contribute to the classification include the following:

- Does the process involve arteries, veins, or both?
- What are the patient’s demographic characteristics (age, gender, ethnicity, smoking status)?
- Which organs are involved?
- Is there evidence of immune complex deposition?
- Is there granulomatous inflammation on tissue biopsy?
- Are antineutrophil cytoplasmic antibodies (ANCA) present?

In addition to the disorders considered to be primary vasculitides, there are also multiple forms of vasculitis that are associated with other known underlying conditions. These “secondary” forms of vasculitis occur in the setting of chronic infections (eg, hepatitis B or C, subacute bacterial endocarditis), connective tissue disorders, inflammatory bowel disease, malignancies, and reactions to medications. Only the major primary forms of vasculitis are discussed here.

POLYARTERITIS NODOSA

ESSENTIALS OF DIAGNOSIS

- Medium-sized arteries are always affected; smaller arterioles are sometimes involved; lung is spared but kidney often affected, causing renin-mediated hypertension.
- Clinical findings depend on the arteries involved.
- Common features include fever, abdominal pain, livedo reticularis, mononeuritis multiplex, anemia, and ele-

vated acute phase reactants (ESR or C-reactive protein or both).

- ▶ Associated with hepatitis B (10% of cases).

▶ General Considerations

Polyarteritis nodosa, described in 1866, is acknowledged widely as the first form of vasculitis reported in the medical literature. For many years, all forms of inflammatory vascular disease were termed “polyarteritis nodosa.” In recent decades, numerous subtypes of vasculitis have been recognized, greatly narrowing the spectrum of vasculitis called polyarteritis nodosa. Although the term is reserved currently for necrotizing arteritis of medium-sized vessels that has a predilection for involving the skin, peripheral nerves, mesenteric vessels (including renal arteries), heart, and brain, the disease can involve most organs. Polyarteritis nodosa is relatively rare, with a prevalence of about 30 per 1 million people. Approximately 10% of cases of polyarteritis nodosa are caused by hepatitis B. Most cases of hepatitis B–associated disease occur within 6 months of hepatitis B infection.

Stone JH. Vasculitis: a collection of pearls and myths. *Rheum Dis Clin North Am.* 2007 Nov;33(4):691–739. [PMID: 18037113]

▶ Clinical Findings

A. Symptoms and Signs

The clinical onset is usually insidious, with fever, malaise, weight loss, and other symptoms developing over weeks to months. Pain in the extremities is often a prominent early feature caused by arthralgia, myalgia (particularly affecting the calves), or neuropathy. The combination of mononeuritis multiplex (with the most common finding being foot-drop) and features of a systemic illness is one of the earliest specific clues to the presence of an underlying vasculitis. Polyarteritis nodosa is among the forms of vasculitis most commonly associated with vasculitic neuropathy.

In polyarteritis nodosa, the typical skin findings—livedo reticularis, subcutaneous nodules, and skin ulcers—reflect the involvement of deeper, medium-sized blood vessels. Digital gangrene is not an unusual occurrence. The most common cutaneous presentation is lower extremity ulcerations, usually occurring near the malleoli. Involvement of the renal arteries leads to a renin-mediated hypertension (much less characteristic of vasculitides involving smaller blood vessels). For unclear reasons, classic polyarteritis nodosa seldom (if ever) involves the lung, with the occasional exception of the bronchial arteries.

Abdominal pain—particularly diffuse periumbilical pain precipitated by eating—is common but often difficult to attribute to mesenteric vasculitis in the early stages. Nausea and vomiting are common symptoms. Infarction compromises the function of major viscera and may lead to acalculous cholecystitis or appendicitis. Some patients present dramatically with an acute abdomen caused by mesenteric vasculitis and gut perforation or with hypotension resulting from rupture of a microaneurysm in the liver, kidney, or bowel.

Subclinical cardiac involvement is common in polyarteritis nodosa, and overt cardiac dysfunction occasionally occurs (eg, myocardial infarction secondary to coronary vasculitis, or myocarditis).

B. Laboratory Findings

Most patients with polyarteritis nodosa have a slight anemia, and leukocytosis is common. Acute phase reactants are often (but not always) strikingly elevated. A major challenge in making the diagnosis of polyarteritis nodosa, however, is the absence of a disease-specific serologic test (eg, an autoantibody). Patients with classic polyarteritis nodosa are ANCA-negative and may have low titers of rheumatoid factor or antinuclear antibodies, both of which are nonspecific findings. In patients with polyarteritis nodosa, appropriate serologic tests for active hepatitis B infection must be performed.

C. Biopsy and Angiography

The diagnosis of polyarteritis nodosa requires confirmation with either a tissue biopsy or an angiogram. Biopsies of symptomatic sites such as skin (from the edge of an ulcer or the center of a nodule), nerve, or muscle have sensitivities of approximately 70%. The least invasive tests should usually be obtained first, but biopsy of an involved organ is essential. If performed by experienced physicians, tissue biopsies normally have high benefit-risk ratios because of the importance of establishing the diagnosis. Patients in whom polyarteritis nodosa is suspected—eg, on the basis of mesenteric ischemia or new-onset hypertension occurring in the setting of a systemic illness—may be diagnosed by the angiographic finding of aneurysmal dilations in the renal, mesenteric, or hepatic arteries. Angiography must be performed cautiously in patients with baseline renal dysfunction.

▶ Treatment

For polyarteritis nodosa, corticosteroids in high doses (up to 60 mg of oral prednisone daily) may control fever and constitutional symptoms and heal vascular lesions. Pulse methylprednisolone (eg, 1 g intravenously daily for 3 days) may be necessary for patients who are critically ill at presentation. Immunosuppressive agents, especially cyclophosphamide, lower the risk of disease-related death and morbidity among patients who have severe disease. For patients with polyarteritis nodosa associated with hepatitis B, the preferred treatment regimen is a short course of prednisone accompanied by antiviral therapy and plasmapheresis (three times a week for up to 6 weeks).

▶ Prognosis

Without treatment, the 5-year survival rate in these disorders is poor—on the order of 10%. With appropriate therapy, remissions are possible in many cases and the 5-year survival rate has improved to 60–90%. Poor prognostic factors are chronic kidney disease with serum creatinine > 1.6 mg/dL, proteinuria > 1 g/d, gastrointestinal ischemia, central nervous system disease, and cardiac involvement. In the absence of any of these five factors, 5-year survival is

nearly 90%. Survival at 5 years drops to 75% with one poor prognostic factor present and to about 50% with two or more factors. Substantial morbidity and even death may result from adverse effects of cyclophosphamide and corticosteroids. Consequently, these therapies require careful monitoring and expert management. In contrast to many other forms of systemic vasculitis, disease relapses in polyarteritis following the successful induction of remission are the exception rather than the rule, occurring in only about 10% of cases.

POLYMYALGIA RHEUMATICA & GIANT CELL ARTERITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Giant cell (temporal) arteritis is characterized by headache, jaw claudication, polymyalgia rheumatica, visual abnormalities, and a markedly elevated ESR.
- ▶ The hallmark of polymyalgia rheumatica is pain and stiffness in shoulders and hips lasting for several weeks without other explanation.

▶ General Considerations

Polymyalgia rheumatica and giant cell arteritis probably represent a spectrum of one disease: Both affect the same population (patients over the age of 50), show preference for the same HLA haplotypes, and show similar patterns of cytokines in blood and arteries. Polymyalgia rheumatica and giant cell arteritis also frequently coexist. The important differences between the two conditions are that polymyalgia rheumatica alone does not cause blindness and responds to low-dose (10–20 mg/d orally) prednisone therapy, whereas giant cell arteritis can cause blindness and large artery complications and requires high-dose (40–60 mg/d) prednisone.

▶ Clinical Findings

A. Polymyalgia Rheumatica

Polymyalgia rheumatica is a clinical diagnosis based on pain and stiffness of the shoulder and pelvic girdle areas, fre-

quently in association with fever, malaise, and weight loss. In approximately two-thirds of cases, polymyalgia occurs in the absence of giant cell arteritis. Because of the stiffness and pain in the shoulders, hips, and lower back, patients have trouble combing their hair, putting on a coat, or rising from a chair. In contrast to polymyositis and polyarteritis nodosa, polymyalgia rheumatica does not cause muscular weakness either through primary muscle inflammation or secondary to nerve infarction. A few patients have joint swelling, particularly of the knees, wrists, and sternoclavicular joints. Anemia and elevated acute phase reactants (often markedly elevated ESRs, for example) are present in the most cases, but cases of polymyalgia rheumatica occurring with normal acute phase reactants are well documented. The differential diagnosis of malaise, anemia, and striking acute phase reactant elevations includes rheumatic diseases such as rheumatoid arthritis, other systemic vasculitides, multiple myeloma and other malignant disorders, and chronic infections such as bacterial endocarditis and osteomyelitis.

B. Giant Cell Arteritis

Giant cell arteritis is a systemic panarteritis affecting medium-sized and large vessels in patients over the age of 50. The incidence of this disease increases with each decade of life. The mean age at onset is approximately 72 years. Giant cell arteritis is also called temporal arteritis because that artery is frequently involved, as are other extracranial branches of the carotid artery. About 50% of patients with giant cell arteritis also have polymyalgia rheumatica. The classic symptoms suggesting that a patient has arteritis are headache, scalp tenderness, visual symptoms (particularly amaurosis fugax or diplopia), jaw claudication, or throat pain. Of these symptoms, jaw claudication has the highest positive predictive value. The temporal artery is usually normal on physical examination but may be nodular, enlarged, tender, or pulseless. Blindness usually results from the syndrome of anterior ischemic optic neuropathy, caused by occlusive arteritis of the posterior ciliary branch of the ophthalmic artery. The ischemic optic neuropathy of giant cell arteritis may produce no funduscopic findings for the first 24–48 hours after the onset of blindness.

Asymmetry of pulses in the arms, a murmur of aortic regurgitation, or bruits heard near the clavicle resulting from subclavian artery stenoses identify patients in whom giant cell arteritis has affected the aorta or its major branches. Clinically evident large vessel involvement—characterized chiefly by aneurysm of the thoracic aorta or stenosis of the subclavian, vertebral, carotid, and basilar arteries—occurs in approximately 25% of patients with giant cell arteritis, sometimes years after the diagnosis. Subclinical large artery disease is the rule: positron emission tomography scans reveal inflammation in the aorta and its major branches in nearly 85% of untreated patients. Forty percent of patients with giant cell arteritis have nonclassic symptoms at presentation, chiefly respiratory tract problems (most frequently dry cough), mononeuritis multiplex (most frequently with painful paralysis of a shoulder), or fever of unknown origin. Giant cell arteritis accounts for 15% of all cases of fever of unknown origin in patients over the age of

65. The fever can be as high as 40 °C and is frequently associated with rigors and sweats. In contrast to patients with infection, patients with giant cell arteritis and fever usually have normal white blood cell counts (before prednisone is started). Thus, in an older patient with fever of unknown origin, marked elevations of acute phase reactants, and a normal white blood count, giant cell arteritis must be considered even in the absence of specific features such as headache or jaw claudication. In some cases, instead of having the well-known symptom of jaw claudication, patients complain of vague pain affecting other locations, including the tongue, nose, or ears. Indeed, unexplained head or neck pain in an older patient may signal the presence of giant cell arteritis.

C. Laboratory Findings

Nearly 90% of patients with giant cell arteritis have ESRs > 50 mm/h. The ESR in this disorder is often > 100 mm/h, but cases in which the ESR is low or even normal do occur. In one series, 5% of patients with biopsy-proven giant cell arteritis had ESRs < 40 mm/h. Although the C-reactive protein is slightly more sensitive, patients with biopsy-proven giant cell arteritis with normal C-reactive proteins have also been described. Most patients also have a mild normochromic, normocytic anemia and thrombocytosis. The alkaline phosphatase (liver source) is elevated in 20% of patients with giant cell arteritis.

► Treatment

A. Polymyalgia Rheumatica

Patients with isolated polymyalgia rheumatica (ie, those not having “above the neck” symptoms of headache, jaw claudication, scalp tenderness, or visual symptoms) are treated with prednisone, 10–20 mg/d orally. If the patient does not experience a dramatic improvement within 72 hours, the diagnosis should be revisited. Usually after 2–4 weeks of treatment, slow tapering of the prednisone can be attempted. Most patients require some dose of prednisone for a minimum of approximately 1 year; 6 months is too short in most cases. Disease flares are common (50% or more) as prednisone is tapered. The addition of weekly methotrexate may increase the chance of successfully tapering prednisone in some patients.

B. Giant Cell Arteritis

The urgency of early diagnosis and treatment in giant cell arteritis relates to the prevention of blindness. Once blindness develops, it is usually permanent. Therefore, when a patient has symptoms and findings suggestive of temporal arteritis, therapy with prednisone (60 mg/d orally) should be initiated immediately and a temporal artery biopsy performed promptly. For patients who seek medical attention for visual loss, intravenous pulse methylprednisolone (eg, 1 g daily for 3 days) has been advocated; unfortunately, few patients recover vision no matter what the initial treatment. One study—too small and too preliminary to change the standard therapy recommendations mentioned above—suggested that initiating treatment with intravenous pulse

methylprednisolone may increase the chance that a patient with giant cell arteritis will achieve remission and be able to taper off of prednisone. Retrospective studies suggest that low-dose aspirin (~81 mg/d orally) may reduce the chance of visual loss or stroke in patients with giant cell arteritis and should be added to prednisone in the initial treatment. Although it is prudent to obtain a temporal artery biopsy as soon as possible after instituting treatment, diagnostic findings of giant cell arteritis may still be present 2 weeks (or even considerably longer) after starting corticosteroids. Typically, a positive biopsy shows inflammatory infiltrate in the media and adventitia with lymphocytes, histiocytes, plasma cells, and giant cells. An adequate biopsy specimen is essential (at least 2 cm in length is ideal), because the disease may be segmental. Unilateral temporal artery biopsies are positive in approximately 80–85% of patients, but bilateral biopsies add incrementally to the yield (10–15% in some studies, less in others). Prednisone should be continued in a dosage of 60 mg/d orally for about 1 month before tapering. When only the symptoms of polymyalgia rheumatica are present, temporal artery biopsy is not necessary.

After 1 month of high-dose prednisone, almost all patients will have a normal ESR. When tapering and adjusting the dosage of prednisone, the ESR (or C-reactive protein) is a useful but not absolute guide to disease activity. A common error is treating the ESR rather than the patient. The ESR often rises slightly as the prednisone is tapered, even as the disease remains quiescent. Because elderly individuals often have baseline ESRs that are above the normal range, mild ESR elevations should not be an occasion for renewed treatment with prednisone in patients who are asymptomatic. Unfortunately, no highly effective prednisone-sparing therapy has been identified. Methotrexate was modestly effective in one double-blind, placebo-controlled treatment trial but ineffective in another. Anti-TNF therapies do not work in giant cell arteritis. Thoracic aortic aneurysms occur 17 times more frequently in patients with giant cell arteritis than in normal individuals and can result in aortic regurgitation, dissection, or rupture. The aneurysms can develop at any time but typically occur 7 years after the diagnosis of giant cell arteritis is made.

WEGENER GRANULOMATOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Classic triad of upper and lower respiratory tract disease and glomerulonephritis.
- ▶ Suspect if mild respiratory symptoms (eg, nasal congestion, sinusitis) are refractory to usual treatment.
- ▶ Pathology defined by the triad of small vessel vasculitis, granulomatous inflammation, and necrosis.
- ▶ ANCA, usually directed against proteinase-3 (less commonly against myeloperoxidase present in severe, active disease) (90% of patients).
- ▶ Kidney disease often rapidly progressive without treatment.

▶ General Considerations

Wegener granulomatosis, which has an estimated incidence of approximately 12 cases per million individuals per year, is the prototype of diseases associated with antineutrophil cytoplasmic antibodies (ANCA). (Other “ANCA-associated vasculitides” include microscopic polyangiitis and the Churg-Strauss syndrome.) Wegener granulomatosis is characterized in its full expression by vasculitis of small arteries, arterioles, and capillaries, necrotizing granulomatous lesions of both upper and lower respiratory tract, glomerulonephritis, and other organ manifestations. Without treatment, generalized disease is invariably fatal, with most patients surviving less than 1 year after diagnosis. It occurs most commonly in the fourth and fifth decades of life and affects men and women with equal frequency.

▶ Clinical Findings

A. Symptoms and Signs

The disorder usually develops over 4–12 months, with 90% of patients presenting with upper or lower respiratory tract symptoms or both. Upper respiratory tract symptoms can include nasal congestion, sinusitis, otitis media, mastoiditis, inflammation of the gums, or stridor due to subglottic stenosis. Since many of these symptoms are common, the underlying disease is not often suspected until the patient develops systemic symptoms or the original problem is refractory to treatment. The lungs are affected initially in 40% and eventually in 80%, with symptoms including cough, dyspnea, and hemoptysis. Other early symptoms can include a migratory oligoarthritis with a predilection for large joints; a variety of symptoms related to ocular disease (unilateral proptosis from orbital pseudotumor; red eye from scleritis, episcleritis, anterior uveitis, or peripheral ulcerative keratitis); purpura or other skin lesions; and dysesthesia due to neuropathy (Plate 85). Renal involvement, which develops in three-fourths of the cases, may be subclinical until chronic kidney disease is advanced. Fever, malaise, and weight loss are common.

Physical examination can be remarkable for congestion, crusting, ulceration, bleeding, and even perforation of the nasal septum. Destruction of the nasal cartilage with “saddle nose” deformity occurs late. Otitis media, proptosis, scleritis, episcleritis, and conjunctivitis are other common findings. Newly acquired hypertension, a frequent feature of polyarteritis nodosa, is rare in Wegener granulomatosis. Venous thrombotic events (eg, deep venous thrombosis and pulmonary embolism) are a common occurrence in Wegener granulomatosis, at least in part because of the tendency of the disease to involve veins as well as arteries. Although limited forms of Wegener granulomatosis have been described in which the kidney is spared initially, kidney disease will develop in the majority of untreated patients.

B. Laboratory Findings

1. Serum tests and urinalysis—Most patients have slight anemia, mild leukocytosis, and elevated acute phase reactants. If there is renal involvement, the urinary sediment invariably contains red cells, with or without white cells, and often has red cell casts.

Serum tests for ANCA help in the diagnosis of Wegener granulomatosis and related forms of vasculitis (Table 20–10). Several different types of ANCA are recognized, but the two subtypes relevant to systemic vasculitis are those directed against proteinase-3 (PR3) and myeloperoxidase (MPO). Antibodies to these two antigens are termed “PR3-ANCA” and “MPO-ANCA,” respectively. The cytoplasmic pattern of immunofluorescence (C-ANCA) caused by PR3-ANCA has a high specificity (> 90%) for either Wegener granulomatosis or a closely related disease, microscopic polyangiitis (or, less commonly, the Churg-Strauss syndrome). In the setting of active disease, particularly cases in which the disease is severe and generalized to multiple organ systems, the sensitivity of PR3-ANCA is > 95%. A substantial percentage of patients with “limited” Wegener granulomatosis—disease that does not pose an immediate threat to life and is often confined to the respiratory tract—are ANCA-negative. Although ANCA testing may be very helpful when used properly, it does not eliminate the need in most cases for confirmation of the diagnosis by tissue biopsy. Furthermore, ANCA levels correlate erratically with disease activity, and changes in titer should not dictate changes in therapy in the absence of supporting clinical data. The perinuclear (P-ANCA) pattern, caused by MPO-ANCA, is more likely to occur in microscopic polyangiitis or Churg-Strauss but may also be found in Wegener granulomatosis. Approximately 10–25% of patients with classic Wegener granulomatosis have MPO-ANCA. All positive immunofluorescence assays for ANCA should be confirmed by enzyme immunoassays for the specific autoantibodies directed against PR3 or MPO.

2. Histologic findings—Histologic features of Wegener granulomatosis include vasculitis, granulomatous inflammation, geographic necrosis, and acute and chronic inflammation. The full range of pathologic changes is usually evident only on thoracoscopic lung biopsy. Granulomas, observed only rarely in renal biopsy specimens, are

found much more commonly on lung biopsy specimens. Nasal biopsies often do not show vasculitis but may show chronic inflammation and other changes which, interpreted by an experienced pathologist, can serve as convincing evidence of the diagnosis. Renal biopsy discloses a segmental necrotizing glomerulonephritis with multiple crescents; this is characteristic but not diagnostic. Pathologists characterize the renal lesion of Wegener granulomatosis (and other forms of “ANCA-associated vasculitis”) as a pauci-immune glomerulonephritis because of the relative absence (compared with immune complex-mediated disorders) of immunoreactants—IgG, IgM, IgA, and complement proteins—within glomeruli.

C. Imaging

Chest CT is more sensitive than chest radiography; lesions include infiltrates, nodules, masses, and cavities. Often the radiographs prompt concern about lung cancer. Hilar adenopathy is unusual in Wegener granulomatosis; if present, sarcoidosis, tumor, or infection is more likely. Other common radiographic abnormalities include extensive sinusitis and even bony sinus erosions.

► Differential Diagnosis

In most patients with Wegener granulomatosis, refractory sinusitis or otitis media is initially suspected. When upper respiratory tract inflammation persists and is accompanied by additional systemic inflammatory signs (eg, red eye from scleritis, joint pain and swelling), the diagnosis of Wegener granulomatosis should be considered. Rheumatoid arthritis will wrongly be suspected in a substantial minority of patients who chiefly complain of joint pain. Arriving at the correct diagnosis is aided by awareness that rheumatoid arthritis typically involves small joints of the hand, whereas Wegener granulomatosis favors large joints, such as the hip, knee, elbow, and shoulder. Lung cancer may be the first diagnostic consideration for some middle-aged patients in whom cough, hemoptysis, and lung masses are presenting symptoms and signs; typically, evidence of glomerulonephritis, a positive ANCA or, ultimately, the lung biopsy findings will point to the proper diagnosis. Wegener granulomatosis shares with SLE, Goodpasture syndrome, and microscopic polyangiitis the ability to cause an acute pulmonary-renal syndrome. Approximately 10–25% of patients with classic Wegener granulomatosis have MPO-ANCA. Owing to involvement of the same types of blood vessels, similar patterns of organ involvement, and the possibility of failing to identify granulomatous pathology on tissue biopsies because of sampling error, Wegener granulomatosis is often difficult to differentiate from microscopic polyangiitis. The crucial distinctions between the two disorders are the tendencies for Wegener granulomatosis to involve the upper respiratory tract (including the ears) and to cause granulomatous inflammation.

► Treatment

Early treatment is crucial in preventing the devastating end-organ complications of this disease, and often in preserving

life. While Wegener granulomatosis may involve the sinuses or lung for months, once proteinuria or hematuria develops, progression to advanced chronic kidney disease can be rapid (over several weeks). Remissions of at least a temporary nature have been induced in more than 90% of patients treated with prednisone (1 mg/kg daily) and cyclophosphamide. Unfortunately, the traditional therapy of oral cyclophosphamide continued for 12 months after the patient achieves remission has resulted in severe toxicity, including a 2.4 times increased risk of all malignancies, a 33-fold increase in bladder cancer, and a 60% chance of ovarian failure. Moreover, disease relapses occur in a substantial proportion of those patients who achieve remission. Still, for patients with severe Wegener granulomatosis, cyclophosphamide and prednisone remain the standard of care for remission induction. Consequently, the current approach to remission induction in severe cases is to use cyclophosphamide for 3–6 months, followed by a switch to a regimen more likely to be tolerated well. Cyclophosphamide is best given daily by mouth; intermittent high-dose intravenous cyclophosphamide is less effective. In patients with remission induced by 3–6 months of cyclophosphamide and corticosteroids, azathioprine (up to 2 mg/kg/d orally) has been shown to be as effective as cyclophosphamide in maintaining disease remissions (at least for up to 12–15 months). Before the institution of azathioprine, patients should be tested (through a commercially available blood test) for deficiencies in the level of thiopurine methyltransferase, an enzyme essential to the metabolism of azathioprine. Another current option for remission maintenance is methotrexate, 20–25 mg/wk (administered either orally or intramuscularly). Because of its superior side-effect profile, methotrexate is viewed as an appropriate substitute for cyclophosphamide in patients who do not have significant renal dysfunction (of any cause) or immediately life-threatening disease. Treatment with TNF inhibitors, particularly etanercept, is not effective. Several small, uncontrolled studies suggest that rituximab, a B-cell-depleting monoclonal antibody, may have efficacy.

MICROSCOPIC POLYANGIITIS

ESSENTIALS OF DIAGNOSIS

- Necrotizing vasculitis of small- and medium-sized arteries and veins.

- ▶ Pulmonary alveolar hemorrhage and glomerulonephritis.
- ▶ Associated with ANCA in 75% of cases, usually anti-myeloperoxidase antibodies (MPO-ANCA) that cause a P-ANCA pattern on immunofluorescence testing. ANCA directed against proteinase-3 (PR3-ANCA) can also be observed.

▶ General Considerations

Microscopic polyangiitis is a pauci-immune nongranulomatous necrotizing vasculitis that (1) affects small blood vessels (capillaries, venules, or arterioles), (2) often causes glomerulonephritis and pulmonary capillaritis, and (3) is often associated with ANCA on immunofluorescence testing (directed against MPO, a constituent of neutrophil granules). Because microscopic polyangiitis may involve medium-sized as well as small blood vessels and because it tends to affect capillaries within the lungs and kidneys, its spectrum overlaps those of both polyarteritis nodosa and Wegener granulomatosis.

In a minority of cases, microscopic polyangiitis appears to be induced by reactions to medications, particularly propylthiouracil, hydralazine, allopurinol, penicillamine, minocycline, and sulfasalazine. In rare instances, these drugs induce a systemic vasculitis associated with MPO-ANCA. Such syndromes usually resolve with discontinuation of the offending drug.

▶ Clinical Findings

A. Symptoms and Signs

A wide variety of findings suggesting vasculitis of small blood vessels may develop in microscopic polyangiitis. These include “palpable” (or “raised”) purpura and other signs of cutaneous vasculitis (ulcers, splinter hemorrhages, vesiculobullous lesions).

Microscopic polyangiitis is the most common cause of pulmonary-renal syndromes, being several times more common than Goodpasture (antiglomerular basement membrane) syndrome. Interstitial lung fibrosis that mimics usual interstitial pneumonitis is the presenting condition. Pulmonary hemorrhage may occur. The pathologic findings in the lung are typically those of capillaritis.

Hematuria, proteinuria, and red blood cell casts in the urine may occur. The renal lesion is a segmental, necrotizing glomerulonephritis, often with localized intravascular coagulation and the observation of intraglomerular thrombi upon renal biopsy.

Vasculitic neuropathy (mononeuritis multiplex) is also common in microscopic polyangiitis.

B. Laboratory Findings

As noted, three-fourths of patients with microscopic polyangiitis are ANCA-positive. Elevated acute phase reactants are also typical of active disease. Careful scrutiny of the urine sediment is essential to excluding active kidney disease.

▶ Differential Diagnosis

Distinguishing this disease from Wegener granulomatosis may be challenging in some cases. Microscopic polyangiitis is not associated with the chronic destructive upper respiratory tract disease often found in Wegener granulomatosis. Moreover, as noted, a critical difference between the two diseases is the absence of granulomatous inflammation in microscopic polyangiitis. Because their treatments may differ, microscopic polyangiitis must also be differentiated from polyarteritis nodosa.

▶ Treatment

In microscopic polyangiitis, patients are likely to require prednisone and cyclophosphamide because of the urgency in treating pulmonary hemorrhage and glomerulonephritis. Cyclophosphamide may be administered either in an oral daily regimen or via intermittent (usually monthly) intravenous pulses. Whenever cyclophosphamide is used, *Pneumocystis jiroveci* prophylaxis with either single-strength oral trimethoprim-sulfamethoxazole or dapsone 100 mg/d is essential. Following the induction of remission, azathioprine is a reasonable choice to replace cyclophosphamide.

▶ Prognosis

The key to effecting good outcomes is early diagnosis. Compared with patients who have Wegener granulomatosis, those who have microscopic polyangiitis are more likely to have significant fibrosis on renal biopsy because of later diagnosis. The likelihood of disease recurrence following remission in microscopic polyangiitis is about 33%.

CRYOGLOBULINEMIA

Cryoglobulinemia can be associated with an immune-complex mediated, small-vessel vasculitis. Chronic infection with hepatitis C is the most common underlying condition; cryoglobulinemic vasculitis also can occur in the setting of other chronic infections, such as subacute bacterial endocarditis and osteomyelitis, and with connective tissues diseases, especially Sjögren syndrome. The cryoglobulins associated with vasculitis are cold-precipitable immune complexes consisting of rheumatoid factor and IgG (rheumatoid factor is an autoantibody to the constant region of IgG). The

rheumatoid factor component can be monoclonal (type II cryoglobulins) or polyclonal (type III cryoglobulins). (Type I cryoglobulins are cryoprecipitable monoclonal proteins that lack rheumatoid factor activity; these cause cold-induced hyperviscosity syndromes, not vasculitis, and are associated with lymphoproliferative disease.) Cryoglobulinemic vasculitis typically manifests as recurrent palpable purpura and peripheral neuropathy. A proliferative glomerulonephritis can develop and can manifest as rapidly progressive glomerulonephritis. Abnormal liver function tests, abdominal pain, and pulmonary disease may also occur. The diagnosis is based on a compatible clinical picture and a positive serum test for cryoglobulins. The presence of a disproportionately low C4 level can be a diagnostic clue to the presence of cryoglobulinemia. The optimal approach to treatment of hepatitis C–associated cryoglobulinemic vasculitis is viral suppression with pegylated forms of interferon- α , with or without ribavirin. Because immunosuppressive agents may facilitate viral replication, corticosteroids, cyclophosphamide, and other interventions (including plasmapheresis) should be reserved for organ-threatening complications. B cell depletion using rituximab appears to be a promising avenue of therapy. Asymptomatic cryoglobulinemia is common in hepatitis C–infected individuals and does not in itself warrant treatment.

HENOCH-SCHÖNLEIN PURPURA

Henoch-Schönlein purpura, the most common systemic vasculitis in children, occurs in adults as well. Typical features are palpable purpura, abdominal pain, arthritis, and hematuria (Plate 86). Pathologic features include leukocytoclastic vasculitis with IgA deposition. The cause is not known.

The purpuric skin lesions are typically located on the lower extremities but may also be seen on the hands, arms, trunk, and buttocks. Joint symptoms are present in the majority of patients, the knees and ankles being most commonly involved. Abdominal pain secondary to vasculitis of the intestinal tract is often associated with gastrointestinal bleeding. Hematuria signals the presence of a renal lesion that is usually reversible, although it occasionally may progress to chronic kidney disease. Children tend to have more frequent and more serious gastrointestinal vasculitis, whereas adults more often suffer from chronic kidney disease. Biopsy of the kidney reveals segmental glomerulonephritis with crescents and mesangial deposition of IgA.

Chronic courses with persistent or intermittent skin disease are more likely to occur in adults than in children.

The value of corticosteroids has been controversial. In children, prednisone (1 mg/kg/d orally) may benefit those with severe extrarenal manifestations and with evidence of kidney disease. The incremental efficacy of steroid-sparing drugs such as azathioprine and mycophenolate mofetil—often used in the setting of kidney disease—is not known.

RELAPSING POLYCHONDritis

This disease is characterized by inflammatory destructive lesions of cartilaginous structures, principally the ears, nose, trachea, and larynx. Nearly 40% of cases are associated with another disease, especially either other immunologic disorders (such as SLE, rheumatoid arthritis, or Hashimoto thyroiditis) or cancers (such as multiple myeloma) or hematologic disorders (such as myelodysplastic syndrome). The disease, which is usually episodic, affects males and females equally. The cartilage is painful, swollen, and tender during an attack and subsequently becomes atrophic, resulting in permanent deformity. Biopsy of the involved cartilage shows inflammation and chondrolysis. Noncartilaginous manifestations of the disease include fever, episcleritis, uveitis, deafness, aortic insufficiency, and rarely glomerulonephritis. In 85% of patients, a migratory, asymmetric, and seronegative arthropathy occurs, affecting both large and small joints and the costochondral junctions. Diagnosing this uncommon disease is especially difficult since the signs of cartilage inflammation (such as red ears or nasal pain) may be more subtle than the fever, arthritis, rash, or other systemic manifestations.

Prednisone, 0.5–1 mg/kg/d orally, is often effective. Dapsone (100–200 mg/d orally) or methotrexate (7.5–20 mg orally per week) may also have efficacy, sparing the need for long-term high-dose corticosteroid treatment. Involvement of the tracheobronchial tree, leading to tracheomalacia, may lead to difficult management issues.

BEHÇET SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Most commonly occurs among persons of Asian, Turkish, or Middle Eastern background, but may affect persons of any demographic profile.
- ▶ Recurrent, painful aphthous ulcers of the mouth and genitals.

- ▶ Additional cutaneous findings include erythema nodosum-like lesions, a follicular rash, and the “pathergy” phenomenon (formation of a sterile pustule at the site of a needle stick).
- ▶ Either anterior or posterior uveitis. Posterior uveitis may be asymptomatic until significant damage to the retina has occurred.
- ▶ Variety of neurologic lesions that can mimic multiple sclerosis, particularly through involvement of the white matter of the brainstem.

▶ General Considerations

Named after the Turkish dermatologist who first described it, this disease is of unknown cause. Essentially all of its protean manifestations, however, are believed to result from vasculitis that may involve all types of blood vessels: small, medium, and large, on both the arterial and venous side of the circulation.

▶ Clinical Findings

A. Symptoms and Signs

The hallmark of Behçet disease is painful aphthous ulceration in the mouth (Plate 63). These lesions, which usually occur multiply, may be found on the tongue, gums, and inner surfaces of the oral cavity. Genital lesions, similar in appearance, are also common but do not occur in all patients. Other cutaneous lesions of Behçet disease include tender, erythematous, papular lesions that resemble erythema nodosum. (On biopsy, however, many of these lesions are shown to be secondary to vasculitis rather than septal panniculitis.) These erythema nodosum-like lesions have a tendency to ulcerate, a major difference between the lesions of Behçet disease and the erythema nodosum seen in cases of sarcoidosis and inflammatory bowel disease. An erythematous follicular rash that occurs frequently on the upper extremities may be a subtle feature of the disease. The pathergy phenomenon is frequently underappreciated (unless the patient is asked); in this phenomenon, sterile pustules develop at sites where needles have been inserted into the skin (eg, for phlebotomy) in some patients.

A nonerosive arthritis occurs in about two-thirds of patients, most commonly affecting the knees and ankles. Eye involvement may be one of the most devastating complications of Behçet disease. Posterior uveitis, in essence a retinal venulitis, may lead to the insidious destruction of large areas of the retina before the patient becomes aware of visual problems. Anterior uveitis, associated with photophobia and a red eye, is intensely symptomatic. This complication may lead to a hypopyon, the accumulation of pus in the anterior chamber. If not treated properly with mydriatic agents to dilate the pupil and corticosteroid eyedrops to diminish inflammation, the anterior uveitis of Behçet may lead to synechial formation between the iris and lens, resulting in permanent pupillary distortion.

Central nervous system involvement is another cause of major potential morbidity in Behçet disease. The central nervous system lesions that may mimic multiple sclerosis

radiologically often result in serious disability or death. Findings include sterile meningitis (recurrent meningeal headaches associated with a lymphocytic pleocytosis), cranial nerve palsies, seizures, encephalitis, mental disturbances, and spinal cord lesions. Finally, patients with Behçet disease have a hypercoagulable tendency that may lead to complicated venous thrombotic events, particularly multiple deep venous thrombosis, pulmonary emboli, cerebral sinus thrombosis, and other problems associated with clotting.

The clinical course may be chronic but is often characterized by remissions and exacerbations.

B. Laboratory Findings

There are no pathognomonic laboratory features of Behçet disease. Although patients with Behçet disease often have elevated acute phase reactants, there is no autoantibody or other assay that is distinctive. No markers of hypercoagulability specific to Behçet have been identified.

▶ Treatment

Corticosteroids (1 mg/kg/d of oral prednisone) are a mainstay of therapy for severe disease manifestations. Azathioprine (2 mg/kg/d orally) may be an effective steroid-sparing agent. Cyclophosphamide (2 mg/kg/d orally) or chlorambucil (0.1–0.2 mg/kg/d orally) is indicated for severe ocular and central nervous system complications of Behçet disease. Both colchicine (0.6 mg once to three times daily orally) and thalidomide (100 mg/d orally) help ameliorate the mucocutaneous findings. TNF inhibition and interferon alfa-2a demonstrates some promise as a therapeutic approach, but large studies are lacking to date.

PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM

Primary angiitis of the central nervous system is a syndrome with several possible causes that produces small and medium-sized vasculitis limited to the brain and spinal cord. Biopsy-proved cases have predominated in men who have a history of weeks to months of headaches, encephalopathy, and multifocal strokes. Systemic signs and symptoms are absent, and routine laboratory tests are usually normal. MRI of the brain is almost always abnormal, and the spinal fluid often reveals a mild lymphocytosis and a modest increase in protein level. Angiograms classically reveal a “string of beads” pattern produced by alternating segments of arterial narrowing and dilation. However, neither the MRI nor the angiogram appearance is specific for vasculitis. Indeed, in one study, none of the patients who had biopsy-proved central nervous system vasculitis had an angiogram showing “the string of beads,” and none of the patients with the classic angiographic findings had a positive brain biopsy for vasculitis. Many conditions,

including vasospasm, can produce the same angiographic pattern as vasculitis. Definitive diagnosis requires a compatible clinical picture; exclusion of infection, neoplasm, or metabolic disorder or drug exposure (eg, cocaine) that can mimic primary angiitis of the central nervous system; and a positive brain biopsy. In contrast to biopsy-proved cases, patients with angiographically defined central nervous system vasculopathy are chiefly women who have had an abrupt onset of headaches and stroke (often in the absence of encephalopathy) with normal spinal fluid findings. Many patients who fit this clinical profile may have reversible cerebral vasoconstriction rather than true vasculitis. Such cases may best be treated with calcium channel blockers (such as nimodipine or verapamil) and possibly short course of corticosteroids. Biopsy-proved cases usually improve with prednisone therapy and often require cyclophosphamide. In recent years, cases of central nervous system vasculitis associated with cerebral amyloid angiopathy have been reported. These cases often respond well to corticosteroids, albeit the long-term natural history remains poorly defined.

Calabrese LH et al. Narrative review: reversible cerebral vasoconstriction syndromes. *Ann Intern Med.* 2007 Jan 2;146(1):34–44. [PMID: 17200220]

LIVEDO RETICULARIS

Livedo reticularis produces a mottled, purplish discoloration of the skin with reticulated cyanotic areas surrounding paler central cores. This distinctive “fishnet” pattern is caused by spasm or obstruction of perpendicular arterioles, combined with pooling of blood in surrounding venous plexuses. Livedo reticularis can be idiopathic or a manifestation of a serious underlying condition.

Idiopathic livedo reticularis is a benign condition that worsens with cold exposure, improves with warming, and primarily affects the extremities. Apart from cosmetic concerns, it is usually asymptomatic. The presence of systemic symptoms or the development of cutaneous ulcerations points to the presence of an underlying disease.

Secondary livedo reticularis occurs in association with a variety of diseases that cause vascular obstruction or inflammation. Of particular importance is the link with antiphospholipid antibody syndrome. Livedo reticularis is the presenting manifestation of 25% of patients with antiphospholipid antibody syndrome and is strongly associated with the subgroup that has arterial thromboses, including those with Sneddon syndrome (livedo reticularis and cerebrovascular events). Other underlying causes of livedo reticularis include the vasculitides (particularly polyarteritis nodosa), cholesterol emboli syndrome, thrombocytopenia, cryoglobulinemia, cold agglutinin disease, primary hyperoxaluria (due to vascular deposits of calcium oxalate), and disseminated intravascular coagulation.

Weinstein S et al. Cutaneous manifestations of antiphospholipid antibody syndrome. *Hematol Oncol Clin North Am.* 2008 Feb;22(1):67–77. [PMID: 18207066]

SERONEGATIVE SPONDYLOARTHROPATHIES

The seronegative spondyloarthropathies are ankylosing spondylitis, psoriatic arthritis, reactive arthritis (also called Reiter syndrome), the arthritis associated with inflammatory bowel disease, and undifferentiated spondyloarthritis. These disorders are noted for male predominance, onset usually before age 40, inflammatory arthritis of the spine or the large peripheral joints (or both), enthesopathy (inflammation of where ligaments, tendons, and joint capsule insert into bone), uveitis in a significant minority, the absence of autoantibodies in the serum, and a striking association with HLA-B27. Present in only 8% of normal whites and 4% of normal blacks, HLA-B27 is positive in 90% of patients with ankylosing spondylitis and 75% with reactive arthritis. HLA-B27 also occurs in 50% of the psoriatic and inflammatory bowel disease patients who have sacroiliitis. Patients with only peripheral arthritis in these latter two syndromes do not show an increase in HLA-B27.

ANKYLOSING SPONDYLITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Chronic low backache in young adults, generally worst in the morning.
- ▶ Progressive limitation of back motion and of chest expansion.
- ▶ Transient (50%) or persistent (25%) peripheral arthritis.
- ▶ Anterior uveitis in 20–25%.
- ▶ Diagnostic radiographic changes in sacroiliac joints.
- ▶ Negative serologic tests for rheumatoid factor.
- ▶ HLA-B27 testing is most helpful when there is an indeterminate probability of disease.

▶ General Considerations

Ankylosing spondylitis is a chronic inflammatory disease of the joints of the axial skeleton, manifested clinically by pain and progressive stiffening of the spine. The age at onset is usually in the late teens or early 20s. The incidence is greater in males than in females, and symptoms are more prominent in men, with ascending involvement of the spine more likely to occur.

▶ Clinical Findings

A. Symptoms and Signs

The onset is usually gradual, with intermittent bouts of back pain that may radiate into the buttocks. The back pain is worse in the morning and usually associated with stiffness that lasts hours. The pain and stiffness improve with activity, in contrast to back pain due to mechanical causes and degenerative disease, which improves with rest and worsens with activity. As the disease advances, symp-

toms progress in a cephalad direction and back motion becomes limited, with the normal lumbar curve flattened and the thoracic curvature exaggerated. Chest expansion is often limited as a consequence of costovertebral joint involvement. In advanced cases, the entire spine becomes fused, allowing no motion in any direction. Transient acute arthritis of the peripheral joints occurs in about 50% of cases, and permanent changes in the peripheral joints—most commonly the hips, shoulders, and knees—are seen in about 25%. Enthesopathy, a hallmark of the spondyloarthropathies, can manifest as swelling of the Achilles tendon at its insertion, plantar fasciitis (producing heel pain), or “sausage” swelling of a finger or toe (less common in ankylosing spondylitis than in psoriatic arthritis).

Anterior uveitis is associated in as many as 25% of cases and may be a presenting feature. Spondylitic heart disease, characterized chiefly by atrioventricular conduction defects and aortic insufficiency, occurs in 3–5% of patients with long-standing severe disease. Pulmonary fibrosis of the upper lobes, with progression to cavitation and bronchiectasis mimicking tuberculosis, may rarely occur, characteristically long after the onset of skeletal symptoms. Radicular symptoms due to cauda equina fibrosis may develop years after onset of the disease. Constitutional symptoms similar to those of rheumatoid arthritis are absent in most patients.

B. Laboratory Findings

The ESR is elevated in 85% of cases, but serologic tests for rheumatoid factor are characteristically negative. Anemia may be present but is often mild. HLA-B27 is found in 90% of white patients and 50% of black patients with ankylosing spondylitis. Because this antigen occurs in 8% of the healthy white population (and 2% of healthy blacks), it is not a specific diagnostic test.

C. Imaging

The earliest radiographic changes are usually in the sacroiliac joints. In the first 2 years of the disease process, the sacroiliac changes may be detectable only by MRI. Later, erosion and sclerosis of these joints are evident on plain radiographs; the sacroiliitis of ankylosing spondylitis is bilateral and symmetric. Inflammation where the annulus fibrosus attaches to the vertebral bodies initially causes sclerosis (“the shiny corner sign”) and then characteristic squaring of the vertebral bodies. The term “bamboo spine” describes the late radiographic appearance of the spinal column in which the vertebral bodies are fused by vertically oriented, bridging syndesmophytes formed by the ossification of the annulus fibrosus and calcification of the anterior and lateral spinal ligaments. Fusion of the posterior facet joints of the spine is also common.

Additional radiographic findings include periosteal new bone formation on the iliac crest, ischial tuberosities and calcanei, and alterations of the pubic symphysis and sternomanubrial joint similar to those of the sacroiliacs. Radiologic changes in peripheral joints, when present, tend to be asymmetric and lack the demineralization and erosions seen in rheumatoid arthritis.

► Differential Diagnosis

Low back pain due to mechanical causes, disk disease, and degenerative arthritis is very common. Onset of back pain prior to age 30 and an “inflammatory” quality of the back pain (ie, morning stiffness and pain that improve with activity) should raise the possibility of ankylosing spondylitis. In contrast to ankylosing spondylitis, rheumatoid arthritis predominantly affects multiple, small, peripheral joints of the hands and feet. Rheumatoid arthritis spares the sacroiliac joints and only affects the cervical component of the spine. Bilateral sacroiliitis indistinguishable from ankylosing spondylitis is seen with the spondylitis associated with inflammatory bowel disease. Sacroiliitis associated with reactive arthritis and psoriasis, on the other hand, is often asymmetric or even unilateral. Osteitis condensans ilii (sclerosis on the iliac side of the sacroiliac joint) is an asymptomatic, postpartum radiographic finding that is occasionally mistaken for sacroiliitis. Diffuse idiopathic skeletal hyperostosis (DISH) causes exuberant osteophytes of the spine that occasionally are difficult to distinguish from the syndesmophytes of ankylosing spondylitis. The osteophytes of DISH are thicker and more anterior than the syndesmophytes of ankylosing spondylitis, and the sacroiliac joints are normal in DISH.

► Treatment

A. Basic Program

The general principles of managing chronic arthritis (see above) apply equally well to ankylosing spondylitis. The importance of postural and breathing exercises should be stressed.

B. Drug Therapy

NSAIDs remain first-line treatment of ankylosing spondylitis and may slow radiographic progression of spinal disease. Because individual patients differ in their response to particular NSAIDs, empiric trials of several different NSAIDs are warranted if the response to any given NSAID is not satisfactory. TNF inhibitors have established efficacy for NSAID-resistant axial disease; responses are often substantial and durable. Etanercept (50 mg subcutaneously once a week), adalimumab (40 mg subcutaneously every other week), or infliximab (5 mg/kg every other month by IV infusion) is reasonable for patients whose symptoms are refractory to NSAIDs. Sulfasalazine (1000 mg orally twice daily) is sometimes useful for peripheral arthritis but lacks effectiveness for spinal and sacroiliac joint disease. Corticosteroids have minimal impact on the arthritis—particularly the spondylitis—of ankylosing spondylitis and can worsen osteopenia.

► Prognosis

Almost all patients have persistent symptoms over decades; rare individuals experience long-term remissions. The severity of disease varies greatly, with about 10% of patients having work disability after 10 years. Developing hip disease within the first 2 years of disease onset presages

a worse prognosis. The availability of TNF inhibitors has improved the outlook dramatically for many patients with ankylosing spondylitis, and the early use of these therapies may attenuate many of the long-term disabilities otherwise characteristic of this disease.

PSORIATIC ARTHRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Psoriasis precedes onset of arthritis in 80% of cases.
- ▶ Arthritis usually asymmetric, with “sausage” appearance of fingers and toes but a polyarthritis that resembles rheumatoid arthritis also occurs.
- ▶ Sacroiliac joint involvement common; ankylosis of the sacroiliac joints may occur.
- ▶ Radiographic findings: osteolysis; pencil-in-cup deformity; relative lack of osteoporosis; bony ankylosis; asymmetric sacroiliitis and atypical syndesmophytes.

▶ General Considerations

Arthritis occurs in 15–20% of patients with psoriasis.

▶ Clinical Findings

A. Symptoms and Signs

The patterns or subsets of psoriatic arthritis include the following:

1. A symmetric polyarthritis that resembles rheumatoid arthritis. Usually, fewer joints are involved than in rheumatoid arthritis.
2. An oligoarticular form that may lead to considerable destruction of the affected joints.
3. A pattern of disease in which the DIP joints are primarily affected. Early, this may be monoarticular, and often the joint involvement is asymmetric. Pitting of the nails and onycholysis frequently accompany DIP involvement.
4. A severe deforming arthritis (arthritis mutilans) in which osteolysis is marked.

5. A spondylitic form in which sacroiliitis and spinal involvement predominate; 50% of these patients are HLA-B27-positive.

Although psoriasis usually precedes the onset of arthritis, arthritis precedes (by up to 2 years) or occurs simultaneously with the skin disease in approximately 20% of cases. Arthritis is at least five times more common in patients with severe skin disease than in those with only mild skin findings. Occasionally, however, patients may have a single patch of psoriasis (typically hidden in the scalp, gluteal cleft, or umbilicus) and are unaware of its connection to the arthritis. Thus, a detailed search for cutaneous lesions is essential in patients with arthritis of new onset. Also, the psoriatic lesions may have cleared when arthritis appears—in such cases, the history is most useful in diagnosing previously unexplained cases of mono- or oligoarthritis. Nail pitting is sometimes a clue. “Sausage” swelling of one or more digits is a common manifestation of enthesopathy in psoriatic arthritis.

B. Laboratory Findings

Laboratory studies show an elevation of the ESR, but rheumatoid factor is not present. Uric acid levels may be high, reflecting the active turnover of skin affected by psoriasis. There is a correlation between the extent of psoriatic involvement and the level of uric acid, but gout is no more common than in patients without psoriasis. Desquamation of the skin may also reduce iron stores.

C. Imaging

Radiographic findings are most helpful in distinguishing the disease from other forms of arthritis. There are marginal erosions of bone and irregular destruction of joint and bone, which, in the phalanx, may give the appearance of a sharpened pencil. Fluffy periosteal new bone may be marked, especially at the insertion of muscles and ligaments into bone. Such changes will also be seen along the shafts of metacarpals, metatarsals, and phalanges. Psoriatic spondylitis causes asymmetric sacroiliitis and syndesmophytes, which are coarser than those seen in ankylosing spondylitis.

▶ Treatment

NSAIDs are usually sufficient for mild cases. Methotrexate (7.5–20 mg orally once a week) is generally considered the drug of choice for patients who have not responded to NSAIDs; methotrexate can improve both the cutaneous and arthritic manifestations. For cases with disease that is refractory to methotrexate, the addition of TNF inhibitors is usually effective for both arthritis and psoriatic skin disease. Alefacept, a biologic agent that is administered by subcutaneous injection, blocks the activation and proliferation of memory effector T cells by binding to CD2; this drug also appears to be effective in the treatment of psoriatic arthritis as well as cutaneous disease. Corticosteroids are less effective in psoriatic arthritis than in other forms of inflammatory arthritis and may precipitate pustular psoriasis during tapers. Antimalarials may also exacerbate psoriasis. Successful treatment directed at the skin lesions alone

(eg, by PUVA therapy) occasionally is accompanied by an improvement in peripheral articular symptoms.

Griffiths CE et al. Pathogenesis and clinical features of psoriasis. *Lancet*. 2007 Jul 21;370(9583):263–71. [PMID: 17658397]

REACTIVE ARTHRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Fifty to 80 percent of patients are HLA-B27-positive.
- ▶ Oligoarthritis, conjunctivitis, urethritis, and mouth ulcers most common features.
- ▶ Usually follows dysentery or a sexually transmitted infection.

▶ General Considerations

Reactive arthritis (formerly called Reiter syndrome) is precipitated by antecedent gastrointestinal and genitourinary infections and manifests as an asymmetric sterile oligoarthritis, typically of the lower extremities. It is frequently associated with enthesitis. Extra-articular manifestations are common and include urethritis, conjunctivitis, uveitis, and mucocutaneous lesions. Reactive arthritis occurs most commonly in young men and is associated with HLA-B27 in 80% of white patients and 50–60% of blacks.

▶ Clinical Findings

A. Symptoms and Signs

Most cases of reactive arthritis develop within 1–4 weeks after either a gastrointestinal infection (with *Shigella*, *Salmonella*, *Yersinia*, *Campylobacter*) or a sexually transmitted infection (with *Chlamydia trachomatis* or perhaps *Ureaplasma urealyticum*). Whether the inciting infection is sexually transmitted or dysenteric does not affect the subsequent manifestations but does influence the gender ratio: The ratio is 1:1 after enteric infections but 9:1 with male predominance after sexually transmitted infections. Synovial fluid from affected joints is culture-negative. A clinically indistinguishable syndrome can occur without an apparent antecedent infection, suggesting that subclinical infection can precipitate reactive arthritis or that there are other, as yet unrecognized, triggers.

The arthritis is most commonly asymmetric and frequently involves the large weight-bearing joints (chiefly the knee and ankle); sacroiliitis or ankylosing spondylitis is observed in at least 20% of patients, especially after frequent recurrences. Systemic symptoms including fever and weight loss are common at the onset of disease. The mucocutaneous lesions may include balanitis, stomatitis, and keratoderma blennorrhagicum, indistinguishable from pustular

psoriasis (Plates 87 and 88). Involvement of the fingernails in reactive arthritis also mimics psoriatic changes. Carditis and aortic regurgitation may occur. While most signs of the disease disappear within days or weeks, the arthritis may persist for several months or become chronic. Recurrences involving any combination of the clinical manifestations are common and are sometimes followed by permanent sequelae, especially in the joints.

B. Imaging

Radiographic signs of permanent or progressive joint disease may be seen in the sacroiliac as well as the peripheral joints.

▶ Differential Diagnosis

Gonococcal arthritis can initially mimic reactive arthritis, but the marked improvement after 24–48 hours of antibiotic administration and the culture results distinguish the two disorders. Rheumatoid arthritis, ankylosing spondylitis, and psoriatic arthritis must also be considered. By causing similar oral, ocular, and joint lesions, Behçet disease may also mimic reactive arthritis. The oral lesions of reactive arthritis, however, are typically painless, in contrast to those of Behçet disease.

The association of reactive arthritis and HIV has been debated, but evidence now indicates that it is equally common in sexually active men regardless of HIV status.

▶ Treatment

NSAIDs have been the mainstay of therapy. Antibiotics given at the time of a nongonococcal sexually transmitted infection reduce the chance that the individual will develop this disorder. Unfortunately, once reactive arthritis has developed, antibiotics do not alleviate symptoms. Patients who do not respond to NSAIDs may respond to sulfasalazine, 1000 mg orally twice daily, or to methotrexate, 7.5–20 mg orally per week. There are very limited data on the efficacy of the anti-TNF agents, which are effective in the other spondyloarthropathies.

ARTHRITIS & INFLAMMATORY INTESTINAL DISEASES

One-fifth of patients with inflammatory bowel disease have arthritis, which complicates Crohn disease somewhat more frequently than it does ulcerative colitis. In both diseases, two distinct forms of arthritis occur. The first is peripheral arthritis—usually a nondeforming asymmetric oligoarthritis of large joints—in which the activity of the joint disease parallels that of the bowel disease. The arthritis usually begins months to years after the bowel disease, but occasionally the joint symptoms develop earlier and

may be prominent enough to cause the patient to overlook intestinal symptoms. The second form of arthritis is a spondylitis that is indistinguishable by symptoms or radiographs from ankylosing spondylitis and follows a course independent of the bowel disease. About 50% of these patients are HLA-B27-positive.

Controlling the intestinal inflammation usually eliminates the peripheral arthritis. The spondylitis often requires NSAIDs, which need to be used cautiously since these agents may activate the bowel disease in a few patients. Range-of-motion exercises as prescribed for ankylosing spondylitis can be helpful.

About two-thirds of patients with Whipple disease experience arthralgia or arthritis, most often an episodic, large-joint polyarthritis. The arthritis usually precedes the gastrointestinal manifestations by years. In fact, the arthritis resolves as the diarrhea develops. Thus, Whipple disease should be considered in the differential diagnosis of unexplained episodic arthritis.

INFECTIOUS ARTHRITIS*

NONGONOCOCCAL ACUTE BACTERIAL (Septic) ARTHRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Acute onset of inflammatory monoarticular arthritis, most often in large weight-bearing joints and wrists.
- ▶ Previous joint damage or injection drug abuse common risk factors.
- ▶ Infection with causative organisms commonly found elsewhere in body.
- ▶ Joint effusions are usually large, with white blood counts commonly > 50,000/mcL.

▶ General Considerations

Nongonococcal acute bacterial arthritis is often a disease that occurs when there is an underlying abnormality. The key risk factors are bacteremia (eg, injection drug use, endocarditis, infection at other sites), damaged or prosthetic joints (eg, rheumatoid arthritis), compromised immunity (eg, diabetes, advanced chronic kidney disease, alcoholism, cirrhosis, and immunosuppressive therapy), and loss of skin integrity (eg, cutaneous ulcer or psoriasis). *Staphylococcus aureus* is the most common cause of nongonococcal septic arthritis, accounting for about 50% of all cases. Methicillin-resistant *S aureus* (MRSA) and group B streptococcus have become increasing frequent and

important causes of septic arthritis. Gram-negative septic arthritis causes about 10% of cases and is especially common in injection drug users and in immunocompromised persons. *Escherichia coli* and *Pseudomonas aeruginosa* are the most common gram-negative isolates in adults. Pathologic changes include varying degrees of acute inflammation, with synovitis, effusion, abscess formation in synovial or subchondral tissues, and, if treatment is not adequate, articular destruction.

▶ Clinical Findings

A. Symptoms and Signs

The onset is usually acute, with pain, swelling, and heat of the affected joint worsening over hours. The knee is most frequently involved; other commonly affected sites are the hip, wrist, shoulder, and ankle. Unusual sites, such as the sternoclavicular or sacroiliac joint, can be involved in injection drug users. Chills and fever are common but are absent in up to 20% of patients. Infection of the hip usually does not produce apparent swelling but results in groin pain greatly aggravated by walking. More than one joint is involved in 15% of cases of septic arthritis; risk factors for multiple joint involvement include rheumatoid arthritis, associated endocarditis, and infection with group B streptococci.

B. Laboratory Findings

Synovial fluid analysis is critical for diagnosis. The leukocyte count of the synovial fluid usually exceeds 50,000/mcL and often is greater than 100,000/mcL, with 90% or more polymorphonuclear cells (Table 20–2). Gram stain of the synovial fluid is positive in 75% of staphylococcal infections and in 50% of gram-negative infections. Synovial fluid cultures are positive in 70–90% of cases; administration of antibiotics prior to arthrocentesis reduces the likelihood of a positive culture result. Blood cultures are positive in approximately 50% of patients.

C. Imaging

Imaging tests generally add little to the diagnosis of septic arthritis. Indeed, other than demonstrating joint effusion, radiographs are usually normal early in the disease; evidence of demineralization may develop within days of onset. MRI and CT are more sensitive in detecting fluid in joints that are not accessible to physical examination (eg, the hip). Bony erosions and narrowing of the joint space followed by osteomyelitis and periostitis may be seen within 2 weeks.

▶ Differential Diagnosis

Gout and pseudogout can cause acute, very inflammatory monoarticular arthritis and high-grade fever; the failure to find crystals on synovial fluid analysis excludes these diagnoses. A well-recognized but uncommon initial presentation of rheumatoid arthritis is an acute inflammatory monoarthritis (“pseudoseptic”). Acute rheumatic fever commonly involves many joints; Still disease may mimic septic arthritis, but laboratory evidence of infection is

*Lyme disease is discussed in Chapter 34.

absent. Pyogenic arthritis may be superimposed on other types of joint disease, notably rheumatoid arthritis. Indeed, septic arthritis must be excluded (by joint fluid examination) in any patient with rheumatoid arthritis who has a joint strikingly more inflamed than the other joints.

▶ Treatment

The effective treatment of septic arthritis requires appropriate antibiotic therapy together with drainage of the infected joint. Hospitalization is always necessary. If the likely causative organism cannot be determined clinically or from the synovial fluid Gram stain, treatment should be started with broad-spectrum antibiotic coverage effective against staphylococci, streptococci, and gram-negative organisms. Vancomycin should be used whenever MRSA is reasonably likely. Antibiotic therapy should be adjusted when culture results become available; the duration of antibiotic therapy is usually 6 weeks.

Early orthopedic consultation is essential. Effective drainage is usually achieved through early arthroscopic lavage and debridement together with drain placement. Open surgical drainage should be performed when conservative treatment fails, when there is concomitant osteomyelitis requiring debridement, or when the involved joint (eg, hip, shoulder, sacroiliac joint) cannot be drained by more conservative means. Immobilization with a splint and elevation are used at the onset of treatment. Early active motion exercises within the limits of tolerance will hasten recovery.

▶ Prognosis

The outcome of septic arthritis depends largely on the antecedent health of the patient, the causative organism (eg, *S aureus* bacterial arthritis is associated with a poor functional outcome in about 40% of cases), and the promptness of treatment. Five to 10 percent of patients with an infected joint die of respiratory complications of sepsis. The mortality rate is 30% for patients with polyarticular sepsis. Bony ankylosis and articular destruction commonly also occur if treatment is delayed or inadequate.

Mathews CJ et al. Septic arthritis: current diagnostic and therapeutic algorithm. *Curr Opin Rheumatol*. 2008 Jul;20(4):457–62. [PMID: 18525361]

GONOCOCCAL ARTHRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Prodromal migratory polyarthralgias.
- ▶ Tenosynovitis most common sign.
- ▶ Purulent monoarthritis in 50%.
- ▶ Characteristic skin lesions.
- ▶ Most common in young women during menses or pregnancy.

- ▶ Symptoms of urethritis frequently absent.
- ▶ Dramatic response to antibiotics.

▶ General Considerations

In contrast to nongonococcal bacterial arthritis, gonococcal arthritis usually occurs in otherwise healthy individuals. Host factors, however, influence the expression of the disease: Gonococcal arthritis is two to three times more common in women than in men, is especially common during menses and pregnancy, and is rare after age 40. Gonococcal arthritis is also common in male homosexuals, whose high incidence of asymptomatic gonococcal pharyngitis and proctitis predisposes them to disseminated gonococcal infection. Recurrent disseminated gonococcal infection should prompt testing of the patient's CH50 level to evaluate for a congenital deficiency of the terminal complement components C7 and C8.

▶ Clinical Findings

A. Symptoms and Signs

One to 4 days of migratory polyarthralgias involving the wrist, knee, ankle, or elbow are common at the outset. Thereafter, two patterns emerge. The first pattern is characterized by tenosynovitis that most often affects wrists, fingers, ankles, or toes and is seen in 60% of patients. The second pattern is purulent monoarthritis that most frequently involves the knee, wrist, ankle, or elbow and is seen in 40% of patients. Less than half of patients have fever, and less than one-fourth have any genitourinary symptoms. Most patients will have asymptomatic but highly characteristic skin lesions that usually consist of two to ten small necrotic pustules distributed over the extremities, especially the palms and soles.

B. Laboratory Findings

The peripheral blood leukocyte count averages about 10,000 cells/mcL and is elevated in less than one-third of patients. The synovial fluid white blood cell count usually ranges from 30,000 to 60,000 cells/mcL. The synovial fluid Gram stain is positive in one-fourth of cases and culture in less than half. Positive blood cultures are seen in 40% of patients with tenosynovitis and virtually never in patients with suppurative arthritis. Urethral, throat, and rectal cultures should be done in all patients, since they are often positive in the absence of local symptoms.

C. Imaging

Radiographs are usually normal or show only soft tissue swelling.

▶ Differential Diagnosis

Reactive arthritis can produce acute monoarthritis in a young person but is distinguished by negative cultures, sacroiliitis, and failure to respond to antibiotics. Lyme disease involving the knee is less acute, does not show

positive cultures, and may be preceded by known tick exposure and characteristic rash. The synovial fluid analysis will exclude gout, pseudogout, and nongonococcal bacterial arthritis. Rheumatic fever and sarcoidosis can produce migratory tenosynovitis but have other distinguishing features. Infective endocarditis with septic arthritis can mimic disseminated gonococcal infection. Meningococemia occasionally presents with a clinical picture that resembles disseminated gonococcal infection; blood cultures establish the correct diagnosis.

► Treatment

In most cases, patients in whom gonococcal arthritis is suspected should be admitted to the hospital to confirm the diagnosis, to exclude endocarditis, and to start treatment. While outpatient treatment has been recommended in the past, the rapid rise in gonococci resistant to penicillin makes initial inpatient treatment advisable. Approximately 4–5% of all gonococcal isolates produce a β -lactamase that confers penicillin resistance. An additional 15–20% of gonococcal species have chromosomal mutations that result in relative resistance to penicillin. The recommendation for initial treatment is to give a third-generation cephalosporin: ceftriaxone, 1 g intravenously daily (or every 12 hours if concomitant meningitis or endocarditis is suspected); or cefotaxime, 1 g intravenously every 8 hours; or ceftizoxime, 1 g intravenously every 8 hours. Because fluoroquinolone resistance is now found in more than 6% of infected heterosexual men, fluoroquinolone antibiotics are no longer recommended for treatment of gonococcal infections in the United States. Fluoroquinolone antibiotics can be used if antimicrobial sensitivity has been established through culture results. Once improvement from parenteral antibiotics has been achieved for 24–48 hours, patients can be switched to cefixime, 400 mg orally twice daily, or cefpodoxime, 400 mg orally twice daily, to complete a 7- to 10-day course.

► Prognosis

Generally, gonococcal arthritis responds dramatically in 24–48 hours after initiation of antibiotics, and drainage of the infected joint(s) is required infrequently. Complete recovery is the rule.

Rice PA. Gonococcal arthritis (disseminated gonococcal infection). *Infect Dis Clin North Am.* 2005 Dec;19(4):853–61. [PMID: 16297736]

RHEUMATIC MANIFESTATIONS OF HIV INFECTION

Infection with HIV has been associated with various rheumatic disorders, most commonly arthralgias and arthritis. HIV painful articular syndrome causes severe arthralgias in an oligoarticular, asymmetric pattern that resolve within 24 hours; the joint examination is normal. HIV-associated arthritis is an asymmetric oligoarticular process with objective findings of arthritis and a self-limited course that ranges from weeks to months. Psoriatic arthritis and reac-

tive arthritis occur in HIV-infected individuals and can be severe; it remains uncertain whether the incidence of these disorders is increased in HIV-infected populations. These spondyloarthropathies can respond to NSAIDs, though many cases are unresponsive. In the era of highly active antiretroviral therapies, immunosuppressive medications can be used if necessary in HIV patients, though with reluctance and great caution. Muscle weakness associated with an elevated creatine kinase can be due to nucleoside reverse transcriptase inhibitor-associated myopathy or HIV-associated myopathy; the clinical presentations of each resemble idiopathic polymyositis but the muscle biopsies show minimal inflammation. Less commonly, an inflammatory myositis indistinguishable from idiopathic polymyositis occurs.

Louthrenoo W. Rheumatic manifestations of human immunodeficiency virus infection. *Curr Opin Rheumatol.* 2008 Jan;20(1):92–9. [PMID: 18281864]

VIRAL ARTHRITIS

Arthralgias occur frequently in the course of acute infections with many viruses, but frank arthritis is uncommon. A notable exception is acute parvovirus B19 infection, which leads to acute polyarthritis in 50–60% of adult cases (infected children develop the febrile exanthem known as “slapped cheek fever”). The arthritis can mimic rheumatoid arthritis but is almost always self-limited and resolves within several weeks. The diagnosis is established by the presence of IgM antibodies specific for parvovirus B19. Self-limited polyarthritis is also common in acute hepatitis B infection and typically occurs before the onset of jaundice. Urticaria or other types of skin rash may be present. Indeed, the clinical picture resembles that of serum sickness (see Atopic Disease below). Serum transaminase levels are elevated, and tests for hepatitis B surface antigen are positive. Serum complement levels are often low during active arthritis and become normal after remission of arthritis. The incidence of hepatitis B–associated polyarthritis has fallen substantially with the introduction of hepatitis B vaccination. Effective vaccination programs in the United States have eliminated acute rubella infections, formerly a common cause of virally induced polyarthritis. Changes in the rubella vaccine (an attenuated live vaccine) have greatly reduced the incidence of rubella vaccine-induced polyarthritis as well.

Chronic infection with hepatitis C is associated with chronic polyarthralgia in up to 20% of cases and with chronic polyarthritis in 3–5%. Both can mimic rheumatoid arthritis, and the presence of rheumatoid factor in most hepatitis C–infected individuals leads to further diagnostic confusion. Indeed, hepatitis C–associated arthritis is frequently misdiagnosed as rheumatoid arthritis. Distinguishing viral arthritis/arthralgias from true rheumatoid arthritis can be difficult in hepatitis C–infected individuals. Rheumatoid arthritis always causes objective arthritis (not just arthralgias) and can be erosive (hepatitis C–associated arthritis is nonerosive). The presence of anti-CCP antibodies points to the diagnosis of rheumatoid arthritis.

Franssila R et al. Infection and musculoskeletal conditions: viral causes of arthritis. *Best Pract Res Clin Rheumatol.* 2006 Dec;20(6):1139–57. [PMID: 17127201]

INFECTIONS OF BONES

ACUTE PYOGENIC OSTEOMYELITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Fever and chills associated with pain and tenderness of involved bone.
- ▶ Diagnosis usually requires culture of bone biopsy.
- ▶ ESR often extremely high (eg, > 100 mm/h).
- ▶ Radiographs early in the course are typically negative.

▶ General Considerations

Osteomyelitis is a serious infection that is often difficult to diagnose and treat. Infection of bone occurs as a consequence of (1) hematogenous dissemination of bacteria, (2) invasion from a contiguous focus of infection, and (3) skin breakdown in the setting of vascular insufficiency.

▶ Clinical Findings

A. Symptoms and Signs

1. Hematogenous osteomyelitis—Osteomyelitis resulting from bacteremia is a disease associated with sickle cell disease, injection drug users, or the elderly. Patients with this form of osteomyelitis often present with sudden onset of high fever, chills, and pain and tenderness of the involved bone. The site of osteomyelitis and the causative organism depend on the host. Among patients with hemoglobinopathies such as sickle cell anemia, osteomyelitis is caused by salmonellae ten times as often as by other bacteria. Osteomyelitis in injection drug users develops most commonly in the spine. Although in this setting *S aureus* is most common, gram-negative infections, especially *P aeruginosa* and *Serratia* species, are also frequent pathogens. Rapid progression to epidural abscess causing fever, pain, and sensory and motor loss is not uncommon. In older patients with hematogenous osteomyelitis, the most common sites are the thoracic and lumbar vertebral bodies. Risk factors for these patients include diabetes, intravenous catheters, and indwelling urinary catheters. These patients often have more subtle presentations, with low-grade fever and gradually increasing bone pain.

2. Osteomyelitis from a contiguous focus of infection—Prosthetic joint replacement, decubitus ulcer, neurosurgery, and trauma most frequently cause soft tissue infections that can spread to bone. *S aureus* and *Staphylococcus epidermidis* are the most common organisms. Localized signs of inflammation are usually evident, but high fever and other signs of toxicity are usually absent.

Septic arthritis and cellulitis can also spread to contiguous bone.

3. Osteomyelitis associated with vascular insufficiency—Patients with diabetes and vascular insufficiency are susceptible to developing a very challenging form of osteomyelitis. The foot and ankle are the most commonly affected sites. Infection originates from an ulcer or other break in the skin that is usually still present when the patient presents but may appear disarmingly unimpressive. Bone pain is often absent or muted by the associated neuropathy. Fever is also commonly absent. Two of the best bedside clues that the patient has osteomyelitis are the ability to easily advance a sterile probe through a skin ulcer to bone and an ulcer area greater than 2 cm².

B. Imaging and Laboratory Findings

The plain film is the most readily available imaging procedure to establish the diagnosis of osteomyelitis, but it can be falsely negative early. Early radiographic findings may include soft tissue swelling, loss of tissue planes, and periarticular demineralization of bone. About 2 weeks after onset of symptoms, erosion of bone and alteration of cancellous bone appear, followed by periostitis.

MRI, CT, and nuclear medicine bone scanning are more sensitive than conventional radiography. MRI is the most sensitive and is particularly helpful in demonstrating the extent of soft tissue involvement. Radionuclide bone scanning is most valuable when osteomyelitis is suspected but no site is obvious. Nuclear medicine studies may also detect multifocal sites of infection. Ultrasound is useful in diagnosing the presence of effusions within joints and extra-articular soft tissue fluid collections but not in detecting bone infections.

Identifying the offending organism is a crucial step in selection of antibiotic therapy. Bone biopsy for culture is required except in those with hematogenous osteomyelitis, who have positive blood cultures. Cultures from overlying ulcers, wounds, or fistulas are unreliable.

▶ Differential Diagnosis

Acute hematogenous osteomyelitis should be distinguished from suppurative arthritis, rheumatic fever, and cellulitis. More subacute forms must be differentiated from tuberculosis or mycotic infections of bone and Ewing sarcoma or, in the case of vertebral osteomyelitis, from metastatic tumor. When osteomyelitis involves the vertebrae, it commonly traverses the disk—a finding not observed in tumor.

▶ Complications

Inadequate treatment of bone infections results in chronicity of infection, and this possibility is increased by delaying diagnosis and treatment. Extension to adjacent bone or joints may complicate acute osteomyelitis. Recurrence of bone infections often results in anemia, a markedly elevated ESR, weight loss, weakness and, rarely, amyloidosis or nephrotic syndrome. Pseudoepitheliomatous hyperplasia, squamous cell carcinoma, or fibrosarcoma may occasionally arise in persistently infected tissues.

▶ Treatment

Most patients require both debridement of necrotic bone and prolonged administration of antibiotics. Patients with vertebral body osteomyelitis and epidural abscess may require urgent neurosurgical decompression. Depending on the site and extent of debridement, surgical procedures to stabilize, fill in, cover, or revascularize may be needed. Traditionally, antibiotics have been administered parenterally for at least 6 weeks. Oral therapy with quinolones (eg, ciprofloxacin, 750 mg twice daily) for 6–8 weeks has been shown to be as effective as standard parenteral antibiotic therapy for chronic osteomyelitis with susceptible organisms. When treating osteomyelitis caused by *S aureus*, quinolones are usually combined with rifampin, 300 mg orally twice daily.

▶ Prognosis

If sterility of the lesion is achieved within 2–4 days, a good result can be expected in most cases if there is no compromise of the patient's immune system. However, progression of the disease to a chronic form may occur. It is especially common in the lower extremities and in patients in whom circulation is impaired (eg, diabetics).

Butalia S et al. Does this patient with diabetes have osteomyelitis of the lower extremity? *JAMA*. 2008 Feb 20;299(7):806–13. [PMID: 18285592]

Karamanis EM et al. Fluoroquinolones versus beta-lactam based regimens for the treatment of osteomyelitis: a meta-analysis of randomized controlled trials. *Spine*. 2008 May 1;33(10):E297–304. [PMID: 18449029]

MYCOTIC INFECTIONS OF BONES & JOINTS

Fungal infections of the skeletal system are usually secondary to a primary infection in another organ, frequently the lungs (see Chapter 36). Although skeletal lesions have a predilection for the cancellous portions of long bones and vertebral bodies, the predominant lesion—a granuloma with varying degrees of necrosis and abscess formation—does not produce a characteristic clinical picture.

Differentiation from other chronic focal infections depends on culture studies of synovial fluid or tissue obtained from the local lesion. Serologic tests provide presumptive support of the diagnosis.

1. Candidiasis

Candidal osteomyelitis most commonly develops in debilitated, malnourished patients undergoing prolonged hospitalization for cancer, neutropenia, trauma, complicated abdominal surgical procedures, or injection drug use. Infected intravenous catheters frequently serve as a hematogenous source. Prosthetic joints can also be infected by *Candida*.

For susceptible *Candida* species, fluconazole, 200 mg orally twice daily, is probably as effective as amphotericin B (see Chapter 36).

Richardson M et al. Changing epidemiology of systemic fungal infections. *Clin Microbiol Infect*. 2008 May;14(Suppl 4):5–24. [PMID: 18430126]

2. Coccidioidomycosis

Coccidioidomycosis of bones and joints is usually secondary to primary pulmonary infection. Arthralgia with periarticular swelling, especially in the knees and ankles, occurring as a nonspecific manifestation of systemic coccidioidomycosis, should be distinguished from actual bone or joint infection. Osseous lesions commonly occur in cancellous bone of the vertebrae or near the ends of long bones at tendinous insertions. These lesions are initially osteolytic and thus may mimic metastatic tumor or myeloma.

The precise diagnosis depends on recovery of *Coccidioides immitis* from the lesion or histologic examination of tissue obtained by open biopsy. Rising titers of complement-fixing antibodies also provide evidence of the disseminated nature of the disease.

Oral azole antifungal agents (fluconazole 200–400 mg daily, or itraconazole 200 mg twice daily) have become the treatment of choice for bone and joint coccidioidomycosis. Chronic infection is rarely cured with antifungal agents and may require operative excision of infected bone and soft tissue; amputation may be the only solution for stubbornly progressive infections. Immobilization of joints by plaster casts and avoidance of weight bearing provide benefit. Synovectomy, joint debridement, and arthrodesis are reserved for more advanced joint infections.

Blair JE. State-of-the-art treatment of coccidioidomycosis skeletal infections. *Ann N Y Acad Sci*. 2007 Sep;1111:422–33. [PMID: 17395727]

3. Histoplasmosis

Focal skeletal or joint involvement in histoplasmosis is rare and generally represents dissemination from a primary focus in the lungs. Skeletal lesions may be single or multiple and are not characteristic.

Sen D et al. Articular presentation of disseminated histoplasmosis. *Clin Rheumatol*. 2007 May;26(5):823–4. [PMID: 16724167]

TUBERCULOSIS OF BONES & JOINTS

SPINAL TUBERCULOSIS (Pott Disease)

ESSENTIALS OF DIAGNOSIS

- ▶ Seen primarily in immigrants from developing countries or immunocompromised patients.
- ▶ Back pain and gibbus deformity.
- ▶ Radiographic evidence of vertebral involvement.
- ▶ Evidence of *Mycobacterium tuberculosis* in aspirates or biopsies of spinal lesions.

▶ General Considerations

In the developing world, children primarily bear the burden of musculoskeletal tuberculosis. In the United States,

however, musculoskeletal infection is more often seen in adult immigrants from countries where tuberculosis is prevalent, or it develops in the setting of immunosuppression (eg, HIV infection, therapy with TNF inhibitors). Spinal tuberculosis (Pott disease) accounts for about 50% of musculoskeletal infection due to *M tuberculosis* (see Chapter 9). Seeding of the vertebrae may occur through hematogenous spread from the respiratory tract at the time of primary infection, with clinical disease developing years later as a consequence of reactivation. The thoracic and lumbar vertebrae are the most common sites of spinal involvement; vertebral infection is associated with paravertebral cold abscesses in 75% of cases.

► Clinical Findings

A. Symptoms and Signs

Patients complain of back pain, often present for months and sometimes associated with radicular pain and lower extremity weakness. Constitutional symptoms are usually absent, and less than 20% have active pulmonary disease. Destruction of the anterior aspect of the vertebral body can produce the characteristic gibbus deformity.

B. Laboratory Findings

Most patients have a positive reaction to purified protein derivative (PPD). Cultures of paravertebral abscesses and biopsies of vertebral lesions are positive in up to 70–90%. Biopsies reveal characteristic caseating granulomas in most cases. Isolation of *M tuberculosis* from an extraspinal site is sufficient to establish the diagnosis in the proper clinical setting.

C. Imaging

Radiographs can reveal lytic and sclerotic lesions and bony destruction of vertebrae but are normal early in the disease course. CT scanning can demonstrate paraspinal soft tissue extensions of the infection; MRI is the imaging technique of choice to detect compression of the spinal cord or cauda equina.

► Differential Diagnosis

Spinal tuberculosis must be differentiated from subacute and chronic spinal infections due to pyogenic organisms, *Brucella*, and fungi as well as from malignancy.

► Complications

Paraplegia due to compression of the spinal cord or cauda equina is the most serious complication of spinal tuberculosis.

► Treatment

Antimicrobial therapy should be administered for 6–9 months, usually in the form of isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months followed by isoniazid and rifampin for an additional 4–7 months (see also Chapter 9). Medical management alone is often sufficient. Surgical intervention, however, may be indi-

cated when there is neurologic compromise or severe spinal instability.

Kourbeti IS et al. Spinal infections: evolving concepts. *Curr Opin Rheumatol*. 2008 Jul;20(4):471–9. [PMID: 18525363]

TUBERCULOUS ARTHRITIS

Infection of peripheral joints by *M tuberculosis* usually presents as a monoarticular arthritis lasting for weeks to months (or longer), but less often, it can have an acute presentation that mimics septic arthritis. Any joint can be involved; the hip and knee are most commonly affected. Constitutional symptoms and fever are present in only a small number of cases. Tuberculosis also can cause a chronic tenosynovitis of the hand and wrist. Joint destruction occurs far more slowly than in septic arthritis due to pyogenic organisms. Synovial fluid is inflammatory but not to the degree seen in pyogenic infections, with synovial white cell counts in the range of 10,000–20,000 cells/mcL. Smears of synovial fluid are positive for acid-fast bacilli in a minority of cases; synovial fluid cultures, however, are positive in 80% of cases. Because culture results may take weeks, the diagnostic procedure of choice usually is synovial biopsy, which yields characteristic pathologic findings and positive cultures in greater than 90%. Antimicrobial therapy is the mainstay of treatment. Rarely, a reactive, sterile polyarthritis associated with erythema nodosum (Poncet disease) develops in patients with active pulmonary tuberculosis.

Gardam M et al. Mycobacterial osteomyelitis and arthritis. *Infect Dis Clin North Am*. 2005 Dec;19(4):819–30. [PMID: 16297734]

Kroot EJ et al. Poncet's disease: reactive arthritis accompanying tuberculosis. Two case reports and a review of the literature. *Rheumatology (Oxford)*. 2007 Mar;46(3):484–9. [PMID: 16935915]

ARTHRITIS IN SARCOIDOSIS

The frequency of arthritis among patients with sarcoidosis is variously reported between 10% and 35%. It is usually acute in onset, but articular symptoms may appear insidiously and often antedate other manifestations of the disease. Knees and ankles are most commonly involved, but any joint may be affected. Distribution of joint involvement is usually polyarticular and symmetric. The arthritis is commonly self-limited, resolving after several weeks or months and rarely resulting in chronic arthritis, joint destruction, or significant deformity. Sarcoid arthropathy is often associated with erythema nodosum, but the diagnosis is contingent on the demonstration of other extra-articular manifestations of sarcoidosis and, notably, biopsy evidence of noncaseating granulomas. In chronic arthritis, radiographs show typical changes in the bones of the extremities with intact cortex and cystic changes.

Treatment of arthritis in sarcoidosis is usually symptomatic and supportive. Colchicine may be of value. A short course of corticosteroids may be effective in patients with severe and progressive joint disease.

OTHER RHEUMATIC DISORDERS

RHEUMATIC MANIFESTATIONS OF CANCER

Rheumatologic syndromes may be the presenting manifestations for a variety of cancers (see Table 39–13). Dermatomyositis in adults, for example, is often associated with cancer. Hypertrophic pulmonary osteoarthropathy is characterized by the triad of polyarthritis, new onset of clubbing, and periosteal new bone formation. It is associated with both malignant diseases (eg, lung and intrathoracic cancers) and nonmalignant ones (eg, cyanotic heart disease, cirrhosis, and lung abscess). Cancer-associated polyarthritis is rare, has both oligoarticular and polyarticular forms, and should be considered when “seronegative rheumatoid arthritis” develops abruptly in an elderly patient. Palmar fasciitis manifests as bilateral palmar swelling with finger contractures and may be the first indication of cancer, particularly ovarian carcinoma. Remitting seronegative synovitis with non-pitting edema (“RS3PE”) presents with a symmetric small joint polyarthritis associated with non-pitting edema of the hands; it can be idiopathic or associated with malignancy. Palpable purpura due to leukocytoclastic vasculitis may be the presenting complaint in myeloproliferative disorders. Hairy cell leukemia can be associated with medium-sized vessel vasculitis such as polyarteritis nodosa. Acute leukemia can produce joint pains that are disproportionately severe in comparison to the minimal swelling and heat that are present. Leukemic arthritis complicates approximately 5% of cases. Rheumatic manifestations of myelodysplastic syndromes include cutaneous vasculitis, lupus-like syndromes, neuropathy, and episodic intense arthritis. Erythromelalgia, a painful warmth and redness of the extremities that (unlike Raynaud) improves with cold exposure or with elevation of the extremity, is often associated with myeloproliferative diseases, particularly essential thrombocythemia.

Naschitz JE et al. Musculoskeletal syndromes associated with malignancy (excluding hypertrophic osteoarthropathy). *Curr Opin Rheumatol*. 2008 Jan;20(1):100–5. [PMID: 18281865]
 Racanelli V et al. Rheumatic disorders as paraneoplastic syndromes. *Autoimmun Rev*. 2008 May;7(5):352–8. [PMID: 18486921]

NEUROGENIC ARTHROPATHY (Charcot Joint)

Neurogenic arthropathy is joint destruction resulting from loss or diminution of proprioception, pain, and temperature perception. Although traditionally associated with tabes dorsalis, it is more frequently seen in diabetic neuropathy, syringomyelia, spinal cord injury, pernicious anemia, leprosy, and peripheral nerve injury. As normal muscle tone and protective reflexes are lost, secondary degenerative joint disease ensues, resulting in an enlarged, boggy, relatively painless joint with extensive cartilage erosion, osteophyte formation, and multiple loose joint bodies. Radiographic changes may be degenerative or hypertrophic in the same patient.

Treatment is directed toward the primary disease; mechanical devices are used to assist in weight bearing and prevention of further trauma. In some instances, amputation becomes unavoidable.

Wrobel M et al. Charcot's joint of the wrist in type 2 diabetes mellitus. *Exp Clin Endocrinol Diabetes*. 2007 Jan;115(1):55–7. [PMID: 17286237]

PALINDROMIC RHEUMATISM

Palindromic rheumatism is a disease of unknown cause characterized by frequent recurring attacks (at irregular intervals) of acutely inflamed joints. Periarticular pain with swelling and transient subcutaneous nodules may also occur. The attacks cease within several hours to several days. The knee and finger joints are most commonly affected, but any peripheral joint may be involved. Systemic manifestations other than fever do not occur. Although hundreds of attacks may take place over a period of years, there is no permanent articular damage. Laboratory findings are usually normal. Palindromic rheumatism must be distinguished from acute gouty arthritis and an atypical acute onset of rheumatoid arthritis. In some patients, palindromic rheumatism is a prodrome of rheumatoid arthritis.

Symptomatic treatment with NSAIDs is usually all that is required during the attacks. Hydroxychloroquine may be of value in preventing recurrences.

OSTEONECROSIS (Avascular Necrosis of Bone)

Osteonecrosis is a complication of corticosteroid use, alcoholism, trauma, SLE, pancreatitis, gout, sickle cell disease, dysbaric syndromes (eg, “the bends”), and infiltrative diseases (eg, Gaucher disease). The most commonly affected sites are the proximal and distal femoral heads, leading to hip or knee pain. Other commonly affected sites include the ankle, shoulder, and elbow. Osteonecrosis of the jaw has been rarely associated with use of bisphosphonate therapy, almost always when the bisphosphonate is used for treating metastatic cancer or multiple myeloma rather than osteoporosis. Initially, radiographs are often normal; MRI, CT scan, and bone scan are all more sensitive techniques. Treatment involves avoidance of weight bearing on the affected joint for at least several weeks. The value of surgical core decompression is controversial. For osteonecrosis of the hip, a variety of procedures designed to preserve the femoral head have been developed for early disease, including vascularized and nonvascularized bone grafting procedures. These procedures are most effective in avoiding or forestalling the need for total hip arthroplasty in young patients who do not have advanced disease. Without a successful intervention of this nature, the natural history of avascular necrosis is usually progression of the bony infarction to cortical collapse, resulting in significant joint dysfunction. Total hip replacement is the usual outcome for all patients who are candidates for that procedure.

ALLERGIC DISEASES

Allergy is an immunologically mediated hypersensitivity reaction to a foreign antigen manifested by tissue inflammation and organ dysfunction. These responses have a genetic basis, but the clinical expression of disease depends on both immunologic responsiveness and antigen exposure. Allergic disorders may be local or systemic. Because the allergen is foreign (ie, environmental), the skin and respiratory tract are the organs most frequently involved in allergic disease. Allergic reactions may also localize to the vasculature, gastrointestinal tract, or other visceral organs. Anaphylaxis is the most extreme form of systemic allergy.

▶ Immunologic Classification

An immunologic classification for hypersensitivity reactions serves as a rational basis for diagnosis and treatment. The classification follows.

A. Type I—IgE-Mediated (Immediate) Hypersensitivity

IgE antibodies occupy receptor sites on mast cells. Within minutes after exposure to the allergen, a multivalent antigen links adjacent IgE molecules, activating and degranulating mast cells. Clinical manifestations depend on the effects of released mediators on target end organs. Both preformed and newly generated mediators cause vasodilation, visceral smooth muscle contraction, mucus secretory gland stimulation, vascular permeability, and tissue inflammation. Arachidonic acid metabolites, cytokines, and other mediators induce a late-phase inflammatory response that appears several hours later. There are two clinical subgroups of IgE-mediated allergy: atopy and anaphylaxis.

1. Atopy—The term “atopy” is applied to a group of diseases (allergic rhinitis, allergic asthma, atopic dermatitis, and allergic gastroenteropathy) occurring in persons with an inherited tendency to develop antigen-specific IgE reaction to environmental allergens or food antigens. Aeroallergens such as pollens, mold spores, animal danders, and house dust mite antigen are common triggers for allergic conjunctivitis, allergic rhinitis, and allergic asthma. The allergic origin of atopic dermatitis is less well understood, but some patients’ symptoms can be triggered by exposure to dust mite antigen and ingestion of certain foods. There is a strong familial tendency toward the development of atopy.

2. Anaphylaxis—Certain allergens—especially drugs, insect venoms, latex, and foods—may induce an IgE antibody response, causing a generalized release of mediators from mast cells and resulting in systemic anaphylaxis. This is characterized by (1) hypotension or shock from wide-

spread vasodilation, (2) bronchospasm, (3) gastrointestinal and uterine muscle contraction, and (4) urticaria or angioedema. The condition is potentially fatal and can affect both nonatopic and atopic persons. Isolated urticaria and angioedema are cutaneous forms of anaphylaxis, are much more common, and have a better prognosis.

B. Type II—Antibody-Mediated (Cytotoxic) Hypersensitivity

Cytotoxic reactions involve the specific reaction of either IgG or IgM antibody to cell-bound antigens. This results in activation of the complement cascade and the destruction of the cell to which the antigen is bound. Examples include immune hemolytic anemia and Rh hemolytic disease in the newborn.

C. Type III—Immune Complex-Mediated Hypersensitivity

Immune complex-mediated reactions occur when antigen and IgG or IgM antibodies form circulating immune complexes. Deposition of these complexes in tissues or in vascular endothelium can produce immune complex-mediated tissue injury through activation of the complement cascade, anaphylatoxin generation, and chemotaxis of polymorphonuclear leukocytes. Serum sickness is the classic example of type III hypersensitivity. Immune complex disease also can develop in the setting of chronic infections such as subacute bacterial endocarditis and hepatitis B.

D. Type IV—T Cell-Mediated Hypersensitivity (Delayed Hypersensitivity, Cell-Mediated Hypersensitivity)

Type IV delayed hypersensitivity is mediated by activated T cells, which accumulate in areas of antigen deposition. The most common expression of delayed hypersensitivity is allergic contact dermatitis, which develops when a low-molecular-weight sensitizing substance haptens with dermal proteins, becoming a complete antigen. Sensitized T cells release cytokines, activating macrophages and promoting the subsequent dermal inflammation; this occurs 1–2 days after the time of contact. Common topical agents associated with allergic contact dermatitis include nickel, formaldehyde, potassium dichromate, thiurams, mercaptos, parabens, quaternium-15, and ethylenediamine. Rhus (poison oak and ivy) contact dermatitis is caused by cutaneous exposure to oils from the toxicodendron plants. Acute contact dermatitis is characterized by erythema and induration with vesicle formation, often with pruritus, with exudation and crusting in more severe cases. Chronic allergic contact dermatitis may be associated with fissuring, lichenification, or dyspigmentation and may be mistaken for other forms of dermatitis. To diagnose allergic contact dermatitis, patch testing can be performed.

ATOPIC DISEASE

Clinical manifestations resembling allergic hypersensitivity can also occur in the absence of an immunologic mechanism. Therefore, the diagnosis of allergy requires answers

to the following questions: (1) What is the nature of the disease? (2) Is the disease caused by an IgE-mediated mechanism? (3) What specific allergens are responsible?

The relevant history includes a survey of allergen exposure associated with home, work, hobbies, and habits as well as medications. Physical examination is most useful if performed during exposure. Demonstration of allergic hypersensitivity by *in vivo* or *in vitro* testing confirms clinical suspicions of allergic disease.

► Specific IgE Antibody Tests

To maximize the positive predictive value of allergy testing, a positive test result must be correlated with the history. Patients selected for testing include those with moderate to severe disease, those who are potential candidates for allergen immunotherapy, and those with strong predisposing factors for atopic diatheses, eg, a strong family history of atopy or ongoing exposure to potential sources of allergen. Since the development of rhinitis precedes the presentation of asthma in over half of cases, early intervention may decrease the risk of more severe clinical allergic disease. The type of immune response must be consistent with the nature of the disease. IgE antibody causes allergic rhinitis but not allergic contact dermatitis. IgE antibodies are detected by *in vivo* (skin tests) or *in vitro* methods.

SERUM SICKNESS

ESSENTIALS OF DIAGNOSIS

- Fever, pruritic rash, arthralgias, and arthritis; nephritis in severe cases.
- Occurs 7–10 days following administration of an exogenous antigen (eg, heterologous gamma globulin) when specific IgG antibodies develop against the antigen.
- Immune-complex mediated small vessel vasculitis and tissue injury.

► General Considerations

Serum sickness occurs when an antibody response to exogenously administered antigens results in the formation of

immune complexes. Deposition of these complexes in vascular endothelium and tissues produces immune complex-mediated small vessel vasculitis and tissue injury through activation of complement, generation of anaphylatoxins, and chemoattraction of polymorphonuclear leukocytes. The skin, joints, and kidneys are commonly affected. It is self-limited and resolves after the antigen is cleared. First observed in the preantibiotic era when heterologous serum preparations were used for passive immunization, serum sickness is now less common but still occurs with the use of heterologous anti-thymocyte globulin for transplant rejection and, infrequently, after the administration of murine monoclonal antibodies or even non-protein drugs.

► Clinical Findings

A. Symptoms and Signs

Sustained high fever (> 101 °F) is typical. The earliest manifestation is often a maculopapular or urticarial pruritic rash. Angioedema can occur. Polyarthralgias, frank polyarthritis, and lymphadenopathy are common. Nephritis is usually mild but can progress to acute renal failure.

B. Laboratory Findings

The ESR is increased, and leukocytosis is common. Other nonspecific laboratory findings include elevated hepatic aminotransferases. When nephritis is present, the urinalysis reveals proteinuria, hematuria, and red cell casts. Hypocomplementemia is usually present in cases due to administration of heterologous gamma globulin but not in milder cases precipitated by non-protein drugs. Circulating immune complexes may be found, but current assays are limited in sensitivity.

► Treatment

This disease is self-limited, and treatment is usually conservative for mild cases. NSAIDs help relieve the arthralgias, and antihistamines and topical corticosteroids can be of benefit for the skin manifestation. A high-dose course of corticosteroids is administered for serious reactions, especially those complicated by glomerulonephritis and other manifestations of vasculitis. Plasma exchange may be of benefit for cases refractory to corticosteroids.

Lundquist AL et al. Serum sickness following rabbit antithymocyte globulin induction in a liver transplant recipient: case report and literature review. *Liver Transpl*. 2007 May;13(5):647–650. [PMID: 17377915]

PSEUDOALLERGIC REACTIONS*

These reactions resemble immediate hypersensitivity reactions but are not mediated by allergen-IgE interaction. Instead, direct mast cell activation occurs. Examples of pseudoallergic or “anaphylactoid” reactions include the now rare “red man syndrome” from rapid infusion of

*The contribution of Jeffrey L. Kishiyama, MD and Daniel C. Adelman, MD, is gratefully acknowledged.

vancomycin, direct mast cell activation by opioids, and radiocontrast reactions. In contrast to IgE-mediated reactions, these can often be prevented by prophylactic medical regimens.

Radiocontrast Media Reactions

Reactions to radiocontrast media do not appear to be mediated by IgE antibodies, yet clinically they are similar to anaphylaxis. If a patient has had an anaphylactoid reaction to conventional radiocontrast media, the risk for a second reaction upon reexposure may be as high as 30%. Patients with asthma or those being treated with β -adrenergic blocking medications may be at increased risk. The management of patients at risk for radiocontrast medium reactions includes use of the low-osmolality contrast preparations and prophylactic administration of prednisone (50 mg orally every 6 hours beginning 18 hours before the procedure) and diphenhydramine (25–50 mg intramuscularly 60 minutes before the procedure). The use of the lower-osmolality radiocontrast media in combination with the pretreatment regimen decreases the incidence of reactions to less than 1%.

PRIMARY IMMUNODEFICIENCY DISORDERS

The primary immunologic deficiency diseases include congenital and acquired disorders of humoral immunity (B cell function) or cell-mediated immunity (T cell function). Most of these diseases are rare and, because they are genetically determined, usually present in childhood. Nonetheless, several immunodeficiency disorders can present in adulthood, most notably selective IgA deficiency and common variable immunodeficiency.

Bonilla FA et al. Update on primary immunodeficiency diseases. *J Allergy Clin Immunol.* 2006 Feb;117(2 Suppl Mini-Primer):S435–41. [PMID: 16455342]

Buckley RH. Primary immunodeficiency or not? Making the correct diagnosis. *J Allergy Clin Immunol.* 2006 Apr;117(4):756–8. [PMID: 16630930]

Rudd CE. Disabled receptor signaling and new primary immunodeficiency disorders. *N Engl J Med.* 2006 May 4;354(18):1874–7. [PMID: 16672698]

SELECTIVE IMMUNOGLOBULIN A DEFICIENCY

Selective IgA deficiency is the most common primary immunodeficiency disorder and is characterized by serum IgA levels less than 15 mg/dL with normal levels of IgG and IgM; its prevalence is about 1:500 individuals. Most persons

are asymptomatic because of compensatory increases in secreted IgG and IgM. Some affected patients have frequent and recurrent infections, such as sinusitis, otitis, and bronchitis. Some cases of IgA deficiency may spontaneously remit. When IgG₂ subclass deficiency occurs in combination with IgA deficiency, affected patients are more susceptible to encapsulated bacteria and the degree of immune impairment can be more severe. Patients with a combined IgA and IgG subclass deficiency should be assessed for functional antibody responses to glycoprotein antigen immunization.

Atopic disease and autoimmune disorders can be associated with IgA deficiency. Occasionally, a sprue-like syndrome with steatorrhea has been associated with an isolated IgA deficit. Treatment with commercial immune globulin is ineffective, since IgA and IgM are present only in trace quantities in these preparations.

Individuals with selective IgA deficiency may have high titers of anti-IgA antibodies and are at risk for anaphylactic reactions following exposure to IgA through infusions of plasma (or blood transfusions). These anti-IgA antibodies develop in the absence of prior exposure to human plasma or blood, possibly due to crossreactivity to bovine IgA in cow's milk or prior sensitization to maternal IgA in breast milk.

Woof JM et al. The function of immunoglobulin A in immunity. *J Pathol.* 2006 Jan;208(2):270–82. [PMID: 16362985]

COMMON VARIABLE IMMUNODEFICIENCY

ESSENTIALS OF DIAGNOSIS

- ▶ Defect in terminal differentiation of B cells, with absent plasma cells and deficient synthesis of secreted antibody.
- ▶ Frequent sinopulmonary infections secondary to humoral immune deficiency.
- ▶ Confirmation by evaluation of serum immunoglobulin levels and deficient functional antibody responses.

▶ General Considerations

The most common cause of panhypogammaglobulinemia in adults is common variable immunodeficiency, a heterogeneous immunodeficiency disorder clinically characterized by an increased incidence of recurrent infections, autoimmune phenomena, and neoplastic diseases. The onset generally is during adolescence or early adulthood but can occur at any age. The prevalence of common variable immunodeficiency is about 1:80,000 in the United States. Most cases are sporadic; 10–20% are familial.

▶ Clinical Findings

A. Symptoms and Signs

The pattern of immunoglobulin isotype deficiency is variable. Most patients present with significantly depressed IgG levels, but over time all antibody classes (IgG, IgA, and

IgM) may be affected. Increased susceptibility to pyogenic infections is the hallmark of the disease. Virtually all patients suffer from recurrent sinusitis, with bronchitis, otitis, pharyngitis, and pneumonia also being common infections. Infections may be prolonged or associated with unusual complications such as meningitis or sepsis.

Gastrointestinal disorders are commonly associated with common variable immunodeficiency, and a sprue-like syndrome, with diarrhea, steatorrhea, malabsorption, protein-losing enteropathy, and hepatosplenomegaly, may develop in patients. Paradoxically, there is an increased incidence of autoimmune disease (20%), although patients may not display the usual serologic markers. Autoimmune cytopenias are most common, but autoimmune endocrinopathies, seronegative rheumatic disease, and gastrointestinal disorders are also commonly seen. Lymph nodes may be enlarged in these patients, yet biopsies show marked reduction in plasma cells. Noncaseating granulomas are frequently found in the spleen, liver, lungs, or skin. There is an increased propensity for the development of B cell neoplasms (50- to 400-fold increase risk of lymphoma), gastric carcinomas, and skin cancers.

B. Laboratory Findings

Diagnosis is confirmed in patients with recurrent infections by demonstration of functional or quantitative defects in antibody production. Serum IgG levels are usually less than 250 mg/dL; serum IgA and IgM levels are also subnormal. Decreased to absent functional antibody responses to protein antigen immunizations establish the diagnosis.

The causes of the panhypogammaglobulinemia in common variable immunodeficiency patients include intrinsic

B cell defects that prevent terminal maturation into antibody-secreting plasma cells. The absolute B cell count in the peripheral blood in most patients, despite the underlying cellular defect, is normal. A subset of these patients have concomitant T cell immunodeficiency with increased numbers of activated CD8 cells, splenomegaly, and decreased delayed-type hypersensitivity.

▶ Treatment

Patients may be treated aggressively with antibiotics at the first sign of infection. Since antibody deficiency predisposes patients to high-risk pyogenic infections, antibiotic coverage should be sure to cover encapsulated bacteria. Only after the development of bronchiectasis or after sinus surgery do patients become significantly affected by more virulent organisms such as *S aureus* or *P aeruginosa*. Maintenance intravenous immune globulin therapy is indicated, with infusions of 300–500 mg/kg of intravenous immune globulin given at about monthly intervals. Adjustment of dosage or of the infusion interval is made on the basis of clinical responses and steady-state trough serum IgG levels. Such therapy is effective in decreasing the incidence of potentially life-threatening infections and increasing quality of life. The yearly cost of monthly infusions can be in excess of \$20,000–\$30,000.

Fluid & Electrolyte Disorders

Kerry C. Cho, MD

ASSESSMENT OF THE PATIENT

The diagnosis and treatment of fluid and electrolyte disorders are based on (1) careful history, (2) physical examination and assessment of total body water and its distribution, (3) serum electrolyte concentrations, (4) urine electrolyte concentrations, and (5) serum osmolality. The pathophysiology of electrolyte disorders is rooted in basic principles of total body water and its distribution across fluid compartments.

A. Body Water and Fluid Distribution

Total body water is different in men than in women, and it decreases with aging (Table 21-1). Approximately 50-60% of total body weight is water; two-thirds (40% of body weight) is intracellular, while one-third (20% of body weight) is extracellular. One-fourth of extracellular fluid (5% of body weight) is intravascular. Water may be lost from either or both compartments (intracellular and extracellular). Changes in total body water content are best evaluated by documenting changes in body weight. Effective circulating volume may be assessed by physical examination (eg, blood pressure, pulse, jugular venous distention). Quantitative measurements of effective circulating volume and intravascular volume may be invasive (ie, central venous pressure or pulmonary wedge pressure) or noninvasive (ie, inferior vena cava diameter and right atrial pressure by echocardiography) but still require careful interpretation.

B. Serum Electrolytes

The cause of electrolyte disorders may be determined by reviewing the history, underlying diseases, and medications.

C. Evaluation of Urine

The urine concentration of an electrolyte indicates renal handling of the electrolyte and whether the kidney is appropriately excreting or retaining the electrolyte. A 24-hour urine collection for daily electrolyte excretion is the gold standard for renal electrolyte handling, but it is slow and onerous. A more convenient method is the fractional

excretion (F_E) of an electrolyte X (F_{E_x}) calculated from a spot urine sample:

$$F_{E_x}(\%) = \frac{\text{Urine X/Serum X}}{\text{Urine Cr/Serum Cr}} \times 100$$

A low fractional excretion indicates renal reabsorption (high avidity or electrolyte retention), while a high fractional excretion indicates renal wasting (low avidity or electrolyte excretion). Thus, the fractional excretion helps the clinician determine whether the kidney's response is appropriate for a specific electrolyte disorder.

D. Serum Osmolality

Solute concentration is measured by osmolality. Osmoles per kilogram of water is *osmolality*; osmoles per liter of solution is *osmolarity*. At physiological solute concentrations (normally 285-295 mosm/kg), the two measurements are clinically interchangeable. Tonicity refers to osmolytes that are impermeable to cell membranes. Differences in osmolyte concentration across cell membranes lead to osmosis and fluid shifts, stimulation of thirst, and secretion of antidiuretic hormone (ADH). Substances that easily permeate cell membranes (eg, urea, ethanol) are ineffective osmolytes that do not cause fluid shifts across fluid compartments.

Serum osmolality can be estimated from the following formula:

Osmolality =

$$2(\text{Na}^+ \text{ mEq/L}) + \frac{\text{Glucose mg/dL}}{18} + \frac{\text{BUN mg/dL}}{2.8}$$

(1 mosm/L of glucose equals 180 mg/L and 1 mosm/L of urea nitrogen equals 28 mg/L). Sodium is the major extracellular cation; doubling the serum sodium in the formula for estimated osmolality accounts for the counterbalancing anions. A discrepancy between measured and estimated osmolality of more than 10 mosm/kg suggests an osmolal gap, which is the presence of other unmeasured osmoles such as ethanol, methanol, isopropanol, and ethylene glycol.

Table 21-1. Total body water (as percentage of body weight) in relation to age and sex.

| Age | Male | Female |
|---------|--------|--------|
| 18-40 | 60% | 50% |
| 41-60 | 60-50% | 50-40% |
| Over 60 | 50% | 40% |

DISORDERS OF SODIUM CONCENTRATION

HYONATREMIA

ESSENTIALS OF DIAGNOSIS

- ▶ The patient's volume status and serum osmolality are essential to determine etiology.
- ▶ Hyponatremia usually reflects excess water retention relative to sodium rather than sodium deficiency.
- ▶ Hypotonic fluids commonly cause hyponatremia in hospitalized patients.

General Considerations

Defined as a serum sodium concentration less than 135 mEq/L, hyponatremia is the most common electrolyte abnormality in hospitalized patients. The clinician should be wary about hyponatremia since mismanagement can result in catastrophic neurologic consequences due to cerebral osmotic demyelination. Indeed, iatrogenic complications from aggressive or inappropriate therapy can be more harmful than hyponatremia itself.

A common misperception is that the sodium concentration is a reflection of total body sodium or total body water. In fact, total body water and total body sodium can be low, normal, or high in hyponatremia since the kidney can regulate sodium and water homeostasis independently. Most cases of hyponatremia reflect water imbalance and abnormal water handling, not sodium imbalance, indicating the primary role of ADH in the pathophysiology of many cases of hyponatremia. A diagnostic algorithm using serum osmolality and volume status separates the causes of hyponatremia into therapeutically useful categories (Figure 21-1).

Etiology

A. Isotonic & Hypertonic Hyponatremia

Serum osmolality identifies isotonic and hypertonic hyponatremia, although these cases can often be identified by careful history or previous laboratory tests.

Isotonic hyponatremia is seen with severe hyperlipidemia and hyperproteinemia. Lipids (including chylomicrons, triglycerides, and cholesterol) and proteins (> 10 g/dL, eg, paraproteinemias and intravenous immunoglobu-

lin therapy) interfere with the measurement of serum sodium, causing an artifactual pseudohyponatremia. Serum osmolality is isotonic because lipids and proteins do not affect osmolality measurement. Newer sodium measurements using ion-specific electrodes will not produce pseudohyponatremia.

Hypertonic hyponatremia occurs with hyperglycemia and mannitol administration for increased intracranial pressure. Glucose and mannitol osmotically pull intracellular water into the extracellular space. The translocation of water lowers the serum sodium concentration. Translocational hyponatremia is not pseudohyponatremia or an artifact of sodium measurement. The sodium concentration falls 2 mEq/L for every 100 mg/dL rise in glucose when the glucose concentration is between 200 and 400 mg/dL. If the glucose concentration is above 400 mg/dL, the sodium concentration falls 4 mEq/L for every 100 mg/dL rise in glucose. An overall sodium correction factor of 2.4 mEq/L for every 100 mg/dL increase in glucose concentration is more accurate than the 1.6 mg/dL that has been used previously.

B. Hypotonic Hyponatremia

Most cases of hyponatremia are hypotonic, highlighting sodium's role as the predominant extracellular osmole. The next step is classifying hypotonic cases by the patient's volume status.

1. Hypovolemic hypotonic hyponatremia—Hypovolemic hyponatremia occurs with renal or extrarenal volume loss and hypotonic fluid replacement (Figure 21-1). Total body sodium and total body water are decreased. To maintain intravascular volume, the pituitary increases ADH secretion, causing free water retention from hypotonic fluid replacement. The body sacrifices serum osmolality to preserve intravascular volume. In short, losses of water and salt are replaced by water alone. Without ongoing hypotonic fluid intake, the renal or extrarenal volume loss would produce hypovolemic hypernatremia.

Cerebral salt wasting is a distinct and rare subset of hypovolemic hyponatremia seen in patients with intracranial disease (eg, infections, cerebrovascular accidents, tumors, and neurosurgery). Clinical features include refractory hypovolemia and hypotension, often requiring continuous infusion of isotonic or hypertonic saline and ICU monitoring. The exact pathophysiology is unclear but includes renal sodium wasting possibly through brain natriuretic peptide, ADH release, and decreased aldosterone secretion.

2. Euvolemic hypotonic hyponatremia—Euvolemic hyponatremia causes the most anxiety for clinicians because of the broad differential diagnosis. Most processes are mediated directly or indirectly through ADH, including hypothyroidism, adrenal insufficiency, medications, and the syndrome of inappropriate ADH (SIADH). The exceptions are primary polydipsia, beer potomania, and reset osmostat.

A. HORMONAL ABNORMALITIES—Hypothyroidism and adrenal insufficiency can cause hyponatremia. Exactly how hypothyroidism induces hyponatremia is unclear but may be related to ADH. Adrenal insufficiency may be associated

▲ **Figure 21-1.** Evaluation of hyponatremia using serum osmolality and extracellular fluid volume status. ACE, angiotensin-converting enzyme; SIADH, syndrome of inappropriate antidiuretic hormone. (Adapted, with permission, from Narins RG et al. Diagnostic strategies in disorders of fluid, electrolyte and acid-base homeostasis. *Am J Med.* 1982 Mar;72(3):496–520.)

with the hyperkalemia and metabolic acidosis of hypoaldosteronism. Cortisol provides feedback inhibition for ADH release.

B. THIAZIDE DIURETICS AND OTHER MEDICATIONS—Thiazides induce hyponatremia typically in older female patients within days of initiating therapy. The mechanism appears to be a combination of mild diuretic-induced volume contraction, ADH effect, and intact urinary concentrating ability resulting in water retention and hyponatremia. Loop diuretics do not cause hyponatremia as frequently because of disrupted medullary concentrating gradient and impaired urine concentration.

Nonsteroidal anti-inflammatory drugs (NSAIDs) increase ADH by inhibiting prostaglandin formation. Prostaglandins, selective serotonin reuptake inhibitors (eg, fluoxetine, paroxetine, and citalopram) can cause hyponatremia, especially in geriatric patients. Enhanced secretion or action of ADH may result from increased serotonergic tone. Angiotensin-converting enzyme (ACE) inhibitors do not block the conversion of angiotensin I to angiotensin II in the brain. Angiotensin II stimulates thirst and ADH secretion. Hyponatremia during amiodarone-loading has been reported; it usually improves with dose reduction.

Abuse of 3,4-methylenedioxymethylamphetamine (MDMA, also known as Ecstasy) can lead to hyponatremia and severe neurologic symptoms, including seizures, cerebral edema, and brainstem herniation. MDMA and its metabolites increase ADH release from the hypothalamus. There may be a component of primary polydipsia since MDMA users typically increase fluid intake in an attempt to prevent hyperthermia.

C. NAUSEA, PAIN, SURGERY, AND MEDICAL PROCEDURES—Nausea and pain are potent stimulators of ADH release. Severe hyponatremia can develop after elective surgery in healthy patients, especially premenopausal women. Hypotonic fluids in the setting of elevated ADH levels can produce severe and life-threatening hyponatremia. Other medical procedures, such as colonoscopy, have also been associated with hyponatremia.

D. HIV INFECTION—Hyponatremia is seen in up to 50% of hospitalized HIV patients and 20% of ambulatory HIV patients. The differential diagnosis is broad: medication effect, adrenal insufficiency, hypoaldosteronism, central nervous system or pulmonary disease, SIADH, malignancy, and volume depletion.

E. ENDURANCE EXERCISE HYPONATREMIA—Hyponatremia after endurance exercise (eg, triathlon events and marathons) may be caused by a combination of excessive hypotonic fluid intake and continued ADH secretion. Reperfusion of the exercise-induced ischemic splanchnic bed causes delayed absorption of excessive quantities of hypotonic fluid ingested during exercise. Sustained elevation of ADH prevents water excretion in this setting. New guidelines encourage runners to drink between 400 mL/h and 800 mL/h as opposed to the previous “as much as possible” advice. However, the clinical relevance of this new recommendation remains to be determined.

F. SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION—Under normal circumstances, hypovolemia and hyperosmolality stimulate ADH secretion. ADH release is inappropriate without these physiological cues. Normal regulation of ADH release occurs from both the central nervous system and the chest via baroreceptors and neural input. The major causes of SIADH (Table 21–2) are disorders affecting the central nervous system (structural, metabolic, psychiatric, or pharmacologic processes) or the lungs (infectious, mechanical, oncologic). Medications commonly cause SIADH by increasing ADH or its action. Some carcinomas, especially small cell lung carcinoma, can autonomously secrete ADH.

G. PSYCHOGENIC POLYDIPSIA AND BEER POTOMANIA—Marked free water intake (generally > 10 L/d) may produce hyponatremia. Euvolemia is maintained through renal excretion of sodium. Urine sodium is therefore generally elevated (> 20 mEq/L), and ADH levels are appropriately suppressed. As the increased free water is excreted, the urine osmolality approaches the minimum urine osmolality of 50 mosm/kg. Psychogenic polydipsia occurs in patients with psychiatric disease. Psychiatric medications may interfere with water excretion or increase thirst through anticholinergic side effects, further increasing water intake. The hyponatremia of beer potomania occurs in patients who consume large amounts of beer. Free water excretion is decreased in these patients because of decreased solute consumption and production; muscle wasting and malnutrition are contributing factors. Without enough solute, these patients have decreased free water excretory capacity even if they can maximally dilute the urine.

H. RESET OSMOSTAT—Reset osmostat is a rare cause of hyponatremia characterized by appropriate ADH regulation in response to water deprivation and fluid challenges. Patients with reset osmostat regulate serum sodium and serum osmolality around a lower set point, concentrating or diluting urine in response to hyperosmolality and hypo-osmolality. The mild hypo-osmolality of pregnancy is a form of reset osmostat.

3. Hypervolemic hypotonic hyponatremia—Hypervolemic hyponatremia occurs in the edematous states of cirrhosis, heart failure, nephrotic syndrome, and advanced kidney disease (Figure 21–1). In cirrhosis and heart failure, effective circulating volume is decreased due to peripheral vasodilation or decreased cardiac output. Increased renin-angiotensin-aldosterone system activity and ADH secre-

tion result in water retention. Notice the pathophysiological similarity to hypovolemic hyponatremia—the body sacrifices osmolality in an attempt to restore effective circulating volume.

The pathophysiology of hyponatremia in nephrotic syndrome is not completely understood, but the primary disturbance may be renal sodium retention, resulting in overfilling of the intravascular space and secondary edema

formation as fluid seeped into the interstitial space. Previously, it was believed that the decreased oncotic pressure of hypoalbuminemia meant that the intravascular space lost fluid to the interstitial compartment. This intravascular underfilling led to secondary renal sodium retention. However, from a clinical standpoint, patients receiving therapy for glomerular disease and nephrotic syndrome often have edema resolution prior to improvements in the serum albumin.

Patients with advanced kidney disease typically have sodium retention with decreased free water excretory capacity, resulting in hypervolemic hyponatremia.

► Clinical Findings

A. Symptoms and Signs

Whether hyponatremia is symptomatic depends on its severity and acuity. Chronic disease can be severe (sodium concentration less than 110 mEq/L), yet remarkably asymptomatic because the brain has adapted by decreasing its tonicity over weeks to months. Acute disease that has developed over hours to days can be severely symptomatic with relatively moderate hyponatremia. Mild hyponatremia (sodium concentrations of 130–135 mEq/L) is usually asymptomatic.

Mild symptoms of nausea and malaise progress to headache, lethargy, and disorientation as the sodium concentration drops. The most serious symptoms are respiratory arrest, seizure, coma, permanent brain damage, brainstem herniation, and death. Premenopausal women are much more likely than menopausal women to die or suffer permanent brain injury from hyponatremic encephalopathy, suggesting a hormonal role in the pathophysiology.

Evaluation starts with a careful history for new medications, changes in fluid intake (polydipsia, anorexia, intravenous fluid rates and composition), fluid output (nausea and vomiting, diarrhea, ostomy output, polyuria, oliguria, insensible losses). The physical examination should help categorize the patient's volume status into hypovolemia, euvolemia, or hypervolemia.

B. Laboratory Findings

Laboratory assessment should include serum electrolytes, serum creatinine, serum osmolality, and urine sodium. The etiology of most cases of hyponatremia will be apparent from the history, physical, and these basic laboratory tests. Additional tests of thyroid and adrenal function will occasionally be necessary.

SIADH is a clinical diagnosis characterized by (1) hyponatremia; (2) decreased osmolality (< 280 mosm/kg); (3) absence of heart, kidney, or liver disease; (4) normal thyroid and adrenal function (see Chapter 26); and (5) urine sodium usually over 20 mEq/L. In clinical practice, ADH levels are not measured in these patients. Patients with SIADH may have low blood urea nitrogen (BUN) (< 10 mg/dL) and hypouricemia (< 4 mg/dL), which are not only dilutional but result from increased urea and uric acid clearances in response to the volume-expanded state. An elevated BUN (azotemia) may reflect volume contraction, ruling out SIADH, which is seen in euvolemic patients.

► Complications

The most serious complication of hyponatremia is iatrogenic cerebral osmotic demyelination from overly rapid or inappropriate sodium correction.

► Treatment

Regardless of the patient's volume status, another common feature is to restrict free water and hypotonic fluid intake, since these solutions can only exacerbate hyponatremia. Free water intake from oral intake and intravenous fluids should generally be less than 1–1.5 L/d.

Hypovolemic patients require adequate fluid resuscitation from isotonic fluids (either normal saline or lactated Ringer solution) to suppress the hypovolemic stimulus for ADH release. Patients with **cerebral salt wasting** may require hypertonic saline or normal saline to prevent circulatory collapse; some may respond to fludrocortisone. **Hypervolemic** patients may require loop diuretics or dialysis, or both, (or other extracorporeal ultrafiltration) to correct the increased total body water and sodium. Euvolemic patients may respond to free water restriction alone.

Pseudohyponatremia from hypertriglyceridemia or hyperproteinemia requires no therapy except perhaps confirmation with the clinical laboratory. **Translocational hyponatremia** from glucose or mannitol can be managed with glucose correction or mannitol discontinuation (if possible). No specific therapy is necessary in patients with **reset osmostat** since they can successfully regulate their serum sodium with fluid challenges and water deprivation.

Symptomatic and/or severe hyponatremia generally requires hospitalization for observation, careful monitoring of fluid balance and weights, and frequent sodium checks. Any inciting medications should be discontinued if possible.

There is no consensus about the optimal rate of sodium correction in symptomatic hyponatremic patients. A reasonable rate is 10–12 mEq/L/d in mildly to moderately symptomatic patients. A more aggressive rate of 1–1.5 mEq/L/h (to a maximum correction of 10–12 mEq/L) has been used in severely symptomatic patients. Sodium concentration should be monitored as frequently as every 1–2 hours. As the symptoms improve or resolve, the correction rate should be reduced to roughly 0.5 mEq/L/h. To avoid overcorrection, the physician should stabilize the sodium in the range of 125 to 130 mEq/L.

Also called central pontine myelinolysis, cerebral osmotic demyelination may occur outside the brainstem. Demyelination may occur days after sodium correction or initial neurologic recovery from hyponatremia. Hypoxic episodes during hyponatremia may contribute to demyelination. Unfortunately, the neurologic effects are generally disastrous and irreversible.

In severely symptomatic patients, the physician should calculate the patient's sodium deficit and deliver **hypertonic saline** (ie, 3% saline) at the appropriate rate. In general the saline infusion rate should be approximately 0.5 mL/kg body weight/h; rates of 1 mL/kg/h or greater may represent a miscalculation of the sodium deficit or mathematical error. Hypertonic saline in hypervolemic

patients can be hazardous, resulting in worsening volume overload, pulmonary edema, and ascites.

Demeclocycline (300–600 mg orally twice daily) is used for patients who cannot adequately restrict water restriction or have an inadequate response to conservative measures. It inhibits the effect of ADH on the distal tubule. Onset of action may require 1 week, and urinary concentrating ability may be permanently impaired, resulting in nephrogenic diabetes insipidus and even hypernatremia. Demeclocycline may be more nephrotoxic in patients with cirrhosis.

Vasopressin antagonists may revolutionize the treatment of euvolemic and hypervolemic hyponatremia, especially in persons with heart failure. Unfortunately, oral versions are not available in the United States; these include lixivaptan, tolvaptan, and satavaptan, which are selective vasopressin-2 receptor antagonists. V₂ receptors primarily mediate the diuretic effect of ADH. For hospitalized patients with euvolemic SIADH, conivaptan is given as an intravenous loading dose of 20 mg delivered over 30 minutes, then as 20 mg continuously over 24 hours. Subsequent infusions may be administered every 1–3 days at 20–40 mg/d by continuous infusion.

▶ When to Refer

- Nephrology or endocrinology consultation should be considered in severe, symptomatic, refractory, or complicated cases of hyponatremia.
- Aggressive therapies such as hypertonic saline, demeclocycline, vasopressin antagonists, and dialysis mandate specialist consultation.
- Consultation may be necessary for patients with end-stage liver or heart disease.

▶ When to Admit

Hospital admission is necessary for symptomatic patients or those requiring aggressive therapies for close monitoring and frequent laboratory testing.

HYPERNATREMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Increased thirst and water intake is the first defense against hypernatremia.

- ▶ Urine osmolality helps differentiate renal from non-renal water loss.

▶ General Considerations

Hypernatremia is defined as a sodium concentration > 145 mEq/L. All patients with hypernatremia have hyperosmolality, unlike hyponatremic patients who can have a low, normal, or high serum osmolality. The hypernatremic patient is typically hypovolemic due to free water losses, although hypervolemic hypernatremia is frequently seen, often an iatrogenic complication in hospitalized patients with impaired access to free water. Rarely, excessive sodium intake may cause hypernatremia. Hypernatremia in primary aldosteronism is mild and usually does not cause symptoms.

An intact thirst mechanism and access to water are the primary defense against hypernatremia. The hypothalamus can sense minimal changes in serum osmolality, triggering the thirst mechanism and increased water intake. Thus, whatever the underlying disorder (eg, dehydration, lactulose or mannitol therapy, central and nephrogenic diabetes insipidus), excess water loss can cause hypernatremia only when adequate water intake is not possible, as with unconscious patients.

▶ Clinical Findings

A. Symptoms and Signs

When the patient is dehydrated, orthostatic hypotension and oliguria are typical findings. Because water shifts from the cells to the intravascular space to protect volume status, these symptoms may be delayed. Lethargy, irritability, and weakness are early signs. Hyperthermia, delirium, seizures, and coma may be seen with severe hypernatremia (ie, sodium > 158 mEq/L). Symptoms in the elderly may not be specific; a recent change in consciousness is associated with a poor prognosis. Osmotic demyelination is an uncommon but reported consequence of severe hypernatremia.

B. Laboratory Findings

1. Urine osmolality > 400 mosm/kg—Renal water-conserving ability is functioning.

A. NONRENAL LOSSES—Hypernatremia will develop if water intake falls behind hypotonic fluid losses from excessive sweating, the respiratory tract, or bowel movements. Lactulose causes an osmotic diarrhea with loss of free water.

B. RENAL LOSSES—While severe hyperglycemia can cause translocational hyponatremia (see above), progressive volume depletion from osmotic glucosuria can result in hypernatremia. Osmotic diuresis can occur with the use of mannitol or urea.

2. Urine osmolality < 250 mosm/kg—A dilute urine with osmolality less than 250 mosm/kg with hypernatremia is characteristic of central and nephrogenic diabetes insipidus. Nephrogenic diabetes insipidus results from renal insensitivity to ADH; common causes include lith-

ium, demeclocycline, relief of urinary obstruction, interstitial nephritis, hypercalcemia, and hypokalemia.

► Treatment

Treatment of hypernatremia includes correcting the cause of the fluid loss, replacing water, and replacing electrolytes (as needed). In response to increases in plasma osmolality, brain cells synthesize solutes—or idiogenic osmoles—which increase osmotic flow of water back into the brain cells to regulate their volume. This begins 4–6 hours after dehydration and takes several days to reach a steady state. If hypernatremia is too rapidly corrected, the osmotic imbalance may cause water to preferentially enter brain cells, causing cerebral edema and potentially severe neurologic impairment. Fluid therapy should be administered over a 48-hour period, aiming for a decrease in serum sodium of approximately 1 mEq/L/h (1 mmol/L/h). Unfortunately, there is no consensus about the optimal rates of sodium correction in hypernatremia and hyponatremia.

A. Choice of Type of Fluid for Replacement

1. Hypernatremia with hypovolemia—Hypovolemic patients should receive isotonic (0.9%) saline to restore the volume deficit and to treat the hyperosmolality, since the osmolality of isotonic saline (308 mosm/kg) is often lower than that of the plasma. After adequate volume resuscitation with normal saline, 0.45% saline or 5% dextrose (or both) can be used to replace any remaining free water deficit. Milder volume deficits may be treated with 0.45% saline and 5% dextrose.

2. Hypernatremia with euvolemia—Water ingestion or intravenous 5% dextrose will result in the excretion of excess sodium in the urine. If the glomerular filtration rate (GFR) is decreased, diuretics will increase urinary sodium excretion but may impair renal concentrating ability, increasing the quantity of water that needs to be replaced.

3. Hypernatremia with hypervolemia—Treatment includes 5% dextrose solution to reduce hyperosmolality. Loop diuretics may be necessary to promote natriuresis and lower the total body sodium. In severe rare cases with kidney disease, hemodialysis may be necessary to correct the excess total body sodium and water.

B. Calculation of Water Deficit

Fluid replacement should include the free water deficit as well as the maintenance fluid to replace ongoing and anticipated fluid losses.

1. Acute hypernatremia—In acute dehydration without much solute loss, free water loss is similar to the weight loss. Initially, a 5% dextrose solution may be used. As correction of water deficit progresses, therapy should continue with 0.45% saline with dextrose.

2. Chronic hypernatremia—The water deficit is calculated to restore normal sodium concentration, typically 140 mEq/L. Total body water (TBW) (Table 21–1) correlates with muscle mass and therefore decreases with advancing

age, cachexia, and dehydration and is lower in women than in men. Current TBW equals 40–60% current body weight.

$$\text{Volume (in L) to be replaced} = \text{Current TBW} \times \frac{[\text{Na}^+] - 140}{140}$$

► When to Refer

Patients with refractory or unexplained hypernatremia should be referred for subspecialist consultation.

► When to Admit

- Patients with symptomatic hypernatremia require hospitalization for evaluation and treatment.
- Significant comorbidities or concomitant acute illnesses, especially if contributing to hypernatremia, may necessitate hospitalization.

VOLUME OVERLOAD

ESSENTIALS OF DIAGNOSIS

- Disorder of excessive sodium retention in the setting of low arterial underfilling (eg, congestive heart failure or cirrhosis).
- Hyponatremia from water retention in edematous states is associated with sodium retention.

The hallmark of a volume overloaded state is sodium retention. Abnormally low arterial filling, such as from congestive heart failure or cirrhosis, activates the neurohumoral axis, which stimulates the renin-angiotensin-aldosterone system, the sympathetic nervous system, and ADH (vasopressin) release. Sodium retention with edema results. The stimulus for the release of vasopressin is nonosmotic. Instead, vasopressin is released in response to activation of baroreceptors because of a decrease in arterial baroreceptor stretch. Vasopressin stimulates renal V_2 receptors, which increase water reabsorption; hyponatremia may develop in the edematous state.

HYPEROSMOLAR DISORDERS & OSMOLAR GAPS

HYPEROSMOLALITY WITH TRANSIENT OR NO SIGNIFICANT SHIFT IN WATER

Urea and alcohol readily cross cell membranes and can produce hyperosmolality. Urea is an ineffective osmole with little effect on osmotic water movement across cell membranes. Alcohol quickly equilibrates between the intracellular and extracellular compartments, adding 22 mosm/L for every 1000 mg/L of ethanol. Ethanol intoxication should be considered in any case of stupor or coma with an elevated osmolal gap (measured osmolality – calculated osmolality > 10 mosm/kg). Other toxic alcohols such as methanol and ethylene glycol cause an osmolal gap and a metabolic acidosis with an increased anion gap (see Chapter 39). The combination of an increased anion gap metabolic acidosis and an osmolal gap exceeding 10 mosm/kg is not specific for toxic alcohol ingestion and may occur with alcoholic ketoacidosis or lactic acidosis (see Metabolic Acidosis).

HYPEROSMOLALITY ASSOCIATED WITH SIGNIFICANT SHIFTS IN WATER

Increased concentrations of solutes that do not readily enter cells cause a shift of water from the intracellular compartment to the extracellular compartment. Hyperosmolality of effective osmoles such as sodium and glucose causes symptoms, primarily in the central nervous system. The severity of symptoms depends on the degree of hyperosmolality and rapidity of development. In acute hyperosmolality, somnolence and confusion can appear when the osmolality exceeds 320–330 mosm/kg; coma, respiratory arrest, and death can result when osmolality exceeds 340–350 mosm/kg.

DISORDERS OF POTASSIUM CONCENTRATION

HYPOKALEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Severe hypokalemia may induce dangerous arrhythmias and rhabdomyolysis.

- ▶ Transtubular potassium concentration gradient (TTKG) can distinguish renal from nonrenal loss of potassium.

General Considerations

Hypokalemia can result from insufficient dietary potassium intake, intracellular shifting of potassium from the extracellular space, extrarenal potassium loss, or renal potassium loss (Table 21–3). Cellular uptake of potassium is increased by insulin and β -adrenergic stimulation and blocked by α -adrenergic stimulation. Aldosterone is an important regulator of total body potassium, increasing potassium secretion in the distal renal tubule. The most common cause of hypokalemia, especially in developing countries, is gastrointestinal loss due to infectious diarrhea. The potassium concentration in intestinal secretion is ten times higher (80 mEq/L) than in gastric secretions. Hypokalemia in the presence of acidosis suggests profound potassium depletion and requires urgent treatment. Self-limited hypokalemia occurs in 50–60% of trauma patients, perhaps related to enhanced release of epinephrine.

Table 21–3. Causes of hypokalemia.

| |
|---|
| Decreased potassium intake |
| Potassium shift into the cell |
| Increased postprandial secretion of insulin |
| Alkalosis |
| Trauma (via β -adrenergic stimulation?) |
| Periodic paralysis (hypokalemic) |
| Barium intoxication |
| Renal potassium loss |
| Increased aldosterone (mineralocorticoid) effects |
| Primary hyperaldosteronism |
| Secondary aldosteronism (dehydration, heart failure) |
| Renovascular hypertension |
| Malignant hypertension |
| Ectopic ACTH-producing tumor |
| Gitelman syndrome |
| Bartter syndrome |
| Cushing syndrome |
| Licorice (European) |
| Renin-producing tumor |
| Congenital abnormality of steroid metabolism (eg, adrenogenital syndrome, 17α -hydroxylase defect, apparent mineralocorticoid excess, 11β -hydroxylase deficiency) |
| Increased flow of distal nephron |
| Diuretics (furosemide, thiazides) |
| Salt-losing nephropathy |
| Hypomagnesemia |
| Unreabsorbable anion |
| Carbenicillin, penicillin |
| Renal tubular acidosis (type I or II) |
| Fanconi syndrome |
| Interstitial nephritis |
| Metabolic alkalosis (bicarbonaturia) |
| Congenital defect of distal nephron |
| Liddle syndrome |
| Extrarenal potassium loss |
| Vomiting, diarrhea, laxative abuse |
| Villous adenoma, Zollinger-Ellison syndrome |

Hypokalemia increases the likelihood of digitalis toxicity. In patients with heart disease, hypokalemia induced by β_2 -adrenergic agonists and diuretics may impose a substantial risk. Numerous genetic mutations affect fluid and electrolyte metabolism, including disorders of potassium metabolism (Table 21–4).

Magnesium is an important cofactor for potassium uptake and for maintenance of intracellular potassium levels. Loop diuretics (eg, furosemide) cause substantial renal potassium and magnesium losses. Magnesium depletion should be suspected in refractory hypokalemia.

► Clinical Findings

A. Symptoms and Signs

Muscular weakness, fatigue, and muscle cramps are frequent complaints in mild to moderate hypokalemia. Gastrointestinal smooth muscle involvement may result in constipation or ileus. Flaccid paralysis, hyporeflexia, hypercapnia, tetany, and rhabdomyolysis may be seen with severe hypokalemia (< 2.5 mEq/L). The presence of hypertension may be a clue to the diagnosis of hypokalemia from aldosterone or mineralocorticoid excess (Table 21–4). Renal manifestations include nephrogenic diabetes insipidus and interstitial nephritis.

B. Laboratory Findings

Urinary potassium concentration is low (< 20 mEq/L) as a result of extrarenal fluid loss (eg, diarrhea, vomiting) and inappropriately high (> 40 mEq/L) with urinary losses (eg, mineralocorticoid excess, Bartter syndrome, Liddle syndrome) (Table 21–3).

The transtubular [K^+] gradient (TTKG) is a simple and rapid evaluation of net potassium secretion. TTKG is calculated as follows:

$$\text{TTKG} = \frac{\text{Urine } K^+ / \text{Plasma } K^+}{\text{Urine osm} / \text{Plasma osm}}$$

Hypokalemia with a TTKG > 4 suggests renal potassium loss with increased distal K^+ secretion. In such cases, plasma renin and aldosterone levels are helpful in differential diagnosis. The presence of nonabsorbed anions, such as bicarbonate, increases TTKG.

C. Electrocardiogram

The electrocardiogram (ECG) shows decreased amplitude and broadening of T waves, prominent U waves, premature ventricular contractions, and depressed ST segments.

► Treatment

Oral potassium supplementation is the safest and easiest treatment for mild to moderate deficiency. Dietary potassium is almost entirely coupled to phosphate—rather than chloride—and is therefore not effective in correcting potassium loss associated with chloride depletion from diuretics or vomiting. In the setting of abnormal kidney function and mild to moderate diuretic dosage, 20 mEq/d of oral potassium is generally sufficient to prevent hypokalemia, but 40–

Table 21–4. Genetic disorders associated with electrolyte metabolism disturbances.

| Disease | Site of Mutation |
|---|--|
| Potassium | |
| Hypokalemia | |
| Hypokalemic periodic paralysis | Dihydropyridine-sensitive skeletal muscle voltage-gated calcium channel |
| Bartter syndrome | $Na^+K^+2Cl^-$ cotransporter, K^+ channel (ROMK), or Cl^- channel of thick ascending limb of Henle (hypofunction), barttin |
| Gitelman syndrome | Thiazide-sensitive Na^+Cl^- cotransporter |
| Liddle syndrome | β or γ subunit of amiloride-sensitive Na^+ channel (hyperfunction) |
| Apparent mineralocorticoid excess | 11 β -hydroxysteroid dehydrogenase (failure to inactivate cortisol) |
| Glucocorticoid-remediable hyperaldosteronism | Regulatory sequence of 11 β -hydroxylase controls aldosterone synthase inappropriately |
| Hyperkalemia | |
| Hyperkalemic periodic paralysis | α subunit of calcium channel |
| Pseudohypoaldosteronism type I | β or γ subunit of amiloride-sensitive Na^+ channel (hypofunction) |
| Pseudohypoaldosteronism type II (Gordon syndrome) | HNK2, HNK4 |
| Calcium | |
| Familial hypocalciuric hypercalcemia | Ca^{2+} -sensing protein (hypofunction) |
| Familial hypocalcemia | Ca^{2+} -sensing protein (hyperfunction) |
| Phosphate | |
| Hypophosphatemic rickets | <i>PEX</i> gene, FGF23 |
| Magnesium | |
| Hypomagnesemia-hypercalciuria syndrome | Paracellin-1 |
| Water | |
| Nephrogenic diabetes insipidus | Vasopressin receptor-2 (Type 1), aquaporin-2 |
| Acid-base | |
| Proximal RTA | $Na^+ HCO_3^-$ cotransporter |
| Distal RTA | $Cl^- HCO_3^-$ exchanger H^+ -ATPase |
| Proximal and distal RTA | Carbonic anhydrase II |

FGF23, fibroblast growth factor 23; RTA, renal tubular acidosis.

100 mEq/d over a period of days to weeks is needed to treat hypokalemia and fully replete potassium stores.

Intravenous potassium is indicated for patients with severe hypokalemia and for those who cannot take oral

supplementation. For severe deficiency, potassium may be given through a peripheral intravenous line in a concentration up to 40 mEq/L and at rates up to 10 mEq/h. A rate of 20 mEq/h may be given through a central venous catheter. Continuous ECG monitoring is indicated, and the serum potassium level should be checked every 3–6 hours. For the initial administration, avoid glucose-containing fluid to prevent further shifts of potassium into the cells. Magnesium deficiency also needs to be corrected at the same time, particularly in refractory hypokalemia.

▶ When to Refer

Patients with unexplained hypokalemia, refractory hyperkalemia, or clinical features suggesting alternative diagnoses (eg, aldosteronism or hypokalemic periodic paralysis) should be referred for endocrinology or nephrology consultation.

▶ When to Admit

Patients with symptomatic or severe hypokalemia, especially with cardiac manifestations, require hospital admission for cardiac monitoring, frequent laboratory testing, and potassium supplementation.

HYPERKALEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Hyperkalemia may develop in patients taking ACE inhibitors, ARBs, potassium-sparing diuretics, or their combination, even with no or only mild kidney dysfunction.
- ▶ The ECG may show peaked T waves, widened QRS and biphasic QRS-T complexes, or may be normal despite life-threatening hyperkalemia.
- ▶ Measurement of plasma potassium level differentiates potassium leak from blood cells in cases of clotting, leukocytosis, and thrombocytosis from elevated serum potassium.
- ▶ Rule out extracellular potassium shift from the cells in acidosis and assess renal potassium excretion.

▶ General Considerations

Hyperkalemia usually occurs in patients with advanced kidney disease but can also develop with no or only mild kidney dysfunction (Table 21–5). Intracellular potassium

Table 21–5. Causes of hyperkalemia.

Spurious

- Leakage from erythrocytes when separation of serum from clot is delayed (plasma K⁺ normal)
- Marked thrombocytosis or leukocytosis with release of intracellular K⁺ (plasma K⁺ normal)
- Repeated fist clenching during phlebotomy, with release of K⁺ from forearm muscles
- Specimen drawn from arm with intravenous K⁺ infusion

Decreased excretion

- Kidney disease, acute and chronic
- Renal secretory defects (may or may not have frank kidney disease): kidney transplant, interstitial nephritis, systemic lupus erythematosus, sickle cell disease, amyloidosis, obstructive nephropathy
- Hyporeninemic hypoaldosteronism (often in diabetic patients with mild to moderate nephropathy) or selective hypoaldosteronism (some patients with AIDS)
- Drugs that inhibit potassium excretion: spironolactone, eplerenone, drospirenone, NSAIDs, ACE inhibitors, angiotensin II receptor blockers, triamterene, amiloride, trimethoprim, pentamidine, cyclosporine, tacrolimus)

Shift of K⁺ from within the cell

- Massive release of intracellular K⁺ in burns, rhabdomyolysis, hemolysis, severe infection, internal bleeding, vigorous exercise
- Metabolic acidosis (in the case of organic acid accumulation—eg, lactic acidosis—a shift of K⁺ does not occur since organic acid can easily move across the cell membrane)
- Hypertonicity (solvent drag)
- Insulin deficiency (metabolic acidosis may not be apparent)
- Hyperkalemic periodic paralysis
- Drugs: succinylcholine, arginine, digitalis toxicity, β-adrenergic antagonists
- α-Adrenergic stimulation?

Excessive intake of K⁺

- Especially in patients taking medications that decrease potassium secretion (see above)

ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

shifts to the ECF in hyperkalemia associated with acidosis. Serum potassium concentration rises about 0.7 mEq/L for every decrease of 0.1 pH unit during acidosis. Fist clenching during venipuncture may raise the potassium concentration by 1–2 mEq/L by causing acidosis and potassium shift from cells. In the absence of acidosis, serum potassium concentration rises about 1 mEq/L when there is a total body potassium excess of 1–4 mEq/kg. However, the higher the serum potassium concentration, the smaller the excess necessary to raise the potassium levels further.

Mineralocorticoid deficiency from Addison disease or chronic kidney disease (CKD) is another cause of hyperkalemia with decreased renal excretion of potassium. Mineralocorticoid resistance due to genetic disorders, interstitial kidney disease, or urinary tract obstruction also leads to hyperkalemia.

ACE inhibitors or angiotensin-receptor blockers (ARBs), commonly used in patients with congestive heart failure or CKD, may cause hyperkalemia. The concomitant use of spironolactone, eplerenone, or β-blockers further increases the risk of hyperkalemia. Thiazide or loop diuretics and sodium bicarbonate may minimize hyperkalemia.

Persistent mild hyperkalemia in the absence of ACE inhibitor or ARB therapy is usually due to type IV renal tubular acidosis (RTA). Heparin inhibits aldosterone production in the adrenal glands, causing hyperkalemia.

Trimethoprim is structurally similar to amiloride and triamterene, and all three drugs inhibit renal potassium excretion through suppression of sodium channels in the distal nephron.

Immunosuppressive drugs such as cyclosporine and tacrolimus can induce hyperkalemia in organ transplant recipients, especially kidney transplant patients, partly due to suppression of the basolateral Na^+-K^+ -ATPase in principal cells. Hyperkalemia is commonly seen in HIV-infected patients and has been attributed to impaired renal excretion of potassium due to the use of pentamidine or trimethoprim-sulfamethoxazole or to hyporeninemic hypoaldosteronism.

Clinical Findings

Hyperkalemia impairs neuromuscular transmission, causing muscle weakness, flaccid paralysis, and ileus. Electrocardiography is not a sensitive method for detecting hyperkalemia, since nearly half of patients with a serum potassium level greater than 6.5 mEq/L will not manifest ECG changes. ECG changes in hyperkalemia include bradycardia, PR interval prolongation, peaked T waves, QRS widening, and biphasic QRS-T complexes. Conduction disturbances, such as bundle branch block and atrioventricular block, may occur. Ventricular fibrillation and cardiac arrest are terminal events.

Prevention

Inhibitors of the renin-angiotensin-aldosterone axis (ie, ACE inhibitors, ARBs, and spironolactone) and potassium-sparing diuretics should be used cautiously in patients with heart failure, liver failure, and kidney disease. Laboratory monitoring should be performed within 1 week of drug initiation or dosage increase.

Treatment

The diagnosis should be confirmed by repeat laboratory testing to rule out spurious hyperkalemia, especially in the absence of medications that cause hyperkalemia or in patients without kidney disease or a previous history of hyperkalemia. Plasma potassium concentration can be measured to avoid hyperkalemia due to potassium leakage out of red cells, white cells, and platelets. Kidney dysfunction should be ruled out at the initial assessment.

Treatment consists of withholding exogenous potassium, identifying the cause, reviewing the patient's medications and dietary potassium intake, and correcting the hyperkalemia. Emergent treatment of hyperkalemia is indicated when cardiac toxicity or muscular paralysis or severe hyperkalemia (potassium > 6.5 mEq/L) is present, even in the absence of ECG changes. Insulin, bicarbonate, and β -agonists shift potassium intracellularly within minutes of administration (Table 21-6). Intravenous calcium may be given to antagonize the cell membrane effects of potassium, but its use should be restricted to life-threaten-

ing hyperkalemia in patients taking digitalis because hypercalcemia may cause digitalis toxicity. Hemodialysis may be required to remove potassium in patients with acute or chronic kidney injury.

When to Refer

- Patients with hyperkalemia from kidney disease and reduced renal potassium excretion should see a nephrologist.
- Transplant patients may need adjustment of their immunosuppression regimen by transplant specialists.

When to Admit

Patients with severe hyperkalemia greater than 6 mEq/L, any degree of hyperkalemia associated with ECG changes, or concomitant illness (eg, tumor lysis, rhabdomyolysis, metabolic acidosis) should be sent to the emergency department or admitted to the hospital for urgent treatment.

Weisberg LS. Management of severe hyperkalemia. *Crit Care Med*. 2008 Dec;36(12):3246-51. [PMID: 18936701]

DISORDERS OF CALCIUM CONCENTRATION

The normal total plasma (or serum) calcium concentration is 9–10.3 mg/dL. Ionized calcium (normal: 4.7–5.3 mg/dL or 1.1–1.3 mmol/L) is physiologically active and necessary for muscle contraction and nerve function.

The calcium-sensing receptor, a transmembrane protein that detects the extracellular calcium concentration, has been identified in the parathyroid gland and the kidney. Functional defects in this protein are associated with diseases of abnormal calcium metabolism such as familial hypocalcemia and familial hypocalciuric hypercalcemia (Table 21-4).

HYPOCALCEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Often mistaken as a neurologic disorder.
- ▶ Check for decreased parathyroid hormone (PTH), vitamin D, or magnesium depletion.
- ▶ If the ionized calcium level is normal despite a low total serum calcium, calcium metabolism is usually normal.

Table 21–6. Treatment of hyperkalemia.

| EMERGENCY | | | | | |
|---|--|-----------------------|---|---|----------------------------------|
| Modality | Mechanism of Action | Onset | Duration | Prescription | K ⁺ Removed from Body |
| Calcium | Antagonizes cardiac conduction abnormalities | 0–5 minutes | 1 hour | Calcium gluconate 10%, 5–30 mL intravenously; or calcium chloride 5%, 5–30 mL intravenously | 0 |
| Bicarbonate | Distributes K ⁺ into cells | 15–30 minutes | 1–2 hours | NaHCO ₃ , 44–88 mEq (1–2 ampules) intravenously Note: Sodium bicarbonate may not be effective in end-stage renal disease patients; dialysis is more expedient and effective. Some patients may not tolerate the additional sodium load of bicarbonate therapy. | 0 |
| Insulin | Distributes K ⁺ into cells | 15–60 minutes | 4–6 hours | Regular insulin, 5–10 units intravenously, plus glucose 50%, 25 g (1 ampule) intravenously | 0 |
| Albuterol | Distributes K ⁺ into cells | 15–30 minutes | 2–4 hours | Nebulized albuterol, 10–20 mg in 4 mL normal saline, inhaled over 10 minutes Note: Much higher doses are necessary for hyperkalemia therapy (10–20 mg) than for airway disease (2.5 mg). | 0 |
| NONEMERGENCY | | | | | |
| Modality | Mechanism of Action | Duration of Treatment | Prescription | K ⁺ Removed from Body | |
| Loop diuretic | ↑ Renal K ⁺ excretion | 0.5–2 hours | Furosemide, 40–160 mg intravenously or orally with or without NaHCO ₃ , 0.5–3 mEq/kg daily Note: Diuretics may not be effective in patients with acute and chronic kidney diseases. | Variable | |
| Sodium polystyrene sulfonate (Kayexalate) | Ion-exchange resin binds K ⁺ | 1–3 hours | Oral: 15–30 g in 20% sorbitol (50–100 mL) Rectal: 50 g in 20% sorbitol Note: Resins with sorbitol may cause bowel necrosis and intestinal perforation. | 0.5–1 mEq/g | |
| Hemodialysis ¹ | Extracorporeal K ⁺ removal | 48 hours | Blood flow ≥ 200–300 mL/min Dialysate [K ⁺] ~ 0 Note: A fast and effective therapy for hyperkalemia, hemodialysis can be delayed by vascular access placement and equipment and staffing availability. | 200–300 mEq | |
| Peritoneal dialysis | Peritoneal K ⁺ removal | 48 hours | Fast exchange, 3–4 L/h | 200–300 mEq | |

¹Can be both emergency and nonemergency treatment of hyperkalemia.

Modified and reproduced, with permission, from Cogan MG. *Fluid and Electrolytes: Physiology and Pathophysiology*. McGraw-Hill, 1991.

► General Considerations

The most common cause of low total serum calcium is hypoalbuminemia. When serum albumin concentration is lower than 4 g/dL, serum Ca²⁺ concentration is reduced by 0.8–1 mg/dL for every 1 g/dL of albumin. Thus,

$$\text{Corrected calcium}^{2+} \text{ (mg/dL)} = \text{Ca}^{2+} \text{ (mg/dL)} + 0.8 (4 - \text{albumin [g/dL]})$$

The most accurate measurement of serum calcium is the ionized calcium concentration. True hypocalcemia (decreased ionized calcium) implies insufficient action of PTH or active vitamin D. Important causes of hypocalcemia are listed in Table 21–7.

The most common cause of hypocalcemia is advanced CKD, in which decreased production of active vitamin D₃

(1,25 dihydroxyvitamin D₃) and hyperphosphatemia both play a role (see Chapter 22). Some cases of primary hypoparathyroidism are due to mutations of the calcium-sensing receptor in which inappropriate suppression of PTH release leads to hypocalcemia (see Chapter 26). Magnesium depletion reduces both PTH release and tissue responsiveness to PTH, causing hypocalcemia. Hypocalcemia in pancreatitis is a marker for severe disease. Elderly hospitalized patients with hypocalcemia and hypophosphatemia, with or without an elevated PTH level, are likely vitamin D deficient.

► Clinical Findings

A. Symptoms and Signs

Hypocalcemia increases excitation of nerve and muscle cells, primarily affecting the neuromuscular and cardiovascular

| Decreased end-organ response to vitamin D |
| Hyperphosphatemia |
| Induced by aminoglycoside antibiotics, plicamycin, loop diuretics, foscarnet |

¹Ionized calcium concentration is normal.

systems. Spasm of skeletal muscle causes cramps and tetany. Laryngospasm with stridor can obstruct the airway. Convulsions, perioral and peripheral paresthesias, and abdominal pain can develop. Classic physical findings include Chvostek sign (contraction of the facial muscle in response to tapping the facial nerve) and Trousseau sign (carpal spasm occurring with occlusion of the brachial artery by a blood pressure cuff). QT prolongation predisposes to ventricular arrhythmias. In chronic hypoparathyroidism, cataracts and calcification of basal ganglia may appear (see Chapter 26).

B. Laboratory Findings

Serum calcium concentration is low (< 9 mg/dL). In true hypocalcemia, the ionized serum calcium concentration is also low (< 4.7 mg/dL or 1.1 mmol/L). Serum phosphate is usually elevated in hypoparathyroidism or in advanced CKD, whereas it is suppressed in early CKD or vitamin D deficiency.

Serum magnesium concentration is commonly low. In respiratory alkalosis, total serum calcium is normal but ionized calcium is low. The ECG shows a prolonged QT interval.

▶ Treatment*

A. Severe, Symptomatic Hypocalcemia

In the presence of tetany, arrhythmias, or seizures, intravenous calcium gluconate is indicated. Because of the short

duration of action, continuous calcium infusion is usually required. Ten to 15 milligrams of calcium per kilogram body weight, or six to eight 10-mL vials of 10% calcium gluconate (558–744 mg of calcium), is added to 1 L of D₅W and infused over 4–6 hours. By monitoring the serum calcium level frequently (every 4–6 hours), the infusion rate is adjusted to maintain the serum calcium level at 7–8.5 mg/dL.

B. Asymptomatic Hypocalcemia

Oral calcium (1–2 g) and vitamin D preparations, including active vitamin D sterols, are used. Calcium carbonate is well tolerated and less expensive than many other calcium tablets. A check of urinary calcium excretion is recommended after the initiation of therapy because hypercalciuria (urine calcium excretion > 200 mg/d or urine calcium/urine creatinine ratio > 0.3) may impair kidney function in these patients. The low serum calcium associated with hypoalbuminemia does not require replacement therapy. If serum Mg²⁺ is low, therapy must include magnesium replacement, which by itself will usually correct hypocalcemia.

▶ When to Refer

Patients with complicated hypocalcemia from hypoparathyroidism, familial hypocalcemia, or CKD require referral from an endocrinologist or nephrologist.

▶ When to Admit

Patients with tetany, arrhythmias, seizures, or other symptoms of hypocalcemia require immediate evaluation and therapy in the emergency department or hospital.

HYPERCALCEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Primary hyperparathyroidism and malignancy-associated hypercalcemia are the most common causes.
- ▶ Hypercalciuria usually precedes hypercalcemia.
- ▶ Most often, asymptomatic, mild hypercalcemia (≤ 11 mg/dL) is due to primary hyperparathyroidism, whereas the symptomatic, severe hypercalcemia (≥ 14 mg/dL) is due to hypercalcemia of malignancy.

▶ General Considerations

Important causes of hypercalcemia are listed in Table 21–8. Primary hyperparathyroidism and malignancy account for 90% of cases. Primary hyperparathyroidism is the most com-

*See also Chapter 26 for discussion of the treatment of hypoparathyroidism.

PTH, parathyroid hormone.

mon cause of hypercalcemia (usually mild) in ambulatory patients. Chronic hypercalcemia (over 6 months) or some manifestation such as nephrolithiasis also suggests a benign cause. Tumor production of PTH-related proteins (PTHrP) is the most common paraneoplastic endocrine syndrome, accounting for most cases of hypercalcemia in inpatients (see Table 39–13). The neoplasm is clinically apparent in nearly all cases when the hypercalcemia is detected, and the prognosis is poor. Granulomatous diseases, such as sarcoidosis and tuberculosis, cause hypercalcemia from production of active vitamin D₃ (1,25 dihydroxyvitamin D₃).

Milk-alkali syndrome has had a resurgence related to calcium ingestion for prevention of osteoporosis. In the milk-alkali syndrome, massive calcium and vitamin D ingestion can cause hypercalcemic nephropathy. Because of the decreased GFR, retention of the alkali in the calcium antacid occurs and causes metabolic alkalosis, which can be worsened by the vomiting associated with this disorder.

Hypercalcemia also causes nephrogenic diabetes insipidus. Development of polyuria is mediated through activation of calcium-sensing receptors in collecting ducts. Volume depletion further worsens hypercalcemia.

▶ Clinical Findings

A. Symptoms and Signs

Hypercalcemia may affect gastrointestinal, kidney, and neurologic function. The history and physical examination should focus on the duration of hypercalcemia and evidence for a neoplasm. Mild hypercalcemia is often asymptomatic. Symptoms usually occur if the serum calcium is above 12 mg/dL and tend to be more severe if hypercalcemia devel-

ops acutely. Irrespective of cause, symptoms include constipation and polyuria, except in hypocalciuric hypercalcemia, in which polyuria is absent. Other abdominal symptoms include nausea, vomiting, anorexia, peptic ulcer disease, renal colic, and hematuria from nephrolithiasis. Polyuria from hypercalciuria-induced nephrogenic diabetes insipidus can result in volume depletion and acute kidney injury. Neurologic manifestations may range from mild drowsiness to weakness, depression, lethargy, stupor, and coma in severe hypercalcemia. Ventricular ectopy and idioventricular rhythm occur and can be accentuated by digitalis.

B. Laboratory Findings

The ionized calcium exceeds 1.32 mmol/L. A high serum chloride concentration and a low serum phosphate concentration in a ratio > 33 to 1 suggest primary hyperparathyroidism where PTH decreases proximal tubular phosphate reabsorption. A low serum chloride concentration with a high serum bicarbonate concentration, along with elevated BUN and creatinine, suggests milk-alkali syndrome. The highest serum calcium levels (> 15 mg/dL) generally occur in malignancy. More than 200 mg/d of urinary calcium excretion suggests hypercalciuria; less than 100 mg/d suggests hypocalciuria. Hypercalciuric patients—such as those with malignancy or those receiving oral active vitamin D therapy—may easily develop hypercalcemia in case of volume depletion. Serum phosphate may or may not be low, depending on the cause. Hypocalciuric hypercalcemia occurs in milk-alkali syndrome, thiazide diuretic use, and familial hypocalciuric hypercalcemia.

The chest radiograph may reveal malignancy or granulomatous disease. The ECG shows a shortened QT interval. Measurements of PTH and PTHrP help distinguish between malignancy-associated hypercalcemia (suppressed PTH, elevated PTHrP) and hyperparathyroidism (elevated PTH).

▶ Treatment

Until the primary disease can be brought under control, renal excretion of calcium with resultant decrease in serum calcium concentration is promoted. Excretion of Na⁺ is accompanied by excretion of Ca²⁺. The tendency in hypercalcemia is toward volume depletion from nephrogenic diabetes insipidus. Therefore, intravenous saline for aggressive hydration and forced calciuresis is the mainstay of treatment. In dehydrated patients with normal cardiac and kidney function, 0.45% saline or 0.9% saline can be given rapidly (250–500 mL/h). A recent meta-analysis questioned the efficacy and safety profile of intravenous furosemide for hypercalcemia. Thiazides can worsen hypercalcemia.

Bisphosphonates are the treatment of choice for hypercalcemia of malignancy. Although they are safe, effective, and normalize calcium in more than 70% of patients, bisphosphonates may require up to 48–72 hours before reaching full therapeutic effect. Calcitonin may be helpful to treat hypercalcemia before the onset of action of bisphosphonates. In emergency cases, dialysis with low calcium dialysate may be needed. The calcimimetic agent cinacalcet hydrochloride suppresses PTH secretion and decreases serum calcium concentration and holds promise

as a treatment option. See Chapter 39 for a discussion of the treatment of hypercalcemia of malignancy and Chapter 26 for a discussion of the treatment of hypercalcemia of hyperparathyroidism.

Typically, if dialysis patients do not receive proper supplementation of calcium and active vitamin D, hypocalcemia and hyperphosphatemia develop. On the other hand, hypercalcemia can sometimes develop, particularly in the setting of severe secondary hyperparathyroidism, characterized by high levels of PTH and subsequent release of calcium from bone. Therapy may include intravenous vitamin D, which further increases the serum calcium concentration. Another type of hypercalcemia occurs when the PTH levels are low. In this setting, bone turnover is decreased, which results in a low buffering capacity for calcium. When calcium is administered in calcium-containing phosphate binders or in the dialysate, or when vitamin D is administered, hypercalcemia results. Hypercalcemia in dialysis patients usually occurs in the presence of hyperphosphatemia, and metastatic calcification may occur. Malignancy should be considered as a cause of the hypercalcemia.

▶ When to Refer

- Patients with malignancy-related hypercalcemia should be referred to an oncologist.
- Patients with endocrine disorders should be referred to an endocrinologist.
- Patients with granulomatous diseases (eg, tuberculosis and other chronic infections, Wegener granulomatosis, sarcoidosis) may require assistance from infectious disease specialists, rheumatologists, or pulmonologists.

▶ When to Admit

- Patients with symptomatic or severe hypercalcemia require immediate treatment.
- Unexplained hypercalcemia with associated conditions, such as acute kidney injury or suspected malignancy, may also require hospitalization for treatment and expedited evaluation.

DISORDERS OF PHOSPHORUS CONCENTRATION

In plasma, phosphate is mainly present as inorganic phosphate, and this fraction is very small (< 0.2% of total phosphate). However, body phosphate metabolism is regulated through plasma inorganic phosphate.

Important determinants of plasma inorganic phosphate concentration are renal excretion, intestinal absorption, and shift between the intracellular and extracellular spaces. The kidney is the most important regulator of the serum phosphate level. PTH decreases the absorption of phosphate in the proximal tubule while 1,25-dihydroxyvitamin D₃ increases tubular phosphate reabsorption. Renal proximal tubular reabsorption of phosphate is decreased by volume expansion, corticosteroids, and proximal tubular dysfunction (as in Fanconi syndrome). Fibroblast growth factor 23 (FGF23) is another potent phosphaturic hormone. Intestinal absorption of phosphate is facilitated by active vitamin D. PTH stimulates phosphate release from bone and renal phosphate excretion; it can lead to hypophosphatemia and depletion of bone phosphate store if hypersecretion continues. By contrast, growth hormone augments proximal tubular reabsorption of phosphate. Cellular phosphate uptake is stimulated by various factors and conditions, including alkalemia, insulin, epinephrine, feeding, hungry bone syndrome, and accelerated cell proliferation.

Phosphorus metabolism and homeostasis are intimately related to calcium metabolism. See sections on metabolic bone disease in Chapter 26.

HYPOPHOSPHATEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Severe hypophosphatemia may cause tissue hypoxia and rhabdomyolysis.
- ▶ Renal loss of phosphate can be diagnosed by measuring urinary phosphate excretion and by calculating maximal tubular phosphate reabsorption rate (TmP/GFR).
- ▶ PTH and FGF23 are the major factors that decrease TmP/GFR, leading to renal loss of phosphate.

▶ General Considerations

The leading causes of hypophosphatemia are listed in Table 21–9. Hypophosphatemia may occur in the presence of normal phosphate stores. Serious depletion of body phosphate stores may exist with low, normal, or high serum phosphate concentrations.

Serum phosphate levels decrease transiently after food intake, thus fasting samples are recommended for accuracy. **Moderate** hypophosphatemia (1.0–2.5 mg/dL) occurs commonly in hospitalized patients and may not reflect decreased phosphate stores.

In **severe** hypophosphatemia (1 mg/dL or less), the affinity of hemoglobin for oxygen increases through a decrease in the erythrocyte 2,3-diphosphoglycerate concentration. This impairs tissue oxygenation and thus cell metabolism, which underlies the effects of hypophosphatemia such as muscle weakness or even rhabdomyolysis. **Severe** hypophosphatemia is common and multifactorial in alcoholic patients. In acute alcohol withdrawal, increased plasma insu-

| Recovery from severe burns |

FGF23, fibroblast growth factor 23.

lin and epinephrine along with respiratory alkalosis promote intracellular shift of phosphate. Vomiting, diarrhea, and poor dietary intake contribute to hypophosphatemia. Chronic alcohol use results in a decrease in the renal threshold of phosphate excretion. This renal tubular dysfunction reverses after a month of abstinence. Patients with chronic obstructive pulmonary disease and asthma commonly have hypophosphatemia, attributed to xanthine derivatives causing shifts of phosphate intracellularly and the phosphaturic effects of β -adrenergic agonists, loop diuretics, xanthine derivatives, and corticosteroids. The metabolic syndrome, a major contributor to coronary heart disease risk, is associated with low phosphate (and magnesium) levels but the clinical significance of these disturbances is unclear. Refeeding or glucose administration to phosphate-depleted patients may cause fatal hypophosphatemia.

► Clinical Findings

A. Symptoms and Signs

Acute, severe hypophosphatemia (< 1.0 mg/dL) can lead to rhabdomyolysis, paresthesias, and encephalopathy (irritabil-

ity, confusion, dysarthria, seizures, and coma). Respiratory failure or failure to wean from mechanical ventilation may occur as a result of diaphragmatic weakness. Arrhythmias and heart failure are uncommon but serious manifestations. Hematologic manifestations include acute hemolytic anemia from increased erythrocyte fragility, platelet dysfunction with petechial hemorrhages, and impaired chemotaxis of leukocytes (leading to increased susceptibility to gram-negative sepsis).

Chronic severe depletion may cause anorexia, pain in muscles and bones, and fractures.

B. Laboratory Findings

Evaluation of urinary phosphate excretion is a useful clue to the diagnosis of hypophosphatemia. A spot urine with > 20 mg/dL of phosphate suggests inappropriate renal phosphate loss. Tubular phosphate reabsorption can be assessed by TmP/GFR:

$$\frac{\text{TmP}}{\text{GFR}} = \frac{\text{Serum Pi} - (\text{UPi} \times \text{UV})}{\text{GFR}}$$

where serum Pi = serum phosphate concentration

UPi = urine phosphate concentration

UV = urine volume

The normal range of TmP/GFR is 2.5–4.5 mg/dL; lower values indicate urinary phosphate loss. The main factors regulating TmP/GFR are PTH and phosphate intake. Increase of PTH or phosphate intake decreases TmP/GFR, so that more phosphate is excreted into the urine.

Measurement of plasma PTH or PTHrP levels may be helpful. The clinical utility of serum FGF levels is underdetermined except in uncommon diseases.

Other clinical features may be suggestive of specific causes of hypophosphatemia. Evidence of hemolytic anemia may be present (eg, elevated serum lactate dehydrogenase). Rhabdomyolysis results in elevated serum creatine kinase, myoglobinuria, and often acute kidney injury. Fanconi syndrome may present with any combination of uricosuria, aminoaciduria, glucosuria (with normoglycemia), normal anion gap metabolic acidosis, and phosphaturia. In chronic depletion, radiographs and bone biopsies show changes resembling osteomalacia.

► Treatment

Hypophosphatemia can be prevented by including phosphate in repletion and maintenance fluids. A rapid decline in calcium levels can occur with parenteral administration of phosphate; oral replacement of phosphate is preferable. Moderate hypophosphatemia (1.0–2.5 mg/dL) is usually asymptomatic and does not require treatment. The hypophosphatemia in patients with diabetic ketoacidosis will usually correct with normal dietary intake. Chronic hypophosphatemia can be treated with oral phosphate repletion. Mixtures of sodium and potassium phosphate salts may be given to provide 0.5–1 g (18–32 mmol) of phosphate per day. For severe, symptomatic hypophosphatemia (< 1 mg/dL), an infusion should provide 279–310 mg (9–10 mmol)/12 h until the serum phosphorus exceeds 1 mg/dL and the

patient can be switched to oral therapy. The infusion rate should be decreased if hypotension occurs. Monitoring of plasma phosphate, calcium, and potassium every 6 hours is necessary because the response to phosphate supplementation is not predictable. Magnesium deficiency often coexists and should be treated simultaneously.

Contraindications to therapy with phosphate salts include hypoparathyroidism, advanced CKD, tissue damage and necrosis, and hypercalcemia. When an associated hyperglycemia is treated, phosphate accompanies glucose into cells, and hypophosphatemia may ensue.

▶ When to Refer

- Patients with refractory hypophosphatemia with increased urinary phosphate excretion may require evaluation by an endocrinologist (for such conditions as hyperparathyroidism and vitamin D disorders) or by a nephrologist (for such conditions such as renal tubular defects).
- Patients with decreased gastrointestinal absorption may require referral to a gastroenterologist.

▶ When to Admit

Patients with severe or refractory hypophosphatemia will require hospitalization for intravenous phosphate.

HYPERPHOSPHATEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Advanced CKD is the most common cause.
- ▶ Hyperphosphatemia in the presence of hypercalcemia imposes a high risk of metastatic calcification.

▶ General Considerations

Advanced CKD with decreased urinary excretion of phosphate is the most common cause of hyperphosphatemia. Other causes are listed in Table 21–10.

▶ Clinical Findings

A. Symptoms and Signs

The clinical manifestations are those of the underlying disorder or associated condition.

Table 21–10. Causes of hyperphosphatemia.

Massive load of phosphate into the extracellular fluid

Exogenous sources

- Hypervitaminosis D
- Laxatives or enemas containing phosphate
- Intravenous phosphate supplement

Endogenous sources

- Rhabdomyolysis (especially if chronic kidney disease coexists)
- Cell lysis by chemotherapy of malignancy, particularly lymphoproliferative diseases
- Metabolic acidosis (lactic acidosis, ketoacidosis)
- Respiratory acidosis (phosphate incorporation into cells is disturbed)

Decreased excretion into urine

- Chronic kidney disease
- Acute kidney injury
- Hypoparathyroidism
- Pseudohypoparathyroidism
- Acromegaly

Pseudohyperphosphatemia

- Multiple myeloma
- Hyperbilirubinemia
- Hypertriglyceridemia
- Hemolysis in vitro

B. Laboratory Findings

In addition to elevated phosphate, blood chemistry abnormalities are those of the underlying disease.

▶ Treatment

Treatment is directed at the underlying cause. Exogenous sources of phosphate, including enteral or parenteral nutrition and medications, should be reduced or eliminated. Absorption of dietary phosphate can be reduced by oral phosphate binders, such as calcium carbonate, calcium acetate, sevelamer hydrochloride, lanthanum carbonate, and aluminum hydroxide. Sevelamer, lanthanum, and aluminum may be used in patients with concomitant hypercalcemia, although aluminum should not be used for more than a few days due to the risk of aluminum accumulation and neurotoxicity. In acute kidney injury and advanced CKD, dialysis will reduce serum phosphate.

▶ When to Admit

Patients with acute severe hyperphosphatemia require hospitalization for emergent therapy, possibly including dialysis. Concomitant illnesses, such as acute kidney injury or cell lysis, may necessitate admission.

DISORDERS OF MAGNESIUM CONCENTRATION

Normal plasma magnesium concentration is 1.5–2.5 mEq/L, with about one-third bound to protein and two-thirds existing as free cation. Magnesium excretion is via the kidney. Magnesium's physiologic effects on the nervous system resemble those of calcium.

Altered magnesium concentration usually provokes an associated alteration of Ca^{2+} . Both hypomagnesemia and hypermagnesemia can decrease PTH secretion or action. Severe hypermagnesemia (> 5 mEq/L) suppresses PTH secretion with consequent hypocalcemia; this disorder is typically seen only in patients receiving magnesium therapy for preeclampsia. Severe hypomagnesemia causes PTH resistance in end-organs and eventually decreased PTH secretion in severe cases.

HYPOMAGNESEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Serum concentration of magnesium may not be decreased even in the presence of magnesium depletion. Check urinary magnesium excretion if renal magnesium wasting is suspected.
- ▶ Causes neurologic symptoms and arrhythmias.
- ▶ Impairs release of PTH.

▶ General Considerations

Causes of hypomagnesemia are listed in Table 21–11. Normomagnesemia does not exclude magnesium depletion because only 1% of total body magnesium is in the ECF. Hypomagnesemia and hypokalemia share many etiologies, including diuretics, diarrhea, alcoholism, aminoglycosides, and amphotericin. Renal potassium wasting also occurs from hypomagnesemia, and is refractory to potassium replacement until magnesium is repleted. Hypomagnesemia also suppresses PTH release and causes end-organ resistance to PTH and low 1,25-dihydroxyvitamin D_3 levels. This form of hypocalcemia is refractory to calcium replacement until the magnesium is normalized. Molecular mechanisms of magnesium wasting have been revealed in some hereditary disorders.

▶ Clinical Findings

A. Symptoms and Signs

Common symptoms are those of hypokalemia and hypocalcemia, with weakness and muscle cramps. Marked neuromuscular and central nervous system hyperirritability may produce tremors, athetoid movements, jerking, nystagmus, a positive Babinski response, confusion, and disorientation. Cardiovascular manifestations include hypertension, tachycardia, and ventricular arrhythmias.

Table 21–11. Causes of hypomagnesemia.

Diminished absorption or intake

Malabsorption, chronic diarrhea, laxative abuse
Prolonged gastrointestinal suction
Small bowel bypass
Malnutrition
Alcoholism
Total parenteral alimentation with inadequate Mg^{2+} content

Increased renal loss

Diuretic therapy (loop diuretics, thiazide diuretics)
Hyperaldosteronism, Gitelman syndrome (a variant of Bartter syndrome)
Hyperparathyroidism, hyperthyroidism
Hypercalcemia
Volume expansion
Tubulointerstitial diseases
Transplant kidney
Drugs (aminoglycoside, cetuximab, cisplatin, amphotericin B, pentamidine)

Others

Diabetes mellitus
Post-parathyroidectomy (hungry bone syndrome)
Respiratory alkalosis
Pregnancy

B. Laboratory Findings

Urinary excretion of magnesium exceeding 10–30 mg/d or a fractional excretion more than 2% indicates renal magnesium wasting. Hypocalcemia and hypokalemia are often present. The ECG shows a prolonged QT interval, due to lengthening of the ST segment. PTH secretion is often suppressed (see Hypocalcemia, above).

▶ Treatment

Magnesium oxide, 250–500 mg orally once or twice daily, is useful for treating chronic hypomagnesemia. Treatment of symptomatic hypomagnesemia should include infusion of 1–2 g of magnesium sulfate, followed by an infusion of 6 g magnesium sulfate in at least 1 L of fluids over 24 hours, repeated for up to 7 days to replete magnesium stores. Magnesium sulfate may also be given intramuscularly in a dosage of 200–800 mg/d (8–33 mmol/d) in four divided doses. Serum levels must be monitored daily and dosage adjusted to keep the concentration from rising above 2.5 mmol/L. Tendon reflexes may also be checked for hyporeflexia of hypermagnesemia. K^+ and Ca^{2+} replacement may be required as well, but patients with hypokalemia and hypocalcemia of hypomagnesemia do not recover without magnesium supplementation.

Patients with normal kidney function can excrete excess magnesium; hypermagnesemia should not develop with replacement dosages. In patients with CKD, magnesium replacement should be done cautiously to avoid hypermagnesemia. Reduced doses (50–75% dose reduction) and more frequent monitoring (at least twice daily) are indicated.

- Tong GM et al. Magnesium deficiency in critical illness. *J Intensive Care Med.* 2005 Jan–Feb;20(1):3–17. [PMID: 15665255]

HYPERMAGNESEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Often associated with advanced CKD and chronic intake of magnesium-containing drugs.

▶ General Considerations

Hypermagnesemia is almost always the result of advanced CKD and the inability to excrete excess magnesium. Antacids and laxatives are underrecognized sources of exogenous magnesium. Pregnant patients may have severe hypermagnesemia from intravenous magnesium therapy for preeclampsia and eclampsia. Magnesium replacement should be done cautiously in patients with CKD, and dose reductions up to 75% may be necessary to avoid hypermagnesemia.

▶ Clinical Findings

A. Symptoms and Signs

Muscle weakness, decreased deep tendon reflexes, mental obtundation, and confusion are characteristic manifestations. Weakness, flaccid paralysis, ileus, urinary retention, and hypotension are noted. Serious findings include respiratory muscle paralysis and cardiac arrest.

B. Laboratory Findings

Serum Mg^{2+} is elevated. In the common setting of CKD, BUN, creatinine, potassium, phosphate, and uric acid may all be elevated. Serum Ca^{2+} is often low. The ECG shows increased PR interval, broadened QRS complexes, and peaked T waves, probably related to associated hyperkalemia.

▶ Treatment

Exogenous sources of magnesium should be discontinued. Calcium antagonizes Mg^{2+} and may be given intravenously as calcium chloride, 500 mg or more at a rate of 100 mg (4.5 mmol)/min. Hemodialysis or peritoneal dialysis may be necessary to remove the magnesium, particularly with severe kidney disease.

Long-term use of magnesium-containing drugs, such as magnesium hydroxylate and magnesium sulfate, should be avoided in patients with advanced stages of CKD.

- Topf JM et al. Hypomagnesemia and hypermagnesemia. *Rev Endocr Metab Disord.* 2003 May;4(2):195–206. [PMID: 12766548]

ACID–BASE DISORDERS

Assessment of a patient's acid–base status requires measurement of arterial pH, PCO_2 , and plasma bicarbonate (HCO_3^-). Blood gas analyzers directly measure pH and PCO_2 . The HCO_3^- value is calculated from the Henderson–Hasselbalch equation:

$$pH = 6.1 + \log \frac{HCO_3^-}{0.3 \times PCO_2}$$

The total venous CO_2 measurement is a more direct determination of HCO_3^- . Because of the dissociation characteristics of carbonic acid (H_2CO_3) at body pH, dissolved CO_2 is almost exclusively in the form of HCO_3^- , and for clinical purposes the total carbon dioxide content is equivalent (± 3 mEq/L) to the HCO_3^- concentration:

Venous blood gases can provide useful information for acid–base assessment since the arteriovenous differences in pH and PCO_2 are small and relatively constant. Venous blood pH is usually 0.03–0.04 units lower than arterial blood pH, and venous blood PCO_2 is 7 or 8 mm Hg higher than arterial blood PCO_2 . Calculated HCO_3^- concentration in venous blood is at most 2 mEq/L higher than arterial blood HCO_3^- . Arterial and venous blood gases will not be equivalent during a cardiopulmonary arrest; arterial samples should be obtained for the most accurate measurements of pH and PCO_2 .

TYPES OF ACID–BASE DISORDERS

There are two types of acid–base disorders: acidoses and alkaloses. These disorders can be either metabolic (decreased or increased HCO_3^-) or respiratory (decreased or increased PCO_2). Primary respiratory disorders affect blood acidity by changes in PCO_2 , and primary metabolic disorders are disturbances in the HCO_3^- concentration. A primary disturbance is usually accompanied by a compensatory response, but the compensation does not fully correct the pH disturbance of the primary disorder. If the pH is less than 7.40, the primary process is acidosis, either respiratory ($PCO_2 > 40$ mm Hg) or metabolic ($HCO_3^- < 24$ mEq/L). If the pH is higher than 7.40, the primary process is alkalosis, either respiratory ($PCO_2 < 40$ mm Hg) or metabolic ($HCO_3^- > 24$ mEq/L). One respiratory or metabolic disorder with its appropriate compensatory response is a simple acid–base disorder.

MIXED ACID–BASE DISORDERS

Two or three simultaneous disorders can be present in a mixed acid–base disorder, but there can never be two primary respiratory disorders. Uncovering a mixed acid–base disorder is clinically important, but challenging without a methodical approach to acid–base analysis (see box,

Table 21-12. Primary acid-base disorders and expected compensation.

| Disorder | Primary Defect | Compensatory Response | Magnitude of Compensation |
|-----------------------|-----------------------|-----------------------|--|
| Respiratory acidosis | | | |
| Acute | $\uparrow P_{CO_2}$ | $\uparrow HCO_3^-$ | $\uparrow HCO_3^-$ 1 mEq/L per 10 mm Hg $\uparrow P_{CO_2}$ |
| Chronic | $\uparrow P_{CO_2}$ | $\uparrow HCO_3^-$ | $\uparrow HCO_3^-$ 3.5 mEq/L per 10 mm Hg $\uparrow P_{CO_2}$ |
| Respiratory alkalosis | | | |
| Acute | $\downarrow P_{CO_2}$ | $\downarrow HCO_3^-$ | $\downarrow HCO_3^-$ 2 mEq/L per 10 mm Hg $\downarrow P_{CO_2}$ |
| Chronic | $\downarrow P_{CO_2}$ | $\downarrow HCO_3^-$ | $\downarrow HCO_3^-$ 5 mEq/L per 10 mm Hg $\downarrow P_{CO_2}$ |
| Metabolic acidosis | $\downarrow HCO_3^-$ | $\downarrow P_{CO_2}$ | $\downarrow P_{CO_2}$ 1.3 mm Hg per 1 mEq/L $\downarrow HCO_3^-$ |
| Metabolic alkalosis | $\uparrow HCO_3^-$ | $\uparrow P_{CO_2}$ | $\uparrow P_{CO_2}$ 0.7 mm Hg per 1 mEq/L $\uparrow HCO_3^-$ |

Step-by-Step Analysis of Acid-Base Status). Once the primary disturbance has been determined, the clinician should assess whether the compensatory response is appropriate (Table 21-12). An inadequate or an exaggerated response indicates the presence of another primary acid-base disturbance.

The anion gap should always be calculated for two reasons. First, it is possible to have an abnormal anion gap even if the sodium, chloride, and bicarbonate levels are normal. Second, a large anion gap (> 20) suggests a primary metabolic acid-base disturbance regardless of the pH or serum bicarbonate level because a markedly abnormal anion gap is never a compensatory response to a respiratory disorder. In patients with an increased anion gap metabolic acidosis, clinicians should calculate the corrected bicarbonate. In increased anion gap acidoses, there should be a mole for mole decrease in HCO_3^- as the anion gap increases. A corrected HCO_3^- value higher or lower than normal (24 mEq/L) indicates the concomitant presence of metabolic alkalosis or normal anion gap metabolic acidosis, respectively.

METABOLIC ACIDOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Decreased HCO_3^- with acidemia.
- ▶ Classified into increased anion gap acidosis and normal anion gap acidosis.
- ▶ Lactic acidosis, ketoacidosis, and toxins produce metabolic acidoses with the largest anion gaps.
- ▶ Normal anion gap acidosis is mainly caused by gastrointestinal HCO_3^- loss or RTA. Urinary anion gap may help distinguish between these causes.

General Considerations

The hallmark of metabolic acidosis is decreased HCO_3^- . Metabolic acidoses are classified by the anion gap, either normal or increased (Table 21-13). The anion gap represents the difference between readily measured anions and cations.

In plasma,

$$Na^+ + \frac{\text{Unmeasured cations}}{\text{Anion gap}} = HCO_3^- + Cl^- + \frac{\text{Unmeasured anions}}{\text{Anion gap}}$$

$$\text{Anion gap} = Na^+ - (HCO_3^- + Cl^-)$$

Major unmeasured cations are calcium (1 mEq/L), magnesium (2 mEq/L), γ -globulins, and potassium (4 mEq/L). Major unmeasured anions are albumin (2 mEq/L per g/dL), phosphate (2 mEq/L), sulfate (1 mEq/L), lactate (1-2 mEq/L), and other organic anions (3-4 mEq/L). Traditionally, the normal anion gap has been 12 ± 4 mEq/L. With current autoanalyzers, the reference range may be lower (6 ± 1 mEq/L), primarily from an increase in Cl^- values. Despite its usefulness, the anion gap can be misleading. Non-acid-base disorders may cause errors in anion gap interpretation; these disorders include hypoalbuminemia, hyponatremia, or

STEP-BY-STEP ANALYSIS OF ACID-BASE STATUS

- Step 1:** Determine the primary (or main) disorder—whether it is metabolic or respiratory—from blood, pH, HCO_3^- , and P_{CO_2} values.
- Step 2:** Determine the presence of mixed acid-base disorders by calculating the range of compensatory responses (Table 21-12).
- Step 3:** Calculate the anion gap (Table 21-13).
- Step 4:** Calculate the corrected HCO_3^- concentration if the anion gap is increased (see above).
- Step 5:** Examine the patient to determine whether the clinical signs are compatible with the acid-base analysis thus obtained.

Table 21-13. Anion gap in metabolic acidosis.¹

| | |
|--|--|
| Decreased (< 6 mEq) | |
| Hypoalbuminemia (decreased unmeasured anion) | |
| Plasma cell dyscrasias | |
| Monoclonal protein (cationic paraprotein) (accompanied by chloride and bicarbonate) | |
| Bromide intoxication | |
| Increased (> 12 mEq) | |
| Metabolic anion | |
| Diabetic ketoacidosis | |
| Alcoholic ketoacidosis | |
| Lactic acidosis | |
| Chronic kidney disease (advanced stages) (PO_4^{3-} , SO_4^{2-}) | |

¹Reference ranges for anion gap may vary based on differing laboratory methods.

hyponatremia; antibiotics (eg, carbenicillin is an unmeasured anion; polymyxin is an unmeasured cation) may also cause errors in anion gap interpretation. Although not usually associated with metabolic acidosis, a decreased anion gap can occur because of a reduction in unmeasured anions or an increase in unmeasured cations. In hypoalbuminemia, a 2 mEq/L decrease in anion gap will occur for every 1 g/dL decline in serum albumin.

INCREASED ANION GAP ACIDOSIS (Increased Unmeasured Anions)

Normochloremic metabolic acidosis generally results from addition of organic acids such as lactate, acetoacetate, β -hydroxybutyrate, and exogenous toxins. Other anions such as isocitrate, alpha-ketoglutarate, malate and D-lactate, may contribute to the anion gap of lactic acidosis, diabetic ketoacidosis, and acidosis of unknown etiology. Uremia produces an increased anion gap metabolic acidosis via unexcreted organic acids and anions.

A. Lactic Acidosis

Lactic acid is formed from pyruvate in anaerobic glycolysis, typically in tissues with high rates of glycolysis, such as gut (responsible for over 50% of lactate production), skeletal

muscle, brain, skin, and erythrocytes. Normally, lactate levels remain low (1 mEq/L) because of metabolism of lactate principally by the liver through gluconeogenesis or oxidation via the Krebs cycle. Furthermore, the kidneys metabolize about 30% of lactate.

In lactic acidosis, lactate levels are at least 4–5 mEq/L but commonly 10–30 mEq/L. There are two basic types of lactic acidosis. Type A is characterized by hypoxia or decreased tissue perfusion. Type B has no clinical evidence of hypoxia.

Type A (hypoxic) lactic acidosis is more common, resulting from decreased tissue perfusion; cardiogenic, septic, or hemorrhagic shock; and carbon monoxide or cyanide poisoning. These conditions increase peripheral lactic acid production and decrease hepatic metabolism of lactate as liver perfusion declines.

Type B lactic acidosis may be due to metabolic causes (eg, diabetes, ketoacidosis, liver disease, kidney disease, infection, leukemia, or lymphoma) or toxins (eg, ethanol, methanol, salicylates, isoniazid, or metformin). Propylene glycol can cause lactic acidosis from decreased liver metabolism; it is used as a vehicle for intravenous agents, such as nitroglycerin, etomidate, and diazepam. Parenteral nutrition without thiamine causes severe refractory lactic acidosis from the deranged metabolism of pyruvate. Patients with short bowel syndrome may develop D-lactic acidosis with encephalopathy due to carbohydrate malabsorption and subsequent fermentation by colonic bacteria.

AIDS without AIDS-related lymphoma is associated with type B lactic acidosis. Nucleoside analog reverse transcriptase inhibitors can cause lactic acidosis due to mitochondrial toxicity.

Idiopathic lactic acidosis, usually in debilitated patients, has an extremely high mortality rate. (For treatment of lactic acidosis, see below and Chapter 27.)

B. Diabetic Ketoacidosis

This metabolic abnormality is characterized by hyperglycemia and metabolic acidosis (pH < 7.25 or plasma bicarbonate < 16 mEq/L). Anion gap metabolic acidosis is the acid–base disturbance generally ascribed to diabetic ketoacidosis:

where B^- is β -hydroxybutyrate or acetoacetate, the ketones responsible for the increased anion gap. The anion gap should be calculated from the serum electrolytes as measured; correction of the serum sodium for the dilutional effect of hyperglycemia will exaggerate the anion gap. Diabetics with ketoacidosis may have lactic acidosis from tissue hypoperfusion and increased anaerobic metabolism.

During the recovery phase of diabetic ketoacidosis, a hyperchloremic non-anion gap acidosis can develop because saline resuscitation results in chloride retention, restoration of GFR, and ketoaciduria. Ketone salts (NaB) are formed as bicarbonate is consumed:

The kidney reabsorbs ketone anions poorly but can compensate for the loss of anions by increasing the reabsorption of Cl^- .

Patients with diabetic ketoacidosis and normal kidney function may have marked ketonuria and severe metabolic acidosis but only a mildly increased anion gap. Thus, the size of the anion gap correlates poorly with the severity of the diabetic ketoacidosis; the urinary loss of Na^+ or K^+ salts of β -hydroxybutyrate will lower the anion gap without altering the H^+ excretion or the severity of the acidosis. Urine dipsticks for ketones test primarily for acetoacetate and, to a lesser degree, acetone but do not detect the predominant ketoacid, β -hydroxybutyrate. Dipstick tests for ketones may become more positive even as the patient improves due to the metabolism of hydroxybutyrate. Thus, the patient's clinical status and pH are better markers of improvement than the anion gap or ketone levels.

C. Alcoholic Ketoacidosis

This is a common disorder of chronically malnourished patients who consume large quantities of alcohol daily. Most of these patients have mixed acid–base disorders (10% have a triple acid–base disorder). Although decreased HCO_3^- is usual, 50% of the patients may have normal or alkalemic pH. Three types of metabolic acidosis are seen in alcoholic ketoacidosis: (1) Ketoacidosis is due to β -hydroxybutyrate and acetoacetate excess. (2) Lactic acidosis: Alcohol metabolism increases the NADH:NAD ratio, causing increased production and decreased utilization of lactate. Accompanying thiamine deficiency, which inhibits pyruvate carboxylase, further enhances lactic acid production in many cases. Moderate to severe elevations of lactate (> 6 mmol/L) are seen with concomitant disorders such as sepsis, pancreatitis, or hypoglycemia. (3) Hyperchloremic acidosis from bicarbonate loss in the urine is associated with ketonuria (see above). Metabolic alkalosis occurs from volume contraction and vomiting. Respiratory alkalosis results from alcohol withdrawal, pain, or associated disorders such

as sepsis or liver disease. Half of the patients have either hypoglycemia or hyperglycemia. When serum glucose levels are greater than 250 mg/dL, the distinction from diabetic ketoacidosis is difficult. The absence of a diabetic history and normoglycemia after initial therapy support the diagnosis of alcoholic ketoacidosis.

D. Toxins

(See also Chapter 38.) Multiple toxins and drugs increase the anion gap by increasing endogenous acid production. Common examples include methanol (metabolized to formic acid), ethylene glycol (glycolic and oxalic acid), and salicylates (salicylic acid and lactic acid). The latter can cause a mixed disorder of metabolic acidosis with respiratory alkalosis. In toluene poisoning, a metabolite hippurate is rapidly excreted by the kidney and may present as a normal anion gap acidosis. Isopropyl alcohol, which is metabolized to acetone, increases the osmolar gap, but not the anion gap.

E. Uremic Acidosis

As the GFR drops below 15–30 mL/min, the kidneys are increasingly unable to excrete H^+ and organic acids, such as phosphate and sulfate, resulting in an increased anion gap acidosis. Hyperchloremic normal anion gap acidosis develops in earlier stages of CKD.

NORMAL ANION GAP ACIDOSIS (Table 21-14)

The most common causes are gastrointestinal HCO_3^- loss and defects in renal acidification (renal tubular acidoses). The urinary anion gap can differentiate between these causes (see below).

A. Gastrointestinal HCO_3^- Loss

Bicarbonate is secreted at multiple sites in the gastrointestinal tract. Small bowel and pancreatic secretions contain

Table 21-14. Hyperchloremic, normal anion gap metabolic acidoses.

| | Renal Defect | Serum $[\text{K}^+]$ | Distal H^+ Secretion | | Urinary Anion Gap | Treatment |
|--|---|----------------------|---|------------------|-------------------|---|
| | | | Urinary NH_4^+ Plus Minimal Urine pH | Titrateable Acid | | |
| Gastrointestinal HCO_3^- loss | None | ↓ | < 5.5 | ↑↑ | Negative | Na^+ , K^+ , and HCO_3^- as required |
| Renal tubular acidosis | | | | | | |
| I. Classic distal | Distal H^+ secretion | ↓ | > 5.5 | ↓ | Positive | NaHCO_3 (1–3 mEq/kg/d) |
| II. Proximal secretion | Proximal H^+ | ↓ | < 5.5 | Normal | Positive | NaHCO_3 or KHCO_3 (10–15 mEq/kg/d), thiazide |
| IV. Hyporeninemic hypoaldosteronism | Distal Na^+ reabsorption, K^+ secretion, and H^+ secretion | ↑ | < 5.5 | ↓ | Positive | Fludrocortisone (0.1–0.5 mg/d), dietary K^+ restriction, furosemide (40–160 mg/d), NaHCO_3 (1–3 mEq/kg/d) |

Modified and reproduced, with permission, from Cogan MG. *Fluid and Electrolytes: Physiology and Pathophysiology*. McGraw-Hill, 1991.

large amounts of HCO_3^- ; massive diarrhea or pancreatic drainage can result in HCO_3^- loss. Hyperchloremia occurs because the ileum and colon secrete HCO_3^- in exchange for Cl^- by countertransport. The resultant volume contraction causes increased Cl^- retention by the kidney in the setting of decreased HCO_3^- . Patients with ureterosigmoidostomies can develop hyperchloremic metabolic acidosis because the colon secretes HCO_3^- in the urine in exchange for Cl^- .

B. Renal Tubular Acidosis (RTA)

Hyperchloremic acidosis with a normal anion gap and normal (or near normal) GFR, and in the absence of diarrhea, defines RTA. The defect is either inability to excrete H^+ (inadequate generation of new HCO_3^-) or inappropriate reabsorption of HCO_3^- . Three major types can be differentiated by the clinical setting, urinary pH, urinary anion gap (see below), and serum K^+ level. Recently, the pathophysiologic mechanisms of RTA have been elucidated by identifying the responsible molecules and their gene mutations.

1. Classic distal RTA (type I)—This disorder is characterized by hypokalemic hyperchloremic metabolic acidosis due to selective deficiency in H^+ secretion in α intercalated cells in the collecting tubule. Despite acidosis, urinary pH cannot be acidified and is above 5.5, which retards the binding of H^+ to phosphate ($\text{H}^+ + \text{HPO}_4^{2-} \rightarrow \text{H}_2\text{PO}_4^-$) and inhibits titratable acid excretion. Furthermore, urinary excretion of NH_4^+Cl^- is decreased, and the urinary anion gap is positive (see below). Enhanced K^+ excretion occurs probably because there is less competition from H^+ in the distal nephron transport system. Furthermore, hyperaldosteronism occurs in response to renal salt wasting, which will increase potassium excretion. Nephrocalcinosis and nephrolithiasis are often seen in patients with distal RTA since chronic acidosis decreases tubular calcium reabsorption. Hypercalciuria, alkaline urine, and lowered level of urinary citrate cause calcium phosphate stones and nephrocalcinosis.

Distal RTA develops as a consequence of dysproteinemic syndromes, autoimmune disease, and drugs and toxins such as amphotericin.

2. Proximal RTA (type II)—Proximal RTA is a hypokalemic hyperchloremic metabolic acidosis due to a selective defect in the proximal tubule's ability to reabsorb filtered HCO_3^- . Carbonic anhydrase inhibitors (acetazolamide) can cause proximal RTA. About 90% of filtered HCO_3^- is absorbed by the proximal tubule. A proximal defect in HCO_3^- reabsorption will overwhelm the limited capacity of the distal tubule to reabsorb HCO_3^- , resulting in bicarbonaturia and metabolic acidosis. Distal delivery of HCO_3^- declines as the plasma HCO_3^- level decreases. When the plasma HCO_3^- level drops to 15–18 mEq/L, the distal nephron can reabsorb the diminished filtered load of HCO_3^- . Bicarbonaturia disappears, and urinary pH can be acidic. Thiazide-induced volume contraction can be used to enhance proximal HCO_3^- reabsorption, leading to the decrease in distal HCO_3^- delivery and improvement of bicarbonaturia and renal acidification. The increased delivery of HCO_3^- to the distal nephron also increases K^+ secretion, and hypokalemia results if a patient is loaded

with excess HCO_3^- and K^+ is not adequately supplemented. Proximal RTA often exists with other defects of absorption in the proximal tubule, resulting in glucosuria, aminoaciduria, phosphaturia, and uricaciduria. Causes include multiple myeloma with Fanconi syndrome and nephrotoxic drugs.

3. Hyporeninemic hypoaldosteronemic RTA (type IV)—Type IV is the most common RTA in clinical practice. The defect is aldosterone deficiency or antagonism, which impairs distal nephron Na^+ reabsorption and K^+ and H^+ excretion. Renal salt wasting and hyperkalemia are frequently present. Common causes are diabetic nephropathy, tubulointerstitial renal diseases, hypertensive nephrosclerosis, and AIDS. In patients with these disorders, caution must be taken when prescribing drugs that can exacerbate the hyperkalemia, such as ACE inhibitors (which will further reduce aldosterone levels), aldosterone receptor blockers such as spironolactone, and NSAIDs.

C. Dilutional Acidosis

Rapid dilution of plasma volume by 0.9% NaCl may cause a mild hyperchloremic acidosis.

D. Recovery from Diabetic Ketoacidosis

See earlier section, Increased Anion Gap Acidosis (Increased Unmeasured Anion).

E. Posthypocapnia

In prolonged respiratory alkalosis, HCO_3^- decreases and Cl^- increases from decreased renal NH_4^+Cl^- excretion. If the respiratory alkalosis is corrected quickly, PCO_2 will increase acutely but HCO_3^- will remain low until the kidneys can generate new HCO_3^- , which generally takes several days. In the meantime, the increased PCO_2 with low HCO_3^- causes metabolic acidosis.

F. Hyperalimentation

Hyperalimentation fluids may contain amino acid solutions that acidify when metabolized, such as arginine hydrochloride and lysine hydrochloride.

▶ Assessment of Hyperchloremic Metabolic Acidosis by Urinary Anion Gap

Increased renal NH_4^+Cl^- excretion to enhance H^+ removal is a normal physiologic response to metabolic acidosis. NH_3 reacts with H^+ to form NH_4^+ , which is accompanied by the anion Cl^- for excretion. The normal daily urinary excretion of NH_4Cl of about 30 mEq can be increased up to 200 mEq in response to acid load.

Urinary anion gap from a random urine sample ($[\text{Na}^+ + \text{K}^+] - \text{Cl}^-$) reflects the ability of the kidney to excrete NH_4Cl as in the following equation:

where 80 is the average value for the difference in the urinary anions and cations other than Na^+ , K^+ , NH_4^+ , and

Cl. Therefore, urinary anion gap is equal to $(80 - \text{NH}_4^+)$, and thus aids in the distinction between gastrointestinal and renal causes of hyperchloremic acidosis. If the cause of the metabolic acidosis is gastrointestinal HCO_3^- loss (diarrhea), the renal acidification ability remains normal and NH_4Cl excretion increases in response to the acidosis. The urinary anion gap is negative (eg, -30 mEq/L). If the cause is distal RTA, the urinary anion gap is positive (eg, $+25$ mEq/L), since the basic lesion in the disorder is the inability of the kidney to excrete H^+ and thus the inability to increase NH_4Cl excretion. In proximal (type II) RTA, the kidney has defective HCO_3^- reabsorption, leading to increased HCO_3^- excretion rather than decreased NH_4Cl excretion. Thus, the urinary anion gap is often negative in proximal (type II) RTA.

Urinary pH may not as readily differentiate between the two causes. Despite acidosis, if volume depletion from diarrhea causes inadequate Na^+ delivery to the distal nephron and therefore decreased exchange with H^+ , urinary pH may not be lower than 5.3. In the presence of this relatively high urine pH, however, H^+ excretion continues due to buffering of NH_3 to NH_4^+ , since the pK of this reaction is as high as 9.1. Potassium depletion, which can accompany diarrhea (and surreptitious laxative abuse), may also impair renal acidification. Thus, when volume depletion is present, the urinary anion gap is a better measurement of ability to acidify the urine than urinary pH.

When large amounts of other anions are present in the urine, the urinary anion gap may not be reliable. In such a situation, NH_4^+ excretion can be estimated using the urinary osmolar gap.

$$\begin{aligned} \text{NH}_4^+ \text{ excretion (mmol/L)} &= \\ &0.5 \times \text{Urinary osmolar gap} = \\ &0.5 [\text{U osm} - 2(\text{U Na}^+ + \text{U K}^+) + \text{U urea} + \text{U glucose}] \end{aligned}$$

where urinary (U) concentrations and osmolality are in millimoles per liter.

► Clinical Findings

A. Symptoms and Signs

Symptoms of metabolic acidosis are mainly those of the underlying disorder. Compensatory hyperventilation is an important clinical sign and may be misinterpreted as a primary respiratory disorder; when severe, Kussmaul respirations (deep, regular, sighing respirations) are seen.

B. Laboratory Findings

Blood pH, serum HCO_3^- , and PCO_2 are decreased. Anion gap may be normal (hyperchloremic) or increased (normochloremic). Hyperkalemia may be seen (see above).

► Treatment

A. Increased Anion Gap Acidosis

Treatment is aimed at the underlying disorder, such as insulin and fluid therapy for diabetes and appropriate volume resuscitation to restore tissue perfusion. The

metabolism of lactate will produce HCO_3^- and increase pH. The use of supplemental HCO_3^- is indicated for treatment of hyperkalemia (Table 21–6) and some forms of normal anion gap acidosis but has been controversial for treatment of increased anion gap metabolic acidosis.

Controversy remains about the efficacy and safety of alkali therapy for severe metabolic acidosis. Administration of large amounts of HCO_3^- may have deleterious effects, including hypernatremia, hyperosmolality, volume overload, and worsening of intracellular acidosis.

In addition, alkali administration is known to stimulate phosphofructokinase activity, thus exacerbating lactic acidosis via enhanced lactate production. Ketogenesis is also augmented by alkali therapy.

In salicylate intoxication, alkali therapy must be started unless blood pH is already alkalinized by respiratory alkalosis, since the increment in pH converts salicylate to more impermeable salicylic acid, decreasing central nervous system damage. In alcoholic ketoacidosis, thiamine should be given with glucose to avoid the development of Wernicke encephalopathy. The amount of HCO_3^- deficit can be calculated as follows:

$$\begin{aligned} \text{Amount of HCO}_3^- \text{ deficit} &= \\ &0.5 \times \text{body weight} \times (24 - \text{HCO}_3^-) \end{aligned}$$

Half of the calculated deficit should be administered within the first 3–4 hours to avoid overcorrection and volume overload. In methanol intoxication, ethanol had been used as a competitive substrate for alcohol dehydrogenase, which metabolizes methanol to formaldehyde. Inhibition of alcohol dehydrogenase by fomepizole is the standard of care.

B. Normal Anion Gap Acidosis

Treatment of RTA is mainly achieved by administration of alkali (either as bicarbonate or citrate) to correct metabolic abnormalities and prevent nephrocalcinosis and chronic kidney disease.

Large amounts of alkali (10–15 mEq/kg/d) may be required to treat proximal RTA because most of the alkali is excreted into the urine, which exacerbates hypokalemia. Thus, a mixture of sodium and potassium salts is preferred. The addition of thiazides may reduce the amount of alkali required, but hypokalemia may develop. Correction of type 1 distal RTA requires a smaller amount of alkali (1–3 mEq/kg/d) and potassium supplementation as needed.

For the treatment of type IV RTA, dietary potassium restriction may be needed and potassium-retaining drugs should be withdrawn. Fludrocortisone may be effective in cases with hypoaldosteronism, but should be used with care, preferably in combination with loop diuretics. In some cases, alkali supplementation (1–3 mEq/kg/d) may be required.

► When to Refer

Most clinicians will refer patients with renal tubular acidosis to a nephrologist for evaluation and possible alkali therapy.

▶ When to Admit

Patients will require emergency department evaluation or hospital admission depending on the severity of the acidosis and underlying conditions.

METABOLIC ALKALOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ High HCO_3^- with alkalemia.
- ▶ Evaluate effective circulating volume by physical examination and check urinary chloride concentration to differentiate saline-responsive metabolic alkalosis from saline-unresponsive alkalosis.

▶ Classification

Metabolic alkalosis is characterized by high HCO_3^- . Abnormalities that generate HCO_3^- within the body are called “initiation factors” of metabolic alkalosis, whereas abnormalities that promote renal conservation of HCO_3^- are called “maintenance factors.” Metabolic alkalosis may remain even after the initiation factors have disappeared.

It is useful to classify the causes of metabolic alkalosis into two groups based on “saline responsiveness” or urinary Cl^- , which are markers for volume status (Table 21–15). Saline-responsive metabolic alkalosis is a sign of extracellular volume contraction, and saline-unresponsive alkalosis implies a volume-expanded state. It is rare for a compensatory increase in PCO_2 to exceed 55 mm Hg. Higher PCO_2 values imply a superimposed respiratory acidosis.

A. Saline-Responsive Metabolic Alkalosis

Much more common than saline-unresponsive alkalosis, saline-responsive alkalosis is characterized by normotensive extracellular volume contraction and hypokalemia. Less frequently, hypotension or orthostatic hypotension may be seen. In vomiting or nasogastric suction, for example, loss of acid (HCl) initiates the alkalosis, but volume contraction from loss of Cl^- sustains the alkalosis because the decline in GFR causes avid renal Na^+ and HCO_3^- reabsorption. Because there is Cl^- depletion from loss of HCl, NaCl, and KCl from the stomach, the available anion is HCO_3^- , whose reabsorption is increased proximally, and urine pH may remain acidic despite alkalemia (paradoxical aciduria). Renal Cl^- reabsorption (as well as Na^+ reabsorption) is high, and the urinary Cl^- is therefore low ($< 10\text{--}20$ mEq/L). In alkalosis, bicarbonaturia may force Na^+ excretion as the accompanying cation even if volume depletion is present. Therefore, urinary Cl^- is preferred to urinary Na^+ as a

Table 21–15. Metabolic alkalosis.

| Saline-Responsive ($U_{\text{Cl}} < 25$ mEq/L) | Saline-Unresponsive ($U_{\text{Cl}} > 40$ mEq/L) |
|--|--|
| Excessive body bicarbonate content | Excessive body bicarbonate content |
| Renal alkalosis | Renal alkalosis |
| Diuretic therapy | Normotensive |
| Poorly reabsorbable anion therapy: carbenicillin, penicillin, sulfate, phosphate | Bartter syndrome (renal salt wasting and secondary hyperaldosteronism) |
| Posthypercapnia | Severe potassium depletion |
| Gastrointestinal alkalosis | Refeeding alkalosis |
| Loss of HCl from vomiting or nasogastric suction | Hypercalcemia and hypoparathyroidism |
| Intestinal alkalosis: chloride diarrhea | Hypertensive |
| NaHCO_3 (baking soda) | Endogenous mineralocorticoids |
| Sodium citrate, lactate, gluconate, acetate | Primary aldosteronism |
| Transfusions | Hyperreninism |
| Antacids | Adrenal enzyme deficiency: 11- and 17-hydroxylase |
| Normal body bicarbonate content | Liddle syndrome |
| “Contraction alkalosis” | Exogenous alkali |
| | Exogenous mineralocorticoids |
| | Licorice |

measure of extracellular volume. An exception to the usefulness of urinary Cl^- is in patients who have recently received diuretics. Their urine may contain high Na^+ and Cl^- despite extracellular volume contraction. If diuretics are discontinued, the urinary Cl^- will decrease.

Metabolic alkalosis is generally associated with hypokalemia. This is due partly to the direct effect of alkalosis per se on renal potassium excretion and partly to secondary hyperaldosteronism from volume depletion. Hypokalemia induced in this fashion further worsens the metabolic alkalosis by increasing bicarbonate reabsorption in the proximal tubule and hydrogen ion secretion in the distal tubule. Administration of KCl will correct the disorder. Repletion of KCl is important to reverse the disorder.

1. Contraction alkalosis—Diuretics can quickly decrease extracellular volume from urinary loss of NaCl and water. There is no associated bicarbonaturia, so total body HCO_3^- remains normal. The plasma HCO_3^- concentration increases because the extracellular fluid volume contracts around a stable total body bicarbonate. This process is the reverse of a dilutional acidosis.

2. Posthypercapnia alkalosis—In chronic respiratory acidosis, compensatory increases in HCO_3^- occur (Table 21–12). Hypercapnia also directly affects the proximal tubule to decrease NaCl reabsorption, which can cause extracellular volume depletion. If PCO_2 is corrected rapidly, metabolic alkalosis will exist until adequate renal bicarbonate excretion occurs. Hypovolemia will inhibit bicarbonaturia until Cl^- is repleted. Many patients with chronic respiratory acidosis receive diuretics, which further exacerbates the metabolic alkalosis.

B. Saline-Unresponsive Alkalosis

1. Hyperaldosteronism—Primary hyperaldosteronism causes expansion of extracellular volume with hypertension. Metabolic alkalosis with hypokalemia results from the renal mineralocorticoid effect. In an attempt to decrease extracellular volume, high levels of NaCl are excreted, and for that reason the urinary Cl^- is high (> 20 mEq/L, often higher). Therapy with NaCl will only increase volume expansion and hypertension and will not treat the underlying problem of mineralocorticoid excess.

2. Alkali administration with decreased GFR—Despite large ingestions of HCO_3^- , enhanced bicarbonaturia almost always prevents a patient with normal kidney function from developing metabolic alkalosis. However, urinary excretion of bicarbonate is inadequate with CKD. If large amounts of HCO_3^- or metabolizable salts of organic acids such as sodium lactate, sodium citrate, or sodium gluconate are consumed, as with intensive antacid therapy, metabolic alkalosis will occur. In milk-alkali syndrome, large and sustained ingestion of absorbable antacids and milk causes CKD from hypercalcemia. Decreased GFR prevents appropriate bicarbonaturia from the ingested alkali, and metabolic alkalosis occurs. Volume contraction from renal hypercalcemic effects further exacerbates the alkalosis.

► Clinical Findings

A. Symptoms and Signs

There are no characteristic symptoms or signs. Orthostatic hypotension may be encountered. Weakness and hyporeflexia occur if serum K^+ is markedly low. Tetany and neuromuscular irritability occur rarely.

B. Laboratory Findings

The arterial blood pH and bicarbonate are elevated. The arterial PCO_2 is increased. Serum potassium and chloride are decreased. There may be an increased anion gap. The spot urinary chloride can differentiate between a saline-responsive (< 25 mEq/L) and unresponsive (> 40 mEq/L) disorder.

► Treatment

Mild alkalosis is generally well tolerated. Severe or symptomatic alkalosis (pH > 7.60) requires urgent treatment.

A. Saline-Responsive Metabolic Alkalosis

Therapy for saline-responsive metabolic alkalosis is correction of the extracellular volume deficit with isotonic saline. Diuretics should be discontinued. H_2 -blockers or proton pump inhibitors may be helpful in patients with alkalosis from nasogastric suctioning. If pulmonary or cardiovascular disease prohibits adequate resuscitation, intravenous acetazolamide will increase renal bicarbonate excretion and improve the metabolic alkalosis. Hypokalemia may develop because bicarbonate excretion may induce kaliuresis. Severe cases, especially those with impaired kidney function, may require dialysis with low-bicarbonate dialysate.

B. Saline-Unresponsive Metabolic Alkalosis

Therapy for saline-unresponsive metabolic alkalosis includes surgical removal of a mineralocorticoid-producing tumor and blockage of aldosterone effect with an ACE inhibitor or with spironolactone. Metabolic alkalosis in primary aldosteronism can be treated only with potassium repletion.

Khanna A et al. Metabolic alkalosis. *J Nephrol.* 2006 Mar-Apr;19(Suppl 9):S86–96. [PMID: 16736446]

RESPIRATORY ACIDOSIS (HYPERCAPNIA)

Respiratory acidosis results from hypoventilation and subsequent hypercapnia. Pulmonary and extrapulmonary disorders can cause hypoventilation. The clinician should identify readily reversible causes of respiratory acidosis, such as opioid-induced respiratory depression.

Acute respiratory failure is associated with severe acidosis and only a small increase in the plasma bicarbonate. After 6–12 hours, the primary increase in PCO_2 evokes a renal compensatory response to excrete more acid and to generate more HCO_3^- , which buffers the respiratory acidosis; complete metabolic compensation by the kidney usually takes several days.

Chronic respiratory acidosis is generally seen in patients with underlying lung disease, such as chronic obstructive pulmonary disease. Urinary excretion of acid in the form of NH_4^+ and Cl^- ions results in the characteristic hypochloremia of chronic respiratory acidosis. When chronic respiratory acidosis is corrected suddenly, there is a 2- to 3-day lag in renal bicarbonate excretion, resulting in posthypercapnic metabolic alkalosis.

► Clinical Findings

A. Symptoms and Signs

With acute onset, somnolence, confusion, mental status changes, asterixis, and myoclonus may develop. Severe hypercapnia increases cerebral blood flow, cerebrospinal fluid pressure, and intracranial pressure; papilledema and pseudotumor cerebri may be seen.

B. Laboratory Findings

Arterial pH is low and PCO_2 is increased. Serum HCO_3^- is elevated but does not compensate for the hypercapnia or correct the pH. If the disorder is chronic, hypochloremia is seen.

► Treatment

If opioid overdose is a possible diagnosis or there is no other obvious cause for hypoventilation, the clinician should consider a diagnostic and therapeutic trial of intravenous naloxone (see Chapter 38). In all forms of respiratory acidosis, treatment is directed at the underlying disorder to improve ventilation.

Madias NE et al. Cross-talk between two organs: how the kidney responds to disruption of acid–base balance by the lung. *Nephron Physiol*. 2003;93(3):61–6. [PMID: 12660492]

RESPIRATORY ALKALOSIS (HYPOCAPNIA)

Respiratory alkalosis occurs when hyperventilation reduces the PCO_2 , increasing serum pH. The most common cause of respiratory alkalosis is hyperventilation syndrome (Table 21–16), but bacterial septicemia and cirrhosis are other common causes. Symptoms in acute respiratory alkalosis are related to decreased cerebral blood flow induced by the disorder. Pregnancy is another cause of chronic respiratory alkalosis, probably from progesterone stimulation of the respiratory center, producing an average PCO_2 of 30 mm Hg.

Determination of appropriate metabolic compensation in the serum HCO_3^- may reveal an associated metabolic disorder (see above under Mixed Acid–Base Disorders).

As in respiratory acidosis, the changes in HCO_3^- values are greater if the respiratory alkalosis is chronic (Table 21–12). Although serum HCO_3^- is frequently below 15 mEq/L in metabolic acidosis, it is unusual to see such a low level in respiratory alkalosis, and its presence would imply a superimposed (noncompensatory) metabolic acidosis.

Table 21–16. Causes of respiratory alkalosis.

Hypoxia

- Decreased inspired oxygen tension
- High altitude
- Ventilation/perfusion inequality
- Hypotension
- Severe anemia

CNS-mediated disorders

- Voluntary hyperventilation
- Anxiety-hyperventilation syndrome
- Neurologic disease
- Cerebrovascular accident (infarction, hemorrhage)
- Infection
- Trauma
- Tumor
- Pharmacologic and hormonal stimulation
 - Salicylates
 - Nicotine
 - Xanthines
 - Pregnancy (progesterone)
- Hepatic failure
- Gram-negative septicemia
- Recovery from metabolic acidosis
- Heat exposure

Pulmonary disease

- Interstitial lung disease
- Pneumonia
- Pulmonary embolism
- Pulmonary edema

Mechanical overventilation

Adapted, with permission, from Gennari FJ. Respiratory acidosis and alkalosis. In: *Maxwell and Kleeman's Clinical Disorders of Fluid and Electrolyte Metabolism*, 5th ed. Narins RG (editor). McGraw-Hill, 1994.

► Clinical Findings

A. Symptoms and Signs

In acute cases (hyperventilation), there is light-headedness, anxiety, perioral numbness, and paresthesias. Tetany occurs in more severe alkalosis from a fall in ionized calcium.

B. Laboratory Findings

Arterial blood pH is elevated, and PCO_2 is low. Serum bicarbonate is decreased in chronic respiratory alkalosis.

► Treatment

Treatment is directed toward the underlying cause. In acute hyperventilation syndrome from anxiety, the traditional treatment of breathing into a paper bag should be discouraged because it does not correct the PCO_2 and may decrease the PO_2 . Reassurance may be sufficient for the anxious patient, but sedation may be necessary if the process persists. Hyperventilation is usually self-limited since muscle weakness caused by the respiratory alkalemia will suppress ventilation. Rapid correction of chronic respiratory alkalosis may result in metabolic acidosis as PCO_2 is increased in the setting of a previous compensatory decrease in HCO_3^- .

Table 21-17. Replacement guidelines for sweat and gastrointestinal fluid losses.

| | Average Electrolyte Composition | | | | Replacement Guidelines per Liter Lost | | | | |
|--------------------|---------------------------------|---------------------------|----------------------------|--|---------------------------------------|----------------------|--------------------------|----------------|---|
| | Na ⁺ (mEq/L) | K ⁺ (mEq/L) | Cl ⁻ (mEq/L) | HCO ₃ ⁻ (mEq/L) | 0.9% Saline (mL) | 0.45% Saline (mL) | D ₅ W (mL) | KCl (mEq/L) | 7.5% NaHCO ₃ (45 mEq HCO ₃ ⁻ /amp) |

Laffey JG et al. Hypocapnia. *N Engl J Med*. 2002 Jul 4;347(1):43-53. [PMID: 12097540]

FLUID MANAGEMENT

Daily parenteral maintenance fluids and electrolytes for an average adult would include 2500–3000 mL of 5% dextrose in 0.2% saline solution (34 mEq Na⁺ plus 34 mEq Cl⁻/L) with 30 mEq/L of KCl. Guidelines for gastrointestinal fluid losses are shown in Table 21-17.

Weight loss or gain is the best indication of water balance. Insensible water loss should be considered in

febrile patients. Water loss increases by 100–150 mL/d for each degree of body temperature over 37 °C.

In patients requiring maintenance and possibly replacement of fluid and electrolytes by parenteral infusion, the total daily ration should be administered continuously over 24 hours to ensure optimal utilization.

If intravenous fluids are the only source of water, electrolytes, and calories for longer than a week, parenteral nutrition containing amino acids, lipids, trace metals, and vitamins may be indicated. (See Chapter 29.)

For parenteral alimentation, 620 mg (20 mmol) of phosphorus is required for every 1000 nonprotein kcal to maintain phosphate balance and to ensure anabolic function. For prolonged parenteral fluid maintenance, a daily ration is 620–1240 mg (20–40 mmol) of phosphorus.

Kidney Disease

Suzanne Watnick, MD
Gail Morrison, MD

Kidney disease presents in one of two ways: discovered incidentally during a routine medical evaluation or with evidence of renal dysfunction, such as hypertension, edema, nausea, and hematuria. The initial approach in both situations should be to assess the cause and severity of renal abnormalities. In all cases this evaluation includes (1) an estimation of disease duration, (2) a careful urinalysis, and (3) an assessment of the glomerular filtration rate (GFR). The history and physical examination, though equally important, are variable among renal syndromes—thus, specific symptoms and signs are discussed under each disease entity.

ASSESSMENT OF KIDNEY DISEASE

▶ Disease Duration

Kidney disease may be acute or chronic. Acute kidney injury, also known as acute renal failure, is worsening of kidney function over hours to days, resulting in the retention of nitrogenous wastes (such as urea nitrogen) and creatinine in the blood. Retention of these substances is called azotemia. Chronic kidney disease results from an abnormal loss of kidney function over months to years. Differentiating between the two is important for diagnosis, treatment, and outcome. Oliguria is unusual in chronic kidney disease. Anemia (from low kidney erythropoietin production) is rare in the initial period of acute kidney disease. Small kidneys are most consistent with chronic kidney disease, whereas normal to large-size kidneys can be seen with both chronic and acute disease.

▶ Urinalysis

A urinalysis has been likened to “a poor man’s renal biopsy.” The urine is collected in midstream or, if that is not feasible, by bladder catheterization. The urine should be examined within 1 hour after collection to avoid destruction of formed elements. Urinalysis includes a dipstick examination followed by microscopic assessment if the dipstick has positive findings. The dipstick examination measures urinary pH, protein, hemoglobin, glucose, ketones, bilirubin,

nitrites, and leukocyte esterase. Urinary specific gravity is often reported, too. Microscopy searches for all formed elements—crystals, cells, casts, and infecting organisms.

Various findings on the urinalysis are indicative of certain patterns of kidney disease. A bland urinary sediment is common, especially in chronic kidney disease and prerenal and postrenal disorders. Casts are composed of Tamm-Horsfall urinary mucoprotein in the shape of the nephron segment where they were formed. Heavy proteinuria and lipiduria are consistent with the nephrotic syndrome. The presence of hematuria with dysmorphic red blood cells, red blood cell casts, and proteinuria is indicative of glomerulonephritis. Dysmorphic red blood cells are misshapen during abnormal passage from the capillary through the glomerular basement membrane (GBM) into the urinary space of Bowman capsule. Pigmented granular casts and renal tubular epithelial cells alone or in casts suggest acute tubular necrosis. White blood cells, including neutrophils and eosinophils, white blood cell casts, red blood cells, and small amounts of protein can be found in interstitial nephritis and pyelonephritis (Table 22–1); Wright and Hansel stains can detect eosinophiluria. Pyuria alone can indicate a urinary tract infection. Hematuria and proteinuria are discussed more thoroughly below.

A. Proteinuria

Proteinuria is defined as excessive protein excretion in the urine, generally greater than 150–160 mg/24 h in adults. Significant proteinuria is a sign of an underlying renal abnormality, usually glomerular in origin when greater than 1 g/d. It can be accompanied by other clinical abnormalities—elevated blood urea nitrogen (BUN) and serum creatinine levels, abnormal urinary sediment, or evidence of systemic illness (eg, fever, rash, vasculitis).

There are four primary reasons for development of proteinuria: (1) Functional proteinuria is a benign process stemming from stressors such as acute illness, exercise, and “orthostatic proteinuria.” The latter condition, generally found in people under age 30 years, usually results in urinary protein excretion of less than 1 g/d. The orthostatic nature of the proteinuria is confirmed by measuring an 8-hour overnight supine urinary protein excretion, which

Table 22-1. Significance of specific urinary casts.

| Type | Significance |
|--------------------------|--|
| Hyaline casts | Concentrated urine, febrile disease, after strenuous exercise, in the course of diuretic therapy (not indicative of renal disease) |
| Red cell casts | Glomerulonephritis |
| White cell casts | Pyelonephritis, interstitial nephritis (indicative of infection or inflammation) |
| Renal tubular cell casts | Acute tubular necrosis, interstitial nephritis |
| Coarse, granular casts | Nonspecific; can represent acute tubular necrosis |
| Broad, waxy casts | Chronic kidney disease (indicative of stasis in enlarged collecting tubules) |

should be less than 50 mg. (2) Overload proteinuria can result from overproduction of circulating, filterable plasma proteins (monoclonal gammopathies), such as Bence Jones proteins associated with multiple myeloma. Urinary protein electrophoresis will exhibit a discrete protein peak. Other examples of overload proteinuria include myoglobinuria in rhabdomyolysis and hemoglobinuria in hemolysis. (3) Glomerular proteinuria results from effacement of epithelial cell foot processes and altered glomerular permeability with an increased filtration fraction of normal plasma proteins. Glomerular diseases exhibit some degree of proteinuria. The urinary protein electrophoresis will have a pattern exhibiting a large albumin spike indicative of increased permeability of albumin across a damaged GBM. (4) Tubular proteinuria occurs as a result of faulty reabsorption of normally filtered proteins in the proximal tubule, such as β_2 -microglobulin and immunoglobulin light chains. Causes include acute tubular necrosis, toxic injury (lead, aminoglycosides), drug-induced interstitial nephritis, and hereditary metabolic disorders (Wilson disease and Fanconi syndrome).

Evaluation of proteinuria by urinary dipstick primarily detects albumin and intact globulins, while overlooking positively charged light chains of immunoglobulins. These proteins can be detected by the addition of sulfosalicylic acid to the urine specimen. Precipitation indicates the presence of paraproteins.

The next step is a 24-hour urine collection. A finding of greater than 150–160 mg/24 h is abnormal, and greater than 3.5 g/24 h is consistent with nephrotic-range proteinuria. A simpler method is to collect a random urine sample. The ratio of urinary protein concentration to urinary creatinine concentration ($U_{\text{protein}}/U_{\text{creatinine}}$) correlates with 24-hour urine protein collection (< 0.2 is normal and corresponds to excretion of less than 200 mg/24 h). The benefit of a urine protein-to-creatinine ratio is the ease of collection and the lack of error from overcollection or undercollection of urine. If a patient has proteinuria with or without loss of kidney function, kidney biopsy may be indicated, particularly if the kidney disease is acute in

onset. The clinical consequences of proteinuria are discussed in the section on the nephrotic syndrome.

B. Hematuria

Hematuria is significant if there are more than three red cells per high-power field on at least two occasions. It is usually detected incidentally by the urine dipstick examination or clinically following an episode of macroscopic hematuria. The diagnosis must be confirmed via microscopic examination, as false-positive dipstick tests can be caused by myoglobin, oxidizing agents, beets and rhubarb, hydrochloric acid, and bacteria. Transient hematuria is common, but in patients younger than 40 years, it is less often of clinical significance due to lower concern for malignancy.

Hematuria may be due to renal or extrarenal causes. Extrarenal causes are addressed in Chapters 23 and 39; most worrisome are urologic malignancies. Renal causes account for approximately 10% of cases and are best considered anatomically as glomerular or nonglomerular. The most common extraglomerular sources include cysts, calculi, interstitial nephritis, and renal neoplasia. Glomerular causes include immunoglobulin A (IgA) nephropathy, thin GBM disease, membranoproliferative glomerulonephritis, and systemic nephritic syndromes.

Currently, the United States Health Preventive Services Task Force does not recommend screening for hematuria. See Chapter 23 for evaluation of hematuria.

▶ Estimation of GFR

The GFR provides a useful index of overall kidney function; however, patients with kidney disease can actually have a normal or increased GFR. The GFR measures the amount of plasma ultrafiltered across the glomerular capillaries and correlates with the ability of the kidneys to filter fluids and various substances. Daily GFR in normal individuals is variable, with a range of 150–250 L/24 h or 100–120 mL/min/1.73 m² of body surface area. GFR can be measured indirectly by determining the renal clearance of plasma substances that are not bound to plasma proteins, are freely filterable across the glomerulus, and are neither secreted nor reabsorbed along the renal tubules. The formula used to determine the renal clearance of a substance is

$$C = \frac{U \times \dot{V}}{P}$$

where C is the clearance, U and P are the urine and plasma concentrations of the substance (mg/dL), and \dot{V} is the urine flow rate (mL/min). In clinical practice, the clearance rate of endogenous creatinine, the creatinine clearance, is one way of estimating GFR. Creatinine is a product of muscle metabolism produced at a relatively constant rate and cleared by renal excretion. It is freely filterable by the glomerulus and not reabsorbed by the renal tubules at steady state. With stable kidney function, creatinine production and excretion are equal; thus, plasma creatinine concentrations remain constant. However, it is not a perfect indicator of GFR for the following reasons: (1) A small amount is normally eliminated by tubular secretion, and

Table 22-2. Conditions affecting serum creatinine independently of glomerular filtration rate.

| Condition | Mechanism |
|--|---|
| Conditions elevating creatinine | |
| Ketoacidosis, cephalothin, cefoxitin, flucytosine | Noncreatinine chromogen |
| Other drugs: aspirin, cimetidine, probenecid, trimethoprim | Inhibition of tubular creatinine secretion |
| Conditions decreasing creatinine | |
| Advanced age | Physiologic decrease in muscle mass |
| Cachexia | Pathologic decrease in muscle mass |
| Liver disease | Decreased hepatic creatine synthesis and cachexia |

the fraction secreted progressively increases as GFR declines (overestimating GFR); (2) with severe kidney failure, gut microorganisms degrade creatinine; (3) an individual's meat intake and muscle mass affect baseline plasma creatinine levels; (4) commonly used drugs such as aspirin, cimetidine, probenecid, and trimethoprim reduce tubular secretion of creatinine, increasing the plasma creatinine concentration and falsely indicating kidney dysfunction; and (5) the accuracy of the measurement necessitates a stable plasma creatinine concentration over a 24-hour period, so that during the development of and recovery from acute kidney injury, the creatinine clearance is of questionable value (Table 22-2).

To measure creatinine clearance, collect a 24-hour urine sample and determine the plasma creatinine level on the same day. An incomplete or prolonged urine collection is a common source of error. One way of estimating the completeness of the collection is to calculate a 24-hour creatinine excretion; the amount should be constant:

$U_{cr} \times V = 15\text{--}20 \text{ mg/kg}$ for healthy young women

$U_{cr} \times V = 20\text{--}25 \text{ mg/kg}$ for healthy young men

The creatinine clearance (C_{cr}) is approximately 100 mL/min/1.73 m² in healthy young women and 120 mL/min/1.73 m² in healthy young men. The C_{cr} declines by an average of 0.8 mL/min/yr after age 40 years as part of the aging process, but 35% of subjects in one study had no decline in kidney function over 10 years.

C_{cr} can be estimated from the formula of Cockcroft and Gault, which incorporates age, sex, and weight to estimate C_{cr} from plasma creatinine levels without any urinary measurements:

$$C_{cr} = \frac{(140 - \text{Age}) \times \text{Weight (kg)}}{P_{cr} \times 72}$$

For women, the creatinine clearance is multiplied by 0.85 because muscle mass is less. This formula overestimates GFR in patients who are obese or edematous and

Table 22-3. Conditions affecting BUN independently of GFR.

| |
|--|
| Increased BUN |
| Reduced effective circulating blood volume (prerenal azotemia) |
| Catabolic states (gastrointestinal bleeding, corticosteroid use) |
| High-protein diets |
| Tetracycline |
| Decreased BUN |
| Liver disease |
| Malnutrition |
| Sickle cell anemia |
| SIADH |

BUN, blood urea nitrogen; GFR, glomerular filtration rate; SIADH, syndrome of inappropriate antidiuretic hormone.

is most accurate when normalized for body surface area of 1.73 m².

Urea is another index helpful in assessing kidney function. It is synthesized mainly in the liver and is the end product of protein catabolism. Urea is freely filtered by the glomerulus, and about 30–70% is reabsorbed in the nephron. Unlike creatinine clearance, which overestimates GFR, urea clearance underestimates GFR. Urea reabsorption may be decreased in volume replete patients, whereas volume depletion causes increased urea reabsorption from the kidney, increasing BUN. A normal BUN:creatinine ratio is 10:1. With volume depletion, the ratio can increase to 20:1 or higher. Other causes of increased BUN include increased catabolism (gastrointestinal bleeding, cell lysis, and corticosteroid usage), increased dietary protein, and decreased renal perfusion (congestive heart failure, renal artery stenosis) (Table 22-3). Reduced BUN is seen in liver disease and in the syndrome of inappropriate antidiuretic hormone (SIADH) secretion.

As patients approach end-stage renal disease (ESRD), a more accurate measure of GFR than creatinine clearance is the average of the creatinine and urea clearances. The creatinine clearance overestimates GFR, as mentioned above, while the urea clearance underestimates GFR. Therefore, an average of the two more accurately approximates the true GFR.

The estimated GFR (eGFR) is a complex four-variable equation, including serum creatinine, age, weight, and race, that is often reported alongside serum creatinine measurements and more accurate than creatinine or urea clearance. This was derived from data collected for the Modification of Diet and Renal Disease study and has been validated in several other populations. Several computer programs exist that will calculate this; one location for this is www.nephron.com.

RENAL BIOPSY

Indications for percutaneous needle biopsy include (1) unexplained acute kidney injury or chronic kidney disease; (2) acute nephritic syndromes; (3) unexplained proteinuria and hematuria; (4) previously identified and treated lesions to plan future therapy; (5) systemic diseases associated with

kidney dysfunction, such as systemic lupus erythematosus, Goodpasture syndrome, and Wegener granulomatosis, to confirm the extent of renal involvement and to guide management; (6) suspected transplant rejection, to differentiate it from other causes of acute kidney injury; and (7) to guide treatment. If a patient is unwilling to accept therapy based on biopsy findings, the risk of biopsy may outweigh its benefit. Relative contraindications include a solitary or ectopic kidney (exception: transplant allografts), horseshoe kidney, uncorrected bleeding disorder, severe uncontrolled hypertension, renal infection, renal neoplasm, hydronephrosis, ESRD, congenital anomalies, multiple cysts, or an uncooperative patient.

Prior to biopsy, patients should have well-controlled blood pressure; blood work should include a hemoglobin, platelet count, prothrombin time, and partial thromboplastin time. After biopsy, hematuria occurs in nearly all patients. Fewer than 10% will have macroscopic hematuria. Patients should remain supine for 4–6 hours postbiopsy. A patient with a 6-hour postbiopsy hematocrit more than 3% lower than baseline should be closely monitored.

Percutaneous kidney biopsies are generally safe. Approximately 1% of patients will experience significant bleeding requiring blood transfusions. More than half of patients will have at least a small hematoma. Risk of major bleeding persists up to 72 hours after the biopsy. Any type of anticoagulation therapy should be held for 5–7 days postbiopsy if possible. The risks of nephrectomy and mortality are about 0.06–0.08%. When a percutaneous needle biopsy is technically not feasible and renal tissue is deemed clinically essential, a closed renal biopsy via interventional radiologic techniques or open renal biopsy under general anesthesia can be done.

- ▶ Oliguria often associated.
- ▶ Symptoms and signs depend on cause.

▶ General Considerations

Acute kidney injury, also known as acute renal failure, is defined as a sudden decrease in kidney function, resulting in an inability to maintain fluid and electrolyte balance and to excrete nitrogenous wastes. Serum creatinine is a convenient marker. In the absence of functioning kidneys, serum creatinine concentration will typically increase by 1–1.5 mg/dL daily—although with certain conditions, such as rhabdomyolysis, serum creatinine can increase more rapidly. Five percent of hospital admissions and 30% of intensive care unit (ICU) admissions carry a diagnosis of acute kidney injury, and it will develop in 25% of hospitalized patients.

▶ Clinical Findings

A. Symptoms and Signs

The uremic milieu of acute kidney injury can cause nonspecific symptoms. When present, they are often due to azotemia or its underlying cause. Azotemia can cause nausea, vomiting, malaise, and altered sensorium. Hypertension is rare, but fluid homeostasis is often altered. Hypovolemia can cause prerenal disease, whereas hypervolemia can result from intrinsic or postrenal disease. Pericardial effusions can occur with azotemia, and a pericardial friction rub can be present. Effusions may result in cardiac tamponade. Arrhythmias occur especially with hyperkalemia. The lung examination may show rales in the presence of hypervolemia. Acute kidney failure can cause nonspecific diffuse abdominal pain and ileus as well as platelet dysfunction; thus, bleeding and clotting disorders are more common in these patients. The neurologic examination reveals encephalopathic changes with asterixis and confusion; seizures may ensue.

B. Laboratory Findings

Elevated BUN and creatinine are present, though these elevations do not in themselves distinguish acute from chronic kidney disease. Hyperkalemia often occurs from impaired renal potassium excretion. The ECG can reveal peaked T waves, PR prolongation, and QRS widening. A long QT segment can occur with hypocalcemia. Anion gap metabolic acidosis (due to decreased organic acid clearance) is often noted. Hyperphosphatemia occurs when phosphorus cannot be secreted by damaged tubules either with or without increased cell catabolism. Hypocalcemia with metastatic calcium phosphate deposition may be observed when the product of calcium and phosphorus exceeds $70 \text{ mg}^2/\text{dL}^2$. Anemia can occur as a result of decreased erythropoietin production over weeks, and associated platelet dysfunction is typical.

▶ Classification & Etiology

Acute kidney injury can be divided into three categories: prerenal azotemia, intrinsic renal disease, and postrenal azotemia. Identifying the cause is the first step toward treating the patient (Table 22–4).

ACUTE KIDNEY INJURY (ACUTE RENAL FAILURE)

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden increase in BUN or serum creatinine.

Table 22-4. Classification and differential diagnosis of acute kidney injury.

| | Prerenal Azotemia | Postrenal Azotemia | Intrinsic Renal Disease | | |
|----------------------------|-------------------------|---|---|---|--|
| | | | Acute Tubular Necrosis (Oliguric or Polyuric) | Acute Glomerulonephritis | Acute Interstitial Nephritis |
| Etiology | Poor renal perfusion | Obstruction of the urinary tract | Ischemia, nephrotoxins | Immune complex-mediated, pauci-immune, anti-GBM related | Allergic reaction; drug reaction; infection, collagen vascular disease |
| Serum BUN:Cr ratio | > 20:1 | > 20:1 | < 20:1 | > 20:1 | < 20:1 |
| Urinary indices | | | | | |
| U _{Na} (mEq/L) | < 20 | Variable | > 20 | < 20 | Variable |
| FeNa (%) | < 1 | Variable | > 1 (when oliguric) | < 1 | < 1; > 1 |
| Urine osmolality (mosm/kg) | > 500 | < 400 | 250–300 | Variable | Variable |
| Urinary sediment | Benign or hyaline casts | Normal or red cells, white cells, or crystals | Granular (muddy brown) casts, renal tubular casts | Red cells, dysmorphic red cells and red cell casts | White cells, white cell casts, with or without eosinophils |

BUN:Cr, blood urea nitrogen:creatinine ratio; FeNa, fractional excretion of sodium; U_{Na}, urinary concentration of sodium.

A. Prerenal Azotemia

Prerenal azotemia is the most common cause of acute kidney injury, accounting for 40–80% of cases, depending on the population studied. It is due to renal hypoperfusion. This is an appropriate physiologic change. If it can be immediately reversed with restoration of renal blood flow, renal parenchymal damage often does not occur. If hypoperfusion persists, ischemia can result, causing intrinsic kidney injury.

Decreased renal perfusion can occur in one of three ways: a decrease in intravascular volume, a change in vascular resistance, or low cardiac output. Causes of volume depletion include hemorrhage, gastrointestinal losses, dehydration, excessive diuresis, extravascular space sequestration, pancreatitis, burns, trauma, and peritonitis.

Changes in vascular resistance can occur systemically with sepsis, anaphylaxis, anesthesia, and afterload-reducing drugs. Angiotensin-converting enzyme (ACE) inhibitors prevent efferent renal arteriolar constriction out of proportion to the afferent arteriolar constriction; thus, GFR will decrease. Nonsteroidal anti-inflammatory drugs (NSAIDs) prevent afferent arteriolar vasodilation by inhibiting prostaglandin-mediated signals. Thus, in cirrhosis and congestive heart failure, when prostaglandins are recruited to increase renal blood flow, NSAIDs will have particularly deleterious effects. Epinephrine, norepinephrine, high-dose dopamine, anesthetic agents, and cyclosporine also can cause renal vasoconstriction. Renal artery stenosis causes increased resistance and decreased renal perfusion.

Low cardiac output is a state of low effective renal arterial blood flow. This occurs in states of cardiogenic shock, congestive heart failure, pulmonary embolism, and pericardial tamponade. Arrhythmias and valvular disorders can also reduce cardiac output. In the ICU setting,

positive pressure ventilation will decrease venous return, also decreasing cardiac output.

When GFR falls acutely, it is important to determine whether acute kidney injury is due to prerenal or intrinsic renal causes. The history and physical examination are important, and urinalysis can be helpful. The BUN:creatinine ratio will typically exceed 20:1 due to increased urea reabsorption. In an oliguric patient, another useful index is the fractional excretion of sodium (FeNa). With decreased GFR, the kidney will reabsorb salt and water avidly if there is no intrinsic tubular dysfunction. Thus, patients with prerenal failure should have a low fractional excretion percent of sodium (< 1%). Oliguric patients with intrinsic kidney dysfunction will have a high fractional excretion of sodium (> 1%). The FeNa is calculated as follows: FeNa = clearance of Na⁺/GFR = clearance of Na⁺/creatinine clearance:

$$\text{FeNa} = \frac{\text{Urine}_{\text{sodium}}/\text{Plasma}_{\text{sodium}}}{\text{Urine}_{\text{creatinine}}/\text{Plasma}_{\text{creatinine}}} \times 100\%$$

Oliguric states are more accurately assessed with this formula than nonoliguric states because the FeNa could be relatively low in nonoliguric acute tubular necrosis if sodium intake and excretion are relatively low. (Oliguria is defined as urinary output < 400–500 mL/d, or < 20 mL/h.) Diuretics can cause increased sodium excretion. Thus, if the FeNa is high within 12–24 hours after diuretic administration, the cause of acute kidney injury may not be accurately predicted. Acute kidney injury due to glomerulonephritis can have a low FeNa because sodium reabsorption and tubular function may not be compromised.

Treatment of prerenal azotemia depends entirely on its cause, but maintenance of euolemia, attention to serum potassium, and avoidance of nephrotoxic drugs are bench-

marks of therapy. This involves careful assessment of volume status, cardiac function, and drug usage.

B. Postrenal Azotemia

Postrenal azotemia is the least common cause of acute kidney injury, accounting for approximately 5–10% of cases, but is important to detect because of its reversibility. It occurs when urinary flow from both kidneys, or a single functioning kidney, is obstructed. Obstruction leads to elevated intraluminal pressure, causing kidney parenchymal damage, with marked effects on renal blood flow and tubular function, and a decrease in GFR.

Causes include urethral obstruction, bladder dysfunction or obstruction, and obstruction of both ureters or renal pelvises. In men, benign prostatic hyperplasia is the most common cause. Patients taking anticholinergic drugs are particularly at risk. Obstruction can also be caused by bladder, prostate, and cervical cancers; retroperitoneal processes; and neurogenic bladder. Less common causes are blood clots, bilateral ureteral stones, urethral stones or stricture, and bilateral papillary necrosis. In patients with a single functioning kidney, obstruction of a solitary ureter can cause postrenal azotemia.

Patients may be anuric or polyuric and may complain of lower abdominal pain. Obstruction can be constant or intermittent and partial or complete. On examination, the patient may have an enlarged prostate, distended bladder, or mass detected on pelvic examination.

Laboratory examination may initially reveal high urine osmolality, low urine sodium, high BUN:creatinine ratio, and low FENa. These indices are similar to a prerenal picture because extensive intrinsic renal damage has not occurred. After several days, the urine sodium increases as the kidneys fail and are unable to concentrate the urine—thus, isosthenuria is present. The urine sediment is generally benign.

Patients with acute kidney injury and suspected postrenal azotemia should undergo bladder catheterization and bladder ultrasonography to assess for hydronephrosis and hydronephrosis. These patients often undergo a postobstructive diuresis and diuresis, and care should be taken to avoid volume depletion. Rarely, obstruction is not diagnosed by ultrasonography. For example, patients with retroperitoneal fibrosis from tumor or radiation may not show dilation of the urinary tract. If suspicion does exist, a CT scan or MRI can establish the diagnosis. Prompt treatment of obstruction within days by catheters, stents, or other surgical procedures can result in partial or complete reversal of the acute process.

C. Intrinsic Renal Failure

Intrinsic renal disorders account for up to 50% of all cases of acute kidney injury. Intrinsic (or parenchymal) dysfunction is considered after prerenal and postrenal causes have been excluded. The sites of injury are the tubules, interstitium, vasculature, and glomeruli.

▶ When to Refer

- If a patient has signs of acute kidney injury that have not reversed over 1–2 weeks, but no signs of acute uremia,

the patient can usually be referred to a nephrologist rather than admitted.

- If a patient has signs of urinary tract obstruction, the patient can be referred to a urologist.

▶ When to Admit

The patient should be admitted if he or she has sudden loss of kidney function resulting in abnormalities that cannot be handled expeditiously in an outpatient setting (eg, hyperkalemia, volume overload, uremia) or other requirements for acute dialysis.

ACUTE TUBULAR NECROSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Acute kidney injury.
- ▶ Ischemic or toxic insult.
- ▶ Urine sediment with pigmented granular casts and renal tubular epithelial cells is pathognomonic but not essential.

▶ General Considerations

Acute kidney injury due to tubular damage is termed acute tubular necrosis and accounts for 85% of intrinsic acute kidney injury. The two major causes of acute tubular necrosis are ischemia and nephrotoxin exposure. Ischemia causes tubular damage from states of low perfusion and is often preceded by a state of prerenal azotemia. Ischemic acute kidney injury is characterized not only by inadequate GFR but also by renal blood flow inadequate to maintain parenchymal cellular formation. This occurs in the setting of prolonged hypotension or hypoxemia, such as volume depletion, shock, and sepsis. Major surgical procedures can involve prolonged periods of hypoperfusion, which are exacerbated by vasodilating anesthetic agents.

Exogenous nephrotoxins more commonly cause damage than endogenous nephrotoxins.

A. Exogenous Nephrotoxins

Up to 25% of hospitalized patients receiving therapeutic levels of aminoglycosides sustain some degree of acute tubular necrosis. Nonoliguric kidney injury typically occurs after 5–10 days of exposure. Predisposing factors include underlying kidney damage, volume depletion, and advanced age. Aminoglycosides can remain in renal tissues for up to a month, so kidney function may not recover for some time after stopping the medication. Monitoring of peak and trough levels is important, but trough levels are more helpful in predicting renal toxicity. Gentamicin is as nephrotoxic as tobramycin; streptomycin is the least nephrotoxic of the aminoglycosides, likely due to the number of cationic amino side chains present on each molecule. Amphotericin B is typically nephrotoxic after a dose of 2–3 g. This causes severe vasoconstriction with distal tubular damage and can lead to

distal renal tubular acidosis with hypokalemia and nephrogenic diabetes insipidus. Vancomycin, intravenous acyclovir, and several cephalosporins have been known to cause acute tubular necrosis.

Radiographic contrast media can be directly nephrotoxic. Contrast nephropathy is the third leading cause of new acute kidney injury in hospitalized patients. It probably results from the synergistic combination of direct renal tubular epithelial cell toxicity and renal medullary ischemia. Predisposing factors include advanced age, preexisting kidney disease (serum creatinine > 2 mg/dL), volume depletion, diabetic nephropathy, congestive heart failure, multiple myeloma, repeated doses of contrast, and recent exposure to other nephrotoxic agents, including NSAIDs and ACE inhibitors. The combination of diabetes mellitus and kidney dysfunction poses the greatest risk (15–50%) for contrast nephropathy. Lower volumes of contrast with lower osmolality are recommended in high-risk patients. Toxicity usually occurs within 24–48 hours after the radiocontrast study. Nonionic contrast media may be less toxic, but this has not been well proven. Prevention should be the goal when using these agents. The mainstay of therapy is a liter of 0.9% saline over 10–12 hours both before and after the contrast administration—cautiously in patients with preexisting cardiac dysfunction. Neither mannitol nor furosemide offers benefit over normal saline administration. In fact, furosemide may lead to increased rates of renal dysfunction in this setting. In some but not all studies, *N*-acetylcysteine given before and after contrast decreased the incidence of dye-induced nephrotoxicity. Acetylcysteine is a thiol-containing antioxidant with little toxicity whose mechanism of action is unclear. Its benefit seems more pronounced in subjects with a lower GFR. With little harm and possible benefit, administering acetylcysteine 600 mg orally every 12 hours twice, before and after a dye load, for patients at risk for acute kidney injury, is a reasonable strategy. Intravenous *N*-acetylcysteine, 1200 mg prior to an emergent procedure, has shown benefit compared with placebo and may be a good option if a patient needs contrast dye urgently. Some investigators have shown a benefit using sodium bicarbonate (154 mEq/L, intravenously at 3 mL/kg/h for 1 hour before the procedure, then 1 mL/kg/h for 6 hours after the procedure) over a more conventional regimen of normal saline as the isotonic volume expander. However, others have shown sodium bicarbonate was not superior to sodium chloride when using similar administration regimens. Other nephrotoxic agents should be avoided during the day before and after dye administration.

Cyclosporine toxicity is usually dose dependent. It causes distal tubular dysfunction from severe vasoconstriction. Regular blood level monitoring is important to prevent nephrotoxicity. With patients who are taking cyclosporine for renal transplant rejection, kidney biopsy is often necessary to distinguish transplant rejection from cyclosporine toxicity. Renal function usually improves after reducing the dose or stopping the drug.

Other exogenous nephrotoxins include antineoplastics, such as cisplatin and organic solvents, and heavy metals such as mercury, cadmium, and arsenic.

B. Endogenous Nephrotoxins

Endogenous nephrotoxins include heme-containing products, uric acid, and paraproteins. **Myoglobinuria** as a consequence of rhabdomyolysis leads to acute tubular necrosis. Necrotic muscle releases large amounts of myoglobin, which is freely filtered across the glomerulus. The myoglobin is reabsorbed by the renal tubules, and direct damage can occur. Distal tubular obstruction from pigmented casts and intrarenal vasoconstriction can also cause damage. This type of kidney injury occurs in the setting of crush injury, or muscle necrosis from prolonged unconsciousness, seizures, cocaine, and alcohol abuse. Dehydration and acidosis predispose to the development of myoglobinuric acute kidney injury. Patients may complain of muscular pain and often have signs of muscle injury. Rhabdomyolysis of clinical importance commonly occurs with a serum creatine kinase (CK) greater than 20,000–50,000 international units/L. One study showed that 58% of patients with acute kidney injury from rhabdomyolysis had CK levels greater than 16,000 international units/L. Only 11% of patients without kidney injury had CK values greater than 16,000 international units/L. The globin moiety of myoglobin will cause the urine dipstick to read falsely positive for hemoglobin: the urine appears dark brown, but no red cells are present. With lysis of muscle cells, patients also become hyperkalemic, hyperphosphatemic, and hyperuricemic. Hypocalcemia may ensue due to phosphorus and calcium precipitation. The mainstay of treatment is volume repletion. Other adjunctive treatments include mannitol for free radical clearance and diuresis as well as alkalization of the urine. These modalities have not been proved to change outcomes in human trials. Hypocalcemia should not be treated unless the patient is symptomatic; as the patient recovers, calcium can move back from tissues to plasma, so early exogenous calcium administration could result in hypercalcemia.

Hemoglobin can cause a similar form of acute tubular necrosis. Massive intravascular hemolysis is seen in transfusion reactions and in certain hemolytic anemias. Reversal of the underlying disorder and hydration are the mainstays of treatment.

Hyperuricemia can occur in the setting of rapid cell turnover and lysis. Chemotherapy for germ cell neoplasms and leukemia and lymphoma are the primary causes. Acute kidney injury occurs with intratubular deposition of uric acid crystals; serum uric acid levels are often greater than 15–20 mg/dL and urine uric acid levels greater than 600 mg/24 h. A urine uric acid to urine creatinine ratio greater than 1.0 indicates risk of acute kidney injury.

Bence Jones protein seen in conjunction with multiple myeloma can cause direct tubular toxicity and tubular obstruction. Other renal complications from multiple myeloma include hypercalcemia and renal tubular dysfunction, including proximal renal tubular acidosis (see Multiple Myeloma, below).

► Clinical Findings

A. Symptoms and Signs

See Acute Kidney Injury.

B. Laboratory Findings

Hyperkalemia and hyperphosphatemia are commonly encountered. Urinalysis may show evidence of acute tubular damage. The urine may be brown. On microscopic examination, an active sediment may show pigmented granular casts or “muddy brown” casts. Renal tubular epithelial cells and epithelial cell casts can be present (see Table 22–1).

▶ Treatment

Treatment is aimed at hastening recovery and avoiding complications. Preventive measures should be taken to avoid volume overload and hyperkalemia. Loop diuretics have been used in large doses (eg, furosemide in doses ranging from 20 mg to 160 mg orally or intravenously twice daily, or as a continuous infusion) to affect adequate diuresis and may help convert oliguric to nonoliguric renal failure. Such a conversion has never been shown to affect outcomes such as mortality, though. One retrospective study has shown potentially worse outcomes in patients who receive doses of furosemide, including nonrecovery of renal function and an increased risk of death. A prospective randomized controlled trial has shown no difference between the administration of large doses of diuretics versus placebo on either recovery from acute kidney injury or death. Widespread use of diuretics in critically ill patients with acute kidney injury should be discouraged. Side effects of supranormal dosing include deafness. This is mainly due to peak furosemide levels and can be avoided by the use of a furosemide drip. A starting dose of 0.1–0.3 mg/kg/h is appropriate, increasing to a maximum of 0.5–1 mg/kg/h. A bolus of 1–1.5 mg/kg should be administered at the beginning of each dose escalation. Intravenous thiazide diuretics can be used to augment urinary output; chlorothiazide, 250–500 mg intravenously every 8–12 hours, is a reasonable choice. Short-term effects also include activation of the renin–angiotensin system. One prospective randomized trial showed the long-term benefits of plasma ultrafiltration over the use of intravenous diuretics in patients with decompensated heart failure. This intervention can be considered in ICU patients with acute kidney injury in need of volume removal who are nonresponsive to diuretics. Nutritional support should maintain adequate intake while preventing excessive catabolism. Dietary protein restriction of 0.6 g/kg/d helps prevent metabolic acidosis. Hypocalcemia and hyperphosphatemia can be improved with diet and phosphate-binding agents, such as aluminum hydroxide (500 mg orally with meals) over the short term, calcium carbonate (500–1500 mg orally three times daily), calcium acetate (667 mg, two or three tablets, orally before meals), or sevelamer (800–1600 mg orally three times daily). Lanthanum carbonate (1000 mg orally with meals) is a less well-studied option. Hypocalcemia should not be treated in patients with rhabdomyolysis unless they are symptomatic. Hypermagnesemia can occur because of reduced magnesium excretion by the renal tubules, so magnesium-containing antacids and laxatives should be avoided in these patients. Dosages of all medications must be adjusted according to the estimated degree of renal impairment for drugs eliminated by the kidney.

Indications for dialysis in acute kidney injury from acute tubular necrosis or other intrinsic disorders include life-threatening electrolyte disturbances (such as hyperkalemia), volume overload unresponsive to diuresis, worsening acidosis, and uremic complications (eg, encephalopathy, pericarditis, and seizures). In gravely ill patients, less severe but worsening abnormalities may also be indications for dialytic support. A prospective randomized control trial of 1124 patients showed that an intensive dialysis dose was not superior to a more conventional dose.

▶ Course & Prognosis

The clinical course of acute tubular necrosis is often divided into three phases: initial injury, maintenance, and recovery. The maintenance phase is expressed as either oliguric (urinary output < 500 mL/d) or nonoliguric. Nonoliguric acute tubular necrosis has a better outcome. Conversion from oliguric to nonoliguric states may be attempted but has not been shown to change the prognosis. Drugs such as dopamine and diuretics are sometimes used for this purpose but have not been shown to improve outcomes. In numerous studies, dopamine use in this setting has been shown to have no benefit. Average duration of the maintenance phase is 1–3 weeks but may be several months. Cellular repair and removal of tubular debris occur during this period. The recovery phase is heralded by diuresis. GFR begins to rise; BUN and serum creatinine fall.

The mortality rate associated with acute kidney injury is 20–50% in medical illness and up to 70% in a surgical setting. Increased mortality is associated with advanced age, severe underlying disease, and multisystem organ failure. Leading causes of death are infections, fluid and electrolyte disturbances, and worsening of underlying disease. Mortality rates may be starting to improve slightly according to two recent retrospective cohort studies.

▶ When to Refer

- A patient with acute tubular necrosis should be referred to a nephrologist when the etiology is unclear or renal function continues to worsen despite intervention.
- Also, referral is appropriate if fluid, electrolyte, and acid-base abnormalities are recalcitrant to interventions.
- Studies have shown that nephrology referral improves outcome in acute kidney injury.

▶ When to Admit

Admission is appropriate when a patient has signs or symptoms of acute kidney injury that require immediate intervention, such as intravenous fluids, dialytic therapy, or a team approach that cannot be coordinated as an outpatient.

INTERSTITIAL NEPHRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Fever.
- ▶ Transient maculopapular rash.

- ▶ Acute or chronic kidney injury.
- ▶ Pyuria (including eosinophiluria), white blood cell casts, and hematuria.

▶ General Considerations

Acute interstitial nephritis accounts for 10–15% of cases of intrinsic renal failure. An interstitial inflammatory response with edema and possible tubular cell damage is the typical pathologic finding. Cell-mediated immune reactions prevail over humoral responses. T lymphocytes can cause direct cytotoxicity or release lymphokines that recruit monocytes and inflammatory cells.

Although drugs account for over 70% of cases, acute interstitial nephritis also occurs in infectious diseases, immunologic disorders, or as an idiopathic condition. The most common drugs are penicillins and cephalosporins, sulfonamides and sulfonamide-containing diuretics, NSAIDs, rifampin, phenytoin, and allopurinol. Proton pump inhibitors have also been recognized as a cause of acute interstitial nephritis. Infectious causes include streptococcal infections, leptospirosis, cytomegalovirus, histoplasmosis, and Rocky Mountain spotted fever. Immunologic entities are more commonly associated with glomerulonephritis, but systemic lupus erythematosus, Sjögren syndrome, sarcoidosis, and cryoglobulinemia can cause interstitial nephritis.

▶ Clinical Findings

Clinical features can include fever (> 80%), rash (25–50%), arthralgias, and peripheral blood eosinophilia (80%). The urine often contains red cells (95%), white cells, and white cell casts. Proteinuria can be a feature, particularly in NSAID-induced interstitial nephritis, but is usually modest. Eosinophiluria can be detected by Wright or Hansel stain.

▶ Treatment & Prognosis

Acute interstitial nephritis often carries a good prognosis. Recovery occurs over weeks to months, but urgent dialytic therapy may be necessary in up to one-third of all referred patients before resolution. Patients rarely progress to ESRD. Those with prolonged courses of oliguric failure and advanced age have a worse prognosis. Treatment consists of supportive measures and removal of the inciting agent. If kidney injury persists after these steps, a short course of corticosteroids can be given, although the data to support use of corticosteroids are not substantial. Short-term, high-dose methylprednisolone (0.5–1 g/d intravenously for 1–4 days) or prednisone (60 mg/d orally for 1–2 weeks) followed by a prednisone taper can be used in these more severe cases of drug-induced interstitial nephritis.

GLOMERULONEPHRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Hematuria, dysmorphic red cells, red cell casts, and mild proteinuria.

- ▶ Dependent edema and hypertension.
- ▶ Acute renal insufficiency.

▶ General Considerations

Acute glomerulonephritis is a relatively uncommon cause of acute kidney injury, accounting for about 5% of cases. Pathologically, inflammatory glomerular lesions are seen. These include mesangioproliferative, focal and diffuse proliferative, and crescentic lesions. The larger the percentage of glomeruli involved and the more severe the lesion, the more likely it is that the patient will have a poor clinical outcome.

Categorization of acute glomerulonephritis can be done by serologic analysis. Markers include antineutrophil cytoplasmic antibodies (ANCA), anti-GBM antibodies, and other immune markers of disease.

Immune complex deposition usually occurs when moderate antigen excess over antibody production occurs. Complexes formed with marked antigen excess tend to remain in the circulation. Antibody excess with large antigen–antibody aggregates usually results in phagocytosis and clearance of the precipitates by the mononuclear phagocytic system in the liver and spleen. Causes include IgA nephropathy (Berger disease), perinfectious or postinfectious glomerulonephritis, endocarditis, lupus nephritis, cryoglobulinemic glomerulonephritis (often associated with hepatitis C virus), and membranoproliferative glomerulonephritis.

Anti-GBM-associated acute glomerulonephritis is either confined to the kidney or associated with pulmonary hemorrhage. The latter is termed “Goodpasture syndrome.” Injury is related to autoantibodies aimed against type IV collagen in the GBM rather than to immune complex deposition.

Pauci-immune acute glomerulonephritis is a form of small-vessel vasculitis associated with anti-neutrophil cytoplasmic antibodies (ANCA), causing primary and secondary kidney diseases that do not have direct immune complex deposition or antibody binding. Tissue injury is believed to be due to cell-mediated immune processes. An example is Wegener granulomatosis, a systemic necrotizing vasculitis of small arteries and veins associated with intravascular and extravascular granuloma formation. In addition to glomerulonephritis, these patients can have upper airway, pulmonary, and skin manifestations of disease. Cytoplasmic ANCA (C-ANCA) is a common pattern. Microscopic polyangiitis is another pauci-immune vasculitis causing acute glomerulonephritis. Perinuclear staining (P-ANCA) is the common pattern. ANCA-associated and anti-GBM-associated acute glomerulonephritis can evolve to crescentic glomerulonephritis and often have poor outcomes unless treatment is started early. Both are described more fully below.

Other vascular causes of acute glomerulonephritis include hypertensive emergencies and the thrombotic microangiopathies such as hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura (see Chapter 14).

► Clinical Findings

A. Symptoms and Signs

Patients with acute glomerulonephritis are often hypertensive and edematous, and have an abnormal urinary sediment. The edema is found first in body parts with low tissue tension, such as the periorbital and scrotal regions.

B. Laboratory Findings

Dipstick and microscopic evaluation will reveal evidence of hematuria, moderate proteinuria (usually < 3 g/d), and cellular elements such as red cells, red cell casts, and white cells. Red cell casts are specific for glomerulonephritis, and a detailed search is warranted. Either spot urinary protein-creatinine ratios or twenty-four hour urine collections can quantify protein excretion, the latter can quantify creatinine clearance when renal function is stable. However, in cases of rapidly changing serum creatinine values, the urinary creatinine clearance is an unreliable marker of GFR. The FeNa is usually low unless the renal tubulo-interstitial space is affected, and renal dysfunction is marked.

Further tests include complement levels (C3, C4, CH50), ASO titer, anti-GBM antibody levels, ANCA, antinuclear antibody titers, cryoglobulins, hepatitis serologies, blood cultures, renal ultrasound, and occasionally renal biopsy.

► Treatment

Depending on the nature and severity of disease, treatment can consist of high-dose corticosteroids and cytotoxic agents such as cyclophosphamide. Plasma exchange can be used in Goodpasture disease and pauci-immune glomerulonephritis as a temporizing measure until chemotherapy can take effect. Treatment and prognosis for specific diseases are discussed more fully below.

▼ CHRONIC KIDNEY DISEASE

ESSENTIALS OF DIAGNOSIS

- Progressive azotemia over months to years.
- Symptoms and signs of uremia when nearing end-stage disease.
- Hypertension in the majority.
- Isosthenuria and broad casts in urinary sediment are common.
- Bilateral small kidneys on ultrasound are diagnostic.

► General Considerations

Chronic kidney disease affects up to 20 million Americans, or one in nine adults. Most are unaware of the condition because they remain asymptomatic until the disease has significantly progressed. The National Kidney Foundation's staging system helps clinicians formulate practice plans (Table 22–5). Over 70% of cases of late-stage (stage 5) chronic kidney disease are due to diabetes mellitus or hypertension. Glomerulonephritis, cystic diseases, and other urologic diseases account for another 12%, and 15% of patients have other or unknown causes. The major causes of chronic kidney disease are listed in Table 22–6.

Table 22–5. Stages of chronic kidney disease: A clinical action plan.^{1,2}

| Stage | Description | GFR (mL/min/1.73 m ²) | Action ³ |
|-------|------------------------------------|--------------------------------------|---|
| 1 | Kidney damage with normal or ↑ GFR | ≥ 90 | Diagnosis and treatment. Treatment of comorbid conditions. Slowing of progression. Cardiovascular disease risk reduction. |
| 2 | Kidney damage with mildly ↓ | 60–89 | Estimating progression. |
| 3 | Moderately ↓ | 30–59 | Evaluating and treating complications. |
| 4 | Severely ↓ | 15–29 | Preparation for kidney replacement therapy. |
| 5 | Kidney failure | < 15 (or dialysis) | Replacement (if uremia is present). |

¹From National Kidney Foundation, KDOQI, chronic kidney disease guidelines.

²Chronic kidney disease is defined as either kidney damage or GFR < 60 mL/min/1.73 m² for 3 or more months. Kidney damage is defined as pathologic abnormalities or markers of damage, including abnormalities in blood or urine tests or imaging studies.

³Includes actions from preceding stages.

GFR, glomerular filtration rate.

Table 22-6. Major causes of chronic kidney disease.

| Glomerulopathies |
|---|
| Primary glomerular diseases |
| Focal and segmental glomerulosclerosis |
| Membranoproliferative glomerulonephritis |
| IgA nephropathy |
| Membranous nephropathy |
| Secondary glomerular diseases |
| Diabetic nephropathy |
| Amyloidosis |
| Postinfectious glomerulonephritis |
| HIV-associated nephropathy |
| Collagen-vascular diseases |
| Sickle cell nephropathy |
| HIV-associated membranoproliferative glomerulonephritis |
| Tubulointerstitial nephritis |
| Drug hypersensitivity |
| Heavy metals |
| Analgesic nephropathy |
| Reflux/chronic pyelonephritis |
| Idiopathic |
| Hereditary diseases |

| Obstructive nephropathies |
| Prostatic disease |
| Nephrolithiasis |
| Retroperitoneal fibrosis/tumor |
| Congenital |
| Vascular diseases |
| Hypertensive nephrosclerosis |
| Renal artery stenosis |

Chronic kidney disease is rarely reversible and leads to a progressive decline in kidney function. This occurs even after the inciting event has been removed. Reduction in renal mass leads to hypertrophy of the remaining nephrons with hyperfiltration. The GFR in these nephrons is transiently at supranormal levels. These adaptations place a burden on the remaining nephrons and lead to progressive glomerular sclerosis and interstitial fibrosis, suggesting that hyperfiltration may worsen kidney function. However, decreased renal mass in kidney donors is not associated with chronic kidney disease.

► Clinical Findings

A. Symptoms and Signs

The symptoms of chronic kidney disease often develop slowly and are nonspecific (Table 22-7). Individuals can remain asymptomatic until kidney disease is far advanced (GFR < 10–15 mL/min). Manifestations include fatigue, weakness, and malaise. Gastrointestinal complaints, such as anorexia, nausea, vomiting, a metallic taste in the mouth, and hiccups, are common. Neurologic problems include irritability, difficulty in concentrating, insomnia, subtle memory defects, restless legs, and twitching. Pruritus is common and difficult to treat. As uremia progresses,

Table 22-7. Symptoms and signs of uremia.

| Organ System | Symptoms | Signs |
|------------------|---|---|
| General | Fatigue, weakness | Sallow-appearing, chronically ill |
| Skin | Pruritus, easy bruisability | Pallor, ecchymoses, excoriations, edema, xerosis |
| ENT | Metallic taste in mouth, epistaxis | Urinous breath |
| Eye | | Pale conjunctiva |
| Pulmonary | Shortness of breath | Rales, pleural effusion |
| Cardiovascular | Dyspnea on exertion, retrosternal pain on inspiration (pericarditis) | Hypertension, cardiomegaly, friction rub |
| Gastrointestinal | Anorexia, nausea, vomiting, hiccups | |
| Genitourinary | Nocturia, impotence | Isosthenuria |
| Neuromuscular | Restless legs, numbness and cramps in legs | |
| Neurologic | Generalized irritability and inability to concentrate, decreased libido | Stupor, asterixis, myoclonus, peripheral neuropathy |

decreased libido, menstrual irregularities, chest pain from pericarditis, and paresthesias can develop. Symptoms of drug toxicity—especially for drugs eliminated by the kidney—increase as renal clearance worsens.

On physical examination, the patient appears chronically ill. Hypertension is common. The skin may be yellow, with signs of easy bruisability. Rarely seen in the current era is uremic frost, a cutaneous reflection of ESRD. Uremic fetor is the characteristic fishy odor of the breath. Cardio-pulmonary signs may include rales, cardiomegaly, edema, and a pericardial friction rub. Mental status can vary from decreased concentration to confusion, stupor, and coma. Myoclonus and asterixis are additional signs of uremic effects on the central nervous system.

The term “uremia” is used for this clinical syndrome, but the exact cause remains unknown. BUN and serum creatinine are considered markers for unknown toxins.

In any patient with kidney disease, it is important to identify and correct all possibly reversible causes. Urinary tract infections, obstruction, extracellular fluid volume depletion, nephrotoxins, hypertension, and congestive heart failure should be excluded (Table 22-8). Any of the above can worsen underlying chronic kidney disease.

B. Laboratory Findings

The diagnosis is made by documenting elevations of the BUN and serum creatinine concentrations. Further evaluation is needed to differentiate between acute and chronic

Table 22–8. Reversible causes of kidney injury.

| Reversible Factors | Diagnostic Clues |
|--|--|
| Infection | Urine culture and sensitivity tests |
| Obstruction | Bladder catheterization, then renal ultrasound |
| Extracellular fluid volume depletion | Orthostatic blood pressure and pulse: ↓ blood pressure and ↑ pulse upon sitting up from a supine position |
| Hypokalemia, hypercalcemia, and hyperuricemia (usually > 15 mg/dL) | Serum electrolytes, calcium, phosphate, uric acid |
| Nephrotoxic agents | Drug history |
| Hypertension | Blood pressure, chest radiograph |
| Congestive heart failure | Physical examination, chest radiograph |

disease. Evidence of previously elevated BUN and creatinine, abnormal prior urinalyses, and stable but abnormal serum creatinine on successive days is most consistent with a chronic process. It is helpful to plot the inverse of serum creatinine ($1/S_{Cr}$) versus time if three or more prior measurements are available; this can estimate time to ESRD (Figure 22–1). If the slope of the line acutely declines, new causes of kidney disease should be excluded as outlined above. Anemia, metabolic acidosis, hyperphosphatemia, hypocalcemia, and hyperkalemia can occur with both acute and chronic kidney disease. The urinalysis shows isosthenuria if tubular concentrating and diluting ability are impaired. The urinary sediment can show broad waxy casts as a result of dilated, hypertrophic nephrons.

C. Imaging

The finding of small echogenic kidneys bilaterally (< 10 cm) by ultrasonography supports a diagnosis of chronic kidney disease, though normal or even large kidneys can be seen with adult polycystic kidney disease, diabetic nephropathy, HIV-associated nephropathy, multiple myeloma, amyloidosis, and obstructive uropathy. Radiologic evidence of renal osteodystrophy is another helpful finding, since radiographic changes of secondary hyperparathyroidism do not appear unless parathyroid levels have been elevated for at least 1 year. Evidence of subperiosteal reabsorption along the radial sides of the digital bones of the hand confirms hyperparathyroidism.

► Complications

A. Hyperkalemia

Potassium balance generally remains intact in chronic kidney disease until the GFR is less than 10–20 mL/min. However, certain states pose an increased risk of hyperkalemia at higher GFRs. Endogenous causes include any type of cellular destruction such as hemolysis and trauma, hyporeninemic hypoaldosteronism (type IV renal tubular acidosis, seen particularly in diabetes mellitus), and acidemic states (0.6 mEq/L elevation in K^+ for each 0.1 unit

¹ Value of serum creatinine level = 1.0 mg/dL

² Value of serum creatinine level = 2.0 mg/dL

³ Value of serum creatinine level = 5.0 mg/dL

▲ **Figure 22–1.** Decline in kidney function plotted against time to end-stage renal disease (ESRD). The solid line indicates the linear decline in kidney function over time. The dotted line indicates the approximate time to ESRD.

decrease in pH). Exogenous causes include diet (eg, citrus fruits and salt substitutes containing potassium) and drugs that decrease K^+ secretion (amiloride, triamterene, spiro-lactone, NSAIDs, ACE inhibitors) or block cellular uptake (β -blockers).

Treatment of acute hyperkalemia is discussed in Chapter 21 (Table 21–7). Cardiac monitoring is indicated for any ECG changes seen with hyperkalemia, or a serum potassium level greater than 6.0–6.5 mEq/L. The ion exchange resin, sodium polystyrene sulfonate, exchanges sodium for potassium and can administer a significant sodium load to a patient, although it can cause voluminous diarrhea, which may volume deplete the patient. Chronic hyperkalemia is best treated with dietary potassium restriction (2 g/d) and sodium polystyrene sulfonate when necessary. The usual dose is 15–30 g once a day in juice or sorbitol.

B. Acid–Base Disorders

Damaged kidneys are unable to excrete the 1 mEq/kg/d of acid generated by metabolism of dietary proteins. The resultant metabolic acidosis is primarily due to loss of renal mass. This limits production of ammonia (NH_3) and limits buffering of H^+ in the urine. (Other causes include decreased filtration of titratable acids such as sulfates and phosphates, decreased proximal tubular bicarbonate resorption, and decreased renal tubular hydrogen ion secretion.) Although patients with chronic kidney disease are in positive hydrogen ion balance, the arterial blood pH is maintained at 7.33–7.37 and serum bicarbonate concentration rarely falls below

15 mEq/L. The excess hydrogen ions are buffered by the large calcium carbonate and calcium phosphate stores in bone. This contributes to the renal mineral and bone disorders of chronic kidney disease described below.

The serum bicarbonate level should be maintained at greater than 21 mEq/L according to national guidelines. Alkali supplements include sodium bicarbonate, calcium bicarbonate, and sodium citrate. Citrate salts increase the absorption of dietary aluminum and should be avoided in patients exposed to aluminum. Administration should begin with 20–30 mmol/d of oral alkali divided into two doses per day and titrated as needed.

C. Cardiovascular Complications

Long-term complications of chronic kidney disease include a high risk of morbidity and mortality of cardiovascular disease in comparison to the general population. Mortality due to a cardiovascular cause accounts for 45% of all deaths of patients receiving dialysis. Over 80–90% of patients with chronic kidney disease die, primarily of cardiovascular disease, before reaching the need for dialysis. The precise biologic mechanisms for this are unclear but may have to do with the uremic milieu, underlying coexistent comorbidities, and a hesitancy to perform investigative procedures in patients with chronic kidney disease.

1. Hypertension—As kidney disease progresses, hypertension due to salt and water retention usually develops. Hyperreninemic states and exogenous erythropoietin administration can also exacerbate hypertension. Hypertension is the most common complication of ESRD and must be meticulously controlled. Failure to do so can accelerate the progression of cardiovascular and kidney damage.

Control of hypertension can be achieved with salt and water restriction, weight loss if indicated, and pharmacologic therapy. The ability of the kidney to adjust to variations in sodium and water intake becomes limited as kidney disease progresses. An elevated sodium chloride intake leads to congestive heart failure, edema, and hypertension, whereas low salt intake leads to volume contraction and hypotension. A mildly decreased salt diet (4 g/d) can be started, and salt intake should be reduced to 2 g/d if hypertension persists. Initial drug therapy can include ACE inhibitors or angiotensin II receptor blockers as recommended by national guidelines (if serum potassium and GFR permit), calcium channel-blocking agents, diuretics, and β -blocking agents. The adjunctive drugs that are often needed (eg, α -blocking agents, clonidine, hydralazine, minoxidil) reflect the difficulty of achieving and maintaining hypertensive control in these patients. Goal blood pressure for patients with chronic kidney disease is less than 130/80 mm Hg.

2. Pericarditis—With uremia, pericarditis may develop but is uncommon. The cause is believed to be retention of metabolic toxins. Symptoms include chest pain and fever. Pulsus paradoxus can be present. A friction rub may be auscultated, but the lack of a rub does not rule out a significant pericardial effusion. Chest radiography can show an enlarged cardiac silhouette, and an ECG will show

characteristic findings as explained in Chapter 10. Cardiac tamponade can occur; these patients have signs of poor cardiac output, with jugular venous distention and lungs clear to auscultation. Uremic pericarditis is an absolute indication for initiation of hemodialysis.

3. Congestive heart failure—Patients with ESRD tend toward a high cardiac output. They often have extracellular fluid overload, shunting of blood through an arteriovenous fistula for dialysis, and anemia. In addition to hypertension, these abnormalities cause increased myocardial work and oxygen demand. Patients with chronic kidney disease may also have accelerated rates of atherosclerosis. All of these factors contribute to left ventricular hypertrophy and dilation, present in 75% of patients starting dialysis. Elevated parathyroid hormone (PTH) levels may also play a role in the pathogenesis of the cardiomyopathy of chronic kidney disease.

Water and salt intake should be controlled in patients who are oliguric or anuric. Diuretics are of value, although thiazides are ineffective by themselves when the GFR is less than 20–30 mL/min. Loop diuretics are commonly used, potentially in combination with thiazide diuretics, and higher doses are required as renal function declines. Digoxin should be used with caution since it is excreted by the kidney. The proved efficacy of ACE inhibitors in congestive heart failure holds true for patients with chronic kidney disease. Despite the risks of hyperkalemia and worsening renal function, ACE inhibitors can be used for patients with a serum creatinine greater than 3 mg/dL with close supervision. Along with angiotensin II receptor blockers, ACE inhibitors have been shown to slow the progression to ESRD, even for patients with advanced chronic kidney disease. (See Nephrotic Syndrome section below regarding treatment of proteinuria.) Once a patient is receiving dialysis, these risks become less relevant. When an ACE inhibitor or an angiotensin-receptor blocker (ARB) drug is initiated or uptitrated, patients should have serum creatinine and potassium checked within 5–14 days.

D. Hematologic Complications

1. Anemia—The anemia of chronic kidney disease is characteristically normochromic and normocytic. It is due primarily to decreased erythropoietin production, which becomes clinically significant when GFR falls below 20–40 mL/min. Many patients are iron deficient as well. Low-grade hemolysis and blood loss from platelet dysfunction or hemodialysis play an additional role.

Recombinant erythropoietin-stimulating agents (eg, erythropoietin and darbepoetin) are used in patients whose hemoglobins are less than 11 g/dL if no other causes are present. The effective dose can vary; the starting dose of erythropoietin is 50 units/kg (3000–4000 units/dose) once or twice a week. Darbepoetin is started at 0.45 mcg/kg and can be administered every 2–4 weeks. These agents can be given intravenously (eg, in the hemodialysis patient) or subcutaneously (eg, in any predialysis or dialysis patient). According to national guidelines, both medications should be titrated to a hemoglobin of 11–12 g/dL for optimal safety. Subcutaneous administration is preferable to intravenous

administration because it requires a 33% lower dose for the same effect. Hypertension is a complication of erythropoietin therapy in about 20% of patients. It develops more abruptly in the patients with the lowest hemoglobin values at initiation of therapy, and in those with the greatest rate of rise in hemoglobin. The dosage may require adjustment, or antihypertensive drugs may need to be given. Hemoglobin levels should rise no more than 1 g/dL every 3–4 weeks.

Iron stores must be adequate to ensure response. Hemodialysis patients typically require 50–200 mg intravenous iron each month due to expected blood loss at dialysis. Other patients with serum ferritin less than 100 ng/mL or iron saturation less than 20% should also receive iron supplementation. Depending on the clinical situation, iron therapy should be withheld if the serum ferritin is greater than 500–800 ng/mL. Oral therapy with ferrous sulfate, 325 mg once daily to three times daily, is adequate but not always well tolerated, and gut absorption of iron is impaired in uremic patients. Ferrous gluconate and fumarate can be better tolerated orally. Intravenous iron may need to be used whether or not a patient is receiving dialysis.

2. Coagulopathy—The coagulopathy of chronic kidney disease is mainly caused by platelet dysfunction. Platelet counts are only mildly decreased, but the bleeding time is prolonged. Platelets show abnormal adhesiveness and aggregation. Clinically, patients can have petechiae, purpura, and an increased tendency for bleeding during surgery.

Treatment is required only in patients who are symptomatic. Raising the hematocrit to 30% can reduce bleeding time in patients with very low hemoglobins (< 10 g/dL) due to the rheologic properties of red blood cells in plasma. Desmopressin (25 mcg intravenously every 8–12 hours for two doses) is effective and often used in preparation for surgery. It causes release of factor VIII bound to von Willebrand factor from endothelial cells. Conjugated estrogens, 0.6 mg/kg diluted in 50 mL of 0.9% sodium chloride infused over 30–40 minutes daily, or 2.5–5 mg orally for 5–7 days, have an effect for several weeks. Dialysis improves the bleeding time but does not normalize it. Cryoprecipitate (10–15 bags) is rarely used and lasts less than 24 hours.

E. Neurologic Complications

Uremic encephalopathy does not occur until GFR falls below 5–15 mL/min. Encephalopathy may be due to the aggregation of uremic toxins. Rarely, hypercalcemia, can be the culprit. Symptoms begin with difficulty in concentrating and can progress to lethargy, confusion, and coma. Physical findings include nystagmus, weakness, asterixis, and hyperreflexia. These symptoms and signs may improve after initiation of dialysis.

Neuropathy is found in 65% of patients who receive dialysis or who will need it soon. Rarely is neuropathy present if the GFR is greater than 10% of normal. Peripheral neuropathies manifest themselves as sensorimotor polyneuropathies (stocking and glove distribution) and isolated or multiple isolated mononeuropathies. Patients can have restless leg syndrome, loss of deep tendon reflexes, and distal pain. The earlier initiation of dialysis

may prevent peripheral neuropathies, and the response to dialysis is variable. Other neuropathies result in impotence and autonomic dysfunction.

F. Disorders of Mineral Metabolism

The disorders of calcium, phosphorus, and bone are referred to as **mineral bone disorders of chronic kidney disease**. The most common disorder detected by bone biopsy is osteitis fibrosa cystica—the bony changes of secondary hyperparathyroidism. This affects ~50% of patients nearing ESRD. As GFR decreases below 25% of normal, phosphorus excretion is impaired. Hyperphosphatemia leads to hypocalcemia, stimulating secretion of PTH, which has a phosphaturic effect and normalizes serum phosphorus. This continuous process leads to markedly elevated PTH levels and high bone turnover with osteoclastic bone resorption and subperiosteal lesions. Metastatic calcifications, such as tumoral calcinosis, can occur. Radiographically, lesions are most prominent in the phalanges and lateral ends of the clavicles.

Osteomalacia is a form of renal osteodystrophy with low bone turnover (affecting ~10% of patients nearing ESRD). With worsening kidney function, there is decreased renal conversion of 25-hydroxycholecalciferol to the 1,25-dihydroxy form. Gut absorption of calcium is diminished, leading to hypocalcemia and abnormal bone mineralization. Deposition of aluminum in bone can also lead to osteomalacia. Elevated aluminum levels are seen in patients after years of chronic aluminum hydroxide administration for phosphorus binding. This entity is seen with decreasing frequency because aluminum-based binders are used less in the chronic setting and water used for hemodialysis is now cleared of aluminum.

Adynamic bone disease is a disorder of low bone turnover. More than 25% of patients nearing ESRD show evidence of minimal osteoid and decreased or absent bone remodeling. Its frequency is increasing because of increased use of active vitamin D analogs, which suppress PTH production.

All of the above entities can cause bony pain and proximal muscle weakness. Spontaneous bone fractures can occur that are slow to heal. Patients with advanced chronic kidney disease are also at higher risk for bony fractures. When the calcium-phosphorus product (serum calcium [mg/dL] × serum phosphate [mg/dL]) is above 60–70, metastatic calcifications are commonly seen in blood vessels, soft tissues, lungs, and myocardium. Treatment should begin with dietary phosphorus restriction to 1000 mg/d.

Oral phosphorus-binding agents, such as calcium carbonate (650 mg orally) or calcium acetate (667 mg orally), act in the gut and are given in divided doses three or four times daily with the beginning of meals. These should be titrated to a serum calcium of less than 10 mg/dL (preventing hypercalcemia) and serum phosphorus of 2.7–4.6 mg/dL in patients with a GFR of 15–59 mL/min/1.73 m² and serum phosphorus of 3.5–5.5 mg/dL in patients with a GFR of less than 15 mL/min/1.73 m². National guidelines recommend maximal elemental calcium doses of 1500 mg/d (eg, nine tablets of calcium acetate).

Phosphorus-binding agents that do not contain calcium are sevelamer and lanthanum. Sevelamer, 800 mg orally, and lanthanum carbonate, 1000 mg orally, are given at the beginning of meals and are particularly useful in patients with hypercalcemia, although long-term effects are unknown. Aluminum hydroxide is an effective phosphorus binder but can cause osteomalacia and neurologic complications. It can be used in the acute setting for serum phosphorus greater than 7 mg/dL or for short periods (eg, 3 weeks) in chronic kidney disease patients, but long-term use should be avoided. If aluminum levels are high, chelation with deferoxamine can be effective. Vitamin D or vitamin D analogs can be given with secondary hyperparathyroidism in stage 3–5 chronic kidney disease (iPTH more than two to three times normal depending on GFR) if phosphorus levels are less than 5.5 mg/dL and calcium less than 10 mg/dL. However, one meta-analysis showed no clear benefit of vitamin D or its analogs in stage 3 and 4 chronic kidney disease. Vitamin D suppresses PTH and increases serum calcium and phosphorus levels; both need to be monitored closely to prevent hypercalcemia and hyperphosphatemia. If calcitriol is used, the dosage should be 0.25–0.5 mcg orally daily or every other day initially. Cinacalcet, 30–90 mg orally once a day, can be used if elevated serum phosphorus or calcium levels prohibit the use of vitamin D analogs. Cinacalcet is a calcimimetic agent that targets the calcium-sensing receptor on the chief cells of the parathyroid gland.

G. Endocrine Disorders

Circulating insulin levels are higher because of decreased renal insulin clearance. Glucose intolerance can occur in chronic renal failure when GFR is less than 10–20 mL/min. Primarily, this is due to peripheral insulin resistance. Fasting glucose levels are usually normal or only slightly elevated. Therefore, patients can be either hyperglycemic or hypoglycemic depending on the predominant disturbance. Most commonly, diabetic patients require decreased doses of hypoglycemic agents.

Decreased libido and impotence are common in chronic kidney disease. Men have decreased testosterone levels; women are often anovulatory. Despite a high degree of infertility, pregnancy can occur—particularly in women who are well dialyzed and well nourished. Fetal mortality approaches 50%. Therefore, contraception is advisable for women who do not wish to become pregnant. Renal transplantation with a stable functioning allograft affords the best chances for a successful pregnancy.

► Treatment

A. Dietary Management

Every patient with chronic kidney disease should be evaluated by a renal nutritionist. Specific recommendations should be made concerning protein, salt, water, potassium, and phosphorus intake.

1. Protein restriction—Experimental models have shown that protein restriction slows the progression to ESRD; however, this has not been consistently proved in clinical trials. The Modification of Diet in Renal Disease Study was

meant to clarify the issue, but the results were inconclusive. A subsequent meta-analysis of five clinical trials did show a significant benefit but did not control for certain effects such as ACE inhibitor therapy. The benefits of protein restriction in slowing the rate of decline of GFR must be weighed against the risk of cachexia upon the initiation of dialysis. Low serum albumin at the start of dialysis is one of the strongest predictors of mortality in this population. In general, protein intake should not exceed 1 g/kg/d, and if protein restriction proves to be beneficial, the level of restriction may be decreased to 0.6–0.8 g/kg/d.

2. Salt and water restriction—In advanced chronic kidney disease, the kidney is unable to adapt to large changes in sodium intake. Intake greater than 3–4 g/d can lead to edema, hypertension, and congestive heart failure, whereas intake of less than 1 g/d can lead to volume depletion and hypotension. For the nondialysis patient approaching ESRD, 2 g/d of sodium is an initial recommendation. A daily intake of 1–2 L of fluid maintains water balance.

3. Potassium restriction—Restriction is needed once the GFR has fallen below 10–20 mL/min. Patients should receive detailed lists concerning potassium content of foods and should limit their intake to less than 50–60 mEq/d (2 g). Normal intake is about 100 mEq/d.

4. Phosphorus restriction—The phosphorus level should be kept in the ‘normal’ range (below 4.6 mg/dL) predialysis and between 3.5 and 5.5 mg/dL when on dialysis, with a dietary restriction of 800–1000 mg/d. Foods rich in phosphorus such as cola beverages, eggs, dairy products, nuts, and meat should be limited. Below a GFR of 20–30 mL/min, phosphorus binders are usually required. The treatment of hyperphosphatemia is discussed in the section on disorders of mineral metabolism.

5. Magnesium restriction—Magnesium is excreted primarily by the kidneys. Dangerous hypermagnesemia is rare unless the patient ingests medications high in magnesium or receives it parenterally. All magnesium-containing laxatives and antacids are relatively contraindicated in chronic kidney disease.

B. Dialysis

When conservative management of ESRD is inadequate, hemodialysis, peritoneal dialysis, and kidney transplantation are alternatives (see below). According to the Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines, dialysis should be started when a patient has a GFR of 10 mL/min or serum creatinine of 8 mg/dL. A diabetic patient should start when the GFR reaches 15 mL/min or serum creatinine is 6 mg/dL. Other indications for dialysis include (1) uremic symptoms, such as pericarditis, encephalopathy, or coagulopathy; (2) fluid overload unresponsive to diuresis; (3) refractory hyperkalemia; (4) severe metabolic acidosis (pH < 7.20); and (5) neurologic symptoms, such as seizures or neuropathy. Preparation for dialysis requires a team approach. Dietitians, social workers, and psychiatrists should be involved as well as primary care physicians and nephrologists. The patient and family need

early counseling regarding the risks and benefits of therapy. Whether the patient should undergo a 90-day trial period, not start dialysis, or withdraw from dialysis should be discussed openly. Kidney transplantation should be considered prior to initiation of dialysis. This expedites the detailed and time-consuming work-up for transplantation for eligible patients.

1. Hemodialysis—Hemodialysis requires a constant flow of blood along one side of a semipermeable membrane with a cleansing solution, or dialysate, along the other. Diffusion and convection allow the dialysate to remove unwanted substances from the blood while adding back needed components. Vascular access for hemodialysis can be accomplished by an arteriovenous fistula (the preferred method) or prosthetic graft. Indwelling catheters should be considered temporary measures. Native fistulas typically last longer than prosthetic shunts but require a longer time (6–8 weeks or more after surgical construction) for maturation. Infection, thrombosis, and aneurysm formation are complications seen more often in grafts than fistulas. *Staphylococcus* species are the most common infecting agents.

Patients typically require hemodialysis three times a week. Sessions last 3–5 hours depending on patient size, type of dialyzer used, and other factors. More recently, daily dialysis and nocturnal dialysis programs have expanded, improving medical and psychosocial parameters for patients receiving hemodialysis, such as blood pressure control, mineral metabolism, and quality of life. Periodic measurement of dialysis adequacy should determine the duration of treatment. Home hemodialysis is an option but requires a trained helper, large equipment, and hidden costs. Unfamiliarity with home hemodialysis and the financial impact with most current reimbursement schemes can limit the availability of these modalities.

2. Peritoneal dialysis—With peritoneal dialysis, the peritoneal membrane is the “dialyzer.” Fluids and solutes move across the capillary bed that lies between the visceral and parietal layers of the membrane into the dialysate. Dialysate enters the peritoneal cavity through a catheter. The most common kind of peritoneal dialysis is continuous ambulatory peritoneal dialysis (CAPD). Patients exchange the dialysate four to six times a day. Continuous cyclic peritoneal dialysis (CCPD) utilizes a cycler machine to automatically perform exchanges at night. The dialysate remains in the peritoneal cavity between exchanges. As with hemodialysis, actual peritoneal dialysis prescriptions are guided by adequacy measurements.

Peritoneal dialysis permits greater patient autonomy; its continuous nature minimizes the symptomatic swings observed in hemodialysis patients; and poorly dialyzable compounds such as phosphates are better cleared, which permits less dietary restriction. The dialysate removes large amounts of albumin, and nutritional status must be closely watched.

The percentage of dialysis patients using peritoneal dialysis has been decreasing over the past several years but is starting to stabilize. The most common complication of peritoneal dialysis is peritonitis. Rates are improving, at

less than 0.5 episodes per patient-year. The patient can experience nausea and vomiting, abdominal pain, diarrhea or constipation, and fever. The dialysate can be cloudy with diagnostic criteria being greater than 100 white cells/mL of which over 50% are polymorphonuclear neutrophils. *Staphylococcus aureus* is the most common infecting organism, but streptococci and gram-negative species are common.

The total costs of peritoneal dialysis and hemodialysis are approximately the same. Equipment expenses are less for peritoneal dialysis, but the costs of peritonitis are high. Patients treated with both modalities more often prefer peritoneal dialysis to hemodialysis.

Survival rates on dialysis depend on the underlying disease process. Five-year Kaplan-Meier survival rates vary from 21% for patients with diabetes to 47% for patients with glomerulonephritis. Overall 5-year survival is currently estimated at 36%. Patients undergoing dialysis have an average life expectancy of 3–5 years, but survival for as long as 25 years is seen depending on the disease entity. Studies are conflicting regarding the survival advantage associated with either peritoneal dialysis or hemodialysis.

C. Kidney Transplantation

Up to 50% of all patients with ESRD are suitable for transplantation. Age is becoming less of a barrier. Two-thirds of kidney transplants come from deceased donors, with the remainder from living related or unrelated donors. Immunosuppressive drugs include corticosteroids, azathioprine, mycophenolate mofetil, tacrolimus, cyclosporine, and sirolimus. A patient with a deceased-donor renal transplant typically requires stronger immunosuppression than a patient with a living related kidney donor transplant. However, this depends to a great extent on the degree of HLA-type matching. The 1- and 3-year kidney graft survival rates are approximately 95% and 88%, respectively, for living donor transplants and 90% and 78%, respectively, for deceased donor transplants. Factors that determine outcome include antigenic disparity (ABO blood groups and major histocompatibility or HLA) between donor and recipient, the type of immunologic response mounted by the host, and the immunosuppressive regimen used to prevent graft rejection. Nonimmunologic factors that affect the risk of chronic rejection include age and race of recipient; donor age; length of time on dialysis; and coexisting hyperlipidemia, hypertension, or cytomegalovirus infection. Kidneys from living related donors who are HLA-identical and also red cell ABO-matched grafts have better survival at 1 year than unrelated donors ABO mismatch. Antigens are matched for HLA-A, -B, and -DR loci, with -DR compatibility most important for long-term graft survival. Grafts from deceased donors with zero HLA mismatches have a half-life of 11 years. Those with six mismatches have a half-life of 7 years, compared with those from HLA-identical siblings, which have a half-life of 24 years.

The average wait for a deceased-donor transplant is 2–6 years depending on geographic location; this is becoming progressively longer as more people are going onto waiting lists while the deceased donor pool is not expanding. Some

donors are highly sensitized to HLA antigens from previous transfusions or transplants, ie, possess high panel reactive antibody levels. It may be difficult to find a suitable donor, since a positive cross-match by cytotoxicity testing is likely and would be a contraindication to transplant. Donor screening is performed in all cases to assess suitability, rule out hypertension or anatomic anomalies, and avoid transmission of hepatitis viruses, HIV, and other infectious agents.

Maintenance immunosuppressive regimens are characterized by lower doses of immunosuppressive agents than at the time of transplant, with the aim of preventing recurrent rejection and chronic allograft nephropathy, prolonging graft survival, and minimizing potentially serious medication side effects. Aside from medication use, the life of a transplanted patient can return to nearly normal.

► Prognosis

Mortality is higher for patients undergoing dialysis than for age-matched controls. Yearly mortality is 21.2 deaths per 100 patient-years. The expected remaining lifetime for the age group 55–64 is 22 years, whereas that of the ESRD population is 5 years. The most common cause of death is cardiac dysfunction (45%). Other causes include infection (14%), cerebrovascular disease (6%), and malignancy (4%). Diabetes, age, a low serum albumin, lower socioeconomic status, and inadequate dialysis are all significant predictors of mortality.

For those who require dialysis to sustain life but elect not to undergo dialysis, death ensues within days to weeks. In general, uremia develops and patients lose consciousness prior to death. Arrhythmias can occur as a result of electrolyte imbalance. Volume overload and dyspnea can be managed by volume restriction and opioids as described in Chapter 5. Meticulous efforts at palliative care are essential.

► When to Refer

- A patient with stage 3–5 chronic kidney disease should be referred to a nephrologist for management of chronic kidney disease in conjunction with the primary care provider.
- A patient with other forms of chronic kidney disease should have an initial visit with a nephrologist to discuss future comanagement needs.

► When to Admit

- Admission should be considered for patients with decompensation of problems related to chronic kidney disease, such as worsening of acid-base status, electrolyte abnormalities, volume status that cannot be appropriately treated in the outpatient setting.
- Admission is appropriate when a patient needs to start renal replacement therapy, and is not stable for outpatient initiation.

RENAL ARTERY STENOSIS

ESSENTIALS OF DIAGNOSIS

- Produced by atherosclerotic occlusive disease (80–90% of patients) or fibromuscular dysplasia (10–15%).
- Hypertension.
- Acute kidney injury in patients starting therapy with an ACE inhibitor.

► General Considerations

Atherosclerotic ischemic renal disease accounts for nearly all cases of renal artery stenosis. Fibromuscular dysplasia can also cause renal artery stenosis. Approximately 5% of Americans with hypertension suffer from renal artery stenosis. It occurs most commonly in those over 45 years of age with a history of atherosclerotic disease. Other risk factors include chronic kidney disease, diabetes mellitus, tobacco use, and hypertension.

► Clinical Findings

A. Symptoms and Signs

Patients with atherosclerotic ischemic renal disease may have refractory hypertension, new-onset hypertension (in an older patient), pulmonary edema with poorly controlled blood pressure, and acute kidney injury upon starting an ACE inhibitor. In addition to hypertension, physical examination may reveal an audible abdominal bruit on the affected side. Fibromuscular dysplasia primarily affects young women. Unexplained hypertension in a young woman is reason to screen for this disorder.

B. Laboratory Findings

Laboratory values can show elevated BUN and serum creatinine levels in the setting of significant renal ischemia.

C. Imaging

Abdominal ultrasound can reveal asymmetric kidney size when one renal artery is affected out of proportion to the other.

Three prevailing methods used for screening are Doppler ultrasonography, CT angiography, and magnetic resonance angiography (MRA). **Doppler ultrasonography** is highly sensitive and specific (> 90% with an experienced ultrasonographer) and relatively inexpensive. However, this method is extremely operator and patient dependent. Measurements of blood flow must be made at the aorta and along each third of the renal artery in order to assess the disease. This test is a poor choice for patients who are obese, unable to lie supine, or have interfering bowel gas patterns.

CT angiography consists of intravenous digital subtraction angiography with arteriography and is a noninvasive procedure. The procedure uses a spiral (helical) CT scan with intravenous contrast injection. The sensitivities from various studies range from 77% to 98%, with less varying specificities in a range of 90–94%.

MRA is an excellent but expensive way to screen for renal artery stenosis, particularly in those with atherosclerotic disease. Sensitivity is 77–100%, although one study with particular flaws showed a sensitivity of only 62%. Specificity ranges from 71% to 96%. Turbulent blood flow can cause false-positive results. The imaging agent for MRA (gadolinium) has been associated with an entity known as nephrogenic systemic fibrosis, which occurs primarily in patients with $\text{GFR} < 30 \text{ mL/min/1.73 m}^2$, acute kidney injury, and kidney transplant.

Renal angiography is the gold standard for diagnosis. CO_2 subtraction angiography can be used in place of dye when the risk of dye nephropathy exists—eg, in diabetic patients with kidney injury. Lesions are most commonly found in the proximal third or ostial region of the renal artery. The risk of atheroembolic phenomena after angiography is not trivial in this population, ranging from 5% to 10%. Fibromuscular dysplasia has a characteristic “beads-on-a-string” appearance on angiography.

▶ Treatment

Treatment of atherosclerotic ischemic renal disease is controversial. Options include medical management, angioplasty with or without stenting, and surgical bypass. Angioplasty might reduce the number of antihypertensive medications but does not significantly change outcome in comparison to patients medically managed. Stenting produces significantly better angioplastic results. However, blood pressure is equally improved, and serum creatinines are similar at 6 months of observation compared with both angioplasty and stents. Angioplasty is equally as effective as, and safer than, surgical revision. Treatment of **fibromuscular dysplasia** with percutaneous transluminal angioplasty is often curative.

GLOMERULONEPHROPATHIES

Abnormalities of glomerular function can be caused by damage to the major components of the glomerulus: the epithelium (podocytes), basement membrane, capillary endothelium, or mesangium. The damage is often manifested as an inflammatory process. A specific histologic pattern of glomerular injury can be seen on renal biopsy, one of the most helpful techniques available for defining the cause of glomerular disease. Clinically, hematuria, proteinuria, hypertension, and a reduced GFR are typical findings of glomerular diseases presenting as *nephritic* syndromes; heavy proteinuria (> 3.5 g/24 h), hypoalbuminemia, hyperlipidemia, and edema are typical findings of glomerular diseases presenting as *nephrotic* syndromes.

▶ Classification

Glomerular diseases generally can be classified into one of three major syndromes: nephritic syndrome, nephrotic syndrome, and asymptomatic renal disease. Specific glomerular diseases usually exhibit characteristics of one of the above syndromes, though some can have varying components of all three.

Glomerular diseases can also be classified according to whether they cause only renal abnormalities (primary renal disease) or whether the renal abnormalities result from a systemic disease (secondary renal disease).

NEPHRITIC SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Edema.
- ▶ Hypertension.
- ▶ Hematuria (with or without dysmorphic red cells, red blood cell casts).

▶ General Considerations

Acute glomerulonephritis usually signifies an inflammatory process causing renal dysfunction over days to weeks that may or may not resolve. If the inflammatory process is severe, the glomerulonephritis may lead to a greater than 50% loss of nephron function over the course of days to weeks to months. Such a process, called rapidly progressive glomerulonephritis, can cause permanent damage to glomeruli if not identified and treated rapidly. Prolonged inflammatory changes can result in chronic glomerulonephritis with persistent renal abnormalities that progress to ESRD.

▶ Clinical Findings

A. Symptoms and Signs

Edema is first seen in regions of low tissue pressure such as the periorbital and scrotal areas. Hypertension, if present,

is due to volume overload rather than vasoactive substances such as angiotensin II, whose levels are low.

B. Laboratory Findings

1. Serum chemistries—There are no serum chemistries characteristic of nephritic syndrome, but certain special tests are often performed depending on the history and the results of the preliminary evaluation. These include complement levels, antinuclear antibodies (ANA), cryoglobulins, hepatitis serologies, ANCA, anti-GBM antibodies, antistreptolysin O (ASO) titers, and C3 nephritic factor (Figure 22–2).

2. Urinalysis—The urinalysis shows red blood cells. These may be misshapen from traversing a damaged capillary membrane—so-called dysmorphic red blood cells. Red blood cell casts and moderate degrees of proteinuria are also characteristic of the urinary sediment. Placing the patient in a lordotic position for an hour increases sensitivity for finding red cell casts in the next urine specimen.

3. Biopsy—Renal biopsy should be considered if there are no other contraindications to biopsy (eg, bleeding disorders, thrombocytopenia, uncontrolled hypertension). Rapidly progressive glomerulonephritis is likely when over 50% of glomeruli contain crescents. The type of disease can be categorized according to the immunofluorescent pattern and appearance on electron microscopy (Table 22–9).

▶ Treatment

Treatment includes aggressive reduction of hypertension and fluid overload and specific therapeutic maneuvers aimed at the underlying cause. Salt and water restriction, diuretic therapy, and possibly dialysis are needed. The inflammatory glomerular injury may require corticosteroids and cytotoxic agents. (See specific diseases discussed below.)

▶ When to Refer

Any patient in whom a glomerulonephritis is suspected should be referred to a nephrologist immediately.

Vinen CS et al. Acute glomerulonephritis. *Postgrad Med J*. 2003 Apr;79(930):206–13. [PMID: 12743337]

POSTINFECTIOUS GLOMERULONEPHRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Proteinuria.
- ▶ Glomerular hematuria.
- ▶ Symptoms 1–3 weeks after infection.

▶ General Considerations

Postinfectious glomerulonephritis is most often due to infection with nephritogenic group A β -hemolytic streptococci, especially type 12. It can occur sporadically or in

clusters and during epidemics can account for up to 10% of known streptococcal infections. It commonly appears after pharyngitis or impetigo. Onset occurs within 1–3 weeks after infection (average, 7–10 days).

Other causes of postinfectious glomerulonephritis include bacteremic states such as systemic *S aureus* infection. Infective endocarditis and shunt infections cause similar lesions.

Viral, fungal, and parasitic causes, including hepatitis B or C, cytomegalovirus infection, infectious mononucleosis, coccidioidomycosis, malaria, and toxoplasmosis, are perinfectious glomerulonephritides.

▶ Clinical Findings

A. Symptoms and Signs

The patient is oliguric, edematous, and variably hypertensive.

B. Laboratory Findings

Serum complement levels are low; in postinfectious glomerulonephritis due to group A streptococcal infection, ASO titers can be high unless the immune response has been blunted with previous antibiotic treatment. Classically, the urine is described as cola-colored. Urinary red blood cells, red cell casts, and proteinuria under 3.5 g/d are present. On microscopy, this entity appears as a diffuse proliferative glomerulonephritis. Immunofluorescence shows IgG and C3 in a granular pattern in the mesangium and along the capillary basement membrane. Electron microscopy shows large, dense subepithelial deposits or “humps.”

▶ Treatment

Treatment for this entity is supportive. Appropriate antibiotics should be used. Antihypertensives, salt restriction, and diuretics should be used if needed. Corticosteroids have not been shown to improve outcome. Prognosis in children is very favorable, but adults are more prone to crescent formation and chronic kidney disease. A rapidly progressive glomerulonephritis will develop in less than 5% of adults, and a smaller percentage of adults will progress to ESRD.

IGA NEPHROPATHY

ESSENTIALS OF DIAGNOSIS

- ▶ Can present with hematuria or proteinuria.
- ▶ Proteinuria: minimal to nephrotic range.
- ▶ Glomerular hematuria: microscopic is common; macroscopic (gross) after infection.
- ▶ Increased serum IgA in 50% of cases.
- ▶ Positive IgA staining on renal biopsy, if performed.

▶ General Considerations

IgA nephropathy (Berger disease) is a primary renal disease of IgA deposition in the glomerular mesangium. The

▲ **Figure 22-2.** Serologic analysis of patients with glomerulonephritis. MPGN, membranoproliferative glomerulonephritis. Diagnosis and management of glomerulonephritis and vasculitis presenting as acute renal failure. *Med Clin North Am*. 1990;74(4):893-908. © Elsevier.)

Table 22–9. Classification and findings in glomerulonephritis: Nephritic syndromes.

| | Etiology | Histopathology | Pathogenesis |
|---|---|--|--------------------------|
| Acute (postinfectious) glomerulonephritis | Streptococci, other bacteria | Light: Diffuse proliferative glomerulonephritis Immunofluorescence: IgG; C3, granular pattern Electron microscopy: Subepithelial deposits or “humps” | Trapped immune complexes |
| IgA nephropathy (Berger disease and Henoch-Schönlein purpura) | In association with viral upper respiratory tract infections; gastrointestinal infection or flu-like syndrome | Light: Mesangioproliferative glomerulonephritis Immunofluorescence: IgA (with or without IgG, C3) Electron microscopy: Mesangial deposits | Unknown |
| Rapidly progressive glomerulonephritis | Lupus erythematosus, mixed cryoglobulinemia, subacute infective endocarditis, shunt infections | Light: Crescentic glomerulonephritis Immunofluorescence: IgG, IgA; C3, granular pattern Electron microscopy: Deposits in subepithelium, sub-endothelium, or mesangium | Trapped immune complexes |
| | Goodpasture syndrome or idiopathic | Light: Crescentic glomerulonephritis Immunofluorescence: IgG; C3, linear pattern Electron microscopy: Widening of GBM | Anti-GBM antibodies |
| | Pauci-immune (Wegener granulomatosis, Churg-Strauss, polyarteritis, idiopathic) | Light: Crescentic glomerulonephritis Immunofluorescence: No immunoglobulins Electron microscopy: No deposits | Unclear role of ANCA |

GBM, glomerular basement membrane.

inciting cause is unknown, but the same lesion is seen in Henoch-Schönlein purpura. IgA nephropathy is also associated with hepatic cirrhosis, celiac disease, and infections such as HIV and cytomegalovirus.

IgA nephropathy is the most common form of acute glomerulonephritis in the United States and is even more prevalent worldwide, particularly in Asia. It is most commonly seen in children and young adults, with males affected two to three times more commonly than females.

► Clinical Findings

An episode of gross hematuria is the most common presenting complaint. Frequently, this is associated with an upper respiratory infection (50%), gastrointestinal symptoms (10%), or a flu-like illness (15%). The urine becomes red or cola-colored 1–2 days after onset. In contrast to postinfectious glomerulonephritis, this feature has been called “synpharyngitic hematuria” since there is no significant latent period. Other findings include asymptomatic microscopic hematuria as an incidental finding and the nephrotic syndrome (see below). Approximately one-third of patients will experience a clinical remission. Forty to 50 percent of patients will have progressive renal insufficiency. The remainder will show chronic microscopic hematuria and a stable serum creatinine. The most unfavorable prognostic indicator is proteinuria greater than 1 g/d; others include hypertension, persistent microscopic hematuria and proteinuria, glomerulosclerosis, and abnormal kidney function.

The serum IgA level is increased in up to 50% of patients, and for that reason a normal serum IgA does not rule out the disease. Serum complement levels are usually normal, and renal biopsy is the standard for diagnosis. Glomeruli show a focal glomerulonephritis with diffuse

mesangial IgA deposits and proliferation of mesangial cells. IgG and C3 can also be seen in the mesangium of all glomeruli. Skin biopsy often reveals granular deposits of IgA in dermal capillaries of affected patients.

► Treatment

In patients with significant proteinuria (> 1 g/d), ACE inhibitors or ARB drugs should be used to reduce proteinuria and hypertension. The target blood pressure is less than 130/80 mm Hg. In patients with proteinuria of 1.0–3.5 g/d, corticosteroid therapy has proven beneficial. One such regimen showed a 2% doubling of creatinine after 6 years in the treatment group versus a 21% doubling of creatinine in the control group. The regimen consisted of giving methylprednisolone, 1 g/d intravenously, for 3 days during months 1, 3, and 5, plus prednisone in a dosage of 0.5 mg/kg orally every other day for 6 months. This was aimed at patients with creatinine clearances greater than 70 mL/min. Other treatments have included fish oil, with variable results in clinical trials. Studies that have shown a benefit also show that low doses (2–5 g/d orally) are just as efficacious as high doses (9–12 g/d orally). A 1997 meta-analysis showed no benefit from fish oil, but there was a trend toward benefit in patients with more proteinuria. There are very few side effects of long-term fish oil administration aside from fishy breath and eructations. Kidney transplantation is an excellent option for patients with ESRD, but recurrent disease has been documented in 30% of patients 5–10 years posttransplant. Fortunately, recurrent disease rarely leads to failure of the allograft.

HENOCH-SCHÖNLEIN PURPURA

This disease is a leukocytoclastic vasculitis of unknown cause. It is most common in children and has a male predominance. It classically presents with palpable purpura, arthralgias, and abdominal symptoms such as nausea, colic, and melena. Purpuric skin lesions are most often found on the lower extremities. A decrease in GFR is common with a nephritic presentation. The renal lesions are identical to those found in IgA nephropathy. Most patients will recover fully over several weeks.

Further details about Henoch-Schönlein purpura are provided in Chapter 20.

Sanders JT et al. IgA nephropathy and Henoch-Schönlein purpura nephritis. *Curr Opin Pediatr.* 2008 Apr;20(2):163–70. [PMID: 18332712]

PAUCI-IMMUNE GLOMERULONEPHRITIS (ANCA-Associated)

Pauci-immune glomerular lesions are seen with Wegener granulomatosis, Churg-Strauss disease, and microscopic polyangiitis. All are small-vessel vasculitides. Wegener granulomatosis also involves granulomatous inflammation of the respiratory tract with a necrotizing vasculitis of small and medium-sized vessels. Microscopic polyangiitis (polyarteritis) is similar to Wegener granulomatosis without granulomatous inflammation, but both commonly exhibit a necrotizing glomerulonephritis. ANCA-associated glomerulonephritis can also present as a primary renal lesion. The pathogenesis of these entities is unknown, but more than 95% of pauci-immune glomerulonephritis is associated with antineutrophil cytoplasmic antibodies.

► Clinical Findings

A. Symptoms and Signs

Symptoms of a systemic inflammatory disease, including fever, malaise, and weight loss, may be present. In addition to hematuria and proteinuria from glomerular inflammation, some patients exhibit purpura from dermal capillary involvement and mononeuritis multiplex from nerve arteriolar involvement. Ninety percent of patients with Wegener granulomatosis will have upper or lower respiratory tract symptoms with nodular lesions that can cavitate and bleed.

B. Laboratory Findings

Serologically, ANCA subtype analysis can be done. A cytoplasmic pattern (C-ANCA) is specific for antiproteinase-3 antibodies, while a perinuclear pattern (P-ANCA) is specific for antimyeloperoxidase antibodies. Over 90% of patients with Wegener syndrome will have C-ANCA; the remainder can have a P-ANCA pattern. Microscopic angiitis will have either a P-ANCA or C-ANCA pattern about 80% of the time. Pathologically, the small vessels and glomeruli will lack immune deposits (pauci-immune); however, a cell-mediated immune response is often seen. Necrotizing lesions and crescents signify a rapidly progressive glomerulonephritis.

► Treatment

Treatment should be instituted early if aggressive disease is suspected. High doses of corticosteroids (methylprednisolone, 1–2 g/d intravenously for 3 days, followed by prednisone, 1 mg/kg orally for 1 month, with a slow taper over the next 6 months) and cytotoxic agents (cyclophosphamide, 0.5–1.0 g/m² intravenously per month or 1.5–2 mg/kg orally for 3–6 months with potential conversion to less toxic agents such as azathioprine or mycophenolate mofetil for 12–18 months) are recommended for controlling end-organ damage. Intravenous cyclophosphamide is likely associated with fewer side effects and is just as efficacious as oral cyclophosphamide. Without treatment, prognosis is extremely poor, but with the above regimen, complete remission can be achieved in about 75% of patients. One trial randomized 137 patients with ANCA-associated glomerulonephritis to corticosteroids and cytotoxic medications versus a similar regimen with the addition of plasmapheresis. Those receiving plasmapheresis had improved kidney function and mortality versus those not receiving it. Prognosis also depends on the extent of glomerular involvement before treatment is started. ANCA levels can be monitored to help determine the efficacy of treatment.

Harper L et al. ANCA-associated renal vasculitis at the end of the twentieth century—a disease of older patients. *Rheumatology (Oxford).* 2005 Apr;44(4):495–501. [PMID: 15613403]

ANTI-GLOMERULAR BASEMENT MEMBRANE GLOMERULONEPHRITIS & GOODPASTURE SYNDROME

Goodpasture syndrome is defined by the clinical constellation of glomerulonephritis and pulmonary hemorrhage; injury to both is mediated by anti-GBM antibodies. Up to one-third of patients with anti-GBM glomerulonephritis have no evidence of lung injury. Anti-GBM-associated glomerulonephritis accounts for about 10% of patients with rapidly progressive acute glomerulonephritis. The incidence in males is approximately six times that in females, and the disease occurs most commonly in the second and third decades but has a wide range. It has been associated with influenza A infection, hydrocarbon solvent exposure, and HLA-DR2 and -B7 antigens.

► Clinical Findings

A. Symptoms and Signs

The onset of disease is preceded by an upper respiratory tract infection in 20–60% of cases. Patients experience hemoptysis, dyspnea, and possible respiratory failure. Hypertension and edema are seen as components of the nephritic syndrome.

B. Laboratory Findings

Laboratory evaluation can show iron deficiency anemia, and complement levels are normal. Sputum contains hemosiderin-laden macrophages. Chest radiographs can show shifting pulmonary infiltrates due to pulmonary

hemorrhage. The diffusion capacity of carbon monoxide is markedly increased. Diagnosis is confirmed by finding circulating anti-GBM antibodies, which are positive in over 90% of patients. About 15% of patients will have positive serum for ANCA, too, showing the importance of performing a renal biopsy in such patients.

► Treatment

The treatment of choice is a combination of plasma exchange therapy to remove circulating antibodies and administration of immunosuppressive drugs to prevent formation of new antibodies and control the inflammatory response. Corticosteroids are typically given initially in pulse doses of methylprednisolone, 1–2 g/d for 3 days, then prednisone orally 1 mg/kg/d. Cyclophosphamide is administered intravenously at a dose of 0.5–1.0 g/m² per month or orally at a dosage of 2–3 mg/kg/d. Daily plasmapheresis is performed for up to 2 weeks. A poorer prognosis exists in patients with oliguria and a serum creatinine greater than 6–7 mg/dL, or requiring dialysis upon presentation. Anti-GBM antibody levels should decrease as the clinical course improves.

Hudson BG et al. Alport's syndrome, Goodpasture's syndrome, and type IV collagen. *N Engl J Med.* 2003 Jun 19;348(25):2543–56. [PMID: 12815141]

Levy JB et al. Long-term outcome of anti-glomerular basement membrane antibody disease treated with plasma exchange and immunosuppression. *Ann Intern Med.* 2001 Jun 5;134(11):1033–42. [PMID: 11388816]

CRYOGLOBULIN-ASSOCIATED GLOMERULONEPHRITIS

Essential (mixed) cryoglobulinemia is a disorder associated with cold-precipitable immunoglobulins (cryoglobulins). Glomerular disease results from the precipitation of cryoglobulins in glomerular capillaries. The cause is typically an underlying infection, such as hepatitis B; hepatitis C; or other occult viral, bacterial, and fungal infections.

Patients exhibit necrotizing skin lesions in dependent areas, arthralgias, fever, and hepatosplenomegaly. Serum complement levels are depressed. Rheumatoid factor is often elevated when cryoglobulins are present. Rapidly progressive glomerulonephritis is seen on pathologic examination with the presence of crescents.

Treatment consists of aggressively treating the underlying infection. Pulse corticosteroids, plasma exchange, and cytotoxic agents can be used. Interferon- α (IFN- α) has been shown to benefit patients with hepatitis C–related cryoglobulinemia.

NEPHROTIC SYNDROME

ESSENTIALS OF DIAGNOSIS

- Urine protein excretion > 3.5 g/1.73 m² per 24 hours.
- Hypoalbuminemia (albumin < 3 g/dL).
- Peripheral edema.

► General Considerations

In adults, about one-third of patients with nephrotic syndrome have a systemic renal disease such as diabetes mellitus, amyloidosis, or systemic lupus erythematosus. With the current epidemic of type 2 diabetes mellitus, this proportion is slowly increasing. The remainder have idiopathic nephrotic syndrome. The four most common are minimal change disease, focal glomerular sclerosis, membranous nephropathy, and membranoproliferative glomerulonephritis.

► Clinical Findings

A. Symptoms and Signs

Peripheral edema is a hallmark of the nephrotic syndrome, occurring when the serum albumin concentration is less than 3 g/dL. Edema is most likely due to sodium retention (from renal disease) rather than arterial underfilling from low plasma oncotic pressure. Initially this presents in the dependent areas of the body such as the lower extremities; however, such edema can become generalized. Patients can experience dyspnea due to pulmonary edema, pleural effusions, and diaphragmatic compromise with ascites. Complaints of abdominal fullness may also be present in patients with ascites.

Patients may show symptoms and signs of infection more frequently than the general population owing to loss of immunoglobulins and certain complement moieties in the urine.

B. Laboratory Findings

1. Urinalysis—Proteinuria occurs as a result of effacement of epithelial cell foot processes and an alteration of the negative charge in the GBM. The screening test for proteinuria is the urinary dipstick analysis; however, this test indicates albumin only. The addition of sulfosalicylic acid to the urine sediment allows abnormal paraproteins to be detected. Urine dipstick testing can detect as little as 15 mg/dL of protein, but the results must be interpreted along with the urine specific gravity. Trace protein seen on highly concentrated specimens may be insignificant, while trace protein on dilute specimens may indicate true renal disease. A spot urine protein to urine creatinine ratio gives a reasonable approximation of grams of protein excreted per day.

Microscopically, the urinary sediment has relatively few cellular elements or casts. However, if marked hyperlipidemia is present, patients can have oval fat bodies in the urine. These represent lipid deposits in sloughed renal tubular epithelial cells. They appear as “grape clusters” under light microscopy and “Maltese crosses” under polarized light.

2. Blood chemistries—Characteristic blood chemistries include a decreased serum albumin (< 3 g/dL) and total serum protein less than 6 g/dL. Hyperlipidemia occurs in over 50% of those with early nephrotic syndrome. As patients excrete larger amounts of protein per day, the frequency and degree of hyperlipidemia increases. There is increased hepatic production of lipids (cholesterol and apolipoprotein B), owing to a fall in oncotic pressure. There is also decreased clearance of very low-density lipoproteins, causing hypertriglyceridemia. Patients can also have an elevated erythrocyte

Table 22–10. Classification and findings in glomerulonephritis: Nephrotic syndromes.

| | Etiology | Histopathology | Pathogenesis |
|---|--|--|----------------------------------|
| Minimal change disease (nil disease; lipid nephrosis) | Associated with allergy, Hodgkin disease, NSAIDs | Light: Normal (with or without mesangial proliferation) Immunofluorescence: No immunoglobulins Electron microscopy: Fusion foot processes | Unknown |
| Focal and segmental glomerulosclerosis | Associated with heroin abuse, HIV infection, reflux nephropathy, obesity | Light: Focal segmental sclerosis Immunofluorescence: IgM and C3 in sclerotic segments Electron microscopy: Fusion foot processes | Unknown |
| Membranous nephropathy | Associated with non-Hodgkin lymphoma, carcinoma (gastrointestinal, renal, bronchogenic, thyroid), gold therapy, penicillamine, lupus erythematosus | Light: Thickened GBM and spikes Immunofluorescence: Granular IgG and C3 along capillary loops Electron microscopy: Dense deposits in subepithelial area | In situ immune complex formation |
| Membranoproliferative glomerulonephropathy | Type I associated with upper respiratory infection | Light: Increased mesangial cells and matrix with splitting of GBM Immunofluorescence: Granular C3, C1q, C4 with IgG and IgM Electron microscopy: Dense deposits in subendothelium | Unknown |
| | Type II | Light: Same as type I Immunofluorescence: C3 only Electron microscopy: Dense material in GBM | Unknown |

GBM, glomerular basement membrane; NSAIDs, nonsteroidal anti-inflammatory drugs.

sedimentation rate as a result of alterations in some plasma components such as increased levels of fibrinogen.

Other less common tests may be necessary depending on the patient's clinical presentation, including complement levels, serum and urine protein electrophoresis, ANA, and serologic tests for hepatitis. Patients may become deficient in vitamin D, zinc, and copper from loss of binding proteins in the urine; they are prone to infection, in part from urinary losses of immunoglobulins.

3. Renal biopsy—Specific classification and findings are shown in Table 22–10. Specimens are examined by light microscopy, with immunofluorescent stains, and by electron microscopy. Renal biopsy is often performed in adults with new-onset idiopathic nephrotic syndrome if a primary renal disease that may require drug therapy (eg, corticosteroids, cytotoxic agents) is suspected. Significantly elevated creatinine levels may indicate irreversible kidney disease mitigating the usefulness of kidney biopsy. Disease due to amyloidosis or diabetes mellitus often does not need to be biopsied, since nephrotic range proteinuria in these diseases represents irreversible damage, although bone marrow transplant with high-dose chemotherapy can be considered in some patients with amyloidosis. The role of biopsy for other systemic kidney diseases is debated. However, it can be useful for prognosis and treatment. An occasional unexpected diagnosis is made, such as membranous nephropathy due to lupus erythematosus without serologic evidence of that illness.

► Treatment

A. Protein Loss

The daily total dietary protein intake should replace the daily urinary protein losses so as to avoid negative nitrogen

balance. Protein malnutrition often occurs with urinary protein losses greater than 10 g/d. In the past, protein restriction was suggested for patients with kidney disease because experimental animal models had demonstrated a decrease in glomerulosclerosis among those animals fed low-protein diets. The largest human trial to date (the MDRD Study) did not show a significant benefit, but two recent meta-analyses have shown a mild renal benefit. For this reason, the KDOQI recommends protein restriction to 0.6–0.8 g/kg/d in patients with a GFR less than 25 mL/min prior to starting dialysis. However, great care must be taken to avoid malnutrition in these patients.

In both diabetic and nondiabetic patients, therapy that is aimed at reducing proteinuria may also reduce progression of renal disease. ACE inhibitors are effective by lowering efferent arteriolar resistance out of proportion to afferent arteriolar resistance, thereby reducing glomerular capillary pressure, reducing kidney damage, and lowering urinary protein excretion. Other effects include alterations of glomerular mesangial proliferation. ACE inhibitors can be used in patients despite compromised GFR as long as significant hyperkalemia ($K^+ > 5.2$ – 5.5 mEq/L) does not occur and serum creatinine rises less than 30%, stabilizing over 2 months. Large randomized controlled trials (ie, the RENAAL and IDNT studies) have also proved the benefit of angiotensin II-receptor blockers in reducing proteinuria and preventing progression of renal disease in diabetic nephropathy. “Head-to-head” comparisons of an ACE-I and an ARB have shown the ARB to be no better than the ACE-I in preventing progression of renal disease in diabetic persons with proteinuria. The combination of ACE-I and ARB versus ARB alone for slowing the progression of diabetic nephropathy is believed to have additional benefits and is being tested in a multi-center, prospective randomized study.

B. Edema

Dietary salt restriction is essential for managing edema; most patients also require diuretic therapy. Commonly used diuretics include thiazide and loop diuretics. Both are highly protein bound. With hypoalbuminemia and poor kidney function, diuretic delivery to the kidney is reduced, and patients often require large doses. The combination of loop and thiazide diuretics can potentiate the diuretic effect. This may be needed for patients with refractory fluid retention associated with pleural effusions and ascites.

C. Hyperlipidemia

Hypercholesterolemia and hypertriglyceridemia occur as outlined above. Dietary management in patients with nephrotic syndrome is of little value; however, dietary modification and exercise should be advocated. Aggressive pharmacologic treatment should be pursued. This is discussed in Chapter 28.

D. Hypercoagulable State

Patients with serum albumin less than 2 g/dL can become hypercoagulable. Nephrotic patients have urinary losses of antithrombin III, protein C, and protein S and increased platelet activation. Patients are prone to renal vein thrombosis and other venous thromboemboli, particularly with membranous glomerulopathy. Anticoagulation therapy is warranted for at least 3–6 months in patients with evidence of thrombosis. Patients with renal vein thrombosis and recurrent thromboemboli require indefinite anticoagulation.

▶ When to Refer

Any patient noted to have nephritic syndrome should be referred immediately to a nephrologist.

▶ When to Admit

Patients with edema refractory to outpatient therapy or rapidly worsening kidney function that may require inpatient interventions should be admitted.

Glasscock RJ. Prophylactic anticoagulation in nephrotic syndrome: a clinical conundrum. *J Am Soc Nephrol.* 2007 Aug;18(8):2221–5. [PMID: 17599972]

NEPHROTIC DISEASE IN PRIMARY RENAL DISORDERS

MINIMAL CHANGE DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Nephrotic range proteinuria.
- ▶ Kidney biopsy shows no changes on light microscopy.
- ▶ There are characteristic foot-process effacement on electron microscopy.

▶ General Considerations

Minimal change disease is most commonly seen in children but is occasionally present in adults. In patients over 40 years with primary nephrotic syndrome, the incidence of minimal change disease is 20–25%, with equal distribution between men and women. In younger patients, there is a male predominance. Minimal change disease can be idiopathic but also occurs following viral upper respiratory infections, in association with tumors such as Hodgkin disease, with drugs (gold and lithium), and with hypersensitivity reactions (especially to NSAIDs and bee stings).

▶ Clinical Findings

A. Symptoms and Signs

Patients can exhibit the manifestations of nephrotic syndrome. They are more susceptible to infection, especially with gram-positive organisms, have a tendency toward thromboembolic events, develop severe hyperlipidemia, and experience protein malnutrition. Minimal change disease can rarely cause acute kidney injury due to tubular changes and interstitial edema.

B. Histologic Findings

Glomeruli show no changes on light microscopy or immunofluorescence. On electron microscopy, there is a characteristic fusion of epithelial foot processes. A subgroup of patients also shows mesangial cell proliferation. These people have more hematuria and hypertension and respond poorly to corticosteroid treatment.

▶ Treatment

Treatment is with prednisone, 1 mg/kg/d orally. Unlike children, adults often require longer therapy. It can take up to 16 weeks to achieve a response to corticosteroids. Treatment should be continued for several weeks after complete remission of proteinuria. A significant number of patients will relapse and require further corticosteroid treatment. Patients with frequent relapses and corticosteroid resistance may need cyclophosphamide or chlorambucil to induce subsequent remissions. Progression to ESRD is rare. Complications most often arise from prolonged corticosteroid use.

Palmer SC et al. Interventions for minimal change disease in adults with nephrotic syndrome. *Cochrane Database Syst Rev.* 2008 Jan 23;(1):CD001537. [PMID: 18253993]

MEMBRANOUS NEPHROPATHY

ESSENTIALS OF DIAGNOSIS

- ▶ Nephrotic range proteinuria.
- ▶ Associated with coagulopathy, eg, renal vein thrombosis.

- ▶ “Spike and dome” pattern on kidney biopsy represents subepithelial deposits.
- ▶ Immunofluorescence on kidney biopsy shows IgG and C3 deposits along capillary loops.

▶ General Considerations

Membranous nephropathy is the most common cause of primary nephrotic syndrome in adults. It is an immune-mediated disease characterized by immune complex deposition in the subepithelial portion of glomerular capillary walls. The antigens in primary disease are not known. Secondary disease is associated with infections, such as hepatitis B, endocarditis, and syphilis; autoimmune disease, such as systemic lupus erythematosus, mixed connective tissue disease, and thyroiditis; carcinomas; and certain drugs, such as gold, penicillamine, and captopril. Membranous nephropathy occurs most commonly in adults in their fifth and sixth decades and almost always after age 30 years.

▶ Clinical Findings

A. Symptoms and Signs

Patients exhibit the signs of nephrotic syndrome and have a higher incidence of renal vein thrombosis than most nephrotic patients. A higher incidence of occult neoplasms of lung, stomach, and colon is found in people over 50 years of age. The course of disease is variable, with about 50% of patients progressing to ESRD over 3–10 years. Poorer outcome is associated with concomitant tubulointerstitial fibrosis, male gender, elevated serum creatinine, hypertension, and heavy proteinuria (> 10 g/d).

B. Laboratory Findings

By light microscopy, capillary wall thickness is increased without inflammatory changes or cellular proliferation. When stained with silver methenamine, a “spike and dome” pattern may be observed owing to projections of excess GBM between the subepithelial deposits. Immunofluorescence shows IgG and C3 uniformly along capillary loops. Electron microscopy shows a discontinuous pattern of dense deposits along the subepithelial surface of the basement membrane.

▶ Treatment

Treatment is controversial. After underlying causes are excluded, treatment depends on the risk of renal disease progression. One algorithm is based on the degree of proteinuria. In patients with proteinuria less than 3.5 g/d, the risk of progression is low. These individuals should be closely monitored with a low-salt diet, strict blood pressure control, and an ACE inhibitor for reduction of proteinuria. Patients with proteinuria of 3.5–8 g/d but normal renal function are at medium risk. They should follow the above suggestions and can elect immunosuppressive regimens with corticosteroids and chlorambucil or cyclophosphamide for 6 months, although 65% of these patients experience partial or complete remission within 3–4 years. Cyclo-

sporine is a second choice. The highest-risk patients—those with greater than 8 g/d of proteinuria and possible renal dysfunction—might receive corticosteroids with a cytotoxic agent as first-line immunosuppressant therapy, though the choice of cyclosporine is also reasonable. These treatments should be carefully chosen in consultation with a nephrologist. Patients with membranous nephropathy are excellent candidates for transplant.

Deegens JK et al. Membranous nephropathy in the older adult: epidemiology, diagnosis and management. *Drugs Aging*. 2007;24(9):717–32. [PMID: 17727303]

FOCAL SEGMENTAL GLOMERULAR SCLEROSIS

This lesion can present as idiopathic disease or secondary to such conditions as heroin use, morbid obesity, and HIV infection. Clinically, patients show evidence of nephrotic syndrome, but they also have more nephritic features than membranous nephropathy or minimal change disease. Eighty percent of patients have microscopic hematuria at presentation, and many are hypertensive. Decreased kidney function is present in 25–50% at time of diagnosis. Patients with focal segmental glomerular sclerosis and nephrotic syndrome typically progress to ESRD in 6–8 years.

Diagnosis requires renal biopsy. Light microscopy shows the lesions of focal segmental glomerular sclerosis. It is thought that these lesions occur first in the juxtamedullary glomeruli and are then seen in the superficial renal cortex. IgM and C3 are seen in the sclerotic lesions on immunofluorescence. Electron microscopy shows fusion of epithelial foot processes as seen in minimal change disease (Table 22–10).

Treatment is controversial, though supportive care for nephrotic patients is indicated. Longer courses of corticosteroids are now being used because a higher percentage of patients enter remission. High-dose oral prednisone (1–1.5 mg/kg/d) for 2–3 months followed by a slow taper can induce remission in over half of patients. Most patients achieve remission within 5–9 months. Other cytotoxic drug therapy can be considered but is disappointing (< 20% remission in most series).

NEPHROTIC DISEASE FROM SYSTEMIC DISORDERS

AMYLOIDOSIS

Amyloidosis consists of extracellular deposition of the fibrous protein amyloid in one or more sites in the body. The amyloid fibrils are composed of proteins that have formed β -pleated sheets, a definitive characteristic. Primary renal amyloidosis (AL amyloidosis) may occur in the absence of systemic disease or associated with multiple myeloma; indeed, both are plasma cell dyscrasias. Second-

ary amyloidosis (AA amyloidosis) is due to a chronic inflammatory disease, such as rheumatoid arthritis, inflammatory bowel disease, or chronic infection. The acute phase reactant serum amyloid A is synthesized in the liver and deposited in the tissues. Primary amyloidosis usually occurs in older age groups and displays a benign urinary sediment; the amyloid is derived from immunoglobulin light chain. The degree of proteinuria is not associated with the extent of renal lesions. Kidneys can be enlarged as a result of amyloid deposition. Pathologically, glomeruli are filled with amorphous deposits that stain positive with Congo red and show green birefringence.

Treatment options are few. Remissions can occur in secondary amyloidosis if the inciting agent is removed. Primary amyloidosis of the kidney progresses to ESRD in an average of 2–3 years. Five-year overall survival is less than 20%, with death occurring from ESRD and heart disease. The use of alkylating agents and corticosteroids—eg, melphalan and prednisone—can reduce proteinuria and improve renal function in a small percentage of patients. Melphalan and stem cell transplantation are associated with high toxicity (45% mortality) but induce remission in 80% of the remaining patients. Renal transplant is an option in patients with secondary amyloid.

DIABETIC NEPHROPATHY

ESSENTIALS OF DIAGNOSIS

- ▶ Prior evidence of diabetes mellitus over years, at minimum.
- ▶ Albuminuria (microscopic or macroscopic) not due to another kidney disorder.
- ▶ Signs of diabetic nephropathy on renal biopsy, if done.
- ▶ Other end-organ damage common, such as diabetic retinopathy, but not required.

▶ General Considerations

Diabetic nephropathy is the most common cause of ESRD in the United States (about 4000 cases a year). Type 1 diabetes mellitus carries a 30–40% chance of nephropathy after 20 years, whereas type 2 has a 15–20% chance after 20 years. ESRD is much more likely to develop in persons with type 1 diabetes mellitus, in part due to fewer comorbidities and deaths before ESRD ensues. With the current epidemic of type 2 diabetes mellitus, rates of diabetic nephropathy are projected to continue to increase over at least the next 2 decades. Patients at higher risk include males, African Americans, and Native Americans.

The most common lesion in diabetic nephropathy is diffuse glomerulosclerosis, but nodular glomerulosclerosis (Kimmelstiel-Wilson nodules) is pathognomonic. The kidneys in these patients are usually enlarged as a result of cellular hypertrophy and proliferation. At the onset of diabetic nephropathy, glomerular disease will cause an increase in GFR. As the nephropathy progresses, with the development of macroalbuminuria, the GFR returns to normal and continues to decrease.

Patients with diabetes are prone to other renal disease. These include papillary necrosis, chronic interstitial nephritis, and type IV (hyporeninemic hypoaldosteronemic) renal tubular acidosis. Patients are more susceptible to acute kidney injury from contrast material and have a poor prognosis once dialysis is begun.

▶ Clinical Findings

The nephrotic syndrome develops in patients at risk for nephropathy. Diabetic retinopathy is often present in these patients. Initial screening of diabetics should always include urine examination for microalbuminuria. Dipstick examination may not be sensitive enough; a 24-hour urine collection is the accepted standard measure. (An albumin excretion of > 30 mg/d is abnormal.) However, an early morning spot urine albumin or albumin-creatinine ratio is adequate. (More than 30 mg of albumin per gram of creatinine is considered abnormal.) In patients prone to nephropathy, microalbuminuria will develop within 10–15 years after onset of diabetes and progress over the next 3–7 years to overt proteinuria.

▶ Treatment

During the onset of microalbuminuria but before clinical proteinuria, aggressive treatment is necessary. Strict glycemic control and treatment of hypertension have been proven to slow progression of disease. In particular, ACE inhibitors and ARBs lower the rate of progression to clinical proteinuria and slow progression to ESRD (see Treatment section under Nephrotic Syndrome, above). They may reduce intraglomerular pressure as well as treat hypertension. Even in the subset of patients with markedly diminished renal function, these agents seem to provide renal benefit if patients can tolerate the medication from the perspective of hyperkalemia and the acute decrease in GFR.

HIV-ASSOCIATED NEPHROPATHY

HIV-associated nephropathy can present as the nephrotic syndrome in patients with HIV infection. Decline in GFR can progress rapidly. Most patients are African American, possibly because of a genetic predisposition (eg, *MYH9* gene). The more common mode of acquisition of HIV in these patients is through injection drug use. Often, patients have low CD4 counts, and have advanced HIV disease, but HIV-associated nephropathy can also be the initial presentation of disease.

Patients can have a nephrotic picture with normal complement levels. Light microscopy shows focal segmental glomerulosclerosis as described above. Lesions are often of the collapsing variety, and renal biopsy specimens exhibit severe tubulointerstitial damage.

Small, uncontrolled studies have shown that highly active antiretroviral therapy (HAART) for a prolonged course can slow progression of disease. Despite this minimal evidence, HAART has been recommended for use in these patients given the therapy's other beneficial effects and reasonable toxicity profile. Either ACE inhibitors or angiotensin II receptor binders augments therapy. Corticosteroid treatment has been used with variable success at a dosage of 1 mg/kg/d, along with cyclosporine.

DISEASES DEMONSTRATING NEPHRITIC & NEPHROTIC COMPONENTS

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus is a systemic autoimmune disease in which renal involvement is common. In various series, clinical renal involvement ranges from 35% to 90% (see Chapter 20).

Patients present with glomerular syndromes such as nephritic or nephrotic syndromes and asymptomatic kidney disease. Nonglomerular syndromes include tubulointerstitial nephritis and vasculitis. All patients with systemic lupus erythematosus should have routine urinalyses to monitor for the appearance of hematuria or proteinuria. If urinary abnormalities are detected, renal biopsy is often performed. The type of glomerular injury depends on the site of immune complex deposition. The World Health Organization (WHO) classification of renal glomerular lesions follows: type I, normal; type II, mesangial proliferative; type III, focal and segmental proliferative; type IV, diffuse proliferative; and type V, membranous nephropathy. These are further classified as acute or chronic and global or segmental, both of which seem to have prognostic value.

Treatment

Individuals with type I and type II patterns require no treatment. Transformation of these types to a more active lesion is usually accompanied by an increase in lupus serologic activity and evidence of deteriorating renal function (eg, rising serum creatinine, increasing proteinuria). Repeat biopsy to confirm the transformation in these patients is standard. Patients with extensive type III lesions and all type IV lesions should receive aggressive immunosuppressive therapy. Poorest prognostic features in patients with type IV lesions are an elevated serum creatinine, hematocrit less than 26%, and African American race. Indications for treatment of type V disease are unclear; however, if superimposed proliferative lesions exist, aggressive therapy should be instituted. Two different trials have used corticosteroids in conjunction with mycophenolate mofetil.

Corticosteroids are the mainstay of treatment (methylprednisolone 1 g intravenously daily for 3 days followed by prednisone, 1 mg/kg orally daily with subsequent taper for 4–6 weeks) but are associated with many side effects and may not prevent progression of chronic lesions. Higher dose alternating day therapy can be considered in conjunction with a nephrologist or rheumatologist to reduce side effects. Cytotoxic agents, such as cyclophosphamide, are necessary adjuncts because they improve long-term renal survival in patients with aggressive type III and type IV nephritis. However, studies have shown the potential benefit of mycophenolate mofetil as an alternative form of induction therapy. In one randomized noninferiority study, patients using mycophenolate mofetil had similar rates of full remission at 24 weeks in comparison to those using cyclophosphamide. These agents are typically used for 18–24 months (eg, cyclophosphamide intravenously every month for six doses and then every 3 months for six doses or switching to mycophenolate mofetil after induction). Studies suggest that mycophenolate mofetil is less toxic than cyclophosphamide, does not cause ovarian failure, and may be more acceptable to patients, although long-term follow-up needs to be examined. Ongoing trials of other therapies include cyclosporine and azathioprine as longer-term options. The return of serologic measurements to normal can be useful in monitoring treatment. Markers include double-stranded DNA (dsDNA) antibodies, C3, C4, CH50, and serum creatinine. Urinary protein and sediment are also helpful markers. Patients with systemic lupus erythematosus who undergo dialysis have a favorable prospect for long-term survival. Patients with kidney transplants have recurrent renal disease in 8% of cases.

HEPATITIS C VIRUS INFECTION

Renal disease in the setting of hepatitis C viral infection was not well-recognized until 1993. Now it accounts for approximately 8% of patients with ESRD. Three clinicopathologic glomerular syndromes associated with hepatitis C are secondary membranoproliferative glomerulonephritis, cryoglobulinemic glomerulonephritis, and membranous nephropathy. A type I membranoproliferative glomerulonephritis (MPGN) (see Idiopathic Membranoproliferative Glomerulonephritis, below) is the most common lesion in patients requiring kidney biopsy. These patients typically have hematuria and proteinuria, hypertension, and anemia. Occasionally, they exhibit the nephrotic syndrome. Many have elevated serum transaminases and an elevated rheumatoid factor. Of patients studied in one series, 50% had hepatomegaly. Hypocomplementemia is very common, with C4 typically more reduced than C3. Cryoglobulinemic disease is discussed above. Membranous glomerulopathy is the least common of the three and presents with a typical nephrotic picture. Neither cryoglobulins nor rheumatoid factor is present.

▶ Treatment

In patients with MPGN not receiving treatment for liver disease, the question arises whether to initiate therapy for kidney disease. The main indications for therapy are poor renal function, nephrotic syndrome, new or worsening hypertension, fibrosis or tubulointerstitial disease on biopsy, and progressive disease. IFN- α may result in suppression of viremia and improvement in hepatic function. Renal function rarely improves unless viral suppression occurs; however, renal function often worsens when therapy is abated. Ribavirin is relatively contraindicated in kidney disease because of the dose-related hemolysis that occurs with renal dysfunction. Despite this, some case series have shown benefit with combined IFN- α and ribavirin in closely monitored settings.

IDIOPATHIC MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

MPGN in its primary form is an idiopathic syndrome that can present with nephritic or nephrotic features. (The secondary form can be seen in the immune complex, paraprotein deposition, and thrombotic microangiopathic glomerulonephritides discussed above.) Most patients are under 30 years of age. At least two major subgroups are recognized: type I and type II.

Patients with **type I MPGN** have a history of recent upper respiratory tract infection about a third of the time. Patients typically have a nephrotic picture, and complement levels are low. Histologically, the GBM is thickened because of immune complex deposition and abnormal mesangial cell proliferation between the GBM and the endothelial cells. This gives a characteristic “splitting” appearance to the capillary wall. Immunofluorescence shows IgG, IgM, and granular deposits of C3, C1q, and C4 (Table 22–10).

Type II MPGN often presents with a nephritic picture and is less common than type I. Light microscopy is similar to type I. Serologically, type II is associated with C3 nephritic factor, which is a circulating IgG antibody. Electron microscopy shows a characteristic dense deposit of homogeneous material that replaces part of the GBM.

Treatment of this disorder is controversial. After ruling out secondary causes, it consists of corticosteroid therapy (there is no standard dosage for adults) and antiplatelet drugs (aspirin, 500–975 mg/d orally, plus dipyridamole 225 mg/d orally). The rationale for antiplatelet therapy is that platelet consumption is increased in MPGN and may play a role in glomerular injury. Fifty percent of patients used to progress to ESRD in 10 years; these rates may now be slightly lower with the introduction of more aggressive therapy. Less favorable prognostic findings include type II disease, early renal insufficiency, hypertension, and persistent nephrotic syndrome. Both types of MPGN will recur after renal transplantation; however, type II recurs more commonly.

Ahmed MS et al. Rapidly deteriorating renal function with membranoproliferative glomerulonephritis type 1 associated with hepatitis C treated successfully with steroids and antiviral therapy: a case report and review of literature. *Clin Nephrol.* 2008 Apr;69(4):298–301. [PMID: 18397706]

TUBULOINTERSTITIAL DISEASES

Tubulointerstitial disease may be acute or chronic. Acute disease is most commonly associated with toxins and ischemia. Interstitial edema, infiltration with polymorphonuclear neutrophils, and tubular cell necrosis can be seen. (See Acute Kidney Injury, above, and Table 22–11.) Chronic disease is associated with insults from an acute factor or progressive insult without any obvious acute cause. Interstitial fibrosis and tubular atrophy are present, with a mononuclear cell predominance. The chronic disorders are described below.

CHRONIC TUBULOINTERSTITIAL DISEASES

ESSENTIALS OF DIAGNOSIS

- ▶ Kidney size is small and contracted.
- ▶ Decreased urinary concentrating ability.
- ▶ Hyperchloremic metabolic acidosis.
- ▶ Reduced GFR.

▶ General Considerations

There are four main causes of chronic tubulointerstitial disease. These are discussed below. Other causes include multiple myeloma and gout, which are discussed in the section on multisystem disease with variable kidney involvement.

Table 22–11. Causes of acute tubulointerstitial nephritis (abbreviated list).

| Drug reactions |
|---|
| Antibiotics |
| β-Lactam antibiotics: methicillin, penicillin, ampicillin, cephalosporins |
| Ciprofloxacin |
| Erythromycin |
| Sulfonamides |
| Tetracycline |
| Vancomycin |
| Trimethoprim-sulfamethoxazole |
| Ethambutol |
| Rifampin |
| Nonsteroidal anti-inflammatory drugs |
| Diuretics |
| Thiazides |
| Furosemide |
| Miscellaneous |
| Allopurinol |
| Cimetidine |
| Phenytoin |
| Systemic infections |
| Bacteria |
| <i>Streptococcus</i> |
| <i>Corynebacterium diphtheriae</i> |
| <i>Legionella</i> |
| Viruses |
| Epstein-Barr |
| Others |
| <i>Mycoplasma</i> |
| <i>Rickettsia rickettsii</i> |
| <i>Leptospira icterohaemorrhagiae</i> |
| <i>Toxoplasma</i> |
| Idiopathic |
| Tubulointerstitial nephritis-uveitis (TIN-U) |

A. Obstructive Uropathy

The most common cause of chronic tubulointerstitial disease is prolonged obstruction of the urinary tract. In partial obstruction, urinary output alternates between polyuria (due to vasopressin insensitivity) and oliguria (due to decreased GFR). Azotemia and hypertension (due to increased renin-angiotensin production) are usually present. The major causes are prostatic disease in men; ureteral calculus in a single functioning kidney; bilateral ureteral calculi; carcinoma of the cervix, colon, and bladder; and retroperitoneal tumors or fibrosis.

Abdominal, rectal, and genitourinary examinations are helpful. Urinalysis can show hematuria, pyuria, and bacteriuria but is often benign. Abdominal ultrasound may detect mass lesions, hydroureter, and hydronephrosis. CT scanning and MRI provide more detailed information.

B. Vesicoureteral Reflux

Reflux nephropathy is primarily a disorder of childhood and occurs when urine passes retrograde from the bladder to the kidneys during voiding. It is the second most common cause of chronic tubulointerstitial disease. It occurs as a result of an incompetent vesicoureteral sphinc-

ter. Urine can extravasate into the interstitium; an inflammatory response develops, and fibrosis occurs. The inflammatory response is due to either bacteria or normal urinary components.

Patients are adolescents or young adults with hypertension, renal insufficiency, and a history of urinary tract infections as a child. Focal glomerulosclerosis is often seen. This is a cause of substantial proteinuria, unusual in most tubular diseases. Renal ultrasound or IVP can show renal scarring and hydronephrosis. Although most damage occurs before age 5 years, progressive renal deterioration to ESRD continues as a result of the early insults.

C. Analgesics

Analgesic nephropathy is most commonly seen in patients who ingest large quantities of analgesic combinations. The drugs of concern are phenacetin, paracetamol, aspirin, and NSAIDs, with acetaminophen a possible but less certain culprit. Ingestion of 1 g/d for 3 years is the typical amount needed for kidney dysfunction. This disorder occurs most frequently in individuals who are using analgesics for chronic headaches, muscular pains, and arthritis. Most patients grossly underestimate their analgesic use.

Tubulointerstitial inflammation and papillary necrosis are seen on pathologic examination. Papillary tip and inner medullary concentrations of some analgesics are tenfold higher than in the renal cortex. Phenacetin—once a common cause of this disorder and now rarely available—is metabolized in the papillae by the prostaglandin hydroperoxidase pathway to reactive intermediates that bind covalently to interstitial cell macromolecules, causing necrosis. Aspirin and other NSAIDs may worsen the damage by decreasing medullary blood flow (via inhibition of prostaglandin synthesis) and decreasing glutathione levels (which are necessary for detoxification).

Patients can exhibit hematuria, mild proteinuria, polyuria (from tubular damage), anemia (from gastrointestinal bleeding), and sterile pyuria. As a result of papillary necrosis, sloughed papillae can be found in the urine. An IVP may be helpful for detecting these—contrast will fill the area of the sloughed papillae, leaving a “ring shadow” sign at the papillary tip. However, IVP is rarely used in patients with significant kidney dysfunction, given the need for dye and associated acute kidney injury.

D. Heavy Metals

Environmental exposure to heavy metals—such as lead and cadmium—is seen infrequently now in the United States. Chronic lead exposure can lead to tubulointerstitial disease. Individuals at risk are those with occupational exposure (eg, welders who work with lead-based paint) and drinkers of alcohol distilled in automobile radiators (moonshine users). Lead is filtered by the glomerulus and is transported across the proximal convoluted tubules, where it accumulates and causes cell damage. Fibrosed arterioles and cortical scarring also lead to damaged kidneys. Proximal tubular damage leads to decreased secretion of uric acid, resulting in hyperuricemia and saturnine gout. Patients commonly are hypertensive. Diagnosis is

most reliably performed with a calcium disodium edetate (EDTA) chelation test. Urinary excretion of more than 600 mg of lead in 24 hours following 1 g of EDTA indicates excessive lead exposure.

Occupational exposure to cadmium also causes proximal tubular dysfunction. Hypercalciuria and nephrolithiasis can be seen. Other heavy metals that can cause tubulointerstitial disease include mercury and bismuth.

► Clinical Findings

A. Symptoms and Signs

Polyuria is common because tubular damage leads to inability to concentrate the urine. Dehydration can also occur as a result of a salt-wasting defect in some individuals.

B. Laboratory Findings

Patients are hyperkalemic because the distal tubules become aldosterone resistant. A hyperchloremic renal tubular acidosis is characteristic. The cause of the renal tubular acidosis is threefold: (1) reduced ammonia production, (2) inability to acidify the distal tubules, and (3) proximal tubular bicarbonate wasting. The urinalysis is nonspecific, as opposed to that seen in acute interstitial nephritis. Proteinuria is typically less than 2 g/d (owing to inability of the proximal tubule to reabsorb freely filterable proteins); a few cells may be seen; and broad waxy casts are often present.

► Treatment

Treatment depends first upon identifying the disorder responsible for renal dysfunction. The degree of interstitial fibrosis that has developed can help predict recovery of renal function. Once there is evidence for loss of parenchyma (small shrunken kidneys or interstitial fibrosis on biopsy), little can prevent the progression toward ESRD. Treatment is then directed at medical management. Tubular dysfunction may require potassium and phosphorus restriction and sodium, calcium, or bicarbonate supplements.

If hydronephrosis is present, relief of obstruction should be accomplished promptly. Prolonged obstruction leads to further tubular damage—particularly in the distal nephron—which may be irreversible despite relief of obstruction. Neither surgical correction of reflux nor medical therapy with antibiotics can prevent deterioration toward ESRD once renal scarring has occurred.

Patients in whom lead nephropathy is suspected should continue chelation therapy with EDTA if there is no evidence of irreversible renal damage (eg, renal scarring or small kidneys). Continued exposure should be avoided.

Treatment of analgesic nephropathy requires withdrawal of all analgesics. Stabilization or improvement of renal function may occur if significant interstitial fibrosis is not present. Hydration during exposure to analgesics may also have some beneficial effects.

► When to Refer

- Patients with stage 3–5 chronic kidney disease should be referred to a nephrologist when tubulointerstitial diseases are suspected. Other select cases of stage 1–2 chronic kidney disease should also be referred.
- Patients with urologic abnormalities should be referred to a urologist.

Huerta C et al. Nonsteroidal anti-inflammatory drugs and risk of ARF in the general population. *Am J Kidney Dis.* 2005 Mar;45(3):531–9. [PMID: 15754275]

CYSTIC DISEASES OF THE KIDNEY

Renal cysts are epithelium-lined cavities filled with fluid or semisolid material. They develop primarily from renal tubular elements. One or more simple cysts are found in 50% of individuals over the age of 50 years. They are rarely symptomatic and have little clinical significance. In contrast, generalized cystic diseases are associated with cysts scattered throughout the cortex and medulla of both kidneys and can progress to ESRD (Table 22–12).

SIMPLE OR SOLITARY CYSTS

Simple cysts account for 65–70% of all renal masses. They are generally found at the outer cortex and contain fluid that is consistent with an ultrafiltrate of plasma. Most are found incidentally on ultrasonographic examination. Simple cysts are typically asymptomatic but can become infected.

The main concern with simple cysts is to differentiate them from malignancy, abscess, or polycystic kidney disease. Renal cystic disease can develop in dialysis patients. These cysts have a potential for progression to malignancy. Ultrasound and CT scanning are the recommended procedures for evaluating these masses. Simple cysts must meet three sonographic criteria to be considered benign: (1) echo free, (2) sharply demarcated mass with smooth walls, and (3) an enhanced back wall (indicating good transmission through the cyst). Complex cysts can have thick walls, calcifications, solid components, and mixed echogenicity. On CT scan, the simple cyst should have a smooth thin wall that is sharply demarcated. It should not enhance with contrast media. A renal cell carcinoma will enhance but typically is of lower density than the rest of the parenchyma. Arteriography can also be used to evaluate a mass preoperatively. A renal cell carcinoma is hypervascular in 80%, hypovascular in 15%, and avascular in 5% of cases.

If a cyst meets the criteria for being benign, periodic reevaluation is the standard of care. If the lesion is not consistent with a simple cyst, surgical exploration is recommended.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Multiple cysts in bilateral kidneys; total number depends on age.
- ▶ Large, palpable kidneys on examination.
- ▶ Combination of hypertension and abdominal mass suggestive of disease.
- ▶ Family history is compelling but not necessary.
- ▶ Chromosomal abnormalities present in some patients.

▶ General Considerations

This disorder is among the most common hereditary diseases in the United States, affecting 500,000 individuals, or 1 in 800 live births. Fifty percent of patients will have ESRD by age 60 years. The disease has variable penetrance but accounts for 10% of dialysis patients in the United States. At least two genes account for this disorder: *ADPKD1* on the short arm of chromosome 16 (85–90% of patients) and *ADPKD2* on chromosome 4 (10–15%). Patients with the *PKD2* mutation have slower progression of disease and longer life expectancy than those with *PKD1*. Other sporadic cases without these mutations have also been recognized.

▶ Clinical Findings

Abdominal or flank pain and microscopic or gross hematuria are present in most patients. A history of urinary tract infections and nephrolithiasis is common. A family history is positive in 75% of cases, and more than 50% of patients have hypertension (see below) that may antedate the clinical manifestations of the disease. Patients have large kid-

neys that may be palpable on abdominal examination. The combination of hypertension and an abdominal mass should suggest the disease. Forty to 50 percent have concurrent hepatic cysts. Pancreatic and splenic cysts occur also. Hemoglobin and hematocrit tend to be maintained as a result of erythropoietin production by the cysts. The urinalysis may show hematuria and mild proteinuria. In patients with *PKD1*, ultrasonography confirms the diagnosis—two or more cysts in patients under age 30 years (sensitivity of 88.5%), two or more cysts in each kidney in patients age 30–59 years (sensitivity of 100%), and four or more cysts in each kidney in patients age 60 years or older are diagnostic for autosomal dominant polycystic kidney disease. If sonographic results are unclear, CT scan is recommended and highly sensitive.

▶ Complications & Treatment

A. Pain

Abdominal or flank pain is caused by infection, bleeding into cysts, and nephrolithiasis. Bed rest and analgesics are recommended. Cyst decompression can help with chronic pain.

B. Hematuria

Gross hematuria is most commonly due to rupture of a cyst into the renal pelvis, but it can also be caused by a kidney stone or urinary tract infection. Hematuria typically resolves within 7 days with bed rest and hydration. Recurrent bleeding should suggest the possibility of underlying renal cell carcinoma, particularly in men over age 50 years.

C. Renal Infection

An infected renal cyst should be suspected in patients who have flank pain, fever, and leukocytosis. Blood cultures may be positive, and urinalysis may be normal because the cyst does not communicate directly with the urinary tract. CT scans can be helpful because an infected cyst may have an increased wall thickness. Bacterial cyst infections are difficult

to treat. Antibiotics with cystic penetration should be used, eg, fluoroquinolones, trimethoprim-sulfamethoxazole, and chloramphenicol. Treatment may require 2 weeks of parenteral therapy followed by long-term oral therapy.

D. Nephrolithiasis

Up to 20% of patients have kidney stones, primarily calcium oxalate. Hydration (2–3 L/d) is recommended.

E. Hypertension

Fifty percent of patients have hypertension at time of presentation, and it will develop in most patients during the course of the disease. Cyst-induced ischemia appears to cause activation of the renin–angiotensin system, and cyst decompression can lower blood pressure temporarily. Hypertension should be treated aggressively, as this may prolong the time to ESRD. (Diuretics should be used cautiously since the effect on renal cyst formation is unknown.)

F. Cerebral Aneurysms

About 10–15% of these patients have arterial aneurysms in the circle of Willis. Screening arteriography is not recommended unless the patient has a family history of aneurysms or is undergoing elective surgery with a high risk of developing hypertension.

G. Other Complications

Vascular problems include mitral valve prolapse in up to 25% of patients, aortic aneurysms, and aortic valve abnormalities. Colonic diverticula are more common in patients with polycystic kidneys.

► Prognosis

Significant research is ongoing regarding therapy. Vasopressin receptor antagonists have been successful in animal models but are not yet well-tested in humans. These agents lower renal epithelial cell intracellular cyclic AMP (cAMP) levels, and in vitro evidence suggests that intracellular cAMP plays a significant role in cystogenesis in polycystic kidney disease. Avoidance of caffeine may prevent cyst formation due to effects on G-coupled proteins. Treatment of hypertension and a low-protein diet may slow the progression of disease, although this is not well proven.

Pei Y. Diagnostic approach in autosomal dominant polycystic kidney disease. *Clin J Am Soc Nephrol.* 2006 Sep;1(5):1108–14. [PMID: 17699332]

Torres VE et al. Autosomal dominant polycystic kidney disease. *Lancet.* 2007 Apr 14;369(9569):1287–301. [PMID: 17434405]

MEDULLARY SPONGE KIDNEY

This disease is a relatively common and benign disorder that is present at birth and not usually diagnosed until the fourth or fifth decade. It is caused by autosomal dominant muta-

tions in the *MCKD1* or *MCKD2* genes on chromosomes 1 and 16, respectively. Kidneys have a marked irregular enlargement of the medullary and interpapillary collecting ducts. This is associated with medullary cysts that are diffuse, giving a “Swiss cheese” appearance in these regions.

► Clinical Findings

Medullary sponge kidney presents with gross or microscopic hematuria, recurrent urinary tract infections, or nephrolithiasis. Common abnormalities are a decreased urinary concentrating ability and nephrocalcinosis; less common is incomplete type I distal renal tubular acidosis. The diagnosis is confirmed with IVP, which shows striations in the papillary portions of the kidney produced by the accumulation of contrast in dilated collecting ducts.

► Treatment

There is no known therapy. Adequate fluid intake (2 L/d) helps prevent stone formation. If hypercalciuria is present, thiazide diuretics are recommended because they decrease calcium excretion. Alkali therapy is recommended if renal tubular acidosis is present.

► Prognosis

Renal function is well maintained unless there are complications from recurrent urinary tract infections and nephrolithiasis.

MULTISYSTEM DISEASES WITH VARIABLE KIDNEY INVOLVEMENT*

MULTIPLE MYELOMA

Multiple myeloma is a malignancy of plasma cells (see Chapter 13). Renal involvement occurs in about 25% of all patients. “Myeloma kidney” is the presence of light chain immunoglobulins (Bence Jones protein) in the urine causing renal toxicity. Bence Jones protein causes direct renal tubular toxicity and results in tubular obstruction by precipitating in the tubules. The earliest tubular damage results in Fanconi syndrome (a type II proximal renal tubular acidosis). The proteinuria seen with multiple myeloma is primarily due to light chains that are not detected on urine dipstick, which mainly detects albumin. Glomerular amyloidosis can develop in patients with multiple myeloma; in these patients, dipstick protein determinations are positive. Hypercalcemia and hyperuricemia are frequently seen. Other conditions resulting in renal dysfunction include plasma cell infiltration of the renal parenchyma and a hyperviscosity syndrome compromising renal blood flow. Therapy for acute kidney injury attributed to multiple myeloma includes correction of hypercalcemia,

*Other diseases with variable involvement described elsewhere in this chapter include systemic lupus erythematosus, diabetes mellitus, and the vasculitides such as Wegener granulomatosis and Goodpasture disease.

volume repletion, and chemotherapy for the underlying malignancy. Previously, plasmapheresis had been considered appropriate to decrease the burden of existing monoclonal proteins while awaiting chemotherapeutic regimens to take effect. However, in the largest randomized prospective trial to date, plasmapheresis did not provide any renal benefit to these patients.

Clark WF et al; Canadian Apheresis Group. Plasma exchange when myeloma presents as acute renal failure: a randomized, controlled trial. *Ann Intern Med.* 2005 Dec 6;143(11):777–84. [PMID: 16330788]

Korbet SM et al. Multiple myeloma. *J Am Soc Nephrol.* 2006 Sep;17(9):2533–45. [PMID: 16885408]

SICKLE CELL DISEASE

Renal dysfunction associated with sickle cell disease is most commonly due to sickling of red blood cells in the renal medulla because of low oxygen tension and hypertonicity. Congestion and stasis lead to hemorrhage, interstitial inflammation, and papillary infarcts. Clinically, hematuria is common. Damage to renal capillaries also leads to diminished concentrating ability. Isosthenuria (urine osmolality equal to that of serum) is routine, and patients can easily become dehydrated. Papillary necrosis occurs as well. These abnormalities are commonly encountered in sickle cell trait. Sickle cell glomerulopathy is less common but will inexorably progress to ESRD. Its primary clinical manifestation is proteinuria. Optimal treatment requires adequate hydration and control of the sickle cell disease.

Davenport A et al. Sickle cell kidney. *J Nephrol.* 2008 Mar–Apr;21(2):253–5. [PMID: 18446721]

TUBERCULOSIS

The classic renal manifestation of tuberculosis is the presence of microscopic pyuria with a sterile urine culture—or “sterile pyuria.” More often, other bacteria are present in addition. Microscopic hematuria is often present with pyuria. Urine cultures are the gold standard for diagnosis. Three to six first morning midstream specimens should be performed to improve sensitivity. Papillary necrosis and cavitation of the renal parenchyma occur less frequently, as do ureteral strictures and calcifications. Adequate drug therapy can result in resolution of renal involvement.

Figueiredo AA et al. Epidemiology of urogenital tuberculosis worldwide. *Int J Urol.* 2008 Sep;15(9):827–32. [PMID: 18637157]

GOUT & THE KIDNEY

The kidney is the primary organ for excretion of uric acid. Patients with proximal tubular dysfunction have decreased excretion of uric acid and are more prone to gouty attacks. Depending on the pH and uric acid concentration, deposition can occur in the tubules, the interstitium, or the urinary tract. The more alkaline pH of the interstitium causes urate salt deposition, whereas the acidic environ-

ment of the tubules and urinary tract causes uric acid crystal deposition at high concentrations.

Three disorders are commonly seen: (1) uric acid nephrolithiasis, (2) acute uric acid nephropathy, and (3) chronic urate nephropathy. Kidney dysfunction with uric acid nephrolithiasis stems from obstructive nephropathy. Acute uric acid nephropathy presents similarly to acute tubulointerstitial nephritis with direct toxicity from uric acid crystals. Chronic urate nephropathy is caused by deposition of urate crystals in the alkaline medium of the interstitium; this can lead to fibrosis and atrophy. Epidemiologically, hyperuricemia and gout have been associated with worsening cardiovascular outcomes.

Treatment between gouty attacks involves avoidance of food and drugs causing hyperuricemia, aggressive hydration, and pharmacotherapy aimed at reducing serum uric acid levels. These disorders are seen in both “overproducers” and “underexcretors” of uric acid. The latter situation may seem counterintuitive; however, these patients have hyperacidic urine, which explains the deposition of relatively insoluble uric acid crystals.

Edwards NL. The role of hyperuricemia and gout in kidney and cardiovascular disease. *Cleve Clin J Med.* 2008 Jul;75 (Suppl 5):S13–6. [PMID: 18822470]

NEPHROGENIC SYSTEMIC FIBROSIS

Nephrogenic systemic fibrosis (NSF) is a multi-system disorder seen only in patients with kidney disease. NSF affects several organ systems, including skin, muscles, lungs, and cardiovascular system. The most common manifestation is a debilitating fibrosing skin disorder that can range from skin-colored to erythematous papules, which coalesce to brawny patches. The skin can be thick and woody in areas and is painful out-of-proportion to findings on examination. Histopathologically, there is an increase in dermal spindle cells positive for CD34 and procollagen I. Collagen bundles with mucin and elastic fibers are also noted. This has been reported in cases of chronic kidney disease, primarily with GFR < 30 mL/min/1.73 m², acute kidney injury, and after kidney transplantation. It was first recognized in hemodialysis patients in 1997 and has been strongly linked to use of contrast agents containing gadolinium. Incidence is projected to be 1–4% in the highest risk (ESRD) population that has received gadolinium, and lower in patients with less severe kidney dysfunction. The FDA has issued a warning regarding avoidance of exposure to this agent for patients with GFR < 30 mL/min/1.73 m², acute kidney injury, and posttransplant, with the caveat that hemodialysis may be beneficial. Despite the latter recommendation, no studies have proven that removal of gadolinium with hemodialysis prevents this disorder. Several case reports and series have described benefit for patients after treatment with corticosteroids, photopheresis, plasmapheresis, and sodium thiosulfate. The true effectiveness of these interventions is still unclear. Alternative imaging agents need to be used for patients requiring MR with contrast at risk for NSF.

Thomas Walsh, MD

HEMATURIA

ESSENTIALS OF DIAGNOSIS

- ▶ Both grossly visible and microscopic hematuria require evaluation.
- ▶ The upper urinary tract should be imaged, and cystoscopy should be performed if there is hematuria in the absence of infection.

▶ General Considerations

In patients with gross or microscopic hematuria, an **upper tract source** (kidneys and ureters) can be identified in 10% of cases. For upper tract sources, stone disease accounts for 40%, medical kidney disease (medullary sponge kidney, glomerulonephritis, papillary necrosis) for 20%, renal cell carcinoma for 10%, and urothelial cell carcinoma of the ureter or renal pelvis for 5%. Drug ingestion and associated medical problems may provide diagnostic clues. Analgesic use (papillary necrosis), cyclophosphamide (chemical cystitis), antibiotics (interstitial nephritis), diabetes mellitus, sickle cell trait or disease (papillary necrosis), a history of stone disease, or malignancy should all be investigated. In the absence of infection, gross hematuria from a **lower tract source** is most commonly from urothelial cell carcinoma of the bladder. Microscopic hematuria in the male is most commonly from benign prostatic hyperplasia. The presence of hematuria in patients receiving anticoagulation therapy cannot be ascribed to the anticoagulation; a complete evaluation is warranted consisting of upper tract imaging, cystoscopy, and urine cytology. **See Chapter 39 for Bladder Cancer, Cancers of the Ureter and Renal Pelvis, Renal Cell Carcinoma, and Kidney and Testis Tumors.**

▶ Clinical Findings

A. Symptoms and Signs

If gross hematuria occurs, a description of the timing (initial, terminal, total) may provide a clue to the localiza-

tion of disease. Associated symptoms (ie, renal colic, irritative voiding symptoms, constitutional symptoms) should be investigated. Physical examination should emphasize signs of systemic disease (fever, rash, lymphadenopathy, abdominal or pelvic masses) as well as signs of medical kidney disease (hypertension, volume overload). Urologic evaluation may demonstrate an enlarged prostate, flank mass, or urethral disease.

B. Laboratory Findings

Initial laboratory investigations include a urinalysis and urine culture. Proteinuria and casts suggest renal origin. Irritative voiding symptoms, bacteriuria, and a positive urine culture in the female suggest urinary tract infection, but follow-up urinalysis is important after treatment to ensure resolution of the hematuria.

Further evaluation includes urinary cytology to assist in the diagnosis of bladder neoplasm.

C. Imaging

Upper tract imaging (usually abdominal and pelvic CT scanning without and with contrast) may identify neoplasms of the kidney or ureter as well as identifying benign conditions such as urolithiasis, obstructive uropathy, papillary necrosis, medullary sponge kidney, or polycystic kidney disease. CT urography and MRI have replaced intravenous urography (IVU) when imaging the upper tracts for sources of hematuria. The role of ultrasonographic evaluation of the urinary tract for hematuria is unclear. Although it may provide adequate information for the kidney, its sensitivity in detecting ureteral disease is lower. In addition, its higher degree of operator dependence may further confound the issue.

D. Cystoscopy

Cystoscopy can be used to assess for bladder or urethral neoplasm, benign prostatic enlargement, and radiation or chemical cystitis. For gross hematuria, cystoscopy is ideally performed while the patient is actively bleeding to allow better localization (ie, lateralize to one side of the upper tracts, bladder, or urethra).

▶ Follow-up

In patients with negative evaluations, repeat evaluations may be warranted to avoid a missed malignancy; however, the ideal frequency of such evaluations is not defined. Urinary cytology can be repeated in 3–6 months, and cystoscopy and upper tract imaging after a year.

▶ When to Refer

In the absence of infection, hematuria (either gross or microscopic) requires evaluation.

GENITOURINARY TRACT INFECTIONS

1. Acute Cystitis

ESSENTIALS OF DIAGNOSIS

- ▶ Irritative voiding symptoms.
- ▶ Patient usually afebrile.
- ▶ Positive urine culture; blood cultures may also be positive.

▶ General Considerations

Acute cystitis is an infection of the bladder most commonly due to the coliform bacteria (especially *Escherichia coli*) and occasionally gram-positive bacteria (enterococci). The route of infection is typically ascending from the urethra. Viral cystitis due to adenovirus is sometimes seen in children but is rare in adults. Cystitis in men is rare and implies a pathologic process such as infected stones, prostatitis, or chronic urinary retention requiring further investigation.

▶ Clinical Findings

A. Symptoms and Signs

Irritative voiding symptoms (frequency, urgency, dysuria) and suprapubic discomfort are common. Women may experience gross hematuria, and symptoms may often appear following sexual intercourse. Physical examination may elicit suprapubic tenderness, but examination is often unremarkable. Systemic toxicity is absent.

B. Laboratory Findings

Urinalysis shows pyuria and bacteriuria and varying degrees of hematuria. The degree of pyuria and bacteriuria does not necessarily correlate with the severity of symptoms. Urine culture is positive for the offending organism, but colony counts exceeding 10^5 /mL are not essential for the diagnosis.

C. Imaging

Because uncomplicated cystitis is rare in men, elucidation of the underlying problem with appropriate investigations, such as abdominal ultrasonography or cystoscopy (or both), is warranted. Follow-up imaging using CT scanning is warranted if pyelonephritis, recurrent infections, or anatomic abnormalities are suspected.

▶ Differential Diagnosis

In women, infectious processes such as vulvovaginitis and pelvic inflammatory disease can usually be distinguished by pelvic examination and urinalysis. In men, urethritis and prostatitis may be distinguished by physical examination (urethral discharge or prostatic tenderness).

Noninfectious causes of cystitis-like symptoms include pelvic irradiation, chemotherapy (cyclophosphamide), bladder carcinoma, interstitial cystitis, voiding dysfunction disorders, and psychosomatic disorders.

▶ Prevention

Women who have more than three episodes of cystitis per year are considered candidates for prophylactic antibiotic therapy to prevent recurrence after treatment of urinary tract infection. Prior to institution of therapy, a thorough urologic evaluation is warranted to exclude any anatomic abnormality (eg, stones, reflux, fistula). The three most commonly used oral agents for prophylaxis are trimethoprim-sulfamethoxazole (40 mg/200 mg), nitrofurantoin (100 mg), and cephalexin (250 mg). Single dosing at bedtime or at the time of intercourse is the recommended schedule.

▶ Treatment

Uncomplicated cystitis in women can be treated with short-term antimicrobial therapy, which consists of single-dose therapy or 1–3 days of therapy. Fluoroquinolones and nitrofurantoin are the drugs of choice for uncomplicated cystitis (Table 23–1). Trimethoprim-sulfamethoxazole can be ineffective because of the emergence of resistant organisms. In men, uncomplicated urinary tract infection is rare, and thus, the duration of antibiotic therapy depends on the underlying etiology. Hot sitz baths or urinary analgesics (phenazopyridine, 200 mg orally three times daily) may provide symptomatic relief.

▶ Prognosis

Infections typically respond rapidly to therapy, and failure to respond suggests resistance to the selected drug or anatomic abnormalities requiring further investigation.

Table 23-1. Empiric therapy for urinary tract infections.

| Diagnosis | Antibiotic | Route | Duration | Cost per Duration Noted ¹ |
|-------------------------------|---|----------------------------------|-------------|---|
| Acute pyelonephritis | Ampicillin, 1 g every 6 hours, and gentamicin, 1 mg/kg every 8 hours | Intravenous | 21 days | \$870.00 not including intravenous supplies |
| | Ciprofloxacin, 750 mg every 12 hours | Oral | 21 days | \$237.00 |
| | Ofloxacin, 200-300 mg every 12 hours | Oral | 21 days | \$239.00 (300 mg) |
| | Trimethoprim-sulfamethoxazole, 160/800 mg every 12 hours ² | Oral | 21 days | \$46.00 |
| Chronic pyelonephritis | Same as for acute pyelonephritis, but duration of therapy is 3-6 months | | | |
| Acute cystitis | Cephalexin, 250-500 mg every 6 hours | Oral | 1-3 days | \$16.80/3 days (500 mg) |
| | Ciprofloxacin, 250-500 mg every 12 hours | Oral | 1-3 days | \$32.00/3 days (500 mg) |
| | Nitrofurantoin (macrocrystals), 100 mg every 12 hours | Oral | 7 days | \$25.90 |
| | Norfloxacin, 400 mg every 12 hours | Oral | 1-3 days | \$23.00/3 days |
| | Ofloxacin, 200 mg every 12 hours | Oral | 1-3 days | \$28.70/3 days |
| | Trimethoprim-sulfamethoxazole, 160/800 mg, two tablets ² | Oral | Single dose | \$2.20 |
| | Acute bacterial prostatitis | Same as for acute pyelonephritis | | 21 days |
| Chronic bacterial prostatitis | Ciprofloxacin, 250-500 mg every 12 hours | Oral | 1-3 months | \$322.00/1 month (500 mg) |
| | Ofloxacin, 200-400 mg every 12 hours | Oral | 1-3 months | \$360.00/1 month (400 mg) |
| | Trimethoprim-sulfamethoxazole, 160/800 mg every 12 hours ² | Oral | 1-3 months | \$69.00/1 month |
| Acute epididymitis | | | | |
| Sexually transmitted | Ceftriaxone, 250 mg as single dose, plus: | Intramuscular | Once | \$16.00/250 mg |
| | Doxycycline, 100 mg every 12 hours | Oral | 10 days | \$12.50 |
| Non-sexually transmitted | Same as for chronic bacterial prostatitis | Oral | 3 weeks | |

¹Average wholesale price, (AWP, for AB-rated generic when available) for quantity listed. Source: *Red Book Update*, Vol. 28, No. 3, March 2009. AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.

²Increasing resistance noted (up to 20%).

▶ When to Refer

- Suspicion or radiographic evidence of anatomic abnormality.
- Evidence of urolithiasis.
- Recurrent cystitis due to bacterial persistence.

Fihn SD. Clinical practice. Acute uncomplicated urinary tract infection in women. *N Engl J Med*. 2003 Jul 17;349(3):259-66. [PMID: 12867610]

Norris DL 2nd et al. Urinary tract infections: diagnosis and management in the emergency department. 2008 May; 26(2):413-30. [PMID: 18406981]

2. Acute Pyelonephritis

ESSENTIALS OF DIAGNOSIS

- ▶ Fever.

- ▶ Flank pain.
- ▶ Irritative voiding symptoms.
- ▶ Positive urine culture.

▶ General Considerations

Acute pyelonephritis is an infectious inflammatory disease involving the kidney parenchyma and renal pelvis. Gram-negative bacteria are the most common causative agents including *E coli*, *Proteus*, *Klebsiella*, *Enterobacter*, and *Pseudomonas*. Gram-positive bacteria are less commonly seen but include *Enterococcus faecalis* and *Staphylococcus aureus*. The infection usually ascends from the lower urinary tract—with the exception of *S aureus*, which usually is spread by a hematogenous route.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms include fever, flank pain, shaking chills, and irritative voiding symptoms (urgency, frequency, dysuria).

Associated nausea and vomiting, and diarrhea are common. Signs include fever and tachycardia. Costovertebral angle tenderness is usually pronounced.

B. Laboratory Findings

Complete blood count shows leukocytosis and a left shift. Urinalysis shows pyuria, bacteriuria, and varying degrees of hematuria. White cell casts may be seen. Urine culture demonstrates heavy growth of the offending agent, and blood culture may also be positive.

C. Imaging

In complicated pyelonephritis, renal ultrasound may show hydronephrosis from a stone or other source of obstruction.

► Differential Diagnosis

Acute intra-abdominal disease such as appendicitis, cholecystitis, pancreatitis, or diverticulitis must be distinguished from pyelonephritis. A normal urinalysis is usually seen in gastrointestinal disorders; however, on occasion, inflammation from adjacent bowel (appendicitis or diverticulitis) may result in hematuria or sterile pyuria. Abnormal liver function tests or elevated amylase levels may assist in the differentiation. Lower lobe pneumonia is distinguishable by the abnormal chest radiograph.

In males, the main differential diagnosis for acute pyelonephritis includes acute epididymitis, acute prostatitis, and acute cystitis. Physical examination and the location of the pain should permit this distinction.

► Complications

Sepsis with shock can occur with acute pyelonephritis. In diabetic patients, emphysematous pyelonephritis resulting from gas-producing organisms may be life-threatening if not adequately treated. Healthy adults usually recover complete kidney function, yet if coexistent kidney disease is present, scarring or chronic pyelonephritis may result. Inadequate therapy could result in abscess formation.

► Treatment

Severe infections or complicating factors require hospital admission. Urine and blood cultures are obtained to identify the causative agent and to determine antimicrobial sensitivity. Intravenous ampicillin and an aminoglycoside are initiated prior to obtaining sensitivity results (Table 23–1). In the outpatient setting, quinolones or nitrofurantoin may be initiated (Table 23–1). Antibiotics are adjusted according to sensitivities. Fevers may persist for up to 72 hours; failure to respond warrants imaging (CT or ultrasound) to exclude complicating factors that may require intervention. Catheter drainage may be necessary in the face of urinary retention and nephrostomy drainage if there is ureteral obstruction. In inpatients, intravenous antibiotics are continued for 24 hours after the fever resolves, and oral antibiotics are then given to complete a 14-day course of therapy. Follow-up urine cultures are mandatory following the completion of treatment.

► Prognosis

With prompt diagnosis and appropriate treatment, acute pyelonephritis carries a good prognosis. Complicating factors, underlying kidney disease, and increasing patient age may lead to a less favorable outcome.

► When to Refer

- Evidence of complicating factors (urolithiasis, obstruction).
- Absence of clinical improvement in 48 hours.

► When to Admit

- Evidence of sepsis and need for parenteral antibiotics.
- Need for radiographic imaging or drainage of urinary tract obstruction.

Meng MV et al. Infections of the upper urinary tract. In: *Urologic Emergencies*, Humana Press, 2005.

3. Acute Bacterial Prostatitis

ESSENTIALS OF DIAGNOSIS

- Fever.
- Irritative voiding symptoms.
- Perineal or suprapubic pain; exquisite tenderness common on rectal examination.
- Positive urine culture.

► General Considerations

Acute bacterial prostatitis is usually caused by gram-negative rods, especially *E coli* and *Pseudomonas* species and less commonly by gram-positive organisms (eg, enterococci). The most likely routes of infection include ascent up the urethra and reflux of infected urine into the prostatic ducts. Lymphatic and hematogenous routes are probably rare.

► Clinical Findings

A. Symptoms and Signs

Perineal, sacral, or suprapubic pain, fever, and irritative voiding complaints are common. Varying degrees of obstructive symptoms may occur as the acutely inflamed prostate swells, which may lead to urinary retention. High fevers and a warm and often exquisitely tender prostate are detected on examination. Care should be taken in performing a gentle rectal examination, as vigorous manipulations may result in septicemia. Prostatic massage is contraindicated.

B. Laboratory Findings

Complete blood count shows leukocytosis and a left shift. Urinalysis shows pyuria, bacteriuria, and varying degrees of hematuria. Urine cultures will demonstrate the offending pathogen.

▶ Differential Diagnosis

Acute pyelonephritis or acute epididymitis should be distinguishable by the location of pain as well as by physical examination. Acute diverticulitis is occasionally confused with acute prostatitis; however, the history and urinalysis should permit clear distinction. Urinary retention from benign or malignant prostatic enlargement is distinguishable by initial or follow-up rectal examination.

▶ Treatment

Hospitalization may be required, and parenteral antibiotics (ampicillin and aminoglycoside) should be initiated until organism sensitivities are available (Table 23–1). After the patient is afebrile for 24–48 hours, oral antibiotics (eg, quinolones) are used to complete 4–6 weeks of therapy. If urinary retention develops, urethral catheterization or instrumentation is contraindicated, and a percutaneous suprapubic tube is required. Follow-up urine culture and examination of prostatic secretions should be performed after the completion of therapy to ensure eradication.

▶ Prognosis

With effective treatment, chronic bacterial prostatitis is rare.

▶ When to Refer

- Evidence of urinary retention.
- Evidence of chronic prostatitis.

▶ When to Admit

- Signs of sepsis.
- Need for surgical drainage of bladder or prostatic abscess.

Hua VN et al. Acute and chronic prostatitis. *Med Clin North Am.* 2004 Mar;88(2):483–94. [PMID: 15049589]

4. Chronic Bacterial Prostatitis

ESSENTIALS OF DIAGNOSIS

- ▶ Irritative voiding symptoms.
- ▶ Perineal or suprapubic discomfort, often dull and poorly localized.
- ▶ Positive expressed prostatic secretions and culture.

▶ General Considerations

Although chronic bacterial prostatitis may evolve from acute bacterial prostatitis, many men have no history of acute infection. Gram-negative rods are the most common etiologic agents, but only one gram-positive organism (*Enterococcus*) is associated with chronic infection. Routes of infection are the same as discussed for acute infection.

▶ Clinical Findings

A. Symptoms and Signs

Clinical manifestations are variable. Some patients are asymptomatic, but most have varying degrees of irritative voiding symptoms. Low back and perineal pain are not uncommon. Many patients report a history of urinary tract infections. Physical examination is often unremarkable, though the prostate may feel normal, boggy, or indurated.

B. Laboratory Findings

Urinalysis is normal unless a secondary cystitis is present. Expressed prostatic secretions demonstrate increased numbers of leukocytes (> 10 per high-power field), especially lipid-laden macrophages. However, this finding is consistent with inflammation and is not diagnostic of bacterial prostatitis. Leukocyte and bacterial counts from expressed prostatic secretions do not correlate with severity of symptoms. Culture of the secretions or the postprostatic massage urine specimen is necessary to make the diagnosis.

C. Imaging

Imaging tests are not necessary, though pelvic radiographs or transrectal ultrasound may demonstrate prostatic calculi.

▶ Differential Diagnosis

Chronic urethritis may mimic chronic prostatitis, though cultures of the fractionated urine may localize the source of infection to the initial specimen. Cystitis may be secondary to prostatitis, but urine samples after prostatic massage may localize the infection to the prostate. Anal disease may share some of the symptoms of prostatitis, but physical examination should permit a distinction between the two.

▶ Treatment

Few antimicrobial agents attain therapeutic intraprostatic levels in the absence of acute inflammation. Trimethoprim does diffuse into the prostate, and trimethoprim-sulfamethoxazole is associated with the best cure rates (Table 23–1). Other effective agents include carbenicillin, erythromycin, cephalexin, and the quinolones. The optimal duration of therapy remains controversial, ranging from 6 to 12 weeks. Symptomatic relief may be provided by anti-inflammatory agents (indomethacin, ibuprofen) and hot sitz baths.

▶ Prognosis

Chronic bacterial prostatitis is difficult to cure, but its symptoms and tendency to cause recurrent urinary tract infections can be controlled by suppressive antibiotic therapy.

▶ When to Refer

- Persistent symptoms.
- Consideration of enrollment in clinical trials.

5. Nonbacterial Prostatitis

ESSENTIALS OF DIAGNOSIS

- ▶ Irritative voiding symptoms.
- ▶ Perineal or suprapubic discomfort, similar to that of chronic bacterial prostatitis.
- ▶ Positive expressed prostatic secretions, but culture is negative.

▶ General Considerations

Nonbacterial prostatitis is the most common of the prostatitis syndromes, and its cause is unknown. Speculation implicates chlamydiae, mycoplasmas, ureaplasmas, and viruses, but no substantial proof exists. In some cases, nonbacterial prostatitis may represent a noninfectious inflammatory or autoimmune disorder. Because the cause of nonbacterial prostatitis remains unknown, the diagnosis is usually one of exclusion.

▶ Clinical Findings

A. Symptoms and Signs

The clinical presentation is identical to that of chronic bacterial prostatitis; however, no history of urinary tract infections is present. The National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI) (<http://www2.niddk.nih.gov/NR/rdonlyres/93B6388F-B429-4603-9C3C-6765BDEB49A1/0/NIHCPSIEnglish.pdf>) has been validated to quantify symptoms of chronic nonbacterial prostatitis or chronic pelvic pain syndrome.

B. Laboratory Findings

Increased numbers of leukocytes are seen on expressed prostatic secretions, but all cultures are negative.

▶ Differential Diagnosis

The major distinction is from chronic bacterial prostatitis. The absence of a history of urinary tract infection and of positive cultures makes the distinction (Table 23–2). In older men with irritative voiding symptoms and negative cultures, the possibility of bladder cancer must be

excluded. Urinary cytologic examination and cystoscopy are warranted.

▶ Treatment

Because of the uncertainty regarding the etiology of nonbacterial prostatitis, a trial of antimicrobial therapy directed against *Ureaplasma*, *Mycoplasma*, or *Chlamydia* is warranted. Erythromycin (250 mg orally four times daily) can be initiated for 14 days yet should be continued (for 3–6 weeks) only if a favorable clinical response ensues. Some symptomatic relief may be obtained with anti-inflammatory agents or sitz baths. Dietary restrictions are not necessary unless the patient relates a history of symptom exacerbation by certain substances such as alcohol, caffeine, and perhaps certain foods.

▶ Prognosis

Annoying, recurrent symptoms are common, but serious sequelae have not been identified.

Nickel JC. The three As of chronic prostatitis therapy: antibiotics, alpha-blockers and anti-inflammatories. What is the evidence? *BJU Int.* 2004 Dec;94(9):1230–3. [PMID: 15610095]

Nickel JC et al. Prevalence, diagnosis, characterization, and treatment of prostatitis, interstitial cystitis, and epididymitis in outpatient urological practice: the Canadian PIE Study. *Urology.* 2005 Nov;66(5):935–40. [PMID: 16286098]

6. Prostatodynia

Prostatodynia is a noninflammatory disorder that affects young and middle-aged men and has variable causes, including voiding dysfunction and pelvic floor musculature dysfunction. The term “prostatodynia” is a misnomer, as the prostate is actually normal.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms are the same as those seen with chronic prostatitis, yet there is no history of urinary tract infection. Additional symptoms may include hesitancy and interruption of flow. Patients may relate a lifelong history of voiding difficulty. Physical examination is unremarkable, but increased anal sphincter tone and periprostatic tenderness may be observed.

Table 23–2. Clinical characteristics of prostatitis and prostatodynia syndromes.

| Findings | Acute Bacterial Prostatitis | Chronic Bacterial Prostatitis | Nonbacterial Prostatitis | Prostatodynia |
|-------------------------------|-----------------------------|-------------------------------|--------------------------|---------------|
| Fever | + | – | – | – |
| Urinalysis | + | – | – | – |
| Expressed prostate secretions | Contraindicated | + | + | – |
| Bacterial culture | + | + | – | – |

B. Laboratory Findings

Urinalysis is normal. Expressed prostatic secretions show normal numbers of leukocytes. Urodynamic testing may show signs of dysfunctional voiding (detrusor contraction without urethral relaxation, high urethral pressures, spasms of the urinary sphincter) and is indicated in patients failing empiric trials of α -blockers or anticholinergics.

► Differential Diagnosis

Normal urinalysis will distinguish it from acute infectious processes. Examination of expressed prostatic secretions will distinguish this entity from prostatitis syndromes (Table 23–2).

► Treatment

Bladder neck and urethral spasms can be treated by α -blocking agents (terazosin, 1–10 mg orally once a day, or doxazosin, 1–8 mg orally once a day). Pelvic floor muscle dysfunction may respond to diazepam and biofeedback techniques. Sitz baths may contribute to symptomatic relief.

► Prognosis

Prognosis is variable depending on the specific cause.

7. Acute Epididymitis

ESSENTIALS OF DIAGNOSIS

- Fever.
- Irritative voiding symptoms.
- Painful enlargement of epididymis.

► General Considerations

Most cases of acute epididymitis are infectious and can be divided into one of two categories that have different age distributions and etiologic agents. Sexually transmitted forms typically occur in men under age 40 years, are associated with urethritis, and result from *Chlamydia trachomatis* or *Neisseria gonorrhoeae*. Non-sexually transmitted forms typically occur in older men, are associated with urinary tract infections and prostatitis, and are caused by gram-negative rods. The route of infection is probably via the urethra to the ejaculatory duct and then down the vas deferens to the epididymis. Amiodarone has been associated with self-limited epididymitis, which is a dose-dependent phenomenon.

► Clinical Findings

A. Symptoms and Signs

Symptoms may follow acute physical strain (heavy lifting), trauma, or sexual activity. Associated symptoms of urethritis (pain at the tip of the penis and urethral discharge) or cystitis (irritative voiding symptoms) may occur. Pain develops in the scrotum and may radiate along the spermatic cord or to the flank. Fever and scrotal swelling are usually apparent. Early in the course, the epididymis may be distinguishable from the testis; however, later the two may appear as one enlarged, tender mass. The prostate may be tender on rectal examination.

B. Laboratory Findings

Complete blood count shows leukocytosis and a left shift. In the sexually transmitted variety, Gram staining of a smear of urethral discharge may be diagnostic of gram-negative intracellular diplococci (*N gonorrhoeae*). White cells without visible organisms on urethral smear represent nongonococcal urethritis, and *C trachomatis* is the most likely pathogen. In the non-sexually transmitted variety, urinalysis shows pyuria, bacteriuria, and varying degrees of hematuria. Urine cultures will demonstrate the offending pathogen.

C. Imaging

Scrotal ultrasound may aid in the diagnosis if examination is difficult because of the presence of a large hydrocele or because questions exist regarding the diagnosis.

► Differential Diagnosis

Tumors generally cause painless enlargement of the testis. Urinalysis is negative, and examination reveals a normal epididymis. Scrotal ultrasound is helpful to define the pathology. Testicular torsion usually occurs in prepubertal males but is occasionally seen in young adults. Acute onset of symptoms and a negative urinalysis favor testicular torsion or torsion of one of the testicular or epididymal appendages. Prehn sign (elevation of the scrotum above the pubic symphysis improves pain from epididymitis) may be helpful but is not reliable.

► Treatment

Bed rest with scrotal elevation is important in the acute phase. Treatment is directed toward the identified pathogen (Table 23–1). The sexually transmitted variety is treated with 10–21 days of antibiotics, and the sexual partner must be treated as well. Non-sexually transmitted forms are treated for 21–28 days with appropriate antibiotics, at which time evaluation of the urinary tract is warranted to identify underlying disease.

► Prognosis

Prompt treatment usually results in a favorable outcome. Delayed or inadequate treatment may result in epididymo-orchitis, decreased fertility, or abscess formation.

▶ When to Refer

- Persistent symptoms and infection despite antibiotic therapy.
- Signs of sepsis or abscess formation.

Tracy CR et al. Diagnosis and management of epididymitis. *Urol Clin North Am.* 2008 Feb;35(1):101–8. [PMID: 18061028]

URINARY STONE DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Flank pain.
- ▶ Nausea and vomiting.
- ▶ Identification on noncontrast CT.

▶ General Considerations

Urinary stone disease is exceeded in frequency as a urinary tract disorder only by infections and prostatic disease and is estimated to afflict 240,000–720,000 Americans per year. Men are more frequently affected by urolithiasis than women, with a ratio of 3:1. Initial presentation predominates in the third and fourth decades. The ratio of men to women approaches parity in the sixth and seventh decades.

Urinary calculi are polycrystalline aggregates composed of varying amounts of crystalloid and a small amount of organic matrix. Stone formation requires saturated urine that is dependent upon pH, ionic strength, solute concentration, and complexation. There are five major types of urinary stones: calcium oxalate, calcium phosphate, struvite, uric acid, and cystine. The most common types are composed of calcium, and for that reason most urinary stones (85%) are radiopaque. Uric acid stones can be radiolucent yet frequently are composed of a combination of uric acid and calcium oxalate and thus are radiopaque. Cystine stones frequently have a smooth-edged ground-glass appearance.

Geographic factors contribute to the development of stones. Areas of high humidity and elevated temperatures appear to be contributing factors, and the incidence of symptomatic ureteral stones is greatest during hot summer months.

Diet and fluid intake may be important factors in the development of urinary stones. Those afflicted with recurrent urinary stone disease are encouraged to maintain a diet restricted in sodium and protein intake. Sodium should be restricted to 100 mEq/d. Increased sodium intake will increase sodium and calcium excretion, increase monosodium urate saturation (that can act as a nidus for stone growth), increase the relative saturation of calcium phosphate, and decrease urinary citrate excretion. All of these factors encourage stone growth. Protein intake should be limited to 1 g/kg/d. An increased protein load can also increase calcium, oxalate, and uric acid excretion and decrease urinary citrate excretion.

Carbohydrates and fats have not been proved to have any impact on urinary stone disease. Bran can significantly

decrease urinary calcium by increasing bowel transit time and mechanically binding to calcium. Excess intake of oxalate and purines can increase the incidence of stones in predisposed individuals. Although a reduction in dietary calcium results in reduced urinary calcium, the concurrent increase in urinary oxalate may promote stone formation. Only type II absorptive hypercalciuric patients (see below) benefit from a low-calcium diet. Persons in sedentary occupations have a higher incidence of stones than manual laborers.

Genetic factors may contribute to urinary stone formation. Cystinuria is an autosomal recessive disorder. Homozygous individuals have markedly increased excretion of cystine and frequently have numerous recurrent episodes of urinary stones despite attempts to optimize medical treatment. Distal renal tubular acidosis may be transmitted as a hereditary trait, and urolithiasis occurs in up to 75% of patients affected with this disorder.

▶ Clinical Findings

A. Symptoms and Signs

Obstructing urinary stones usually present with colic. Pain usually occurs suddenly and may awaken patients from sleep. It is localized to the flank, is usually severe, and may be associated with nausea and vomiting. Patients are constantly moving—in sharp contrast to those with an acute abdomen. The pain may occur episodically and may radiate anteriorly over the abdomen. As the stone progresses down the ureter, the pain may be referred into the ipsilateral testis or labium. If the stone becomes lodged at the ureterovesicular junction, patients will complain of marked urinary urgency and frequency. Stone size does not correlate with the severity of the symptoms.

B. Metabolic Evaluation

Stone analysis should be performed on recovered stones. Controversy exists in deciding which patients need a thorough metabolic evaluation for stone disease. Uncomplicated first-time stone-formers should probably undergo blood screening for abnormalities of serum calcium, phosphate, electrolytes, and uric acid as a baseline.

More extensive evaluation is required in recurrent stone-formers or patients with a family history of stone disease. A 24-hour urine collection on a random diet should ascertain volume, urinary pH, and calcium, uric acid, oxalate, phosphate, sodium, and citrate excretion. A second collection on a restricted calcium (400 mg/d) and sodium (100 mEq/d) diet is undertaken to subcategorize patients, if necessary. Serum parathyroid hormone (PTH) and calcium load tests can be performed at a third visit. A calcium load test is performed as follows: After a patient has been on a restricted calcium diet for at least 1 week, the patient is told to fast from 9 PM. The patient discards the early morning voided specimen (7 AM). While still fasting, the patient voids at 9 AM, which is the fasting sample. The patient then ingests 1 g of calcium gluconate, and all urine is collected from 9 AM to 1 PM, the calcium load sample. Table 23–3 demonstrates the diagnostic criteria for the hypercalciuric states. (See discussion below.)

Table 23–3. Diagnostic criteria of different types of hypercalciuria.

| | Absorptive Type I | Absorptive Type II | Absorptive Type III | Resorptive | Renal |
|------------------------|-------------------|--------------------|---------------------|------------|-------|
| Serum | | | | | |
| Calcium | N | N | N | ↑ | N |
| Phosphorus | N | N | ↓ | ↓ | N |
| PTH | N | N | N | ↑ | ↑ |
| Vitamin D | N | N | ↑ | ↑ | ↑ |
| Urinary calcium | | | | | |
| Fasting | N | N | ↑ | ↑ | ↑ |
| Restricted | ↑ | N | ↑ | ↑ | ↑ |
| After calcium load | ↑ | ↑ | ↑ | ↑ | ↑ |

PTH, parathyroid hormone; ↑, elevated; ↓, low; N, normal.

C. Laboratory Findings

Urinalysis usually reveals microscopic or gross hematuria (~90%). However, the absence of microhematuria does not exclude urinary stones. Infection must be excluded, because the combination of infection and urinary tract obstruction requires prompt intervention as described below. Urinary pH is a valuable clue to the cause of the possible stone. Normal urine pH is 5.9. There is a normal postprandial urinary alkaline tide. Numerous dipstick measurements are valuable in the complete workup of a stone patient. Persistent urinary pH below 5.5 is suggestive of uric acid or cystine stones, both relatively radiolucent as seen on plain films of the abdomen. In contrast, a persistent pH above 7.2 is suggestive of a struvite infection stone, radiopaque on plain films.

D. Imaging

A plain film of the abdomen and renal ultrasound examination will diagnose most stones. Spiral CT has emerged as a first-line tool in evaluating flank pain. All stones whether radiopaque or radiolucent on plain abdominal radiographs will be visible on noncontrast CT except the rare calculi due to the protease inhibitor indinavir. Stones suspected of being located at the ureterovesicular junction can be imaged with abdominal ultrasonography with the aid of the acoustic window of a full bladder. Alternatively, transvaginal or transrectal ultrasonography will help identify calculi near the ureterovesicular junction.

► Medical Treatment & Prevention

To reduce the recurrence rate of urinary stones, one must attempt to achieve a stone-free status. Small stone fragments may serve as a nidus for future stone development. Selected patients must be thoroughly evaluated to reduce stone recurrence rates. Uric acid stone-formers may have recurrences within months if appropriate therapy is not initiated. If no medical treatment is provided after surgical stone removal, stones will generally recur in 50% of patients within 5 years. Of greatest importance in reducing stone recurrence is an increased fluid intake. Absolute volumes are

not established, but doubling previous fluid intake is recommended. Patients are encouraged to ingest fluids during meals, 2 hours after each meal (when the body is most dehydrated), and prior to going to sleep in the evening—enough to awaken the patient to void—and to ingest additional fluids during the night. Increasing fluids only during daylight hours may not dilute a supersaturated urine overnight and thus initiate a new stone.

A. Calcium Nephrolithiasis

1. Hypercalciuric—Hypercalciuric calcium nephrolithiasis (> 200 mg/24 h; > 4 mg/kg/24 h) can be caused by absorptive, resorptive, and renal disorders.

Absorptive hypercalciuria is secondary to increased absorption of calcium at the level of the small bowel, predominantly in the jejunum, and can be further subdivided into types I, II, and III. Type I absorptive hypercalciuria is independent of calcium intake. There is increased urinary calcium on a regular or even a calcium-restricted diet. Treatment is centered upon decreasing bowel absorption of calcium. Cellulose phosphate, a chelating agent, is an effective form of therapy. An average dose is 10–15 g in three divided doses. It binds to the calcium and impedes small bowel absorption due to its increased bulk. Cellulose phosphate does not change the intestinal transport mechanism. It should be given with meals so it will be available to bind to the calcium. Taking this chelating agent prior to bedtime is ineffective. Postmenopausal women should be treated with caution. It is interesting, however, that there is no enhanced decline in bone density after long-term use. Inappropriate use without an initial metabolic evaluation (see above) may result in a negative calcium balance and a secondary parathyroid stimulation. Long-term use without follow-up metabolic surveillance may result in hypomagnesuria and secondary hyperoxaluria and recurrent calculi. Routine follow-up every 6–8 months will help encourage medical compliance and permit adjustments in medical therapy based upon repeat metabolic studies.

Thiazide therapy is an alternative to cellulose phosphate in the treatment of type I absorptive hypercalciuria. Thiazides decrease renal calcium excretion but have no impact

on intestinal absorption. This therapy results in increased bone density of approximately 1% per year. Thiazides have limited long-term utility (< 5 years) since they may lose their hypocalciuric effect with continued therapy.

Type II absorptive hypercalciuria is diet dependent. Decreasing calcium intake by 50% (approximately 400 mg/d) will decrease the hypercalciuria to normal values (150–200 mg/24 h). There is no specific medical therapy.

Type III absorptive hypercalciuria is secondary to a renal phosphate leak. This results in increased vitamin D synthesis and secondarily increased small bowel absorption of calcium. This can be readily reversed by orthophosphates (250 mg three to four times per day). Orthophosphates do not change intestinal absorption but rather inhibit vitamin D synthesis.

Resorptive hypercalciuria is secondary to hyperparathyroidism. Hypercalcemia, hypophosphatemia, hypercalciuria, and an elevated PTH value are found. Appropriate surgical resection of the parathyroid adenoma cures the disease and the urinary stones. Medical management is invariably a failure.

Renal hypercalciuria occurs when the renal tubules are unable to efficiently reabsorb filtered calcium, and hypercalciuria results. Spilling calcium in the urine results in secondary hyperparathyroidism. Serum calcium typically is normal. Thiazides are effective long-term therapy in patients with this disorder.

2. Hyperuricosuric—Hyperuricosuric calcium nephrolithiasis is secondary to dietary excesses or uric acid metabolic defects. Both disorders can be treated with purine dietary restrictions or allopurinol therapy (or both). In contrast to uric acid nephrolithiasis, patients with hyperuricosuric calcium stones typically maintain a urinary pH greater than 5.5. Monosodium urates absorb and adsorb inhibitors and promote heterogeneous nucleation. Hyperuricosuric calcium nephrolithiasis is probably secondary to epitaxy, or heterogeneous nucleation. In such situations, similar crystal structures (ie, uric acid and calcium oxalate) can grow together with the aid of a protein matrix infrastructure.

3. Hyperoxaluric—Hyperoxaluric calcium nephrolithiasis is usually due to primary intestinal disorders. Patients usually present with a history of chronic diarrhea frequently associated with inflammatory bowel disease or steatorrhea. Increased bowel fat combines with intraluminal calcium to form a soap-like product. Calcium is therefore unavailable to bind to oxalate, which is then freely and rapidly absorbed. A small increase in oxalate absorption will significantly increase stone formation. If the diarrhea or steatorrhea cannot be effectively curtailed, oral calcium supplements should be given with meals. More than 2 g/d of ascorbic acid will increase urinary oxalate levels. Emphasis on encouraging increased fluid intake is required for these patients as for all stone-formers.

4. Hypocitraturic—Hypocitraturic calcium nephrolithiasis may be secondary to chronic diarrhea, type I (distal) renal tubular acidosis, chronic hydrochlorothiazide treatment, and, in rare cases, is idiopathic. Any condition that results in metabolic acidosis (including prolonged fasting,

hypomagnesemia, and hypokalemia) will decrease urinary citrate excretion, since it will be consumed by the citric acid cycle within the mitochondria of proximal tubular cells. Hypocitraturia is frequently associated with other forms of calcium stone formation. Citrate appears to bind to calcium in solution, thereby decreasing available calcium for stone formation. Potassium citrate supplements are usually effective. Urinary citrate is decreased in acidosis and is increased during alkalosis. The potassium will supplement the frequently associated hypokalemic states, and citrate will help to correct the acidosis. A typical dose is 20 mEq three times a day (available in solution and in 10-mEq waxed tablets), or 30 mEq of crystal formulations twice a day.

B. Uric Acid Calculi

The average urinary pH is 5.9. Uric acid stone-formers typically have urinary pH values less than 5.5. The pK of uric acid is 5.75, at which point half of the uric acid is ionized as a urate salt and is soluble, while the other half is insoluble. Increasing the pH above 6.5 dramatically increases solubility and can effectively dissolve large calculi. Potassium citrate is the most frequently used medication to increase urinary pH. It can be given in liquid preparation, as crystals that need to be taken with fluids, or as tablets (10 mEq), two by mouth three or four times daily. Compliant urinary alkalinization may dissolve uric acid calculi at a rate of 1 cm (as measured on plain abdominal radiograph) of stone per month. Patients with uric acid calculi should be given Nitrazine pH paper with which to monitor the effectiveness of their urinary alkalinization. Other contributing factors include hyperuricemia, myeloproliferative disorders, malignancy with increased uric acid production, abrupt and dramatic weight loss, and uricosuric medications. If hyperuricemia is present, allopurinol (300 mg/d) may be given. Although pure uric acid stones are relatively radiolucent, most have some calcium components and can be visualized on plain abdominal radiographs. Renal ultrasonography is a helpful adjunct for appropriate diagnosis and long-term management.

C. Struvite Calculi

Struvite stones are synonymous with magnesium-ammonium-phosphate stones. They are commonly seen in women with recurrent urinary tract infections recalcitrant to appropriate antibiotics. They rarely form as ureteral stones without prior upper tract endourologic intervention. Frequently, a struvite stone is discovered as a large staghorn calculus forming a cast of the renal collecting system. Struvite stones are radiodense. Urinary pH is high, usually above 7.2. These stones are formed secondary to urease-producing organisms, including *Proteus*, *Pseudomonas*, *Providencia*, and, less commonly, *Klebsiella*, *Staphylococcus*, and *Mycoplasma*. An *E coli* urinary tract infection is not consistent with an infectious reservoir originating from a struvite calculus. These frequently large stones are relatively soft and amenable to percutaneous nephrolithotomy. Appropriate perioperative antibiotics are required. They can recur rapidly, and efforts should be taken to render the patient stone-free. Postoperative irrigation through nephrostomy tubes can eliminate small fragments. Acetohydroxamic acid is an

effective urease inhibitor, but it is poorly tolerated by most patients because of its gastrointestinal toxicity.

D. Cystine Calculi

Cystine stones are a result of abnormal excretion of cystine, ornithine, lysine, and arginine. Cystine is the only amino acid that becomes insoluble in urine. These stones are particularly difficult to manage medically. Prevention is centered around increased fluid intake, alkalization of the urine above pH 7.5 (monitored with Nitrazine pH paper), and a variety of medications including penicillamine and tiopronin (α -mercaptopyrionylglycine). There are no known inhibitors of cystine calculi.

► Surgical Treatment

Forced intravenous fluids will not push stones down the ureter. Effective peristalsis directing a bolus of urine down the ureter requires opposing ureteral walls to approach each other and touch, which large dilated systems cannot do. In fact, diuresis is counterproductive and will exacerbate the pain. Associated fever may represent infection, a medical emergency requiring prompt drainage by a ureteral catheter or a percutaneous nephrostomy tube. Antibiotics alone are inadequate unless obstruction is drained.

A. Ureteral Stones

Impediment to urine flow by ureteral stones usually occurs at three sites: (1) at the ureteropelvic junction, (2) at the crossing of the ureter over the iliac vessels, and finally (3) as the ureter enters the bladder at the ureterovesicular junction. Prediction of spontaneous stone passage is difficult. Stones less than 6 mm in diameter as seen on a plain abdominal radiograph will usually pass spontaneously. Conservative observation with appropriate pain medications is appropriate for the first 6 weeks. There is evidence that oral corticosteroids, α -blockers, and calcium channel blockers may enhance stone passage of observed ureteral stones. α -Blockers are safe and well tolerated. Typical agents and dosages are tamsulosin, 0.4 mg orally once daily; terazosin, 5 mg orally once daily; or doxazosin, 4 mg orally once daily. If spontaneous stone passage has failed, either because of lack of progression of the stone or intolerance of the pain, therapeutic intervention is required. Distal ureteral stones are best managed either with ureteroscopic stone extraction or in situ extracorporeal shock wave lithotripsy (SWL). Ureteroscopic stone extraction involves placement of a small endoscope through the urethra and into the ureter. Under direct vision, basket extraction or fragmentation followed by extraction is performed. Complications during endoscopic retrieval increase as the duration of conservative observation increases beyond 6 weeks. Indications for earlier intervention include severe pain unresponsive to medications, fever, persistent nausea and vomiting requiring intravenous hydration, social requirements requiring return to work, or anticipated travel. Most upper tract stones that enter the bladder can exit the urethra with minimal discomfort.

In situ SWL, an alternative, utilizes an external energy source that is focused upon the stone. This focused energy

is additive, resulting in minimal tissue insult except at the focus where the stone is positioned with the aid of fluoroscopy or ultrasonography. This can be performed under anesthesia as an outpatient procedure and usually results in stone fragmentation. Most stone fragments will pass uneventfully within 2 weeks, but those that have not passed within 3 months are unlikely to pass without intervention. Women of childbearing age are best not treated with SWL for a stone in the lower ureter, as the impact upon the ovary is unknown.

Proximal and midureteral stones—those above the inferior margin of the sacroiliac joint—can be treated with SWL or ureteroscopy. SWL is delivered directly to the stone (in situ) without the need to push the stone back into the renal pelvis. To help ensure adequate drainage after SWL, a double J ureteral stent is frequently placed, but it does not ensure passage of stone fragments. Occasionally, stone fragments will obstruct the ureter after SWL. Conservative management will usually result in spontaneous resolution with eventual passage of the stone fragments. If this is unsuccessful, adequate proximal drainage through a percutaneous nephrostomy tube will facilitate passage. In rare instances, ureteroscopic extraction will be required.

B. Renal Calculi

Patients with renal calculi presenting without pain, urinary tract infections, or obstruction need not be treated. They should be followed with serial abdominal radiographs or renal ultrasonographic examinations. If calculi are growing or become symptomatic, intervention should be undertaken. Renal calculi less than 2 cm in diameter are best treated with SWL. Calculi located in the inferior calyx frequently result in suboptimal stone-free rates as measured at 3 months by x-ray. Such calculi and others of larger diameter are best treated via percutaneous nephrolithotomy. Perioperative antibiotic coverage should be given on the basis of preoperative urine cultures.

► When to Refer

- Evidence of urinary obstruction.
- Anatomic abnormalities or solitary kidney.
- Concomitant pyelonephritis.

► When to Admit

- Intractable nausea/vomiting or pain.
- Fever.

INTERSTITIAL CYSTITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Pain with a full bladder or urinary urgency.
- ▶ Submucosal petechiae or ulcers on cystoscopic examination.
- ▶ Diagnosis of exclusion.

▶ General Considerations

Interstitial cystitis is characterized by pain with bladder filling that is relieved by emptying and is often associated with urgency and frequency. This is a diagnosis of exclusion, and patients must have a negative urine culture and cytology and no other obvious cause such as radiation cystitis, chemical cystitis (cyclophosphamide), vaginitis, urethral diverticulum, or genital herpes. Up to 40% of patients referred to urologists for interstitial cystitis may actually be found to have a different diagnosis after careful evaluation.

Population-based studies have demonstrated a prevalence of between 18 and 40 per 100,000 people. Both sexes are involved, but most patients are women, with a mean age of 40 years at onset. Patients with interstitial cystitis are more likely to report bladder problems in childhood, and there appears to be a higher prevalence in white and Jewish women. Up to 50% of patients may experience spontaneous remission of symptoms, with a mean duration of 8 months without treatment.

The etiology of interstitial cystitis is unknown, and it is most likely not a single disease but rather several diseases with similar symptoms. Associated diseases include severe allergies, irritable bowel syndrome, or inflammatory bowel disease. Theories regarding the cause of interstitial cystitis include increased epithelial permeability, neurogenic causes (sensory nervous system abnormalities), and autoimmunity.

▶ Clinical Findings

A. Symptoms and Signs

Pain with bladder filling that is relieved with urination or urgency, frequency, and nocturia are the most common symptoms. Exposures such as pelvic radiation or prior cyclophosphamide should be inquired about. Examination should exclude genital herpes, vaginitis, or a urethral diverticulum.

B. Laboratory Findings

Urinalysis and urine culture are obtained to exclude infectious causes. Urinary cytology is obtained to exclude bladder malignancy. Urodynamic testing assesses bladder sensation and compliance and excludes detrusor instability.

C. Cystoscopy

The bladder is distended with fluid (hydrodistention) to detect glomerulations (submucosal hemorrhage), which

may or may not be present. Biopsy should be performed to exclude other causes such as carcinoma, eosinophilic cystitis, and tuberculous cystitis. The presence of submucosal mast cells is not needed to make the diagnosis of interstitial cystitis.

▶ Differential Diagnosis

Exposures to radiation or cyclophosphamide are obtained by the history. Bacterial cystitis, genital herpes, or vaginitis can be excluded by urinalysis, culture, and physical examination. A urethral diverticulum may be suspected if palpation of the urethra demonstrates an indurated mass that results in the expression of pus from the urethral meatus. Urethral carcinoma presents as a firm mass on palpation.

▶ Treatment

There is no cure for interstitial cystitis, but most patients achieve symptomatic relief from one of several approaches, including hydrodistention, which is usually done as part of the diagnostic evaluation. Approximately 20–30% of patients will notice symptomatic improvement following this maneuver. Also of importance is the measurement of bladder capacity during hydrodistention, since patients with very small bladder capacities (< 200 mL) are unlikely to respond to medical therapy.

Amitriptyline is often used as first-line medical therapy in patients with interstitial cystitis. Both central and peripheral mechanisms may contribute to its activity. Nifedipine and other calcium channel blockers have also demonstrated some activity in patients with interstitial cystitis. Pentosan polysulfate sodium (Elmiron) is an oral synthetic sulfated polysaccharide that helps restore integrity to the epithelium of the bladder in a subset of patients and has been evaluated in a placebo-controlled trial. Other options include intravesical instillation of dimethyl sulfoxide (DMSO), heparin, or bacillus Calmette-Guérin (BCG). A group of investigators and the Interstitial Cystitis Clinical Trials Group performed a randomized controlled trial that showed no statistically significant improvement with intravesical BCG over placebo.

Other treatment modalities include transcutaneous electric nerve stimulation (TENS) and acupuncture. Surgical therapy for interstitial cystitis should be considered only as a last resort and may require cystourethrectomy with urinary diversion.

MALE ERECTILE DYSFUNCTION & SEXUAL DYSFUNCTION

ESSENTIALS OF DIAGNOSIS

- ▶ Erectile dysfunction can have organic and psychogenic etiologies.
- ▶ Organic erectile dysfunction may be an early sign of cardiovascular disease and requires evaluation.
- ▶ Incidence increases with age.
- ▶ Multiple treatments are effective, and range from oral agents to injectable agents to mechanical devices.

▶ General Considerations

Erectile dysfunction is defined as the consistent inability to attain or maintain a sufficiently rigid penile erection for sexual performance. This condition affects nearly 30 million American men, and its incidence is age related and rising. Approximately 52% of men aged 40–70 years experience this disorder. Most cases of male erectile disorders have an organic rather than a psychogenic cause. Normal male erection is a neurovascular phenomenon relying on an intact autonomic and somatic nerve supply to the penis, smooth and striated musculature of the corpora cavernosa and pelvic floor, and arterial inflow supplied by the paired pudendal arteries. Erection is precipitated and maintained by an increase in arterial flow, active relaxation of the smooth muscle elements of the sinusoids within the corporal bodies of the penis, and an increase in venous resistance. Contraction of the bulbocavernosus and ischiocavernosus muscles results in further rigidity of the penis. Nitric oxide appears to be the pivotal neurotransmitter that initiates and sustains erections; however, other molecules likely contribute, including acetylcholine, prostaglandins, and vasoactive intestinal peptide.

Male sexual dysfunction may be manifested in a variety of ways, and patient history is critical to the proper classification and treatment. Androgens have a strong influence on the sexual desire of men. A **loss of libido** may indicate androgen deficiency on the basis of either hypothalamic, pituitary, or testicular disease. **Loss of erections** may result from arterial, venous, neurogenic, or psychogenic causes. Concurrent medical problems may damage one or more of the mechanisms. Of particular concern is endothelial dysfunction, defined as the decreased bioavailability of nitric oxide with subsequent impairment of arterial vasodilation. Erectile dysfunction may be an early manifestation of endothelial dysfunction, which precedes more severe, systemic atherosclerotic, cardiovascular disease. In addition, many medications, especially antihypertensive and antidepressant agents, are associated with erectile dysfunction. It is impor-

tant to determine whether the patient has any normal erections in the early morning or during sleep. If normal erections occur, an organic cause is less likely. The gradual loss of erections over time is more suggestive of an organic cause. The ability to attain but not maintain an erection may be the first sign of endothelial dysfunction. The **loss of seminal emission** or anejaculation, may result from androgen deficiency by decreasing prostate and seminal vesicle secretions as well as sympathetic denervation as a result of diabetes mellitus or pelvic or retroperitoneal surgery. **Retrograde ejaculation** may occur as a result of mechanical disruption of the bladder neck, especially following transurethral resection of the prostate, treatment with α -blockers, or due to sympathetic denervation. If libido and erection are intact, the **loss of orgasm** is usually of psychological origin. **Premature ejaculation**, the persistent or recurrent ejaculation with minimal stimulation before a person wishes (associated with distress), is usually an anxiety-related disorder and rarely has an organic cause. The history may elucidate the presence of a new partner, unreasonable expectations about performance, or emotional disorders.

▶ Clinical Findings

A. Symptoms and Signs

Erectile dysfunction should be distinguished from problems of ejaculation, libido, and orgasm. The severity of the dysfunction (maintaining vs attaining; chronic, occasional, or situational) as well as its timing should be noted. The history should include inquiries about hyperlipidemia, hypertension, depression, neurologic disease, diabetes mellitus, chronic kidney disease, and endocrine disorders as well as known cardiac or peripheral vascular disease. Pelvic trauma, surgery, or irradiation identifies patients at increased risk for erectile dysfunction. Medication use should be noted, since 25% of all cases of sexual dysfunction may be drug related. The use of alcohol, tobacco, and recreational drugs should be recorded, since each is associated with an increased risk of sexual dysfunction.

During the physical examination, secondary sexual characteristics should be assessed. Motor and sensory examination should be performed as well as palpation and quantification of lower extremity vascular pulsations. The genitalia should be examined, noting the presence of penile scarring or plaque formation (Peyronie disease) and any abnormalities in size or consistency of either testicle.

B. Laboratory Findings

Laboratory evaluation should consist of a complete blood count, fasting lipid profile and glucose, testosterone, and prolactin. Patients with abnormalities of testosterone or prolactin require further evaluation with measurement of serum follicle-stimulating hormone (FSH) and luteinizing hormone (LH) to distinguish hypothalamic-pituitary dysfunction from testes failure.

C. Special Tests

Further testing is based on the patient's goals and history and is performed when etiology is unclear. Organic and

psychogenic impotence can be differentiated by use of nocturnal penile tumescence testing, where the frequency and rigidity of erections are recorded by a simple tension meter attached to the penis before sleep. Patients with psychogenic impotence will have nocturnal erections of adequate frequency and rigidity.

Patients with inadequate response to oral medications may undergo further evaluation with direct injection of vasoactive substances into the penis. Such substances (prostaglandin E₁, papaverine, phentolamine or a combination of drugs) will induce erections in men with intact vascular systems. Patients who respond with a rigid erection require no further vascular evaluation.

Additional vascular testing is indicated in select patients who do not achieve an erection with injection of vasoactive substances and who are candidates for vascular reconstructive surgery. Diagnostic tests, such as duplex ultrasound, penile cavernosography, and pudendal arteriography, can distinguish arterial from venous erectile dysfunction and help predict which patients may benefit from vascular surgery.

▶ Treatment

Most men suffering from erectile dysfunction can be treated successfully with one of the approaches outlined below. Men who do not suffer from organic dysfunction will probably benefit from behaviorally oriented sex therapy.

A. Hormonal Replacement

Testosterone replacement therapy is offered to men with documented hypogonadism who have undergone endocrinologic evaluation and in whom prostate cancer has been assessed by prostate-specific antigen (PSA) screening and DRE. Although testosterone replacement does not induce the development of prostate cancer, PSA levels do increase and should be monitored at least once a year in addition to DRE.

B. Vasoactive Therapy

Sexual stimulation with subsequent nitric oxide release from the parasympathetic nerves and endothelium initiates penile erection. Nitric oxide enters smooth muscle cells, increases cyclic guanosine monophosphate (cGMP) production, which mediates calcium sequestration and cellular hyperpolarization. Phosphodiesterase 5 (PDE-5) degrades cGMP and fosters penile detumescence.

1. Oral agents—Sildenafil, vardenafil, and tadalafil inhibit PDE-5, allowing cGMP to function unopposed, thereby sustaining inflow of blood into the erect penis. All drugs are similarly effective but have variable half-lives, receptor binding affinity, and side effects. Each drug should be initiated at the lowest dose and titrated to effect. There is no effect on libido, and priapism is exceedingly rare. The additive effect on nitrates may lead to exaggerated cardiac preload reduction and hypotension; therefore, the drug is contraindicated in patients taking nitroglycerin or nitrates. All patients being evaluated for acute chest pain should be asked if they are taking a PDE-5 inhibitor before adminis-

tering nitroglycerin. Fixed atherosclerotic disease in the aortoiliac system is associated with diminished efficacy. Some patients who do not respond to one PDE-5 inhibitor may respond to one of the other agents.

2. Injectable agents—Direct injection of vasoactive prostaglandins into the penis is an acceptable form of treatment for many men with erectile dysfunction. Injections are performed using a tuberculin syringe or a metered-dose injection device. The base and lateral aspect of the penis is used as the injection site to avoid injury to the superficial blood supply located anteriorly. Complications are rare and include bruising, dizziness, local pain, fibrosis, priapism, and infection. Vasoactive prostaglandins (alprostadil) can also be delivered via a urethral suppository with slightly less effectiveness.

The presence of a prolonged erection requires prompt medical attention to prevent erectile dysfunction and fibrosis of the cavernosal tissues. Initial management may include aspiration of blood from the penis or injection of sympathomimetic drugs (epinephrine or phenylephrine); if these maneuvers fail, surgical shunts may need to be performed to drain blood from the corpora cavernosa.

C. Vacuum Constriction Device

The vacuum constriction device induces erection by creating a vacuum chamber around the penis, whereby blood is drawn into the corpora cavernosa. Once adequate tumescence has been achieved, an elastic constriction band is placed around the proximal penile shaft to prevent loss of erection, and the vacuum cylinder is removed. Such devices are suitable for patients with venous disorders of the penis and those who do not achieve an adequate erection with injection of vasoactive substances. Complications are rare and the device is highly effective, but cumbersome with a high rate of discontinued use.

D. Penile Prostheses

Prosthetic devices may be implanted directly into the paired corporal bodies. Such prostheses may be semi-rigid and malleable or inflatable. Each is manufactured in a variety of sizes and diameters. Inflatable models may result in a more cosmetic appearance and better functionality. Complications are rare but include mechanical failure, infection, and injury to adjacent anatomic structures during surgery.

E. Vascular Reconstruction

Patients with disorders of the arterial system are candidates for various forms of arterial reconstruction, including endarterectomy and balloon dilation for proximal arterial occlusion and arterial bypass procedures utilizing arterial (epigastric) or venous (deep dorsal vein) segments for distal occlusion. Patients with venous disorders may be managed with ligation of certain veins (deep dorsal or emissary veins) or the crura of the corpora cavernosa. Experience with vascular reconstructive procedures is still limited, and many patients so treated still fail to achieve a rigid erection.

▶ When to Refer

- Patients with inadequate response to oral medications.
- Patients with Peyronie disease (penile curvature) or other penile deformity.
- Patients with a history of pelvic or perineal trauma or surgery.
- Young patients or those with lifelong erectile dysfunction.

MALE INFERTILITY

ESSENTIALS OF DIAGNOSIS

- ▶ Couple infertility is related to the male partner in 50% of cases.
- ▶ Causes include decreased or absent sperm production or function, or obstruction of the male genital tract.
- ▶ Detailed history, physical examination, and repeated semen analysis are the cornerstones of diagnosis and treatment.

▶ General Considerations

Infertility, the inability of a couple to conceive a child after 1 year of sexual intercourse without contraceptive use, affects 15–20% of US couples. Approximately one-third of cases result from male factors, one-third from female factors, and one-third from combined factors; therefore, evaluation of both partners is critical. Clinical evaluation is warranted following 6 months of unprotected intercourse in select couples. Following a detailed history and physical examination, a semen analysis is essential for diagnosis and should be performed at least twice, on two separate occasions (Figure 23–1). As spermatogenesis takes approximately 74 days, it is thus important to review events from the past 3 months.

▶ Clinical Findings

A. Symptoms and Signs

The history should include prior testicular insults (torsion, cryptorchidism, trauma), infections (mumps orchitis, epi-

didymitis), environmental factors (excessive heat, radiation, chemotherapy, prolonged pesticide exposure), medications (anabolic steroids, cimetidine, and spironolactone may affect spermatogenesis; phenytoin may lower FSH; sulfasalazine and nitrofurantoin affect sperm motility), and drugs (alcohol, tobacco, marijuana). Sexual habits, frequency and timing of intercourse, use of lubricants, and each partner's previous fertility experiences are important. Loss of libido and headaches, visual disturbances, or galactorrhea may indicate a pituitary tumor. The past medical or surgical history may reveal thyroid or liver disease (abnormalities of spermatogenesis), diabetic neuropathy (retrograde or anejaculation), radical pelvic or retroperitoneal surgery (absent seminal emission secondary to sympathetic nerve injury), or hernia repair (damage to the vas deferens or testicular blood supply).

Physical examination should pay particular attention to features of hypogonadism: underdeveloped secondary sexual characteristics, diminished male pattern hair distribution (axillary, body, facial, pubic), body habitus, and gynecostasia. The scrotal contents should be carefully evaluated. Testicular size should be noted (normal size approximately 4.5 × 2.5 cm, volume 18 mL). Varicoceles are abnormally dilated and refluxing veins of the pampiniform plexus that can be identified in the standing position by gentle palpation of the spermatic cord and, on occasion, may only be appreciated with the Valsalva maneuver. The vas deferens, epididymis, and prostate should be palpated (absence of all or part of the vas deferens may indicate the presence a cystic fibrosis variant, congenital bilateral or unilateral absence of the vas deferens).

B. Laboratory Findings

Semen analysis should be performed after 48–72 hours of abstinence. The specimen should be analyzed within 1 hour after collection. Abnormal sperm concentrations are less than 20 million/mL (**oligospermia** is the presence of less than 20 million sperm/mL in the ejaculate; **azoospermia** is the absence of sperm). Normal semen volumes range between 1.5 and 5 mL (volumes < 1.5 mL may result in inadequate buffering of the vaginal acidity and may be due to retrograde ejaculation or androgen insufficiency). Normal sperm motility and morphology demonstrate 50–60% motile cells and more than 30% or 4% normal (World Health Organization and Krueger guidelines, respectively) morphology. Abnormal motility may result from varicocele, antisperm antibodies, infection, abnormalities of the sperm flagella, or partial ejaculatory duct obstruction. Abnormal morphology may result from a varicocele, infection, or exposure history.

Endocrinologic evaluation is warranted if sperm counts are low or if there is a basis from the history and physical examination for suspecting an endocrinologic origin. Initial testing should include serum FSH and testosterone. Specific abnormalities in these hormones should prompt additional testing, including LH and prolactin. Elevated FSH and LH levels and low testosterone levels (hypergonadotropic hypogonadism) are associated with primary testicular failure. Low FSH and LH associated with low testosterone

▲ **Figure 23-1.** Male infertility: evaluation of male factor infertility. FSH, follicle-stimulating hormone; LH, luteinizing hormone; PRL, prolactin; T, testosterone. (From Nicoll D et al [editors]: *Pocket Guide to Diagnostic Tests*. McGraw-Hill, 2004. Adapted, with permission, from Swerdloff RS et al. Evaluation of the male partner of an infertile couple. An algorithmic approach. *JAMA*. 1982 May 7;247(17):2418-22. Copyright © 1982 by The American Medical Association.)

occur in secondary testicular failure (hypogonadotropic hypogonadism) and may be of hypothalamic or pituitary origin. Elevation of serum prolactin may indicate the presence of pituitary prolactinoma.

C. Genetic Testing

Men with sperm concentrations less than 10 million/mL should undergo testing for Y chromosome microdeletions and a karyotyping. Gene deletions from the long arm of the Y chromosome may cause azoospermia or oligospermia with age-related decline in spermatogenesis that is transmissible to male offspring. Karyotyping may reveal Klinefelter syndrome. Partial or complete absence of the vas deferens should prompt testing for cystic fibrosis mutations.

D. Imaging

Scrotal ultrasound may detect a subclinical varicocele. Vasography may be required in patients with suspected genital duct obstruction. Men with low ejaculate volume and no evidence of retrograde ejaculation should undergo transrectal ultrasound to evaluate the prostate and seminal vesicles.

E. Special Tests

Azoospermic patients should have post-ejaculation urine samples centrifuged and analyzed for sperm to evaluate for retrograde ejaculation. In cases of disproportionately low motility, sperm vitality and the presence of autoantibodies should be assessed. Round cells in concentrations greater

than 1 million/mL should prompt leukocyte esterase staining (immature germ cells are found normally, but inflammatory cells may require treatment).

► Treatment

A. General Measures

Education about the proper timing for intercourse in relation to the woman's ovulatory cycle as well as the avoidance of spermicidal lubricants should be discussed. In cases of toxic exposure or medication-related factors, the offending agent should be removed. Patients with active genitourinary tract infections should be treated with appropriate antibiotics.

B. Varicocele

Varicocelectomy is performed by arresting retrograde blood flow in spermatic cord veins. Surgical ligation may be accomplished via subinguinal, inguinal, retroperitoneal, or laparoscopic approaches. Percutaneous venographic embolization of varicoceles is feasible but may have a higher recurrence rate.

C. Endocrine Therapy

Hypogonadotropic hypogonadism may be treated with chorionic gonadotropin once primary pituitary disease has been excluded or treated. Dosage is usually 2000 international units intramuscularly three times a week. If sperm counts fail to rise after 12 months, FSH therapy should be initiated.

D. Ejaculatory Dysfunction Therapy

Patients with retrograde ejaculation may benefit from α -adrenergic agonists (pseudoephedrine, 60 mg orally three times a day) or imipramine (25 mg orally three times a day). Medical failures may require the collection of post-ejaculation urine for intrauterine insemination. Anejaculation can be treated with vibratory stimulation or electroejaculation in select cases.

E. Ductal Obstruction

Obstruction of the ejaculatory ducts may be corrected by transurethral resection of the ducts in the prostatic urethra. If obstruction of the vas deferens or epididymis is suspected, the level of obstruction must be determined via a vasogram prior to operative treatment, with the exception of prior vasectomy. Obstruction of the vas deferens is best managed by a microsurgical approach, and a vasovasostomy or vasoepididymostomy may be required.

F. Assisted Reproductive Techniques

Intrauterine insemination, in vitro fertilization, and intracytoplasmic sperm injection (ICSI) are alternatives to patients in whom other means of treating reduced sperm concentration, motility, or functionality has failed. With the use of ICSI, even azoospermic men can father their genetic progeny by surgical retrieval of sperm from the testicle, epididymis, or vas deferens.

► When to Refer

- Couples with clinical infertility or concern about fertility potential.
- Men with known genital insults, genetic diagnoses, or syndromes that preclude natural fertility.

BENIGN PROSTATIC HYPERPLASIA

ESSENTIALS OF DIAGNOSIS

- Obstructive or irritative voiding symptoms.
- May have enlarged prostate on rectal examination.
- Absence of urinary tract infection, neurologic disorder, stricture disease, prostatic or bladder malignancy.

► General Considerations

Benign prostatic hyperplasia is the most common benign tumor in men, and its incidence is age related. The prevalence of histologic benign prostatic hyperplasia in autopsy studies rises from approximately 20% in men aged 41–50 years, to 50% in men aged 51–60, and to over 90% in men over 80 years of age. Although clinical evidence of disease occurs less commonly, symptoms of prostatic obstruction are also age related. At age 55 years, approximately 25% of men report obstructive voiding symptoms. At age 75 years, 50% of men report a decrease in the force and caliber of the urinary stream.

Risk factors for the development of benign prostatic hyperplasia are poorly understood. Some studies have suggested a genetic predisposition and some have noted racial differences. Approximately 50% of men under age 60 years who undergo surgery for benign prostatic hyperplasia may have a heritable form of the disease. This form is most likely an autosomal dominant trait, and first-degree male relatives of such patients carry an increased relative risk of approximately fourfold.

► Clinical Findings

A. Symptoms

The symptoms of benign prostatic hyperplasia can be divided into obstructive and irritative complaints. Obstructive symptoms include hesitancy, decreased force

Table 23-4. American Urological Association symptom index for benign prostatic hyperplasia.¹

| Questions to Be Answered | Not at All | Less Than One Time in Five | Less Than Half the Time | About Half the Time | More Than Half the Time | Almost Always |
|--|------------|----------------------------|-------------------------|---------------------|-------------------------|---------------|
| 1. Over the past month, how often have you had a sensation of not emptying your bladder completely after you finish urinating? | 0 | 1 | 2 | 3 | 4 | 5 |
| 2. Over the past month, how often have you had to urinate again less than 2 hours after you finished urinating? | 0 | 1 | 2 | 3 | 4 | 5 |
| 3. Over the past month, how often have you found you stopped and started again several times when you urinated? | 0 | 1 | 2 | 3 | 4 | 5 |
| 4. Over the past month, how often have you found it difficult to postpone urination? | 0 | 1 | 2 | 3 | 4 | 5 |
| 5. Over the past month, how often have you had a weak urinary stream? | 0 | 1 | 2 | 3 | 4 | 5 |
| 6. Over the past month, how often have you had to push or strain to begin urination? | 0 | 1 | 2 | 3 | 4 | 5 |
| 7. Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning? | 0 | 1 | 2 | 3 | 4 | 5 |

¹Sum of seven circled numbers equals the symptom score. See text for explanation.

Reproduced, with permission, from Barry MJ et al. The American Urological Association symptom index for benign prostatic hyperplasia. *J Urol.* 1992 Nov;148(5):1549-57.

and caliber of the stream, sensation of incomplete bladder emptying, double voiding (urinating a second time within 2 hours), straining to urinate, and postvoid dribbling. Irritative symptoms include urgency, frequency, and nocturia.

The American Urological Association (AUA) symptom index (Table 23-4) is perhaps the single most important tool used in the evaluation of patients with this disorder and should be calculated for all patients before starting therapy. The answers to seven questions quantitate the severity of obstructive or irritative complaints on a scale of 0-5. Thus, the score can range from 0 to 35, in increasing severity of symptoms.

A detailed history focusing on the urinary tract should be obtained to exclude other possible causes of symptoms such as prostate cancer or disorders unrelated to the prostate such as urinary tract infection, neurogenic bladder, or urethral stricture.

B. Signs

A physical examination, DRE, and a focused neurologic examination should be performed on all patients. The size and consistency of the prostate should be noted, but prostate size does not correlate with the severity of symptoms or the degree of obstruction. Benign prostatic hyperplasia usually results in a smooth, firm, elastic enlargement of the prostate. Induration, if detected, must alert the clinician to the possibility of cancer, and further evaluation is needed (ie, PSA, transrectal ultrasound, and biopsy). Examination of the lower abdomen should be performed to assess for a distended bladder.

C. Laboratory Findings

Urinalysis should be performed to exclude infection or hematuria. A serum PSA is considered optional, yet most clinicians will include it in the initial evaluation, particularly if life expectancy is more than 10 years. PSA certainly increases the ability to detect prostate cancer over DRE alone; however, because there is much overlap between levels seen in benign prostatic hyperplasia and prostate cancer, its use remains controversial (see below in the section on screening for prostate cancer).

D. Imaging

Upper tract imaging (IVU, CT, or renal ultrasound) is recommended only in the presence of concomitant urinary tract disease or complications from benign prostatic hyperplasia (ie, hematuria, urinary tract infection, chronic kidney disease, history of stone disease).

E. Cystoscopy

Cystoscopy is not recommended to determine the need for treatment but may assist in determining the surgical approach in patients opting for invasive therapy.

F. Additional Tests

Cystometrograms and urodynamic profiles should be reserved for patients with suspected neurologic disease or those who have failed prostate surgery. Flow rates, postvoid residual urine determination, and pressure-flow studies are considered optional.

► Differential Diagnosis

A history of prior urethral instrumentation, urethritis, or trauma should be elucidated to exclude urethral stricture or bladder neck contracture. Hematuria and pain are commonly associated with bladder stones. Carcinoma of the prostate may be detected by abnormalities on the DRE or an elevated PSA (see **Chapter 39 for Prostate Cancer**). A urinary tract infection can mimic the irritative symptoms of benign prostatic hyperplasia and can be readily identified by urinalysis and culture; however, a urinary tract infection can also be a complication of benign prostatic hyperplasia. Carcinoma of the bladder, especially carcinoma in situ, may also present with irritative voiding complaints; however, urinalysis usually shows evidence of hematuria (see **Chapter 39 for Bladder Cancer**). Patients with a neurogenic bladder may also have many of the same symptoms and signs as those with benign prostatic hyperplasia; however, a history of neurologic disease, stroke, diabetes mellitus, or back injury may be obtained, and diminished perineal or lower extremity sensation or alterations in rectal sphincter tone or the bulbocavernosus

reflex might be observed on examination. Simultaneous alterations in bowel function (constipation) might also suggest the possibility of a neurologic disorder.

► Treatment

Clinical practice guidelines exist for the evaluation and treatment of patients with benign prostatic hyperplasia (Figure 23–2). Following evaluation as outlined above, patients should be offered various forms of therapy for benign prostatic hyperplasia. Patients are advised to consult with their primary care clinicians and make an educated decision on the basis of the relative efficacy and side effects of the treatment options (Table 23–5).

Patients with mild symptoms (AUA scores 0–7) should be managed by watchful waiting only. Absolute surgical indications are refractory urinary retention (failing at least one attempt at catheter removal), large bladder diverticula, or any of the following sequelae of benign prostatic hyperplasia: recurrent urinary tract infection, recurrent gross hematuria, bladder stones, or chronic kidney disease.

▲ **Figure 23–2.** Benign prostatic hyperplasia decision diagram. DRE, digital rectal examination; PSA, prostate-specific antigen; BPH, benign prostatic hyperplasia; TUIP, transurethral incision of the prostate; TURP, transurethral resection of the prostate.

Table 23-5. Balance sheet for benign prostatic hyperplasia treatment outcomes.¹

| Outcome | TUIP | Open Surgery | TURP | Watchful Waiting | α -Blockers | Finasteride ² |
|--|-----------|--------------|-----------|------------------|--------------------|--------------------------|
| Chance for improvement ¹ | 78-83% | 94-99.8% | 75-96% | 31-55% | 59-86% | 54-78% |
| Degree of symptom improvement (% reduction in symptom score) | 73% | 79% | 85% | Unknown | 51% | 31% |
| Morbidity and complications ¹ | 2.2-33.3% | 7-42.7% | 5.2-30.7% | 1-5% | 2.9-43.3% | 13.6-8.8% |
| Death within 30-90 days ¹ | 0.2-1.5% | 1-4.6% | 0.5-3.3% | 0.8% | 0.8% | 0.8% |
| Total incontinence ¹ | 0.1-1.1% | 0.3-0.7% | 0.7-1.4% | 2% | 2% | 2% |

| Retrograde ejaculation | 6-55% | 36-95% | 25-99% | 0 | 4-11% | 0 |
| Loss of work in days | 7-21 | 21-28 | 7-21 | 1 | 3.5 | 1.5 |
| Hospital stay in days | 1-3 | 5-10 | 3-5 | 0 | 0 | 0 |

¹90% confidence interval.

²Most of the data reviewed for finasteride are derived from three trials that have required an enlarged prostate for entry. The chance of improvement in men with symptoms yet minimally enlarged prostates may be much less, as noted from the VA Cooperative Trial. TUIP, transurethral incision of the prostate; TURP, transurethral resection of the prostate.

A. Watchful Waiting

The risk of progression or complications is uncertain. However, in men with symptomatic disease, it is clear that progression is not inevitable and that some men undergo spontaneous improvement or resolution of their symptoms.

Retrospective studies on the natural history of benign prostatic hyperplasia are inherently subject to bias, relating in part to patient selection and also to the type and extent of follow-up. Very few prospective studies addressing the natural history have been reported. One small series demonstrated that approximately 10% of symptomatic men may progress to urinary retention while 50% of patients demonstrate marked improvement or resolution of symptoms. A large randomized study compared finasteride with placebo in men with moderate to severely symptomatic disease and enlarged prostates on DRE. Patients in the placebo arm demonstrated a 7% risk of developing urinary retention over 4 years.

Men with moderate or severe symptoms can also be observed if they so choose. The optimal interval for follow-up is not defined, nor are the specific end points for intervention.

B. Medical Therapy

1. α -Blockers— α -Blockers can be classified according to their receptor selectivity as well as their half-life (Table 23-6).

Prazosin is effective; however, it requires dose titration and twice daily dosing. Typical side effects include orthostatic hypotension, dizziness, tiredness, retrograde ejaculation, rhinitis, and headache.

Long-acting α -blockers allow for once-a-day dosing, but dose titration is still necessary. Terazosin improves symptoms and in numerous studies is superior to placebo or finasteride. Terazosin is started at a dosage of 1 mg orally

daily for 3 days, increased to 2 mg orally daily for 11 days, then 5 mg orally daily. Additional dose escalation to 10 mg orally daily can be performed if necessary. Doxazosin is started at a dosage of 1 mg orally daily for 7 days, increased to 2 mg orally daily for 7 days, then 4 mg orally daily. Additional dose escalation to 8 mg orally daily can be performed if necessary. Side effects are similar to those described above for prazosin. Alfuzosin is a long-acting α -blocker; its dose is 10 mg orally once daily and does not require titration.

α_{1a} -Receptors are localized to the prostate and bladder neck. Selective blockade of these receptors results in fewer systemic side effects than α -blocker therapy (orthostatic hypotension, dizziness, tiredness, rhinitis, and headache), thus obviating the need for dose titration. The typical dose of tamsulosin is 0.4 mg orally daily taken 30 minutes after a meal. Several randomized, double-blind, placebo-controlled trials have been performed comparing terazosin, doxazosin, tamsulosin, and alfuzosin with placebo. All agents have demonstrated safety and efficacy.

Table 23-6. α -Blockade for benign prostatic hyperplasia.

| Agent | Action | Oral Dose |
|------------------|---------------------------------------|---------------------|
| Phenoxybenzamine | α_1 - and α_2 -Blockade | 5-10 mg twice daily |
| Prazosin | α_1 -Blockade | 1-5 mg twice daily |
| Terazosin | α_1 -Blockade | 1-10 mg daily |
| Doxazosin | α_1 -Blockade | 1-8 mg daily |
| Alfuzosin | α_1 -Blockade | 10 mg daily |
| Tamsulosin | α_{1a} -Blockade | 0.4 or 0.8 mg daily |

2. 5 α -Reductase inhibitors—Finasteride is a 5 α -reductase inhibitor that blocks the conversion of testosterone to dihydrotestosterone. This drug impacts upon the epithelial component of the prostate, resulting in reduction in size of the gland and improvement in symptoms. Six months of therapy is required for maximum effects on prostate size (20% reduction) and symptomatic improvement.

Several randomized, double-blind, placebo-controlled trials have been performed comparing finasteride with placebo. Efficacy, safety, and durability are well established. However, symptomatic improvement is seen only in men with enlarged prostates (> 40 mL by ultrasonographic examination). Side effects include decreased libido, decrease in volume of ejaculate, and impotence. Serum PSA is reduced by approximately 50% in patients receiving finasteride therapy. Therefore, in order to compare with pre-finasteride levels, the serum PSA of a patient taking finasteride should be doubled.

A report suggests that finasteride therapy may decrease the incidence of urinary retention and the need for operative treatment in men with enlarged prostates and moderate to severe symptoms. The larger the prostate over 40 mL, the greater the relative-risk reduction. However, optimal identification of appropriate patients for prophylactic therapy remains to be determined. Dutasteride is a dual 5 α -reductase inhibitor that appears to be similar to finasteride in its effectiveness; its dose is 0.5 mg orally daily.

3. Combination therapy—The four-arm Veterans Administration Cooperative Trial compared placebo, finasteride alone, terazosin alone, and combination of finasteride and terazosin. Over 1200 patients participated, and significant decreases in symptom scores and increases in urinary flow rates were seen only in the arms containing terazosin. However, enlarged prostates were not an entry criterion; in fact, prostate size in this study was much smaller than in previous controlled trials using finasteride (32 versus 52 mL). Other randomized, placebo-controlled trials comparing finasteride with placebo in men with lower urinary tract symptoms and large prostates showed finasteride to be beneficial for reducing symptoms, increasing urinary flow rate, and reducing the risk of complications due to benign prostatic hyperplasia as well as reducing the number of men who required surgery for benign prostatic hyperplasia. The Medical Therapy of Prostatic Symptoms (MTOps) trial is a large, randomized, placebo-controlled trial comparing finasteride, doxazosin, the combination of the two, and placebo in 3047 men observed for a mean of 4.5 years. Long-term combination therapy with doxazosin and finasteride was safe and reduced the risk of overall clinical progression of benign prostatic hyperplasia significantly more than did treatment with either drug alone. Combination therapy and finasteride alone reduced the long-term risk of acute urinary retention and the need for invasive therapy. Combination therapy had the risks of additional side effects and the cost of two medications.

4. Phytotherapy—Phytotherapy is the use of plants or plant extracts for medicinal purposes. Its use in benign prostatic hyperplasia has been popular in Europe for years, and its use in the United States is growing as a result of

patient-driven enthusiasm. Several plant extracts have been popularized, including the saw palmetto berry, the bark of *Pygeum africanum*, the roots of *Echinacea purpurea* and *Hypoxis rooperi*, pollen extract, and the leaves of the trembling poplar. The mechanisms of action of these agents are unknown. A 2006 prospective, randomized, double-blind, placebo-controlled trial revealed no improvement in symptoms, urinary flow rate, or quality of life for men with benign prostatic hyperplasia with saw palmetto treatment compared with placebo.

C. Conventional Surgical Therapy

1. Transurethral resection of the prostate (TURP)—Ninety-five percent of simple prostatectomies can be performed endoscopically. Most of these procedures are performed under a spinal anesthetic and require a 1- to 2-day hospital stay. Symptom scores and flow rate improvement are superior following TURP relative to any minimally invasive therapy; however, the length of the hospital stay is greater. Much controversy revolves around possible higher rates of morbidity and mortality associated with TURP in comparison with open surgery, but the higher rates observed in one study probably related to more significant comorbidities in the TURP patients compared with the patients who received open surgical treatment. Several other studies could not confirm the difference in mortality when controlling for age and comorbidities. The risks of TURP include retrograde ejaculation (75%), impotence (5–10%), and urinary incontinence (< 1%). Complications include bleeding, urethral stricture or bladder neck contracture, perforation of the prostate capsule with extravasation, and, if severe, transurethral resection syndrome, a hypervolemic, hyponatremic state resulting from absorption of the hypotonic irrigating solution. Clinical manifestations of the syndrome include nausea, vomiting, confusion, hypertension, bradycardia, and visual disturbances. The risk of transurethral resection syndrome increases with resection times over 90 minutes. Treatment includes diuresis and, in severe cases, hypertonic saline administration.

2. Transurethral incision of the prostate (TUIP)—Men with moderate to severe symptoms and small prostates often have posterior commissure hyperplasia or an “elevated bladder neck.” These patients will often benefit from incision of the prostate. The procedure is more rapid and less morbid than TURP. Outcomes in well-selected patients are comparable, though a lower rate of retrograde ejaculation has been reported (25%).

3. Open simple prostatectomy—When the prostate is too large to remove endoscopically, open enucleation is necessary. What size is “too large” depends upon the surgeon’s experience with TURP. Glands over 100 g are usually considered for open enucleation. In addition to size, other relative indications for open prostatectomy include concomitant bladder diverticulum or bladder stone and whether dorsal lithotomy positioning is or is not possible.

Open prostatectomies can be performed with either a suprapubic or retropubic approach. Simple suprapubic

prostatectomy is performed transvesically and is the operation of choice if there is concomitant bladder pathology. After the adenoma is removed, both a urethral and a suprapubic catheter are inserted prior to closure.

In simple retropubic prostatectomy, the bladder is not entered but rather a transverse incision is made in the surgical capsule of the prostate and the adenoma is enucleated as described above; only a urethral catheter is needed at the end of the case.

D. Minimally Invasive Therapy

1. Laser therapy—Several different coagulation necrosis techniques have been utilized. Transurethral laser-induced prostatectomy (TULIP) is performed under transrectal ultrasound guidance. The instrument is placed in the urethra and transrectal ultrasound is used to direct the device as it is slowly pulled from the bladder neck to the apex. The depth of treatment is monitored with ultrasound.

Most urologists prefer to use visually directed laser techniques. Visual coagulative necrosis is performed under cystoscopic control, and the laser fiber is pulled through the prostate at several designated areas depending upon the size and configuration of the gland. Four-quadrant and sextant approaches have been described for lateral lobes, with additional treatments directed at enlarged median lobes. Coagulative techniques do not create an immediate visual defect in the prostatic urethra—tissue is sloughed over the course of several weeks up to 3 months following the procedure.

Visual contact ablative techniques take longer in the operating room because the fiber is placed in direct contact with the prostate tissue, which is vaporized. Photovaporization of the prostate (PVP), an alternative laser technique, uses a high-power KTP laser. An immediate defect is obtained in the prostatic urethra, similar to that seen during TURP.

Interstitial laser therapy places fibers directly into the prostate, usually under cystoscopic control. Irritative voiding symptoms may be less in these patients as the urethral mucosa is spared and prostate tissue is resorbed by the body rather than sloughed.

Advantages to laser surgery include minimal blood loss, rare occurrence of transurethral resection syndrome, the ability to treat patients while on anticoagulation therapy, and outpatient surgery. Disadvantages are the lack of tissue for pathologic examination, the longer postoperative catheterization time, the more frequent irritative voiding complaints, and the expense of laser fibers and generators.

Large multicenter, randomized studies with long-term follow-up are needed in comparing laser prostate surgery with TURP and other forms of minimally invasive surgery.

2. Transurethral needle ablation of the prostate (TUNA)—This procedure uses a specially designed urethral catheter that is passed into the urethra. Interstitial radiofrequency needles are then deployed from the tip of the catheter, piercing the mucosa of the prostatic urethra. Radiofrequencies are then used to heat the tissue, resulting in coagulative necrosis. Bladder neck and median lobe enlargement are not well treated by TUNA. Subjective and objective improvement in voiding occurs. In randomized trials comparing TUNA to TURP, similar improvement was seen when comparing life scores, peak urinary flow rates, and postvoid residual urine.

3. Transurethral electrovaporization of the prostate—This technique uses the standard resectoscope. High current densities result in heat vaporization of tissue, creating a cavity in the prostatic urethra. Because the device requires slower sweeping speeds over the prostatic urethra and the depth of vaporization is approximately one-third of a standard loop, this procedure usually takes longer than a standard TURP. Long-term comparative data are needed.

4. Hyperthermia—Microwave hyperthermia is most commonly delivered with a transurethral catheter. Some devices cool the urethral mucosa to decrease the risk of injury. However, if temperatures do not go above 45 °C, cooling is unnecessary. Symptom score and flow rate improvement are obtained, but (as with laser surgery) large randomized studies with long-term follow-up are needed to assess durability and cost-effectiveness.

► When to Refer

- Progression to urinary retention.
- Patient dissatisfaction with medical therapy.
- Need for surgical intervention or further evaluation (cystoscopy).

Nervous System Disorders

Michael J. Aminoff, MD, DSc, FRCP

HEADACHE

Headache is such a common complaint and can occur for so many different reasons that its proper evaluation may be difficult. Headaches of acute onset are discussed in Chapter 2. Chronic headaches are commonly due to migraine, tension, or depression, but they may be related to intracranial lesions, head injury, cervical spondylosis, dental or ocular disease, temporomandibular joint dysfunction, sinusitis, hypertension, and a wide variety of general medical disorders. Although underlying structural lesions are not present in most patients presenting with headache, it is nevertheless important to bear this possibility in mind. About one-third of patients with brain tumors, for example, present with a primary complaint of headache.

The intensity, quality, and site of pain—and especially the duration of the headache and the presence of associated neurologic symptoms—may provide clues to the underlying cause. Migraine headaches are often described as pulsating or throbbing; a sense of tightness or pressure is common with tension headache. Sharp lancinating pain suggests a neuritic cause; ocular or periorbital icepick-like pains occur with migraine or cluster headache; and a dull or steady headache is typical of an intracranial mass lesion. Ocular or periocular pain suggests an ophthalmologic disorder; band-like pain is common with tension headaches; and lateralized headache is common with migraine or cluster headache. In patients with sinusitis, there may be tenderness of overlying skin and bone. With intracranial mass lesions, headache may be focal or generalized; in patients with trigeminal or glossopharyngeal neuralgia, the pain is localized to one of the divisions of the trigeminal nerve or to the pharynx and external auditory meatus, respectively.

Inquiry should be made of precipitating factors. Recent sinusitis, dental surgery, head injury, or symptoms suggestive of a systemic viral infection may suggest the underlying cause. Migraine may be exacerbated by emotional stress, fatigue, foods containing nitrite or tyramine, or the menstrual period. Alcohol may precipitate cluster headache. Temporomandibular joint dysfunction causes headache or facial pain that comes on with chewing; trigeminal or glossopharyngeal neuralgia may also be precipitated by chewing, and masticatory claudication sometimes occurs

with giant cell arteritis. Cough-induced headache occurs with structural lesions of the posterior fossa, but in many instances no specific cause can be found.

The timing of symptoms is important. Headaches are typically worse on awakening in patients with an intracranial mass or sleep apnea. Cluster headaches tend to occur at the same time each day or night. Tension headaches are worse with stress or at the end of the day.

The onset of severe headache in a previously well patient is more likely than chronic headache to relate to an intracranial disorder such as subarachnoid hemorrhage or meningitis. The need for further investigation is determined by the initial clinical impression.

A progressive headache disorder, new onset of headache in middle or later life, headaches that disturb sleep or are related to exertion, and headaches that are associated with neurologic symptoms or a focal neurologic deficit usually require cranial MRI or CT scan to exclude an intracranial mass lesion. Signs of meningeal irritation and impairment of consciousness also indicate the need for further investigation (cranial CT scan or MRI and examination of the cerebrospinal fluid) to exclude subarachnoid hemorrhage or meningeal infection. The diagnosis and treatment of primary neurologic disorders associated with headache are considered separately under these disorders.

1. Tension-type Headache

Although this is the most common type of primary headache disorder, many patients do not seek medical attention. Patients frequently complain of pericranial tenderness, poor concentration, and other vague nonspecific symptoms, in addition to constant daily headaches that are often vise-like or tight in quality but are not pulsatile. Headaches may be exacerbated by emotional stress, fatigue, noise, or glare. The headaches are usually generalized, may be most intense about the neck or back of the head, and are not associated with focal neurologic symptoms.

When treatment with simple analgesics is not effective, a trial of antimigrainous agents (see Migraine, below) is worthwhile. Techniques to induce relaxation are also useful and include massage, hot baths, and biofeedback. Exploration of underlying causes of chronic anxiety is

often rewarding. Local injection of botulinum toxin type A is sometimes helpful, has few systemic adverse effects, and requires only infrequent administration.

2. Depression Headache

Depression headaches are frequently worse on arising in the morning and may be accompanied by other symptoms of depression. Headaches are occasionally the focus of a somatic delusional system. Antidepressant drugs are often helpful, as may be psychiatric consultation.

3. Migraine

ESSENTIALS OF DIAGNOSIS

- ▶ Headache, usually pulsatile.
- ▶ Pain is typically, but not always, unilateral.
- ▶ Nausea, vomiting, photophobia, and phonophobia are common accompaniments.
- ▶ May be transient neurologic symptoms (commonly visual) preceding headache of classic migraine.
- ▶ No preceding aura is common.

▶ General Considerations

The pathophysiology of migraine probably relates to neurovascular dysfunction. Headache results from the dilatation of blood vessels innervated by the trigeminal nerve caused by release of neuropeptides from parasympathetic nerve fibers approximating these vessels. The probable underlying mechanism is activation of the trigeminal nucleus caudalis, nucleus tractus solitarius, and dorsal raphe nucleus. Imaging studies have revealed changes in brainstem regions involved in sensory modulation, suggesting that migraine relates to a failure of normal sensory processing. Before or simultaneous with symptom onset, regional cerebral blood flow is decreased in the cortex corresponding to the clinically affected area; after one to several hours, hyperemia occurs in this same region. Cortical spreading depression of Leão has been implicated.

▶ Clinical Findings

Classic migrainous headache is a lateralized throbbing headache that occurs episodically following its onset in adolescence or early adult life. In many cases, however, the headaches do not conform to this pattern, although their associated features and response to antimigrainous preparations nevertheless suggest that they have a similar basis. In this broader sense, migrainous headaches may be lateralized or generalized, may be dull or throbbing, and are sometimes associated with anorexia, nausea, vomiting, photophobia, phonophobia, osmophobia, cognitive impairment, and blurring of vision. They usually build up gradually and may last for several hours or longer. Focal disturbances of neurologic function may precede or accompany the headaches and have been attributed to constriction of branches

of the internal carotid artery. Visual disturbances occur commonly and may consist of field defects; of luminous visual hallucinations such as stars, sparks, unformed light flashes (photopsia), geometric patterns, or zigzags of light; or of some combination of field defects and luminous hallucinations (scintillating scotomas). Other focal disturbances such as aphasia or numbness, paresthesias, clumsiness, dysarthria, disequilibrium, or weakness in a circumscribed distribution may also occur.

In rare instances, the neurologic or somatic disturbance accompanying typical migrainous headaches becomes the sole manifestation of an attack ("migraine equivalent"). Very rarely, the patient may be left with a permanent neurologic deficit following a migrainous attack.

Patients often give a family history of migraine. Attacks may be triggered by emotional or physical stress, lack or excess of sleep, missed meals, specific foods (eg, chocolate), alcoholic beverages, bright lights, loud noise, menstruation, or use of oral contraceptives.

An uncommon variant is **basilar artery migraine**, in which blindness or visual disturbances throughout both visual fields are initially accompanied or followed by dysarthria, disequilibrium, tinnitus, and perioral and distal paresthesias and are sometimes followed by transient loss or impairment of consciousness or by a confusional state. This, in turn, is followed by a throbbing (usually occipital) headache, often with nausea and vomiting.

In **ophthalmoplegic migraine**, lateralized pain—often about the eye—is accompanied by nausea, vomiting, and diplopia due to transient external ophthalmoplegia. The ophthalmoplegia is due to third nerve palsy, sometimes with accompanying sixth nerve involvement, and may outlast the orbital pain by several days or even weeks. The ophthalmic division of the fifth nerve has also been affected in some patients. Ophthalmoplegic migraine is rare; more common causes of a painful ophthalmoplegia are internal carotid artery aneurysms and diabetes.

Familial hemiplegic migraine (FHM) designates the occurrence of migraine with aura including weakness when at least one first- or second-degree relative has a similar disorder. Specific genetic subtypes are recognized: in FHM1, mutations occur in the *CACNA1A* gene on chromosome 19, and in FHM2, mutations occur in the *ATP1A2* gene on chromosome 1. In **sporadic hemiplegic migraine**, no other family members are affected.

▶ Treatment

Management of migraine consists of avoidance of any precipitating factors, together with prophylactic or symptomatic pharmacologic treatment if necessary.

A. Symptomatic Therapy

During acute attacks, many patients find it helpful to rest in a quiet, darkened room until symptoms subside. A simple analgesic (eg, aspirin, acetaminophen, ibuprofen, or naproxen) taken right away often provides relief, but treatment with prescription therapy is sometimes necessary. To prevent medication overuse, use of simple analgesics should be limited to 15 days or less per month, and

combination analgesics should be limited to less than 10 days per month.

Cafergot, a combination of ergotamine tartrate (1 mg) and caffeine (100 mg), is often particularly helpful; one or two tablets are taken at the onset of headache or warning symptoms, followed by one tablet every 30 minutes, if necessary, up to six tablets per attack and no more than 10 days per month. Because of impaired absorption or vomiting during acute attacks, oral medication sometimes fails to help. Cafergot given rectally as suppositories (one-half to one suppository containing 2 mg of ergotamine) or dihydroergotamine mesylate (0.5–1 mg intravenously or 1–2 mg subcutaneously or intramuscularly) may be useful in such cases. Alternatively, prochlorperazine administered rectally (25 mg suppository) or intravenously (10 mg) may be prescribed. Ergotamine-containing preparations may affect the gravid uterus and thus should be avoided during pregnancy.

Sumatriptan, which has a high affinity for serotonin₁ receptors, is a rapidly effective agent for aborting attacks when given subcutaneously by an autoinjection device. It can also be taken in a nasal form, but absorption is limited, and an oral preparation is available. Zolmitriptan, another selective serotonin₁ receptor agonist, has high bioavailability after oral administration and is also effective for the acute treatment of migraine. The optimal initial dose is 5 mg, and relief usually occurs within 1 hour. It is also available in a nasal formulation, which has a rapid onset of action. A number of other triptans are available, including rizatriptan, naratriptan, almotriptan, frovatriptan, and eletriptan. Eletriptan (up to 80 mg over 24 hours) is useful for acute therapy and frovatriptan, which has a longer half-life, may be worthwhile for patients with prolonged attacks (up to 7.5 mg over 24 hours). Triptans may cause nausea and vomiting. They should probably be avoided in women who are pregnant, in patients with hemiplegic or basilar migraine, and in patients with risk factors for stroke (such

as hypertension, prior stroke or transient ischemic attack, diabetes mellitus, hypercholesterolemia, obesity). Triptans are contraindicated in patients with coronary or peripheral vascular disease. Patients often experience greater benefit when the triptan is combined with naproxen (500 mg).

The neuroleptic droperidol is also helpful in aborting acute attacks. Metoclopramide given intravenously may be helpful and is being studied. Opioid analgesics are needed in rare instances, as when patients are unable to use vasoactive agents or nonsteroidal medications; options include meperidine (100 mg intramuscularly) or butorphanol tartrate by nasal spray (1 mg/spray in one nostril, repeated after 3 or 4 hours if necessary). Intravenous propofol in subanesthetic doses may help in intractable cases.

B. Preventive Therapy

Preventive treatment may be necessary if migrainous headaches occur more frequently than two or three times a month or significant disability is associated with attacks. Some of the more common drugs used for this purpose are listed in Table 24–1. Their mode of action is unclear but may involve alteration of central neurotransmission. Several drugs may have to be tried in turn before the headaches are brought under control. Once a drug has been found to help, it should be continued for several months. If the patient remains headache-free, the dose can then be tapered and the drug eventually withdrawn. Botulinum toxin type A may be effective for migraine prevention in some patients; it has few systemic side effects and need only be given at intervals of several months. However, no statistically significant between-group differences were found in frequency of migraine episodes per 30-day period in a randomized, double-blind, placebo-controlled exploratory study. Although acupuncture has been widely used in the prophylaxis of migraine, a randomized controlled trial failed to show any difference between it and sham acupuncture.

Table 24–1. Prophylactic treatment of migraine.

| Drug | Usual Adult Daily Dose | Common Side Effects |
|--------------------------|------------------------|--|
| Propranolol ¹ | 80–240 mg | Fatigue, lassitude, depression, insomnia, nausea, vomiting, constipation. |
| Amitriptyline | 10–150 mg | Sedation, dry mouth, constipation, weight gain, blurred vision, edema, hypotension, urinary retention. |
| Imipramine | 10–150 mg | Similar to those of amitriptyline (above). |
| Sertraline | 50–200 mg | Anxiety, insomnia, sweating, tremor, gastrointestinal disturbances. |
| Fluoxetine | 20–60 mg | Similar to those of sertraline (above). |
| Cyproheptadine | 12–20 mg | Sedation, dry mouth, epigastric discomfort, gastrointestinal disturbances. |
| Clonidine | 0.2–0.6 mg | Dry mouth, drowsiness, sedation, headache, constipation. |
| Verapamil ² | 80–160 mg | Headache, hypotension, flushing, edema, constipation. May aggravate atrioventricular nodal heart block and congestive heart failure. |

¹Other β -blockers (eg, timolol and metoprolol) have also been used.

²Other calcium channel antagonists (eg, nimodipine, nicardipine, and diltiazem) have also been used.

Botulinum toxin type A injected locally into the scalp is effective for prophylaxis in some patients. The antiseizure agents valproic acid (500–1500 mg), gabapentin (900–2400 mg), and topiramate (50–200 mg) are also effective and are detailed in Table 24–3. Valproic acid should be avoided during pregnancy.

Calcium channel antagonist drugs may decrease the frequency of attacks after an interval of several weeks, but the severity and duration of attacks are not influenced. They should not be used with β -blockers. The angiotensin-converting enzyme receptor blocker, candesartan, may also be effective and is undergoing evaluation.

4. Cluster Headache

Cluster headache affects predominantly middle-aged men. The pathophysiology is unclear but may relate to activation of cells in the ipsilateral hypothalamus, triggering the trigeminal autonomic vascular system. There is often no family history of headache or migraine. Episodes of severe unilateral periorbital pain occur daily for several weeks and are often accompanied by one or more of the following: ipsilateral nasal congestion, rhinorrhea, lacrimation, redness of the eye, and Horner syndrome. During attacks, patients are often restless and agitated. Episodes often occur at night, awaken the patient, and last for between 15 minutes and 3 hours. Spontaneous remission then occurs, and the patient remains well for weeks or months before another bout of closely spaced attacks occurs. Bouts may last for 4 to 8 weeks and may occur up to several times per year. During a bout, many patients report that alcohol triggers an attack; others report that stress, glare, or ingestion of specific foods occasionally precipitates attacks. In occasional patients, typical attacks of pain and associated symptoms recur at intervals without remission. This variant has been referred to as chronic cluster headache.

Examination reveals no abnormality apart from Horner syndrome that either occurs transiently during an attack or, in longstanding cases, remains as a residual deficit between attacks.

Treatment of an individual attack with oral drugs is generally unsatisfactory, but subcutaneous (6 mg dose) or intranasal (20-mg/spray) sumatriptan or inhalation of 100% oxygen (12–15 L/min for 15 minutes via a non-rebreather mask) may be effective. Zolmitriptan (5- and 10-mg nasal spray) is also effective. Dihydroergotamine (0.5–1 mg intramuscularly or intravenously) is sometimes used. Viscous lidocaine (1 mg of 4–6% solution) intranasally is sometimes effective.

Various prophylactic agents that have been found to be effective in individual patients are cyproheptadine, lithium carbonate (monitored by plasma lithium determination), verapamil (240–960 mg daily), topiramate (100–400 mg daily), valproate (750–1500 mg daily), and methysergide (2–12 mg daily). As there is often a delay before these medications are effective, transitional therapy is often used. Ergotamine tartrate is effective and can be given as rectal suppositories (0.5–1 mg at night or twice daily), by mouth (2 mg daily), or by subcutaneous injection (0.25 mg three times daily for 5 days per week). Other options include prednisone (60 mg daily for 5 days followed by gradual withdrawal), dihydroergotamine (9.25 mg intravenously over several days or 0.5 mg intramuscularly twice daily), or greater occipital nerve injection with lidocaine and corticosteroid.

5. Posttraumatic Headache

A variety of nonspecific symptoms may follow closed head injury, regardless of whether consciousness is lost. Headache is often a conspicuous feature.

The headache itself usually appears within a day or so following injury, may worsen over the ensuing weeks, and then gradually subsides. It is usually a constant dull ache, with superimposed throbbing that may be localized, lateralized, or generalized. It is sometimes accompanied by nausea, vomiting, or scintillating scotomas. Headaches occurring more than 1–2 weeks after the inciting event are probably not directly attributable to the head injury.

Disequilibrium, sometimes with a rotatory component, may also occur and is often enhanced by postural change or head movement. Impaired memory, poor concentration, emotional instability, and increased irritability are other common complaints and occasionally are the sole manifestations of the syndrome. The duration of symptoms relates in part to the severity of the original injury, but even trivial injuries are sometimes followed by symptoms that persist for months.

Special investigations are usually not helpful. The electroencephalogram may show minor nonspecific changes, while the electronystagmogram sometimes suggests either peripheral or central vestibulopathy. CT scans or MRI of the head usually show no abnormal findings.

Treatment is difficult, but optimistic encouragement and graduated rehabilitation, depending on the occupational circumstances, are advised as symptoms often resolve spontaneously within several months. Headaches often respond to simple analgesics, but severe headaches may necessitate treatment with amitriptyline, antiseizure medication, propranolol, or ergot derivatives.

6. Cough Headache

Severe head pain may be produced by coughing (and by straining, sneezing, and laughing) but, fortunately, usually lasts for only a few minutes or less. The pathophysiologic basis of the complaint is not known, and often there is no underlying structural lesion. However, intracranial lesions, usually in the posterior fossa (eg, Arnold-Chiari malformation), are present in about 10% of cases, and brain tumors or other space-occupying lesions may certainly present in this way. Accordingly, CT scanning or MRI should be undertaken in all patients and repeated annually for several years, since a small structural lesion may not show up initially.

The disorder is usually self-limited, although it may persist for several years. For unknown reasons, symptoms sometimes clear completely after lumbar puncture. Indomethacin (75–150 mg daily) may provide relief.

7. Headache Due to Giant Cell (Temporal or Cranial) Arteritis

The superficial temporal, vertebral, ophthalmic, and posterior ciliary arteries are often the most severely affected pathologically. Most patients are elderly. The major symptom is headache, often associated with or preceded by myalgia, malaise, anorexia, weight loss, and other nonspe-

cific complaints. Loss of vision is the most feared manifestation and occurs quite commonly. Clinical examination often reveals tenderness of the scalp and over the temporal arteries. Further details, including approaches to treatment, are given in Chapter 20.

8. Headache Due to Intracranial Mass Lesions

Intracranial mass lesions of all types may cause headache owing to displacement of vascular structures and other pain-sensitive tissues. Posterior fossa tumors often cause occipital pain, and supratentorial lesions lead to bifrontal headache, but such findings are too inconsistent to be of value in attempts at localizing a pathologic process. The headaches are nonspecific in character and may vary in severity from mild to severe. They may be worsened by exertion or postural change and may be associated with nausea and vomiting, but this is true of migraine also. Headaches are also a feature of pseudotumor cerebri (see below). Signs of focal or diffuse cerebral dysfunction or of increased intracranial pressure will indicate the need for further investigation. Similarly, a progressive headache disorder or the new onset of headaches in middle or later life merits investigation if no cause is apparent.

9. Medication Overuse (Analgesic Rebound) Headache

In approximately half of all patients with chronic daily headaches, medication overuse is responsible. They present with chronic pain or with complaints of severe headache unresponsive to medication. Diagnosis is important as patients rarely respond to treatment until the offending medications are discontinued. Withdrawal of analgesics leads to relief of headache within several months.

10. Headache Due to Other Neurologic Causes

Cerebrovascular disease may be associated with headache, but the mechanism is unclear. Headache may occur with internal carotid artery occlusion or carotid dissection and after carotid endarterectomy. Diagnosis is facilitated by the clinical accompaniments and the circumstances in which the headache developed.

Acute severe headache accompanies subarachnoid hemorrhage and meningitis; accompanying signs of meningeal irritation and impairment of consciousness indicate the need for further investigations.

Dull or throbbing headache is a frequent sequela of lumbar puncture and may last for several days. It is aggravated by the erect posture and alleviated by recumbency. The exact mechanism is unclear, but it is commonly attributed to leakage of cerebrospinal fluid through the dural puncture site. Its incidence may be reduced if a small-diameter needle is used for the spinal tap, and perhaps also if the patient lies prone or supine after the procedure.

▶ When to Refer

- Acute onset of “worst headache in my life.”

- Increasing headache unresponsive to simple measures.
- History of trauma, hypertension, fever, visual changes.
- Presence of neurologic signs or of scalp tenderness.

▶ When to Admit

- Suspected subarachnoid hemorrhage or structural intracranial lesion.
- Depends on underlying cause.

FACIAL PAIN

1. Trigeminal Neuralgia

ESSENTIALS OF DIAGNOSIS

- ▶ Brief episodes of stabbing facial pain.
- ▶ Pain is in the territory of the second and third division of the trigeminal nerve.
- ▶ Pain exacerbated by touch.

▶ General Considerations

Trigeminal neuralgia (“tic douloureux”) is most common in middle and later life. It affects women more frequently than men.

▶ Clinical Findings

Momentary episodes of sudden lancinating facial pain occur and commonly arise near one side of the mouth and shoot toward the ear, eye, or nostril on that side. The pain may be triggered or precipitated by such factors as touch, movement, drafts, and eating. Indeed, in order to lessen the likelihood of triggering further attacks, many patients

try to hold the face still while talking. Spontaneous remissions for several months or longer may occur. As the disorder progresses, however, the episodes of pain become more frequent, remissions become shorter and less common, and a dull ache may persist between the episodes of stabbing pain. Symptoms remain confined to the distribution of the trigeminal nerve (usually the second or third division) on one side only.

► Differential Diagnosis

The characteristic features of the pain in trigeminal neuralgia usually distinguish it from other causes of facial pain. Neurologic examination shows no abnormality except in a few patients in whom trigeminal neuralgia is symptomatic of some underlying lesion, such as multiple sclerosis or a brainstem neoplasm, in which case the finding will depend on the nature and site of the lesion. Similarly, CT scans and radiologic contrast studies are often normal in patients with classic trigeminal neuralgia.

In a young patient presenting with trigeminal neuralgia, multiple sclerosis must be suspected even if there are no other neurologic signs. In such circumstances, findings on evoked potential testing and examination of cerebrospinal fluid may be corroborative. When the facial pain is due to a posterior fossa tumor, CT scanning and MRI generally reveal the lesion.

► Treatment

The drugs most helpful for treatment are oxcarbazepine (although not approved by the US Food and Drug Administration [FDA] for this indication) or carbamazepine, with monitoring by serial blood counts and liver function tests. If these medications are ineffective or cannot be tolerated, phenytoin should be tried. (Doses and side effects of these drugs are shown in Table 24–3). Baclofen (10–20 mg three or four times daily) or lamotrigine (400 mg orally daily) may also be helpful, either alone or in combination with one of these other agents. Gabapentin may also relieve pain, especially in patients who do not respond to conventional medical therapy and those with multiple sclerosis. Depending on response and tolerance, up to 2400 mg/d is given in divided doses.

In the past, alcohol injection of the affected nerve, rhizotomy, or tractotomy was recommended if pharmacologic treatment was unsuccessful. More recently, however, posterior fossa exploration has frequently revealed some structural cause for the neuralgia (despite normal findings on CT scans, MRI, or arteriograms), such as an anomalous artery or vein impinging on the trigeminal nerve root. In such cases, simple decompression and separation of the anomalous vessel from the nerve root produce lasting relief of symptoms. In elderly patients with a limited life expectancy, radiofrequency rhizotomy is sometimes preferred because it is easy to perform, has few complications, and provides symptomatic relief for a period of time. Gamma radiosurgery to the trigeminal root is another noninvasive approach that appears to be successful in 80% of patients, with essentially no side effects other than facial paresthesias in a few instances. Surgical exploration generally reveals no

abnormality and is inappropriate in patients with trigeminal neuralgia due to multiple sclerosis.

Report of the Quality Standards Subcommittee of the American Academy of Neurology and the European Federation of Neurological Societies. *Neurology*. 2008 Oct 7;71(15):1183–90. [PMID: 18716236]

2. Atypical Facial Pain

Facial pain without the typical features of trigeminal neuralgia is generally a constant, often burning pain that may have a restricted distribution at its onset but soon spreads to the rest of the face on the affected side and sometimes involves the other side, the neck, or the back of the head as well. The disorder is especially common in middle-aged women, many of them depressed, but it is not clear whether depression is the cause of or a reaction to the pain. Simple analgesics should be given a trial, as should tricyclic antidepressants, carbamazepine, oxcarbazepine, and phenytoin; the response is often disappointing. Opioid analgesics pose a danger of addiction in patients with this disorder. Attempts at surgical treatment are not indicated.

3. Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia is an uncommon disorder in which pain similar in quality to that in trigeminal neuralgia occurs in the throat, about the tonsillar fossa, and sometimes deep in the ear and at the back of the tongue. The pain may be precipitated by swallowing, chewing, talking, or yawning and is sometimes accompanied by syncope. In most instances, no underlying structural abnormality is present; multiple sclerosis is sometimes responsible. Oxcarbazepine and carbamazepine (see Table 24–3) are the treatments of choice and should be tried before any surgical procedures are considered. Microvascular decompression is generally preferred over destructive surgical procedures such as partial rhizotomy in medically refractory cases and is often effective without causing severe complications.

4. Postherpetic Neuralgia

Herpes zoster (shingles) is due to infection of the nervous system by varicella-zoster virus. About 15% of patients who develop shingles suffer from postherpetic neuralgia. This complication seems especially likely to occur in the elderly, when the rash is severe, and when the first division of the trigeminal nerve is affected. It also relates to the duration of the rash before medical consultation. A history of shingles and the presence of cutaneous scarring resulting from shingles aid in the diagnosis. Severe pain with shingles correlates with the intensity of postherpetic symptoms.

The incidence of postherpetic neuralgia may be reduced by the treatment of shingles with oral acyclovir or famciclovir, but this is disputed; systemic corticosteroids do not help. Zoster vaccine markedly reduces morbidity from herpes zoster and postherpetic neuralgia among

older adults. Management of the established complication is essentially medical. If simple analgesics fail to help, a trial of a tricyclic antidepressant (eg, amitriptyline, up to 100–150 mg/d) in conjunction with a phenothiazine (eg, perphenazine, 2–8 mg/d) is often effective. Other patients respond to carbamazepine (up to 1200 mg/d), phenytoin (300 mg/d), gabapentin (up to 3600 mg/d), or pregabalin (up to 300 mg/d). A combination of gabapentin and morphine taken orally may provide better analgesia at lower doses of each agent than either taken alone. Topical application of capsaicin cream (eg, Zostrix, 0.025%) is sometimes helpful, perhaps because of depletion of pain-mediating peptides from peripheral sensory neurons, and topical lidocaine (5%) is also worthy of trial. The administration of live-attenuated zoster vaccine to patients over the age of 60 years is important in preventing the occurrence of herpes zoster and thus of postherpetic neuralgia.

5. Facial Pain Due to Other Causes

Facial pain may be caused by temporomandibular joint dysfunction in patients with malocclusion, abnormal bite, or faulty dentures. There may be tenderness of the masticatory muscles, and an association between pain onset and jaw movement is sometimes noted. This pattern differs from that of jaw (masticatory) claudication, a symptom of giant cell arteritis, in which pain develops progressively with mastication. Treatment of the underlying joint dysfunction relieves symptoms.

A relationship of facial pain to chewing or temperature changes may suggest a dental disturbance. The cause is sometimes not obvious, and diagnosis requires careful dental examination and radiographs. Sinusitis and ear infections causing facial pain are usually recognized by the history of respiratory tract infection, fever, and, in some instances, aural discharge. There may be localized tenderness. Radiologic evidence of sinus infection or mastoiditis is confirmatory.

Glaucoma is an important ocular cause of facial pain, usually localized to the periorbital region.

On occasion, pain in the jaw may be the principal manifestation of angina pectoris. Precipitation by exertion and radiation to more typical areas establish the cardiac origin.

▶ When to Refer

- Worsening pain unresponsive to simple measures.
- Continuing pain of uncertain cause.
- For consideration of surgical treatment (trigeminal or glossopharyngeal neuralgia).

EPILEPSY

ESSENTIALS OF DIAGNOSIS

- ▶ Recurrent seizures.
- ▶ Characteristic electroencephalographic changes accompany seizures.
- ▶ Mental status abnormalities or focal neurologic symptoms may persist for hours postictally.

▶ General Considerations

The term “epilepsy” denotes any disorder characterized by recurrent unprovoked seizures. A seizure is a transient disturbance of cerebral function due to an abnormal paroxysmal neuronal discharge in the brain. Epilepsy is common, affecting approximately 0.5% of the population in the United States.

▶ Etiology

Epilepsy has several causes. Its most likely cause in individual patients relates to the age at onset.

A. Idiopathic or Constitutional Epilepsy

Seizures usually begin between 5 and 20 years of age but may start later in life. No specific cause can be identified, and there is no other neurologic abnormality.

B. Symptomatic Epilepsy

There are many causes for recurrent seizures.

1. Pediatric age groups—Congenital abnormalities and perinatal injuries may result in seizures presenting in infancy or childhood.

2. Metabolic disorders—Withdrawal from alcohol or drugs is a common cause of recurrent seizures, and other metabolic disorders such as uremia and hypoglycemia or hyperglycemia may also be responsible. Since these seizures are provoked by a readily reversible cause, this would not be considered as epilepsy.

3. Trauma—Trauma is an important cause of seizures at any age, but especially in young adults. Posttraumatic epilepsy is more likely to develop if the dura mater was penetrated and generally becomes manifest within 2 years following the injury. However, seizures developing in the first week after head injury do not necessarily imply that future attacks will occur. There is no clear evidence that prophylactic anticonvulsant drug treatment reduces the incidence of posttraumatic epilepsy.

4. Tumors and other space-occupying lesions—Neoplasms may lead to seizures at any age, but they are an especially important cause of seizures in middle and later life, when the incidence of neoplastic disease increases. The seizures are commonly the initial symptoms of the tumor and often are partial (focal) in character. They are most

likely to occur with structural lesions involving the frontal, parietal, or temporal regions. Tumors must be excluded by appropriate imaging studies in all patients with onset of seizures after 30 years of age, focal seizures or signs, or a progressive seizure disorder.

5. Vascular diseases—Vascular diseases become increasingly frequent causes of seizures with advancing age and are the most common cause of seizures with onset at age 60 years or older.

6. Degenerative disorders—Alzheimer disease and other degenerative disorders are a cause of seizures in later life.

7. Infectious diseases—Infectious diseases must be considered in all age groups as potentially reversible causes of seizures. Seizures may occur with an acute infective or inflammatory illness, such as bacterial meningitis or herpes encephalitis, or in patients with more longstanding or chronic disorders such as neurosyphilis or cerebral cysticercosis. In patients with AIDS, they may result from central nervous system toxoplasmosis, cryptococcal meningitis, secondary viral encephalitis, or other infective complications. Seizures are a common sequela of supratentorial brain abscess, developing most frequently in the first year after treatment.

► Classification of Seizures

Seizures can be categorized in various ways, but the descriptive classification proposed by the International League Against Epilepsy is clinically the most useful. Seizures are divided into those that are generalized and those affecting only part of the brain (partial seizures) (Table 24–2).

A. Partial Seizures

The initial clinical and electroencephalographic manifestations of partial seizures indicate that only a restricted part of one cerebral hemisphere has been activated. The ictal manifestations depend on the area of the brain involved. Partial seizures are subdivided into simple seizures, in which consciousness is preserved, and complex seizures, in which it is impaired. Partial seizures of either type sometimes become secondarily generalized, leading to a tonic, clonic, or tonic-clonic attack.

1. Simple partial seizures—Simple seizures may be manifested by focal motor symptoms (convulsive jerking) or somatosensory symptoms (eg, paresthesias or tingling) that spread (or “march”) to different parts of the limb or body depending on their cortical representation. In other instances, special sensory symptoms (eg, light flashes or buzzing) indicate involvement of visual, auditory, olfactory, or gustatory regions of the brain, or there may be autonomic symptoms or signs (eg, abnormal epigastric sensations, sweating, flushing, pupillary dilation). The sole manifestations of some seizures are phenomena such as dysphasia, dysmnestic symptoms (eg, déjà vu, jamais vu), affective disturbances, illusions, or structured hallucinations, but such symptoms are usually accompanied by impairment of consciousness.

2. Complex partial seizures—Impaired consciousness may be preceded, accompanied, or followed by the psychic symptoms mentioned above, and automatisms may occur. Such seizures may also begin with some of the other simple symptoms mentioned above.

Table 24–2. Seizure classification.

| Seizure Type | Key Features | Other Associated Features |
|-----------------------------|--|---|
| Partial seizures | Involvement of only restricted part of brain; may become secondarily generalized | |
| Simple partial | Consciousness preserved | May be manifested by focal motor, sensory, or autonomic symptoms |
| Complex partial | Consciousness impaired | Above symptoms may precede, accompany, or follow |
| Generalized seizures | Diffuse involvement of brain at onset | |
| Absence (petit mal) | Consciousness impaired briefly; patient often unaware of attacks | May be clonic, tonic, or atonic components (ie, loss of postural tone); autonomic components (eg, enuresis); or accompanying automatisms Almost always begin in childhood and frequently cease by age 20 |
| Atypical absences | May be more gradual in onset and termination than typical absence | More marked changes in tone may occur |
| Myoclonic | Single or multiple myoclonic jerks | |
| Tonic-clonic (grand mal) | Tonic phase: Sudden loss of consciousness, with rigidity and arrest of respiration, lasting < 1 minute Clonic phase: Jerking occurs, usually for < 2–3 minutes Flaccid coma: Variable duration | May be accompanied by tongue biting, incontinence, or aspiration; commonly followed by postictal confusion variable in duration |
| Status epilepticus | Repeated seizures without recovery between them; a fixed and enduring epileptic condition lasting 30 minutes | |

B. Generalized Seizures

There are several different varieties of generalized seizures, as outlined below. In some circumstances, seizures cannot be classified because of incomplete information or because they do not fit into any category.

1. Absence (petit mal) seizures—These are characterized by impairment of consciousness, sometimes with mild clonic, tonic, or atonic components (ie, reduction or loss of postural tone), autonomic components (eg, enuresis), or accompanying automatisms. Onset and termination of attacks are abrupt. If attacks occur during conversation, the patient may miss a few words or may break off in mid sentence for a few seconds. The impairment of external awareness is so brief that the patient is unaware of it. Absence seizures almost always begin in childhood and frequently cease by the age of 20 years, although occasionally they are then replaced by other forms of generalized seizure. Electroencephalographically, such attacks are associated with bursts of bilaterally synchronous and symmetric 3-Hz spike-and-wave activity. A normal background in the electroencephalogram and normal or above-normal intelligence imply a good prognosis for the ultimate cessation of these seizures.

2. Atypical absences—There may be more marked changes in tone, or attacks may have a more gradual onset and termination than in typical absences. They commonly occur in patients with multiple seizure types, may be accompanied by developmental delay or mental retardation, and are associated with slower spike-wave discharges than those in typical absence attacks.

3. Myoclonic seizures—Myoclonic seizures consist of single or multiple myoclonic jerks.

4. Tonic-clonic (grand mal) seizures—In these seizures, which are characterized by sudden loss of consciousness, the patient becomes rigid and falls to the ground, and respiration is arrested. This tonic phase, which usually lasts for less than a minute, is followed by a clonic phase in which there is jerking of the body musculature that may last for 2 or 3 minutes and is then followed by a stage of flaccid coma. During the seizure, the tongue or lips may be bitten, urinary or fecal incontinence may occur, and the patient may be injured. Immediately after the seizure, the patient may either recover consciousness, drift into sleep, have a further convulsion without recovery of consciousness between the attacks (**status epilepticus**), or after recovering consciousness have a further convulsion (**serial seizures**). In other cases, patients will behave in an abnormal fashion in the immediate postictal period, without subsequent awareness or memory of events (**postepileptic automatism**). Headache, disorientation, confusion, drowsiness, nausea, soreness of the muscles, or some combination of these symptoms commonly occurs postictally.

5. Tonic, clonic, or atonic seizures—Loss of consciousness may occur with either the tonic or clonic accompaniments described above, especially in children. Atonic seizures (**epileptic drop attacks**) have also been described.

▶ Clinical Findings

A. Symptoms and Signs

Nonspecific changes such as headache, mood alterations, lethargy, and myoclonic jerking alert some patients to an impending seizure hours before it occurs. These prodromal symptoms are distinct from the aura which may precede a generalized seizure by a few seconds or minutes and which is itself a part of the attack, arising locally from a restricted region of the brain.

In most patients, seizures occur unpredictably at any time and without any relationship to posture or ongoing activities. Occasionally, however, they occur at a particular time (eg, during sleep) or in relation to external precipitants such as lack of sleep, missed meals, emotional stress, menstruation, alcohol ingestion (or alcohol withdrawal; see below), or use of certain drugs. Fever and nonspecific infections may also precipitate seizures in known epileptics. In a few patients, seizures are provoked by specific stimuli such as flashing lights or a flickering television set (**photosensitive epilepsy**), music, or reading.

Clinical examination between seizures shows no abnormality in patients with idiopathic epilepsy, but in the immediate postictal period, extensor plantar responses may be seen. The presence of lateralized or focal signs postictally suggests that seizures may have a focal origin. In patients with symptomatic epilepsy, the findings on examination will reflect the underlying cause.

B. Imaging

MRI is indicated for patients with focal neurologic symptoms or signs, focal seizures, or electroencephalographic findings of a focal disturbance; some clinicians routinely order imaging studies for all patients with new-onset seizure disorders. Such studies should certainly be performed in patients with clinical evidence of a progressive disorder and in those presenting with new onset of seizures after the age of 20 years, because of the possibility of an underlying neoplasm. A chest radiograph should also be obtained in such patients, since the lungs are a common site for primary or secondary neoplasms.

C. Laboratory and Other Studies

Initial investigations should always include a full blood count, blood glucose determination, liver and kidney function tests, and serologic tests for syphilis. The hematologic and biochemical screening tests are important both in excluding various causes of seizures and in providing a baseline for subsequent monitoring of long-term effects of treatment.

Electroencephalography may support the clinical diagnosis of epilepsy (by demonstrating paroxysmal abnormalities containing spikes or sharp waves), may provide a guide to prognosis, and may help classify the seizure disorder. Classification of the disorder is important for determining the most appropriate anticonvulsant drug with which to start treatment. For example, absence (petit mal) and complex partial seizures may be difficult to distinguish clinically, but the electroencephalographic findings and treat-

ment of choice differ in these two conditions. Finally, by localizing the epileptogenic source, the electroencephalographic findings are important in evaluating candidates for surgical treatment.

► Differential Diagnosis

The distinction between the various disorders likely to be confused with generalized seizures is usually made on the basis of the history. The importance of obtaining an eyewitness account of the attacks cannot be overemphasized.

A. Differential Diagnosis of Partial Seizures

1. Transient ischemic attacks—These attacks are distinguished from seizures by their longer duration, lack of spread, and symptoms. Level of consciousness, which is unaltered, does not distinguish them. There is a loss of motor or sensory function (eg, weakness or numbness) with transient ischemic attacks, whereas positive symptoms (eg, convulsive jerking or paresthesias) characterize seizures.

2. Rage attacks—Rage attacks are usually situational and lead to goal-directed aggressive behavior.

3. Panic attacks—These may be hard to distinguish from simple or complex partial seizures unless there is evidence of psychopathologic disturbances between attacks and the attacks have a clear relationship to external circumstances.

B. Differential Diagnosis of Generalized Seizures

1. Syncope—Syncope usually occurs in relation to postural change, emotional stress, instrumentation, pain, or straining. They are typically preceded by pallor, sweating, nausea, and malaise and lead to loss of consciousness accompanied by flaccidity; recovery occurs rapidly with recumbency, and there is no postictal headache or confusion. In some instances, however, motor accompaniments may simulate a seizure. Serum creatine kinase measured about 3 hours after the event is generally normal after syncopal episodes but markedly elevated after tonic-clonic seizures.

2. Cardiac dysrhythmias—Cerebral hypoperfusion due to a disturbance of cardiac rhythm should be suspected in patients with known cardiac or vascular disease or in elderly patients who present with episodic loss of consciousness. Prodromal symptoms are typically absent. A relationship of attacks to physical activity and the finding of a systolic murmur is suggestive of aortic stenosis. Repeated Holter monitoring may be necessary to establish the diagnosis; monitoring initiated by the patient (“event monitor”) may be valuable if the disturbances of consciousness are rare.

3. Brainstem ischemia—Loss of consciousness is preceded or accompanied by other brainstem signs. Basilar artery migraine and vertebrobasilar vascular disease are discussed elsewhere in this chapter.

4. Pseudoseizures—The term “pseudoseizures” is used to denote both hysterical conversion reactions and attacks due to malingering when these simulate epileptic seizures.

Many patients with pseudoseizures also have true seizures or a family history of epilepsy. Although pseudoseizures tend to occur at times of emotional stress, this may also be the case with true seizures.

Clinically, the attacks superficially resemble tonic-clonic seizures, but there may be obvious preparation before pseudoseizures occur. Moreover, there is usually no tonic phase; instead, there is an asynchronous thrashing of the limbs, which increases if restraints are imposed and which rarely leads to injury. Consciousness may be normal or “lost,” but in the latter context the occurrence of goal-directed behavior or of shouting, swearing, etc, indicates that it is feigned. Postictally, there are no changes in behavior or neurologic findings.

Laboratory studies may aid in recognition of pseudoseizures. There are no electrocerebral changes, whereas the electroencephalogram changes during organic seizures accompanied by loss of consciousness. The serum level of prolactin has been found to increase dramatically between 15 and 30 minutes after a tonic-clonic convulsion in most patients, whereas it is unchanged after a pseudoseizure. Serum creatine kinase levels also increase after convulsions but not pseudoseizures.

► Treatment

A. General Measures

For patients with epilepsy, drug treatment is prescribed with the goal of preventing further attacks and is usually continued until there have been no seizures for at least 3 years. Epileptic patients should be advised to avoid situations that could be dangerous or life-threatening if further seizures should occur. State legislation may require clinicians to report to the state department of public health any patients with seizures or other episodic disturbances of consciousness.

1. Choice of medication—The drug with which treatment is best initiated depends on the type of seizures to be treated (Table 24–3). The dose of the selected drug is gradually increased until seizures are controlled or side effects prevent further increases. If seizures continue despite treatment at the maximal tolerated dose, a second drug is added and the dose increased depending on tolerance; the first drug is then gradually withdrawn. In treatment of partial and secondarily generalized tonic-clonic seizures, the success rate is higher with carbamazepine, phenytoin, or valproic acid than with phenobarbital or primidone. Gabapentin, topiramate, lamotrigine, oxcarbazepine, levetiracetam, and zonisamide are newer antiepileptic drugs that are effective for partial or secondarily generalized seizures. Felbamate is also effective for such seizures but, because it may cause aplastic anemia or fulminant hepatic failure, should be used only in selected patients unresponsive to other measures. Tiagabine is another adjunctive agent for partial seizures. Valproate is better tolerated than topiramate and more efficacious than lamotrigine and is thus preferred for many patients with generalized or unclassified seizures, but its teratogenic potential makes its use undesirable in women of childbearing age.

Table 24-3. Drug treatment for seizures in adults.

| Drug | Usual Adult Daily Dose | Minimum No. of Daily Doses | Time to Steady State Drug Levels | Optimal Drug Level | Selected Side Effects and Idiosyncratic Reactions |
|---|------------------------|----------------------------|----------------------------------|--------------------|---|
| Generalized tonic-clonic (grand mal) or partial (focal) seizures | | | | | |
| Phenytoin | 200-400 mg | 1 | 5-10 days | 10-20 mcg/mL | Nystagmus, ataxia, dysarthria, sedation, confusion, gingival hyperplasia, hirsutism, megaloblastic anemia, blood dyscrasias, skin rashes, fever, systemic lupus erythematosus, lymphadenopathy, peripheral neuropathy, dyskinesias. |
| Carbamazepine (extended-release formulation) | 600-1200 mg | 2-3 (2) | 3-4 days | 4-8 mcg/mL | Nystagmus, dysarthria, diplopia, ataxia, drowsiness, nausea, blood dyscrasias, hepatotoxicity, hyponatremia. May exacerbate myoclonic seizures. |
| Valproic acid | 1500-2000 mg | 2-3 | 2-4 days | 50-100 mcg/mL | Nausea, vomiting, diarrhea, drowsiness, alopecia, weight gain, hepatotoxicity, thrombocytopenia, tremor, pancreatitis. |
| Phenobarbital | 100-200 mg | 1 | 14-21 days | 10-40 mcg/mL | Drowsiness, nystagmus, ataxia, skin rashes, learning difficulties, hyperactivity. |
| Primidone | 750-1500 mg | 3 | 4-7 days | 5-15 mcg/mL | Sedation, nystagmus, ataxia, vertigo, nausea, skin rashes, megaloblastic anemia, irritability. |
| Lamotrigine ^{1,2,5} | 100-500 mg | 2 | 4-5 days | ? | Sedation, skin rash, visual disturbances, dyspepsia, ataxia. |
| Topiramate ¹⁻⁴ | 200-400 mg | 2 | 4 days | ? | Somnolence, nausea, dyspepsia, irritability, dizziness, ataxia, nystagmus, diplopia, glaucoma, renal calculi, weight loss, hypohidrosis, hyperthermia. |
| Oxcarbazepine ^{1,3} | 900-1800 mg | 2 | 2-3 days | ? | As for carbamazepine. |
| Levetiracetam ^{1,2} | 1000-3000 mg | 2 | 2 days | ? | Somnolence, ataxia, headache, behavioral changes. |
| Zonisamide ¹ | 200-600 mg | 1 | 10 days | ? | Somnolence, ataxia, anorexia, nausea, vomiting, rash, confusion, renal calculi. Do not use in patients with sulfonamide allergy. |
| Tiagabine ¹ | 32-56 mg | 2 | 2 days | ? | Somnolence, anxiety, dizziness, poor concentration, tremor, diarrhea. |
| Pregabalin ¹ | 150-300 mg | 2 | 2-4 days | ? | Somnolence, dizziness, poor concentration, weight gain, thrombocytopenia, skin rashes, anaphylactoid reactions. |
| Gabapentin ¹ | 900-3600 mg | 3 | 1 day | ? | Sedation, fatigue, ataxia, nystagmus, weight loss. |
| Felbamate ^{1,3,6} | 1200-3600 mg | 3 | 4-5 days | ? | Anorexia, nausea, vomiting, headache, insomnia, weight loss, dizziness, hepatotoxicity, aplastic anemia. |
| Absence (petit mal) seizures | | | | | |
| Ethosuximide | 100-1500 mg | 2 | 5-10 days | 40-100 mcg/mL | Nausea, vomiting, anorexia, headache, lethargy, unsteadiness, blood dyscrasias, systemic lupus erythematosus, urticaria, pruritus. |
| Valproic acid | 1500-2000 mg | 3 | 2-4 days | 50-100 mcg/mL | See above. |
| Clonazepam | 0.04-0.2 mg/kg | 2 | ? | 20-80 ng/mL | Drowsiness, ataxia, irritability, behavioral changes, exacerbation of tonic-clonic seizures. |
| Myoclonic seizures | | | | | |
| Valproic acid | 1500-2000 mg | 3 | 2-4 days | 50-100 mcg/mL | See above. |
| Clonazepam | 0.04-0.2 mg/kg | 2 | ? | 20-80 ng/mL | See above. |

¹Approved as adjunctive therapy for partial-onset seizures.²Approved as adjunctive therapy for primary generalized tonic-clonic seizures.³Approved as initial monotherapy for partial-onset seizures.⁴Approved as initial monotherapy for primary generalized tonic-clonic seizures.⁵Approved as monotherapy (after conversion from another drug) in partial-onset seizures.⁶Not to be used as a first-line drug; when used, blood counts should be performed regularly (every 2-4 weeks). Should be used only in selected patients because of risk of aplastic anemia and hepatic failure. It is advisable to obtain written informed consent before use.

Phenytoin, phenobarbital, and carbamazepine are also potentially teratogenic. The teratogenicity of the newer antiseizure medications is less clear, although there is evidence that lamotrigine, oxcarbazepine, and topiramate may be teratogenic. In most patients with seizures of a single type, satisfactory control can be achieved with a single anticonvulsant drug. Treatment with two drugs may further reduce seizure frequency or severity, but usually only at the cost of greater toxicity. Treatment with more than two drugs is almost always unhelpful unless the patient is having seizures of different types.

2. Monitoring—Monitoring serum drug levels has led to major advances in the management of seizure disorders. The same daily dose of a particular drug leads to markedly different blood concentrations in different patients, and this will affect the therapeutic response. In general, the dose of an antiepileptic agent is increased depending on the clinical response regardless of the serum drug level. The trough drug level is then measured to provide a reference point for the maximum tolerated dose. Dosing should not be based simply on serum levels because many patients require levels that exceed the therapeutic range (“toxic levels”) but tolerate these without ill effect. Steady-state drug levels in the blood should be measured after treatment is initiated, dosage is changed, or another drug is added to the therapeutic regimen and when seizures are poorly controlled. Dose adjustments are then guided by the laboratory findings. The most common cause of a lower concentration of drug than expected for the prescribed dose is poor patient compliance. Compliance can be improved by limiting to a minimum the number of daily doses. Recurrent seizures or status epilepticus may result if drugs are taken erratically, and in some circumstances noncompliant patients may be better off without any medication.

All anticonvulsant drugs have side effects, and some of these are shown in Table 24–3.

In most patients, a complete blood count should be performed at least annually because of the risk of anemia or blood dyscrasia. Treatment with certain drugs may require more frequent monitoring or use of additional screening tests. For example, periodic tests of hepatic function are necessary if valproic acid, carbamazepine, or felbamate is used, and serial blood counts are important with carbamazepine, ethosuximide, or felbamate.

3. Discontinuance of medication—Only when adult patients have been seizure-free for 2 years should withdrawal of medication be considered. Unfortunately, there is no way of predicting which patients can be managed successfully without treatment, although seizure recurrence is more likely in patients who initially failed to respond to therapy, those with seizures having focal features or of multiple types, and those with continuing electroencephalographic abnormalities. Dose reduction should be gradual over a period of weeks or months, and drugs should be withdrawn one at a time. If seizures recur, treatment is reinstated with the same drugs used previously. Seizures are no more difficult to control after a recurrence than before.

4. Surgical treatment—Patients with surgically remediable epilepsy or seizures refractory to pharmacologic management may be candidates for operative treatment, which is best undertaken in specialized centers.

5. Vagal nerve stimulation—Treatment by chronic vagal nerve stimulation for adults and adolescents with medically refractory partial-onset seizures is approved in the United States and provides an alternative approach for patients who are not optimal candidates for surgical treatment. The mechanism of therapeutic action is unknown. Adverse effects consist mainly of transient hoarseness during stimulus delivery.

B. Special Circumstances

1. Solitary seizures—In patients who have had only one seizure, investigation as outlined above should exclude an underlying cause requiring specific treatment. An EEG should also be performed, preferably within 24 hours after the seizure, because the findings may influence management—especially when focal abnormalities are present. Prophylactic anticonvulsant drug treatment is generally not required unless further attacks occur or investigations reveal some underlying pathology that itself is untreatable. The risk of seizure recurrence varies in different series between about 30% and 70%. Epilepsy should not be diagnosed on the basis of a solitary seizure. If seizures occur in the context of transient, nonrecurrent systemic disorders such as acute cerebral anoxia, the diagnosis of epilepsy is inaccurate, and long-term prophylactic anticonvulsant drug treatment is unnecessary.

2. Alcohol withdrawal seizures—One or more generalized tonic-clonic seizures may occur within 48 hours or so of withdrawal from alcohol after a period of high or chronic intake. Patients should be hospitalized for at least 24 hours for observation and to follow the severity of withdrawal symptoms. If the seizures have consistently focal features, the possibility of an associated structural abnormality, often traumatic in origin, must be considered. Head CT scan or MRI should be performed in patients with new onset of generalized seizures and whenever there are focal features associated with any seizures. Treatment with anticonvulsant drugs is generally not required for alcohol withdrawal seizures, since they are self-limited. Benzodiazepines (diazepam or lorazepam) are effective and safe for preventing further seizures. Status epilepticus may rarely follow alcohol withdrawal and is managed along conventional lines (see below). Further attacks will not occur if the patient abstains from alcohol.

3. Tonic-clonic status epilepticus—Poor compliance with the anticonvulsant drug regimen is the most common cause; others include alcohol withdrawal, intracranial infection or neoplasms, metabolic disorders, and drug overdose. The mortality rate may be as high as 20%, and among survivors the incidence of neurologic and mental sequelae may be high. The prognosis relates to the length of time between onset of status epilepticus and the start of effective treatment.

Status epilepticus is a medical emergency. Initial management includes maintenance of the airway and 50% dextrose (25–50 mL) intravenously in case hypoglycemia is responsible. If seizures continue, an intravenous bolus of lorazepam, 4 mg, is given and repeated once after 10 minutes if necessary; alternatively, 10 mg of diazepam is given intravenously over the course of 2 minutes, and the dose is repeated after 10 minutes if necessary. This is usually effective in halting seizures for a brief period but occasionally causes respiratory depression.

Regardless of the response to lorazepam or diazepam, phenytoin (18–20 mg/kg) is given intravenously at a rate of 50 mg/min; this provides initiation of long-term seizure control. The drug is best injected directly but can also be given in saline; it precipitates, however, if injected into glucose-containing solutions. Because arrhythmias may develop during rapid administration of phenytoin, electrocardiographic monitoring is prudent. Hypotension may complicate phenytoin administration, especially if diazepam has also been given. In many countries, injectable phenytoin has been replaced by fosphenytoin, which is rapidly and completely converted to phenytoin following intravenous administration. No dosing adjustments are necessary because fosphenytoin is expressed in terms of phenytoin equivalents (PE); fosphenytoin is less likely to cause reactions at the infusion site, can be given with all common intravenous solutions, and may be administered at a faster rate (150 mg PE/min). It is also more expensive.

If seizures continue, phenobarbital is then given in a loading dose of 10–20 mg/kg intravenously by slow or intermittent injection (50 mg/min). Respiratory depression and hypotension are common complications and should be anticipated; they may occur also with diazepam alone, although less commonly. If these measures fail, general anesthesia with ventilatory assistance and neuromuscular junction blockade may be required. Alternatively, intravenous midazolam may provide control of refractory status epilepticus; the suggested loading dose is 0.2 mg/kg, followed by 0.05–0.2 mg/kg/h.

After status epilepticus is controlled, an oral drug program for the long-term management of seizures is started, and investigations into the cause of the disorder are pursued.

4. Nonconvulsive status epilepticus—Absence (petit mal) and complex partial status epilepticus are characterized by fluctuating abnormal mental status, confusion, impaired responsiveness, and automatism. Electroencephalography is helpful both in establishing the diagnosis and in distinguishing the two varieties. Initial treatment with intravenous diazepam or lorazepam is usually helpful regardless of the type of status epilepticus, but phenytoin, phenobarbital, carbamazepine, and other drugs may also be needed to obtain and maintain control in complex partial status epilepticus.

▶ When to Refer

- Behavioral episodes are of uncertain nature.
- Seizures are difficult to control or have focal features.

- There are accompanying neurologic signs.
- There is a progressive neurologic disorder.

▶ When to Admit

- Status epilepticus.
- For monitoring, when pseudoseizures are suspected.
- If surgery is contemplated.

DYSAUTONOMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Abnormalities of blood pressure or heart rate regulation, sweating, intestinal motility, sphincter control, sexual function, respiration, or ocular function, occurring in isolation or any combination.

▶ General Considerations

Dysautonomia may occur as a result of central or peripheral pathologic processes. It is manifested by a variety of symptoms that may occur in isolation or in various combinations and relate to abnormalities of blood pressure regulation, thermoregulatory sweating, gastrointestinal function, sphincter control, sexual function, respiration, and ocular function. Syncope, a symptom of dysautonomia, is characterized by a transient loss of consciousness, usually accompanied by hypotension and bradycardia. It may occur in response to emotional stress, postural hypotension, vigorous exercise in a hot environment, obstructed venous return to the heart, acute pain or its anticipation, fluid loss, and a variety of other circumstances.

A. Central Neurologic Causes

Disease at certain sites in the central nervous system, regardless of its nature, may lead to dysautonomic symptoms. Postural hypotension, which is usually the most troublesome and disabling symptom, may result from spinal cord transec-

tion and other myelopathies (eg, due to tumor or syringomyelia) above the T6 level or from brainstem lesions such as syringobulbia and posterior fossa tumors. Sphincter or sexual disturbances may result from cord lesions below T6. Certain primary degenerative disorders are responsible for dysautonomia occurring in isolation (**pure autonomic failure**) or in association with more widespread abnormalities (**multisystem atrophy** or **Shy-Drager syndrome**) that may include parkinsonian, pyramidal symptoms, and cerebellar deficits.

B. Peripheral Neurologic Causes

A pure autonomic neuropathy may occur acutely or subacutely after a viral infection or as a paraneoplastic disorder related usually to small cell lung cancer, particularly in association with certain antibodies, such as anti-Hu or those directed at neuronal nicotinic acetylcholine receptors. Typically, presenting symptoms include postural hypotension, impaired thermoregulatory sweating, xerostomia or xerophthalmia, abnormal gastrointestinal motility, dilated pupils, or acute urinary retention. Dysautonomia is often conspicuous in patients with Guillain-Barré syndrome, manifesting with marked hypotension or hypertension or cardiac arrhythmias that may have a fatal outcome. It may also occur with diabetic, uremic, amyloidotic, and various other metabolic or toxic neuropathies; in association with leprosy or Chagas disease; and as a feature of certain hereditary neuropathies with autosomal dominant or recessive inheritance or an X-linked pattern. Autonomic symptoms are prominent in the crises of hepatic porphyria. Patients with botulism or the Lambert-Eaton myasthenic syndrome may have constipation, urinary retention, and a sicca syndrome as a result of impaired cholinergic function.

▶ Clinical Findings

A. Symptoms and Signs

Dysautonomic symptoms include syncope, postural hypotension, paroxysmal hypertension, persistent tachycardia without other cause, facial flushing, hypohidrosis or hyperhidrosis, vomiting, constipation, diarrhea, dysphagia, abdominal distention, disturbances of micturition or defecation, apneic episodes, and declining night vision. In syncope, prodromal malaise, nausea, headache, diaphoresis, pallor, visual disturbance, loss of postural tone, and a sense of weakness and impending loss of consciousness are followed by actual loss of consciousness. Although the patient is usually flaccid, some motor activity is not uncommon, and urinary (and rarely fecal) incontinence may also occur, thereby simulating a seizure. Recovery is rapid once the patient becomes recumbent, but headache, nausea, and fatigue are common postictally.

B. Evaluation of the Patient

Clinical evaluation is important to exclude reversible, non-neurologic causes of symptoms. Postural hypotension and syncope, for example, may relate to a reduced cardiac output (eg, from aortic stenosis or cardiomyopathy), paroxysmal cardiac dysrhythmias, volume depletion, various medications, and endocrine and metabolic disorders such as Addi-

son disease, hypothyroidism or hyperthyroidism, pheochromocytoma, and carcinoid syndrome. Testing of autonomic function helps establish the diagnosis of dysautonomia, to exclude other causes of symptoms, to assess the severity of involvement, and to guide prognostication. Such testing includes evaluating the cardiovascular response to the Valsalva maneuver, startle, mental stress, postural change, and deep respiration, and the sudomotor (sweating) responses to warming or a deep inspiratory gasp. Tilt-table testing may reproduce syncopal or presyncopal symptoms. Pharmacologic studies to evaluate the pupillary responses, radiologic studies of the bladder or gastrointestinal tract, uroflowmetry and urethral pressure profiles, and recording of nocturnal penile tumescence may also be necessary in selected cases. Further investigation depends on the presence of other associated neurologic abnormalities. In patients with a peripheral cause, work-up for peripheral neuropathy may be required as discussed below and should include testing for ganglionic acetylcholine receptor antibody. For those with evidence of a central lesion, imaging studies will exclude a treatable structural cause.

▶ Treatment

The most disabling symptom of dysautonomia is usually postural hypotension and syncope. Abrupt postural change, prolonged recumbency, and other precipitants should be avoided. Medications associated with postural hypotension should be discontinued or reduced in dose. Treatment may include wearing waist-high elastic hosiery, salt supplementation, sleeping in a semierect position (which minimizes the natriuresis and diuresis that occur during recumbency), and fludrocortisone (0.1–0.2 mg daily). Vasoconstrictor agents may be helpful and include midodrine (2.5–10 mg three times daily) and ephedrine (15–30 mg three times daily). Other agents that have been used occasionally or experimentally are dihydroergotamine, yohimbine, pyridostigmine, and clonidine; refractory cases may respond to erythropoietin (epoetin alfa) or desmopressin. Patients must be monitored for recumbent hypertension. Postprandial hypotension is helped by caffeine. There is no satisfactory treatment for disturbances of sweating, but an air-conditioned environment is helpful in avoiding extreme swings in body temperature.

▶ When to Refer

- When the diagnosis is uncertain.
- When symptoms persist despite conventional treatment.

SENSORY DISTURBANCES

Patients may complain of either lost or abnormal sensations. The term “numbness” is often used by patients to denote loss of feeling, but the word also has other mean-

ings and the patient's intention must be clarified. Abnormal spontaneous sensations are generally called paresthesias, and unpleasant or painful sensations produced by a stimulus that is usually painless are called dysesthesias.

Sensory symptoms may be due to disease located anywhere along the peripheral or central sensory pathways. The character, site, mode of onset, spread, and temporal profile of sensory symptoms must be established and any precipitating or relieving factors identified. These features—and the presence of any associated symptoms—help identify the origin of sensory disturbances, as do the physical signs as well. Sensory symptoms or signs may conform to the territory of individual peripheral nerves or nerve roots. Involvement of one side of the body—or of one limb in its entirety—suggests a central lesion. Distal involvement of all four extremities suggests polyneuropathy, a cervical cord or brainstem lesion, or—when symptoms are transient—a metabolic disturbance such as hyperventilation syndrome. Short-lived sensory complaints may be indicative of sensory seizures or cerebral ischemic phenomena as well as metabolic disturbances. In patients with cord lesions, there may be a transverse sensory level. “Dissociated sensory loss” is characterized by loss of some sensory modalities with preservation of others. Such findings may be encountered in patients with either peripheral or central disease and must therefore be interpreted in the clinical context in which they are found.

The absence of sensory signs in patients with sensory symptoms does not mean that symptoms have a nonorganic basis. Symptoms are often troublesome before signs of sensory dysfunction have had time to develop.

WEAKNESS & PARALYSIS

Loss of muscle power may result from central disease involving the upper or lower motor neurons; from peripheral disease involving the roots, plexus, or peripheral nerves; from disorders of neuromuscular transmission; or from primary disorders of muscle. The clinical findings help localize the lesion and thus reduce the number of diagnostic possibilities.

Weakness due to upper motor neuron lesions is characterized by selective involvement of certain muscle groups and is associated with spasticity, increased tendon reflexes, and extensor plantar responses. The site of upper motor neuron (pyramidal) involvement may be indicated by the presence of other clinical signs or by the distribution of the motor deficit. Lower motor neuron lesions lead to muscle wasting as well as weakness, with flaccidity and loss of tendon reflexes, but no change in the plantar responses unless the neurons subserving them are directly involved. Fasciculations may be evident over affected muscles. In distinguishing between a root, plexus, or peripheral nerve lesion, the distribution of the motor deficit and of any sensory changes is of particular importance. In patients with disturbances of neuromuscular transmission, weakness is patchy in distribution, often fluctuates over short periods of time, and is not associated with sensory changes. In myopathic disorders, weakness is usually most marked proximally in the limbs, is not associated with sensory loss

or sphincter disturbance, and is not accompanied by muscle wasting or loss of tendon reflexes—at least not until an advanced stage.

TRANSIENT ISCHEMIC ATTACKS

ESSENTIALS OF DIAGNOSIS

- ▶ Focal neurologic deficit of acute onset.
- ▶ Clinical deficit resolves completely within 24 hours.
- ▶ Risk factors for vascular disease often present.

▶ General Considerations

Transient ischemic attacks are characterized by focal ischemic cerebral neurologic deficits that last for less than 24 hours (usually less than 1–2 hours). About 30% of patients with stroke have a history of transient ischemic attacks, and proper treatment of the attacks is an important means of prevention. The incidence of stroke does not relate to either the number or the duration of individual attacks but is increased in patients with hypertension or diabetes. The risk of stroke is highest in the month after a transient ischemic attack (particularly in the first 48 hours) and progressively declines thereafter.

▶ Etiology

An important cause of transient cerebral ischemia is embolization. In many patients with these attacks, a source is readily apparent in the heart or a major extracranial artery to the head, and emboli sometimes are visible in the retinal arteries. Moreover, an embolic phenomenon explains why separate attacks may affect different parts of the territory supplied by the same major vessel. Cardiac causes of embolic ischemic attacks include atrial fibrillation, rheumatic heart disease, mitral valve disease, infective endocarditis, atrial myxoma, and mural thrombi complicating myocardial infarction. Atrial septal defects and patent foramen ovale may permit emboli from the veins to reach the brain (“paradoxical emboli”). An ulcerated plaque on a major artery to the brain may serve as a source of emboli. In the anterior circulation, atherosclerotic changes occur most commonly in the region of the carotid bifurcation extracranially, and these changes may cause a bruit. In some patients with transient ischemic attacks or strokes, an acute or recent hemorrhage is found to have occurred into this atherosclerotic plaque, and this finding may have pathologic significance. Patients with AIDS have an increased risk of developing transient ischemic deficits or strokes.

Less common abnormalities of blood vessels that may cause transient ischemic attacks include fibromuscular dysplasia, which affects particularly the cervical internal carotid artery; atherosclerosis of the aortic arch; inflammatory arterial disorders such as giant cell arteritis, systemic lupus erythematosus, polyarteritis, and granulomatous angiitis; and meningovascular syphilis. Hypotension may cause a reduction of cerebral blood flow if a major extra-

cranial artery to the brain is markedly stenosed, but this is a rare cause of transient ischemic attack.

Hematologic causes of ischemic attacks include polycythemia, sickle cell disease, and hyperviscosity syndromes. Severe anemia may also lead to transient focal neurologic deficits in patients with preexisting cerebral arterial disease.

The **subclavian steal syndrome** may lead to transient vertebrobasilar ischemia. Symptoms develop when there is localized stenosis or occlusion of one subclavian artery proximal to the source of the vertebral artery, so that blood is “stolen” from this artery. A bruit in the supraclavicular fossa, unequal radial pulses, and a difference of 20 mm Hg or more between the systolic blood pressures in the arms should suggest the diagnosis in patients with vertebrobasilar transient ischemic attacks.

► Clinical Findings

A. Symptoms and Signs

The symptoms of transient ischemic attacks vary markedly among patients; however, the symptoms in a given individual tend to be constant in type. Onset is abrupt and without warning, and recovery usually occurs rapidly, often within a few minutes.

If the ischemia is in the carotid territory, common symptoms are weakness and heaviness of the contralateral arm, leg, or face, singly or in any combination. Numbness or paresthesias may also occur either as the sole manifestation of the attack or in combination with the motor deficit. There may be slowness of movement, dysphasia, or monocular visual loss in the eye contralateral to affected limbs. During an attack, examination may reveal flaccid weakness with pyramidal distribution, sensory changes, hyperreflexia or an extensor plantar response on the affected side, dysphasia, or any combination of these findings. Subsequently, examination reveals no neurologic abnormality, but the presence of a carotid bruit or cardiac abnormality may provide a clue to the cause of symptoms.

Vertebrobasilar ischemic attacks may be characterized by vertigo, ataxia, diplopia, dysarthria, dimness or blurring of vision, perioral numbness and paresthesias, and weakness or sensory complaints on one, both, or alternating sides of the body. These symptoms may occur singly or in any combination. Drop attacks due to bilateral leg weakness, without headache or loss of consciousness, may occur, sometimes in relation to head movements.

The natural history of attacks is variable. Some patients will have a major stroke after only a few attacks, whereas others may have frequent attacks for weeks or months without having a stroke. The risk of stroke is high in the first 3 months after an attack, particularly in the first month and especially within the first 48 hours. Attacks may occur intermittently over a long period of time, or they may stop spontaneously. In general, carotid ischemic attacks are more liable than vertebrobasilar ischemic attacks to be followed by stroke. The stroke risk is greater in patients older than 60 years, in diabetics, or after transient ischemic attacks that last longer than 10 minutes

and with symptoms or signs of weakness, speech impairment, or gait disturbance.

B. Imaging

CT or MRI scan of the head will exclude the possibility of a small cerebral hemorrhage or a cerebral tumor masquerading as a transient ischemic attack. A number of noninvasive techniques, such as ultrasonography, have been developed for studying the cerebral circulation and imaging the major vessels to the head. Carotid duplex ultrasonography is useful for detecting significant stenosis of the internal carotid artery, but arteriography remains important for demonstrating the status of the cerebrovascular system. MR or CT angiography may reveal stenotic lesions of large vessels but is less sensitive than conventional arteriography. Accordingly, if the findings on CT scan or MRI are normal, if there is no cardiac source of embolization, and if age and general condition indicate that the patient is a good operative risk, bilateral carotid arteriography should be considered in the further evaluation of carotid ischemic attacks, although the ultrasound findings may help in selecting patients for study.

C. Laboratory and Other Studies

Clinical and laboratory evaluation must include assessment for hypertension, heart disease, hematologic disorders, diabetes mellitus, hyperlipidemia, and peripheral vascular disease. It should include complete blood count, fasting blood glucose and serum cholesterol and homocysteine determinations, serologic tests for syphilis, and an ECG and chest radiograph. Echocardiography with bubble contrast is performed if a cardiac source is likely, and blood cultures are obtained if endocarditis is suspected. Holter monitoring is indicated if a transient, paroxysmal disturbance of cardiac rhythm is suspected.

► Differential Diagnosis

Focal seizures usually cause abnormal motor or sensory phenomena such as clonic limb movements, paresthesias, or tingling, rather than weakness or loss of feeling. Symptoms generally spread (“march”) up the limb and may lead to a generalized tonic-clonic seizure.

Classic migraine is easily recognized by the visual premonitory symptoms, followed by nausea, headache, and photophobia, but less typical cases may be hard to distinguish. The patient’s age and medical history (including family history) may be helpful in this regard. Patients with migraine commonly have a history of episodes since adolescence and report that other family members have a similar disorder.

Focal neurologic deficits may occur during periods of hypoglycemia in diabetic patients receiving insulin or oral hypoglycemic agent therapy.

► Treatment

Hospitalization should be considered for patients seen within 48 hours of their first attack or with crescendo attacks, symptoms lasting for more than 1 hour, sympto-

matic carotid stenosis, or a known cardiac source of emboli or hypercoagulable state; such hospitalization facilitates early intervention for any recurrence and rapid institution of secondary prevention measures. When arteriography reveals a surgically accessible high-grade stenosis (70–99% in luminal diameter) on the side appropriate to carotid ischemic attacks and there is relatively little atherosclerosis elsewhere in the cerebrovascular system, operative treatment (carotid thromboendarterectomy) reduces the risk of ipsilateral carotid stroke, especially when transient ischemic attacks are of recent onset (< 1 month). Surgery is not indicated for mild stenosis (< 30%); its benefits are unclear with severe stenosis plus diffuse intracranial atherosclerotic disease. See Chapter 12 for additional discussion.

In patients with carotid ischemic attacks who are poor operative candidates (and thus have not undergone arteriography) or who are found to have extensive vascular disease, medical treatment should be instituted. Similarly, patients with vertebralbasilar ischemic attacks are treated medically and are not subjected to arteriography unless there is clinical evidence of stenosis or occlusion in the carotid or subclavian arteries.

Medical treatment is aimed at preventing further attacks and stroke. Cigarette smoking should be stopped, and cardiac sources of embolization, hypertension, diabetes mellitus, hyperlipidemia, arteritis, or hematologic disorders should be treated appropriately. Weight reduction and regular physical activity should be encouraged when appropriate.

A. Embolization from the Heart

If anticoagulants are indicated for the treatment of embolism from the heart, they should be started immediately, provided there is no contraindication to their use. There is no advantage in delay, and the common fear of causing hemorrhage into a previously infarcted area is misplaced, since there is a far greater risk of further embolism to the cerebral circulation if treatment is withheld. Treatment with warfarin sodium is introduced in a daily dose of 5–15 mg orally, depending on the international normalized ratio (INR). Warfarin is more effective than aspirin in reducing the incidence of cardioembolic events, but when its use is contraindicated, aspirin (325 mg daily) may be used in patients with nonrheumatic atrial fibrillation to reduce the risk of stroke.

B. Non-cardioembolic Attacks

In patients with presumed or angiographically verified atherosclerotic changes in the extracranial or intracranial cerebrovascular circulation, antithrombotic medication is prescribed. Platelets adhere to and aggregate around an atherosclerotic plaque and release various substances including thromboxane A_2 . Treatment with aspirin significantly reduces the frequency of transient ischemic attacks and the incidence of stroke or myocardial infarcts in high-risk patients. A daily dose of 325 mg is adequate. Aspirin can be combined with sustained-release dipyridamole (200 mg twice daily) for optimal stroke prevention. In patients

intolerant of aspirin, clopidogrel (75 mg) can be used; the combination of clopidogrel and aspirin appears to offer no greater benefit than aspirin alone. Anticoagulant drugs (eg, warfarin, with temporary heparinization until the dose of warfarin is adequate) are not recommended; there is no benefit over antiplatelet therapy and the risk of serious hemorrhagic adverse effects is greater.

Surgical extracranial-intracranial arterial anastomosis is generally not helpful in patients with transient ischemic attacks associated with stenotic lesions of the distal internal carotid or the proximal middle cerebral arteries.

▶ When to Refer

All patients should be referred for urgent investigation and treatment to prevent stroke.

▶ When to Admit

All patients with acute or crescendo transient ischemic attacks should be admitted for urgent investigation and treatment to prevent recurrence or stroke.

STROKE

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden onset of characteristic neurologic deficit.
- ▶ Patient often has history of hypertension, diabetes mellitus, valvular heart disease, or atherosclerosis.
- ▶ Distinctive neurologic signs reflect the region of the brain involved.

▶ General Considerations

In the United States, stroke remains the third leading cause of death, despite a general decline in the incidence of stroke in the last 30 years. The precise reasons for this decline are uncertain, but increased awareness of risk factors (hypertension, diabetes, hyperlipidemia, cigarette smoking, cardiac disease, AIDS, recreational drug abuse, heavy alcohol consumption, family history of stroke) and improved prophylactic measures and surveillance of those at increased

risk have been contributory. Elevation of the blood homocysteine level is also a risk factor for stroke, but it is unclear whether this risk is reduced by treatment to lower the level. A previous stroke makes individual patients more susceptible to additional strokes.

For years, strokes have been subdivided pathologically into infarcts (thrombotic or embolic) and hemorrhages, and clinical criteria for distinguishing between these possibilities have been emphasized. However, it is often difficult to determine on clinical grounds the pathologic basis for stroke (Table 24–4).

1. Lacunar Infarction

Lacunar infarcts are small lesions (usually < 5 mm in diameter) that occur in the distribution of short penetrating arterioles in the basal ganglia, pons, cerebellum, anterior limb of the internal capsule, and, less commonly, the deep cerebral white matter. Lacunar infarcts are associated with poorly controlled hypertension or diabetes and have been found in several clinical syndromes, including contralateral pure motor or pure sensory deficit, ipsilateral ataxia with crural paresis, and dysarthria with clumsiness of the hand. The neurologic deficit may progress over 24–36 hours before stabilizing.

Lacunar infarcts are sometimes visible on CT scans as small, punched-out, hypodense areas, but in other patients no abnormality is seen. In some instances, patients with a clinical syndrome suggestive of lacunar infarction are found on CT scanning to have a severe hemispheric infarct.

Early mortality and risk of stroke recurrence is higher for patients with nonlacunar than lacunar infarcts. The prognosis for recovery from the deficit produced by a lacunar infarct is usually good, with partial or complete resolution occurring over the following 4–6 weeks in many instances.

Donnan GA et al. Lacunes and lacunar syndromes. *Handb Clin Neurol*. 2008;93:559–75. [PMID: 18804668]

2. Cerebral Infarction

Thrombotic or embolic occlusion of a major vessel leads to cerebral infarction. Causes include the disorders predisposing to transient ischemic attacks (see above) and atherosclerosis of cerebral arteries. The resulting deficit depends on the particular vessel involved and the extent of any collateral circulation. Cerebral ischemia leads to release of excitatory and other neuropeptides that may augment calcium flux into neurons, thereby leading to cell death and increasing the neurologic deficit.

► Clinical Findings

A. Symptoms and Signs

Onset is usually abrupt, and there may then be very little progression except that due to brain swelling. Clinical evaluation should always include examination of the heart and auscultation over the subclavian and carotid vessels to determine whether there are any bruits.

1. Obstruction of carotid circulation—Occlusion of the ophthalmic artery is probably symptomless in most cases because of the rich orbital collaterals, but its transient embolic obstruction can lead to amaurosis fugax—sudden and brief loss of vision in one eye.

Occlusion of the anterior cerebral artery distal to its junction with the **anterior communicating artery** causes weakness and cortical sensory loss in the contralateral leg and sometimes mild weakness of the arm, especially proximally. There may be a contralateral grasp reflex, paratonic rigidity, and abulia (lack of initiative) or frank confusion. Urinary incontinence is not uncommon, particularly if behavioral disturbances are conspicuous. Bilateral anterior cerebral infarction is especially likely to cause marked behavioral changes and memory disturbances. Unilateral anterior cerebral artery occlusion proximal to the junction with the anterior communicating artery is generally well tolerated because of the collateral supply from the other side.

Middle cerebral artery occlusion leads to contralateral hemiplegia, hemisensory loss, and homonymous hemianopia (ie, bilaterally symmetric loss of vision in half of the visual fields), with the eyes deviated to the side of the lesion. If the dominant hemisphere is involved, global aphasia is also present. It may be impossible to distinguish this clinically from occlusion of the internal carotid artery. With occlusion of either of these arteries, there may also be considerable swelling of the hemisphere, leading to drowsiness, stupor, and coma in extreme cases. Occlusions of different branches of the middle cerebral artery cause more limited findings. For example, involvement of the anterior main division leads to a predominantly expressive dysphasia and to contralateral paralysis and loss of sensations in the arm, the face, and, to a lesser extent, the leg. Posterior branch occlusion produces a receptive (Wernicke) aphasia and a homonymous visual field defect. With involvement of the nondominant hemisphere, speech and comprehension are preserved, but there may be a confusional state, dressing apraxia, and constructional and spatial deficits.

2. Obstruction of vertebrobasilar circulation—Occlusion of the **posterior cerebral artery** may lead to a thalamic syndrome in which contralateral hemisensory disturbance occurs, followed by the development of spontaneous pain and hyperpathia. There is often a macular-sparing homonymous hemianopia and sometimes a mild, usually temporary, hemiparesis. Depending on the site of the lesion and the collateral circulation, the severity of these deficits varies and other deficits may also occur, including involuntary movements and alexia. Occlusion of the main artery beyond the origin of its penetrating branches may lead solely to a macular-sparing hemianopia.

Vertebral artery occlusion distally, below the origin of the anterior spinal and posterior inferior cerebellar arteries, may be clinically silent because the circulation is maintained by the other vertebral artery. If the remaining vertebral artery is congenitally small or severely atherosclerotic, however, a deficit similar to that of basilar artery occlusion is seen unless there is good collateral circulation from the anterior circulation through the circle of Willis. When the small paramedian arteries arising from the vertebral artery

Table 24-4. Features of the major stroke subtypes.

| Stroke Type and Subtype | Clinical Features | Diagnosis | Treatment |
|--------------------------------------|---|--|--|
| Ischemic stroke | | | |
| Lacunar infarct | Small (< 5 mm) lesions in the basal ganglia, pons, cerebellum, or internal capsule; less often in deep cerebral white matter; prognosis generally good; clinical features depend on location, but may worsen over first 24-36 hours. | CT may reveal small hypodensity but is often normal. | Aspirin; long-term management is to control risk factors (hypertension and diabetes mellitus). |
| Carotid circulation obstruction | See text—signs vary depending on occluded vessel. | Noncontrast CT to exclude hemorrhage but findings may be normal during first 6-24 hours of an ischemic stroke; when available, diffusion-weighted MRI plus gradient-echo sequences and FLAIR may also be used; electrocardiography, blood glucose, complete blood count, and tests for hypercoagulable states, hyperlipidemia are indicated; echocardiography or Holter monitoring in selected instances; carotid duplex studies, MR angiography and conventional angiography in selected cases. | Select patients for intravenous thrombolytics or intra-arterial mechanical thrombolysis; aspirin (325 mg/d orally) combined with sustained-release dipyridamole (200 mg twice daily) is first-line therapy; anticoagulation with heparin for cardioembolic strokes when no contraindications exist. |
| Vertebrobasilar occlusion | See text—signs vary based on location of occluded vessel. | As for carotid circulation obstruction. | As for carotid circulation obstruction. |
| Hemorrhagic stroke | | | |
| Spontaneous intracerebral hemorrhage | Commonly associated with hypertension; also with bleeding disorders, amyloid angiopathy. Hypertensive hemorrhage is located commonly in the basal ganglia and less commonly in the pons, thalamus, cerebellum, or cerebral white matter. | Noncontrast CT is superior to MRI for detecting bleeds of < 48 hours duration; laboratory tests to identify bleeding disorder; angiography may be indicated to exclude aneurysm or AVM. Do not perform lumbar puncture. | Most managed supportively, but cerebellar bleeds or hematomas with gross mass effect may require urgent surgical evacuation. |
| Subarachnoid hemorrhage | Present with sudden onset of worst headache of life, may lead rapidly to loss of consciousness; signs of meningeal irritation often present; etiology usually aneurysm or AVM, but 20% have no source identified. | CT to confirm diagnosis, but may be normal in rare instances; if CT negative and suspicion high, perform lumbar puncture to look for red blood cells or xanthochromia; angiography to determine source of bleed in candidates for treatment. | See sections on AVM and aneurysm. |
| Intracranial aneurysm | Most located in the anterior circle of Willis and are typically asymptomatic until subarachnoid bleed occurs; 20% rebleed in first 2 weeks. | CT indicates subarachnoid hemorrhage, and angiography then demonstrates aneurysms; angiography may not reveal aneurysm if vasospasm present. | Prevent further bleeding by clipping aneurysm or coil embolization; nimodipine helps prevent vasospasm; reverse vasospasm by intravenous fluids and induced hypertension after aneurysm has been obliterated, if no other aneurysms are present; angioplasty may also reverse symptomatic vasospasm. |
| AVMs | Focal deficit from hematoma or AVM itself. | CT reveals bleed, and may reveal the AVM; may be seen by MRI. Angiography demonstrates feeding vessels and vascular anatomy. | Surgery indicated if AVM has bled or to prevent further progression of neurologic deficit; other modalities to treat nonoperable AVMs are available at specialized centers. |

AVMs, arteriovenous malformations.

are occluded, contralateral hemiplegia and sensory deficit occur in association with an ipsilateral cranial nerve palsy at the level of the lesion. An obstruction of the **posterior inferior cerebellar artery** or an obstruction of the vertebral artery just before it branches to this vessel leads ipsilaterally to spinothalamic sensory loss involving the face, ninth and tenth cranial nerve lesions, limb ataxia and numbness, and Horner syndrome, combined with contralateral spinothalamic sensory loss involving the limbs.

Occlusion of both **vertebral arteries** or the **basilar artery** leads to coma with pinpoint pupils, flaccid quadriplegia and sensory loss, and variable cranial nerve abnormalities. With partial basilar artery occlusion, there may be diplopia, visual loss, vertigo, dysarthria, ataxia, weakness or sensory disturbances in some or all of the limbs, and discrete cranial nerve palsies. In patients with hemiplegia of pontine origin, the eyes are often deviated to the paralyzed side, whereas in patients with a hemispheric lesion, the eyes commonly deviate from the hemiplegic side.

Occlusion of any of the major **cerebellar arteries** produces vertigo, nausea, vomiting, nystagmus, ipsilateral limb ataxia, and contralateral spinothalamic sensory loss in the limbs. If the superior cerebellar artery is involved, the contralateral spinothalamic loss also involves the face; with occlusion of the anterior inferior cerebellar artery, there is ipsilateral spinothalamic sensory loss involving the face, usually in conjunction with ipsilateral facial weakness and deafness. Massive cerebellar infarction may lead to coma, tonsillar herniation, and death.

3. Coma—Infarction in either the carotid or vertebralis territory may lead to loss of consciousness. For example, an infarct involving one cerebral hemisphere may lead to such swelling that the function of the other hemisphere or the rostral brainstem is disturbed and coma results. Similarly, coma occurs with bilateral brainstem infarction when this involves the reticular formation, and it occurs with brainstem compression after cerebellar infarction.

B. Imaging

Radiography of the chest may reveal cardiomegaly or valvular calcification; the presence of a neoplasm would suggest that the neurologic deficit is due to metastasis rather than stroke, or rarely to nonbacterial thrombotic endocarditis. A CT scan of the head (without contrast) is important in excluding cerebral hemorrhage, but it may not permit distinction between a cerebral infarct and tumor. CT scanning is preferable to MRI in the acute stage because it is quicker and because intracranial hemorrhage is not easily detected by MRI within the first 48 hours after a bleeding episode. In selected patients, carotid duplex studies, MRI and MR angiography, and conventional angiography may also be necessary. Diffusion-weighted MRI is more sensitive than standard MRI in detecting cerebral ischemia.

C. Laboratory and Other Studies

Investigations should include a complete blood count, sedimentation rate, blood glucose determination, and serologic tests for syphilis. Antiphospholipid antibodies (lupus

anticoagulants and anticardiolipin antibodies) promote thrombosis and are associated with an increased incidence of stroke. Similarly, elevated serum cholesterol and lipids and serum homocysteine may indicate an increased risk of thrombotic stroke. Electrocardiography will help exclude a cardiac arrhythmia or recent myocardial infarction that might be serving as a source of embolization. Blood cultures should be performed if endocarditis is suspected, echocardiography if heart disease is suspected, and Holter monitoring if paroxysmal cardiac arrhythmia requires exclusion. Examination of the cerebrospinal fluid is not always necessary but may be helpful if there is diagnostic uncertainty; it should be delayed until after CT scanning.

▶ Treatment

Prophylactic measures were considered earlier in discussing transient ischemic attacks. The management of acute stroke should be in a stroke care unit, when feasible. Intravenous thrombolytic therapy with recombinant tissue plasminogen activator (0.9 mg/kg to a maximum of 90 mg, with 10% given as a bolus over 1 minute and the remainder over 1 hour) is effective in reducing the neurologic deficit in selected patients without CT evidence of intracranial hemorrhage when administered within 3 hours after onset of ischemic stroke, but later administration has not been proved effective or safe. Recent hemorrhage, increased risk of hemorrhage (eg, treatment with anticoagulants), arterial puncture at a noncompressible site, and systolic pressure above 185 mm Hg or diastolic pressure above 110 mm Hg are among the contraindications to this treatment. Another approach involves the mechanical removal of an embolus or clot from an occluded cerebral artery using an intra-arterial mechanical thrombolytic device.

Early management of a completed stroke otherwise requires general supportive measures. During the acute stage, there may be marked brain swelling and edema, with symptoms and signs of increasing intracranial pressure, an increasing neurologic deficit, or herniation syndrome. Prednisone (up to 100 mg/d) or dexamethasone (16 mg/d) has been used to reduce vasogenic cerebral edema, but evidence of benefit is conflicting; dehydrating hyperosmolar agents are also of uncertain benefit. Decompressive surgery, however, may be worthwhile for major supratentorial hemispheric stroke. Neither hypercapnia nor hypocapnia has any benefit. Attempts to lower the blood pressure of hypertensive patients during the acute phase (ie, within 2 weeks) of a stroke should generally be avoided, as there is loss of cerebral autoregulation and lowering the blood pressure may further compromise ischemic areas. However, if the systolic pressure exceeds 220 mm Hg, it can be lowered using intravenous labetalol or nicardipine with continuous monitoring to 170–200 mm Hg and then, after 2 weeks, it can be reduced further to less than 140/90 mm Hg.

Anticoagulant drugs should be started when there is a cardiac source of embolization. Treatment is with warfarin. The target is an INR of 2.0–3.0 for the prothrombin time. If the CT scan shows no evidence of hemorrhage and the cerebrospinal fluid is clear, anticoagulant treatment may be started without delay. Physical therapy has an

important role in the management of patients with impaired motor function. Passive movements at an early stage will help prevent contractures. As cooperation increases and some recovery begins, active movements will improve strength and coordination. In all cases, early mobilization and active rehabilitation are important. Occupational therapy may improve morale and motor skills, while speech therapy may be beneficial in patients with expressive dysphasia or dysarthria. When there is a severe and persisting motor deficit, a device such as a leg brace, toe spring, frame, or cane may help the patient move about, and the provision of other aids to daily living may improve the quality of life.

► Prognosis

The prognosis for survival after cerebral infarction is better than after cerebral or subarachnoid hemorrhage. The only proved effective therapy for acute stroke requires initiation within 3 hours after stroke onset, and the prognosis therefore depends on the time that elapses before arrival at the hospital. Patients receiving such treatment with tissue plasminogen activator are at least 30% more likely to have minimal or no disability at 3 months than those not treated by this means. Loss of consciousness after a cerebral infarct implies a poorer prognosis than otherwise. The extent of the infarct governs the potential for rehabilitation. Patients who have had a cerebral infarct are at risk for additional strokes and for myocardial infarcts. Statin therapy to lower serum lipid levels may reduce this risk. Antiplatelet therapy reduces the recurrence rate by 30% among patients without a cardiac cause for the stroke who are not candidates for carotid endarterectomy. Nevertheless, the cumulative risk of recurrence of noncardioembolic stroke is still 3–7% annually. Treatment with aspirin (325 mg) plus extended-release dipyridamole (200 mg) orally twice daily is as effective as clopidogrel (75 mg) orally once daily in reducing the risk of recurrence.

Patients with massive strokes from which meaningful recovery is unlikely should receive palliative care (see Chapter 5).

► When to Refer

All patients should be referred.

► When to Admit

All patients should be hospitalized, preferably in a stroke care unit.

3. Intracerebral Hemorrhage

Spontaneous intracerebral hemorrhage in patients with no angiographic evidence of an associated vascular anomaly (eg, aneurysm or angioma) is usually due to hypertension. The pathologic basis for hemorrhage is probably the presence of microaneurysms that develop on perforating vessels in hypertensive patients. Hypertensive intracerebral hemorrhage occurs most frequently in the basal ganglia and less commonly in the pons, thalamus, cerebellum, and cerebral white matter. Hemorrhage may extend into the ventricular system or subarachnoid space, and signs of meningeal irritation are then found. Hemorrhages usually occur suddenly and without warning, often during activity.

In addition to its association with hypertension, nontraumatic intracerebral hemorrhage may occur with hematologic and bleeding disorders (eg, leukemia, thrombocytopenia, hemophilia, or disseminated intravascular coagulation), anticoagulant therapy, liver disease, cerebral amyloid angiopathy, high alcohol intake, and primary or secondary brain tumors. There is also an association with advancing age and male sex. Bleeding is primarily into the subarachnoid space when it occurs from an intracranial aneurysm or arteriovenous malformation (see below), but it may be partly intraparenchymal as well. In some cases, no specific cause for cerebral hemorrhage can be identified.

► Clinical Findings

A. Symptoms and Signs

With hemorrhage into the cerebral hemisphere, consciousness is initially lost or impaired in about one-half of patients. Vomiting occurs very frequently at the onset of bleeding, and headache is sometimes present. Focal symptoms and signs then develop, depending on the site of the hemorrhage. With hypertensive hemorrhage, there is generally a rapidly evolving neurologic deficit with hemiplegia or hemiparesis. A hemisensory disturbance is also present with more deeply placed lesions. With lesions of the putamen, loss of conjugate lateral gaze may be conspicuous. With thalamic hemorrhage, there may be a loss of upward gaze, downward or skew deviation of the eyes, lateral gaze palsies, and pupillary inequalities.

Cerebellar hemorrhage may present with sudden onset of nausea and vomiting, disequilibrium, headache, and loss of consciousness that may terminate fatally within 48 hours. Less commonly, the onset is gradual and the course episodic or slowly progressive—clinical features suggesting an expanding cerebellar lesion. In yet other cases, however, the onset and course are intermediate, and examination shows lateral conjugate gaze palsies to the side of the lesion; small reactive pupils; contralateral hemiplegia; peripheral facial weakness; ataxia of gait, limbs, or trunk; periodic respiration; or some combination of these findings.

B. Imaging

CT scanning (without contrast) is important not only in confirming that hemorrhage has occurred but also in determining the size and site of the hematoma. It is superior to MRI for detecting intracranial hemorrhage of less than 48 hours duration. If the patient's condition permits further intervention, cerebral angiography may be undertaken thereafter to determine whether an aneurysm or arteriovenous malformation is present (see below).

C. Laboratory and Other Studies

A complete blood count, platelet count, bleeding time, prothrombin and partial thromboplastin times, and liver and kidney function tests may reveal a predisposing cause for the hemorrhage. Lumbar puncture is contraindicated because it may precipitate a herniation syndrome in patients with a large hematoma, and CT scanning is superior in detecting intracerebral hemorrhage.

▶ Treatment

Neurologic management is generally conservative and supportive, regardless of whether the patient has a profound deficit with associated brainstem compression, in which case the prognosis is grim, or a more localized deficit not causing increased intracranial pressure or brainstem involvement. Such therapy may include ventilatory support, blood pressure regulation, seizure prophylaxis, control of fever, osmotherapy, and nutritional supplementation. Intracranial pressure may require monitoring. Ventricular drainage may be required in patients with intraventricular hemorrhage and acute hydrocephalus. Decompression may be helpful when a superficial hematoma in cerebral white matter is exerting a mass effect and causing incipient herniation. In patients with cerebellar hemorrhage, prompt surgical evacuation of the hematoma is appropriate, because spontaneous unpredictable deterioration may otherwise lead to a fatal outcome and because operative treatment may lead to complete resolution of the clinical deficit. The treatment of underlying structural lesions or bleeding disorders depends on their nature. Hemostatic therapy with recombinant activated factor VII given within a few hours of onset reduces hematoma growth but does not appear to improve survival or functional outcome.

▶ When to Refer

All patients should be referred.

▶ When to Admit

All patients should be hospitalized.

4. Subarachnoid Hemorrhage

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden severe headache.
- ▶ Signs of meningeal irritation usually present.
- ▶ Obtundation is common.
- ▶ Focal deficits frequently absent.

▶ General Considerations

Between 5% and 10% of strokes are due to subarachnoid hemorrhage. Although hemorrhage is usually from rupture of an aneurysm or arteriovenous malformation, no specific cause can be found in 20% of cases.

▶ Clinical Findings

A. Symptoms and Signs

Subarachnoid hemorrhage has a characteristic clinical picture. Its onset is with sudden headache of a severity never experienced previously by the patient. This may be followed by nausea and vomiting and by a loss or impairment of consciousness that can either be transient or progress inexorably to deepening coma and death. If consciousness is regained, the patient is often confused and irritable and may show other symptoms of an altered mental status. Neurologic examination generally reveals nuchal rigidity and other signs of meningeal irritation, except in deeply comatose patients. A focal neurologic deficit is occasionally present and may suggest the site of the underlying lesion.

B. Imaging

A CT scan (preferably a CT angiogram) should be performed immediately to confirm that hemorrhage has occurred and to search for clues regarding its source. It is preferable to MRI because it is faster and more sensitive in detecting hemorrhage in the first 24 hours. CT findings sometimes are normal in patients with suspected hemorrhage, and the cerebrospinal fluid must then be examined for the presence of blood or xanthochromia before the possibility of subarachnoid hemorrhage is discounted.

Cerebral arteriography may be undertaken to determine the source of bleeding; it is not performed unless or until the patient's condition has stabilized and is good enough so that operative treatment is feasible. In general, bilateral carotid and vertebral arteriography are necessary because aneurysms are often multiple, while arteriovenous malformations may be supplied from several sources. MR angiography may also permit these vascular anomalies to be visualized but is less sensitive than conventional arteriography.

▶ Treatment

All patients should be admitted to hospital and seen by a neurologist. The measures outlined below in the section on stupor and coma are applied to comatose patients. Conscious patients are confined to bed, advised against any exertion or straining, treated symptomatically for headache and anxiety, and given laxatives or stool softeners. If there is severe hypertension, the blood pressure can be lowered gradually, but not below a diastolic level of 100 mm Hg. Phenytoin is generally prescribed routinely to prevent seizures. Further comment concerning the specific operative management of arteriovenous malformations and aneurysms follows.

5. Intracranial Aneurysm

ESSENTIALS OF DIAGNOSIS

- ▶ Subarachnoid hemorrhage or focal deficit.
- ▶ Abnormal imaging studies.

▶ General Considerations

Saccular aneurysms (“berry” aneurysms) tend to occur at arterial bifurcations, are frequently multiple (20% of cases), and are usually asymptomatic. They may be associated with polycystic kidney disease and coarctation of the aorta. Risk factors for aneurysm formation include smoking, hypertension, and hypercholesterolemia. Most aneurysms are located on the anterior part of the circle of Willis—particularly on the anterior or posterior communicating arteries, at the bifurcation of the middle cerebral artery, and at the bifurcation of the internal carotid artery.

▶ Clinical Findings

A. Symptoms and Signs

Aneurysms may cause a focal neurologic deficit by compressing adjacent structures. However, most are asymptomatic or produce only nonspecific symptoms until they rupture, at which time subarachnoid hemorrhage results. A higher risk of subarachnoid hemorrhage is associated with older age, female sex, “non-white” ethnicity, hypertension, tobacco smoking, high alcohol consumption (exceeding 150 g per week), previous symptoms, posterior circulation aneurysms, and larger aneurysms. There is often a paucity of focal neurologic signs in patients with subarachnoid hemorrhage, but when present, such signs may relate either to a focal hematoma or to ischemia in the territory of the vessel with the ruptured aneurysm. Hemiplegia or other focal deficit sometimes occurs after a delay of 4–14 days and is due to focal arterial spasm in the vicinity of the ruptured aneurysm. This spasm is of uncertain, probably multifactorial, cause, but it sometimes leads to significant cerebral ischemia or infarction, and it may further aggravate any existing increase in intracranial pressure. Subacute hydrocephalus due to interference with the

flow of cerebrospinal fluid may occur after 2 or more weeks, and this leads to a delayed clinical deterioration that is relieved by shunting.

In some patients, “warning leaks” of a small amount of blood from the aneurysm precede the major hemorrhage by a few hours or days. They lead to headaches, sometimes accompanied by nausea and neck stiffness, but the true cause of these symptoms is often not appreciated until massive hemorrhage occurs.

B. Imaging

The CT scan generally confirms that subarachnoid hemorrhage has occurred, but occasionally it is normal. Angiography (bilateral carotid and vertebral studies) generally indicates the size and site of the lesion, sometimes reveals multiple aneurysms, and may show arterial spasm. CT angiography is becoming increasingly important as a means of evaluating aneurysmal hemorrhage. If subarachnoid hemorrhage is confirmed by lumbar puncture or CT scanning but arteriograms show no abnormality, the examination should be repeated after 2 weeks, because vasospasm may have prevented detection of an aneurysm during the initial study.

C. Laboratory and Other Studies

The cerebrospinal fluid is bloodstained. The electroencephalogram sometimes indicates the side or site of hemorrhage but frequently shows only a diffuse abnormality. Electrocardiographic evidence of arrhythmias or myocardial ischemia has been well described and probably relates to excessive sympathetic activity. Peripheral leukocytosis and transient glycosuria are also common findings.

▶ Treatment

The major aim of treatment is to prevent further hemorrhages. Definitive treatment requires surgical clipping of the aneurysm base or endovascular treatment by interventional radiologists; the latter is sometimes feasible even for inoperable aneurysms. Otherwise, medical management as outlined above for subarachnoid hemorrhage is continued for about 6 weeks and is followed by gradual mobilization.

The risk of further hemorrhage is greatest within a few days of the first hemorrhage; approximately 20% of patients will have further bleeding within 2 weeks and 40% within 6 months. Attempts have been made to reduce this risk pharmacologically. Treatment with an antifibrinolytic agent such as aminocaproic acid during the first 14 days reduces the risk of recurrent hemorrhage but is associated with such an increase in cerebral ischemic complications that the mortality rate and the degree of disability among survivors are unchanged. Thus, early operation (ie, within about 2 days of hemorrhage) is preferred for good operative candidates.

Calcium channel-blocking agents have helped reduce or reverse experimental vasospasm, and nimodipine has been shown to reduce, in neurologically normal patients, the incidence of ischemic deficits from arterial spasm without producing any side effects. The dose of nimodipine is 60 mg

every 4 hours orally for 21 days. After surgical obliteration of any aneurysms, symptomatic vasospasm may also be treated by intravascular volume expansion, induced hypertension, or transluminal balloon angioplasty of involved intracranial vessels; aspirin provides no benefit.

With regard to unruptured aneurysms, those that are symptomatic merit prompt treatment, either surgically or by endovascular techniques, whereas small asymptomatic ones discovered incidentally are often monitored arteriographically and corrected only if they increase in size to over 10 mm.

▶ When to Refer

All patients should be referred.

▶ When to Admit

- All patients with a subarachnoid hemorrhage.
- All patients for detailed imaging.
- All patients undergoing surgical or endovascular treatment.

6. Arteriovenous Malformations

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden onset of subarachnoid and intracerebral hemorrhage.
- ▶ Distinctive neurologic signs reflect the region of the brain involved.
- ▶ Signs of meningeal irritation in patients presenting with subarachnoid hemorrhage.
- ▶ Seizures or focal deficits may occur.

▶ General Considerations

Arteriovenous malformations are congenital vascular malformations that result from a localized maldevelopment of part of the primitive vascular plexus and consist of abnormal arteriovenous communications without intervening capillaries. They vary in size, ranging from massive lesions that are fed by multiple vessels and involve a large part of the brain to lesions so small that they are hard to identify at arteriography, surgery, or autopsy. In approximately 10% of cases, there is an associated arterial aneurysm, while 1–2% of patients presenting with aneurysms have associated arteriovenous malformations. Clinical presentation may relate to hemorrhage from the malformation or an associated aneurysm or may relate to cerebral ischemia due to diversion of

blood by the anomalous arteriovenous shunt or due to venous stagnation. Regional maldevelopment of the brain, compression or distortion of adjacent cerebral tissue by enlarged anomalous vessels, and progressive gliosis due to mechanical and ischemic factors may also be contributory. In addition, communicating or obstructive hydrocephalus may occur and lead to symptoms.

▶ Clinical Findings

A. Symptoms and Signs

1. Supratentorial lesions—Most cerebral arteriovenous malformations are supratentorial, usually lying in the territory of the middle cerebral artery. Initial symptoms consist of hemorrhage in 30–60% of cases, recurrent seizures in 20–40%, headache in 5–25%, and miscellaneous complaints (including focal deficits) in 10–15%. Up to 70% of arteriovenous malformations bleed at some point in their natural history, most commonly before the patient reaches the age of 40 years. This tendency to bleed is unrelated to the lesion site or to the patient's sex, but small arteriovenous malformations are more likely to bleed than large ones. Arteriovenous malformations that have bled once are more likely to bleed again. Hemorrhage is commonly intracerebral as well as into the subarachnoid space, and it has a fatal outcome in about 10% of cases. Focal or generalized seizures may accompany or follow hemorrhage, or they may be the initial presentation, especially with frontal or parietal arteriovenous malformations. Headaches are especially likely when the external carotid arteries are involved in the malformation. These sometimes simulate migraine but more commonly are non-specific in character, with nothing about them to suggest an underlying structural lesion.

In patients presenting with subarachnoid hemorrhage, examination may reveal an abnormal mental status and signs of meningeal irritation. Additional findings may help localize the lesion and sometimes indicate that intracranial pressure is increased. A cranial bruit always suggests the possibility of a cerebral arteriovenous malformation, but bruits may also be found with aneurysms, meningiomas, acquired arteriovenous fistulas, and arteriovenous malformations involving the scalp, calvarium, or orbit. Bruits are best heard over the ipsilateral eye or mastoid region and are of some help in lateralization but of no help in localization. Absence of a bruit in no way excludes the possibility of arteriovenous malformation.

2. Infratentorial lesions—Brainstem arteriovenous malformations are often clinically silent, but they may hemorrhage, cause obstructive hydrocephalus, or lead to progressive or relapsing brainstem deficits. Cerebellar arteriovenous malformations may also be clinically inconspicuous but sometimes lead to cerebellar hemorrhage.

B. Imaging

In patients presenting with suspected hemorrhage, CT scanning indicates whether subarachnoid or intracerebral bleeding has recently occurred, helps localize its source, and may reveal the arteriovenous malformation. If the CT scan shows no evidence of bleeding but subarachnoid hemorrhage is diagnosed clinically, the cerebrospinal fluid should be examined.

When intracranial hemorrhage is confirmed but the source of hemorrhage is not evident on the CT scan, arteriography is necessary to exclude aneurysm or arteriovenous malformation. MR angiography is not sensitive enough for this purpose. Even if the findings on CT scan suggest arteriovenous malformation, arteriography is required to establish the nature of the lesion with certainty and to determine its anatomic features so that treatment can be planned. The examination must generally include bilateral opacification of the internal and external carotid arteries and the vertebral arteries. Arteriovenous malformations typically appear as a tangled vascular mass with distended tortuous afferent and efferent vessels, a rapid circulation time, and arteriovenous shunting. Findings on plain radiographs of the skull are often normal unless an intracerebral hematoma is present, in which case there may be changes suggestive of raised intracranial pressure and displacement of a calcified pineal gland.

In patients presenting without hemorrhage, CT scan or MRI usually reveals the underlying abnormality, and MRI frequently also shows evidence of old or recent hemorrhage that may have been asymptomatic. The nature and detailed anatomy of any focal lesion identified by these means are delineated by angiography, especially if operative treatment is under consideration.

C. Laboratory and Other Studies

Electroencephalography is usually indicated in patients presenting with seizures and may show consistently focal or lateralized abnormalities resulting from the underlying cerebral arteriovenous malformation. This should be followed by CT scanning.

► Treatment

Surgical treatment to prevent further hemorrhage is justified in patients with arteriovenous malformations that have bled, provided that the lesion is accessible and the patient has a reasonable life expectancy. Surgical treatment is also appropriate if intracranial pressure is increased and to prevent further progression of a focal neurologic deficit. In patients presenting solely with seizures, anticonvulsant drug treatment is usually sufficient, and operative treatment is unnecessary unless there are further developments.

Definitive operative treatment consists of excision of the arteriovenous malformation if it is surgically accessible. Arteriovenous malformations that are inoperable because of their location are sometimes treated solely by embolization; although the risk of hemorrhage is not reduced, neurologic deficits may be stabilized or even reversed by this procedure. Two other techniques for the treatment of intracerebral arteriovenous malformations are injection of a vascular occlusive polymer through a flow-guided microcatheter and permanent occlusion of feeding vessels by positioning detachable balloon catheters in the desired sites and then inflating them with quickly solidifying contrast material. Stereotactic radiosurgery with the gamma knife or related approaches is also useful in the management of inoperable cerebral arteriovenous malformations.

► When to Refer

All patients should be referred.

► When to Admit

- All patients with a subarachnoid or cerebral hemorrhage.
- All patients for detailed imaging.
- All patients undergoing surgical or endovascular treatment.

Hartmann A et al. Treatment of arteriovenous malformations of the brain. *Curr Neurol Neurosci Rep.* 2007 Jan;7(1):28–34. [PMID: 17217851]

7. Intracranial Venous Thrombosis

Intracranial venous thrombosis may occur in association with intracranial or maxillofacial infections, hypercoagulable states, polycythemia, sickle cell disease, and cyanotic congenital heart disease and in pregnancy or during the puerperium. It is characterized by headache, focal or generalized convulsions, drowsiness, confusion, increased intracranial pressure, and focal neurologic deficits—and sometimes by evidence of meningeal irritation. The diagnosis is confirmed by CT scanning, MRI, MR venography, or angiography.

Treatment includes anticonvulsant drugs if seizures have occurred and antiedema agents (eg, dexamethasone, 4 mg four times daily and continued as necessary) or other measures to reduce intracranial pressure. Anticoagulation with dose-adjusted intravenous heparin or weight-adjusted subcutaneous low-molecular-weight heparin, followed by oral warfarin anticoagulation for 6 months reduces morbidity and mortality of venous sinus thrombosis. Concomitant intracranial hemorrhage related to the venous thrombosis does not contraindicate heparin therapy. In cases refractory to heparin, endovascular techniques including catheter-directed thrombolytic therapy (urokinase) and thrombectomy, are sometimes helpful.

Masuhr F et al. Treatment of cerebral venous and sinus thrombosis. *Front Neurol Neurosci.* 2008;23:132–43. [PMID: 18004059]

► When to Refer

All patients should be referred.

► When to Admit

All patients should be hospitalized.

8. Spinal Cord Vascular Diseases

ESSENTIALS OF DIAGNOSIS

- Sudden onset of back or limb pain and neurologic deficit in limbs.

- ▶ Motor, sensory, or reflex changes in limbs depending on level of lesion.
- ▶ Imaging studies distinguish between infarct and hematoma.

▶ Infarction of the Spinal Cord

Infarction of the spinal cord is rare. It typically occurs in the territory of the anterior spinal artery because this vessel, which supplies the anterior two-thirds of the cord, is itself supplied by only a limited number of feeders. Infarction usually results from interrupted flow in one or more of these feeders, eg, with aortic dissection, aortography, polyarteritis, or severe hypotension, or after surgical resection of the thoracic aorta. The paired posterior spinal arteries, by contrast, are supplied by numerous arteries at different levels of the cord. Spinal cord hypoperfusion may lead to a central cord syndrome with distal weakness of lower motor neuron type and loss of pain and temperature appreciation, with preserved posterior column function.

Since the anterior spinal artery receives numerous feeders in the cervical region, infarcts almost always occur caudally. Clinical presentation is characterized by acute onset of flaccid, areflexive paraplegia that evolves after a few days or weeks into a spastic paraplegia with extensor plantar responses. There is an accompanying dissociated sensory loss, with impairment of appreciation of pain and temperature but preservation of sensations of vibration and position. Treatment is symptomatic.

Novy J et al. Spinal cord ischemia: clinical and imaging patterns, pathogenesis, and outcomes in 27 patients. *Arch Neurol.* 2006 Aug;63(8):1113–20. [PMID: 16908737]

▶ Epidural or Subdural Hemorrhage

Epidural or subdural hemorrhage may lead to sudden severe back pain followed by an acute compressive myelopathy necessitating urgent spinal MRI or myelography and surgical evacuation. It may occur in patients with bleeding disorders or those who are taking anticoagulant drugs, sometimes following trauma or lumbar puncture. Epidural hemorrhage may also be related to a vascular malformation or tumor deposit.

▶ Spinal Dural Arteriovenous Fistulae

Spinal dural arteriovenous fistulae are congenital lesions that present with spinal subarachnoid hemorrhage or myeloradiculopathy. Since most of these malformations are located in the thoracolumbar region, they lead to motor and sensory disturbances in the legs and to sphincter disorders. Pain in the legs or back is often severe. Examination reveals an upper, lower, or mixed motor deficit in the legs; sensory deficits are also present and are usually extensive, although occasionally they are confined to radicular distribution. Cervical spinal dural arteriovenous fistulae lead also to symptoms and signs in the arms. Spinal MRI may not detect the spinal dural arteriovenous fistulae, and negative findings do not exclude the diagno-

sis. Myelography (performed with the patient prone and supine) detects serpiginous filling defects due to enlarged vessels. Selective spinal arteriography confirms the diagnosis. Most lesions are extramedullary, are posterior to the cord (lying either intra- or extradurally), and can easily be treated by ligation of feeding vessels and excision of the fistulous anomaly or by embolization procedures. Delay in treatment may lead to increased and irreversible disability or to death from recurrent subarachnoid hemorrhage.

▶ When to Refer

All patients should be referred.

▶ When to Admit

All patients should be hospitalized.

INTRACRANIAL & SPINAL TUMORS

1. Primary Intracranial Tumors

ESSENTIALS OF DIAGNOSIS

- ▶ Generalized or focal disturbance of cerebral function, or both.
- ▶ Increased intracranial pressure in some patients.
- ▶ Neuroradiologic evidence of space-occupying lesion.

▶ General Considerations

Half of all primary intracranial neoplasms (Table 24–5) are gliomas and the remainder meningiomas, pituitary adenomas, neurofibromas, and other tumors. Certain tumors, especially neurofibromas, hemangioblastomas, and retinoblastomas, may have a familial basis, and congenital factors bear on the development of craniopharyngiomas. Tumors may occur at any age, but certain gliomas show particular age predilections (Table 24–5).

▶ Clinical Findings

A. Symptoms and Signs

Intracranial tumors may lead to a generalized disturbance of cerebral function and to symptoms and signs of increased intracranial pressure. In consequence, there may be personality changes, intellectual decline, emotional lability, seizures, headaches, nausea, and malaise. If the pressure is increased in a particular cranial compartment, brain tissue may herniate into a compartment with lower pressure. The most familiar syndrome is herniation of the temporal lobe uncus through the tentorial hiatus, which causes compression of the third cranial nerve, midbrain, and posterior cerebral artery. The earliest sign of this is ipsilateral pupillary dilation, followed by stupor, coma, decerebrate postur-

Table 24-5. Primary intracranial tumors.

| Tumor | Clinical Features | Treatment and Prognosis |
|------------------------------|--|---|
| Glioblastoma multiforme | Presents commonly with nonspecific complaints and increased intracranial pressure. As it grows, focal deficits develop. | Course is rapidly progressive, with poor prognosis. Total surgical removal is usually not possible. Radiation therapy and chemotherapy may prolong survival. |
| Astrocytoma | Presentation similar to glioblastoma multiforme but course more protracted, often over several years. Cerebellar astrocytoma may have a more benign course. | Prognosis is variable. By the time of diagnosis, total excision is usually impossible; tumor may be radiosensitive and chemotherapy may also be helpful. In cerebellar astrocytoma, total surgical removal is often possible. |
| Medulloblastoma | Seen most frequently in children. Generally arises from roof of fourth ventricle and leads to increased intracranial pressure accompanied by brainstem and cerebellar signs. May seed subarachnoid space. | Treatment consists of surgery combined with radiation therapy and chemotherapy. |
| Ependymoma | Glioma arising from the ependyma of a ventricle, especially the fourth ventricle; leads to early signs of increased intracranial pressure. Arises also from central canal of cord. | Tumor is best treated surgically if possible. Radiation therapy may be used for residual tumor. |
| Oligodendroglioma | Slow-growing. Usually arises in cerebral hemisphere in adults. Calcification may be visible on skull radiograph. | Treatment is surgical and usually successful. Radiation and chemotherapy may be used if tumor has malignant features. |
| Brainstem glioma | Presents during childhood with cranial nerve palsies and then with long tract signs in the limbs. Signs of increased intracranial pressure occur late. | Tumor is inoperable; treatment is by irradiation and shunt for increased intracranial pressure. |
| Cerebellar heman-gioblastoma | Presents with disequilibrium, ataxia of trunk or limbs, and signs of increased intracranial pressure. Sometimes familial. May be associated with retinal and spinal vascular lesions, polycythemia, and renal cell carcinoma. | Treatment is surgical. Radiation is used for residual tumor. |
| Pineal tumor | Presents with increased intracranial pressure, sometimes associated with impaired upward gaze (Parinaud syndrome) and other deficits indicative of midbrain lesion. | Ventricular decompression by shunting is followed by surgical approach to tumor; irradiation is indicated if tumor is malignant. Prognosis depends on histopathologic findings and extent of tumor. |
| Craniopharyngioma | Originates from remnants of Rathke pouch above the sella, depressing the optic chiasm. May present at any age but usually in childhood, with endocrine dysfunction and bitemporal field defects. | Treatment is surgical, but total removal may not be possible. Radiation may be used for residual tumor. |
| Acoustic neuroma | Ipsilateral hearing loss is most common initial symptom. Subsequent symptoms may include tinnitus, headache, vertigo, facial weakness or numbness, and long tract signs. (May be familial and bilateral when related to neurofibromatosis.) Most sensitive screening tests are MRI and brainstem auditory evoked potential. | Treatment is excision by translabyrinthine surgery, craniectomy, or a combined approach. Outcome is usually good. |
| Meningioma | Originates from the dura mater or arachnoid; compresses rather than invades adjacent neural structures. Increasingly common with advancing age. Tumor size varies greatly. Symptoms vary with tumor site—eg, unilateral proptosis (sphenoidal ridge); anosmia and optic nerve compression (olfactory groove). Tumor is usually benign and readily detected by CT scanning; may lead to calcification and bone erosion visible on plain radiographs of skull. | Treatment is surgical. Tumor may recur if removal is incomplete. |
| Primary cerebral lymphoma | Associated with AIDS and other immunodeficient states. Presentation may be with focal deficits or with disturbances of cognition and consciousness. May be indistinguishable from cerebral toxoplasmosis. | Treatment is high-dose methotrexate followed by radiation therapy. Prognosis depends on CD4 count at diagnosis. |

ing, and respiratory arrest. Another important herniation syndrome consists of displacement of the cerebellar tonsils through the foramen magnum, which causes medullary compression leading to apnea, circulatory collapse, and death. Other herniation syndromes are less common and of less clear clinical importance.

Intracranial tumors also lead to focal deficits depending on their location.

1. Frontal lobe lesions—Tumors of the frontal lobe often lead to progressive intellectual decline, slowing of mental activity, personality changes, and contralateral grasp reflexes.

They may lead to expressive aphasia if the posterior part of the left inferior frontal gyrus is involved. Anosmia may also occur as a consequence of pressure on the olfactory nerve. Precentral lesions may cause focal motor seizures or contralateral pyramidal deficits.

2. Temporal lobe lesions—Tumors of the uncinate region may be manifested by seizures with olfactory or gustatory hallucinations, motor phenomena such as licking or smacking of the lips, and some impairment of external awareness without actual loss of consciousness. Temporal lobe lesions also lead to depersonalization, emotional changes, behavioral disturbances, sensations of *déjà vu* or *jamais vu*, micropsia or macropsia (objects appear smaller or larger than they are), visual field defects (crossed upper quadrantanopia), and auditory illusions or hallucinations. Left-sided lesions may lead to dysnomia and receptive aphasia, while right-sided involvement sometimes disturbs the perception of musical notes and melodies.

3. Parietal lobe lesions—Tumors in this location characteristically cause contralateral disturbances of sensation and may cause sensory seizures, sensory loss or inattention, or some combination of these symptoms. The sensory loss is cortical in type and involves postural sensibility and tactile discrimination, so that the appreciation of shape, size, weight, and texture is impaired. Objects placed in the hand may not be recognized (astereognosis). Extensive parietal lobe lesions may produce contralateral hyperpathia and spontaneous pain (thalamic syndrome). Involvement of the optic radiation leads to a contralateral homonymous field defect that sometimes consists solely of lower quadrantopia. Lesions of the left angular gyrus cause Gerstmann syndrome (a combination of alexia, agraphia, acalculia, right-left confusion, and finger agnosia), whereas involvement of the left submarginal gyrus causes ideational apraxia. Anosognosia (the denial, neglect, or rejection of a paralyzed limb) is seen in patients with lesions of the nondominant (right) hemisphere. Constructional apraxia and dressing apraxia may also occur with right-sided lesions.

4. Occipital lobe lesions—Tumors of the occipital lobe characteristically produce crossed homonymous hemianopia or a partial field defect. With left-sided or bilateral lesions, there may be visual agnosia both for objects and for colors, while irritative lesions on either side can cause unformed visual hallucinations. Bilateral occipital lobe involvement causes cortical blindness in which there is preservation of pupillary responses to light and lack of awareness of the defect by the patient. There may also be loss of color perception, prosopagnosia (inability to identify a familiar face), simultagnosia (inability to integrate and interpret a composite scene as opposed to its individual elements), and Balint syndrome (failure to turn the eyes to a particular point in space, despite preservation of spontaneous and reflex eye movements). The denial of blindness or a field defect constitutes Anton syndrome.

5. Brainstem and cerebellar lesions—Brainstem lesions lead to cranial nerve palsies, ataxia, incoordination, nystagmus, and pyramidal and sensory deficits in the limbs on one or both sides. Intrinsic brainstem tumors, such as

gliomas, tend to produce an increase in intracranial pressure only late in their course. Cerebellar tumors produce marked ataxia of the trunk if the vermis cerebelli is involved and ipsilateral appendicular deficits (ataxia, incoordination and hypotonia of the limbs) if the cerebellar hemispheres are affected.

6. False localizing signs—Tumors may lead to neurologic signs other than by direct compression or infiltration, thereby leading to errors of clinical localization. These false localizing signs include third or sixth nerve palsy and bilateral extensor plantar responses produced by herniation syndromes, and an extensor plantar response occurring ipsilateral to a hemispheric tumor as a result of compression of the opposite cerebral peduncle against the tentorium.

B. Imaging

CT scanning or MRI with gadolinium enhancement may detect the lesion and may also define its location, shape, and size; the extent to which normal anatomy is distorted; and the degree of any associated cerebral edema or mass effect. CT scanning is less helpful with tumors in the posterior fossa, but MRI is of particular value there. The characteristic appearance of meningiomas on CT scanning is virtually diagnostic, ie, a lesion in a typical site (parasagittal and sylvian regions, olfactory groove, sphenoidal ridge, tuberculum sellae) that appears as a homogeneous area of increased density in noncontrast CT scans and enhances uniformly with contrast. Newer neuroimaging techniques may help identify brain tumors by increased blood perfusion (perfusion-weighted MRI, single photon-emitted computed tomography, positron-emission tomography) and high metabolism or cell turnover (magnetic resonance spectroscopy, positron-emission tomography), but non-neoplastic diseases, such as stroke and inflammatory or infectious diseases, are sometimes associated with hyperperfusion and hypermetabolism. Diffusion-weighted MRI may also be helpful. Arteriography may show stretching or displacement of normal cerebral vessels by the tumor and the presence of tumor vascularity. The presence of an avascular mass is a nonspecific finding that could be due to tumor, hematoma, abscess, or any space-occupying lesion. In patients with normal hormone levels and an intrasellar mass, angiography is necessary to distinguish with confidence between a pituitary adenoma and an arterial aneurysm.

C. Laboratory and Other Studies

The electroencephalogram provides supporting information concerning cerebral function and may show either a focal disturbance due to the neoplasm or a more diffuse change reflecting altered mental status. Lumbar puncture is rarely necessary; the findings are seldom diagnostic, and the procedure carries the risk of causing a herniation syndrome.

▶ Treatment

Treatment depends on the type and site of the tumor (Table 24–5) and the condition of the patient. Complete surgical removal may be possible if the tumor is extra-axial (eg, meningioma, acoustic neuroma) or is not in a critical or

inaccessible region of the brain (eg, cerebellar hemangioblastoma). Surgery also permits the diagnosis to be verified and may be beneficial in reducing intracranial pressure and relieving symptoms even if the neoplasm cannot be completely removed. Clinical deficits are sometimes due in part to obstructive hydrocephalus, in which case simple surgical shunting procedures often produce dramatic benefit. In patients with malignant gliomas, radiation therapy increases median survival rates regardless of any preceding surgery, and its combination with chemotherapy provides additional benefit. Indications for irradiation in the treatment of patients with other primary intracranial neoplasms depend on tumor type and accessibility and the feasibility of complete surgical removal. Corticosteroids help reduce cerebral edema and are usually started before surgery. Herniation is treated with intravenous dexamethasone (10–20 mg as a bolus, followed by 4 mg every 6 hours) and intravenous mannitol (20% solution given in a dose of 1.5 g/kg over about 30 minutes). Anticonvulsants are also commonly administered in standard doses (see Table 24–3) but are not indicated for prophylaxis in patients who have no history of seizures. Long-term neurocognitive deficits may complicate radiation therapy. For those patients whose disease deteriorates despite treatment, palliative care is important (see Chapter 5).

▶ When to Refer

All patients should be referred.

▶ When to Admit

- All patients with increased intracranial pressure.
- All patients requiring biopsy, surgical treatment, or shunting procedures.

2. Metastatic Intracranial Tumors

Cerebral Metastases

Metastatic brain tumors present in the same way as other cerebral neoplasms, ie, with increased intracranial pressure, with focal or diffuse disturbance of cerebral function, or with both of these manifestations. Indeed, in patients with a single cerebral lesion, the metastatic nature of the

lesion may only become evident on histopathologic examination. In other patients, there is evidence of widespread metastatic disease, or an isolated cerebral metastasis develops during treatment of the primary neoplasm.

The most common source of intracranial metastasis is carcinoma of the lung; other primary sites are the breast, kidney, and gastrointestinal tract. Most cerebral metastases are located supratentorially. Laboratory and radiologic studies used to evaluate patients with metastases are those described for primary neoplasms. They include MRI and CT scanning performed both with and without contrast material. Lumbar puncture is necessary only in patients with suspected carcinomatous meningitis (see below). In patients with verified cerebral metastasis from an unknown primary, investigation is guided by symptoms and signs. In women, mammography is indicated; in men under 50, germ cell origin is sought since both have therapeutic implications.

In patients with only a single, surgically accessible cerebral metastasis who are otherwise well (ie, a high level of functioning and little or no evidence of extracranial disease), it may be possible to remove the lesion and then treat with irradiation; the latter may also be selected as the sole treatment. In patients with multiple metastases or widespread systemic disease, the prognosis is poor; stereotactic radiosurgery, whole-brain radiotherapy, or both, may help in some instances, but in others treatment is palliative only.

 Smith ML et al. Stereotactic radiosurgery in the management of brain metastasis. *Neurosurg Focus*. 2007 Mar 15;22(3):E5. [PMID: 17608358]

Leptomeningeal Metastases (Carcinomatous Meningitis)

The neoplasms metastasizing most commonly to the leptomeninges are carcinoma of the breast, lymphomas, and leukemia. Leptomeningeal metastases lead to multifocal neurologic deficits, which may be associated with infiltration of cranial and spinal nerve roots, direct invasion of the brain or spinal cord, obstructive hydrocephalus, or some combination of these factors.

The diagnosis is confirmed by examination of the cerebrospinal fluid. Findings may include elevated cerebrospinal fluid pressure, pleocytosis, increased protein concentration, and decreased glucose concentration. Cytologic studies may indicate that malignant cells are present; if not, spinal tap should be repeated at least twice to obtain further samples for analysis.

CT scans showing contrast enhancement in the basal cisterns or showing hydrocephalus without any evidence of a mass lesion support the diagnosis. Gadolinium-enhanced MRI frequently shows enhancing foci in the leptomeninges. Myelography may show deposits on multiple nerve roots.

Treatment is by irradiation to symptomatic areas, combined with intrathecal methotrexate. The long-term prognosis is poor—only about 10% of patients survive for 1 year—and palliative care is therefore important (see Chapter 5).

3. Intracranial Mass Lesions in AIDS Patients

Primary cerebral lymphoma is a common complication in patients with AIDS. This leads to disturbances in cognition or consciousness, focal motor or sensory deficits, aphasia, seizures, and cranial neuropathies. Similar clinical disturbances may result from **cerebral toxoplasmosis**, which is also a common complication in patients with AIDS (see Chapters 31 and 35). Neither CT nor MRI findings distinguish these two disorders, and serologic tests for toxoplasmosis are unreliable in AIDS patients. Accordingly, for neurologically stable patients, a trial of treatment for toxoplasmosis with sulfadiazine (100 mg/kg/d up to 8 g/d in four divided doses) and pyrimethamine (75 mg/d for 3 days, then 25 mg/d) is recommended for 3 weeks; the imaging studies are then repeated, and if any lesion has improved, the regimen is continued indefinitely. If any lesion does not improve, cerebral biopsy is necessary. Primary cerebral lymphoma is treated with whole-brain irradiation.

Cryptococcal meningitis is a common opportunistic infection in AIDS patients. Clinically, it may resemble cerebral toxoplasmosis or lymphoma, but cranial CT scans are usually normal. The diagnosis is made on the basis of cerebrospinal fluid studies, with positive India ink staining in 75–80% and cryptococcal antigen tests in 95% of cases. Treatment is with amphotericin B plus flucytosine, as set forth in Table 36–1, followed by fluconazole.

4. Primary & Metastatic Spinal Tumors

Approximately 10% of spinal tumors are intramedullary. Ependymoma is the most common type of intramedullary tumor; the remainder are other types of glioma. Extramedullary tumors may be extradural or intradural in location. Among the primary extramedullary tumors, neurofibromas and meningiomas are relatively common, are benign, and may be intradural or extradural. Carcinomatous metastases, lymphomatous or leukemic deposits, and myeloma are usually extradural; in the case of metastases, the prostate, breast, lung, and kidney are common primary sites.

Tumors may lead to spinal cord dysfunction by direct compression, by ischemia secondary to arterial or venous obstruction, and, in the case of intramedullary lesions, by invasive infiltration.

► Clinical Findings

A. Symptoms and Signs

Symptoms usually develop insidiously. Pain is often conspicuous with extradural lesions; is characteristically aggravated by coughing or straining; may be radicular, localized to the back, or felt diffusely in an extremity; and may be accompanied by motor deficits, paresthesias, or numbness, especially in the legs. When sphincter disturbances occur, they are usually particularly disabling. Pain, however, often

precedes specific neurologic symptoms from epidural metastases.

Examination may reveal localized spinal tenderness. A segmental lower motor neuron deficit or dermatomal sensory changes (or both) are sometimes found at the level of the lesion, while an upper motor neuron deficit and sensory disturbance are found below it.

B. Imaging

Findings on plain radiography of the spine may be normal but are commonly abnormal when there are metastatic deposits. CT myelography or MRI may be necessary to identify and localize the site of cord compression. The combination of known tumor elsewhere in the body, back pain, and either abnormal plain films of the spine or neurologic signs of cord compression is an indication to perform these studies on an urgent basis. Some clinicians proceed to myelography based solely on new back pain in a cancer patient. If a complete block is present at lumbar myelography, a cisternal myelogram is performed to determine the upper level of the block and to investigate the possibility of block higher in the cord.

C. Laboratory Findings

The cerebrospinal fluid removed at myelography is often xanthochromic and contains a greatly increased protein concentration with normal cell content and glucose concentration.

► Treatment

Intramedullary tumors are treated by decompression and surgical excision (when feasible) and by irradiation. The prognosis depends on the cause and severity of cord compression before it is relieved.

Treatment of epidural spinal metastases consists of irradiation, irrespective of cell type. Dexamethasone is also given in a high dosage (eg, 25 mg four times daily for 3 days, followed by rapid tapering of the dosage, depending on response) to reduce cord swelling and relieve pain. Surgical decompression is reserved for patients with tumors that are unresponsive to irradiation or have previously been irradiated and for cases in which there is some uncertainty about the diagnosis. The long-term outlook is poor, but radiation treatment may at least delay the onset of major disability.

Cole JS et al. Metastatic epidural spinal cord compression. *Lancet Neurol*. 2008 May;7(5):459–66. [PMID: 18420159]

5. Brain Abscess

ESSENTIALS OF DIAGNOSIS

- Symptoms and signs of expanding intracranial mass.
- Signs of primary infection or congenital heart disease are sometimes present.
- Fever may be absent.

► General Considerations

Brain abscess presents as an intracranial space-occupying lesion and arises as a sequela of disease of the ear or nose, may be a complication of infection elsewhere in the body, or may result from infection introduced intracranially by trauma or surgical procedures. The most common infective organisms are streptococci, staphylococci, and anaerobes; mixed infections are not uncommon.

► Clinical Findings

A. Symptoms and Signs

Headache, drowsiness, inattention, confusion, and seizures are early symptoms, followed by signs of increasing intracranial pressure and then a focal neurologic deficit. There may be little or no systemic evidence of infection.

B. Imaging and Other Investigations

A CT scan of the head characteristically shows an area of contrast enhancement surrounding a low-density core. Similar abnormalities may be found in patients with metastatic neoplasms. MRI findings often permit earlier recognition of focal cerebritis or an abscess. Arteriography indicates the presence of a space-occupying lesion, which appears as an avascular mass with displacement of normal cerebral vessels, but this procedure provides no clue to the nature of the lesion. Stereotactic needle aspiration may enable a specific etiologic organism to be identified. Examination of the cerebrospinal fluid does not help in diagnosis and may precipitate a herniation syndrome. Peripheral leukocytosis is sometimes present.

► Treatment

Treatment consists of intravenous antibiotics, combined with surgical drainage (aspiration or excision) if necessary to reduce the mass effect, or sometimes to establish the diagnosis. Abscesses smaller than 2 cm can often be cured medically. Broad-spectrum antibiotics, selected based on risk factors and likely organisms, are used if the infecting organism is unknown (see Chapter 33). A common regimen is with penicillin G plus a third-generation cephalosporin plus metronidazole. Nafcillin is added if *Staphylococcus aureus* infection is suspected. The regimen is altered once culture and sensitivity data are available. Antimicrobial treatment is usually continued parenterally for 6–8 weeks, followed by orally for 2–3 months. The patient should be monitored by serial CT scans or MRI every 2 weeks and at deterioration. Dexamethasone (4–25 mg four times daily, depending on severity, followed by tapering of dose, depending on response) may reduce any associated edema, but intravenous mannitol is sometimes required.

Carpenter J et al. Retrospective analysis of 49 cases of brain abscess and review of the literature. *Eur J Clin Microbiol Infect Dis.* 2007 Jan;26(1):1–11. [PMID: 17180609]

NONMETASTATIC NEUROLOGIC COMPLICATIONS OF MALIGNANT DISEASE

A variety of nonmetastatic neurologic complications of malignant disease (see Table 39–13) can be recognized. Metabolic

encephalopathy due to electrolyte abnormalities, infections, drug overdose, or the failure of some vital organ may be reflected by drowsiness, lethargy, restlessness, insomnia, agitation, confusion, stupor, or coma. The mental changes are usually associated with tremor, asterixis, and multifocal myoclonus. The electroencephalogram is generally diffusely slowed. Laboratory studies are necessary to detect the cause of the encephalopathy, which must then be treated appropriately.

Immune suppression resulting from either the malignant disease or its treatment (eg, by chemotherapy) predisposes patients to brain abscess, progressive multifocal leukoencephalopathy, meningitis, herpes zoster infection, and other opportunistic infectious diseases. Moreover, an overt or occult cerebrospinal fluid fistula, as occurs with some tumors, may also increase the risk of infection. CT scanning aids in the early recognition of a brain abscess, but metastatic brain tumors may have a similar appearance. Examination of the cerebrospinal fluid is essential in the evaluation of patients with meningitis but is of no help in the diagnosis of brain abscess.

Cerebrovascular disorders that cause neurologic complications in patients with systemic cancer include nonbacterial thrombotic endocarditis and septic embolization. Cerebral, subarachnoid, or subdural hemorrhages may occur in patients with myelogenous leukemia and may be found in association with metastatic tumors, especially malignant melanoma. Spinal subdural hemorrhage sometimes occurs after lumbar puncture in patients with marked thrombocytopenia.

Disseminated intravascular coagulation occurs most commonly in patients with acute promyelocytic leukemia or with some adenocarcinomas and is characterized by a fluctuating encephalopathy, often with associated seizures, that frequently progresses to coma or death. There may be few accompanying neurologic signs. Venous sinus thrombosis, which usually presents with convulsions and headaches, may also occur in patients with leukemia or lymphoma. Examination commonly reveals papilledema and focal or diffuse neurologic signs. Anticonvulsants, anticoagulants, and drugs to lower the intracranial pressure may be of value.

Paraneoplastic cerebellar degeneration occurs most commonly in association with carcinoma of the lung. Symptoms may precede those due to the neoplasm itself, which may be undetected for several months or even longer. Typically, there is a pancerebellar syndrome causing dysarthria, nystagmus, and ataxia of the trunk and limbs. The disorder probably has an autoimmune basis. Treatment is of the underlying malignant disease.

Encephalopathy, characterized by impaired recent memory, disturbed affect, hallucinations, and seizures, occurs in some patients with carcinomas. The cerebrospinal fluid is often abnormal. EEGs may show diffuse slow-wave activity, especially over the temporal regions. Pathologic changes are most marked in the inferomedian portions of the temporal lobes. There is no specific treatment.

Malignant disease may be associated with sensorimotor polyneuropathy and less commonly with pure sensory neuropathy (ie, dorsal root ganglionitis) or autonomic neuropathy. A subacute motor neuronopathy may be associated with lymphomas.

Dermatomyositis or a myasthenic syndrome may be seen in patients with underlying carcinoma (see Chapter

20). The myasthenic syndrome may have an autoimmune basis and differs clinically from myasthenia gravis.

Dalmau J et al. Paraneoplastic syndromes of the CNS. *Lancet Neurol.* 2008 Apr;7(4):327–40. [PMID: 18339348]

PSEUDOTUMOR CEREBRI (Benign Intracranial Hypertension)

ESSENTIALS OF DIAGNOSIS

- ▶ Headache, worse on straining.
- ▶ Visual obscurations or diplopia may occur.
- ▶ Examination reveals papilledema.
- ▶ Abducens palsy is commonly present.

▶ General Considerations

There are many causes of pseudotumor cerebri. Thrombosis of the transverse venous sinus as a noninfectious complication of otitis media or chronic mastoiditis is one cause, and sagittal sinus thrombosis may lead to a clinically similar picture. Other causes include chronic pulmonary disease, endocrine disturbances such as hypoparathyroidism or Addison disease, vitamin A toxicity, and the use of tetracycline or oral contraceptives. Cases have also followed withdrawal of corticosteroids after long-term use. In many instances, however, no specific cause can be found, and the disorder remits spontaneously after several months.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms of pseudotumor cerebri consist of headache, diplopia, and other visual disturbances due to papilledema and abducens nerve dysfunction. Pulse-synchronous tinnitus may also occur. Examination reveals the papilledema and some enlargement of the blind spots, but patients otherwise look well.

B. Imaging

Investigations reveal no evidence of a space-occupying lesion, and the CT scan shows small or normal ventricles. MR venography is helpful in screening for thrombosis of the intracranial venous sinuses.

C. Laboratory Findings

Lumbar puncture confirms the presence of intracranial hypertension, but the cerebrospinal fluid is normal. Laboratory studies help exclude some of the other causes mentioned earlier.

▶ Treatment

Untreated pseudotumor cerebri leads to secondary optic atrophy and permanent visual loss. Acetazolamide (250 mg orally three times daily) reduces formation of cerebrospinal

fluid and can be used to start treatment. Oral corticosteroids (eg, prednisone, 60–80 mg daily) may also be necessary. Obese patients should be advised to lose weight. Repeated lumbar puncture to lower the intracranial pressure by removal of cerebrospinal fluid is effective, but pharmacologic approaches to treatment are now more satisfactory. Treatment is monitored by checking visual acuity and visual fields, fundoscopic appearance, and pressure of the cerebrospinal fluid. The disorder may worsen after a period of stability, indicating the need for long-term follow-up.

If medical treatment fails to control the intracranial pressure, surgical placement of a lumboperitoneal or other shunt or optic nerve sheath fenestration should be undertaken to preserve vision.

In addition to the above measures, any specific cause of pseudotumor cerebri requires appropriate treatment. Thus, hormone therapy should be initiated if there is an underlying endocrine disturbance. Discontinuing the use of tetracycline, oral contraceptives, or vitamin A will allow for resolution of pseudotumor cerebri due to these agents. If corticosteroid withdrawal is responsible, the medication should be reintroduced and then tapered more gradually.

▶ When to Refer

All patients should be referred.

▶ When to Admit

All patients requiring shunt placement or optic nerve sheath fenestration should be hospitalized.

SELECTED NEUROCUTANEOUS DISEASES

1. Tuberos Sclerosis

Tuberous sclerosis may occur sporadically or on a familial basis with autosomal dominant inheritance. There is genetic heterogeneity; mutations involving 9q34 and 16p13 are well described. Neurologic presentation is with seizures and progressive psychomotor retardation beginning in early childhood. The cutaneous abnormality, adenoma sebaceum, becomes manifest usually between 5 and 10 years of age and typically consists of reddened nodules on the face (cheeks, nasolabial folds, sides of the nose, and chin) and sometimes on the forehead and neck. Other typical cutaneous lesions include subungual fibromas, shagreen patches (leathery plaques of subepidermal fibrosis, situated usually on the trunk), and leaf-shaped hypopigmented spots. Associated abnormalities include retinal lesions and tumors, benign rhabdomyomas of the heart, lung cysts, benign tumors in the viscera, and bone cysts.

The disease is slowly progressive and leads to increasing mental deterioration. There is no specific treatment, but anticonvulsant drugs may help in controlling seizures.

Curatolo P et al. Tuberous sclerosis. *Lancet*. 2008 Aug 23;372(9639):657–68. [PMID: 18722871]

2. Neurofibromatosis

Neurofibromatosis may occur either sporadically or on a familial basis with autosomal dominant inheritance. Two distinct forms are recognized: Type 1 (**Recklinghausen disease**) is characterized by multiple hyperpigmented macules and neurofibromas and type 2 by **eighth nerve tumors**, often accompanied by other intracranial or intraspinal tumors. Among familial cases, the gene for type 1 is located on chromosome 17 and that for type 2 on chromosome 22.

Neurologic presentation is usually with symptoms and signs of tumor. Multiple neurofibromas characteristically are present and may involve spinal or cranial nerves, especially the eighth nerve (Plate 89). Examination of the superficial cutaneous nerves usually reveals palpable mobile nodules. In some cases, there is an associated marked overgrowth of subcutaneous tissues (plexiform neuromas), sometimes with an underlying bony abnormality. Associated cutaneous lesions include axillary freckling and patches of cutaneous pigmentation (café au lait spots). Malignant degeneration of neurofibromas occasionally occurs and may lead to peripheral sarcomas. Meningiomas, gliomas (especially optic nerve gliomas), bone cysts, pheochromocytomas, scoliosis, and obstructive hydrocephalus may also occur.

Yohay K. Neurofibromatosis types 1 and 2. *Neurologist*. 2006 Mar;12(2):86–93. [PMID: 16534445]

3. Sturge-Weber Syndrome

Sturge-Weber syndrome consists of a congenital, usually unilateral, cutaneous capillary angioma involving the upper face, leptomeningeal angiomatosis, and, in many patients, choroidal angioma. It has no sex predilection and usually occurs sporadically. The cutaneous angioma sometimes has a more extensive distribution over the head and neck and is often quite disfiguring, especially if there is associated overgrowth of connective tissue. Focal or generalized seizures are the usual neurologic presentation and may commence at any age. There may be contralateral homonymous hemianopia, hemiparesis and hemisensory disturbance, ipsilateral glaucoma, and mental subnormality. Skull radiographs taken after the first 2 years of life usually reveal gyriform (“tramline”) intracranial calcification, especially in the parieto-occipital region, due to mineral deposition in the cortex beneath the intracranial angioma.

Treatment is aimed at controlling seizures pharmacologically, but surgical treatment may be necessary. Ophthalmologic advice should be sought concerning the management of choroidal angioma and of increased intraocular pressure.

Pascual-Castroviejo I et al. Sturge-Weber syndrome: study of 55 patients. *Canad J Neurol Sci*. 2008 Jul;35(3):301–7. [PMID: 18714797]

MOVEMENT DISORDERS

1. Benign Essential (Familial) Tremor

ESSENTIALS OF DIAGNOSIS

- ▶ Postural tremor of hands, head, or voice.
- ▶ Family history common.
- ▶ May improve temporarily with alcohol.
- ▶ No abnormal findings other than tremor.

▶ General Considerations

The cause of benign essential tremor is uncertain, but it is sometimes inherited in an autosomal dominant manner. Responsible genes have been identified at 3q13, 2p22-p25, and 6p23.

▶ Clinical Findings

Tremor may begin at any age and is enhanced by emotional stress. The tremor usually involves one or both hands, the head, or the hands and head, while the legs tend to be spared. Examination reveals no other abnormalities. Ingestion of a small quantity of alcohol commonly provides remarkable but short-lived relief by an unknown mechanism.

Although the tremor may become more conspicuous with time, it generally leads to little disability. Occasionally, it interferes with manual skills and leads to impairment of handwriting. Speech may also be affected if the laryngeal muscles are involved.

▶ Treatment

Treatment is often unnecessary. When it is required because of disability, propranolol may be helpful but will need to be continued indefinitely in daily doses of 60–240 mg. However, intermittent therapy is sometimes useful in patients whose tremor becomes exacerbated in specific predictable situations. Primidone may be helpful when propranolol is ineffective, but patients with essential tremor are often very sensitive to it. Therefore, the starting dose is 50 mg daily, and the daily dose is increased by 50 mg every 2 weeks depending on the patient's response; a maintenance dose of 125 mg three times daily is commonly effective. Occasional patients do not respond to these measures but are helped by alprazolam (up to 3 mg daily in divided doses), clozapine (30–50 mg twice daily), topiramate (titrated up to a dose of 400 mg daily in divided doses over about 8 weeks), gabapentin (1800 mg daily in divided doses), or mirtazapine (15 or 30 mg at night). Other antiepileptic agents including levetiracetam and zonisamide are reportedly sometimes effective. Botulinum toxin A may reduce tremor, but adverse effects include dose-dependent weakness of the injected muscles.

Disabling tremor unresponsive to medical treatment may be helped by contralateral thalamotomy. Unilateral

high-frequency thalamic stimulation is an alternative approach that is equally effective, is associated with only mild and transient side effects, and is therefore preferred. Bilateral thalamotomy has significant morbidity, whereas the risks of bilateral stimulation are appreciably lower.

▶ When to Refer

All patients should be referred.

▶ When to Admit

Patients requiring surgical treatment (deep brain stimulation placement) should be hospitalized.

Ondo WG. Essential tremor: treatment options. *Curr Treat Options Neurol*. 2006 May;8(3):256–67. [PMID: 16569384]

2. Parkinsonism

ESSENTIALS OF DIAGNOSIS

- ▶ Any combination of tremor, rigidity, bradykinesia, progressive postural instability.
- ▶ Cognitive impairment is sometimes prominent.

▶ General Considerations

Parkinsonism is a relatively common disorder that occurs in all ethnic groups, with an approximately equal sex distribution. The most common variety, idiopathic Parkinson disease (paralysis agitans), begins most often between 45 and 65 years of age and is a progressive disease.

▶ Etiology

Parkinsonism may rarely occur on a familial basis, and the parkinsonian phenotype may result from mutations of several different genes (alpha-synuclein, parkin, *LRKK2*, *DJ1*, and *PINK1*). Postencephalitic parkinsonism is becoming increasingly rare. Exposure to certain toxins (eg, manganese dust, carbon disulfide) and severe carbon monoxide poisoning may lead to parkinsonism. Typical parkinsonism has occurred in individuals who have taken 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP) for recreational purposes. This compound is converted in the body to a neurotoxin that selectively destroys dopaminergic neurons in the substantia nigra. Reversible parkinsonism may develop in patients receiving neuroleptic drugs (see Chapter 25), reserpine, or metoclopramide. Only rarely is hemiparkinsonism the presenting feature of a progressive space-occupying lesion.

In idiopathic parkinsonism, dopamine depletion due to degeneration of the dopaminergic nigrostriatal system leads to an imbalance of dopamine and acetylcholine,

which are neurotransmitters normally present in the corpus striatum. Treatment is directed at redressing this imbalance by blocking the effect of acetylcholine by anticholinergic drugs or by the administration of levodopa, the precursor of dopamine. The serum urate level may be a prognostic indicator—the rate of progression declines as the urate level increases.

▶ Clinical Findings

Tremor, rigidity, bradykinesia, and postural instability are the cardinal features of parkinsonism and may be present in any combination. There may also be a mild decline in intellectual function. The tremor of about four to six cycles per second is most conspicuous at rest, is enhanced by emotional stress, and is often less severe during voluntary activity. Although it may ultimately be present in all limbs, the tremor is commonly confined to one limb or to the limbs on one side for months or years before it becomes more generalized. In some patients, tremor is absent.

Rigidity (an increase in resistance to passive movement) is responsible for the characteristically flexed posture seen in many patients, but the most disabling symptoms of parkinsonism are due to bradykinesia, manifested as a slowness of voluntary movement and a reduction in automatic movements such as swinging of the arms while walking. Curiously, however, effective voluntary activity may briefly be regained during an emergency (eg, the patient is able to leap aside to avoid an oncoming motor vehicle).

Clinical diagnosis of the well-developed syndrome is usually simple. The patient has a relatively immobile face with widened palpebral fissures, infrequent blinking, and a certain fixity of facial expression. Seborrhea of the scalp and face is common. There is often mild blepharoclonus, and a tremor may be present about the mouth and lips. Repetitive tapping (about twice per second) over the bridge of the nose produces a sustained blink response (Myerson sign). Other findings may include saliva drooling from the mouth, perhaps due to impairment of swallowing; soft and poorly modulated voice; a variable rest tremor and rigidity in some or all of the limbs; slowness of voluntary movements; impairment of fine or rapidly alternating movements; and micrographia. There is typically no muscle weakness (provided that sufficient time is allowed for power to be developed) and no alteration in the tendon reflexes or plantar responses. It is difficult for the patient to arise from a sitting position and begin walking. The gait itself is characterized by small shuffling steps and a loss of the normal automatic arm swing; there may be unsteadiness on turning, difficulty in stopping, and a tendency to fall.

▶ Differential Diagnosis

Diagnostic problems may occur in mild cases, especially if tremor is minimal or absent. For example, mild hypokinesia or slight tremor is commonly attributed to old age. Depression, with its associated expressionless face, poorly modulated voice, and reduction in voluntary activity, can be difficult to distinguish from mild parkinsonism, especially since the two disorders may coexist; in some cases, a trial of antidepressant drug therapy is necessary. The family

history, the character of the tremor, and lack of other neurologic signs should distinguish essential tremor from parkinsonism. Wilson disease can be distinguished by its early age at onset, the presence of other abnormal movements, Kayser-Fleischer rings, and chronic hepatitis, and by increased concentrations of copper in the tissues. Huntington disease presenting with rigidity and bradykinesia may be mistaken for parkinsonism unless the family history and accompanying dementia are recognized. In Shy-Drager syndrome (also called multisystem atrophy), the clinical features of parkinsonism are accompanied by autonomic insufficiency (leading to postural hypotension, anhidrosis, disturbances of sphincter control, impotence, etc) and more widespread neurologic deficits (pyramidal, lower motor neuron, or cerebellar signs). In progressive supranuclear palsy, bradykinesia and rigidity are accompanied by a supranuclear disorder of eye movements, pseudobulbar palsy, pseudo-emotional lability (pseudobulbar affect), and axial dystonia. Creutzfeldt-Jakob disease may be accompanied by features of parkinsonism, but dementia is usual, myoclonic jerking is common, ataxia and pyramidal signs may be conspicuous, and the electroencephalographic findings are usually characteristic. In cortical-basal ganglionic degeneration, parkinsonism is accompanied by conspicuous signs of cortical dysfunction (eg, apraxia, sensory inattention, dementia, aphasia).

► Treatment

Treatment is symptomatic. Recent studies, however, suggest that rasagiline, 1 mg daily, slows progression of Parkinson disease (see Selective monoamine oxidase inhibitors below), and trials of several other putative neuroprotective agents are in progress, as are various trials of gene therapy.

A. Medical Measures

Drug treatment is not required early in the course of Parkinson disease, but the nature of the disorder and the availability of medical treatment for use when necessary should be discussed with the patient.

1. Amantadine—Patients with mild symptoms but no disability may be helped by amantadine. This drug improves all of the clinical features of parkinsonism, but its mode of action is unclear. Side effects include restlessness, confusion, depression, skin rashes, edema, nausea, constipation, anorexia, postural hypotension, and disturbances of cardiac rhythm. However, these are relatively uncommon with the usual dose (100 mg twice daily).

2. Anticholinergic drugs—Anticholinergics are more helpful in alleviating tremor and rigidity than bradykinesia. Treatment is started with a small dose (Table 24–6) and gradually increased until benefit occurs or side effects limit further increments. If treatment is ineffective, the drug is gradually withdrawn and another preparation then tried.

Common side effects include dryness of the mouth, nausea, constipation, palpitations, cardiac arrhythmias, urinary retention, confusion, agitation, restlessness, drowsiness, mydriasis, increased intraocular pressure, and defective accommodation.

Table 24–6. Some anticholinergic antiparkinsonian drugs.

| Drug | Usual Daily Dose |
|----------------------------------|------------------|
| Benzotropine mesylate (Cogentin) | 1–6 mg |
| Biperiden (Akineton) | 2–12 mg |
| Orphenadrine (Disipal, Norflex) | 150–400 mg |
| Procyclidine (Kemadrin) | 7.5–30 mg |
| Trihexyphenidyl (Artane) | 6–20 mg |

Modified, with permission, from Aminoff MJ: Pharmacologic management of parkinsonism and other movement disorders. In: *Basic & Clinical Pharmacology*, 10th ed. Katzung BG (editor). McGraw-Hill, 2007.

Anticholinergic drugs are contraindicated in patients with prostatic hyperplasia, narrow-angle glaucoma, or obstructive gastrointestinal disease and are often tolerated poorly by the elderly.

3. Levodopa—Levodopa, which is converted in the body to dopamine, improves all of the major features of parkinsonism, including bradykinesia, but does not stop progression of the disorder. The most common early side effects of levodopa are nausea, vomiting, and hypotension, but cardiac arrhythmias may also occur. Dyskinesias, restlessness, confusion, and other behavioral changes tend to occur somewhat later and become more common with time. Levodopa-induced dyskinesias may take any conceivable form, including chorea, athetosis, dystonia, tremor, tics, and myoclonus. An even later complication is the “on-off phenomenon,” in which abrupt but transient fluctuations in the severity of parkinsonism occur unpredictably but frequently during the day. The “off” period of marked bradykinesia has been shown to relate in some instances to falling plasma levels of levodopa. During the “on” phase, dyskinesias are often conspicuous but mobility is increased.

Carbidopa, which inhibits the enzyme responsible for the breakdown of levodopa to dopamine, does not cross the blood-brain barrier. When levodopa is given in combination with carbidopa, the extracerebral breakdown of levodopa is diminished. This reduces the amount of levodopa required daily for beneficial effects, and it lowers the incidence of nausea, vomiting, hypotension, and cardiac irregularities. Such a combination does not prevent the development of the “on-off phenomenon,” and the incidence of other side effects (dyskinesias or psychiatric complications) may actually be increased.

Sinemet, a commercially available preparation that contains carbidopa and levodopa in a fixed ratio (1:10 or 1:4), is generally used. Treatment is started with a small dose—eg, one tablet of Sinemet 25/100 (containing 25 mg of carbidopa and 100 mg of levodopa) three times daily—and gradually increased depending on the response. Sinemet CR is a controlled-release formulation (containing 25 or 50 mg of carbidopa and 100 or 200 mg of levodopa). It is sometimes helpful in reducing fluctuations in clinical response to treatment and in reducing the frequency with which medication must be taken. The commercially available combina-

tion of levodopa with both carbidopa and entacapone (Stalevo) may also be helpful in this context and is discussed in the following section on COMT inhibitors. Response fluctuations are also reduced by keeping the daily intake of protein at the recommended minimum and taking the main protein meal as the last meal of the day.

The dyskinesias and behavioral side effects of levodopa are dose-related, but reduction in dose may eliminate any therapeutic benefit. Levodopa-induced dyskinesias may also respond to amantadine.

Levodopa therapy is contraindicated in patients with psychotic illness or narrow-angle glaucoma. It should not be given to patients taking monoamine oxidase A inhibitors or within 2 weeks of their withdrawal, because hypertensive crises may result. Levodopa should be used with care in patients with suspected malignant melanomas or with active peptic ulcers because of concerns that it may exacerbate these disorders.

4. Dopamine agonists—Dopamine agonists act directly on dopamine receptors, and their use in parkinsonism is associated with a lower incidence of the response fluctuations and dyskinesias that occur with long-term levodopa therapy. They were previously reserved for patients who had either become refractory to levodopa or developed the “on-off phenomenon.” However, they are now best given either before the introduction of levodopa or with a low dose of Sinemet 25/100 (carbidopa 25 mg and levodopa 100 mg), one tablet three times daily when dopaminergic therapy is first introduced; the dose of Sinemet is kept constant, while the dose of the agonist is gradually increased. Bromocriptine, an ergot derivative is not widely used in the United States because of side effects, including anorexia; nausea; vomiting; constipation; postural hypotension; digital vasospasm; cardiac arrhythmias; various dyskinesias and mental disturbances; headache; nasal congestion; erythromelalgia; pulmonary infiltrates; and pericardial, pleural, or pulmonary fibrosis. In 2007, the manufacturer of pergolide, another ergot derivative and dopamine agonist, withdrew the drug from the US market after two studies showed that serious cardiac valvular abnormalities developed in some patients while taking the drug.

Pramipexole and ropinirole are two newer dopamine agonists that are not ergot derivatives. They are effective in early Parkinson disease as well as in advanced stages of the disease. In each case, the daily dose is built up gradually. Pramipexole is started at a dosage of 0.125 mg three times daily, and the dose is doubled after 1 week and again after another week; the daily dose is then increased by 0.75 mg at weekly intervals depending on response and tolerance. Most patients require between 0.5 and 1.5 mg three times daily. Ropinirole is begun in a dosage of 0.25 mg three times daily, and the total daily dose is increased at weekly intervals by 0.75 mg until the fourth week and by 1.5 mg thereafter. Most patients require between 2 and 8 mg three times daily for benefit. Adverse effects include fatigue, somnolence, nausea, peripheral edema, dyskinesias, confusion, and postural hypotension. Less commonly, an irresistible urge to sleep may occur, sometimes in inappropriate and hazardous circumstances. Impulse control disorders involving

gambling, shopping, or sexual activity have also been related to use of dopamine agonists.

5. Selective monoamine oxidase inhibitors—Rasagiline, a selective monoamine oxidase B inhibitor, has a clear symptomatic benefit in a daily oral dose of 1 mg, taken in the morning; it may also be used for adjunctive therapy in patients with response fluctuations to levodopa. Selegiline (5 mg orally with breakfast and lunch) is another monoamine oxidase B inhibitor that is sometimes used as adjunctive treatment for parkinsonism; by inhibiting the metabolic breakdown of dopamine, it may improve fluctuations or declining response to levodopa. Tyramine-rich foods are best avoided when either of these agents is taken because of the theoretical possibility of a hypertensive (“cheese”) effect.

Recent studies suggest that rasagiline slows the progression of Parkinson disease and this remains an important consideration for patients who are young or have mild disease.

6. COMT inhibitors—Catecholamine-O-methyltransferase inhibitors reduce the metabolism of levodopa to 3-O-methyl-dopa and thereby alter the plasma pharmacokinetics of levodopa, leading to more sustained plasma levels and more constant dopaminergic stimulation of the brain. Two such agents, tolcapone and entacapone, are currently available and may be used as an adjunct to levodopa-carbidopa in patients with response fluctuations or an otherwise inadequate response and who either have failed with other adjunctive therapies or are not candidates for such therapies. Treatment results in reduced response fluctuations, with a greater period of responsiveness to administered levodopa. Tolcapone is given in a dosage of 100 mg or 200 mg three times daily, and entacapone is given as 200 mg with each dose of Sinemet (levodopa-carbidopa). With either preparation, the dose of Sinemet taken concurrently may have to be reduced by up to one-third to avoid side effects such as dyskinesias, confusion, hypotension, and syncope. Diarrhea is sometimes troublesome. Because rare cases of fulminant hepatic failure have followed its use, tolcapone should be avoided in patients with preexisting liver disease. Serial liver function tests should be performed at 2-week intervals for the first year and at longer intervals thereafter in patients receiving the drug—as recommended by the manufacturer. Hepatotoxicity has not been reported with entacapone, which is therefore the preferred agent, and serial liver function tests are not required.

Stalevo is the commercial preparation of levodopa combined with both carbidopa and entacapone. It is best used in patients already stabilized on equivalent doses of carbidopa/levodopa and entacapone. It is priced at or below the price of the individual ingredients (ie, carbidopa/levodopa and entacapone) and has the added convenience of requiring fewer tablets to be taken daily. It is available in three strengths: Stalevo 50 (12.5 mg of carbidopa, 50 mg of levodopa, and 200 mg of entacapone), Stalevo 100 (25 mg of carbidopa, 100 mg of levodopa, and 200 mg of entacapone), and Stalevo 150 (37.5 mg of carbidopa, 150 mg of levodopa, and 200 mg of entacapone).

7. Atypical antipsychotics—Confusion and psychotic symptoms, which may be iatrogenic, often respond to

atypical antipsychotic agents, which have few extrapyramidal side effects and do not block the effects of dopaminergic medication. Olanzapine, quetiapine, and risperidone may be tried, but the most effective of these agents is clozapine, a dibenzodiazepine derivative. Clozapine may rarely cause marrow suppression, and weekly blood counts are therefore necessary for patients taking it. The patient is started on 6.25 mg at bedtime and the dosage increased to 25–100 mg/d as needed. In low doses, it may also improve iatrogenic dyskinesias.

B. General Measures

Physical therapy or speech therapy helps many patients. Cognitive impairment and psychiatric symptoms may be helped by rivastigmine (3–12 mg daily). The quality of life can often be improved by the provision of simple aids to daily living, eg, rails or banisters placed strategically about the home, special table cutlery with large handles, nonslip rubber table mats, and devices to amplify the voice.

C. Surgical Measures

Thalamotomy or pallidotomy may be helpful for patients who become unresponsive to medical treatment or have intolerable side effects from antiparkinsonian agents, especially if they have no evidence of diffuse vascular disease or significant cognitive decline. Ablative surgery should generally be confined to one side because the morbidity is considerably greater after bilateral procedures. Because of their morbidity, ablative procedures have generally been supplanted by deep brain stimulation, discussed in the following section.

D. Brain Stimulation

High-frequency thalamic stimulation is effective in suppressing the rest tremor of Parkinson disease, and chronic bilateral stimulation of the subthalamic nuclei or globus pallidus internus may benefit all the major features of the disease. Electrical stimulation of the brain has the advantage over ablative procedures of being reversible and of causing minimal or no damage to the brain, and is therefore the preferred surgical approach to treatment. There is no evidence that the natural history of Parkinson disease is affected.

▶ When to Refer

All patients should be referred.

▶ When to Admit

Patients requiring surgical treatment should be admitted.

3. Huntington Disease

ESSENTIALS OF DIAGNOSIS

- ▶ Gradual onset and progression of chorea and dementia or behavioral change.
- ▶ Family history of the disorder.
- ▶ Responsible gene identified on chromosome 4.

▶ General Considerations

Huntington disease is characterized by chorea and dementia. It is inherited in an autosomal dominant manner and occurs throughout the world, in all ethnic groups, with a prevalence rate of about 5 per 100,000. There is an expanded and unstable CAG trinucleotide repeat in the huntingtin gene at 4p16.3; repeat length may affect rate of progression.

▶ Clinical Findings

A. Symptoms and Signs

Clinical onset is usually between 30 and 50 years of age. The disease is progressive and usually leads to a fatal outcome within 15–20 years. The initial symptoms may consist of either abnormal movements or intellectual changes, but ultimately both occur. The earliest mental changes are often behavioral, with irritability, moodiness, antisocial behavior, or a psychiatric disturbance, but a more obvious dementia subsequently develops. The dyskinesia may initially be no more than an apparent fidgetiness or restlessness, but eventually choreiform movements and some dystonic posturing occur. Progressive rigidity and akinesia (rather than chorea) sometimes occur in association with dementia, especially in cases with childhood onset.

B. Imaging

CT scanning or MRI usually demonstrates cerebral atrophy and atrophy of the caudate nucleus in established

cases. Positron emission tomography (PET) has shown reduced striatal metabolic rate.

► Differential Diagnosis

Chorea developing with no family history of choreoathetosis should not be attributed to Huntington disease, at least not until other causes of chorea have been excluded clinically and by appropriate laboratory studies. Nongenetic causes of chorea include stroke, systemic lupus erythematosus and related disorders, paraneoplastic syndromes, infection with HIV, and various medications. In younger patients, self-limiting Sydenham chorea develops after group A streptococcal infections on rare occasions. If a patient presents solely with progressive intellectual failure, it may not be possible to distinguish Huntington disease from other causes of dementia unless there is a characteristic family history or a dyskinesia develops.

Huntington disease–like (HDL) disorders resemble Huntington disease but the CAG trinucleotide repeat number of the huntingtin gene is normal. There are autosomal dominant (HDL1, 20pter-p12; HDL2, 16q24.3) and recessive forms (HDL3, 4p15.3).

A clinically similar autosomal dominant disorder (**dentatorubral-pallidoluysian atrophy**), manifested by chorea, dementia, ataxia, and myoclonic epilepsy, is uncommon except in persons of Japanese ancestry. It is due to a mutant gene mapping to 12p13.31. Treatment is as for Huntington disease.

► Treatment

There is no cure for Huntington disease; progression cannot be halted; and treatment is purely symptomatic. The reported biochemical changes suggest a relative underactivity of neurons containing gamma-aminobutyric acid (GABA) and acetylcholine or a relative overactivity of dopaminergic neurons. Tetrabenazine, a drug that interferes with the vesicular storage of biogenic amines, is widely used to treat the dyskinesia. The starting dose is 12.5 mg twice or three times daily, increasing by 12.5 mg every 5 days depending on response and tolerance; the usual maintenance dose is 25 mg three times daily. Side effects include depression, postural hypotension, drowsiness, and parkinsonian features; tetrabenazine should not be given within 14 days of taking monoamine oxidase inhibitors and is not indicated for the treatment of levodopa-induced dyskinesias. Reserpine is similar in depleting central monoamines but has more peripheral effects and a worse side-effect profile, making its use problematic in Huntington disease; if utilized, the daily dose is built up gradually to between 2 mg and 5 mg, depending on the response. Treatment with drugs blocking dopamine receptors, such as phenothiazines or haloperidol, may control the dyskinesia and any behavioral disturbances. Haloperidol treatment is usually begun with a dose of 1 mg once or twice daily, which is then increased every 3 or 4 days depending on the response; alternatively, atypical antipsychotic agents such as quetiapine (increasing from 25 mg daily up to 100 mg twice daily as tolerated) may be tried. Amantadine in a

daily dose of 200 mg to 400 mg is sometimes helpful for chorea. Behavioral disturbances may respond to clozapine. Attempts to compensate for the relative GABA deficiency by enhancing central GABA activity or to compensate for the relative cholinergic underactivity by giving choline chloride have not been therapeutically helpful. Neuroprotective strategies are being explored.

Offspring should be offered genetic counseling. Genetic testing permits presymptomatic detection and definitive diagnosis of the disease.

► When to Refer

All patients should be referred.

4. Idiopathic Torsion Dystonia

ESSENTIALS OF DIAGNOSIS

- Dystonic movements and postures.
- Normal birth and developmental history. No other neurologic signs.
- Investigations (including CT scan or MRI) reveal no cause of dystonia.

► General Considerations

Idiopathic torsion dystonia may occur sporadically or on a hereditary basis, with autosomal dominant, autosomal recessive, and X-linked recessive modes of transmission. One responsible gene is located at 9q34 (and has been named *DYT1*) and involves a unique mutation consisting of a GAG deletion in the dominantly inherited disorder, and maps to the long arm of the X chromosome in the X-linked recessive form; the responsible gene in the autosomal recessive disorder is unknown. Other autosomal dominant forms have also been recognized, with different or unidentified genetic loci. Symptoms may begin in childhood or later and persist throughout life.

► Clinical Findings

The disorder is characterized by the onset of abnormal movements and postures in a patient with a normal birth and developmental history, no relevant past medical illness, and no other neurologic signs. Investigations (including CT scan) reveal no cause for the abnormal movements. Dystonic movements of the head and neck may take the form of torticollis, blepharospasm, facial grimacing, or forced opening or closing of the mouth. The limbs may also adopt

abnormal but characteristic postures. The age at onset influences both the clinical findings and the prognosis. With onset in childhood, there is usually a family history of the disorder, symptoms commonly commence in the legs, and progression is likely until there is severe disability from generalized dystonia. In contrast, when onset is later, a positive family history is unlikely, initial symptoms are often in the arms or axial structures, and severe disability does not usually occur, although generalized dystonia may ultimately develop in some patients. If all cases are considered together, about one-third of patients eventually become so severely disabled that they are confined to chair or bed, while another one-third are affected only mildly.

► Differential Diagnosis

Before a diagnosis of idiopathic torsion dystonia is made, it is imperative to exclude other causes of dystonia. Perinatal anoxia, birth trauma, and kernicterus are common causes of dystonia, but abnormal movements usually then develop before the age of 5, the early development of the patient is usually abnormal, and a history of seizures is not unusual. Moreover, examination may reveal signs of mental retardation or pyramidal deficit in addition to the movement disorder. Dystonic posturing may also occur in Wilson disease, Huntington disease, or parkinsonism; as a sequela of encephalitis lethargica or previous neuroleptic drug therapy; and in certain other disorders. In these cases, diagnosis is based on the history and accompanying clinical manifestations.

► Treatment

Idiopathic torsion dystonia usually responds poorly to drugs. Levodopa, diazepam, baclofen, carbamazepine, amantadine, or anticholinergic medication (in high dosage) is occasionally helpful; if not, a trial of treatment with tetrabenazine, phenothiazines, or haloperidol may be worthwhile. In each case, the dose has to be individualized, depending on response and tolerance. However, the doses of these latter drugs that are required for benefit lead usually to mild parkinsonism. Pallidal deep brain stimulation is helpful for medically refractory dystonia and has a lower morbidity than stereotactic thalamotomy, which is sometimes helpful in patients with predominantly unilateral limb dystonia. Potential adverse events of deep brain stimulation include cerebral infection or hemorrhage, broken leads, affective changes, and dysarthria.

A distinct variety of dominantly inherited dystonia, mapping to a genetic locus on chromosome 14q, is remarkably responsive to levodopa.

► When to Refer

All patients should be referred.

► When to Admit

Patients requiring surgical treatment should be admitted.

Ostrem JL et al. Treatment of dystonia with deep brain stimulation. *Neurotherapeutics*. 2008 Apr;5(2):320–30. [PMID: 18394573]
Tarsy D et al. Dystonia. *N Engl J Med*. 2006 Aug 24;355(8):818–29. [PMID: 16928997]

5. Focal Torsion Dystonia

A number of the dystonic manifestations that occur in idiopathic torsion dystonia may also occur as isolated phenomena. They are best regarded as focal dystonias that either occur as formes frustes of idiopathic torsion dystonia in patients with a positive family history or represent a focal manifestation of the adult-onset form of that disorder when there is no family history. Mapping of responsible genes to chromosome 8 (*DYT6*) and chromosome 18 (*DYT7*) has been reported in some instances of cervical or cranial dystonia. Medical treatment is generally unsatisfactory. A trial of the drugs used in idiopathic torsion dystonia is worthwhile, however, since a few patients do show some response. In addition, with restricted dystonias such as blepharospasm or torticollis, local injection of botulinum A toxin into the overactive muscles may produce worthwhile benefit for several weeks or months and can be repeated as needed.

Both blepharospasm and oromandibular dystonia may occur as an isolated focal dystonia. The former is characterized by spontaneous involuntary forced closure of the eyelids for a variable interval. Oromandibular dystonia is manifested by involuntary contraction of the muscles about the mouth causing, for example, involuntary opening or closing of the mouth, roving or protruding tongue movements, and retraction of the platysma.

Spasmodic torticollis, usually with onset between 25 and 50 years of age, is characterized by a tendency for the neck to twist to one side. This initially occurs episodically, but eventually the neck is held to the side. Spontaneous resolution may occur in the first year or so. The disorder is otherwise usually lifelong. Selective section of the spinal accessory nerve and the upper cervical nerve roots is sometimes helpful if medical treatment is unsuccessful. Local injection of botulinum A toxin provides benefit in most cases.

Writer's cramp is characterized by dystonic posturing of the hand and forearm when the hand is used for writing and sometimes when it is used for other tasks, eg, playing the piano or using a screwdriver or eating utensils. Drug treatment is usually unrewarding, and patients are often best advised to learn to use the other hand for activities requiring manual dexterity. Injections of botulinum A toxin are helpful in some instances.

6. Myoclonus

Occasional myoclonic jerks may occur in anyone, especially when drifting into sleep. General or multifocal myoclonus is common in patients with idiopathic epilepsy and is especially prominent in certain hereditary disorders characterized by seizures and progressive intellectual decline, such as the lipid storage diseases. It is also a feature of various rare degenerative disorders, notably Ramsay Hunt syndrome, and is common in subacute sclerosing panencephalitis and Creutzfeldt-Jakob disease. Generalized myoclonic jerking may accompany uremic and other metabolic encephalopathies, result from therapy with levodopa or cyclic antidepressants, occur in alcohol or drug withdrawal states, or follow anoxic brain damage. It also

occurs on a hereditary or sporadic basis as an isolated phenomenon in otherwise healthy subjects.

Segmental myoclonus is a rare manifestation of a focal spinal cord lesion. It may also be the clinical expression of **epilepsia partialis continua**, a disorder in which a repetitive focal epileptic discharge arises in the contralateral sensorimotor cortex, sometimes from an underlying structural lesion. An electroencephalogram is often helpful in clarifying the epileptic nature of the disorder, and CT or MRI scan may reveal the causal lesion.

Myoclonus may respond to certain anticonvulsant drugs, especially valproic acid, or to one of the benzodiazepines, particularly clonazepam (see Table 24–3). It may also respond to piracetam (up to 16.8 g daily). Myoclonus following anoxic brain damage is often responsive to oxitriptan (5-hydroxytryptophan), an investigational agent that is the precursor of serotonin, and sometimes to clonazepam. Oxitriptan is given in gradually increasing doses up to 1–1.5 mg daily. In patients with segmental myoclonus, a localized lesion should be searched for and treated appropriately.

Chang VC et al. Myoclonus. *Curr Treat Options Neurol.* 2008 May;10(3):222–9. [PMID: 18579026]

7. Wilson Disease

In this metabolic disorder, abnormal movement and posture may occur with or without coexisting signs of liver involvement. It is discussed in Chapter 16.

8. Drug-Induced Abnormal Movements

Phenothiazines, butyrophenones, and metoclopramide may produce a wide variety of abnormal movements, including parkinsonism, akathisia (ie, motor restlessness), acute dystonia, chorea, and tardive dyskinesias or dystonia; several of these are also produced by aripiprazole. These complications are discussed in Chapter 25. Chorea may also develop in patients receiving levodopa, bromocriptine, anticholinergic drugs, phenytoin, carbamazepine, lithium, amphetamines, or oral contraceptives, and it resolves with withdrawal of the offending substance. Similarly, dystonia may be produced by levodopa, bromocriptine, lithium, or carbamazepine; and parkinsonism by reserpine and tetraabenazine. Postural tremor may occur with a variety of drugs, including epinephrine, isoproterenol, theophylline, caffeine, lithium, thyroid hormone, tricyclic antidepressants, and valproic acid.

9. Restless Legs Syndrome

This disorder may occur as a primary (idiopathic) disorder or in relation to pregnancy, iron deficiency anemia, peripheral neuropathy (especially uremic or diabetic), or periodic leg movements of sleep. It may have a hereditary basis and several genetic loci have been associated with the disorder (12q12–q21, 14q13–q31, 9p24–p22, 2q33, and 20p13). Restlessness and curious sensory disturbances lead to an irresistible urge to move the limbs, especially during periods of relaxation. Disturbed nocturnal sleep and excessive daytime somnolences may result. Therapy is with nonergot dopamine agonists, such as pramipexole (0.125–0.5 mg once

daily or ropinirole (0.25–4.0 mg once daily) 2 to 3 hours before bedtime, or with benzodiazepines, such as clonazepam. Gabapentin may also provide symptom relief and is taken once or twice daily (in the evening and before sleep), starting with 300 mg daily; the dose is built up depending on response and tolerance (to approximately 1800 mg daily). Levodopa is helpful but may lead to an augmentation of symptoms, so that its use is generally reserved for those who do not respond to other measures. In some instances, opioids are required to control symptoms.

10. Gilles de la Tourette Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ Multiple motor and phonic tics.
- ▶ Symptoms begin before age 21 years.
- ▶ Tics occur frequently for at least 1 year.
- ▶ Tics vary in number, frequency, and nature over time.

Clinical Findings

Motor tics are the initial manifestation in 80% of cases and most commonly involve the face, whereas in the remaining 20%, the initial symptoms are phonic tics; ultimately a combination of different motor and phonic tics develop in all patients. These are noted first in childhood, generally between the ages of 2 and 15. Motor tics occur especially about the face, head, and shoulders (eg, sniffing, blinking, frowning, shoulder shrugging, head thrusting, etc). Phonic tics commonly consist of grunts, barks, hisses, throat-clearing, coughs, etc, but sometimes also of verbal utterances including coprolalia (obscene speech). There may also be echolalia (repetition of the speech of others), echopraxia (imitation of others' movements), and palilalia (repetition of words or phrases). Some tics may be self-mutilating in nature, such as nail-biting, hair-pulling, or biting of the lips or tongue. The disorder is chronic, but the course may be punctuated by relapses and remissions. Obsessive-compulsive behaviors are commonly associated and may be more disabling than the tics themselves. A family history is sometimes obtained and inheritance has been attributed to an autosomal dominant gene with variable penetrance. In some instances, mutations in the *SLITRK1* gene on chromosome 13q have been incriminated.

Examination usually reveals no abnormalities other than the tics. In addition to obsessive-compulsive behavior disorders, psychiatric disturbances may occur because of the associated cosmetic and social embarrassment. Electro-

encephalography may show minor nonspecific abnormalities of no diagnostic relevance.

The diagnosis of the disorder is often delayed for years, the tics being interpreted as psychiatric illness or some other form of abnormal movement. Patients are thus often subjected to unnecessary treatment before the disorder is recognized. The tic-like character of the abnormal movements and the absence of other neurologic signs should differentiate this disorder from other movement disorders presenting in childhood. Wilson disease, however, can simulate the condition and should be excluded.

► Treatment

Treatment is symptomatic and may need to be continued indefinitely. Haloperidol is generally regarded as the drug of choice. It is started in a low daily dose (0.25 mg) that is gradually increased (by 0.25 mg every 4 or 5 days) until there is maximum benefit with a minimum of side effects or until side effects limit further increments. A total daily dose of between 2 and 8 mg is usually optimal, but higher doses are sometimes necessary. Treatment with clonazepam (in a dose that depends on response and tolerance) or clonidine (2–5 mcg/kg/d) may also be helpful, and it seems sensible to begin with one of these drugs in order to avoid some of the long-term extrapyramidal side effects of haloperidol. Phenothiazines, such as fluphenazine (2–15 mg daily), have been used, but patients unresponsive to haloperidol are usually unresponsive to these as well.

Pimozide, an oral dopamine-blocking drug related to haloperidol, may be helpful in patients who cannot tolerate or have not responded to haloperidol. Treatment is started with 1 mg daily and the daily dose increased by 1–2 mg every 10 days; the average dose is between 7 and 16 mg daily. Injection of botulinum toxin type A at the site of the most distressing tics is sometimes worthwhile.

Treatment with risperidone, calcium channel blockers, tetrabenazine, clomipramine, or metoclopramide has yielded mixed results or encouraging findings in preliminary studies that require confirmation. Bilateral high-frequency deep brain stimulation at various sites has been helpful in some, otherwise intractable, cases.

► When to Refer

All patients with Gilles de la Tourette syndrome should be referred.

► When to Admit

Patients undergoing surgical (deep brain stimulation) treatment should be admitted.

Welter ML et al. Internal pallidal and thalamic stimulation in patients with Tourette syndrome. *Arch Neurol.* 2008 Jul;65(7):952–7. [PMID: 18625864]

DEMENTIA

Dementia, the symptom complex of progressive global impairment of intellectual function, is a major medical, social, and economic problem that is worsening as the num-

ber of elderly people in the general population increases. It is discussed in Chapter 4, and the only point to be reiterated here is the importance of recognizing early any treatable or reversible causes of dementia, such as normal-pressure hydrocephalus, intracranial mass lesions, vascular disease, hypothyroidism, thiamine or vitamin B₁₂ deficiency, Wilson disease, liver or kidney failure, neurosyphilis, and the chronic meningitides.

MULTIPLE SCLEROSIS

ESSENTIALS OF DIAGNOSIS

- Episodic neurologic symptoms.
- Patient usually under 55 years of age at onset.
- Single pathologic lesion cannot explain clinical findings.
- Multiple foci best visualized by MRI.

► General Considerations

This common neurologic disorder, which probably has an autoimmune basis, has its greatest incidence in young adults. Epidemiologic studies indicate that multiple sclerosis is much more common in persons of western European lineage who live in temperate zones. No population with a high risk for multiple sclerosis exists between latitudes 40° N and 40° S. A genetic susceptibility to the disease is present, based on twin studies, familial cases, and an association with specific HLA antigens (HLA-DR2) and alleles of *IL2RA* (the interleukin-2 receptor α gene) and *IL7RA* (the interleukin-7 receptor α gene). Pathologically, focal—often perivenular—areas of demyelination with reactive gliosis are found scattered in the white matter of brain and spinal cord and in the optic nerves. Axonal damage also occurs.

► Clinical Findings

A. Symptoms and Signs

The common initial presentation is weakness, numbness, tingling, or unsteadiness in a limb; spastic paraparesis; retrobulbar neuritis; diplopia; disequilibrium; or a sphincter disturbance such as urinary urgency or hesitancy. Symptoms may disappear after a few days or weeks, although examination often reveals a residual deficit.

Several forms of the disease are recognized. In most patients, there is an interval of months or years after the initial episode before new symptoms develop or the original ones recur (**relapsing-remitting disease**). Eventually, however, relapses and usually incomplete remissions lead to increasing disability, with weakness, spasticity, and ataxia of the limbs, impaired vision, and urinary incontinence. The findings on examination at this stage commonly include optic atrophy, nystagmus, dysarthria, and pyramidal, sensory, or cerebellar deficits in some or all of the limbs. In some of these patients, the clinical course changes so that a steady deterioration occurs, unrelated to acute relapses (**secondary progressive disease**).

Less commonly, symptoms are steadily progressive from their onset, and disability develops at a relatively early stage (**primary progressive disease**). The diagnosis cannot be made with confidence unless the total clinical picture indicates involvement of different parts of the central nervous system at different times.

A number of factors (eg, infection) may precipitate or trigger exacerbations. Relapses are reduced in pregnancy but are more likely during the 2 or 3 months following pregnancy, possibly because of the increased demands and stresses that occur in the postpartum period.

B. Imaging

MRI of the brain or cervical cord has a major role in demonstrating the presence of multiple lesions. In T1-weighted images, hypointense "black holes" probably represent areas of permanent axonal damage; hyperintense lesions are also found. Gadolinium-enhanced T1-weighted images may highlight areas of inflammation with breakdown of the blood-brain barrier. T2-weighted images provide information about disease burden or total number of lesions, which typically appear as areas of high signal intensity. CT scans are less helpful than MRI.

In patients presenting with myelopathy alone and in whom there is no clinical or laboratory evidence of more widespread disease, myelography or MRI may be necessary to exclude a congenital or acquired surgically treatable lesion. The foramen magnum region must be visualized to exclude the possibility of Arnold-Chiari malformation, in which parts of the cerebellum and the lower brainstem are displaced into the cervical canal and produce mixed pyramidal and cerebellar deficits in the limbs.

C. Laboratory and Other Studies

A definitive diagnosis can never be based solely on the laboratory findings. If there is clinical evidence of only a single lesion in the central nervous system, multiple sclerosis cannot properly be diagnosed unless it can be shown that other regions are affected subclinically. The electrocerebral responses evoked by monocular visual stimulation with a checkerboard pattern stimulus, by monaural click stimulation, and by electrical stimulation of a sensory or mixed peripheral nerve have been used to detect subclinical involvement of the visual, brainstem auditory, and somatosensory pathways, respectively. Other disorders may also be characterized by multifocal electrophysiologic abnormalities.

There may be mild lymphocytosis or a slightly increased protein concentration in the cerebrospinal fluid, especially soon after an acute relapse. Elevated IgG in cerebrospinal fluid and discrete bands of IgG (oligoclonal bands) are present in many patients. The presence of such bands is not specific, however, since they have been found in a variety of inflammatory neurologic disorders and occasionally in patients with vascular or neoplastic disorders of the nervous system.

D. Diagnosis

Multiple sclerosis should not be diagnosed unless there is evidence that two or more different regions of the central

white matter have been affected at different times. A diagnosis of clinically definite disease can be made in patients with a relapsing-remitting course and evidence on examination of at least two lesions involving different regions of the central white matter. The diagnosis is probable in patients with multifocal white matter disease but only one clinical attack, or with a history of at least two clinical attacks but signs of only a single lesion. Imaging may reveal involvement of the nervous system at different times if a gadolinium-enhancing lesion is present at least 3 months after an initial clinical event at a different site than one corresponding to that event or if a new T2 lesion is found at any time compared with a baseline scan obtained at least 30 days after the initial clinical event. Dissemination in space requires three of the following: (1) at least one gadolinium-enhancing lesion or nine T2 hyperintense lesions if there is no enhancing lesion; (2) one or more infratentorial (or spinal cord) lesions; (3) one or more juxtacortical lesions; and (4) at least three periventricular lesions.

▶ Treatment

At least partial recovery from acute exacerbations can reasonably be expected, but further relapses may occur without warning, and there is no means of preventing progression of the disorder. Some disability is likely to result eventually, but about half of all patients are without significant disability even 10 years after onset of symptoms.

Recovery from acute relapses may be hastened by treatment with corticosteroids, but the extent of recovery is unchanged. A high dose (eg, prednisone, 60 or 80 mg) is given daily for 1 week, after which medication is tapered over the following 2 or 3 weeks. Such a regimen is often preceded by methylprednisolone, 1 g intravenously for 3 days. Long-term treatment with corticosteroids provides no benefit and does not prevent further relapses.

In patients with relapsing-remitting or secondary progressive disease, indefinite treatment with β -interferon (dosing regimen depends on the formulation) or with daily subcutaneous administration of glatiramer acetate reduces the frequency of exacerbations with equal efficacy. Natalizumab, an α 4 integrin antagonist that reduces the development of brain lesions in experimental models, reduces the relapse rate. However, it can only be prescribed under a risk management plan because of rare reports of progressive multifocal leukoencephalopathy developing in patients while receiving treatment. Natalizumab is sometimes used in patients having lesions with very high disease activity on MRI and in those with progressive or poorly controlled disease despite treatment with β -interferon or glatiramer acetate. Several studies have suggested that immunosuppressive therapy with cyclophosphamide, azathioprine, methotrexate, cladribine, or mitoxantrone may help arrest the course of secondary progressive multiple sclerosis. The evidence of benefit is incomplete, however. Plasmapheresis is sometimes helpful in patients with severe relapses unresponsive to corticosteroids. Intravenous immunoglobulins (IVIGs) may reduce the clinical attack rate in relapsing-remitting disease, but the available studies are inadequate to permit treatment recommendations. Statins may have

immunomodulatory effects, and their possible role in the treatment of multiple sclerosis is being studied.

Treatment for spasticity (see below) and for neurogenic bladder may be needed in advanced cases. Excessive fatigue must be avoided, and patients should rest during periods of acute relapse.

► When to Refer

All patients, but especially those with progressive disease despite standard therapy, should be referred.

► When to Admit

- Patients requiring plasma exchange.
- During severe relapses.
- Patient unable to manage at home.

NEUROMYELITIS OPTICA

This disorder is characterized by optic neuritis and acute myelitis with MRI changes that extend over at least three segments of the spinal cord. An isolated myelitis or optic neuritis may also occur. Previously known as Devic disease and once regarded as a variant of multiple sclerosis, neuromyelitis optica is associated with a specific antibody marker (NMO-IgG) targeting the water channel aquaporin-4. MRI of the brain typically does not show widespread white matter involvement but such changes do not exclude the diagnosis. Treatment is by long-term immunosuppression. Rituximab may help in reducing the risk of relapses and is undergoing clinical trials.

Cree B. Neuromyelitis optica: diagnosis, pathogenesis, and treatment. *Curr Neurol Neurosci Rep.* 2008 Sep;8(5):427–33. [PMID: 18713580]

VITAMIN E DEFICIENCY

Vitamin E deficiency may produce a disorder somewhat similar to Friedreich ataxia (see below). There is spinocerebellar degeneration involving particularly the posterior columns of the spinal cord and leading to limb ataxia, sensory loss, absent tendon reflexes, slurring of speech, and, in some cases, pigmentary retinal degeneration. The disorder may occur as a consequence of malabsorption or on a hereditary basis. Treatment is with α -tocopheryl acetate (eg, Aquasol E capsules or drops) as discussed in Chapter 29.

SPASTICITY

The term “spasticity” is commonly used for an upper motor neuron deficit, but it properly refers to a velocity-dependent increase in resistance to passive movement that affects different muscles to a different extent, is not uniform in degree throughout the range of a particular movement, and is commonly associated with other features of pyramidal deficit. It is often a major complication of stroke, cerebral or spinal injury, static perinatal encephalopathy, and multiple sclerosis.

Physical therapy with appropriate stretching programs is important during rehabilitation after the development of an upper motor neuron lesion and in subsequent management of the patient. The aim is to prevent joint and muscle contractures and perhaps to modulate spasticity.

Drug management is important also, but treatment may increase functional disability when increased extensor tone is providing additional support for patients with weak legs. Dantrolene weakens muscle contraction by interfering with the role of calcium. It is best avoided in patients with poor respiratory function or severe myocardial disease. Treatment is begun with 25 mg once daily, and the daily dose is built up by 25 mg increments every 3 days, depending on tolerance, to a maximum of 100 mg four times daily. Side effects include diarrhea, nausea, weakness, hepatic dysfunction (that may rarely be fatal, especially in women older than 35), drowsiness, light-headedness, and hallucinations.

Lioresal is an effective drug for treating spasticity of spinal origin and painful flexor (or extensor) spasms. The maximum recommended daily dose is 80 mg; treatment is started with a dose of 5 or 10 mg twice daily and then built up gradually. Side effects include gastrointestinal disturbances, lassitude, fatigue, sedation, unsteadiness, confusion, and hallucinations. Diazepam may modify spasticity by its action on spinal interneurons and perhaps also by influencing supraspinal centers, but effective doses often cause intolerable drowsiness and vary with different patients. Tizanidine, a centrally acting α_2 -adrenergic agonist, is as effective as these other agents but is probably better tolerated. The daily dose is built up gradually, usually to 8 mg taken three times daily. Side effects include sedation, lassitude, hypotension, and dryness of the mouth.

Motor-point blocks by intramuscular phenol have been used to reduce spasticity selectively in one or a few important muscles and may permit return of function in patients with incomplete myelopathies. Intramuscular administration of botulinum toxin may also be helpful. Intrathecal injection of phenol or absolute alcohol may be helpful in more severe cases, but greater selectivity can be achieved by nerve root or peripheral nerve neurolysis. These procedures should not be undertaken until the spasticity syndrome is fully evolved, ie, only after about 1 year or so, and only if long-term drug treatment either has been unhelpful or carries a significant risk to the patient.

In patients with severe spasticity and limited use of the legs, a surgically implanted lioresal pump may provide significant relief and improve hygiene. Repeated transcutaneous electrical nerve stimulation may supplement medical treatment. A number of surgical procedures, eg, adductor or

heel cord tenotomy, may also help in the management of spasticity and facilitate patient management. For example, obturator neurectomy is helpful in patients with marked adductor spasms that interfere with personal hygiene or cause gait disturbances. Posterior rhizotomy reduces spasticity, but its effect may be short-lived, whereas anterior rhizotomy produces permanent wasting and weakness in the muscles that are denervated.

Spasticity may be exacerbated by decubitus ulcers, urinary or other infections, and nociceptive stimuli.

Simpson DM et al. Botulinum neurotoxin for the treatment of spasticity (an evidence-based review): report of the Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology. *Neurology*. 2008 May 6;70(19):1691–8. [PMID: 18458229]

MYELOPATHIES IN AIDS

A variety of myelopathies may occur in patients with AIDS. These are discussed in Chapter 31.

MYELOPATHY OF HUMAN T CELL LEUKEMIA VIRUS INFECTION

Human T cell leukemia virus (HTLV-1), a human retrovirus, is transmitted by breast-feeding, sexual contact, blood transfusion, and contaminated needles. Most patients are asymptomatic, but after a variable latent period (which may be as long as several years) a myelopathy develops in some instances. The MRI, electrophysiologic, and cerebrospinal fluid findings are similar to those of multiple sclerosis, but HTLV-1 antibodies are present in serum and spinal fluid. There is no specific treatment, but intravenous or oral corticosteroids may help in the initial inflammatory phase of the disease. Prophylactic measures are important. Needles or syringes should not be shared; infected patients should not breastfeed their infants or donate blood, semen, or other tissue. Infected patients should use condoms to prevent sexual transmission.

SUBACUTE COMBINED DEGENERATION OF THE SPINAL CORD

Subacute combined degeneration of the spinal cord is due to vitamin B₁₂ deficiency, such as occurs in pernicious anemia. It is characterized by myelopathy with predominant pyramidal and posterior column deficits, sometimes in association with polyneuropathy, mental changes, or optic neuropathy. Megaloblastic anemia may also occur, but this does not parallel the neurologic disorder, and the former may be obscured if folic acid supplements have been taken. Treatment is with vitamin B₁₂. For pernicious anemia, a convenient therapeutic regimen is 100 mg cyanocobalamin intramuscularly daily for 1 week, then weekly for 1 month, and then monthly for the remainder of the patient's life.

WERNICKE ENCEPHALOPATHY

Wernicke encephalopathy is characterized by confusion, ataxia, and nystagmus leading to ophthalmoplegia (lateral

rectus muscle weakness, conjugate gaze palsies); peripheral neuropathy may also be present. It is due to thiamine deficiency and in the United States occurs most commonly in alcoholics. It may also occur in patients with AIDS or hyperemesis gravidarum, and after surgery for obesity. In suspected cases, thiamine (50 mg) is given intravenously immediately and then intramuscularly on a daily basis until a satisfactory diet can be ensured. Intravenous glucose given before thiamine may precipitate the syndrome or worsen the symptoms. The diagnosis is confirmed by the response in 1 or 2 days to treatment, which must not be delayed while laboratory confirmation is obtained.

Sechi G et al. Wernicke's encephalopathy: new clinical settings and recent advances in diagnosis and management. *Lancet Neurol*. 2007 May;6(5):442–55. [PMID: 17434099]

STUPOR & COMA

ESSENTIALS OF DIAGNOSIS

- ▶ Level of consciousness is depressed.
- ▶ Stuporous patients respond only to repeated vigorous stimuli.
- ▶ Comatose patients are unarousable and unresponsive.

▶ General Considerations

The patient who is stuporous is unresponsive except when subjected to repeated vigorous stimuli, while the comatose patient is unarousable and unable to respond to external events or inner needs, although reflex movements and posturing may be present.

Coma is a major complication of serious central nervous system disorders. It can result from seizures, hypothermia, metabolic disturbances, or structural lesions causing bilateral cerebral hemispheric dysfunction or a disturbance of the brainstem reticular activating system. A mass lesion involving one cerebral hemisphere may cause coma by compression of the brainstem. All comatose patients should be admitted to hospital and referred to a neurologist or neurosurgeon.

▶ Assessment & Emergency Measures

The diagnostic workup of the comatose patient must proceed concomitantly with management. Supportive therapy for respiration or blood pressure is initiated; in hypothermia, all vital signs may be absent and all such patients should be rewarmed before the prognosis is assessed.

The patient can be positioned on one side with the neck partly extended, dentures removed, and secretions cleared by suction; if necessary, the patency of the airways is maintained with an oropharyngeal airway. Blood is drawn for serum glucose, electrolyte, and calcium levels; arterial blood gases; liver and kidney function tests; and toxicologic studies as indicated. Dextrose 50% (25 g), naloxone (0.4–1.2 mg), and thiamine (50 mg) are given intravenously.

Further details are then obtained from attendants of the patient's medical history, the circumstances surrounding the onset of coma, and the time course of subsequent events. Abrupt onset of coma suggests subarachnoid hemorrhage, brainstem stroke, or intracerebral hemorrhage, whereas a slower onset and progression occur with other structural or mass lesions. A metabolic cause is likely with a preceding intoxicated state or agitated delirium. On examination, attention is paid to the behavioral response to painful stimuli, the pupils and their response to light, the position of the eyes and their movement in response to passive movement of the head and ice-water caloric stimulation, and the respiratory pattern.

A. Response to Painful Stimuli

Purposive limb withdrawal from painful stimuli implies that sensory pathways from and motor pathways to the stimulated limb are functionally intact. Unilateral absence of responses despite application of stimuli to both sides of the body in turn implies a corticospinal lesion; bilateral absence of responsiveness suggests brainstem involvement, bilateral pyramidal tract lesions, or psychogenic unresponsiveness. Inappropriate responses may also occur. Decorticate posturing may occur with lesions of the internal capsule and rostral cerebral peduncle, decerebrate posturing with dysfunction or destruction of the midbrain and rostral pons, and decerebrate posturing in the arms accompanied by flaccidity or slight flexor responses in the legs in patients with extensive brainstem damage extending down to the pons at the trigeminal level.

B. Ocular Findings

1. Pupils—Hypothalamic disease processes may lead to unilateral Horner syndrome, while bilateral diencephalic involvement or destructive pontine lesions may lead to small but reactive pupils. Ipsilateral pupillary dilation with no direct or consensual response to light occurs with compression of the third cranial nerve, eg, with uncal herniation. The pupils are slightly smaller than normal but responsive to light in many metabolic encephalopathies; however, they may be fixed and dilated following overdose with atropine, scopolamine, or glutethimide, and pinpoint (but responsive) with opioids. Pupillary dilation for several hours following cardiopulmonary arrest implies a poor prognosis.

2. Eye movements—Conjugate deviation of the eyes to the side suggests the presence of an ipsilateral hemispheric lesion or a contralateral pontine lesion. A mesencephalic lesion leads to downward conjugate deviation. Dysconjugate ocular deviation in coma implies a structural brainstem lesion unless there was preexisting strabismus.

The oculomotor responses to passive head turning and to caloric stimulation relate to each other and provide complementary information. In response to brisk rotation of the head from side to side and to flexion and extension of the head, normally conscious patients with open eyes do not exhibit contraversive conjugate eye deviation (doll's-head eye response) unless there is voluntary visual fixation

or bilateral frontal pathology. With cortical depression in lightly comatose patients, a brisk doll's-head eye response is seen. With brainstem lesions, this oculocephalic reflex becomes impaired or lost, depending on the site of the lesion.

The oculovestibular reflex is tested by caloric stimulation using irrigation with ice water. In normal subjects, jerk nystagmus is elicited for about 2 or 3 minutes, with the slow component toward the irrigated ear. In unconscious patients with an intact brainstem, the fast component of the nystagmus disappears, so that the eyes tonically deviate toward the irrigated side for 2–3 minutes before returning to their original position. With impairment of brainstem function, the response becomes perverted and finally disappears. In metabolic coma, oculocephalic and oculovestibular reflex responses are preserved, at least initially.

C. Respiratory Patterns

Diseases causing coma may lead to respiratory abnormalities. Cheyne-Stokes respiration may occur with bihemispheric or diencephalic disease or in metabolic disorders. Central neurogenic hyperventilation occurs with lesions of the brainstem tegmentum; apneustic breathing (in which there are prominent end-inspiratory pauses) suggests damage at the pontine level (eg, due to basilar artery occlusion); and atactic breathing (a completely irregular pattern of breathing with deep and shallow breaths occurring randomly) is associated with lesions of the lower pontine tegmentum and medulla.

1. Stupor & Coma Due to Structural Lesions

Supratentorial mass lesions tend to affect brain function in an orderly way. There may initially be signs of hemispheric dysfunction, such as hemiparesis. As coma develops and deepens, cerebral function becomes progressively disturbed, producing a predictable progression of neurologic signs that suggest rostrocaudal deterioration.

Thus, as a supratentorial mass lesion begins to impair the diencephalon, the patient becomes drowsy, then stuporous, and finally comatose. There may be Cheyne-Stokes respiration; small but reactive pupils; doll's-head eye responses with side-to-side head movements but sometimes an impairment of reflex upward gaze with brisk flexion of the head; tonic ipsilateral deviation of the eyes in response to vestibular stimulation with cold water; and initially a positive response to pain but subsequently only decorticate posturing. With further progression, midbrain failure occurs. Motor dysfunction progresses from decorticate to bilateral decerebrate posturing in response to painful stimuli; Cheyne-Stokes respiration is gradually replaced by sustained central hyperventilation; the pupils become middle-sized and fixed; and the oculocephalic and oculovestibular reflex responses become impaired, perverted, or lost. As the pons and then the medulla fail, the pupils remain unresponsive; oculovestibular responses are unobtainable; respiration is rapid and shallow; and painful stimuli may lead only to flexor responses in the legs. Finally, respiration becomes irregular and stops, the pupils often then dilating widely.

In contrast, a subtentorial (ie, brainstem) lesion may lead to an early, sometimes abrupt disturbance of consciousness without any orderly rostrocaudal progression of neurologic signs. Compressive lesions of the brainstem, especially cerebellar hemorrhage, may be clinically indistinguishable from intraparenchymal processes.

A structural lesion is suspected if the findings suggest focality. In such circumstances, a CT scan should be performed before, or instead of, a lumbar puncture in order to avoid any risk of cerebral herniation. Further management is of the causal lesion and is considered separately under the individual disorders.

2. Stupor & Coma Due to Metabolic Disturbances

Patients with a metabolic cause of coma generally have signs of patchy, diffuse, and symmetric neurologic involvement that cannot be explained by loss of function at any single level or in a sequential manner, although focal or lateralized deficits may occur in hypoglycemia. Moreover, pupillary reactivity is usually preserved, while other brainstem functions are often grossly impaired. Comatose patients with meningitis, encephalitis, or subarachnoid hemorrhage may also exhibit little in the way of focal neurologic signs, however, and clinical evidence of meningeal irritation is sometimes very subtle in comatose patients. Examination of the cerebrospinal fluid in such patients is essential to establish the correct diagnosis.

In patients with coma due to cerebral ischemia and hypoxia, the absence of pupillary light reflexes at the time of initial examination indicates that there is little chance of regaining independence; by contrast, preserved pupillary light responses, the development of spontaneous eye movements (roving, conjugate, or better), and extensor, flexor, or withdrawal responses to pain at this early stage imply a relatively good prognosis.

Treatment of metabolic encephalopathy is of the underlying disturbance and is considered in other chapters. If the cause of the encephalopathy is obscure, all drugs except essential ones may have to be withdrawn in case they are responsible for the altered mental status.

Wijdicks EF et al. Practice parameter: Prediction of outcome in comatose survivors after cardiopulmonary resuscitation (an evidence-based review): Report of the Quality Standards Subcommittee of the American Academy of Neurology. *Neurology.* 2006 Jul 25;67(2):203–10. [PMID: 16864809]

3. Brain Death

The definition of brain death is controversial, and diagnostic criteria have been published by many different professional organizations. In order to establish brain death, the irreversibly comatose patient must be shown to have lost all brainstem reflex responses, including the pupillary, corneal, oculocephalic, oculocephalic, oropharyngeal, and respiratory reflexes, and should have been in this condition for at least 6 hours. Spinal reflex movements do not exclude the diagnosis, but ongoing seizure activity or decerebrate or decorticate

posturing is not consistent with brain death. The apnea test (presence or absence of spontaneous respiratory activity at a P_{aCO_2} of at least 60 mm Hg) serves to determine whether the patient is capable of respiratory activity.

Reversible coma simulating brain death may be seen with hypothermia (temperature < 32 °C) and overdosage with central nervous system depressant drugs, and these conditions must be excluded. Certain ancillary tests may assist the determination of brain death but are not essential. An isoelectric electroencephalogram, when the recording is made according to the recommendations of the American Electroencephalographic Society, may help in confirming the diagnosis. Alternatively, the demonstration of an absent cerebral circulation by intravenous radioisotope cerebral angiography or by four-vessel contrast cerebral angiography is confirmatory.

Wijdicks EF et al. Pronouncing brain death: contemporary practice and safety of the apnea test. *Neurology.* 2008 Oct 14;71(16):1240–4. [PMID: 18852438]

4. Persistent Vegetative State

Patients with severe bilateral hemispheric disease may show some improvement from an initially comatose state, so that, after a variable interval, they appear to be awake but lie motionless and without evidence of awareness or higher mental activity. This persistent vegetative state has been variously referred to as akinetic mutism, apallic state, or coma vigil. Most patients in this persistent vegetative state will die in months or years, but partial recovery has occasionally occurred and in rare instances has been sufficient to permit communication or even independent living.

5. Minimally Conscious State

In this state, patients exhibit inconsistent evidence of consciousness. There is some degree of functional recovery of behaviors suggesting self- or environmental awareness, such as basic verbalization or context-appropriate gestures, emotional responses (eg, smiling) to emotional but not neutral stimuli, or purposive responses to environmental stimuli (eg, a finger movement or eye blink apparently to command). Further improvement is manifest by the restoration of communication with the patient. The minimally conscious state may be temporary or permanent. Little information is available about its natural history or long-term outlook, which reflect the underlying cause. The likelihood of useful functional recovery diminishes with time; after 12 months, patients are likely to remain severely disabled and without a reliable means of communication. Prognostication is difficult.

6. Locked-In Syndrome (De-efferented State)

Acute destructive lesions (eg, infarction, hemorrhage, demyelination, encephalitis) involving the ventral pons and sparing the tegmentum may lead to a mute, quadriparetic but conscious state in which the patient is capable of blinking and of voluntary eye movement in the vertical plane, with preserved pupillary responses to light. Such a patient can

mistakenly be regarded as comatose. Physicians should recognize that “locked-in” individuals are fully aware of their surroundings. The prognosis is variable, but recovery has occasionally been reported—in some cases including resumption of independent daily life, though this may take up to 2 or 3 years.

HEAD INJURY

Trauma is the most common cause of death in young people, and head injury accounts for almost half of these trauma-related deaths. The prognosis following head injury depends on the site and severity of brain damage. Some guide to prognosis is provided by the mental status, since loss of consciousness implies a worse prognosis than otherwise. Similarly, the degree of retrograde and posttraumatic amnesia provides an indication of the severity of injury and thus of the prognosis. Absence of skull fracture does not exclude the possibility of severe head injury. During the physical examination, special attention should be given to the level of consciousness and extent of any brainstem dysfunction.

Note: Patients (especially elderly, >65 years) who are intoxicated with drugs or alcohol or have evidence of soft-tissue injury above the clavicles following head injury should be admitted to the hospital for observation, as should patients with recurrent vomiting, persistent anterograde amnesia, retrograde amnesia for more than 30 minutes, focal neurologic deficits, lethargy, or skull fractures. If admission is declined, responsible family members should be given clear instructions about the need for, and manner of, checking on them at regular (hourly) intervals and for obtaining additional medical help if necessary.

Skull radiographs or CT scans may provide evidence of fractures. Because injury to the spine may have accompanied head trauma, cervical spine radiographs (especially in the lateral projection) should always be obtained in comatose patients and in patients with severe neck pain or a deficit possibly related to cord compression.

CT scanning has an important role in demonstrating intracranial hemorrhage and may also provide evidence of cerebral edema and displacement of midline structures.

1. Cerebral Injuries

These are summarized in Table 24–7 along with comments about treatment. Increased intracranial pressure may result from ventilatory obstruction, abnormal neck position, seizures, dilutional hyponatremia, or cerebral edema; an intracranial hematoma requiring surgical evacuation may also be responsible. Other measures that may be necessary to reduce intracranial pressure include induced hyperventilation, intravenous mannitol infusion, and intravenous furosemide; corticosteroids provide no benefit in this context.

2. Scalp Injuries & Skull Fractures

Scalp lacerations and depressed or compound depressed skull fractures should be treated surgically as appropriate. Simple skull fractures require no specific treatment.

The clinical signs of basilar skull fracture include bruising about the orbit (raccoon sign), blood in the external auditory meatus (Battle sign), and leakage of cerebrospinal fluid (which can be identified by its glucose content) from the ear or nose. Cranial nerve palsies (involving especially the first, second, third, fourth, fifth, seventh, and eighth nerves in any combination) may also occur. If there is any leakage of cerebrospinal fluid, conservative treatment, with elevation of the head, restriction of fluids, and administration of acetazolamide (250 mg four times daily), is often helpful; but if the leak continues for more than a few days, lumbar subarachnoid drainage may be necessary. Antibiotics are given if infection occurs, based on culture and sensitivity studies. Only very occasional patients require intracranial repair of the dural defect because of persistence of the leak or recurrent meningitis.

3. Late Complications of Head Injury

The relationship of chronic subdural hemorrhage to head injury is not always clear. In many elderly persons there is no

Table 24-7. Acute cerebral sequelae of head injury.

| Sequelae | Clinical Features | Pathology |
|----------------------------------|--|---|
| Concussion | Transient loss of consciousness with bradycardia, hypotension, and respiratory arrest for a few seconds followed by retrograde and posttraumatic amnesia. Occasionally followed by transient neurologic deficit. | Bruising on side of impact (coup injury) or contralaterally (contrecoup injury). |
| Cerebral contusion or laceration | Loss of consciousness longer than with concussion. May lead to death or severe residual neurologic deficit. | Cerebral contusion, edema, hemorrhage, and necrosis. May have subarachnoid bleeding. |
| Acute epidural hemorrhage | Headache, confusion, somnolence, seizures, and focal deficits occur several hours after injury and lead to coma, respiratory depression, and death unless treated by surgical evacuation. | Tear in meningeal artery, vein, or dural sinus, leading to hematoma visible on CT scan. |
| Acute subdural hemorrhage | Similar to epidural hemorrhage, but interval before onset of symptoms is longer. Treatment is by surgical evacuation. | Hematoma from tear in veins from cortex to superior sagittal sinus or from cerebral laceration, visible on CT scan. |
| Cerebral hemorrhage | Generally develops immediately after injury. Clinically resembles hypertensive hemorrhage. Surgical evacuation is sometimes helpful. | Hematoma, visible on CT scan. |

history of trauma, but in other cases a head injury, often trivial, precedes the onset of symptoms by several weeks. The clinical presentation is usually with mental changes such as slowness, drowsiness, headache, confusion, memory disturbances, personality change, or even dementia. Focal neurologic deficits such as hemiparesis or hemisensory disturbance may also occur but are less common. CT scan is an important means of detecting the hematoma, which is sometimes bilateral. Treatment is by surgical evacuation to prevent cerebral compression and tentorial herniation. There is no clear evidence that prophylactic anticonvulsant therapy reduces the incidence of posttraumatic seizures.

Normal-pressure hydrocephalus may follow head injury, subarachnoid hemorrhage, or meningoencephalitis.

Other late complications of head injury include post-traumatic seizure disorder and posttraumatic headache.

▶ When to Refer

- Patients with focal neurologic deficits, altered consciousness, or skull fracture.
- Patients with late complications of head injury, eg, posttraumatic seizure disorder or normal pressure hydrocephalus.

▶ When to Admit

- Patients (especially elderly, >65 years) who are intoxicated with drugs or alcohol or have evidence of soft-tissue injury above the clavicles should be admitted for observation.
- Patients with recurrent vomiting, focal neurologic deficits, persistent anterograde amnesia, retrograde amnesia for more than 30 minutes, altered consciousness, or skull fracture.
- Patients with acute epidural, subdural, or cerebral hematoma.
- Patients requiring shunt placement for normal pressure hydrocephalus.

SPINAL TRAUMA

ESSENTIALS OF DIAGNOSIS

- ▶ History of preceding trauma.
- ▶ Development of acute neurologic deficit.
- ▶ Signs of myelopathy on examination.

▶ General Considerations

While spinal cord damage may result from whiplash injury, severe injury usually relates to fracture-dislocation causing compression or angular deformity of the cord

either cervically or in the lower thoracic and upper lumbar regions. Extreme hypotension following injury may also lead to cord infarction.

▶ Clinical Findings

Total cord transection results in immediate flaccid paralysis and loss of sensation below the level of the lesion. Reflex activity is lost for a variable period, and there is urinary and fecal retention. As reflex function returns over the following days and weeks, spastic paraplegia or quadriplegia develops, with hyperreflexia and extensor plantar responses, but a flaccid atrophic (lower motor neuron) paralysis may be found depending on the segments of the cord that are affected. The bladder and bowels also regain some reflex function, permitting urine and feces to be expelled at intervals. As spasticity increases, flexor or extensor spasms (or both) of the legs become troublesome, especially if the patient develops bed sores or a urinary tract infection. Paraplegia with the legs in flexion or extension may eventually result.

With lesser degrees of injury, patients may be left with mild limb weakness, distal sensory disturbance, or both. Sphincter function may also be impaired, urinary urgency and urgency incontinence being especially common. More particularly, a unilateral cord lesion leads to an ipsilateral motor disturbance with accompanying impairment of proprioception and contralateral loss of pain and temperature appreciation below the lesion (Brown-Séquard syndrome). A central cord syndrome may lead to a lower motor neuron deficit and loss of pain and temperature appreciation, with sparing of posterior column functions. A radicular deficit may occur at the level of the injury—or, if the cauda equina is involved, there may be evidence of disturbed function in several lumbosacral roots.

▶ Treatment

Treatment of the injury consists of immobilization and—if there is cord compression—decompressive laminectomy and fusion. Early treatment with high doses of corticosteroids (eg, methylprednisolone, 30 mg/kg by intravenous bolus, followed by 5.4 mg/kg/h for 23 hours) may improve neurologic recovery if commenced within 8 hours after injury; the findings from various studies are conflicting, however, and evaluation of the published evidence suggest that significant benefit is unlikely. Various other therapies are being investigated. Anatomic realignment of the spinal cord by traction and other orthopedic procedures is important. Subsequent care of the residual neurologic deficit—paraplegia or quadriplegia—requires treatment of spasticity and care of the skin, bladder, and bowels.

▶ When to Refer

All patients with focal neurologic deficits should be referred.

▶ When to Admit

- Patients with neurologic deficits.

- Patients with spinal cord injury, compression, or acute epidural or subdural hematoma.
- Patients with vertebral fracture-dislocation likely to compress the cord.

SYRINGOMYELIA

Destruction or degeneration of gray and white matter adjacent to the central canal of the cervical spinal cord leads to cavitation and accumulation of fluid within the spinal cord. The precise pathogenesis is unclear, but many cases are associated with Arnold-Chiari malformation, in which there is displacement of the cerebellar tonsils, medulla, and fourth ventricle into the spinal canal, sometimes with accompanying meningocele. In such circumstances, the cord cavity connects with and may merely represent a dilated central canal. In other cases, the cause of cavitation is less clear. There is a characteristic clinical picture, with segmental atrophy and areflexia and loss of pain and temperature appreciation in a “cape” distribution owing to the destruction of fibers crossing in front of the central canal. Thoracic kyphoscoliosis is usually present. With progression, involvement of the long motor and sensory tracts occurs as well, so that a pyramidal and sensory deficit develops in the legs. Upward extension of the cavitation (syringobulbia) leads to dysfunction of the lower brainstem and thus to bulbar palsy, nystagmus, and sensory impairment over one or both sides of the face.

Syringomyelia, ie, cord cavitation, may also occur in association with an intramedullary tumor or following severe cord injury, and the cavity then does not communicate with the central canal.

In patients with Arnold-Chiari malformation, there are commonly skeletal abnormalities on plain radiographs of the skull and cervical spine. CT scans show caudal displacement of the fourth ventricle. MRI or positive contrast myelography may demonstrate the malformation itself. Focal cord enlargement is found at myelography or by MRI in patients with cavitation related to past injury or intramedullary neoplasms.

Treatment of Arnold-Chiari malformation with associated syringomyelia is by suboccipital craniectomy and upper cervical laminectomy, with the aim of decompressing the malformation at the foramen magnum. The cord cavity should be drained, and if necessary an outlet for the fourth ventricle can be made. In cavitation associated with intramedullary tumor, treatment is surgical, but radiation therapy may be necessary if complete removal is not possible. Posttraumatic syringomyelia is also treated surgically if it leads to increasing neurologic deficits or to intolerable pain.

DEGENERATIVE MOTOR NEURON DISEASES

ESSENTIALS OF DIAGNOSIS

- ▶ Weakness.
- ▶ No sensory loss or sphincter disturbance.
- ▶ Progressive course.
- ▶ No identifiable underlying cause other than genetic basis in familial cases.

▶ General Considerations

This group of degenerative disorders is characterized clinically by weakness and variable wasting of affected muscles, without accompanying sensory changes.

Motor neuron disease in adults generally commences between 30 and 60 years of age. There is degeneration of the anterior horn cells in the spinal cord, the motor nuclei of the lower cranial nerves, and the corticospinal and corticobulbar pathways. The disorder is usually sporadic, but familial cases may occur and several genetic mutations or loci have been identified.

▶ Classification

Five varieties have been distinguished on clinical grounds.

A. Progressive Bulbar Palsy

Bulbar involvement predominates owing to disease processes affecting primarily the motor nuclei of the cranial nerves.

B. Pseudobulbar Palsy

Bulbar involvement predominates in this variety also, but it is due to bilateral corticobulbar disease and thus reflects upper motor neuron dysfunction. There may be a “pseudobulbar affect,” with uncontrollable episodes of laughing or crying to stimuli that would not normally have elicited such marked reactions.

C. Progressive Spinal Muscular Atrophy

This is characterized primarily by a lower motor neuron deficit in the limbs due to degeneration of the anterior horn cells in the spinal cord.

D. Primary Lateral Sclerosis

There is a purely upper motor neuron deficit in the limbs.

E. Amyotrophic Lateral Sclerosis

A mixed upper and lower motor neuron deficit is found in the limbs. This disorder is sometimes associated with cognitive decline (in a pattern consistent with frontotemporal dementia), a pseudobulbar affect, or parkinsonism.

▶ Clinical Findings

A. Symptoms and Signs

Difficulty in swallowing, chewing, coughing, breathing, and talking (dysarthria) occur with bulbar involvement. In progressive bulbar palsy, there is drooping of the palate; a depressed gag reflex; pooling of saliva in the pharynx; a weak cough; and a wasted, fasciculating tongue. In pseudobulbar palsy, the tongue is contracted and spastic and cannot be moved rapidly from side to side. Limb involvement is characterized by motor disturbances (weakness, stiffness, wasting, fasciculations) reflecting lower or upper motor neuron dysfunction; there are no objective changes on sensory examination, although there may be vague sensory complaints. The sphincters are generally spared. Cognitive changes or pseudobulbar affect may be present. The disorder is progressive, and amyotrophic lateral sclerosis is usually fatal within 3–5 years; death usually results from pulmonary infections. Patients with bulbar involvement generally have the poorest prognosis.

B. Laboratory and Other Studies

Electromyography may show changes of chronic partial denervation, with abnormal spontaneous activity in the resting muscle and a reduction in the number of motor units under voluntary control. In patients with suspected spinal muscular atrophy or amyotrophic lateral sclerosis, the diagnosis should not be made with confidence unless such changes are found in at least three spinal regions (cervical, thoracic, lumbosacral) or two spinal regions and the bulbar musculature. Motor conduction velocity is usually normal but may be slightly reduced, and sensory conduction studies are also normal. Biopsy of a wasted muscle shows the histologic changes of denervation. The serum creatine kinase may be slightly elevated but never reaches the extremely high values seen in some of the muscular dystrophies. The cerebrospinal fluid is normal.

A familial form of amyotrophic lateral sclerosis has been described with autosomal dominant inheritance, related to mutations in the copper-zinc superoxide dismutase gene on the long arm of chromosome 21. Other familial forms with dominant or recessive inheritance have also been identified and mapped to other genetic loci. X-linked bulbospinal neuronopathy is associated with an expanded trinucleotide repeat sequence on the androgen receptor gene and carries a more benign prognosis than other forms of motor neuron disease. There have been recent reports of juvenile spinal muscular atrophy due to hexosaminidase deficiency, with abnormal findings on rectal biopsy and reduced hexosaminidase A in serum and leukocytes. Pure motor syndromes resembling motor neuron disease may also occur in association with monoclonal gammopathy or multifocal motor neuropathies with conduction block. A motor neuronopathy may also develop in Hodgkin disease and has a relatively benign prognosis. Infective anterior horn cell diseases (polio virus or West Nile virus infection) can generally be distinguished by the acute onset and monophasic course of the illness, as discussed elsewhere in this book.

▶ Treatment

Riluzole, 50 mg orally twice daily, which reduces the presynaptic release of glutamate, may slow progression of amyotrophic lateral sclerosis. There is otherwise no specific treatment except in patients with gammopathy, in whom plasmapheresis and immunosuppression may lead to improvement. Therapeutic trials of various neurotrophic factors to slow disease progression have yielded generally disappointing results as have trials of celecoxib, a cyclooxygenase-2 (COX-2) inhibitor, and pentoxifylline. Symptomatic and supportive measures may include prescription of anticholinergic drugs (such as trihexyphenidyl, amitriptyline, or atropine) or use of a portable suction machine if drooling is troublesome, braces or a walker to improve mobility, and physical therapy to prevent contractures. Behavioral modification (eg, exercising facial muscles and encouraging frequent swallowing) or over-the-counter decongestants may also help mild drooling. Spasticity may be helped by baclofen or diazepam. A semiliquid diet or nasogastric tube feeding may be needed if dysphagia is severe. Gastrostomy or cricopharyngomyotomy is sometimes resorted to in extreme cases of predominant bulbar involvement, and tracheostomy may be necessary if respiratory muscles are severely affected; however, in the terminal stages of these disorders, the aim of treatment should be to keep patients as comfortable as possible. Information on palliative care is provided in Chapter 5.

▶ When to Refer

All patients (to exclude other treatable causes of symptoms and signs) should be referred.

▶ When to Admit

Patients should be admitted during the terminal stages of the disorders for palliative care.

PERIPHERAL NEUROPATHIES

Peripheral neuropathies can be categorized on the basis of the structure primarily affected. The predominant pathologic feature may be axonal degeneration (axonal or neuronal neuropathies) or paranodal or segmental demyelination. The distinction may be possible on the basis of neurophysiologic findings. Motor and sensory conduction velocity can be measured in accessible segments of peripheral nerves. In axonal neuropathies, conduction velocity is normal or reduced only mildly and needle electromyography provides evidence of denervation in affected muscles. In demyelinating neuropathies, conduction may be slowed considerably in affected fibers, and in more severe cases,

conduction is blocked completely, without accompanying electromyographic signs of denervation.

Nerves may be injured or compressed by neighboring anatomic structures at any point along their course. Common **mononeuropathies** of this sort are considered below. They lead to a sensory, motor, or mixed deficit that is restricted to the territory of the affected nerve. A similar clinical disturbance is produced by peripheral nerve tumors, but these are rare except in patients with Recklinghausen disease. Multiple mononeuropathies suggest a patchy multifocal disease process such as vasculopathy (eg, diabetes, arteritis), an infiltrative process (eg, leprosy, sarcoidosis), radiation damage, or an immunologic disorder (eg, brachial plexopathy). Diffuse **polyneuropathies** lead to a symmetric sensory, motor, or mixed deficit, often most marked distally. They include the hereditary, metabolic, and toxic disorders; idiopathic inflammatory polyneuropathy (Guillain-Barré syndrome); and the peripheral neuropathies that may occur as a nonmetastatic complication of malignant diseases. Involvement of motor fibers leads to flaccid weakness that is most marked distally; dysfunction of sensory fibers causes impaired sensory perception. Tendon reflexes are depressed or absent. Paresthesias, pain, and muscle tenderness may also occur.

POLYNEUROPATHIES & MONONEURITIS MULTIPLEX

ESSENTIALS OF DIAGNOSIS

- ▶ Weakness, sensory disturbances, or both in the extremities.
- ▶ Pain sometimes common.
- ▶ Depressed or absent tendon reflexes.
- ▶ May be family history of neuropathy.
- ▶ May be history of systemic illness or toxic exposure.

The cause of polyneuropathy or mononeuritis multiplex is suggested by the history, mode of onset, and predominant clinical manifestations. Laboratory workup includes a complete blood count and sedimentation rate, serum protein electrophoresis, and immunophoresis, determination of plasma urea and electrolytes, liver and thyroid function tests, tests for rheumatoid factor and antinuclear antibody, HBsAg determination, a serologic test for syphilis, fasting blood glucose level, urinary heavy metal levels, cerebrospinal fluid examination, and chest radiography. These tests should be ordered selectively, as guided by symptoms and signs. Measurement of nerve conduction velocity is important in confirming the peripheral nerve origin of symptoms and providing a means of following clinical changes, as well as indicating the likely disease process (ie, axonal or demyelinating neuropathy). Cutaneous nerve biopsy may help establish a precise diagnosis (eg, polyarteritis, amyloidosis). In about half of cases, no specific cause can be established; of these, slightly less than half are subsequently found to be hereditary.

Treatment is of the underlying cause, when feasible, and is discussed below under the individual disorders. Physical therapy helps prevent contractures, and splints can maintain a weak extremity in a position of useful function. Anesthetic extremities must be protected from injury. To guard against burns, patients should check the temperature of water and hot surfaces with a portion of skin having normal sensation, measure water temperature with a thermometer, and use cold water for washing or lower the temperature setting of their hot-water heaters. Shoes should be examined frequently during the day for grit or foreign objects in order to prevent pressure lesions.

Patients with polyneuropathies or mononeuritis multiplex are subject to additional nerve injury at pressure points and should therefore avoid such behavior as leaning on elbows or sitting with crossed legs for lengthy periods.

Neuropathic, burning pain is sometimes troublesome and may respond to simple analgesics, such as aspirin or nonsteroidal anti-inflammatory agents, and to gabapentin. Duloxetine or venlafaxine may be helpful, especially in painful diabetic neuropathy. Opioids may be necessary for severe hyperpathia or pain induced by minimal stimuli, but their use should be avoided as much as possible. The use of a frame or cradle to reduce contact with bedclothes may be helpful. Many patients experience episodic stabbing pains, which may respond to gabapentin, pregabalin, phenytoin, carbamazepine, or tricyclic antidepressants.

Symptoms of autonomic dysfunction are occasionally troublesome. Postural hypotension is often helped by wearing waist-high elastic stockings and sleeping in a semierect position at night. Fludrocortisone reduces postural hypotension, but doses as high as 1 mg/d are sometimes necessary in diabetics and may lead to recumbent hypertension. Midodrine, an α -agonist, is sometimes helpful in a dose of 2.5–10 mg three times daily. Impotence and diarrhea are difficult to treat; a flaccid neuropathic bladder may respond to parasympathomimetic drugs such as bethanechol chloride, 10–50 mg three or four times daily.

1. Inherited Neuropathies

A. Charcot-Marie-Tooth Disease (HMSN Type I, II)

Several distinct varieties of Charcot-Marie-Tooth disease can be recognized. There is usually an autosomal dominant mode of inheritance, but occasional cases occur on a sporadic, recessive, or X-linked basis. The responsible gene is commonly located on the short arm of chromosome 17 and less often shows linkage to chromosome 1 or the X chromosome. It has also been linked to several other chromosomes, emphasizing the genetic heterogeneity of the disorder. Clinical presentation may be with foot deformities or gait disturbances in childhood or early adult life. Slow progression leads to the typical features of polyneuropathy, with distal weakness and wasting that begin in the legs, a variable amount of distal sensory loss, and depressed or absent tendon reflexes. Tremor is a conspicuous feature in some instances. Electrodiagnostic studies show a marked reduction in motor and sensory conduction velocity (hereditary motor and sensory neuropathy [HMSN] type I).

In other instances (HMSN type II), motor conduction velocity is normal or only slightly reduced, sensory nerve action potentials may be absent, and signs of chronic partial denervation are found in affected muscles electromyographically. The predominant pathologic change is axonal loss rather than segmental demyelination.

A similar disorder may occur in patients with progressive distal spinal muscular atrophy, but there is no sensory loss; electrophysiologic investigation reveals that motor conduction velocity is normal or only slightly reduced, and nerve action potentials are normal.

B. Dejerine-Sottas Disease (HMSN Type III)

The disorder may occur on a sporadic, autosomal dominant or, less commonly, autosomal recessive basis. Onset in infancy or childhood leads to a progressive motor and sensory polyneuropathy with weakness, ataxia, sensory loss, and depressed or absent tendon reflexes. The peripheral nerves may be palpably enlarged and are characterized pathologically by segmental demyelination, Schwann cell hyperplasia, and thin myelin sheaths. Electrophysiologically, there is slowing of conduction, and sensory action potentials may be unrecordable.

C. Friedreich Ataxia

Patients generally present in childhood or early adult life with this autosomal recessive disorder, which has been related to an unstable mutation of the *X25* gene on chromosome 9q13–q21.1. The gait becomes atactic, the hands become clumsy, and other signs of cerebellar dysfunction develop accompanied by weakness of the legs and extensor plantar responses. Involvement of peripheral sensory fibers leads to sensory disturbances in the limbs and depressed tendon reflexes. There is bilateral pes cavus. Pathologically, there is a marked loss of cells in the posterior root ganglia and degeneration of peripheral sensory fibers. In the central nervous system, changes are conspicuous in the posterior and lateral columns of the cord. Electrophysiologically, conduction velocity in motor fibers is normal or only mildly reduced, but sensory action potentials are small or absent.

D. Refsum Disease (HMSN Type IV)

This autosomal recessive disorder is due to a disturbance in phytanic acid metabolism. Clinically, pigmentary retinal degeneration is accompanied by progressive sensorimotor polyneuropathy and cerebellar signs. Auditory dysfunction, cardiomyopathy, and cutaneous manifestations may also occur. Motor and sensory conduction velocity are reduced, often markedly, and there may be electromyographic evidence of denervation in affected muscles. Dietary restriction of phytanic acid and its precursors may be helpful therapeutically. Plasmapheresis to reduce stored phytanic acid may help at the initiation of treatment.

E. Porphyria

Peripheral nerve involvement may occur during acute attacks in both variegate porphyria and acute intermittent porphyria. Motor symptoms usually occur first, and weak-

ness is often most marked proximally and in the upper limbs rather than the lower. Sensory symptoms and signs may be proximal or distal in distribution. Autonomic involvement is sometimes pronounced. The electrophysiologic findings are in keeping with the results of neuropathologic studies suggesting that the neuropathy is axonal in type. Hematin (4 mg/kg intravenously over 15 minutes once or twice daily) may lead to rapid improvement. A high-carbohydrate diet and, in severe cases, intravenous glucose or levulose may also be helpful. Propranolol (up to 100 mg every 4 hours) may control tachycardia and hypertension in acute attacks.

2. Neuropathies Associated with Systemic & Metabolic Disorders

A. Diabetes Mellitus

In this disorder, involvement of the peripheral nervous system may lead to symmetric sensory or mixed polyneuropathy, asymmetric motor radiculoneuropathy or plexopathy (diabetic amyotrophy), thoracoabdominal radiculopathy, autonomic neuropathy, or isolated lesions of individual nerves. These may occur singly or in any combination and are discussed in Chapter 27.

B. Uremia

Uremia may lead to a symmetric sensorimotor polyneuropathy that tends to affect the lower limbs more than the upper limbs and is more marked distally than proximally (see Chapter 22). The diagnosis can be confirmed electrophysiologically, for motor and sensory conduction velocity is moderately reduced. The neuropathy improves both clinically and electrophysiologically with kidney transplantation and to a lesser extent with chronic dialysis.

C. Alcoholism and Nutritional Deficiency

Many alcoholics have an axonal distal sensorimotor polyneuropathy that is frequently accompanied by painful cramps, muscle tenderness, and painful paresthesias and is often more marked in the legs than in the arms. Symptoms of autonomic dysfunction may also be conspicuous. Motor and sensory conduction velocity may be slightly reduced, even in subclinical cases, but gross slowing of conduction is uncommon. A similar distal sensorimotor polyneuropathy is a well-recognized feature of beriberi (thiamine deficiency). In vitamin B₁₂ deficiency, distal sensory polyneuropathy may develop but is usually overshadowed by central nervous system manifestations (eg, myelopathy, optic neuropathy, or intellectual changes).

D. Paraproteinemias

A symmetric sensorimotor polyneuropathy that is gradual in onset, progressive in course, and often accompanied by pain and dysesthesias in the limbs may occur in patients (especially men) with multiple myeloma. The neuropathy is of the axonal type in classic lytic myeloma, but segmental demyelination (primary or secondary) and axonal loss may occur in sclerotic myeloma and lead to predominantly motor clinical manifestations. Both demyelinating and

axonal neuropathies are also observed in patients with paraproteinemias without myeloma. A small fraction will develop myeloma if serially followed. The demyelinating neuropathy in these patients may be due to the monoclonal protein's reacting to a component of the nerve myelin. The neuropathy of classic multiple myeloma is poorly responsive to therapy. The polyneuropathy of benign monoclonal gammopathy may respond to immunosuppressant drugs and plasmapheresis.

Polyneuropathy may also occur in association with macroglobulinemia and cryoglobulinemia and sometimes responds to plasmapheresis. Entrapment neuropathy, such as carpal tunnel syndrome, is more common than polyneuropathy in patients with (nonhereditary) generalized amyloidosis. With polyneuropathy due to amyloidosis, sensory and autonomic symptoms are especially conspicuous, whereas distal wasting and weakness occur later; there is no specific treatment.

3. Neuropathies Associated with Infectious & Inflammatory Diseases

A. Leprosy

Leprosy is an important cause of peripheral neuropathy in certain parts of the world. Sensory disturbances are mainly due to involvement of intracutaneous nerves. In tuberculoid leprosy, they develop at the same time and in the same distribution as the skin lesion but may be more extensive if nerve trunks lying beneath the lesion are also involved. In lepromatous leprosy, there is more extensive sensory loss, and this develops earlier and to a greater extent in the coolest regions of the body, such as the dorsal surfaces of the hands and feet, where the bacilli proliferate most actively. Motor deficits result from involvement of superficial nerves where their temperature is lowest, eg, the ulnar nerve in the region proximal to the olecranon groove, the median nerve as it emerges from beneath the forearm flexor muscle to run toward the carpal tunnel, the peroneal nerve at the head of the fibula, and the posterior tibial nerve in the lower part of the leg; patchy facial muscular weakness may also occur owing to involvement of the superficial branches of the seventh cranial nerve.

Motor disturbances in leprosy are suggestive of multiple mononeuropathy, whereas sensory changes resemble those of distal polyneuropathy. Examination, however, relates the distribution of sensory deficits to the temperature of the tissues; in the legs, for example, sparing frequently occurs between the toes and in the popliteal fossae, where the temperature is higher. Treatment is with antileprotic agents (see Chapter 33).

B. AIDS

A variety of neuropathies occur in HIV-infected patients (see Chapter 31). Patients with AIDS may develop a chronic symmetric sensorimotor axonal **polyneuropathy** associated usually with no abnormal cerebrospinal fluid findings. Treatment is symptomatic. AIDS patients may also develop progressive **polyradiculopathy** or radiculomyelopathy that leads to leg weakness and urinary reten-

tion; sensory loss is less conspicuous than in polyneuropathy. The cerebrospinal fluid may show mononuclear pleocytosis and increased protein and low glucose concentrations. Cytomegalovirus is responsible in at least some cases. The prognosis is generally poor, but some patients respond to intravenous ganciclovir (2.5 mg/kg every 8 hours for 10 days, then 7.5 mg/kg daily 5 days per week).

An inflammatory **demyelinating polyradiculoneuropathy** sometimes occurs in HIV-seropositive patients without AIDS and may follow an acute, subacute, or chronic course. Weakness is usually more conspicuous distally than proximally and tends to overshadow sensory symptoms. Tendon reflexes are depressed or absent. The cerebrospinal fluid shows an increased cell count and protein concentration. Treatment with plasmapheresis has helped some patients. Spontaneous improvement may also occur. Seropositive patients without AIDS may also develop a **mononeuropathy multiplex** that sometimes responds to treatment with plasmapheresis.

C. Lyme Borreliosis

The neurologic manifestations of Lyme disease include meningitis, meningoencephalitis, polyradiculoneuropathy, mononeuropathy multiplex, and cranial neuropathy. Serologic tests establish the underlying disorder. Treatment is described in Chapter 34.

D. Sarcoidosis

Cranial nerve palsies (especially facial palsy), multiple mononeuropathy and, less commonly, symmetric polyneuropathy may all occur, the latter sometimes preferentially affecting either motor or sensory fibers. Improvement may occur with use of corticosteroids.

E. Polyarteritis

Involvement of the vasa nervorum by the vasculitic process may result in infarction of the nerve. Clinically, one encounters an asymmetric sensorimotor polyneuropathy (mononeuritis multiplex) that pursues a waxing and waning course. Corticosteroids and cytotoxic agents—especially cyclophosphamide—may be of benefit in severe cases.

F. Rheumatoid Arthritis

Compressive or entrapment neuropathies, ischemic neuropathies, mild distal sensory polyneuropathy, and severe progressive sensorimotor polyneuropathy can occur in rheumatoid arthritis.

4. Neuropathy Associated with Critical Illness

Patients in intensive care units with sepsis and multiorgan failure sometimes develop polyneuropathies. This may be manifested initially by unexpected difficulty in weaning patients from a mechanical ventilator and in more advanced cases by wasting and weakness of the extremities and loss of tendon reflexes. Sensory abnormalities are relatively inconspicuous. The neuropathy is axonal in type. Its pathogenesis

is obscure, and treatment is supportive. The prognosis is good provided patients recover from the underlying critical illness.

5. Toxic Neuropathies

Axonal polyneuropathy may follow exposure to industrial agents or pesticides such as acrylamide, organophosphorus compounds, hexacarbon solvents, methyl bromide, and carbon disulfide; metals such as arsenic, thallium, mercury, and lead; and drugs such as phenytoin, perhexiline, isoniazid, nitrofurantoin, vincristine, and pyridoxine in high doses. Detailed occupational, environmental, and medical histories and recognition of clusters of cases are important in suggesting the diagnosis. Treatment is by preventing further exposure to the causal agent. Isoniazid neuropathy is prevented by pyridoxine supplementation.

Diphtheritic neuropathy results from a neurotoxin released by the causative organism and is common in many areas. Palatal weakness may develop 2–4 weeks after infection of the throat, and infection of the skin may similarly be followed by focal weakness of neighboring muscles. Disturbances of accommodation may occur about 4–5 weeks after infection and distal sensorimotor demyelinating polyneuropathy after 1–3 months.

6. Neuropathies Associated with Malignant Diseases

Both a sensorimotor and a purely sensory polyneuropathy may occur as a nonmetastatic complication of malignant diseases (see Table 39–13), and have been associated with circulating anti-MAG or anti-Hu antibodies that can be detected by a paraneoplastic antibody panel that is available commercially. The sensorimotor polyneuropathy may be mild and occur in the course of known malignant disease, or it may have an acute or subacute onset, lead to severe disability, and occur before there is any clinical evidence of the cancer, occasionally following a remitting course. An autonomic neuropathy may also occur as a paraneoplastic disorder related to the presence of anti-Hu antibodies or to an antibody against ganglionic acetylcholine receptors (anti-nAChR).

7. Acute Idiopathic Polyneuropathy (Guillain-Barré Syndrome)

ESSENTIALS OF DIAGNOSIS

- ▶ Acute or subacute progressive polyradiculoneuropathy.
- ▶ Weakness is more severe than sensory disturbances.
- ▶ Acute dysautonomia may be life-threatening.

▶ General Considerations

This acute or subacute polyradiculoneuropathy sometimes follows infective illness, inoculations, or surgical procedures. There is an association with preceding *Campylo-*

bacter jejuni enteritis. The disorder probably has an immunologic basis, but the precise mechanism is unclear.

▶ Clinical Findings

A. Symptoms and Signs

The main complaint is of weakness that varies widely in severity in different patients and often has a proximal emphasis and symmetric distribution. It usually begins in the legs, spreading to a variable extent but frequently involving the arms and often one or both sides of the face. The muscles of respiration or deglutition may also be affected. Sensory symptoms are usually less conspicuous than motor ones, but distal paresthesias and dysesthesias are common, and neuropathic or radicular pain is present in many patients. Autonomic disturbances are also common, may be severe, and are sometimes life-threatening; they include tachycardia, cardiac irregularities, hypotension or hypertension, facial flushing, abnormalities of sweating, pulmonary dysfunction, and impaired sphincter control. The axonal subtypes of the syndrome (acute motor axonal neuropathy [AMAN] and acute motor and sensory axonal neuropathy [AMSAN]) are caused by antibodies to gangliosides on the axon membrane and especially by antibodies to GM1, GM1b, and GD1a (and GalNac-GD1a to AMAN).

B. Laboratory Findings

The cerebrospinal fluid characteristically contains a high protein concentration with a normal cell content, but these changes may take 2 or 3 weeks to develop. Electrophysiologic studies may reveal marked abnormalities, which do not necessarily parallel the clinical disorder in their temporal course. Pathologic examination shows primary demyelination or, less commonly, axonal degeneration.

▶ Differential Diagnosis

When the diagnosis is made, the history and appropriate laboratory studies should exclude the possibility of porphyric, diphtheritic, or toxic (heavy metal, hexacarbon, organophosphate) neuropathies. The temporal course excludes other peripheral neuropathies. Poliomyelitis, botulism, and tick paralysis must also be considered as they cause weakness of acute onset. The presence of pyramidal signs, a markedly asymmetric motor deficit, a sharp sensory level, or early sphincter involvement should suggest a focal cord lesion.

▶ Treatment

Treatment with prednisone is ineffective and may prolong recovery time. Plasmapheresis is of value; it is best performed within the first few days of illness and is particularly useful for clinically severe or rapidly progressive cases or those with ventilatory impairment. IVIG (400 mg/kg/d for 5 days) is equally helpful and imposes less stress on the cardiovascular system than plasmapheresis. Patients should be admitted to intensive care units if their forced vital capacity is declining, and intubation is considered if the forced vital capacity reaches 15 mL/kg, dyspnea becomes

evident, or the oxygen saturation declines. Respiratory toilet and chest physical therapy help prevent atelectasis. Marked hypotension may respond to volume replacement or pressor agents. Low-dose heparin to prevent pulmonary embolism should be considered.

Approximately 3% of patients with acute idiopathic polyneuropathy have one or more clinically similar relapses, sometimes several years after the initial illness. Plasma exchange therapy may produce improvement in chronic and relapsing inflammatory polyneuropathy.

► Prognosis

Most patients eventually make a good recovery, but this may take many months, and about 20% of patients are left with persisting disability.

► When to Refer

All patients should be referred.

► When to Admit

All patients should be hospitalized until their condition is stable and there is no respiratory compromise.

8. Chronic Inflammatory Polyneuropathy

Chronic inflammatory demyelinating polyneuropathy, an acquired immunologically mediated disorder, is clinically similar to Guillain-Barré syndrome except that it has a relapsing or steadily progressive course over months or years and that autonomic dysfunction is generally less common. It may present as an exclusively motor disorder or with a mixed sensorimotor disturbance. In the relapsing form, partial recovery may occur after some relapses, but in other instances there is no recovery between exacerbations. Although remission may occur spontaneously with time, the disorder frequently follows a progressive downhill course leading to severe functional disability.

Electrodiagnostic studies show marked slowing of motor and sensory conduction, and focal conduction block. Signs of partial denervation may also be present owing to secondary axonal degeneration. Nerve biopsy may show chronic perivascular inflammatory infiltrates in the endoneurium and epineurium, without accompanying evidence of vasculitis. However, a normal nerve biopsy result or the presence of nonspecific abnormalities does not exclude the diagnosis.

Corticosteroids may arrest or reverse the downhill course. Treatment is usually begun with prednisone, 60–80 mg daily, continued for 2–3 months or until a definite response has occurred. If no response has occurred despite 3 months of treatment, a higher dose may be tried. In responsive cases, the dose is gradually tapered, but most patients become corticosteroid-dependent, often requiring prednisone, 20 mg daily on alternate days, on a long-term basis. IVIG can be used in place of—or in addition to—corticosteroids and is best used as the initial treatment in pure motor syndromes. When both IVIG and corticosteroids are ineffective, plasma exchange may be worthwhile. Immunosuppressant or immunomodulatory drugs (such

as azathioprine) may be added when the response to other measures is unsatisfactory or to enable maintenance doses of corticosteroids to be lowered. Symptomatic treatment is also important.

MONONEUROPATHIES

ESSENTIALS OF DIAGNOSIS

- Focal motor or sensory deficit.
- Deficit is in territory of an individual peripheral nerve.

An individual nerve may be injured along its course or may be compressed, angulated, or stretched by neighboring anatomic structures, especially at a point where it passes through a narrow space (entrapment neuropathy). The relative contributions of mechanical factors and ischemia to the local damage are not clear. With involvement of a sensory or mixed nerve, pain is commonly felt distal to the lesion. Symptoms never develop with some entrapment neuropathies, resolve rapidly and spontaneously in others, and become progressively more disabling and distressing in yet other cases. The precise neurologic deficit depends on the nerve involved. Percussion of the nerve at the site of the lesion may lead to paresthesias in its distal distribution.

Entrapment neuropathy may be the sole manifestation of subclinical polyneuropathy, and this must be borne in mind and excluded by nerve conduction studies. Such studies are also indispensable for the accurate localization of the focal lesion.

In patients with acute compression neuropathy such as may occur in intoxicated individuals (“Saturday night palsy”), no treatment is necessary. Complete recovery generally occurs, usually within 2 months, presumably because

the underlying pathology is demyelination. However, axonal degeneration can occur in severe cases, and recovery then takes longer and may never be complete.

In chronic compressive or entrapment neuropathies, avoidance of aggravating factors and correction of any underlying systemic conditions are important. Local infiltration of the region about the nerve with corticosteroids may be of value; in addition, surgical decompression may help if there is a progressively increasing neurologic deficit or if electrodiagnostic studies show evidence of partial denervation in weak muscles.

Peripheral nerve tumors are uncommon, except in Recklinghausen disease, but also give rise to mononeuropathy. This may be distinguishable from entrapment neuropathy only by noting the presence of a mass along the course of the nerve and by demonstrating the precise site of the lesion with appropriate electrophysiologic studies. Treatment of symptomatic lesions is by surgical removal if possible.

1. Carpal Tunnel Syndrome

See Chapter 20.

2. Pronator Teres or Anterior Interosseous Syndrome

The median nerve gives off its motor branch, the anterior interosseous nerve, below the elbow as it descends between the two heads of the pronator teres muscle. A lesion of either nerve may occur in this region, sometimes after trauma or owing to compression from, for example, a fibrous band. With anterior interosseous nerve involvement, there is no sensory loss, and weakness is confined to the pronator quadratus, flexor pollicis longus, and the flexor digitorum profundus to the second and third digits. Weakness is more widespread and sensory changes occur in an appropriate distribution when the median nerve itself is affected. The prognosis is variable. If improvement does not occur spontaneously, decompressive surgery may be helpful.

3. Ulnar Nerve Lesions

Ulnar nerve lesions are likely to occur in the elbow region as the nerve runs behind the medial epicondyle and descends into the cubital tunnel. In the condylar groove, the ulnar nerve is exposed to pressure or trauma. Moreover, any increase in the carrying angle of the elbow, whether congenital, degenerative, or traumatic, may cause excessive stretching of the nerve when the elbow is flexed. Ulnar nerve lesions may also result from thickening or distortion of the anatomic structures forming the cubital tunnel, and the resulting symptoms may also be aggravated by flexion of the elbow, because the tunnel is then narrowed by tightening of its roof or inward bulging of its floor. A severe lesion at either site causes sensory changes in the medial 1¹/₂ digits and along the medial border of the hand. There is weakness of the ulnar-innervated muscles in the forearm and hand. With a cubital tunnel lesion, however, there may be relative sparing of the flexor carpi ulnaris muscle. Electrophysiologic evaluation using nerve

stimulation techniques allows more precise localization of the lesion.

If conservative measures are unsuccessful in relieving symptoms and preventing further progression, surgical treatment may be necessary. This consists of nerve transposition if the lesion is in the condylar groove, or a release procedure if it is in the cubital tunnel.

Ulnar nerve lesions may also develop at the wrist or in the palm of the hand, usually owing to repetitive trauma or to compression from ganglia or benign tumors. They can be subdivided depending on their presumed site. Compressive lesions are treated surgically. If repetitive mechanical trauma is responsible, this is avoided by occupational adjustment or job retraining.

4. Radial Nerve Lesions

The radial nerve is particularly liable to compression or injury in the axilla (eg, by crutches or by pressure when the arm hangs over the back of a chair). This leads to weakness or paralysis of all the muscles supplied by the nerve, including the triceps. Sensory changes may also occur but are often surprisingly inconspicuous, being marked only in a small area on the back of the hand between the thumb and index finger. Injuries to the radial nerve in the spiral groove occur characteristically during deep sleep, as in intoxicated individuals (Saturday night palsy), and there is then sparing of the triceps muscle, which is supplied more proximally. The nerve may also be injured at or above the elbow; its purely motor posterior interosseous branch, supplying the extensors of the wrist and fingers, may be involved immediately below the elbow, but then there is sparing of the extensor carpi radialis longus, so that the wrist can still be extended. The superficial radial nerve may be compressed by handcuffs or a tight watch strap.

5. Femoral Neuropathy

The clinical features of femoral nerve palsy consist of weakness and wasting of the quadriceps muscle, with sensory impairment over the anteromedian aspect of the thigh and sometimes also of the leg to the medial malleolus, and a depressed or absent knee jerk. Isolated femoral neuropathy may occur in diabetics or from compression by retroperitoneal neoplasms or hematomas (eg, expanding aortic aneurysm). Femoral neuropathy may also result from pressure from the inguinal ligament when the thighs are markedly flexed and abducted, as in the lithotomy position.

6. Meralgia Paresthetica

The lateral femoral cutaneous nerve, a sensory nerve arising from the L2 and L3 roots, may be compressed or stretched in obese or diabetic patients and during pregnancy. The nerve usually runs under the outer portion of the inguinal ligament to reach the thigh, but the ligament sometimes splits to enclose it. Hyperextension of the hip or increased lumbar lordosis—such as occurs during pregnancy—leads to nerve compression by the posterior fascicle of the ligament. However, entrapment of the nerve at any point along its course may cause similar symptoms, and several other

anatomic variations predispose the nerve to damage when it is stretched. Pain, paresthesia, or numbness occurs about the outer aspect of the thigh, usually unilaterally, and is sometimes relieved by sitting. Examination shows no abnormalities except in severe cases when cutaneous sensation is impaired in the affected area. Symptoms are usually mild and commonly settle spontaneously. Hydrocortisone injections medial to the anterosuperior iliac spine often relieve symptoms temporarily, while nerve decompression by transposition may provide more lasting relief.

7. Sciatic & Common Peroneal Nerve Palsies

Misplaced deep intramuscular injections are probably still the most common cause of sciatic nerve palsy. Trauma to the buttock, hip, or thigh may also be responsible. The resulting clinical deficit depends on whether the whole nerve has been affected or only certain fibers. In general, the peroneal fibers of the sciatic nerve are more susceptible to damage than those destined for the tibial nerve. A sciatic nerve lesion may therefore be difficult to distinguish from peroneal neuropathy unless there is electromyographic evidence of involvement of the short head of the biceps femoris muscle. The common peroneal nerve itself may be compressed or injured in the region of the head and neck of the fibula, eg, by sitting with crossed legs or wearing high boots. There is weakness of dorsiflexion and eversion of the foot, accompanied by numbness or blunted sensation of the anterolateral aspect of the calf and dorsum of the foot.

8. Tarsal Tunnel Syndrome

The tibial nerve, the other branch of the sciatic, supplies several muscles in the lower extremity, gives origin to the sural nerve, and then continues as the posterior tibial nerve to supply the plantar flexors of the foot and toes. It passes through the tarsal tunnel behind and below the medial malleolus, giving off calcaneal branches and the medial and lateral plantar nerves that supply small muscles of the foot and the skin on the plantar aspect of the foot and toes. Compression of the posterior tibial nerve or its branches between the bony floor and ligamentous roof of the tarsal tunnel leads to pain, paresthesias, and numbness over the bottom of the foot, especially at night, with sparing of the heel. Muscle weakness may be hard to recognize clinically. Compressive lesions of the individual plantar nerves may also occur more distally, with clinical features similar to those of the tarsal tunnel syndrome. Treatment is surgical decompression.

9. Facial Neuropathy

An isolated facial palsy may occur in patients with HIV seropositivity, sarcoidosis, or Lyme disease (Plate 90; also see Chapter 34), but most often it is idiopathic (Bell palsy).

▶ When to Refer

- If there is uncertainty about the diagnosis.
- Symptoms or signs are progressing despite treatment.

▶ When to Admit

When a patient should be hospitalized depends on the cause and treatment.

BELL PALSY

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden onset of lower motor neuron facial palsy.
- ▶ Hyperacusis or impaired taste may occur.
- ▶ No other neurologic abnormalities.

▶ General Considerations

Bell palsy is an idiopathic facial paresis of lower motor neuron type that has been attributed to an inflammatory reaction involving the facial nerve near the stylomastoid foramen or in the bony facial canal. Increasing evidence incriminates reactivation of herpes simplex virus infection in the geniculate ganglion at least in some instances. The disorder is more common in pregnant women or in persons with diabetes.

▶ Clinical Findings

The facial paresis generally comes on abruptly, but it may worsen over the following day or so. Pain about the ear precedes or accompanies the weakness in many cases but usually lasts for only a few days. The face itself feels stiff and pulled to one side. There may be ipsilateral restriction of eye closure and difficulty with eating and fine facial movements. A disturbance of taste is common, owing to involvement of chorda tympani fibers, and hyperacusis due to involvement of fibers to the stapedius occurs occasionally.

▶ Treatment

Other disorders that can produce a facial palsy and require specific treatment, such as tumors, Lyme disease, AIDS, sarcoidosis, and herpes zoster infection of the geniculate ganglion, must be excluded. The management of Bell palsy is controversial. Approximately 60% of cases recover completely without treatment, presumably because the lesion is so mild that it leads merely to conduction block. Considerable improvement occurs in most other cases, and only about 10% of all patients have permanent disfigurement or other long-term sequelae. Treatment is unnecessary in most cases but is indicated for patients in whom an unsatisfactory outcome can be predicted. The best clinical guide to progress is the severity of the palsy during the first few days after presentation. Patients with clinically complete palsy when first seen are less likely to make a full recovery than those with an incomplete one. A poor prognosis for recovery is also associated with advanced age, hyperacusis, and severe initial pain. Electromyography and nerve excitability or conduction studies provide a guide to prognosis but not early enough to aid in the selection of patients for treatment.

The only medical treatment that may influence the outcome is administration of corticosteroids, but this must be commenced within 5 days of onset. Treatment with prednisone, 60 or 80 mg daily in divided doses for 4 or 5 days, followed by tapering of the dose over the next 7–10 days, is a satisfactory regimen. It is helpful to protect the eye with lubricating drops (or lubricating ointment at night) and a patch if eye closure is not possible. Acyclovir does not confer any additional benefit. There is no evidence that surgical procedures to decompress the facial nerve are of benefit.

Sullivan FM et al. Early treatment with prednisolone or acyclovir in Bell's palsy. *N Engl J Med.* 2007 Oct 18;357(16):1598–607. [PMID: 17942873]

DISCOGENIC NECK PAIN

ESSENTIALS OF DIAGNOSIS

- ▶ Neck pain, sometimes radiating to arms.
- ▶ Restricted neck movements.
- ▶ Motor, sensory, or reflex changes in arms with root involvement.
- ▶ Neurologic deficit in legs, gait disorder, or sphincter disturbance with cord involvement.

▶ General Considerations

A variety of congenital abnormalities may involve the cervical spine and lead to neck pain; these include hemivertebrae, fused vertebrae, basilar impression, and instability of the atlantoaxial joint. Traumatic, degenerative, infective, and neoplastic disorders may also lead to pain in the neck. When rheumatoid arthritis involves the spine, it tends to affect especially the cervical region, leading to pain, stiffness, and reduced mobility; displacement of vertebrae or atlantoaxial subluxation may lead to cord compression that can be life-threatening if not treated by fixation. Further details are given in Chapter 20 (including a discussion on low back pain), and discussion here is restricted to disk disease.

1. Acute Cervical Disk Protrusion

Acute cervical disk protrusion leads to pain in the neck and radicular pain in the arm, exacerbated by head movement. With lateral herniation of the disk, motor, sensory, or reflex changes may be found in a radicular (usually C6 or C7) distribution on the affected side (Figure 24–1); with more centrally directed herniations, the spinal cord may also be involved, leading to spastic paraparesis and sensory disturbances in the legs, sometimes accompanied by impaired sphincter function. The diagnosis is confirmed by MRI or CT myelography. In mild cases, bed rest or intermittent neck traction may help, followed by immobilization of the neck in a collar for several weeks. If these measures are unsuccessful or the patient has a significant neurologic deficit, surgical removal of the protruding disk may be necessary.

2. Cervical Spondylosis

Cervical spondylosis results from chronic cervical disk degeneration, with herniation of disk material, secondary calcification, and associated osteophytic outgrowths. One or more of the cervical nerve roots may be compressed, stretched, or angulated; and myelopathy may also develop as a result of compression, vascular insufficiency, or recurrent minor trauma to the cord. Patients present with neck pain and restricted head movement, occipital headaches, radicular pain and other sensory disturbances in the arms, weakness of the arms or legs, or some combination of these symptoms. Examination generally reveals that lateral flexion and rotation of the neck are limited. A segmental pattern of weakness or dermatomal sensory loss (or both) may be found unilaterally or bilaterally in the upper limbs, and tendon reflexes mediated by the affected root or roots are depressed. The C5 and C6 nerve roots are most commonly involved, and examination frequently then reveals weakness of muscles supplied by these roots (eg, deltoids, supraspinatus and infraspinatus, biceps, brachioradialis), pain or sensory loss about the shoulder and outer border of the arm and forearm, and depressed biceps and brachioradialis reflexes. Spastic paraparesis may also be present if there is an associated myelopathy, sometimes accompanied by posterior column or spinothalamic sensory deficits in the legs.

Plain radiographs of the cervical spine show osteophyte formation, narrowing of disk spaces, and encroachment on the intervertebral foramina, but such changes are common in middle-aged persons and may be unrelated to the presenting complaint. CT or MRI helps confirm the diagnosis and exclude other structural causes of the myelopathy.

Restriction of neck movements by a cervical collar may relieve pain. Operative treatment may be necessary to prevent further progression if there is a significant neurologic deficit or if root pain is severe, persistent, and unresponsive to conservative measures.

▶ When to Refer

- Pain unresponsive to simple measures.
- Patients with neurologic deficits.
- Patients in whom surgical treatment is under consideration.

▶ When to Admit

- Patients with progressive or significant neurologic deficit.
- Patients with sphincter involvement (from cord compression).
- Patients requiring surgical treatment.

BRACHIAL & LUMBAR PLEXUS LESIONS

1. Brachial Plexus Neuropathy

Brachial plexus neuropathy may be idiopathic, sometimes occurring in relationship to a number of different nonspecific illnesses or factors. In other instances, brachial plexus

Peripheral nerve

Nerve root

▲ **Figure 24-1.** Cutaneous innervation. The segmental or radicular (root) distribution is shown on the left side of the body and the peripheral nerve distribution on the right side. Above: anterior view; facing page: posterior view. (Reproduced, with permission, from Simon RP et al. *Clinical Neurology*, 4th ed. McGraw-Hill, 1999.) (Continued)

lesions follow trauma or result from congenital anomalies, neoplastic involvement, or injury by various physical agents. In rare instances, the disorder occurs on a familial basis.

Idiopathic brachial plexus neuropathy (neuralgic amyotrophy) characteristically begins with severe pain about the

shoulder, followed within a few days by weakness, reflex changes, and sensory disturbances involving especially the C5 and C6 segments but affecting any nerve in the brachial plexus. Symptoms and signs are usually unilateral but may be bilateral. Wasting of affected muscles is sometimes pro-

▲ Figure 24-1. (Continued)

found. The disorder relates to disturbed function of cervical roots or part of the brachial plexus, but its precise cause is unknown. Recovery occurs over the ensuing months but may be incomplete. Treatment is purely symptomatic.

van Alfen N et al. The clinical spectrum of neuralgic amyotrophy in 246 cases. *Brain*. 2006 Feb;129(Pt 2):438–50. [PMID: 16371410]

2. Cervical Rib Syndrome

Compression of the C8 and T1 roots or the lower trunk of the brachial plexus by a cervical rib or band arising from the seventh cervical vertebra leads to weakness and wasting of intrinsic hand muscles, especially those in the thenar eminence, accompanied by pain and numbness in the medial two fingers and the ulnar border of the hand and

forearm. The subclavian artery may also be compressed, and this forms the basis of Adson test for diagnosing the disorder; the radial pulse is diminished or obliterated on the affected side when the seated patient inhales deeply and turns the head to one side or the other. Electromyography, nerve conduction studies, and somatosensory evoked potential studies may help confirm the diagnosis. MRI may be especially helpful in revealing the underlying compressive structure. Plain radiographs or CT scanning sometimes shows the cervical rib or a large transverse process of the seventh cervical vertebra, but normal findings do not exclude the possibility of a cervical band. Treatment of the disorder is by surgical excision of the rib or band.

3. Lumbosacral Plexus Lesions

A lumbosacral plexus lesion may develop in association with diseases such as diabetes, cancer, or bleeding disorders or in relation to injury. It occasionally occurs as an isolated phenomenon similar to idiopathic brachial plexopathy, and pain and weakness then tend to be more conspicuous than sensory symptoms. The distribution of symptoms and signs depends on the level and pattern of neurologic involvement.

Wilbourn AJ. Plexopathies. *Neurol Clin.* 2007 Feb;25(1):139–71. [PMID: 17324724]

DISORDERS OF NEUROMUSCULAR TRANSMISSION

1. Myasthenia Gravis

ESSENTIALS OF DIAGNOSIS

- ▶ Fluctuating weakness of commonly used voluntary muscles, producing symptoms such as diplopia, ptosis, and difficulty in swallowing.
- ▶ Activity increases weakness of affected muscles.
- ▶ Short-acting anticholinesterases transiently improve the weakness.

▶ General Considerations

Myasthenia gravis occurs at all ages, sometimes in association with a thymic tumor or thyrotoxicosis, as well as in rheumatoid arthritis and lupus erythematosus. It is most common in young women with HLA-DR3; if thymoma is associated, older men are more commonly affected. Onset is usually insidious, but the disorder is sometimes unmasked by a coincidental infection that leads to exacerbation of symptoms. Exacerbations may also occur before the menstrual period and during or shortly after pregnancy. Symptoms are due to a variable degree of block of neuromuscular transmission caused by autoantibodies binding to acetylcholine receptors; these are found in most patients with the disease and have a primary role in reducing the number of functioning acetylcholine receptors. Additionally, cellular

immune activity against the receptor is found. Clinically, this leads to weakness; initially powerful movements fatigue readily. The external ocular muscles and certain other cranial muscles, including the masticatory, facial, and pharyngeal muscles, are especially likely to be affected, and the respiratory and limb muscles may also be involved.

▶ Clinical Findings

A. Symptoms and Signs

Patients present with ptosis, diplopia, difficulty in chewing or swallowing, respiratory difficulties, limb weakness, or some combination of these problems. Weakness may remain localized to a few muscle groups, especially the ocular muscles, or may become generalized. Symptoms often fluctuate in intensity during the day, and this diurnal variation is superimposed on a tendency to longer-term spontaneous relapses and remissions that may last for weeks. Nevertheless, the disorder follows a slowly progressive course and may have a fatal outcome owing to respiratory complications such as aspiration pneumonia.

Clinical examination confirms the weakness and fatigability of affected muscles. In most cases, the extraocular muscles are involved, and this leads to ocular palsies and ptosis, which are commonly asymmetric. Pupillary responses are normal. The bulbar and limb muscles are often weak, but the pattern of involvement is variable. Sustained activity of affected muscles increases the weakness, which improves after a brief rest. Sensation is normal, and there are usually no reflex changes.

The diagnosis can generally be confirmed by the response to a short-acting anticholinesterase. Edrophonium can be given intravenously in a dose of 10 mg (1 mL), 2 mg being given initially and the remaining 8 mg about 30 seconds later if the test dose is well tolerated; in myasthenic patients, there is an obvious improvement in strength of weak muscles lasting for about 5 minutes. Alternatively, 1.5 mg of neostigmine can be given intramuscularly, and the response then lasts for about 2 hours; atropine sulfate (0.6 mg) should be available to reverse muscarinic side effects.

B. Imaging

Lateral and anteroposterior radiographs of the chest and CT scans should be obtained to demonstrate a coexisting thymoma, but normal studies do not exclude this possibility.

C. Laboratory and Other Studies

Electrophysiologic demonstration of a decrementing muscle response to repetitive 2- or 3-Hz stimulation of motor nerves indicates a disturbance of neuromuscular transmission. Such an abnormality may even be detected in clinically strong muscles with certain provocative procedures. Needle electromyography of affected muscles shows a marked variation in configuration and size of individual motor unit potentials, and single-fiber electromyography reveals an increased jitter, or variability, in the time interval between two muscle fiber action potentials from the same motor unit.

Assay of serum for elevated levels of circulating acetylcholine receptor antibodies is useful because it has a sensitivity of 80–90% for the diagnosis of myasthenia gravis. Certain

patients without antibodies to acetylcholine receptors have serum antibodies to muscle-specific tyrosine kinase (MuSK), which should therefore be determined; these patients are more likely to have facial, respiratory, and proximal muscle weakness than those with antibodies to acetylcholine receptors.

▶ Treatment

Medication such as aminoglycosides that may exacerbate myasthenia gravis should be avoided. Anticholinesterase drugs provide symptomatic benefit without influencing the course of the disease. Neostigmine, pyridostigmine, or both can be used, the dose being determined on an individual basis. The usual dose of neostigmine is 7.5–30 mg (average, 15 mg) taken four times daily; of pyridostigmine, 30–180 mg (average, 60 mg) four times daily. Overmedication may temporarily increase weakness, which is then unaffected or enhanced by intravenous edrophonium.

Thymectomy usually leads to symptomatic benefit or remission and should be considered in all patients younger than age 60, unless weakness is restricted to the extraocular muscles. If the disease is of recent onset and only slowly progressive, operation is sometimes delayed for a year or so, in the hope that spontaneous remission will occur.

Treatment with corticosteroids is indicated for patients who have responded poorly to anticholinesterase drugs and have already undergone thymectomy. It is often introduced with the patient in the hospital, since weakness may initially be aggravated. Once weakness has stabilized after 2–3 weeks or any improvement is sustained, further management can be on an outpatient basis. Alternate-day treatment is usually well tolerated, but if weakness is enhanced on the nontreatment day it may be necessary for medication to be taken daily. The dose of corticosteroids is determined on an individual basis, but an initial high daily dose (eg, prednisone, 60–100 mg) can gradually be tapered to a relatively low maintenance level as improvement occurs; total withdrawal is difficult, however. Treatment with azathioprine may also be effective. The usual dose is 2–3 mg/kg orally daily after a lower initial dose.

In patients with major disability, plasmapheresis or IVIG therapy may be beneficial. It is also useful for stabilizing patients before thymectomy and for managing acute crisis. Mycophenolate mofetil, an immunosuppressant, may provide symptomatic benefit and allow the corticosteroid dose to be reduced.

▶ When to Refer

All patients should be referred.

▶ When to Admit

- Patients with acute exacerbation or bulbar involvement.
- Patients requiring plasmapheresis.
- Patients who are starting corticosteroid therapy.
- For thymectomy.

Mahadeva B et al. Autoimmune disorders of neuromuscular transmission. *Semin Neurol*. 2008 Apr;28(2):212–27. [PMID: 18351523]

2. Myasthenic Syndrome (Lambert-Eaton Syndrome)

ESSENTIALS OF DIAGNOSIS

- ▶ Variable weakness, typically improving with activity.
- ▶ Dysautonomic symptoms may also be present.
- ▶ A history of malignant disease may be obtained.

▶ General Considerations

Myasthenic syndrome (see Table 39–13) may be associated with small-cell carcinoma, sometimes developing before the tumor is diagnosed, and occasionally occurs with certain autoimmune diseases. There is defective release of acetylcholine in response to a nerve impulse, caused by P/Q-type voltage-gated calcium-channel antibody, and this leads to weakness, especially of the proximal muscles of the limbs. Unlike myasthenia gravis, however, power steadily increases with sustained contraction. The diagnosis can be confirmed electrophysiologically, because the muscle response to stimulation of its motor nerve increases remarkably if the nerve is stimulated repetitively at high rates, even in muscles that are not clinically weak.

Treatment with plasmapheresis and immunosuppressive drug therapy (prednisone and azathioprine) may lead to clinical and electrophysiologic improvement, in addition to therapy aimed at tumor when present. Prednisone is usually initiated in a daily dose of 60–80 mg and azathioprine in a daily dose of 2 mg/kg. Guanidine hydrochloride (25–50 mg/kg/d in divided doses) is occasionally helpful in seriously disabled patients, but adverse effects of the drug include marrow suppression. The response to treatment with anticholinesterase drugs such as pyridostigmine or neostigmine, either alone or in combination with guanidine, is variable.

3. Botulism

The toxin of *Clostridium botulinum* prevents the release of acetylcholine at neuromuscular junctions and autonomic synapses. Botulism occurs most commonly following the ingestion of contaminated home-canned food and should be suggested by the development of sudden, fluctuating, severe weakness in a previously healthy person. Symptoms begin within 72 hours following ingestion of the toxin and may progress for several days. Typically, there is diplopia, ptosis, facial weakness, dysphagia, and nasal speech, followed by respiratory difficulty and finally by weakness that appears last in the limbs. Blurring of vision (with unreactive dilated pupils) is characteristic, and there may be dryness of the mouth, constipation (paralytic ileus), and

postural hypotension. Sensation is preserved, and the tendon reflexes are not affected unless the involved muscles are very weak. If the diagnosis is suspected, the local health authority should be notified and a sample of serum and contaminated food (if available) sent to be assayed for toxin. Support for the diagnosis may be obtained by electrophysiologic studies; with repetitive stimulation of motor nerves at fast rates, the muscle response increases in size progressively.

Patients should be hospitalized in case respiratory assistance becomes necessary. Treatment is with trivalent antitoxin, once it is established that the patient is not allergic to horse serum. Guanidine hydrochloride (25–50 mg/kg/d in divided doses) to facilitate release of acetylcholine from nerve endings sometimes helps to increase muscle strength. Anticholinesterase drugs are of no value. Respiratory assistance and other supportive measures should be provided as necessary. Further details are provided in Chapter 33.

4. Disorders Associated with Use of Aminoglycosides

Aminoglycoside antibiotics, eg, gentamicin, may produce a clinical disturbance similar to botulism by preventing the release of acetylcholine from nerve endings, but symptoms subside rapidly as the responsible drug is eliminated from the body. These antibiotics are particularly dangerous in patients with preexisting disturbances of neuromuscular

transmission and are therefore best avoided in patients with myasthenia gravis.

MYOPATHIC DISORDERS

1. Muscular Dystrophies

ESSENTIALS OF DIAGNOSIS

- ▶ Muscle weakness, often in a characteristic distribution.
- ▶ Age at onset and inheritance pattern depend on the specific dystrophy.

▶ General Considerations

These inherited myopathic disorders are characterized by progressive muscle weakness and wasting. They are subdivided by mode of inheritance, age at onset, and clinical features, as shown in Table 24–8. In the Duchenne type, pseudohypertrophy of muscles frequently occurs at some stage; intellectual retardation is common; and there may be skeletal deformities, muscle contractures, and cardiac involvement. The serum creatine kinase level is increased, especially in the Duchenne and Becker varieties, and mildly increased also in limb-girdle dystrophy. Electromyography may help confirm that weakness

Table 24–8. The muscular dystrophies.¹

| Disorder | Inheritance | Age at Onset (years) | Distribution | Prognosis | Genetic Locus |
|----------------------|---|-------------------------|---|---|---------------------------|
| Duchenne type | X-linked recessive | 1–5 | Pelvic, then shoulder girdle; later, limb and respiratory muscles. | Rapid progression. Death within about 15 years after onset. | Xp21 |
| Becker | X-linked recessive | 5–25 | Pelvic, then shoulder girdle. | Slow progression. May have normal life span. | Xp21 |
| Limb-girdle (Erb) | Autosomal recessive, dominant or sporadic | 10–30 | Pelvic or shoulder girdle initially, with later spread to the other. | Variable severity and rate of progression. Possible severe disability in middle life. | Multiple |
| Facioscapulo-humeral | Autosomal dominant | Any age | Face and shoulder girdle initially; later, pelvic girdle and legs. | Slow progression. Minor disability. Usually normal life span. | 4q35 |
| Emery-Dreifuss | X-linked recessive or autosomal dominant | 5–10 | Humeroperoneal or scapuloperoneal. | Variable. | Xq28, 1q21.2 |
| Distal | Autosomal dominant or recessive | 40–60 | Onset distally in extremities; proximal involvement later. | Slow progression. | 2p13, 14q12 |
| Ocular | Autosomal dominant (may be recessive) | Any age (usually 5–30) | External ocular muscles; may also be mild weakness of face, neck, and arms. | | |
| Oculopharyngeal | Autosomal dominant | Any age | As in the ocular form but with dysphagia. | | 14q11.2–q13 |
| Myotonic dystrophy | Autosomal dominant | Any age (usually 20–40) | Face, neck, distal limbs. | Slow progression. | 19q13.2–q13.3; 3q13.3–q24 |

¹Not all possible genetic loci are shown.

is myopathic rather than neurogenic. Similarly, histopathologic examination of a muscle biopsy specimen may help confirm that weakness is due to a primary disorder of muscle and to distinguish between various muscle diseases.

A genetic defect on the short arm of the X chromosome has been identified in Duchenne dystrophy. The affected gene codes for the protein dystrophin, which is markedly reduced or absent from the muscle of patients with the disease. Dystrophin levels are generally normal in the Becker variety, but the protein is qualitatively altered.

Duchenne muscular dystrophy can now be recognized early in pregnancy in about 95% of women by genetic studies; in late pregnancy, DNA probes can be used on fetal tissue obtained for this purpose by amniocentesis. The genes causing some of the other muscular dystrophies are listed in Table 24–8.

There is no specific treatment for the muscular dystrophies, but it is important to encourage patients to lead as normal lives as possible. Prednisone (0.75 mg/kg daily) improves muscle strength and function in boys with Duchenne dystrophy, but side effects need to be monitored. Prolonged bed rest must be avoided, as inactivity often leads to worsening of the underlying muscle disease. Physical therapy and orthopedic procedures may help counteract deformities or contractures.

Angelini C. The role of corticosteroids in muscular dystrophy: a critical appraisal. *Muscle Nerve*. 2007 Oct;36(4):424–35. [PMID: 17541998]

Guglieri M et al. Limb-girdle muscular dystrophies. *Curr Opin Neurol*. 2008 Oct;21(5):576–84. [PMID: 18769252]

Rodino-Klapac LR et al. Gene therapy for Duchenne muscular dystrophy: expectations and challenges. *Arch Neurol*. 2007 Sep;64(9):1236–41. [PMID: 17846262]

Tawil R et al. Facioscapulohumeral muscular dystrophy. *Muscle Nerve*. 2006 Jul;34(1):1–15. [PMID: 16508966]

2. Myotonic Dystrophy

Myotonic dystrophy, a slowly progressive, dominantly inherited disorder, usually manifests itself in the third or fourth decade but occasionally appears early in childhood. The genetic defect has been localized to the long arm of chromosome 19 in the type 1 disorder. Myotonia leads to complaints of muscle stiffness and is evidenced by the marked delay that occurs before affected muscles can relax after a contraction. This can often be demonstrated clinically by delayed relaxation of the hand after sustained grip or by percussion of the belly of a muscle. In addition, there is weakness and wasting of the facial, sternocleidomastoid, and distal limb muscles. Associated clinical features include cataracts, frontal baldness, testicular atrophy, diabetes mellitus, cardiac abnormalities, and intellectual changes. In myotonic dystrophy type 2, the clinical features are similar but a different gene is involved (3q21.3). Electromyographic sampling of affected muscles reveals myotonic discharges in addition to changes suggestive of myopathy.

It is difficult to determine whether drug therapy for myotonia is safe or effective. Myotonia is widely treated with phenytoin (100 mg three times daily), quinine sulfate (300–400 mg three times daily), or procainamide (0.5–1 g four times daily). More recently, tocainide and mexiletine have been used. Phen-

ytoin is preferred, since the other drugs may have undesirable effects on cardiac conduction. Neither the weakness nor the course of the disorder is influenced by treatment.

Miller TM. Differential diagnosis of myotonic disorders. *Muscle Nerve*. 2008 Mar;37(3):293–9. [PMID: 18067134]

Trip J et al. Drug treatment for myotonia. *Cochrane Database Syst Rev*. 2006 Jan 25;(1):CD004762. [PMID: 16437496]

3. Myotonia Congenita

Myotonia congenita is commonly inherited as a dominant trait. The responsible gene may be on the long arm of chromosome 7. Generalized myotonia without weakness is usually present from birth, but symptoms may not appear until early childhood. Patients complain of muscle stiffness that is enhanced by cold and inactivity and relieved by exercise. Muscle hypertrophy, at times pronounced, is also a feature. A recessive form with later onset is associated with slight weakness and atrophy of distal muscles. Treatment with quinine sulfate, procainamide, tocainide, mexiletine, or phenytoin may help the myotonia, as in myotonic dystrophy.

4. Polymyositis & Dermatomyositis

See Chapter 20.

5. Inclusion Body Myositis

This disorder, of unknown cause, begins insidiously, usually after middle age, with progressive proximal weakness of first the lower and then the upper extremities, and affecting facial and pharyngeal muscles. Weakness often begins in the quadriceps femoris in the lower limbs and the forearm flexors in the upper limbs. Distal weakness is usually mild. Serum creatine kinase levels may be normal or increased. The diagnosis is confirmed by muscle biopsy. Corticosteroid and immunosuppressive therapy is usually ineffective, but IVIG therapy is occasionally of mild benefit.

Griggs RC. The current status of treatment for inclusion-body myositis. *Neurology*. 2006 Jan 24;66(2 Suppl 1):S30–2. [PMID: 16432142]

6. Mitochondrial Myopathies

The mitochondrial myopathies are a clinically diverse group of disorders that on pathologic examination of skeletal muscle with the modified Gomori stain show characteristic “ragged red fibers” containing accumulations of abnormal mitochondria. Patients may present with progressive external ophthalmoplegia or with limb weakness that is exacerbated or induced by activity. Other patients present with central neurologic dysfunction, eg, myoclonic epilepsy (myoclonic epilepsy, ragged red fiber syndrome, or MERRF), or the combination of myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS). These disorders result from separate abnormalities of mitochondrial DNA. (See also Chapter 20.) Treatment is symptomatic and palliative, but various experimental approaches are being explored.

A mitochondrial myopathy may develop in patients receiving zidovudine for treatment of AIDS, and patients

receiving highly active antiretroviral therapy (HAART) for HIV-1 infection may develop a **lipodystrophy**, with fat accumulating in muscle.

DiMauro S et al. Approaches to the treatment of mitochondrial diseases. *Muscle Nerve*. 2006 Sep;34(3):265–83. [PMID: 16810684]

7. Myopathies Associated with Other Disorders

Myopathy may occur in association with chronic hypokalemia, any endocrinopathy, and in patients taking corticosteroids, chloroquine, colchicine, clofibrate, emetine, aminocaproic acid, lovastatin, bretylium tosylate, or drugs causing potassium depletion. Weakness is mainly proximal, and serum creatine kinase is typically normal, except in hypothyroidism and some of the toxic myopathies. Treatment is of the underlying cause. Myopathy also occurs with chronic alcoholism, whereas acute reversible muscle necrosis may occur shortly after acute alcohol intoxication. Inflammatory myopathy may occur in patients taking penicillamine; myotonia may be induced by clofibrate, and preexisting myotonia may be exacerbated or unmasked by depolarizing muscle relaxants (eg, suxamethonium), β -blockers (eg, propranolol), fenoterol, ritodrine and, possibly, certain diuretics.

▶ When to Refer

All patients should be referred (to establish the diagnosis and underlying cause).

▶ When to Admit

- For respiratory assistance.
- For rhabdomyolysis.

PERIODIC PARALYSIS SYNDROMES

Periodic paralysis may have a familial (dominant inheritance) basis. The syndromes to be described are channelo-

pathies that manifest as abnormal, often potassium-sensitive, muscle-membrane excitability and lead clinically to episodes of flaccid weakness or paralysis, sometimes in association with abnormalities of the plasma potassium level. Strength is normal between attacks. Mutations in genes encoding three ion channels [*CACNA1S* (1q32), *SCN4A* (17q23.1-q25.3), and *KCNJ2* (17q23.1-q24.2)] account for most cases. **Hypokalemic periodic paralysis** has been related to mutations in the *CACNL1A3*, *SCN4A*, or *KCNE3* (11q13-q14) gene and is characterized by attacks that tend to occur on awakening, after exercise, or after a heavy meal and may last for several days. Patients should avoid excessive exertion. A low-carbohydrate and low-salt diet may help prevent attacks, as may acetazolamide, 250–750 mg/d. Nonselective β -adrenergic blockers may also prevent recurrent paralytic attacks. An ongoing attack may be aborted by potassium chloride given orally or by intravenous drip, provided the ECG can be monitored and kidney function is satisfactory. In young Asian men, it is commonly associated with hyperthyroidism and has been related to polymorphism in the *CACNA1S* gene; treatment of the endocrine disorder prevents recurrences. In **hyperkalemic periodic paralysis**, which is mostly associated with mutations in the *SCN4A* gene, attacks also tend to occur after exercise but usually last for less than an hour. They may be terminated by intravenous calcium gluconate (1–2 g) or by intravenous diuretics (furosemide, 20–40 mg), glucose, or glucose and insulin; daily acetazolamide or chlorothiazide may prevent recurrences. **Normokalemic periodic paralysis** is similar clinically to the hyperkalemic variety, but the plasma potassium level remains normal during attacks; treatment is with acetazolamide.

▶ When to Refer

All patients should be referred.

Psychiatric Disorders

Stuart J. Eisendrath, MD
Jonathan E. Lichtmacher, MD

25

COMMON PSYCHIATRIC DISORDERS

STRESS & ADJUSTMENT DISORDERS (Situational Disorders)

ESSENTIALS OF DIAGNOSIS

- ▶ Anxiety or depression clearly secondary to an identifiable stress.
- ▶ Subsequent symptoms of anxiety or depression commonly elicited by similar stress of lesser magnitude.
- ▶ Alcohol and other drugs are commonly used in self-treatment.

▶ General Considerations

Stress exists when the adaptive capacity of the individual is overwhelmed by events. The event may be an insignificant one objectively considered, and even favorable changes (eg, promotion and transfer) requiring adaptive behavior can produce stress. For each individual, stress is subjectively defined, and the response to stress is a function of each person's personality and physiologic endowment.

Opinion differs about what events are most apt to produce stress reactions. The causes of stress are different at different ages—eg, in young adulthood, the sources of stress are found in the marriage or parent-child relationship, the employment relationship, and the struggle to achieve financial stability; in the middle years, the focus shifts to changing spousal relationships, problems with aging parents, and problems associated with having young adult offspring who themselves are encountering stressful situations; in old age, the principal concerns are apt to be retirement, loss of physical capacity, major personal losses, and thoughts of death.

▶ Clinical Findings

An individual may react to stress by becoming anxious or depressed, by developing a physical symptom, by running

away, having a drink, starting an affair, or in limitless other ways. Common subjective responses are fear (of repetition of the stress-inducing event), rage (at frustration), guilt (over aggressive impulses), and shame (over helplessness). Acute and reactivated stress may be manifested by restlessness, irritability, fatigue, increased startle reaction, and a feeling of tension. Inability to concentrate, sleep disturbances (insomnia, bad dreams), and somatic preoccupations often lead to self-medication, most commonly with alcohol or other central nervous system depressants. Maladaptive behavior in response to stress is called adjustment disorder, with the major symptom specified (eg, "adjustment disorder with depressed mood").

▶ Differential Diagnosis

Adjustment disorders must be distinguished from anxiety disorders, affective disorders, and personality disorders exacerbated by stress and from somatic disorders with psychic overlay.

▶ Treatment

A. Behavioral

Stress reduction techniques include immediate symptom reduction (eg, rebreathing in a bag for hyperventilation) or early recognition and removal from a stress source before full-blown symptoms appear. It is often helpful for the patient to keep a daily log of stress precipitators, responses, and alleviators. Relaxation and exercise techniques are also helpful in reducing the reaction to stressful events.

B. Social

The stress reactions of life crisis problems are a function of psychosocial upheaval, and patients frequently present with somatic symptoms. While it is not easy for the patient to make necessary changes (or they would have been made long ago), it is important for the therapist to establish the framework of the problem, since the patient's denial system may obscure the issues. Clarifying the problem allows the patient to begin viewing it within the proper context and facilitates the sometimes difficult decisions the patient

eventually must make (eg, change of job or relocation of adult-dependent offspring).

C. Psychological

Prolonged in-depth psychotherapy is seldom necessary in cases of isolated stress response or adjustment disorder. Supportive psychotherapy (see above) with an emphasis on the here and now and strengthening of existing coping mechanisms is a helpful approach so that time and the patient's own resiliency can restore the previous level of function.

D. Medical

Judicious use of sedatives (eg, lorazepam, 1–2 mg orally daily) for a limited time and as part of an overall treatment plan can provide relief from acute anxiety symptoms. Problems arise when the situation becomes chronic through inappropriate treatment or when the treatment approach supports the development of chronicity.

► Prognosis

Return to satisfactory function after a short period is part of the clinical picture of this syndrome. Resolution may be delayed if others' responses to the patient's difficulties are thoughtlessly harmful or if the secondary gains outweigh the advantages of recovery. The longer the symptoms persist, the worse the prognosis.

POSTTRAUMATIC STRESS DISORDER

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure to traumatic (life-threatening) event.
- ▶ Symptoms, such as flashbacks, intrusive images, and nightmares, often represent reexperiencing the event.
- ▶ Avoidance symptoms, including numbing, social withdrawal, and avoidance of stimuli associated with the event.
- ▶ Increased vigilance, such as startle reactions and difficulty falling asleep.
- ▶ Symptoms impair functioning.

► General Considerations

Posttraumatic stress disorder (PTSD)—included among the anxiety disorders in *DSM-IV*—is a syndrome characterized by “reexperiencing” a traumatic event (eg, severe

burns, military combat) and decreased responsiveness and avoidance of current events associated with the trauma. The 2005 National Comorbidity Survey Report estimated the lifetime prevalence of PTSD among adult Americans at 6.8% with women having rates twice as high as men. These rates indicate that traumas are not invariably associated with producing PTSD since approximately 60% of men and 50% of women report having experienced at least one lifetime trauma. The National Veterans Vietnam Readjustment Survey indicated that 53.4% of male and 48.1% of female Vietnam war veterans experienced some symptoms of PTSD, with approximately 60% of these affected veterans experiencing the full syndrome. Of the male veterans, 44.7% experienced a lifetime prevalence of alcohol or drug abuse, with 13% experiencing current abuse or dependence. Data indicate that 13% of veterans who served in Iraq and 6% of those who served in Afghanistan have experienced PTSD. In the US population, recent estimates indicate a lifetime prevalence of 7% with a current prevalence of 3.6%. PTSD is more common when the event is associated with physical injury than when it is not. Many individuals with PTSD (20–40%) have experienced other associated problems, including divorce, parenting problems, difficulties with the law, and substance abuse. Since the terrorist attacks in the United States on September 11, 2001, estimates of PTSD have ranged from 4.7% to 10.2% and have been associated with functional impairment as well as increased rates of substance use.

► Clinical Findings

Patients with PTSD experience physiologic hyperarousal, including startle reactions, intrusive thoughts, illusions, overgeneralized associations, sleep problems, nightmares, dreams about the precipitating event, impulsivity, difficulties in concentration, and hyperalertness. The symptoms may be precipitated or exacerbated by events that are a reminder of the original stress. Symptoms frequently arise after a long latency period (eg, child abuse can result in later-onset posttraumatic stress disorder).

► Differential Diagnosis

In 75% of cases, PTSD occurs with comorbid depression or panic disorder, and there is considerable overlap in the symptom complexes of all three conditions. The key to establishing the PTSD diagnosis lies in the history of exposure to a life-threatening event followed by intrusive (eg, flashbacks, nightmares) or avoidance (eg, withdrawal) symptoms. Acute stress disorder occurs during or shortly after a traumatic event and has many of the same symptoms as PTSD but lasts between 2 and 28 days. Some individuals with dissociative features, such as borderline personality disorders, may mimic some of the symptoms of PTSD, but those disorders are typically more related to chronic childhood maltreatment not a specific traumatic event.

► Treatment

A. Psychotherapy

Psychotherapy should be initiated as soon as possible after the traumatic event, and it should be brief and simple (once

in a safe environment). Psychological debriefing in a single session, once a mainstay in prevention of PTSD, is now considered to be ineffective and possibly harmful. Posttraumatic stress syndromes respond to interventions that help patients integrate the event in an adaptive way with some sense of mastery in having survived the trauma. Early cognitive behavioral therapy has been shown to speed recovery. Marital problems are a major area of concern, and it is important that the clinician have available a dependable referral source when marriage counseling is indicated.

Treatment initiated later, when symptoms have crystallized, includes programs for cessation of alcohol and other drug abuse, group and individual psychotherapy, and improved social support systems. The therapeutic approach is to facilitate the normal recovery that was blocked at the time of the trauma.

B. Medication

Early treatment of anxious arousal with β -blockers (eg, propranolol, 80–160 mg orally daily) may lessen the peripheral symptoms of anxiety (eg, tremors, palpitations) and help prevent development of PTSD; however, research in this area is preliminary. Antidepressant drugs—particularly selective serotonin reuptake inhibitors (SSRIs)—in full dosage are helpful in ameliorating depression, panic attacks, sleep disruption, and startle responses in chronic PTSD. Sertraline and paroxetine are approved by the US Food and Drug Administration (FDA) for this purpose. Antiseizure medications such as carbamazepine (400–800 mg orally daily) will often mitigate impulsivity and difficulty with anger management. Benzodiazepines, such as clonazepam (1–4 mg orally daily), will reduce anxiety and panic attacks when used in adequate dosage, but dependency problems are a concern, particularly when the patient has had such problems in the past. The α -adrenergic blocking agent prazosin (2–10 mg orally at bedtime) has been successfully used to decrease nightmares and improve quality of sleep in PTSD.

► Prognosis

The sooner therapy is initiated after the trauma, the better the prognosis. Treatment reduces the duration of symptoms significantly from an average of 64 months to 36 months. Approximately half of patients experience chronic symptoms. Prognosis is best in those with good premorbid psychiatric functioning. Individuals experiencing an acute stress disorder typically do better than those experiencing a delayed posttraumatic disorder. Individuals who experience trauma resulting from a natural disaster (eg, earthquake or hurricane) tend to do better than those who experience a traumatic interpersonal encounter (eg, rape or combat).

ANXIETY DISORDERS & DISSOCIATIVE DISORDERS

ESSENTIALS OF DIAGNOSIS

- Overt anxiety or an overt manifestation of a coping mechanism (such as a phobia), or both.
- Not limited to an adjustment disorder.
- Somatic symptoms referable to the autonomic nervous system or to a specific organ system (eg, dyspnea, palpitations, paresthesias).
- Not a result of physical disorders, psychiatric conditions (eg, schizophrenia), or drug abuse (eg, cocaine).

► General Considerations

Stress, fear, and anxiety all tend to be interactive. The principal components of anxiety are **psychological** (tension, fears, difficulty in concentration, apprehension) and **somatic** (tachycardia, hyperventilation, palpitations, tremor, sweating). Other organ systems (eg, gastrointestinal) may be involved in multiple-system complaints. Fatigue and sleep disturbances are common. Sympathomimetic symptoms of anxiety are both a response to a central nervous system state and a reinforcement of further anxiety. Anxiety can become self-generating, since the symptoms reinforce the reaction, causing it to spiral. This is often the case when the anxiety is an epiphenomenon of other medical or psychiatric disorders.

Anxiety may be free-floating, resulting in acute anxiety attacks, occasionally becoming chronic. When one or several coping mechanisms (see above) are functioning, the consequences are well-known problems such as phobias, conversion reactions, dissociative states, obsessions, and compulsions. Lack of structure is frequently a contributing factor, as noted in those people who have “Sunday neuroses.” They do well during the week with a planned work schedule but cannot tolerate the unstructured weekend. Planned-time activities tend to bind anxiety, and many people have increased difficulties when this is lost, as in retirement.

Some believe that various manifestations of anxiety are not a result of unconscious conflicts but are “habits”—persistent patterns of nonadaptive behavior acquired by learning. The “habits,” being nonadaptive, are unsatisfactory ways of dealing with life’s problems—hence the resultant anxiety. Help is sought only when the anxiety becomes too painful. Exogenous factors such as stimulants (eg, caffeine, cocaine) must be considered as a contributing factor.

▶ Clinical Findings

A. Generalized Anxiety Disorder

This is the most common of the clinically significant anxiety disorders. Initial manifestations appear at age 20–35 years, and there is a slight predominance in women. The anxiety symptoms of apprehension, worry, irritability, difficulty in concentrating, insomnia, and somatic complaints are present more days than not for at least 6 months. Manifestations can include cardiac (eg, tachycardia, increased blood pressure), gastrointestinal (eg, increased acidity, nausea, epigastric pain), and neurologic (eg, headache, near-syncope) systems. The focus of the anxiety may be a number of everyday activities.

B. Panic Disorder

This is characterized by short-lived, recurrent, unpredictable episodes of intense anxiety accompanied by marked physiologic manifestations. **Agoraphobia**, fear of being in places where escape is difficult, such as open spaces or public places, may be present and may lead the individual to confine his or her life to the home environment. Distressing symptoms and signs such as dyspnea, tachycardia, palpitations, headaches, dizziness, paresthesias, choking, smothering feelings, nausea, and bloating are associated with feelings of impending doom (alarm response). Recurrent **sleep panic attacks** (not nightmares) occur in about 30% of panic disorders. Anticipatory anxiety develops in all these patients and further constricts their daily lives. Panic disorder tends to be familial, with onset usually under age 25; it affects 3–5% of the population, and the female-to-male ratio is 2:1. The premenstrual period is one of heightened vulnerability. Patients frequently undergo emergency medical evaluations (eg, for “heart attacks” or “hypoglycemia”) before the correct diagnosis is made. Gastrointestinal symptoms are especially common, occurring in about one-third of cases. Myocardial infarction, pheochromocytoma, hyperthyroidism, and various recreational drug reactions can mimic panic disorder. Mitral valve prolapse may be present but is not usually a significant factor. Patients who have recurrent panic disorder often become **demoralized, hypochondriacal, agoraphobic, and depressed**. These individuals are at increased risk for major depression and the suicide attempts associated with that disorder. Alcohol abuse (about 20%) results from self-treatment and is not infrequently combined with dependence on sedatives. Some patients have atypical panic attacks associated with seizure-like symptoms that often include psychosensory phenomena (a history of stimulant abuse often emerges). About 25% of panic disorder patients also have obsessive-compulsive disorder (OCD).

C. Obsessive-Compulsive Disorder

In the obsessive-compulsive reaction, the irrational idea or the impulse persistently intrudes into awareness. Obsessions (constantly recurring thoughts such as fears of exposure to germs) and compulsions (repetitive actions such as washing the hands many times) are recognized by

the individual as absurd and are resisted, but anxiety is alleviated only by ritualistic performance of the action or by deliberate contemplation of the intruding idea or emotion. Many patients do not mention the symptoms and must be asked about them. These patients are usually predictable, orderly, conscientious, and intelligent—traits that are seen in many compulsive behaviors such as food binging and purging and compulsive exercise. There is an overlapping of OCD and other behaviors (“OCD spectrum”), including tics, trichotillomania (hair pulling), onychophagia (nail biting), hypochondriasis, Tourette syndrome, and eating disorders (see Chapter 29). The 2–3% incidence of OCD in the general population is much higher than was previously recognized. In addition, there is a high comorbidity of OCD and major depression; two-thirds of OCD patients will develop major depression during their lifetime. Male to female ratios are similar, with the highest rates occurring in the young, divorced, separated, and unemployed (all high-stress categories). Neurologic abnormalities of fine motor coordination and involuntary movements are common. Under extreme stress, these patients sometimes exhibit paranoid and delusional behaviors, often associated with depression, and can mimic schizophrenia.

D. Phobic Disorder

Phobic ideation can be considered a form of “displacement” in which patients transfer feelings of anxiety from their true object to one that can be avoided. However, since phobias are ineffective coping mechanisms, there tends to be an increase in their scope, intensity, and number. Social phobias are global or specific; in the former, all social situations are poorly tolerated, while the latter group includes performance anxiety or well-delineated phobias (eg, fear of bridges). Agoraphobia (fear of open places and public areas) is frequently associated with severe panic attacks, and it often develops in early adult life, making a normal lifestyle difficult.

E. Dissociative Disorder

Fugue (the sudden, unexpected travel away from one’s home with inability to recall one’s past), amnesia, somnambulism, dissociative identity disorder (multiple personality disorder), and depersonalization are all dissociative states. The reaction is precipitated by emotional crisis. The symptom produces anxiety reduction and a temporary solution of the crisis. Mechanisms include repression and isolation as well as particularly limited scope of attention as seen in hypnotic states. Dissociative symptoms are similar in many ways to symptoms seen in patients with temporal lobe dysfunction.

▶ Treatment

In all cases, underlying medical disorders must be ruled out (eg, cardiovascular, endocrine, respiratory, and neurologic disorders and substance-related syndromes, both intoxication and withdrawal states). These and other disorders can coexist with panic disorder.

Table 25–1. Commonly used antianxiety and hypnotic agents.

| Drug | Usual Daily Oral Doses | Usual Daily Maximum Doses | Cost for 30 Days Treatment Based on Maximum Dosage ¹ |
|---|------------------------|---------------------------|---|
| Benzodiazepines (used for anxiety) | | | |
| Alprazolam (Xanax) ² | 0.5 mg | 4 mg | \$117.87 |
| Chlordiazepoxide (Librium) ³ | 10–20 mg | 100 mg | \$40.82 |
| Clonazepam (Klonopin) ³ | 1–2 mg | 10 mg | \$177.68 |
| Clorazepate (Tranxene) ³ | 15–30 mg | 60 mg | \$260.94 |
| Diazepam (Valium) ³ | 5–15 mg | 30 mg | \$28.13 |
| Lorazepam (Ativan) ² | 2–4 mg | 4 mg | \$76.80 |
| Oxazepam (Serax) ² | 10–30 mg | 60 mg | \$98.40 |
| Benzodiazepines (used for sleep) | | | |
| Estazolam (Prosom) ² | 1 mg | 2 mg | \$29.70 |
| Flurazepam (Dalmane) ³ | 15 mg | 30 mg | \$10.50 |
| Midazolam (Versed IV) ⁴ | 5 mg IV | | \$3.58/dose |
| Quazepam (Doral) ³ | 7.5 mg | 15 mg | \$138.00 |
| Temazepam (Restoril) ² | 15 mg | 30 mg | \$26.40 |
| Triazolam (Halcion) ⁵ | 0.125 mg | 0.25 mg | \$20.25 |
| Miscellaneous (used for anxiety) | | | |
| Buspirone (Buspar) ² | 10–30 mg | 60 mg | \$218.10 |

A. Medical

1. Generalized anxiety—Benzodiazepines are the anxiolytics of choice in the acute management of generalized anxiety (Table 25–1). They are almost immediately effective. Antidepressants can be efficacious for the long-term treatment of generalized anxiety disorder, panic disorder, social phobia, and OCD.

All of the benzodiazepines may be given orally, and several are available in parenteral formulations. Benzodiazepines such as lorazepam are absorbed rapidly when given intramuscularly. In psychiatric disorders, the benzodiazepines are usually given orally; in controlled medical environments (eg, the ICU), where the rapid onset of respiratory depression can be assessed, they are often given

intravenously. Onset of action is a function of the rate of absorption (related to lipophilic property) and varies, with diazepam and clorazepate being the most rapidly absorbed orally. This characteristic, along with high lipid solubility, may explain the popularity of diazepam. In the average case of anxiety, diazepam, 5–10 mg orally twice daily as needed, is a reasonable starting regimen.

The duration of action of the benzodiazepines varies as a function of the active metabolites they produce. Benzodiazepines such as lorazepam do not produce active metabolites and have intermediate half-lives of 10–20 hours, characteristics useful in treating elderly patients. Ultra-short-acting agents such as triazolam have half-lives of 1–3 hours and may lead to rebound withdrawal anxiety. Longer-acting benzodiazepines such as flurazepam and

diazepam produce active metabolites, have half-lives of 20–120 hours, and should be avoided in the elderly. Since people vary widely in their response and since the drugs are long-lasting, the dosage must be individualized. Once this is established, an adequate dose early in the course of symptom development will obviate the need for “pill popping,” which contributes to dependency problems. Panic disorder does not usually respond to benzodiazepines other than clonazepam and alprazolam. Those high-potency benzodiazepines and the antidepressants are most commonly used for panic disorder. Notably, alprazolam has a relatively short half-life and over time can lead to interdose rebound anxiety, although the extended release form is available and obviates some of this difficulty.

Whether the indications for benzodiazepines are anxiety or insomnia, the drugs should be used judiciously. The longer-acting benzodiazepines are used for the treatment of alcohol withdrawal and anxiety symptoms; the intermediate drugs are useful as sedatives for insomnia (eg, lorazepam), while short-acting agents (eg, midazolam) are used for medical procedures such as endoscopy.

The side effects of all the benzodiazepine antianxiety agents are patient and dose dependent. As the dosage exceeds the levels necessary for sedation, the side effects include disinhibition, ataxia, dysarthria, nystagmus, and delirium. (The patient should be told not to operate machinery until he or she is well stabilized without side effects.)

Paradoxical agitation, anxiety, psychosis, confusion, mood lability, and anterograde amnesia have been reported, particularly with the shorter-acting benzodiazepines. These agents produce cumulative clinical effects with repeated dosage (especially if the patient has not had time to metabolize the previous dose), additive effects when given with other classes of sedatives or alcohol (many apparently “accidental” deaths are the result of concomitant use of sedatives and alcohol), and residual effects after termination of treatment (particularly in the case of drugs that undergo slow biotransformation).

Overdosage results in respiratory depression, hypotension, shock syndrome, coma, and death. Flumazenil, a benzodiazepine antagonist, is effective in overdosage. Overdosage (see Chapter 38) and withdrawal states are medical emergencies. Serious side effects of chronic excessive dosage are development of tolerance, resulting in increasing dose requirements, and physiologic dependence, resulting in withdrawal symptoms similar in appearance to alcohol and barbiturate withdrawal (withdrawal effects must be distinguished from reemergent anxiety). Abrupt withdrawal of sedative drugs may cause serious and even fatal convulsive seizures. Psychosis, delirium, and autonomic dysfunction have also been described. Both duration of action and duration of exposure are major factors related to likelihood of withdrawal.

Common withdrawal symptoms after low to moderate daily use of benzodiazepines are classified as somatic (disturbed sleep, tremor, nausea, muscle aches), psychological (anxiety, poor concentration, irritability, mild depression), or perceptual (poor coordination, mild paranoia, mild confusion). The presentation of symptoms will vary depending

Table 25–2. Benzodiazepine interactions with other drugs.

| Drug | Effects |
|----------------|---|
| Antacids | Decreased absorption of benzodiazepines |
| Cimetidine | Increased half-life of diazepam and triazolam |
| Contraceptives | Increased levels of diazepam and triazolam |
| Digoxin | Alprazolam and diazepam raise digoxin level |
| Disulfiram | Increased duration of action of sedatives |
| Isoniazid | Increased plasma diazepam |
| Levodopa | Inhibition of antiparkinsonism effect |
| Propoxyphene | Impaired clearance of diazepam |
| Rifampin | Decreased plasma diazepam |
| Warfarin | Decreased prothrombin time |

on the half-life of the drug. There are no significant side effects on organ systems other than the brain, and the drugs are safe in most medical conditions. Benzodiazepine interactions with other drugs are listed in Table 25–2.

Antidepressants are the first-line medications for sustained treatment of generalized anxiety disorder, having the advantage of not causing serious physiologic dependency problems. At initiation of treatment, antidepressants can themselves be anxiogenic—thus, an initial dose, in conjunction with short-term treatment with a benzodiazepine, is often indicated. Venlafaxine and duloxetine (serotonin and norepinephrine reuptake inhibitors) are FDA-approved for the treatment of generalized anxiety disorder in usual antidepressant doses. Initial daily dosing should start low (37.5–75 mg for venlafaxine and 30 mg for duloxetine) and be titrated upward as needed. SSRIs, such as paroxetine, are also used. Similarly, buspirone, sometimes used as an augmenting agent in the treatment of depression and compulsive behaviors, is also effective for generalized anxiety. Buspirone is usually given in a total dosage of 15–60 mg/d in three divided doses. Higher doses tend to be counterproductive and produce gastrointestinal symptoms and dizziness. There is a 2- to 4-week delay before antidepressants and buspirone take effect, and patients require education regarding this lag. Sleep is sometimes negatively affected. β -Blockers such as propranolol may help reduce peripheral somatic symptoms. Alcohol is the most frequently self-administered drug and should be interdicted. The highly addicting drugs with a narrow margin of safety such as glutethimide, ethchlorvynol, methprylon, meprobamate, and the barbiturates (with the exception of phenobarbital) should be avoided. Phenobarbital, in addition to its anticonvulsant properties, is a reasonably safe and very inexpensive sedative but has the disadvantage of causing hepatic microsomal enzyme stimulation (not the case with benzodiazepines), which may affect the metabolism of other medications.

2. Panic attacks—Panic attacks may be treated in several ways. A sublingual dose of lorazepam (0.5–2 mg) or alprazolam (0.5–1 mg) is often effective for urgent treatment.

For sustained treatment, SSRIs are the initial drugs of choice (adequate blood levels will require dosages similar to those used in the treatment of depression). For example, sertraline starting at 25 mg/d and increased after 1 week to 50 mg/d may be effective. Because of initial agitation in response to antidepressants, doses should start low and be very gradually increased. High-potency benzodiazepines may be used for symptomatic treatment as the antidepressant dose is titrated upward. Clonazepam (1–6 mg/d orally) and alprazolam (0.5–6 mg/d orally) are effective alternatives to antidepressants. Both drugs may produce marked withdrawal if stopped abruptly and should always be tapered. Because of chronicity of the disorders and the problem of dependency with benzodiazepine drugs, it is generally desirable to use antidepressant drugs as the principal pharmacologic approach. Antidepressants have been used in conjunction with β -blockers in resistant cases. Propranolol (40–160 mg/d orally) can mute the peripheral symptoms of anxiety without significantly affecting motor and cognitive performance. They block symptoms mediated by sympathetic stimulation (eg, palpitations, tremulousness) but not nonadrenergic symptoms (eg, diarrhea, muscle tension). Contrary to current belief, they usually do not cause depression as a side effect and can be used cautiously in patients with depression. Valproate has been found to be as effective in panic disorder as the antidepressants and is another useful alternative.

3. Phobic disorder—Phobic disorder may be part of the panic disorder and is treated within that framework. Global social phobias may be treated with SSRIs, such as paroxetine, sertraline, and fluvoxamine, or monoamine oxidase (MAO) inhibitors in the same dosage as used for depression. Gabapentin, an anticonvulsant with anxiolytic properties, may be an alternative to antidepressants in the treatment of social phobia in a dosage of 300–3600 mg/d, depending on response versus sedation. Specific phobias such as performance anxiety may respond to moderate doses of β -blockers, such as propranolol, 20–40 mg 1 hour prior to exposure. D-cycloserine (DCS), an antituberculosis drug, has recently been investigated as an augmenting agent in exposure treatment. As a partial agonist at the NMDA receptor in the amygdala, DCS may be useful in reducing fear responses. Importantly, such medications must be used in combination with cognitive behavioral exposure strategies.

4. Obsessive-compulsive disorder—OCD responds to serotonergic drugs in about 60% of cases and usually requires a longer response time than for depression (up to 12 weeks). Clomipramine has proved effective in doses equivalent to those used for depression. Fluoxetine (an SSRI drug) has been widely used in this disorder but in doses higher than those used in depression (up to 60–80 mg/d). The other SSRI drugs such as sertraline, paroxetine, and fluvoxamine are being used with comparable efficacy, each with its own side-effect profile. Buspirone in doses of 15–60 mg/d appears to be effective primarily as an anti-obsessional augmenting agent for the SSRI drugs. There is some evidence that antipsychotics may be helpful as adjuncts to the SSRIs in treatment-resistant cases. Psycho-

surgery has a limited place in selected cases of severe unremitting OCD. The stereotactic techniques now being used, including modified cingulotomy, are great improvements over the crude methods of the past. Recently, experimental work has suggested a role for deep brain stimulation in OCD.

B. Behavioral

Behavioral approaches are widely used in various anxiety disorders, often in conjunction with medication. Any of the behavioral techniques can be used beneficially in altering the contingencies (precipitating factors or rewards) supporting any anxiety-provoking behavior. Relaxation techniques can sometimes be helpful in reducing anxiety. Desensitization, by exposing the patient to graded doses of a phobic object or situation, is an effective technique and one that the patient can practice outside the therapy session. Emotive imagery, wherein the patient imagines the anxiety-provoking situation while at the same time learning to relax, helps decrease the anxiety when the patient faces the real-life situation. Physiologic symptoms in panic attacks respond well to relaxation training. Exposure techniques with response prevention are useful for OCD.

C. Psychological

Cognitive behavioral approaches have been effective in treatment of panic disorders, phobias, and OCD when erroneous beliefs need correction. These approaches share a common technique of exposing the individual to the feared object or situation. The combination of medical and cognitive behavioral therapy is more effective than either alone. Group therapy is the treatment of choice when the anxiety is clearly a function of the patient's difficulties in dealing with social settings.

D. Social

Peer support groups for panic disorder and agoraphobia have been particularly helpful. Social modification may require measures such as family counseling to aid acceptance of the patient's symptoms and avoid counterproductive behavior in behavioral training. Any help in maintaining the social structure is anxiety-alleviating, and work, school, and social activities should be maintained. School and vocational counseling may be provided by professionals, who often need help from the clinician in defining the patient's limitations.

► Prognosis

Anxiety disorders are usually of longstanding and may be quite difficult to treat. All can be relieved to varying degrees with medications and behavioral techniques. The prognosis is much better if the commonly observed anxiety-panic-phobia-depression cycle can be broken with a combination of the therapeutic interventions discussed above.

SOMATOFORM DISORDERS (Abnormal Illness Behaviors)

ESSENTIALS OF DIAGNOSIS

- ▶ Physical symptoms may involve one or more organ systems and are not intentional.
- ▶ Subjective complaints exceed objective findings.
- ▶ Correlations of symptom development and psychosocial stresses.
- ▶ Combination of biogenetic and developmental patterns.

▶ General Considerations

Somatoform disorders can occur focused on any organ system. Vulnerability in one or more organ systems and exposure to family members with somatization problems play a major role in the development of particular symptoms, and the “functional” versus “organic” dichotomy is a hindrance to good treatment. Clinicians should suspect psychiatric disorders in a number of conditions. For example, 45% of patients complaining of palpitations had lifetime psychiatric diagnoses including generalized anxiety, depression, panic, and somatization disorders. Similarly, 33–44% of patients who undergo coronary angiography for chest pain but have negative results have been found to have panic disorder.

In any patient presenting with a condition judged to be somatoform, depression must be considered in the diagnosis.

▶ Clinical Findings

A. Conversion Disorder

“Conversion” (formerly “hysterical conversion”) of psychic conflict into physical symptoms in parts of the body innervated by the sensorimotor system (eg, paralysis, aphonia) is a disorder that is more common in individuals from lower socioeconomic classes and certain cultures. The coping mechanisms used in this condition are repression (a barring from consciousness) and isolation (a splitting of the affect from the idea). The somatic manifestation that takes the place of anxiety is typically paralysis, and in some instances the organ dysfunction may have symbolic meaning (eg, arm paralysis in marked anger). Pseudoepileptic (“hysterical”) seizures are often difficult to differentiate from intoxication states or panic attacks. Retention of consciousness, random flailing with asynchronous movements of the right and left sides, and resistance to having the nose and mouth pinched closed during the attack, all point toward a pseudoepileptic event. Electroencephalography, particularly in a video-EEG assessment unit, during the attack is the most helpful diag-

nostic aid in excluding genuine seizure states. Serum prolactin levels rise abruptly in the postictal state only in true epilepsy. *La belle indifférence* (an unconcerned affect) is not a significant identifying characteristic, as commonly believed, since individuals even with genuine medical illness, may exhibit a high level of denial. Important conversion disorder criteria include a history of conversion or somatization disorder, modeling the symptom after someone else who had a similar presentation, a serious precipitating emotional event, associated psychopathology (eg, depression, schizophrenia, personality disorders), a temporal correlation between the precipitating event and the symptom, and a temporary “solving of the problem” by the conversion. It is important to identify physical disorders with unusual presentations (eg, multiple sclerosis, systemic lupus erythematosus).

B. Somatization Disorder (Briquet Syndrome, Hysteria)

This is characterized by multiple physical complaints referable to several organ systems. Anxiety, panic disorder, and depression are often present, and **major depression** is an important consideration in the differential diagnosis. There is a significant relationship (20%) to a lifetime history of panic-agoraphobia-depression. It usually occurs before age 30 and is ten times more common in women. Polysurgery is often a feature of the history. Preoccupation with medical and surgical therapy becomes a lifestyle that excludes most other activities. The symptoms are a reflection of maladaptive coping techniques and reactivity of the particular organ system. There is often evidence of longstanding somatic symptoms (particularly dysmenorrhea, a lump in the throat, vomiting, shortness of breath, burning in the sex organs, painful extremities, and amnesia), often with a history of similar organ system involvement in other family members. Multiple symptoms that constantly change and inability of more than three doctors to make a diagnosis are strong clues to the problem.

C. Pain Disorder Associated with Psychological Factors (Formerly Somatoform Pain Disorder)

This involves a long history of complaints of severe pain not consonant with anatomic and clinical signs. This diagnosis must not be one of exclusion and should be made only after extended evaluation has established a clear correlation of psychogenic factors with exacerbations and remissions of complaints.

D. Hypochondriasis

This is a fear of disease and preoccupation with the body, with perceptual amplification and heightened responsiveness. A process of social learning is usually involved, frequently with a role model who was a member of the family and may be a part of the underlying psychodynamic causation. It is common in panic disorders.

E. Factitious Disorders

These disorders, in which symptom production is intentional, are not somatoform conditions in that symptoms

are produced consciously, in contrast to the unconscious process of the above conditions. They are characterized by self-induced symptoms or false physical and laboratory findings for the purpose of deceiving clinicians or other hospital personnel. The deceptions may involve self-mutilation, fever, hemorrhage, hypoglycemia, seizures, and an almost endless variety of manifestations—often presented in an exaggerated and dramatic fashion (Munchausen syndrome). “Munchausen by proxy” is the term used when a parent creates an illness in a child so the adult (usually the mother) can maintain a relationship with clinicians. The duplicity may be either simple or extremely complex and difficult to recognize. The patients are frequently connected in some way with the health professions; they are often migratory; and there is no apparent external motivation other than achieving the patient role.

► Complications

A poor doctor-patient relationship, with iatrogenic disorders and “doctor shopping,” tends to exacerbate the problem. Sedative and analgesic dependency is the most common iatrogenic complication.

► Treatment

A. Medical

Medical support with careful attention to building a therapeutic practitioner-patient relationship is the mainstay of treatment. It must be accepted that the patient's distress is real. Every problem not found to have an organic basis is not necessarily a mental disease. Diligent attempts should be made to relate symptoms to adverse developments in the patient's life. It may be useful to have the patient keep a meticulous diary, paying particular attention to various pertinent factors evident in the history. Regular, frequent, short appointments that are not symptom-contingent may be helpful. Drugs (frequently abused) should not be prescribed to replace appointments. One person should be the primary clinician, and consultants should be used mainly for evaluation. An empathic, realistic, optimistic approach must be maintained in the face of the expected ups and downs. Ongoing reevaluation is necessary, since somatization can coexist with a concurrent physical illness.

B. Psychological

Psychological approaches can be used by the primary clinician when it is clear that the patient is ready to make some changes in lifestyle in order to achieve symptomatic relief. This is often best approached on a here-and-now basis and oriented toward pragmatic changes rather than an exploration of early experiences that the patient frequently fails to relate to current distress. Group therapy with other individuals who have similar problems is sometimes of value to improve coping, allow ventilation, and focus on interpersonal adjustment. Hypnosis or lorazepam interviews used early are helpful in resolving conversion disorders. If the primary clinician has been working with the patient on psychological problems

related to the physical illness, the groundwork is often laid for successful psychiatric referral.

For patients who have been identified as having a factitious disorder, early psychiatric consultation is indicated. There are two main treatment strategies for these patients. One consists of a conjoint confrontation of the patient by both the primary clinician and the psychiatrist. The patient's disorder is portrayed as a cry for help, and psychiatric treatment is recommended. The second approach avoids direct confrontation and attempts to provide a face-saving way to relinquish the symptom without overt disclosure of the disorder's origin. Techniques such as biofeedback and self-hypnosis may foster recovery using this strategy. Another face-saving approach is to use a double bind with the patient. For example, the patient is told there are two possible diagnoses: (1) an organic disease that should respond to the next medical intervention (usually modest and noninvasive), or (2) factitious disorder for which the patient will need psychiatric treatment. Given these options, many patients will choose to recover and not have to admit the origin of their problem.

C. Behavioral

Behavioral therapy is probably best exemplified by biofeedback techniques. In biofeedback, the particular abnormality (eg, increased peristalsis) must be recognized and monitored by the patient and therapist (eg, by an electronic stethoscope to amplify the sounds). This is immediate feedback, and after learning to recognize it, the patient can then learn to identify any change thus produced (eg, a decrease in bowel sounds) and so become a conscious originator of the feedback instead of a passive recipient. Relief of the symptom operantly conditions the patient to utilize the maneuver that relieves symptoms (eg, relaxation causing a decrease in bowel sounds). With emphasis on this type of learning, the patient is able to identify symptoms early and initiate the countermeasures, thus decreasing the symptomatic problem. Migrainoid and tension headaches have been particularly responsive to biofeedback methods.

D. Social

Social endeavors include family, work, and other interpersonal activity. Family members should come for some appointments with the patient so they can learn how best to live with the patient. This is particularly important in treatment of somatization and pain disorders. Peer support groups provide a climate for encouraging the patient to accept and live with the problem. Ongoing communication with the employer may be necessary to encourage long-term continued interest in the employee. Employers can become just as discouraged as clinicians in dealing with employees who have chronic problems.

► Prognosis

The prognosis is much better if the primary clinician is able to intervene early before the situation has deteriorated. After the problem has crystallized into chronicity, it is very difficult to effect change.

CHRONIC PAIN DISORDERS

ESSENTIALS OF DIAGNOSIS

- ▶ Chronic complaints of pain.
- ▶ Symptoms frequently exceed signs.
- ▶ Minimal relief with standard treatment.
- ▶ History of having seen many clinicians.
- ▶ Frequent use of several nonspecific medications.

▶ General Considerations

A problem in the management of pain is the lack of distinction between acute and chronic pain syndromes. Most clinicians are adept at dealing with acute pain problems but have difficulty handling the patient with a chronic pain disorder. This type of patient frequently takes too many medications, stays in bed a great deal, has seen many clinicians, has lost skills, and experiences little joy in either work or play. All relationships suffer (including those with clinicians), and life becomes a constant search for succor. The search results in complex clinician-patient relationships that usually include many drug trials, particularly sedatives, with adverse consequences (eg, irritability, depressed mood) related to long-term use. Treatment failures provoke angry responses and depression from both the patient and the clinician, and the pain syndrome is exacerbated. When frustration becomes too great, a new clinician is found, and the cycle is repeated. The longer the existence of the pain disorder, the more important become the psychological factors of anxiety and depression. As with all other conditions, it is counterproductive to speculate about whether the pain is “real.” It is real to the patient, and acceptance of the problem must precede a mutual endeavor to alleviate the disturbance.

▶ Clinical Findings

Components of the chronic pain syndrome consist of anatomic changes, chronic anxiety and depression, anger, and changed lifestyle. Usually, the anatomic problem is irreversible, since it has already been subjected to many interventions with increasingly unsatisfactory results. An algorithm for assessing chronic pain and differentiating it from other psychiatric conditions is illustrated in Figure 25–1.

Chronic anxiety and depression produce heightened irritability and overreaction to stimuli. A marked decrease in pain threshold is apparent. This pattern develops into a hypochondriacal preoccupation with the body and a constant need for reassurance. The pressure on the clinician becomes wearing and often leads to covert rejection of the

patient, such as not being available or making referrals to other clinicians.

This is perceived by the patient, who then intensifies the effort to find help, and the typical cycle is repeated. Anxiety and depression are seldom discussed, almost as if there is a tacit agreement not to deal with these issues.

Changes in lifestyle involve some of the pain behaviors. These usually take the form of a family script in which the patient accepts the role of being sick, and this role then becomes the focus of most family interactions and may become important in maintaining the family, so that neither the patient nor the family wants the patient’s role to change. Demands for attention and efforts to control the behavior of others revolve around the central issue of control of other people (including clinicians). Cultural factors frequently play a role in the behavior of the patient and how the significant people around the patient cope with the problem. Some cultures encourage demonstrative behavior, while others value the stoic role.

Another secondary gain that frequently maintains the patient in the sick role is financial compensation or other benefits. Frequently, such systems are structured so that they reinforce the maintenance of sickness and discourage any attempts to give up the role. Clinicians unwittingly reinforce this role because of the very nature of the practice of medicine, which is to respond to complaints of illness. Helpful suggestions from the clinician are often met with responses like, “Yes, but....” Medications then become the principal approach, and drug dependency problems may develop.

▶ Treatment

A. Behavioral

The cornerstone of a unified approach to chronic pain syndromes is a comprehensive behavioral program. This is necessary to identify and eliminate pain reinforcers, to decrease drug use, and to use effectively those positive reinforcers that shift the focus from the pain. It is critical that the patient be made a partner in the effort to alleviate pain. The clinician must shift from the idea of biomedical cure to ongoing care of the patient. The patient should agree to discuss the pain only with the clinician and not with family members; this tends to stabilize the patient’s personal life, since the family is usually tired of the subject. At the beginning of treatment, the patient should be assigned self-help tasks graded up to maximal activity as a means of positive reinforcement. The tasks should not exceed capability. The patient can also be asked to keep a self-rating chart to log accomplishments, so that progress can be measured and remembered. Instruct the patient to record degrees of pain on a self-rating scale in relation to various situations and mental attitudes so that similar circumstances can be avoided or modified.

Avoid positive reinforcers for pain such as marked sympathy and attention to pain. Emphasize a positive response to productive activities, which remove the focus of attention from the pain. Activity is also desensitizing, since the patient learns to tolerate increasing activity levels.

Biofeedback techniques (see Somatoform Disorders, above) and hypnosis have been successful in ameliorating some pain syndromes. Hypnosis tends to be most effective

▲ **Figure 25-1.** Algorithm for assessing psychiatric component of chronic pain. (Adapted and reproduced, with permission, from Eisendrath SJ. Psychiatric aspects of chronic pain. *Neurology*. 1995 Dec;45(12 Suppl 9):S26-34.)

in patients with a high level of denial, who are more responsive to suggestion. Hypnosis can be used to lessen anxiety, alter perception of the length of time that pain is experienced, and encourage relaxation. Mindfulness-based stress reduction programs have been useful in helping individuals develop an enhanced capacity to live a higher quality life with persistent pain (see Chapter 41).

B. Medical

A *single clinician* in charge of the comprehensive treatment approach is the highest priority. Consultations as indicated and technical procedures done by others are appropriate, but the care of the patient should remain in the hands of the primary clinician. Referrals should not be allowed to raise the patient's hopes unrealistically or to become a way for the clinician to reject the case. The attitude of the doctor should be one of honesty, interest, and hopefulness—not for a cure but for control of pain and improved function. If the patient manifests opioid addiction, detoxification may be an early treatment goal.

Nonsteroidal anti-inflammatory drugs are often the first-line of treatment for pain. If opioid analgesics or sedatives are prescribed, they should not be given on an “as-needed” schedule (see Chapter 5). A fixed schedule lessens the conditioning effects of these drugs. Tricyclic antidepressants (TCAs) (eg, nortriptyline), venlafaxine, and duloxetine in doses up to those used in depression may be helpful, particularly in neuropathic pain syndromes. In other conditions, their effects on pain may be less clear, but ameliorating depression is usually important nonetheless. Gabapentin, an anticonvulsant with possible applications in the treatment of anxiety disorders, has been shown to be useful in postherpetic and diabetic neuropathy and somatoform disorders.

In addition to medications, a variety of alternative strategies may be offered, including physical therapy and acupuncture.

C. Social

Involvement of family members and other significant persons in the patient's life should be an early priority. The

best efforts of both patient and therapists can be unwittingly sabotaged by other persons who may feel that they are “helping” the patient. They frequently tend to reinforce the negative aspects of the chronic pain disorder. The patient becomes more dependent and less active, and the pain syndrome becomes an immutable way of life. The more destructive pain behaviors described by many experts in chronic pain disorders are the results of well-meaning but misguided efforts of family members. Ongoing therapy with the family can be helpful in the early identification and elimination of these behavior patterns.

D. Psychological

In addition to group therapy with family members and others, groups of patients can be helpful if properly led. The major goal, whether of individual or group therapy, is to gain patient involvement. A group can be a powerful instrument for achieving this goal, with the development of group loyalties and cooperation. People will frequently make efforts with group encouragement that they would never make alone. Individual therapy should be directed toward strengthening existing coping mechanisms and improving self-esteem. For example, teaching patients to challenge expectations induced by chronic pain may lead to improved functioning. As an illustration, many chronic pain patients, making assumptions more derived from acute injuries, incorrectly believe they will damage themselves by attempting to function. The rapport between patient and clinician, as in all psychotherapeutic efforts, is the major factor in therapeutic success.

PSYCHOSEXUAL DISORDERS

The stages of sexual activity include **excitement** (arousal), **orgasm**, and **resolution**. The precipitating excitement or arousal is psychologically determined. Arousal response leading to plateau is a physiologic and psychological phenomenon of vasocongestion, a parasympathetic reaction causing erection in men and labial-clitoral congestion in women. The orgasmic response includes emission in men and clonic contractions of the analogous striated perineal muscles of both men and women. Resolution is a gradual return to normal physiologic status.

While the arousal stimuli—vasocongestive and orgasmic responses—constitute a single response in a well-adjusted person, they can be considered as separate stages that can produce different syndromes responding to different treatment procedures.

Clinical Findings

There are three major groups of sexual disorders.

A. Paraphilias (Sexual Arousal Disorders)

In these conditions, formerly called “deviations” or “variations,” the excitement stage of sexual activity is associated with sexual objects or orientations different from those usually associated with adult sexual stimulation. The stimulus may be a woman’s shoe, a child, animals, instruments of torture, or incidents of aggression. The pattern of sexual stimulation is usually one that has early psychological roots. Poor experiences with sexual activity frequently reinforce this pattern over time.

Exhibitionism is the impulsive behavior of exposing the genitalia to unsuspecting strangers in order to achieve sexual excitation. It is a childhood sexual behavior carried into adult life.

Transvestism consists of recurrent cross-dressing behavior in a heterosexual man for the purpose of sexual excitation. Such fetishistic behavior can be part of masturbation foreplay. Transvestism in homosexuality and transsexualism is not for the purpose of sexual excitement but is a function of preference or gender identity disorder.

Voyeurism involves the achievement of sexual arousal by watching the activities of an unsuspecting person, usually in various stages of undress or sexual activity. In both exhibitionism and voyeurism, excitation leads to masturbation as a replacement for sexual activity.

Pedophilia is the use of a child of either sex to achieve sexual arousal and, in many cases, gratification. Contact is frequently oral, with either participant being dominant, but pedophilia includes intercourse of any type. Adults of both sexes engage in this behavior, but because of social and cultural factors it is more commonly identified with men. The pedophile has difficulty in adult sexual relationships, and men who perform this act are frequently impotent.

Incest involves a sexual relationship with a person in the immediate family, most frequently a child. In many ways it is similar to pedophilia (intrafamilial pedophilia). Incestuous feelings are fairly common, but cultural mores are usually sufficiently strong to act as a barrier to the expression of sexual feelings.

Sexual sadism is the attainment of sexual arousal by inflicting pain upon the sexual object. Much sexual activity has aggressive components (eg, biting, scratching). However, forced sexual acquiescence (eg, rape) is considered to be primarily an act of aggression.

Sexual masochism is the achievement of erotic pleasure by being humiliated, enslaved, physically bound, and restrained. It may be life-threatening, since neck binding or partial asphyxiation usually forms part of the ritual. The practice is much more common in men than in women.

B. Gender Identity Disorder

Core gender identity reflects a biologic self-image—the conviction that “I am a boy” or “I am a girl” that is usually well developed by age 3 or 4. Gender dysphoria refers to

the development of a sexual identity that is the opposite of the biologic one.

Transsexualism is an attempt to deny and reverse biologic sex by maintaining sexual identity with the opposite gender. Transsexuals do not alternate between gender roles; rather, they assume a fixed role of attitudes, feelings, fantasies, and choices consonant with those of the opposite sex, all of which clearly date back to early development. For example, male to female transsexuals in early childhood behave, talk, and fantasize as if they were girls. They do not grow out of feminine patterns; they do not work in professions traditionally considered to be masculine; and they have no interest in their own penises either as evidence of maleness or as organs for erotic behavior. The desire for sex change starts early and may culminate in assumption of a feminine lifestyle, hormonal treatment, and use of surgical procedures, eg, castration and vaginoplasty.

C. Psychosexual Dysfunction

This category includes a large group of vasocongestive and orgasmic disorders. Often, they involve problems of sexual adaptation, education, and technique that are often initially discussed with, diagnosed by, and treated by the primary care provider.

There are two conditions common in men: erectile dysfunction and ejaculation disturbances.

Erectile dysfunction (impotence) is inability to achieve or maintain an erection firm enough for satisfactory intercourse; patients sometimes use the term to mean premature ejaculation. Careful questioning is necessary, since causes of this vasocongestive disorder can be psychological, physiologic, or both. The majority are pathophysiologic and, to varying degrees, treatable. After onset of the problem, a history of occasional erections—especially nocturnal penile tumescence, which may be evaluated by a simple monitoring device, or a sleep study in the sleep laboratory—is usually evidence that the dysfunction is psychological in origin, with the caveat that decreased nocturnal penile tumescence occurs in some depressed patients. **Psychological erectile dysfunction** is caused by interpersonal or intrapsychic factors (eg, marital disharmony, depression). **Organic factors** are discussed in Chapter 23.

Ejaculation disturbances include premature ejaculation, inability to ejaculate, and retrograde ejaculation. (One may ejaculate even though impotent.) Ejaculation is usually connected with orgasm, and ejaculatory control is an acquired behavior that is minimal in adolescence and increases with experience. Pathogenic factors are those that interfere with learning control, most frequently sexual ignorance. Intrapsychic factors (anxiety, guilt, depression) and interpersonal maladaptation (marital problems, unresponsiveness of mate, power struggles) are also common. Organic causes include interference with sympathetic nerve distribution (often due to surgery or trauma) and the effects of pharmacologic agents (eg, SSRIs or sympatholytics).

In women, the two most common forms of sexual dysfunction are vaginismus and frigidity.

Vaginismus is a conditioned response in which a spasm of the perineal muscles occurs if there is any stimu-

lation of the area. The desire is to avoid penetration. Sexual responsiveness and vasocongestion may be present, and orgasm can result from clitoral stimulation.

Frigidity is a complex condition in which there is a general lack of sexual responsiveness. The woman has difficulty in experiencing erotic sensation and does not have the vasocongestive response. Sexual activity varies from active avoidance of sex to an occasional orgasm. Orgasmic dysfunction—in which a woman has a vasocongestive response but varying degrees of difficulty in reaching orgasm—is sometimes differentiated from frigidity. Causes for the dysfunctions include poor sexual techniques, early traumatic sexual experiences, interpersonal disharmony (marital struggles, use of sex as a means of control), and intrapsychic problems (anxiety, fear, guilt). Organic causes include any conditions that might cause pain in intercourse, pelvic pathology, mechanical obstruction, and neurologic deficits.

Disorders of sexual desire consist of diminished or absent libido in either sex and may be a function of organic or psychological difficulties (eg, anxiety, phobic avoidance). Any chronic illness can reduce desire. Hormonal disorders, including hypogonadism or use of antiandrogen compounds such as cyproterone acetate, and chronic kidney disease contribute to deterioration in sexual activity. Although menopause may lead to diminution of sexual desire in some women, the relationship between menopause and libido is complicated and may be influenced by socio-cultural factors. Alcohol, sedatives, opioids, marijuana, and some medications may affect sexual drive and performance.

▶ Treatment

A. Paraphilias and Gender Identity Disorders

1. Psychological—Sexual arousal disorders involving variant sexual activity (paraphilia), particularly those of a more superficial nature (eg, voyeurism) and those of recent onset, are responsive to psychotherapy in a moderate percentage of cases. The prognosis is much better if the motivation comes from the individual rather than the legal system; unfortunately, however, judicial intervention is frequently the only stimulus to treatment, because the condition persists and is reinforced until conflict with the law occurs. Therapies frequently focus on barriers to normal arousal response; the expectation is that the variant behavior will decrease as normal behavior increases.

2. Behavioral—Aversive and operant conditioning techniques have been tried frequently in gender role disorders but have only occasionally been successful. In some cases, the sexual arousal disorders improve with modeling, role-playing, and conditioning procedures. Emotive imagery is occasionally helpful in lessening anxiety in fetish problems.

3. Social—Although they do not produce a change in sexual arousal patterns or gender role, self-help groups have facilitated adjustment to an often hostile society. Attention to the family is particularly important in helping persons in such groups to accept their situation and alleviate their guilt about the role they think they had in creating the problem.

4. Medical—Medroxyprogesterone acetate, a suppressor of libidinal drive, is used to mute disruptive sexual behavior in men of all ages. Onset of action is usually within 3 weeks, and the effects are generally reversible. Fluoxetine or other SSRIs at depression doses (see Table 25–8) may reduce some of the compulsive sexual behaviors including the paraphilias. A focus of study in the treatment of severe paraphilia has been agonists of luteinizing hormone–releasing hormone. Although some transsexuals are treated with genital reconstructive surgery, many others are screened out by trial periods of living as the other sex prior to operation.

B. Psychosexual Dysfunction

1. Medical—Identification of a contributory reversible cause is most important. Even if the condition is not reversible, identification of the specific cause helps the patient to accept the condition. Marital disharmony, with its exacerbating effects, may thus be avoided. Of all the sexual dysfunctions, erectile dysfunction is the condition most likely to have an organic basis. Sildenafil, tadalafil, and vardenafil are phosphodiesterase type 5 inhibitors that are effective oral agents for the treatment of penile erectile dysfunction (eg, sildenafil 25–100 mg orally 1 hour prior to intercourse). These agents are effective for SSRI-induced erectile dysfunction in men and in some cases for SSRI-associated sexual dysfunction in women. Use of the medications in conjunction with any nitrates, particularly in individuals with coronary artery disease, can have significant hypotensive effects leading to death in some cases. The medication, which does not appear to impact sexual desire, should be used only once a day. Because of their common effect in delaying ejaculation, the SSRIs have been effective in premature ejaculation.

2. Behavioral—Syndromes resulting from conditioned responses have been treated by conditioning techniques, with excellent results. Vaginismus responds well to desensitization with graduated Hegar dilators along with relaxation techniques. Masters and Johnson have used behavioral approaches in all of the sexual dysfunctions, with concomitant supportive psychotherapy and with improvement of the communication patterns of the couple.

3. Psychological—The use of psychotherapy by itself is best suited for those cases in which interpersonal difficulties or intrapsychic problems predominate. Anxiety and guilt about parental injunctions against sex may contribute to sexual dysfunction. Even in these cases, however, a combined behavioral-psychological approach usually produces results most quickly.

4. Social—The proximity of other people (eg, a mother-in-law) in a household is frequently an inhibiting factor in sexual relationships. In such cases, some social engineering may alleviate the problem.

PERSONALITY DISORDERS

ESSENTIALS OF DIAGNOSIS

- ▶ Long history dating back to childhood.
- ▶ Recurrent maladaptive behavior.
- ▶ Low self-esteem and lack of confidence.
- ▶ Minimal introspective ability with a tendency to blame others for all problems.
- ▶ Major difficulties with interpersonal relationships or society.
- ▶ Depression with anxiety when maladaptive behavior fails.

▶ General Considerations

An individual's personality structure, or character, is an integral part of self-image. It reflects genetics, interpersonal influences, and recurring patterns of behavior adopted in order to cope with the environment. The classification of subtypes of personality disorders depends on the predominant symptoms and their severity. The most severe disorders—those that bring the patient into greatest conflict with society—tend to be classified as antisocial (psychopathic) or borderline.

Personality disorders can be considered a matrix for some of the more severe psychiatric problems (eg, schizotypal, relating to schizophrenia, and avoidance types, relating to some anxiety disorders).

▶ Classification & Clinical Findings

See Table 25–3.

▶ Differential Diagnosis

Patients with personality disorders tend to show anxiety and depression when pathologic coping mechanisms fail, and their symptoms can be similar to those disorders. Occasionally, the more severe cases may decompensate into psychosis under stress and mimic other psychotic disorders.

▶ Treatment

A. Social

Social and therapeutic environments such as day hospitals, halfway houses, and self-help communities utilize peer pressures to modify the self-destructive behavior. The patient with a personality disorder often has failed to profit from experience, and difficulties with authority impair the learning experience. The use of peer relationships and the repetition possible in a structured setting of a helpful community enhance the behavioral treatment opportunities and increase learning. When problems are detected

Table 25–3. Personality disorders: Classification and clinical findings.

| Personality Disorder | Clinical Findings |
|-------------------------|---|
| Paranoid | Defensive, oversensitive, secretive, suspicious, hyperalert, with limited emotional response. |
| Schizoid | Shy, introverted, withdrawn, avoids close relationships. |
| Obsessive compulsive | Perfectionist, egocentric, indecisive, with rigid thought patterns and need for control. |
| Histrionic (hysterical) | Dependent, immature, seductive, egocentric, vain, emotionally labile. |
| Schizotypal | Superstitious, socially isolated, suspicious, with limited interpersonal ability, eccentric behaviors, and odd speech. |
| Narcissistic | Exhibitionist, grandiose, preoccupied with power, lacks interest in others, with excessive demands for attention. |
| Avoidant | Fears rejection, hyperreacts to rejection and failure, with poor social endeavors and low self-esteem. |
| Dependent | Passive, overaccepting, unable to make decisions, lacks confidence, with poor self-esteem. |
| Antisocial | Selfish, callous, promiscuous, impulsive, unable to learn from experience, has legal problems. |
| Borderline | Impulsive; has unstable and intense interpersonal relationships; is suffused with anger, fear, and guilt; lacks self-control and self-fulfillment; has identity problems and affective instability; is suicidal (a serious problem—up to 80% of hospitalized borderline patients make an attempt at some time during treatment, and the incidence of completed suicide is as high as 5%); aggressive behavior, feelings of emptiness, and occasional psychotic decompensation. This group has a high drug abuse rate, which plays a role in symptoms. There is extensive overlap with other diagnostic categories, particularly mood disorders and posttraumatic stress disorder. |

early, both the school and the home can serve as foci of intensified social pressure to change the behavior, particularly with the use of behavioral techniques.

B. Behavioral

The behavioral techniques used are principally operant conditioning and aversive conditioning. The former simply emphasizes the recognition of acceptable behavior and its reinforcement with praise or other tangible rewards. Aversive responses usually mean punishment, although this can range from a mild rebuke to some specific punitive responses such as deprivation of privileges. Extinction plays a role in that an attempt is made not to respond to inappropriate behavior, and the lack of response eventually causes the person to abandon that type of behavior. Pouting and tantrums, for example, diminish quickly when such behavior elicits no reaction. Dialectical behavioral therapy is a program of individual and group therapy specifically designed for patients with chronic suicidality and borderline personality disorder. It blends mindfulness and a cognitive-behavioral model to address self-awareness, interpersonal functioning, affective lability, and reactions to stress.

C. Psychological

Psychological intervention is best conducted in group settings. Group therapy is helpful when specific interpersonal behavior needs to be improved. This mode of treatment also has a place with so-called acting-out patients, ie, those who frequently act in an impulsive and inappropriate way. The peer pressure in the group tends to impose restraints on rash behavior. The group also quickly identifies the patient's types of behavior and helps improve the validity of the patient's self-assessment, so that the antecedents of the unacceptable behavior can be effectively handled, thus decreasing its frequency. Individual therapy

should initially be supportive, ie, helping the patient to restabilize and mobilize coping mechanisms. If the individual has the ability to observe his or her own behavior, a longer-term and more introspective therapy may be warranted. The therapist must be able to handle countertransference feelings (which are frequently negative), maintain appropriate boundaries in the relationship (no physical contacts, however well-meaning), and refrain from premature confrontations and interpretations.

D. Medical

Hospitalization is indicated in the case of serious suicidal or homicidal danger. In most cases, treatment can be accomplished in the day treatment center or self-help community. Antipsychotics may be required for short periods in conditions that have temporarily decompensated into transient psychoses (eg, haloperidol, 2–5 mg orally every 3–4 hours until the patient has quieted down and is regaining contact with reality). Olanzapine (2.5–10 mg/d orally) or risperidone (0.5–2 mg/d orally) may be given with lorazepam (1–2 mg orally every 4 hours as needed). In some cases, these drugs are required only for several days and can be discontinued after the patient has regained a previously established level of adjustment; they can also provide ongoing support. Carbamazepine, 400–800 mg orally daily in divided doses, decreases the severity of behavioral dyscontrol. Antidepressants have improved anxiety, depression, and sensitivity to rejection in some borderline patients. SSRIs may have a role in reducing aggressive behavior in impulsive aggressive patients.

► Prognosis

Antisocial and borderline categories generally have a guarded prognosis. Those patients with a history of parental abuse and a family history of mood disorder tend to have the most challenging treatments.

 Linehann MM et al. Two-year randomized controlled trial and follow-up of dialectical behavior therapy vs therapy by experts for suicidal behaviors and borderline personality disorder. *Arch Gen Psychiatry.* 2006 Jul;63(7):757–66. [PMID: 16818865]

SCHIZOPHRENIC & OTHER PSYCHOTIC DISORDERS

ESSENTIALS OF DIAGNOSIS

- ▶ Social withdrawal, usually slowly progressive, often with deterioration in personal care.
- ▶ Loss of ego boundaries, with inability to perceive oneself as a separate entity.
- ▶ Loose thought associations, often with slowed thinking or overinclusive and rapid shifting from topic to topic.
- ▶ Autistic absorption in inner thoughts and frequent sexual or religious preoccupations.
- ▶ Auditory hallucinations, often of a derogatory nature.
- ▶ Delusions, frequently of a grandiose or persecutory nature.
- ▶ Symptoms of at least 6 months' duration.

Frequent additional signs:

- ▶ Flat affect and rapidly alternating mood shifts irrespective of circumstances.
- ▶ Hypersensitivity to environmental stimuli, with a feeling of enhanced sensory awareness.
- ▶ Variability or changeable behavior incongruent with the external environment.
- ▶ Concrete thinking with inability to abstract; inappropriate symbolism.
- ▶ Impaired concentration worsened by hallucinations and delusions.
- ▶ Depersonalization, wherein one behaves like a detached observer of one's own actions.

▶ General Considerations

The schizophrenic disorders are a group of syndromes manifested by massive disruption of thinking, mood, and overall behavior as well as poor filtering of stimuli. The characterization and nomenclature of the disorders are quite arbitrary and are influenced by sociocultural factors and schools of psychiatric thought.

It is currently believed that the schizophrenic disorders are of multifactorial cause, with genetic, environmental, and neurotransmitter pathophysiologic components. At present, there is no laboratory method for confirming the diagnosis of schizophrenia. There may or may not be a history of a major disruption in the individual's life (failure, loss, physical illness) before gross psychotic deterioration is evident.

Schizophrenic symptoms have been classified into positive and negative categories. Positive symptoms include hallucinations, delusions, and formal thought disorders; these symptoms appear to be related to increased dopaminergic (D₂) activity in the mesolimbic region. Negative symptoms include diminished sociability, restricted affect, and poverty of speech; these symptoms appear to be related to decreased D₂ activity in the mesocortical system.

"Other psychotic disorders" are conditions that are similar to schizophrenic disorders in their acute symptoms but have a less pervasive influence over the long term. The patient usually attains higher levels of functioning. The acute psychotic episodes tend to be less disruptive of the person's lifestyle, with a fairly quick return to previous levels of functioning.

▶ Classification

A. Schizophrenic Disorders

Schizophrenic disorders are subdivided on the basis of certain prominent phenomena that are frequently present. **Disorganized (hebephrenic) schizophrenia** is characterized by marked incoherence and an incongruous or silly affect. **Catatonic schizophrenia** is distinguished by a marked psychomotor disturbance of either excitement (purposeless and stereotyped) or rigidity with mutism. Infrequently, there may be rapid alternation between excitement and stupor (see under catatonic syndrome, below). **Paranoid schizophrenia** includes marked persecutory or grandiose delusions often consonant with hallucinations of similar content and with less marked disorganization of speech and behavior. **Undifferentiated schizophrenia** denotes a category in which symptoms are not specific enough to warrant inclusion of the illness in the other subtypes. **Residual schizophrenia** is a classification that includes persons who have clearly had an episode warranting a diagnosis of schizophrenia but who at present have no overt psychotic symptoms, although they show milder signs such as social withdrawal, flat affect, and eccentric behaviors.

B. Delusional Disorders

Delusional disorders are psychoses in which the predominant symptoms are persistent, nonbizarre delusions with minimal impairment of daily functioning. (The schizophrenic disorders show significant impairment.) Intellectual and occupational activities are little affected, whereas social and marital functioning tend to be markedly involved. Hallucinations are not usually present. Common delusional themes include paranoid delusions of persecution, delusions of being related to or loved by a well-known person, and delusions that one's partner is unfaithful.

C. Schizoaffective Disorders

Schizoaffective disorders are those cases that fail to fit comfortably either in the schizophrenic or in the affective categories. They are usually cases with affective symptoms that precede or develop concurrently with psychotic manifestations. There has been increasing interest in studying prodromal schizophrenia with a goal of prevention or early treatment.

D. Schizophreniform Disorders

Schizophreniform disorders are similar in their symptoms to schizophrenic disorders except that the duration of prodromal, acute, and residual symptoms is more than 1 week but less than 6 months.

E. Brief Psychotic Disorders

These disorders last less than 1 week. They are the result of psychological stress. The shorter duration is significant and correlates with a more acute onset and resolution as well as a much better prognosis.

F. Late Life Psychosis

Brain abnormalities occur in 40% of patients who develop psychotic symptoms after age 60. The psychotic symptoms are typical, and there are other findings such as low IQ scores and diminished cognitive function.

G. Atypical Psychoses

This group includes a wide range of conditions with psychotic symptoms. The cause is often not clear, but later events (eg, new symptoms) may clarify the diagnosis. The most common example is chronic psychosis developing either during periods of heavy abuse of drugs or at some time after the drug use has ceased. Other conditions include temporal lobe dysfunction, HIV infection, and a number of the conditions noted in the differential diagnosis (see below). They often have a good premorbid history, a precipitous onset, and an episodic course with symptom-free intervals.

► Clinical Findings

A. Symptoms and Signs

The symptoms and signs of schizophrenia vary markedly among individuals as well as in the same person at different times. The patient's **appearance** may be bizarre, although the usual finding is a mild to moderate unkempt blandness. **Motor activity** is generally reduced, although extremes ranging from catatonic stupor to frenzied excitement occur. **Social behavior** is characterized by marked withdrawal coupled with disturbed interpersonal relationships and a reduced ability to experience pleasure. Dependency and a poor self-image are common. **Verbal utterances** are variable, the language being concrete yet symbolic, with unassociated rambling statements (at times interspersed with mutism) during an acute episode. Neologisms (made-up words or phrases), echolalia (repetition of words spoken by others), and verbigeration (repetition of senseless words or phrases) are occasionally present. **Affect** is usually flattened, with occasional inappropriateness. **Depression** is present in almost all cases but may be less apparent during the acute psychotic episode and more obvious during recovery. Depression is sometimes confused with akinetic side effects of antipsychotic drugs. It is also related to **boredom**, which increases symptoms and decreases the response to treatment. Work is generally unavailable and time unfilled, providing opportunities for counterproductive activities

such as drug abuse, withdrawal, and increased psychotic symptoms.

Thought content may vary from a paucity of ideas to a rich complex of delusional fantasy with archaic thinking. One frequently notes after a period of conversation that little if any information has actually been conveyed. Incoming stimuli produce varied responses. In some cases a simple question may trigger explosive outbursts, whereas at other times there may be no overt response whatsoever (catatonia). When paranoid ideation is present, the patient is often irritable and less cooperative. **Delusions** (false beliefs) are characteristic of paranoid thinking, and they usually take the form of a preoccupation with the supposedly threatening behavior exhibited by other individuals. This ideation may cause the patient to adopt active countermeasures such as locking doors and windows, taking up weapons, covering the ceiling with aluminum foil to counteract radar waves, and other bizarre efforts. Somatic delusions revolve around issues of bodily decay or infestation. **Perceptual distortions** usually include auditory hallucinations—visual hallucinations are more commonly associated with organic mental states—and may include illusions (distortions of reality) such as figures changing in size or lights varying in intensity. Cenesthetic hallucinations (eg, a burning sensation in the brain, feeling blood flowing in blood vessels) occasionally occur. Lack of humor, feelings of dread, depersonalization (a feeling of being apart from the self), and fears of annihilation may be present. Any of the above symptoms generate higher anxiety levels, with heightened arousal and occasional panic and suicidal ideation, as the individual fails to cope.

The development of the acute episode in schizophrenia frequently is the end product of a gradual decompensation. Frustration and anxiety appear early, followed by depression and alienation, along with progressive ineffectiveness in day-to-day coping. This often leads to feelings of panic and increasing disorganization, with loss of the ability to test and evaluate the reality of perceptions. The stage of so-called psychotic resolution includes delusions, autistic pre-occupations, and psychotic insight, with acceptance of the decompensated state. The process is frequently complicated by the use of caffeine, alcohol, and other recreational drugs. Life expectancy of schizophrenic patients is as much as 20% shorter than that of cohorts in the general population and is often associated with comorbid conditions such as the metabolic syndrome.

Polydipsia may produce water intoxication with hyponatremia—characterized by symptoms of confusion, lethargy, psychosis, seizures, and occasionally death—in any psychiatric disorder, but most commonly in schizophrenia. These problems exacerbate the schizophrenic symptoms and can be confused with them. Possible pathogenetic factors in polydipsia include a hypothalamic defect, inappropriate antidiuretic hormone (ADH) secretion, neuroleptic medications (anticholinergic effects, stimulation of hypothalamic thirst center, effect on ADH), smoking (nicotine and syndrome of inappropriate antidiuretic hormone [SIADH]), psychotic thought processes (delusions), and other medications (eg, diuretics, antidepressants, lithium, alcohol). Other causes of polydipsia must be

ruled out (eg, diabetes mellitus, diabetes insipidus, kidney disease).

B. Imaging

Ventricular enlargement and cortical atrophy, as seen on CT scan, have been correlated with chronic course, severe cognitive impairment, and nonresponsiveness to neuroleptic medications. Decreased frontal lobe activity seen on PET scan has been associated with negative symptoms.

► Differential Diagnosis

One should not hesitate to reconsider the diagnosis of schizophrenia in any person who has received that diagnosis in the past, particularly when the clinical course has been atypical. A number of these patients have been found to actually have atypical episodic affective disorders that have responded well to lithium. Manic episodes often mimic schizophrenia. Furthermore, schizophrenia has been diagnosed in many individuals because of inadequacies in psychiatric nomenclature. Thus, schizophrenia was often inappropriately diagnosed in persons with brief reactive psychoses, OCD, paranoid disorders, and schizophreniform disorders.

Psychotic depressions, psychotic organic mental states, and any illness with psychotic ideation tend to be confused with schizophrenia, partly because of the regrettable tendency to use the terms interchangeably. Adolescent phases of growth and counterculture behaviors constitute another area of diagnostic confusion. It is particularly important to avoid a misdiagnosis in these groups, because of the long-term implications arising from having such a serious diagnosis made in a formative stage of life.

Medical disorders such as thyroid dysfunction, adrenal and pituitary disorders, reactions to toxic materials (eg, mercury, PCBs), and almost all of the organic mental states in the early stages must be ruled out. Postpartum psychosis is discussed under Mood Disorders. **Complex partial seizures**, especially when psychosensory phenomena are present, are an important differential consideration. Toxic drug states arising from prescription, over-the-counter, herbal and street drugs may mimic all of the psychotic disorders. The chronic use of amphetamines, cocaine, and other stimulants frequently produces a psychosis that is almost identical to the acute paranoid schizophrenic episode. The presence of formication and stereotypy suggests the possibility of stimulant abuse. Phencyclidine (see below), a very common street drug, may cause a reaction that is difficult to distinguish from other psychotic disorders. Cerebellar signs, excessive salivation, dilated pupils, and increased deep tendon reflexes should alert the clinician to the possibility of a toxic psychosis. Industrial chemical toxicity (both organic and metallic), degenerative disorders, and metabolic deficiencies must be considered in the differential diagnosis.

Catatonic syndrome, frequently assumed to exist solely as a component of schizophrenic disorders, is actually the end product of a number of illnesses, including various organic conditions. Neoplasms, viral and bacterial encephalopathies, central nervous system hemorrhage, metabolic

derangements such as diabetic ketoacidosis, sedative withdrawal, and hepatic and renal malfunction have all been implicated. It is particularly important to realize that drug toxicity (eg, overdoses of antipsychotic medications such as fluphenazine or haloperidol) can cause catatonic syndrome, which may be misdiagnosed as a catatonic schizophrenic disorder and inappropriately treated with more antipsychotic medication.

► Treatment

A. Medical

Hospitalization is often necessary, particularly when the patient's behavior shows gross disorganization. The presence of competent family members lessens the need for hospitalization, and each case should be judged individually. The major considerations are to prevent self-inflicted harm or harm to others and to provide the patient's basic needs. A full medical evaluation and CT scan or MRI should be considered in first episodes of schizophreniform disorder and other psychotic episodes of unknown cause.

Antipsychotic medications (see below) are the treatment of choice. They block the response to stimulation. The relapse rate can be reduced by 50% with proper maintenance neuroleptic therapy. Long-acting, injectable depot neuroleptics are used in noncompliant patients or nonresponders to oral medication.

Antipsychotic drugs include the "typical" neuroleptics **phenothiazines, thioxanthenes** (both similar in structure), **butyrophenones, dihydroindolones, dibenzoxazepines**, and **benzisoxazoles**, and the newer "atypical" neuroleptics clozapine, risperidone, olanzapine, quetiapine, aripiprazole, and ziprasidone (Table 25-4). Generally, increasing milligram potency of the typical neuroleptics is associated with decreasing anticholinergic and adrenergic side effects and increasing extrapyramidal symptoms (Table 25-5). For example, chlorpromazine has lower potency and more severe anticholinergic and adrenergic side effects. The increased anticholinergic effect of chlorpromazine, however, lowers the risk of extrapyramidal symptoms.

The Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study was a complex investigation that compared "atypical" and "typical" neuroleptic drugs. Although it was not definitive, it suggested similar antipsychotic efficacy for both classes and a tendency for the atypicals, particularly olanzapine, to be better tolerated leading to enhanced compliance. It also highlighted lack of patient adherence as a major factor in treatments.

The phenothiazines comprise the bulk of the currently used "typical" neuroleptic drugs. The only butyrophenone commonly used in psychiatry is haloperidol, which is different in structure but similar in action and side effects to the piperazine phenothiazines such as fluphenazine, perphenazine, and trifluoperazine. These drugs and haloperidol (dopamine [D₂] receptor blockers) have high potency and a paucity of autonomic side effects and act to markedly lower arousal levels. Molindone and loxapine, while less potent, are similar in action, side effects, and safety to the piperazine phenothiazines.

Table 25-4. Commonly used antipsychotics.

| Drug | Usual Daily Oral Dose | Usual Daily Maximum Dose ¹ | Cost per Unit | Cost for 30 Days Treatment Based on Maximum Dosage ² |
|--|-----------------------|---------------------------------------|---------------|---|
| Phenothiazines | | | | |
| Chlorpromazine (Thorazine; others) | 100-400 mg | 1 g | \$1.05/200 mg | \$157.50 |
| Thioridazine (Mellaril) | 100-400 mg | 600 mg | \$.67/100 mg | \$120.60 |
| Mesoridazine (Serentil) | 50-200 mg | 400 mg | | Not available in United States |
| Perphenazine (Trilafon) ³ | 16-32 mg | 64 mg | \$1.85/16 mg | \$222.00 |
| Trifluoperazine (Stelazine) | 5-15 mg | 60 mg | \$1.63/10 mg | \$293.60 |
| Fluphenazine (Permitil, Prolixin) ³ | 2-10 mg | 60 mg | \$1.25/10 mg | \$225.00 |
| Thioxanthenes | | | | |
| Thiothixene (Navane) ³ | 5-10 mg | 80 mg | \$0.65/10 mg | \$156.00 |
| Dihydroindolone | | | | |
| Molindone (Moban) | 30-100 mg | 225 mg | \$4.03/50 mg | \$544.05 |
| Dibenzoxazepine | | | | |
| Loxapine (Loxitane) | 20-60 mg | 200 mg | \$2.57/50 mg | \$308.40 |
| Dibenzodiazepine | | | | |
| Clozapine (clozaril) | 300-450 mg | 900 mg | \$3.42/100 mg | \$923.40 |
| Butyrophenone | | | | |
| Haloperidol (Haldol) | 2-5 mg | 60 mg | \$2.76/20 mg | \$248.40 |
| Benzisoxazole | | | | |
| Risperidone ⁴ (Risperdal) | 2-6 mg | 10 mg | \$7.59/2 mg | \$946.16 |
| Thienobenzodiazepine | | | | |
| Olanzapine (Zyprexa) | 5-10 mg | 10 mg | \$14.64/10 mg | \$439.20 |
| Dibenzothiazepine | | | | |
| Quetiapine (Seroquel) | 200-400 mg | 800 mg | \$8.18/200 mg | \$755.92 |
| Benzisothiazolyl piperazine | | | | |
| Ziprasidone (Geodon) | 40-160 mg | 160 mg | \$7.66/80 mg | \$459.37 |
| Dipiperazine | | | | |
| Aripiprazole (Abilify) | 10-15 mg | 30 mg | \$21.57/30 mg | \$646.97 |

¹Can be higher in some cases.

³Indicates piperazine structure.

⁴For risperidone, daily doses above 6 mg increase the risk of extrapyramidal syndrome. Risperidone 6 mg is approximately equivalent to haloperidol 20 mg.

The first “atypical” (novel) antipsychotic drug developed, clozapine, a dibenzodiazepine derivative, has dopamine (D₄) receptor-blocking activity as well as central serotonergic, histaminergic, and α -noradrenergic receptor-blocking activity. It is effective in the treatment of about 30% of psychoses resistant to other neuroleptic drugs. Research suggests that clozapine may have specific efficacy in decreasing suicidality in patients with schizophrenia. It is associated with a 1% risk of agranulocytosis, which requires weekly white blood cell count monitoring for the first 6 months followed by monitoring every other week. Weekly monitoring for 1 month after discontinuation of the medication is recommended. Because of an

association between clozapine and myocarditis, the drug is contraindicated in patients with severe heart disease.

Risperidone is an antipsychotic that blocks some serotonin receptors (5-HT₂) and dopamine receptors (D₂). Risperidone causes fewer extrapyramidal side effects than the typical antipsychotics at doses less than 6 mg. It appears to be as effective as haloperidol and possibly as effective as clozapine in treatment-resistant patients without requiring weekly white cell counts. Risperidone-induced hyperprolactinemia, even on low doses, has been reported, and that effect is thought to be more common with risperidone than with other atypical antipsychotics. Risperidone is available in a long-acting injectable preparation.

Table 25–5. Relative potency and side effects of antipsychotics.

| Drug | Chlorpromazine: Drug Potency Ratio | Anticholinergic Effects ¹ | Extrapyramidal Effect ¹ |
|------------------------------------|------------------------------------|--------------------------------------|------------------------------------|

| Aripiprazole | 1:20 | 1 | 0 |

¹4, strong effect; 1, weak effect.

Olanzapine is a potent blocker of muscarinic, anticholinergic, 5-HT₂, and dopamine D₁, D₂, and D₄ receptors. High doses of olanzapine (12.5–17.5 mg daily) appear to be more effective than lower doses. The drug appears to be more effective than haloperidol in the treatment of negative symptoms, such as withdrawal, psychomotor retardation, and poor interpersonal relationships. It is available in an orally disintegrating form for patients who are unable to tolerate standard oral dosing and in an injectable form for the management of acute agitation associated with schizophrenia and bipolar disorder. Serum alanine aminotransferase is more elevated in patients taking olanzapine than in those taking haloperidol. Olanzapine is associated with a much lower incidence of dystonic reaction than haloperidol and is perhaps less likely to induce tardive dyskinesia. Its most common side effects include somnolence, agitation, nervousness, headache, insomnia, dizziness, and significant weight gain. Multiple case reports have linked olanzapine

and clozapine to new-onset type 2 diabetes and other atypical drugs should be monitored for this adverse effect as well. Further investigation is ongoing to clarify the risk, risk factors, and pathophysiology. The manufacturer has alerted physicians to an association between olanzapine and a significantly higher risk of stroke and death in elderly patients, which has also been noted with other atypical agents.

Quetiapine is a neuroleptic with greater 5-HT₂ relative to D₂ receptor blockade as well as a relatively high affinity for α_1 - and α_2 -adrenergic receptors. It appears to be as efficacious as haloperidol in treating positive and negative symptoms of schizophrenia, with less extrapyramidal side effects even at high doses. More common side effects include somnolence, dizziness, and postural hypotension. Because of an association with lens changes seen in patients on long-term treatment, an eye examination to detect cataract formation is recommended at initiation of treatment and then at 6-month intervals during treatment.

Ziprasidone has both anti-dopamine receptor and anti-serotonin receptor effects, with good efficacy for both positive and negative symptoms of schizophrenia. Ziprasidone is not associated with significant weight gain, hyperlipidemia, or new-onset diabetes and offers a good alternative for some patients. It has been implicated in QTc interval delay of > 500 ms in some patients, although in several cases of overdose there were no incidents of torsades de pointes or sudden death. Patients taking ziprasidone should be screened for cardiac risk factors. A pretreatment ECG is indicated for patients at risk for cardiac sequelae (including patients taking other medications that might prolong the QTc interval).

Aripiprazole is the first neuroleptic that is a dopamine stabilizer. A partial agonist at the dopamine D₂ and serotonin 5-HT₁ receptors and an antagonist at 5-HT₂ receptors, it is effective against positive and negative symptoms of schizophrenia. It functions as an antagonist or agonist, depending on the dopaminergic activity at the dopamine receptors. This may help decrease side effects. More activating than sedating, aripiprazole is thought to impose a low risk of extrapyramidal symptoms, weight gain, hyperprolactinemia, and delayed QT interval. Aripiprazole has been approved as an augmentation agent for treatment-resistant depression even when psychosis is not present.

None of the antipsychotics produce true physical dependency. All decrease adrenergic responses. Despite higher costs, atypical neuroleptics are often considered preferable to traditional neuroleptics because they are thought to be associated with reduced extrapyramidal symptoms and a lesser risk of tardive dyskinesia.

► Clinical Indications

The antipsychotics are used to treat all forms of the schizophrenias as well as psychotic ideation in organic brain psychoses, delirium and dementia, drug-induced psychoses, psychotic depression, and mania. They are also effective in Tourette disorder. They quickly lower the arousal (activity) level and, perhaps indirectly, gradually improve socialization and thinking. The improvement rate is about 80%. Patients whose behavioral symptoms worsen with use of antipsychotic drugs may have an undiagnosed organic condition such as anticholinergic toxicity.

Symptoms that are ameliorated by these drugs include hyperactivity, hostility, aggression, delusions, hallucinations, irritability, and poor sleep. Individuals with acute psychosis and good premorbid function respond quite well. The most common cause of failure in the treatment of acute psychosis is inadequate dosage, and the most common cause of relapse is noncompliance.

Although typical antipsychotics are efficacious in the treatment of so-called positive symptoms of schizophrenia, such as hallucinations and delusions, atypical antipsychotics are thought to have efficacy in reducing both positive and negative symptoms. Antidepressant drugs may be used in conjunction with neuroleptics if significant depression is present. Resistant cases may require concomitant use of lithium, carbamazepine, or valproic acid. The addition of a benzodiazepine drug to the neuroleptic regimen may

prove helpful in treating the agitated or catatonic psychotic patient who has not responded to neuroleptics alone—lorazepam, 1–2 mg orally, can produce a rapid resolution of catatonic symptoms and may allow maintenance with a lower neuroleptic dose. Electroconvulsive therapy (ECT) has also been effective in treating catatonia.

► Dosage Forms & Patterns

The dosage range is quite broad. For example, risperidone, 0.25–1 mg orally at bedtime, may be sufficient for the elderly person with mild dementia with psychosis (especially in view of the increased risk of stroke and death in the elderly), whereas up to 6 mg/d may be used in a young patient with acute schizophrenia. For quick response, an atypical antipsychotic may be started in combination with a benzodiazepine (eg, risperidone oral solution, 2 mg, or olanzapine, 10 mg orally, and lorazepam, 2 mg orally, every 2–4 hours as needed). In an acutely distressed, psychotic patient one might use haloperidol, 10 mg intramuscularly, which is absorbed rapidly and achieves an initial tenfold plasma level advantage over equal oral doses. Psychomotor agitation, racing thoughts, and general arousal are quickly reduced. The dose can be repeated every 3–4 hours; when the patient is less symptomatic, oral doses can replace parenteral administration in most cases. In the elderly, both atypical (eg, risperidone 0.25 mg–0.5 mg daily or olanzapine 1.25 mg daily) and conventional (eg haloperidol 0.5 mg daily or perphenazine 2 mg daily) antipsychotics, often used effectively in small doses for behavioral control, have been linked to premature death in some cases.

Various factors play a role in the absorption of oral medications. Of particular importance are previous gastrointestinal surgery and concomitant administration of other drugs. There are racial differences in metabolizing the neuroleptic drugs—eg, many Asians require only about half the usual dosage. Bioavailability is influenced by other factors such as smoking or hepatic microsomal enzyme stimulation with alcohol or barbiturates and enzyme-altering drugs such as carbamazepine or methylphenidate. Neuroleptic plasma drug level determinations are not currently of major clinical assistance.

Divided daily doses are not necessary after a maintenance dose has been established, and most patients can then be maintained on a single daily dose, usually taken at bedtime. This is particularly appropriate in a case where the sedative effect of the drug is desired for nighttime sleep, and undesirable sedative effects can be avoided during the day. Risperidone is an exception, being given twice daily. First-episode patients especially should be tapered off medications after about 6 months of stability and carefully monitored; their rate of relapse is lower than that of multiple-episode patients.

Psychiatric patients—particularly paranoid individuals—often neglect to take their medication. In these cases and in nonresponders to oral medication, the enanthate and decanoate (the latter is slightly longer-lasting and has fewer extrapyramidal side effects) forms of fluphenazine or the decanoate form of haloperidol may be given by deep subcutaneous injection or intramuscularly to achieve an

effect that will usually last 7–28 days. A patient who cannot be depended on to take oral medication (or who overdoses on minimal provocation) will generally agree to come to the clinician's office for a "shot." The usual dose of the fluphenazine long-acting preparations is 25 mg every 2 weeks. Dosage and frequency of administration vary from about 100 mg weekly to 12.5 mg monthly. Use the smallest effective amount as infrequently as possible. A monthly injection of 25 mg of fluphenazine decanoate is equivalent to about 15–20 mg of oral fluphenazine daily. Risperidone is the first atypical neuroleptic available in a long-acting injectable form (25–50 mg intramuscularly every 2 weeks). Concomitant use of a benzodiazepine (eg, lorazepam, 2 mg orally twice daily) may permit reduction of the required dosage of oral or parenteral antipsychotic drug.

Intravenous haloperidol, the neuroleptic most commonly used by this route, is often used in critical care units in the management of agitated, delirious patients. Intravenous haloperidol should be given no faster than 1 mg/min to reduce cardiovascular side effects, such as torsades de pointes. Current practice indicates that ECG monitoring should be used whenever haloperidol is being administered intravenously.

▶ Side Effects

For both typical and atypical neuroleptic agents, a range of side effects has been reported. The most common anticholinergic side effects include dry mouth (which can lead to ingestion of caloric liquids and weight gain or hyponatremia), blurred near vision, urinary retention (particularly in elderly men with enlarged prostates), delayed gastric emptying, esophageal reflux, ileus, delirium, and precipitation of acute glaucoma in patients with narrow anterior chamber angles. Other autonomic effects include orthostatic hypotension and sexual dysfunction—problems in achieving erection, ejaculation (including retrograde ejaculation), and orgasm in men (approximately 50% of cases) and women (approximately 30%). Delay in achieving orgasm is often a factor in medication noncompliance. Electrocardiographic changes occur frequently, but clinically significant arrhythmias are much less common. Elderly patients and those with preexisting cardiac disease are at greater risk. The

most frequently seen electrocardiographic changes include diminution of the T wave amplitude, appearance of prominent U waves, depression of the ST segment, and prolongation of the QT interval. Thioridazine has been given an FDA warning for dose-related QTc delay and risk of fatal cardiac arrhythmias. As noted above, ziprasidone can produce QTc prolongation. An ECG prior to treatment in some patients may be indicated. In some critical care patients, torsades de pointes has been associated with the use of high-dose intravenous haloperidol (usually > 30 mg/24 h).

Associations have been suggested between the atypical neuroleptics and new-onset diabetes, hyperlipidemia, QTc prolongation, and weight gain (Table 25–6). The FDA has particularly noted the risk of hyperglycemia and new-onset diabetes in this class of medication that is not related to weight gain. Monitoring of weight, fasting blood sugar and lipids prior to initiation of treatment and at regular intervals thereafter is an important part of medication monitoring. Early research suggests that the addition of metformin to olanzapine may improve drug-induced weight gain in patients with drug-naïve, first-episode schizophrenia. Neuroleptic medications in general may have metabolic and endocrine effects, including weight gain, hyperglycemia, impaired temperature regulation in hot weather, and water intoxication, that may be due to inappropriate ADH secretion. Lactation and menstrual irregularities are common (antipsychotic drugs should be avoided, if possible, in breast cancer patients because of potential trophic effects of elevated prolactin levels on the breast). Both antipsychotic and antidepressant drugs inhibit sperm motility. Bone marrow depression and cholestatic jaundice occur rarely; these are hypersensitivity reactions, and they usually appear in the first 2 months of treatment. They subside on discontinuance of the drug. There is cross-sensitivity among all of the phenothiazines, and a drug from a different group should be used when allergic reactions occur.

Clozapine is associated with a 1.6% risk of **agranulocytosis** (higher in persons of Ashkenazi Jewish ancestry), and its use must be strictly monitored with weekly blood counts during the first 6 months of treatment, with monitoring every other week thereafter. Discontinuation of the medication requires weekly monitoring of the white blood cell count for 1 month. Clozapine has been associated with fatal

Table 25–6. Adverse factors associated with atypical antipsychotics.

| | Weight Gain | Hyperlipidemia | New-Onset Diabetes | QTc Prolongation ¹ |
|-------------|-------------|----------------|--------------------|-------------------------------|
| Clozapine | +++ | + | + | +/- |
| Olanzapine | +++ | + | + | +/- |
| Risperidone | ++ | Unclear data | Unclear data | + |
| Quetiapine | ++ | Unclear data | Unclear data | ++ |
| Ziprasidone | +/- | - | - | +++ |

¹QTc prolongation is a side effect of many medications and suggests a possible risk for arrhythmia. Among atypical neuroleptics, only ziprasidone carries a special warning regarding the risk of QTc prolongation.

Adapted, with permission, from American Diabetes Association: Consensus Development Conference on Antipsychotic Drugs and Obesity and Diabetes. *Diabetes Care*. 2004 Feb;27(2):596–601.

myocarditis and is contraindicated in patients with severe heart disease. In addition, clozapine lowers the seizure threshold and has many side effects, including sedation, hypotension, increased liver enzyme levels, hypersalivation, respiratory arrest, weight gain, and changes in both the ECG and the EEG.

Photosensitivity, retinopathy, and hyperpigmentation are associated with use of fairly high dosages of chlorpromazine and thioridazine. The appearance of particulate melanin deposits in the lens of the eye is related to the total dose given, and patients on long-term medication should have periodic eye examinations. Teratogenicity has not been causally related to these drugs, but prudence is indicated particularly in the first trimester of pregnancy. The seizure threshold is lowered, but it is safe to use these medications in epileptics who take anticonvulsants.

The **neuroleptic malignant syndrome (NMS)** is a catatonia-like state manifested by extrapyramidal signs, blood pressure changes, altered consciousness, and hyperpyrexia; it is an uncommon but serious complication of neuroleptic treatment. Muscle rigidity, involuntary movements, confusion, dysarthria, and dysphagia are accompanied by pallor, cardiovascular instability, fever, pulmonary congestion, and diaphoresis and may result in stupor, coma, and death. The cause may be related to a number of factors, including poor dosage control of neuroleptic medication, affective illness, decreased serum iron, dehydration, and increased sensitivity of dopamine receptor sites. Lithium in combination with a neuroleptic drug may increase vulnerability, which is already increased in patients with an affective disorder. In most cases, the symptoms develop within the first 2 weeks of antipsychotic drug treatment. The syndrome may occur with small doses of the drugs. Intramuscular administration is a risk factor. Elevated creatine kinase and leukocytosis with a shift to the left are present early in about half of cases. Treatment includes controlling fever and providing fluid support. Dopamine agonists such as bromocriptine, 2.5–10 mg orally three times a day, and amantadine, 100–200 mg orally twice a day, have also been useful. Dantrolene, 50 mg intravenously as needed, is used to alleviate rigidity (do not exceed 10 mg/kg/d due to hepatotoxicity risk). There is ongoing controversy about the efficacy of these three agents as well as the use of calcium channel blockers and benzodiazepines. ECT has been used effectively in resistant cases. Clozapine has been used with relative safety and fair success as an antipsychotic drug for patients who have had NMS. The syndrome must be differentiated from acute lethal catatonia, malignant hyperthermia, neurotoxic syndromes (including AIDS), and a variety of other conditions such as viral encephalitis, Wilson disease, central anticholinergic syndrome, and hypertonic states (eg, tetany, strychnine poisoning).

Akathisia is the most common (about 20%) so-called **extrapyramidal symptom**. It usually occurs early in treatment (but may persist after neuroleptics are discontinued) and is frequently mistaken for anxiety or exacerbation of psychosis. It is characterized by a subjective desire to be in constant motion followed by an inability to sit or stand still and consequent pacing. It may induce suicidality or feelings of fright, rage, terror, or sexual torment. Insomnia is often

present. It is crucial to educate patients in advance about these potential side effects so that the patients do not misinterpret them as signs of increased illness. In all cases, reevaluate the dosage requirement or the type of neuroleptic drug. One should inquire also about cigarette smoking, which in women has been associated with an increased incidence of akathisia. Antiparkinsonism drugs (such as trihexyphenidyl, 2–5 mg orally three times daily) may be helpful, but first-line treatment often includes a benzodiazepine (such as clonazepam 0.5–1.0 mg orally three times daily). In resistant cases, symptoms may be alleviated by propranolol, 30–80 mg/d orally, diazepam, 5 mg orally three times daily, or amantadine, 100 mg orally three times daily.

Acute dystonias usually occur early, although a late (tardive) occurrence is reported in patients (mostly men after several years of therapy) who previously had early severe dystonic reactions and a mood disorder (see below). Younger patients are at higher risk for acute dystonias. The most common signs are bizarre muscle spasms of the head, neck, and tongue. Frequently present are torticollis, oculogyric crises, swallowing or chewing difficulties, and masseter spasms. Laryngospasm is particularly dangerous. Back, arm, or leg muscle spasms are occasionally reported. Diphenhydramine, 50 mg intramuscularly, is effective for the acute crisis; one should then give benztropine mesylate, 2 mg orally twice daily, for several weeks, and then discontinue gradually, since few of the extrapyramidal symptoms require long-term use of the antiparkinsonism drugs (all of which are about equally efficacious—though trihexyphenidyl tends to be mildly stimulating and benztropine mildly sedating).

Drug-induced parkinsonism is indistinguishable from idiopathic parkinsonism, but it is reversible, occurs later in treatment than the preceding extrapyramidal symptoms, and in some cases appears after neuroleptic withdrawal. The condition includes the typical signs of apathy and reduction of facial and arm movements (akinesia, which can mimic depression), festinating gait, rigidity, loss of postural reflexes, and pill-rolling tremor. AIDS patients seem particularly vulnerable to extrapyramidal side effects. High-potency neuroleptics often require antiparkinsonism drugs (see Table 24–6). The neuroleptic dosage should be reduced, and immediate relief can be achieved with antiparkinsonism drugs in the same dosages as above. After 4–6 weeks, these antiparkinsonism drugs can often be discontinued with no recurrent symptoms. In any of the extrapyramidal symptoms, amantadine, 100–400 mg orally daily, may be used instead of the antiparkinsonism drugs. Neuroleptic-induced catatonia is similar to catatonic stupor with rigidity, drooling, urinary incontinence, and cogwheeling. It usually responds slowly to withdrawal of the offending medication and use of antiparkinsonism agents.

Tardive dyskinesia is a syndrome of abnormal involuntary stereotyped movements of the face, mouth, tongue, trunk, and limbs that may occur after months or (usually) years of treatment with neuroleptic agents. The syndrome affects 20–35% of patients who have undergone long-term neuroleptic therapy. Predisposing factors include older age, many years of treatment, cigarette smoking, and diabetes mellitus. Pineal calcification is higher in this condition by a margin of 3:1. There are no known differ-

ences among any of the antipsychotic drugs in the development of this syndrome. Although the atypical antipsychotics appear to offer lower risk, the CATIE study did not address the long-term effects of these drugs.

Early manifestations include fine worm-like movements of the tongue at rest, difficulty in sticking out the tongue, facial tics, increased blink frequency, or jaw movements of recent onset. Later manifestations may include bucco-linguo-masticatory movements, lip smacking, chewing motions, mouth opening and closing, disturbed gag reflex, puffing of the cheeks, disrupted speech, respiratory distress, or choreoathetoid movements of the extremities (the last being more prevalent in younger patients). The symptoms do not necessarily worsen and in rare cases may lessen even though neuroleptic drugs are continued. The dyskinesias do not occur during sleep and can be voluntarily suppressed for short periods. Stress and movements in other parts of the body will often aggravate the condition.

Early signs of dyskinesia must be differentiated from those reversible signs produced by ill-fitting dentures or nonneuroleptic drugs such as levodopa, TCAs, antiparkinsonism agents, anticonvulsants, and antihistamines. Other neurologic conditions such as Huntington chorea can be differentiated by history and examination.

The emphasis should be on prevention. Use the least amount of neuroleptic drug necessary to mute the psychotic symptoms; atypical drugs appear to offer less risk as first line agents. Detect early manifestations of dyskinesias. When these occur, stop anticholinergic drugs and gradually discontinue neuroleptic drugs, if clinically feasible. Weight loss and cachexia sometimes appear on withdrawal of neuroleptics. In an indeterminate number of cases, the dyskinesias will remit. Keep the patient off the drugs until reemergent psychotic symptoms dictate their resumption, at which point they are restarted in low doses and gradually increased until there is clinical improvement. If neuroleptic drugs are restarted, clozapine and olanzapine appear to offer less risk of recurrence. The use of adjunctive agents such as benzodiazepines or lithium may help directly or indirectly by allowing control of psychotic symptoms with a low dosage of neuroleptics. If the dyskinesic syndrome recurs and it is necessary to continue neuroleptic drugs to control psychotic symptoms, informed consent should be obtained. Benzodiazepines, buspirone (in doses of 15–60 mg/d orally), phosphatidylcholine, clonidine, calcium channel blockers, vitamin E, omega-3 fatty acids, and propranolol all have had limited usefulness in treating the dyskinetic side effects.

B. Social

Environmental considerations are most important in the individual with a chronic illness, who usually has a history of repeated hospitalizations, a continued low level of functioning, and symptoms that never completely remit. Family rejection and work failure are common. In these cases, board and care homes staffed by personnel experienced in caring for psychiatric patients are most important. There is frequently an inverse relationship between stability of the living situation and the amounts of required antipsychotic

drugs, since the most salutary environment is one that reduces stimuli. Nonresidential self-help groups such as Recovery, Inc., should be utilized whenever possible. They provide a setting for sharing, learning, and mutual support and are frequently the only social involvement with which this type of patient is comfortable. Vocational rehabilitation and work agencies (eg, Goodwill Industries, Inc.) provide assessment, training, and job opportunities at a level commensurate with the person's clinical condition.

C. Psychological

The need for psychotherapy varies markedly depending on the patient's current status and history. In a person with a single psychotic episode and a previously good level of adjustment, supportive psychotherapy may help the patient reintegrate the experience, gain some insight into antecedent problems, and become a more self-observant individual who can recognize early signs of stress. Insight-oriented psychotherapy is often counterproductive in this type of disorder. Research suggests that cognitive behavioral therapy—in conjunction with medication management—may have some efficacy in the treatment of symptoms of schizophrenia. Cognitive behavioral therapy for schizophrenia involves helping the individual challenge psychotic thinking and alters response to hallucinations. Similarly, a new form of psychotherapy called acceptance and commitment therapy has shown value in helping prevent hospitalizations in schizophrenia. Cognitive remediation therapy is another new approach to treatment that shows promise in helping schizophrenics become better able to focus their disorganized thinking. Family therapy may also help alleviate the patient's stress and to assist relatives in coping with the patient.

D. Behavioral

Behavioral techniques (see above) are most frequently used in therapeutic settings such as day treatment centers, but there is no reason why they cannot be incorporated into family situations or any therapeutic setting. Many behavioral techniques (eg, positive reinforcement—whether it be a word of praise or an approving nod—after some positive behavior), can be a powerful instrument for helping a person learn behaviors that will facilitate social acceptance. Music from portable digital players with earphones is one of many ways to divert the patient's attention from auditory hallucinations.

► Prognosis

In any psychosis, in the large majority of patients the prognosis is excellent for alleviation of positive symptoms such as hallucinations or delusions treated with medication. Negative symptoms such as diminished affect and sociability are much more difficult to treat but appear responsive to atypical antipsychotics. Unavailability of structured work situations and lack of family therapy are two other reasons why the prognosis is so guarded in such a large percentage of schizophrenic patients. Psychosis connected with a history of serious drug abuse has a guarded prognosis because of the

central nervous system damage, usually from the drugs themselves and associated medical illnesses.

MOOD DISORDERS (Depression & Mania)

ESSENTIALS OF DIAGNOSIS

Present in most depressions:

- ▶ Mood varies from mild sadness to intense feelings of guilt, worthlessness, and hopelessness.
- ▶ Difficulty in thinking, including inability to concentrate, ruminations, and lack of decisiveness.
- ▶ Loss of interest, with diminished involvement in work and recreation.
- ▶ Somatic complaints such as headache; disrupted, lessened, or excessive sleep; loss of energy; change in appetite; decreased sexual drive.
- ▶ Anxiety.

Present in some severe depressions:

- ▶ Psychomotor retardation or agitation.
- ▶ Delusions of a hypochondriacal or persecutory nature.
- ▶ Withdrawal from activities.
- ▶ Physical symptoms of major severity, eg, anorexia, insomnia, reduced sexual drive, weight loss, and various somatic complaints.
- ▶ Suicidal ideation.

Present in mania:

- ▶ Mood ranging from euphoria to irritability.
- ▶ Sleep disruption.
- ▶ Hyperactivity.
- ▶ Racing thoughts.
- ▶ Grandiosity.
- ▶ Variable psychotic symptoms.

▶ General Considerations

Depression is extremely common, with up to 30% of primary care patients having depressive symptoms. Depression may be the final expression of (1) genetic factors (neu-

rotransmitter dysfunction), (2) developmental problems (personality problems, childhood events), or (3) psychosocial stresses (divorce, unemployment). It frequently presents in the form of somatic complaints with negative medical workups. Although sadness and grief are normal responses to loss, depression is not. Patients experiencing normal grief tend to produce sympathy and sadness in the clinician caregiver; depression often produces frustration and irritation in the clinician. Grief is usually accompanied by intact self-esteem, whereas depression is marked by a sense of guilt and worthlessness.

Mania is often combined with depression and may occur alone, together with mania in a mixed episode, or in cyclic fashion with depression.

▶ Clinical Findings

In general, there are four major types of depressions, with similar symptoms in each group.

A. Adjustment Disorder with Depressed Mood

Depression may occur in reaction to some identifiable stressor or adverse life situation, usually loss of a person by death (grief reaction), divorce, etc; financial reversal (crisis); or loss of an established role, such as being needed. Anger is frequently associated with the loss, and this in turn often produces a feeling of guilt. The disorder occurs within 3 months of the stressor and causes significant impairment in social or occupational functioning. The symptoms range from mild sadness, anxiety, irritability, worry, lack of concentration, discouragement, and somatic complaints to the more severe symptoms of the next group.

B. Depressive Disorders

The subclassifications include major depressive disorder and dysthymia.

1. Major depressive disorder—A major depressive disorder (eg, “endogenous” unipolar disorder, melancholia) consists of at least one episode of serious mood depression that occurs at any time of life. Many consider a physiologic or metabolic aberration to be causative. Complaints vary widely but most frequently include a loss of interest and pleasure (anhedonia), withdrawal from activities, and feelings of guilt. Also included are inability to concentrate, some cognitive dysfunction, anxiety, chronic fatigue, feelings of worthlessness, somatic complaints (unidentifiable somatic complaints frequently indicate depression), loss of sexual drive, and thoughts of death. Diurnal variation with improvement as the day progresses is common. Vegetative signs that frequently occur are insomnia, anorexia with weight loss, and constipation. Occasionally, severe agitation and psychotic ideation (paranoid thinking, somatic delusions) are present. These symptoms are more common in depressed persons who are older than 50 years. Paranoid symptoms may range from general suspiciousness to ideas of reference with delusions. The somatic delusions frequently revolve around feelings of impending annihilation or hypochondriacal beliefs (eg, that the body is rotting away with cancer). Hallucinations are uncommon.

Subcategories include **major depression with atypical features** characterized by hypersomnia, overeating, lethargy, and rejection sensitivity. **Major depression with a seasonal onset (seasonal affective disorder)** is a dysfunction of circadian rhythms that occurs more commonly in the winter months and is believed to be due to decreased exposure to full-spectrum light. Common symptoms include carbohydrate craving, lethargy, hyperphagia, and hypersomnia. **Major depression with postpartum onset** usually occurs 2 weeks to 6 months postpartum.

Most women (up to 80%) experience some mild let-down of mood in the postpartum period. For some of these (10–15%), the symptoms are more severe and similar to those usually seen in serious depression, with an increased emphasis on concerns related to the baby (obsessive thoughts about harming it or inability to care for it). When psychotic symptoms occur, there is frequently associated sleep deprivation, volatility of behavior, and manic-like symptoms. Postpartum psychosis is much less common (< 2%), often occurs within the first 2 weeks, and requires early and aggressive management. Biologic vulnerability with hormonal changes and psychosocial stressors all play a role. The chances of a second episode are about 25% and may be reduced with prophylactic treatment.

2. Dysthymia—Dysthymia is a chronic depressive disturbance. Sadness, loss of interest, and withdrawal from activities over a period of 2 or more years with a relatively persistent course is necessary for this diagnosis. Generally, the symptoms are milder but longer-lasting than those in a major depressive episode.

3. Premenstrual dysphoric disorder—Depressive symptoms occur during the late luteal phase (last 2 weeks) of the menstrual cycle.

C. Bipolar Disorders

Bipolar disorders consist of episodic mood shifts into mania, major depression, hypomania, and mixed mood states. The ability of bipolar disorder to mimic aspects of many other Axis I disorders and a high comorbidity with substance abuse can make the initial diagnosis of bipolar disorder difficult.

1. Mania—A manic episode is a mood change characterized by elation with hyperactivity, over involvement in life activities, increased irritability, flight of ideas, easy distractibility, and little need for sleep. The overenthusiastic quality of the mood and the expansive behavior initially attract others, but the irritability, mood lability with swings into depression, aggressive behavior, and grandiosity usually lead to marked interpersonal difficulties. Activities may occur that are later regretted, eg, excessive spending, resignation from a job, a hasty marriage, sexual acting out, and exhibitionistic behavior, with alienation of friends and family. Atypical manic episodes can include gross delusions, paranoid ideation of severe proportions, and auditory hallucinations usually related to some grandiose perception. The episodes begin abruptly (sometimes precipitated by life stresses) and may last from several days to months. Spring and summer tend

to be the peak periods. Generally, the manic episodes are of shorter duration than the depressive episodes. In almost all cases, the manic episode is part of a broader bipolar (manic-depressive) disorder. Patients with four or more discrete episodes of a mood disturbance in 1 year are called “rapid cyclers.” (Substance abuse, particularly cocaine, can mimic rapid cycling.) These patients have a higher incidence of hypothyroidism. Manic patients differ from patients with schizophrenia in that the former use more effective interpersonal maneuvers, are more sensitive to the social maneuvers of others, and are more able to utilize weakness and vulnerability in others to their own advantage. Creativity has been positively correlated with mood disorders, but the best work done is between episodes of mania and depression.

2. Cyclothymic disorders—These are chronic mood disturbances with episodes of depression and hypomania. The symptoms must have at least a 2-year duration and are milder than those that occur in depressive or manic episodes. Occasionally, the symptoms will escalate into a full-blown manic or depressive episode, in which case reclassification as bipolar I or bipolar II disorder would be warranted.

D. Mood Disorders Secondary to Illness and Drugs

Any illness, severe or mild, can cause significant depression. Conditions such as rheumatoid arthritis, multiple sclerosis, and chronic heart disease are particularly likely to be associated with depression, as are other chronic illnesses. Hormonal variations clearly play a role in some depressions. Varying degrees of depression occur at various times in schizophrenic disorders, central nervous system disease, and organic mental states. **Alcohol dependency** frequently coexists with serious depression.

The classic model of drug-induced depression occurs with the use of reserpine, both in a clinical and a neurochemical sense. Corticosteroids and oral contraceptives are commonly associated with affective changes. Antihypertensive medications such as methyldopa, guanethidine, and clonidine have been associated with the development of depressive syndromes, as have digitalis and antiparkinsonism drugs (eg, levodopa). It is unusual for β -blockers to produce depression when given for short periods, such as in the treatment of performance anxiety. Sustained use of β -blockers for medical conditions such as hypertension may produce depression in some patients, although most individuals do not suffer this adverse effect. Infrequently, disulfiram and anticholinesterase drugs may be associated with symptoms of depression. All stimulant use results in a depressive syndrome when the drug is withdrawn. Alcohol, sedatives, opiates, and most of the psychedelic drugs are depressants and, paradoxically, are often used in self-treatment of depression.

▶ Differential Diagnosis

Since depression may be a part of any illness—either reactively or as a secondary symptom—careful attention must be given to personal life adjustment problems and the role of medications (eg, reserpine, corticosteroids, levodopa).

Schizophrenia, partial complex seizures, organic brain syndromes, panic disorders, and anxiety disorders must be differentiated. Subtle thyroid dysfunction must be ruled out.

► Complications

The most important complication is suicide, which often includes some elements of aggression. Suicide rates in the general population vary from 9 per 100,000 in Spain to 20 per 100,000 in the United States to 58 per 100,000 in Hungary. In individuals with depression, the lifetime risk rises to 10–15%. Men tend toward successful suicide, particularly in older age groups, whereas women make more attempts with lower mortality rates. An increased suicide rate is being observed in the younger population, ages 15–35. Patients with cancer, respiratory illnesses, AIDS, and those being maintained on hemodialysis have higher suicide rates. Alcohol is a significant factor in many suicide attempts.

There are several groups of people who make suicide attempts. One group includes those individuals with acute **situational problems**. These individuals may be acutely distressed by a recent breakup in a relationship or another type of disappointment. This group also includes those who may not be diagnosed as having depression but who are overwhelmed by a stressful situation often with an aspect of public humiliation (eg, the man charged with child molestation who hangs himself in his cell). A suicide attempt in such cases may be an impulsive or aggressive act not associated with significant depression. In such cases, a suicide attempt is clearly a stratagem for **controlling or hurting others or an attempted escape**.

Another high-risk group includes individuals with severe depression. **Severe depression** may be due to conditions such as medical illness (eg, AIDS, whose victims have a suicide rate over 30 times that of the general population) or comorbid psychiatric disorders (eg, panic disorders). Anxiety, panic, and fear are major findings in suicidal behavior. A patient may seem to make a dramatic improvement, but the lifting of depression may be due to the patient's decision to commit suicide. Another high-risk group are individuals with **psychotic illness** who tend not to verbalize their concerns, are unpredictable, and are often successful in their suicide attempt, although they make up only a small percentage of the total.

Finally, suicide is ten times more prevalent in patients with schizophrenia than in the general population, and jumping from bridges is a more common means of attempted suicide by schizophrenics than by others. In one study of 100 jumpers, 47% had schizophrenia.

The immediate goal of psychiatric evaluation is to assess the current suicidal risk and the need for hospitalization versus outpatient management. The intent is less likely to be truly suicidal, for example, if small amounts of poison or drugs were ingested or scratching of wrists was superficial, if the act was performed in the vicinity of others or with early notification of others, or if the attempt was arranged so that early detection would be anticipated. Alcohol, hopelessness, delusional thoughts, and complete or nearly complete loss of interest in life or ability to experience pleasure

are all positively correlated with suicide attempts. Other risk factors are previous attempts, a family history of suicide, medical or psychiatric illness (eg, anxiety, depression, psychosis), male sex, older age, contemplation of violent methods, a humiliating social stressor, and drug use (including long-term sedative or alcohol use), which contributes to impulsiveness or mood swings. Successful treatment of the patient at risk for suicide cannot be achieved if the patient continues to abuse drugs.

The patient's current mood status is best evaluated by direct evaluation of plans and concerns about the future, personal reactions to the attempt, and thoughts about the reactions of others. The patient's immediate resources should be assessed—people who can be significantly involved (most important), family support, job situation, financial resources, etc.

If hospitalization is not indicated (eg, gestures, impulsive attempts; see above), the clinician must formulate and institute a treatment plan or make an adequate referral. Medication should be dispensed in small amounts to at-risk patients. Although TCAs and SSRIs are associated with an equal incidence of suicide attempts, the risk of successful suicide is higher with TCA overdose. Guns and drugs should be removed from the patient's household. Driving should be interdicted until the patient improves. The problem is often worsened by the long-term complications of the suicide attempt, eg, brain damage due to hypoxia, peripheral neuropathies caused by staying for long periods in one position causing nerve compressions, and medical or surgical problems such as esophageal strictures and tendon dysfunctions.

The reasons for self-mutilation, most commonly wrist cutting (but also autocastration, autoamputation, and autoenucleation, which are associated with psychoses), may be very different from the reasons for a suicide attempt. The initial treatment plan, however, should presume suicidal ideation, and conservative treatment should be initiated.

Sleep disturbances in the depressions are discussed below.

► Treatment of Depression

A. Medical

Depression associated with reactive disorders usually does not call for drug therapy and can be managed by psychotherapy and the passage of time. In severe cases—particularly when vegetative signs are significant and symptoms have persisted for more than a few weeks—antidepressant drug therapy is often effective. Drug therapy is also suggested by a family history of major depression in first-degree relatives or a past history of prior episodes.

The antidepressant drugs may be conveniently classified into three groups: (1) the newer antidepressants, including the SSRIs and bupropion, duloxetine, venlafaxine, nefazodone, and mirtazapine, (2) the TCAs and clinically similar drugs, and (3) the MAO inhibitors (see Table 25–8). These groups are described in greater detail below. ECT is effective in all types of depression and will also rapidly resolve a manic episode. It is also very effective for

postpartum depression. Megavitamin treatment, acupuncture, and electrosleep are of unproved usefulness for any psychiatric condition.

Hospitalization is necessary if suicide is a major consideration or if complex treatment modalities are required.

Drug selection is influenced by the history of previous responses if that information is available. If a relative has responded to a particular drug, this suggests that the patient may respond similarly. If no background information is available, a drug such as sertraline, 25 mg orally daily and increasing gradually up to 200 mg orally, or desipramine, starting with 50 mg orally and gradually increasing to 150 mg daily, can be selected and a *full trial* instituted. The medication trial should be monitored for worsening mood or suicidal ideation with patient assessments every 1–2 weeks until week 6. If successful, the medication should be continued for 6–12 months at the full therapeutic dose before tapering is considered. Antidepressants should usually be continued indefinitely at full dosage in individuals with more than two episodes after age 40 or one episode after age 50. If the response is inadequate the best alternatives are to switch to a second agent or to try augmenting the first agent according to the STAR*D study. The latter course is often taken when there has been at least a partial response to the initial drug. If a second drug is tried, it does not appear to matter whether that drug is from the same or different class. If the second drug fails or augmentation was selected as the second step, the choices include lithium (eg, 600–900 mg/d orally), buspirone (eg, 30–60 mg/d orally), or thyroid medication (eg, liothyronine, 25 mcg/d orally). Dysthymia is also treated in this way. The Agency for Health Care Policy and Research has produced clinical practice guidelines that outline one algorithm of treatment decisions (Figure 25–2).

Psychotic depression should be treated with a combination of an antipsychotic such as olanzapine and an antidepressant such as an SSRI at their usual doses. Mifepristone may have specific and early activity against psychotic depression.

Major depression with atypical features or seasonal onset can be treated with an MAO inhibitor or an SSRI with good results.

Stimulants such as dextroamphetamine (5–30 mg/d orally) and methylphenidate (10–45 mg/d orally) have enjoyed a resurgence of interest for the short-term treatment of depression in medically ill and geriatric patients. Their 50–60% efficacy rate is slightly below that of other agents. The stimulants are notable for rapid onset of action (hours) and a paucity of side effects (tachycardia, agitation) in most patients. They are usually given in two divided doses early in the day (eg, 7 am and noon) so as to avoid interfering with sleep. These agents may also be useful as adjunctive agents in refractory depression.

Caution: Depressed patients may have suicidal thoughts, and the amount of drug dispensed should be appropriately controlled. It appears that in children and adolescent populations, antidepressants may be associated with some slightly increased risk of suicidality, but this diminishes by age 25. After that, antidepressants have neutral or possibly protective effects until age 65 years or older when they have

protective effects. The older TCAs have a narrow therapeutic index, and one advantage of the newer drugs is their wider margin of safety. Nonetheless, even with newer agents, because of the possibility of suicidality early in antidepressant treatment, close follow-up is indicated. In all cases of pharmacologic management of depressed states, caution is indicated until the risk of suicide is considered minimal.

1. SSRIs and atypical antidepressants—The chief advantages of these agents are that they do not generally cause significant cardiovascular or anticholinergic side effects, and they have much lower lethality in overdose compared to TCAs. The SSRIs include fluoxetine, sertraline, paroxetine, fluvoxamine, citalopram and its enantiomer escitalopram. The atypical antidepressants are bupropion, which appears to exert its effect through the dopamine neurotransmitter system; venlafaxine and duloxetine, both of which inhibit the reuptake of both serotonin and norepinephrine; nefazodone, which blocks the reuptake of serotonin but also inhibits the 5-HT₂ postsynaptic receptors; and mirtazapine, which selectively blocks presynaptic α_2 -adrenergic receptors and enhances both noradrenergic and serotonergic transmission. All of these antidepressants are effective in the treatment of depression, both typical and atypical. The SSRI drugs have been effective in the treatment of panic attacks, bulimia, generalized anxiety disorder, OCD, and PTSD. They do not seem to be as clearly effective in some pain syndromes as the TCAs, although venlafaxine may have some efficacy in the treatment of neuropathic pain, and duloxetine is FDA-approved for the treatment of diabetic peripheral neuropathy.

Most of the drugs in this group tend to be activating and are given in the morning so as not to interfere with sleep. Some patients, however, may have sedation, requiring that the drug be given at bedtime. This reaction occurs most commonly with paroxetine, fluvoxamine, and mirtazapine. The SSRIs can be given in once-daily dosage. Nefazodone and venlafaxine are usually given twice daily. Bupropion and venlafaxine are available in extended-release formulations and can be given once daily. There is usually some delay in response; fluoxetine, for example, requires 2–6 weeks to act in depression, 4–8 weeks to be effective in panic disorder, and 6–12 weeks in treatment of OCD. The starting dose (10 mg) is given for 1 week before increasing to the average daily oral dose of 20 mg for depression, while OCD may require up to 80 mg daily. Some patients, particularly the elderly, may tolerate and benefit from as little as 10 mg/d or every other day. The other SSRIs have shorter half-lives and a lesser effect on hepatic enzymes, which reduces their impact on the metabolism of other drugs (thus not increasing significantly the serum concentrations of other drugs as much as fluoxetine). The shorter half-lives also allow for more rapid clearing if adverse side effects appear. Venlafaxine appears to be more effective with doses greater than 200 mg/d, although some individuals respond to doses as low as 75 mg/d.

The side effects common to all of these drugs are headache, nausea, tinnitus, insomnia, and nervousness. Akathisia has been common with the SSRIs; other extrapyramidal symptoms (eg, dystonias) have occurred infrequently but

¹Times of assessment (weeks 6 and 12) rest on very modest data. It may be necessary to revise the treatment plan earlier for patients not responding at all.

▲ **Figure 25-2.** Overview of treatment for depression. (Reproduced from Agency for Health Care Policy and Research: Depression in Primary Care. Vol. 2: Treatment of Major Depression. United States Department of Health and Human Services, 1993.)

particularly in withdrawal states. Sexual side effects of erectile dysfunction, retrograde ejaculation, and dysorgasmia are very common with the SSRIs. Antidotes to SSRI-induced sexual dysfunction are occasionally helpful. Sildenafil, 25–50 mg orally 1 hour prior to sexual activity, can improve erectile dysfunction in some patients. Cyproheptadine, 4 mg

orally prior to sexual activity, may be helpful in countering drug-induced anorgasmia. Adjunctive bupropion (75–150 mg orally daily) may also help with restoring erectile function. The SSRIs are strong serotonin uptake blockers and may in high dosage or in combination with MAO inhibitors, including the antiparkinsonian drug selegiline, cause a

“serotonin syndrome.” This syndrome is manifested by rigidity, hyperthermia, autonomic instability, myoclonus, confusion, delirium, and coma. This syndrome can be a particularly troublesome problem in the elderly. Several cases of angina have been reported in association with SSRIs. However, current research indicates that SSRIs are safer agents to use than TCAs in patients with cardiac disease. A study has found that sertraline is a safe and effective antidepressant treatment in patients with acute myocardial infarction or unstable angina.

Withdrawal syndromes have been reported for the SSRIs and venlafaxine. These include dysphoric mood, agitation, and a flu-like state. These medications should be discontinued gradually over a period of weeks or months to reduce the risk of withdrawal phenomena.

Fluoxetine, fluvoxamine, sertraline, venlafaxine, and citalopram in customary antidepressant doses do not appear to increase the risk of major fetal malformation when used during pregnancy. At the same time, paroxetine may be associated with a twofold increased risk of cardiac abnormalities. A recent study of SSRI use in the first trimester suggests that despite the association of specific medications with specific congenital defects, the absolute risk of rare defects is low. Postpartum developmental effects of antidepressants are thought to be minimal, however, this question calls for ongoing investigation. Peripartum effects may be a concern and are documented anecdotally in the literature. The risk of depression to the mother and fetus needs to be part of the discussion with the patient about treatment options. The decision to use SSRIs and other psychotropic agents during pregnancy and postpartum must be based on a thorough risk-benefit analysis for each individual.

Venlafaxine is reported to be well-tolerated without significant anticholinergic or cardiovascular side effects. Nausea, nervousness, and profuse sweating appear to be the major side effects. Venlafaxine appears to have few drug-drug interactions. It does require monitoring of blood pressure because dose-related hypertension may develop in some individuals. Desvenlafaxine, a new form of the drug, is started at its target dose of 50 mg/d and does not require upward titration. Duloxetine may also result in small increases in blood pressure. Common side effects include dry mouth, dizziness, and fatigue. Inhibitors of 1A2 and 2D6 may increase duloxetine levels with a risk of toxicity.

Nefazodone appears to lack the anticholinergic effects of the TCAs and the agitation sometimes induced by SSRIs. Nefazodone should not be given with terfenadine, astemizole, or cisapride. (Terfenadine and astemizole are not commercially available in the United States.) Because nefazodone inhibits the liver's cytochrome P450 3A4 isoenzymes, concurrent use of these medications can lead to serious QT prolongation, ventricular tachycardia, or death. Through the same mechanism of enzyme inhibition, nefazodone can elevate cyclosporine levels sixfold to tenfold. Nefazodone has been given an FDA warning because it has been implicated in liver failure in rare cases. Pretreatment and ongoing monitoring of liver enzymes are indicated.

Mirtazapine is thought to enhance central noradrenergic and serotonergic activity with minimal sexual side effects compared with the SSRIs. Its action as a potent

antagonist of histaminergic receptors may make it a useful agent for patients with depression and insomnia. Its most common adverse side effects include somnolence, increased appetite, weight gain, lipid abnormalities, and dizziness. There have been reports of agranulocytosis in 2 of 2796 patients. Although it is metabolized by P450 isoenzymes, it is not an inhibitor of this system. It is given in a single oral dose at bedtime starting at 15 mg and increasing in 15-mg increments every week or every other week up to 45 mg.

2. Tricyclic antidepressants and clinically similar drugs—These drugs were the mainstay of drug therapy for depression for many years. They have also been effective in panic disorders, pain syndromes, and anxiety states. Specific ones have been effective in OCD (clomipramine), enuresis (imipramine), psychotic depression (amoxapine), and reduction of craving in cocaine withdrawal (desipramine).

TCAs are characterized more by their similarities than by their differences. There is a lag in clinical response for up to several weeks, largely the result of anticholinergic side effects that prevent rapid increase in dosage. They tend to affect both serotonin and norepinephrine reuptake; some drugs act mainly on the former and others principally on the latter neurotransmitter system. Individuals receiving the same dosages vary markedly in therapeutic drug levels achieved (elderly patients require smaller doses), and determination of plasma drug levels is helpful when clinical response has been disappointing. Nortriptyline is usually effective when plasma levels are between 50 and 150 ng/mL; imipramine at plasma levels of 200–250 ng/mL; and desipramine at plasma levels of 100–250 ng/mL. High blood levels are not more effective than moderate levels and may be counterproductive (eg, delirium, seizures). Patients with gastrointestinal side effects benefit from plasma level monitoring to assess absorption of the drug. Most TCAs can be given in a single dose at bedtime, starting at fairly low doses (eg, nortriptyline 25 mg orally) and increasing by 25 mg every several days as tolerated until the therapeutic response is achieved (eg, nortriptyline, 100–150 mg) or to maximum dose if necessary (eg, nortriptyline, 150 mg). The most common cause of treatment failure is an inadequate trial. A full trial consists of giving maximum daily dosage for at least 6 weeks. Because of marked anticholinergic and sedating side effects, clomipramine is started at a low dose (25 mg/d orally) and increased slowly in divided doses up to 100 mg/d, held at that level for several days, and then gradually increased as necessary up to 250 mg/d. Any of the TCA-like drugs should be started at very low doses (eg, 10–25 mg/d) and increased slowly in the treatment of panic disorder.

The TCAs have anticholinergic side effects to varying degrees (amitriptyline 100 mg is equivalent to atropine 5 mg). One must be particularly wary of the effect in elderly men with prostatic hyperplasia. The anticholinergic effects also predispose to other medical problems such as constipation, heat stroke, or dental problems from xerostomia. Orthostatic hypotension is fairly common, is not dose-dependent and may not remit with time on medication; this may predispose to falls and hip fractures in the elderly. Cardiac effects of the TCAs are functions of the anticholin-

ergic effect, direct myocardial depression (quinidine-like effect), and interference with adrenergic neurons. These factors may produce altered rate, rhythm, and contractility, particularly in patients with preexisting cardiac disease, such as bundle-branch or bifascicular block. Electrocardiographic changes range from benign ST segment and T wave changes and sinus tachycardia to a variety of complex and serious arrhythmias, the latter requiring a change in medication. Because TCAs have class I antiarrhythmic effects, they should be used with caution in patients with ischemic heart disease, arrhythmias, or conduction disturbances. SSRIs or the atypical antidepressants are better initial choices for this population. TCAs lower the seizure threshold so this is of particular concern in patients with a propensity for seizures (eg, previous head injury, alcohol withdrawal). Loss of libido and erectile, ejaculatory, and orgasmic dysfunction are fairly common and can compromise compliance. Trazodone rarely causes priapism, which requires treatment within 12 hours (epinephrine 1:1000 injected into the corpus cavernosum). Delirium, agitation, and mania are infrequent complications. Sudden discontinuation of some of these drugs can produce “cholinergic rebound,” manifested by headaches and nausea with abdominal cramps. Overdoses of TCAs are often serious because of the narrow therapeutic index and quinidine-like effects (see Chapter 38).

3. Monoamine oxidase inhibitors—The MAO inhibitors are generally used as third-line drugs for depression (after a failure of SSRIs, TCAs, or the atypical antidepressants) because of the dietary and other restrictions required (see below and Table 25–7). They should be considered third-line drugs for refractory panic disorder and depression; however, this has changed since MAO inhibitor skin patches (selegilene) have become available. They deliver the MAO inhibitor to the bloodstream bypassing the gastrointestinal tract so that dietary restrictions are not necessary in the lowest dosage strength (6 mg/24h).

Oral MAO inhibitors are administered in gradual stepwise dosage and may be given in the morning or evening, depending upon their effect on sleep. They tend to take effect in a fairly low dosage range (Table 25–8). Blood levels are not congruent with therapeutic response.

The MAO inhibitors commonly cause symptoms of orthostatic hypotension (which may persist) and sympathomimetic effects of tachycardia, sweating, and tremor. Nausea, insomnia (often associated with intense afternoon drowsiness), and sexual dysfunction are common. Trazo-

done, 25–75 mg orally at bedtime, may ameliorate the MAO-induced insomnia. Central nervous system effects include agitation and toxic psychoses. Dietary limitations (see Table 25–7) and abstinence from drug products containing phenylpropanolamine, phenylephrine, meperidine, dextromethorphan, and pseudoephedrine are mandatory for MAO-A type inhibitors (those marketed for treatment of depression), since the reduction of available MAO leaves the patient vulnerable to exogenous amines (eg, tyramine in foodstuffs).

Treatment for a resultant hypertensive crisis has been the same as for pheochromocytoma (see Chapter 26), but there have been reports of success with nifedipine, 10 mg chewed and placed under the tongue, normalizing blood pressure in 1–5 minutes. The restrictions on the proscribed foodstuffs and sympathomimetic drugs are in effect during treatment and for 2–3 weeks after cessation of therapy. Termination of therapy with MAO inhibitors may be associated with anxiety, agitation, cognitive slowing, and headache. Very gradual withdrawal and short-term benzodiazepine therapy will ameliorate symptoms.

4. Switching and combination therapy—If the therapeutic response has been poor after an adequate trial with the chosen drug, the diagnosis should be reassessed. Assuming that the trial has been adequate and the diagnosis is correct, a trial with a second drug is appropriate. In switching from one group to another, an adequate “wash-out time” must be allowed. This is critical in certain situations—eg, in switching from an MAO inhibitor to a TCA, allow 2–3 weeks between stopping one drug and starting another; in switching from an SSRI to an MAO inhibitor, allow 4–5 weeks. In switching within groups—eg, from one TCA to another (amitriptyline to desipramine, etc)—no washout time is needed, and one can rapidly decrease the dosage of one drug while increasing the other. The adjunctive use of low-dose atypical antipsychotics such as aripiprazole and risperidone in the treatment of patients with refractory depression is supported by recent research, although the side effect risk is the same as when treating psychosis. The FDA recently approved aripiprazole for this purpose. Combining two antidepressants, or adding an antipsychotic to an antidepressant, requires caution and is usually reserved for clinicians who feel comfortable managing this or after psychiatric consultation.

5. Maintenance and tapering—When clinical relief of symptoms is obtained, medication is continued for 12 months in the effective maintenance dosage, which is the dosage required in the acute stage. The full dosage should be continued indefinitely when the individual has a first episode before age 20 or after age 50, is over age 40 with two episodes, or has had three episodes at any age. Major depression should often be considered as a chronic disease. If the medication is being tapered, it should be done gradually over several months, monitoring closely for relapse.

6. Drug interactions—Interactions with other drugs are listed in Table 25–9.

7. Electroconvulsive therapy—ECT causes a generalized central nervous system seizure (peripheral convulsion is not

³Wellbutrin XL is a once-daily form of bupropion. Bupropion is still available as immediate release, and, if used, no single dose should exceed 150 mg.

⁴200 mg twice daily.

SSRIs, serotonin selective reuptake inhibitors.

necessary) by means of electric current. The key objective is to exceed the seizure threshold, which can be accomplished by a variety of means. The mechanism of action is not known, but it is thought to involve major neurotransmitter responses at the cell membrane. Electrical current insufficient to cause a seizure produces no therapeutic benefit.

ECT is the most effective (about 70–85%) treatment of severe depression—particularly the delusions and agitation commonly seen with depression in the elderly. It is indicated when medical conditions preclude the use of antidepressants, nonresponsiveness to these medications, and extreme suicidality. Comparative controlled studies of ECT in severe

Table 25–9. Antidepressant drug interactions with other drugs.

| Drug | Effects |
|---|---|
| Tricyclic and other non-MAOI antidepressants | |
| Antacids | Decreased absorption of antidepressants |
| Anticoagulants | Increased hypoprothrombinemic effect |
| Cimetidine | Increased antidepressant blood levels and psychosis |
| Clonidine | Decreased antihypertensive effect |

| Succinylcholine | Increased neuromuscular blockade |
| Sulfonylureas | Decreased blood sugar |
| Sympathomimetic drugs | Increased blood pressure |

¹Terfenadine, astemizole, and cisapride are not commercially available in the United States. MAOIs, monoamine oxidase inhibitors.

depression show that it is more effective than chemotherapy. It is also effective in the manic disorders and psychoses during pregnancy (when drugs may be contraindicated). It has not been shown to be helpful in chronic schizophrenic disorders, and it is generally not used in acute schizophrenic episodes unless drugs are not effective and it is urgent that the psychosis be controlled (eg, a catatonic stupor complicating an acute medical condition).

The most common side effects are memory disturbance and headache. Memory loss or confusion is usually related to the number and frequency of ECT treatments and proper oxygenation during treatment. Unilateral ECT is associated with less memory loss than bilateral ECT. Some memory loss is occasionally permanent, but most memory faculties return to full capacity within several weeks. There have been reports that lithium administration concurrent with ECT resulted in greater memory loss.

Increased intracranial pressure is a serious contraindication. Other problems such as cardiac disorders, aortic aneurysms, bronchopulmonary disease, and venous thrombosis are relative contraindications and must be evaluated in light of the severity of the medical problem versus the need for ECT. Serious complications arising from ECT occur in less than 1 in 1000 cases. Most of these problems are cardiovascular or respiratory in nature (eg, aspiration of gastric contents). Poor patient understanding and lack of acceptance of the technique by the public are the biggest obstacles to the use of ECT.

8. Phototherapy—Phototherapy is used in major depression with seasonal onset. It consists of exposure (at a 3-foot distance) to a light source of 2500 lux for 2 hours daily. Light visors are an adaptation that provides greater mobility and an adjustable light intensity. The dosage varies, with some patients requiring morning and night exposure. One effect is alteration of biorhythm through melatonin mechanisms.

9. Experimental treatments—In preliminary studies, transcranial magnetic stimulation appears to be effective in nonpsychotic depression. Its use in this condition has been approved by the FDA for individuals who have not responded to an antidepressant. It is usually delivered in a course of 16–20 sessions over 1 month. Vagal nerve stimulation has shown some promise in extremely refractory cases and is approved by the FDA but has not been approved by many insurers.

B. Psychological

It is seldom possible to engage an individual in penetrating psychotherapeutic endeavors during the acute stage of a severe depression. While medications may be taking effect, a supportive approach to strengthen existing coping mechanisms and appropriate consideration of the patient's continuing need to function at work, to engage in recreational activities, etc, are necessary as the severity of the depression lessens. If the patient is not seriously depressed, it is often quite appropriate to initiate intensive psychotherapeutic efforts, since flux periods are a good time to effect change. A catharsis of repressed anger and guilt may be beneficial.

Therapy during or just after the acute stage may focus on coping techniques, with some practice of alternative choices. Depression-specific psychotherapies help improve self-esteem, increase assertiveness, and lessen dependency. Interpersonal psychotherapy for depression has shown efficacy in the treatment of acute depression, helping patients master interpersonal stresses and develop new coping strategies. Cognitive behavioral therapy for depression addresses patients' patterns of negative thoughts, called cognitive distortions, that lead to feelings of depression and anxiety. Treatment usually includes homework assignments such as keeping a journal of cognitive distortions and of positive responses to them. As previously noted, numerous studies have shown that the combination of drug therapy plus interpersonal psychotherapy or cognitive behavioral therapy is more effective than either modality alone. It is usually helpful to involve the spouse or other significant family members early in treatment. Mindfulness-based cognitive therapy is a new form of therapy that has reduced relapse rates in several randomized controlled trials. In one study, it was as effective as maintenance medication in preventing relapse. This therapy incorporates meditation and teaches patients to distance themselves from depressive thinking.

C. Social

Flexible use of appropriate social services can be of major importance in the treatment of depression. Since alcohol is often associated with depression, early involvement in alcohol treatment programs such as Alcoholics Anonymous can be important to future success (see Alcohol Dependency and Abuse, below). The structuring of daily activities during severe depression is often quite difficult for the patient, and loneliness is often a major factor. The help of family, employer, or friends is often necessary to mobilize the patient who experiences no joy in daily activities and tends to remain uninvolved and to deteriorate. Insistence on sharing activities will help involve the patient in simple but important daily functions. In some severe cases, the use of day treatment centers or support groups of a specific type (eg, mastectomy groups) is indicated. It is not unusual for a patient to have multiple legal, financial, and vocational problems requiring legal and vocational assistance.

D. Behavioral

When depression is a function of self-defeating coping techniques such as passivity, the role-playing approach can be useful. Behavioral techniques, including desensitization, may be used in problems such as phobias where depression is a by-product. When depression is a regularly used interpersonal style, behavioral counseling to family members or others can help in extinguishing the behavior in the patient.

► Treatment of Mania

Acute manic or hypomanic symptoms will respond to lithium or valproic acid after several days of treatment, but it is increasingly common to use atypical neuroleptics as adjunctive treatment or monotherapy. High-potency benzodiazepines (eg, clonazepam) may also be useful adjuncts

in managing acute cases. Some schizoaffective disorders and some cases of so-called schizophrenia are probably atypical bipolar affective disorder, for which lithium treatment may be effective.

A. Neuroleptics

Acute manic symptoms of agitation and psychosis may be treated initially with the atypical antipsychotic olanzapine, (eg, 5–20 mg orally), risperidone (2–3 mg orally), or aripiprazole (15–30 mg) in conjunction with a benzodiazepine if indicated. Alternatively, when behavioral control is immediately necessary, olanzapine in an injectable form (2.5–10 mg intramuscularly) or haloperidol, 5–10 mg orally or intramuscularly repeated as needed until symptoms subside, may be used. The dosage of the neuroleptic may be gradually reduced after lithium or another mood stabilizer is started (see below). Olanzapine is approved as a maintenance treatment for bipolar disorder.

B. Clonazepam

Clonazepam can be an alternative or adjunct to a neuroleptic in controlling acute behavioral symptoms. Clonazepam has the advantage of causing no extrapyramidal side effects. Although 1–2 mg orally every 4–6 hours may be effective, up to 16 mg/d may be necessary.

C. Lithium

As a prophylactic drug for bipolar affective disorder, lithium significantly decreases the frequency and severity of both manic and depressive attacks in about 70% of patients. A positive response is more predictable if the patient has a low frequency of episodes (no more than two per year with intervals free of psychopathology). A positive response occurs more frequently in individuals who have blood relatives with a diagnosis of manic or hypomanic attacks. Patients who swing rapidly back and forth between manic and depressive attacks (at least four cycles per year) usually respond poorly to lithium prophylaxis initially, but some improve with continued long-term treatment. Carbamazepine (see below) has been used with success in this group.

In addition to its use in manic states, lithium is sometimes useful in the prophylaxis of recurrent unipolar depressions (perhaps undiagnosed bipolar disorder). Lithium may ameliorate nonspecific aggressive behaviors and dyscontrol syndromes. The dosages are the same as used in bipolar disorder. Most patients with bipolar disease can be managed long-term with lithium alone, although some will require continued or intermittent use of a neuroleptic, antidepressant, or carbamazepine. An excellent resource for information is the Lithium Information Center, Madison Institute of Medicine, 7617 Mineral Point Road, Suite 300, Madison, WI 53717-1914, <http://www.miminc.org/aboutlithinfoctr.html>.

Before treatment, the clinical workup should include a medical history and physical examination; complete blood count; T₄, thyroid-stimulating hormone, blood urea nitrogen (BUN), serum creatinine, and serum electrolyte determinations; urinalysis; and electrocardiography in patients over age 45 or with a history of cardiac disease.

1. Dosage—The common starting dosage of lithium carbonate is 300 mg two or three times daily, with trough blood levels measured after 5 days of treatment. In a small minority of patients, a slow release form or units of different dosage may be required. Lithium citrate is available as a syrup. The dosage is that required to maintain blood levels in the therapeutic range. For acute attacks, this ranges from 1 to 1.5 mEq/L. Although there is controversy about the optimal long-term maintenance dose, many clinicians reduce the acute level to 0.6–1 mEq/L in order to reduce side effects. The dose required to meet this need will vary in different individuals. For acute mania, doses of 1200–1800 mg/d are generally recommended. Augmentation of antidepressants is usually achieved with half of these doses. Once-a-day dosage is acceptable, but most patients have less nausea when they take the drug in divided doses with meals.

Lithium is readily absorbed, with peak serum levels occurring within 1–3 hours and complete absorption in 8 hours. Half of the total body lithium is excreted in 18–24 hours (95% in the urine). Blood for lithium levels should be drawn 12 hours after the last dose. Serum levels should be measured 5–7 days after initiation of treatment and changes in dose. For maintenance treatment, lithium levels should be monitored initially every 1–2 months but may be measured every 6–12 months in stable, long-term patients. Levels should be monitored more closely when there is any condition that causes volume depletion (eg, diarrhea, dehydration, use of diuretics).

2. Side effects—Mild gastrointestinal symptoms (take lithium with food and in divided doses), fine tremors (treat with propranolol, 20–60 mg/d orally, only if persistent), slight muscle weakness, and some degree of somnolence are early side effects that are usually transient. Moderate polyuria (reduced renal responsiveness to ADH) and polydipsia (associated with increased plasma renin concentration) are often present. Potassium administration can blunt this effect, as may once-daily dosing of lithium. Weight gain (often a result of calories in fluids taken for polydipsia) and leukocytosis not due to infection are fairly common.

Other side effects include goiter (3%; often euthyroid), hypothyroidism (10%; concomitant administration of lithium and iodide or lithium and carbamazepine enhances the hypothyroid and goitrogenic effect of either drug), changes in the glucose tolerance test toward a diabetes-like curve, nephrogenic diabetes insipidus (usually resolving about 8 weeks after cessation of lithium therapy), nephrotic syndrome, edema, folate deficiency, and pseudotumor cerebri (ophthalmoscopy is indicated if there are complaints of headache or blurred vision). A metallic taste, hair loss, and Raynaud phenomenon have been reported in a few cases. Thyroid and kidney function should be checked at 3- to 4-month intervals. Most of these side effects subside when lithium is discontinued; when residual side effects exist, they are usually not serious. Most clinicians treat lithium-induced hypothyroidism (more common in women) with thyroid hormone while continuing lithium therapy. Hypercalcemia and elevated parathyroid hormone levels occur in some patients. Electrocardiographic abnormalities (principally T wave flattening or inversion) may occur during

lithium administration but are not of major clinical significance. Sinoatrial block may occur, particularly in the elderly. Other drugs that prolong intraventricular conduction, such as TCAs, must be used cautiously in conjunction with lithium. Lithium impairs ventilatory function in patients with airway obstruction. Lithium alone does not have a significant effect on sexual function, but when combined with benzodiazepines (clonazepam in most symptomatic patients) it causes sexual dysfunction in about 50% of men. Lithium may precipitate or exacerbate psoriasis in some patients.

Patients receiving long-term lithium therapy may have cogwheel rigidity and, occasionally, other extrapyramidal signs. Lithium potentiates the parkinsonian effects of haloperidol. Long-term lithium therapy has also been associated with a relative lowering of the level of memory and perceptual processing (affecting compliance in some cases). Some impairment of attention and emotional reactivity has also been noted. Lithium-induced delirium with therapeutic lithium levels is an infrequent complication usually occurring in the elderly and may persist for several days after serum levels have become negligible. Encephalopathy has occurred in patients receiving combined lithium and neuroleptic therapy and in those who have cerebrovascular disease, thus requiring careful evaluation of patients who develop neurotoxic signs at subtoxic blood levels.

Some reports have suggested that the long-term use of lithium may have adverse effects on kidney function (with interstitial fibrosis or tubular atrophy). A rise in serum creatinine levels is an indication for in-depth evaluation of kidney function and consideration of alternative treatments if the individual can tolerate a change. Incontinence has been reported in women, apparently related to changes in bladder cholinergic-adrenergic balance.

Prospective studies suggest that the overall risk imposed by lithium in pregnancy may be overemphasized. However, lithium exposure in early pregnancy does increase the frequency of congenital anomalies, especially Ebstein and other major cardiovascular anomalies. For women who take psychotropic medications who become pregnant, the decision to make a change in medication is complex and requires informed consent regarding the relative risks to the patient and fetus. Indeed, the risk of untreated bipolar disorder carries its own risks for pregnancy. Formula feeding should be considered in mothers taking lithium, since concentration in breast milk is one-third to half that in serum.

Frank toxicity usually occurs at blood lithium levels above 2 mEq/L. Because sodium and lithium are reabsorbed at the same loci in the proximal renal tubules, any sodium loss (diarrhea, use of diuretics, or excessive perspiration) results in increased lithium levels. Symptoms and signs include vomiting and diarrhea, the latter exacerbating the problem since more sodium is lost and more lithium is absorbed. Other symptoms and signs, some of which may not be reversible, include tremors, marked muscle weakness, confusion, dysarthria, vertigo, choreoathetosis, ataxia, hyperreflexia, rigidity, lack of coordination, myoclonus, seizures, opisthotonos, and coma. Toxicity is more severe in the elderly, who should be maintained on slightly lower

serum levels. Lithium overdosage may be accidental or intentional or may occur as a result of poor monitoring.

Patients with massive ingestions of lithium or blood lithium levels above 2.5 mEq/L should be treated with induced emesis and gastric lavage. If kidney function is normal, osmotic and saline diuresis increases renal lithium clearance. Urinary alkalization is also helpful, since sodium bicarbonate decreases lithium reabsorption in the proximal tubule, as does acetazolamide as well. Aminophylline potentiates the diuretic effect by increasing the clearance of lithium. Drugs affecting the distal loop have no effect on lithium reabsorption. Blood lithium levels above 2.5 mEq/L (confirmed by cerebrospinal fluid lithium levels) should be considered an indication for hemodialysis.

Compliance with lithium therapy is adversely affected by the loss of some hypomanic experiences valued by the patient. These include social extroversion and a sense of heightened enjoyment in many activities such as sex and business dealings, often with increased productivity in the latter.

3. Drug interactions—Patients receiving lithium should use diuretics with caution and only under close medical supervision. The thiazide diuretics cause increased lithium reabsorption from the proximal renal tubules, resulting in increased serum lithium levels (Table 25–10), and adjustment of lithium intake must be made to compensate for this. Reduce lithium dosage by 25–40% when the patient is receiving 50 mg of hydrochlorothiazide daily. Potassium-sparing diuretics (spironolactone, amiloride, triamterene) may also increase serum lithium levels and require careful monitoring of lithium levels. Loop diuretics (furosemide, ethacrynic acid, bumetanide) do not appear to alter serum

lithium levels. Concurrent use of lithium and angiotensin-converting enzyme inhibitors requires a 50–75% reduction in lithium intake to achieve therapeutic lithium levels.

D. Valproic Acid

Valproic acid (divalproex) is an antiseizure drug whose activity is at least partially related to GABA neurotransmission. It is a first-line treatment for mania because it has a broader index of safety than lithium. This issue is particularly important in AIDS or other medically ill patients prone to dehydration or malabsorption with wide swings in serum lithium levels. Valproic acid has also been used effectively in panic disorder and migraine headache. Treatment is often started at a dose of 750 mg/d orally in divided doses, and dosage is then titrated to achieve therapeutic serum levels. Oral loading in acutely manic bipolar patients in an inpatient setting (initiated at a dosage of 20 mg/kg/d) can safely achieve serum therapeutic levels in 2–3 days. Concomitant use of aspirin, carbamazepine, warfarin, or phenytoin may affect serum levels. Gastrointestinal symptoms and weight gain are the main side effects. Liver function tests, complete blood counts, glucose levels, and weight should be monitored, and significant teratogenic effects are a concern so pregnancy should be ruled out prior to initiation.

E. Carbamazepine

Carbamazepine, an antiseizure drug that stabilizes the activity of cell membranes, has been used with increasing frequency in the treatment of bipolar patients who cannot be satisfactorily treated with lithium (nonresponsive, excessive side effects, or rapid cycling). It is often effective at 800–1600 mg/d orally. It has also been used in the treatment of resistant depressions, alcohol withdrawal, and hallucinations (in conjunction with neuroleptics) and in patients with behavioral dyscontrol or panic attacks. It suppresses some phases of kindling (see Stimulants) and has been used to treat residual symptoms in previous stimulant abusers (eg, PTSD with impulse control problems). Dose-related side effects include sedation and ataxia. Dosages start at 400–600 mg orally daily and are increased slowly to therapeutic levels. Skin rashes and a mild reduction in white count are common. SIADH occurs rarely. Nonsteroidal anti-inflammatory drugs (except aspirin), the antibiotics erythromycin and isoniazid, the calcium channel blockers verapamil and diltiazem (but not nifedipine), fluoxetine, propoxyphene, and cimetidine all increase carbamazepine levels. Carbamazepine can be effective in conjunction with lithium, although there have been reports of reversible neurotoxicity with the combination. Carbamazepine stimulates hepatic microsomal enzymes and so tends to decrease levels of haloperidol and oral contraceptives. It also lowers T_4 , free T_4 , and T_3 levels. Cases of fetal malformation (particularly spina bifida) have been reported along with growth deficiency and developmental delay. Liver tests and complete blood counts should be monitored in patients taking carbamazepine. **Oxcarbazepine**, a derivative of carbamazepine, does not appear to induce its own metabolism and is associated with fewer drug interactions, although it may impose a higher risk of hyponatremia. FDA-approved for partial seizures,

Table 25–10. Lithium interactions with other drugs.

| Drug | Effects |
|--|---|
| ACE inhibitors | ↑ Lithium levels |
| Fluoxetine | ↑ Lithium levels |
| Ibuprofen | ↑ Lithium levels |
| Indomethacin | ↑ Lithium levels |
| Methyl dopa | Rigidity, mutism, fascicular twitching |
| Osmotic diuretics (urea, mannitol) | ↑ Lithium excretion |
| Phenylbutazone | ↑ Lithium levels |
| Potassium-sparing diuretics (spironolactone, amiloride, triamterene) | ↑ Lithium levels |
| Sodium bicarbonate | ↑ Lithium excretion |
| Succinylcholine | ↑ Duration of action of succinylcholine |
| Theophylline, aminophylline | ↑ Lithium excretion |
| Thiazide diuretics | ↑ Lithium levels |
| Valproic acid | ↓ Lithium levels |
| COX-2 inhibitors | ↑ Lithium levels |

ACE, angiotensin-converting enzyme; COX-2, cyclooxygenase-2.

oxcarbazepine may have efficacy in acute mania. It appears to be a safer alternative to carbamazepine due to its lower risk of hepatotoxicity.

F. Lamotrigine

Lamotrigine is thought to inhibit neuronal sodium channels and the release of the excitatory amino acids, glutamate and aspartate. It is FDA approved for long-term maintenance of bipolar disorder. Two double-blind studies support its efficacy in the treatment of acute bipolar depression as adjunctive therapy or as monotherapy. Its metabolism is inhibited by coadministration of valproic acid—doubling its half-life—and accelerated by hepatic enzyme-inducing agents such as carbamazepine. More frequent mild side effects include headache, dizziness, nausea, and diplopia. Rash occurring in 10% of patients is an indication for immediate cessation of dosing, since lamotrigine has been associated with Stevens-Johnson syndrome (1:1000) and, rarely, toxic epidermal necrolysis. Dosing starts at 25–50 mg/d orally and is titrated upward slowly to decrease the likelihood of rash. Slower titration and a lower total dose are indicated for patients taking valproic acid.

G. Calcium Channel Blockers

Calcium channel blockers (eg, verapamil) have been used in bipolar states that have failed to respond to lithium, carbamazepine, or valproic acid. This has come about with the realization that a number of drugs used in psychiatry (eg, lithium, antidepressants, neuroleptics, and carbamazepine) have calcium channel-blocking activity. Verapamil may be safer than lithium or carbamazepine during pregnancy, although it decreases uterine contractility and must be discontinued before delivery.

► Prognosis

Reactive depressions are usually time-limited, and the prognosis with treatment is good if a pathologic pattern of adjustment does not intervene. Major affective disorders frequently respond well to a full trial of drug treatment.

Mania and bipolar disorder have a good prognosis with adequate treatment, although patient adherence to treatment is often quite challenging.

SLEEP DISORDERS

Sleep consists of two distinct states as shown by electroencephalographic studies: (1) REM (rapid eye movement) sleep, also called dream sleep, D state sleep, paradoxical sleep, and (2) NREM (non-REM) sleep, also called S stage sleep, which is divided into stages 1, 2, 3, and 4 and is recognizable by different electroencephalographic patterns. Stages 3 and 4 are “delta” sleep. Dreaming occurs mostly in REM and to a lesser extent in NREM sleep.

Sleep is a cyclic phenomenon, with four or five REM periods during the night accounting for about one-fourth of the total night's sleep (1.5–2 hours). The first REM period occurs about 80–120 minutes after onset of sleep and lasts about 10 minutes. Later REM periods are longer (15–40 minutes) and occur mostly in the last several hours of sleep. Most stage 4 (deepest) sleep occurs in the first several hours.

Age-related changes in normal sleep include an unchanging percentage of REM sleep and a marked decrease in stage 3 and stage 4 sleep, with an increase in wakeful periods during the night. These normal changes, early bedtimes, and daytime naps play a role in the increased complaints of insomnia in older people. Variations in sleep patterns may be due to circumstances (eg, “jet lag”) or to idiosyncratic patterns (“night owls”) in persons who perhaps because of different “biologic rhythms” habitually go to bed late and sleep late in the morning. Creativity and rapidity of response to unfamiliar situations are impaired by loss of sleep. There are also rare individuals who have chronic difficulty in adapting to a 24-hour sleep-wake cycle (desynchronization sleep disorder), which can be resynchronized by altering exposure to light.

The three major sleep disorders are discussed below.

1. Dyssomnias (Insomnia)

► Classification & Clinical Findings

Patients may complain of difficulty getting to sleep or staying asleep, intermittent wakefulness during the night, early morning awakening, or combinations of any of these. Transient episodes are usually of little significance. Stress, caffeine, physical discomfort, daytime napping, and early bedtimes are common factors.

Psychiatric disorders are often associated with persistent insomnia. **Depression** is usually associated with fragmented sleep, decreased total sleep time, earlier onset of REM sleep, a shift of REM activity to the first half of the night, and a loss of slow wave sleep—all of which are nonspecific findings. In **manic disorders**, sleeplessness is a cardinal feature and an important early sign of impending mania in bipolar cases. Total sleep time is decreased, with shortened REM latency and increased REM activity. Sleep-related panic attacks occur in the transition from stage 2 to stage 3 sleep in some patients with a longer REM latency in the sleep pattern preceding the attacks.

Abuse of alcohol may cause or be secondary to the sleep disturbance. There is a tendency to use alcohol as a means of getting to sleep without realizing that it disrupts the normal sleep cycle. Acute alcohol intake produces a decreased sleep latency with reduced REM sleep during the first half of the night. REM sleep is increased in the second half of the night, with an increase in total amount of slow wave sleep (stages 3 and 4). Vivid dreams and frequent awakenings are common. Chronic alcohol abuse increases stage 1 and decreases REM sleep (most drugs delay or block REM sleep), with symptoms persisting for many months after the individual has stopped drinking. Acute alcohol or other sedative withdrawal causes delayed onset of sleep and REM rebound with intermittent awakening during the night.

Heavy smoking (more than a pack a day) causes difficulty falling asleep—apparently independently of the often associated increase in coffee drinking. Excess intake near bedtime of caffeine, cocaine, and other stimulants (eg, over-the-counter cold remedies) causes decreased total sleep time—mostly NREM sleep—with some increased sleep latency.

Sedative-hypnotics—specifically, the benzodiazepines, which are the most commonly prescribed drugs to promote sleep—tend to increase total sleep time, decrease sleep latency, and decrease nocturnal awakening, with variable effects on NREM sleep. Withdrawal causes just the opposite effects and results in continued use of the drug for the purpose of preventing withdrawal symptoms. Antidepressants decrease REM sleep (with marked rebound on withdrawal in the form of nightmares) and have varying effects on NREM sleep. The effect on REM sleep correlates with reports that REM sleep deprivation produces improvement in some depressions.

Persistent insomnias are also related to a wide variety of medical conditions, particularly delirium, pain, respiratory distress syndromes, uremia, asthma, and thyroid disorders. Adequate analgesia and proper treatment of medical disorders will reduce symptoms and decrease the need for sedatives.

► Treatment

In general, there are two broad classes of treatment for insomnia, and the two may be combined: psychological (cognitive-behavioral) and pharmacologic. In situations of acute distress, such as a grief reaction, pharmacologic measures may be most appropriate. With primary insomnia, however, initial efforts should be psychologically

based. This is particularly true in the elderly to avoid the potential adverse reactions of medications. The elderly population is at risk for complaints of insomnia because sleep becomes lighter and more easily disrupted with aging. Medical disorders that become more common with age may also predispose to insomnia.

A. Psychological

Psychological strategies should include educating the patient regarding good sleep hygiene: (1) Go to bed only when sleepy. (2) Use the bed and bedroom only for sleeping and sex. (3) If still awake after 20 minutes, leave the bedroom and only return when sleepy. (4) Get up at the same time every morning regardless of the amount of sleep during the night. (5) Discontinue caffeine and nicotine, at least in the evening if not completely. (6) Establish a daily exercise regimen. (7) Avoid alcohol as it may disrupt continuity of sleep. (8) Limit fluids in the evening. (9) Learn and practice relaxation techniques. A recent study suggests that cognitive behavioral therapy for insomnia was as effective as zolpidem with benefits sustained 1 year after treatment.

B. Medical

When the above measures are insufficient, medications may be useful. Pharmacologic measures currently rely primarily on safe hypnotic medications that are difficult to overdose with. Lorazepam (0.5 mg orally nightly), temazepam (7.5–15 mg orally nightly) and the nonbenzodiazepine hypnotics, zolpidem (5–10 mg orally nightly), and zaleplon (5–10 mg orally nightly), are often effective for the elderly population and can be given in larger doses—twice what is prescribed for the elderly—in younger patients. A nonbenzodiazepine hypnotic, eszopiclone (2–3 mg), is similar in action to zolpidem and zaleplon but dissimilar in that it is not restricted to short-term use. A lower dose of 1 mg is indicated in the elderly or those with hepatic impairment. It is important to note that short-acting agents like triazolam or zolpidem may lead to amnesic episodes if used on a daily ongoing basis. Longer-acting agents such as flurazepam (half-life of > 48 hours) may accumulate in the elderly and lead to cognitive slowing, ataxia, falls, and somnolence. In general, it is appropriate to use medications for short courses of 1–2 weeks. The medications described above have largely replaced barbiturates as hypnotic agents because of their greater safety in overdose and their lesser hepatic enzyme induction effects. Antihistamines such as diphenhydramine (25 mg nightly) or hydroxyzine (25 mg nightly) may also be useful for sleep, as they produce no pharmacologic dependency; their anticholinergic effects may, however, produce confusion or urinary symptoms in the elderly. Trazodone, an atypical antidepressant, is a non-habit-forming, effective sleep medication in lower than antidepressant doses (25–150 mg at bedtime). Priapism is a rare side effect requiring emergent treatment. Ramelteon, 8 mg orally at bedtime, is a melatonin receptor agonist that helps with sleep onset and does not appear to have abuse potential. It appears to be safe for ongoing use without the development of tolerance.

Triazolam has achieved popularity as a hypnotic drug because of its very short duration of action. However, because it has been associated with dependency, transient psychotic reactions, anterograde amnesia, and rebound anxiety, it has been removed from the market in several European countries. If used, it must be prescribed only for short periods of time.

2. Hypersomnias (Disorders of Excessive Sleepiness)

The hypersomnias are a more severe problem than insomnia.

► Classification & Clinical Findings

A. Sleep Apnea

This disorder is characterized by cessation of breathing for at least 30 episodes (each lasting about 10 seconds) during the night. There are two types: obstructive and central. (See Chapter 9.)

B. Narcolepsy

Narcolepsy consists of a tetrad of symptoms: (1) Sudden, brief (about 15 minutes) sleep attacks that may occur during any type of activity; (2) cataplexy—sudden loss of muscle tone involving specific small muscle groups or generalized muscle weakness that may cause the person to slump to the floor, unable to move, often associated with emotional reactions and sometimes confused with seizure disorder; (3) sleep paralysis—a generalized flaccidity of muscles with full consciousness in the transition zone between sleep and waking; and (4) hypnagogic hallucinations, visual or auditory, which may precede sleep or occur during the sleep attack. The attacks are characterized by an abrupt transition into REM sleep—a necessary criterion for diagnosis. The disorder begins in early adult life, affects both sexes equally, and usually levels off in severity at about 30 years of age.

REM sleep behavior disorder, characterized by motor dyscontrol and often violent dreams during REM sleep, may be related to narcolepsy.

C. Kleine-Levin Syndrome

This syndrome, which occurs mostly in young men, is characterized by hypersomnic attacks three or four times a year lasting up to 2 days, with hyperphagia, hypersexuality, irritability, and confusion on awakening. It has often been associated with antecedent neurologic insults. It usually remits after age 40.

D. Nocturnal Myoclonus

Periodic lower leg movements occur during sleep with subsequent daytime sleepiness, anxiety, depression, and cognitive impairment.

► Treatment

Narcolepsy can be managed by daily administration of a stimulant such as dextroamphetamine sulfate, 10 mg orally

in the morning, with increased dosage as necessary. Modafinil is a schedule IV medication FDA-approved for treating the excessive daytime fatigue of narcolepsy. Usual dosing is 200 mg orally each morning. Its mechanism of action is unknown, yet it is thought to be less of an abuse risk than stimulants that are primarily dopaminergic. Common side effects include headache and anxiety; however, modafinil appears to be generally well tolerated. Modafinil may reduce the efficacy of cyclosporine, oral contraceptives, and other medications by inducing their hepatic metabolism. Imipramine, 75–100 mg orally daily, has been effective in treatment of cataplexy but not narcolepsy.

Nocturnal myoclonus and REM sleep behavior disorder can be treated with clonazepam with variable results. There is no treatment for Kleine-Levin syndrome.

Treatment of sleep apnea is discussed in Chapter 9.

3. Parasomnias (Abnormal Behaviors during Sleep)

These disorders are fairly common in children and less so in adults.

► Classification & Clinical Findings

A. Sleep Terror

Sleep terror (*pavor nocturnus*) is an abrupt, terrifying arousal from sleep, usually in preadolescent boys although it may occur in adults as well. It is distinct from sleep panic attacks. Symptoms are fear, sweating, tachycardia, and confusion for several minutes, with amnesia for the event.

B. Nightmares

Nightmares occur during REM sleep; sleep terrors in stage 3 or stage 4 sleep.

C. Sleepwalking

Sleepwalking (*somnambulism*) includes ambulation or other intricate behaviors while still asleep, with amnesia for the event. It affects mostly children aged 6–12 years, and episodes occur during stage 3 or stage 4 sleep in the first third of the night and in REM sleep in the later sleep hours. Sleepwalking in elderly people may be a feature of dementia. Idiosyncratic reactions to drugs (eg, marijuana, alcohol) and medical conditions (eg, partial complex seizures) may be causative factors in adults.

D. Enuresis

Enuresis is involuntary micturition during sleep in a person who usually has voluntary control. Like other parasomnias, it is more common in children, usually in the 3–4 hours after bedtime, but is not limited to a specific stage of sleep. Confusion during the episode and amnesia for the event are common.

► Treatment

Treatment for sleep terrors is with benzodiazepines (eg, diazepam, 5–20 orally mg at bedtime), since it will sup-

press stage 3 and stage 4 sleep. Somnambulism responds to the same treatment for the same reason, but simple safety measures should not be neglected. Enuresis may respond to imipramine, 50–100 mg orally at bedtime, although desmopressin nasal spray (an ADH preparation) has increasingly become the treatment of choice for nocturnal enuresis. Behavioral approaches (eg, bells that ring when the pad gets wet) have also been successful.

DISORDERS OF AGGRESSION

Aggression and violence are symptoms rather than diseases, and most frequently they are not associated with an underlying medical condition. Clinicians are unable to predict dangerous behavior with greater than chance accuracy. Depression, schizophrenia, personality disorders, mania, paranoia, temporal lobe dysfunction, and organic mental states may be associated with acts of aggression. Impulse control disorders are characterized by physical abuse (usually of the aggressor's domestic partner or children), by pathologic intoxication, by impulsive sexual activities, and by reckless driving. Anabolic steroid usage by athletes has been associated with increased tendencies toward violent behavior.

In the United States, a significant proportion of all violent deaths are alcohol-related. The ingestion of even small amounts of alcohol can result in pathologic intoxication that resembles an acute organic mental condition. Amphetamines, crack cocaine, and other stimulants are frequently associated with aggressive behavior. Phencyclidine is a drug commonly associated with violent behavior that is occasionally of a bizarre nature, partly due to lowering of the pain threshold. Domestic violence and rape are much more widespread than previously recognized. Awareness of the problem is to some degree due to increasing recognition of the rights of women and the understanding by women that they do not have to accept abuse. Acceptance of this kind of aggressive behavior inevitably leads to more, with the ultimate aggression being murder—20–50% of murders in the United States occur within the family. Police are called in more domestic disputes than all other criminal incidents combined. Children living in such family situations frequently become victims of abuse.

Features of individuals who have been subjected to long-term physical or sexual abuse are as follows: trouble expressing anger, staying angry longer, general passivity in relationships, feeling “marked for life” with an accompanying feeling of deserving to be victimized, lack of trust, and dissociation of affect from experiences. They are prone to express their psychological distress with somatization symptoms, often pain complaints. They may also have

symptoms related to posttraumatic stress, as discussed above. The clinician should be suspicious about the origin of any injuries not fully explained, particularly if such incidents recur.

► Treatment

A. Psychological

Management of any violent individual includes appropriate psychological maneuvers. Move slowly, talk slowly with clarity and reassurance, and evaluate the situation. Strive to create a setting that is minimally disturbing, and eliminate people or things threatening to the violent individual. Do not threaten or abuse, and do not touch or crowd the person. Allow no weapons in the area (an increasing problem in hospital emergency departments). Proximity to a door is comforting to both the patient and the examiner. Use a negotiator the violent person can relate to comfortably. Food and drink are helpful in defusing the situation (as are cigarettes for those who smoke). Honesty is important. Make no false promises, bolster the patient's self-esteem, and continue to engage the subject verbally until the situation is under control. This type of individual does better with strong external controls to replace the lack of inner controls over the long term. Close probationary supervision and judicially mandated restrictions can be most helpful. There should be a major effort to help the individual avoid drug use (eg, Alcoholics Anonymous). Victims of abuse are essentially treated as any victim of trauma and, not infrequently, have evidence of PTSD.

B. Pharmacologic

Pharmacologic means are often necessary whether or not psychological approaches have been successful. This is particularly true in the agitated or psychotic patient. The drug of choice in psychotic aggressive states is haloperidol, 5–10 mg intramuscularly every hour until symptoms are alleviated. Benzodiazepine sedatives (eg, diazepam, 5 mg orally or intravenously every several hours) can be used for mild to moderate agitation, but an antipsychotic drug is preferred for management of the seriously violent and psychotic patient. Chronic aggressive states, particularly in retardation and brain damage (rule out causative organic conditions and medications such as anticholinergic drugs in amounts sufficient to cause confusion), have been ameliorated with risperidone, 0.5–2 mg/d orally, propranolol, 40–240 mg/d orally, or pindolol, 5 mg twice daily orally (pindolol causes less bradycardia and hypotension). Carbamazepine and valproic acid are effective in the treatment of aggression and explosive disorders, particularly when associated with known or suspected brain lesions. Lithium and SSRIs are also effective for some intermittent explosive outbursts. Buspirone (10–45 mg/d orally) is helpful for aggression, particularly in mentally retarded patients.

C. Physical

Physical management is necessary if psychological and pharmacologic means are not sufficient. It requires the active and visible presence of an adequate number of

personnel (five or six) to reinforce the idea that the situation is under control despite the patient's lack of inner controls. Such an approach often precludes the need for actual physical restraint. When adequate personnel are not available, however, two people shielded by a mattress (single-bed size) can usually corner and subdue the patient without injury to anyone. Seclusion rooms and restraints should be used only when necessary (ambulatory restraints are an alternative), and the patient must then be observed at frequent intervals. Design of corridors and seclusion rooms is important. Narrow corridors, small spaces, and crowded areas exacerbate the potential for violence in an anxious patient.

D. Other Interventions

The treatment of victims (eg, battered women) is challenging and often complicated by their reluctance to leave the situation. Reasons for staying vary, but common themes include the fear of more violence because of leaving, the hope that the situation may ameliorate (in spite of steady worsening), and the financial aspects of the situation, which are seldom to the woman's advantage. Concerns for the children often finally compel the woman to seek help. An early step is to get the woman into a therapeutic situation that provides the support of others in similar straits. Al-Anon is frequently a valuable asset and quite appropriate when alcohol is a factor. The group can support the victim while she gathers strength to consider alternatives without being paralyzed by fear. Many cities now offer temporary emergency centers and counseling. Use the available resources, attend to any medical or psychiatric problems, and maintain a compassionate interest. Some states now require physicians to report injuries caused by abuse to police authorities.

SUBSTANCE USE DISORDERS (DRUG DEPENDENCY, DRUG ABUSE)

The term “drug dependency” is used in a broad sense here to include both addictions and habituations. It involves the triad of compulsive drug use referred to as drug addiction, which includes: (1) a **psychological dependence** or craving and the behavior involved in procurement of the drug; (2) **physiologic dependence**, with withdrawal symptoms on discontinuance of the drug; and (3) **tolerance**, ie, the need to increase the dose to obtain the desired effects. Drug dependency is a function of the amount of drug used and the duration of usage. The amount needed to produce

dependency varies with the nature of the drug and the idiosyncratic nature of the user. The frequency of use is usually daily, and the duration is inevitably greater than 2–3 weeks. Polydrug abuse is very common. Transgenerational continuity of drug abuse is also common.

There is accumulating evidence that an impairment syndrome exists in many former (and current) drug users. It is believed that drug use produces damaged neurotransmitter receptor sites and that the consequent imbalance produces symptoms that may mimic other psychiatric illnesses. “**Kindling**”—repeated stimulation of the brain—renders the individual more susceptible to focal brain activity with minimal stimulation. Stimulants and depressants can produce kindling, leading to relatively spontaneous effects no longer dependent on the original stimulus. These effects may be manifested as mood swings, panic, psychosis, and occasionally overt seizure activity. The imbalance also results in frequent job changes, marital problems, and generally erratic behavior. Patients with PTSD frequently have treated themselves with a variety of drugs. Chronic abusers of a wide variety of drugs exhibit cerebral atrophy on CT scans, a finding that may relate to the above symptoms. Early recognition is important, mainly to establish realistic treatment programs that are chiefly symptom-directed.

The clinician faces three problems with substance abuse: (1) the prescribing of substances such as sedatives, stimulants, or opioids that might produce dependency; (2) the treatment of individuals who have already abused drugs, most commonly alcohol; and (3) the detection of illicit drug use in patients presenting with psychiatric symptoms. The usefulness of urinalysis for detection of drugs varies markedly with different drugs and under different circumstances (pharmacokinetics is a major factor). Water-soluble drugs (eg, alcohol, stimulants, opioids) are eliminated in a day or so. Lipophilic substances (eg, barbiturates, tetrahydrocannabinol) appear in the urine over longer periods of time: several days in most cases, 1–2 months in chronic marijuana users. Sedative drug determinations are quite variable, amount of drug and duration of use being important determinants. False-positives can be a problem related to ingestion of some legitimate drugs (eg, phenytoin for barbiturates, phenylpropanolamine for amphetamines, chlorpromazine for opioids) and some foods (eg, poppy seeds for opioids, coca leaf tea for cocaine). Manipulations can alter the legitimacy of the testing. Dilution, either in vivo or in vitro, can be detected by checking urine specific gravity. Addition of ammonia, vinegar, or salt may invalidate the test, but odor and pH determinations are simple. Hair analysis can determine drug use over longer periods, particularly sequential drug-taking patterns. The sensitivity and reliability of such tests are considered good, and the method may be complementary to urinalysis.

ALCOHOL DEPENDENCY & ABUSE (Alcoholism)

ESSENTIALS OF DIAGNOSIS

Major criteria:

- ▶ Physiologic dependence as manifested by evidence of withdrawal when intake is interrupted.
- ▶ Tolerance to the effects of alcohol.
- ▶ Evidence of alcohol-associated illnesses, such as alcoholic liver disease, cerebellar degeneration.
- ▶ Continued drinking despite strong medical and social contraindications and life disruptions.
- ▶ Impairment in social and occupational functioning.
- ▶ Depression.
- ▶ Blackouts.

Other signs:

- ▶ Alcohol stigmas: alcohol odor on breath, alcoholic facies, flushed face, scleral injection, tremor, echymoses, peripheral neuropathy.
- ▶ Surreptitious drinking.
- ▶ Unexplained work absences.
- ▶ Frequent accidents, falls, or injuries of vague origin; in smokers, cigarette burns on hands or chest.
- ▶ Laboratory tests: elevated values of liver function tests, mean corpuscular volume, serum uric acid, and triglycerides.

▶ General Considerations

Alcoholism is a syndrome consisting of two phases: problem drinking and alcohol addiction. Problem drinking is the repetitive use of alcohol, often to alleviate anxiety or solve other emotional problems. Alcohol addiction is a true addiction similar to that which occurs following the repeated use of other sedative-hypnotics. Alcohol and other drug abuse patients have a much higher prevalence of lifetime psychiatric disorders. While male-to-female ratios in alcoholic treatment agencies remain at 4:1, there is evidence that the rates are converging. Women delay seeking help, and when they do they tend to seek it in medical or mental health settings. Adoption and twin studies indicate some genetic influence. Ethnic distinctions are important—eg, 40% of Japanese have aldehyde dehydrogenase deficiency and are more susceptible to the effects of alcohol. Depression is often present and should be evaluated carefully. The majority of suicides and intrafamily homicides involve alcohol. Alcohol is a major factor in rapes and other assaults.

There are several screening instruments that may help identify alcoholism. One of the most useful is the CAGE questionnaire (see Table 1–10).

▶ Clinical Findings

A. Acute Intoxication

The signs of alcoholic intoxication are the same as those of overdosage with any other central nervous system depressant: drowsiness, errors of commission, psychomotor dysfunction, disinhibition, dysarthria, ataxia, and nystagmus. For a 70-kg person, an ounce of whiskey, a 4- to 6-oz glass of wine, or a 12-oz bottle of beer (roughly 15, 11, and 13 grams of alcohol, respectively) may raise the level of alcohol in the blood by 25 mg/dL. For a 50-kg person, the blood alcohol level would rise even higher (35 mg/dL) with the same consumption. Blood alcohol levels below 50 mg/dL rarely cause significant motor dysfunction (the legal limit for driving under the influence is commonly 80 mg/dL). Intoxication as manifested by ataxia, dysarthria, and nausea and vomiting indicates a blood level above 150 mg/dL, and lethal blood levels range from 350 to 900 mg/dL. In severe cases, overdosage is marked by respiratory depression, stupor, seizures, shock syndrome, coma, and death. Serious overdoses are frequently due to a combination of alcohol with other sedatives.

B. Withdrawal

There is a wide spectrum of manifestations of alcoholic withdrawal, ranging from anxiety, decreased cognition, and tremulousness through increasing irritability and hyperreactivity to full-blown delirium tremens. Symptoms of mild withdrawal, including tremor, elevated vital signs, and anxiety, begin within about 8 hours after the last drink and usually have passed by day 3. Generalized seizures occur within the first 24–38 hours and are more prevalent in persons who have a history of withdrawal syndromes. Delirium tremens is an acute organic psychosis that is usually manifest within 24–72 hours after the last drink (but may occur up to 7–10 days later). It is characterized by mental confusion, tremor, sensory hyperacuity, visual hallucinations (often of snakes, bugs, etc), autonomic hyperactivity, diaphoresis, dehydration, electrolyte disturbances (hypokalemia, hypomagnesemia), seizures, and cardiovascular abnormalities. The acute withdrawal syndrome is often completely unexpected and occurs when the patient has been hospitalized for some unrelated problem and presents as a diagnostic problem. Suspect alcohol withdrawal in every unexplained delirium. The mortality rate from delirium tremens has steadily decreased with early diagnosis and improved treatment.

In addition to the immediate withdrawal symptoms, there is evidence of persistent longer-term ones, including sleep disturbances, anxiety, depression, excitability, fatigue, and emotional volatility. These symptoms may persist for 3–12 months, and in some cases they become chronic.

C. Alcoholic (Organic) Hallucinosi

This syndrome occurs either during heavy drinking or on withdrawal and is characterized by a paranoid psychosis

without the tremulousness, confusion, and clouded sensorium seen in withdrawal syndromes. The patient appears normal except for the auditory hallucinations, which are frequently persecutory and may cause the patient to behave aggressively and in a paranoid fashion.

D. Chronic Alcoholic Brain Syndromes

These encephalopathies are characterized by increasing erratic behavior, memory and recall problems, and emotional instability—the usual signs of organic brain injury due to any cause. Wernicke-Korsakoff syndrome due to thiamine deficiency may develop with a series of episodes. Wernicke encephalopathy consists of the triad of confusion, ataxia, and ophthalmoplegia (typically sixth nerve). Early recognition and treatment with thiamine can minimize damage. One of the possible sequelae is Korsakoff psychosis, characterized by both anterograde and retrograde amnesia, with confabulation early in the course. Early recognition and treatment of the alcoholic with intravenous thiamine and B complex vitamins can minimize damage.

E. Laboratory Findings

Ethanol may contribute to the presence of an otherwise unexplained osmolar gap. There may also be elevated liver function tests, increased serum uric acid and triglycerides, and decreased serum potassium and magnesium. The most definitive biologic marker for chronic alcoholism is carbohydrate deficient transferrin, which can detect heavy use (60 mg/d over 7–10 days) with high specificity. Two other tests that may provide clues to an alcohol problem are γ -glutamyl transpeptidase measurement (levels above 30 units/L are suggestive of heavy drinking) and mean corpuscular volume (> 95 fL in men and > 100 fL in women). If both are elevated, a serious drinking problem is likely. Use of other recreational drugs with alcohol skews and negates the significance of these tests. High-density lipoprotein cholesterol elevations combined with elevated γ -glutamyl transpeptidase concentrations also can help identify heavy drinkers.

► Differential Diagnosis

The differential diagnosis of problem drinking is essentially between primary alcoholism (when no other major psychiatric diagnosis exists) and secondary alcoholism, when alcohol is used as self-medication for major underlying psychiatric problems such as schizophrenia or affective disorder. The differentiation is important, since the latter group requires treatment for the specific psychiatric problem.

The differential diagnosis of alcohol withdrawal includes other sedative withdrawals and other causes of delirium. Acute alcoholic hallucinosis must be differentiated from other acute paranoid states such as amphetamine psychosis or paranoid schizophrenia. The history and laboratory test results are the most important features in differentiating chronic organic brain syndromes due to alcohol from those due to other causes. The form of the brain syndrome is of

little help—eg, chronic brain syndromes from lupus erythematosus may be associated with confabulation similar to that resulting from longstanding alcoholism.

► Complications

The medical, economic, and psychosocial problems of alcoholism are staggering. The central and peripheral nervous system complications include chronic brain syndromes, cerebellar degeneration, cardiomyopathy, and peripheral neuropathies. Direct effects on the liver include cirrhosis, esophageal varices, and eventual hepatic failure. Indirect effects include protein abnormalities, coagulation defects, hormone deficiencies, and an increased incidence of liver neoplasms.

Fetal alcohol syndrome includes one or more of the following developmental defects in the offspring of alcoholic women: (1) low birth weight and small size with failure to catch up in size or weight, (2) mental retardation, with an average IQ in the 60s, and (3) a variety of birth defects, with a large percentage of facial and cardiac abnormalities. The fetuses are very quiet in utero, and there is an increased frequency of breech presentations. There is a higher incidence of delayed postnatal growth and behavior development. The risk is appreciably higher the more alcohol ingested by the mother each day. Cigarette and marijuana smoking as well as cocaine use can produce similar effects on the fetus.

► Treatment of Problem Drinking

A. Psychological

The most important consideration for the clinician is to suspect the problem early and take a nonjudgmental attitude, although this does not mean a passive one. The problem of **denial** must be faced, preferably with significant family members at the first meeting. This means dealing from the beginning with any enabling behavior of the spouse or other significant people. Enabling behavior allows the alcoholic to avoid facing the consequences of his or her behavior.

There must be an emphasis on the things that can be done. This approach emphasizes the fact that the clinician cares and strikes a positive and hopeful note early in treatment. Valuable time should not be wasted trying to find out why the patient drinks; come to grips early with the immediate problem of how to stop the drinking. Although total abstinence should be the ultimate goal, a harm reduction model indicates that gradual progress toward abstinence can be a useful treatment stratagem.

B. Social

Get the patient into Alcoholics Anonymous and the spouse into Al-Anon. Success is usually proportionate to the utilization of Alcoholics Anonymous, religious counseling, and other resources. The patient should be seen frequently for short periods and charged an appropriate fee.

Do not underestimate the importance of religion, particularly since the alcoholic is often a dependent person who needs a great deal of support. Early enlistment of the

help of a concerned religious adviser can often provide the turning point for a personal conversion to sobriety.

One of the most important considerations is the patient's job—fear of losing a job is one of the most powerful motivations for giving up drink. The business community has become painfully aware of the problem, with the result that about 70% of the Fortune 500 companies offer programs to their employees to help with the problem of alcoholism. In the latter case, some specific recommendations to employers can be offered: (1) Avoid placement in jobs where the alcoholic must be alone, eg, as a traveling buyer or sales executive. (2) Use supervision but not surveillance. (3) Keep competition with others to a minimum. (4) Avoid positions that require quick decision making on important matters (high-stress situations). In general, commitment to abstinence and avoidance of situations that might be conducive to drinking are most predictive of a good outcome.

C. Medical

Hospitalization is not usually necessary. It is sometimes used to dramatize a situation and force the patient to face the problem of alcoholism, but generally it should be used for medical indications.

Because of the many medical complications of alcoholism, a complete physical examination with appropriate laboratory tests is mandatory, with special attention to the liver and nervous system. Use of sedatives as a replacement for alcohol is not desirable. The usual result is concomitant use of sedatives and alcohol and worsening of the problem. Lithium is not helpful in the treatment of alcoholism.

Disulfiram (250–500 mg/d orally) has been used for many years as an aversive drug to discourage alcohol use. Disulfiram inhibits alcohol dehydrogenase, causing toxic reactions when alcohol is consumed. The results have generally been of limited effectiveness and depend on the motivation of the individual to be compliant.

Naltrexone, an opiate antagonist, in a dosage of 50 mg orally daily, has been helpful in lowering relapse rates over the 3–6 months after cessation of drinking, apparently by lessening the pleasurable effects of alcohol. One study suggests that naltrexone is most effective when given during periods of drinking in combination with therapy that supports abstinence but accepts the fact that relapses occur. Naltrexone is FDA-approved for maintenance therapy. Studies indicate that it reduces alcohol craving when used as part of a comprehensive treatment program. Acamprosate (333–666 mg orally three times daily) helps reduce craving and maintain abstinence, and can be continued even during periods of relapse.

D. Behavioral

Conditioning approaches historically have been used in some settings in the treatment of alcoholism, most commonly as a type of aversion therapy. For example, the patient is given a drink of whiskey and then a shot of apomorphine, and proceeds to vomit. In this way a strong association is built up between the drinking and vomiting. Although this kind of treatment has been successful in

some cases, after appropriate informed consent, many people do not sustain the learned aversive response.

▶ Treatment of Hallucinosi s & Withdrawal

A. Medical

1. Alcoholic hallucinosi s—Alcoholic hallucinosi s, which can occur either during or on cessation of a prolonged drinking period, is not a typical withdrawal syndrome and is handled differently. Since the symptoms are primarily those of a psychosis in the presence of a clear sensorium, they are handled like any other psychosis: hospitalization (when indicated) and adequate amounts of antipsychotic drugs. Haloperidol, 5 mg orally twice a day for the first day or so, usually ameliorates symptoms quickly, and the drug can be decreased and discontinued over several days as the patient improves. It then becomes necessary to deal with the chronic alcohol abuse, which has been discussed.

2. Withdrawal symptoms—The onset of withdrawal symptoms is usually 8–12 hours and the peak intensity of symptoms is 48–72 hours after alcohol consumption is stopped. Providing adequate central nervous system depressants (eg, benzodiazepines) is important to counteract the excitability resulting from sudden cessation of alcohol intake. The choice of a specific sedative is less important than using adequate doses to bring the patient to a level of moderate sedation, and this will vary from person to person. Mild dependency requires “drying out.” In some instances for outpatients, a short course of tapering benzodiazepines—eg, diazepam, 20 mg orally daily initially, decreasing by 5 mg daily—may be a useful adjunct. In moderate to severe withdrawal, hospitalize the patient and use diazepam orally in a dosage of 5–10 mg hourly depending on the clinical need as judged by withdrawal symptoms, including nausea, tremor, autonomic hyperactivity, agitation; tactile, visual, and auditory hallucinations; and disorientation. This type of symptom-driven medication regimen for withdrawal appears to reduce total benzodiazepine usage over fixed-dose schedules. Antipsychotic drugs should not be used. Monitoring of vital signs and fluid and electrolyte levels is essential for the severely ill patient.

In very severe withdrawal, intravenous administration is necessary. After stabilization, the amount of diazepam required to maintain a sedated state may be given orally every 8–12 hours. If restlessness, tremulousness, and other signs of withdrawal persist, the dosage is increased until moderate sedation occurs. The dosage is then gradually reduced by 20% every 24 hours until withdrawal is complete. This usually requires a week or so of treatment. Clonidine, 5 mcg/kg orally every 2 hours, or the patch formulation of appropriate dosage strength, suppresses cardiovascular signs of withdrawal and has some anxiolytic effect. Carbamazepine, 400–800 mg daily orally, compares favorably with benzodiazepines for alcohol withdrawal.

Atenolol, as an adjunct to benzodiazepines, can reduce symptoms of alcohol withdrawal. The daily oral atenolol dose is 100 mg when the heart rate is above 80 beats per minute and 50 mg for a heart rate between 50 and 80 beats

per minute. Atenolol should not be used when bradycardia is present.

Meticulous examination for other medical problems is necessary. Alcoholic hypoglycemia can occur with low blood alcohol levels (see Chapter 27). Alcoholics commonly have liver disease and associated clotting problems and are also prone to injury—and the combination all too frequently leads to undiagnosed subdural hematoma.

Phenytoin does not appear to be useful in managing alcohol withdrawal seizures *per se*. Sedating doses of benzodiazepines are effective in treating alcohol withdrawal seizures. Thus, other anticonvulsants are not usually needed unless there is a preexisting seizure disorder.

A general diet should be given, and vitamins in high doses: thiamine, 50 mg intravenously initially, then intramuscularly on a daily basis; pyridoxine, 100 mg/d; folic acid, 1 mg/d; and ascorbic acid, 100 mg twice a day. Intravenous glucose solutions should not be given prior to thiamine for fear of precipitating Wernicke syndrome. Thiamine is necessary as a ketolase enzyme cofactor. Concurrent administration is satisfactory, and hydration should be meticulously assessed on an ongoing basis.

Chronic brain syndromes secondary to a long history of alcohol intake are not clearly responsive to thiamine and vitamin replenishment. Attention to the social and environmental care of this type of patient is paramount.

B. Psychological and Behavioral

The comments in the section on problem drinking apply here also; these methods of treatment become the primary consideration after successful treatment of withdrawal or alcoholic hallucinosis. Psychological and social measures should be initiated in the hospital prior to discharge. This increases the possibility of continued post-hospitalization treatment.

OTHER DRUG & SUBSTANCE DEPENDENCIES

1. Opioids

The terms “opioids” and “narcotics” are used interchangeably and include a group of drugs with actions that mimic those of morphine. The group includes natural derivatives of opium (opiates), synthetic surrogates (opioids), and a

number of polypeptides, some of which have been discovered to be natural neurotransmitters. The principal narcotic of abuse is heroin (metabolized to morphine), which is not used as a legitimate medication. The other common opioids are prescription drugs that differ in milligram potency, duration of action, and agonist and antagonist capabilities (see Chapter 1). All of the opioid analgesics can be reversed by the opioid antagonist naloxone.

The clinical symptoms and signs of mild narcotic intoxication include changes in mood, with feelings of euphoria; drowsiness; nausea with occasional emesis; needle tracks; and miosis. The incidence of snorting and inhaling heroin (“smoking”) is increasing, particularly among cocaine users. This coincides with a decrease in the availability of methaqualone (no longer marketed) and other sedatives used to temper the cocaine “high” (see discussion of cocaine under Stimulants, below). Overdosage causes respiratory depression, peripheral vasodilation, pinpoint pupils, pulmonary edema, coma, and death.

Dependency is a major concern when continued use of narcotics occurs, although withdrawal causes only moderate morbidity (similar in severity to a bout of “flu”). Addicted patients sometimes consider themselves more addicted than they really are and may not require a withdrawal program. Grades of withdrawal are categorized from 0 to 4: grade 0 includes craving and anxiety; grade 1, yawning, lacrimation, rhinorrhea, and perspiration; grade 2, previous symptoms plus mydriasis, piloerection, anorexia, tremors, and hot and cold flashes with generalized aching; grades 3 and 4, increased intensity of previous symptoms and signs, with increased temperature, blood pressure, pulse, and respiratory rate and depth. In withdrawal from the most severe addiction, vomiting, diarrhea, weight loss, hemoconcentration, and spontaneous ejaculation or orgasm commonly occur. Complications of heroin administration include infections (eg, pneumonia, septic emboli, hepatitis, and HIV infection from using nonsterile needles), traumatic insults (eg, arterial spasm due to drug injection, gangrene), and pulmonary edema.

Treatment for overdosage (or suspected overdosage) is naloxone, 2 mg intravenously. If an overdose has been taken, the results are dramatic and occur within 2 minutes. Since the duration of action of naloxone is much shorter than that of the narcotics, the patient must be under close observation. Hospitalization, supportive care, repeated naloxone administration, and observation for withdrawal from other drugs should be maintained for as long as necessary.

Treatment for withdrawal begins if grade 2 signs develop. If a withdrawal program is necessary, use methadone, 10 mg orally (use parenteral administration if the patient is vomiting), and observe. If signs (piloerection, mydriasis, cardiovascular changes) persist for more than 4–6 hours, give another 10 mg; continue to administer methadone at 4- to 6-hour intervals until signs are not present (rarely more than 40 mg of methadone in 24 hours). Divide the total amount of drug required over the first 24-hour period by 2 and give that amount every 12 hours. Each day, reduce the total 24-hour dose by 5–10 mg. Thus, a moderately addicted patient initially requiring 30–

40 mg of methadone could be withdrawn over a 4- to 8-day period. Clonidine, 0.1 mg orally several times daily over a 10- to 14-day period, is both an alternative and an adjunct to methadone detoxification; it is not necessary to taper the dose. Clonidine is helpful in alleviating cardiovascular symptoms but does not significantly relieve anxiety, insomnia, or generalized aching. There is a protracted abstinence syndrome of metabolic, respiratory, and blood pressure changes over a period of 3–6 months.

Narcotic antagonists (eg, naltrexone) can also be used successfully for treatment of the patient who has been free of opioids for 7–10 days. Naltrexone blocks the narcotic “high” of heroin when 50 mg is given orally every 24 hours initially for several days and then 100 mg is given every 48–72 hours. Liver disorders are a major contraindication. Compliance tends to be poor, partly because of the dysphoria that can persist long after opioid discontinuance. Buprenorphine, a partial agonist, is a mainstay of office-based treatment of opiate dependency. Its use requires special training.

Alternative strategies for the treatment of opioid withdrawal have included rapid and ultrarapid detoxification techniques. However, recent data do not support the use of either method. Methadone maintenance programs are of some value in chronic recidivism. Under carefully controlled supervision, the narcotic addict is maintained on fairly high doses of methadone (40–120 mg/d) that satisfy craving and block the effects of heroin to a great degree.

2. Sedatives (Anxiolytics)

See Anxiety Disorders, this chapter.

3. Psychedelics

About 6000 species of plants have psychoactive properties. All of the common psychedelics (LSD, mescaline, psilocybin, dimethyltryptamine, and other derivatives of phenylalanine and tryptophan) can produce similar behavioral and physiologic effects. An initial feeling of tension is followed by emotional release such as crying or laughing (1–2 hours). Later, perceptual distortions occur, with visual illusions and hallucinations, and occasionally there is fear of ego disintegration (2–3 hours). Major changes in time sense and mood lability then occur (3–4 hours). A feeling of detachment and a sense of destiny and control occur (4–6 hours). Of course, reactions vary among individuals, and some of the drugs produce markedly different time frames. Occasionally, the acute episode is terrifying (a “bad trip”), which may include panic, depression, confusion, or psychotic symptoms. Preexisting emotional problems, the attitude of the user, and the setting where the drug is used affect the experience.

Treatment of the acute episode primarily involves protection of the individual from erratic behavior that may lead to injury or death. A structured environment is usually sufficient until the drug is metabolized. In severe cases, antipsychotic drugs with minimal side effects (eg, haloperidol, 5 mg intramuscularly) may be given every several hours until the individual has regained control. In cases where “flashbacks” occur (mental imagery from a “bad trip” that

is later triggered by mild stimuli such as marijuana, alcohol, or psychic trauma), a short course of an antipsychotic drug—eg, olanzapine, 5–10 mg/d, or risperidone, 2 mg/d, initially, and up to 20 mg/d and 6 mg/d, respectively—is usually sufficient. Lorazepam, 1–2 mg orally or intramuscularly every 2 hours as needed for acute agitation, may be a useful adjunct. An occasional patient may have “flashbacks” for much longer periods and require small doses of neuroleptic drugs over the longer term.

4. Phencyclidine

Phencyclidine (PCP, angel dust, peace pill, hog), developed as an anesthetic agent, first appeared as a street drug deceptively sold as tetrahydrocannabinol (THC). Because it is simple to produce and mimics to some degree the traditional psychedelic drugs, PCP has become a common deceptive substitute for LSD, THC, and mescaline. It is available in crystals, capsules, and tablets to be inhaled, injected, swallowed, or smoked (it is commonly sprinkled on marijuana).

Absorption after smoking is rapid, with onset of symptoms in several minutes and peak symptoms in 15–30 minutes. Mild intoxication produces euphoria accompanied by a feeling of numbness. Moderate intoxication (5–10 mg) results in disorientation, detachment from surroundings, distortion of body image, combativeness, unusual feats of strength (partly due to its anesthetic activity), and loss of ability to integrate sensory input, especially touch and proprioception. Physical symptoms include dizziness, ataxia, dysarthria, nystagmus, retracted upper eyelid with blank stare, hyperreflexia, and tachycardia. There are increases in blood pressure, respiration, muscle tone, and urine production. Usage in the first trimester of pregnancy is associated with an increase in spontaneous abortion and congenital defects. Severe intoxication (20 mg or more) produces an increase in degree of moderate symptoms, with the addition of seizures, deepening coma, hypertensive crisis, and severe psychotic ideation. The drug is particularly long-lasting (several days to several weeks) owing to high lipid solubility, gastrointestinal recycling, and the production of active metabolites. Overdosage may be fatal, with the major causes of death being hypertensive crisis, respiratory arrest, and convulsions. Acute rhabdomyolysis has been reported and can result in myoglobinuric kidney failure.

Differential diagnosis involves the whole spectrum of street drugs, since in some ways phencyclidine mimics sedatives, psychedelics, and marijuana in its effects. Blood and urine testing can detect the acute problem.

Treatment is discussed in Chapter 38.

5. Marijuana

Cannabis sativa, a hemp plant, is the source of marijuana. The parts of the plant vary in potency. The resinous exudate of the flowering tops of the female plant (hashish, charas) is the most potent, followed by the dried leaves and flowering shoots of the female plant (bhanga) and the resinous mass from small leaves of inflorescence (ganja). The least potent parts are the lower branches and the leaves

of the female plant and all parts of the male plant. Mercury may be a contaminant in marijuana grown in volcanic soil. The drug is usually inhaled by smoking. Effects occur in 10–20 minutes and last 2–3 hours. “Joints” of good quality contain about 500 mg of marijuana (which contains approximately 5–15 mg of tetrahydrocannabinol with a half-life of 7 days). Marijuana soaked in formaldehyde and dried (“AMP”) has produced unusual effects, including autonomic discharge and severe though transient cognitive impairment.

With moderate dosage, marijuana produces two phases: mild euphoria followed by sleepiness. In the acute state, the user has an altered time perception, less inhibited emotions, psychomotor problems, impaired immediate memory, and conjunctival injection. High doses produce transient psychotomimetic effects. No specific treatment is necessary except in the case of the occasional “bad trip,” in which case the person is treated in the same way as for psychedelic usage. Marijuana frequently aggravates existing mental illness and adversely affects motor performance.

Studies of long-term effects have conclusively shown abnormalities in the pulmonary tree. Laryngitis and rhinitis are related to prolonged use, along with chronic obstructive pulmonary disease. Electrocardiographic abnormalities are common, but no chronic cardiac disease has been linked to marijuana use. Long-term usage has resulted in depression of plasma testosterone levels and reduced sperm counts. Abnormal menstruation and failure to ovulate have occurred in some women. Cognitive impairments are common. Health care utilization for a variety of health problems is increased in long-term marijuana smokers. Sudden withdrawal produces insomnia, nausea, myalgia, and irritability. Psychological effects of long-term marijuana usage are still unclear. Urine testing is reliable if samples are carefully collected and tested. Detection periods span 4–6 days in short-term users and 20–50 days in long-term users.

6. Stimulants: Amphetamines & Cocaine

Stimulant abuse is quite common, either alone or in combination with abuse of other drugs. The **amphetamines**, including Methedrine (“speed”)—one variant is a smokable form called “ice,” which gives an intense and fairly long-lasting high—methylphenidate, and phenmetrazine, are under prescription control, but street availability remains high. Moderate usage of any of the stimulants produces hyperactivity, a sense of enhanced physical and mental capacity, and sympathomimetic effects. The clinical picture of acute stimulant intoxication includes sweating, tachycardia, elevated blood pressure, mydriasis, hyperactivity, and an acute brain syndrome with confusion and disorientation. Tolerance develops quickly, and, as the dosage is increased, hypervigilance, paranoid ideation (with delusions of parasitosis), stereotypy, bruxism, tactile hallucinations of insect infestation, and full-blown psychoses occur, often with persecutory ideation and aggressive responses. Stimulant withdrawal is characterized by depression with symptoms of hyperphagia and hypersomnia.

People who have used stimulants chronically (eg, anorexigenics) occasionally become sensitized (“**kindling**”) to

future use of stimulants. In these individuals, even small amounts of mild stimulants such as caffeine can cause symptoms of paranoia and auditory hallucinations.

Cocaine is a stimulant. It is a product of the coca plant. The derivatives include seeds, leaves, coca paste, cocaine hydrochloride, and the free base of cocaine. Cocaine hydrochloride is the salt and the most commonly used form. Free base, a purer (and stronger) derivative called “crack,” is prepared by simple extraction from cocaine hydrochloride.

There are various modes of use. Coca leaf chewing involves toasting the leaves and chewing with alkaline material (eg, the ash of other burned leaves) to enhance buccal absorption. One achieves a mild high, with onset in 5–10 minutes and lasting for about an hour. Intranasal use is simply snorting cocaine through a straw. Absorption is slowed somewhat by vasoconstriction (which may eventually cause tissue necrosis and septal perforation); the onset of action is in 2–3 minutes, with a moderate high (euphoria, excitement, increased energy) lasting about 30 minutes. The purity of the cocaine is a major determinant of the high. Intravenous use of cocaine hydrochloride or “freebase” is effective in 30 seconds and produces a short-lasting, fairly intense high of about 15 minutes’ duration. The combined use of cocaine and ethanol results in the metabolic production of cocaethylene by the liver. This substance produces more intense and long-lasting cocaine-like effects. Smoking freebase (volatilized cocaine because of the lower boiling point) acts in seconds and results in an intense high lasting several minutes. The intensity of the reaction is related to the marked lipid solubility of the freebase form and produces by far the most severe medical and psychiatric symptoms.

Cardiovascular collapse, arrhythmias, myocardial infarction, and transient ischemic attacks have been reported. Seizures, strokes, migraine symptoms, hyperthermia, and lung damage may occur, and there are several obstetric complications, including spontaneous abortion, abruptio placentae, teratogenic effects, delayed fetal growth, and prematurity. Cocaine can cause anxiety, mood swings, and delirium, and chronic use can cause the same problems as other stimulants (see above).

Clinicians should be alert to cocaine use in patients presenting with unexplained nasal bleeding, headaches, fatigue, insomnia, anxiety, depression, and chronic hoarseness. Sudden withdrawal of the drug is not life-threatening but usually produces craving, sleep disturbances, hyperphagia, lassitude, and severe depression (sometimes with suicidal ideation) lasting days to weeks.

Treatment is imprecise and difficult. Since the high is related to blockage of dopamine reuptake, the dopamine agonist bromocriptine, 1.5 mg orally three times a day, alleviates some of the symptoms of craving associated with acute cocaine withdrawal. Other dopamine agonists such as apomorphine, levodopa, and amantadine are under study for this purpose. Carbamazepine may be a useful adjunct in treating symptoms of alcohol withdrawal, and desipramine in moderate doses has been useful in helping maintain abstinence in the early stages of treatment. Treatment of psychosis is the same as that of any psychosis: antipsychotic drugs in dosages sufficient to alleviate the

symptoms. Any medical symptoms (eg, hyperthermia, seizures, hypertension) are treated specifically. These approaches should be used in conjunction with a structured program, most often based on the Alcoholics Anonymous model. Hospitalization may be required if self-harm or violence toward others is a perceived threat (usually indicated by paranoid delusions).

7. Caffeine

Caffeine, along with nicotine and alcohol, is one of the most commonly used drugs worldwide. About 10 billion pounds of coffee (the richest source of caffeine) are consumed yearly throughout the world. Tea, cocoa, and cola drinks also contribute to an intake of caffeine that is often astoundingly high in a large number of people. Low to moderate doses (30–200 mg/d) tend to improve some aspects of performance (eg, vigilance). The approximate content of caffeine in a (180-mL) cup of beverage is as follows: brewed coffee, 80–140 mg; instant coffee, 60–100 mg; decaffeinated coffee, 1–6 mg; black leaf tea, 30–80 mg; tea bags, 25–75 mg; instant tea, 30–60 mg; cocoa, 10–50 mg; and 12-oz cola drinks, 30–65 mg. A 2-oz chocolate candy bar has about 20 mg. Some herbal teas (eg, “morning thunder”) contain caffeine. Caffeine-containing analgesics usually contain approximately 30 mg per unit. Symptoms of caffeinism (usually associated with ingestion of over 500 mg/d) include anxiety, agitation, restlessness, insomnia, a feeling of being “wired,” and somatic symptoms referable to the heart and gastrointestinal tract. It is common for a case of caffeinism to present as an anxiety disorder. It is also common for caffeine and other stimulants to precipitate severe symptoms in compensated schizophrenic and manic-depressive patients. Chronically depressed patients often use caffeine drinks as self-medication. This diagnostic clue may help distinguish some major affective disorders. Withdrawal from caffeine (> 250 mg/d) can produce headaches, irritability, lethargy, and occasional nausea.

8. Miscellaneous Drugs, Solvents

The principal over-the-counter drugs of concern have been phenylpropanolamine and an assortment of antihistaminic agents, frequently in combination with a mild analgesic promoted as cold remedies. Medications containing phenylpropanolamine have been removed from sale in the United States due to an FDA ban. The major problem in use of phenylpropanolamine relates to its side effects as a stimulant, including precipitation of anxiety states, increased pressure effects, auditory and visual hallucinations, paranoid ideation, and occasionally delirium. Aggressiveness and some loss of impulse control were reported as well as sleep disturbances even with small doses.

Antihistamines usually produce some central nervous system depression—thus their use as over-the-counter sedatives. Practically all of the so-called sleep aids are antihistamines. The mixture of antihistamines with alcohol usually exacerbates the central nervous system effects. Scopolamine and bromides have generally been removed from over-the-counter products.

The abuse of laxatives sometimes can lead to electrolyte disturbances that may contribute to the manifestations of a delirium. The greatest use of laxatives tends to be in the elderly and in those with eating disorders, both of whom are the most vulnerable to physiologic changes.

Anabolic steroids are being abused by people who wish to increase muscle mass for cosmetic reasons or for greater strength. In addition to the medical problems, the practice is associated with significant mood swings, aggressiveness, and paranoid delusions. Alcohol and stimulant use is higher in these individuals. Withdrawal symptoms of steroid dependency include fatigue, depressed mood, restlessness, and insomnia.

Amyl nitrite has been used as an “orgasm expander.” The changes in time perception, “rush,” and mild euphoria caused by the drug prompted its nonmedical use, and popular lore concerning the effects of inhalation just prior to orgasm has led to increased use. Subjective effects last from 5 seconds to 15 minutes. Tolerance develops readily, but there are no known withdrawal symptoms. Abstinence for several days reestablishes the previous level of responsiveness. Long-term effects may include damage to the immune system and respiratory difficulties.

Sniffing of solvents and inhaling of gases (including aerosols) produce a form of inebriation similar to that of the volatile anesthetics. Agents include gasoline, toluene, petroleum ether, lighter fluids, cleaning fluids, paint thinners, and solvents that are present in many household products (eg, nail polish, typewriter correction fluid). Typical intoxication states include euphoria, slurred speech, hallucinations, and confusion, and with high doses, acute manifestations are unconsciousness and cardiorespiratory depression or failure; chronic exposure produces a variety of symptoms related to the liver, kidney, bone marrow, or heart. Lead encephalopathy can be associated with sniffing leaded gasoline. In addition, studies of workers chronically exposed to jet fuel showed significant increases in neurasthenic symptoms, including fatigue, anxiety, mood changes, memory difficulties, and somatic complaints. These same problems have been noted in long-term solvent abuse.

The so-called designer drugs are synthetic substitutes for commonly used recreational drugs and are produced in small, clandestine laboratories. The most common designer drugs have been methyl analogues of fentanyl and have been used as heroin substitutes. MDMA (methylenedioxymethamphetamine), an amphetamine derivative sometimes called “ecstasy,” is also a designer drug with high abuse potential and neurotoxicity. Often not detected by standard toxicology screens, these substances can present a vexing problem for clinicians faced with symptoms from a totally unknown cause.

DELIRIUM, DEMENTIA, & OTHER COGNITIVE DISORDERS (FORMERLY: ORGANIC BRAIN SYNDROME)

ESSENTIALS OF DIAGNOSIS

- ▶ Transient or permanent brain dysfunction.
- ▶ Cognitive impairment to varying degrees.
- ▶ Impaired recall and recent memory, inability to focus attention, random psychomotor activity such as stereotypy, and problems in perceptual processing, often with psychotic ideation.
- ▶ Emotional disorders frequently present: depression, anxiety, irritability.

- ▶ Behavioral disturbances: impulse control, sexual acting-out, attention deficits, aggression, and exhibitionism.

General Considerations

The organic problem may be a primary brain disease or a secondary manifestation of some general disorder. All of the cognitive disorders show some degree of impaired thinking depending on the site of involvement, the rate of onset and progression, and the duration of the underlying brain lesion. Emotional disturbances (eg, depression) are often present as significant comorbidities. The behavioral disturbances tend to be more common with chronicity, more directly related to the underlying personality or central nervous system vulnerability to drug side effects, and not necessarily correlated with cognitive dysfunction.

The causes of cognitive disorders are listed in Table 25–11.

Clinical Findings

The manifestations are many and varied and include problems with orientation, short or fluctuating attention span, loss of recent memory and recall, impaired judgment, emotional lability, lack of initiative, impaired impulse control, inability to reason through problems, depression (worse in

Table 25–11. Etiology of delirium and other cognitive disorders.

| Disorder | Possible Causes |
|---|--|
| Intoxication | Alcohol, sedatives, bromides, analgesics (eg, pentazocine), psychedelic drugs, stimulants, and household solvents. |
| Drug withdrawal | Withdrawal from alcohol, sedative-hypnotics, corticosteroids. |
| Long-term effects of alcohol | Wernicke-Korsakoff syndrome. |
| Infections | Septicemia; meningitis and encephalitis due to bacterial, viral, fungal, parasitic, or tuberculous organisms or to central nervous system syphilis; acute and chronic infections due to the entire range of microbiologic pathogens. |
| Endocrine disorders | Thyrotoxicosis, hypothyroidism, adrenocortical dysfunction (including Addison disease and Cushing syndrome), pheochromocytoma, insulinoma, hypoglycemia, hyperparathyroidism, hypoparathyroidism, panhypopituitarism, diabetic ketoacidosis. |
| Respiratory disorders | Hypoxia, hypercapnia. |
| Metabolic disturbances | Fluid and electrolyte disturbances (especially hyponatremia, hypomagnesemia, and hypercalcemia), acid-base disorders, hepatic disease (hepatic encephalopathy), kidney failure, porphyria. |
| Nutritional deficiencies | Deficiency of vitamin B ₁ (beriberi), vitamin B ₁₂ (pernicious anemia), folic acid, nicotinic acid (pellagra); protein-calorie malnutrition. |
| Trauma | Subdural hematoma, subarachnoid hemorrhage, intracerebral bleeding, concussion syndrome. |
| Cardiovascular disorders | Myocardial infarctions, cardiac arrhythmias, cerebrovascular spasms, hypertensive encephalopathy, hemorrhages, embolisms, and occlusions indirectly cause decreased cognitive function. |
| Neoplasms | Primary or metastatic lesions of the central nervous system, cancer-induced hypercalcemia. |
| Seizure disorders | Ictal, interictal, and postictal dysfunction. |
| Collagen-vascular and immunologic disorders | Autoimmune disorders, including systemic lupus erythematosus, Sjögren syndrome, and AIDS. |
| Degenerative diseases | Alzheimer disease, Pick disease, multiple sclerosis, parkinsonism, Huntington chorea, normal pressure hydrocephalus. |
| Medications | Anticholinergic drugs, antidepressants, H ₂ -blocking agents, digoxin, salicylates (long-term use), and a wide variety of other over-the-counter and prescribed drugs. |

mild to moderate types), confabulation (not limited to alcohol organic brain syndrome), constriction of intellectual functions, visual and auditory hallucinations, and delusions. Physical findings will naturally vary according to the cause. The EEG usually shows generalized slowing in delirium.

A. Delirium

Delirium (acute confusional state) is a transient global disorder of attention, with clouding of consciousness, usually a result of systemic problems (eg, drugs, hypoxemia). Onset is usually rapid. The mental status fluctuates (impairment is usually least in the morning), with varying inability to concentrate, maintain attention, and sustain purposeful behavior. (“Sundowning”—mild to moderate delirium at night—is more common in patients with preexisting dementia and may be precipitated by hospitalization, drugs, and sensory deprivation.) There is a marked deficit of short-term memory and recall. Anxiety and irritability are common. Amnesia is retrograde (impaired recall of past memories) and anterograde (inability to recall events after the onset of the delirium). Orientation problems follow the inability to retain information. Perceptual disturbances (often visual hallucinations) and psychomotor restlessness with insomnia are common. Autonomic changes include tachycardia, dilated pupils, and sweating. The average duration is about 1 week, with full recovery in most cases. Delirium can coexist with dementia.

B. Dementia

(See also Chapter 4.) Dementia is characterized by chronicity and deterioration of selective mental functions. Onset is insidious over months to years in most cases. Formal cognitive screens can quantify impairments and point to the need for further evaluation. The Mini-Mental State Examination produces a numerical score with up to 30 points given for correct answers to questions (likely organic < 27 points) (see Figure 4–3). Specific cognitive assessment must be performed, since many patients are able to cover a deficit in routine conversation.

Dementia is usually progressive, more common in the elderly, and rarely reversible even if underlying disease can be corrected. Dementia can be classified as cortical or subcortical.

There are three types of cortical dementia: (1) primary degenerative dementia (eg, Alzheimer dementia), accounting for about 50–60% of cases; (2) atherosclerotic (multi-infarct) dementia, 15–20% of cases (this figure is probably low because of the tendency to overuse the diagnosis of Alzheimer dementia); and (3) mixtures of the first two types or dementia due to miscellaneous causes, 15–20% of cases (see also Chapter 4). Examples of primary degenerative dementia are Alzheimer dementia (most common) and Pick, Creutzfeldt-Jakob, and Huntington dementias (less common).

In all types, loss of impulse control (sexual and language) is common. The tenuous level of functioning makes the individual most susceptible to minor physical and psychological stresses. The course depends on the underlying cause, and the general trend is steady deterioration.

HIV infection can produce a primary neurogenic disorder (partially due to neuronal loss) and secondary effects due to opportunistic infections, neoplasias, or the effects of drug therapy. At present there has been a reduction in dementia symptoms in both early and late stages, perhaps due to earlier use of zidovudine. The general trend is variable, and patients require ongoing monitoring of neuropsychiatric status.

Pseudodementia is a term applied to depressed patients who appear to be demented. These patients are often identifiable by their tendency to complain about memory problems vociferously rather than try to cover them up. They usually say they can't complete cognitive tasks but with encouragement can often do so. They can be considered to have depression-induced reversible dementia that remits when the depression resolves.

C. Amnestic Syndrome

This is a memory disturbance without delirium or dementia. It is usually associated with thiamine deficiency and chronic alcohol use (eg, Korsakoff syndrome). There is an impairment in the ability to learn new information or recall previously learned information.

D. Substance-Induced Hallucinosi

This condition is characterized by persistent or recurrent hallucinations (usually auditory) without the other symptoms usually found in delirium or dementia. Alcohol or hallucinogens are often the cause. There does not have to be any other mental disorder, and there may be complete spontaneous resolution.

E. Personality Changes Due to a General Medical Condition (Formerly Organic Personality Syndrome)

This syndrome is characterized by emotional lability and loss of impulse control along with a general change in personality. Cognitive functions are preserved. Social inappropriateness is common. Loss of interest and lack of concern with the consequences of one's actions are often present. The course depends on the underlying cause (eg, frontal lobe contusion may resolve completely).

► Differential Diagnosis

The differential diagnosis consists mainly of schizophrenia and the other psychoses, which are sometimes confused with cognitive disorders and are often accompanied by psychotic symptoms.

► Complications

Chronicity may result from delayed correction of the defect, eg, subdural hematoma, low-pressure hydrocephalus. Accidents secondary to impulsive behavior and poor judgment are a major consideration. Secondary depression and impulsive behavior not infrequently lead to suicide attempts. Drugs—particularly sedatives—may worsen thinking abilities and contribute to the overall problems.

► Treatment

(See also Chapter 4.)

A. Medical

Delirium should be considered a syndrome of acute brain dysfunction analogous to acute kidney failure. The first aim of treatment is to identify and correct the etiologic medical problem. Evaluation should consist of a comprehensive physical examination including a search for neurologic abnormalities, infection, or hypoxia. Routine laboratory tests may include serum electrolytes, serum glucose, BUN, serum creatinine, liver function tests, thyroid function tests, arterial blood gases, complete blood count, serum calcium, phosphorus, magnesium, vitamin B₁₂, folate, blood cultures, urinalysis, and cerebrospinal fluid analysis. Discontinue drugs that may be contributing to the problem (eg, analgesics, corticosteroids, cimetidine, lidocaine, anticholinergic drugs, central nervous system depressants, mefloquine). Do not overlook any possibility of reversible organic disease. Electroencephalography, CT, and MRI evaluations may be helpful in diagnosis. Ideally, the patient should be monitored without further medications while the evaluation is carried out. There are, however, two indications for medication in delirious states: behavioral control (eg, pulling out lines) and subjective distress (eg, pronounced fear due to hallucinations). If these indications are present, medications may be used. If there is any hint of alcohol or substance withdrawal (the most common cause of delirium in the general hospital), a benzodiazepine such as lorazepam (1–2 mg every hour) can be given parenterally. If there is little likelihood of withdrawal syndrome, haloperidol is often used in doses of 1–10 mg every hour. Given intravenously under ECG monitoring, it appears to impose slight risk of extrapyramidal side effects. In addition to the medication, a pleasant, comfortable, nonthreatening, and physically safe environment with adequate nursing or attendant services should be provided. Once the underlying condition has been identified and treated, adjunctive medications can be tapered.

Treatment of dementia syndrome usually involves symptomatic management with one exception. Since there is a cholinergic deficiency in Alzheimer disease, research has focused on drugs to increase cholinergic activity by inhibiting cholinesterase. Tacrine was the first reversible cholinesterase inhibitor approved by the FDA. Three better-tolerated FDA-approved cholinesterase inhibitors are donepezil (5–10 mg at night), rivastigmine (3–6 mg orally twice daily), and galantamine (8–12 mg orally twice daily). Donepezil and galantamine doses need adjustment for liver disease, and the galantamine dose should be adjusted for kidney failure. They are thought to be efficacious in the short-term preservation of cognitive function and activities of daily living in mild to moderate dementia and, unlike tacrine, are not thought to be hepatotoxic. Gastrointestinal side effects are common but may be least frequent with donepezil. Further research continues to clarify the long-term efficacy of these medications on cognition and behavior. None of the cholinesterase inhibitors to date are thought to slow disease pro-

gression. An *N*-methyl-D-aspartate (NMDA) receptor antagonist, memantine 20 mg orally daily (begin at 5 mg daily and titrate upwards by 5 mg weekly) is the first medication approved by the FDA for the treatment of moderate to severe Alzheimer disease. Memantine may improve performance and cognition in some patients and has been used as an augmenting agent with the cholinesterase inhibitors. Although not yet FDA approved, preliminary research suggests that the nonselective antihistamine dimenhydrinate may also improve cognition and function in patients with mild to moderate Alzheimer disease.

Aggressiveness and rage states in central nervous system disease can be reduced with lipophilic β -blockers (eg, propranolol, metoprolol) in moderate doses. Since the serotonergic system has been implicated in arousal conditions, drugs that affect serotonin have been found to be of some benefit in aggression and agitation. Included in this group are lithium, trazodone, buspirone, and clonazepam. Dopamine blockers (eg, the neuroleptic drugs such as haloperidol) have been used for many years to attenuate aggression. Atypical neuroleptics may have a role in selected geriatric patients; however, there are reports of increased mortality in some studies related to the use of atypical neuroleptics in this population. There are also reports of reduced agitation in Alzheimer disease from carbamazepine, 100–400 mg/d orally (with slow increase as needed). Emotional lability in some cases responds to small doses of imipramine (25 mg orally one to three times per day) or fluoxetine (5–20 mg/d orally); depression, which often occurs early in the course of Alzheimer dementia, responds to the usual doses of antidepressant drugs, preferably those with the least anticholinergic side effects (eg, SSRIs and MAO inhibitors).

Cerebral vasodilators were originally used on the assumption that cerebral arteriosclerosis and ischemia were the principal causes of the dementias. Although there is a slight reduction of blood flow in primary degenerative dementia (probably as a result of the basic disorder), there is no evidence that this is a major factor in this group of disorders or that vasodilators are of value. Ergotamine alkaloids (ergotamine mesylates: Hydergine, others) have been studied with mixed results; improvement in ambulatory self-care and depressed mood has been noted, but there has been no improvement of cognitive functioning on any standardized tests. Hyperbaric oxygen treatment has not produced significant improvement. Stimulant drugs (eg, methylphenidate) do not change cognitive function but can improve affect and mood, which helps the caretakers cope with the problem.

Failing sensory functions should be supported as necessary, with hearing aids, cataract surgery, etc.

B. Social

Substitute home care, board and care, or convalescent home care may be most useful when the family is unable to care for the patient. The setting should include familiar people and objects, lights at night, and a simple schedule. Counseling may help the family to cope with problems and may help keep the patient at home as long as possible. Information about local groups can be obtained from the Alzheimer's Disease and Related Disorders Association, 70

East Lake Street, Suite 600, Chicago, IL 60601. Volunteer services, including homemakers, visiting nurses, and adult protective services, may be helpful in maintaining the patient at home.

C. Behavioral

Behavioral techniques include operant responses that can be used to induce positive behaviors, eg, paying attention to the patient who is trying to communicate appropriately, and extinction by ignoring inappropriate responses. Patients with Alzheimer disease can learn skills and retain them but do not recall the circumstances in which they were learned.

D. Psychological

Formal psychological therapies are not usually helpful and may make things worse by taxing the patient's limited cognitive resources.

► Prognosis

The prognosis is good for recovery of mental functioning in delirium when the underlying condition is reversible. For most dementia syndromes, the prognosis is for gradual deterioration, although new drug treatments may prove helpful.

PSYCHIATRIC PROBLEMS ASSOCIATED WITH HOSPITALIZATION & ILLNESS

► Diagnostic Categories

A. Acute Problems

1. Delirium with psychotic features secondary to the medical or surgical problem, or compounded by effect of treatment.
2. Acute anxiety, often related to ignorance and fear of the immediate problem as well as uncertainty about the future.
3. Anxiety as an intrinsic aspect of the medical problem (eg, hyperthyroidism).
4. Denial of illness, which may present during acute or intermediate phases of illness.

B. Intermediate Problems

1. Depression as a function of the illness or acceptance of the illness, often associated with realistic or fantasied hopelessness about the future.

2. Behavioral problems, often related to denial of illness and, in extreme cases, causing the patient to leave the hospital against medical advice.

C. Recuperative Problems

1. Decreasing cooperation as the patient sees improvement and compliance are not compelled.
2. Readjustment problems with family, job, and society.

► General Considerations

A. Acute Problems

1. "Intensive care unit psychosis"—The stressful ICU environment may be a cause of delirium. Critical care unit factors include sleep deprivation, increased arousal, mechanical ventilation, and social isolation. Other causes include those common to delirium and require vigorous investigation (see Delirium, above).

2. Pre- and postsurgical anxiety states—Such problems are common and commonly ignored. Presurgical anxiety is very common and is principally a fear of death (many surgical patients make out their wills). Patients may be fearful of anesthesia (improved by the preoperative anesthesia interview), the mysterious operating room, and the disease processes that might be uncovered by the surgeon. Such fears frequently cause people to delay examinations that might result in earlier surgery and a greater chance of cure.

The opposite of this is **surgery proneness**, the quest for surgery to escape from overwhelming life stresses. Polysurgery patients may be classified as having factitious disorders. Dynamic motivations include the need to get medical care as a way of getting dependency needs met, the desire to outwit authority figures, unconscious guilt, or a masochistic need to suffer. Frequent surgery may also be related to a somatoform disorder, particularly body dysmorphic disorder (an obsession that a body part is disfigured). More apparent reasons may include an attempt to get relief from pain and a lifestyle that has become almost exclusively medically oriented, with all of the risks entailed in such an endeavor.

Postsurgical anxiety states are usually related to pain, procedures, and loss of body image. Acute pain problems are quite different from chronic pain disorders (see Chronic Pain Disorders, this chapter); the former are readily handled with adequate analgesic medication (see Chapter 5). Alterations in body image, as with amputations, ostomies, and mastectomies, often raise concerns about relationships with others.

3. Iatrogenic problems—These usually pertain to medications, complications of diagnostic and treatment procedures, and impersonal and unsympathetic staff behavior. Polypharmacy is often a factor. Patients with unsolved diagnostic problems are at higher risk. They are desirous of relief, and the quest engenders more diagnostic procedures with a higher incidence of complications. The upset patient and family may be very demanding. Excessive demands usually result from anxiety. Such behavior is best handled with calm and measured responses.

B. Intermediate Problems

1. Prolonged hospitalization—Prolonged hospitalization presents unique problems in certain hospital services, eg, burn units, orthopedic services, and tuberculosis wards. The acute problems of the severely burned patient are discussed in Chapter 37. The problems often are behavioral difficulties related to length of hospitalization and necessary procedures. For example, in burn units, pain is a major problem in addition to anxiety about procedures. Disputes with staff are common and often concern pain medication or ward privileges. Some patients regress to infantile behavior and dependency. Staff members must agree about their approach to the patient in order to ensure the smooth functioning of the unit.

Denial of illness may present in some patients. Intervention by an authority figure (eg, immediate work supervisor) may help the patient accept treatment and eventually abandon the coping mechanism of denial.

2. Depression—Depression frequently occurs during this period. Therapeutic drugs (eg, corticosteroids) may be a factor. Depression can contribute to irritability and overt anger. Severe depression can lead to anorexia, which further complicates healing and metabolic balance. It is during this period that the issue of disfigurement arises—relief at survival gives way to concern about future function and appearance.

C. Recuperative Problems

1. Anxiety—Anxiety about return to the posthospital environment can cause regression to a dependent position. Complications increase, and staff forbearance again is tested. Anxiety occurring at this stage usually is handled more easily than previous behavior problems.

2. Posthospital adjustment—Adjustment difficulties after discharge are related to the severity of the deficits and the use of outpatient facilities (eg, physical therapy, rehabilitation programs, psychiatric outpatient treatment). Some patients may experience posttraumatic stress symptoms (eg, from traumatic injuries or even from necessary medical treatments). Lack of appropriate follow-up can contribute to depression in the patient, who may feel that he or she is making poor progress and may have thoughts of “giving up.” Reintegration into work, educational, and social endeavors may be slow. Life is simply much more difficult when one is disfigured, disabled, or disenfranchised.

► Clinical Findings

The symptoms that occur in these patients are similar to those discussed in previous sections of this chapter, eg, delirium, stress and adjustment disorders, anxiety, and depression. Behavior problems may include lack of cooperation, increased complaints, demands for medication, sexual approaches to nurses, threats to leave the hospital, and actual signing out against medical recommendations. The underlying personality structure of the individual is a major factor in coping styles (eg, the compulsive individual increases indecision, the hysterical individual increases dramatic behavior).

► Differential Diagnosis

Delirium and dementia (including cases associated with HIV infection and drug abuse) must always be ruled out, since they often present with symptoms resembling anxiety, depression, or psychosis. Personality disorders existing prior to hospitalization often underlie the various behavior problems, but particularly the management problems.

► Complications

Prolongation of hospitalization causes increased expense, deterioration of patient-staff relationships, and increased probabilities of iatrogenic and legal problems. The possibility of increasing posthospital treatment problems is enhanced.

► Treatment

A. Medical

The most important consideration by far is to have one clinician in charge, a clinician whom the patient trusts and who is able to oversee multiple treatment approaches (see Somatoform Disorders, above). In acute problems, attention must be paid to metabolic imbalance, alcohol withdrawal, and previous drug use—prescribed, recreational, or over-the-counter. Adequate sleep and analgesia are important in the prevention of delirium. When absolute behavioral control is urgently needed, agents such as propofol, dexmedetomidine, opioids, and midazolam have been used.

Many clinicians are attuned to the early detection of the surgery-prone patient. Plastic and orthopedic surgeons are at particular risk. Appropriate consultations may help detect some problems and mitigate future ones.

Postsurgical anxiety states can be alleviated by personal attention from the surgeon. Anxiety is not so effectively lessened by ancillary medical personnel, whom the patient perceives as lesser authorities, until after the physician has reassured the patient. Inappropriate use of “as needed” analgesia places an unfair burden on the nurse. “Patient-controlled analgesia” can improve pain control, decrease anxiety, and minimize side effects.

Depression should be recognized early. If severe, it may be treated by antidepressant medications (see Antidepressant Drugs, above). High levels of anxiety can be lowered with judicious use of anxiolytic agents. Unnecessary medications tend to reinforce the patient’s impression that there must be a serious illness or medication would not be required.

B. Psychological

Prepare the patient and family for what is to come. This includes the types of units where the patient will be quartered, the procedures that will be performed, and any disfigurements that will result from surgery. Repetition improves understanding. The nursing staff can be helpful, since patients frequently confide a lack of understanding to a nurse but are reluctant to do so to the physician.

Denial of illness is frequently a block to acceptance of treatment. This too should be handled with family mem-

bers present (to help the patient face the reality of the situation) in a series of short interviews (for reinforcement). Dependency problems resulting from long hospitalization are best handled by focusing on the changes to come as the patient makes the transition to the outside world. Key figures are teachers, vocational counselors, and physical therapists. Challenges should be realistic and practical and handled in small steps.

Depression is usually related to the loss of familiar hospital supports, and the outpatient therapists and counselors help to lessen the impact of the loss. Some of the impact can be alleviated by anticipating, with the patient and family, the signal features of the common depression to help prevent the patient from assuming a permanent sick role (invalidism).

Suicide is always a concern when a patient is faced with despair. An honest, compassionate, and supportive approach will help sustain the patient during this trying period.

C. Behavioral

Prior desensitization can significantly allay anxiety about medical procedures. A “dry run” can be done to reinforce the oral description. Cooperation during acute problem periods can be enhanced by the use of appropriate reinforcers such as a favorite nurse or helpful family member. People who are positive reinforcers are even more helpful during the intermediate phases when the patient becomes resistant to the seemingly endless procedures (eg, debridement of burned areas).

Specific situations (eg, psychological dependency on the respirator) can be corrected by weaning with appropriate reinforcers (eg, watching a favorite movie on a video recorder when disconnected from the ventilator). Behavioral approaches should be used in a positive and optimistic way for maximal reinforcement.

Relaxation techniques and attentional distraction can be used to block side effects of a necessary treatment (eg, nausea in cancer chemotherapy).

D. Social

A change in environment requires adaptation. Because of the illness, admission and hospitalization may be more easily handled than discharge. Reintegration into society can be difficult. In some cases, the family is a negative influence. A predischarge evaluation must be made to determine whether the family will be able to cope with the physical or mental changes in the patient. Working with the family while the patient is in the acute stage may presage a successful transition later on.

Development of a new social life can be facilitated by various self-help organizations (eg, the stoma club). Sharing problems with others in similar circumstances eases the return to a social life, which may be quite different from that prior to the illness.

► Prognosis

The prognosis is good in all patients who have reversible medical and surgical conditions. It is guarded when there is serious functional loss that impairs vocational, educational, or societal possibilities—especially in the case of progressive and ultimately life-threatening illness.

26

DISEASES OF THE HYPOTHALAMUS & PITUITARY GLAND

ANTERIOR HYPOPITUITARISM

ESSENTIALS OF DIAGNOSIS

- ▶ Loss of one, all, or any combination of anterior pituitary hormones.
- ▶ Adrenocorticotropic hormone deficiency reduces adrenal secretion of cortisol, testosterone, and epinephrine; aldosterone secretion remains intact.
- ▶ Growth hormone (GH) deficiency in children causes short stature; GH deficiency in adults causes asthenia, obesity, and increased cardiac mortality.
- ▶ Prolactin deficiency inhibits postpartum lactation.
- ▶ Thyroid-stimulating hormone deficiency causes secondary hypothyroidism.
- ▶ Luteinizing hormone and follicle-stimulating hormone deficiency cause hypogonadism and infertility in men and women.

▶ General Considerations

Hypopituitarism can be caused by either hypothalamic or pituitary dysfunction. Patients with hypopituitarism may have single or multiple hormonal deficiencies (Table 26–1). When one hormonal deficiency is discovered, others may be present.

Mass lesions causing hypopituitarism are commonly pituitary adenomas, which are usually sporadic but are sometimes part of multiple endocrine neoplasia type 1 (MEN 1). Pituitary tumors that arise in MEN 1 usually secrete prolactin (63%), GH (9%), or both (10%) and are more aggressive than sporadic adenomas. Other types of mass lesions include granulomas, Rathke cleft cysts, apoplexy, metastatic carcinomas, aneurysms, and brain tumors (craniopharyngioma, meningioma, germinoma, glioma, chondrosarcoma, chordoma of the clivus). Langerhans cell

histiocytosis usually presents in youth with diabetes insipidus or hypopituitarism. Osteolytic bone lesions are noted on radiographs. Autoimmune hypophysitis, postpartum pituitary necrosis (Sheehan syndrome), eclampsia–pre-eclampsia, sickle cell disease, and African trypanosomiasis are rare causes.

Hypopituitarism without mass lesions may be congenital malformations in syndromes such as septo-optic dysplasia (de Morsier syndrome). Hypopituitarism may also be caused by trauma, cranial radiation, surgery, encephalitis, hemochromatosis, autoimmunity, or stroke. It may also occur after coronary artery bypass grafting. At least one pituitary hormone deficiency develops in about 25–30% of survivors of moderate to severe traumatic brain injury (Glasgow Coma Scale \leq 13/15) and in about 55% of survivors of aneurysmal subarachnoid hemorrhage.

Kallmann syndrome is the most common cause of congenital isolated gonadotropin deficiency. It is usually sporadic but may be familial. Three different genetic inheritance patterns can occur: X-linked recessive (Kal 1), autosomal dominant (Kal 2), or autosomal recessive (Kal 3). Kallmann syndrome has an incidence of 1:10,000 males and 1:50,000 females. It is associated with hyposmia caused by hypoplasia of the olfactory bulbs. Another cause of congenital gonadotropin deficiency is congenital adrenal hypoplasia that can be caused by *DAX 1* gene mutations. Congenital hypopituitarism also develops in patients with *PROP 1* gene mutations.

▶ Clinical Findings

Manifestations of hypopituitarism vary depending on which specific hormones are lacking and whether their deficiency is partial or complete.

A. Symptoms and Signs

Gonadotropin deficiency includes loss of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which causes hypogonadism and infertility. This condition is also known as hypogonadotropic hypogonadism and may be associated with anosmia (Kallmann syndrome) or normal olfaction. In Kallmann syndrome, about 50% of patients have unilateral renal agenesis; some patients may

Table 26-1. Pituitary hormones.

|---|--|
| Anterior pituitary | |
| Growth hormone (GH) ¹ | |
| Prolactin (PRL) | |
| Adrenocorticotrophic hormone (ACTH) | |
| Thyroid-stimulating hormone (TSH) | |
| Luteinizing hormone (LH) ² | |
| Follicle-stimulating hormone (FSH) | |
| Posterior pituitary | |
| Arginine vasopressin (AVP) ³ | |
| Oxytocin | |

¹GH closely resembles human placental lactogen (hPL).

²LH closely resembles human chorionic gonadotropin (hCG).

³AVP is identical with antidiuretic hormone (ADH).

also exhibit cryptorchidism, sensorineural deafness, cerebellar dysfunction, bilateral synkinesis, nystagmus, cleft lip, or high-arched palate. Patients with isolated gonadotropin deficiency may seek medical attention for delayed adolescence. (See also discussion of primary amenorrhea.) Congenital gonadotropin deficiency in males may be associated with congenital micropenis or cryptorchidism.

Hypogonadotropic hypogonadism is also seen in patients with *congenital adrenal hypoplasia*, a rare autosomal recessive or X-linked disorder; the X-linked form is caused by a mutation in the *DAX 1* gene. Adrenal insufficiency, caused by failure to form the permanent zone of the adrenal cortex, can present during infancy or childhood in boys with *DAX 1* gene mutations. Boys who survive beyond childhood usually do not enter puberty as a result of hypogonadotropic hypogonadism. However, hypogonadotropic hypogonadism and subtle signs of adrenal failure can present in adulthood in males with partial loss-of-function mutations in *DAX 1*.

In *acquired* gonadotropin deficiency, both men and women lose axillary, pubic, and body hair gradually, particularly if they are also hypoadrenal. Men may note diminished beard growth. Libido is diminished. Women have amenorrhea; men note decreased erections. Most patients are infertile. Androgen deficiency predisposes patients to osteopenia and muscle atrophy. (See section on secondary amenorrhea.)

Thyroid-stimulating hormone (TSH) deficiency causes hypothyroidism with manifestations such as fatigue, weakness, weight change, and hyperlipidemia. (See Hypothyroidism and Myxedema.)

Adrenocorticotrophic hormone (ACTH) deficiency results in diminished cortisol secretion (see Adrenocortical Hypofunction). Symptoms may include weakness, fatigue, weight loss, and hypotension. Patients with partial ACTH deficiency continue to have some cortisol secretion and may not have symptoms until stressed by illness or surgery. Adrenal mineralocorticoid secretion continues, so manifestations of adrenal insufficiency in hypopituitarism are usually less striking than in bilateral adrenal gland destruction (Addison disease); hyponatremia may occur, especially when ACTH and TSH deficiencies are both present.

GH deficiency in adulthood tends to cause mild to moderate central obesity, increased systolic blood pressure,

increased low-density lipoprotein (LDL) cholesterol, and reduced cardiac output. Affected patients may also have reduced muscle and bone mass, reduced physical and mental energy, impaired concentration and memory, and depression. Laron syndrome is an autosomal recessive disorder that is mainly associated with mutations in GH receptor gene. This causes resistance to GH and severe IGF-I deficiency, resulting in short stature (dwarfism). Affected individuals have a prominent forehead, depressed nasal bridge, small mandible, and central obesity. They may have recurrent hypoglycemic seizures. Partial resistance to GH may cause some cases of idiopathic short stature without features of Laron syndrome.

Panhypopituitarism is the absence of all anterior pituitary hormones. Combined pituitary hormone deficiency (CPHD) refers to a deficiency of several anterior pituitary hormones. CPHD gradually develops in patients with *PROP 1* gene mutations, usually presenting with short stature and growth failure due to GH and TSH deficiency; lack of pubertal development occurs due to deficiencies in FSH and LH. ACTH-cortisol deficiency gradually develops in patients with *PROP 1* gene mutations; these patients typically require corticosteroid replacement therapy by age 18 years. In addition to the manifestations noted above, patients with long-standing hypopituitarism tend to have dry, pale, finely textured skin. The face has fine wrinkles and an apathetic countenance.

B. Laboratory Findings

The fasting blood glucose may be low. Hyponatremia is often present due to hypothyroidism or hypoadrenalism. Hyperkalemia usually does not occur, since aldosterone production is not affected.

For men, an accurate serum total testosterone measurement must be obtained with an assay that uses extraction and chromatography, followed by mass spectrometry or immunoassay. For older men, free testosterone is best measured by calculation, using accurate assays for testosterone and sex hormone binding globulin (SHBG). Serum gonadotropins (FSH and LH) are obtained if the serum testosterone is low in order to distinguish primary hypogonadism from pituitary dysfunction.

The free thyroxine (FT₄) level is low, and TSH is not elevated. Plasma levels of sex steroids (testosterone and estradiol) are low or low normal, as are the serum gonadotropins as well. Elevated prolactin (PRL) levels are found in patients with prolactinomas, acromegaly, and hypothalamic disease.

ACTH deficiency causes functional atrophy of the adrenal cortex within 2 weeks of pituitary damage. Therefore, the diagnosis of secondary hypoadrenalism may be confirmed by holding any corticosteroid medication on the day of the test and by administering cosyntropin (synthetic ACTH₁₋₂₄), 0.25 mg (intramuscularly or intravenously); blood is drawn 30–60 minutes after the injection. A serum cortisol of ≥ 20 mcg/dL (550 nmol/mL), random or stimulated, rules out the diagnosis. A baseline ACTH level is low or normal in secondary hypoadrenalism, distinguishing it from primary adrenal disease. Serum dehydroepiandroster-

one (DHEA) levels are low in patients with ACTH deficiency, helping confirm the diagnosis. Metirapone testing is unnecessary.

Deficiency of epinephrine occurs with secondary adrenal insufficiency, since high local concentrations of cortisol are required to induce the production of the enzyme phenylethanolamine *N*-methyltransferase (PNMT) that catalyzes the conversion of norepinephrine to epinephrine in the adrenal medulla.

The diagnosis of GH deficiency is difficult since normal GH secretion is pulsatile and serum GH levels are nearly undetectable for most of the day. Also, adults normally tend to produce less GH as they age. Therefore, GH deficiency is often inferred by symptoms of GH deficiency in the presence of pituitary destruction or other pituitary hormone deficiencies. GH deficiency is present in 96% of patients with three or more other pituitary hormone deficiencies. GH stimulates the production of insulin-like growth factor-I (IGF-I). Unfortunately, serum IGF-I is not sensitive for GH deficiency since IGF-I levels are in the normal range in about 50% of adults with GH deficiency. Low serum IGF-I levels are not specific for GH deficiency. However, very low levels of IGF-I (< 84 mcg/L) are indicative of GH deficiency, except in conditions that naturally suppress serum IGF-I (eg, malnutrition, prolonged fasting, oral estrogen, hypothyroidism, uncontrolled diabetes mellitus, liver failure). In GH deficiency, exercise-stimulated serum GH levels remain at < 5 ng/mL and usually fail to rise; however, by age 40 years, most normal adults have lost their GH response to exercise.

Provocative GH-stimulation tests are commonly used but are poor tests for GH deficiency. The insulin hypoglycemia test, long considered the “gold standard,” is insensitive; it is contraindicated in the elderly, in patients with cardiovascular or cerebrovascular disease, and in patients with any history of seizures, an abnormal electroencephalogram (EEG), or recent brain surgery. Other GH stimulation tests require the administration of intravenous arginine and growth hormone-releasing hormone (GHRH) and oral clonidine or carbidopa/levodopa (combination) in patients pretreated with propranolol or estrogen. However, these tests do not discriminate well between normal individuals and patients with presumed GH deficiency (patients with three or more other pituitary hormone deficiencies). Also, normal overweight adults (body mass index [BMI] \geq 25 kg/m²) typically have blunted peak GH levels (below 20 ng/mL) after arginine-GHRH administration.

Despite the limitations of intravenous GHRH/arginine sulfhydryl stimulation testing, some insurance companies insist that patients have an abnormal test before covering the costs of GH replacement therapy. However, the latter test has a sensitivity of only 66% for GH deficiency. Therefore, when patients have a serum insulin-like growth factor (IGF-I) < 84 mcg/L or three other pituitary hormone deficiencies, the likelihood of GH deficiency is so high that symptomatic patients should have a therapeutic trial of GH therapy, even with a “normal” stimulation test.

The differential diagnosis of GH deficiency is congenital GH resistance with deficiency of IGF-I; at its worst, IGF-I deficiency results in Laron dwarfism that is resistant to GH therapy.

Because hemochromatosis can cause hypopituitarism, in patients with hypopituitarism without an established etiology, it is prudent to screen for hemochromatosis with a serum iron and transferrin saturation or ferritin.

C. Imaging

MRI provides the best visualization of pituitary tumors. Thickening of the pituitary stalk can be caused by sarcoidosis or hypophysitis.

► Differential Diagnosis

Reversible hypogonadotropic hypogonadism may occur with serious illness, malnutrition, or anorexia nervosa. The clinical situation and the presence of normal adrenal and thyroid function allow ready distinction from hypopituitarism. Profound hypogonadotropic hypogonadism develops in men who receive gonadotropin-releasing hormone (GnRH) therapy for prostate cancer; it usually persists following cessation of the therapy. Hypogonadotropic hypogonadism usually develops in patients receiving high-dose methadone or chronic intrathecal infusion of opioids; both GH deficiency and secondary adrenal insufficiency occur in 15% of such patients. Secondary adrenal insufficiency may persist for many months following high-dose corticosteroid therapy.

Severe illness causes functional suppression of TSH and T₄. Hyperthyroxinemia reversibly suppresses TSH. Administration of triiodothyronine (Cytomel) suppresses TSH and T₄. Bexarotene, used to treat cutaneous T cell lymphoma, suppresses TSH secretion, resulting in temporary central hypothyroidism. Corticosteroids or megestrol treatment reversibly suppresses endogenous ACTH and cortisol secretion.

► Complications

Among patients with craniopharyngiomas, diabetes insipidus is found in 16% preoperatively and in 60% postoperatively. Hyponatremia often presents abruptly during the first 2 weeks following pituitary surgery. Visual field impairment may occur. Hypothalamic damage may result in morbid obesity as well as cognitive and emotional problems. Conventional radiation therapy results in an increased incidence of small vessel ischemic strokes and second tumors.

Patients with untreated hypoadrenalism and a stressful illness may become febrile and die in shock and coma.

Adults with GH deficiency have experienced an increased cardiovascular morbidity. Rarely, acute hemorrhage may occur in large pituitary tumors, manifested by rapid loss of vision, headache, and evidence of acute pituitary failure (pituitary apoplexy) requiring emergency decompression of the sella.

► Treatment

Transsphenoidal removal of pituitary tumors will sometimes reverse hypopituitarism. Postoperative hyponatremia often occurs; serum sodium must be checked frequently for 2 weeks after pituitary surgery. Hypogonadism due to PRL excess usually resolves during treatment with

dopamine agonists. Endocrine substitution therapy must be given before, during, and, often, permanently after such procedures.

GH-secreting tumors may respond to octreotide (see section on acromegaly). Radiation therapy with x-ray, gamma knife, or heavy particles may be necessary but increases the likelihood of hypopituitarism.

The mainstay of substitution therapy for pituitary insufficiency remains lifetime hormone replacement.

A. Corticosteroids

Hydrocortisone tablets, 15–35 mg/d orally in divided doses, should be given. Most patients do well with 10–20 mg in the morning and 5–15 mg in the late afternoon. Patients with partial ACTH deficiency (basal morning serum cortisol above 8 mg/dL [220 mmol/L]) require hydrocortisone replacement in lower doses of about 5 mg orally twice daily. Some patients feel better taking prednisone, 3–7.5 mg/d orally. A mineralocorticoid is rarely needed. To determine the optimal corticosteroid replacement dosage, it is necessary to monitor patients carefully for manifestations of overreplacement (Cushing syndrome) or underreplacement. A serum white blood cell count (WBC) with a relative differential can be useful, since a relative neutrophilia and lymphopenia can indicate overreplacement with corticosteroid, and vice versa. Additional corticosteroids must be given during states of stress, eg, during infection, trauma, or surgical procedures. For mild illness, corticosteroid doses are doubled or tripled. For trauma or surgical stress, hydrocortisone is given in doses of 50 mg intramuscularly or intravenously every 6 hours and then reduced to normal doses as the stress subsides. Patients with adrenal insufficiency are advised to wear a medical alert bracelet describing their condition and treatment.

Patients with secondary adrenal insufficiency due to treatment with corticosteroids at supraphysiologic doses require their usual daily dose of corticosteroid during surgery and acute illness; supplemental hydrocortisone is not usually required.

B. Thyroid

Levothyroxine is given to correct hypothyroidism only after the patient is assessed for cortisol deficiency or is already receiving corticosteroids. (See Hypothyroidism.) The typical maintenance dose is about 1.6 mcg/kg body weight. However, dosage requirements vary widely, averaging 125 mcg daily with a range of 25–300 mcg daily. The optimal replacement dose of thyroxine for each patient must be carefully assessed clinically on an individual basis. Serum FT₄ levels usually need to be in the high-normal range for adequate replacement. Assessment of serum TSH is useless for monitoring patients, since levels are always low with TSH deficiency.

C. Sex Hormones

Hypogonadotropic hypogonadism often develops in patients with hyperprolactinemia; it may be reversed with treatment of the hyperprolactinemia. (See Hyperprolactinemia.)

Androgen replacement is discussed in the section on male hypogonadism. Estrogen replacement is discussed in the section on female hypogonadism. Patients with idiopathic hypogonadotropic hypogonadism, who have received several years of hormone replacement therapy, may have a trial off hormonal therapy to assess whether spontaneous sexual maturation may have occurred.

Women with hypopituitarism and androgen deficiency may be treated with compounded DHEA in doses of about 50 mg/d orally. DHEA therapy tends to increase pubic and axillary hair and may modestly improve libido, alertness, stamina, and overall psychological well-being after 6 months of therapy.

To improve spermatogenesis, human chorionic gonadotropin (hCG) (equivalent to LH) may be given at a dosage of 2000–3000 units intramuscularly three times weekly and testosterone replacement is discontinued. The dose of hCG is adjusted to normalize serum testosterone levels. After 6–12 months of hCG treatment, if the sperm count remains low, hCG injections are continued along with injections of FSH: follitropin- β (synthetic recombinant FSH) or urofollitropins (urine-derived FSH). An alternative for patients with an intact pituitary (eg, Kallmann syndrome) is the use of leuprolide (GnRH analog) by intermittent subcutaneous infusion. With either treatment, testicular volumes double within 5–12 months, and spermatogenesis occurs in most cases. With persistent treatment and the help of intracystoplasmic sperm injection for some cases, the total pregnancy success rate is about 70%. Clomiphene, 25–50 mg orally daily, can sometimes stimulate a man's own pituitary gonadotropins (when his pituitary is intact), thereby increasing testosterone and sperm production.

For fertility induction in females, ovulation may be induced with clomiphene, 50 mg daily for 5 days every 2 months. Follitropins and hCG can induce multiple births and should be used only by those experienced with their administration. (See Hypogonadism.)

D. Human Growth Hormone (hGH)

Symptomatic adults with severe GH deficiency (serum IGF-I below 85 mcg/L) may be treated with a subcutaneous recombinant human growth hormone (rhGH) injection starting at a dosage of about 0.2 mg (0.6 international units)/day, administered three or four times weekly. The dosage of rhGH is increased every 2–4 weeks by increments of 0.1 mg (0.3 international units) until side effects occur or a sufficient salutary response and a normal serum IGF-I level are achieved. A sustained-release injectable suspension of depot GH is available (Nutropin Depot). It can be given twice monthly and is therefore more convenient than standard rhGH preparations. In a study of 20 Brazilian GH-deficient adults, depot GH, given in doses of 13.5 mg subcutaneously twice monthly over 6 months, improved body morphology and lipid profiles but was associated with an increase in carotid plaque. Therefore, more long-term studies are required to determine the safety and optimal dosing and method for administering GH to adults. If the desired effects (eg, improved energy and mentation, reduction in visceral adiposity) are not seen

within 3–6 months at maximum tolerated dosage, rhGH therapy is discontinued.

During pregnancy, rhGH may be safely administered to women with hypopituitarism at their usual pregestational dose during the first trimester, tapering the dose during the second trimester, and discontinuing rhGH during the third trimester.

Oral estrogen replacement reduces hepatic IGF-I production. Therefore, prior to commencing rhGH therapy, oral estrogen is changed to a transdermal or transvaginal estradiol.

Side effects of rhGH therapy may include peripheral edema, hand stiffness, arthralgias, myalgias, headache, pseudotumor cerebri, gynecomastia, carpal tunnel syndrome, tarsal tunnel syndrome, hypertension, and proliferative retinopathy. Side effects are more common in older patients, those with greater weight and higher BMI, and those with adult-onset GH deficiency. Such symptoms usually remit promptly after a sufficient reduction in dosage. Excessive doses of rhGH could cause acromegaly; patients receiving long-term therapy require careful clinical monitoring. Serum IGF-I levels should be kept in the normal range and periodic determinations of serum IGF-I levels are helpful in guiding therapeutic dosing.

GH should not be administered during critical illness since, in one study, administration of very high doses of rhGH to patients in an intensive care unit was shown to increase overall mortality. There is no role for GH replacement in the somatopause of aging.

IGF-I (mecasermin) is available to treat patients with Laron syndrome.

E. Other Treatment

Selective transsphenoidal resection of pituitary adenomas can often restore normal pituitary function. Cabergoline, bromocriptine, or quinagolide may reverse the hypogonadism seen in hyperprolactinomas. (See Disorders of Prolactin Secretion.) Disseminated Langerhans cell histiocytosis may be treated with bisphosphonates to improve bone pain; treatment with 2-chlorodeoxyadenosine (cladribine) has been reported to produce remissions.

► Prognosis

The prognosis depends on the primary cause. Hypopituitarism resulting from a pituitary tumor may be reversible with dopamine agonists or with careful selective resection of the tumor. Spontaneous recovery from hypopituitarism associated with pituitary stalk thickening has been reported. Patients can also recover from functional hypopituitarism, eg, hypogonadism due to starvation or severe illness, suppression of ACTH by corticosteroids, or suppression of TSH by hyperthyroidism. Spontaneous reversal of isolated idiopathic hypogonadotropic hypogonadism occurs in about 10% of patients after several years of hormone replacement therapy.

Functionally, most patients with hypopituitarism do very well with hormone replacement. Men with infertility who are treated with hCG/FSH or GnRH are likely to resume spermatogenesis if they have a history of sexual

maturation, descended testicles, and a baseline serum inhibin level over 60 pg/mL. Women under age 40 years, with infertility due to hypogonadotropic hypogonadism, can usually have successful induction of ovulation.

DIABETES INSIPIDUS

ESSENTIALS OF DIAGNOSIS

- Antidiuretic hormone (ADH) deficiency causes central diabetes insipidus with polyuria (2–20 L/d) and polydipsia.
- Hyponatremia occurs if fluid intake is inadequate.

► General Considerations

Diabetes insipidus is an uncommon disease characterized by an increase in thirst and the passage of large quantities of urine of low specific gravity (usually < 1.006 with ad libitum fluid intake). The urine is otherwise normal. It is caused by a deficiency of vasopressin or resistance to vasopressin.

Primary central diabetes insipidus (without an identifiable lesion noted on MRI of the pituitary and hypothalamus) accounts for about one-third of all cases of diabetes insipidus. Many such cases appear to be due to autoimmunity against hypothalamic arginine vasopressin (AVP)-secreting cells; pituitary stalk thickening can often be detected on pituitary MRI scanning. The cause may also be genetic. Familial diabetes insipidus occurs as a dominant genetic trait with symptoms developing at about 2 years of age. Diabetes insipidus also occurs in Wolfram syndrome, a rare autosomal recessive disorder that is also known by the acronym DIDMOAD (diabetes insipidus, type 1 diabetes mellitus, optic atrophy, and deafness). DIDMOAD manifestations usually present in childhood but may not occur until adulthood, along with depression and cognitive problems. **Secondary central diabetes insipidus** is due to

damage to the hypothalamus or pituitary stalk by tumor, hypophysitis, anoxic encephalopathy, surgical or accidental trauma, infection (eg, encephalitis, tuberculosis, syphilis), sarcoidosis, or multifocal Langerhans cell (eosinophilic) granulomatosis (“histiocytosis X”). Metastases to the pituitary are more likely to cause diabetes insipidus (33%) than are pituitary adenomas (1%).

Vasopressinase-induced diabetes insipidus may be seen in the last trimester of pregnancy and in the puerperium; it is often associated with oligohydramnios, preeclampsia, or hepatic dysfunction. A circulating enzyme destroys native vasopressin; however, synthetic desmopressin is unaffected. The condition usually responds to desmopressin therapy (see below) and subsides spontaneously.

Nephrogenic diabetes insipidus is a disorder caused by a defect in the kidney tubules that interferes with water reabsorption. These patients have normal secretion of vasopressin, and the polyuria is unresponsive to it. Congenital nephrogenic diabetes insipidus is present from birth and is due to defective expression of renal vasopressin V2 receptors or vasopressin-sensitive water channels. It occurs as a familial X-linked trait; adults often have hyperuricemia as well.

Acquired forms of vasopressin-resistant diabetes insipidus are usually less severe and are seen in pyelonephritis, renal amyloidosis, myeloma, potassium depletion, Sjögren syndrome, sickle cell anemia, or chronic hypercalcemia. The disorder may occur also as a corticosteroid effect or as an acute side effect of diuretics. Certain drugs (eg, demeclocycline, lithium, foscarnet, or methicillin) may induce nephrogenic diabetes insipidus. The recovery from acute tubular necrosis may also be associated with transient nephrogenic diabetes insipidus. (See Kidney Disorders.)

► Clinical Findings

A. Symptoms and Signs

The symptoms of the disease are intense thirst, especially with a craving for ice water, and polyuria, the volume of ingested fluid varying from 2 L to 20 L daily, with correspondingly large urine volumes. Partial diabetes insipidus presents with less intense symptoms and should be suspected in patients with unremitting enuresis. Most patients with diabetes insipidus are able to maintain fluid balance by continuing to ingest large volumes of water. However, diabetes insipidus may present with hypernatremia and dehydration in patients without free access to water, or with a damaged hypothalamic thirst center and altered thirst sensation. Diabetes insipidus is aggravated by administration of high-dose corticosteroids, which increases renal free water clearance.

B. Laboratory Findings

The diagnosis of diabetes insipidus as a cause of polyuria or hypernatremia requires clinical judgment. There is no single diagnostic laboratory test. Evaluation for diabetes insipidus should include an accurate 24-hour urine collection that is measured for volume and creatinine. A urine volume of < 2 L/24 h (in the absence of hypernatremia) essentially rules out diabetes insipidus. Serum is assayed for glucose, urea

nitrogen, calcium, potassium, sodium, and uric acid. Hyperuricemia occurs in many patients with diabetes insipidus, since reduced vasopressin stimulation of the renal V1 receptor causes a reduction in the renal tubular clearance of urate.

A supervised “vasopressin challenge test” may be given: Desmopressin acetate is given in an initial dose of 0.05–0.1 mL (5–10 mcg) intranasally (or 1 mcg subcutaneously or intravenously), with measurement of urine volume for 12 hours before and 12 hours after administration. Serum sodium must be obtained immediately in the event of symptoms of hyponatremia. The dosage of desmopressin is doubled if the response is marginal. Patients with central diabetes insipidus notice a distinct reduction in thirst and polyuria; serum sodium stays normal except in some salt-losing conditions.

In **nonfamilial central diabetes insipidus**, MRI of the pituitary and hypothalamus and of the skull is done to look for mass lesions. The pituitary stalk may be thickened, which may be a manifestation of Langerhans cell histiocytosis, sarcoidosis, or lymphocytic hypophysitis. When **nephrogenic diabetes insipidus** is a diagnostic consideration, measurement of serum vasopressin is done during modest fluid restriction; typically, the vasopressin level is high.

► Differential Diagnosis

Central diabetes insipidus must be distinguished from polyuria caused by diabetes mellitus, Cushing syndrome or corticosteroid treatment, lithium, hypercalcemia, hypokalemia, and the nocturnal polyuria of Parkinson disease. It must also be distinguished from nephrogenic diabetes insipidus (see above), psychogenic polydipsia, central nervous system sarcoidosis, and intravenous fluid administration.

► Complications

If water is not readily available, the excessive output of urine will lead to severe dehydration. Patients with an impaired thirst mechanism are very prone to hypernatremia, particularly since they usually also have impaired mentation and forget to take their desmopressin. All the complications of the primary disease may eventually become evident. In patients who are receiving desmopressin acetate therapy, there is a danger of induced water intoxication.

► Treatment

Mild cases of diabetes insipidus require no treatment other than adequate fluid intake. Reduction of aggravating factors (eg, corticosteroids, which directly increase renal free water clearance) will improve polyuria.

Desmopressin acetate is the treatment of choice for central diabetes insipidus. It is also useful in diabetes insipidus associated with pregnancy or the puerperium, since desmopressin is resistant to degradation by the circulating vasopressinase.

Desmopressin is available as an oral preparation (0.1 or 0.2 mg tablets) that is given in a starting dose of 0.05 mg twice daily and increased to a maximum of 0.4 mg every 8 hours, if required. Oral desmopressin is particularly useful for patients with sinusitis from the nasal preparation.

Gastrointestinal symptoms, asthenia, and mild increases in hepatic enzymes can occur with the oral preparation.

The nasal preparation (100 mcg/mL solution) is given every 12–24 hours as needed for thirst and polyuria. It may be administered via metered-dose nasal inhaler containing 0.1 mL/spray or via a plastic calibrated tube. The starting dose is 0.05–0.1 mL every 12–24 hours, and the dose is then individualized according to response. Nasal desmopressin may cause nasal irritation.

Desmopressin is also available as a parenteral preparation containing 4 mcg/mL. For central diabetes insipidus, it is given intravenously, intramuscularly, or subcutaneously in doses of 1–4 mcg every 12–24 hours as needed to treat thirst or hyponatremia.

All desmopressin preparations may cause hyponatremia, which is uncommon if minimum effective doses are used and the patient allows thirst to occur periodically. All preparations of desmopressin can sometimes cause emotional changes, such as depression or agitation; erythromelalgia occurs rarely. All desmopressin preparations, including tablets, are subject to heat degradation and should be refrigerated.

Both central and nephrogenic diabetes insipidus respond partially to hydrochlorothiazide, 50–100 mg/d orally (with potassium supplement or amiloride). Nephrogenic diabetes insipidus may respond to combined treatments of indomethacin-hydrochlorothiazide, indomethacin-desmopressin, or indomethacin-amiloride. Indomethacin, 50 mg orally every 8 hours, is effective in acute cases.

Psychotherapy is required for most patients with psychogenic polydipsia. Thioridazine and lithium are best avoided if psychiatric drug therapy is needed, since they cause polyuria.

► Prognosis

Central diabetes insipidus appearing after pituitary surgery usually remits after days to weeks but may be permanent if the upper pituitary stalk is cut.

Chronic central diabetes insipidus is ordinarily more an inconvenience than a dire medical condition. Treatment with desmopressin allows normal sleep and activity. Hyponatremia can occur, especially when the thirst center is damaged, but diabetes insipidus does not otherwise reduce life expectancy, and the prognosis is that of the underlying disorder.

ACROMEGALY & GIGANTISM

ESSENTIALS OF DIAGNOSIS

- Excessive growth of hands, feet, jaw, and internal organs; or gigantism before closure of epiphyses.

- Amenorrhea, headaches, visual field loss, weakness.
- Soft, doughy, sweaty handshake.
- Elevated IGF-1.
- Serum GH not suppressed following oral glucose.

► General Considerations

GH exerts much of its growth-promoting effects by stimulating the release of IGF-I from the liver and other tissues.

Acromegaly is nearly always caused by a pituitary adenoma. These tumors may be locally invasive, particularly into the cavernous sinus. Less than 1% are malignant. Most are macroadenomas (over 1 cm in diameter). Acromegaly is usually sporadic but may rarely be familial. The disease may also be associated with endocrine tumors of the parathyroids or pancreas (MEN 1). Acromegaly may also be seen in McCune–Albright syndrome and as part of Carney syndrome (atrial myxoma, acoustic neuroma, lentiginosities, adrenal hypercortisolism). Acromegaly is rarely caused by ectopic secretion of GHRH or GH secreted by a lymphoma, hypothalamic tumor, bronchial carcinoid, or pancreatic tumor.

► Clinical Findings

A. Symptoms and Signs

Excessive GH causes tall stature and gigantism if it occurs in youth, before closure of epiphyses. Afterward, acromegaly develops. The term “acromegaly,” meaning extremity enlargement, seriously understates the manifestations. The hands enlarge and a doughy, moist handshake is characteristic. The fingers widen, causing patients to enlarge their rings. Carpal tunnel syndrome is common. The feet also grow, particularly in shoe width. Facial features coarsen since the bones and sinuses of the skull enlarge; hat size increases. The mandible becomes more prominent, causing prognathism and malocclusion. Tooth spacing widens.

Macroglossia occurs, as does hypertrophy of pharyngeal and laryngeal tissue; this causes a deep, coarse voice and sometimes makes intubation difficult. Obstructive sleep apnea may occur. A goiter may be noted. Hypertension (50%) and cardiomegaly are common. At diagnosis, about 10% of acromegalic patients have overt heart failure, with a dilated left ventricle and a reduced ejection fraction. Weight gain is typical, particularly of muscle and bone. Insulin resistance is usually present and frequently causes diabetes mellitus (30%). Arthralgias and degenerative arthritis occur. Overgrowth of vertebral bone can cause spinal stenosis. Colon polyps are common, especially in patients with skin papillomas. The skin may also manifest hyperhidrosis, thickening, cystic acne, skin tags, and areas of acanthosis nigricans.

GH-secreting pituitary tumors usually cause some degree of hypogonadism, either by cosecretion of PRL or by direct pressure upon normal pituitary tissue. Decreased libido and impotence are common, as are irregular menses or amenorrhea. Secondary hypothyroidism sometimes occurs; hypoadrenalism is unusual. Headaches are frequent.

Temporal hemianopia may occur as a result of the optic chiasm being impinged by a suprasellar growth of the tumor.

B. Laboratory Findings

For screening purposes, a random serum IGF-I can be obtained. If it is normal for age, acromegaly is ruled out. For further evaluation, the patient should be fasting for at least 8 hours (except for water), not acutely ill, and should not have exercised on the day of testing. Assay for the following: IGF-I (increased to over five times normal in most acromegalic patients), PRL (cosecreted by many GH-secreting tumors), glucose (diabetes is common in acromegaly), liver enzymes and blood urea nitrogen (BUN) (liver failure or kidney disease can misleadingly elevate GH), serum calcium (to screen for hyperparathyroidism), serum inorganic phosphorus (frequently elevated), serum free T_4 , and TSH (secondary hypothyroidism is common in acromegaly; primary hypothyroidism may increase PRL; hyperthyroidism may occur as a result of excess TSH).

Glucose syrup (75 g) is then administered orally, and serum GH is measured 60 minutes afterward; acromegaly is excluded if the serum GH is less than 1 ng/mL (immunoradiometric assay [IRMA] or chemiluminescent assays). For ultrasensitive GH assays, GH should be suppressed to less than 0.3 ng/mL to exclude acromegaly.

C. Imaging

MRI shows a pituitary tumor in 90% of acromegalic patients. These tumors ordinarily involve the sella and cavernous sinus; rare ectopic tumors may arise in the sphenoid bone. MRI is generally superior to CT scanning, especially in the postoperative setting. Radiographs of the skull may show an enlarged sella and thickened skull. Radiographs may also show tufting of the terminal phalanges of the fingers and toes. A lateral view of the foot shows increased thickness of the heel pad.

► Differential Diagnosis

Active acromegaly must be distinguished from familial coarse features, large hands and feet, and isolated prognathism and from inactive (“burned-out”) acromegaly in which there has been a spontaneous remission due to infarction of the pituitary adenoma. GH-induced gigantism must be differentiated from familial tall stature and from aromatase deficiency. (See Osteoporosis.)

Misleadingly high serum GH levels can be caused by exercise or eating just prior to the test; acute illness or agitation; liver failure or kidney disease; malnourishment; diabetes mellitus; or concurrent treatment with estrogens, β -blockers, or clonidine. During normal adolescence, serum IGF-I is usually elevated and GH may fail to be suppressed.

► Complications

Complications include hypopituitarism, hypertension, glucose intolerance or frank diabetes mellitus, cardiac enlargement, and cardiac failure. Carpal tunnel syndrome

may cause thumb weakness and thenar atrophy. Arthritis of hips, knees, and spine can be troublesome. Cord compression may be seen. Visual field defects may be severe and progressive. Acute loss of vision or cranial nerve palsy may occur if the tumor undergoes spontaneous hemorrhage and necrosis (pituitary apoplexy). Colon polyps are more likely to develop in patients with acromegaly.

► Treatment

Pituitary microsurgery is the treatment of choice for patients with acromegaly. Many patients have an apparent surgical cure and a remission in all clinical symptoms but continue to have a mildly elevated serum GH or IGF-I postoperatively. If no residual tumor is apparent on MRI, the patient may elect to be monitored closely, rather than embark on adjuvant medical therapy that is expensive and carries its own risks (see below).

A. Pituitary Microsurgery

Endoscopic transnasal, transsphenoidal pituitary microsurgery removes the adenoma while preserving anterior pituitary function in most patients. Surgical remission is achieved in about 70% of patients followed over 3 years. GH levels fall immediately; diaphoresis and carpal tunnel syndrome often improve within a day after surgery. Transsphenoidal surgery is usually well tolerated, but complications occur in about 10% of patients, including infection, cerebrospinal fluid leak, and hypopituitarism. Transsphenoidal pituitary surgery may be difficult in patients with McCune–Albright syndrome because of fibrous dysplasia of the skull base. Hyponatremia can occur 4–13 days postoperatively and is manifested by nausea, vomiting, headache, malaise, or seizure. It is prudent to monitor serum sodium levels postoperatively. Dietary salt supplements for 2 weeks postoperatively may prevent this complication. Corticosteroids are administered perioperatively and tapered to replacement doses over 1 week; hydrocortisone is discontinued and cosyntropin stimulation test is performed about 6 weeks after surgery. At that time, a serum T_4 can be checked (to screen for secondary hypothyroidism) and the patient is screened for secondary hypogonadism (see above).

B. Medications

Patients who do not have a clinical or biochemical remission after surgery are treated with a dopamine agonist (eg, cabergoline), somatostatin analogs, pegvisomant, or a combination of these medications. **Cabergoline** may be used first, since it is an oral medication. Cabergoline therapy is most successful for tumors that secrete both PRL and GH but can also be effective for patients with normal serum PRL levels. Therapy with cabergoline will shrink one-third of such tumors by more than 50%. The initial dose is 0.25 mg orally twice weekly, which is gradually increased to a maximum dosage of 1 mg twice weekly, if tolerated by the patient based on serum GH and IGF-I levels. Side effects of cabergoline include nausea, fatigue, constipation, abdominal pain, and dizziness. Cabergoline is expensive. Long-term, high-dose therapy with the dopamine agonists caber-

goline, bromocriptine, and pergolide for Parkinson disease has caused some cases of serious cardiac valve regurgitation, similar to that seen with other ergot alkaloids such as methysergide. In such cases of valvulopathy, cabergoline or pergolide had been given in doses of > 2.8 mg/d for over 6 months. Doses such as these are seldom used for patients with pituitary tumors. In a study of 78 patients who had taken cabergoline for a mean of 8 years, there was no increased risk of significant valvular insufficiency, but there was an increased risk of aortic valve calcification and mild tricuspid regurgitation compared with controls. Therefore, it is prudent to minimize cabergoline doses and to obtain baseline and periodic echocardiograms in patients receiving long-term cabergoline therapy.

Octreotide and **lanreotide** are somatostatin analogs that are given by subcutaneous injection. Octreotide (Sandostatin LAR depot) is given at a dose of 20–40 mg intragluteally monthly. Lanreotide acetate (Somatuline Depot) is given by subcutaneous intragluteal injection at a dosage of 60–120 mg monthly. Whichever preparation is used, the dosage can be adjusted to achieve serum GH levels under 2 ng/mL. Such long-acting somatostatin analogs can achieve serum GH levels under 2 ng/mL in 79% of patients and normal serum IGF-I levels in 53% of patients. Headaches often improve, and tumor shrinkage of about 30% may be expected. Acromegalic patients with pretreatment serum GH levels exceeding 20 ng/mL are less likely to respond to octreotide or lanreotide therapy. Side effects are experienced by about one-third of patients and include injection site pain, loose acholic stools, abdominal discomfort, or cholelithiasis. All somatostatin analogs are expensive and must be continued indefinitely or until other treatment has been effective.

Pegvisomant is a GH receptor antagonist that blocks hepatic IGF-I production. Pegvisomant therapy produces symptomatic relief and normalizes serum IGF-I levels in over 90% of patients. The starting dosage is 10 mg subcutaneously daily. The maintenance dosage can be increased by 5–10 mg every 4–6 weeks, based on serum IGF-I levels and liver transaminase levels; the maximum dosage is 40 mg subcutaneously daily. Pegvisomant does not shrink GH-secreting tumors. Patients need to be monitored carefully with visual field examinations, GH levels, and MRI scanning of the pituitary. Side effects of pegvisomant can include hepatitis, edema, flu-like syndrome, nausea, and hypertension. Lipohypertrophy can occur at injection sites, so injection sites must be diligently rotated and inspected. In acromegalic diabetics, hypoglycemic drugs are reduced to avoid hypoglycemia during pegvisomant therapy. The effectiveness of pegvisomant is reduced by coadministration of opioids or propoxyphene. Pegvisomant is detected in some GH assays, which could overestimate serum GH levels. Pegvisomant is extremely expensive.

C. Stereotactic Radiosurgery

Acromegalic patients who have not had a complete remission with transsphenoidal surgery or medical therapy may be treated with **stereotactic radiosurgery** administered by gamma knife, heavy particle radiation, or adapted linear

accelerator. Some medical centers are using pituitary gamma knife radiosurgery as the initial treatment with reported success rates of 20–90%. Radiosurgery precisely radiates the pituitary tumor in a single session and reduces radiation to the normal brain. However, it cannot be used for pituitary tumors with suprasellar extension due to the risk of damaging the optic chiasm. Radiosurgery can be used for pituitary tumors invading the cavernous sinus, since cranial nerves III, IV, V, and VI are less susceptible to radiation damage. Radiosurgery can also be used for patients who have not responded to conventional radiation therapy.

► Prognosis

Patients with acromegaly have increased morbidity and mortality from cardiovascular disorders and progressive acromegalic symptoms; those who are treated and have a glucose-suppressed serum GH level less than 2.5 ng/mL (radioimmunoassay) or under 1 ng/mL (immunofluorometric assay) and normal age-adjusted serum IGF-I levels have reduced morbidity and mortality. Transsphenoidal pituitary surgery is successful in 80–90% of patients with tumors less than 2 cm in diameter and GH levels less than 50 ng/mL. Extrasellar extension of the pituitary tumor, particularly cavernous sinus invasion, reduces the likelihood of surgical cure.

Adjuvant medical therapy has been quite successful in treating patients who are not cured by pituitary surgery. Postoperatively, normal pituitary function is usually preserved. Soft tissue swelling regresses but bone enlargement is permanent. Hypertension frequently persists despite successful surgery. Conventional radiation therapy (alone) produces a remission in about 40% of patients by 2 years and 75% of patients by 5 years after treatment. Gamma knife or cyberknife radiosurgery reduces GH levels an average of 77%, with 20% of patients having a full remission after 12 months. Patients with pituitary adenomas that abut the optic chiasm can be treated with cyberknife radiosurgery, controlling tumor growth and preserving vision in most patients. Heavy particle pituitary radiation produces a remission in about 70% of patients by 2 years and 80% of patients by 5 years. Radiation therapy eventually produces some degree of hypopituitarism in most patients. Conventional radiation therapy may cause some degree of organic brain syndrome and predisposes to small strokes. Patients must receive lifelong follow-up, with regular monitoring of serum GH and IGF-I levels. Serum GH levels over 5 ng/mL and rising IGF-I levels usually indicate a recurrent tumor.

Hypopituitarism may occur, due to the tumor itself, pituitary surgery, or radiation therapy. Hypopituitarism may develop years following radiation therapy, so patients must have regular clinical monitoring of their pituitary function.

HYPERPROLACTINEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ **Women:** Oligomenorrhea, amenorrhea; galactorrhea; infertility.
- ▶ Prolactin normally elevated during pregnancy.
- ▶ **Men:** Hypogonadism; decreased libido and erectile dysfunction; infertility.
- ▶ Elevated serum PRL.
- ▶ CT scan or MRI often demonstrates pituitary adenoma.

▶ General Considerations

Non-gestational elevations in serum PRL can be caused by numerous conditions (Table 26–2). PRL-secreting pituitary tumors are more common in women than in men and are usually sporadic but may rarely be familial as part of MEN 1. Most are microadenomas (< 1 cm in diameter) that do not grow even with pregnancy or oral contraceptives. However, some giant prolactinomas (over 3 cm in diameter) can spread into the cavernous sinuses and suprasellar areas; rarely, they may erode the floor of the sella to invade the sinuses.

▶ Clinical Findings

A. Symptoms and Signs

Hyperprolactinemia may result in hypogonadotropic hypogonadism and reduced fertility. Men usually have erectile dysfunction and diminished libido; gynecomastia sometimes occurs but rarely with galactorrhea. Women may note oligomenorrhea or amenorrhea, although some women continue to menstruate normally. Galactorrhea, defined as lactation in the absence of nursing, is common. Of women with secondary amenorrhea and galactorrhea, about 70% have hyperprolactinemia. Untreated hypogonadism ultimately increases the risk of developing osteoporosis.

Pituitary prolactinomas may cosecrete GH and cause acromegaly (see above). Large tumors may cause headaches, visual symptoms, and pituitary insufficiency.

Aside from pituitary tumors, some women secrete an abnormal form of prolactin that appears to cause peripartum cardiomyopathy (see Chapter 10). Suppression of prolactin secretion with dopamine agonists has reversed the cardiomyopathy.

Table 26–2. Causes of hyperprolactinemia.

| Physiologic Causes | Pharmacologic Causes | Pathologic Causes |
|--------------------------------------|--|--|
| Exercise | Amoxapine | Acromegaly |
| Idiopathic | Amphetamines | Chronic chest wall stimulation (post-thoracotomy, post-mastectomy, herpes zoster, breast problems, chest acupuncture, nipple rings, etc) |
| Macroprolactinemia (“big prolactin”) | Anesthetic agents | Cirrhosis |
| Pregnancy | Antipsychotics (conventional and atypical) | Hypothalamic disease |
| Puerperium | Butyrophenones | Hypothyroidism |
| Sleep (REM phase) | Cimetidine and ranitidine (not famotidine or nizatidine) | Kidney disease (especially with zinc deficiency) |
| Stress (trauma, surgery) | Estrogens | Multiple sclerosis |
| Suckling | Hydroxyzine | Optic neuromyelitis |
| | Methyldopa | Pituitary stalk section |
| | Metoclopramide | Prolactin-secreting tumors |
| | Opioids | Pseudocyesis (false pregnancy) |
| | Nicotine | Spinal cord lesions |
| | Phenothiazines | Systemic lupus erythematosus |
| | Protease inhibitors | |
| | Progestins | |
| | Reserpine | |
| | Risperidone | |
| | Selective serotonin reuptake inhibitors | |
| | Testosterone | |
| | Tricyclic antidepressants | |
| | Verapamil | |

B. Laboratory Findings

Evaluate for conditions known to cause hyperprolactinemia, particularly pregnancy (serum hCG), hypothyroidism (serum FT₄ and TSH), kidney disease (BUN and serum creatinine), cirrhosis (clinical evaluation and serum bilirubin and liver enzymes) and hyperparathyroidism (serum calcium). Men are evaluated for hypogonadism with determinations of serum total and free testosterone, LH, and FSH. Women who have amenorrhea are assessed for hypogonadism with determinations of serum estradiol, LH, and FSH. An assay for macroprolactinemia should be considered for patients with hyperprolactinemia who are relatively asymptomatic and have no apparent cause for hyperprolactinemia. Patients with pituitary macroadenomas (> 3 cm in diameter) should have PRL measured on serial dilutions of serum, since IRMA assays may otherwise report falsely low titers, the “high-dose hook effect.” Patients with macroprolactinomas or manifestations of possible hypopituitarism should be evaluated for hypopituitarism as described above.

C. Imaging

When hyperprolactinemia persists without obvious cause, MRI of the pituitary and hypothalamus is indicated. Small prolactinomas may thus be demonstrated, but clear differentiation from normal variants is not always possible.

► Differential Diagnosis

The causes of hyperprolactinemia are shown in Table 26–2. Chronic nipple stimulation, nipple piercing, augmentation or reduction mammoplasty, and mastectomy may stimulate PRL secretion. The pituitary tumor of acromegaly can cosecrete GH and PRL. Hyperprolactinemia may also be idiopathic. Increased pituitary size is a normal variant in young women. About 10% of hyperprolactinemic patients are found to be secreting macroprolactin, a relatively inactive “big prolactin”; pituitary MRI is normal in 78% of cases.

The differential diagnosis for galactorrhea includes the small amount of breast milk that can be expressed from the nipple in many parous women that is not cause for concern. Nipple stimulation from nipple rings, chest surgery, or acupuncture can cause galactorrhea; serum PRL levels may be normal or minimally elevated. Some women can have galactorrhea with normal serum PRL levels and no discernible cause (idiopathic). Normal breast milk may be various colors besides white. Bloody galactorrhea requires an evaluation for breast malignancy.

► Treatment

Medications known to increase PRL should be stopped if possible. Hyperprolactinemia due to hypothyroidism is corrected by thyroxine. Patients with hyperprolactinemia not induced by drugs, hypothyroidism, or pregnancy should be examined by pituitary MRI.

Women with microprolactinomas who have amenorrhea or are desirous of contraception may safely take oral contraceptives or estrogen replacement—there is minimal risk of stimulating enlargement of the microadenoma. Patients with infertility and hyperprolactinemia may be treated with a dopamine agonist in an effort to improve fertility. Women with amenorrhea who elect to receive no treatment have an increased risk of developing osteoporosis; such women require periodic bone densitometry.

Pituitary macroprolactinomas (> 10 mm in diameter) have a higher risk of progressive growth, particularly during treatment with estrogen or testosterone replacement therapy or during pregnancy. Therefore, patients with macroprolactinomas should not be treated with sex hormone replacement therapy (HRT) unless they are in remission with dopamine agonist medication or surgery. Pregnant women with macroprolactinomas should continue to receive treatment with dopamine agonists throughout the pregnancy to prevent tumor growth.

A. Dopamine Agonists

Dopamine agonists are the initial treatment of choice for patients with giant prolactinomas and those with hyperprolactinemia desiring restoration of normal sexual function and fertility. Of the ergot-derived dopamine agonists, cabergoline is usually the best tolerated. The beginning dosage is 0.25 mg orally once weekly for 1 week, then 0.25 mg twice weekly for the next week, then 0.5 mg twice weekly. Further dosage increases may be required monthly, based on serum PRL levels, up to a maximum of 1.5 mg twice weekly. Alternative drugs include bromocriptine

(1.25–20 mg/d orally). Women who experience nausea with oral preparations may find relief with deep vaginal insertion of cabergoline or bromocriptine tablets; vaginal irritation sometimes occurs. Quinagolide (Norprolac; not available in the United States) is a non-ergot-derived dopamine agonist for patients intolerant or resistant to ergot-derived medications; the starting dosage is 0.075 mg/d orally, increasing as needed and tolerated to a maximum of 0.6 mg/d. Patients whose tumor is resistant to one dopamine agonist may be switched to another in an effort to induce a tolerable remission.

Dopamine agonists are given at bedtime to minimize side effects of fatigue, nausea, dizziness, and orthostatic hypotension. These symptoms usually improve with dosage reduction and continued use. Erythromelalgia is rare. Dopamine agonists can cause a variety of psychiatric side effects that are not dose related and may take weeks to resolve once the dopamine agonist is discontinued. Therefore, dopamine agonists should be used judiciously in psychiatric patients whose antipsychotic medications have caused hyperprolactinemia. Cabergoline has caused cardiac valve insufficiency in patients with Parkinson disease after prolonged administration at doses greater than 3 mg/d, but such doses are not used for suppression of pituitary prolactinomas.

With dopamine agonist treatment, 90% of patients with prolactinomas experience a fall in serum PRL to 10% or less of pretreatment levels; about 80% of treated patients achieve a normal serum PRL level. Shrinkage of a pituitary adenoma occurs early, but the maximum effect may take up to a year. Nearly half of prolactinomas—even massive tumors—shrink more than 50%. Such shrinkage of giant prolactinomas can result in spinal fluid rhinorrhea. Discontinuing therapy after months or years usually results in the reappearance of hyperprolactinemia and galactorrhea-amenorrhea, but some patients with microadenomas remain in remission.

Because dopamine agonists usually restore fertility promptly, many pregnancies have resulted; no teratogenicity has been noted with any of the dopamine agonists. However, women with microadenomas may have treatment withdrawn during pregnancy. Macroadenomas may enlarge significantly during pregnancy; if therapy is withdrawn, such patients must be monitored clinically with serum PRL determinations and with computer-assisted visual field perimetry. Women with macroprolactinomas who have responded to dopamine agonists may safely receive oral contraceptive agents as long as they continue receiving therapy.

The initial dose is 0.25 mg orally twice weekly, which is gradually increased to a maximum dosage of 1 mg twice weekly according to serum prolactin levels. Side effects of cabergoline include nausea, fatigue, constipation, abdominal pain, and dizziness. Cabergoline is expensive. Long-term high-dose therapy for patients with Parkinson disease with the dopamine agonists cabergoline, bromocriptine, and pergolide has caused some cases of serious cardiac valve regurgitation, similar to that seen with other ergot alkaloids such as methysergide. In such cases of valvulopathy, cabergoline or pergolide had been given in doses of > 2 mg/d for

over 6 months. Doses such as these are seldom used for patients with pituitary tumors. In a study of 78 patients who had taken cabergoline for a mean of 8 years, there was no increased risk of significant valvular insufficiency, but there was an increased risk of aortic valve calcification and mild tricuspid regurgitation compared with controls. Therefore, it is prudent to minimize cabergoline doses and to obtain baseline and periodic echocardiograms in patients receiving long-term cabergoline therapy.

B. Surgical Treatment

Transsphenoidal pituitary surgery may be urgently required for large tumors undergoing apoplexy or those severely compromising visual fields. It is also used electively for patients who do not tolerate or respond to dopamine agonists. Pituitary transsphenoidal surgery is generally well-tolerated, with a surgical mortality rate of less than 0.5%. Complications, such as cerebrospinal fluid leakage, meningitis, stroke, or visual loss, occur in about 3% of cases; sinusitis, nasal septal perforation, or infection complicates about 6.5% of surgeries. Postoperative hyponatremia occurs quite commonly, and it is advisable to monitor serum sodium levels for the first 2 weeks postoperatively. For pituitary microprolactinomas, skilled neurosurgeons are successful in normalizing prolactin in 87% of patients; the 10-year recurrence rate is 13%. Pituitary function can be preserved in over 95% of cases. However, the surgical success rate for macroprolactinomas is much lower, and the complication rates are higher. Craniotomy is rarely indicated, since even large tumors can usually be decompressed via the transsphenoidal approach.

C. Radiation Therapy

Radiation therapy is reserved for patients with macroadenomas that are growing despite treatment with dopamine agonists. A single gamma knife or cyberknife treatment is preferable for certain patients whose optic chiasm is clear of tumor, since it is generally safer and more convenient than conventional radiation therapy. Conventional radiation therapy must be given over 5 weeks and carries a high risk of eventual hypopituitarism. Other possible side effects include some degree of memory impairment and an increased long-term risk of second tumors and small vessel ischemic strokes. After radiation therapy, patients are advised to take low-dose aspirin daily for life to reduce their stroke risk.

DISEASES OF THE THYROID GLAND

THYROID TESTING

Assays for FT₄, total triiodothyronine (T₃), and free triiodothyronine (FT₃) have largely supplanted measurements of total T₄, resin T₃ uptake (RT₃U), and free thyroxine index (FT₄I). It is particularly important to determine “free” serum levels (FT₄ and FT₃) in conditions associated with high circulating levels of thyroxine-binding globulin, such as during pregnancy or therapy with oral estrogen. Ultrasensitive assays for serum TSH have largely replaced older TSH assays. Table 26–3 shows the appropriate use of thyroid tests.

► Effects of Nonthyroidal Illness & Drugs on Thyroid Function Tests

Many factors affect thyroid function tests, causing misleading laboratory evidence of hypothyroidism (Table 26–4) or hyperthyroidism (Table 26–5) in patients who are clinically euthyroid.

Serum T₄ is frequently low in patients with severe illness, caloric deprivation, or major surgery who have accelerated peripheral metabolism of serum T₄ to reverse T₃ (rT₃). Furthermore, in most patients who are critically ill, there is a circulating inhibitor of thyroid hormone binding to serum thyroxine-binding proteins (TBPs). This causes the RT₃U to be misleadingly low, causing the computed FT₄I to be very low. The presence of a very low serum T₄ in severe nonthyroidal illness indicates a poor prognosis.

Direct assays of FT₄ often show low levels of FT₄ in severe illness. Because studies of giving replacement T₄ to such patients have shown no improvement in survival, they are considered “**euthyroid sick**.” Serum TSH tends to be suppressed in severe nonthyroidal illness, making the diagnosis of concurrent primary hypothyroidism quite difficult, although the presence of a goiter suggests the diagnosis.

The clinician must decide whether such severely ill patients (with a low serum T₄ but nonelevated TSH) might have hypothyroidism due to pituitary insufficiency. Patients without symptoms of prior brain lesion or hypopituitarism are very unlikely to suddenly develop hypopituitarism during an unrelated illness. Patients with diabetes insipidus, hypopituitarism, or other signs of a central nervous system lesion may have T₄ given empirically. True secondary hypothyroidism due to direct dopamine suppression of TSH-secreting cells may develop in patients receiving prolonged dopamine infusions.

Certain antiseizure medications cause low serum FT₄ levels by accelerating hepatic conversion of T₄ to T₃; serum TSH levels are normal.

HYPOTHYROIDISM & MYXEDEMA

ESSENTIALS OF DIAGNOSIS

- ▶ Weakness, fatigue, cold intolerance, constipation, weight change, depression, menorrhagia, hoarseness.
- ▶ Dry skin, bradycardia, delayed return of deep tendon reflexes.
- ▶ Anemia, hyponatremia, hyperlipidemia.
- ▶ FT₄ level is usually low.
- ▶ TSH elevated in primary hypothyroidism.

▶ General Considerations

Hypothyroidism is common, affecting over 1% of the general population and about 5% of individuals over age 60 years. Thyroid hormone deficiency affects almost all body functions. The degree of severity ranges from mild and unrecognized hypothyroid states to striking myxedema. The fluid retention seen in myxedema is caused by the interstitial accumulation of hydrophilic mucopolysaccharides, which leads to lymphedema. Hyponatremia is the result of impaired renal tubular sodium reabsorption due to reductions in Na⁺-K⁺-ATPase.

Hypothyroidism may be due to failure or resection of the thyroid gland itself or deficiency of pituitary TSH (see Hypopituitarism, above). The condition must be distinguished from the functional hypothyroidism that occurs in severe nonthyroidal illness, which does not require treatment with thyroxine (see Euthyroid Sick, above).

Maternal hypothyroidism during pregnancy results in offspring with IQ scores that are an average 7 points lower than those of euthyroid mothers.

Goiter may be present with thyroiditis, iodide deficiency, genetic thyroid enzyme defects, drug goitrogens (lithium, iodide, propylthiouracil or methimazole, phenylbutazone, sulfonamides, amiodarone, interferon- α , interferon- β , interleukin-2), food goitrogens in iodide-deficient areas (eg, turnips, cassavas) or, rarely, peripheral resistance to thyroid hormone or infiltrating diseases (eg, cancer, sarcoidosis). A hypothyroid phase occurs in subacute (de Quervain) viral thyroiditis following initial hyperthyroidism. Hashimoto thyroiditis is the most common cause of hypothyroidism (see Thyroiditis section).

Goiter is usually absent when hypothyroidism is due to destruction of the gland by surgery, radiation therapy (to the head, neck, chest, and shoulder region), or ¹³¹I. Chemotherapy can reduce thyroid function, causing hypothyroidism. Sunitinib, a protein-tyrosine kinase inhibitor used to treat gastrointestinal stromal malignancies, causes transient primary hypothyroidism in about 50% of treated patients.

Amiodarone, because of its high iodine content, causes clinically significant hypothyroidism in about 8% of patients who receive it. The T₄ level is normal or low, and the TSH is elevated, usually over 20 ng/dL. Another 17% of

¹True primary hypothyroidism may coexist.

T₄, levothyroxine; T₃, triiodothyronine; TSH, thyroid-stimulating hormone.

patients develop milder elevations of TSH and are asymptomatic. Low-dose amiodarone is less likely to cause hypothyroidism. Cardiac patients with amiodarone-induced symptomatic hypothyroidism are treated with just enough thyroxine to relieve symptoms. Hypothyroidism usually resolves over several months if amiodarone is discontinued. Hypothyroidism may also develop in patients with a high iodine intake from other sources, especially if they have underlying lymphocytic thyroiditis.

Hepatitis C is associated with an increased risk of autoimmune thyroiditis, with 21% of affected patients having antithyroid antibodies and 13% having hypothyroidism. The risk of thyroid dysfunction is even higher when patients are treated with interferon. Interferon- α and interferon- β treatment can induce thyroid dysfunction (usually hypothyroidism, sometimes hyperthyroidism) in 6% of patients. Spontaneous resolution occurs in over 50% of cases once interferon is discontinued.

► Clinical Findings

These may vary from the rather rare full-blown myxedema to mild states of hypothyroidism, which are far more

common. Mild hypothyroidism often escapes detection without screening (ie, serum TSH). Hypothyroidism is a common disorder; therefore, a clinician should request thyroid function tests for any patient with the nonspecific symptoms or signs of hypothyroidism.

A. Symptoms and Signs

1. Common manifestations—Common symptoms of hypothyroidism include weight gain, fatigue, lethargy, depression, weakness, dyspnea on exertion, arthralgias or myalgias, muscle cramps, paresthesias, cold intolerance, constipation, dry skin, headache, carpal tunnel syndrome, and menorrhagia. Physical findings can include bradycardia; diastolic hypertension; thin, brittle nails; thinning of hair; peripheral edema; puffy face and eyelids; and skin pallor or yellowing (carotenemia). Delayed relaxation of deep tendon reflexes may be present. Patients often have a palpably enlarged thyroid (goiter) that arises due to elevated serum TSH levels or the underlying thyroid pathology, such as Hashimoto thyroiditis.

2. Less common manifestations—Less common symptoms of hypothyroidism include diminished appetite and

weight loss, hoarseness, decreased sense of taste and smell, and diminished auditory acuity. Some patients may complain of dysphagia or neck discomfort. Although most menstruating women have menorrhagia, some women have scant menses or amenorrhea. Physical findings may include thinning of the outer halves of the eyebrows; thickening of the tongue; hard pitting edema; and effusions into the pleural and peritoneal cavities as well as into joints. Galactorrhea may also be present. Cardiac enlargement (“myxedema heart”) and pericardial effusions may occur. Psychosis may occur and is termed “myxedema madness.” Hypothermia and stupor or myxedema coma, which is often associated with infection (especially pneumonia), may develop in patients with severe hypothyroidism. Pituitary enlargement due to hyperplasia of TSH-secreting cells, which is reversible following thyroid therapy, may be seen in long-standing hypothyroidism.

B. Laboratory Findings

The single best screening test for hypothyroidism is the serum TSH (Table 26-3). Serum TSH is increased with primary hypothyroidism but is low or normal with pituitary insufficiency. The FT₄ may be low or low-normal. Other laboratory abnormalities may often be seen: increased serum LDL cholesterol, triglycerides, lipoprotein (a), liver enzymes, and creatine kinase; increased serum PRL; and hyponatremia, hypoglycemia, and anemia (with normal or increased mean corpuscular volume). Semen analysis shows an increase in abnormal sperm morphology. In patients with autoimmune thyroiditis, titers of antibodies against thyroperoxidase and thyroglobulin are high; serum antinuclear antibodies (ANA) are usually present and are not indicative of lupus.

The normal range for ultrasensitive TSH levels is generally stated to be 0.4–4.0 mU/L. However, the normal range of TSH varies with age such that newborns have a much higher normal range; children and elderly patients have a mildly higher normal range. Over 95% of normal adults have serum TSH concentrations under 3.0 mU/L. There is a high risk of finding antithyroid antibodies in patients with serum TSH in the upper range of normal, but most such patients are asymptomatic. TSH may be mildly elevated in some euthyroid individuals, especially elderly women (10% incidence). Such patients with normal FT₄ levels must be evaluated carefully for subtle signs of hypothyroidism (eg, fatigue, depression, hyperlipidemia). About 18% later become definitely hypothyroid.

C. Imaging

Radiologic imaging is usually not necessary for patients with hypothyroidism. However, on CT or MRI, a goiter may be noted in the neck or in the mediastinum (retrosternal goiter). An enlarged thymus is frequently seen in the mediastinum in cases of autoimmune thyroiditis. In primary hypothyroidism with elevated serum TSH levels, MRI of the head will frequently show an enlargement of the pituitary gland from thyrotrophe hyperplasia; such enlargement can be mistaken for a pituitary tumor.

► Differential Diagnosis

Many clinical manifestations of hypothyroidism (see above) are common in the general population without thyroid illness. The differential diagnoses are the conditions and drugs that can cause aberrations in laboratory tests, resulting in a low serum T₄ or T₃ or high serum TSH in the absence of hypothyroidism (see Table 26-4). The pituitary is often quite enlarged in primary hypothyroidism due to reversible hyperplasia of TSH-secreting cells; the concomitant hyperprolactinemia seen in hypothyroidism can lead to the mistaken diagnosis of a TSH-secreting or PRL-secreting pituitary adenoma.

► Complications

Complications are mostly cardiac in nature, occurring as a result of advanced coronary artery disease and congestive heart failure, which may be precipitated by overly vigorous thyroid therapy. There is an increased susceptibility to infection. Megacolon has been described in long-standing hypothyroidism. Organic psychoses with paranoid delusions may occur (“myxedema madness”). Rarely, adrenal crisis may be precipitated by thyroid therapy. Hypothyroidism is a rare cause of infertility, which may respond to thyroid medication. Pregnancy in a woman with untreated hypothyroidism often results in miscarriage. Sellar enlargement and even well-defined TSH-secreting tumors may develop in untreated cases. These tumors decrease in size after replacement therapy is instituted.

Myxedema crisis refers to severe, life-threatening hypothyroidism. The manifestations of hypothyroidism are present and more severe. Affected patients have impaired cognition, ranging from confusion to somnolence to coma (myxedema coma). Convulsions and abnormal central nervous system signs may occur. Patients have severe hypothermia, hypoventilation, hyponatremia, hypoglycemia, and hypotension. Rhabdomyolysis and acute kidney injury may occur. Myxedema coma is often induced by an underlying infection; cardiac, respiratory, or central nervous system illness; cold exposure; or drug use. It is most often seen in elderly women who have had a stroke or who have stopped taking their thyroxine medication. The mortality rate from myxedema coma is high. Myxedematous patients are unusually sensitive to opioids and may die from average doses. Patients with severe myxedema may have hyponatremia that is severe and refractory to treatment.

► Treatment

Levothyroxine (thyroxine; T₄) is the treatment of choice. It is partially converted in the body to T₃, the active thyroid hormone. Hypothyroid patients who are taking thyroxine replacement typically have serum T₃ levels that are lower than normal, owing to their lack of thyroidal T₃ secretion. Oral administration of T₃ or T₄/T₃ combination preparations causes abnormal peaks in serum T₃ and the usefulness of T₃ for hypothyroidism is controversial; a sustained-release T₃ preparation is not commercially available.

In patients taking levothyroxine daily, significant increases in serum T₄ levels are seen within 1–2 weeks, and

near-peak levels are seen within 3–4 weeks. Thyroxine is best taken in the morning with water, avoiding concomitant intake of foods and drugs that may interfere with its absorption (see below).

Before therapy with thyroid hormone is commenced, the hypothyroid patient requires at least a clinical assessment for adrenal insufficiency, for which the patient would require evaluation and concurrent treatment.

A. Beginning Treatment for Hypothyroidism

Otherwise healthy young and middle-age adults with hypothyroidism may be treated initially with levothyroxine in doses of 25–75 mcg daily. The lower doses are used for very mild hypothyroidism, while higher doses are given for more symptomatic hypothyroidism. The average daily thyroxine requirement averages 1.7 mcg/kg for this group of patients. The thyroxine dosage may be increased according to clinical response and serum TSH measurements, trying to keep the serum TSH level between 0.4 mU/L and 2.0 mU/L. The ultimate levothyroxine dosage requirement varies considerably.

Women who are pregnant with significant hypothyroidism may begin therapy with levothyroxine at higher doses of 100–150 mcg orally daily.

Patients with coronary disease or those who are over age 60 years are treated with smaller initial doses of levothyroxine, 25–50 mcg daily; higher initial doses may be used if such patients are severely hypothyroid. The dose can be increased by 25 mcg every 1–3 weeks until the patient is euthyroid. The average daily requirement for elderly patients averages 1 mcg/kg. Patients with hypothyroidism and known ischemic heart disease may begin thyroxine therapy following restoration of coronary perfusion by coronary artery angioplasty or bypass.

Myxedema crisis requires larger initial doses of levothyroxine intravenously, since myxedema itself can interfere with levothyroxine's intestinal absorption. Levothyroxine sodium 400 mcg is given intravenously as a loading dose, followed by 50–100 mcg intravenously daily; the lower dose is given to patients with suspected coronary insufficiency. In patients with myxedema coma, liothyronine (T_3 , Triostat) can be given intravenously in doses of 5–10 mcg every 8 hours for the first 48 hours. The hypothermic patient is warmed only with blankets, since faster warming can precipitate cardiovascular collapse. Patients with hypercapnia require intubation and assisted mechanical ventilation. Infections must be detected and treated aggressively. Patients in whom concomitant adrenal insufficiency is suspected are treated with hydrocortisone, 100 mg intravenously, followed by 25–50 mg every 8 hours.

B. Monitoring & Optimizing Treatment of Hypothyroidism

It is important to stress to the patient that levothyroxine therapy must be continued long-term (usually in doses 50–250 mcg orally daily) and that regular clinical reassessments will be required for life.

For most patients with hypothyroidism, a stable maintenance dose can usually be found. However, the dosage

requirement can rise due to increased hepatic metabolism of thyroxine induced by certain medications: carbamazepine, phenobarbital, primidone, phenytoin, rifabutin, rifampin, and the antitumor drug imatinib (Gleevec). Amiodarone can cause changes in thyroxine dose requirements, making it necessary to closely monitor serum TSH and adjust the thyroxine dosage accordingly in these patients. Malabsorption of thyroxine can be caused by coadministration of binding substances, particularly iron preparations (including iron found in multivitamins), raloxifene, sucralfate, aluminum hydroxide antacids, calcium and magnesium supplements, and soy milk or soy protein supplements. Bile acid-binding resins such as cholestyramine can bind T_4 and impair its absorption even when administered 5 hours before the T_4 . Proton pump inhibitors interfere slightly with the absorption of levothyroxine. Compared with Synthroid brand of T_4 (100%), there are varying bioavailabilities of different thyroxine preparations: Lannet generic T_4 (Unithyroid), 103%; Mylar generic T_4 , 109%; Sandoz generic T_4 , 109%; and Levoxyl brand T_4 , 114%. Such differences in bioavailability of different T_4 formulations may have a subtle but significant clinical impact. It is therefore recommended that patients always continue to take the same brand name of thyroxine or the same manufacturer's generic thyroxine.

Women with hypothyroidism typically require increased doses of T_4 during pregnancy and during therapy with oral estrogen. Conversely, T_4 dosage requirements for women often decrease with delivery, cessation of oral estrogen, and menopause.

There is no standardized optimal dose of levothyroxine, so each patient's dose must be based on careful clinical assessment. Although serum TSH levels can be helpful in determining optimal dosing, it is important not to rely entirely on this test alone.

During pregnancy, it is critical to administer adequate levothyroxine to a hypothyroid woman. Although the fetal thyroid begins secreting thyroid hormone at about 18 weeks of gestation, fetal thyroid development is not complete until term. The fetus is at least partially dependent upon maternal T_4 for central nervous system development—particularly in the second trimester. Maternal hypothyroidism after the first trimester appears to cause some developmental delay in offspring. It is therefore important to carefully monitor women with hypothyroidism during their pregnancies with serum TSH (FT_4 concentrations in hypopituitarism) determinations every 4–6 weeks and to increase T_4 replacement progressively as required (see Chapter 19, Obstetrics & Obstetric Disorders).

There is considerable individual variation in the requirement for additional T_4 replacement during pregnancy. An increase in thyroxine requirement has been noted as early as the fifth week of pregnancy. Therefore, for women receiving replacement thyroxine, it is prudent to increase thyroxine dosages by approximately 30% as soon as pregnancy is confirmed. By mid pregnancy, women require an average of 47% increase in their thyroxine dosage.

The increased T_4 dosage requirements during pregnancy are believed to be due to several factors: (1) Rising estrogen levels during pregnancy increase thyroxine binding globulin

(T₄) serum concentrations, reducing FT₄ levels. (2) Placental deiodinase promotes the turnover of T₄. (3) Supplemental iron and prenatal multivitamins containing iron can bind to oral T₄ and reduce its intestinal absorption. Similarly, supplemental calcium can also reduce T₄ absorption. Therefore, it is important that patients take their T₄ replacement at least 4 hours before or after such dietary supplements. Postpartum, T₄ replacement requirements ordinarily return to prepregnancy levels.

Elevated serum TSH levels usually indicate underreplacement with levothyroxine. However, before increasing the T₄ dosage, confirm compliance and ask the patient about the presence of angina. It is also important to consider the following: A high TSH in a patient receiving standard replacement doses of T₄ may indicate malabsorption of levothyroxine due to concurrent administration with binding substances (see above). Malabsorption of T₄ can also occur in short bowel syndrome; therapy with medium chain triglyceride oil may improve absorption. Impaired absorption of T₄ can also be caused by diarrhea of any cause or malabsorption due to sprue, regional enteritis, liver disease, or pancreatic exocrine insufficiency. Serum TSH may be elevated transiently in acute psychiatric illness and during recovery from nonthyroidal illness. Autoimmune disease can cause false elevations of TSH by interfering with the assay. A high TSH can also be caused by thyrotropin-secreting pituitary tumors. TSH may be increased by phenothiazines and atypical antipsychotics.

Suppressed serum TSH levels < 0.1 mU/L (using a sensitive assay) may indicate overreplacement with levothyroxine; if such a patient has manifestations of hyperthyroidism, the dosage of levothyroxine is reduced. However, some patients with suppressed serum TSH levels exhibit no symptoms of hyperthyroidism. For such patients, it is important to determine whether hypopituitarism or severe nonthyroidal illness is present, which can result in low serum TSH levels without hyperthyroidism. TSH can also be suppressed by certain medications, such as nonsteroidal anti-inflammatory drugs, opioids, nifedipine, verapamil, and urgent administration of corticosteroids. Absent such conditions, a clinically euthyroid patient with a low serum TSH should be given a lower dosage of levothyroxine. Patients who exhibit hypothyroid symptoms on the reduced dosage of levothyroxine may have their higher dosage resumed, unless they have coronary insufficiency.

Some hypothyroid patients treated with levothyroxine complain of hypothyroid-type symptoms, particularly fatigue, despite having normal or suppressed levels of TSH and normal levels of FT₄. Such patients require careful assessment for other concurrent illnesses such as adrenal insufficiency, hypogonadism, anemia, or depression. If such conditions are treated and hypothyroid-type symptoms persist despite normal or low TSH levels, a serum T₃ level (FT₃ in pregnancy and women receiving oral estrogens) may help make the difficult decision about whether to increase the levothyroxine dose. If the serum T₃ level is low or low normal, such a patient may benefit from a careful increase in T₄ dosage; if a definite clinical benefit is achieved, the higher dose is continued. However, long-term monitoring for atrial arrhythmias and for osteoporosis is recommended for such

patients, though such complications are uncommon in those who are clinically euthyroid. The malaise felt by some hypothyroid patients despite apparent optimal replacement therapy with T₄ may be caused by a low concentration of T₃ in certain tissues. Studies adding T₃ to T₄ therapy have not typically shown objective improvement, but patients tend to lose weight and to subjectively prefer combined T₄/T₃ mixtures to T₄ alone. A Dutch double-blind study of 141 hypothyroid patients found that most patients subjectively preferred not T₄ but a combined T₄/T₃ preparation in 5:1 or 10:1 ratios, such that TSH was often suppressed; satisfaction correlated with weight loss.

▶ Prognosis

Hypothyroidism caused by interferon- α resolves within 17 months of stopping the drug in 50% of patients. Patients with mild hypothyroidism caused by Hashimoto thyroiditis have a remission rate of 11%. With early treatment of hypothyroidism, striking transformations take place both in appearance and mental function. Return to a normal state is usually the rule, but relapses will occur if treatment is interrupted. On the whole, response to thyroid treatment is most satisfactory. However, untreated hypothyroid patients with myxedema crisis have a mortality rate approaching 100%. Even with optimal treatment, patients with myxedema crisis have a mortality rate of 20–50%.

HYPERTHYROIDISM (Thyrototoxicosis)

ESSENTIALS OF DIAGNOSIS

- ▶ Sweating, weight loss or gain, anxiety, palpitations, loose stools, heat intolerance, irritability, fatigue, weakness, menstrual irregularity.
- ▶ Tachycardia; warm, moist skin; stare; tremor.
- ▶ In Graves disease: goiter (often with bruit); ophthalmopathy.
- ▶ Suppressed TSH in primary hyperthyroidism; increased T₄, FT₄, T₃, FT₃.

► General Considerations

The term “thyrotoxicosis” refers to the clinical manifestations associated with serum levels of T_4 or T_3 that are excessive for the individual (hyperthyroidism). Serum TSH levels are suppressed in primary hyperthyroidism. However, laboratory tests can be affected by certain conditions and drugs that may lead to the erroneous diagnosis of hyperthyroidism in euthyroid individuals (Table 26–5). The causes of hyperthyroidism are many and diverse, as described below.

A. Graves Disease

Graves disease (known as Basedow disease in Europe) is the most common cause of thyrotoxicosis. It is an autoimmune disorder affecting the thyroid gland, characterized by an increase in synthesis and release of thyroid hormones; the thyroid gland is typically enlarged. Graves disease is much more common in women than in men (8:1), and its onset is usually between the ages of 20 and 40 years. It may be accompanied by infiltrative ophthalmopathy (Graves exophthalmos) and, less commonly, by infiltrative dermopathy (pretibial myxedema). The thymus gland is typically hyperplastic and enlarged. Graves disease may also be associated with other systemic autoimmune disorders such as pernicious anemia, myasthenia gravis, and diabetes mellitus. It has a familial tendency, and histocompatibility studies have shown an association with group HLA-B8 and HLA-DR3. The pathogenesis of the hyperthyroidism of Graves disease involves the formation of autoantibodies that bind to the TSH receptor in thyroid cell membranes and stimulate the gland to hyperfunction. Antibodies increased in most patients include thyrotropin receptor antibody (TRAb), ANA, and thyroperoxidase (TPO) or thyroglobulin (Tg) antibodies.

Patients with Graves disease have an increased risk of developing Sjögren syndrome, Addison disease, alopecia areata, vitiligo, celiac disease, autoimmune diabetes mellitus type 1, hypoparathyroidism, myasthenia gravis, and cardiomyopathy.

B. Toxic Multinodular Goiter and Thyroid Adenomas

Autonomous toxic adenomas of the thyroid may be single (Plummer disease) or multiple (toxic multinodular goiter). **Jodbasedow disease**, or iodine-induced hyperthyroidism, may occur in patients with multinodular goiters after intake of large amounts of iodine in the diet or in the form of radiographic contrast materials or drugs, especially amiodarone. This condition is not associated with infiltrative ophthalmopathy or dermopathy. Antithyroid antibodies are usually not present in the plasma, and tests for TRAb are negative.

C. Subacute (de Quervain) Thyroiditis

Subacute thyroiditis typically presents with a moderately enlarged, tender thyroid, and hyperthyroidism. It is thought to be due to a viral infection. If the gland is nontender, the disorder is called “silent thyroiditis.” Hyperthyroidism is followed by hypothyroidism. During thyro-

toxicosis, thyroid radioactive iodine (RAI) uptake is low. A similar problem of low RAI is seen with interleukin-2 therapy and after neck surgery for hyperparathyroidism. Patients taking lithium may rarely experience thyrotoxicosis due to silent thyroiditis. Symptoms mimic a manic episode such that the diagnosis is often missed.

D. Thyrotoxicosis Factitia

Thyrotoxicosis factitia is due to ingestion of excessive amounts of exogenous thyroid hormone. Isolated epidemics of thyrotoxicosis have been caused by consumption of ground beef contaminated with bovine thyroid gland.

E. Struma Ovarii

Thyroid tissue is contained in about 3% of ovarian dermoid tumors and teratomas. This thyroid tissue may autonomously secrete thyroid hormone due to a toxic nodule or in concert with the woman’s thyroid gland in Graves disease or toxic multinodular goiter.

F. Pituitary Tumor

TSH hypersecretion by the pituitary may be caused by a tumor or thyrotroph cell hyperplasia and is a rare cause of hyperthyroidism. Serum TSH is elevated or normal in the presence of true thyrotoxicosis. Pituitary hyperplasia may be detected on MRI scan as pituitary enlargement without a discrete adenoma being visible. This condition appears to be due to a diminished feedback effect of T_4 upon the pituitary. It may be familial, but it can also be caused by prolonged untreated hypothyroidism, especially in youth.

G. Hashimoto Thyroiditis

Hashimoto thyroiditis may cause transient hyperthyroidism during the initial destructive phase. This is also seen in some patients receiving interferon- α , interferon- β , and interleukin-2. Postpartum thyroiditis refers to Hashimoto thyroiditis that occurs in the first 6 months after delivery. It is common, occurring postpartum in 5–10% of women in the United States. Hyperthyroidism results from the release of stored thyroid hormone following damage to the thyroid (see Thyroiditis, below).

H. Pregnancy and Trophoblastic Tumors

The prevalence of hyperthyroidism in pregnancy—most commonly due to Graves disease—is about 0.2%. Struma ovarii is rare. Newborns have an increased risk of intrauterine growth retardation, prematurity, and transient thyrotoxicosis from transplacental transfer of TRAb.

Although hCG generally has a low affinity for the thyroid’s TSH receptors, very high serum levels of hCG may cause sufficient receptor activation to cause thyrotoxicosis. Mild gestational hyperthyroidism may occur during the first 4 months of pregnancy, when hCG levels are very high. Pregnant women are more likely to have thyrotoxicosis and hyperemesis gravidarum if they have high serum levels of asialo-hCG, a subfraction of hCG with greater affinity for TSH receptors.

Thyrotoxicosis may also be caused by the high serum levels of hCG seen in molar pregnancy, choriocarcinoma, and testicular malignancies.

I. Thyroid Carcinoma

Metastatic functioning thyroid carcinoma is a rare cause of thyrotoxicosis. (See Thyroid Cancer section.)

J. Amiodarone-Induced Thyrotoxicosis

Amiodarone is 38% iodine by weight; its elimination half-life can be as long as 100 days. Among patients in the United States taking amiodarone, hyperthyroidism develops in about 3%; the incidence of hyperthyroidism is higher in Europe and in iodine-deficient geographic areas. Hyperthyroidism can occur 4 months to 3 years after initiation of amiodarone and may develop many months after amiodarone has been discontinued.

Type I amiodarone-induced thyrotoxicosis is caused by active elaboration of excessive thyroid hormone and may occur by either of two mechanisms: (1) Free iodine may cause toxic multinodular goiter in iodine-deficient patients with preexisting autonomous thyroid nodules (jodbasedow phenomenon). This is infrequently encountered in iodine-sufficient countries such as the United States. Thyroid RAI uptake ranges from low to high. (2) Excessive free iodine can trigger an immunologic attack on the thyroid; this may cause Graves disease, commonly with diffuse thyroid enlargement and antithyroid peroxidase antibodies (70%). Type II amiodarone-induced thyrotoxicosis is caused by destructive thyroiditis, which releases stored thyroid hormone from damaged cells; hyperthyroidism can last 1–3 months and may be followed by hypothyroidism.

► Clinical Findings

A. Symptoms and Signs

Thyrotoxicosis due to any cause produces many different manifestations of variable intensity among different individuals. Patients may complain of nervousness, restlessness, heat intolerance, increased sweating, pruritus, fatigue, weakness, muscle cramps, frequent bowel movements, or weight change (usually loss). There may be palpitations or angina pectoris. Women frequently report menstrual irregularities.

Signs of thyrotoxicosis may include stare and lid lag, fine resting finger tremors, moist warm skin, hyperreflexia, fine hair, and onycholysis. Certain eye findings—such as upper eyelid retraction (Dalrymple sign), lid lag with downward gaze (von Graefe sign), and a staring appearance (Kocher sign)—can occur with hyperthyroidism of any etiology. Chronic thyrotoxicosis may cause osteoporosis. Clubbing and swelling of the fingers (acropachy) develop in a small number of patients. Graves disease usually presents with additional findings of goiter (often with a bruit), but some patients have no palpable thyroid enlargement.

Cardiac manifestations of thyrotoxicosis commonly include a forceful heart beat, premature atrial contractions, and sinus tachycardia. Atrial fibrillation or atrial tachycardia occurs in about 8% of patients with thyrotoxicosis, more

commonly in men, the elderly, and those with ischemic or valvular heart disease. The ventricular response from the atrial fibrillation may be difficult to control. Thyrotoxicosis itself can cause a thyrotoxic cardiomyopathy, and the onset of atrial fibrillation can precipitate congestive heart failure.

Ophthalmopathy is clinically apparent in 20–40% of patients with Graves disease and type I amiodarone-induced thyrotoxicosis, but in no other conditions causing hyperthyroidism. It usually consists of conjunctival edema (chemosis), conjunctivitis, and mild exophthalmos (proptosis). More severe lymphocytic infiltration of the eye muscles occurs in 5–10%, pushing the eye forward, producing clinical exophthalmos and sometimes diplopia due to extraocular muscle entrapment. There may be weakness of upward gaze (Stellwag sign). The optic nerve may be compressed in severe cases, causing progressive loss of color vision, visual fields, and visual acuity. Corneal drying may occur with inadequate lid closure. Eye changes may sometimes be asymmetric or unilateral. The severity of the eye disease is not closely correlated with the severity of the thyrotoxicosis. Some patients with Graves ophthalmopathy are clinically euthyroid.

Exophthalmometry should be performed on all patients with Graves disease to document their degree of exophthalmos and detect progression of orbitopathy. The protrusion of the eye beyond the orbital rim is measured with a prism instrument (Hertel exophthalmometer). Maximum normal eye protrusion varies between kindreds and races, being about 22 mm for blacks, 20 mm for whites, and 18 mm for Asians.

Diplopia can be caused by exophthalmus or by coexistent **ocular myasthenia gravis**, which is more common in Graves disease and is usually mild, often with selective eye involvement. Acetylcholinesterase receptor antibody (AChR Ab) levels are elevated in only 36% of such patients, and a thymoma is present in 9%.

Graves dermopathy (pretibial myxedema) occurs in about 3% of patients with Graves disease, usually in the pretibial region. Glycosaminoglycan accumulation and lymphoid infiltration occur in affected skin, which becomes erythematous with a thickened, rough texture.

Thyroid acropachy is an extreme and unusual manifestation of Graves disease. It presents with digital clubbing, swelling of fingers and toes, and a periosteal reaction of extremity bones. It is ordinarily associated with ophthalmopathy and thyroid dermopathy. Most patients are smokers. The presence of thyroid acropachy is an indication of the severity of the autoimmunity; most patients have high serum titers of thyroid-stimulating immunoglobulin. Patients with thyroid acropachy are at greater risk for having concurrent Graves dermopathy and severe ophthalmopathy. However, acropachy itself does not usually cause clinical complaints.

Hyperthyroidism during pregnancy shares many of the features of normal pregnancy: tachycardia, warm skin, heat intolerance, increased sweating, and a palpable thyroid. Pregnancy can have a beneficial effect on the thyrotoxicosis of Graves disease. However, there is an increased risk of thyroid storm, preeclampsia–eclampsia, congestive heart failure, premature delivery, and abruptio placentae.

Hypokalemic periodic paralysis occurs in about 15% of Asian or Native American men with thyrotoxicosis. It usually presents abruptly with symmetric flaccid paralysis (and few thyrotoxic symptoms), often after intravenous dextrose, oral carbohydrate, or vigorous exercise. Attacks last 7–72 hours.

B. Laboratory Findings

Serum T_3 , T_4 , thyroid resin uptake, and FT_4 are usually all increased. Sometimes the T_4 level may be normal but the serum T_3 is elevated. Serum T_3 can be misleadingly elevated when blood is collected in tubes using a gel barrier, which causes certain immunoassays (eg, Immulite but not AxSYM analyzers) to report serum total T_3 levels that are falsely elevated in 24% of normal patients. Serum T_4 or T_3 can be elevated in other nonthyroidal conditions (Table 26–5).

Serum TSH is suppressed in hyperthyroidism, except in the very rare cases of pituitary inappropriate secretion of thyrotropin. Serum TSH may be misleadingly low in other nonthyroidal conditions. Hyperthyroidism can cause other laboratory abnormalities, including hypercalcemia, increased alkaline phosphatase, anemia, and decreased granulocytes. Hypokalemia and hypophosphatemia occur in thyrotoxic periodic paralysis.

Problems of diagnosis occur in patients with acute psychiatric disorders; about 30% of these patients have hyperthyroxinemia without thyrotoxicosis. The TSH is not usually suppressed, distinguishing psychiatric disorder from true hyperthyroidism. T_4 levels return to normal gradually.

In **Graves disease**, TSH receptor antibody (TRAb) levels are usually detectable (65%). Antithyroglobulin or antithyroxidase antibodies are usually elevated but are non-specific. Serum ANA and anti-double-stranded DNA antibodies are also usually elevated without any evidence of lupus erythematosus or other collagen-vascular disease.

With **subacute thyroiditis**, patients often have an increased erythrocyte sedimentation rate (ESR).

With **hyperthyroidism during pregnancy**, women have an elevated FT_4 while the TSH is suppressed. However, apparent lack of full TSH suppression can be seen due to misidentification of hCG as TSH in certain assays. Although the total T_4 is elevated in most pregnant women, values over 20 mcg/dL are encountered only in hyperthyroidism. The T_3 resin uptake, which is low in normal pregnancy because of high TBG concentration, is normal or high in thyrotoxic persons. Pregnancy can have a beneficial effect on the thyrotoxicosis of Graves disease, with decreasing antibody titers and decreasing FT_4 levels as the pregnancy advances.

Since high levels of T_4 and FT_4 are normally seen in patients taking **amiodarone**, suppressed TSH (sensitive assay) must be present along with a greatly elevated T_4 (> 20 mcg/dL) or T_3 (> 200 ng/dL) in order to diagnose hyperthyroidism. (**Note:** Hypothyroidism occurs in an additional 6% of patients receiving amiodarone after 2–39 weeks of therapy.) In **type I amiodarone-induced thyrotoxicosis**, the presence of proptosis, TSH-R Ab[stim], or thyrotropin-binding inhibitory immunoglobulin (TBII) is diagnostic. In **type II amiodarone-induced thyrotoxicosis**, serum levels of interleukin-6 (IL-6) are usually quite elevated.

C. Imaging

Patients with an established diagnosis of thyrotoxicosis usually undergo thyroid RAI uptake and scan. Women with hyperthyroidism due to Graves disease should ideally have the RAI scan extended to include the pelvis in order to screen for concomitant struma ovarii (rare). A high RAI uptake is seen in **Graves disease** and **toxic nodular goiter** but can be seen in other conditions as well. A low RAI uptake is characteristic of subacute thyroiditis but can also be seen after an iodine load and in other conditions. In the United States, thyroid RAI uptake is usually negligible in patients with **type I amiodarone-induced thyrotoxicosis**; however, in Europe, up to 80% of such patients have detectable or normal RAI uptake. In **type II amiodarone-induced thyrotoxicosis**, thyroid RAI uptake is very low.

MRI of the orbits is the imaging method of choice to visualize Graves ophthalmopathy affecting the extraocular muscles. CT scanning and ultrasonography can also be used. Imaging is required only in severe or unilateral cases or in euthyroid exophthalmos that must be distinguished from orbital pseudotumor, tumors, and other lesions.

► Differential Diagnosis

True thyrotoxicosis must be distinguished from those conditions elevating serum T_4 and T_3 or suppressing serum TSH without affecting clinical status.

Some states of hypermetabolism without thyrotoxicosis—notably severe anemia, leukemia, polycythemia, and cancer—rarely cause confusion. Pheochromocytoma is often associated with hypermetabolism, tachycardia, weight loss, and profuse sweating. Acromegaly may also produce tachycardia, sweating, and thyroid enlargement. Appropriate laboratory tests will easily distinguish these entities.

Cardiac disease (eg, atrial fibrillation, angina) refractory to treatment suggests the possibility of underlying (“apathetic”) hyperthyroidism. Other causes of ophthalmoplegia (eg, myasthenia gravis) and exophthalmos (eg, orbital tumor, pseudotumor) must be considered. Thyrotoxicosis must also be considered in the differential diagnosis of muscle weakness and osteoporosis. Diabetes mellitus and Addison disease may coexist with thyrotoxicosis.

► Complications

Hypercalcemia, osteoporosis, and nephrocalcinosis may occur. Decreased libido, impotence, diminished sperm motility, and gynecomastia may be noted in men with hyperthyroidism. Other complications include cardiac arrhythmias and heart failure, thyroid crisis, ophthalmopathy, dermatopathy, and thyrotoxic hypokalemic periodic paralysis (see below.)

► Treatment

A. Graves Disease

The treatment of Graves disease involves a choice of methods rather than a method of choice.

1. Propranolol—Propranolol is generally used for symptomatic relief until the hyperthyroidism is resolved. It

effectively relieves the tachycardia, tremor, diaphoresis, and anxiety that occur with hyperthyroidism due to any cause. It is the initial treatment of choice for thyroid storm. The periodic paralysis seen in association with thyrotoxicosis is also effectively treated with β -blockade. It has no effect on thyroid hormone secretion. Treatment is usually begun with propranolol ER 60 mg orally twice daily, with dosage increases every 2 days. The available doses of propranolol ER are 60, 80, 120, and 160 mg. Propranolol ER is initially given every 12 hours for patients with severe hyperthyroidism, due to accelerated metabolism of the propranolol; it may be given once daily as hyperthyroidism improves.

2. Thiourea drugs—Methimazole or propylthiouracil is generally used for young adults or patients with mild thyrotoxicosis, small goiters, or fear of isotopes. Carbimazole is another thiourea that is converted to methimazole in vivo and is available outside the United States. Elderly patients usually respond particularly well. These drugs are also useful for preparing hyperthyroid patients for surgery and elderly patients for RAI treatment. The drugs do not permanently damage the thyroid and are associated with a lower chance of posttreatment hypothyroidism (compared with RAI or surgery). When thiourea therapy is discontinued, there is a high recurrence rate for hyperthyroidism (about 50%). A better likelihood of long-term remission is seen in patients with small goiters or mild hyperthyroidism and those requiring small doses of thiourea. Patients whose thyroperoxidase and thyroglobulin antibodies remain high after 2 years of therapy have been reported to have only a 10% rate of relapse. Thiourea therapy may be continued long-term for patients who are tolerating it well.

Agranulocytosis occurs in about 0.3% of patients taking methimazole and about 0.4% of patients taking propylthiouracil. Agranulocytosis usually occurs in the first 60 days of therapy, and it develops in a few patients after 5 months of therapy. There is a genetic tendency to develop agranulocytosis with thiourea therapy; if a close relative has had this adverse reaction, other therapies should be considered for the patient. Patients are warned that if a sore throat or febrile illness develops, they should stop the drug while a WBC is rechecked. The agranulocytosis is generally reversible; recovery is not improved by filgrastim (granulocyte colony-stimulating factor [G-CSF]). Periodic surveillance of the WBC during treatment has been advocated, but the onset of agranulocytosis is generally abrupt.

Other side effects common to thiourea drugs include pruritus, allergic dermatitis, nausea, and dyspepsia. Antihistamines may control mild pruritus without discontinuation of the drug. Since the two thiourea drugs are similar, patients who have had a major allergic reaction from one should not be given the other.

Primary hypothyroidism may occur. The patient may become clinically hypothyroid for 2 weeks or more before TSH levels rise, having been suppressed by the preceding hyperthyroidism. Therefore, the patient's changing thyroid status is best monitored clinically and with serum levels of FT₄. Rapid growth of the goiter usually occurs if prolonged hypothyroidism is allowed to develop; the goiter may some-

times become massive but usually regresses rapidly with thyroid hormone replacement.

A. METHIMAZOLE—Methimazole is generally preferred over propylthiouracil since the methimazole is more convenient to use and is less likely to cause fulminant hepatic necrosis. Methimazole therapy is also less likely to cause ¹³¹I treatment failure. Rare complications peculiar to methimazole include serum sickness, cholestatic jaundice, loss of taste, alopecia, nephrotic syndrome, and hypoglycemia. Methimazole is given orally in initial doses of 30–60 mg once daily. Some patients with very mild hyperthyroidism may respond well to smaller initial doses of methimazole (10–20 mg daily). Methimazole may also be administered twice daily to reduce the likelihood of gastrointestinal upset. Methimazole use in pregnancy has been associated with a possibly increased risk of fetal anomalies such as aplasia cutis, esophageal atresia, and coanal atresia. However, methimazole may be used if the patient cannot tolerate propylthiouracil (see below). If methimazole is used during pregnancy or breastfeeding, the dose should not exceed 20 mg daily. The dosage is reduced as manifestations of hyperthyroidism resolve and as the FT₄ level falls toward normal. For patients who have elected to receive ¹³¹I therapy, methimazole is discontinued 4 days prior to receiving the ¹³¹I and is resumed at a lower dose 3 days afterwards to avoid recurrence of hyperthyroidism. About 4 weeks after ¹³¹I therapy, methimazole may be discontinued if the patient is euthyroid.

B. PROPYLTHIOURACIL—Propylthiouracil has been the drug of choice during breastfeeding since it is not concentrated in the milk as much as methimazole. Propylthiouracil is also favored during pregnancy, possibly causing fewer problems in the newborn. Rare complications peculiar to propylthiouracil include arthritis, lupus erythematosus, aplastic anemia, thrombocytopenia, and hypoprothrombinemia. Acute hepatitis occurs rarely and is treated with prednisone but may progress to liver failure. Propylthiouracil is given orally in initial doses of 300–600 mg daily in four divided doses. The dosage and frequency of administration are reduced as symptoms of hyperthyroidism resolve and the FT₄ level approaches normal. During pregnancy, the dose of propylthiouracil is kept below 200 mg/d to avoid goitrous hypothyroidism in the infant.

3. Iodinated contrast agents—These agents provide effective temporary treatment for thyrotoxicosis of any cause. Iopanoic acid (Telepaque) or ipodate sodium (Bilivist, Oragrafin) is given orally in a dosage of 500 mg twice daily for 3 days, then 500 mg once daily. These agents inhibit peripheral 5'-monodeiodination of T₄, thereby blocking its conversion to active T₃. Within 24 hours, serum T₃ levels fall an average of 62%. For patients with Graves disease, methimazole is begun first to block iodine organification; the next day, ipodate sodium or iopanoic acid may be added. The iodinated contrast agents are particularly useful for patients who are very symptomatically thyrotoxic (see Thyroid Storm, below). They offer a therapeutic option for patients with T₄ overdosage, subacute thyroiditis, and amiodarone-induced thyrotoxicosis

and for those intolerant to thioureas and for newborns with thyrotoxicosis (due to maternal Graves disease). Treatment periods of 8 months or more are possible, but efficacy tends to wane with time. In Graves disease, thyroid RAI uptake may be suppressed during treatment but typically returns to pretreatment uptake by 7 days after discontinuation of the drug, allowing ^{131}I treatment.

4. Radioactive iodine (^{131}I , RAI)—The administration of ^{131}I is an excellent method of destroying overactive thyroid tissue (either diffuse or toxic nodular goiter). There are ample data to conclude that patients who are treated with RAI in adulthood do not have an increased risk of subsequent thyroid cancer, leukemia, or other malignancies. Similarly, individuals who were treated with RAI as teenagers have not shown any increased risk of malignancy in a 36-year retrospective study. Children born to parents previously treated with ^{131}I show normal rates of congenital abnormalities.

Because fetal radiation is harmful, *RAI should not be given to pregnant women*. It is prudent to obtain a sensitive pregnancy test (serum β -hCG) on all women of reproductive age prior to ^{131}I therapy.

Most patients may receive ^{131}I while being symptomatically treated with just propranolol LA, which is then reduced in dosage as hyperthyroxinemia resolves. However, some patients (those with coronary diseases, the elderly, or those with severe hyperthyroidism) are usually rendered euthyroid with a thiouracil drug (see above) while the dosage of propranolol is reduced. A higher rate of ^{131}I treatment failure has been reported in patients with Graves disease who have been receiving methimazole or propylthiouracil. However, therapy with ^{131}I will usually be effective if the methimazole is discontinued at least 4 days before RAI therapy and if the therapeutic dosage of ^{131}I is adjusted (upward) according to RAI uptake on the pretherapy scan. Prior to ^{131}I therapy, patients are instructed against receiving intravenous iodinated contrast or ingesting large quantities of dietary iodine, but severe restriction of dietary iodine is not usually necessary.

Following ^{131}I treatment for hyperthyroidism, Graves ophthalmopathy appears or worsens in 15% of patients (23% in smokers and 6% in nonsmokers) and improves in none, whereas during treatment with methimazole, ophthalmopathy worsens in 3% and improves in 2% of patients. Among patients receiving 3 months of prednisone following ^{131}I treatment, preexistent ophthalmopathy worsens in none and improves in 67%.

Smoking increases the risk of having a flare in ophthalmopathy following ^{131}I treatment and also reduces the effectiveness of prednisone treatment. Therefore, patients who smoke are strongly encouraged to quit prior to ^{131}I treatment.

FT_4 levels may sometimes drop within 2 months after ^{131}I treatment, but then rise again to thyrotoxic levels, at which time thyroid RAI uptake is low. This phenomenon is caused by a release of stored thyroid hormone from injured thyroid cells and does not indicate a treatment failure. In fact, serum FT_4 then falls abruptly to hypothyroid levels.

There is a high incidence of hypothyroidism in the months to years after ^{131}I , even when small doses are given. However, hypothyroidism also occurs quite frequently years after surgical or medical treatment of Graves disease, and eventual hypothyroidism may be part of the natural history of this condition. Lifelong clinical follow-up is mandatory, with measurements of FT_4 and TSH when indicated.

5. Thyroid surgery—Thyroid surgery for Graves disease and toxic nodular goiter has been performed less frequently since the increased use of RAI treatment. Thyroidectomy may be performed for pregnant women whose thyrotoxicosis is not controlled with low doses of thioureas, and for women who desire to become pregnant in the very near future. Surgery is also an option for nodular goiters, when there is a suspicion for malignancy. The Hartley–Dunhill operation is the surgical procedure of choice for patients with Graves disease; this operation consists of a total resection of one lobe and a subtotal resection of the other lobe, leaving about 4 g of thyroid tissue. Subtotal thyroidectomy of both lobes is often used, but ultimately results in a 9% recurrence rate for hyperthyroidism. Total thyroidectomy of both lobes poses an increased risk for hypoparathyroidism and damage to the recurrent laryngeal nerve.

Patients are ordinarily rendered euthyroid preoperatively with a thiourea drug. Iodate sodium or iopanoic acid (500 mg orally twice daily) may be used in addition to a thiourea to accelerate the decline in serum T_3 . Propranolol is given until the serum T_3 (or free T_3) is normal preoperatively. Thyroid vascularity is reduced by preoperative treatment with either ipodate sodium or iopanoic acid (500 mg twice daily for 3 days) or iodine (eg, Lugol solution, two or three drops orally daily for several days). If a patient undergoes surgery while thyrotoxic, larger doses of propranolol are given perioperatively to reduce the likelihood of thyroid crisis.

Morbidity includes possible damage to the recurrent laryngeal nerve, with resultant vocal cord paralysis. Hypoparathyroidism also occurs, which means that calcium levels must be checked postoperatively. When a thyroidectomy is performed by a competent, experienced neck surgeon, surgical complications are uncommon. Thyroid surgery should be performed as an inpatient, with at least an overnight observational period.

B. Toxic Solitary Thyroid Nodules

Toxic solitary thyroid nodules are usually benign but may rarely be malignant. If a nonsurgical therapy is elected, the nodule should be evaluated with a fine-needle aspiration biopsy (FNA). Hyperthyroidism caused by a single hyperfunctioning thyroid nodule may be treated symptomatically with propranolol ER and methimazole or propylthiouracil, as in Graves disease (see above). Patients who tolerate methimazole well may elect to continue it for long-term therapy. When using methimazole, the serum TSH should be monitored and the dose of methimazole adjusted to be kept slightly suppressed, so the risk of TSH-stimulated growth of the nodule is reduced. For patients under

age 40 years and for healthy older patients, surgery is usually recommended; patients are made euthyroid with a thiourea preoperatively and given several days of iodine, ipodate sodium, or iopanoic acid before surgery as in Graves disease (see above). Transient postoperative hypothyroidism resolves spontaneously. Permanent hypothyroidism occurs in about 14% of patients by 6 years after surgery. Patients with a toxic solitary nodule who are over age 40 years or in poor health may be offered ^{131}I therapy. If the patient has been receiving methimazole preparatory to ^{131}I , the TSH should be kept slightly suppressed in order to reduce the uptake of ^{131}I by the normal thyroid. Nevertheless, permanent hypothyroidism occurs in about one-third of patients after 8 years of ^{131}I therapy. The nodule remains palpable in 50% and may grow in 10% of patients after ^{131}I .

C. Toxic Multinodular Goiter

Hyperthyroidism caused by a toxic multinodular goiter may also be treated with propranolol ER and methimazole, as in Graves disease. Methimazole does reverse hyperthyroidism, but there is a 95% recurrence rate if it is stopped. Definitive treatment for large multinodular goiters is surgery, prior to which patients are rendered euthyroid. Surgery is particularly indicated to relieve pressure symptoms or for cosmetic indications. Patients with toxic multinodular goiter are prepared for surgery the same as those with Graves disease (see above). Patients who are to receive ^{131}I treatment are rendered nearly euthyroid with methimazole, which is stopped at least 4 days before RAI treatment. Meanwhile, the patient follows a low-iodine diet; this is done to enhance the thyroid gland's uptake of RAI, which may be relatively low in this condition (compared to Graves disease). Relatively high doses of ^{131}I are usually required; recurrent thyrotoxicosis and hypothyroidism are common, so patients must be monitored closely. Particularly, in about 5% of patients with diffusely nodular toxic goiter, the administration of ^{131}I therapy may induce Graves disease. Also, Graves' eye disease has occurred rarely following ^{131}I therapy for multinodular goiter.

D. Subacute (de Quervain) Thyroiditis

Patients with hyperthyroidism due to subacute thyroiditis are treated symptomatically with propranolol ER. Ipodate sodium or iopanoic acid, 500 mg orally daily, promptly corrects elevated T_3 levels and is continued for 15–60 days until the serum FT_4 level normalizes. The condition subsides spontaneously within weeks to months. Thioureas are ineffective, since thyroid hormone production is actually low in this condition. RAI is ineffective, since the thyroid's iodine uptake is low. Since periods of hypothyroidism may occur following the initial inflammatory episode, patients should have close clinical follow-up, with serum FT_4 measurement when necessary. Prompt treatment of the transient hypothyroidism may reduce the incidence of recurrent thyroiditis. Pain can usually be managed with non-aspirin nonsteroidal anti-inflammatory drugs.

E. Hashimoto Thyroiditis (Hashitoxicosis)

Rarely, hyperthyroidism develops as a result of release of stored thyroid hormone during severe Hashimoto thyroiditis. The thyroperoxidase or thyroglobulin antibodies are usually high, but RAI uptake is low, thus distinguishing it from Graves disease. This is especially common in postpartum women, in whom it may be transient. Treatment is with propranolol ER. Ipodate sodium or iopanoic acid may also be used as described above. Patients are monitored carefully for the development of hypothyroidism and treated.

F. Hyperthyroidism during Pregnancy and Lactation

Pregnant women with hyperthyroidism are treated with propylthiouracil, which is generally preferred over methimazole on the basis of uncontrolled reports of fetal anomalies in the offspring of women taking methimazole during pregnancy. Whichever thiourea is used, it should be given in the smallest dose possible, permitting mild hyperthyroidism to occur since it is usually well tolerated. Both propylthiouracil and methimazole cross the placenta and can induce hypothyroidism, with fetal TSH hypersecretion and goiter. Thyroid hormone administration to the mother does not prevent hypothyroidism in the fetus, since T_4 and T_3 do not freely cross the placenta. Fetal hypothyroidism is rare if the mother's hyperthyroidism is controlled with small daily doses of propylthiouracil (50–150 mg/d orally) or methimazole (5–15 mg/d orally). Thyroidectomy is reserved for women who are allergic or resistant to antithyroid drugs (usually due to noncompliance) or who have very large goiters. Fetal ultrasound at 32 weeks gestation can visualize any fetal goiter, so fetal thyroid dysfunction can be diagnosed and treated.

During lactation, women treated with propylthiouracil secrete very little of it into breast milk. Methimazole is secreted in somewhat higher concentrations in breast milk. However, the use of either propylthiouracil or methimazole during breast-feeding does not significantly affect the infant's thyroid hormone levels, and both drugs are approved for nursing mothers by the American Academy of Pediatrics. No adverse reactions to these drugs (eg, rash, hepatic dysfunction, leukopenia) have been reported in breast-fed infants. Recommended doses are 20 mg orally daily or less for methimazole and 450 mg orally daily or less for propylthiouracil. It is recommended that the medication be taken just after breast-feeding.

G. Other Causes of Hyperthyroidism

Patients with thyrotoxicosis from **thyrotrophe pituitary hyperplasia** are treated with propranolol LA as described above. Definitive treatment is with RAI or thyroid surgery. Patients with thyrotoxicosis caused by a **thyrotrophe pituitary adenoma** are treated with propranolol LA and methimazole, followed by transsphenoidal resection of the pituitary tumor, when possible. Treatment of patients with **type I amiodarone-induced thyrotoxicosis** usually requires propranolol ER and a prolonged course of methimazole. After

two doses of methimazole, iopanoic acid or sodium ipodate may be added to the regimen to further block conversion of T_4 to T_3 ; the recommended dosage for each is 500 mg orally twice daily for 3 days, followed by 500 mg once daily until thyrotoxicosis is resolved. β -Blockers may be required. Withdrawal of amiodarone does not have a significant therapeutic effect for several months. Therapy with ^{131}I may be successful in some patients with adequate RAI uptake. Thyroidectomy is reserved for resistant cases. Treatment of patients with **type II amiodarone-induced thyrotoxicosis** consists of propranolol ER and prednisone plus either iopanoic acid or ipodate sodium (see above). Withdrawal of amiodarone is not usually necessary. Because the condition is transient, thyroidectomy is rarely required.

H. Treatment of Complications

1. Graves ophthalmopathy—The risk of having a “flare” of ophthalmopathy following ^{131}I treatment for hyperthyroidism is about 6% for nonsmokers and 23% for smokers. Graves ophthalmopathy can also be aggravated by thiazolidinediones (eg, pioglitazone, rosiglitazone); these oral diabetic agents should be avoided or withdrawn in patients with Graves disease. For acute, progressive exophthalmos, intravenous methylprednisolone, begun promptly, is superior to oral prednisone, possibly due to improved compliance. Methylprednisolone is given intravenously, 500 mg weekly for 6 weeks, then 250 mg weekly for 6 weeks. If oral prednisone is chosen for treatment, it must be given promptly in daily doses of 40–60 mg/d orally, with dosage reduction over several weeks. Higher initial prednisone doses of 80–120 mg/d are used when there is optic nerve compression. Prednisone alleviates eye symptoms in 64% of nonsmokers, but only 14% of smokers respond well.

Progressive active exophthalmos may be treated with retrobulbar radiation therapy using a supervoltage linear accelerator (4–6 MeV) to deliver 20 Gy over 2 weeks to the extraocular muscles, avoiding the cornea and lens. Prednisone in high doses is given concurrently. Patients who respond well to orbital radiation include those with signs of acute inflammation, recent exophthalmos (< 6 months), or optic nerve compression. Patients with chronic proptosis and orbital muscle restriction respond less well. Retrobulbar radiation does not cause cataracts or tumors; however, it can cause radiation-induced retinopathy (usually subclinical) in about 5% of patients overall, mostly in diabetics.

For severe cases, orbital decompression surgery may save vision, though diplopia often persists postoperatively. General eye protective measures include wearing glasses to protect the protruding eye and taping the lids shut during sleep if corneal drying is a problem. Methylcellulose drops and gels (“artificial tears”) may also help. Tarsorrhaphy or canthoplasty can frequently help protect the cornea and provide improved appearance. Hypothyroidism and hyperthyroidism must be treated promptly.

2. Cardiac complications

A. SINUS TACHYCARDIA—Treatment consists of treating the thyrotoxicosis. A β -blocker (as described above) such

as propranolol is used in the interim unless there is an associated cardiomyopathy.

B. ATRIAL FIBRILLATION—Electrical cardioversion is unlikely to convert atrial fibrillation to normal sinus rhythm while the patient is thyrotoxic. Spontaneous conversion to normal sinus rhythm tends to occur in about 56% of patients with achievement of euthyroidism, but that likelihood decreases with age. Elective cardioversion may be used for those patients in whom atrial fibrillation persists for 4 months after resolution of hyperthyroidism. Hyperthyroidism must be treated immediately (see above). Other drugs, including digoxin, β -blockers, anticoagulants, may be required.

(1) Digoxin—Digoxin is used to slow a fast ventricular response to thyrotoxic atrial fibrillation; it must be used in larger than normal doses because of increased clearance and an increased number of cardiac cellular sodium pumps requiring inhibition. Digoxin doses are reduced as hyperthyroidism is corrected.

(2) β -Blockers— β -Blockers may also reduce the ventricular rate, but they must be used with caution—particularly in patients with cardiomegaly or signs of heart failure—since their negative inotropic effect may precipitate congestive heart failure. Therefore, an initial trial of a short-duration β -blocker should be considered, such as esmolol intravenously. If a β -blocker is used, doses of digoxin must be reduced.

(3) Anticoagulants—Anticoagulation is indicated in the following situations: left atrial enlargement on echocardiogram, global left ventricular dysfunction, recent congestive heart failure, hypertension, recurrent atrial fibrillation, or a history of previous thromboembolism. The doses of warfarin required in thyrotoxicosis are smaller than normal because of an accelerated plasma clearance of vitamin K–dependent clotting factors. Higher warfarin doses are usually required as hyperthyroidism subsides.

C. HEART FAILURE—Heart failure due to thyrotoxicosis may be caused by extreme tachycardia, cardiomyopathy, or both. Very aggressive treatment of the hyperthyroidism is required in either case (see Thyroid Crisis, below). The tachycardia from atrial fibrillation is treated with digoxin as above. Intravenous furosemide is typically required. Oral spironolactone or eplerenone may be helpful. If tachycardia appears to be the main cause of the failure, β -blockers are administered cautiously as described above.

Congestive heart failure may occur as a result of low-output dilated cardiomyopathy in the setting of hyperthyroidism. It is uncommon and may be caused by an idiosyncratic severe toxic effect of hyperthyroidism upon certain hearts. Cardiomyopathy may occur at any age and without preexisting cardiac disease. β -Blockers and calcium channel blockers are avoided. Emergency treatment may include afterload reduction, diuretics, digoxin, and other inotropic agents while the patient is being rendered euthyroid. Heart failure usually persists despite correction of hyperthyroidism.

D. APATHETIC HYPERTHYROIDISM—Apathetic hyperthyroidism may present with angina pectoris. Treatment is

directed at reversing the hyperthyroidism as well as providing standard antianginal therapy. Coronary angioplasty or bypass grafting can often be avoided by prompt diagnosis and treatment.

3. Thyroid crisis or “storm”—This disorder, rarely seen today, is an extreme form of thyrotoxicosis that may be triggered by stressful illness, thyroid surgery, or RAI administration and is manifested by marked delirium, severe tachycardia, vomiting, diarrhea, dehydration and, in many cases, very high fever. The mortality rate is high.

A thiourea drug is given (eg, methimazole, 15–25 mg orally every 6 hours or propylthiouracil, 150–250 mg orally every 6 hours). Iodate sodium (500 mg/d orally) can be helpful if begun 1 hour after the first dose of thiourea. Iodide is given 1 hour later as Lugol solution (10 drops three times daily orally) or as sodium iodide (1 g intravenously slowly). Propranolol is given (cautiously in the presence of heart failure; see above) in a dosage of 0.5–2 mg intravenously every 4 hours or 20–120 mg orally every 6 hours. Hydrocortisone is usually given in doses of 50 mg orally every 6 hours, with rapid dosage reduction as the clinical situation improves. Aspirin is avoided since it displaces T_4 from TBG, raising FT_4 serum levels. Definitive treatment with ^{131}I or surgery is delayed until the patient is euthyroid.

4. Hyperthyroidism from postpartum thyroiditis—Propranolol ER is given during the hyperthyroid phase followed by levothyroxine during the hypothyroidism phase (see Thyroiditis, below).

5. Graves dermopathy—Treatment involves application of a topical corticosteroid (eg, fluocinolone) with nocturnal plastic occlusive dressings.

6. Thyrotoxic hypokalemic periodic paralysis—Sudden symmetric flaccid paralysis, along with hypokalemia and hypophosphatemia and few signs of thyrotoxicosis, may develop in Asian and Native American men with hyperthyroidism. Therapy with oral propranolol, 3 mg/kg, normalizes the serum potassium and phosphate levels and reverses the paralysis within 2–3 hours. No intravenous potassium or phosphate is ordinarily required. Intravenous dextrose and oral carbohydrate aggravate the condition and are to be avoided. Therapy is continued with propranolol, 60–80 mg every 8 hours (or sustained-action propranolol ER daily at equivalent daily dosage), along with a thiourea drug such as methimazole to treat the hyperthyroidism.

► Prognosis

Graves disease may rarely subside spontaneously, particularly when it is mild or subclinical. However, it usually persists. The ocular, cardiac, and psychological complications can become very serious and persistent even after treatment. Permanent hypoparathyroidism and vocal cord palsy are risks of surgical thyroidectomy. Recurrences are common following thiourea therapy but also occur after low-dose ^{131}I therapy or subtotal thyroidectomy. With adequate treatment and long-term follow-up, the results

are usually good. However, despite treatment for their hyperthyroidism, women experience an increased long-term risk of death from thyroid disease, cardiovascular disease, stroke, and fracture of the femur. Posttreatment hypothyroidism is common. It may occur within a few months or up to several years after RAI therapy or subtotal thyroidectomy. Malignant exophthalmos has a poor prognosis unless treated aggressively.

Subclinical hyperthyroidism refers to a condition in which asymptomatic individuals have a low serum TSH and normal FT_4 and T_3 . Most such patients do well without treatment. In one series, clinical hyperthyroidism developed in only one of seven patients after 2 years. However, most patients do not progress to overt thyrotoxicosis, and the serum TSH may revert to normal within 2 years. Most such patients do not have accelerated bone loss. However, if a baseline bone density shows significant osteopenia, bone densitometry may be performed periodically. In persons over age 60 years, serum TSH is very low (< 0.1 mU/L) in 3% and mildly low (0.1–0.4 mU/L) in 9%. The chance of developing atrial fibrillation is 2.8% yearly in elderly patients with very low TSH and 1.1% yearly in those with mildly low TSH. Asymptomatic persons with very low TSH are monitored closely but are not treated unless atrial fibrillation or other manifestations of hyperthyroidism develop.

THYROIDITIS

ESSENTIALS OF DIAGNOSIS

- Swelling of thyroid gland, sometimes causing pressure symptoms in acute and subacute forms; painless enlargement and rubbery firmness in chronic form.
- Thyroid function tests variable.
- Serum antithyroperoxidase and antithyroglobulin antibody levels usually elevated in Hashimoto thyroiditis.

► General Considerations

Thyroiditis may be classified as follows: (1) chronic lymphocytic thyroiditis due to autoimmunity (also called Hashimoto thyroiditis), (2) subacute thyroiditis, (3) suppurative thyroiditis, and (4) Riedel thyroiditis.

Hashimoto thyroiditis is an autoimmune condition and the most common thyroid disorder in the United States. B-lymphocytes invade the thyroid gland, such that the condition is also known as *chronic lymphocytic thyroiditis*. Detectable levels of antithyroid antibodies are usually present: antithyroperoxidase (antimitochondrial) antibodies or antithyroglobulin antibodies, or both. However, only a small subset of individuals with elevated antithyroid antibody levels ever develops thyroid dysfunction. Elevated serum levels of antithyroid antibodies are found in 3% of men and 13% of women. Women over the age of 60 years have a 25% incidence of elevated serum levels of antithyroid antibodies. The incidence of Hashimoto thyroiditis varies by kindred and by race; in persons older than 12 years of age in the United States, elevated levels of antithyroid antibodies are found in 14.3% of whites, 10.9% of Mexican-Americans, and 5.3% of blacks. Subclinical thyroiditis is extremely common, as evidenced in autopsy series that have found focal thyroiditis in about 40% of women and 20% of men. However, only 1% of the population has serum antithyroid antibody titers greater than 1:6400.

Hashimoto thyroiditis tends to be familial and is six times more common in women than in men. Its frequency is increased by dietary iodine supplementation. Certain drugs (amiodarone, interferon- α , interferon- β , interleukin-2, G-CSF) frequently induce thyroid autoantibodies. Childhood or occupational exposure to head–neck external beam radiation increases the lifetime risk of Hashimoto thyroiditis.

Hashimoto thyroiditis often progresses to hypothyroidism. The development of hypothyroidism may be linked to thyrotropin receptor–blocking antibodies, which are detected in 10% of patients with Hashimoto thyroiditis. Among patients with Hashimoto thyroiditis, hypothyroidism is more likely to develop in smokers than in nonsmokers, possibly due to the thiocyanates found in cigarette smoke. High serum levels of thyroid peroxidase antibody also predict progression from subclinical hypothyroidism to symptomatic hypothyroidism. Although the hypothyroidism is usually permanent, up to 11% of patients experience a remission after several years. There are two possible causes for such remissions: (1) the Hashimoto thyroiditis may improve spontaneously; and (2) thyroid-stimulating immunoglobulin (TSI) is produced in sufficient quantities to overwhelm the destructive effects of concurrent Hashimoto thyroiditis, causing the thyroid to produce more thyroid hormone. Rarely, if the thyroid gland goes on to produce *excessive* thyroid hormone, the result is an autoimmune hyperthyroidism (see Graves disease).

Hashimoto thyroiditis is sometimes associated with other endocrine deficiencies as part of polyglandular autoimmune (PGA). Adults with type 2 PGA are prone to autoimmune thyroiditis, diabetes mellitus type 1, autoimmune gonadal failure, hypoparathyroidism, and adrenal insufficiency (see Adrenal Insufficiency). Thyroiditis is associated with other autoimmune conditions, such as pernicious anemia, Sjögren syndrome, vitiligo, inflammatory bowel disease, and celiac disease. The incidence of celiac disease in patients with Hashimoto thyroiditis is about 5%. Hashimoto thyroiditis is very rarely associated with other

autoimmune conditions such as myocarditis, hypophysitis, alopecia areata, encephalitis, primary pulmonary hypertension, or membranous nephropathy. Women with gonadal dysgenesis (Turner syndrome) have a 15% incidence of significant thyroid dysfunction by age 40 years. Thyroiditis is also commonly seen in patients with hepatitis C.

Painless postpartum thyroiditis refers to autoimmune thyroiditis that occurs soon after delivery in 7.2% of women. Women in whom postpartum thyroiditis develops have a 70% chance of recurrence after subsequent pregnancies. It occurs most commonly in women who have high levels of thyroid peroxidase antibody in the first trimester of pregnancy or immediately after delivery. It is also more common in women with other autoimmunity or a family history of Hashimoto thyroiditis. There is some evidence that the autoimmunity may be triggered by the accumulation of fetal cells in the maternal thyroid during pregnancy, a condition known as microchimerism.

Painless sporadic thyroiditis is thought to be a subacute form of Hashimoto thyroiditis that is similar to painless postpartum thyroiditis (see above), except that it is not related to pregnancy. It accounts for about 1% of cases of thyrotoxicosis.

Subacute thyroiditis—also called de Quervain thyroiditis, granulomatous thyroiditis, and giant cell thyroiditis—is relatively common and is believed to be caused by a viral infection. It accounts for up to 5% of clinical thyroid disease.

Suppurative thyroiditis refers to a nonviral infection of the thyroid gland. It is usually bacterial. However, mycobacterial, fungal, and parasitic infections can occur, particularly in immunosuppressed individuals. Suppurative thyroiditis is quite rare, since the thyroid is resistant to infection, largely due to its high iodine content. Congenital pyriform sinus fistulas are a cause for recurrent suppurative thyroiditis in otherwise normal individuals.

Riedel thyroiditis is also called invasive fibrous thyroiditis, Riedel struma, woody thyroiditis, ligneous thyroiditis, and invasive thyroiditis. It is usually a manifestation of a multifocal systemic fibrosis syndrome.

► Clinical Findings

A. Symptoms and Signs

In **Hashimoto thyroiditis**, the thyroid gland is usually diffusely enlarged, firm, and finely nodular. One thyroid lobe may be asymmetrically enlarged, raising concerns about neoplasm. Although patients may complain of neck tightness, pain and tenderness are not usually present. About 10% of cases are atrophic, the gland being fibrotic, particularly in elderly women.

Systemic manifestations are mostly related to ambient levels of thyroid hormone. However, depression and chronic fatigue are more common in such patients, even after correction of hypothyroidism. About one-third of patients have mild dry mouth (xerostomia) or dry eyes (keratoconjunctivitis sicca) of an autoimmune nature related to Sjögren syndrome. It may be associated with myasthenia gravis, which is usually of mild severity, mainly affecting the extraocular muscles and having a relatively low incidence of detectable AChR Ab or thymic disease.

Postpartum thyroiditis is typically accompanied by hyperthyroidism that begins 1–6 months after delivery and persists for only 1–2 months. Then, hypothyroidism tends to develop in affected women beginning 4–8 months after delivery. Although 80% of affected women subsequently recover normal thyroid function, permanent hypothyroidism eventually develops in about 50% within 7 years. Permanent hypothyroidism is more common in women who are multiparous or who have had a spontaneous abortion.

Thyrotoxic symptoms in **painless sporadic thyroiditis** are usually mild; a small, nontender goiter may be palpated in about 50% of such patients. High serum thyroid peroxidase antibody concentrations are found in only 50% of such patients. The course is similar to painless postpartum thyroiditis.

Subacute thyroiditis usually presents with an acute, usually painful enlargement of the thyroid gland, often with dysphagia. The pain may radiate to the ears. Patients usually have a low-grade fever and fatigue. The manifestations may persist for weeks or months and may be associated with malaise. In patients who experience pain, it is called **painful subacute thyroiditis**. If there is no pain, it is called **silent thyroiditis**. Subacute thyroiditis often follows an upper respiratory infection and its incidence peaks in the summer. A viral etiology has been proposed but not firmly established. Thyrotoxicosis develops in 50% of affected patients and tends to last for several weeks. Subsequently, hypothyroidism develops that lasts 4–6 months. Normal thyroid function typically returns within 12 months, but persistent hypothyroidism develops in 5% of patients. Young and middle-aged women are most commonly affected.

Patients with **suppurative thyroiditis** usually are febrile and have severe pain, tenderness, redness, and fluctuation in the region of the thyroid gland. It tends to affect patients with preexistent thyroid disease. It is also more likely to affect patients who are immunosuppressed or infirm.

Riedel thyroiditis usually causes hypothyroidism and may cause hypoparathyroidism as well. It is the rarest form of thyroiditis and is found most frequently in middle-aged or elderly women. Thyroid enlargement is often asymmetric; the gland is stony hard and adherent to the neck structures, causing signs of compression and invasion, including dysphagia, dyspnea, pain, and hoarseness. Related conditions include retroperitoneal fibrosis, fibrosing mediastinitis, sclerosing cervicitis, subretinal fibrosis, and biliary tract sclerosis. It may respond to therapy with tamoxifen (see Treatment, below).

B. Laboratory Findings

With hyperthyroidism due to Hashimoto thyroiditis or subacute thyroiditis, serum FT₄ levels tend to be proportionally higher than T₃ levels, since the hyperthyroidism is due to the passive release of stored thyroid hormone, which is predominantly T₄; this is in contrast to Graves disease and toxic nodular goiter, where T₃ is relatively more elevated. Because T₄ is less active than T₃, the hyperthyroidism seen in thyroiditis is usually less severe. Serum levels of TSH are suppressed in hyperthyroidism due to thyroiditis.

Thyroid autoantibodies are most commonly demonstrable in Hashimoto thyroiditis but may also be present in the other types of thyroiditis. Patients with Hashimoto thyroiditis and clinically evident disease usually have increased circulating levels of antithyroid peroxidase (90%) or antithyroglobulin (40%) antibodies. Antithyroid antibodies decline during pregnancy and are often undetectable in the third trimester. Once Hashimoto thyroiditis has been diagnosed, monitoring of these antibody levels is not necessary. The serum TSH level is elevated if thyroid hormone is not elaborated in adequate amounts by the thyroid gland. In subacute thyroiditis, the ESR is markedly elevated while antithyroid antibody titers are low, distinguishing it from autoimmune thyroiditis. In **suppurative thyroiditis**, both the leukocyte count and ESR are usually elevated.

C. Imaging

Ultrasound in cases of Hashimoto thyroiditis typically shows a gland with characteristic diffuse heterogeneous density and hypoechogenicity. Ultrasonography of the thyroid helps distinguish thyroiditis from multinodular goiter or thyroid nodules that are suspicious for malignancy. It is also helpful in guiding FNA biopsy of small suspicious thyroid nodules. Color-flow Doppler ultrasonography can help distinguish thyroiditis from Graves disease, since patients with Graves disease have a hypervascular thyroid gland, whereas in thyroiditis there is normal or reduced vascularity.

RAI uptake and scan may be helpful in determining the cause of hyperthyroidism, distinguishing thyroiditis from Graves disease, since patients with subacute thyroiditis exhibit a very low RAI uptake. In patients with chronic Hashimoto thyroiditis (euthyroid or hypothyroid), RAI uptake may be normal or high with uneven uptake on the scan; scanning is not useful in making the diagnosis.

D. Fine-Needle Aspiration Biopsy

Patients with **Hashimoto thyroiditis** who have a thyroid nodule should have an ultrasound-guided FNA biopsy, since the risk of papillary thyroid cancer is about 8% in such nodules. When **suppurative thyroiditis** is suspected, an FNA biopsy with Gram stain and culture is required. FNA biopsy is usually not required for subacute thyroiditis but shows characteristic giant multinucleated cells.

► Complications

In the suppurative forms of thyroiditis, any of the complications of infection may occur; the subacute and chronic forms of the disease are complicated by the effects of pressure on the neck structures: dyspnea and, in Riedel struma, vocal cord palsy. Hashimoto thyroiditis may lead to hypothyroidism or transient thyrotoxicosis. Perimenopausal women with high serum levels of antithyropoxidase antibodies have a higher relative risk of depression independently of ambient thyroid hormone levels.

Pregnant women with Hashimoto thyroiditis have an increased risk of spontaneous miscarriage in the first trimester of pregnancy. Hyperthyroidism may develop in patients

with Hashimoto thyroiditis, either due to the emergence of Graves disease or due to the release of stored hormone by the thyroid, which is caused by inflammation. The latter condition has variably been termed “hashitoxicosis” or “painless sporadic thyroiditis;” it is known as postpartum painless thyroiditis when it occurs in women after delivery.

Papillary thyroid carcinoma or thyroid lymphoma may rarely be associated with chronic thyroiditis and must be considered in the diagnosis of uneven painless enlargements that continue in spite of treatment; such patients require FNA biopsy. Hashimoto thyroiditis may be associated with Addison disease, hypoparathyroidism, diabetes, pernicious anemia, biliary cirrhosis, vitiligo, and other autoimmune conditions.

► Differential Diagnosis

Thyroiditis must be considered in the differential diagnosis of all types of goiters, especially if enlargement is rapid. The very low RAI uptake in subacute thyroiditis with elevated T_4 and T_3 is helpful. Chronic thyroiditis, especially if the enlargement is uneven and if there is pressure on surrounding structures, may resemble carcinoma, and both disorders may be present in the same gland. The subacute and suppurative forms of thyroiditis may resemble any infectious process in or near the neck structures. Thyroid autoantibody tests have been of help in the diagnosis of Hashimoto thyroiditis, but the tests are not specific and may also be positive in patients with multinodular goiters, malignancy (eg, thyroid carcinoma, lymphoma), and concurrent Graves disease.

► Treatment

A. Hashimoto Thyroiditis

If hypothyroidism is present, levothyroxine should be given in the usual replacement doses (0.05–0.2 mg orally daily). In patients with a large goiter and normal or elevated serum TSH, T_4 may be given in doses sufficient to suppress serum TSH in an effort to shrink the thyroid. Suppressing doses of T_4 tend to shrink the goiter an average of 30% over 6 months. If the goiter does not regress, lower replacement doses of T_4 may be given. If the thyroid gland is only minimally enlarged and the patient is euthyroid (with normal TSH levels), regular observation is in order, since hypothyroidism may develop subsequently—often years later. (See Hypothyroidism section.)

In one study involving 21 patients with Hashimoto thyroiditis and subclinical hypothyroidism, simvastatin (20 mg orally daily) improved thyroid function over 8 weeks, possibly by stimulating apoptosis of certain types of lymphocytes. In another study, selenium selenite (200 mcg daily orally for 3 months) reduced the serum levels of antithyroperoxidase antibodies by 49% versus a 10% reduction in the placebo arm. The long-term effectiveness of statins or selenium therapy on the course of Hashimoto thyroiditis is unknown.

B. Subacute Thyroiditis

All treatment is empiric and must be continued for several weeks. Recurrence is common. The drug of choice is

aspirin, which relieves pain and inflammation. Thyrotoxic symptoms are treated with propranolol, 10–40 mg orally every 6 hours. Iodinated contrast agents cause a prompt fall in serum T_3 levels and a dramatic improvement in thyrotoxic symptoms. Sodium ipodate (Oragrafin, Bilivist) or iopanoic acid (Telepaque) is given orally in doses of 500 mg orally daily until serum FT_4 levels return to normal. Transient hypothyroidism is treated with T_4 (0.05–0.1 mg orally daily) if symptomatic.

C. Suppurative Thyroiditis

Treatment is with antibiotics and with surgical drainage when fluctuation is marked.

D. Riedel Struma

The treatment of choice for invasive fibrous thyroiditis, like that of its related conditions, is tamoxifen, 20 mg orally twice daily, which must be continued for years. Tamoxifen can induce partial to complete remissions in most patients within 3–6 months. Its mode of action appears to be unrelated to its antiestrogen activity. Short-term corticosteroid treatment may be added for partial alleviation of pain and compression symptoms. Surgical decompression usually fails to permanently alleviate compression symptoms; such surgery is difficult due to dense fibrous adhesions, making surgical complications more likely.

► Prognosis

In subacute thyroiditis, spontaneous remissions and exacerbations are common, and therapy is supportive; the disease process may smolder for months. Hashimoto thyroiditis is occasionally associated with other autoimmune disorders (diabetes mellitus, Addison disease, pernicious anemia, etc). In general, however, patients with Hashimoto thyroiditis have an excellent prognosis, since the condition either remains stable for years or progresses slowly to hypothyroidism, which is easily treated. Women with postpartum thyroiditis usually regain normal thyroid function. Papillary thyroid carcinoma carries a relatively good prognosis when it occurs in patients with Hashimoto thyroiditis.

THYROID NODULES & MULTINODULAR GOITER

ESSENTIALS OF DIAGNOSIS

- ▶ Single or multiple thyroid nodules are commonly found with careful thyroid examinations.
- ▶ Thyroid function tests mandatory.
- ▶ Thyroid biopsy for single or dominant nodules or for a history of prior head-neck or chest-shoulder radiation.
- ▶ Ultrasound examination useful for biopsy and follow-up.
- ▶ Clinical follow-up required.

▶ General Considerations

Nodular enlargement of the thyroid is detectable by palpation in 4–7% of the adult population in areas of the world with sufficient intake of iodine. Each year in the United States, about 275,000 thyroid nodules are detected by palpation. Palpable thyroid nodules are even more common in iodine-deficient geographic areas (see Iodine Deficiency Disorder & Endemic Goiter, below). Palpable thyroid nodules are increasingly prevalent with age. A thyroid nodule is four times more likely to develop in women than men. On thyroid ultrasound, about 50% palpable “solitary nodules” are found to be just one nodule in a multinodular goiter.

About 95% of thyroid nodules are benign, but the presence of a thyroid nodule warrants follow-up and further testing for function and malignancy. Most patients with a thyroid nodule are euthyroid, but there is a high incidence of hypothyroidism or hyperthyroidism. Goiter may be caused by numerous conditions, including multinodular goiter, iodine deficiency, pregnancy (in areas of iodine deficiency), Graves disease, Hashimoto thyroiditis, subacute

thyroiditis, or infections. About 95% of thyroid nodules are benign adenoma, colloid nodule, or cyst but may sometimes be a primary thyroid malignancy or (less frequently) a metastatic neoplasm. Patients with multiple thyroid nodules have the same overall risk of thyroid cancer as patients with solitary nodules. The risk of a thyroid nodule being malignant is higher among patients with a history of head-neck radiation, a family history of thyroid cancer, or a personal history of another malignancy. The risk of malignancy is also higher if a thyroid nodule is large, adherent to the trachea or strap muscles, or associated with lymphadenopathy. The presence of Hashimoto thyroiditis does not reduce the risk of malignancy; a nodule of ≥ 1 cm in a gland with thyroiditis carries an 8% chance of malignancy.

▶ Clinical Findings

Table 26–6 illustrates the approach to the evaluation of thyroid nodules based on the index of suspicion for malignancy.

A. Symptoms and Signs

Most small thyroid nodules cause no symptoms. They may sometimes be detected only by having the patient swallow during careful inspection and palpation of the thyroid.

A thyroid nodule or multinodular goiter can grow to become visible and of concern to the patient. Particularly large nodular goiters can become a cosmetic embarrassment. Nodules can grow large enough to cause discomfort, hoarseness, or dysphagia. Retrosternal large multinodular goiters can cause dyspnea due to tracheal compression. Large substernal goiters may cause superior vena cava syndrome, manifested by facial erythema and jugular vein distention that progress to cyanosis and facial edema when both arms are kept raised over the head (Pemberton sign).

Depending on their cause, goiters and thyroid nodules may be associated with hypothyroidism (Hashimoto thy-

Table 26–6. Clinical evaluation of thyroid nodules.¹

| Clinical Evidence | Low Index of Suspicion | High Index of Suspicion |
|-------------------------------|---|--|
| History | Family history of goiter; residence in area of endemic goiter | Previous therapeutic radiation of head, neck, or chest; hoarseness |
| Physical characteristics | Older women; soft nodule; multinodular goiter | Young adults, men; solitary, firm nodule; vocal cord paralysis; enlarged lymph nodes; distant metastatic lesions |
| Serum factors | High titer of antithyroid antibody; hypothyroidism; hyperthyroidism | Elevated serum calcitonin |
| Fine-needle aspiration biopsy | Colloid nodule or adenoma | Papillary carcinoma, follicular lesion, medullary or anaplastic carcinoma |
| Scanning techniques | | |
| Uptake of ¹²³ I | “Hot” nodule | “Cold” nodule |
| Ultrasonogram | Cystic lesion | Solid lesion |
| Roentgenogram | Shell-like calcification | Punctate calcification |
| Thyroxine therapy | Regression after 0.05–0.1 mg/d for 6 months or more | Increase in size |

¹Clinically suspicious nodules should be evaluated with fine-needle aspiration biopsy.

roiditis, endemic goiter) or hyperthyroidism (Graves disease, toxic nodular goiter, subacute thyroiditis, and thyroid cancer with metastases).

B. Laboratory Findings

Thyroid nodules are an indication for thyroid function testing. Serum determinations for TSH (sensitive assay) and FT₄ are preferred. Tests for antithyroperoxidase antibodies and antithyroglobulin antibodies may also be helpful. Very high antibody levels are found in Hashimoto thyroiditis. However, thyroiditis frequently coexists with malignancy, so suspicious nodules should always be biopsied. Serum calcitonin is obtained if a medullary thyroid carcinoma is suspected in a family member with a history of familial medullary thyroid carcinoma or MEN type 2.

C. Imaging

Neck ultrasonography should be performed to measure the size of a nodule and to determine whether a palpable nodule is part of a multinodular goiter. The following ultrasound characteristics of thyroid nodules increase the likelihood of malignancy: irregular or indistinct margins, heterogenous nodule echogenicity, intranodular vascular images, microcalcifications, complex cyst, or diameter over 1 cm. Ultrasound is also useful for long-term surveillance of thyroid nodules and multinodular goiter. Ultrasonography is generally preferred over CT and MRI because of its accuracy, ease of use, and lower cost.

RAI (¹²³I or ¹³¹I) scans have limited usefulness in the evaluation of thyroid nodules. Hypofunctioning (cold) nodules have a somewhat increased risk of being malignant but most are benign. Hyperfunctioning (hot) nodules are ordinarily benign but may sometimes be malignant. RAI uptake and scanning is helpful if a patient is found to have evidence of hyperthyroidism. (See Hyperthyroidism, above.)

CT scanning is helpful for larger thyroid nodules and multinodular goiter; it can determine the degree of tracheal compression and the degree of extension into the mediastinum.

D. Incidentally Discovered Thyroid Nodules

Thyroid nodules are frequently discovered as an incidental finding, with an incidence that depends on the imaging modality: MRI, 50%; CT, 13%; and [¹⁸F]fluorodeoxyglucose positron emission tomography (¹⁸FDG-PET), 2%. When such scanning detects a thyroid nodule, an ultrasound is performed to better determine the nodule's risk for malignancy and the need for FNA biopsy (see above), and to establish a baseline for ultrasound follow-up. The malignancy risk is about 17% for nodules discovered incidentally on CT or MRI, and 25–50% for nodules discovered incidentally by ¹⁸FDG-PET. For incidentally discovered thyroid nodules of borderline concern, follow-up thyroid ultrasound in 3–6 months may be helpful; growing lesions may be biopsied or resected.

E. Fine-Needle Aspiration Biopsy

FNA biopsy is the best method to assess a thyroid nodule for malignancy. FNA biopsy can be done while patients con-

tinue taking anticoagulants or aspirin. For multinodular goiters, the four largest nodules (≥ 1 cm diameter) should be biopsied to minimize the risk of missing a malignancy. Smaller thyroid nodules (8–10 mm) with a suspicious appearance on ultrasound should also be considered for ultrasound-guided FNA biopsy. Using ultrasound guidance for FNA biopsy improves the diagnostic accuracy for both palpable and nonpalpable thyroid nodules. The chance of an optimal tissue sampling is also improved by having an experienced clinician perform the FNA biopsy and by having the aspirate interpreted by a skilled cytopathologist.

In one review of thyroid FNA biopsies, about 70% were benign, 5% were malignant, 15% were nondiagnostic, and 10% were indeterminate or “suspicious.”

When FNA cytology is “suspicious” for papillary thyroid carcinoma, the risk of malignancy is 57%. When FNA cytology yields a “suspicious” follicular lesion, the overall risk of the lesion being malignant is about 20–25%. However, the risk is lower in patients aged 50 years. The risk that a follicular lesion is malignant increases for patients who are much younger or older than age 50. Most patients with suspicious FNA cytology undergo thyroid surgery.

Cystic nodules yielding serous fluid are usually benign, but fluid should be submitted for cytologic testing. Cystic nodules yielding bloody fluid have a higher chance of being malignant. Repeat FNA biopsy is done with ultrasound guidance if the cytologic test results are nondiagnostic (eg, diluted with blood or hypocellular) and the lesion remains palpable.

False-positive thyroid FNA biopsy results occur at a rate of about 4%. False-negative thyroid FNA biopsy results also occur at an overall rate of about 4%, less commonly when performed under ultrasound guidance and interpreted by cytopathologists. False-negative results delay surgical excision and lead to an increased risk of vascular and capsular invasion by the malignancy. Some false-negative FNA biopsy results may not have actually been inaccurate, since truly benign thyroid nodules can later become malignant. Patients who have a negative thyroid FNA should have observational follow-up, ideally with both palpation and ultrasound; nodules that continue to grow should be rebiopsied or excised.

▶ Treatment

All thyroid nodules, including those that are benign, need to be monitored by regular periodic palpation and ultrasound and rebiopsied if growth occurs. A toxic multinodular goiter and hyperthyroidism, associated with the ingestion or intravenous administration of large amounts of iodine, may develop in patients with multinodular goiters. It is therefore prudent to minimize excessive dietary iodine intake and intravenous iodinated contrast. Patients found to have hyperthyroidism may have a RAI uptake and scan for additional evaluation, especially if ¹³¹I is a therapeutic consideration. Patients with toxic multinodular goiters may also be treated with methimazole, propranolol, or surgery (see Hyperthyroidism section).

A. Levothyroxine Suppression Therapy

Patients with elevated levels of serum TSH are treated with levothyroxine replacement. Otherwise, for small benign thy-

roid nodules, levothyroxine suppression therapy is not required. For larger nodules (> 2 cm), if TSH levels are elevated or normal, "suppression" with levothyroxine (starting doses of 50 mcg daily) can be considered. Levothyroxine should not be administered if the baseline TSH is low, since that is an indication of autonomous thyroid secretion, such that levothyroxine therapy will be ineffective and liable to cause clinical thyrotoxicosis. Long-term levothyroxine suppression of TSH tends to keep nodules from enlarging, but only a few will actually shrink. In one 5-year study, thyroid nodule size increased in 29% of patients treated with levothyroxine, compared to growth in 56% of nodules in patients not receiving levothyroxine. Levothyroxine suppression also reduces the emergency of new nodules: 8% with levothyroxine and 29% without levothyroxine.

Levothyroxine suppression needs to be carefully monitored, since it carries a 17% risk of inducing symptoms of hyperthyroidism. This can occur due to excessive levothyroxine dosing, the emergence of an autonomous or toxic nodule or Graves disease, or a reduction in thyroid binding globulin seen in early menopause or with discontinuing oral estrogen therapy. Therefore, levothyroxine suppression therapy is most suitable for younger patients. All patients require regular careful clinical evaluation and thyroid palpation or ultrasound examinations. Levothyroxine suppression therapy is not usually given to patients with cardiac disease, since it increases the risk for angina and atrial fibrillation. Levothyroxine suppression causes a small loss of bone density, particularly in postmenopausal women. Patients at risk for osteoporosis are advised to have periodic bone density testing. Bisphosphonate or other therapy for osteoporosis may be indicated.

B. Surgery

Total thyroidectomy is required for thyroid nodules that are malignant on FNA biopsy (see Thyroid Cancer section). More limited thyroid surgery is indicated for benign nodules with indeterminate or suspicious cytologic test results, compression symptoms, discomfort, or cosmetic embarrassment. Surgery may also be used to remove hyperfunctioning "hot" thyroid adenomas or toxic multinodular goiter causing hyperthyroidism (see Hyperthyroidism section).

C. Ethanol Injection

Percutaneous ethanol injection has been used to shrink benign (biopsy proven) thyroid nodules, both solid and cystic. Most nodules undergo partial shrinkage after percutaneous ethanol injection. The complication rate is about 9%, although serious or permanent complications are rare.

D. Radioiodine (¹³¹I) Therapy

Radioactive ¹³¹I is a treatment option for hyperthyroid patients with toxic thyroid adenomas, multinodular goiter, or Graves disease (see Hyperthyroidism section). It may also be used to shrink benign nontoxic thyroid nodules. Thyroid nodules shrink an average of 40% by 1 year and 59% by 2 years after ¹³¹I therapy. Nodules that shrink after ¹³¹I therapy generally remain palpable and become firmer;

they may develop unusual cytologic characteristics on FNA biopsy. Hypothyroidism is a risk and may occur years after ¹³¹I therapy, so thyroid function testing must be performed regularly.

► Prognosis

The great majority of thyroid nodules are benign. Benign thyroid nodules may involute but usually persist or grow slowly. About 90% of thyroid nodules will increase their volume by ≥ 15% over 5 years; cystic nodules are less likely to grow. Cytologically benign nodules that grow are unlikely to be malignant; in one series, only 1 of 78 rebiopsied nodules was found to be malignant. The prognosis for patients with thyroid nodules that prove to be malignant is determined by the histologic type and other factors (see below). Multinodular goiters tend to persist or grow slowly, even in iodine-deficient areas where iodine repletion usually does not shrink established goiters. Patients with very small, incidentally discovered, nonpalpable thyroid nodules do require follow-up with thyroid ultrasound but are at low risk for malignancy. Nodules that are malignant have a minor effect on morbidity and mortality.

THYROID CANCER

ESSENTIALS OF DIAGNOSIS

- Painless swelling in region of thyroid.
- Thyroid function tests usually normal.
- Past history of irradiation to head and neck region may be present.
- Positive thyroid needle aspiration.

► General Considerations

The incidence of papillary and follicular (differentiated) thyroid carcinomas increases with age. The overall female:male ratio is 3:1. The yearly incidence of thyroid cancer has been increasing in the United States, with the

Table 26-7. Some characteristics of thyroid cancer.

| | Papillary | Follicular | Medullary | Undifferentiated |
|-------------------------|-------------|------------|-----------|------------------|
| Incidence | Most common | Common | Uncommon | Uncommon |
| Average age | 42 | 50 | 50 | 57 |
| Females | 70% | 72% | 56% | 56% |
| Invasion | | | | |
| Juxtaneural | +++++ | + | +++++ | +++ |
| Blood vessels | + | +++ | +++ | +++++ |
| Distant sites | + | +++ | ++ | ++++ |
| ¹²³ I uptake | + | ++++ | 0 | 0 |
| Mortality | + | ++ to +++ | + to ++++ | +++++++ |

number of cases diagnosed annually reaching 33,500, probably as a result of the wider use of CT, MRI, PET, and ultrasound that incidentally find small thyroid malignancies. Thyroid cancer mortality has been stable, accounting for about 1500 deaths in the United States annually. At autopsy, microscopic thyroid cancer is found with surprising frequency. Clearly, most thyroid cancers remain microscopic and indolent. However, larger thyroid cancers (palpable or ≥ 1 cm in diameter) are more malignant and require treatment.

Papillary thyroid carcinoma is the most common thyroid malignancy (Table 26-7).

Pure papillary and mixed papillary-follicular carcinoma represent about 80% of all thyroid cancers. It usually presents as a single thyroid nodule, but it can arise out of a multinodular goiter. Papillary thyroid carcinoma is commonly multifocal within the gland, with other foci usually arising *de novo* rather than representing intraglandular metastases. About 10% of cases present with palpable cervical lymph node metastases from a small thyroid cancer. Papillary thyroid carcinomas tend to grow slowly and often remain confined to the thyroid and regional lymph nodes for years. However, they may become more aggressive, especially in patients over age 45 years, and most particularly in the elderly. The cancer may invade the trachea and local muscles and may spread to the lungs.

Papillary thyroid carcinoma is caused by certain genetic mutations or translocations. Activating mutations of the *ras* oncogene can cause benign thyroid adenomas or nodular goiter. Additional activating mutations in *BRAF* or *TRK* genes can lead to papillary carcinoma. About 45% of papillary thyroid carcinomas are caused by over expression of the *ret* oncogene by the translocation of certain gene promoters to it, producing *retPTC-1*, *retPTC-2*, or *retPTC-3*. Radiation treatments to the head and neck region tend to cause *retPTC-1*. Nuclear fallout exposure tends to cause *retPTC-3*, resulting in more aggressive papillary thyroid carcinomas. Additional loss of the *p53* tumor suppressor gene can cause progression of papillary thyroid carcinoma to anaplastic thyroid carcinoma.

Exposure to radiation therapy to the head and neck poses a particular threat to children who then have an

increased lifetime risk of developing thyroid pathology, including papillary thyroid carcinoma; thyroid malignancy may emerge between 10 and 40 years after exposure, with a peak occurrence 20–25 years later. After an explosion at the Chernobyl Nuclear Plant in the Ukraine in 1986, the risk of developing papillary thyroid carcinoma was highest among children who were under age 5 at the time of exposure to radiation; emergence of more aggressive papillary thyroid carcinoma occurred within 6–7 years after exposure.

Papillary thyroid carcinoma can occur in familial syndromes as an autosomal dominant trait, caused by loss of various tumor suppressor genes. Such syndromes (with associated features) include familial papillary carcinoma (with papillary renal carcinoma); familial nonmedullary thyroid carcinoma; familial polyposis (with large intestine polyps and gastrointestinal tumors); Gardner syndrome (with small and large intestine polyps, fibromas, lipomas, osteomas); and Turcot syndrome (with large intestine polyps and brain tumors). Older patients with multinodular goiter may rarely develop a papillary thyroid carcinoma. Papillary carcinoma can sometimes undergo a late anaplastic transformation into an aggressive carcinoma.

Generally speaking, papillary carcinoma is the least aggressive thyroid malignancy. However, the tumor spreads via lymphatics within the thyroid, appearing to be multifocal in 60% of patients and involving both lobes in 30% of patients. About 80% of patients have microscopic metastases to cervical lymph nodes. Unlike other forms of cancer, patients with papillary thyroid carcinoma who have palpable lymph node metastases do not have a particularly increased mortality rate; however, their risk of local recurrence is increased.

Occult metastases to the lung occur in 10–15% of differentiated thyroid cancer. About 70% of small lung metastases resolve following ¹³¹I therapy; however, larger pulmonary metastases have only a 10% remission rate.

Microscopic “micropapillary” carcinoma (≤ 1 mm and invisible even on thyroid ultrasound) is a variant of normal, being found in 24% of thyroidectomies performed for benign thyroid disease when 2-mm sections were carefully examined. It thus appears that the overwhelming majority

of these microscopic foci never become clinically significant. The surgical pathology report of such a tiny papillary carcinoma that is otherwise benign does not justify aggressive follow-up or treatment because a cancer diagnosis is unwarranted and harmful. All that may be required is yearly follow-up with palpation of the neck and mild TSH suppression by thyroxine.

Follicular thyroid carcinoma and its variants (eg, Hürthle cell carcinoma) account for about 14% of thyroid malignancies; follicular thyroid carcinoma is generally more aggressive than papillary carcinoma. Rarely, some follicular carcinomas secrete enough T_4 to cause thyrotoxicosis if the tumor load becomes significant. Metastases commonly are found in neck nodes, bones, and lungs. Most follicular thyroid carcinomas avidly absorb iodine, making possible diagnostic scanning and treatment with ^{131}I after total thyroidectomy. Certain follicular histopathologic features are associated with a high risk of metastasis and recurrence: poorly differentiated and Hürthle cell (oncocyctic) variants. The latter variants do not take up RAI.

Follicular carcinoma results from certain gene mutations or translocations. Aberrant DNA methylation, activation of the *ras* oncogene, and mutations of the *MEN1* gene can result in benign follicular adenomas. Loss of function of *PPAR γ* or the *3P* tumor suppressor gene can lead to follicular carcinoma, and additional loss of the *p53* tumor suppressor gene can produce anaplastic carcinoma.

Follicular thyroid carcinoma and adenomas develop in patients with Cowden disease, a rare autosomal dominant familial syndrome caused by loss of a tumor suppressor gene; such patients tend to have macrocephaly, multiple hamartomas, early-onset breast cancer, intestinal polyps, facial papules, and other skin and mucosal lesions.

Medullary thyroid carcinoma represents about 3% of thyroid cancers. About one-third of cases are sporadic, one-third are familial, and one-third are associated with MEN type 2. Medullary thyroid carcinoma is often caused by an activating mutation of the *ret* oncogene on chromosome 10. Mutation analysis of the *ret* oncogene's exons 10, 11, 13, and 14 detects 95% of the mutations causing MEN 2A and 90% of the mutations causing familial medullary thyroid carcinoma. Patients with MEN 2B have activating mutations in exon 16 of the *ret* oncogene. These germline mutations can be detected by DNA analysis of peripheral WBCs. Therefore, discovery of a medullary thyroid carcinoma makes genetic analysis mandatory. If a gene defect is discovered, related family members must have genetic screening for that specific gene defect. When a family member with MEN 2A or familial medullary thyroid carcinoma does not have an identifiable *ret* oncogene mutation, gene carriers may still be identified using family linkage analysis. Even when no gene defect is detectable, family members should have regular thyroid surveillance. Somatic mutations of the *ret* oncogene can be identified in the tumors of 30% of patients with sporadic (nonfamilial) medullary thyroid carcinoma. (See Multiple Endocrine Neoplasia.)

Medullary thyroid carcinoma arises from parafollicular thyroid cells that can secrete calcitonin, prostaglandins, serotonin, ACTH, corticotropin-releasing hormone (CRH), and other peptides. These peptides can cause symptoms and

can be used as tumor markers. Early local metastases are usually present, usually to adjacent muscle and trachea as well as to local and mediastinal lymph nodes. Eventually, late metastases may appear in the bones, lungs, adrenals, or liver. Medullary thyroid carcinoma does not concentrate iodine.

Anaplastic thyroid carcinoma represents about 2% of thyroid cancers. It usually presents in an older patient as a rapidly enlarging mass in a multinodular goiter. It is the most aggressive thyroid carcinoma and metastasizes early to surrounding nodes and distant sites. Local pressure symptoms include dysphagia or vocal cord paralysis. This tumor does not concentrate iodine.

Anaplastic thyroid carcinoma is caused by certain gene mutations, including inactivating mutations of the *p53* tumor suppressor gene, as described above for papillary and follicular thyroid carcinomas.

Other thyroid malignancies together represent about 3% of thyroid cancers. **Lymphoma** of the thyroid is more common in older women. Thyroid lymphomas are most commonly B cell lymphomas (50%) or mucosa-associated lymphoid tissue (MALT; 23%); other types include follicular, small lymphocytic, and Burkitt lymphoma and Hodgkin disease. Thyroidectomy is rarely required. **Other cancers** may sometimes metastasize to the thyroid, particularly bronchogenic, breast, and renal carcinomas and malignant melanoma.

► Clinical Findings

A. Symptoms and Signs

Thyroid carcinoma usually presents as a palpable, firm, nontender nodule in the thyroid. Most thyroid carcinomas are asymptomatic, but large thyroid cancers can cause neck discomfort, dysphagia, or hoarseness (due to pressure on the recurrent laryngeal nerve). About 3% of thyroid malignancies present with a metastasis, usually to local lymph nodes but sometimes to distant sites such as bone or lung. Palpable lymph node involvement is present in 15% of adults and 60% of youths. Metastatic functioning differentiated thyroid carcinoma can sometimes secrete enough thyroid hormone to produce thyrotoxicosis. **Anaplastic thyroid carcinoma** is more apt to be advanced at the time of diagnosis, presenting with dysphagia, hoarseness, dyspnea, and metastases to the lungs. Occasionally, such carcinomas may be discovered while they are still relatively small and localized.

Medullary thyroid carcinoma frequently causes flushing and persistent diarrhea (30%), which may be the initial clinical feature. Patients with metastases often experience fatigue as well as other symptoms. Cushing syndrome develops in about 5% of patients from secretion of ACTH or CRH. Signs of pressure or invasion of surrounding tissues are present in anaplastic or large tumors; recurrent laryngeal nerve palsy can occur.

Lymphoma usually presents as a rapidly enlarging, painful mass arising out of a multinodular or diffuse goiter affected by autoimmune thyroiditis, with which it may be confused microscopically. About 20% of cases have concomitant hypothyroidism.

B. Laboratory Findings

(FNA biopsy is discussed above in the section on nodular thyroid.) Thyroid function tests are generally normal unless there is concomitant thyroiditis. Follicular carcinoma may secrete enough T₄ to suppress TSH and cause clinical hyperthyroidism.

Serum thyroglobulin is high in most metastatic papillary and follicular tumors, making this a useful marker for recurrent or metastatic disease. Caution must be exercised for the following reasons: (1) Circulating antithyroglobulin antibodies can cause erroneous thyroglobulin determinations. (2) Thyroglobulin levels may be misleadingly elevated in thyroiditis, which often coexists with carcinoma. (3) Certain thyroglobulin assays falsely report the continued presence of thyroglobulin after total thyroidectomy and tumor resection, causing undue concern about possible metastases. Therefore, unexpected thyroglobulin levels should prompt a repeat assay in another reference laboratory.

Serum calcitonin levels are usually elevated in medullary thyroid carcinoma, making this a marker for metastatic disease. However, serum calcitonin may be elevated in many other conditions, such as thyroiditis; pregnancy; azotemia; hypercalcemia; and other malignancies, including pheochromocytomas, carcinoid tumors, and carcinomas of the lung, pancreas, breast, and colon.

Serum calcitonin and carcinoembryonic antigen (CEA) determinations should be obtained before surgery for medullary carcinoma, then regularly in postoperative follow-up: every 4 months for 5 years, then every 6 months for life. Calcitonin levels remain elevated in patients with persistent tumor but also in some patients with apparent cure or indolent disease. Therefore, rising levels of calcitonin (or CEA) are the best indication for recurrence. Serum calcitonin levels > 250 pg/mL are also an indication for recurrent or metastatic medullary thyroid carcinoma. Serum CEA levels are usually elevated with medullary carcinoma, making this a useful second marker; however, it is not specific for this carcinoma.

C. Imaging

1. Ultrasound of the neck—Ultrasound of the neck should be performed routinely on all patients with thyroid cancer for the initial diagnosis and for follow-up. Ultrasound is useful in determining the size and location of the malignancy as well as the location of any neck metastases.

2. Radioactive iodine scanning—RAI (¹³¹I or ¹²³I) thyroid and whole-body scanning is used after thyroidectomy for surveillance as described below, supplanting its previous use to determine whether a nodule was “cold” as a sign of malignancy.

3. CT scanning—CT scanning may demonstrate metastases and is particularly useful for localizing and monitoring lung metastases. However, CT scanning is less sensitive than ultrasound for detecting metastases within the neck. Iodinated contrast should never be given prior to RAI scanning or RAI therapy, since the large amounts of iodine in contrast media competitively inhibit the uptake of RAI

by the thyroid, greatly reducing the effectiveness of subsequent RAI scanning and therapy. Medullary carcinoma in the thyroid, nodes, and liver may calcify, but lung metastases rarely do so.

4. MRI—MRI is particularly useful for imaging bone metastases.

5. PET scanning—PET scanning is particularly useful for detecting thyroid cancer metastases that do not have sufficient iodine uptake to be visible on RAI scans. Metastases are best detected using ¹⁸F-DG-PET whole-body scanning. The sensitivity of ¹⁸F-DG-PET scanning for differentiated thyroid cancer is enhanced if the patient is hypothyroid or receiving thyrotropin, which increases the metabolic activity of differentiated thyroid cancer. Disadvantages of PET scanning include its lack of specificity for thyroid cancer as well as its expense and lack of availability in many locations. ¹⁸F-DG-PET scanning has prognostic implications, since differentiated thyroid cancer metastases with low standard uptake value scores are associated with a better prognosis.

► Differential Diagnosis

Neuroendocrine carcinomas may metastasize to the thyroid and be confused with medullary thyroid carcinoma.

False-positive ¹³¹I scans are common with normal residual thyroid tissue and have been reported with Zenker diverticulum, struma ovarii, pleuropericardial cyst, gastric pull-up, and ¹³¹I-contaminated bodily secretions. False-negative ¹³¹I scans are common in early metastatic differentiated thyroid carcinoma but occur also in more advanced disease, including 14% of bone metastases.

► Complications

The complications vary with the type of carcinoma. Differentiated thyroid carcinomas may have local or distant metastases. One-third of medullary carcinomas may secrete serotonin and prostaglandins, producing flushing and diarrhea, and may be complicated by the coexistence of pheochromocytomas or hyperparathyroidism. The risks of radical neck surgery include permanent hypoparathyroidism and vocal cord palsy due to recurrent laryngeal nerve damage; permanent hypothyroidism is expected after thyroidectomy and should always be treated adequately.

► Treatment of Differentiated Thyroid Carcinoma

A. Surgical Treatment

Surgical removal is the treatment of choice for thyroid carcinomas. For differentiated papillary and follicular carcinoma, thyroidectomy with limited removal of cervical lymph nodes is adequate. The advantage of near-total thyroidectomy for differentiated thyroid carcinoma is that multicentric foci of carcinoma are more apt to be resected and there is then less normal thyroid tissue to compete with cancer for ¹³¹I administered later for scans or treatment. Subtotal thyroidectomy is acceptable for adults under age 45 years who have a single small tumor (≤ 1 cm in diame-

ter). Patients with bulky metastases in the neck region also benefit from surgery. Neck muscle resections are usually avoided for differentiated thyroid carcinoma. However, patients with the Hürthle cell variant of follicular carcinoma may benefit from a modified radical neck dissection. Metastases to the brain are best treated surgically, since treatment with radiation or RAI is ineffective. Levothyroxine is prescribed in doses of 0.05–0.1 mg/d immediately postoperatively (see Thyroxine Suppression and Chemotherapy, below). About 2–4 months after surgery, patients require reevaluation and often require therapy with ^{131}I (see below).

Highly skilled surgeons can perform near-total thyroidectomies with a less than 1% rate of serious complications (hypoparathyroidism or recurrent laryngeal nerve damage). Other series have reported up to an 11% incidence of permanent hypoparathyroidism after total thyroidectomy. The incidence of hypoparathyroidism may be reduced if accidentally resected parathyroids are immediately autotransplanted into the neck muscles.

Thyroidectomy requires at least an overnight hospital admission, since late bleeding, airway problems, and tetany can occur. Ambulatory thyroidectomy is potentially dangerous and should not be done.

B. Thyroxine Suppression and Chemotherapy

Patients who have had a thyroidectomy for differentiated thyroid cancer must take thyroxine replacement for life. Oral thyroxine should be given in doses that suppress serum TSH without causing clinical thyrotoxicosis. An ultrasensitive TSH assay should be used; serum TSH should be suppressed below 0.1 mU/L for patients with stage II disease and below 0.05 mU/L for patients with stage III–IV disease. (See Table 26–8.) Patients receiving thyroxine suppression therapy have been reported, as a group, to have slightly lower bone density than age-matched controls. However, for patients who are clinically euthyroid, thyroxine suppression therapy has a minimal effect upon bone and fracture risk. Nevertheless, patients receiving thyroxine suppression therapy are advised to have periodic bone densitometry.

Thyroid carcinomas are extraordinarily resistant to chemotherapy. Zoledronic acid, an intravenous bisphosphonate, has proven useful for osteolytic metastases from other solid tumors and has been used for patients with thyroid bone metastases, but its effectiveness is unknown.

C. Radioactive Iodine Therapy

Differentiated thyroid cancers variably retain the normal thyroid's ability to respond to TSH, secrete thyroglobulin, and concentrate iodine. Patients with stage II–IV cancer are usually treated with adjuvant ^{131}I therapy, when possible. The use of postoperative RAI therapy for patients with stage I differentiated thyroid cancer is controversial; there has been no demonstrable improvement in survival in this group of patients following RAI therapy. Most clinicians give RAI therapy to patients with stage I cancer only if the primary tumor was greater than 1–2 cm in diameter or of histologic higher risk.

About 2–4 months after thyroidectomy, patients follow a low iodine diet for at least 2 weeks before RAI therapy. **The low iodine diet** consists of avoiding the following: iodized table salt, sea salt, fish, shellfish, seaweed, commercial bread, dairy products, processed meats, canned or dried fruit, canned fruit juices, highly salted soups and snack foods, black tea, instant coffee, food coloring with Red Dye #3, egg yolks, multivitamins with iodine, or topical iodine. Patients must not be given intravenous radiologic contrast dyes containing iodine.

In order to stimulate radioiodine uptake by residual cancer tissue, patients are given recombinant human thyroid stimulating hormone (rhTSH, Thyrogen) as described below. Thyroxine withdrawal (2 weeks before ^{131}I therapy) is an alternative to Thyrogen, allowing the body's TSH levels to rise naturally and increasing the body's retention of administered ^{131}I . This technique avoids the high costs of Thyrogen. Also, whether Thyrogen-stimulated ^{131}I therapy is adequate to treat patients with stage III–IV cancer remains controversial. However, hypothyroidism is uncomfortable for most patients.

Just before ^{131}I therapy, serum is obtained for measurement of TSH (to make certain it is > 30 mcU/mL), thyro-

Table 26–8. Pathologic tumor-node-metastasis (pTNM) staging and tumor-related approximate survival rates for adults with appropriately treated differentiated (papillary) thyroid carcinoma based upon patient age, primary tumor size and invasiveness (T), lymph node involvement (N), and distant metastases (M).¹

| Stage | Description | Five-Year Survival | Ten-Year Survival |
|-------|---|--------------------|-------------------|
| 1 | Under 45: any T, any N, no M Over 45: T ≤ 1 cm, no N, no M | 99% | 98% |
| 2 | Under 45: any T, any N, any M Over 45: T > 1 cm limited to thyroid, no N, no M | 99% | 90% |
| 3 | Over 45: T beyond thyroid capsule, no N, no M; or any T, regional N, no M | 95% | 75% |
| 4 | Over 45: any T, any N, any M | 85% | 65% |

¹Patients having a relatively worse prognosis include those with follicular thyroid carcinoma and those with familial differentiated thyroid carcinoma.

globulin, and hCG (in all reproductive-age women). Pregnant women may not receive RAI therapy. Women are advised to avoid pregnancy for at least 4 months following ^{131}I therapy. Men have been found to have abnormal spermatozoa for up to 6 months following ^{131}I therapy and are advised to use contraceptive methods during that time.

^{131}I is administered orally. The dose of ^{131}I for thyroid “remnant ablation” in those with no nodal involvement is 30 mCi (1110 MBq). Higher doses (50–100 mCi) of ^{131}I may be given to patients with large primary tumors or tumors at the surgical margin. Patients with local lymph node involvement typically receive 100 mCi of ^{131}I ; patients with more extensive neck node involvement or distant metastases receive ^{131}I at a dose of 125–200 mCi (4625–7400 MBq). A post-therapy whole-body scan, performed about 1 week after ^{131}I treatment, will often detect metastases that were not visible on pretreatment scans. Unfortunately, about 35% of patients with differentiated thyroid carcinoma have poor uptake of ^{131}I into metastases.

Patients who have been withdrawn from thyroid hormone may resume thyroxine at the full replacement dose 4 days following ^{131}I therapy. They may also cease their low iodine diet. To accelerate the return to euthyroidism, Cytomel may be added to thyroxine for 2 weeks at a dose of 25 mcg orally twice daily for 1 week, reduced to 12.5 mcg twice daily for the next week.

^{131}I therapy in doses over 100 mCi (3800 MBq) can cause gastritis, temporary oligospermia, sialadenitis, and xerostomia. RAI therapy can cause neurologic decompensation in patients with brain metastases; it is advisable to treat such patients with prednisone 30–40 mg orally daily for several days before and after ^{131}I therapy. Cumulative doses of ^{131}I over 500 mCi can cause infertility, pancytopenia (4%), and leukemia (0.3%). The kidneys excrete RAI. Patients receiving dialysis for kidney disease require a dosage reduction to only 20% of the usual dose of ^{131}I .

National Cancer Institute surveillance data for 30,278 patients with thyroid cancer has indicated that patients with differentiated thyroid cancer, treated with only surgery, had a 5% increased risk of developing a second non-thyroid malignancy (especially breast cancer). Patients with thyroid cancer who received ^{131}I therapy had a 20% increased risk of developing a second non-thyroid malignancy (especially leukemia and lymphoma). The greatest risk of second cancers appeared within 5 years of ^{131}I therapy and was most significant for younger patients.

D. Treatment of Other Thyroid Malignancies

Patients with anaplastic thyroid carcinoma are treated with local resection and radiation. Lovastatin, an HMG-CoA inhibitor, has been demonstrated to cause differentiation and apoptosis of anaplastic thyroid carcinoma cells in vitro; however, clinical studies have not been performed. Anaplastic thyroid carcinoma does not respond to ^{131}I therapy and is resistant to chemotherapy.

Patients with thyroid MALT lymphomas have a low risk of recurrence after simple thyroidectomy. Patients with other thyroid lymphomas are best treated with external radiation therapy; chemotherapy is added for extensive

lymphoma. Patients with systemic lymphomas involving the thyroid are usually treated with chemotherapy.

Patients with a *ret* protooncogene mutation should have a prophylactic total thyroidectomy, ideally by age 6 years (MEN 2A) or at age 6 months (MEN 2B). Patients with medullary thyroid carcinoma are treated surgically; repeated neck dissections are often required over time. Medullary thyroid carcinomas do not respond to ^{131}I therapy and are generally resistant to chemotherapy.

E. External Radiation Therapy

External radiation may be delivered to bone metastases. Brain metastases do not usually respond to ^{131}I and are best resected or treated with gamma knife radiosurgery.

F. Surveillance

Patients with differentiated thyroid carcinoma must be observed long-term for recurrent or metastatic disease. Follow-up must include physical examinations and laboratory testing to ensure that patients remain clinically euthyroid with a suppressed TSH. To achieve suppression of serum TSH, the required dose of thyroxine may be such that serum FT₄ levels may be slightly elevated; in that case, measurement of serum T₃ or free T₃ (women who are pregnant or receiving oral estrogens) can be useful to ensure the patient is not frankly hyperthyroid. Thyrotoxicosis can be caused by overreplacement with thyroxine or by the growth of functioning metastases.

Neck palpation has a sensitivity of only 16% for detecting cervical lymph node metastases. For surveillance, neck ultrasound and serum thyroglobulin determinations (baseline and rhTSH-stimulated) have largely replaced whole-body radioiodine scanning, which has a false-negative rate of about 80%. Follow-up intervals of 4–6 months are usually satisfactory.

1. Neck ultrasound—Neck ultrasound should be used in all patients with thyroid carcinoma to supplement neck palpation. It is prudent to perform a thyroid/neck ultrasound in all patients with thyroid cancer preoperatively, 3 months postoperatively, and regularly thereafter. Ultrasound is more sensitive for lymph node metastases than either CT or MRI scanning. Small inflammatory nodes may be detected postoperatively and do not necessarily indicate metastatic disease, but follow-up is necessary. Ultrasound-guided FNA biopsy should be performed on suspicious lesions.

2. Serum thyroglobulin (Tg)—Thyroglobulin is produced by normal thyroid tissue and by most differentiated thyroid carcinomas. It is only after a total or near-total thyroidectomy and ^{131}I remnant ablation that Tg becomes a useful tumor marker for patients with differentiated papillary or follicular thyroid cancer, particularly for patients who do not have serum anti-Tg antibodies. Anti-Tg antibodies mainly interfere with immunometric assays and interfere less with radioimmunoassays for Tg. Anti-Tg antibodies tend to persist but may become less evident several years after total thyroidectomy and during the last trimester of pregnancy.

Detectable levels of thyroglobulin are commonly encountered in patients who have had incomplete thyroidectomies and ^{131}I remnant ablations. Detectable thyroglobulin levels do not necessarily indicate the presence of residual or metastatic thyroid cancer. However, baseline or stimulated serum Tg levels ≥ 2 ng/mL indicate the need for a repeat neck ultrasound and further scanning with RAI or ^{18}F FDG-PET. If serum Tg levels remain ≥ 2 ng/mL in the presence of normal scanning, it is prudent to repeat the serum Tg in a national reference laboratory. Rising serum levels of thyroglobulin are particularly worrisome.

In one series of patients with differentiated thyroid cancer following thyroidectomy, there was a 21% incidence of metastases in patients with serum Tg < 1 ng/mL (while receiving thyroxine for TSH suppression). Therefore, baseline serum Tg levels are inadequately sensitive and *stimulated* serum Tg measurements should be used and *always* with neck ultrasound. The usefulness of routinely doing a radioiodine scan (see below) in low-risk patients is controversial but continues to be done in many centers during stimulation following either rhTSH or thyroid hormone withdrawal, according to the protocols described below.

3. Radioactive iodine (RAI: ^{131}I or ^{123}I) whole-body scanning—Despite its limitations, RAI has traditionally been used to detect metastatic differentiated thyroid cancer and to determine whether the cancer is amenable to treatment with ^{131}I . RAI scanning is particularly useful for high-risk patients and those with persistent anti-thyroglobulin antibodies that make serum thyroglobulin determinations unreliable.

The ^{131}I isotope may be used in scanning doses of < 3 mCi (111 MBq) or given within 2 weeks of RAI treatment to avoid “stunning” metastases such that they take up less of the RAI therapy dose. The radioisotope ^{123}I may be used in scanning doses of 5 mCi (185 MBq), does not stun tumors, and allows single-photon emission computed tomography (SPECT) to better localize metastases. Initial RAI scanning is typically performed about 2–4 months following surgery for differentiated thyroid carcinoma. Whole-body scanning should be performed for at least 30 minutes for at least 140,000 counts and spot views of the neck should be obtained for at least 35,000 counts.

About 65% of metastases are detectable by RAI scanning, but only after optimal preparation: Patients should ideally have a total or near-total thyroidectomy, since any residual normal thyroid competes for RAI with metastases, which are less avid for iodine. To avoid nonradioactive iodine competitive inhibition of RAI uptake, intravenous iodinated contrast must be avoided for at least 2 months before scanning; patients must follow a low-iodine diet for at least 2 weeks before scanning and continue to limit iodine consumption until the scan is complete or until after ^{131}I therapy. In addition, patients must have high levels of TSH to stimulate metastases to take up more RAI, making them visible on scanning. This can be accomplished by administering synthetic rhTSH or by allowing the patient to become hypothyroid. The use of rhTSH has become more widespread for surveillance scanning and

stimulated thyroglobulin determinations following thyroidectomy for differentiated thyroid carcinoma, due to its convenience for the patient. For stage I–II patients, it is reasonable to perform a rhTSH-stimulated scan and thyroglobulin level 2–3 months after the initial neck surgery; if the scan is negative and the serum thyroglobulin is < 2 ng/mL, the patient may be monitored with yearly neck ultrasound and serum thyroglobulin levels. For higher-risk patients, the rhTSH-stimulated thyroglobulin and RAI scan may be repeated about 1 year after surgery and then again if warranted.

A. THYROTROPIN-STIMULATED SERUM Tg AND RADIOIODINE SCANNING—For surveillance, recombinant human thyrotropin- α (Thyrogen; rhTSH) is given in order to increase the sensitivity of serum thyroglobulin and RAI scanning. The use of rhTSH is particularly suited to “low-risk” patients: those with a small papillary thyroid carcinoma who have had a total or near-total thyroidectomy and have no known local or distal metastases and a serum thyroglobulin < 1 mcg/L during thyroxine suppression of serum TSH. In about 21% of such low-risk patients, rhTSH stimulates serum thyroglobulin to above 2 mcg/L; such patients have a 23% risk of local neck metastases and a 13% risk of distant metastases. Stimulated radioiodine neck and whole-body scanning can detect only about half of these metastases because they are small or not avid for iodine.

Thyrotropin must be kept refrigerated and may be administered according to the following protocol: Thyroxine replacement is held for 2 days before rhTSH and for 3 days afterward. On Monday and Tuesday, thyrotropin 0.9 mg is administered intraglutely (not intravenously). On Wednesday, serum is drawn for TSH and thyroglobulin determinations. Immediately thereafter, RAI is administered in a scanning dose (see above). On Friday, serum is drawn for thyroglobulin and the whole-body scan is performed.

Side effects of thyrotropin injections include nausea (11%) and headache (7%). Hyperthyroidism can occur in patients with significant metastases or residual normal thyroid. Thyrotropin has caused neurologic deterioration in 7% of patients with central nervous system metastases.

The combination of thyrotropin-stimulated scanning and thyroglobulin levels detects a thyroid remnant or cancer with a sensitivity of 84%. However, the presence of anti-thyroglobulin antibodies renders the serum thyroglobulin determination uninterpretable. Thyrotropin stimulation does not prepare patients for ^{131}I treatment; they must be prepared for treatment by becoming hypothyroid as described below.

B. THYROID WITHDRAWAL-STIMULATED SERUM Tg AND RADIOIODINE SCANNING—Recombinant human TSH (rhTSH, Thyrogen) has largely replaced thyroid withdrawal, as noted above. But thyroid hormone withdrawal is still used, allowing the patient to become hypothyroid; high levels of endogenous TSH stimulate the uptake of RAI and production of thyroglobulin by thyroid cancer or residual thyroid. Serum thyroxine is held for 14 days. Prior to scanning, serum TSH is assayed to confirm that it is > 30 mcU/mL; serum hCG is assayed to screen for pregnancy; serum thyroglobulin titers are also determined.

Following radioisotope scanning, or 4 days after ^{131}I therapy (see above), thyroxine therapy may be resumed at full replacement dose.

Patients with **differentiated thyroid carcinoma** have traditionally required at least two annual consecutively negative stimulated serum thyroglobulin determinations < 1 mcg/L and normal RAI scans (if done) and neck ultrasound before they are considered to be in remission. Patients with persistent RAI uptake restricted to the thyroid bed need not have repeated ^{131}I therapies if neck ultrasound appears benign and serum thyroglobulin is < 5 ng/mL. Further radioiodine or other scans may be required for patients with more aggressive papillary-follicular, follicular, or medullary thyroid carcinomas, prior metastases, rising serum thyroglobulin levels, or other evidence of metastases.

Patients often have a negative whole-body radioiodine scan but have serum thyroglobulin levels that are > 2 ng/mL. In such cases, another thyroglobulin assay should be sent to a different reference laboratory to confirm the accuracy of the thyroglobulin determination. Patients with serum Tg levels > 2 ng/mL require close continued monitoring. Those with progressively rising Tg levels are at high risk for occult thyroid cancer metastases. Other scanning methods may be used in an effort to detect such metastases.

4. Positron emission tomography scanning—PET whole-body scanning using ^{18}F FDG-PET is a relatively sensitive method for detecting thyroid cancer metastases—particularly those that are not revealed on RAI scanning. PET scanning is particularly useful for detecting thyroid cancer metastases in patients with a detectable serum thyroglobulin (especially serum thyroglobulin levels > 10 ng/mL and rising) who have a normal whole-body RAI scan and an unrevealing neck ultrasound. PET scanning can be combined with a CT scan; the resultant PET/CT fusion scan is 60% sensitive for detecting metastases that are not visible by other methods. This scan is less sensitive for small brain metastases. ^{18}F FDG-PET scanning detects the metabolic activity of tumor tissue; for differentiated thyroid carcinoma, this scan is more sensitive when the patient is pretreated with thyrotropin as described above. One problem with ^{18}F FDG-PET scanning is its lack of specificity. For example, false-positives can occur with benign hepatic tumors, sarcoidosis, radiation therapy, suture granulomas, reactive lymph nodes, or inflammation at surgical sites that can persist for months. False-positive uptake can also occur in muscles and brown fat in the neck and shoulders, axillae, mediastinum, perinephric regions, intercostal paravertebral spaces, and paravertebral muscles. A fusion ^{18}F FDG-PET/CT (noniodine contrast) scan improves specificity but cannot distinguish thyroid carcinoma from other unrelated malignancies that may be present concurrently. Smaller metastases are often present on PET scanning before becoming visible on CT or MRI scanning.

^{18}F FDG-PET scanning is particularly sensitive for detecting medullary thyroid carcinoma metastases, and prescan thyrotropin does not improve the PET scan sensitivity for medullary thyroid carcinoma.

5. Other scanning—Thallium-201 (^{201}Tl) scans may be useful for detecting metastatic differentiated thyroid carcinoma when the ^{131}I scan is normal but serum thyroglobulin is elevated. MRI scanning is particularly useful for imaging metastases in the brain, mediastinum, or bones. CT scanning is useful for imaging and monitoring pulmonary metastases.

► Staging & Prognosis

Staging and survival for **papillary thyroid cancer** is shown on Table 26–8. Papillary thyroid cancer carries a generally good prognosis, particularly for adults under age 45 years, despite the fact that about 15% of these patients are subsequently found to have metastases. The following characteristics imply a worse prognosis: older age, male sex, bone or brain metastases, large pulmonary metastases, and lack of ^{131}I uptake into metastases. Younger patients with pulmonary metastases tend to respond better to ^{131}I therapy than do older adults. Certain papillary histologic types are associated with a higher risk of recurrence: tall cell, columnar cell, and diffuse sclerosing types. Brain metastases are detected in 1%; they reduce median survival to 12 months, but the patient's prognosis is improved by surgical resection. Patients with a **follicular variant of papillary carcinoma** have a prognosis somewhere between that of papillary and follicular thyroid carcinoma.

Patients with **follicular carcinoma** have a cancer mortality rate that is 3.4 times higher than patients with papillary carcinoma. The Hürthle cell variant of follicular carcinoma is even more aggressive. Patients with primary tumors over 1 cm in diameter who undergo limited thyroid surgery (subtotal thyroidectomy or lobectomy) have a 2.2-fold increased mortality over those having total or near-total thyroidectomies. Patients who have not received ^{131}I ablation have mortality rates that are increased twofold by 10 years and threefold by 25 years (over those who have received ablation). The risk of cancer recurrence is twofold higher in men than in women and 1.7-fold higher in multifocal than in unifocal tumors.

Medullary thyroid carcinoma is more aggressive than differentiated thyroid cancer but is typically fairly indolent. The overall 10-year survival rate is 90% when the tumor is confined to the thyroid, 70% for those with metastases to cervical lymph nodes, and 20% for those with distant metastases. Patients with sporadic disease usually have lymph node involvement noted at the time of diagnosis, whereas distal metastases may not be noted for years. For patients with medullary thyroid carcinoma who have metastases to lymph nodes, modified radical neck dissection is recommended. Familial cases or those associated with MEN 2A tend to be less aggressive; the 10-year survival rate is higher, in part due to earlier detection. Medullary thyroid carcinoma that is seen in MEN 2B is more aggressive, arises earlier in life, and carries a worse overall prognosis. Women with medullary thyroid carcinoma who are under age 40 years have a better prognosis. A better prognosis is also obtained in patients undergoing total thyroidectomy and neck dissection; radiation therapy reduces recurrence in patients with metastases to neck nodes. The

mortality rate is increased 4.5-fold when primary or metastatic tumor tissue stains heavily for myelomonocytic antigen M-1. Conversely, tumors with heavy immunoperoxidase staining for calcitonin are associated with prolonged survival even in the presence of significant metastases.

Anaplastic thyroid carcinoma carries a 1-year survival rate of about 10% and a 5-year survival rate of about 5%. Patients with fully localized tumors on MRI have a better prognosis.

Localized lymphoma carries a 5-year survival of nearly 100%. Those with disease outside the thyroid have a 63% 5-year survival. However, the prognosis is better for those with the MALT type. Patients presenting with stridor, pain, laryngeal nerve palsies, or mediastinal extension tend to fare worse.

IODINE DEFICIENCY DISORDER & ENDEMIC GOITER

ESSENTIALS OF DIAGNOSIS

- ▶ Common in regions of the world with low-iodine diets.
- ▶ High rate of congenital hypothyroidism and cretinism.
- ▶ Goiters may become multinodular and grow to great size.
- ▶ Most adults with endemic goiter are found to be euthyroid; however, some are hypothyroid or hyperthyroid.
- ▶ Impaired cognition and hearing may be subtle or severe in congenital hypothyroidism.

▶ General Considerations

About 1 billion people are iodine deficient, having no access to iodized salt and living in areas with iodine-depleted soil. Severe iodine deficiency increases the risk of miscarriage and stillbirth. About 0.5% of live births in iodine-deficient areas have full-blown cretinism. Moderate iodine deficiency during gestation and infancy cause other manifestations of congenital hypothyroidism, such as deafness and short stature and permanently lowers a child's IQ by 10–15 points. Such children belong to the most isolated and impoverished families whose affected children serve to perpetuate the cycle of poverty in these areas.

Populations in areas of iodine deficiency have a high incidence of goiter. One such area is Pescopagano, Italy, where 60% of adults have goiters. Hyperthyroidism (present or past) occurred in 2.9%; hypothyroidism was overt in 0.2% and subclinical in 3.8%.

Although iodine deficiency is the most common cause of endemic goiter, certain foods (eg, sorghum, millet, maize, cassava), mineral deficiencies (selenium, iron), and water pollutants can themselves cause goiter or aggravate a goiter proclivity caused by iodine deficiency. In iodine-deficient patients, smoking can induce goiter growth. Pregnancy aggravates iodine deficiency and is associated with an increase in size of thyroid nodules and the emergence of new nodules. Some individuals are particularly susceptible to goiter owing to congenital partial defects in thyroid enzyme activity.

▶ Clinical Findings

A. Symptoms and Signs

Endemic goiters may become multinodular and very large. Growth often occurs during pregnancy and may cause compressive symptoms.

Substernal goiters are usually asymptomatic but can cause tracheal compression, respiratory distress and failure, dysphagia, superior vena cava syndrome, gastrointestinal bleeding from esophageal varices, palsies of the phrenic or recurrent laryngeal nerves, or Horner syndrome. Cerebral ischemia and stroke can result from arterial compression or thyrocervical steal syndrome. Substernal goiters can rarely cause pleural or pericardial effusions. The incidence of significant malignancy is less than 1%.

Some patients with endemic goiter may become hypothyroid. Others may become thyrotoxic as the goiter grows and becomes more autonomous, especially if iodine is added to the diet.

B. Laboratory Findings

The serum T_4 is usually normal. Serum TSH is generally normal. TSH falls in the presence of hyperthyroidism if a multinodular goiter has become autonomous in the presence of sufficient amounts of iodine for thyroid hormone synthesis. TSH rises with hypothyroidism. Thyroid RAI uptake is usually elevated, but it may be normal if iodine intake has improved. Serum levels of antithyroid antibodies are usually either undetectable or in low titers. Serum thyroglobulin is often elevated.

▶ Differential Diagnosis

Endemic goiter must be distinguished from all other forms of nodular goiter that may coexist in an endemic region (see above).

▶ Prevention

Iodine deficiency is prevented by adding iodine to commercial salt. In the United States, potassium iodide is used. Some tropical countries use potassium iodate, since it is more stable than potassium iodide in hot and humid climates. Iodized salt contains iodine at about 20 mg per kg salt. The

minimum dietary requirement for iodine is about 50 mcg daily, with optimal iodine intake being 150–300 mcg daily. Iodine sufficiency is assessed by measurement of urinary iodide excretion, the target being more than 10 mcg/dL. Initiating iodine supplementation in an iodine-deficient area greatly reduces the emergence of new goiters but causes an increased frequency of hyperthyroidism during the first year.

▶ Treatment

The addition of potassium iodide to table salt greatly reduces the prevalence of endemic goiter and cretinism but is less effective in shrinking established goiter. Concurrent deficiencies in both vitamin A and iodine increase the risk of endemic goiter and concurrent repletion of both iodide and vitamin A reduces goiter in endemic goiter regions.

Adults with large multinodular goiter may require thyroidectomy for cosmesis, compressive symptoms, or thyrotoxicosis. Following partial thyroidectomy in iodine-deficient geographic areas, there is a high goiter recurrence rate, so near-total thyroidectomy is preferred when surgery is indicated. Certain patients may be treated with ¹³¹I for large compressive goiters.

▶ Complications

Dietary iodine supplementation increases the risk of autoimmune thyroid dysfunction, which may cause hypothyroidism or hyperthyroidism. Excessive iodine supplementation increases the risk of goiter. Thyroxine suppression carries the risk of inducing hyperthyroidism, particularly in patients with autonomous multinodular goiters; therefore, thyroxine suppression should not be started in patients with a low TSH level. Rarely, Graves disease can develop 3–10 months after ¹³¹I treatment in patients with large multinodular goiters.

THE PARATHYROIDS

Parathyroid hormone (PTH) increases osteoclastic activity in bone, increases the renal tubular reabsorption of calcium, and stimulates the synthesis of 1,25-dihydroxycholecalciferol by the kidney. Meanwhile, PTH inhibits the absorption of phosphate and bicarbonate by the renal tubule. All of these actions cause a net increase in serum calcium.

HYPOPARATHYROIDISM & PSEUDOHYPOPARATHYROIDISM

ESSENTIALS OF DIAGNOSIS

- ▶ Tetany, carpopedal spasms, tingling of lips and hands, muscle and abdominal cramps, psychological changes.

- ▶ Positive Chvostek sign and Trousseau phenomenon.
- ▶ Serum calcium low; serum phosphate high; alkaline phosphatase normal; urine calcium excretion reduced.
- ▶ Low or low-normal serum PTH in presence of hypocalcemia.
- ▶ Serum magnesium may be low.

▶ General Considerations

Acquired hypoparathyroidism is most commonly seen following thyroidectomy, when it is usually transient but may be permanent. It may also occur after multiple parathyroidectomies. Hypoparathyroidism may occur transiently after surgical removal of a parathyroid adenoma for primary hyperparathyroidism due to suppression of the remaining normal parathyroids and accelerated remineralization of the skeleton (hungry bone syndrome). Neck irradiation may rarely cause hypoparathyroidism.

Parathyroid deficiency may also be the result of damage from heavy metals such as copper (Wilson disease) or iron (hemochromatosis, transfusion hemosiderosis), granulomas, sporadic autoimmunity, Riedel thyroiditis, tumors, or infection.

Functional hypoparathyroidism may also occur as a result of magnesium deficiency (malabsorption, chronic alcoholism), which prevents the secretion of PTH. Correction of hypomagnesemia results in rapid disappearance of the condition.

PGA type I (PGA-1) is also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED). PGA-1 presents in childhood with at least two of the following manifestations: candidiasis, hypoparathyroidism, or Addison disease. Cataracts, uveitis, alopecia, vitiligo, or autoimmune thyroid disease may also develop.

Fat malabsorption occurs in 20% of patients with PGA-1 and may present as weight loss, diarrhea, or malabsorption of vitamin D, a fat-soluble vitamin used to treat the hypoparathyroidism. The fat malabsorption may be due to a deficiency in the jejunal enteroendocrine cells that produce cholecystokinin, causing a reduction in bile acid secretion.

In **congenital hypoparathyroidism**, parathyroid cells have calcium-sensing receptors (CaSR) that sense the serum calcium concentration and suppress PTH secretion by way of G-protein-coupled mechanisms. Gain-of-function mutations (constitutive activation) of the *CaSR* gene suppress the parathyroid glands, resulting in hypocalcemia without elevations in serum PTH levels. Such mutations cause “autosomal dominant hypocalcemia with hypercalciuria” (ADHH) from deficient secretion of PTH. The prevalence of ADHH in the population is about 1 in 70,000, and it typically presents in infancy with hypocalcemic seizures.

Hypoparathyroidism, deafness, and renal dysplasia (HDR or Barakat) syndrome is an autosomal dominant condition caused by haploinsufficiency or mutations of the gene *GATA3*. The hypocalcemia is present from birth but may not be detected until the occurrence of mental retardation or hypocalcemic tetany. The mostly high-frequency

deafness is present at birth. Various renal and vesicoureteral anomalies occur.

Hypoparathyroidism may also be seen in DiGeorge syndrome, along with congenital cardiac and facial anomalies; hypocalcemia usually presents with tetany in infancy, but some cases are not detected until adulthood.

► Clinical Findings

A. Symptoms and Signs

Acute hypoparathyroidism causes tetany, with muscle cramps, irritability, carpopedal spasm, and convulsions; tingling of the circumoral area, hands, and feet is almost always present. Symptoms of the chronic disease are lethargy, personality changes, anxiety state, blurring of vision due to cataracts, parkinsonism, and mental retardation.

Chvostek sign (facial muscle contraction on tapping the facial nerve in front of the ear) is positive, and Trousseau phenomenon (carpal spasm after application of a sphygmomanometer cuff) is present. Cataracts may occur; the nails may be thin and brittle; the skin is dry and scaly, at times with fungus infection (candidiasis), and there may be loss of hair (eyebrows); and deep tendon reflexes may be hyperactive. Papilledema and elevated cerebrospinal fluid pressure are occasionally seen. Teeth may be defective if the onset of the disease occurs in childhood.

B. Laboratory Findings

Serum calcium is low, serum phosphate high, urinary calcium low, and alkaline phosphatase normal. Serum calcium is largely bound to albumin. In hypoalbuminemia, the serum ionized calcium may be determined, but it has had surprisingly poor clinical utility. Alternatively, the serum calcium level can be corrected for serum albumin level as follows:

$$\text{“Corrected” serum Ca}^{2+} = \text{Serum Ca}^{2+} \text{ mg/dL} + (0.8 \times [4.0 - \text{Albumin g/dL}])$$

PTH levels are low. Serum magnesium should be determined since hypomagnesemia frequently accompanies hypocalcemia and may exacerbate symptoms and decrease parathyroid function.

C. Imaging

Radiographs or CT scans of the skull may show basal ganglia calcifications; the bones may be denser than normal. Cutaneous calcification may occur.

D. Other Examinations

Slit-lamp examination may show early posterior lenticular cataract formation. The electrocardiogram (ECG) shows prolonged QT intervals and T wave abnormalities. Patients with chronic hypoparathyroidism tend to have increased bone mineral density, particularly in the lumbar spine.

► Complications

Acute tetany with stridor, especially if associated with vocal cord palsy, may lead to respiratory obstruction requiring

tracheostomy. The complications of chronic hypoparathyroidism largely depend on the duration of the disease. There may be associated autoimmunity causing sprue syndrome, pernicious anemia, or Addison disease. In long-standing cases, cataract formation and calcification of the basal ganglia are seen. Occasionally, parkinsonian symptoms or choreoathetosis develop. Ossification of the paravertebral ligaments may occur with nerve root compression; surgical decompression may be required. Seizures are common in untreated patients. Overtreatment with vitamin D and calcium may produce nephrocalcinosis and impairment of kidney function. Chronic hypocalcemia can cause heart failure.

► Differential Diagnosis

Paresthesias, muscle cramps, or tetany due to respiratory alkalosis, in which the serum calcium is normal, can be confused with hypocalcemia. In fact, hyperventilation tends to accentuate hypocalcemic symptoms.

At times hypoparathyroidism is misdiagnosed as idiopathic epilepsy, choreoathetosis, or brain tumor (on the basis of brain calcifications, convulsions, choked disks) or, more rarely, as “asthma” (on the basis of stridor and dyspnea). In patients with hypoalbuminemia, serum levels of ionized calcium are normal.

Hypocalcemia may also be due to malabsorption of calcium, magnesium, or vitamin D; patients do not always have diarrhea. Hypocalcemia may also be caused by certain drugs: loop diuretics, plicamycin, phenytoin, alendronate, and foscarnet. In addition, hypocalcemia may be seen in cases of rapid intravascular volume expansion or due to chelation from transfusions of large volumes of citrated blood. It is also observed in patients with acute pancreatitis. Hypocalcemia may develop in some patients with certain osteoblastic metastatic carcinomas (especially breast, prostate) instead of the expected hypercalcemia. Hypocalcemia with hyperphosphatemia (simulating hypoparathyroidism) is seen in azotemia but may also be caused by large doses of intravenous, oral, or rectal phosphate preparations and by chemotherapy of responsive lymphomas or leukemias.

Hypocalcemia with hypercalciuria may be due to a familial syndrome involving a mutation in the calcium-sensing receptor; such patients have levels of serum PTH that are in the normal range, distinguishing it from hypoparathyroidism. It is transmitted as an autosomal dominant disorder. Such patients are hypercalciuric; treatment with calcium and vitamin D may cause nephrocalcinosis.

Congenital pseudohypoparathyroidism is a group of disorders characterized by resistance to PTH. There are several subtypes caused by different mutations involving the PTH receptor or its G protein or adenyl cyclase. Renal tubular resistance to PTH causes hypercalciuria with resultant hypocalcemia. PTH levels are high and the PTH receptors in bone are typically not involved, such that bony changes of hyperparathyroidism may be evident. Various phenotypic abnormalities—classically, short stature, round face, obesity, short fourth metacarpals, ectopic bone formation, and mental retardation—may be associated with congenital pseudohypoparathyroidism. Patients without hypo-

Table 26–9. Vitamin D preparations used in the treatment of hypoparathyroidism.

| | Available Preparations | Daily Dose | Duration of Action |
|--|---|---------------------|--------------------|
| Ergocalciferol ergosterol, (vitamin D ₂ , Calciferol) | Capsules of 50,000 international units; 8000 international units/mL oral solution | 2000–200,000 units | 1–2 weeks |
| Cholecalciferol (vitamin D ₃) | Capsules of 50,000 international units not available commercially in United States; may be compounded | 10,000–50,000 units | 4–8 weeks |
| Calcitriol (Rocaltrol) | Capsules of 0.25 and 0.5 mcg; 1 mcg/mL oral solution; 1 mcg/mL for injection | 0.25–4 mcg | 1/2–2 weeks |

calcemia but sharing the phenotypic abnormalities are said to have “pseudopseudohypoparathyroidism.”

► Treatment

A. Emergency Treatment for Acute Attack (Hypoparathyroid Tetany)

This usually occurs after surgery and requires immediate treatment.

- 1. Airway**—Be sure an adequate airway is present.
- 2. Intravenous calcium gluconate**—Calcium gluconate, 10–20 mL of 10% solution intravenously, may be given *slowly* until tetany ceases. Ten to 50 mL of 10% calcium gluconate may be added to 1 L of 5% glucose in water or saline and administered by slow intravenous drip. The rate should be adjusted so that the serum calcium is maintained between 8 mg/dL and 9 mg/dL.
- 3. Oral calcium**—Calcium salts should be given orally as soon as possible to supply 1–2 g of calcium daily. Liquid calcium carbonate, 500 mg/5 mL, may be especially useful. The dosage is 1–3 g calcium daily. Calcium citrate contains 21% calcium, but a higher proportion is absorbed with less gastrointestinal intolerance.

4. Vitamin D preparations—(Table 26–9.) Therapy should be started as soon as oral calcium is begun. The active metabolite of vitamin D, 1,25-dihydroxycholecalciferol (calcitriol), has a very rapid onset of action and is not long-lasting if hypercalcemia occurs. It is of great use in the treatment of acute hypocalcemia. Therapy is commenced at a dosage of 0.25 mcg orally each morning with upward dosage titration to near normocalcemia. Ultimately, doses of 0.5–2 mcg/d are usually required.

Calcifediol (25-hydroxyvitamin D₃), another option for treatment, has an intermediate onset and duration of action; the usual starting dose is 20 mcg/d orally.

5. Magnesium—If hypomagnesemia is present (chronic alcoholism, malnutrition, renal loss, drugs such as cisplatin, etc), it must be corrected to treat the resulting hypocalcemia. Acutely, magnesium sulfate is given intravenously, 1–2 g every 6 hours. Long-term magnesium replacement may be given as magnesium oxide tablets (600 mg), one or two per day, or as a combined magnesium and calcium preparation (CalMag, others).

6. Transplantation of cryopreserved parathyroid tissue removed during prior surgery—Transplantation restores normocalcemia in about 23% of cases.

B. Maintenance Treatment

The goal should be to maintain the serum calcium in a slightly low but asymptomatic range (8–8.6 mg/dL). This will minimize the hypercalciuria that would otherwise occur and provides a margin of safety against overdosage and hypercalcemia, which may produce permanent damage to kidney function. Calcium supplementation (1–2 g/d) is given, along with a vitamin D preparation.

Patients with chronic hypoparathyroidism must usually be treated with some type of vitamin D (Table 26–9). Vitamin D₂ (ergocalciferol) is derived from plants and is commercially available. The usual dose ranges from 25,000 to 150,000 units/d. Vitamin D₃ (cholecalciferol), the form of vitamin D that is naturally produced in unprotected human skin with UV sunlight exposure, is not generally commercially available in the United States in large doses but may be compounded. Vitamin D₃ is at least three times more bioavailable than vitamin D₂, so that appropriate dosing adjustments must be made when changing from one type of vitamin D to another. Both forms of vitamin D are slow-acting preparation, and if toxicity develops, hypercalcemia—treatable with hydration and prednisone—may persist for weeks after it is discontinued. Ergocalciferol and cholecalciferol usually produce a more stable serum calcium level than do the shorter-acting preparations.

Despite its high cost, calcitriol is being used with increasing frequency for the treatment of chronic hypoparathyroidism; the maintenance dosage of calcitriol ranges from 0.25 mcg/d to 2.0 mcg/d. Monitoring of serum calcium at regular intervals (at least every 3 months) is mandatory.

PTH acts upon the kidney to increase tubular reabsorption of calcium. Therefore, patients with hypoparathyroidism are prone to hypercalciuria and calcium nephrolithiasis during treatment. Target serum calcium levels should be 8–8.6 mg/dL, keeping it mildly low to avoid hypercalciuria. It is prudent to monitor urine calcium with “spot” urine determinations and keep the level below 30 mg/dL if possible. Hypercalciuria may respond to oral hydrochlorothiazide, usually given with a potassium supplement.

Caution: Phenothiazine drugs should be administered with caution, since they may precipitate extrapyramidal

symptoms in hypocalcemic patients. Furosemide should be avoided, since it may worsen hypocalcemia.

► Prognosis

The outlook is good if the diagnosis is made promptly and treatment instituted. Any dental changes, cataracts, and brain calcifications are permanent. Periodic blood chemical evaluation is required, since changes in calcium levels may call for modification of the treatment schedule. Hypercalcemia that develops in patients with seemingly stable, treated hypoparathyroidism may be a presenting sign of Addison disease.

HYPERPARATHYROIDISM

ESSENTIALS OF DIAGNOSIS

- Frequently detected incidentally by screening.
- Renal calculi, polyuria, hypertension, constipation, fatigue, mental changes.
- Bone pain; rarely, cystic lesions and pathologic fractures.
- Serum and urine calcium elevated; urine phosphate high with low to normal serum phosphate; alkaline phosphatase normal to elevated.
- Elevated PTH.

► General Considerations

Primary hyperparathyroidism is characterized by chronic poorly regulated excessive secretion of PTH by one or more parathyroid glands that results in hypercalcemia. It is an increasingly recognized disorder, present in up to 0.1% of adult patients examined. It can be seen at any age but is more frequent in persons over the age of 50 years and is three times more common in women than in men.

The disease is caused by hypersecretion of PTH, usually by a single parathyroid adenoma (80%), and less commonly by hyperplasia by two or more parathyroid glands (20%), or carcinoma ($\leq 1\%$). However, when hyperparathyroidism presents before age 30 years, there is a higher incidence of multiglandular disease (36%) and carcinoma (5%). The size of the parathyroid adenoma correlates with the serum PTH level.

Hyperparathyroidism is familial in about 10% of cases. Parathyroid hyperplasia may arise in MEN types 1, 2A, and 2B. In MEN 1, multiglandular hyperparathyroidism is usually the initial manifestation and ultimately occurs in 90% of affected individuals. Hyperparathyroidism in MEN 2A is less frequent than in MEN 1 and is usually milder. Familial hyperparathyroidism can also occur in the hyperparathyroidism-jaw tumor syndrome, a rare autosomal

dominant familial condition in which parathyroid cystic adenomas or carcinomas are associated with ossifying fibromas of the mandible and maxilla as well as renal lesions (cysts, hamartomas, Wilms tumors). Affected individuals usually present with severe hypercalcemia as teenagers or young adults; the pathology is usually a single parathyroid adenoma. (See Table 26–16.)

Hyperparathyroidism results in the excessive excretion of calcium and phosphate by the kidneys. PTH stimulates renal tubular reabsorption of calcium; however, hyperparathyroidism causes hypercalcemia and an increase in calcium in the glomerular filtrate that overwhelms tubular reabsorption capacity, resulting in hypercalciuria. At least 5% of renal calculi are associated with this disease. Diffuse parenchymal calcification (nephrocalcinosis) is seen less commonly. Chronic bone resorption induced by excessive PTH in the circulation may produce diffuse demineralization, pathologic fractures, or cystic bone lesions throughout the skeleton (“osteitis fibrosa cystica”).

In chronic kidney disease, hyperphosphatemia and decreased renal production of 1,25-dihydroxycholecalciferol ($1,25[\text{OH}]_2\text{D}_3$) initially produce a decrease in ionized calcium. The parathyroid glands are stimulated (secondary hyperparathyroidism) and may enlarge, becoming autonomous (tertiary hyperparathyroidism). The bone disease seen in this setting is known as “renal osteodystrophy.” Parathyroid hyperplasia in uremia can result in extremely high serum PTH levels that are associated with uremic vascular calcification. Hypercalcemia often occurs after kidney transplant.

Parathyroid carcinoma is a rare cause of hyperparathyroidism but is more common in patients with severe hypercalcemia. About 50% of parathyroid carcinomas are palpable.

► Clinical Findings

A. Symptoms and Signs

Hypercalcemia of hyperparathyroidism is typically discovered accidentally by routine chemistry panels. Many patients are asymptomatic or have mild symptoms that may be elicited only upon questioning. Parathyroid adenomas are usually so small and deeply located in the neck that they are almost never palpable; when a mass is palpated, it usually turns out to be an incidental thyroid nodule.

Symptomatic patients are said to have problems with “bones, stones, abdominal groans, psychic moans, with fatigue overtones.” The manifestations are categorized as skeletal, urinary tract, and those associated with hypercalcemia.

1. Skeletal manifestations—Hyperparathyroidism causes a loss of cortical bone and a gain of trabecular bone. Significant bone demineralization is uncommon in mild hyperparathyroidism, but osteitis fibrosa cystica may present as pathologic fractures or as “brown tumors” or cysts of the jaw. More commonly, patients have bone pain and arthralgias.

2. Manifestations of hypercalcemia—Mild hypercalcemia may be asymptomatic. However, hypercalcemia has a variety of manifestations that become progressively

worse with more severe hypercalcemia. Paresthesias, muscular weakness, and diminished deep tendon reflexes are examples of **neuromuscular manifestations**. **Central nervous system** manifestations include malaise, fatigue, intellectual weariness, depression, increased sleep requirement, progressing to cognitive impairment, disorientation, psychosis, or stupor. **Cardiovascular symptoms** that can indicate hypercalcemia are hypertension, prolonged P-R interval, shortened Q-T interval, sensitivity to arrhythmic effects of digitalis, bradyarrhythmias, heart block, asystole. **Renal** manifestations include polyuria and polydipsia, caused by hypercalcemia-induced nephrogenic diabetes insipidus. Calcium-containing kidney stones are reported in about 18% of those with newly discovered primary hyperparathyroidism. Nephrocalcinosis and kidney disease can occur. Gastrointestinal symptoms include anorexia, nausea, vomiting, abdominal pain, weight loss, constipation, and obstipation. Pancreatitis occurs in 3%. **Pruritus** may be present. **Calcium** may precipitate in the corneas (“band keratopathy”). Calcium may also precipitate in extravascular tissues as well as in small arteries, causing small vessel thrombosis and skin necrosis (calciophylaxis).

3. Hyperparathyroidism during pregnancy—About 67% of women with primary hyperparathyroidism during pregnancy experience complications such as nephrolithiasis, hyperemesis, pancreatitis, muscle weakness, cognitive changes, and hypercalcemic crisis. About 80% of fetuses experience complications of maternal hyperparathyroidism, including fetal demise, preterm delivery, low birth weight, postpartum neonatal tetany, and permanent hypoparathyroidism.

B. Laboratory Findings

The hallmark of primary hyperparathyroidism is the serum calcium > 10.5 mg/dL (Figure 26–1). In hyperproteinemic states, the total serum calcium may be elevated but the ionized fraction is normal, whereas in primary hyperparathyroidism, the ionized calcium is almost always over 5.4 mg/dL (1.4 mmol/L). In practice, serum ionized calcium determinations have not proved to be very helpful clinically. The serum phosphate is often low (< 2.5 mg/dL). The urine calcium excretion may be high or normal (averaging 250 mg/g creatinine) but it is usually low for the degree of hypercalcemia. There is an excessive loss of phosphate in the urine in the presence of hypophosphatemia (25% of cases). (In secondary hyperparathyroidism due to kidney disease, the serum phosphate is high.) The alkaline phosphatase is elevated only if bone disease is present. The plasma chloride and uric acid levels may be elevated. Vitamin D deficiency is common in patients with hyperparathyroidism, and it is prudent to screen for vitamin D deficiency with a serum 25-OH vitamin D determination. Low serum 25-OH vitamin D levels (< 20 mcg/L; < 50 nmol/L) can aggravate hyperparathyroidism and its bone manifestations; vitamin D replacement may be helpful in treating patients with hyperparathyroidism. (See below.)

Elevated serum levels of intact PTH (IRMA assay) confirm the diagnosis of hyperparathyroidism. Patients with apparent hyperparathyroidism should be screened for familial benign hypocalciuric hypercalcemia with a 24-hour urine for calcium and creatinine.

Patients should discontinue thiazide diuretics prior to this test. Calcium excretion of < 50 mg/24 hours (or < 5 mg/dL on a random urine) is not typical for primary

▲ **Figure 26–1.** Parathyroid hormone and calcium nomogram. Relationship between serum intact parathyroid hormone (PTH) and serum calcium levels in patients with hypoparathyroidism, pseudohypoparathyroidism, nonparathyroid hypercalcemia, primary hyperparathyroidism (HPT), and secondary hyperparathyroidism. (Courtesy of GJ Strewler.)

hyperparathyroidism and indicates possible familial benign hypocalciuric hypercalcemia. (See below.)

C. Imaging

Preoperative sestamibi-iodine subtraction scanning and neck ultrasonography have been used to locate parathyroid adenomas in patients with hyperparathyroidism, in an effort to improve the outcome and limit the invasiveness of neck surgery. Parathyroid imaging is crucial for patients who have had prior neck surgery. However, the usefulness of preoperative parathyroid localizing imaging studies for first neck explorations remains controversial. Imaging is not useful for the diagnosis of hyperparathyroidism, which must be made by serum calcium and PTH determinations. Preoperative scanning does not improve the outcome of initial bilateral neck explorations performed by a surgeon with special expertise in parathyroid surgery. Therefore, preoperative imaging has been used mainly to improve the outcome for limited neck exploration, with only modest success. (See Surgery, below.) Small benign thyroid nodules are discovered incidentally in nearly 50% of patients with hyperparathyroidism who have imaging with ultrasound or MRI.

CT and MRI scanning are not ordinarily required or useful for initial preoperative parathyroid localizing studies, since these scanning techniques are less sensitive for identifying tiny parathyroid adenomas. However, for repeat neck operations and when ectopic parathyroids are suspected, MRI is preferred since it offers better soft tissue contrast than CT scanning and is less adversely affected by postoperative changes in the neck. Three-dimensional technetium-99m sestamibi scanning can also help localize ectopic parathyroid glands.

Bone density measurements by dual energy x-ray absorptiometry (DXA) is helpful in determining the amount of bone loss in patients with hyperparathyroidism. Bone loss occurs mostly in long bones, and DXA should ideally include three areas: lumbar spine, hip, and distal radius.

Bone radiographs are usually normal and are not required to make the diagnosis of hyperparathyroidism. There may be demineralization, subperiosteal resorption of bone (especially in the radial aspects of the fingers), or loss of the lamina dura of the teeth. There may be cysts throughout the skeleton, mottling of the skull (“salt-and-pepper appearance”), or pathologic fractures. Articular cartilage calcification (chondrocalcinosis) is sometimes found.

Patients with renal osteodystrophy may have ectopic calcifications around joints or in soft tissue. Such patients may exhibit radiographic changes of osteopenia, osteitis fibrosa, or osteosclerosis, alone or in combination. Osteosclerosis of the vertebral bodies is known as “rugger jersey spine.”

► Complications

Pathologic long bone fractures are more common in patients with hyperparathyroidism than in the general population. Urinary tract infection due to stone and obstruction may lead to kidney disease and uremia. If the serum calcium

level rises rapidly, clouding of sensorium, kidney disease, and rapid precipitation of calcium throughout the soft tissues may occur. Peptic ulcer and pancreatitis may be intractable before surgery. Insulinomas or gastrinomas may be associated, as well as pituitary tumors (MEN type 1). Pseudogout may complicate hyperparathyroidism both before and after surgical removal of tumors. Hypercalcemia during gestation produces neonatal hypocalcemia.

In tertiary hyperparathyroidism due to chronic kidney disease, high serum calcium and phosphate levels may cause disseminated calcification in the skin, soft tissues, and arteries (calciophylaxis); this can result in painful ischemic necrosis of skin and gangrene, cardiac arrhythmias, and respiratory failure. The actual serum levels of calcium and phosphate have not correlated well with calciophylaxis, but a calcium (mg/dL) \times phosphate (mg/dL) product over 70 is usually present.

► Differential Diagnosis

A. Artifact

A report of hypercalcemia may be due to laboratory error or excess tourniquet time and should always be repeated. Hypercalcemia may be due to high serum protein concentrations; in the presence of high or low serum albumin concentrations, a serum ionized calcium is more dependable than the total serum calcium concentration. Hypercalcemia may also be seen with dehydration; spurious elevations in serum calcium have been reported with severe hypertriglyceridemia, when the calcium assay uses spectrophotometry.

B. Vitamin D Deficiency

Secondary hyperparathyroidism predictably develops in patients with a deficiency in vitamin D. Serum calcium levels are typically in the normal range, but may rise to become borderline elevated with time, due to parathyroid glandular hyperplasia. (See Osteomalacia section.)

C. Hypercalcemia of Malignancy

Many malignant tumors (breast, lung, pancreas, uterus, hypernephroma, paraganglioma, etc) can produce hypercalcemia. In some cases (breast carcinoma especially), bony metastases are present. In others, no metastases to bone can be demonstrated. Most of these tumors secrete PTH-related protein (PTHrP), which has tertiary structural homologies to PTH and causes bone resorption and hypercalcemia similar to those of PTH. The clinical features of the hypercalcemia of cancer can closely simulate hyperparathyroidism. Serum phosphate is often low, but the plasma level of PTH by IRMA is *low*. Serum PTHrP may be elevated.

Multiple myeloma is a common cause of hypercalcemia in the older population. Many other hematologic cancers, such as monocytic leukemia, T cell leukemia and lymphoma, and Burkitt lymphoma, have also been associated with hypercalcemia. Multiple myeloma causes kidney dysfunction; resultant increased levels of carboxyl terminal PTH may cause it to be confused with hyperparathyroidism if a carboxyl terminal PTH assay is used.

D. Sarcoidosis and Other Granulomatous Disorders

Macrophages and perhaps other cells present in granulomatous tissue have the ability to synthesize $1,25(\text{OH})_2\text{D}_3$. Hypercalcemia has been reported in patients with sarcoidosis, tuberculosis, berylliosis, histoplasmosis, coccidioidomycosis, leprosy, and even foreign-body granuloma. Increased intestinal calcium absorption and hypercalciuria are more common than hypercalcemia. Serum levels of $1,25(\text{OH})_2\text{D}_3$ are elevated.

E. Calcium or Vitamin D Ingestion

Ingestion of large amounts of calcium or vitamin D can cause hypercalcemia, especially in patients who concurrently take thiazide diuretics, which reduce urinary calcium loss. Hypercalcemia is reversible following withdrawal of calcium and vitamin D supplements. If hypercalcemia persists, the possibility of associated hyperparathyroidism should be strongly considered.

In vitamin D intoxication, patients may be taking large amounts of vitamin D for unclear reasons, so a thorough review of all medications is important. Hypercalcemia may persist for several weeks. Serum levels of 25-hydroxycholecalciferol ($25[\text{OH}]\text{D}_3$) are helpful to confirm the diagnosis. A brief course of corticosteroid therapy may be necessary if hypercalcemia is severe.

F. Familial Benign Hypocalciuric Hypercalcemia

Familial benign hypocalciuric hypercalcemia can be easily mistaken for mild hyperparathyroidism. It is a common autosomal dominant inherited disorder (prevalence: 1 in 16,000) caused by a loss-of-function mutation in the gene encoding the CaSR. CaSRs are found on the surface of the parathyroid glands and allow the parathyroid glands to vary PTH secretion according to serum calcium levels. Reduced function of the CaSR causes the parathyroid glands to falsely “sense” hypocalcemia and inappropriately release slightly excessive amounts of PTH. At the same time, the renal tubule CaSRs are also affected, causing hypocalciuria. Familial benign hypocalciuric hypercalcemia is characterized by hypercalcemia, hypocalciuria (usually $< 50 \text{ mg}/24 \text{ h}$), variable hypermagnesemia, and normal or minimally elevated levels of PTH. These patients do not normalize their hypercalcemia after subtotal parathyroid removal and should not be subjected to surgery. The condition has an excellent prognosis and is easily diagnosed with a family history and urinary calcium clearance determination.

G. Adrenal Insufficiency

Hypercalcemia is common in untreated Addison disease. This is partly due to disinhibition of calcium uptake by the renal tubule and gut. Additionally, Addison disease can cause dehydration and hyperproteinemia, resulting in higher levels of nonionized calcium.

H. Hyperthyroidism

Increased bone turnover is a feature of thyrotoxicosis. Mild hypercalcemia may also be present.

I. Other Causes

Other causes of hypercalcemia are shown in Table 21–8. Modest hypercalcemia is also occasionally seen in patients taking thiazide diuretics or lithium; such patients may have an inappropriately nonsuppressed PTH level with hypercalcemia. Prolonged immobilization at bed rest may also cause hypercalcemia, especially in adolescents and patients with extensive Paget disease of bone. Hypercalcemia is noted in up to one-third of acutely ill patients being treated in intensive care units, particularly patients with acute renal injury. Serum PTH levels are usually slightly elevated, consistent with mild hyperparathyroidism. Bisphosphonates can increase serum calcium in 20% and serum PTH becomes high in 10%, mimicking hyperparathyroidism.

► Treatment

A. Surgical Parathyroidectomy

Parathyroidectomy is recommended for patients with symptomatic hyperparathyroidism, kidney stones, bone disease, and pregnancy.

Some patients with seemingly asymptomatic hyperparathyroidism may be surgical candidates for other reasons such as (1) serum calcium $1 \text{ mg}/\text{dL}$ above the upper limit of normal with urine calcium excretion $> 50 \text{ mg}/24 \text{ h}$ (off thiazide diuretics), (2) urine calcium excretion over $400 \text{ mg}/24 \text{ h}$, (3) cortical bone density (wrist, hip) $\geq 2 \text{ SD}$ below normal, (4) relative youth (under age 50–60 years), (5) difficulty ensuring medical follow-up, or (6) pregnancy. During pregnancy, parathyroidectomy is performed in the second trimester.

Patients who undergo surgery for “asymptomatic” hyperparathyroidism have been reported to have modest benefits in social and emotional function, with improvements in anxiety and phobias being reported in comparison to similar patients who are monitored without surgery.

Preoperative parathyroid imaging has been used in an attempt to allow unilateral minimally invasive neck surgery. The usefulness of preoperative parathyroid imaging was evaluated in a series of 350 patients with sporadic primary hyperparathyroidism. A single gland was predicted by sestamibi in 83%, by ultrasound in 85%, and by concordance of both in 59% of patients. Unilateral neck exploration, directed by these studies, resulted in success rate of only 73%, 77%, and 82%, respectively, despite the intraoperative quick PTH assay predicting success. Even in patients with concordant sestamibi and ultrasound scans, and an intraoperative PTH drop of $> 50\%$, at least one additional abnormal parathyroid gland is left behind in the contralateral neck in 15% of patients.

Bilateral neck exploration is usually advisable for all patients without preoperative localization studies for the following: (1) patients with a family history of hyperparathyroidism, (2) patients with a personal or family history of MEN, and (3) patients wanting an optimal chance of success with a single surgery. Patients undergoing unilateral neck exploration can have the incision widened for bilateral neck exploration if two abnormal glands are found or if the serum quick PTH falls by $< 50\%$. Parathyroid glands are not

uncommonly supernumerary (five or more) or ectopic (eg, intrathyroidal, carotid sheath, mediastinum).

Parathyroid hyperplasia is commonly seen with uremic calciphylaxis. When surgery is performed, a subtotal parathyroidectomy is optimally treated surgically; three and one-half glands are usually removed, and a metal clip is left to mark the location of residual parathyroid tissue.

Parathyroid carcinoma can cause severe hypercalcemia associated with very high serum levels of PTH. Preoperative localizing studies usually detect a large invasive tumor. Therapy consists of en bloc resection of the tumor and the ipsilateral thyroid lobe. Metastases to local and to distant sites occur in about 50% of patients. Reoperation for neck recurrence is usually necessary. Adjuvant treatment includes radiation therapy. Intravenous bisphosphonate (zoledronic acid) and calcimimetic agents (NPS R-568) are used for treatment of hypercalcemia.

Complications: Serum PTH levels fall below normal in 70% of patients within hours after successful surgery, commonly causing hypocalcemic paresthesias or even tetany. Hypocalcemia tends to occur the evening after surgery or on the next day. Therefore, frequent postoperative monitoring of serum ionized calcium (or serum calcium plus albumin) is advisable beginning the evening after surgery. Once hypercalcemia has resolved, liquid or chewable calcium carbonate is given orally to reduce the likelihood of hypocalcemia. Symptomatic hypocalcemia is treated with larger doses of calcium; calcitriol (0.25–1 mcg daily orally) may be added, with the dosage depending on symptom severity. Magnesium salts are sometimes required postoperatively, since adequate magnesium is required for functional recovery of the remaining suppressed parathyroid glands.

In about 12% of patients having successful parathyroid surgery, PTH levels rise above normal (while serum calcium is normal or low) by 1 week postoperatively. This secondary hyperparathyroidism is probably due to “hungry bones” and is treated with calcium and vitamin D preparations. Such therapy is usually needed only for 3–6 months but is required long-term by some patients.

Hyperthyroidism commonly occurs immediately following parathyroid surgery. It is caused by release of stored thyroid hormone during surgical manipulation of the thyroid. Short-term treatment with propranolol may be required for several days.

B. Medical Measures

1. Fluids—Hypercalcemia is treated with a large fluid intake unless contraindicated. Severe hypercalcemia requires hospitalization and intensive hydration with intravenous saline. (See Chapter 21.)

2. Bisphosphonates—Intravenous bisphosphonates are potent inhibitors of bone resorption and can temporarily treat the hypercalcemia of hyperparathyroidism, malignancy, or immobilization. They may relieve bone pain as with patients with metastatic breast or prostate cancer. Pamidronate in doses of 30–90 mg (in 0.9% saline) is administered intravenously over 2–4 hours. Zoledronic acid 2–4 mg is administered intravenously over 15 to 20 minutes; it is quite effective but also very expensive. These drugs cause

a gradual decline in serum calcium over several days that may last for weeks to months. Such intravenous bisphosphonates are used generally for patients with severe hyperparathyroidism in preparation for surgery. Oral bisphosphonates, such as alendronate, are not effective for treating the hypercalcemia or hypercalciuria of hyperparathyroidism. However, oral alendronate has been shown to improve bone mineral density in the lumbar spine and hip (not distal radius) and may be used for asymptomatic patients with hyperparathyroidism who have a low bone mineral density.

3. Cinacalcet—Cinacalcet hydrochloride is a calcimimetic agent that binds to sites of the parathyroid glands' extracellular CaSRs to increase their affinity for extracellular calcium, thereby decreasing PTH secretion. Cinacalcet may be administered orally in doses of 30–250 mg daily. Patients with primary hyperparathyroidism have also been treated successfully with cinacalcet in oral doses of 30–50 mg twice daily, with 73% of patients achieving normocalcemia. Administering cinacalcet for secondary parathyroidism of kidney disease causes a drop of serum PTH levels to < 250 pg/mL in 41% of patients receiving dialysis. Cinacalcet is given to patients with severe hypercalcemia due to parathyroid carcinoma at initial doses of 30 mg orally twice daily and increased progressively to 60 mg twice daily, then 90 mg twice daily to a maximum of 90 mg every 6–8 hours. Cinacalcet is usually well tolerated but may cause nausea and vomiting, which are usually transient. It is very expensive.

4. Vitamin D and vitamin D analogs

A. PRIMARY HYPERPARATHYROIDISM—For patients with vitamin D deficiency, careful vitamin D replacement may be beneficial to patients with hyperparathyroidism. Aggravation of hypercalcemia does not ordinarily occur. Serum PTH levels may fall with vitamin D replacement in doses of 800–2000 units daily. Occasionally, larger doses are required to achieve normal 25-OH vitamin D levels.

B. SECONDARY AND TERTIARY HYPERPARATHYROIDISM ASSOCIATED WITH KIDNEY DISEASE—*Calcitriol*, given orally or intravenously after dialysis, suppresses parathyroid hyperplasia of kidney disease. Certain vitamin D analogs suppress PTH secretion but cause less hypercalcemia than calcitriol. *Doxercalciferol* (Hectorol) is administered three times weekly orally with hemodialysis to patients with azotemic secondary hyperparathyroidism in the following doses according to serum immunoradiometric PTH (iPTH) levels: give 10 mcg three times weekly for iPTH > 400 pg/mL and increase the dose by 2.5 mcg every 8 weeks if iPTH remains > 300 pg/mL, to a maximum dose of 20 mcg three times weekly. If iPTH drops to < 100 pg/mL, doxercalciferol is held for 1 week and the dose is reduced by at least 2.5 mcg. *Paricalcitol* (Zemlar) is administered intravenously during dialysis three times weekly in starting doses of 0.04–0.1 mcg/kg body weight; the dosage is increased for iPTH levels > 300 pg/mL to a maximum dose of 0.24 mcg/kg three times weekly; paricalcitol is held if iPTH levels drop to < 100 pg/mL.

5. Other measures—Patients with mild, asymptomatic hyperparathyroidism may be monitored closely medically.

Such patients are advised to keep active, avoid immobilization, and drink adequate fluids. They need to avoid thiazide diuretics, large doses of vitamins A, and calcium-containing antacids or supplements. Serum calcium and albumin are checked about twice yearly, kidney function and urine calcium once yearly, and three-site bone density (distal radius, hip, and spine) every 2 years.

Estrogen replacement, given to postmenopausal women, reduces hypercalcemia slightly. Similarly, raloxifene also reduces the hypercalcemia of hyperparathyroidism, reducing serum calcium levels an average of 0.4 mg/dL. Propranolol may be useful for preventing the adverse cardiac effects of hypercalcemia.

Renal osteodystrophy is caused by secondary or tertiary hyperparathyroidism during kidney disease. It can be prevented or delayed by reducing hyperphosphatemia with phosphate binding medication and dietary phosphate restriction.

C. Monitoring Patients with Asymptomatic Primary Hyperparathyroidism

Patients with mild asymptomatic hyperparathyroidism may not need therapy. However, they should be monitored closely for the development of symptoms of hypercalcemia and worsening hypercalcemia. Patients should be evaluated every 6 months with determination of blood pressure and serum calcium. Rising serum calcium should prompt further evaluation and determination of PTH levels. Serum creatinine should be measured yearly. A bone density should ideally be determined every 1 to 2 years at 3 points: wrist, hip, and vertebrae.

► Prognosis

Completely asymptomatic patients with mild hypercalcemia may be observed and treated medically without compromising survival. There can be unexplained exacerbations and partial remissions. Surgical removal of sporadic parathyroid adenomas generally results in a permanent cure. Patients with MEN 1 undergoing subtotal parathyroidectomy may experience long remissions, but hyperparathyroidism usually recurs.

Spontaneous cure due to necrosis of the tumor has been reported but is exceedingly rare. The bones, in spite of severe cyst formation, deformity, and fracture, will heal if a parathyroid tumor is successfully removed. The presence of pancreatitis increases the mortality rate. Acute pancreatitis usually resolves with correction of hypercalcemia, whereas subacute or chronic pancreatitis tends to persist. Significant renal damage may progress even after removal of an adenoma. Parathyroid carcinoma tends to invade local structures and may sometimes metastasize; repeat surgical resections and radiation therapy can prolong life. Aggressive surgical and medical management of parathyroid carcinoma can result in an 85% 5-year survival rate and a 57% 10-year survival rate.

METABOLIC BONE DISEASE

The term “metabolic bone disease” denotes those conditions producing diffusely decreased bone density and diminished bone strength. It is categorized by histologic appearance: osteoporosis (bone matrix and mineral both decreased) and osteomalacia (bone matrix intact, mineral decreased). Osteoporosis and osteomalacia often coexist in the same patient.

OSTEOPOROSIS

ESSENTIALS OF DIAGNOSIS

- Asymptomatic to severe backache from vertebral fractures.
- Spontaneous fractures often discovered incidentally on radiography; loss of height.
- Serum PTH, calcium, phosphorus, and alkaline phosphatase usually normal.
- Serum 25-hydroxyvitamin D levels often low as a comorbid condition.
- Demineralization, especially of spine, hip, pelvis, and wrist.

► General Considerations

Osteoporosis is estimated to cause 1.5 million fractures annually in the United States—mainly of the spine and hip. The morbidity and indirect mortality rates are very high. Since the usual form of the disease is clinically evident in middle life and beyond and since women are more frequently affected than men, it is often referred to as “postmenopausal” osteoporosis. It is characterized by a decrease in the amount of bone present to a level below which it is capable of maintaining the structural integrity of the skeleton. The rate of bone formation is often normal, whereas the rate of bone resorption is increased.

Osteoporosis can be caused by a variety of factors. The long-term use of a selective serotonin reuptake inhibitor (SSRI) has been associated with reduced hip density, increased falls, and increased fracture risk, particularly in the elderly. Rosiglitazone appears to decrease bone mineral density in men with type 2 diabetes mellitus. The causes of osteoporosis are listed in Table 26–10.

Table 26–10. Causes of osteoporosis.¹

| | |
|---|--|
| Hormone deficiency | Genetic disorders |
| Estrogen (women) | Aromatase deficiency |
| Androgen (men) | Type I collagen mutations |
| Hormone excess | Osteogenesis imperfecta |
| Cushing syndrome or corticosteroid administration | Idiopathic juvenile and adult osteoporosis |
| Thyrotoxicosis | Ehlers-Danlos syndrome |
| Hyperparathyroidism | Marfan syndrome |
| Immobilization and microgravity | Homocystinuria |
| Tobacco | Miscellaneous |
| Alcoholism | Celiac disease |
| Malignancy, especially multiple myeloma | Anorexia nervosa |
| Medications | Hyponatremia (chronic) |
| Excessive vitamin D intake | Protein-calorie malnutrition |
| Excessive vitamin A intake | Vitamin C deficiency |
| Heparin therapy | Copper deficiency |
| Selective serotonin reuptake inhibitors | Liver disease |
| Rosiglitazone | Rheumatoid arthritis |
| | Uncontrolled diabetes mellitus |
| | Systemic mastocytosis |

¹See Table 26–11 for causes of osteomalacia.

Osteoporosis is caused by a reduction and disarray of bone's microarchitectural organic collagenous matrix, which normally accounts for about 40% of bone mass and provides bone's tensile strength. Inorganic calcium and phosphate compounds, largely calcium hydroxyapatite, mineralize the available collagenous bone matrix and normally provide about 60% of bone mass and most of bone's compressive strength.

Osteogenesis imperfecta is caused by a major mutation in the gene encoding for type I collagen, the major collagen constituent of bone. This causes severe osteoporosis; spontaneous fractures occur in utero or during childhood. Blue sclerae may be present. Certain polymorphisms in the genes encoding type I collagen are common, particularly in whites, resulting in collagen disarray and predisposing to hypogonadal (eg, menopausal) or idiopathic osteoporosis.

► Clinical Findings

A. Symptoms and Signs

Osteoporosis is usually asymptomatic until fractures occur. It may present as backache of varying degrees of severity or as a spontaneous fracture or collapse of a vertebra. Loss of height is common. Once osteoporosis is identified, a carefully directed history and physical examination must be performed to determine its cause (Table 26–10).

B. Laboratory Findings

Serum calcium, phosphate, and PTH are normal. The alkaline phosphatase is usually normal but may be slightly elevated, especially following a fracture. Vitamin D deficiency is very common and serum determination of 25-hydroxyvitamin D should be obtained for every individual with low bone density. Serum 25-hydroxyvitamin D levels below 20 ng/mL are considered frank vitamin D deficiency.

Lesser degrees of vitamin D deficiency (serum 25-hydroxyvitamin D levels between 20 ng/mL and 30 ng/mL) may also increase the risk for hip fracture. (See Osteomalacia, below.) Testing for thyrotoxicosis and hypogonadism may be required. Celiac disease may be screened for with serum immunoglobulin A (IgA) endomysial antibody and tissue transglutaminase antibody determinations.

C. Bone Densitometry

DXA is used to determine the bone density of the lumbar spine and hip. Bone densitometry should be performed on all patients who are at risk for osteoporosis or osteomalacia or have pathologic fractures or radiographic evidence of diminished bone density. This test delivers negligible radiation, and the measurements are quite accurate. However, bone densitometry cannot distinguish osteoporosis from osteomalacia; in fact, both are often present. Also, the bone mineral density does not directly measure bone quality and is only fairly successful at predicting fractures. Vertebral bone mineral density may be misleadingly high in compressed vertebrae and in patients with extensive arthritis. DXA also overestimates the bone mineral density of taller persons and underestimates the bone mineral density of smaller persons. Quantitative CT delivers more radiation but is more accurate in the latter situations.

Bone mineral density is typically expressed in g/cm², for which there are different normal ranges for each bone and for each type of DXA-measuring machine. The “T score” is a simplified way of reporting bone density in which the patient's bone mineral density is compared to the young normal mean and expressed as a standard deviation score. The World Health Organization has established criteria for defining osteoporosis in postmenopausal white women, based on T score:

T score ≥ -1.0 : Normal.

T score -1.0 to -2.5 : Osteopenia (“low bone density”).

T score < -2.5 : Osteoporosis.

T score < -2.5 with a fracture: Severe osteoporosis.

This classification is somewhat arbitrary and there really is no bone mineral density fracture threshold; instead, the fracture risk increases about twofold for each standard deviation drop in bone mineral density. In fact, most women with fragility fractures have bone densities above -2.5 . Surveillance DXA bone densitometry is recommended for postmenopausal women with a frequency according to their T scores: obtain DXA every 5 years for T scores -1.0 to -1.5 , every 3–5 years for scores -1.5 to -2.0 , and every 1–2 years for scores under -2.0 .

The “Z score” is used to express bone density in premenopausal women, younger men, and children. The Z score is a statistical term that is used for expressing an individual's bone density as standard deviation from age-matched, race-matched, and sex-matched means.

► Differential Diagnosis

Osteoporosis has many causes (see Table 26–10). Additionally, osteopenia and fractures can be caused by osteo-

malacia (see below) and bone marrow neoplasia such as myeloma or metastatic bone disease. These conditions coexist in many patients.

► Treatment

A. Specific Measures

Several treatment options are available, so a regimen is tailored to each patient. Generally, treatment is indicated for all women with osteoporosis (T scores below -2.5) and for all patients who have had fragility fractures. Prophylactic treatment should also be considered for patients with advanced osteopenia (T scores between -2.0 and -2.5).

1. Vitamin D and calcium—Osteoporosis and osteomalacia often coexist (see Osteomalacia section). Sun exposure and vitamin D supplementation are useful in preventing and treating osteomalacia. Vitamin D supplementation reduces the incidence of vertebral fractures by 37% and may slightly reduce the incidence of nonvertebral fractures. Oral vitamin D is given in doses of 800–2000 international units daily. Higher doses of vitamin D may be required during winter months and for patients having prolonged hospitalization or nursing home care, for patients with serum levels of 25-hydroxyvitamin D below 20 ng/mL, and those with intestinal malabsorption.

Calcium supplementation has not reduced the fracture risk in otherwise healthy postmenopausal women. Therefore, calcium supplementation is indicated principally for those with diets low in calcium. More important is the assurance of adequate vitamin D through sun exposure or oral vitamin D supplementation, and calcium supplementation should include vitamin D. Calcium supplementation may be given as calcium citrate (0.4–0.7 g elemental calcium per day) or calcium carbonate (1–1.5 g elemental calcium per day).

2. Bisphosphonates—Bisphosphonates work similarly, inhibiting osteoclast-induced bone resorption. They increase bone density significantly and reduce the incidence of both vertebral and nonvertebral fractures. Bisphosphonates have also been effective in preventing corticosteroid-induced osteoporosis. To ensure intestinal absorption, oral bisphosphonates must be taken in the morning with at least 8 oz of plain water at least 40 minutes before consumption of anything else. The patient must remain upright after taking bisphosphonates to reduce the risk of esophagitis. These medications are excreted in the urine. However, no dosage adjustments are required for patients with creatinine clearances above 35 mL/min. There has been little experience giving bisphosphonates to patients with severe kidney disease; if given, the dose would need to be greatly reduced and serum phosphate levels monitored.

Bisphosphonates may be given orally once monthly or weekly; which is more convenient than daily therapy and equally effective. Available oral preparations include **alendronate**, 70 mg orally once weekly (tablet or solution), and **risedronate**, 35 mg orally once weekly. Both these medications reduce the risk of both vertebral and nonvertebral fractures. Studies sponsored by the manufacturer of alen-

dronate found that alendronate was significantly more potent than risedronate and equally well tolerated. Another bisphosphonate, **ibandronate sodium**, is taken once monthly in a dose of 150 mg orally. Once-monthly ibandronate is convenient and reduces the risk of vertebral fractures but not nonvertebral fractures; its effectiveness has not been directly compared with other bisphosphonates. Oral bisphosphonates can cause esophagitis, especially in patients with hiatal hernia and gastroesophageal reflux.

For patients who cannot tolerate oral bisphosphonates or for whom oral bisphosphonates are contraindicated, intravenous bisphosphonates are available. **Zoledronic acid** is a third-generation bisphosphonate and a potent osteoclast inhibitor. It can be given every 12 months in doses of 2–4 mg intravenously over 15–30 minutes. **Pamidronate** is an older parenteral bisphosphonate that can be given in doses of 30–60 mg by slow intravenous infusion in normal saline solution every 3–6 months. Transient postinfusion fever occurs fairly commonly (26%).

Both oral and parenteral bisphosphonates can cause bone, joint, or muscle pains as well as fatigue, particularly after the first dose. The onset of pain may occur from 1 day to 1 year after therapy is initiated, with a mean of 14 days. The pain can be transient, lasting several days and usually resolving spontaneously but typically recurring with subsequent doses. When the bisphosphonate is discontinued, most patients experience gradual relief of pain. Some patients taking alendronate or risedronate for osteoporosis have experienced bone osteonecrosis: painful, necrotic, nonhealing lesions of the jaw, particularly after tooth extraction. The incidence of osteonecrosis is very low. In a prospective 3-year trial of 7714 women who received intravenous zoledronic acid 5 mg/y or placebo, there were no cases of osteonecrosis. For such patients with painful exposed bone, treatment is 90% effective (without resolution of the exposed bone) using antibiotics along with 0.12% chlorhexidine antiseptic mouth wash. Patients receiving bisphosphonates must receive regular dental care and try to avoid dental extraction. Osteonecrosis of the jaw has also been reported in patients receiving intravenous zoledronic acid and pamidronate for treatment of hypercalcemia and bone metastases, for which the drugs had been administered more frequently than for osteoporosis. Another adverse effect reported with bisphosphonates is ocular inflammation, manifested by blurred vision, eye pain, uveitis, conjunctivitis, and scleritis, which remits after discontinuation of the drug. Other side effects can include nausea, anemia, dyspnea, and leg edema. In patients taking bisphosphonates, hypercalcemia is seen in 20% and serum PTH levels increase above normal in 10%, mimicking primary hyperparathyroidism.

The half-life of alendronate in bone is 10 years. Therefore, patients with mild osteoporosis may discontinue bisphosphonates after a 5-year course of therapy. Bone density falls in 18% of patients during their first year of treatment with bisphosphonates, but 80% of such patients have gain in bone density with continued bisphosphonate treatment.

3. Sex hormones—Hypogonadal women who take estrogen replacement therapy (ERT) have a lower risk of devel-

oping osteoporosis. Postmenopausal estrogen replacement is valuable as an osteoporosis prevention measure and this should be one factor in the complex decision about whether to take ERT. Low doses of estrogen appear to be adequate to prevent postmenopausal osteoporosis (see Estrogen Replacement Therapy). Once osteoporosis has developed, estrogen replacement is not an effective treatment. Although ERT does increase bone mineral density in postmenopausal women with osteoporosis, it has not been demonstrated to significantly reduce fracture rates. Men with hypogonadism may be treated with testosterone (see Male Hypogonadism).

4. Selective estrogen receptor modulators—Raloxifene, 60 mg/d orally, can be used by postmenopausal women in place of estrogen for prevention of osteoporosis. Bone density increases about 1% over 2 years in postmenopausal women versus 2% increases with estrogen replacement. It reduces the risk of vertebral fractures by about 40% but does not appear to reduce the risk of nonvertebral fractures. Raloxifene produces a reduction in LDL cholesterol but not the rise in high-density lipoprotein (HDL) cholesterol seen with estrogen. It has no direct effect on coronary plaque. Unlike estrogen, raloxifene does not reduce hot flashes; in fact, it often intensifies them. It does not relieve vaginal dryness. Unlike estrogen, raloxifene does not cause endometrial hyperplasia, uterine bleeding, or cancer, nor does it cause breast soreness. The risk of breast cancer is reduced 76% in women taking raloxifene for 3 years. Since it is a potential teratogen, it is relatively contraindicated in women capable of pregnancy.

Raloxifene increases the risk for thromboembolism and should not be used by women with such a history. Leg cramps can also occur.

5. Teriparatide—Teriparatide (Forteo, Parathar) is an analog of PTH. Teriparatide stimulates the production of new collagenous bone matrix that must be mineralized. Patients receiving teriparatide must have sufficient intake of vitamin D and calcium. When administered to patients with osteoporosis in doses of 20 mcg/d subcutaneously for 2 years, teriparatide dramatically improves bone density in most bones except the distal radius. The recommended dose should not be exceeded, since teriparatide has caused osteosarcoma in rats when administered in very high doses. Patients with Paget disease of bone or patients with open epiphyses or hypercalcemia should not use the drug. Patients with a past history of osteosarcoma or chondrosarcoma should not use this medication. Side effects may include dizziness and leg cramps. Teriparatide is approved only for a 2-year course of treatment.

Precautions: Hypercalcemia may develop in patients who are taking teriparatide if they also take corticosteroids and thiazide diuretics along with oral calcium supplementation.

Following a course of teriparatide, a course of bisphosphonates should be considered in order to retain the improved bone density.

6. Calcitonin—A nasal spray of calcitonin-salmon (Miacalcin) is available that contains 2200 units/mL in 2-mL metered-dose bottles. The usual dose is one puff (0.09 mL,

200 international units) once daily, alternating nostrils. Nasal administration causes significantly less nausea and flushing than the parenteral route. However, nasal symptoms such as rhinitis and epistaxis occur commonly; other less common adverse reactions include flu-like symptoms, allergy, arthralgias, back pain, and headache. Five years of therapy increases bone 2–3% and reduces the number of new vertebral fractures. Both nasal and parenteral calcitonin have analgesic effects on bone pain; reduction of pain may be noted within 2–4 weeks after commencing therapy. Calcitonin reduces the incidence of vertebral fractures, but its effect upon nonvertebral fractures has not been established.

7. Denosumab—Denosumab is a promising treatment for osteoporosis that is in clinical trials. It is a monoclonal antibody that inhibits osteoclast activation by binding to the osteoclasts' receptor activator of nuclear factor-kappa B ligand (RANKL). Denosumab is effective at doses of 60 mg subcutaneously every 6 months. It has been relatively well tolerated, with an 8% incidence of flu-like symptoms.

B. General Measures

For prevention and treatment of osteoporosis, the diet should be adequate in protein, total calories, calcium, and vitamin D. Pharmacologic corticosteroid doses should be reduced or discontinued if possible. Thiazides may be useful if hypercalciuria is present. High-impact physical activity (eg, jogging) significantly increases bone density in men and women. Stair-climbing increases bone density in women. Patients who cannot exercise vigorously should be encouraged to engage in other exercise regularly, thereby increasing strength and reducing the risk of falling. Weight training is helpful to increase muscle strength as well as bone density. Measures should be taken to avoid falls at home (eg, adequate lighting, handrails on stairs, handholds in bathrooms). Patients who have weakness or balance problems must use a cane or a walker; rolling walkers should have a brake mechanism. Balance exercises can reduce the risk of falls. Patients should be kept active; bedridden patients should be given active or passive exercises. The spine may be adequately supported (though braces or corsets are usually not well tolerated), but rigid or excessive immobilization must be avoided. Alcohol and smoking should be avoided.

▶ Prognosis

Bone mineral density densitometries can detect whether progressive osteopenia or frank osteoporosis is developing. Hypogonadal women, especially those not receiving HRT, must ensure sufficient intake of vitamin D to prevent osteomalacia. Bisphosphonates and raloxifene can reverse progressive osteopenia and osteoporosis and decrease fracture risk.

Hypogonadal men are also at risk for developing osteoporosis. Testosterone administration can prevent osteoporosis. Men with prostate cancer may not receive testosterone replacement and should be monitored with bone densitometries. Bisphosphonate therapy can reverse progressive osteopenia and osteoporosis in men.

OSTEOMALACIA

ESSENTIALS OF DIAGNOSIS

- ▶ Painful proximal muscle weakness (especially pelvic girdle); bone pain and tenderness.
- ▶ Decreased bone density from defective mineralization.
- ▶ Laboratory abnormalities may include increases in alkaline phosphatase, decreased 25-hydroxyvitamin D, or hypocalcemia, hypocalciuria, hypophosphatemia, secondary hyperparathyroidism.
- ▶ Classic radiologic features may be present.

▶ General Considerations

Defective mineralization of the growing skeleton in childhood causes permanent bone deformities (rickets). Defective skeletal mineralization in adults is known as osteomalacia. It is caused by any condition that results in inadequate calcium or phosphate mineralization of bone osteoid.

▶ Etiology (Table 26–11)

A. Vitamin D Deficiency and Resistance

Vitamin D deficiency decreases the intestinal absorption of calcium and is the most common cause of osteomalacia. Significant vitamin D deficiency (serum 25[OH]D < 50 nmol/L or < 20 ng/mL) was found in 24.3% of postmenopausal women from 25 countries in the MORE study. The incidence varied: < 1% in Southeast Asia, 29% in the

Table 26–11. Causes of osteomalacia.¹

Vitamin disorders

- Decreased availability of vitamin D
- Insufficient sunlight exposure
- Nutritional deficiency of vitamin D
- Malabsorption; aging, excess wheat bran, bariatric surgery, pancreatic enzyme deficiency
- Nephrotic syndrome
- Vitamin D-dependent rickets type I
- Liver disease
- Chronic kidney disease
- Kidney transplantation
- Phenytoin, carbamazepine, or barbiturate therapy

Dietary calcium deficiency

Phosphate deficiency

- Decreased intestinal absorption
- Nutritional deficiency of phosphorus
- Malabsorption
- Phosphate-binding antacid therapy
- Increased renal loss
 - X-linked hypophosphatemic rickets
 - Tumoral hypophosphatemic osteomalacia
 - Association with other disorders, including paraproteinemias, glycogen storage diseases, neurofibromatosis, Wilson disease, Fanconi syndrome, renal tubular acidosis, and alcoholism

Disorders of bone matrix

- Hypophosphatasia
- Fibrogenesis imperfecta
- Axial osteomalacia

Inhibitors of mineralization

- Aluminum
- Bisphosphonates

¹See Table 26–10 for causes of osteoporosis.

United States, and 36% in Italy. Severe vitamin D deficiency (serum 25[OH]D < 25 nmol/L or < 10 ng/mL) was found in 4% of these women; 3.5% in the United States and 12.5% in Italy. Vitamin D deficiency is particularly common in the institutionalized elderly, with the incidence exceeding 60% in some groups not receiving vitamin D supplementation. Deficiency of vitamin D may arise from insufficient sun exposure, malnutrition, or malabsorption (due to pancreatic insufficiency, cholestatic liver disease, sprue, inflammatory bowel disease, jejunioileal bypass, Billroth type II gastrectomy, etc). Cholestyramine binds bile acids necessary for vitamin D absorption. Patients with severe nephrotic syndrome lose large amounts of vitamin D-binding protein in the urine, and osteomalacia may also develop.

Anticonvulsants (eg, phenytoin, carbamazepine, valproate, phenobarbital) inhibit the hepatic production of 25(OH)D and sometimes cause osteomalacia. Phenytoin can also directly inhibit bone mineralization. Serum levels of 1,25(OH)₂D are usually normal.

Vitamin D-dependent rickets type I is caused by a rare autosomal recessive disorder with a defect in the renal enzyme 1- α -hydroxylase leading to defective synthesis of 1,25(OH)₂D. It presents in childhood with rickets and alopecia; osteomalacia develops in adults with this condition unless treated with oral calcitriol in doses of 0.5–1 mcg daily.

Vitamin D–dependent rickets type II (better known as hereditary 1,25(OH)₂D-resistant rickets) is caused by a genetic defect in the 1,25(OH)₂D receptor. Patients have hypocalcemia with childhood rickets and adult osteomalacia. Alopecia is common. These patients respond variably to oral calcitriol in very large doses (2–6 mcg daily).

B. Deficient Calcium Intake

Rickets and osteomalacia continue to be common problems in many tropical countries despite adequate exposure to sunlight. A nutritional deficiency of calcium can occur in any severely malnourished patient. Some degree of calcium deficiency is common in the elderly, since intestinal calcium absorption declines with age. Ingestion of excessive wheat bran also causes calcium malabsorption.

C. Phosphate Deficiency

Phosphatonin is a circulating peptide that inhibits sodium-dependent phosphate transport in the renal tubule; high levels of this peptide cause excessive phosphaturia, resulting in hypophosphatemia. X-linked hypophosphatemic rickets is associated with high levels of phosphatonin, probably caused by familial or sporadic mutations in PHEX endopeptidase, which fails to cleave phosphatonin.

Oncogenic osteomalacia is caused by excessive production of phosphatonin by a wide variety of soft tissue tumors (87% benign). Such tumors may be hard to find. OctreoScan has been reported to detect many of these small tumors. The condition is characterized by hypophosphatemia, excessive phosphaturia, reduced or normal serum 1,25(OH)₂D concentrations, and osteomalacia. Excessive renal phosphate losses are also seen in proximal renal tubular acidosis and Fanconi syndrome. Some cases of hyperphosphaturia are idiopathic.

Other causes of hypophosphatemic osteomalacia include poor nutrition, alcoholism, or chelation of phosphate in the gut by aluminum hydroxide antacids, calcium acetate (Phos-Lo), or sevelamer hydrochloride (Renagel).

D. Aluminum Toxicity

Bone mineralization is inhibited by aluminum. Osteomalacia may occur in patients receiving long-term renal hemodialysis with tap water dialysate or from aluminum-containing antacids used to reduce phosphate levels. Osteomalacia may develop in patients being maintained on long-term total parenteral nutrition if the casein hydrolysate used for amino acids contains high levels of aluminum.

E. Hypophosphatasia

Hypophosphatasia, a deficiency of bone alkaline phosphatase effect, is a rare genetic cause of osteomalacia that is commonly misdiagnosed as osteoporosis. The incidence in the United States is about 1 in 100,000 live births; about 1 in 300 adults is a carrier. Many different mutations in the gene (designated *ALPL*) encoding bone alkaline phosphatase have been described, and transmission can be either autosomal recessive or autosomal dominant. The phenotypic presentation of hypophosphatasia is extremely vari-

able. At its worst extreme, it can present as a stillborn without dentition or calcified bones. At its mildest, hypophosphatasia can present in middle age with premature loss of teeth, foot pain (due to metatarsal stress fractures), thigh pain (due to femoral pseudofractures), or arthritis (due to chondrocalcinosis). Serum alkaline phosphatase (collected in a non-EDTA tube) is low for age in patients with hypophosphatasia. To confirm the diagnosis, a 24-hour urine should be assayed for phosphoethanolamine, a substrate for tissue-nonspecific alkaline phosphatase, whose excretion is always elevated in patients with hypophosphatasia. Prenatal genetic testing, by way of chorionic villus biopsy, is available for the infantile form of hypophosphatasia. There is no proven therapy for hypophosphatasia, except for supportive care. Teriparatide, a useful therapy for osteoporosis, has been administered to some patients with hypophosphatasia, but its long-term efficacy is unknown.

F. Fibrogenesis Imperfecta Ossium

This rare condition sporadically affects middle-aged patients, who present with progressive bone pain and pathologic fractures. Bones have a dense “fishnet” appearance on radiographs. Serum alkaline phosphatase levels are elevated. Some patients have a monoclonal gammopathy, indicating a possible plasma cell dyscrasia causing an impairment in osteoblast function and collagen disarray. Remission has been reported after repeated courses of melphalan, corticosteroids, and vitamin D analog over 3 years.

▶ Clinical Findings

The clinical manifestations of defective bone mineralization depend on the age at onset and the severity. In adults, osteomalacia is typically asymptomatic at first. Eventually, bone pain occurs, along with muscle weakness due to calcium deficiency. Pathologic fractures may occur with little or no trauma. Vitamin D deficiency has also been associated with a possible increased risk of multiple sclerosis, rheumatoid arthritis, and diabetes mellitus (types 1 and 2).

▶ Diagnostic Tests

Serum is obtained for calcium, albumin, phosphate, alkaline phosphatase, PTH, and 25(OH)D₃ determinations. Bone densitometry helps document the degree of osteopenia. Radiographs may show diagnostic features.

In one series of biopsy-proved osteomalacia, alkaline phosphatase was elevated in 94% of patients; the calcium or phosphorus was low in 47% of patients; 25(OH)D₃ was low in 29% of patients; pseudofractures were seen in 18% of patients; and urinary calcium was low in 18% of patients. 1,25(OH)₂D₃ may be low even when 25(OH)D₂ levels are normal.

Bone biopsy is not usually necessary but is diagnostic of osteomalacia if there is significant unmineralized osteoid.

▶ Differential Diagnosis

Osteomalacia is often seen together with osteoporosis, and its presence can be inferred by finding low serum levels of 25(OH) vitamin D, low serum calcium, or low serum phosphate. A high serum alkaline phosphatase may be

present in severe osteomalacia but not osteoporosis. The relative contribution of the two entities to diminished bone density may not be apparent until treatment, since a dramatic rise in bone density is often seen with therapy for osteomalacia. Phosphate deficiency must be distinguished from hypophosphatemia seen in hyperparathyroidism.

► Prevention & Treatment

To obtain adequate sunshine vitamin D, the face, arms, hands, or back must have sun exposure without sunscreen for 15 minutes at least twice weekly. The main natural food source of vitamin D is fish, particularly, salmon, mackerel, cod liver oil, and sardines or tuna canned in oil. Most commercial cow's milk is fortified with vitamin D at about 400 international units per quart; however, skim milk and other dairy products contain much less vitamin D. Vitamin supplements containing vitamin D are widely available, but contain plant-derived vitamin D₂, which has less biologic availability than once believed. In sunlight-deprived individuals (eg, veiled women, confined patients, or residents of higher latitudes during winter), the recommended daily allowance should be 1000 international units daily. In such individuals, vitamin D supplements should be given prophylactically. Patients receiving long-term phenytoin therapy may be treated prophylactically with vitamin D, 50,000 international units orally every 2–4 weeks.

Frank vitamin D deficiency is treated with ergocalciferol (D₂), 50,000 international units orally once or twice weekly for 6–12 months, followed by 1000–2000 international units daily. Some patients require long-term supplementation with ergocalciferol of up to 50,000 international units weekly. In patients with intestinal malabsorption, oral doses of 25,000–100,000 international units of vitamin D₂ daily may be required. Some patients with steatorrhea respond better to oral 25(OH)D₃ (calcifediol), 50–100 mcg/d.

Beyond increasing the intestinal absorption of calcium, vitamin D supplementation may have additional effects. Vitamin D supplementation has been associated with improved muscle strength and a reduced fall risk, factors that reduce the risk of bone fracture.

The addition of calcium supplements to vitamin D is probably not necessary for the prevention of osteomalacia in the majority of otherwise well-nourished patients. However, patients with malabsorption or poor nutrition should receive calcium supplementation. Recommended doses of calcium are as follows: calcium citrate (eg, Citracal), 0.4–0.6 g elemental calcium per day, or calcium carbonate (eg, OsCal, Tums), 1–1.5 g elemental calcium per day. Calcium supplements are best administered with meals.

In hypophosphatemic osteomalacia, nutritional deficiencies are corrected, aluminum-containing antacids are discontinued, and patients with renal tubular acidosis are given bicarbonate therapy. In patients with sporadic adult-onset hypophosphatemia, hyperphosphaturia, and low serum 1,25(OH)₂D levels, a search is conducted for occult tumors that may be resected; whole-body MRI scanning may be required.

For those with X-linked or idiopathic hypophosphatemia and hyperphosphaturia, oral phosphate supplements must

be given long-term; calcitriol, 0.25–0.5 mcg/d, is given also to improve the impaired calcium absorption caused by the oral phosphate. Human recombinant growth hormone reduces phosphaturia and may be added to the above regimen.

PAGET DISEASE OF BONE (Osteitis Deformans)

ESSENTIALS OF DIAGNOSIS

- Often asymptomatic.
- Bone pain may be the first symptom.
- Kyphosis, bowed tibias, large head, deafness, and frequent fractures.
- Serum calcium and phosphate normal; alkaline phosphatase elevated; urinary hydroxyproline elevated.
- Dense, expanded bones on radiographs.

► General Considerations

Paget disease of bone is a common condition manifested by one or more bony lesions having high bone turnover and disorganized osteoid formation. Involved bones become vascular, weak, and deformed. Paget disease is most common in the United Kingdom but is also common in other areas of the world, particularly in those with British ancestry. It is uncommon in Africa, Asia, and Scandinavia. Paget disease is present in 1–2% of the population of the United States and affects men more commonly than women. It is usually diagnosed in patients over age 40 years and its prevalence doubles with each decade thereafter, reaching an incidence of about 10% after age 80. It is usually discovered incidentally during radiology imaging or because of incidentally discovered elevations in serum alkaline phosphatase. The cause of Paget disease is unknown. However, there is often a genetic component since about 15% of affected patients have a first-degree relative with the disease. Similar familial disorders occur at an earlier age and their genetics has been established (see Differential Diagnosis).

► Clinical Findings

A. Symptoms and Signs

Paget disease is often mild and asymptomatic. Only 27% of affected individuals are symptomatic at the time of diagnosis. It can involve just one bone (monostotic) or multiple

bones (polyostotic), particularly the skull, femur, tibia, pelvis, and humerus. The affected bones are typically involved right away and the disease tends not to involve additional bones during its course. Pain is the usual first symptom. It may occur in the involved bone or in an adjacent joint, which can be involved with degenerative arthritis. The bones can become soft, leading to bowed tibias, kyphosis, and frequent “chalkstick” fractures with slight trauma. If the skull is involved, the patient may report headaches and an increased hat size. Deafness may occur. Increased vascularity over the involved bones causes increased warmth and can cause vascular “steal” syndromes (see Complications).

B. Laboratory Findings

Serum alkaline phosphatase is usually markedly elevated. However, some patients with limited monostotic involvement may have serum alkaline phosphatase levels within the normal range. A serum bone-specific alkaline phosphatase determination can be useful for patients with a normal serum total alkaline phosphatase level and to distinguish the source of an elevated serum alkaline phosphatase as being from bone (rather than liver). Other markers of bone turnover may be elevated. Serum C-telopeptide (CTX) is usually high. Urinary hydroxyproline is also elevated in active disease. Serum calcium may be elevated, particularly if the patient is at bed rest. A serum 25-OH vitamin D determination should be obtained to screen for vitamin D deficiency, which can also present with an increased alkaline phosphatase and bone pain. Also, any vitamin D deficiency should be corrected before prescribing a bisphosphonate.

C. Imaging

On radiographs, the initial lesions are typically osteolytic, with focal radiolucencies (“osteoporosis circumscripta”) in the skull or advancing flame-shaped lytic lesions in long bones. Bone lesions may subsequently become sclerotic and have a mixed lytic and sclerotic appearance. The affected bones eventually become thickened and deformed. Technetium pyrophosphate bone scans are helpful in delineating activity of bone lesions even before any radiologic changes are apparent.

► Differential Diagnosis

Certain rare familial osteoclastic bone disorders share phenotypic homologies with Paget disease of bone. Familial expansile osteolysis, familial early-onset Paget disease, and familial skeletal hyperphosphatasia are autosomal dominant disorders caused by different tandem duplications of the gene encoding RANK, resulting in its constitutive activation. Juvenile Paget disease is an autosomal recessive disorder caused by an inactivating mutation in the gene encoding osteoprotegerin. The syndrome of Paget disease, inclusion body myopathy, and frontotemporal dementia is caused by a mutation in the gene that encodes valosin-containing protein.

Paget disease must be differentiated from primary bone lesions such as osteogenic sarcoma, multiple myeloma, and

fibrous dysplasia and from secondary bone lesions such as metastatic carcinoma and osteitis fibrosa cystica. Fibrogenesis imperfecta ossium is a rare symmetric disorder that can mimic the features of Paget disease; alkaline phosphatase is likewise elevated. If serum calcium is elevated, hyperparathyroidism may be present in some patients as well.

► Complications

If immobilization occurs, hypercalcemia and renal calculi may develop. Vertebral collapse may lead to spinal cord compression. The increased vascularity may give rise to high-output cardiac failure. Arthritis frequently develops in joints adjacent to involved bone.

Extensive skull involvement may cause cranial nerve palsies from impingement of the neural foramina. Involvement of the petrous temporal bone frequently causes hearing loss (mixed sensorineural and conductive) and occasionally tinnitus or vertigo. Vertebral involvement can cause compression of spinal nerves, resulting in radiculopathy or paralysis. The affected bones have a high blood flow and can thereby cause a vascular “steal” syndrome. Skull involvement can cause a vascular steal syndrome with somnolence or ischemic neurologic events; the optic nerve may be affected, resulting in loss of vision. Vertebral involvement can cause a vascular steal syndrome with paralysis. Jaw involvement can cause the teeth to spread intraorally and become misaligned.

Osteosarcoma may develop in long-standing lesions but is rare (< 1%). Sarcomatous change is suggested by a marked increase in bone pain, sudden rise in alkaline phosphatase, and appearance of a new lytic lesion.

► Treatment

Asymptomatic patients may require only clinical surveillance and no treatment. However, treatment should be considered for asymptomatic patients who have extensive involvement of the skull, long bones, or vertebrae. Patients must be monitored carefully before, during, and after treatment with clinical examinations and serial serum alkaline phosphatase determinations.

A. Bisphosphonates

Bisphosphonates are the treatment of choice for Paget disease. Bisphosphonates are usually given cyclically. Therapy is given until a therapeutic response occurs, as evidenced by normalization of the serum alkaline phosphatase. After a course of therapy, patients are given a break for about 3 months or until the serum alkaline phosphatase begins rising again; another cycle is then commenced.

Patients frequently experience a paradoxical increase in pain soon after commencing bisphosphonate therapy; this is the “first dose effect” and the pain usually subsides with further treatment. Flu-like symptoms occur fairly frequently. Osteonecrosis, particularly of the jaw, is rare but can occur spontaneously or after tooth extraction.

The oral bisphosphonates should all be taken with 8 oz of plain water only; they are relatively contraindicated in patients with a history of esophagitis, esophageal stricture,

dysphagia, hiatal hernia, or achalasia. **Alendronate**, 40 mg orally daily for 3–6 month cycles, must be taken in the morning with water only, at least 30–40 minutes before any other food, liquids, or medications. Patients should not lie down for at least 30 minutes after taking alendronate to reduce the risk of esophagitis. **Tiludronate**, 400 mg orally daily for 3-month cycles, should not be taken within 2 hours of meals, aspirin, indomethacin, calcium, magnesium, or aluminum-containing antacids. Esophagitis is uncommon, but it is still advisable to avoid recumbency for 30 minutes after dosing; but the drug may be taken in the evening as well as during the day. The most common side effects have been gastrointestinal, including abdominal pain in 13% and nausea in 9%. **Risedronate**, 30 mg orally daily for 2-month cycles, must be taken in the morning with water only, at least 30–40 minutes before any other food, liquids, or medications. Patients should not lie down for at least 30 minutes after taking risedronate to reduce the risk of esophagitis.

Parenteral bisphosphonates are particularly useful for patients who cannot tolerate oral bisphosphonates. Intravenous bisphosphonates can produce clinical improvements that last several months. Serum alkaline phosphatase levels may continue to drop for 6 months after treatment. They appear to be more effective than oral bisphosphonates but have more systemic side effects. Postinfusion fever, fatigue, myalgia, bone pain, and ocular problems occur commonly and may sometimes be severe. Serious side effects are rare but include uveitis and acute kidney disease. Hypocalcemia is common and may be severe, especially if intravenous bisphosphonates are given along with loop diuretics. It is advisable to administer calcium and vitamin D supplements, especially during the first 2 weeks following treatment. Asthma may occur in aspirin-sensitive patients. **Pamidronate**, 30–60 mg is infused intravenously over 2–4 hours. Depending on the disease severity, one to three additional doses may be given days or weeks apart. **Zoledronic acid** can be given every 6–12 months in doses of 2–5 mg intravenously over 20 minutes. Six months following a single infusion of zoledronic acid, patients had a clinical response rate of 96%, compared with 74% in patients receiving daily oral risedronate. Intravenous zoledronic acid has been demonstrated to be significantly more effective than daily risedronate.

B. Nasal Calcitonin-Salmon

Miacalcin, 200 international units/unit dose spray, is administered as one spray daily, alternating nostrils. It is just as effective as the parenteral preparation and is associated with fewer side effects. Nasal irritation may occur, as may occasional epistaxis. Calcitonin has been used for many years to treat Paget disease. However, its use has declined dramatically with the introduction of more potent bisphosphonates.

► Prognosis

The prognosis in general is good, but sarcomatous changes (in 1–3%) can alter it unfavorably. In general, the prognosis is worse the earlier in life the disease starts. Fractures

usually heal well. In the severe forms, marked deformity, intractable pain, and cardiac failure are found. These complications should become rare with prompt bisphosphonate treatment.

DISEASES OF THE ADRENAL CORTEX

ACUTE ADRENOCORTICAL INSUFFICIENCY (Adrenal Crisis)

ESSENTIALS OF DIAGNOSIS

- Weakness, abdominal pain, fever, confusion, nausea, vomiting, and diarrhea.
- Low blood pressure, dehydration; skin pigmentation may be increased.
- Serum potassium high, sodium low, BUN high.
- Cosyntropin (ACTH₁₋₂₄) unable to stimulate an increase in serum cortisol to ≥ 20 mcg/dL.

► General Considerations

Acute adrenal insufficiency is an emergency caused by insufficient cortisol. Crisis may occur in the course of treatment of chronic insufficiency, or it may be the presenting manifestation of adrenal insufficiency. Acute adrenal crisis is more commonly seen in primary adrenal insufficiency (Addison disease) than in disorders of the pituitary gland causing secondary adrenocortical hypofunction.

Adrenal crisis may occur in the following situations: (1) during stress, (eg, trauma, surgery, infection, hyperthyroidism, or prolonged fasting) in a patient with latent or treated adrenal insufficiency; (2) following sudden withdrawal of adrenocortical hormone in a patient with chronic insufficiency or in a patient with temporary insufficiency due to suppression by exogenous corticosteroids or megestrol; (3) following bilateral adrenalectomy or removal of a functioning adrenal tumor that had suppressed the other adrenal; (4) following sudden destruction of the pituitary gland (pituitary necrosis), or when thyroid hormone is given to a patient with hypoadrenalism; and (5) following injury to both adrenals by trauma, hemorrhage, anticoagulant therapy, thrombosis, infection or, rarely, metastatic carcinoma; (6) following administration of etomidate, which is used intravenously for rapid anesthesia induction or intubation.

► Clinical Findings

A. Symptoms and Signs

The patient complains of headache, lassitude, nausea and vomiting, abdominal pain, and often diarrhea. Confusion or coma may be present. Fever may be 40.6 °C or more. The blood pressure is low. Recurrent hypoglycemia and reduced insulin requirements may present in patients with preexisting type 1 diabetes mellitus. Other signs may include cyanosis, dehydration, skin hyperpigmentation, and sparse axillary hair (if hypogonadism is also present). Meningococcemia may be associated with purpura and adrenal insufficiency secondary to adrenal infarction (Waterhouse–Friderichsen syndrome).

B. Laboratory Findings

The eosinophil count may be high. Hyponatremia or hyperkalemia (or both) are usually present. Hypoglycemia is frequent. Hypercalcemia may be present. Blood, sputum, or urine culture may be positive if bacterial infection is the precipitating cause of the crisis.

The diagnosis is made by a simplified cosyntropin stimulation test, which is performed as follows: (1) Synthetic ACTH_{1–24} (cosyntropin), 0.25 mg, is given parenterally. (2) Serum is obtained for cortisol between 30 and 60 minutes after cosyntropin is administered. Normally, serum cortisol rises to at least 20 mcg/dL. For patients receiving corticosteroid treatment, hydrocortisone must not be given for at least 8 hours before the test. Other corticosteroids (eg, prednisone, dexamethasone) do not interfere with specific assays for cortisol.

Plasma ACTH is markedly elevated if the patient has primary adrenal disease (generally > 200 pg/mL).

► Differential Diagnosis

Acute adrenal insufficiency must be distinguished from other causes of shock (eg, septic, hemorrhagic, cardiogenic). Hyperkalemia is also seen with gastrointestinal bleeding, rhabdomyolysis, hyperkalemic paralysis, and certain drugs (eg, angiotensin-converting enzyme [ACE] inhibitors, spironolactone). Hyponatremia is seen in many other conditions (eg, hypothyroidism, diuretic use, heart failure, cirrhosis, vomiting, diarrhea, severe illness, or major surgery). Acute adrenal insufficiency must be distinguished from an acute abdomen in which neutrophilia is the rule, whereas adrenal insufficiency is characterized by a relative lymphocytosis and eosinophilia.

More than 90% of serum cortisol is protein bound and low serum levels of binding proteins result in misleadingly low serum cortisol determinations by most assays. Nearly 40% of critically ill patients, with serum albumin < 2.5 g/dL, have low serum total cortisol levels but normal serum free cortisol or salivary cortisol levels and normal adrenal function.

► Treatment

A. Acute Phase

If the diagnosis is suspected, draw a blood sample for cortisol determination and treat with hydrocortisone, 100–

300 mg intravenously, and saline *immediately*, without waiting for the results. Thereafter, give hydrocortisone phosphate or hydrocortisone sodium succinate, 100 mg intravenously immediately, and continue intravenous infusions of 50–100 mg every 6 hours for the first day. Give the same amount every 8 hours on the second day and then adjust the dosage in view of the clinical picture.

Since bacterial infection frequently precipitates acute adrenal crisis, broad-spectrum antibiotics should be administered empirically while waiting for the results of initial cultures. Hypoglycemia should be vigorously treated while serum electrolytes, BUN, and creatinine are monitored.

B. Convalescent Phase

When the patient is able to take food by mouth, give oral hydrocortisone, 10–20 mg every 6 hours, and reduce dosage to maintenance levels as needed. Most patients ultimately require hydrocortisone twice daily (am, 10–20 mg; pm, 5–10 mg). Mineralocorticoid therapy is not needed when large amounts of hydrocortisone are being given, but as the dose is reduced it is usually necessary to add fludrocortisone acetate, 0.05–0.2 mg daily. Some patients never require fludrocortisone or become edematous at doses of more than 0.05 mg once or twice weekly. Once the crisis has passed, the patient must be evaluated to assess the degree of permanent adrenal insufficiency and to establish the cause if possible.

► Prognosis

Rapid treatment will usually be life-saving. However, acute adrenal insufficiency is frequently unrecognized and untreated since its manifestations mimic more common conditions; lack of treatment leads to shock that is unresponsive to volume replacement and vasopressors, resulting in death.

CHRONIC ADRENOCORTICAL INSUFFICIENCY (Addison Disease)

ESSENTIALS OF DIAGNOSIS

- Weakness, fatigability, anorexia, weight loss; nausea and vomiting, diarrhea; abdominal pain, muscle and joint pains; amenorrhea.
- Sparse axillary hair; increased skin pigmentation, especially of creases, pressure areas, and nipples.
- Hypotension, small heart.
- Serum sodium may be low; potassium, calcium, and BUN may be elevated; neutropenia, mild anemia, eosinophilia, and relative lymphocytosis may be present.

- ▶ Plasma cortisol levels are low or fail to rise after administration of corticotropin.
- ▶ Plasma ACTH level is elevated.

▶ General Considerations

Addison disease is an uncommon disorder caused by destruction or dysfunction of the adrenal cortices. It is characterized by chronic deficiency of cortisol, aldosterone, and adrenal androgens and causes skin pigmentation that can be subtle or strikingly dark. Volume and sodium depletion and potassium excess eventually occur in primary adrenal failure. In contrast, if chronic adrenal insufficiency is secondary to pituitary failure (atrophy, necrosis, tumor), mineralocorticoid production (controlled by the renin–angiotensin system) persists and hyperkalemia is not present. Furthermore, if ACTH is not elevated, skin pigmentary changes are not encountered.

▶ Etiology

Autoimmune destruction of the adrenals is the most common cause of Addison disease in the United States (accounting for about 80% of spontaneous cases). With such autoimmunity, adrenal function decreases over several years as it progresses to overt adrenal insufficiency. It may occur alone or as part of a **polyglandular autoimmune (PGA) syndrome**. *Type 1 PGA* is also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APCED) syndrome and is caused by a defect in T cell-mediated immunity inherited as an autosomal recessive trait. *Type 1 PGA* usually presents in early childhood with mucocutaneous candidiasis, followed by hypoparathyroidism and dystrophy of the teeth and nails; Addison disease usually appears by age 15 years. Partial or late expression of the syndrome is common. A varied spectrum of associated diseases may be seen in adulthood, including hypogonadism, hypothyroidism, pernicious anemia, alopecia, vitiligo, hepatitis, malabsorption, and Sjögren syndrome.

Type 2 PGA usually presents in young adults age 20–40 years, usually women (female:male ration is 3:1). The following conditions may be presentations of *type 2 PGA*: autoimmune adrenal insufficiency, *type 1 diabetes mellitus*, or autoimmune thyroid disease (usually hypothyroidism, sometimes hyperthyroidism). The combination of Addison disease and hypothyroidism is known as **Schmidt syndrome**. Patients may also have vitiligo, alopecia areata, Sjögren syndrome, or celiac sprue. *Type 2 PGA* is also associated with autoimmune primary ovarian failure; testicular failure (5%); pernicious anemia (4%); and, rarely, autoimmune hypophysitis, encephalitis, or hypoparathyroidism (late-onset).

Tuberculosis as a leading cause of Addison disease is relatively rare in the United States but common where tuberculosis is more prevalent.

Bilateral **adrenal hemorrhage** may occur during sepsis, heparin-associated thrombocytopenia or anticoagulation, or with antiphospholipid antibody syndrome. It may occur in association with major surgery or trauma, presenting

about 1 week later with pain, fever, and shock. It may also occur spontaneously.

Adrenoleukodystrophy is an X-linked peroxisomal disorder causing accumulation of very long-chain fatty acids in the adrenal cortex, testes, brain, and spinal cord. It may present at any age and accounts for one-third of cases of Addison disease in boys. Aldosterone deficiency occurs in 9%. Hypogonadism is common. Psychiatric symptoms often include mania, psychosis, or cognitive impairment. Neurologic deterioration may be severe or mild (particularly in heterozygote women), mimics symptoms of multiple sclerosis, and can occur years after the onset of adrenal insufficiency.

Rare causes of adrenal insufficiency include lymphoma, metastatic carcinoma, coccidioidomycosis, histoplasmosis, cytomegalovirus infection (more frequent in patients with AIDS), syphilitic gummas, scleroderma, amyloid disease, and hemochromatosis.

Congenital adrenal insufficiency occurs in several conditions. **Familial glucocorticoid deficiency** is caused by a mutation in the gene encoding the adrenal ACTH receptor. **Triple A (Allgrove) syndrome** is characterized by variable expression of the following: adrenal ACTH resistance with cortisol deficiency, achalasia, alacrima, nasal voice, and neuromuscular disease of varying severity (hyperreflexia to spastic paraplegia). Cortisol deficiency usually presents in infancy but may not occur until the third decade of life. **Congenital adrenal hypoplasia** causes adrenal insufficiency due to absence of the adrenal cortex; patients may also have hypogonadotropic hypogonadism, myopathy, and high-frequency hearing loss. Patients with hereditary defects in adrenal enzymes for cortisol synthesis develop **congenital adrenal hyperplasia** due to ACTH stimulation. The most common enzyme defect is P450c21 (21-hydroxylase). Patients with severely defective P450c21 enzymes manifest deficiency of mineralocorticoids (salt wasting) in addition to deficient cortisol and excessive androgens. Women with milder enzyme defects have adequate cortisol but develop hirsutism in adolescence or adulthood and are said to have “late-onset” congenital adrenal hyperplasia. (See Hirsutism section.)

▶ Clinical Findings

A. Symptoms and Signs

The symptoms may include weakness and fatigability, weight loss, myalgias, arthralgias, fever, anorexia, nausea and vomiting, anxiety, and mental irritability. Some of these symptoms may be due to high serum levels of IL-6. Pigmentary changes consist of diffuse tanning over nonexposed as well as exposed parts or multiple freckles; hyperpigmentation is especially prominent over the knuckles, elbows, knees, and posterior neck and in palmar creases. Nail beds may develop longitudinal pigmented bands. Nipples and areolas tend to darken. The skin in pressure areas such as the belt or brassiere lines and the buttocks also darkens. New scars are pigmented. Some patients have associated vitiligo (10%). Emotional changes are common. Hypoglycemia, when present, may worsen the patient’s weakness and mental functioning, rarely leading to coma.

Manifestations of other autoimmune disease (see above) may be present. Patients tend to be hypotensive and orthostatic; about 90% have systolic blood pressures under 110 mm Hg; blood pressure over 130 mm Hg is rare. Other findings may include a small heart, hyperplasia of lymphoid tissues, and scant axillary and pubic hair (especially in women).

Patients with adult-onset adrenoleukodystrophy may present with neuropsychiatric symptoms, sometimes without adrenal insufficiency.

B. Laboratory Findings

The WBC count usually shows moderate neutropenia, lymphocytosis, and a total eosinophil count over 300/mcL. Among patients with *chronic* Addison disease, the serum sodium is usually low (90%) while the potassium is elevated (65%). Patients with diarrhea may not be hyperkalemic. Fasting blood glucose may be low. Hypercalcemia may be present. Young men with idiopathic Addison disease are screened for adrenoleukodystrophy by determining plasma very long-chain fatty acid levels; affected patients have high levels.

Low plasma cortisol (< 3 mcg/dL) at 8 am is diagnostic, especially if accompanied by simultaneous elevation of the plasma ACTH level (usually > 200 pg/mL). The diagnosis is made by a simplified cosyntropin stimulation test, which is performed as follows: (1) Synthetic ACTH₁₋₂₄ (cosyntropin), 0.25 mg, is given parenterally. (2) Serum is obtained for cortisol between 30 and 60 minutes after cosyntropin is administered. Normally, serum cortisol rises to at least 20 mcg/dL. For patients receiving corticosteroid treatment, hydrocortisone must not be given for at least 8 hours before the test. Other corticosteroids (eg, prednisone, dexamethasone) do not interfere with specific assays for cortisol.

Serum DHEA levels are under 1000 ng/mL in 100% of patients with Addison disease and a serum DHEA above 1000 ng/mL excludes the diagnosis. However, serum DHEA levels below 1000 ng/mL are not helpful, since about 15% of the general population have such low DHEA levels, particularly children and elderly individuals. Anti-adrenal antibodies are found in the serum in about 50% of cases of autoimmune Addison disease. Antibodies to thyroid (45%) and other tissues may be present.

Elevated plasma renin activity (PRA) indicates the presence of depleted intravascular volume and the need for higher doses of fludrocortisone replacement. Serum epinephrine levels are low in patients with adrenal insufficiency, since these patients do not have the high local concentrations of cortisol that are required to induce the enzyme PNMT in adrenal medulla for the synthesis of epinephrine from norepinephrine.

C. Imaging

When Addison disease is not clearly autoimmune, a chest radiograph is obtained to look for tuberculosis, fungal infection, or cancer as possible causes. CT scan of the abdomen will show small noncalcified adrenals in autoimmune Addison disease. The adrenals are enlarged in about 85% of cases due to metastatic or granulomatous disease.

Calcification is noted in about 50% of cases of tuberculous Addison disease but is also seen with hemorrhage, fungal infection, pheochromocytoma, and melanoma.

► Differential Diagnosis

Addison disease should be considered in any patient with unexplained hypotension, but shock is usually caused by more common conditions such as gastrointestinal bleeding or sepsis. Hyponatremia or hyperkalemia may be seen in numerous other conditions (see Chapter 21). Drospirenone, the progestin component in certain oral contraceptives, may cause hyperkalemia.

Unexplained weight loss, weakness, and anorexia may be mistaken for occult cancer. Nausea, vomiting, diarrhea, and abdominal pain may be misdiagnosed as intrinsic gastrointestinal disease. The hyperpigmentation may be confused with that due to ethnic or racial factors. Weight loss may simulate anorexia nervosa. The neurologic manifestations of Allgrove syndrome and adrenoleukodystrophy (especially in women) may mimic multiple sclerosis. Hemochromatosis also enters the differential diagnosis of skin hyperpigmentation, but it should be remembered that it may truly be a cause of Addison disease as well as diabetes mellitus and hypoparathyroidism. Serum ferritin is increased in most cases of hemochromatosis and is a useful screening test. About 17% of patients with AIDS have symptoms of cortisol resistance. AIDS can also cause frank adrenal insufficiency.

Hyperkalemia can be caused by isolated hypoaldosteronism and is seen in various conditions. Hyporeninemic hypoaldosteronism can be caused by renal tubular acidosis type IV and is commonly seen with diabetic nephropathy, hypertensive nephrosclerosis, tubulointerstitial diseases, and AIDS; hyperkalemia, hyperchloremia, and metabolic acidosis (see Chapter 21) are presenting signs. Hyperreninemic hypoaldosteronism can be seen in patients with myotonic dystrophy, aldosterone synthase deficiency, and congenital adrenal hyperplasia. Hyperkalemia, hypertension, and hypogonadism may present as delayed adolescence or in adulthood in some patients with congenital adrenal hyperplasia (CYP17 deficiency); cortisol deficiency is also usually present but may not be clinically evident.

► Complications

Any of the complications of the underlying disease (eg, tuberculosis) are more likely to occur, and the patient is susceptible to intercurrent infections that may precipitate crisis. Associated autoimmune diseases are common (see above).

► Treatment

A. Specific Therapy

Replacement therapy should include a combination of corticosteroids and mineralocorticoids. In mild cases, hydrocortisone alone may be adequate.

Hydrocortisone is the drug of choice. Most Addisonian patients are well maintained on 15–30 mg of hydrocortisone orally daily in two divided doses, two-thirds in the

morning and one-third in the late afternoon or early evening. Some patients respond better to prednisone in a dosage of about 2–4 mg in the morning and 1–2 mg in the evening. Adjustments in dosage are made according to the clinical response. A proper dose usually results in a normal differential WBC count.

Fludrocortisone acetate has a potent sodium-retaining effect. The dosage is 0.05–0.3 mg orally daily or every other day. In the presence of postural hypotension, hyponatremia, or hyperkalemia, the dosage is increased. Similarly, in patients with fatigue, elevated PRA indicates the need for a higher replacement dose of fludrocortisone. If edema, hypokalemia, or hypertension ensues, the dose is decreased.

DHEA is given to some patients with adrenal insufficiency. In a double-blind clinical trial, patients taking DHEA 50 mg orally each morning have experienced an improvement in their overall sense of well-being, an increase in muscle mass, and a reversal in bone loss at the femoral neck. DHEA replacement did not improve fatigue or sexual dysfunction; however, its placebo effect may be significant in that regard. Older women who receive DHEA should be monitored for androgenic effects. Because over-the-counter preparations of DHEA have variable potencies, it is best to have the pharmacy formulate this with pharmaceutical-grade micronized DHEA.

B. General Measures

Patients with Addison disease must be thoroughly informed about their condition. All infections should be treated immediately and vigorously, with the dose of hydrocortisone increased appropriately. The dose of corticosteroid should also be raised in case of trauma, surgery, stressful diagnostic procedures, or other forms of stress. The maximum hydrocortisone dose for severe stress is 50 mg intravenously or intramuscularly every 6 hours. Lower doses, oral or parenteral, are used for less severe stress. The dose is reduced back to normal as the stress subsides. Patients are advised to wear a medical alert bracelet or medal reading, “Adrenal insufficiency—takes hydrocortisone.”

► Prognosis

The life expectancy of patients with Addison disease has been considered reasonably normal, as long as they are very compliant with taking their medications and are knowledgeable about their condition. However, a retrospective Swedish study of 1675 patients with Addison disease found an unexpected increase in all-cause mortality, mostly from cardiovascular disease, malignancy, and infectious causes. Associated conditions can pose additional health risks. For example, patients with adrenoleukodystrophy or Allgrove syndrome may suffer from neurologic disease. Patients with adrenal tuberculosis may have a serious systemic infection that requires treatment. Adrenal crisis can occur in patients who stop their medication or who experience stress such as infection, trauma, or surgery without appropriately higher doses of corticosteroids. Patients who take excessive doses of corticosteroid replacement can develop Cushing syndrome, which imposes its own risks.

Many patients with treated Addison disease complain of chronic low-grade fatigue.

Many patients with Addison disease do not feel entirely normal, despite glucocorticoid and mineralocorticoid replacement. This may be due, in part, to the inadequacy of oral replacement to duplicate cortisol’s normal circadian rhythm. Also, patients with Addison disease are deficient in epinephrine, but replacement epinephrine is not available. Fatigue may also be an indication of suboptimal dosing of medication, electrolyte imbalance, or concurrent problems such as hypothyroidism or diabetes mellitus. However, most patients with Addison disease are able to live fully active lives.

CUSHING SYNDROME (Hypercortisolism)

ESSENTIALS OF DIAGNOSIS

- Central obesity, muscle wasting, thin skin, hirsutism, purple striae.
- Psychological changes.
- Osteoporosis, hypertension, poor wound healing.
- Hyperglycemia, glycosuria, leukocytosis, lymphocytopenia, hypokalemia.
- Elevated serum cortisol and urinary free cortisol. Lack of normal suppression by dexamethasone.

► General Considerations

The term Cushing “syndrome” refers to the manifestations of excessive corticosteroids, commonly due to supraphysiologic doses of corticosteroid drugs and rarely due to spontaneous production of excessive corticosteroids by the adrenal cortex. Cases of spontaneous Cushing syndrome are rare (2.6 new cases yearly per million population) and have several possible causes.

About 40% of cases are due to Cushing “disease,” by which is meant the manifestations of hypercortisolism due to ACTH hypersecretion by the pituitary. Cushing disease is caused by a benign pituitary adenoma that is typically very small (< 5 mm) and usually located in the anterior pituitary (98%) or in the posterior pituitary (2%). It is at least three times more frequent in women than men.

About 10% of cases are due to nonpituitary ACTH-secreting neoplasms (eg, small cell lung carcinoma), which

produce excessive amounts of ectopic ACTH. Hypokalemia and hyperpigmentation are commonly found in this group.

About 15% of cases are due to ACTH from a source that cannot be initially located.

About 30% of cases are due to excessive autonomous secretion of cortisol by the adrenals—independently of ACTH, serum levels of which are usually low. Most such cases are due to a unilateral adrenal tumor: Benign adrenal adenomas are generally small and produce mostly cortisol; adrenal carcinomas are usually large when discovered and can produce excessive cortisol as well as androgens, with resultant hirsutism and virilization. ACTH-independent macronodular adrenal hyperplasia can also produce hypercortisolism due to the adrenal cortex cells' abnormal stimulation by hormones such as catecholamines, arginine vasopressin, serotonin, hCG/LH, or gastric inhibitory polypeptide; in the latter case, hypercortisolism may be intermittent and food dependent and serum ACTH may not be completely suppressed. Pigmented bilateral adrenal macronodular adrenal hyperplasia is a rare cause of Cushing syndrome in children and young adults; it may be an isolated condition or part of the Carney complex.

► Clinical Findings

A. Symptoms and Signs

Patients with Cushing syndrome usually have central obesity with a plethoric “moon face,” “buffalo hump,” supraclavicular fat pads, protuberant abdomen, and thin extremities; oligomenorrhea or amenorrhea (or impotence in the male); weakness, backache, and headache; hypertension; osteoporosis; avascular bone necrosis; and acne and superficial skin infections. Patients may have thirst and polyuria (with or without glycosuria), renal calculi, glaucoma, purple striae (especially around the thighs, breasts, and abdomen), and easy bruisability. Wound healing is impaired. Mental symptoms may range from diminished ability to concentrate to increased lability of mood to frank psychosis. Patients are susceptible to opportunistic infections.

B. Laboratory Findings

Glucose tolerance is impaired as a result of insulin resistance. Polyuria is present as a result of increased free water clearance; diabetes mellitus with glycosuria may worsen it. Patients with Cushing syndrome often have leukocytosis with relative granulocytosis and lymphopenia. Hypokalemia may be present, particularly in cases of ectopic ACTH secretion.

► Tests for Hypercortisolism

The easiest screening test for Cushing syndrome is the dexamethasone suppression test: dexamethasone 1 mg is given orally at 11 pm and serum is collected for cortisol determination at about 8 am the next morning; a cortisol level under 5 mcg/dL (< 135 nmol/L, fluorometric assay) or under 2 mcg/dL (< 54 nmol/L, high-performance liquid chromatography [HPLC] assay) excludes Cushing syndrome with some certainty. However, 8% of established

patients with pituitary Cushing disease have dexamethasone-suppressed cortisol levels < 2 mcg/dL. Therefore, when other clinical criteria suggest hypercortisolism, further evaluation is warranted even in the face of normal dexamethasone-suppressed serum cortisol. Antiepileptic drugs (eg, phenytoin, phenobarbital, primidone) and rifampin accelerate the metabolism of dexamethasone, in that way causing a lack of cortisol suppression by dexamethasone. Estrogens—during pregnancy or as oral contraceptives or ERT—may also cause lack of dexamethasone suppressibility.

Patients with an abnormal dexamethasone suppression test require further investigation, which includes a 24-hour urine collection for free cortisol and creatinine. An abnormally high 24-hour urine free cortisol (or free cortisol to creatinine ratio of > 95 mcg cortisol/g creatinine) helps confirm hypercortisolism. A misleadingly high urine free cortisol excretion occurs with high fluid intake. In pregnancy, urine free cortisol is increased, while 17-hydroxycorticosteroids remain normal and diurnal variability of serum cortisol is normal. Carbamazepine and fenofibrate cause false elevations of urine free cortisol when determined by HPLC.

A midnight serum cortisol level > 7.5 mcg/dL is indicative of Cushing syndrome and distinguishes it from other conditions associated with a high urine free cortisol (pseudo-Cushing states; see Differential Diagnosis, below). Requirements for this test include being in the same time zone for at least 3 days, being without food for at least 3 hours, and having an indwelling intravenous line established in advance for the blood draw.

Due to the inconvenience of obtaining a midnight blood specimen for serum cortisol, late-night salivary cortisol assays have proved useful. Salivary cortisol kits can be ordered at www.acllaboratories.com. A standardized enzyme-linked immunosorbent assay (ELISA) is used by reliable laboratories. Using ELISA, midnight salivary cortisol levels are normally < 0.15 mcg/dL (4.0 nmol/L). Midnight salivary cortisol levels that are consistently > 0.25 mcg/dL (7.0 nmol/L) are considered very abnormal. The late-night salivary cortisol test has a high sensitivity and specificity for Cushing syndrome, but false-positive and false-negative tests have occurred.

Interestingly, hypercortisolism without Cushing syndrome can occur in several conditions, such as severe depression, anorexia nervosa, alcoholism, and familial cortisol resistance. (See Differential Diagnosis, below.)

► Finding the Cause of Hypercortisolism

Once hypercortisolism is confirmed, a plasma or serum ACTH is obtained. It must be collected properly in a plastic tube on ice and processed quickly by a laboratory with a reliable, sensitive assay. A level of ACTH below about 20 pg/mL indicates a probable adrenal tumor, whereas higher levels are produced by pituitary or ectopic ACTH-secreting tumors.

► Localizing Techniques

In ACTH-dependent Cushing syndrome, MRI of the pituitary demonstrates a pituitary lesion in about 50% of cases.

Premature cerebral atrophy is often noted. When the pituitary MRI is normal or shows a tiny (< 5 mm diameter) irregularity that may be incidental, selective catheterization of the inferior petrosal sinus veins draining the pituitary is performed. ACTH levels in the inferior petrosal sinus that are more than twice the simultaneous peripheral venous ACTH levels are indicative of pituitary Cushing disease. Inferior petrosal sinus sampling is also done during CRH administration, which ordinarily causes the ACTH levels in the inferior petrosal sinus to be over three times the peripheral ACTH level when the pituitary is the source of ACTH.

When inferior petrosal sinus ACTH concentrations are not above the requisite levels, a search for an ectopic source of ACTH is undertaken. Location of ectopic sources of ACTH commences with CT scanning of the chest and abdomen, with special attention to the lungs (for carcinoid or small cell carcinomas), the thymus, the pancreas, and the adrenals. In patients with ACTH-dependent Cushing syndrome, chest masses should not be assumed to be the source of ACTH, since opportunistic infections are common, so it is prudent to biopsy a chest mass to confirm the pathologic diagnosis prior to resection.

CT scanning fails to detect the source of ACTH in about 40% of patients with ectopic ACTH secretion.¹¹¹ In-octreotide (OCT, somatostatin receptor scintigraphy) scanning is also useful in detecting occult tumors. A low-dose scan with 6 mCi OCT is used first; a high-dose scan with 12 mCi OCT may be used if the low-dose scan gives equivocal results.¹⁸FDG-PET scanning is not usually helpful. Some ectopic ACTH-secreting tumors elude discovery, necessitating bilateral adrenalectomy. The ectopic source of ACTH should continue to be sought, since they may become detectable by OCT or CT scanning at a later date.

In non-ACTH-dependent Cushing syndrome, a CT scan of the adrenals can localize the adrenal tumor in most cases.

► Differential Diagnosis

Alcoholic patients can have hypercortisolism and many clinical manifestations of Cushing syndrome. Regular use of the “party drug” gamma hydroxybutyrate (GHB, sodium oxybate) has been reported to cause reversible ACTH-dependent Cushing syndrome. Depressed patients also have hypercortisolism that can be nearly impossible to distinguish biochemically from Cushing syndrome but without clinical signs of Cushing syndrome. Some adolescents develop violaceous striae on the abdomen, back, and breasts; these are known as “striae distensae” and are not indicative of Cushing syndrome. Cushing syndrome can be misdiagnosed as anorexia nervosa (and vice versa) owing to the muscle wasting and extraordinarily high urine free cortisol levels found in anorexia. Patients with severe obesity frequently have an abnormal dexamethasone suppression test, but the urine free cortisol is usually normal, as is diurnal variation of serum cortisol. Patients with familial cortisol resistance have hyperandrogenism, hypertension, and hypercortisolism without actual Cushing syndrome. In patients with familial partial lipodystrophy type I, central obesity and a moon facies develop, along with thin extremi-

ties due to atrophy of subcutaneous fat. However, these patients’ muscles are strong and may be hypertrophic, distinguishing this condition from Cushing syndrome. Patients receiving antiretroviral therapy for HIV-1 infection frequently develop partial lipodystrophy with thin extremities and central obesity with a dorsocervical fat pad (“buffalo hump”) that may mimic Cushing syndrome.

► Complications

Cushing syndrome, if untreated, produces serious morbidity and even death. The patient may suffer from any of the complications of hypertension or of diabetes. Susceptibility to infections is increased. Compression fractures of the osteoporotic spine and aseptic necrosis of the femoral head may cause marked disability. Nephrolithiasis and psychosis may occur. Following bilateral adrenalectomy for Cushing disease, a pituitary adenoma may enlarge progressively, causing local destruction (eg, visual field impairment) and hyperpigmentation; this complication is known as Nelson syndrome.

► Treatment

Cushing disease is best treated by transsphenoidal selective resection of the pituitary adenoma. After pituitary surgery, the rest of the pituitary usually returns to normal function; however, the pituitary corticotrophs remain suppressed and require 6–36 months to recover normal function. Hydrocortisone or prednisone replacement therapy is necessary in the meantime. Patients who do not have a remission (or who have a recurrence) should be treated by bilateral laparoscopic adrenalectomy. Another treatment option for patients with ACTH-secreting pituitary tumors is stereotactic pituitary radiosurgery (gamma knife or cyberknife), which normalizes urine free cortisol in two-thirds of patients within 12 months. Conventional radiation therapy results in a 23% cure rate.

Pituitary radiosurgery can also be used to treat Nelson syndrome, the progressive enlargement of ACTH-secreting pituitary tumors following bilateral adrenalectomy. Patients who are not surgical candidates may be given a trial of ketoconazole in doses of about 200 mg every 6 hours; liver enzymes must be monitored for progressive elevation.

Adrenal neoplasms secreting cortisol are resected laparoscopically. The contralateral adrenal is suppressed, so postoperative hydrocortisone replacement is required until recovery occurs. Metastatic adrenal carcinomas may be treated with mitotane; ketoconazole or metyrapone can help suppress hypercortisolism in unresectable adrenal carcinoma. The thiazolidinedione rosiglitazone has slowed the growth of adrenal carcinomas in-vitro, but clinical trials are lacking.

Ectopic ACTH-secreting tumors should be located, when possible, and surgically resected. If that cannot be done, laparoscopic bilateral adrenalectomy is recommended. Medical treatment with ketoconazole or metyrapone (or both) may partially suppress the hypercortisolism; however, metyrapone may exacerbate female virilization. The somatostatin analog octreotide, given parenterally, suppresses ACTH secretion in about one-third of such cases.

Patients who are successfully treated for Cushing syndrome typically develop “cortisol withdrawal syndrome,” even when given replacement corticosteroids for adrenal insufficiency. Manifestations can include hypotension, nausea, fatigue, arthralgias, myalgias, pruritus, and flaking skin. Increasing the hydrocortisone replacement to 30 mg twice daily can improve these symptoms; the dosage is then reduced as tolerated.

▶ Prognosis

Patients with Cushing syndrome from a benign adrenal adenoma experience a 5-year survival of 95% and a 10-year survival of 90%, following a successful adrenalectomy. Patients with Cushing disease from a pituitary adenoma experience a similar survival if their pituitary surgery is successful. However, transphenoidal surgery incurs a failure rate of about 10–20%, often due to the adenoma’s ectopic position or invasion of the cavernous sinus. Those patients who have a complete remission after transphenoidal surgery have about a 15–20% chance of recurrence over the next 10 years. Patients with failed pituitary surgery may require pituitary radiation therapy, which has its own morbidity. Bilateral adrenalectomy is often complicated by infection; recurrence of hypercortisolism may occur as a result of growth of an adrenal remnant stimulated by high levels of ACTH. The prognosis for patients with ectopic ACTH-producing tumors depends on the aggressiveness and stage of the particular tumor. Patients with ACTH of unknown source have a 5-year survival rate of 65% and a 10-year survival rate of 55%. Patients with adrenal carcinoma have a median survival of 7 months.

HIRsutISM & VIRILIZATION

ESSENTIALS OF DIAGNOSIS

- ▶ Hirsutism, acne, menstrual disorders.
- ▶ Virilization: increased muscularity, androgenic alopecia, deepening of the voice, clitoromegaly.
- ▶ Rarely, a palpable pelvic tumor.
- ▶ Urinary 17-ketosteroids and serum DHEAS and androstenedione elevated in adrenal disorders; variable in others.
- ▶ Serum testosterone is often elevated.

▶ General Considerations

Hirsutism is defined as excessive terminal hair growth that appears in a male pattern in women. Hirsutism is frequently

quantitated according to the Ferriman-Gallwey scale, which grades the presence of androgen sensitive hair from 0 (no hair) to 4 (virile) in 9 areas of the body (maximum score = 36). About 5% of reproductive age women are hirsute, with Ferriman-Gallwey scores 8.

▶ Etiology

Hirsutism may be idiopathic or familial or be caused by the following disorders: polycystic ovary syndrome (PCOS), steroidogenic enzyme defects, neoplastic disorders or rarely by medications, acromegaly, or ACTH-induced Cushing disease.

A. Idiopathic or Familial

Most women with hirsutism or androgenic alopecia have no detectable hyperandrogenism. Patients often have a strong familial predisposition to hirsutism that may be considered normal in the context of their genetic background. Such patients may have elevated serum levels of androstenediol glucuronide, a metabolite of dihydrotestosterone that is produced by skin in cosmetically unacceptable amounts.

B. Polycystic Ovary Syndrome (Hyperthecosis, Stein-Leventhal Syndrome)

PCOS is a common functional disorder of the ovaries, affecting about 4–6% of premenopausal women in the United States and accounting for at least 50% of all cases of hirsutism associated with elevated testosterone levels. It is familial and transmitted as a modified autosomal dominant trait. Affected women have elevated serum testosterone or free testosterone levels. Affected women have signs of androgen excess, including hirsutism, acne, and male-pattern thinning of scalp hair. About 50% of affected women have oligomenorrhea or amenorrhea with anovulation. Despite the syndrome’s name, the presence of ovarian cysts is not helpful diagnostically, since about 30% of women with PCOS do *not* have cystic ovaries and 25–30% of normal menstruating women *have* cystic ovaries. Obesity and high serum insulin levels (due to insulin resistance) contribute to the syndrome in 70% of women. The serum LH:FSH ratio is often greater than 2.0. Both adrenal and ovarian androgen hypersecretion are commonly present. Women with PCOS have a 35% risk of depression, compared with 11% in age-matched controls. Diabetes mellitus is present in about 13% of cases. Untreated women with amenorrhea have a slightly increased risk of endometrial carcinoma. Hypertension and hyperlipidemia are often present, increasing the risk of cardiovascular disease. Women frequently regain normal menstrual cycles with aging.

C. Steroidogenic Enzyme Defects

Baby girls with “classic” 21-hydroxylase deficiency have ambiguous genitalia and may become virilized unless treated with corticosteroid replacement; about 50% of such patients have clinically evident mineralocorticoid deficiency (salt-wasting) as well.

About 2% of patients with adult-onset hirsutism have been found to have a partial defect in adrenal 21-hydroxy-

lase, whose phenotypic expression is delayed until adolescence or adulthood; such patients do not have salt-wasting. Polycystic ovaries and adrenal adenomas are more likely to develop in these women.

Some rare patients with hyperandrogenism and hypertension have 11-hydroxylase deficiency. This is distinguished from cortisol resistance by high cortisol serum levels in the latter and by high serum 11-deoxycortisol levels in the former.

Patients with an XY karyotype and a deficiency in 17 β -hydroxysteroid dehydrogenase-3 or a deficiency in 5 α -reductase-2 may present as phenotypic girls in whom virilization develops at puberty.

D. Neoplastic Disorders

Ovarian tumors are very uncommon causes of hirsutism (0.8%) and include arrhenoblastomas, Sertoli-Leydig cell tumors, dysgerminomas, and hilar cell tumors. Adrenal carcinoma is a rare cause of Cushing syndrome and hyperandrogenism that can be quite virilizing. Pure androgen-secreting adrenal tumors occur very rarely; about 50% are malignant.

E. Rare Causes of Hirsutism

Acromegaly and ACTH-induced Cushing syndrome can cause hirsutism. Maternal virilization during pregnancy may occur as a result of a luteoma of pregnancy, hyperreactio luteinalis, or polycystic ovaries. In postmenopausal women, diffuse stromal Leydig cell hyperplasia is a rare cause of hyperandrogenism. Acquired hypertrichosis lanuginosa is manifested by the appearance of diffuse fine lanugo hair growth on the face and body along with stomatologic symptoms; the disorder is usually associated with an internal malignancy, especially colorectal cancer, and may regress after tumor removal. Pharmacologic causes include minoxidil, cyclosporine, phenytoin, anabolic steroids, diazoxide, and certain progestins.

► Clinical Findings

A. Symptoms and Signs

Modest androgen excess from any source increases sexual hair (chin, upper lip, abdomen, and chest) and increases sebaceous gland activity, producing acne. Menstrual irregularities, anovulation, and amenorrhea are common. If androgen excess is pronounced, defeminization (decrease in breast size, loss of feminine adipose tissue) and virilization (frontal balding, muscularity, clitoromegaly, and deepening of the voice) occur. Virilization implicates the presence of an androgen-producing neoplasm.

Hypertension may be seen in rare patients with Cushing syndrome, adrenal 11-hydroxylase deficiency, or cortisol resistance syndrome.

A pelvic examination may disclose clitoromegaly or ovarian enlargement that may be cystic or neoplastic.

B. Laboratory Testing and Imaging

Serum androgen testing is mainly useful to screen for rare occult adrenal or ovarian neoplasms. Some general guidelines are presented here, though exceptions are common.

Serum is assayed for total testosterone and free testosterone. A serum testosterone level > 200 ng/dL or free testosterone > 40 ng/dL indicates the need for pelvic examination and ultrasound. If that is negative, an adrenal CT scan is performed.

Most radioimmunoassays and ELISA for testosterone are inaccurate below serum testosterone levels of 300 ng/dL. The more accurate testosterone assays rely upon extraction and chromatography, followed by mass spectrometry or immunoassay. Free testosterone is best measured by calculation, using accurate assays for testosterone and SHBG.

A serum androstenedione level > 1000 ng/dL also implicates an ovarian or adrenal neoplasm.

Patients with milder elevations of serum testosterone or androstenedione usually are treated with an oral contraceptive.

Patients with very elevated serum DHEAS (> 700 mcg/dL) have an adrenal source of androgen. This usually is due to adrenal hyperplasia and rarely to adrenal carcinoma. An adrenal CT scan is performed.

No firm guidelines exist as to which patients (if any) with hyperandrogenism should be screened for “late-onset” 21-hydroxylase deficiency. The evaluation requires levels of serum 17-hydroxyprogesterone to be drawn at baseline and at 30–60 minutes after the intramuscular injection of 0.25 mg of cosyntropin (ACTH₁₋₂₄). This test should ideally be done during the follicular phase of a woman’s menstrual cycle. Patients with congenital adrenal hyperplasia will usually have a baseline 17-hydroxyprogesterone level over 300 ng/dL or a stimulated level over 1000 ng/dL. The diagnosis, once made, is interesting academically but not helpful to the patient since corticosteroid treatment is not particularly more effective in this condition than are other treatment modalities (see below).

Patients with any clinical signs of Cushing syndrome should receive a screening test. (See Cushing Syndrome.)

Serum levels of FSH and LH are elevated if amenorrhea is due to ovarian failure. An LH:FSH ratio greater than 2.0 is common in patients with PCOS. On abdominal ultrasound, about 25–30% of normal young women have polycystic ovaries, so the appearance of ovarian cysts on ultrasound is not helpful. So, the “polycystic” ovary syndrome is actually a misnomer and the diagnostic criteria for PCOS does not include imaging evidence of polycystic ovaries.

Virilizing tumors of the ovary can usually be detected by pelvic ultrasound or MRI. However, small virilizing ovarian tumors may not be detectable on imaging studies; selective venous sampling for testosterone may be used for diagnosis in such patients.

► Treatment

Postmenopausal women with severe hyperandrogenism should undergo laparoscopic bilateral oophorectomy (if CT scan of the adrenals and ovaries is normal), since small hilar cell tumors of the ovary may not be visible on scans. Girls with hyperandrogenism due to classic salt-wasting congenital adrenal hyperplasia may be treated with laparoscopic bilateral adrenalectomy. Any drugs causing hirsutism are stopped.

Spironolactone may be taken in doses of 50–100 mg orally twice daily on days 5–25 of the menstrual cycle or daily if used concomitantly with an oral contraceptive. Hyperkalemia or hyponatremia is uncommon.

Cyproterone acetate is a potent antiandrogen with progestational activity. A dose of 2 mg orally is effective. An oral contraceptive is usually prescribed also. Cyproterone is not available in the United States but is available elsewhere as the progestin element in an oral contraceptive (Diane-35: ethinyl estradiol 35 mcg with cyproterone acetate 2 mg). Side effects may include fatigue, nausea, depression, or hyperlipidemia.

Finasteride inhibits 5 α -reductase, the enzyme that converts testosterone to active dihydrotestosterone in the skin. Given as 2.5-mg doses orally daily, it provides modest reduction in hirsutism over 6 months—somewhat less than that achieved with spironolactone. Finasteride is ineffective for androgenic alopecia in women. Side effects are rare.

Flutamide inhibits androgen reception uptake and also suppresses serum androgen. It is given orally in a dosage of 250 mg/d for the first year and then 125 mg/d for maintenance. Used with an oral contraceptive, it appears to be more effective than spironolactone in improving hirsutism, acne, and male pattern baldness. Women with congenital adrenal hyperplasia who take replacement hydrocortisone experience decreased renal cortisol clearance when treated with flutamide, resulting in lower hydrocortisone dosage requirements; corticosteroid replacement doses should be reduced when flutamide is added for treatment of hirsutism. Hepatotoxicity has been reported but is rare.

Oral contraceptives stimulate menses (if that is desired) and reduce acne vulgaris, but are less effective for hirsutism. Contraceptives containing antiandrogen progestins (either desogestrel 0.15 mg or levonorgestrel 0.15 mg) may be more effective for treating hirsutism but are associated with an increased risk of deep venous thrombosis. Simvastatin, when added to oral contraceptive therapy, has been reported to further decrease serum free testosterone by 16%, besides improving patients' serum lipid profiles.

Metformin may improve menstrual function in women with PCOS and amenorrhea or oligomenorrhea, but is less effective than oral contraceptives. Metformin is not effective in promoting fertility or in improving hirsutism in women with PCOS. Metformin therapy is usually given with meals and is started at a dose of 500 mg/d with breakfast for 1 week, then 500 mg with breakfast and dinner for 1 week, then 500 mg with breakfast and 1000 mg with dinner for 1 week, then 1000 mg with breakfast and dinner. The most common side effects are dose-related gastrointestinal upset and diarrhea. Patients are advised to take the highest tolerated dosage. Metformin appears to be nonteratogenic. Although metformin reduces insulin resistance, it does not cause hypoglycemia in nondiabetics. Metformin is contraindicated in renal and hepatic disease.

Clomiphene is the treatment of choice for women with PCOS and infertility. Over 6 months, clomiphene therapy resulted in a 22.5% rate of conception with live births. The rate of pregnancy with multiple fetuses is 6%.

Women with classic congenital adrenal hyperplasia (21-hydroxylase deficiency) have hirsutism and adrenal

insufficiency that requires glucocorticoid and mineralocorticoid replacement. However, women with partial "late onset" 21-hydroxylase deficiency do not require hormone replacement. Treating such women with dexamethasone risks iatrogenic Cushing syndrome and is not particularly more effective than the other treatments for hirsutism listed in this section.

Local treatment by shaving or depilatories, waxing, electrolysis, or bleaching should be encouraged. Eflornithine (Vaniqua 13.9%) topical cream retards hair growth when applied twice daily to unwanted facial hair; improvement is noted within 4–8 weeks. However, local skin irritation may occur. Hirsutism returns with discontinuation. Laser therapy (photoepilation) is an effective treatment for facial hirsutism, particularly for women with dark hair and light skin; complications include skin hypopigmentation (rare) and hyperpigmentation, which occurs in 20% but usually resolves.

Women with androgenic alopecia may be effectively treated with topical minoxidil 2% solution applied twice daily to a dry scalp. Hypertrichosis is an unwanted side effect of topical minoxidil, occurring in 3–5% of treated women; it may affect the forehead, cheeks, upper lip, or chin. Hypertrichosis resolves within 1–6 months after the drug is stopped.

Note: Antiandrogen treatments must be given only to nonpregnant women. Women must be counseled to take oral contraceptives, when indicated, and avoid pregnancy, since use during pregnancy causes malformations and pseudohermaphroditism in male infants.

PRIMARY ALDOSTERONISM

ESSENTIALS OF DIAGNOSIS

- ▶ Hypertension that may be severe or drug-resistant.
- ▶ Hypokalemia (in minority of patients) may cause polyuria, polydipsia, muscle weakness.
- ▶ Elevated plasma and urine aldosterone levels and low plasma renin level.

▶ General Considerations

Primary aldosteronism (hyperaldosteronism) is common, accounting for 5–10% of all cases of hypertension. Patients

of all ages may be affected, but the peak incidence is between 30–60 years. Excessive aldosterone production increases sodium retention and suppresses plasma renin. It increases renal potassium excretion that can lead to hypokalemia. Cardiovascular events are more prevalent in patients with aldosteronism (35%) than in those with essential hypertension (11%). Primary aldosteronism is most commonly caused by an adrenal adenoma (Conn syndrome), and unilateral or bilateral adrenal hyperplasia. Bilateral aldosteronism may be corticosteroid suppressible, due to an autosomal-dominant genetic defect allowing ACTH stimulation of aldosterone production.

► Clinical Findings

A. Symptoms and Signs

Patients have hypertension that is typically moderate. Some patients have only diastolic hypertension, without other symptoms and signs. Malignant hypertension is rare. Edema is rarely seen in primary aldosteronism. About 37% of patients have hypokalemia and may consequently have symptoms of muscular weakness (at times with paralysis simulating periodic paralysis), paresthesias with frank tetany, headache, polyuria, and polydipsia.

B. Laboratory Findings

Ideally, all hypertensive patients should be screened for hyperaldosteronism prior to treatment. Such screening can include PRA. About 20% of hypertensive patients have a low PRA, and a significant portion of these patients have primary aldosteronism. Initial screening can also include both PRA and aldosterone to determine a renin:aldosterone ratio (see below).

Plasma potassium should also be determined in all hypertensive individuals. However, hypokalemia, once thought to be the hallmark of hyperaldosteronism, is present in only 37% of affected patients: 50% of those with an adrenal adenoma and 17% of those with adrenal hyperplasia. Proper phlebotomy technique is important to avoid spurious increases in potassium. The blood should be drawn slowly with a syringe and needle (rather than a vacutainer) at least 5 seconds after tourniquet release and without fist-clenching. Plasma potassium should be measured, with the separation of plasma from cells within 30 minutes of collection. Besides hypokalemia, many patients with primary aldosteronism also have metabolic alkalosis with an elevated serum bicarbonate (HCO_3^-) concentration.

Testing for primary aldosteronism should be done for all hypertensive patients with hypokalemia, whether spontaneous or diuretic induced. But since only a minority of patients have hypokalemia, testing should also be considered for normokalemic hypertensive patients with (1) treatment-resistant hypertension (despite three drugs); (2) severe hypertension: > 160 mm Hg systolic or > 100 mm Hg diastolic; (3) early-onset hypertension; (4) low-renin hypertension; (5) hypertension with an adrenal mass; and (6) family history of aldosteronism.

For a patient to be properly tested for primary aldosteronism, certain antihypertensive medications should

ideally be held. Diuretics should be discontinued for 3 weeks. Dihydropyridine calcium channel blockers can normalize aldosterone secretion, thus interfering with the diagnosis. β -Blockers suppress PRA in patients with essential hypertension. ACE inhibitors and α -blockers are less likely to affect testing. Antihypertensive medications that have minimal effects on the plasma aldosterone:renin ratio include verapamil, hydralazine, prazosin, doxazosin, and terazosin. However, it may be impractical to hold or change antihypertensive medicines; in such cases, testing should proceed.

During the testing period, the patient should have an unrestricted high sodium intake. The patient should be out of bed for at least 2 hours and seated for 5–15 minutes before the blood draw, which should preferably be obtained between 8 am and 10 am. Renin is measured as either PRA or direct renin concentration. Serum aldosterone should ideally be measured with a tandem mass spectrometry assay.

For patients who have not been receiving diuretics for at least 3 weeks, a plasma renin that is normal or elevated makes primary aldosteronism very unlikely. However, a low plasma renin is insufficient to establish the presence of primary aldosteronism, since many patients with essential hypertension have low plasma renin activity. A plasma aldosterone:renin ratio is a sensitive screening test. Plasma aldosterone (ng/dL):PRA (ng/mL/h) ratios < 24 exclude primary aldosteronism, whereas ratios between 24 and 67 are suspicious and ratios > 67 are very suggestive of primary aldosteronism. Such elevated ratios are not diagnostic; rather, they indicate the need to document increased aldosterone secretion with a 24-hour urine collection. Another problem with the aldosterone:renin ratio is the use of different units and measurements. For aldosterone, 1 ng/dL converts to 27.7 pmol/L. For renin, a PRA of 1 ng/mL/h (12.8 pmol/L/min) converts to a direct renin concentration of 5.2 ng/L (8.2 mU/L).

When the aldosterone:renin ratio is high, a 24-hour urine collection is assayed for aldosterone, free cortisol, and creatinine. A low PRA (< 5 mcg/L/h) with a urine aldosterone over 20 mcg/24 h indicates primary aldosteronism.

Once primary aldosteronism is diagnosed, unilateral adrenal aldosteronism may be distinguished from bilateral adrenal aldosteronism by adrenal vein sampling (see below) and by further biochemical testing. Plasma may be assayed for 18-hydroxycorticosterone; a level > 100 ng/dL is seen with adrenal neoplasms, whereas levels < 100 ng/dL are nondiagnostic. In addition, a posture stimulation test may be performed, but this requires overnight hospitalization. The test is performed by drawing blood for aldosterone at 8 am while the patient is supine after overnight recumbency and again after the patient is upright for 4 hours. Patients with a unilateral adrenal adenoma usually have a baseline plasma aldosterone level > 20 ng/dL that does not rise. Patients with bilateral adrenal hyperplasia typically have a baseline plasma aldosterone level < 20 ng/dL that rises during upright posture. The accuracy of the posture stimulation test is about 85%.

C. Imaging

All patients with biochemically confirmed primary aldosteronism require a thin-section CT scan of the adrenals to screen for a rare adrenal carcinoma. In the absence of a large adrenal carcinoma, adrenal CT scanning cannot reliably distinguish unilateral from bilateral aldosterone excess, having a sensitivity of 78% and a specificity of 78% for unilateral aldosteronism. Therefore, the decision to perform a unilateral adrenalectomy should not be based solely on an adrenal CT scan. Instead, patients with primary aldosteronism should be considered for a trial of medical therapy with spironolactone or eplerenone (see below). If medical therapy is ineffective or if surgery is desired for an apparent adrenal adenoma, further evaluation for surgical candidacy should be done with laboratory testing (see above). However, since CT scanning and laboratory testing is often inconclusive, adrenal vein sampling is often required.

D. Adrenal Vein Sampling

Bilateral selective adrenal vein sampling is the most accurate way to determine whether primary aldosteronism is due to unilateral aldosterone excess, which can be treated by adrenalectomy. It is indicated only to direct the surgeon to the correct adrenal and should be performed only if surgery is contemplated. It is particularly useful for patients who are not hypokalemic, who are over age 40 years, or who have an adrenal adenoma < 1 cm diameter. It is particularly difficult to catheterize the right adrenal vein. Therefore, the venous samples are assayed for both aldosterone and cortisol during a cosyntropin (ACTH₁₋₂₄) infusion to be sure that the sampling has included both adrenal veins. The procedure has a sensitivity of 95% and a specificity of 100% but only when performed by an experienced radiologist. The complication rate is 2.5%. Risks can be minimized if the radiologist avoids adrenal venography and limits the use of contrast.

► Differential Diagnosis

The differential diagnosis of primary aldosteronism includes other causes of hypokalemia (see Chapter 21) in patients with essential hypertension, especially diuretic therapy. Chronic depletion of intravascular volume stimulates renin secretion and secondary hyperaldosteronism. Thus, it is important to discontinue diuretics and ensure adequate hydration and sodium intake when assessing a patient for primary hyperaldosteronism (see above).

Excessive ingestion of real licorice (black and derived from anise) can cause hypertension and hypokalemia. Licorice contains glycyrrhizic acid, which has a metabolite that inhibits the adrenal enzyme 11 β -hydroxysteroid dehydrogenase, thereby blocking the production of cortisol and causing accumulation of the precursor mineralocorticoid deoxycorticosterone. Oral contraceptives may increase aldosterone secretion in some patients. Renal vascular disease can cause severe hypertension with hypokalemia; PRA is high, distinguishing it from primary aldosteronism.

Excessive adrenal secretion of other corticosteroids (besides aldosterone) may also cause hypertension with

hypokalemia. This occurs with certain congenital adrenal enzyme disorders such as P450c11 deficiency (increased deoxycorticosterone with virilization and deficient cortisol) or P450c17 deficiency (increased deoxycorticosterone, corticosterone, and progesterone but deficient estradiol and testosterone). P450c17 deficiency results from a defect in the 17-hydroxylase enzyme in both the adrenal and ovarian steroidogenic pathways. Presenting signs include hypertension and ambiguous genitalia or primary amenorrhea. Urinary aldosterone secretion is less than 20 mcg/24 h and plasma renin is low in both P450c11 and P450c17 deficiencies. Primary cortisol resistance can cause hypertension and hypokalemia; renin and aldosterone are suppressed, while plasma levels of cortisol, ACTH, and deoxycorticosterone are high. Liddle syndrome is an autosomal dominant cause of hypertension and hypokalemia resulting from excessive sodium absorption from the renal tubule; renin and aldosterone levels are low. Thyrotoxicosis and familial periodic paralysis may also present with hypokalemia. Hyperaldosteronism may rarely be due to a malignant ovarian tumor.

► Complications

The incidence of cardiovascular complications from hypertension are higher in primary aldosteronism than in idiopathic hypertension. Following unilateral adrenalectomy for Conn syndrome, suppression of the contralateral adrenal may result in temporary postoperative hypoaldosteronism, characterized by hyperkalemia and hypotension.

► Treatment

Conn syndrome (unilateral aldosterone-secreting adrenal adenoma) is treated by laparoscopic adrenalectomy, though long-term therapy with spironolactone or eplerenone is an option. Bilateral adrenal hyperplasia is best treated with spironolactone or eplerenone. Spironolactone also has anti-androgen activity and frequently causes breast tenderness, gynecomastia, or reduced libido; it is given at initial doses of 12.5–25 mg once daily. Eplerenone is becoming favored for men since it does not have anti-androgen effects; it is usually given at an initial dose of 25 mg twice daily. Eplerenone is metabolized by hepatic CYP 3A4 and drugs that inhibit or compete for this enzyme may increase serum eplerenone levels excessively. Blood pressure must be monitored daily when beginning these anti-mineralocorticoid medications; significant drops in blood pressure have occurred when these drugs are added to other antihypertensives. Other antihypertensive drugs may also be required. Glucocorticoid-remediable aldosteronism is very rare but may respond well to suppression with low-dose dexamethasone.

► Prognosis

The hypertension is reversible in about two-thirds of cases but persists or returns in spite of surgery in the remainder. The prognosis is much improved by early diagnosis and treatment. Only 2% of aldosterone-secreting adrenal tumors are malignant.

PHOCHROMOCYTOMA & PARANGLIOMA

ESSENTIALS OF DIAGNOSIS

- ▶ “Attacks” of headache, perspiration, palpitations, anxiety.
- ▶ Hypertension, frequently sustained but often paroxysmal, especially during surgery or delivery.
- ▶ Elevated urinary catecholamines or their metabolites. Normal serum T_4 and TSH.

▶ General Considerations

Both pheochromocytomas and non-head-neck paragangliomas are tumors of the sympathetic nervous system. Pheochromocytomas arise from the adrenal medulla and usually secrete both epinephrine and norepinephrine. Paragangliomas (“extra-adrenal pheochromocytomas”) arise from sympathetic paraganglia, often metastasize, and secrete norepinephrine or are nonsecretory. Excessive levels of norepinephrine or neuropeptide Y cause hypertension, while epinephrine causes tachyarrhythmias. These tumors may be located in either or both adrenals or anywhere along the sympathetic nervous chain, and rarely in such aberrant locations as the mediastinum, heart, or bladder.

These rare tumors are deceptive and deadly. They are a rare cause of hypertension, being found in less than 0.3% of hypertensive individuals. The incidence is higher in patients with moderate to severe hypertension. About two to three new cases per million population are diagnosed annually. However, in autopsy cases, the incidence of pheochromocytoma is 250–1300 cases per million, indicating that most cases are not diagnosed during life.

About 25% of patients with pheochromocytomas/paragangliomas harbor germline mutations making them prone to develop the tumor. The chance of harboring a germline mutation is nearly 100% in patients with a family history of pheochromocytomas/paragangliomas and 17% in patients without any known family history of pheochromocytomas/paragangliomas.

Pheochromocytomas develop in about 20% of patients with type 2 von Hippel–Lindau (VHL) disease (hemangiomas of the retina, cerebellum, brainstem, and spinal cord; hyperparathyroidism; pancreatic cysts; endolymphatic sac tumors; cystadenomas of the adnexa or epididymis; renal cysts, adenomas, and carcinomas); inheritance is autosomal dominant. Patients with VHL develop pheochromocytomas that are less likely to be malignant or extra-adrenal,

more likely to be bilateral, and more likely to present at an early age. Pheochromocytomas that arise in patients with VHL secrete exclusively norepinephrine and its metabolite normetanephrine. Therefore, individuals who carry type 2 VHL mutations should be screened for pheochromocytoma with plasma normetanephrine levels.

MEN 2A is associated with pheochromocytomas and medullary thyroid carcinoma. *MEN 2B* is associated with pheochromocytomas, aggressive medullary thyroid carcinoma, mucosal neuromas, and marfanoid habitus. *von Recklinghausen neurofibromatosis type 1 (NF-1)* is associated with an increased risk of pheochromocytomas/paragangliomas as well as cutaneous neurofibromas, optic gliomas, vascular anomalies, hamartomas, malignant nerve sheath tumors, and smooth-bordered café au lait spots. *Familial paraganglioma* can be caused by mutations in the genes encoding succinate dehydrogenase (SDH) subunits B, C, or D. Patients with such germline mutations are more apt to have bilateral pheochromocytomas or multicentric paragangliomas.

▶ Clinical Findings

A. Symptoms and Signs

Pheochromocytomas can be lethal unless they are diagnosed and treated appropriately. They typically cause attacks or “paroxysms” that can be spontaneous or triggered by exercise, bending, lifting, emotional stress, surgery, or minor procedures. Certain drugs can precipitate attacks: monoamine oxidase (MAO) inhibitors, caffeine, nicotine, decongestants, amphetamines, cocaine, ionic intravenous contrast, and epinephrine. Bladder paragangliomas may present with paroxysms during micturition. Paroxysms typically produce hypertension and symptoms such as severe headache (80%), perspiration (70%), and palpitations (60%); other symptoms may include anxiety (50%), a sense of impending doom, or tremor (40%). Vasomotor changes during an attack cause mottled cyanosis and facial pallor; as the attack subsides, facial flushing may occur as a result of reflex vasodilation. Epinephrine secretion by an adrenal pheochromocytoma may cause episodic tachyarrhythmias, hypotension, or even syncope. Acute coronary syndrome can be caused by coronary vasoconstriction. Confusion, psychosis, seizures, transient ischemic attacks, or stroke may occur with cerebrovascular vasoconstriction or hemorrhagic stroke. Aortic aneurysms may dissect and rupture. Abdominal pain, nausea, vomiting, and even ischemic bowel can be due to splanchnic vasoconstriction. Large or hemorrhagic abdominal tumors can also cause abdominal pain. Peripheral vasoconstriction can cause Raynaud phenomenon or even gangrene. Patients may experience nervousness and irritability, increased appetite, and loss of weight. Other patients have pulmonary edema and heart failure due to cardiomyopathy. Cytokine release can cause nephrotic syndrome or acute respiratory distress syndrome (ARDS). Other manifestations can include hyperglycemia, bradycardia, constipation, and paresthesias.

Physical findings usually include hypertension (90% of patients), which may be sustained (20% of patients), sustained with paroxysms (50% of patients), or paroxysmal only (25% of patients). Postural changes in blood pressure

and pulse are often encountered, with blood pressure decreasing and pulse increasing (change of > 20 beats/min) after arising from a supine to a standing position. There may be cardiac enlargement and cardiomyopathy. Fever and elevation of basal body temperature can occur. Retinal hemorrhage or cerebrovascular hemorrhage occurs occasionally. Although most patients are symptomatic, some patients are normotensive and asymptomatic, particularly when the tumor is nonsecretory or discovered at an early stage.

Catastrophic hypertensive crisis and fatal cardiac arrhythmias can occur spontaneously or may be triggered by intravenous contrast dye or glucagon injection, needle biopsy of the mass, anesthesia, and surgical procedures.

In addition to catecholamines and their metabolites, pheochromocytomas secrete a wide range of other peptides that can sometimes cause symptoms of Cushing syndrome (ACTH), erythrocytosis (erythropoietin), or hypercalcemia (PTHrP).

B. Laboratory Findings

Plasma fractionated free metanephrines is the single most sensitive test for secretory pheochromocytomas and paragangliomas. Normal levels rule out pheochromocytoma and paraganglioma with some certainty and the work-up can usually end there. However, misleading elevations in metanephrines or normetanephrines can be caused by factors such as physical or emotional stress, sleep apnea, and MAO inhibitors. Therefore, patients with elevated plasma metanephrines or normetanephrines levels require further evaluation.

Assay of urinary fractionated metanephrines and creatinine effectively confirms most pheochromocytomas that were detected by elevated plasma fractionated metanephrines. A 24-hour urine specimen is usually obtained, although an overnight or shorter collection may be used; patients with pheochromocytomas generally have more than 2.2 mcg of total metanephrine per milligram of creatinine, and more than 135 mcg total catecholamines per gram creatinine. Urinary assay for total metanephrines is about 97% sensitive for detecting functioning pheochromocytomas. Urinary assay for vanillylmandelic acid (VMA) is about 89% sensitive and is not usually required.

Some drugs and foods can interfere with certain assays for catecholamines, and stresses can also cause misleading elevations in catecholamine excretion (Table 26–12). About 10% of hypertensive patients have a misleadingly elevated level of one or more tests.

Direct assay of epinephrine and norepinephrine in blood and urine during or following an attack is a sensitive test for pheochromocytoma associated with paroxysmal hypertension. Plasma free metanephrine concentrations may also be used. Proper, quiet collection of plasma specimens is essential.

Serum chromogranin A is elevated in 90% of patients with pheochromocytoma and the levels correlate with tumor size, being higher in patients with metastatic disease. Serum chromogranin A levels can be misleadingly elevated in patients with azotemia or hypergastrinemia, and in those treated with corticosteroids or proton pump

Table 26–12. Factors potentially causing misleading catecholamine results: High-performance liquid chromatography with electrochemical detection (HPLC-ECD).

inhibitors. Serum may also be assayed for neuron-specific enolase; high levels implicate a malignant pheochromocytoma, while normal levels are nonspecific.

Pharmacologic provocative and suppressive tests that evaluate the rise or fall in blood pressure are usually not required or recommended.

Hyperglycemia is present in about 35% of patients but is usually mild. Leukocytosis is common. The ESR is sometimes elevated. PRA may be increased by catecholamines.

Genetic testing should ideally be performed on all patients with pheochromocytoma or paraganglioma. Testing for VHL, *ret* protooncogene, and SDHB/SDHD mutations is advisable. Family members may then be screened for the specific gene mutation.

C. Imaging

1. CT and MRI scanning—Imaging should not usually replace biochemical testing, since incidental adrenal adenomas are common (2–4% of scans) and can be misleading. When a pheochromocytoma is suspected because of biochemical testing or a genetic condition predisposing to pheochromocytoma, a CT scan of the abdomen is performed, with thin sections through the adrenals. A *noncontrast CT should be followed by a CT scan using nonionic contrast, which reduces the risk of catecholamine release from a pheochromocytoma and a hypertensive crisis.* Glucagon should not be used during scanning, since it can provoke hypertensive crisis; similarly, intravenous contrast can pre-

cipitate hypertensive crisis, particularly in patients whose hypertension is uncontrolled.

MRI scanning has the advantage of not requiring intravenous contrast dye; its lack of radiation makes it the imaging of choice during pregnancy and childhood. Both CT and MRI scanning have a sensitivity of about 90% for adrenal pheochromocytoma and a sensitivity of 95% for adrenal tumors over 0.5 cm in diameter. However, both CT and MRI are less sensitive for detecting recurrent tumors, metastases, and extra-adrenal paragangliomas. If no adrenal tumor is found, the scan is extended to include the entire abdomen, pelvis, and chest.

2. Nuclear imaging—A whole-body [^{123}I]*m*-Iodobenzylguanidine (^{123}I -MIBG) scan can localize tumors with a sensitivity of 85% and a specificity of 99%. It is less sensitive for MEN 2A- or MEN 2B-related pheochromocytomas. Preoperative ^{123}I -MIBG scanning is not usually required to confirm that a unilateral adrenal mass is a pheochromocytoma in a patient with classic clinical and biochemical presentation. Preoperative whole-body ^{123}I -MIBG scanning can be useful when the CT scan cannot locate a suspected pheochromocytoma, making a paraganglioma more likely; it can also be useful when the CT scan is ambiguous for pheochromocytoma. It is prudent to perform a whole-body ^{123}I -MIBG scan about 3 months postoperatively to determine if metastatic or recurrent tumor is present. Drugs that reduce ^{123}I -MIBG uptake should be avoided, including tricyclic antidepressants and cyclobenzaprine (6 weeks), amphetamines, nasal decongestants, phenothiazines, haloperidol, diet pills, labetalol, and cocaine (2 weeks).

Somatostatin receptor imaging using ^{111}In -labeled octreotide is only 25% sensitive for detecting an adrenal pheochromocytoma. However, ^{111}In -labeled octreotide scanning is quite sensitive for detecting extra-adrenal pheochromocytomas (paragangliomas) and metastatic pheochromocytomas, sometimes locating tumors that were missed by ^{123}I -MIBG scanning.

PET scanning usually detects tumors using ^{18}F -labeled deoxyglucose (^{18}F -FDG-PET) or ^{18}F -labeled dopamine (^{18}F -DOPA-PET), and may demonstrate tumors that are not visible on ^{123}I -MIBG scanning. Combining PET scan with noncontrast CT produces a PET/CT fusion scan with exceptional sensitivity.

► Differential Diagnosis

Pheochromocytoma may be misdiagnosed as thyrotoxicosis, essential hypertension, myocarditis, glomerulonephritis or other renal lesions, toxemia of pregnancy, eclampsia, and psychoneurosis (anxiety attack). It can sometimes be mistaken for an acute abdomen.

Conditions that have manifestations similar to those of pheochromocytoma include the following: essential labile hypertension, renal hypertension, anxiety attacks, thyrotoxicosis, toxemia of pregnancy, acute intermittent porphyria, hypogonadal vascular instability (hot flushes), cocaine or amphetamine use, and clonidine withdrawal. Patients taking nonselective MAO inhibitor antidepressants can have hypertensive crisis after eating foods that contain tyramine (eg, fermented cheeses, aged wines, certain beers, fava

beans, vegemite, marmite). Patients with erythromelalgia can have hypertensive crises; their episodic painful flushing and leg swelling are relieved by cold, distinguishing this condition from pheochromocytoma. Pheochromocytomas can cause chest pain and ECG changes that mimic acute cardiac ischemia. Renal artery stenosis can cause severe hypertension and may coexist with pheochromocytoma.

False-positive testing for catecholamines and metabolites occurs in about 10% of hypertensives, but levels are usually less than 50% above normal and typically normalize with repeat testing.

► Complications

All of the complications of severe hypertension may be encountered. In addition, a catecholamine-induced cardiomyopathy may develop. Severe heart failure and cardiovascular collapse may develop in patients during a paroxysm. Sudden death may occur due to cardiac arrhythmia. ARDS has been reported. Hypertensive crises with sudden blindness or cerebrovascular accidents are not uncommon. Paroxysms may be precipitated by sudden movement, by manipulation during or after pregnancy, by emotional stress or trauma, or during surgical removal of the tumor. Decongestant medications, fluoxetine, and other selective serotonin reuptake inhibitors may induce hypertensive paroxysms and death. Occasionally, the initial manifestation of pheochromocytoma may be hypotension or even shock.

After removal of the tumor, a state of severe hypotension and shock (resistant to epinephrine and norepinephrine) may ensue with precipitation of kidney disease or myocardial infarction. Hypotension and shock may occur from spontaneous infarction or hemorrhage of the tumor.

On rare occasions, a patient dies as a result of the complications of diagnostic tests or during surgery. During surgery, pheochromocytoma cells may be seeded within the peritoneum, resulting in multifocal recurrent tumors.

► Medical Treatment

Patients must receive adequate treatment for hypertension and tachyarrhythmias prior to surgery for pheochromocytoma/paraganglioma. Patients are advised to use a portable sphyngomanometer and measure their blood pressures daily and immediately during paroxysms.

α -Blockers (prazosin or phenoxybenzamine) are typically administered preparatory to surgery. Many surgeons insist upon α -blockade preoperatively. Phenoxybenzamine is given initially in a dosage of 10 mg orally every 12 hours, increasing gradually—about every 3 days—until hypertension is controlled. Maintenance doses range from 10 mg/d to 120 mg/d. Optimal α -blockade is achieved when supine arterial pressure is below 140/90 mm Hg or as low as possible for the patient to have a standing arterial pressure above 80/45 mm Hg.

Calcium channel blockers (nifedipine ER or nicaldipine ER) are very effective and may be used with or without α -blockers. They are superior to phenoxybenzamine for long-term use, since they cause less fatigue, nasal congestion, and orthostatic hypotension. For acute hypertensive crisis (systolic blood pressure > 170 mm Hg)

a nifedipine 10-mg capsule may be chewed and swallowed. Nifedipine is quite successful for treating acute hypertension in patients with pheochromocytoma/paraganglioma, even at home; it is reasonably safe as long as the blood pressure is monitored.

β-Blockers (eg, metoprolol XL) are required by most patients after institution of α-blockade or calcium channel blockade. The use of a β-blocker as initial antihypertensive therapy has resulted in “unopposed alpha” that causes paradoxical worsening of hypertension. Labetalol has combined α- and β-blocking activity and is an effective agent but can cause paradoxical hypertension if used as the initial antihypertensive agent. Labetalol can also interfere with catecholamine determinations in some laboratories and reduces the tumor’s uptake-1, such that it must be discontinued for at least 4–7 days before diagnostic scanning with ¹²³I-MIBG or ¹⁸F-DOPA-PET or ¹³¹I-MIBG therapy.

► Surgical Treatment

Surgical removal of pheochromocytomas or abdominal paragangliomas is the treatment of choice. For surgery, a team approach—endocrinologist, anesthesiologist, and surgeon—is critically important. Laparoscopic surgery is preferred, but large and invasive tumors require open laparotomy. Patients with small familial or bilateral pheochromocytomas may undergo selective resection of the tumors, sparing the adrenal cortex; however, there is a recurrence rate of 10% over 10 years.

Prior to surgery, blood pressure control should be maintained for a minimum of 4–7 days or until optimal cardiac status is established. The ECG should be monitored until it becomes stable. (It may take a week or even months to correct ECG changes in patients with catecholamine myocarditis, and it may be prudent to defer surgery until then in such cases.) Patients must be very closely monitored during surgery to promptly detect sudden changes in blood pressure or cardiac arrhythmias.

Intraoperative severe hypertension is managed with continuous intravenous nicardipine (a short-acting calcium channel blocker), 2–6 mcg/kg/min, or nitroprusside, 0.5–10 mcg/kg/min. Prolonged nitroprusside administration can cause cyanide toxicity. Tachyarrhythmia is treated with intravenous atenolol (1 mg boluses), esmolol, or lidocaine.

Autotransfusion of 1–2 units of blood at 12 hours preoperatively plus generous intraoperative volume replacement reduces the risk of postresection hypotension caused by desensitization of the vascular α₁-receptors. Shock may therefore occur following removal of the pheochromocytoma. It is treated with intravenous saline or colloid and high doses of intravenous norepinephrine. Intravenous 5% dextrose is infused postoperatively to prevent hypoglycemia.

Surgical histopathology for pheochromocytoma/paraganglioma cannot reliably determine whether a tumor is malignant. Therefore, all pheochromocytomas and paragangliomas must be approached as possibly malignant. Even if no metastases are visible at the time of surgery, patients require lifetime follow-up. Therefore, it is essential to recheck plasma fractionated metanephrine levels postoperatively, at least 2–4 weeks after surgery and when the

patient has minimal residual pain. It is also prudent to perform a whole-body [¹²³I]mIBG scan about 3 months postoperatively, since previously undetected metastases may become visible. Thereafter, blood pressure and symptoms must be rechecked regularly for life; plasma fractionated metanephrines are also rechecked regularly, at least every 6 months for 5 years, and immediately if hypertension or symptoms recur or if metastases become evident.

For inoperable or metastatic tumors, metyrosine reduces catecholamine synthesis; the initial dosage is 250 mg four times daily, increased daily by increments of 250–500 mg to a maximum of 4 g/d. Metyrosine causes central nervous system side effects and crystalluria; hydration must be ensured. Metastatic pheochromocytomas may be treated with combination chemotherapy (eg, cyclophosphamide, vincristine, and dacarbazine) or with high doses of ¹³¹I-MIBG.

► Prognosis

The malignancy of a pheochromocytoma cannot be determined by histologic examination. A tumor is considered malignant if metastases are present; this may take many years to become clinically evident. Therefore, lifetime surveillance is required. Malignancy is more likely for paragangliomas and for large pheochromocytomas (> 7 cm in diameter). The prognosis is good for patients with smaller, benign pheochromocytomas that are resected before causing cardiovascular damage. Hypertension usually resolves after successful surgery but may persist or return in 25% of patients despite successful surgery. Although this may be essential hypertension, biochemical reevaluation is then required, looking for a second or metastatic pheochromocytoma.

Before the advent of blocking agents, the surgical mortality rate was as high as 30%, but this has rapidly decreased. With optimal management, the surgical mortality rate is less than 3%.

Patients with metastatic pheochromocytoma and paraganglioma have a 5-year survival rate of 44% after surgery; patients who have their primary tumor resected and subsequently receive high-dose [¹³¹I]mIBG therapy have been reported to have a 5-year survival rate of 75%. Patients with a heavy and increasing tumor burden and distant metastases have a worse prognosis; patients with multiple pulmonary metastases have limited survival. Those with metastases limited to the abdomen have a better prognosis. Some patients have an indolent malignancy and experience a prolonged survival.

PANCREATIC & DUODENAL NEUROENDOCRINE TUMORS*

ISLET CELL TUMORS

ESSENTIALS OF DIAGNOSIS

- ▶ Half the tumors are nonsecretory; weight loss, abdominal pain, or jaundice may be presenting signs.
- ▶ Secretory tumors cause a variety of manifestations depending on the hormones secreted.

▶ General Considerations

The pancreatic islets are composed of several types of cells, each with distinct chemical and microscopic features: the A cells (20%) secrete glucagon, the B cells (70%) secrete insulin, and the D cells (5%) secrete somatostatin or gastrin. F cells secrete “pancreatic polypeptide.” Although most pancreatic and duodenal neuroendocrine tumors arise spontaneously, they may occur as part of four different inherited disorders: multiple endocrine neoplasia type 1 (MEN 1), von Hippel-Lindau disease (VHL), neurofibromatosis 1 (NF-1) and the rare tuberous sclerosis complex (TSC).

Insulinomas are usually (about 82%) benign and secrete excessive amounts of insulin (as well as proinsulin and C-peptide), which causes hypoglycemia. The tumors may be multiple, especially in familial MEN 1—about 12% of cases (see Chapter 27).

Gastrinomas secrete excessive quantities of the hormone gastrin (as well as “big” gastrin), which stimulates the stomach to hypersecrete acid, thereby causing hyperplastic gastric rugae and peptic ulceration (Zollinger–Ellison syndrome). Most gastrinomas are benign, but some are malignant and metastasize to the liver. Gastrinomas are typically found in the duodenum (49%), pancreas (24%), or lymph nodes (11%). Sporadic Zollinger–Ellison syndrome is rarely suspected at the onset of symptoms; typically, there is a 5-year delay in diagnosis. About 22% of patients have MEN 1. MEN 1 usually presents in patients who are younger; hyperparathyroidism may occur from 14 years preceding the Zollinger–Ellison diagnosis to 38 years afterward. (See Multiple Endocrine Neoplasia, below.)

Glucagonomas are usually malignant; liver metastases are ordinarily present by the time of diagnosis. They usually secrete other hormones besides glucagon, often gastrin.

Somatostatinomas are very rare and are associated with weight loss, diabetes mellitus, malabsorption, and hypochlorhydria.

Other rare tumors secrete excessive amounts of **vasoactive intestinal polypeptide (VIP)**, a substance that causes profuse watery diarrhea (Verner–Morrison syndrome).

▶ Clinical Findings

A. Symptoms and Signs

Presenting symptoms and signs of **gastrinomas** include abdominal pain (75%), diarrhea (73%), heartburn (44%), bleeding (25%), or weight loss (17%). Endoscopy usually discovers prominent gastric folds (94%).

The 5-, 10-, and 20-year survival rates with MEN 1 are 94%, 75%, and 58%, respectively, while the survival rates for sporadic Zollinger–Ellison syndrome are 62%, 50%, and 31%, respectively. (See Chapter 15.)

Initial symptoms of **glucagonoma** often include weight loss, diarrhea, nausea, peptic ulcer, or necrolytic migratory erythema. About 35% of patients ultimately develop diabetes. The median survival is 2.8 years after diagnosis.

Islet cell tumors can secrete ectopic hormones in addition to native hormones, often in combinations producing a variety of clinical syndromes. They may secrete ACTH, producing Cushing syndrome. Secretion of serotonin can produce an atypical carcinoid syndrome manifested by pain, diarrhea, and weight loss; skin flushing occurs in only 39% of patients. Pancreatic carcinoid tumors grow slowly but usually metastasize to local and distant sites, particularly to other endocrine organs.

Islet cell tumors may be part of the syndrome of multiple endocrine adenomatosis type I (with pituitary and parathyroid adenomas).

B. Imaging

Localization of noninsulinoma pancreatic islet cell tumors and their metastases is best done with somatostatin receptor scintigraphy (SRS); SRS detects about 75% of noninsulinomas. CT and MRI are also useful. Insulinomas can usually be located preoperatively by endoscopic ultrasonography. For insulinomas, preoperative localization studies are less successful and have the following sensitivities: ultrasonography 25%, CT 25%, endoscopic ultrasonography 27%, transhepatic portal vein sampling 40%, arteriography 45%, intraoperative palpation 55%, and intraoperative pancreatic ultrasound 75%. Nearly all insulinomas can be successfully located at surgery by intraoperative palpation and ultrasound. An abdominal CT scan is usually obtained, but extensive preoperative localization procedures, especially with invasive methods, are not required. Tumors may be located in the pancreatic head or neck (57%), body (15%), or tail (19%) or in the duodenum (9%).

▶ Treatment

Direct resection of the tumor (or tumors), which often spreads locally, is the primary form of therapy for all types of islet cell neoplasm except Zollinger–Ellison syndrome, where use of high doses of a proton pump inhibitor is the therapy of choice (quadruple the usual doses). Note that serum gastrin levels tend to be high in any patient who is taking a proton pump inhibitor; hypercalcemia also stimulates gastrin release. Insulinomas are resected. However, in MEN 1, insulinomas are rarely cured, so surgery is reserved for dominant masses in such cases. Palliation of

*Diabetes mellitus and hyperglycemia are discussed in Chapter 27.

functioning malignant disease often requires both antihormonal and anticancer chemotherapy. The use of streptozocin, doxorubicin, and asparaginase, especially for malignant insulinoma, has produced some encouraging results, though these drugs are quite toxic (see Table 39–11). The hypoglycemia of insulinoma may be counteracted by verapamil or diazoxide. Octreotide LAR is useful in the therapy of islet cell tumors with the exception of insulinoma; monthly subcutaneous injections of 20–30 mg are required. Treatment with octreotide improves the symptoms of VIP but does not halt tumor growth. Symptomatic improvement with calcitonin treatment has also been reported.

The prognosis in these neoplasms is variable. The surgical complication rate is about 40%, with patients commonly developing fistulas and infections. Extensive pancreatic resection may cause diabetes mellitus. The overall 5-year survival is higher with functional tumors (77%) than with nonfunctional ones (55%) and higher with benign tumors (91%) than with malignant ones (55%).

DISEASES OF THE TESTES & MALE BREAST

MALE HYPOGONADISM

ESSENTIALS OF DIAGNOSIS

- ▶ Diminished libido and erections.
- ▶ Decreased growth of body hair.
- ▶ Testes may be small or normal in size. Serum testosterone is usually decreased.
- ▶ Serum gonadotropins (LH and FSH) are decreased in hypogonadotropic hypogonadism; they are increased in testicular failure (hypergonadotropic hypogonadism).

▶ General Considerations

Male hypogonadism is caused by deficient testosterone secretion by the testes. It may be classified according to whether it is due to (1) insufficient gonadotropin secretion by the pituitary (hypogonadotropic) or (2) pathology in the testes themselves (hypergonadotropic) (Table 26–13).

Table 26–13. Causes of male hypogonadism.

| Hypogonadotropic (Low or Normal LH) | Hypergonadotropic (High LH) |
|---|-----------------------------|
| Alcohol | Antitumor chemotherapy |
| Chronic illness | Bilateral anorchia |
| Congenital syndromes | Idiopathic |
| Constitutional delay | Klinefelter syndrome |
| Cushing syndrome | Leprosy |
| Drugs | Lymphoma |
| Estrogen-secreting tumors (testicular, adrenal) | Male climacteric |
| GnRH agonist (leuprolide) | Mumps |
| Hemochromatosis | Myotonic dystrophy |
| Hypopituitarism | Noonan syndrome |
| Hypothyroidism | Orchitis |
| Idiopathic | Radiation therapy |
| Kallmann syndrome | Sertoli cell-only syndrome |
| Ketoconazole | Testicular trauma |
| 17-Ketosteroid reductase deficiency | Tuberculosis |
| Malnourishment | Uremia |
| Marijuana | |
| Obesity (BMI > 40) | |
| Prader-Willi syndrome | |
| Prior androgens | |
| Spirolactone | |

BMI, body mass index; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

▶ Etiology

A. Hypogonadotropic Hypogonadism

A deficiency in FSH and LH may be isolated or associated with other pituitary hormonal abnormalities. (See Hypopituitarism.) Patients must be evaluated for signs of Cushing syndrome or adrenal insufficiency, growth hormone excess or deficiency, and thyroid hormone excess or deficiency.

Acquired hypogonadotropic hypogonadism may be due to pituitary or hypothalamic factors but may be idiopathic. Hyperprolactinemia (see Table 26–2) may also induce hypogonadism.

Hypogonadotropic hypogonadism can develop in men receiving GnRH agonist therapy for prostate cancer and can persist following cessation of therapy.

B. Hypergonadotropic Hypogonadism

A failure in testicular secretion of testosterone causes a rise in LH. If testicular Sertoli cell function is deficient, FSH will be elevated. Conditions that can cause testicular failure include viral infection (eg, mumps), irradiation, cancer chemotherapy, autoimmunity, myotonic dystrophy, uremia, XY gonadal dysgenesis, partial 17-ketosteroid reductase deficiency, Klinefelter syndrome, and male climacteric.

Klinefelter syndrome (47,XXY and its variants) is the most common chromosomal abnormality among males, with an incidence of about 1:500. It is caused by the expression of an abnormal karyotype, classically 47,XXY. Other forms are common, eg, 46,XY/47,XXY mosaicism, 48,XXYY, 48,XXXY, or 46,XX males.

The manifestations of Klinefelter syndrome are variable. Testes feel normal during childhood, but during adolescence they usually become firm, fibrotic, small, and nontender to palpation. Although puberty occurs at the normal time, the degree of virilization is variable. About 85% of patients have some gynecomastia at puberty.

Other common findings include tall stature and abnormal body proportions that are unusual for hypogonadal men (height greater than arm span; crown-pubis length greater than pubis-floor). Patients with multiple X or Y chromosomes are more apt to have mental deficiency and other abnormalities such as clinodactyly or synostosis. They may also exhibit problems with coordination and social skills. Other problems include a higher incidence of breast cancer, chronic pulmonary disease, varicosities of the legs, and diabetes mellitus (8% of patients); impaired glucose tolerance occurs in an additional 19% of patients.

On semen analysis, most men (about 95%) with classic Klinefelter syndrome have azoospermia, but men with 46,XY/47,XXY mosaicism may have spontaneous fertility. Also, testicular biopsy reveals sperm in up to 50% of affected patients, allowing some of them to be fertile with the use of in vitro fertilization using intracytoplasmic sperm injection (ICSI). The diagnosis is confirmed by karyotyping or by determining the presence of RNA for X-inactive-specific transcriptase (XIST) in peripheral blood leukocytes by polymerase chain reaction.

All causes of gynecomastia (see Table 26–14) must be differentiated from Klinefelter syndrome.

C. Androgen Insensitivity

Partial resistance to testosterone is a rare condition in which phenotypic males have variable degrees of apparent hypogonadism, hypospadias, cryptorchism, and gynecomastia. Serum testosterone levels are normal.

► Clinical Findings

A. Symptoms and Signs

Hypogonadism that is congenital or acquired during childhood presents as delayed puberty. Men with acquired hypogonadism have variable manifestations. Most men experience decreased libido. Others complain of erectile dysfunction, hot sweats, fatigue, or depression. Their presenting complaint may also be infertility, gynecomastia, headache, fracture, or other symptoms related to the cause or result of the hypogonadism. The patient's history often gives a clue to the cause (Table 26–13).

Physical signs associated with hypogonadism may include decreased body, axillary, beard, or pubic hair; such diminished sexual hair growth is not reliably present except after years of severe hypogonadism. Men in whom hypogonadism develops tend to lose muscle mass and gain weight due to an increase in subcutaneous fat. Examination should include measurements of arm span and height. Testicular size should be assessed with an orchidometer (normal volume is about 10–25 mL; normal length is usually over 6 cm). Testicular size may decrease but usually remains within the normal range in men with postpubertal

hypogonadotropic hypogonadism, but it may be diminished with testicular injury or Klinefelter syndrome. The testes must also be carefully palpated for masses, since Leydig cell tumors may secrete estrogen and present with hypogonadism. The testicles must be carefully examined for evidence of trauma, infiltrative lesions (eg, lymphoma), or ongoing infection (eg, leprosy, tuberculosis).

B. Laboratory Findings

The evaluation for hypogonadism begins with a morning serum testosterone or free testosterone measurement. Normal ranges for serum testosterone have been derived from nonfasting morning blood specimens, which tend to be the highest of the day. Later in the day, serum testosterone levels can be 25–50% lower. Therefore, a serum testosterone drawn fasting or late in the day may be misleadingly below the “normal range.” Serum testosterone levels in men are

highest at age 20–30 years and slightly lower at age 30–40 years; testosterone falls gradually but progressively after age 40 years. Testing for serum free testosterone is especially important for detecting hypogonadism in elderly men, who generally have high levels of SHBG. A low serum testosterone is evaluated with serum LH and FSH levels. LH and FSH tend to be high in patients with hypergonadotropic hypogonadism but low or inappropriately normal in men with hypogonadotropic hypogonadism. Patients with low gonadotropins are further evaluated for other pituitary abnormalities, including hyperprolactinemia.

Testosterone stimulates erythropoiesis in men, causing the normal red blood count range to be higher in men than in women; mild anemia is common in men with hypogonadism, with red blood counts below the normal male range. For men with long-standing male hypogonadism, bone densitometry is recommended. Men with severe osteoporosis may require treatment with bisphosphonates and vitamin D, in addition to testosterone replacement therapy. (See Osteoporosis section.)

Most radioimmunoassays and ELISA for testosterone are inaccurate below serum testosterone levels of 300 ng/dL. The more accurate testosterone assays rely upon extraction and chromatography, followed by mass spectrometry or immunoassay. Free testosterone is best measured by calculation, using accurate assays for testosterone and SHBG.

1. Hypogonadotropic hypogonadism—A serum PRL determination is obtained but may be elevated for many reasons (see Table 26–2). Men with gynecomastia may be screened for partial 17-ketosteroid reductase deficiency with serum determinations for androstenedione and estrone, which are elevated in this condition. X-linked congenital adrenal hypoplasia is a rare condition in which a *DAX-1* gene mutation causes hypogonadotropic hypogonadism and azoospermia, which usually presents in adolescence; the associated primary adrenal insufficiency usually presents in childhood, but it may remain undiagnosed into adulthood. The serum estradiol level may be elevated in patients with cirrhosis and in rare cases of estrogen-secreting tumors (testicular Leydig cell tumor or adrenal carcinoma). Men with no discernible definite cause for hypogonadotropic hypogonadism should be screened for hemochromatosis and have an MRI of the pituitary and hypothalamic region to look for a tumor or other lesion. (See Hypopituitarism.)

2. Hypergonadotropic hypogonadism—Men with hypergonadotropic hypogonadism have low serum testosterone levels with a compensatory increase in FSH and LH. Klinefelter syndrome can be confirmed by karyotyping or by measurement of leukocyte XIST. Testicular biopsy is usually reserved for younger patients in whom the reason for primary hypogonadism is unclear.

► Treatment

Testosterone replacement is the usual treatment for hypogonadism. It is prudent to screen older men for prostate cancer before testosterone therapy is begun. Testosterone

helps reverse sexual dysfunction and muscle atrophy. Men with Klinefelter syndrome have a reduced risk of developing verbal fluency problems if testosterone therapy is begun at the time of normal puberty.

Topical testosterone gel is the preferred method for administering testosterone. Topical 1% testosterone gel is commercially available as AndroGel or Testim (2.5-g and 5-g packets); AndroGel is odorless, while Testim has a musky odor. The starting dose is 5 g (50 mg testosterone) applied once daily to clean, dry skin of the shoulders, upper arms, or abdomen. The skin serves as a reservoir that slowly releases about 10% of the testosterone into the blood; serum testosterone levels reach a steady state in 1–3 days. The gel should not be applied to the genitals. The entire contents of a packet are squeezed onto the palm and then immediately applied. After the application of testosterone gel, the hands should be washed. The application site should be allowed to dry for 5–10 minutes before donning a shirt to prevent the gel from rubbing off the skin. A shirt must be worn during contact with women or children to prevent transfer of testosterone to them. The serum testosterone level should be determined about 14 days after starting therapy; if the level remains below normal or the clinical response is inadequate, the daily dose may be increased to 7.5 g or 10 g.

Testosterone transdermal systems (skin patches) are available in two formulations for application to nongenital skin. Testoderm II, 5 mg/d leaves a sticky residue but causes little skin irritation. Androderm adheres more tightly to the skin but may cause more skin irritation. Both produce reliable serum levels of testosterone that are somewhat lower than those achieved with injections. The patch systems also suffer from being rather inconvenient and expensive.

Hypogonadism may also be treated with parenteral testosterone (enanthate or cypionate). The usual dose is about 300 mg intramuscularly in the gluteal area every 3 weeks or 200 mg every 2 weeks. The preparation is oil based and is usually given in the gluteal area. The dose is adjusted according to the patient's response.

Oral androgen preparations include methyltestosterone and fluoxymesterone. These oral preparations have rarely caused liver tumors or peliosis hepatis with long-term use. Cholestatic jaundice occurs in 1–2% of patients but usually remits after the medication is discontinued. The oral androgens are not as effective as parenteral testosterone.

Men with mosaic Klinefelter syndrome (eg, 46,XY/47,XXY) may be fertile. However, men with nonmosaic Klinefelter syndrome (eg, 47,XXY) are usually azoospermic; fertility may be achieved by testicular sperm retrieval and in vitro intracytoplasmic sperm injection (ICSI) into an ovum.

Testosterone replacement therapy may cause a minimal reduction in serum HDL levels and has no effect on LDL levels; testosterone therapy has never been demonstrated to increase the incidence of cardiovascular disease, myocardial infarction, or stroke.

Testosterone therapy can aggravate benign prostatic hypertrophy (BPH). However, aggravation of voiding problems is uncommon. In men with BPH, finasteride may be coadministered with testosterone to reduce prostate size. The incidence of prostate cancer does not appear to be

increased by testosterone therapy. However, testosterone therapy is contraindicated in the presence of active prostate cancer. In men over age 50 years, serum prostate-specific antigen (PSA) levels should be monitored before testosterone therapy as well as each year during therapy. Hypogonadal men who have had a prostatectomy for low-grade prostate cancer, and who have remained in complete remission for several years, may have testosterone therapy given cautiously while monitoring sensitive serum PSA levels.

Erythrocytosis develops in some men who are treated with testosterone. Erythrocytosis is more common with intramuscular injections of testosterone enanthate than with transcutaneous testosterone. It is particularly common in men receiving intramuscular testosterone enanthate in doses of 200 mg intramuscularly every 2 weeks. However, no increase in the incidence of thromboembolic events has been reported.

Testosterone therapy tends to aggravate sleep apnea in older men, likely through central nervous system effects. Surveillance for sleep apnea is recommended during testosterone therapy and a formal evaluation with nocturnal pulse oximetry recording is recommended for all high-risk patients. A man's risk for sleep apnea may be approximated by determining an "adjusted neck circumference" with the following algorithm: Measure the neck circumference in centimeters; add 4 cm if the patient is hypertensive; add 3 cm if the patient snores; add 3 cm if the patient chokes or gasps most nights. Adjusted neck circumference: < 43 = low risk; 43–48 = moderate risk; > 48 = high risk.

Men who are treated with testosterone frequently experience some increase in acne, which is usually mild and tolerated; topical antiacne therapy or a reduction in testosterone replacement dosage may be required. Increases in intraocular pressure have occurred during testosterone therapy. During the initiation of testosterone replacement therapy, gynecomastia develops in some men, which usually is mild and tends to resolve spontaneously; switching from testosterone injections to testosterone transdermal gel may help this condition.

► Prognosis of Male Hypogonadism

If hypogonadism is due to a pituitary lesion, the prognosis is that of the primary disease (eg, tumor, necrosis). The prognosis for restoration of virility is good if testosterone is given.

Rosner W et al. Position statement: utility, limitations, and pitfalls in measuring testosterone: an Endocrine Society position statement. *J Clin Endocrinol Metab.* 2007 Feb;92(2):405–13. [PMID: 17090633]

TESTICULAR TUMORS IN ADULTS (See Also Chapter 39)

About 95% of testicular tumors are germ cell tumors (seminomas or nonseminomas). Seminomas do not pro-

duce α -fetoprotein, but about 5–10% produce some hCG. Nonseminomas, on the other hand, produce increased serum levels of one or both of these markers in about 90% of cases. Men with liver disease may have misleadingly high levels of α -fetoprotein. Most germ cell tumors are sensitive to cisplatin-based combined chemotherapy. Sperm banking is advised.

About 5% of testicular tumors are Leydig or Sertoli cell tumors. Leydig cell tumors tend to produce estrogen (75%) and cause gynecomastia and impotence on that basis; they may sometimes produce androgens that can cause pseudoprecocious puberty in boys. Sertoli cell tumors may also produce estrogen (30%) with feminization; gynecomastia may be due to hCG secretion (25%).

Some testicular tumors may be small and nonpalpable yet may secrete sufficient amounts of hCG or estrogen to cause gynecomastia or impotence. Testicular ultrasound may help reveal small tumors.

After unilateral orchiectomy for testicular cancer, an elevated FSH level prior to further treatment indicates a patient at higher risk for cancer in the remaining testis.

CRYPTORCHISM

One or both testes may be absent from the scrotum at birth in about 20% of premature or low-birth-weight male infants and in 3–6% at full term infants. Cryptorchism is found in 1–2% of males after 1 year of age but must be distinguished from retractile testes, which require no treatment. Cryptorchism should be corrected before age 12–24 months in an attempt to reduce the risk of infertility, which occurs in up to 75% of men with bilateral cryptorchism and in 50% of men with unilateral cryptorchism. It is not clear, however, whether such early orchiopexy improves ultimate fertility. Some patients have underlying hypogonadism.

The ultimate incidence of significant testicular neoplasia is about 0.002% in normal males, 0.06% in cryptorchid males, and up to 5% in patients with intra-abdominal testes.

If the testes are not palpable, ultrasound or MRI can be used to locate them. Alternatively, hCG, 1500 units intramuscularly daily for 3 days, causes a significant rise in testosterone if the testes are present. Therapy with hCG results in a testicular descent rate of about 25%.

Orchiopexy decreases the risk of neoplasia when performed before 10 years of age. Orchiectomy after puberty is an option for intra-abdominal testes.

GYNECOMASTIA

ESSENTIALS OF DIAGNOSIS

- Enlargement of the male breast, often asymmetric or unilateral.

- ▶ Glandular gynecomastia characterized by tenderness.
- ▶ Fatty gynecomastia typically nontender.
- ▶ Must be distinguished from tumors or mastitis.

▶ General Considerations

Gynecomastia refers to a female-appearing male breast. Pubertal gynecomastia is common and the swelling usually subsides spontaneously within a year. Gynecomastia is particularly common in teenagers who are very tall or overweight. Gynecomastia develops in about 50% of athletes who abuse androgens and anabolic steroids. It is seen in Klinefelter syndrome, which affects 1:500 men. (See section on Klinefelter syndrome.) Gynecomastia can develop in HIV-infected patients treated with highly active antiretroviral therapy (HAART), especially in men receiving efavirenz or didanosine; breast enlargement resolves spontaneously in 73% of patients within 9 months. Gynecomastia is common among elderly men, particularly when there is associated weight gain. However, it can be the first sign of a serious disorder. Patients with Peutz–Jeghers syndrome are prone to development of gynecomastia caused by testicular tumors.

The causes of gynecomastia are multiple and diverse (Table 26–14).

▶ Clinical Findings

A. Symptoms and Signs

Gynecomastia is graded according to severity: I, mild; II, moderate; III, severe. Fatty gynecomastia is usually diffuse and nontender. Glandular enlargement beneath the areola may be tender. Pubertal gynecomastia is characterized by tender discoid enlargement of breast tissue 2–3 cm in diameter beneath the areola.

B. Laboratory Findings

Laboratory measurements of plasma levels of PRL (see Hyperprolactinemia) and the β -subunit of hCG (β -hCG). Detectable levels of β -hCG implicate a testicular tumor (germ cell or Sertoli cell) or other malignancy (usually lung or liver). Detectable low levels of serum β -hCG (< 5 mU/mL) may be reported in men with primary hypogonadism and high serum LH levels if the assay for β -hCG cross-reacts with LH. Measurements of plasma testosterone and LH are valuable in the diagnosis of primary or secondary hypogonadism. A low testosterone and high LH are seen in primary hypogonadism. High testosterone levels plus high LH levels characterize partial androgen resistance. Serum estradiol is determined but is usually normal; increased levels may result from testicular tumors, increased β -hCG, liver disease, obesity, adrenal tumors (rare), true hermaphroditism (rare), or gain of function mutations affecting the aromatase gene (rare). Many estrogens and substances with estrogenic activity are not detected by estradiol assays. Serum TSH (sensitive) and FT₄ levels are also determined. A karyotype (for Klinefelter syndrome) is obtained in men with persistent gynecomastia without obvious cause.

Investigation of unclear cases should include a chest radiograph to search for metastatic or bronchogenic carcinoma. Needle biopsy with cytologic examination may be performed on suspicious areas of male breast enlargement (especially when unilateral or asymmetric) to distinguish gynecomastia from tumor or mastitis.

▶ Treatment

Pubertal gynecomastia often resolves spontaneously within 1–2 years. Drug-induced gynecomastia resolves after the offending drug is removed. Spironolactone can be stopped, with substitution of a selective aldosterone antagonist such as eplerenone. Patients with painful or persistent (> 12 months) gynecomastia may be treated with a 3- to 9-month course of a SERM (eg, raloxifene or tamoxifen). SERM therapy is much more effective for glandular (“lumpy”) gynecomastia than for diffuse fatty gynecomastia. There is some evidence that raloxifene, taken orally in a dose of 60 mg daily, may be the more effective drug. Aromatase inhibitors (eg, letrozole, anastrozole, or exemestane) are marginally effective and should not ordinarily be used for adolescent boys, since long-term therapy may prevent epiphyseal fusion. Surgical correction is reserved for patients with persistent or severe gynecomastia, since results are often disappointing. Endoscopically assisted transaxillary liposuction and subcutaneous mastectomy may produce acceptable results. Generally, it is prudent to treat patients for gynecomastia only when it becomes a troubling and continuing problem for them.

AMENORRHEA & MENOPAUSE (SEE ALSO CHAPTER 18)

PRIMARY AMENORRHEA

Menarche ordinarily occurs between ages 11 and 15 years (average in the United States: 12.7 years). The failure of any menses to appear is termed “primary amenorrhea,” and evaluation is commenced (1) at age 14 years if neither menarche nor breast development has occurred or if height is in the lowest 3%, or (2) at age 16 years if menarche has not occurred.

▶ Etiology of Primary Amenorrhea

The causes of primary amenorrhea include hypothalamic-pituitary causes, hyperandrogenism, ovarian causes, pseudohermaphroditism, uterine causes, and pregnancy.

A. Hypothalamic-Pituitary Causes (with Low or Normal FSH)

A genetic deficiency of GnRH and gonadotropins may be isolated or associated with other pituitary deficiencies or diminished olfaction (Kallmann syndrome). Hypothalamic

lesions, particularly craniopharyngioma, may be present. Pituitary tumors may be nonsecreting or may secrete PRL or GH. Cushing syndrome may be caused by corticosteroid treatment, a cortisol-secreting adrenal tumor, or an ACTH-secreting pituitary tumor. Hypothyroidism can delay adolescence. Head trauma or encephalitis can cause gonadotropin deficiency. Primary amenorrhea may also be caused by constitutional delay of adolescence, organic illness, vigorous exercise (eg, ballet dancing, running), stressful life events, dieting, or anorexia nervosa; however, these conditions should not be assumed to account for amenorrhea without a full physical and endocrinologic evaluation. (See section on Hypopituitarism.)

B. Hyperandrogenism (with Low or Normal FSH)

Excess testosterone may be secreted by adrenal tumors or by adrenal hyperplasia caused by steroidogenic enzyme defects such as P450c21 deficiency (salt-wasting) or P450c11 deficiency (hypertension). Ovarian tumors or polycystic ovaries may also secrete excess testosterone. Androgenic steroids may also cause this syndrome.

C. Ovarian Causes (with High FSH)

Gonadal dysgenesis (Turner syndrome and variants; see below) is a frequent cause of primary amenorrhea. Ovarian failure due to autoimmunity is a common cause. Rare deficiencies in certain ovarian steroidogenic enzymes are causes of primary hypogonadism without virilization: 3 β -hydroxysteroid dehydrogenase deficiency (adrenal insufficiency with low serum 17-hydroxyprogesterone) and P450c17 deficiency (hypertension and hypokalemia with high serum 17-hydroxyprogesterone). A whole-body deficiency in P450 aromatase (P450arom) activity produces female hypogonadism associated with polycystic ovaries, tall stature, osteoporosis, and virilization.

D. Pseudohermaphroditism (with High LH)

An enzymatic defect in testosterone synthesis may present as a sexually immature phenotypic girl with primary amenorrhea. Complete androgen resistance (testicular feminization) presents as a phenotypic young woman without sexual hair but with normal breast development and primary amenorrhea. In both cases, the uterus is absent and testes are intra-abdominal or cryptorchid. Intra-abdominal testes are surgically resected. Such patients are treated as normal but infertile, hypogonadal women.

E. Uterine Causes (with Normal FSH)

Congenital absence or malformation of the uterus may be responsible for primary amenorrhea, as may an unresponsive or atrophic endometrium. An imperforate hymen is occasionally the reason for the absence of visible menses.

F. Pregnancy (with High hCG)

Pregnancy may be the cause of primary amenorrhea even when the patient denies ever having had sexual intercourse.

► Clinical Findings

A. Symptoms and Signs

Patients with primary amenorrhea require a thorough history and physical examination to look for signs of the conditions noted above. Headaches or visual field abnormalities implicate a hypothalamic or pituitary tumor. Signs of pregnancy may be present. Blood pressure abnormalities, acne, and hirsutism should be noted. Short stature may be seen with an associated GH or thyroid hormone deficiency. Short stature with manifestations of gonadal dysgenesis indicates Turner syndrome (see below). Olfaction testing screens for Kallmann syndrome. Obesity and short stature may be signs of Cushing syndrome. Tall stature may be due to eunuchoidism or gigantism. Hirsutism or virilization suggests excessive testosterone.

An external pelvic examination plus a rectal examination should be performed to assess hymenal patency and the presence of a uterus.

B. Laboratory Findings

The initial endocrine evaluation should include serum determinations of FSH, LH, PRL, testosterone, TSH, FT₄, and hCG (pregnancy test). Patients who are virilized or hypertensive require serum electrolyte determinations and further hormonal evaluation. Girls with low-normal FSH and LH—especially those with high PRL levels—are evaluated by MRI of the hypothalamus and pituitary. Girls who have a normal uterus and high FSH without the classic features of Turner syndrome may require a karyotype to diagnose X chromosome mosaicism.

► Treatment

Treatment of primary amenorrhea is directed at the underlying cause. Girls with permanent hypogonadism are treated with ERT (see below).

Torstveit MK et al. Participation in leanness sports but not training volume is associated with menstrual dysfunction: a national survey of 1276 elite athletes and controls. *Br J Sports Med.* 2005 Mar;39(3):141–7. [PMID: 15728691]

SECONDARY AMENORRHEA & MENOPAUSE

Secondary amenorrhea is defined as the absence of menses for 3 consecutive months in women who have passed menarche. Menopause is defined as the terminal episode of naturally occurring menses; it is a retrospective diagnosis, usually made after 6 months of amenorrhea.

► Etiology

The causes of secondary amenorrhea include pregnancy, hypothalamic-pituitary causes, hyperandrogenism, uterine causes, premature ovarian failure, and menopause.

A. Pregnancy (High hCG)

Pregnancy is the most common cause for secondary amenorrhea in women of childbearing age. The differential diag-

nosis includes rare ectopic secretion of hCG by a choriocarcinoma or bronchogenic carcinoma.

B. Hypothalamic-Pituitary Causes (with Low or Normal FSH)

The hypothalamus must release GnRH in a pulsatile manner for the pituitary to secrete gonadotropins. GnRH pulses occurring more than once per hour favor LH secretion, while less frequent pulses favor FSH secretion. In normal ovulatory cycles, GnRH pulses in the follicular phase are rapid and favor LH synthesis and ovulation; ovarian luteal progesterone is then secreted that slows GnRH pulses, causing FSH secretion during the luteal phase. Most women with hypothalamic amenorrhea have a persistently low frequency of GnRH pulses.

Secondary "hypothalamic" amenorrhea may be caused by stressful life events such as school examinations or leaving home. Such women usually have a history of normal sexual development and irregular menses since menarche. Amenorrhea may also be the result of strict dieting, vigorous exercise, organic illness, or anorexia nervosa. Intrathecal infusion of opioids causes amenorrhea in most women. These conditions should not be assumed to account for amenorrhea without a full physical and endocrinologic evaluation. Young women in whom the results of evaluation and progestin withdrawal test are normal have noncyclic secretion of gonadotropins resulting in anovulation. Such women typically recover spontaneously but should have regular evaluations and a progestin withdrawal test about every 3 months to detect loss of estrogen effect.

PRL elevation due to any cause (see section on hyperprolactinemia) may cause amenorrhea. Pituitary tumors or other lesions may cause hypopituitarism. Corticosteroid excess of any cause suppresses gonadotropins.

C. Hyperandrogenism (with Low-Normal FSH)

Elevated serum levels of testosterone can cause hirsutism, virilization, and amenorrhea. In PCOS, GnRH pulses are persistently rapid, favoring LH synthesis with excessive androgen secretion; reduced FSH secretion impairs follicular maturation. Progesterone administration can slow the GnRH pulses, thus favoring FSH secretion that induces follicular maturation. Rare causes include adrenal P450c21 deficiency, ovarian or adrenal malignancies, ectopic ACTH secretion by a malignancy, and Cushing disease. Anabolic steroids also cause amenorrhea.

D. Uterine Causes (with Normal FSH)

Infection of the uterus commonly occurs following delivery or D&C but may occur spontaneously. Endometritis due to tuberculosis or schistosomiasis should be suspected in endemic areas. Endometrial scarring may result, causing amenorrhea (Asherman syndrome). Such women typically continue to have monthly premenstrual symptoms. The vaginal estrogen effect is normal.

E. Premature Ovarian Failure (with High FSH)

This refers to primary hypogonadism that occurs before age 40 years. It affects about 1% of women. About 30% of

such cases are due to autoimmunity against the ovary. About 8% of cases are due to X chromosome mosaicism. Other causes include surgical bilateral oophorectomy, radiation therapy for pelvic malignancy, and chemotherapy. Women who have undergone hysterectomy are prone to premature ovarian failure even though the ovaries were left intact. Myotonic dystrophy, galactosemia, and mumps oophoritis are additional causes. Other cases may be familial or idiopathic. Ovarian failure is usually irreversible.

F. Menopause (with High FSH)

"Climacteric" is defined as the period of natural physiologic decline in ovarian function, generally occurring over about 10 years. By about age 40 years, the remaining ovarian follicles are those that are the least sensitive to gonadotropins. Increasing titers of FSH are required to stimulate estradiol secretion. Estradiol levels may actually rise during early climacteric.

The normal age for menopause in the United States ranges between 48 and 55 years, with an average of about 51.5 years. Serum estradiol levels fall and the remaining estrogen after menopause is estrone, derived mainly from peripheral aromatization of adrenal androstenedione. Such peripheral production of estrone is enhanced by obesity and liver disease. Individual differences in estrone levels partly explain why the symptoms noted above may be minimal in some women but severe in others.

► Clinical Findings

A. Symptoms and Signs

All women with amenorrhea require a complete history and physical examination. Nausea and breast engorgement are typical signs of early pregnancy. Headache or visual field abnormalities are seen with pituitary or hypothalamic tumors. Complaints of thirst and polyuria require evaluation; diabetes insipidus implicates a hypothalamic lesion. Goiter may be due to hyperthyroidism. Weight loss, diarrhea, or skin darkening may indicate adrenal insufficiency. Weight loss with a distorted body image implicates anorexia nervosa. The breasts are examined carefully for galactorrhea, a common sign of hyperprolactinemia. Hirsutism or virilization may be a sign of hyperandrogenism. Manifestations of hypercortisolism (eg, weakness, psychiatric changes, hypertension, central obesity, hirsutism, thin skin, ecchymoses) may indicate alcoholism or Cushing syndrome. Signs of acromegaly or gigantism may also indicate a pituitary tumor. Signs of systemic illness (eg, cirrhosis, kidney disease) should be appreciated. Various drugs may elevate PRL and cause amenorrhea (see section on Hyperprolactinemia). Needle tracks may indicate heroin or amphetamine abuse.

Psychological symptoms of "climacteric" may include depression and irritability. Women may experience fatigue, insomnia, headache, diminished libido, or rheumatologic symptoms. Vasomotor instability (hot flashes) is experienced by 80% of women, lasting seconds to many minutes. Hot flashes with drenching sweats may be most severe at night or may be triggered by emotional stress. Some women continue to menstruate for many months despite symp-

toms of estrogen deficiency. The acute symptoms of estrogen deficiency noted above tend to decline in severity within several years after menopause. However, about 35% of women have symptoms for more than 5 years. The late manifestations of estrogen deficiency include urogenital atrophy with vaginal dryness and dyspareunia; dysuria, frequency, and incontinence may occur. Increased bone osteoclastic activity increases the risk for osteoporosis and fractures. The skin becomes more wrinkled. Increases in the LDL:HDL cholesterol ratio cause an increased risk for arteriosclerosis.

A careful pelvic examination is always required to check for uterine or adnexal enlargement and to obtain a Papanicolaou smear and a vaginal smear for assessment of estrogen effect. Various life stresses, vigorous exercise, and “crash” dieting all predispose to amenorrhea; however, such factors should not be assumed to account for amenorrhea without a complete workup to screen for other causes.

B. Laboratory Findings

Since pregnancy is the most common cause of amenorrhea, women of childbearing age are immediately screened with a serum or urine hCG (pregnancy test). An elevated hCG overwhelmingly indicates pregnancy; false-positive testing may occur very rarely with ectopic hCG secretion (eg, choriocarcinoma or bronchogenic carcinoma). Women without an elevated hCG receive further laboratory evaluation including serum PRL, FSH, LH, TSH, and plasma potassium. Hyperprolactinemia or hypopituitarism (without obvious cause; see section on Hypopituitarism) should prompt an MRI study of the pituitary region. Routine testing for kidney and liver function (eg, BUN, serum creatinine, bilirubin, alkaline phosphatase, and alanine aminotransferase) is also performed. A serum testosterone level is obtained in hirsute or virilized women. Patients with manifestations of hypercortisolism receive a 1-mg overnight dexamethasone suppression test for initial screening (see section on Cushing syndrome). Nonpregnant women without any laboratory abnormality may receive a 10-day course of a progestin (eg, medroxyprogesterone acetate, 10 mg/d); absence of withdrawal menses typically indicates a lack of estrogen or a uterine abnormality.

▶ Treatment

Therapy of symptomatic hypogonadism generally consists of ERT (see below). Slow, deep breathing can ameliorate hot flashes. For women with severe hot flashes who cannot take estrogen, gabapentin is quite effective in oral doses titrated up to 800 mg every 8 hours; gabapentin is frequently associated with side effects such as fatigue, headache, dizziness, and cognitive impairment. Tamoxifen and raloxifene offer bone protection but aggravate hot flashes. Treatment or prevention of postmenopausal osteoporosis with bisphosphonates such as alendronate, risedronate, or intravenous zoledronic acid (see section on Osteoporosis) is another therapeutic option. Women with low serum testosterone levels may experience hypoactive sexual desire disorder (HSDD) that may respond to low-dose testosterone replacement.

▶ Estrogen Replacement Therapy

The Women’s Health Initiative (WHI) monitored 16,606 postmenopausal women in the United States in a prospective, double-blinded, placebo-controlled study of postmenopausal HRT. A control group of women taking a daily placebo was compared with (1) women receiving daily conventional-dose oral combined HRT (conjugated equine estrogens [CEE] 0.625 mg/d with medroxyprogesterone acetate [MPA] 2.5 mg/d) and (2) women, having had a hysterectomy, receiving only CEE 0.625 mg/d.

The WHI risk–benefit findings (described below) have dramatically changed postmenopausal HRT. To reduce the risks of HRT, lower-dose estrogen regimens are preferred over conventional-dose therapy. Estrogen preparations other than CEE are increasingly favored. Transdermal and vaginal estrogen preparations are widely preferred over oral estrogen replacement. Also, the potential adverse effects of progestins are now recognized, such that women taking very low-dose estrogen replacement may receive progestin therapy only periodically, if at all. For moderate to high-dose estrogen therapy, progestins are being used in lower doses. Also, clinicians are now tending to prescribe progestins other than MPA or progesterone-eluting intrauterine devices. **Oral estrogen preparations** include CEEs (0.3, 0.45, 0.625, 0.9, and 1.25 mg), ethinyl estradiol (20 and 50 mcg), estradiol (0.5, 1, 1.5, and 2 mg), estropipate (0.75, 1.5, 3, and 6 mg), plant-derived esterified estrogens (eg, Menest, Estratab, 0.3, 0.625, and 2.5 mg), and synthetic estrogens (eg, Cenestin, 0.3, 0.625, 0.9, and 1.25 mg).

Oral estrogen plus progestin preparations include CEE with MPA (Prempro 0.3/1.5, 0.45/1.5, 0.625/2.5, and 0.625/5), CEE for 14 days cycled with CEE plus MPA for 14 days (Premphase 0.625, 0.625/5), estradiol with norethindrone acetate (Activella 1/0.5), ethinyl estradiol with norethindrone acetate (Femhrt 1/5, 5 mcg/1 mg/tablet), and estradiol with norgestimate (Ortho-Prefest, sequences of estradiol 1 mg/d for 3 days, alternating with a combination of 1 mg estradiol/0.09 mg norgestimate daily for 3 days). Oral contraceptives can also be used for combined HRT.

Transdermal estradiol: Estradiol can be delivered systemically with different transdermal systems. Because transdermal absorption of estradiol is somewhat variable, this delivery method will not work for all women.

1. Transdermal systems with estradiol mixed with adhesive: These systems tend to cause minimal skin irritation. Of the following preparations, the Vivelle-Dot patches are the smallest and least obtrusive. Available preparations include Esclim, Vivelle, and Vivelle-Dot (0.025, 0.0375, 0.05, 0.075, or 0.1 mg/d), replaced twice weekly; Alora (0.025, 0.05, 0.075, or 0.1 mg/d), replaced twice weekly; Climara (0.025, 0.0375, 0.05, 0.06, 0.075, or 0.1 mg/d), replaced weekly; FemPatch (0.025 mg/d), replaced weekly; and Menostar (0.014 mg/d), replaced weekly. This type of estradiol skin patch can be cut in half and applied to the skin without proportionately greater loss of potency.

2. Transdermal systems with estradiol in a drug reservoir: These systems cause significant skin irritation in some women. Available preparations include Estraderm (0.05 or 0.1 mg/d), replaced twice weekly.

3. Transdermal systems with estradiol (E) and norethindrone acetate (NA) mixed with adhesive: Available preparations include Combipatch (0.05 mg/d E and 0.14 mg/d NA or 0.05 mg/d E and 0.25 mg/d NA), replaced twice weekly. The addition of a progestin increases the likelihood of side effects compared with therapy with estrogen alone.

4. Transdermal estradiol gel (EstroGel, 0.6%) is available in a metered-dose dispenser that delivers 1.25 g estradiol per actuation. The gel is applied to one arm from the wrist to the shoulder daily after bathing. To avoid spreading the estradiol to others, the hands should be washed and precautions taken to avoid prolonged skin contact with children. Application of sunscreen prior to estradiol gel has been reported to *increase* the transdermal absorption of estradiol.

Vaginal estrogen: Urogenital atrophy commonly develops in postmenopausal women and can cause dryness of the vagina, genital itching, burning, and dyspareunia. Urinary symptoms can include urgency and dysuria. Vaginal estrogen is intended to deliver estrogen directly to local tissues in an effort to reduce these symptoms, while minimizing systemic estrogen exposure. Some estrogen is absorbed systemically and can relieve menopausal symptoms. Systemically absorbed estrogen avoids first-pass liver metabolism, causing less hypertriglyceridemia and prothrombotic effects than oral estrogen. Manufacturers recommend that these preparations be used for only 3–6 months in women with an intact uterus, since vaginal estrogen can cause endometrial proliferation. However, most clinicians use them for longer periods. Vaginal estrogen can be administered in three different ways:

1. Estrogen vaginal creams: These creams are administered intravaginally with a measured-dose applicator daily for 2 weeks for atrophic vaginitis, then administered one to three times weekly. Available preparations include CEEs (Premarin, 0.626 mg/g cream), 0.25–0.5 g cream vaginally; dienestrol (Ortho Dienestrol, 10 mg/g cream), 0.25–0.5 g cream vaginally; estradiol (Estrace, 0.1 mg/g cream), 1 g cream vaginally; and estropipate (Ogen, 1.5 mg/g cream), 0.25–0.5 g vaginally.

2. Estradiol vaginal tablets: These tablets are sold prepackaged in a disposable applicator and can be administered deep intravaginally daily for 2 weeks for atrophic vaginitis, then twice weekly. The tablets dissolve into a gel that gradually releases estradiol. Available preparations include vaginal estradiol tablets (Vagifem, 25 mcg/tablet).

3. Estradiol vaginal rings: These rings are inserted manually into the upper third of the vagina, worn continuously, and replaced every 90 days. Only a small amount of the released estradiol enters the systemic circulation. Vaginal rings do not usually interfere with sexual intercourse. If a ring is removed or descends into the introitus, it may be washed in warm water and reinserted. Available preparations include Estring (2 mg estradiol/ring, releasing 0.0075 mg/d) and Femring (12.4 mg estradiol/ring, releasing 0.05 mg/d, or 24.8 mg estradiol/ring, releasing 0.10 mg/d).

Oral progestins: For a woman with an intact uterus, long-term conventional-dose unopposed systemic estrogen therapy can cause endometrial hyperplasia, which typically results in dysfunctional uterine bleeding (DUB)

and can rarely lead to endometrial cancer. Progestin therapy transforms proliferative into secretory endometrium, causing a menses when given intermittently or no bleeding when given continuously.

The type of progestin preparation, its dosage, and the timing of administration may be tailored to the given situation. Progestins may be given daily, monthly, or at longer intervals. When given episodically, progestins are usually administered for 7–14 day periods. Progestins are available in different formulations: Micronized progesterone (Prometrium, 100 mg/capsule), medroxyprogesterone acetate (Provera, Amen, Cycrin; 2.5, 5.0, and 10 mg/scored tablet), norethindrone acetate (Aygestin, 5 mg/tablet), and norethindrone (Micronor, Nor-QD; 0.35 mg/tablet).

Topical progesterone (20–50 mg/d) may reduce hot flushes in women who are intolerant to oral HRT. It may be applied to the upper arms, thighs, or inner wrists daily. It may be compounded as micronized progesterone 250 mg/mL in a transdermal gel. Its effects upon the breast and endometrium are unknown.

Progesterone-releasing intrauterine devices: Progesterone-releasing intrauterine devices can be useful for women receiving ERT, since they can reduce the incidence of DUB and endometrial carcinoma without exposing women to the significant risks of systemic progestins.

Benefits of ERT: Estrogen replacement without progestin (unopposed): Surprisingly, the WHI study found that postmenopausal women who received conventional-dose estrogen-only therapy had a reduced risk for breast cancer (seven fewer cases/year per 10,000 women) compared with a placebo group. The WHI study also found that women who received estrogen therapy experienced a reduced number of hip fractures (six fewer fractures/year per 10,000 women) compared with placebo. In the WHI study, unopposed estrogen therapy had no discernible effect upon the risk for heart attacks, colorectal cancer, or overall mortality. A 20-year study of 8801 women living in a retirement community found that estrogen use was associated with improved survival. Age-adjusted mortality rates were 56.4 (per 1000 person-years) among nonusers and 50.4 among women who had used estrogen for 15 years or longer.

Women receiving unopposed conventional-dose daily conjugated estrogen and medroxyprogesterone acetate (0.625 mg and 2.5 mg, respectively) for an average of 5.6 years, experienced a lower risk of developing diabetes (3.5%) versus those taking a placebo (4.2%).

Serum levels of atherogenic lipoprotein(a) are reduced by estrogen replacement with or without daily or cycled progestins. Improvement in serum HDL cholesterol is greatest with unopposed estrogen but is also seen with the addition of a progestin.

Estrogen replacement improves or eliminates postmenopausal hot flushes and diaphoretic episodes. Vaginal moisture is improved. Libido is enhanced in some women. Sleep disturbances are common in menopause and can be reversed with estrogen replacement. Sex hormone replacement may also improve the body pain and reduced physical function experienced by some women at the time of menopause.

Perimenopause-related depression is improved by unopposed estrogen replacement; the addition of a proges-

tin may negate this effect. Estrogen replacement, when initiated at the time of menopause or oophorectomy, has been reported to help protect cognitive function, particularly verbal memory, whereas estrogen replacement that is begun many years after menopause confers little or no benefit on cognition. Estrogen therapy does not appear to reduce the risk of Alzheimer dementia.

Unopposed estrogen replacement improves glycemic control in women with type 2 diabetes mellitus. Estrogen replacement does not prevent facial skin wrinkling; however, it may improve facial skin moisture and thickness, reducing seborrhea and atrophy.

Risks of ERT: The risks of estrogen replacement depend on the dose. Conventional doses (eg, oral conjugated estrogens ≥ 0.625 mg/d or transdermal estradiol ≥ 0.05 mg/d) carry higher risks than lower doses (eg, oral conjugated estrogens, ≤ 0.3 mg/d or transdermal estradiol ≤ 0.025 mg/d). Route of administration also affects risks, since oral estrogens pass through the liver and increase hepatic production of clotting factors (thereby increasing the risks of thrombotic stroke), whereas transdermal or vaginal administration of estrogen does not significantly increase clotting proclivity. The risks for HRT also depend on whether estrogen is administered alone (unopposed HRT) or with a progestin (combined HRT).

Estrogen replacement without progestin (unopposed HRT): Conventional-dose unopposed estrogen replacement increases the risk of endometrial hyperplasia and DUB, which often prompts patients to stop the estrogen. Lower-dose unopposed estrogen has a much lower risk of DUB. Recurrent dysfunctional bleeding necessitates a pelvic examination and possibly an endometrial biopsy.

Unopposed estrogen in conventional doses may increase the risk for endometrial carcinoma, although the absolute risk remains low. A Cochrane Database Review found no increased risk of endometrial carcinoma in a review of 30 randomized controlled trials. Therefore, lower-dose unopposed estrogen replacement confers a negligible risk for endometrial cancer.

Long-term conventional-dose unopposed estrogen increases the mortality risk from ovarian cancer, although the absolute risk is small. The annual age-adjusted ovarian cancer death rates for women taking estrogen replacement for ≥ 10 years are 64:100,000 for current users, 38:100,000 for former users, and 26:100,000 for women who had never taken estrogen. Lower-dose estrogen replacement is believed to confer a negligible increased risk for ovarian cancer.

The WHI study has reported that conventional doses of unopposed oral estrogen do not increase the risk of breast cancer; in fact, somewhat fewer breast cancers were found in women taking estrogen alone, compared with placebo. However, the WHI trial was stopped in 2002 because of an increased risk of stroke among women taking conjugated oral estrogens in doses of 0.625 mg daily; the risk was about 44 strokes per 10,000 person-years versus about 32 per 10,000 person-years in women taking placebo. Transdermal or transvaginal estrogen is not expected to increase the risk of stroke.

Conventional-dose oral estrogen replacement increases the risk of deep venous thrombosis. It can cause hypertri-

lyceridemia, particularly in women with preexistent hyperlipidemia, rarely resulting in pancreatitis. Postmenopausal estrogen therapy also slightly increases the risk of gallstones and cholecystitis. Oral estrogens reduce the effectiveness of growth hormone replacement. These side effects can be reduced or avoided by using nonoral estrogen replacement.

Elderly women, receiving long-term conventional-dose estrogen replacement, experience an increased risk of urinary incontinence. Some women complain of estrogen-induced edema or mastalgia. Estrogen replacement has been reported to lower the seizure threshold in some women with epilepsy. Untreated large pituitary prolactinomas may enlarge if exposed to estrogen.

Estrogen replacement with a progestin (combined HRT): The WHI study found that women who received long-term conventional oral doses of combined HRT (conjugated estrogens 0.625 mg/d plus medroxyprogesterone acetate 2.5 mg/d) had an increased risk of deep venous thrombosis (3.5 per 1000 person-years) compared with women receiving placebo (1.7 per 1000 person-years).

Conventional-dose oral combined HRT results in an increased risk for myocardial infarction (24% or six additional heart attacks per 10,000 women), mostly in women with high-risk LDL levels or preexistent coronary disease. Most of the risk for myocardial infarction occurs in the first year of therapy. This increased risk is attributable to the progestin component, since the estrogen-only arm of the WHI study found no increased risk of myocardial infarction.

Long-term conventional-dose oral combined HRT increases breast density and increases the risk for abnormal mammograms (9.4% versus 5.4% for placebo). There is also a higher risk for breast cancer (8 cases per 10,000 women/year versus 6.5 cases per 10,000 women/year for placebo); no increased risk of breast cancer has been found with estrogen-only HRT. This increased risk for breast cancer appears to mostly affect relatively thin women with a BMI < 24.4 . The Iowa Women's Health Study reported an increase in breast cancer with HRT only in women consuming more than 1 oz of alcohol weekly. No accelerated risk of breast cancer has been seen in users of HRT who have benign breast disease or a family history of breast cancer.

The Women's Health Initiative Mental Study (WHIMS) followed the effect of combined conventional-dose oral HRT on cognitive function in women 65–79 years old. HRT did not protect these older women from cognitive decline. In fact, they experienced an increased risk for severe dementia at a rate of 23 more cases/year for every 10,000 women over age 65 years.

In the WHI study, women receiving conventional-dose combined oral HRT experienced an increased risk of stroke (31 strokes per 10,000 women/year versus 26 strokes per 10,000 women/year for placebo). Stroke risk was also increased by hypertension, diabetes, and smoking.

Women taking combined estrogen–progestin replacement do not experience an increased risk of ovarian cancer. They do experience an increased risk of developing asthma.

Progestins may cause moodiness, particularly in women with a history of premenstrual dysphoric disorder. Cycled

progesterins may trigger migraines in certain women. Many other adverse reactions have been reported, including breast tenderness, alopecia, and fluid retention. Contraindications to the use of progesterins include thromboembolic disorders, liver disease, breast cancer, and pregnancy.

SERMs (eg, raloxifene; Evista) are an alternative to estrogen replacement for hypogonadal women at risk for osteoporosis who prefer not to take estrogens because of their contraindications (eg, breast or uterine cancer) or side effects. Raloxifene does not reduce hot flashes, vaginal dryness, skin wrinkling, or breast atrophy; it does not improve cognition. However, in doses of 60 mg/d orally, it inhibits bone loss without stimulating effects upon the breasts or endometrium. Because raloxifene may slightly increase the risk of venous thromboembolism, it should not be used by women at prolonged bed rest or by those prone to thrombosis. In contrast with the use of ERT, concomitant progesterone therapy is not needed, and raloxifene does not increase the risk of development of breast cancer. Tibolone (Livial) is an SERM whose metabolites have mixed estrogenic, progestogenic, and weak androgenic activity. It is comparable to HRT for the treatment of climacteric-related complaints. It does not appear to significantly stimulate proliferation of breast or endometrial tissue. It depresses both serum triglycerides and HDL cholesterol. Long-term studies are lacking. It is not available in the United States.

Phytoestrogens are substances found in plants that bind to estrogen receptors. Phytoestrogens, found in soy and red clover extracts, do not appear to significantly improve menopausal hot flashes, cognitive function, bone density, or plasma lipids.

Testosterone replacement therapy in women: In premenopausal women, serum testosterone levels decline with age. Between 25 and 45 years of age, women's testosterone levels fall 50%. After natural menopause, the ovaries remain a significant source for testosterone. In fact, following natural menopause, serum testosterone levels do not fall abruptly and serum free testosterone levels may actually rise. In contrast, very low serum testosterone levels are found in women after bilateral oophorectomy, autoimmune ovarian failure, adrenalectomy, and hypopituitarism. Testosterone deficiency contributes to hot flashes, loss of sexual hair, muscle atrophy, osteoporosis, and diminished libido, also known as hypoactive sexual desire disorder (HSDD).

In women, diminished libido is common and multifactorial. Although low serum testosterone levels may contribute to HSDD, hysterectomy and sexual isolation are major causes. Low serum testosterone levels may also cause fatigue, a diminished sense of well-being, and a dulled enthusiasm for life. Androgen replacement may improve these problems.

Testosterone therapy is often effective, while DHEA therapy is not. Selected women may be treated with low-dose testosterone. Methyltestosterone can be taken orally in doses of 1.25–2.5 mg daily. Testosterone can also be compounded as a cream containing 1 mg/mL, with 1 mL applied to the low abdomen daily. Methyltestosterone is also available in combination with conjugated estrogens (eg, Estrat-

est). This formulation is convenient but carries the same disadvantage as oral estrogen—increased risk of thromboembolism. Tablets contain either 1.25 mg conjugated estrogens with 2.5 mg methyltestosterone or 0.625 mg conjugated estrogens with 1.25 mg methyltestosterone. Estratest is usually started at the lowest strength. It should be given cyclically at the lowest dose that controls symptoms.

Women receiving testosterone therapy must be monitored for the appearance of any acne or hirsutism, and serum testosterone levels are determined periodically if women feel that they are benefitting and long-term testosterone therapy is instituted. Side effects of low-dose testosterone therapy are usually minimal but may include polycythemia, emotional changes hirsutism, acne, an adverse effect on lipids, and potentiation of warfarin anticoagulation therapy. Testosterone replacement tends to reduce both triglyceride and HDL cholesterol levels. Hepatocellular neoplasms and peliosis hepatis, rare complications of oral androgens at higher doses, have not been reported with methyltestosterone at lower doses of 2.5 mg orally daily. Androgens should not be given to women with liver disease or during pregnancy or breast-feeding. Testosterone replacement therapy for women should be used judiciously, since long-term prospective clinical trials are lacking. An analysis of the Nurses' Health Study found that women who had been taking CEEs plus methyltestosterone experienced an increased risk of breast cancer. Yearly mammography is recommended for all women over 40 years of age.

TURNER SYNDROME (Gonadal Dysgenesis)

ESSENTIALS OF DIAGNOSIS

- ▶ Short stature with normal growth hormone levels.
- ▶ Primary amenorrhea or early ovarian failure.

- ▶ Epicanthal folds, webbed neck, short fourth metacarpals.
- ▶ Renal and cardiovascular anomalies.

Turner syndrome comprises a group of X chromosome disorders that are associated with spontaneous abortion, primary hypogonadism, short stature, and other phenotypic anomalies. It affects 1–2% of fetuses, of which about 97% abort, accounting for about 10% of all spontaneous abortions. Nevertheless, it affects about 1 in every 2500 live female births. Patients with the classic syndrome (about 50% of cases) lack one of the two chromosomes (45,XO karyotype). Other patients with Turner syndrome have X chromosome abnormalities, such as ring X or Xq (X/abnormal X) or X chromosome deletions affecting all or some somatic cells (mosaicism, XX/XO).

1. Classic Turner Syndrome (Table 26–15) (45,XO Gonadal Dysgenesis)

Features of Turner syndrome are variable and may be subtle in girls with mosaicism. Typical manifestations in adulthood include short stature, hypogonadism, webbed neck, high-arched palate, wide-spaced nipples, hypertension, and renal abnormalities. Emotional disorders are common.

Girls with Turner syndrome may be diagnosed at birth, since they tend to be small and may exhibit severe lymphedema. Evaluation for childhood short stature often leads to the diagnosis. Growth hormone and IGF-1 levels are normal. Hypogonadism presents as “delayed adolescence” (primary amenorrhea, 80%) or early ovarian failure (20%); girls with 45,XO Turner (blood karyotyping) who enter puberty are typically found to have mosaicism if other tissues are karyotyped. Hypogonadism is confirmed in girls who have high serum levels of FSH and LH. A blood karyotype showing 45,XO (or X chromosome abnormalities or mosaicism) establishes the diagnosis.

Treatment of short stature with daily injections of GH (0.1 unit/kg/d) plus an androgen (eg, oxandrolone) for at least 4 years before epiphyseal fusion increases final height by a mean of about 10.3 cm over the mean predicted height of 144.2 cm. Such GH treatment rarely causes pseudotumor cerebri. After age 12 years, estrogen therapy is begun with low doses of conjugated estrogens (0.3 mg) or ethinyl estradiol (5 mcg) given on days 1–21 per month. When growth stops, HRT is begun with estrogen and progestin; transdermal estrogen may be used to initiate pubertal development.

Girls and women with Turner syndrome have an increased risk of aortic coarctation (11%) and bicuspid aortic valves (16%); these cardiac abnormalities are more common in patients with webbed necks. Bicuspid aortic valves are associated with an increased risk for infective endocarditis, aortic valvular stenosis or insufficiency, and ascending aortic aneurysm and dissection. Partial anomalous pulmonary vein connections occur in 13% and can lead to left-to-right shunting of blood. Adults with Turner syndrome have a high incidence of ECG abnormalities.

Women with Turner syndrome have a reduced life expectancy due in part to their increased risk for diabetes mellitus (types 1 and 2), hypertension, dyslipidemia, and osteoporosis.

Table 26–15. Manifestations of Turner syndrome.

| |
|--|
| Short stature |
| Distinctive facial features |
| Ptosis |
| Micrognathia |
| Low-set ears |
| Epicanthal folds |
| Sexual infantilism due to gonadal dysgenesis with primary amenorrhea (80%) |
| Early ovarian failure with secondary amenorrhea (20%) |
| Webbed neck (40%) |
| Low hairline |
| High-arched palate |
| Cubitus valgus |
| Short fourth metacarpals (50%) |
| Lymphedema of hands and feet (30%) |
| Hypoplastic widely spaced nipples |
| Hyperconvex nails |
| Pigmented nevi |
| Keloid formation (eg, surgical scars or after ear piercing) |
| Recurrent otitis media |

Diagnostic vigilance and aggressive treatment of these conditions reduce the risk of aortic aneurysm dissection, ischemic heart disease, stroke, and fracture. Patients are prone to keloid formation after surgery or ear piercing. Yearly ocular examinations and periodic thyroid evaluations are recommended. It is advisable to evaluate all patients with Turner syndrome with an ultrasound, along with MRI examination of the chest and abdomen, looking for cardiac, aortic, and renal abnormalities. Repeat cardiovascular evaluations should be done every 3–4 years. Patients with the classic 45,XO karyotype have a high risk of renal structural abnormalities, whereas those with 46 X/abnormal X are

more prone to malformations of the urinary collecting system. The risk of aortic dissection is increased more than 100-fold in women with Turner syndrome, particularly those with pronounced neck webbing and shield chest. Patients with aortic root enlargement are usually treated with β -blockade and serial imaging. Women with Turner syndrome who are able to become pregnant are strongly advised to deliver via cesarean section due to the risk of aortic aneurysm rupture during vaginal delivery.

2. Turner Syndrome Variants

A. 46,X (Abnormal X) Karyotype

Patients with small distal short arm deletions of the X chromosome (Xp-) that include the SHOX gene often have short stature and skeletal abnormalities but have a low risk of ovarian failure. Transmission of Turner syndrome from mother to daughter can occur. There may be an increased risk of trisomy 21 in the conceptuses of women with Turner syndrome. Patients with deletions of the long arm of the X chromosome (distal to Xq24) often have amenorrhea without short stature or other features of Turner syndrome. Abnormalities or deletions of other genes located on both the long and short arms of the X chromosome can produce gonadal dysgenesis with few other somatic features.

B. 45,XO/46,XX Mosaicism

This karyotype results in a modified form of Turner syndrome. Such girls tend to be taller and may have more gonadal function and fewer other manifestations of Turner syndrome.

C. Other Variants

45,XO/46,XY mosaicism can produce some manifestations of Turner syndrome. Patients may have ambiguous genitalia or male infertility with an otherwise normal phenotype. Germ cell tumors, such as gonadoblastomas and seminomas, develop in about 10% of patients with 45,XO/46,XY mosaicism; most such tumors are benign.

MULTIPLE ENDOCRINE NEOPLASIA

ESSENTIALS OF DIAGNOSIS

- ▶ **MEN 1:** tumors of the parathyroid glands, endocrine pancreas and duodenum, pituitary, adrenal, thyroid; lipomas and facial angiofibromas.

- ▶ **MEN 2A:** medullary thyroid cancers, pheochromocytomas, Hirschsprung disease.
- ▶ **MEN 2B:** medullary thyroid cancers, pheochromocytomas, Marfan-like habitus, mucosal neuromas, intestinal ganglioneuroma, delayed puberty.

Syndromes of MEN are inherited as autosomal dominant traits and cause a predisposition to the development of tumors in different tissues, particularly involving endocrine glands (Table 26–16).

1. MEN 1 (Wermer Syndrome)

MEN 1 is a familial multiglandular endocrine tumor syndrome, with a prevalence of 2–10 per 100,000 people. The presentation of MEN 1 is quite variable, even in the same kindred. Parathyroid, enteropancreatic, and pituitary tumors can be present in one individual, though not necessarily at the same time. Nonendocrine tumors also occur, such as subcutaneous lipomas, facial angiofibromas, and collagenomas. In some affected individuals, tumors may start developing in childhood, whereas in others, tumors develop late in adult life.

About 90% of patients with MEN 1 have germline mutations that are inherited as an autosomal dominant trait. Patients with MEN 1 usually have detectable mutations in the *menin* gene, located on the long arm of chromosome 11 (11q13). MEN 1 gene testing is available at a few centers and is able to detect the specific mutation in 60–95% of cases. If no mutation is detected, genetic linkage analysis can be done if there are several affected members in the kindred. Gene testing permits the rest of the kindred to be tested for the specific gene defect and allows informed genetic counseling.

With close endocrine surveillance of affected individuals, the initial biochemical manifestations (usually hypercalcemia) can often be detected as early as age 14–18 years in patients with a MEN 1 gene mutation, although clinical manifestations do not usually present until the third or fourth decade.

Hyperparathyroidism is the first clinical manifestation of MEN 1 in two-thirds of affected patients, but it may present at any time of life. Patients with the MEN 1 mutation have a > 90% lifetime risk of developing hyperparathyroidism. The hyperparathyroidism of MEN 1 is notoriously difficult to treat surgically, due to multiple gland involvement and the frequency of supernumerary glands and ectopic parathyroid tissue. Typically, three and one-half glands are resected, leaving one-half of the most normal-appearing gland intact. Also, during neck surgery, a thymectomy is performed to resect any intrathymic parathyroid glands or occult thymic carcinoid tumors. Nevertheless, the surgical failure rate is about 38%, and there is a recurrence rate of about 16%, with hypercalcemia often recurring many years after neck surgery. Aggressive parathyroid resection can cause permanent hypoparathyroidism. Patients with persistent or recurrent hyperparathyroidism should avoid oral calcium supplements and thiazide diuretics; oral therapy with calcimimetic drug, such as cinacalcet, is effective but expensive. The diagnosis

Table 26–16. Multiple endocrine neoplasia (MEN) syndromes: Incidence of tumor types.

| Tumor Type | MEN 1 (Wermer Syndrome) | MEN 2A (Sipple Syndrome) | MEN 2B |
|--|-------------------------|--------------------------|--------|
| Parathyroid | 95% | 20–50% | Rare |
| Pancreatic | 54% | | |
| Pituitary | 42% | | |
| Medullary thyroid carcinoma | | > 90% | 80% |
| Pheochromocytoma | Rare | 20–35% | 60% |
| Mucosal and gastrointestinal ganglioneuromas | | Rare | > 90% |
| Subcutaneous lipoma | 30% | | |
| Adrenocortical adenoma | 30% | | |
| Thoracic carcinoid | 15% | | |
| Thyroid adenoma | 55% | | |
| Facial angiofibromas and collagenomas | 85% | | |

and treatment of hyperparathyroidism is described earlier in this chapter.

Enteropancreatic tumors occur in about 75% of patients with MEN 1. **Nonsecretory neuroendocrine tumors** occur and do not secrete hormones; they tend to be large and very aggressive. **Gastrinomas** occur in about 35% of patients with MEN 1; they secrete gastrin, thereby causing severe gastric hyperacidity (Zollinger–Ellison syndrome) with peptic ulcer disease or diarrhea. Concurrent hypercalcemia, due to hyperparathyroidism (see above), stimulates gastrin and gastric acid secretion; control of the hypercalcemia often reduces gastric acid secretion and serum gastrin levels. These gastrinomas tend to be small, multiple, and ectopic; they are frequently found outside the pancreas, usually in the duodenum. Gastrinomas of MEN 1 can metastasize to the liver; but in patients with MEN 1, depending upon the kindred, hepatic metastases tend to be less aggressive than those from sporadic gastrinomas. Treatment of patients with gastrinomas in MEN 1 is usually conservative, utilizing long-term high-dose proton pump inhibitor therapy and control of hypercalcemia; surgery is palliative and usually reserved for aggressive gastrinomas and those tumors arising in the duodenum. Zollinger–Ellison syndrome is also discussed in Chapter 15.

Insulinomas cause hyperinsulinism and fasting hypoglycemia. They occur in about 15% of patients with MEN 1. Surgery is usually attempted, but the tumors can be small, multiple, and difficult to detect. The diagnosis and treatment of insulinomas are described in Chapter 27. Glucagonomas (1.6%) secrete glucagon and cause diabetes and migratory necrolytic erythema. VIPomas (1%) secrete VIP and cause profuse watery diarrhea, hypokalemia, and achlorhydria (WDHA, Verner–Morrison syndrome). Somatostatinomas (0.7%) can cause diabetes mellitus, steatorrhea, and cholelithiasis.

Pituitary adenomas occur in about 42% of patients with MEN 1. They are more common in women (50%) than men (31%) and are the presenting tumor in 17% of patients with MEN 1. These tumors tend to be more aggressive macroadenomas (> 1 cm diameter, 85%) com-

pared to sporadic pituitary tumors (42%). Of MEN 1–associated pituitary tumors, about 62% secrete PRL, 8% secrete GH, 13% secrete both PRL and GH, and 13% are nonsecretory; only 4% secrete ACTH and cause Cushing disease. The diagnosis and treatment of pituitary tumors and Cushing disease were described earlier in this chapter. These pituitary tumors can produce local pressure effects and hypopituitarism.

Adrenal adenomas or hyperplasia occurs in about 37% of patients with MEN 1 and 50% are bilateral. They are generally benign and nonfunctional. In one series, one out of 12 of these patients developed a feminizing adrenal carcinoma. These adrenal lesions are pituitary independent.

Nonendocrine tumors occur commonly in MEN 1. Small facial angiofibromas and subcutaneous lipomas are common. Collagenomas can present as firm dermal nodules. Malignant melanomas have been reported.

The differential diagnosis of MEN 1 includes sporadic or familial tumors of the pituitary, parathyroids, or pancreatic islets. Hypercalcemia (from any cause) may cause gastrointestinal symptoms and increased gastrin levels, simulating a gastrinoma. Routine suppression of gastric acid secretion with H₂-blockers or proton pump inhibitors causes a physiologic increase in serum gastrin that can be mistaken for a gastrinoma. H₂-blockers and metoclopramide cause hyperprolactinemia, simulating a pituitary prolactinoma.

Variants of MEN 1 also occur. Kindreds with MEN 1 Burin variant have a high prevalence of prolactinomas, late-onset hyperparathyroidism, and carcinoid tumors, but rarely enteropancreatic tumors.

2. MEN 2A (Sipple Syndrome)

MEN 2A is a rare familial multiglandular syndrome that is inherited as an autosomal dominant trait. Patients with MEN 2A should have genetic testing for a *ret* protooncogene (RET) mutation. Their first-degree relatives may then be tested for the specific RET mutation. Patients with MEN 2A may have **medullary thyroid carcinoma** (> 90%); hyperparathyroidism (20–50%), due to hyperplasia or mul-

tiple adenomas in over 70% of cases; **pheochromocytomas** (20–35%), which are often bilateral; or **Hirschsprung disease**. The medullary thyroid carcinoma is of mild to moderate aggressiveness. Children harboring an MEN 2A RET gene mutation are advised to have a prophylactic total thyroidectomy by age 6 years.

Siblings or children of patients with MEN 2A should have genetic testing to determine if they have a mutation of the *ret* protooncogene (RET) on chromosome 10cen-10q11.2; this identifies about 95% of affected individuals. Each kindred has a certain *ret* codon mutation that correlates with the particular variation in the MEN 2 syndrome, such as the age of onset and aggressiveness of medullary thyroid cancer. The specific mutation as well as case histories of family members should guide the timing for prophylactic thyroidectomy. Before any surgical procedure, MEN 2 carriers should be screened for pheochromocytoma. There is incomplete penetrance, and about 30% of those with such mutations never manifest endocrine tumors.

Patients may be screened for medullary thyroid carcinoma with a serum calcitonin drawn after 3 days of omeprazole, 20 mg orally twice daily; calcitonin levels rise in the presence of medullary thyroid carcinoma to above 80 pg/mL in women or above 190 pg/mL in men.

3. MEN 2B

MEN 2B is a familial, autosomal dominant multiglandular syndrome that is caused by a mutation of the *ret* protooncogene (RET) on chromosome 10. MEN 2B is characterized by mucosal neuromas (> 90%) with bumpy and enlarged lips and tongue, Marfan-like habitus (75%), adrenal pheochromocytomas (60%) that are rarely malignant and often bilateral, and medullary thyroid carcinoma (80%). Patients also have intestinal abnormalities (75%) such as intestinal ganglioneuromas, skeletal abnormalities (87%), and delayed puberty (43%). Medullary thyroid carcinoma is aggressive and presents early in life. Therefore, infants having a parent with MEN 2B receive genetic screening; those carrying the RET mutation undergo a prophylactic total thyroidectomy by age 6 months.

OTHER SYNDROMES OF MULTIPLE ENDOCRINE NEOPLASIA

Patients with *Carney complex* develop tumors in the adrenal cortex, pituitary, thyroid, and gonads as well as cardiac myxomas and hyperpigmentation. Patients with *Cowden disease* develop thyroid abnormalities (66%) such as benign adenomas and follicular adenocarcinomas, along with breast cancer (20–36% in women), and multiple hamartomas that affect the skin and multiple other organs. Patients with McCune-Albright syndrome may develop precocious puberty (particularly girls) due to gonadal hypersecretion, Cushing syndrome caused by multiple adrenal nodules, hyperthyroidism from hypersecretory thyroid nodules, and acromegaly caused by GH-secreting pituitary tumors. Patients have fibrous dysplasia of bones and hypophosphatemia, with bone fractures being common. Sudden death has been reported. It is caused by a postzygotic

somatic mutation in the gene coding for the stimulatory G_s protein, resulting in constitutive activation of affected cells.

CLINICAL USE OF CORTICOSTEROIDS

Mechanisms of Action

Cortisol is a steroid hormone that is normally secreted by the adrenal cortex in response to ACTH. It exerts its action by binding to nuclear receptors, which then act upon chromatin to regulate gene expression, producing effects throughout the body.

Relative Potencies (Table 26-17)

Hydrocortisone and cortisone acetate, like cortisol, have mineralocorticoid effects that become excessive at higher doses. Other synthetic corticosteroids such as prednisone, dexamethasone, and deflazacort (an oxazoline derivative of prednisolone) have minimal mineralocorticoid activity. Anticonvulsant drugs (eg, phenytoin, carbamazepine, phenobarbital) accelerate the metabolism of corticosteroids other than hydrocortisone, making them significantly less potent. Megestrol, a synthetic progestin, has slight corticosteroid activity that becomes significant when administered in high doses for appetite stimulation.

Table 26-17. Systemic versus topical activity of corticosteroids.¹

| | Systemic Activity | Topical Activity |
|---------------------------|-------------------|------------------|
| Prednisone | 4-5 | 1-2 |
| Fluprednisolone | 8-10 | 10 |
| Triamcinolone | 5 | 1 |
| Triamcinolone acetonide | 5 | 40 |
| Dexamethasone | 30-120 | 10 |
| Betamethasone | 30 | 5-10 |
| Betamethasone valerate | — | 50-150 |
| Methylprednisolone | 5 | 5 |
| Fluocinolone acetonide | — | 40-100 |
| Flurandrenolone acetonide | — | 20-50 |
| Fluorometholone | 1-2 | 40 |
| Deflazacort | 3-4 | — |

¹Hydrocortisone = 1 in potency.

Table 26–18. Management of patients receiving systemic corticosteroids.**Recommendations for prescribing**

- Do not administer corticosteroids unless absolutely indicated or more conservative measures have failed.
- Keep dosage and duration of administration to the minimum required for adequate treatment.

Monitoring recommendations

- Screen for tuberculosis with a purified protein derivative (PPD) test or chest radiograph before commencing long-term corticosteroid therapy.
- Screen for diabetes mellitus before treatment and at each physician visit.
 - Have patient test urine weekly for glucose.
 - Teach patient about the symptoms of hyperglycemia.
- Screen for hypertension before treatment and at each clinician visit.
- Screen for glaucoma and cataracts before treatment, 3 months after treatment inception, and then at least yearly.
- Monitor plasma potassium for hypokalemia and treat as indicated.
- Obtain bone densitometry before treatment and then periodically. Treat osteoporosis.
- Weigh daily. Use dietary measures to avoid obesity and optimize nutrition.
- Measure height frequently to document the degree of axial spine demineralization and compression.
- Watch for fungal or yeast infections of skin, nails, mouth, vagina, and rectum, and treat appropriately.
- With dosage reduction, watch for signs of adrenal insufficiency or corticosteroid withdrawal syndrome.

Patient information

- Prepare the patient and family for possible adverse effects on mood, memory, and cognitive function.
- Inform the patient about other possible side effects, particularly weight gain, osteoporosis, and aseptic necrosis of bone.
- Counsel to avoid smoking and excessive ethanol consumption.

Prophylactic measures

- Institute a vigorous physical exercise and isometric regimen tailored to each patient's disabilities.
- Administer calcium (1 g elemental calcium) and vitamin D₃, 400–800 international units orally daily.
 - Check spot morning urines, and alter dosage to keep urine calcium concentration below 30 mg/dL.
 - If the patient is receiving thiazide diuretics, check for hypercalcemia, and administer only 500 mg elemental calcium daily.
 - Consider a bisphosphonate such as alendronate (70 mg orally weekly) or periodic intravenous infusions of pamidronate or zoledronic acid.
- Avoid prolonged bed rest that will accelerate muscle weakness and bone mineral loss. Ambulate early after fractures.
- Avoid elective surgery, if possible. Vitamin A in a daily dose of 20,000 units orally for 1 week may improve wound healing, but it is not prescribed in pregnancy.
- Avoid activities that could cause falls or other trauma.
- For ulcer prophylaxis, if administering corticosteroids with nonsteroidals, prescribe a proton pump inhibitor (not required for corticosteroids alone). Avoid large doses of antacids containing aluminum hydroxide (many popular brands) because aluminum hydroxide binds phosphate and may cause a hypophosphatemic osteomalacia that can compound corticosteroid osteoporosis.
- Treat hypogonadism.
- Treat infections aggressively. Consider unusual pathogens.
- Treat edema as indicated.

Adverse Effects

Prolonged treatment with systemic corticosteroids causes a variety of adverse effects that can be life-threatening. Patients should be thoroughly informed of the major possible side effects of treatment such as insomnia, personality change, weight gain, muscle weakness, polyuria, kidney stones, diabetes mellitus, sex hormone suppression, occasional amenorrhea in women, candidiasis and opportunistic infections, osteoporosis with fractures, or aseptic necrosis of bones (particularly of the hips), which may become manifest many months after even brief treatment (see section on Cushing syndrome). Patients who receive intermittent high-dose corticosteroids (eg, prednisone \geq 15 mg daily and cumulative dose $>$ 1 g) are at increased risk for osteoporotic fractures. Avascular necrosis of bone develops in about 15% of patients who receive corticosteroids at high doses (eg, prednisone \geq 15 mg daily) for more than 1 month with cumulative prednisone doses of \geq 10 g.

Bisphosphonates (eg, alendronate, 70 mg orally weekly) prevent the development of osteoporosis among patients

receiving prolonged courses of corticosteroids. For patients who are unable to tolerate oral bisphosphonates (due to esophagitis, hiatal hernia, or gastritis), periodic intravenous infusions of pamidronate, 60–90 mg, or zoledronic acid, 2–4 mg, should also be effective. Teriparatide, 20 mcg subcutaneously daily for up to 2 years, is also effective against corticosteroid-induced osteoporosis. (See further discussion in Osteoporosis section.) It is wise to follow an organized treatment plan such as the one outlined in Table 26–18.

Diabetes Mellitus & Hypoglycemia

Umesh Masharani, MB, BS, MRCP(UK)

27

DIABETES MELLITUS

ESSENTIALS OF DIAGNOSIS

Type 1 diabetes:

- ▶ Polyuria, polydipsia, and weight loss associated with random plasma glucose ≥ 200 mg/dL.
- ▶ Plasma glucose of 126 mg/dL or higher after an overnight fast, documented on more than one occasion.
- ▶ Ketonemia, ketonuria, or both.
- ▶ Islet autoantibodies are frequently present.

Type 2 diabetes:

- ▶ Most patients are over 40 years of age and obese.
- ▶ Polyuria and polydipsia. Ketonuria and weight loss generally are uncommon at time of diagnosis. Candidal vaginitis in women may be an initial manifestation. Many patients have few or no symptoms.
- ▶ Plasma glucose of 126 mg/dL or higher after an overnight fast on more than one occasion. After 75 g oral glucose, diagnostic values are 200 mg/dL or more 2 hours after the oral glucose.
- ▶ Hypertension, dyslipidemia, and atherosclerosis are often associated.

▶ Epidemiologic Considerations

In 2007, an estimated 23.6 million people in the United States had diabetes mellitus, of which approximately 1 million have type 1 diabetes and the rest mostly have type 2 diabetes. A third group that was designated as “other specific types” by the American Diabetes Association (ADA) (Table 27–1) number only in the thousands. Among these are the rare monogenic defects of either B cell function or of insulin action, primary diseases of the exocrine pancreas, endocrinopathies, and drug-induced diabetes. Updated information about the prevalence of diabetes in the United States is available from the Centers for Disease Control and Prevention (<http://www.cdc.gov/diabetes/pubs/estimates.htm#prev>).

▶ Classification & Pathogenesis

Diabetes mellitus is a syndrome with disordered metabolism and inappropriate hyperglycemia due to either a deficiency of insulin secretion or to a combination of insulin resistance and inadequate insulin secretion to compensate. Type 1 diabetes is due to pancreatic islet B cell destruction predominantly by an autoimmune process, and these patients are prone to ketoacidosis. Type 2 diabetes is the more prevalent form and results from insulin resistance with a defect in compensatory insulin secretion (Table 27–2).

A. Type 1 Diabetes Mellitus

This form of diabetes is immune-mediated in over 90% of cases and idiopathic in less than 10%. The rate of pancreatic B cell destruction is quite variable, being rapid in some individuals and slow in others. Type 1 diabetes is usually associated with ketosis in its untreated state. It occurs at any age but most commonly arises in children and young adults with a peak incidence before school age and again at around puberty. It is a catabolic disorder in which circulating insulin is virtually absent, plasma glucagon is elevated, and the pancreatic B cells fail to respond to all insulinogenic stimuli. Exogenous insulin is therefore required to reverse the catabolic state, prevent ketosis, reduce the hyperglucagonemia, and reduce blood glucose.

1. Immune-mediated type 1 diabetes mellitus (type 1A)

—The highest incidence of immune-mediated type 1 diabetes mellitus is in Scandinavia and northern Europe, where the annual incidence is as high as 37 per 100,000 children aged 14 years or younger in Finland, 27 per 100,000 in Sweden, 22 per 100,000 in Norway, and 19 per 100,000 in the United Kingdom. The annual incidence of type 1 diabetes decreases across the rest of Europe to 10 per 100,000 in Greece and 8 per 100,000 in France. Surprisingly, the island of Sardinia has as high an annual incidence as Finland (37 per 100,000) even though in the rest of Italy, including the island of Sicily, it is only 10 per 100,000 per year. In the United States, the annual incidence of type 1 diabetes averages 15 per 100,000, with higher rates in states more densely populated with persons of Scandinavian descent such as Minnesota. Worldwide, the lowest incidence of type 1 diabetes

MODY, maturity-onset diabetes of the young.

tes (< 1 case per 100,000 per year) is in China and parts of South America. The global incidence of type 1 diabetes is increasing (approximately 3% each year).

Approximately one-third of the disease susceptibility is due to genes and two-thirds to environmental factors. Genes that are related to the HLA locus contribute about 40% of the genetic risk. About 95% of patients with type 1 diabetes possess either HLA-DR3 or HLA-DR4, compared with 45–50% of white controls. *HLA-DQ* genes are even more specific markers of type 1 susceptibility, since a particular variety (*HLA-DQB1*0302*) is found in the DR4 patients with type 1, while a “protective” gene (*HLA-DQB1*0602*) is often present in the DR4 controls. The other important gene that contributes to about 10% of the genetic risk is found at the 5′ polymorphic region of the insulin gene. This polymorphic region affects the expression of the insulin gene in the thymus and results in depletion of insulin-specific T lymphocytes. In linkage studies, 16 other genetic regions of the human genome have been identified as being important to pathogenesis but less is known about them.

Table 27-3. Diagnostic sensitivity and specificity of autoimmune markers in patients with newly diagnosed type 1 diabetes mellitus.

| | Sensitivity | Specificity |
|-------------------------------------|-------------|-------------|
| Glutamic acid decarboxylase (GAD65) | 70–90% | 99% |
| Insulin (IAA) | 40–70% | 99% |
| Tyrosine phosphatase (IA-2) | 50–70% | 99% |

Most patients with type 1 diabetes mellitus have circulating antibodies to islet cells (ICA), insulin (IAA), glutamic acid decarboxylase (GAD65), and tyrosine phosphatases (IA-2 and IA2- β) at the time the diagnosis is made. These antibodies facilitate screening for an autoimmune cause of diabetes, particularly screening siblings of affected children, as well as adults with atypical features of type 2 diabetes (Table 27-3). An additional autoantibody to a zinc transporter ZnT8 (Slc30A8) was recently found to be present in about 28% of type 1 diabetes patients who were negative for the other antibodies. Screening with zinc transporter, GAD65, IA2 and IAA autoantibodies may identify about 98% of people who have an autoimmune basis for their beta cell loss. Antibody levels decline with increasing duration of disease. Also, low levels of anti-insulin antibodies develop in almost all patients once they are treated with insulin.

Family members of diabetic probands are at increased lifetime risk for developing type 1 diabetes. A child whose mother has type 1 diabetes has a 3% risk of developing the disease and a 6% risk if the child’s father has it. The risk in siblings is related to the number of HLA haplotypes that the sibling shares with the diabetic proband. If one haplotype is shared, the risk is 6% and if two haplotypes are shared, the risk increases to 12–25%. The highest risk is for identical twins, where the concordance rate is 25–50%.

Some patients with a milder expression of type 1 diabetes mellitus initially retain enough B cell function to avoid ketosis, but as their B cell mass diminishes later in life, dependence on insulin therapy develops. Islet cell antibody surveys among northern Europeans indicate that up to 15% of “type 2” diabetic patients may actually have this mild

Table 27-2. Clinical classification of common diabetes mellitus syndromes.

| Type | Ketosis | Islet Cell Antibodies | HLA Association | Treatment |
|---------------------|---------|-----------------------|-----------------|---|
| Type 1 | | | | |
| (A) Immune-mediated | Present | Present at onset | Positive | Eucaloric healthy diet and preprandial rapidly acting insulin, plus basal insulin replacement with intermediate-acting or long-acting insulin |
| (B) Idiopathic | Present | Absent | Absent | |
| Type 2 | | | | |
| (A) Nonobese | Absent | Absent | Negative | (1) Eucaloric diet alone (2) Diet plus insulin or oral agents |
| (B) Obese | Absent | Absent | Negative | (1) Weight reduction (2) Hypocaloric diet, plus oral agents or insulin |

form of type 1 diabetes (latent autoimmune diabetes of adulthood; LADA). Evidence for environmental factors playing a role in the development of type 1 diabetes include the observation that the disease is more common in Scandinavian countries and becomes progressively less frequent in countries nearer and nearer to the equator. Also, the risk for type 1 diabetes increases when individuals who normally have a low risk emigrate to the Northern Hemisphere. For example, it was recently shown that Pakistani children born and raised in Bradford, England have a higher risk for developing type 1 diabetes compared with children who lived in Pakistan all their lives.

Which environmental factor is responsible for the increased risk is not known. There have been a number of different hypotheses including infections with certain viruses (rubella, Coxsackie B4) and consumption of cow's milk. Also, in developed countries, childhood infections have become less frequent and so perhaps the immune system becomes dysregulated with development of autoimmunity and conditions such as asthma and diabetes. This theory is referred to as the hygiene hypothesis. None of these factors has so far been confirmed as the culprit. Part of the difficulty is that autoimmune injury undoubtedly starts many years before clinical diabetes mellitus develops.

2. Idiopathic type 1 diabetes mellitus (type 1B)—Less than 10% of subjects have no evidence of pancreatic B cell autoimmunity to explain their insulinopenia and ketoacidosis. This subgroup has been classified as “idiopathic type 1 diabetes” and designated as “type 1B.” Although only a minority of patients with type 1 diabetes fall into this group, most of these are of Asian or African origin. It was recently reported that about 4% of the West Africans with ketosis-prone diabetes are homozygous for a mutation in *PAX-4* (*Arg133Trp*)—a gene that is essential for the development of pancreatic islets.

B. Type 2 Diabetes Mellitus

This represents a heterogeneous group of conditions that used to occur predominantly in adults, but it is now more frequently encountered in children and adolescents. More than 90% of all diabetic persons in the United States are included under this classification. Circulating endogenous insulin is sufficient to prevent ketoacidosis but is inadequate to prevent hyperglycemia in the face of increased needs owing to tissue insensitivity (insulin resistance).

Genetic and environmental factors combine to cause both the insulin resistance and the beta cell loss. Most epidemiologic data indicate strong genetic influences, since in monozygotic twins over 40 years of age, concordance develops in over 70% of cases within a year whenever type 2 diabetes develops in one twin. Genome-wide association studies have made considerable progress in identifying the at-risk genes. So far, 18 different genetic loci have been associated with an increased risk of type 2 diabetes. A significant number of the identified loci appear to code for proteins that have a role in beta cell function or development. One of the genetic loci with the largest risk effect is *TCF7L2*. This gene codes for a transcription factor involved in the WNT signaling pathway that is required for normal

pancreatic development. Alleles at other genetic loci (*CDKAL1*, *SLC30A8*, *HHEX-IDE*, *CDKN2A/B*, *KCNJ11*, and *IGF2BP2*) are thought to affect insulin secretion. Two loci (*FTO* and *MC4R*) affect fat mass and obesity risk. The *PPARG* locus has been implicated in insulin resistance. The loci identified to date still explain only some of the heritable risk for diabetes; clearly, other loci remain to be discovered.

Early in the disease process, hyperplasia of pancreatic B cells occurs and probably accounts for the fasting hyperinsulinism and exaggerated insulin and proinsulin responses to glucose and other stimuli. With time, chronic deposition of amyloid in the islets may combine with inherited genetic defects progressively to impair B cell function.

Obesity is the most important environmental factor causing insulin resistance. The degree and prevalence of obesity varies among different racial groups with type 2 diabetes. While obesity is apparent in no more than 30% of Chinese and Japanese patients with type 2, it is found in 60–70% of North Americans, Europeans, or Africans with type 2 and approaches 100% of patients with type 2 among Pima Indians or Pacific Islanders from Nauru or Samoa.

Visceral obesity, due to accumulation of fat in the omental and mesenteric regions, correlates with insulin resistance; subcutaneous abdominal fat seems to have less of an association with insulin insensitivity. There are many patients with type 2 diabetes who, while not overtly obese, have increased visceral fat; they are termed the “metabolically obese.” Exercise may affect the deposition of visceral fat as suggested by CT scans of Japanese wrestlers, whose extreme obesity is predominantly subcutaneous. Their daily vigorous exercise program prevents accumulation of visceral fat, and they have normal serum lipids and euglycemia despite daily intakes of 5000–7000 kcal and development of massive subcutaneous obesity. Several **adipokines**, secreted by fat cells, can affect insulin action in obesity. Two of these, **leptin** and **adiponectin**, seem to increase sensitivity to insulin, presumably by increasing hepatic responsiveness. Two others—**tumor necrosis factor- α** , which inactivates insulin receptors, and **resistin**, which interferes with insulin action on glucose metabolism—have been reported to be elevated in obese animal models. Abnormal levels of these adipokines may contribute to the development of insulin resistance in human obesity.

Hyperglycemia per se can impair insulin action by causing accumulation of hexosamines in muscle and fat tissue and by inhibiting glucose transport (acquired glucose toxicity). Correction of hyperglycemia reverses this acquired insulin resistance.

C. Other Specific Types of Diabetes Mellitus

1. Maturity-onset diabetes of the young (MODY)—This subgroup is a relatively rare monogenic disorder characterized by non-insulin-dependent diabetes with autosomal dominant inheritance and an age at onset of 25 years or younger. Patients are nonobese, and their hyperglycemia is due to impaired glucose-induced secretion of insulin. Six types of MODY have been described. Except for MODY 2, in which a glucokinase gene is defective, all other types involve mutations of a nuclear transcription factor that regulates islet gene expression.

MODY 2 is quite mild, associated with only slight fasting hyperglycemia and few if any microvascular diabetic complications. It generally responds well to hygienic measures or low doses of oral hypoglycemic agents. MODY 3—the most common form—accounts for two-thirds of all MODY cases. The clinical course is similar to that of idiopathic type 2 diabetes in terms of microangiopathy and failure to respond to oral agents with time.

2. Diabetes due to mutant insulins—This is a very rare subtype of nonobese type 2 diabetes, with no more than ten families having been described. Since affected individuals were heterozygous and possessed one normal insulin gene, diabetes was mild, did not appear until middle age, and showed autosomal dominant genetic transmission. There is generally no evidence of clinical insulin resistance, and these patients respond well to standard therapy.

3. Diabetes due to mutant insulin receptors—Defects in one of their insulin receptor genes have been found in more than 40 people with diabetes, and most have extreme insulin resistance associated with acanthosis nigricans (Plate 91). In very rare instances when both insulin receptor genes are abnormal, newborns present with a leprechaun-like phenotype and seldom live through infancy.

4. Diabetes mellitus associated with a mutation of mitochondrial DNA—Since sperm do not contain mitochondria, only the mother transmits mitochondrial genes to her offspring. Diabetes due to mutations of mitochondrial DNA occurs in less than 2% of patients with diabetes. The most common cause is the A3243G mutation in the gene coding for the tRNA (Leu,UUR). Diabetes occurs even when a small percentage of the mitochondria in the cell carry the mutation; the heteroplasmy levels in the leukocytes range from 1% to 40%. Diabetes usually develops in these patients in their late 30s, and characteristically, they also have hearing loss (maternally inherited diabetes and deafness [MIDD]). In some patients, the beta cell failure can be rapidly progressive and patients require insulin soon after diagnosis. Other patients can be managed by diet or oral agents for a while but most eventually require insulin. MIDD patients are not usually overweight; they resemble patients with type 1 diabetes mellitus but without evidence for autoimmunity.

5. Wolfram syndrome—Wolfram syndrome is an autosomal recessive neurodegenerative disorder first evident in childhood. It consists of diabetes insipidus, diabetes mellitus, optic atrophy, and deafness, hence the acronym DID-MOAD. It is due to mutations in a gene named *WFS1*, which encodes a 100.3 kDa transmembrane protein localized in the endoplasmic reticulum. Diabetes develops in mice with mutated form of this protein; and isolated islets from these mice show impairment in insulin secretion to glucose stimulus and increased apoptosis. The diabetes mellitus usually presents in the first decade together with the optic atrophy. Cranial diabetes insipidus and sensorineural deafness develop during the second decade in 60–75% of patients. Ureterohydronephrosis, neurogenic bladder, cerebellar ataxia, peripheral neuropathy, and psychiatric illness develop later in many patients.

▶ Insulin Resistance Syndrome (Syndrome X; Metabolic Syndrome)

Twenty-five percent of the general nonobese nondiabetic population has insulin resistance of a magnitude similar to that seen in type 2 diabetes. These insulin-resistant nondiabetic individuals are at much higher risk for developing type 2 diabetes than insulin-sensitive persons. In addition to diabetes, these individuals have increased risk for elevated plasma triglycerides, lower high-density lipoproteins (HDLs), and higher blood pressure—a cluster of abnormalities termed syndrome X. These associations have now been expanded to include small, dense, low-density lipoprotein (LDL), hyperuricemia, abdominal obesity, prothrombotic state with increased levels of plasminogen activator inhibitor type 1 (PAI-1), and proinflammatory state. These clusters of abnormalities significantly increase the risk of atherosclerotic disease.

It has been postulated that hyperinsulinemia and insulin resistance play a direct role in these metabolic abnormalities, but supportive evidence is inconclusive. Although hyperinsulinism and hypertension often coexist in whites, that is not the case in blacks or Pima Indians. Moreover, patients with hyperinsulinism due to insulinoma are not hypertensive, and there is no fall in blood pressure after surgical removal of the insulinoma restores normal insulin levels. The main value of grouping these disorders as a syndrome, however, is to remind clinicians that the therapeutic goals are not only to correct hyperglycemia but also to manage the elevated blood pressure and dyslipidemia that result in increased cerebrovascular and cardiac morbidity and mortality in these patients.

▶ Clinical Findings

The principal clinical features of the two major types of diabetes mellitus are listed for comparison in Table 27-4.

Patients with type 1 diabetes have a characteristic symptom complex.

An absolute deficiency of insulin results in accumulation of circulating glucose and fatty acids, with consequent hyperosmolality and hyperketonemia.

Patients with type 2 diabetes may or may not have characteristic features. The presence of obesity or a strongly

Table 27-4. Clinical features of diabetes at diagnosis.

| | Type 1 Diabetes | Type 2 Diabetes |
|-----------------------------|-----------------|-----------------|
| Polyuria and thirst | ++ | + |
| Weakness or fatigue | ++ | + |
| Polyphagia with weight loss | ++ | – |
| Recurrent blurred vision | + | ++ |
| Vulvovaginitis or pruritus | + | ++ |
| Peripheral neuropathy | + | ++ |
| Nocturnal enuresis | ++ | – |
| Often asymptomatic | – | ++ |

positive family history for mild diabetes suggests a high risk for the development of type 2 diabetes.

A. Symptoms and Signs

1. Type 1 diabetes—Increased urination is a consequence of osmotic diuresis secondary to sustained hyperglycemia. This results in a loss of glucose as well as free water and electrolytes in the urine. Thirst is a consequence of the hyperosmolar state, as is blurred vision, which often develops as the lenses are exposed to hyperosmolar fluids.

Weight loss despite normal or increased appetite is a common feature of type 1 when it develops subacutely. The weight loss is initially due to depletion of water, glycogen, and triglycerides; thereafter, reduced muscle mass occurs as amino acids are diverted to form glucose and ketone bodies.

Lowered plasma volume produces symptoms of postural hypotension. Total body potassium loss and the general catabolism of muscle protein contribute to the weakness.

Paresthesias may be present at the time of diagnosis, particularly when the onset is subacute. They reflect a temporary dysfunction of peripheral sensory nerves, which clears as insulin replacement restores glycemic levels closer to normal, suggesting neurotoxicity from sustained hyperglycemia.

When absolute insulin deficiency is of acute onset, the above symptoms develop abruptly. Ketoacidosis exacerbates the dehydration and hyperosmolality by producing anorexia and nausea and vomiting, interfering with oral fluid replacement.

The patient's level of consciousness can vary depending on the degree of hyperosmolality. When insulin deficiency develops relatively slowly and sufficient water intake is maintained, patients remain relatively alert and physical findings may be minimal. When vomiting occurs in response to worsening ketoacidosis, dehydration progresses and compensatory mechanisms become inadequate to keep serum osmolality below 320–330 mosm/L. Under these circumstances, stupor or even coma may occur. The fruity breath odor of acetone further suggests the diagnosis of diabetic ketoacidosis.

Hypotension in the recumbent position is a serious prognostic sign. Loss of subcutaneous fat and muscle wasting are features of more slowly developing insulin deficiency. In occasional patients with slow, insidious onset of insulin deficiency, subcutaneous fat may be considerably depleted.

2. Type 2 diabetes—While many patients with type 2 diabetes present with increased urination and thirst, many others have an insidious onset of hyperglycemia and are asymptomatic initially. This is particularly true in obese patients, whose diabetes may be detected only after glycosuria or hyperglycemia is noted during routine laboratory studies. Occasionally, type 2 patients may present with evidence of neuropathic or cardiovascular complications because of occult disease present for some time prior to diagnosis. Chronic skin infections are common. Generalized pruritus and symptoms of vaginitis are frequently the initial complaints of women. Diabetes should be suspected in women with chronic candidal vulvovaginitis as well as in those who have delivered large babies (> 9 lb, or 4.1 kg) or

have had polyhydramnios, preeclampsia, or unexplained fetal losses.

Obese diabetics may have any variety of fat distribution; however, diabetes seems to be more often associated in both men and women with localization of fat deposits on the upper segment of the body (particularly the abdomen, chest, neck, and face) and relatively less fat on the appendages, which may be quite muscular. Standardized tables of waist-to-hip ratio indicate that ratios of “greater than 0.9” in men and “greater than 0.8” in women are associated with an increased risk of diabetes in obese subjects. Mild hypertension is often present in obese diabetics. Eruptive xanthomas on the flexor surface of the limbs and on the buttocks and lipemia retinalis due to hyperchylomicronemia can occur in patients with uncontrolled type 2 diabetes who also have a familial form of hypertriglyceridemia.

B. Laboratory Findings

1. Urinalysis

A. GLUCOSURIA—A specific and convenient method to detect glucosuria is the paper strip impregnated with glucose oxidase and a chromogen system (Clinistix, Diastix), which is sensitive to as little as 0.1% glucose in urine. Diastix can be directly applied to the urinary stream, and differing color responses of the indicator strip reflect glucose concentration.

A normal renal threshold for glucose as well as reliable bladder emptying is essential for interpretation.

B. KETONURIA—Qualitative detection of ketone bodies can be accomplished by nitroprusside tests (Acetest or Ketostix). Although these tests do not detect β -hydroxybutyric acid, which lacks a ketone group, the semiquantitative estimation of ketonuria thus obtained is nonetheless usually adequate for clinical purposes. Many laboratories now measure β -hydroxybutyric acid, and there is now a meter available (Precision Xtra, Abbott Diabetes Care) for patient use that measures β -hydroxybutyric acid levels in capillary glucose samples.

2. Blood testing procedures

A. GLUCOSE TOLERANCE TEST

(1) *Methodology and normal fasting glucose*—Plasma or serum from venous blood samples has the advantage over whole blood of providing values for glucose that are independent of hematocrit and that reflect the glucose concentration to which body tissues are exposed. For these reasons, and because plasma and serum are more readily measured on automated equipment, they are used in most laboratories. If serum is used or if plasma is collected from tubes that lack an agent to block glucose metabolism (such as fluoride), samples should be refrigerated and separated within 1 hour after collection. The glucose concentration is 10–15% higher in plasma or serum than in whole blood because structural components of blood cells are absent.

(2) *Criteria for laboratory confirmation of diabetes mellitus*—If the fasting plasma glucose level is 126 mg/dL or higher on more than one occasion, further evaluation of the patient with a glucose challenge is unnecessary. How-

Table 27-5. The Diabetes Expert Committee criteria for evaluating the standard oral glucose tolerance test.¹

| | Normal Glucose Tolerance | Impaired Glucose Tolerance | Diabetes Mellitus ² |
|--------------------------------------|--------------------------|----------------------------|--------------------------------|
| Fasting plasma glucose (mg/dL) | < 100 | 100-125 | ≥ 126 |
| Two hours after glucose load (mg/dL) | < 140 | ≥ 140-199 | ≥ 200 |

¹Give 75 g of glucose dissolved in 300 mL of water after an overnight fast in persons who have been receiving at least 150–200 g of carbohydrate daily for 3 days before the test.

²A fasting plasma glucose ≥ 126 mg/dL is diagnostic of diabetes if confirmed on a subsequent day.

ever, when fasting plasma glucose is less than 126 mg/dL in suspected cases, a standardized oral glucose tolerance test may be done (Table 27-5).

For proper evaluation of the test, the subjects should be normally active and free from acute illness. Medications that may impair glucose tolerance include diuretics, contraceptive drugs, glucocorticoids, niacin, and phenytoin.

Because of difficulties in interpreting oral glucose tolerance tests and the lack of standards related to aging, these tests are being replaced by documentation of fasting hyperglycemia.

B. GLYCATED HEMOGLOBIN (HEMOGLOBIN A_{1c}) MEASUREMENTS—

Hemoglobin becomes glycosylated by ketoamine reactions between glucose and other sugars and the free amino groups on the α and β chains. Only glycation of the N-terminal valine of the beta chain imparts sufficient negative charge to the hemoglobin molecule to allow separation by charge dependent techniques. These charge separated hemoglobins are collectively referred to as hemoglobin A₁ (HbA₁). The major form of HbA₁ is hemoglobin A_{1c} (HbA_{1c}) where glucose is the carbohydrate. HbA_{1c} comprises 4–6% of total hemoglobin A₁. The remaining HbA₁ species contain fructose-1,6 diphosphate (HbA_{1a1}); glucose-6-phosphate (HbA_{1a2}); and unknown carbohydrate moiety (HbA_{1b}). The hemoglobin A_{1c} fraction is abnormally elevated in diabetic persons with chronic hyperglycemia. Methods for measuring HbA_{1c} include electrophoresis, cation-exchange chromatography, boronate affinity chromatography, and immunoassays. Office-based immunoassays using capillary blood give a result in about 9 minutes and this allows for immediate feedback to the patients regarding their glycemic control.

Since glycohemoglobins circulate within red blood cells whose life span lasts up to 120 days, they generally reflect the state of glycemia over the preceding 8–12 weeks, thereby providing an improved method of assessing diabetic control. The HbA_{1c} value, however, is weighted to more recent glucose levels (previous month) and this explains why significant changes in HbA_{1c} are observed with short-term (1 month) changes in mean plasma glucose levels. Measurements should be made in patients with either type of diabetes mellitus at 3- to 4-month intervals so that adjust-

ments in therapy can be made if HbA_{1c} is either subnormal or if it is more than 2% above the upper limits of normal for a particular laboratory. In patients monitoring their own blood glucose levels, HbA_{1c} values provide a valuable check on the accuracy of monitoring. In patients who do not monitor their own blood glucose levels, HbA_{1c} values are essential for adjusting therapy. There is a linear relationship between the HbA_{1c} and the average glucose levels in the previous 3 months as determined from continuous glucose monitoring data and from seven-point capillary blood glucose profiles (preprandial, postprandial, and bedtime). Table 27-6 gives the mean capillary glucose values for HbA_{1c} values ranging from 5% to 12%. Use of HbA_{1c} for screening is controversial. Sensitivity in detecting known diabetes cases by HbA_{1c} measurements is only 85%, indicating that diabetes cannot be excluded by a normal value. On the other hand, elevated HbA_{1c} assays are fairly specific (91%) in identifying the presence of diabetes.

The accuracy of HbA_{1c} values can be affected by hemoglobin variants or derivatives; the effect depends on the specific hemoglobin variant or derivative and the specific assay used. Immunoassays that use an antibody to the glycosylated amino terminus of β globin do not recognize the terminus of the γ globin of hemoglobin F. Thus, in patients with high levels of hemoglobin F, immunoassays give falsely low values of HbA_{1c}. Cation-exchange chromatography separates hemoglobin species by charge differences. Hemoglobin variants that co-elute with HbA_{1c} can lead to an overestimation of the HbA_{1c} value. Chemically modified derivatives of hemoglobin such as carbamylation (in end-stage chronic kidney disease) or acetylation (high-dose aspirin therapy) can similarly co-elute with HbA_{1c} by some assay methods.

Any condition that shortens erythrocyte survival or decreases mean erythrocyte age (eg, recovery from acute blood loss, hemolytic anemia) will falsely lower HbA_{1c} irrespective of the assay method used. Alternative methods such as fructosamine (see below) should be considered for these

Table 27-6. Correlations of HbA_{1c} levels with average of capillary glucose measurements (preprandial, postprandial and bedtime) in the previous 3 months.

| HbA _{1c} Value (%) Determined Using DCCT Aligned Assays | Mean Capillary Blood Glucose Levels (mg/dL) |
|--|---|
| 5 | 97 |
| 6 | 126 |
| 7 | 154 |
| 8 | 183 |
| 9 | 212 |
| 10 | 240 |
| 11 | 269 |
| 12 | 298 |

Adapted, with permission, from Nathan et al. Translating the A_{1c} assay into estimated average glucose values. *Diabetes Care* 2008 Aug;31(8):1473–8.

patients. Vitamins C and E are reported to falsely lower test results possibly by inhibiting glycation of hemoglobin.

C. SERUM FRUCTOSAMINE—Serum fructosamine is formed by nonenzymatic glycosylation of serum proteins (predominantly albumin). Since serum albumin has a much shorter half-life than hemoglobin, serum fructosamine generally reflects the state of glycemic control for only the preceding 1–2 weeks. Reductions in serum albumin (eg, nephrotic state or hepatic disease) will lower the serum fructosamine value. When abnormal hemoglobins or hemolytic states affect the interpretation of glycohemoglobin or when a narrower time frame is required, such as for ascertaining glycemic control at the time of conception in a diabetic woman who has recently become pregnant, serum fructosamine assays offer some advantage. Normal values vary in relation to the serum albumin concentration and are 1.5–2.4 mmol/L when the serum albumin level is 5 g/dL.

D. SELF-MONITORING OF BLOOD GLUCOSE—Capillary blood glucose measurements performed by patients themselves, as outpatients, are extremely useful. In type 1 patients in whom “tight” metabolic control is attempted, they are indispensable. There are several paper strip (glucose oxidase, glucose dehydrogenase, or hexokinase) methods for measuring glucose on capillary blood samples. A reflectance photometer or an amperometric system is then used to measure the reaction that takes place on the reagent strip. A large number of blood glucose meters are now available. All are accurate, but they vary with regard to speed, convenience, size of blood samples required, and cost. Popular models include those manufactured by LifeScan (One Touch), Bayer Corporation (Ascencia), Roche Diagnostics (Accu-Chek), Abbott Laboratories (Precision, FreeStyle), and Home Diagnostics (Prestige). These blood glucose meters are relatively inexpensive, ranging from \$50 to \$100 each. Test strips remain a major expense, costing \$.50 to \$.75 apiece. Each glucose meter comes with a lancet device and disposable 26- to 33-gauge lancets. For some meters, there is a code associated with every batch of test strips, and this code needs to be entered into the meter before the strips can be used. Failure to properly code the meter can result in inaccurate readings. Patients not infrequently forget to change the code and it is preferable to give patients meters that do not require coding. The accuracy of data obtained by home glucose monitoring does require education of the patient in sampling and measuring procedures as well as in properly calibrating the instruments.

The clinician should be aware of the limitations of the self-monitoring glucose systems. First, a few of the older meters (such as the One Touch Profile) are calibrated against whole blood glucose concentrations even though the test strip measures the glucose in the plasma fraction. This means the displayed values are 10% to 15% lower than the laboratory glucose result. Second, increases or decreases in hematocrit can decrease or increase the measured glucose values. The mechanism underlying this effect is not known but presumably it is due to the impact of red cells on the diffusion of plasma into the reagent layer. Third, the meters and the test strips are calibrated over the glucose concentrations ranging from 60 mg/dL to 160 mg/dL, and

the accuracy is not as good for higher and lower glucose levels. When the glucose is less than 60 mg/dL, the difference between the meter and the laboratory value may be as much as 20%. Fourth, glucose oxidase-based amperometric systems underestimate glucose levels in the presence of high oxygen tension. This may be important in the critically ill who are receiving supplemental oxygen; under these circumstances, a glucose dehydrogenase-based system may be preferable. Fifth, some meters have been approved for measuring glucose in blood samples obtained at alternative sites such as the forearm and thigh. There is, however, a 5- to 20-minute lag in the glucose response on the arm with respect to the glucose response on the finger. Forearm blood glucose measurements could therefore result in a delay in detection of rapidly developing hypoglycemia.

E. CONTINUOUS GLUCOSE MONITORING SYSTEMS—Three continuous glucose monitoring systems are currently available for clinical use. The MiniMed Medtronic, Navigator, and DexCom systems involve inserting a subcutaneous sensor (rather like an insulin pump cannula) that measures glucose concentrations in the interstitial fluid for 3, 5, or 7 days, respectively. The data are transmitted to a separate pager-like device with a screen. The MiniMed system also has the option to wirelessly transmit the data to the screen of their insulin pump. The systems allow the patient to set “alerts” for low and high glucose values and rate of change of glucose levels. Patients still have to calibrate the devices with periodic fingerstick glucose levels, and since there are concerns regarding reliability, it is still necessary to confirm the displayed glucose level with a fingerstick glucose before making interventions such as injecting extra insulin or eating extra carbohydrates. A 6-month randomized controlled study of type 1 patients showed that adults (25 years and older) using these systems had improved glycemic control without an increase in the incidence of hypoglycemia. A randomized controlled study of continuous glucose monitoring during pregnancy showed improved glycemic control in the third trimester, lower birth weight, and reduced risk of macrosomia. The individual glucose values are not that critical—what matters is the direction and the rate at which the glucose is changing, allowing the user to take corrective action. The wearer also gains insight into the way particular foods and activities affect their glucose levels. The other main benefit is the low glucose alert warning. These systems are not covered by insurance and the initial cost is about \$800 to \$1000, and the sensor, which has to be changed every 3 to 7 days, costs \$35 to \$60. This adds up to an out-of-pocket expense of about \$4000 annually.

3. Lipoprotein abnormalities in diabetes—Circulating lipoproteins are just as dependent on insulin as is the plasma glucose. In type 1 diabetes, moderately deficient control of hyperglycemia is associated with only a slight elevation of LDL cholesterol and serum triglycerides and little if any change in HDL cholesterol. Once the hyperglycemia is corrected, lipoprotein levels are generally normal. However, in patients with type 2 diabetes, a distinct “diabetic dyslipidemia” is characteristic of the insulin resistance syndrome. Its features are a high serum triglyceride level (300–400 mg/dL), a low HDL cholesterol (less than 30 mg/dL),

and a qualitative change in LDL particles, producing a smaller dense particle whose membrane carries supranormal amounts of free cholesterol. These smaller dense LDL particles are more susceptible to oxidation, which renders them more atherogenic. Since a low HDL cholesterol is a major feature predisposing to macrovascular disease, the term “dyslipidemia” has preempted the term “hyperlipidemia,” which mainly denoted the elevated triglycerides. Measures designed to correct the obesity and hyperglycemia, such as exercise, diet, and hypoglycemic therapy, are the treatment of choice for diabetic dyslipidemia, and in occasional patients in whom normal weight was achieved, all features of the lipoprotein abnormalities cleared. Since primary disorders of lipid metabolism may coexist with diabetes, persistence of lipid abnormalities after restoration of normal weight and blood glucose should prompt a diagnostic workup and possible pharmacotherapy of the lipid disorder. Chapter 28 discusses these matters in detail.

► Differential Diagnosis

A. Hyperglycemia Secondary to Other Causes

Secondary hyperglycemia has been associated with various disorders of insulin target tissues (liver, muscle, and adipose tissue) (Table 27–7). Other secondary causes of carbohydrate intolerance include endocrine disorders—often specific endocrine tumors—associated with excess production of growth hormone, glucocorticoids, catecholamines, glucagon, or somatostatin. In the first four situations, peripheral responsiveness to insulin is impaired. With excess of glucocorticoids, catecholamines, or glucagon, increased hepatic output of glucose is a contributory factor; in the case of catecholamines, decreased insulin release is an additional factor in producing carbohydrate intolerance, and with excess somatostatin production it is the major factor.

A rare syndrome of extreme insulin resistance associated with acanthosis nigricans afflicts either young women with androgenic features as well as insulin receptor mutations or older people, mostly women, in whom a circulating immunoglobulin binds to insulin receptors and reduces their affinity to insulin.

Table 27–7. Secondary causes of hyperglycemia.

| |
|---|
| Hyperglycemia due to tissue insensitivity to insulin |
| Hormonal tumors (acromegaly, Cushing syndrome, glucagonoma, pheochromocytoma) |
| Pharmacologic agents (corticosteroids, sympathomimetic drugs, niacin) |
| Liver disease (cirrhosis, hemochromatosis) |
| Muscle disorders (myotonic dystrophy) |
| Adipose tissue disorders (lipodystrophy, truncal obesity) |
| Insulin receptor disorders (acanthosis nigricans syndromes, leprechaunism) |
| Hyperglycemia due to reduced insulin secretion |
| Hormonal tumors (somatostatinoma, pheochromocytoma) |
| Pancreatic disorders (pancreatitis, hemosiderosis, hemochromatosis) |
| Pharmacologic agents (thiazide diuretics, phenytoin, pentamidine) |

Medications such as diuretics, phenytoin, niacin, and high-dose corticosteroids can produce hyperglycemia that is reversible once the drugs are discontinued or when diuretic-induced hypokalemia is corrected. Chronic pancreatitis or subtotal pancreatectomy reduces the number of functioning B cells and can result in a metabolic derangement very similar to that of genetic type 1 diabetes except that a concomitant reduction in pancreatic A cells may reduce glucagon secretion so that relatively lower doses of insulin replacement are needed. Insulin-dependent diabetes is occasionally associated with Addison disease and autoimmune thyroiditis (**Schmidt syndrome**, or **polyglandular failure syndrome**). This occurs more commonly in women and represents an autoimmune disorder in which there are circulating antibodies to adrenocortical and thyroid tissue, thyroglobulin, and gastric parietal cells.

B. Nondiabetic Glycosuria

Nondiabetic glycosuria (renal glycosuria) is a benign asymptomatic condition wherein glucose appears in the urine despite a normal amount of glucose in the blood, either basally or during a glucose tolerance test. Its cause may vary from an autosomally transmitted genetic disorder to one associated with dysfunction of the proximal renal tubule (Fanconi syndrome, chronic kidney disease), or it may merely be a consequence of the increased load of glucose presented to the tubules by the elevated glomerular filtration rate during pregnancy. As many as 50% of pregnant women normally have demonstrable sugar in the urine, especially during the third and fourth months. This sugar is practically always glucose except during the late weeks of pregnancy, when lactose may be present.

► Clinical Trials in Diabetes

Findings of the Diabetes Complications and Control Trial (DCCT) and of the United Kingdom Prospective Diabetes Study (UKPDS), have confirmed the beneficial effects of improved glycemic control in both type 1 and type 2 diabetes, respectively (see below). In addition, with increased understanding of the pathophysiology of both type 1 and type 2 diabetes, large prospective studies—Diabetes Prevention Trial 1 (DPT-1) and the Diabetes Prevention Program (DPP)—have been performed in attempts to prevent onset of these disorders (see below).

A. Clinical Trials in Type 1 Diabetes

1. Diabetes Prevention Trial-1—This multicenter study sponsored by the National Institutes of Health was designed to determine whether the development of type 1 diabetes mellitus could be prevented or delayed by immune intervention therapy. Daily low-dose insulin injections were administered for up to 8 years in first-degree relatives of type 1 diabetic patients who were selected as being at high risk for development of type 1 diabetes because of detectable islet cell antibodies and reduced early-insulin release. Unfortunately, this immune intervention failed to affect the onset of type 1 diabetes compared with a randomized untreated group. A related study using oral insulin in lower

risk first-degree relatives who have islet cell antibodies but whose early insulin release remains intact also failed to show an effect on the onset of type 1 diabetes. After an average of 4.3 years of observation, type 1 diabetes developed in about 35% of persons in both the oral insulin and the placebo groups.

2. The Diabetes Control and Complications Trial—

A long-term therapeutic study involving 1441 patients with type 1 diabetes mellitus reported that “near” normalization of blood glucose resulted in a delay in the onset and a major slowing of the progression of established microvascular and neuropathic complications of diabetes during a follow-up period of up to 10 years. Multiple insulin injections (66%) or insulin pumps (34%) were used in the intensively treated group, who were trained to modify their therapy in response to frequent glucose monitoring. The conventionally treated groups used no more than two insulin injections, and clinical well-being was the goal with no attempt to modify management based on HbA_{1c} determinations or the glucose results.

In half of the patients, a mean hemoglobin A_{1c} of 7.2% (normal: < 6%) and a mean blood glucose of 155 mg/dL were achieved using intensive therapy, while in the conventionally treated group HbA_{1c} averaged 8.9% with an average blood glucose of 225 mg/dL. Over the study period, which averaged 7 years, there was an approximately 60% reduction in risk between the two groups in regard to diabetic retinopathy, nephropathy, and neuropathy. The intensively treated group also had a nonsignificant reduction in the risk of macrovascular disease of 41% (95% CI, -10 to 68). Intensively treated patients had a threefold greater risk of serious hypoglycemia as well as a greater tendency toward weight gain. However, there were no deaths definitely attributable to hypoglycemia in any persons in the DCCT study, and no evidence of posthypoglycemic cognitive damage was detected.

Subjects participating in the DCCT study were subsequently enrolled in a follow-up observational study, the Epidemiology of Diabetes Interventions and Complications (EDIC) study. Even though the between-group differences in mean HbA_{1c} narrowed over 4 years, the group assigned to intensive therapy had a lower risk of retinopathy at 4 years and microalbuminuria at 7 to 8 years of continued study follow-up. Moreover, by the end of the 11-year follow-up period, the intensive therapy group had significantly reduced their risk of any cardiovascular disease events by 42% (95% CI, 9% to 23%; $P = 0.02$). Thus, it seems that the benefits of good glucose control persist even if control deteriorates at a later date.

The general consensus of the ADA is that intensive insulin therapy associated with comprehensive self-management training should become standard therapy in patients with type 1 diabetes mellitus after the age of puberty. Exceptions include those with advanced chronic kidney disease and the elderly, since in these groups the detrimental risks of hypoglycemia outweigh the benefits of tight glyce-mic control.

3. Immune intervention trials in new-onset type 1 diabetes—At the time of diagnosis of type 1 diabetes, patients still have significant B cell function. This explains

why soon after diagnosis patients go into a partial clinical remission (“honeymoon”) requiring little or no insulin. This clinical remission is short-lived, however, and eventually patients lose all B cell function and have more labile glucose control. Attempts have been made to prolong this partial clinical remission using drugs such as cyclosporine, azathioprine, prednisone, and antithymocyte globulin. These drugs have had limited efficacy, and there are concerns about toxicity and the need for continuous treatment.

Newer agents that may induce immune tolerance and appear to have few side effects have been used in new-onset type 1 patients. Two studies with anti-CD3 antibodies have demonstrated that these agents can preserve endogenous insulin production. Larger phase 2 clinical trials are currently in progress.

B. Clinical Trials in Type 2 Diabetes

1. The Diabetes Prevention Program—This study was aimed at discovering whether treatment with either diet and exercise or metformin could prevent the onset of type 2 diabetes in people with impaired glucose tolerance; 3234 overweight men and women aged 25–85 years with impaired glucose tolerance participated in the study. Intervention with a low-fat diet and 150 minutes of moderate exercise (equivalent to a brisk walk) per week reduced the risk of progression to type 2 diabetes by 71% compared with a matched control group. Participants taking 80 mg of metformin twice a day reduced their risk of developing type 2 diabetes by 31%, but this intervention was relatively ineffective in those who were either less obese or in the older age group.

With the demonstration that intervention can be successful in preventing progression to diabetes in these subjects, a recommendation has been made to change the terminology from the less comprehensible “impaired glucose tolerance” to “prediabetes.” The latter is a term that the public can better understand and thus respond to by implementing healthier diet and exercise habits.

2. Kumamoto study—The Kumamoto study involved a relatively small number of patients with type 2 diabetes ($n = 110$) who were nonobese and only slightly insulin-resistant, requiring less than 30 units of insulin per day for intensive therapy. Over a 6-year period, it was shown that intensive insulin therapy, achieving a mean HbA_{1c} of 7.1%, significantly reduced microvascular end points compared with conventional insulin therapy achieving a mean HbA_{1c} of 9.4%. Cardiovascular events were neither worsened nor improved by intensive therapy, and weight changes were likewise not influenced by either form of treatment.

3. The United Kingdom Prospective Diabetes Study—This multicenter study was designed to establish, in type 2 diabetic patients, whether the risk of macrovascular or microvascular complications could be reduced by intensive blood glucose control with oral hypoglycemic agents or insulin and whether any particular therapy was of advantage. A total of 3867 patients aged 25–65 years with newly diagnosed diabetes were recruited between 1977 and 1991, and studied over 10 years. The median age at baseline was 54 years; 44% were overweight (> 120% over ideal weight); and

baseline HbA_{1c} was 9.1%. Therapies were randomized to include a control group on diet alone and separate groups intensively treated with either insulin or sulfonylurea (chlorpropamide, glyburide, or glipizide). Metformin was included as a randomization option in a subgroup of 342 overweight or obese patients, and much later in the study an additional subgroup of both normal-weight and overweight patients who were responding unsatisfactorily to sulfonylurea therapy were randomized to either continue on their sulfonylurea therapy alone or to have metformin combined with it.

A. HYPERTENSION CONTROL SUBSTUDY—In 1987, an additional modification was made to evaluate whether tight control of blood pressure with stepwise antihypertensive therapy would prevent macrovascular and microvascular complications in 758 hypertensive patients among this UKPDS population compared with 390 of them whose blood pressure was treated less intensively. The tight control group was randomly assigned to treatment with either an angiotensin-converting enzyme (ACE) inhibitor (captopril) or a β -blocker (atenolol). Both drugs were stepped up to maximum dosages of 100 mg/d and then, if blood pressure remained higher than the target level of < 150/85 mm Hg, more drugs were added in the following stepwise sequence: a diuretic, slow-release nifedipine, methyldopa, and prazosin—until the target level of tight control was achieved. In the control group, hypertension was conventionally treated to achieve target levels < 180/105 mm Hg, but these patients were not prescribed either ACE inhibitors or β -blockers.

B. RESULTS OF THE UKPDS—Intensive treatment with either sulfonylureas, metformin, combinations of those two, or insulin achieved mean HbA_{1c} levels of 7%. This level of glycemic control decreases the risk of microvascular complications (retinopathy and nephropathy) in comparison with conventional therapy (mostly diet alone), which achieved mean levels of HbA_{1c} of 7.9%. Weight gain occurred in intensively treated patients except when metformin was used as monotherapy. No cardiovascular benefit and no adverse cardiovascular outcomes were noted regardless of the therapeutic agent. Hypoglycemic reactions occurred in the intensive treatment groups, but only one death from hypoglycemia was documented during 27,000 patient-years of intensive therapy.

When therapeutic subgroups were analyzed, some unexpected and paradoxical results were noted. Among the obese patients, intensive treatment with insulin or sulfonylureas did not reduce microvascular complications compared with diet therapy alone. This was in contrast to the significant benefit of intensive therapy with these drugs in the total group. Furthermore, intensive therapy with metformin was more beneficial in the overweight or obese persons than diet alone with regard to fewer myocardial infarctions, strokes, and diabetes-related deaths, but there was no significant reduction by metformin of diabetic microvascular complications as compared with the diet group. Moreover, in the subgroup of obese and nonobese patients in whom metformin was added to sulfonylurea failures, rather than showing a benefit, there was a 96% increase in diabetes-related deaths compared with the matched cohort of patients with unsatisfactory glycemic

control on sulfonylureas who remained on their sulfonylurea therapy. Chlorpropamide also came out poorly on subgroup analysis in that those receiving it as intensive therapy did less well regarding progression to retinopathy than those conventionally treated with diet.

Intensive antihypertensive therapy to a mean of 144/82 mm Hg had beneficial effects on microvascular disease as well as on all diabetes-related end points, including virtually all cardiovascular outcomes, in comparison with looser control at a mean of 154/87 mm Hg. In fact, the advantage of reducing hypertension by this amount was substantially more impressive than the benefit achieved by improving the degree of glycemic control from a mean HbA_{1c} of 7.9% to 7%. More than half of the patients needed two or more drugs for adequate therapy of their hypertension, and there was no demonstrable advantage of ACE inhibitor therapy over therapy with β -blockers with regard to diabetes end points. Use of a calcium channel blocker added to both treatment groups appeared to be safe over the long term in this diabetic population despite some controversy in the recent literature about its safety in diabetics.

Like the DCCT trialists, the UKPDS researchers performed post-trial monitoring to determine whether there were long-term benefits of having been in the intensively treated glucose and blood pressure arms of the study. The between-group differences in HbA_{1c} were lost within the first year of follow-up, but the reduced risk (24%, $P = 0.001$) of development or progression of microvascular complications in the intensively treated group persisted for 10 years. The intensively treated group also had significantly reduced risk of myocardial infarction (15%, $P = 0.01$) and death from any cause (13%, $P = 0.007$) during the follow-up period. The subgroup of overweight or obese subjects who were initially randomized to metformin therapy showed sustained reduction in risk of myocardial infarction and death from any cause in the follow-up period. The between-group blood pressure differences disappeared within 2 years of the end of the trial. Unlike the sustained benefits seen with glucose control, there were no sustained benefits from having been in the more tightly controlled blood pressure group. Both blood pressure groups were at similar risk for microvascular events and diabetes-related end points during the follow-up period.

Thus, the follow-up of the UKPDS type 2 diabetes cohort showed that, as in type 1 diabetes, the benefits of good glucose control persist even if control deteriorates at a later date. Blood pressure benefits, however, last only as long as the blood pressure is well controlled.

4. The Steno-2 study—The Steno-2 study was designed in 1990 to validate the efficacy of targeting multiple concomitant risk factors for both microvascular and macrovascular disorders in type 2 diabetes. A prospective, randomized, open, blinded end point design was used where 160 patients with type 2 diabetes and microalbuminuria were assigned to conventional therapy with their general practitioner or to intensive care at the Steno Diabetes Center. The intensively treated group had step-wise introduction of lifestyle and pharmacologic interventions aimed at keeping glycated hemoglobin less than 6.5%, blood pressure less than 130/80

mm Hg; total cholesterol < 175 mg/dL, and triglycerides < 150 mg/dL. All the intensively treated group received ACE inhibitors and if intolerant, an angiotensin II-receptor blocker. The lifestyle component of intensive intervention included reduction in dietary fat intake to less than 30% of total calories; smoking cessation program; light to moderate exercise; daily vitamin-mineral supplement of vitamin C, E, and chromium picolinate. Initially, aspirin was only given as secondary prevention to patients with a history of ischemic cardiovascular disease; later, all patients received aspirin. After a mean follow-up of 7.8 years, cardiovascular events (eg, myocardial infarction, angioplasties, coronary bypass grafts, strokes, amputations, vascular surgical interventions) developed in 44% of patients in the conventional arm and only in 24% in the intensive multifactorial arm—about a 50% reduction. Rates of nephropathy, retinopathy, and autonomic neuropathy were also lower in the multifactorial intervention arm by 62% and 63%, respectively.

The data from the UKPDS and this study provide support for guidelines recommending vigorous treatment of concomitant microvascular and cardiovascular risk factors in patients with type 2 diabetes.

5. ACCORD and ADVANCE studies—The ACCORD study was a randomized controlled study designed to determine whether normal HbA_{1c} levels would reduce the risk of cardiovascular events in middle-aged or older individuals with type 2 diabetes. About 35% of the 10,251 recruited subjects had established cardiovascular disease at study entry. The intensive arm of the study was discontinued after 3.5 years of follow-up because of more unexplained deaths in the intensive arm when compared with the control arm (22%, $P = 0.020$). Analysis of the data at time of discontinuation showed that the intensively treated group (mean HbA_{1c} 6.4%) had a 10% reduction in cardiovascular event rate compared with the standard treated group (mean HbA_{1c} 7.5%), but this difference was not statistically significant.

The ADVANCE trial randomly assigned 11,140 patients with type 2 diabetes to standard or intensive glucose control. The primary outcomes were major macrovascular cardiovascular events (nonfatal myocardial infarction or stroke or death from cardiovascular causes) or microvascular events. Overall, one-third (32%) of the subjects had established cardiovascular disease at study entry. After a median follow-up of 5 years, there was a nonsignificant reduction (6%) in major macrovascular event rate in the intensively treated group (mean HbA_{1c} 6.5%) compared with the standard therapy group (HbA_{1c} 7.3%).

Thus, the ACCORD and ADVANCE results do not provide support for the hypothesis that near-normal glucose control in patients with type 2 diabetes will reduce cardiovascular events. It is, however, important not to overinterpret the results of these two studies. The results do not exclude the possibility that cardiovascular benefits might accrue with longer duration of near-normal glucose control. In the UKPDS, risk reductions for myocardial infarction and death from any cause were only observed during 10 years of post-trial follow-up. Specific subgroups of type 2 diabetic patients may also have different outcomes. The ACCORD and ADVANCE studies recruited patients who had diabetes

for 8–10 years and one-third of them already had established cardiovascular disease. Patients in the UKPDS, in contrast, had newly diagnosed diabetes and only 7.5% had a history of macrovascular disease. It is possible that the benefits of tight glycemic control on macrovascular events are attenuated in patients with longer duration of diabetes or with established vascular disease. Specific therapies used to lower glucose may also affect cardiovascular event rate or mortality. Severe hypoglycemia occurred more frequently in the intensively treated groups of the ACCORD and ADVANCE studies; the ACCORD investigators were not able to exclude undiagnosed hypoglycemia as a potential cause for the increased death rate in the intensive treatment group.

▶ Treatment Regimens

A. Diet

A well-balanced, nutritious diet remains a fundamental element of therapy. The American Diabetes Association (ADA) recommends about 45–65% of total daily calories in the form of carbohydrates; 25–35% in the form of fat (of which less than 7% are from saturated fat), and 10–35% in the form of protein. In patients with type 2 diabetes, limiting the carbohydrate intake and substituting some of the calories with monounsaturated fats, such as olive oil, rapeseed (canola) oil, or the oils in nuts and avocados, can lower triglycerides and increase HDL cholesterol. Patients with type 1 diabetes or type 2 diabetes who take insulin should be taught “carbohydrate counting,” so they can administer their insulin bolus for each meal based on its carbohydrate content. In obese individuals with diabetes, an additional goal is weight reduction by caloric restriction (see Chapter 29).

The current recommendations for both types of diabetes continue to limit cholesterol to 300 mg daily, and individuals with LDL cholesterol more than 100 mg/dL should limit dietary cholesterol to 200 mg daily. High protein intake may cause progression of kidney disease in patients with diabetic nephropathy; for these individuals, a reduction in protein intake to 0.8 kg/day (or about 10% of total calories daily) is recommended.

Exchange lists for meal planning can be obtained from the American Diabetes Association and its affiliate associations or from the American Dietetic Association, 216 W. Jackson Blvd., Chicago, IL 60606 (312-899-0040). Their Internet address is <http://www.eatright.org>.

1. Dietary fiber—Plant components such as cellulose, gum, and pectin are indigestible by humans and are termed dietary “fiber.” Insoluble fibers such as cellulose or hemicellulose, as found in bran, tend to increase intestinal transit and may have beneficial effects on colonic function. In contrast, soluble fibers such as gums and pectins, as found in beans, oatmeal, or apple skin, tend to retard nutrient absorption rates so that glucose absorption is slower and hyperglycemia may be slightly diminished. Although its recommendations do not include insoluble fiber supplements such as added bran, the ADA recommends food such as oatmeal, cereals, and beans with relatively high soluble fiber content as staple components of the diet in diabetics. High soluble fiber

content in the diet may also have a favorable effect on blood cholesterol levels.

2. Artificial and other sweeteners—Aspartame (Nutra Sweet) consists of two major amino acids, aspartic acid and phenylalanine, which combine to produce a sweetener 180 times as sweet as sucrose. A major limitation is that it is not heat stable, so it cannot be used in cooking. Saccharin (Sweet 'N Low), Sucralose (Splenda), and Acesulfame potassium (Sweet One) are other “artificial” sweeteners that can be used in cooking and baking.

Fructose represents a “natural” sugar substance that is a highly effective sweetener, induces only slight increases in plasma glucose levels, and does not require insulin for its metabolism. However, because of potential adverse effects of large amounts of fructose on raising serum cholesterol, triglycerides, and LDL cholesterol, it does not have any advantage as a sweetening agent in the diabetic diet. This does not preclude, however, ingestion of fructose-containing fruits and vegetables or fructose-sweetened foods in moderation.

Sugar alcohols, also known as polyols or polyalcohol, are commonly used as sweeteners and bulking agents. They occur naturally in a variety of fruits and vegetables but are also commercially made from sucrose, glucose, and starch. Examples are sorbitol, xylitol, mannitol, lactitol, isomalt, maltitol, and hydrogenated starch hydrolysates (HSH). They are not as easily absorbed as sugar, so they do not raise blood glucose levels as much. Therefore, sugar alcohols are often used in food products that are labeled as “sugar free,” such as chewing gum, lozenges, hard candy, and sugar-free ice cream. However, if consumed in large quantities, they will raise blood glucose and can cause bloating and diarrhea.

B. Drugs for Treating Hyperglycemia

(Table 27–8.) The drugs for treating type 2 diabetes fall into several categories: (1) Drugs that primarily stimulate insulin secretion by binding to the sulfonylurea receptor. Sulfonylureas remain the most widely prescribed drugs for treating hyperglycemia. The meglitinide analog repaglinide and the D-phenylalanine derivative nateglinide also bind the sulfonylurea receptor and stimulate insulin secretion. (2) Drugs that alter insulin action: Metformin works in the liver. The thiazolidinediones appear to have their main effect on skeletal muscle and adipose tissue. (3) Drugs that principally affect absorption of glucose: The α -glucosidase inhibitors acarbose and miglitol are such currently available drugs. (4) Drugs that mimic incretin effect or prolong incretin action: Exenatide and DPP IV inhibitors fall into this category. (5) Other: Pramlintide lowers glucose by suppressing glucagon and slowing gastric emptying.

1. Drugs that primarily stimulate insulin secretion by binding to the sulfonylurea receptor on the beta cell

A. SULFONYLUREAS—The primary mechanism of action of the sulfonylureas is to stimulate insulin release from pancreatic B cells. Specific receptors on the surface of pancreatic B cells bind sulfonylureas in the rank order of their insulinotropic potency (glyburide with the greatest affinity and tolbutamide with the least affinity). It has been shown

that activation of these receptors closes potassium channels, resulting in depolarization of the B cell. This depolarized state permits calcium to enter the cell and actively promote insulin release.

Sulfonylureas are not indicated for use in type 1 diabetes patients since these drugs require functioning pancreatic B cells to produce their effect on blood glucose. These drugs are used in patients with type 2 diabetes, in whom acute administration improves the early phase of insulin release that is refractory to acute glucose stimulation. Sulfonylureas are metabolized by the liver and apart from acetohexamide, whose metabolite is more active than the parent compound, the metabolites of all the other sulfonylureas are weakly active or inactive. The metabolites are excreted by the kidney and, in the case of the second-generation sulfonylureas, partly excreted in the bile. Sulfonylureas are generally contraindicated in patients with severe liver or kidney impairment. Idiosyncratic reactions are rare, with skin rashes or hematologic toxicity (leukopenia, thrombocytopenia) occurring in less than 0.1% of users.

(1) First-generation sulfonylureas (tolbutamide, tolazamide, acetohexamide, chlorpropamide)—**Tolbutamide** is supplied as 500-mg tablets. It is rapidly oxidized in the liver to inactive metabolites, and its approximate duration of effect is relatively short (6–10 hours). Tolbutamide is probably best administered in divided doses (eg, 500 mg before each meal and at bedtime); however, some patients require only one or two tablets daily with a maximum dose of 3000 mg/d. Because of its short duration of action, which is independent of kidney function, tolbutamide is probably the safest sulfonylurea to use if liver function is normal. Prolonged hypoglycemia has been reported rarely with tolbutamide, mostly in patients receiving certain antibacterial sulfonamides (sulfisoxazole), phenylbutazone for arthralgias, or the oral azole antifungal drugs to treat candidiasis. These drugs apparently compete with tolbutamide for oxidative enzyme systems in the liver, resulting in maintenance of high levels of unmetabolized, active sulfonylurea in the circulation.

Tolazamide, acetohexamide, and chlorpropamide are rarely used. Chlorpropamide has a prolonged biologic effect, and severe hypoglycemia can occur especially in the elderly as their renal clearance declines with aging. Its other side effects include alcohol-induced flushing and hyponatremia due to its effect on vasopressin secretion and action.

(2) Second-generation sulfonylureas (glyburide, glipizide, gliclazide, glimepiride)—Glyburide, glipizide, gliclazide, and glimepiride are 100–200 times more potent than tolbutamide. These drugs should be used with caution in patients with cardiovascular disease or in elderly patients, in whom prolonged hypoglycemia would be especially dangerous.

Glyburide is available in 1.25-mg, 2.5-mg, and 5-mg tablets. The usual starting dose is 2.5 mg/d, and the average maintenance dose is 5–10 mg/d given as a single morning dose; maintenance doses higher than 20 mg/d are not recommended. Some reports suggest that 10 mg is a maximum daily therapeutic dose, with 15–20 mg having no additional benefit in poor responders and doses over 20 mg actually worsening hyperglycemia. Glyburide is metabolized

Table 27–8. Drugs for treatment of type 2 diabetes mellitus.

| Drug | Tablet Size | Daily Dose | Duration of Action |
|---|---|--|--------------------|
| Sulfonylureas | | | |
| Tolbutamide (Orinase) | 500 mg | 0.5–2 g in two or three divided doses | 6–12 hours |
| Tolazamide (Tolinase) | 100, 250, and 500 mg | 0.1–1 g as single dose or in two divided doses | Up to 24 hours |
| Acetohexamide (Dymelor) | 250 and 500 mg | 0.25–1.5 g as single dose or in two divided doses | 8–24 hours |
| Chlorpropamide (Diabinese) | 100 and 250 mg | 0.1–0.5 g as single dose | 24–72 hours |
| Glyburide (DiaBeta, Micronase) | 1.25, 2.5, and 5 mg | 1.25–20 mg as single dose or in two divided doses | Up to 24 hours |
| (Glynase) | 1.5, 3, and 6 mg | 1.5–12 mg as single dose or in two divided doses | Up to 24 hours |
| Glipizide | | | |
| (Glucotrol) | 5 and 10 mg | 2.5–20 mg twice a day 30 minutes before meals | 6–12 hours |
| (Glucotrol XL) | 2.5, 5, and 10 mg | 2.5 to 10 mg once a day is usual dose; 20 mg once a day is maximal dose | Up to 24 hours |
| Gliclazide (not available in US) | 80 mg | 40–80 mg as single dose; 160–320 mg as divided dose | 12 hours |
| Glimepiride (Amaryl) | 1, 2, and 4 mg | 1–4 mg once a day is usual dose; 8 mg once a day is maximal dose | Up to 24 hours |
| Meglitinide analogs | | | |
| Repaglinide (Prandin) | 0.5, 1, and 2 mg | 0.5 to 4 mg three times a day before meals | 3 hours |
| D-Phenylalanine derivative | | | |
| Nateglinide (Starlix) | 60 and 120 mg | 60 or 120 mg three times a day before meals | 1.5 hours |
| Biguanides | | | |
| Metformin (Glucophage) | 500, 850, and 1000 mg | 1–2.5 g; 1 tablet with meals two or three times daily | 7–12 hours |
| Extended-release metformin (Glucophage XR) | 500 mg | 500–2000 mg once a day | Up to 24 hours |
| Thiazolidinediones | | | |
| Rosiglitazone (Avandia) | 2, 4, and 8 mg | 4–8 mg daily (can be divided) | Up to 24 hours |
| Pioglitazone (Actos) | 15, 30, and 45 mg | 15–45 mg daily | Up to 24 hours |
| α-Glucosidase inhibitors | | | |
| Acarbose (Precose) | 50 and 100 mg | 25 to 100 mg three times a day just before meals | 4 hours |
| Miglitol (Glyset) | 25, 50, and 100 mg | 25–100 mg three times a day just before meals | 4 hours |
| Incretins | | | |
| Exenatide (Byetta) | 1.2 mL and 2.4 mL pre-filled pens containing 5 mcg and 10 mcg (subcutaneous injection) | 5 mcg subcutaneously twice a day within 1 hour of breakfast and dinner. Increase to 10 mcg subcutaneously twice a day after about a month. Do not use if calculated creatinine clearance is less than 30 mL/min. | 6 hours |
| Sitagliptin (Januvia) | 25, 50, and 100 mg | 100 mg once daily is usual dose; dose is 50 mg once daily if calculated creatinine clearance is 30 to 50 mL/min and 25 mg once daily if clearance is less than 30 mL/min. | 24 hours |
| Others | | | |
| Pramlintide (Symlin) | 5 mL vial containing 0.6 mg/mL; also available as pre-filled pens. Symlin pen 60 or Symlin pen 120 (subcutaneous injection) | For insulin-treated type 2 patients, start at 60 mcg dose three times a day (10 units on U100 insulin syringe). Increase to 120 mcg three times a day (20 units on U100 insulin syringe) if no nausea for 3–7 days. Give immediately before meal. For type 1 patients, start at 15 mcg three times a day (2.5 units on U100 insulin syringe) and increase by increments of 15 mcg to a maximum of 60 mcg three times a day, as tolerated. To avoid hypoglycemia, lower insulin dose by 50% on initiation of therapy. | |

in the liver into products with hypoglycemic activity, which probably explains why assays specific for the unmetabolized compound suggest a plasma half-life of only 1–2 hours, yet the biologic effects of glyburide are clearly persistent 24 hours after a single morning dose in diabetic patients. Glyburide is unique among sulfonylureas in that it not only binds to the pancreatic B cell membrane sulfonylurea receptor but also becomes sequestered within the B cell. This may also contribute to its prolonged biologic effect despite its relatively short circulating half-life. A “Press Tab” formulation of “micronized” glyburide—easy to divide in half with slight pressure if necessary—is available in tablet sizes of 1.5 mg, 3 mg, and 6 mg.

Glyburide has few adverse effects other than its potential for causing hypoglycemia, which at times can be prolonged. Flushing has rarely been reported after ethanol ingestion. It does not cause water retention, as chlorpropamide does, but rather slightly enhances free water clearance. Glyburide is absolutely contraindicated in the presence of hepatic impairment and should not be used in patients with chronic kidney disease, in elderly patients, or in those who would be put at serious risk from an episode of hypoglycemia.

Glipizide is available in 5-mg and 10-mg tablets. For maximum effect in reducing postprandial hyperglycemia, this agent should be ingested 30 minutes before meals, since rapid absorption is delayed when the drug is taken with food. The recommended starting dose is 5 mg/d, with up to 15 mg/d given as a single daily dose before breakfast. When higher daily doses are required, they should be divided and given before meals. The maximum dose recommended by the manufacturer is 40 mg/d, although doses above 10–15 mg probably provide little additional benefit in poor responders and may even be *less* effective than smaller doses.

At least 90% of glipizide is metabolized in the liver to inactive products, and 10% is excreted unchanged in the urine. Glipizide therapy is therefore contraindicated in patients with liver or kidney impairment, who would be at high risk for hypoglycemia; but because of its lower potency and shorter duration of action, it is preferable to glyburide in elderly patients. Glipizide has also been marketed as Glucotrol-XL in 5-mg and 10-mg tablets. It provides extended release during transit through the gastrointestinal tract with greater effectiveness in lowering prebreakfast hyperglycemia than the shorter-duration immediate-release standard glipizide tablets. However, this formulation appears to have sacrificed its lower propensity for severe hypoglycemia compared with longer-acting glyburide without showing any demonstrable therapeutic advantages over glyburide.

Gliclazide (not available in the United States) is another intermediate duration sulfonylurea with a duration of action of about 12 hours. It is available as 80 mg tablets. The recommended starting dose is 40–80 mg/d with a maximum dose of 320 mg. Doses of 160 mg and above are given as divided doses before breakfast and dinner. The drug is metabolized by the liver; the metabolites and conjugates have no hypoglycemic effect. An extended release preparation is available.

Glimepiride is given once daily as monotherapy or in combination with insulin to lower blood glucose in diabetes

patients who cannot control their glucose level through diet and exercise. Glimepiride achieves blood glucose lowering with the lowest dose of any sulfonylurea compound, and this tends to increase its cost-effectiveness. A single daily dose of 1 mg/d has been shown to be effective, and the maximal recommended dose is 8 mg. It has a long duration of action with a pharmacodynamic half-life of 5 hours, allowing once-daily administration, which improves compliance. It is completely metabolized by the liver to relatively inactive metabolic products.

B. MEGLITINIDE ANALOGS—Repaglinide is structurally similar to glyburide but lacks the sulfonic acid-urea moiety. It acts by binding to the sulfonylurea receptor and closing the ATP-sensitive potassium channel. It is rapidly absorbed from the intestine and then undergoes complete metabolism in the liver to inactive biliary products, giving it a plasma half-life of less than 1 hour. The drug therefore causes a brief but rapid pulse of insulin. The starting dose is 0.5 mg three times a day 15 minutes before each meal. The dose can be titrated to a maximal daily dose of 16 mg. Like the sulfonylureas, repaglinide can be used in combination with metformin. Hypoglycemia is the main side effect. In clinical trials, when the drug was compared with a long-duration sulfonylurea (glyburide), there was a trend toward less hypoglycemia. Like the sulfonylureas also, repaglinide causes weight gain. Metabolism is by cytochrome P450 3A4 isoenzyme, and other drugs that induce or inhibit this isoenzyme may increase or inhibit (respectively) the metabolism of repaglinide. The drug may be useful in patients with kidney impairment or in the elderly.

C. D-PHENYLALANINE DERIVATIVE—Nateglinide stimulates insulin secretion by binding to the sulfonylurea receptor and closing the ATP-sensitive potassium channel. This compound is rapidly absorbed from the intestine, reaching peak plasma levels within 1 hour. It is metabolized in the liver and has a plasma half-life of about 1.5 hours. Like repaglinide, it causes a brief rapid pulse of insulin, and when given before a meal it reduces the postprandial rise in blood glucose. The drug is available as 60-mg and 120-mg tablets. The 60-mg dose is used in patients who have mild elevations in HbA_{1c}. For most patients, the recommended starting and maintenance dose is 120 mg three times a day before meals. Like the other insulin secretagogues, its main side effects are hypoglycemia and weight gain.

2. Drugs that alter insulin action

A. METFORMIN—Metformin (1,1-dimethylbiguanide hydrochloride) is used, either alone or in conjunction with other oral agents or insulin, in the treatment of patients with type 2 diabetes.

Metformin's primary action is on the liver, reducing hepatic gluconeogenesis by activating adenosine monophosphate-activated protein kinase (AMPK), which acts as an intracellular energy sensor, and has a critical role regulating gluconeogenesis. LKB1 is a protein threonine kinase that phosphorylates and activates AMPK; it was recently reported that in mice the deletion of LKB1 function in the liver results in hyperglycemia with increased gluconeogenic and lipogenic gene expression. The deletion of LKB1 also eliminated the

glucose lowering effect of metformin, providing genetic proof for the hypothesis that metformin lowers glucose levels by AMP kinase activation.

Metformin has a half-life of 1.5–3 hours, is not bound to plasma proteins, and is not metabolized in humans, being excreted unchanged by the kidneys.

Metformin may be used as an adjunct to diet for the control of hyperglycemia and its associated symptoms in patients with type 2 diabetes, particularly those who are obese or are not responding optimally to maximal doses of sulfonylureas. A side benefit of metformin therapy is its tendency to improve both fasting and postprandial hyperglycemia and hypertriglyceridemia in obese diabetics without the weight gain associated with insulin or sulfonylurea therapy. Metformin is not indicated for patients with type 1 diabetes and is contraindicated in diabetics with serum creatinine levels of 1.5 mg/dL or higher, hepatic insufficiency, alcoholism, or a propensity to develop tissue hypoxia.

Metformin is dispensed as 500 mg, 850 mg, and 1000 mg tablets. A 500 mg extended-release preparation is also available. Although the maximal dosage is 2.55 g, little benefit is seen above a total dose of 2000 mg. It is important to begin with a low dose and increase the dosage very gradually in divided doses—taken with meals—to reduce minor gastrointestinal upsets. A common schedule would be one 500 mg tablet three times a day with meals or one 850 mg or 1000 mg tablet twice daily at breakfast and dinner. One to four tablets of the extended-release preparation can be given once a day.

The most frequent side effects of metformin are gastrointestinal symptoms (anorexia, nausea, vomiting, abdominal discomfort, diarrhea), which occur in up to 20% of patients. These effects are dose-related, tend to occur at onset of therapy, and often are transient. However, in 3–5% of patients, therapy may have to be discontinued because of persistent diarrheal discomfort. In a retrospective analysis, it has been reported that patients switched from immediate-release metformin to comparable dose of extended-release metformin experienced fewer gastrointestinal side effects.

Hypoglycemia does not occur with therapeutic doses of metformin, which permits its description as a “euglycemic” or “antihyperglycemic” drug rather than an oral hypoglycemic agent. Dermatologic or hematologic toxicity is rare.

Lactic acidosis has been reported as a side effect but is uncommon with metformin in contrast to phenformin. While therapeutic doses of metformin reduce lactate uptake by the liver, serum lactate levels rise only minimally if at all, since other organs such as the kidney can remove the slight excess. However, if tissue hypoxia occurs, the metformin-treated patient is at higher risk for lactic acidosis due to compromised lactate removal. Similarly, when kidney function deteriorates, affecting not only lactate removal by the kidney but also metformin excretion, plasma levels of metformin rise far above the therapeutic range and block hepatic uptake enough to provoke lactic acidosis without associated increases in lactic acid production. Almost all reported cases have involved subjects with associated risk factors that should have contraindicated its use (kidney, liver, or cardiorespiratory insufficiency, alcoholism, advanced age). Acute kidney failure can occur rarely in certain patients

receiving radiocontrast agents. Metformin therapy should therefore be temporarily halted on the day of the test and for 2 days following injection of radiocontrast agents to avoid potential lactic acidosis if end-stage chronic kidney failure occurs.

B. THIAZOLIDINEDIONES—Drugs of this class of antihyperglycemic agents sensitize peripheral tissues to insulin. They bind a nuclear receptor called peroxisome proliferator-activated receptor gamma (PPAR- γ) and affect the expression of a number of genes and regulate the release of the adipokines—resistin and adiponectin—from adipocytes. Adiponectin secretion is stimulated, which sensitizes tissues to the effects of insulin, and resistin secretion is inhibited, which reduces insulin resistance. Observed effects of thiazolidinediones include increased glucose transporter expression (GLUT 1 and GLUT 4), decreased free fatty acid levels, decreased hepatic glucose output, and increased differentiation of preadipocytes into adipocytes. Like the biguanides, this class of drugs does not cause hypoglycemia.

Two drugs of this class, rosiglitazone and pioglitazone, are available for clinical use. Both are effective as monotherapy and in combination with sulfonylureas or metformin or insulin. When used as monotherapy, these drugs lower HbA_{1c} by about 1 or 2 percentage points. When used in combination with insulin, they can result in a 30–50% reduction in insulin dosage, and some patients can come off insulin completely. The dosage of rosiglitazone is 4–8 mg daily and of pioglitazone, 15–45 mg daily, and the drugs do not have to be taken with food. Rosiglitazone is primarily metabolized by the CYP 2C8 isoenzyme and pioglitazone is metabolized by CYP 2C8 and CYP 3A4.

The combination of a thiazolidinedione and metformin has the advantage of not causing hypoglycemia. Patients inadequately managed on sulfonylureas can do well on a combination of sulfonylurea and rosiglitazone or pioglitazone. About 25% of patients in clinical trials fail to respond to these drugs, presumably because they are significantly insulinopenic.

These drugs have some additional effects apart from glucose lowering. Rosiglitazone therapy is associated with increases in total cholesterol, LDL-cholesterol (15%), and HDL-cholesterol (10%). There is a reduction in free fatty acids of about 8–15%. The changes in triglycerides were generally not different from placebo. Pioglitazone in clinical trials lowered triglycerides (9%) and increased HDL-cholesterol (15%), but did not cause a consistent change in total cholesterol and LDL-cholesterol levels. A prospective randomized comparison of the metabolic effects of pioglitazone and rosiglitazone on patients who had previously taken troglitazone (now withdrawn from the US market) showed similar effects on HbA_{1c} and weight gain. Pioglitazone-treated persons, however, had lower total cholesterol, LDL-cholesterol, and triglycerides when compared with rosiglitazone-treated persons. The thiazolidinediones have also been demonstrated to decrease levels of plasminogen activator inhibitor type 1, matrix metalloproteinase 9, C-reactive protein, and interleukin 6. Small prospective studies have demonstrated that treatment with these drugs leads to improvements in the biochemical and histologic features of

nonalcoholic fatty liver disease. The thiazolidinediones also may limit vascular smooth muscle proliferation after injury, and there are reports that pioglitazone and troglitazone (subsequently withdrawn from the US market) reduced neointimal proliferation after coronary stent placement. Finally, in one double-blind, placebo-controlled study, rosiglitazone was shown to be associated with a decrease in the ratio of urinary albumin to creatinine excretion.

Safety concerns and some troublesome side effects have emerged about this class of drugs that potentially limit their use.

A meta-analysis of 42 randomized clinical trials with rosiglitazone suggested that this drug increases the risk of angina pectoris or myocardial infarction. Even though definitive evidence is lacking, the FDA has required the manufacturer to include a boxed warning about the potential risk of heart attacks on the drug label. A meta-analysis of clinical trials with pioglitazone did not show a similar finding. Many physicians, because of these findings, have stopped prescribing rosiglitazone and instead use pioglitazone, if indicated.

Edema occurs in about 3–4% of patients receiving monotherapy with rosiglitazone or pioglitazone. The edema occurs more frequently (10–15%) in patients receiving concomitant insulin therapy and may result in congestive heart failure. The drugs are contraindicated in diabetic individuals with New York Heart Association class III and IV cardiac status. Thiazolidinediones have also been reported as being associated with new onset or worsening macular edema. Apparently, this is a rare side effect, and most of these patients also had peripheral edema. The macular edema resolved or improved once the drug was discontinued.

In experimental animals, rosiglitazone stimulates bone marrow adipogenesis at the expense of osteoblastogenesis resulting in a decrease in bone density. An increase in fracture risk in women (but not men) has been reported with both rosiglitazone and pioglitazone. The fracture risk is in the range of 1.9 per 100 patient-years with the thiazolidinedione compared to 1.1 per 100 patient years on comparison treatment. In at least one study of rosiglitazone, the fracture risk was increased in premenopausal as well as postmenopausal women.

Other side effects include anemia, which occurs in 4% of patients treated with these drugs; it may be due to a dilutional effect of increased plasma volume rather than a reduction in red cell mass. Weight gain occurs, especially when the drug is combined with a sulfonylurea or insulin. Some of the weight gain is fluid retention, but there is also an increase in total fat mass.

Troglitazone, the first drug in this class to go into widespread clinical use, was withdrawn from clinical use because of drug-associated fatal liver failure. The two currently available agents, rosiglitazone and pioglitazone, have thus far not caused hepatotoxicity. The FDA has, however, recommended that patients should not initiate drug therapy if there is clinical evidence of active liver disease or pre-treatment elevation of the alanine aminotransferase (ALT) level that is 2.5 times greater than the upper limit of normal. Obviously, caution should be used in initiation of therapy in patients with even mild ALT

elevations. Liver biochemical tests should be performed prior to initiation of treatment and periodically thereafter.

3. Drugs that affect absorption of glucose— α -Glucosidase inhibitors competitively inhibit the α -glucosidase enzymes in the gut that digest dietary starch and sucrose. Two of these drugs—acarbose and miglitol—are available for clinical use. Both are potent inhibitors of glucoamylase, α -amylase, and sucrase but have less effect on isomaltase and hardly any on trehalase and lactase. Acarbose binds 1000 times more avidly to the intestinal disaccharidases than do products of carbohydrate digestion or sucrose. A fundamental difference between acarbose and miglitol is in their absorption. Acarbose has the molecular mass and structural features of a tetrasaccharide, and very little (about 2%) crosses the microvillar membrane. Miglitol, however, has a structural similarity with glucose and is absorbable. Both drugs delay the absorption of carbohydrate and lower postprandial glycemic excursion.

A. ACARBOSE—Acarbose is available as 50-mg and 100-mg tablets. The recommended starting dose of acarbose is 50 mg twice daily, gradually increasing to 100 mg three times daily. For maximal benefit on postprandial hyperglycemia, acarbose should be given with the first mouthful of food ingested. In diabetic patients, it reduces postprandial hyperglycemia by 30–50%, and its overall effect is to lower the HbA_{1c} by 0.5–1%.

The principal adverse effect, seen in 20–30% of patients, is flatulence. This is caused by undigested carbohydrate reaching the lower bowel, where gases are produced by bacterial flora. In 3% of cases, troublesome diarrhea occurs. This gastrointestinal discomfort tends to discourage excessive carbohydrate consumption and promotes improved compliance of type 2 patients with their diet prescriptions. When acarbose is given alone, there is no risk of hypoglycemia. However, if combined with insulin or sulfonylureas, it might increase the risk of hypoglycemia from these agents. A slight rise in hepatic aminotransferases has been noted in clinical trials with acarbose (5% versus 2% in placebo controls, and particularly with doses > 300 mg/d). The levels generally return to normal on stopping the drug.

In the UKPDS, approximately 2000 patients on diet, sulfonylurea, metformin, or insulin therapy were randomized to acarbose or placebo therapy. By 3 years, 60% of the patients had discontinued the drug, mostly because of gastrointestinal symptoms. If one looked only at the 40% who remained on the drug, they had an 0.5% lower HbA_{1c} compared with placebo.

B. MIGLITOL—Miglitol is similar to acarbose in terms of its clinical effects. It is indicated for use in diet- or sulfonylurea-treated patients with type 2 diabetes. Therapy is initiated at the lowest effective dosage of 25 mg three times a day. The usual maintenance dose is 50 mg three times a day, although some patients may benefit from increasing the dose to 100 mg three times a day. Gastrointestinal side effects occur as with acarbose. The drug is not metabolized and is excreted unchanged by the kidney. Theoretically, absorbable α -glucosidase inhibitors could induce a deficiency of one or more of the α -glucosidases involved in

cellular glycogen metabolism and biosynthesis of glycoproteins. This does not occur in practice because, unlike the intestinal mucosa, which sees a high concentration of the drug, the blood level is 200-fold to 1000-fold lower than the concentration needed to inhibit intracellular α -glucosidases. Miglitol should not be used in end-stage chronic kidney disease, when its clearance would be impaired.

4. Incretins—Oral glucose provokes a threefold to fourfold higher insulin response than an equivalent dose of glucose given intravenously. This is because the oral glucose causes a release of gut hormones, principally glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP), that amplify the glucose-induced insulin release. This “incretin effect” is reduced in patients with type 2 diabetes. GLP-1 secretion (but not GIP secretion) is impaired in patients with type 2 diabetes and when GLP-1 is infused in patients with type 2 diabetes, it stimulates insulin secretion and lowers glucose levels. GLP-1, unlike the sulfonylureas, has only a modest insulin stimulatory effect at normoglycemic concentrations. This means that GLP-1 has a lower risk for hypoglycemia than the sulfonylureas.

In addition to its insulin stimulatory effect, GLP-1 also has a number of other pancreatic and extrapancreatic effects. It suppresses glucagon secretion and so may ameliorate the hyperglucagonemia that is present in people with diabetes and improve postprandial hyperglycemia. GLP-1 preserves islet integrity and reduces apoptotic cell death of human islet cells in culture. In mice, streptozotocin-induced apoptosis is significantly reduced by coadministration of exendin-4 or exenatide, a GLP-1 receptor agonist. GLP-1 acts on the stomach delaying gastric emptying; the importance of this effect on glucose lowering is illustrated by the observation that antagonizing the deceleration of gastric emptying markedly reduces the glucose lowering effect of GLP-1. GLP-1 receptors are present in the central nervous system, and intracerebroventricular administration of GLP-1 in wild type mice, but not in GLP-1 receptor knockout mice, inhibits feeding. Type 2 diabetic patients undergoing GLP-1 infusion are less hungry; it is unclear whether this is mainly due to a deceleration of gastric emptying or whether there is a central nervous system effect as well.

A. EXENATIDE—GLP-1 is rapidly proteolyzed by dipeptidyl peptidase 4 (DPP-4), and therefore for clinical effect would need to be administered as a continuous infusion. Exendin 4 or exenatide is a GLP-1 receptor agonist isolated from the saliva of the Gila Monster (a venomous lizard) that is more resistant to DPP-4 action and so its half-life is 2.4 hours and its glucose lowering effect is about 6 hours. When this drug is given to patients with type 2 diabetes by subcutaneous injection twice daily, it lowers blood glucose and HbA_{1c} levels. Exenatide appears to have the same effects as GLP-1 on glucagon suppression and gastric emptying. In clinical trials, adding exenatide therapy to patients with type 2 diabetes already taking metformin or a sulfonylurea, or both, further lowered the HbA_{1c} value by 0.4% to 0.6% over a 30-week period. These patients also experienced a weight loss of 3–6 pounds. In an open label extension study up to 80 weeks, the HbA_{1c} reduction was sustained and there was further weight loss (to a total loss of about 10 pounds). The

main side effect was nausea, affecting over 40% of the patients. The nausea was dose-dependent and declined with time. The risk of hypoglycemia was higher in persons taking sulfonylureas. The FDA has received 30 post-marketing reports of acute pancreatitis in patients taking exenatide. Many of these patients had other risk factors for pancreatitis, but the possibility remains that the drug was causally responsible for some cases. Patients taking exenatide should be advised to seek immediate medical care if they experience unexplained persistent severe abdominal pain. The delay in gastric emptying may affect the absorption of some other drugs; therefore, antibiotics and oral contraceptives should be taken 1 hour before exenatide doses. Low-titer antibodies against exenatide develop in over one-third (38%) of patients, but the clinical effects are not attenuated. High-titer antibodies develop in a subset of patients (~6%), and in about half of these cases, an attenuation of glycemic response has been seen.

Exenatide is dispensed as two fixed-dose pens (5 mcg and 10 mcg). It is injected 60 minutes before breakfast and before dinner. Patients should be prescribed the 5 mcg pen for the first month and, if tolerated, the dose can then be increased to 10 mcg twice a day. The drug is not recommended in patients with glomerular filtration rate less than 30 mL/min.

B. SITAGLIPTIN—The oral DPP-4 inhibitors prolong the action of endogenously released GLP-1 and GIP. A number of neuropeptides, growth factors, cytokines, and chemokines are potential DPP-4 substrates; DPP-4 inhibitors prolong the actions of neuropeptide Y and substance P. Sitagliptin in clinical trials was shown to be effective in lowering glucose when used alone and in combination with metformin and pioglitazone. In various clinical trials, improvements in HbA_{1c} ranged from 0.5% to 1.4%. The usual dose of sitagliptin is 100 mg once daily, but the dose is reduced to 50 mg daily if the calculated creatinine clearance is 30–50 mL/min and to 25 mg for clearances less than 30 mL/min. Unlike exenatide, sitagliptin does not cause nausea or vomiting. It also does not result in weight loss. The main adverse effect appears to be a predisposition to nasopharyngitis or upper respiratory tract infection. A small increase in neutrophil count of ~200 cells/mcL has also occurred. Since its FDA approval and clinical use, there have been reports of serious allergic reactions to sitagliptin, including anaphylaxis, angioedema, and exfoliative skin conditions including Stevens-Johnson syndrome. The frequency of these events is unclear.

5. Others—**Pramlintide** is a synthetic analog of islet amyloid polypeptide (IAPP or amylin). When given subcutaneously, it delays gastric emptying, suppresses glucagon secretion, and decreases appetite. It is approved for use both in type 1 diabetes and in insulin-treated type 2 diabetes. In 6-month clinical studies with type 1 and insulin-treated type 2 patients, those on the drug had an approximately 0.4% reduction in HbA_{1c} and about 1.7 kg weight loss compared with placebo. The HbA_{1c} reduction was sustained for 2 years but some of the weight was regained. The drug is given by injection immediately before the meal. Hypoglycemia can occur, and it is recommended that the short-acting or

premixed insulin doses be reduced by 50% when the drug is started. Nausea was the other main side effect, affecting 30–50% of persons but tended to improve with time. In patients with type 1 diabetes, the initial dose of pramlintide is 15 mcg before each meal and titrated up by 15 mcg increments to a maintenance dose of 30 mcg or 60 mcg before each meal. In patients with type 2 diabetes, the starting dose is 60 mcg premeals increased to 120 mcg in 3 to 7 days if no significant nausea occurs.

6. Drug combinations—Several drug combinations are available in different dose sizes, including glyburide and metformin (Glucovance); glipizide and metformin (Metaglip); rosiglitazone and metformin (Avandamet); pioglitazone and metformin (ACTOplus Met); rosiglitazone and glimepiride (Avandaryl); pioglitazone and glimepiride (Duetact); and sitagliptin and metformin (Janumet). These drug combinations, however, limit the clinician's ability to optimally adjust dosage of the individual drugs and for that reason are not recommended.

C. Insulin

Insulin is indicated for type 1 diabetes as well as for type 2 diabetic patients with insulinopenia whose hyperglycemia does not respond to diet therapy either alone or combined with other hypoglycemic drugs.

With the development of highly purified human insulin preparations, immunogenicity has been markedly reduced, thereby decreasing the incidence of therapeutic complications such as insulin allergy, immune insulin resistance, and localized lipoatrophy at the injection site. However, the problem of achieving optimal insulin delivery remains unsolved with the present state of technology. It has not been possible to reproduce the physiologic patterns of intraportal insulin secretion with subcutaneous injections of short-acting or longer-acting insulin preparations. Even so, with the help of appropriate modifications of diet and exercise and careful monitoring of capillary blood glucose levels at home, it has often been possible to achieve acceptable control of blood glucose by using various mixtures of short- and longer-acting insulins injected at least twice daily or portable insulin infusion pumps.

1. Characteristics of available insulin preparations—

Commercial insulin preparations differ with respect to the time of onset and duration of their biologic action (Table 27–9).

A. SPECIES OF INSULIN—Human insulin is produced by recombinant DNA techniques (biosynthetic human insulin) as Humulin (Eli Lilly) and as Novolin (Novo Nordisk). It is dispensed as either regular (R) or NPH (N) formulations. Five analogs of human insulin—three rapidly acting (insulin lispro, insulin aspart, insulin glulisine) and two long-acting (insulin glargine and insulin detemir)—have been approved by the FDA for clinical use (see below) (Table 27–10). Animal insulins are no longer available in the United States.

B. PURITY OF INSULIN—“Purified” insulin is defined by FDA regulations as the degree of purity wherein proinsulin contamination is less than 10 ppm. All insulins presently

Table 27–9. Summary of bioavailability characteristics of the insulins.

| Insulin Preparations | Onset of Action | Peak Action | Effective Duration |
|------------------------------------|-----------------|-------------|--------------------|
| Insulins lispro, aspart, glulisine | 5–15 minutes | 1–1.5 hours | 3–4 hours |
| Human regular | 30–60 minutes | 2 hours | 6–8 hours |
| Human NPH | 2–4 hours | 6–7 hours | 10–20 hours |
| Insulin glargine | 1.5 hours | Flat | ~24 hours |
| Insulin detemir | 1 hour | Flat | 17 hours |

available contain less than 10 ppm of proinsulin and are labeled as “purified.” These purified insulins seem to preserve their potency quite well, so that refrigeration is recommended but not crucial. During travel, reserve supplies of insulin can thus be readily transported for weeks without losing potency if protected from extremes of heat or cold.

C. CONCENTRATION OF INSULIN—At present, insulins in the United States are available in a concentration of 100 units/mL (U100), and all are dispensed in 10-mL vials. With the popularity of “low-dose” (0.5- or 0.3-mL) disposable insulin syringes, U100 can be measured with acceptable accuracy in doses as low as 1–2 units. For use in rare cases of severe insulin resistance in which large quantities of insulin are required, U500 regular human insulin (Humulin R) is available from Eli Lilly.

2. Insulin preparations—Insulins are classified into short-acting and long-acting insulin preparations. The short-act-

Long-acting human insulin analogs

Insulin glargine (Lantus, Sanofi Aventis)
Insulin detemir (Levemir, Novo Nordisk)

¹All insulins available in the United States are recombinant human or human insulin analog origin. All the insulins are dispensed at U100 concentration. There is an additional U500 preparation of regular insulin.

NPH, neutral protamine Hagedorn.

▲ **Figure 27-1.** Extent and duration of action of various types of insulin-euglycemic hyperinsulinemic clamps in normal volunteers. **A.** Intermediate neutral protamine Hagedorn (NPH) insulin and long-acting insulin analogs. **B.** Regular insulin and rapidly acting insulin analogs.

ing preparations are regular insulin and the rapidly acting insulin analogs (Figure 27-1). They are dispensed as clear solutions at neutral pH and contain small amounts of zinc to improve their stability and shelf life. The long-acting preparations are NPH insulin and the long-acting insulin analogs. NPH insulin is dispensed as a turbid suspension at neutral pH with protamine in phosphate buffer. The long-acting insulin analogs are also dispensed as clear solutions; insulin glargine is at acidic pH and insulin detemir is at neutral pH. The Lente series of insulin (ultralente and lente) are no longer available in the United States. The rapidly acting insulin analogs and the long-acting insulins are designed for subcutaneous administration, while regular insulin can also be given intravenously. While insulin aspart has been approved for intravenous use (eg, in hyperglycemic emergencies), there is no advantage in using insulin aspart over regular insulin by this route.

A. SHORT-ACTING INSULIN PREPARATIONS

(1) **Regular insulin**—Regular insulin is a short-acting soluble crystalline zinc insulin whose effect appears within 30 minutes after subcutaneous injection and lasts 5–7 hours when usual quantities are administered. Intravenous infusions of regular insulin are particularly useful in the treatment of diabetic ketoacidosis and during the perioperative management of insulin-requiring diabetics. Regular insulin

is indicated when the subcutaneous insulin requirement is changing rapidly, such as after surgery or during acute infections—although the rapidly acting insulin analogs may be preferable in these situations.

For markedly insulin-resistant persons who would otherwise require large volumes of insulin solution, a U500 preparation of human regular insulin is available. Since a U500 syringe is not available, a U100 insulin syringe or tuberculin syringe is used to measure doses. The physician should carefully note dosages in both units and volume to avoid overdosage.

(2) **Rapidly acting insulin analogs**—Insulin lispro (Humalog) is an insulin analog produced by recombinant technology, wherein two amino acids near the carboxyl terminal of the B chain have been reversed in position: Proline at position B28 has been moved to B29 and lysine has been moved from B29 to B28. Insulin aspart (Novolog) is a single substitution of proline by aspartic acid at position B28. Insulin glulisine (Apidra) differs from human insulin in that the amino acid asparagine at position B3 is replaced by lysine and the lysine in position B29 by glutamic acid. These changes result in these three analogs having less tendency to form hexamers, in contrast to human insulin. When injected subcutaneously, the analogs quickly dissociate into monomers and are absorbed very rapidly, reaching peak serum values in as soon as 1 hour—in contrast to regular

human insulin, whose hexamers require considerably more time to dissociate and become absorbed. The amino acid changes in these analogs do not interfere with their binding to the insulin receptor, with the circulating half-life, or with their immunogenicity, which are all identical with those of human regular insulin.

Clinical trials have demonstrated that the optimal times of preprandial subcutaneous injection of comparable doses of the rapidly acting insulin analogs and of regular human insulin are 20 minutes and 60 minutes, respectively, before the meal. While this more rapid onset of action has been welcomed as a great convenience by diabetic patients who object to waiting as long as 60 minutes after injecting regular human insulin before they can begin their meal, patients must be taught to ingest adequate absorbable carbohydrate early in the meal to avoid hypoglycemia during the meal. Another desirable feature of insulin lispro is that its duration of action remains at about 4 hours irrespective of dosage. This contrasts with regular insulin, whose duration of action is prolonged when larger doses are used.

The rapidly acting analogs are also commonly used in pumps. In a double-blind crossover study comparing insulin lispro with regular insulin in insulin pumps, persons using insulin lispro had lower HbA_{1c} values and improved postprandial glucose control with the same frequency of hypoglycemia. The concern remains that in the event of pump failure, users of the rapidly acting insulin analogs will have more rapid onset of hyperglycemia and ketosis.

B. LONG-ACTING INSULIN PREPARATIONS

(1) *NPH (neutral protamine Hagedorn or isophane) insulin*—NPH is an intermediate-acting insulin whose onset of action is delayed by combining 2 parts soluble crystalline zinc insulin with 1 part protamine zinc insulin. This produces equivalent amounts of insulin and protamine, so that neither is present in an uncomplexed form (“isophane”).

Its onset of action is delayed to 2–4 hours, and its peak response is generally reached in about 8–10 hours. Because its duration of action is often less than 24 hours (with a range of 10–20 hours), most patients require at least two injections daily to maintain a sustained insulin effect. Occasional vials of NPH insulin have tended to show unusual clumping of their contents or “frosting” of the container, with considerable loss of bioactivity. This instability is rare and occurs less frequently if NPH human insulin is refrigerated when not in use and if bottles are discarded after 1 month of use.

(2) *Insulin glargine*—Insulin glargine is an insulin analog in which the asparagine at position 21 of the A chain of the human insulin molecule is replaced by glycine and two arginines are added to the carboxyl terminal of the B chain. The arginines raise the isoelectric point of the molecule closer to neutral, making it more soluble in an acidic environment. In contrast, human insulin has an isoelectric point of pH 5.4. Insulin glargine is a clear insulin which, when injected into the neutral pH environment of the subcutaneous tissue, forms microprecipitates that slowly release the insulin into the circulation. It lasts for about 24

hours without any pronounced peaks and is given once a day to provide basal coverage. This insulin cannot be mixed with the other human insulins because of its acidic pH. When this insulin was given as a single injection at bedtime to type 1 patients, fasting hyperglycemia was better controlled when compared with bedtime NPH insulin. The clinical trials also suggest that there may be less nocturnal hypoglycemia with this insulin when compared with NPH insulin.

In one clinical trial involving type 2 patients, insulin glargine was associated with a slightly higher progression of retinopathy when compared with NPH insulin. The frequency was 7.5% with the analog and 2.7% with the NPH. This finding, however, was not seen in other clinical trials with this analog. Insulin glargine does have a sixfold greater affinity for IGF-1 receptor compared with the human insulin. There has also been a report that insulin glargine had increased mitogenicity compared with human insulin in a human osteosarcoma cell line. The significance of these observations is not yet clear. Because of lack of safety data, use of insulin glargine during pregnancy is not recommended.

(3) *Insulin detemir*—Insulin detemir is an insulin analog in which the tyrosine at position 30 of the β chain has been removed and a 14-C fatty acid chain (tetradecanoic acid) is attached to the lysine at position 29 by acylation. The fatty acid chain makes the molecule more lipophilic than native insulin and the addition of zinc stabilizes the molecule and leads to formation of hexamers. After injection, self-association at the injection site and albumin binding in the circulation via the fatty acid side chain, leads to slower distribution to peripheral target tissues and prolonged duration of action. The affinity of insulin detemir is fourfold to fivefold lower than that of human soluble insulin and therefore the U100 formulation of insulin detemir has an insulin concentration of 2400 nmol/mL compared with 600 nmol/mL for NPH. The duration of action for insulin detemir is about 17 hours at therapeutically relevant doses. It is recommended that the insulin be injected once or twice a day to achieve a stable basal coverage. This insulin has been reported to have lower within-subject pharmacodynamic variability compared with NPH insulin and insulin glargine. In vitro studies do not suggest any clinically relevant albumin binding interactions between insulin detemir and fatty acids or protein-bound drugs. Since there is a vast excess (~400,000) of albumin binding sites available in plasma per insulin detemir molecule, it is unlikely that hypoalbuminemic disease states will affect the ratio of bound to free insulin detemir.

C. *MIXED INSULIN PREPARATIONS*—Since intermediate insulins require several hours to reach adequate therapeutic levels, their use in patients with type 1 diabetes requires supplements of regular or rapidly acting insulin analogs preprandially. For convenience, regular or rapidly acting insulin analogs and NPH insulin may be mixed together in the same syringe and injected subcutaneously in split dosage before breakfast and supper. It is recommended that the regular insulin or rapidly acting insulin analog be withdrawn first, then the NPH insulin and that the injec-

tion be given immediately after loading the syringe. Stable premixed insulins (70% NPH and 30% regular or 50% of each) are available as a convenience to patients who have difficulty mixing insulin because of visual problems or impairment of manual dexterity. Premixed preparations of insulin lispro and NPH insulins are unstable because of exchange of insulin lispro with the human insulin in the protamine complex. Consequently, the soluble component becomes over time a mixture of regular and insulin lispro at varying ratios. In an attempt to remedy this, an intermediate insulin composed of isophane complexes of protamine with insulin lispro was developed called NPL (neutral protamine lispro). This insulin has the same duration of action as NPH insulin. Premixed combinations of NPL and insulin lispro (eg, 75:25, 50:50, and 25:75 of NPL:insulin lispro) have been tested. Both 75% NPL/25% insulin lispro mixture (Humalog Mix 75/25) and 50% NPL/50% insulin lispro mixture (Humalog Mix 50/50) are available for clinical use. Similarly, a 70% insulin aspart protamine/30% insulin aspart (NovoLog Mix 70/30) is available. The main advantages of these mixtures are that they can be given within 15 minutes of starting a meal and they are superior in controlling the postprandial glucose rise after a carbohydrate rich meal. These benefits have not translated into improvements in HbA_{1c} levels when compared with the usual 70% NPH/30% regular mixture.

The longer-acting insulin analogs cannot be mixed with either regular insulin or the rapidly acting insulin analogs.

3. Methods of insulin administration

A. INSULIN SYRINGES AND NEEDLES—Plastic disposable syringes are available in 1-mL, 0.5-mL, and 0.3-mL sizes. The “low-dose” 0.3-mL syringes have become increasingly popular, because many diabetics do not take more than 30 units of insulin in a single injection except in rare instances of extreme insulin resistance. Two lengths of needles are available: short (8 mm) and long (12.7 mm). Long needles are preferable in obese patients to reduce variability of insulin absorption. Ultrafine needles as small as 31 gauge reduce the pain of injections. “Disposable” syringes may be reused until blunting of the needle occurs (usually after three to five injections). Sterility adequate to avoid infection with reuse appears to be maintained by recapping syringes between uses. Cleansing the needle with alcohol may not be desirable since it can dissolve the silicone coating and can increase the pain of skin puncturing.

Any part of the body covered by loose skin can be used, such as the abdomen, thighs, upper arms, flanks, and upper buttocks. Preparation with alcohol is no longer required prior to injection as long as the skin is clean. Rotation of sites continues to be recommended to avoid delayed absorption when fibrosis or lipohypertrophy occurs from repeated use of a single site. However, considerable variability of absorption rates from different sites, particularly with exercise, may contribute to the instability of glycemic control in certain type 1 patients if injection sites are rotated too frequently in different areas of the body. Consequently, it is best to limit injection sites to a single region of the body and rotate sites within that region. The abdomen is recommended for subcutaneous injections, since regular insulin has been shown

to absorb more rapidly from there than from other subcutaneous sites. The effect of anatomic regions appears to be much less pronounced with the analog insulins.

B. INSULIN PEN INJECTOR DEVICES—Insulin pens eliminate the need for carrying insulin vials and syringes. Cartridges of insulin lispro, insulin aspart, insulin glargine, regular insulin, NPH insulin, and 70% NPH/30% regular insulin are available for reusable pens (Novo Nordisk, Becton Dickinson, and Sanofi Aventis pens). Disposable prefilled pens are also available for insulin lispro, insulin aspart, insulin detemir, insulin glargine, NPH, 70% NPH/30% regular, 75% NPL/25% insulin lispro, 50% NPL/50% insulin lispro, and 70% insulin aspart protamine/30% insulin aspart. Thirty-one gauge needles (5, 6, and 8 mm long) for these pens make injections almost painless.

C. INSULIN PUMPS—In the United States, Medtronic Mini-Med, Animas, Deltec, Insulet, and Roche make insulin infusion pumps for subcutaneous delivery of insulin. These pumps are small (about the size of a pager) and very easy to program. They offer many features, including the ability to set a number of different basal rates throughout the 24 hours and to adjust the time over which bolus doses are given. They also are able to detect pressure build-up if the catheter is kinked. Improvements have also been made in the infusion sets. The catheter connecting the insulin reservoir to the subcutaneous cannula can be disconnected, allowing the patient to remove the pump temporarily (eg, for bathing). The great advantage of continuous subcutaneous insulin infusion (CSII) is that it allows for establishment of a basal profile tailored to the patient. The patient therefore is able to eat with less regard to timing because the basal insulin infusion should maintain constant blood glucose between meals. Also the ability to adjust the basal insulin infusion makes it easier for the patient to manage glycemic excursions that occur with exercise.

CSII therapy is appropriate for patients who are motivated, mechanically inclined, educated about diabetes (diet, insulin action, treatment of hypoglycemia and hyperglycemia), and willing to monitor their blood glucose four to six times a day. Known complications of CSII include ketoacidosis, which can occur when insulin delivery is interrupted, and skin infections. Another disadvantage is its cost and the time demanded of physicians and staff in initiating therapy.

D. INHALED INSULIN—Exubera, the first inhaled insulin preparation approved by the FDA is no longer available; the manufacturer stopped marketing it because of lack of demand. In clinical trials, Exubera was as effective as subcutaneous regular insulin in controlling postprandial glucose excursions. Physicians, however, were reluctant to prescribe Exubera for a number of reasons, including a lack of long-term safety data on pulmonary function, awkward dosing schedule, availability of other insulin delivery systems, and cost and lack of insurance coverage.

D. Transplantation

Pancreas transplantation at the time of kidney transplantation is becoming more widely accepted. Patients undergoing simultaneous pancreas and kidney transplantation

have an 85% chance of pancreatic graft survival and a 92% chance of kidney graft survival after 1 year. Solitary pancreatic transplantation in the absence of a need for kidney transplantation should be considered only in those rare patients who fail all other insulin therapeutic approaches and who have frequent severe hypoglycemia or who have life-threatening complications related to their lack of metabolic control.

Islet cell transplantation is a minimally invasive procedure, and investigators in Edmonton, Canada, have reported initial insulin independence in a small number of patients with type 1 diabetes who underwent this procedure. Using islets from multiple donors and corticosteroid-free immunosuppression, percutaneous transhepatic portal vein transplantation of islets was achieved in over 20 subjects. Although all of the initial cohort was able to achieve insulin independence posttransplantation (some for more than 2 years of follow-up), a decline in insulin secretion has occurred over time and the subjects have again required supplemental insulin. All patients had complete correction of severe hypoglycemic reactions, leading to a marked improvement in overall quality of life. Even if long-term insulin independence is demonstrated, wide application of this procedure for the treatment of type 1 diabetes is limited by the dependence on multiple donors and the requirement for potent long-term immunotherapy.

► General Considerations in Treatment of Diabetes

Insulin-treated patients with diabetes can have a full and satisfying life. However, “free” diets and unrestricted activity are still not advised. Until new methods of insulin replacement are developed that provide more normal patterns of insulin delivery in response to metabolic demands, multiple feedings with carbohydrate counting will continue to be recommended, and certain occupations potentially hazardous to the patient or others will continue to be prohibited because of risks due to hypoglycemia. The American Diabetic Association can act as a patient advocate in case of employment questions.

Exercise increases the effectiveness of insulin, and moderate exercise is an excellent means of improving utilization of fat and carbohydrate in diabetic patients. A judicious balance of the size and frequency of meals with moderate regular exercise can often stabilize the insulin dosage in diabetics who tend to slip out of control easily. Strenuous exercise can precipitate hypoglycemia in an unprepared patient, and diabetics must therefore be taught to reduce their insulin dosage in anticipation of strenuous activity or to take supplemental carbohydrate. Injection of insulin into a site farthest away from the muscles most involved in exercise may help ameliorate exercise-induced hypoglycemia, since insulin injected in the proximity of exercising muscle may be more rapidly mobilized.

All diabetic patients must receive adequate instruction on personal hygiene, especially with regard to care of the feet, skin, and teeth. All infections (especially pyogenic ones) provoke the release of high levels of insulin antagonists such as catecholamines or glucagon and thus bring

about a marked increase in insulin requirements. Supplemental regular insulin is often required to correct hyperglycemia during infection.

► Steps in the Management of the Diabetic Patient

A. Diagnostic Examination

Any features of the clinical picture that suggest end-organ insensitivity to insulin, such as visceral obesity, must be identified. The family history should document not only the incidence of diabetes in other members of the family but also the age at onset, whether it was associated with obesity, and whether insulin was required. An attempt should be made to characterize the diabetes as type 1 or type 2, based on the clinical features present and on whether or not ketonuria accompanies the glycosuria. For the occasional patient, measurement of ICA, GAD65, IAA, and ICA 512 antibodies can help distinguish between type 1 and type 2 diabetes. Many patients in whom type 1 diabetes is newly diagnosed still have significant endogenous insulin production, and C peptide levels do not reliably distinguish between type 1 and type 2 diabetes. Other factors that increase cardiac risk, such as smoking history, presence of hypertension or hyperlipidemia, or oral contraceptive pill use, should be recorded.

Laboratory diagnosis should document fasting plasma glucose levels above 126 mg/dL or postprandial values consistently above 200 mg/dL and whether ketonuria accompanies the glycosuria. A glycohemoglobin measurement is useful for assessing the effectiveness of future therapy. Some flexibility of clinical judgment is appropriate when diagnosing diabetes mellitus in the elderly patient with borderline hyperglycemia.

Baseline values include fasting plasma triglycerides, total cholesterol and HDL-cholesterol, electrocardiography, kidney function studies, peripheral pulses, and neurologic, podiatric, and ophthalmologic examinations to help guide future assessments.

B. Patient Education (Self-Management Training)

Since diabetes is a lifelong disorder, education of the patient and the family is probably the most important obligation of the clinician who provides initial care. The best persons to manage a disease that is affected so markedly by daily fluctuations in environmental stress, exercise, diet, and infections are the patients themselves and their families. The “teaching curriculum” should include explanations by the physician or nurse of the nature of diabetes and its potential acute and chronic hazards and how they can be recognized early and prevented or treated. Self-monitoring of blood glucose should be emphasized, especially in insulin-requiring diabetic patients, and instructions must be given on proper testing and recording of data. Patients should be provided with algorithms they can use to adjust the timing and quantity of their insulin dose, food, and exercise in response to measured blood glucose values. The targets for blood glucose control should be elevated appro-

privately in elderly patients since they have the greatest risk if subjected to hypoglycemia and the least long-term benefit from more rigid glycemic control. Advice on personal hygiene, including detailed instructions on foot care as well as individual instruction on diet and specific hypoglycemic therapy, should be provided. Patients should be told about community agencies, such as Diabetes Association chapters, that can serve as a continuing source of instruction. Finally, vigorous efforts should be made to persuade new diabetics who smoke to give up the habit, since large vessel peripheral vascular disease and debilitating retinopathy are less common in nonsmoking diabetic patients.

C. Therapy

Treatment must be individualized on the basis of the type of diabetes and specific needs of each patient. However, certain general principles of management can be outlined for hyperglycemic states of different types.

1. Type 2 diabetes

A. THE OBESE PATIENT WITH TYPE 2 DIABETES—The most common type of diabetic patient is obese, is non-insulin-dependent, and has hyperglycemia because of a combination of insulin resistance and beta cell failure.

(1) Weight reduction—Treatment is directed toward achieving weight reduction, and prescribing a diet is only one means to this end. Behavior modification to achieve adherence to the diet—as well as increased physical activity to expend energy—is also required. Cure can be achieved by reducing adipose stores, with consequent restoration of tissue sensitivity to insulin, but weight reduction is hard to achieve and even more difficult to maintain with our current therapies. The presence of diabetes with its added risk factors may motivate the obese diabetic to greater efforts to lose weight. (See also Chapter 29.)

(2) Hypoglycemic agents—If the patient is not able to achieve target glycemic control with weight management and exercise, then pharmacologic therapy is indicated. The choice of initial agent depends on a number of factors, including comorbid conditions, adverse reactions to the medications, ability of the patient to monitor for hypoglycemia, drug cost, and patient and physician preferences. **Metformin** is advantageous because apart from lowering glucose without the risk of hypoglycemia, it also lowers triglycerides and promotes some modest weight loss. The drug, however, cannot be used in patients with end-stage chronic kidney disease, and gastrointestinal side effects develop in some patients at even the lowest doses. **Thiazolidinediones** improve peripheral insulin resistance and lower glucose without causing hypoglycemia. Both of the available thiazolidinediones, however, can cause fluid retention and are contraindicated in patients with heart failure. They also very commonly increase weight, which patients find distressing, affecting adherence. The drugs increase fracture risk in women further limiting their use. Pioglitazone is the preferred choice until there is more definitive data regarding rosiglitazone and the risk of ischemic heart disease. Both drugs are contraindicated in patients with active liver disease and in patients with liver enzymes ≥ 2.5 times the upper limit of normal. **Sulfonylureas** have been

available for many years and their use in combination with metformin is well established. They do, however, have the propensity of causing hypoglycemia and weight gain. The **α -glucosidase inhibitors** have modest glucose lowering effects and have gastrointestinal side effects. **Exenatide** has a lower risk of hypoglycemia than the sulfonylureas and promotes weight loss. However, it needs to be given by injection, causes nausea, may cause pancreatitis, and is contraindicated in patients with gastroparesis. **Sitagliptin** also has a low risk of hypoglycemia, and it does not cause nausea or vomiting. It can also be used in patients with kidney impairment. There are, however, reports of serious allergic reactions, including anaphylaxis, angioedema, and Stevens-Johnson syndrome.

For most obese patients with mild type 2 diabetes, metformin is the first-line agent. If it proves to be inadequate, then a second agent should be added. In those patients where the problem is hyperglycemia after a carbohydrate rich meal (such as dinner), then a short-acting secretagogue before meals may suffice to get the glucose levels into the target range. Patients with severe insulin resistance may be candidates for pioglitazone. Subjects who are very concerned about weight gain may benefit from a trial of exenatide. If two agents are inadequate, then a third agent is added, although data regarding efficacy of such combined therapy are limited. Experienced clinicians have found that instead of maximizing the dose of each agent before adding another agent, some patients are more tolerant of submaximal combinations of drugs. Insulin therapy should be instituted if combination of oral agents (and exenatide) fail to restore euglycemia or if there are concerns about side effects. Weight-reducing interventions should continue and may allow for simplification of this regimen in the future.

When the combination of oral agents (and exenatide) fail to achieve euglycemia in patients with type 2 diabetes, various insulin regimens may be effective. One proposed regimen is to continue the oral combination therapy and then simply add a bedtime dose of NPH or long-acting insulin analog (insulin glargine or insulin detemir) to reduce excessive nocturnal hepatic glucose output and improve fasting glucose levels. If the patient does not achieve target glucose levels during the day, then daytime insulin treatment can be initiated. A convenient insulin regimen under these circumstances is a split dose of 70/30 NPH/regular mixture (or Humalog Mix 75/25 or NovoLogMix 70/30) before breakfast and before dinner. If this regimen fails to achieve satisfactory glycemic goals or is associated with unacceptable frequency of hypoglycemic episodes, then a more intensive regimen of multiple insulin injections can be instituted as in patients with type 1 diabetes. Metformin principally reduces hepatic glucose output and pioglitazone improves peripheral insulin resistance, so it is a reasonable option to continue these drugs when insulin therapy is instituted. The sulfonylureas also have been shown to be of continued benefit. Thus, the continued use of the oral drugs may permit the use of lower doses of insulin and simpler regimens. There is no data on the continued administration of exenatide under these circumstances.

B. THE NONOBESE PATIENT WITH TYPE 2 DIABETES—Nonobese patients with type 2 diabetes frequently have increased visceral adiposity—the so-called metabolically

obese normal weight patient—and the treatment algorithm is much the same as in the obese patient except there is not as much emphasis on weight loss. However, exercise remains an important aspect of treatment. Persons who do not have central obesity or insulin resistance should be evaluated for other types of diabetes such as LADA or MODY. Patients with LADA can initially be treated with oral agents but require insulin within a few years, so experienced clinicians often prescribe insulin for these patients when the diagnosis is made.

2. Type 1 diabetes—Traditional once- or twice-daily insulin regimens are usually ineffective in type 1 patients without residual endogenous insulin. In these patients, information and counseling based on the findings of the DCCT (see above) should be provided about the advantages of taking multiple injections of insulin in conjunction with self-blood glucose monitoring. If near-normalization of blood glucose is attempted, at least four measurements of capillary blood glucose and three or four insulin injections are necessary.

A combination of rapidly acting insulin analogs and long-acting insulin analogs allows for more physiologic insulin replacement. The rapidly acting insulin analogs have been advocated as a safer and much more convenient alternative to regular human insulin for preprandial use. In a study comparing regular insulin with insulin lispro, daily insulin doses and HbA_{1c} levels were similar, but insulin lispro improved postprandial control, reduced hypoglycemic episodes, and improved patient convenience compared with regular insulin. However, because of their relatively short duration (no more than 3–4 hours), the rapidly acting insulin analogs need to be combined with longer-acting insulins to provide basal coverage and avoid hyperglycemia prior to the next meal. In addition to carbohydrate content of the meal, the effect of simultaneous fat ingestion must also be considered a factor in determining the rapidly acting insulin analog dosage required to control the glycemic increment during and just after the meal. With low-carbohydrate content and high-fat intake, there is an increased risk of hypoglycemia from insulin lispro within 2 hours after the meal. Table 27–11 illustrates a regimen with a rapidly acting insulin analog and insulin detemir or insulin glargine that might be appropriate for a 70-kg person with type 1 diabetes eating meals providing standard carbohydrate intake and moderate to low fat content.

Insulin glargine is usually given once in the evening to provide 24-hour coverage. This insulin *cannot be mixed* with any of the other insulins and must be given as a separate injection. There are occasional patients in whom insulin glargine does not seem to last for 24 hours, and in such cases it needs to be given twice a day. As shown, insulin detemir may also need to be given twice a day to get adequate 24-hour basal coverage. Alternatively, small doses of NPH (~ 3 to 4 units) can be given with each meal to provide daytime basal coverage with a larger dose at night. Unlike the long-acting insulin analogs, NPH can be mixed in the same syringe as the insulin lispro, insulin aspart, and insulin glulisine.

Continuous subcutaneous insulin infusion (CSII) by portable battery-operated “open loop” devices currently

Table 27–11. Examples of intensive insulin regimens using rapidly acting insulin analogs (insulin lispro, aspart, or glulisine) and insulin detemir, or insulin glargine in a 70-kg man with type 1 diabetes.^{1–3}

| | Pre-Breakfast | Pre-Lunch | Pre-Dinner | At Bedtime |
|-------------------------------|---------------|-----------|------------|-------------|
| Rapidly acting insulin analog | 5 units | 4 units | 6 units | — |
| Insulin detemir | 6-7 units | | | 8-9 units |
| OR | | | | |
| Rapidly acting insulin analog | 5 units | 4 units | 6 units | — |
| Insulin glargine | — | — | — | 15-16 units |

¹Assumes that patient is consuming approximately 75 g carbohydrate at breakfast, 60 g at lunch, and 90 g at dinner.

²The dose of rapidly acting insulin can be raised by 1 or 2 units if extra carbohydrate (15–30 g) is ingested or if premeal blood glucose is > 170 mg/dL.

³Insulin glargine or insulin detemir must be given as a separate injection.

provides the most flexible approach, allowing the setting of different basal rates throughout the 24 hours and permitting patients to delay or skip meals and vary meal size and composition. The dosage is usually based on providing 50% of the estimated insulin dose as basal and the remainder as intermittent boluses prior to meals. For example, a 70-kg man requiring 35 units of insulin per day may require a basal rate of 0.7 units per hour throughout the 24 hours with the exception of 3 AM to 8 AM, when 0.8 units per hour might be appropriate (for the dawn phenomenon). The meal bolus would depend on the carbohydrate content of the meal and the premeal blood glucose value. One unit per 15 g of carbohydrate plus 1 unit for 50 mg/dL of blood glucose above a target value (eg, 120 mg/dL) is a common starting point. Further adjustments to basal and bolus dosages would depend on the results of blood glucose monitoring. The majority of patients use the rapidly acting insulin analogs in the pumps. One of the more difficult therapeutic problems in managing patients with type 1 diabetes is determining the proper adjustment of insulin dose when the prebreakfast blood glucose level is high. Occasionally, the prebreakfast hyperglycemia is due to the Somogyi effect, in which nocturnal hypoglycemia leads to a surge of counterregulatory hormones to produce high blood glucose levels by 7 AM. However, a more common cause for prebreakfast hyperglycemia is the waning of circulating insulin levels by the morning. Also, the “dawn phenomenon”—reduced tissue sensitivity to insulin between 5 AM and 8 AM—is present in as many as 75% of type 1 patients and can aggravate the hyperglycemia.

Table 27–12 shows that diagnosis of the cause of prebreakfast hyperglycemia can be facilitated by self-monitoring of blood glucose at 3 AM in addition to the usual bedtime and 7 AM measurements. This is required for only a few

Table 27-12. Prebreakfast hyperglycemia: Classification by blood glucose and insulin levels.

| | Blood Glucose (mg/dL) | | | Free Immunoreactive Insulin (microunit/mL) | | |
|---|-----------------------|---------|---------|--|---------------|---------|
| | 10:00 PM | 3:00 AM | 7:00 AM | 10:00 PM | 3:00 AM | 7:00 AM |
| Somogyi effect | 90 | 40 | 200 | High | Slightly high | Normal |
| Dawn phenomenon | 110 | 110 | 150 | Normal | Normal | Normal |
| Waning of insulin dose plus dawn phenomenon | 110 | 190 | 220 | Normal | Low | Low |
| Waning of insulin dose plus dawn phenomenon plus Somogyi effect | 110 | 40 | 380 | High | Normal | Low |

nights, and when a particular pattern emerges from monitoring blood glucose levels overnight, appropriate therapeutic measures can be taken. The Somogyi effect can be treated by eliminating the dose of intermediate insulin at dinnertime and giving it at a lower dosage at bedtime or by supplying more food at bedtime. When a waning insulin level is the cause, then either increasing the evening dose or shifting it from dinnertime to bedtime (or both) can be effective. A bedtime dose either of insulin glargine or insulin detemir provides more sustained overnight insulin levels than human NPH and may be effective in managing refractory prebreakfast hyperglycemia. If this fails, insulin pump therapy may be required. When the dawn phenomenon alone is present, the dosage of intermediate insulin can be divided between dinnertime and bedtime; when insulin pumps are used, the basal infusion rate can be increased (eg, from 0.8 unit/h to 0.9 unit/h from 6 AM until breakfast).

► Acceptable Levels of Glycemic Control

A reasonable aim of therapy is to approach normal glycaemic excursions without provoking severe or frequent hypoglycemia. What has been considered “acceptable” control includes blood glucose levels of 90–130 mg/dL before meals and after an overnight fast, and levels no higher than 180 mg/dL 1 hour after meals and 150 mg/dL 2 hours after meals. Glycohemoglobin levels should be no higher than 1% above the upper limit of the normal range for any particular laboratory. It should be emphasized that the value of blood pressure control was as great as or greater than glycaemic control in type 2 patients as regards microvascular as well as macrovascular complications.

► Complications of Insulin Therapy

A. Hypoglycemia

When the blood glucose falls to around 54 mg/dL, the patient starts to experience both sympathetic (tachycardia, palpitations, sweating, tremulousness) and parasympathetic (nausea, hunger) nervous system symptoms. If these autonomic symptoms are ignored and the glucose levels fall further (to around 50 mg/dL), then neuroglycopenic symptoms appear, including irritability, confusion, blurred vision, tiredness, headache, and difficulty speaking. A further decline in glucose can then lead to loss of consciousness or even a seizure. With repeated episodes of hypoglycemia,

there is adaptation, and autonomic symptoms do not occur until the blood glucose levels are much lower and so the first symptoms are often due to neuroglycopenia. This condition is referred to as “hypoglycemic unawareness.” It has been shown that hypoglycemic unawareness can be reversed by keeping glucose levels high for a period of several weeks. Except for sweating, most of the sympathetic symptoms of hypoglycemia are blunted in patients receiving β -blocking agents for angina pectoris or hypertension. Though not absolutely contraindicated, these drugs must be used with caution in insulin-requiring diabetics, and β_1 -selective blocking agents are preferred.

Hypoglycemia in insulin-treated patients with diabetes occurs as a consequence of three factors: behavioral issues, impaired counterregulatory systems, and complications of diabetes.

Behavioral issues include injecting too much insulin for the amount of carbohydrates ingested. Drinking alcohol in excess, especially on an empty stomach, can also cause hypoglycemia. In patients with type 1 diabetes, hypoglycemia can occur during or even several hours after exercise, and so glucose levels need to be monitored and food and insulin adjusted. Some patients do not like their glucose levels to be high, and they treat every high glucose level aggressively. These individuals who “stack” their insulin—that is, give another dose of insulin before the first injection has had its full action—can develop hypoglycemia.

Counterregulatory issues resulting in hypoglycemia include impaired glucagon response, sympatho-adrenal responses, and cortisol deficiency. Patients with diabetes of greater than 5 years duration lose their glucagon response to hypoglycemia. As a result, they are at a significant disadvantage in protecting themselves against falling glucose levels. Once the glucagon response is lost, their sympatho-adrenal responses take on added importance. Unfortunately, aging, autonomic neuropathy, or hypoglycemic unawareness due to repeated low glucose levels further blunts the sympatho-adrenal responses. Occasionally, Addison disease develops in persons with type 1 diabetes mellitus; when this happens, insulin requirements fall significantly, and unless insulin dose is reduced, recurrent hypoglycemia will develop.

Complications of diabetes that increase the risk for hypoglycemia include autonomic neuropathy, gastroparesis, and end-stage chronic kidney disease. The sympathetic nervous system is an important system alerting the individual that the glucose level is falling by causing symptoms

of tachycardia, palpitations, sweating, and tremulousness. Failure of the sympatho-adrenal responses increases the risk of hypoglycemia. In addition, in patients with gastroparesis, if insulin is given before a meal, the peak of insulin action may occur before the food is absorbed causing the glucose levels to fall. Finally, in end-stage chronic kidney disease, hypoglycemia can occur presumably because of decreased insulin clearance as well as loss of renal contribution to gluconeogenesis in the postabsorptive state.

To prevent and treat insulin-induced hypoglycemia, the diabetic patient should carry glucose tablets or juice at all times. For most episodes, ingestion of 15 grams of carbohydrate is sufficient to reverse the hypoglycemia. The patient should be instructed to check the blood glucose in 15 minutes and treat again if the glucose level is still low. A parenteral glucagon emergency kit (1 mg) should be provided to every patient with diabetes who is receiving insulin therapy. Family or friends should be instructed how to inject it subcutaneously or intramuscularly into the buttock, arm, or thigh in the event that the patient is unconscious or refuses food. The drug can occasionally cause vomiting, and the unconscious patient should be turned on his or her side to protect the airway. The glucagon mobilizes glycogen from the liver, raising the blood glucose by about 36 mg/dL in about 15 minutes. After the patient recovers consciousness, additional oral carbohydrate should be given. People with diabetes receiving hypoglycemic drug therapy should also wear an identification MedicAlert bracelet or necklace or carry a card in his or her wallet. The telephone number for the MedicAlert Foundation International in Turlock, California, is 1-800-ID-ALERT and the Internet address is www.medicalert.org.

Medical personnel treating severe hypoglycemia can give 50 mL of 50% glucose solution by rapid intravenous infusion. If intravenous therapy is not available, 1 mg of glucagon can be injected intramuscularly. If the patient is stuporous and glucagon is not available, small amounts of honey or syrup or glucose gel (15 g) can be inserted within the buccal pouch, but, in general, oral feeding is contraindicated in unconscious patients. Rectal administration of syrup or honey (30 mL per 500 mL of warm water) has been effective.

B. Immunopathology of Insulin Therapy

At least five molecular classes of insulin antibodies are produced during the course of insulin therapy in diabetes, including IgA, IgD, IgE, IgG, and IgM. With the increased therapeutic use of purified pork and especially human insulin, the various immunopathologic syndromes such as insulin allergy, immune insulin resistance, and lipoatrophy have become quite rare since the titers and avidity of these induced antibodies are generally quite low.

1. Insulin allergy—Insulin allergy, or immediate-type hypersensitivity, is a rare condition in which local or systemic urticaria is due to histamine release from tissue mast cells sensitized by adherence of anti-insulin IgE antibodies. In severe cases, anaphylaxis results. When only human insulin has been used from the onset of insulin therapy, insulin allergy is exceedingly rare. Antihistamines, corticosteroids, and even desensitization may be required, espe-

cially for systemic hypersensitivity. There have been case reports of successful use of insulin lispro in those rare patients who have a generalized allergy to human insulin or insulin resistance due to a high titer of insulin antibodies.

2. Immune insulin resistance—Most insulin-treated patients develop a low titer of circulating IgG anti-insulin antibodies that neutralize to a small extent the action of insulin. With the old animal insulins, a high titer of circulating antibodies sometimes developed, resulting in extremely high insulin requirements—often more than 200 units daily. This is now rarely seen with the switch to highly purified pork or human insulins and has not been reported with the analogs.

C. Lipodystrophy at Injection Sites

Atrophy of subcutaneous fatty tissue leading to disfiguring excavations and depressed areas may rarely occur at the site of injection. This complication results from an immune reaction, and it has become rarer with the development of pure and human insulin preparations. Lipohypertrophy, on the other hand, is a consequence of the pharmacologic effects of insulin being deposited in the same location repeatedly. It can occur with purified insulins as well. Rotation of injection sites will prevent lipohypertrophy. There is a case report of a patient who had intractable lipohypertrophy with human insulin but no longer had the problem when he switched to insulin lispro.

▶ Chronic Complications of Diabetes

Late clinical manifestations of diabetes mellitus include a number of pathologic changes that involve small and large blood vessels, cranial and peripheral nerves, the skin, and the lens of the eye. These lesions lead to hypertension, end-stage chronic kidney disease, blindness, autonomic and peripheral neuropathy, amputations of the lower extremities, myocardial infarction, and cerebrovascular accidents. These late manifestations correlate with the duration of the diabetic state subsequent to the onset of puberty. In type 1 diabetes, end-stage chronic kidney disease develops in up to 40% of patients, compared with less than 20% of patients with type 2 diabetes. As regards proliferative retinopathy, it ultimately develops in both types of diabetes but has a slightly higher prevalence in type 1 patients (25% after 15 years' duration). In patients with type 1 diabetes, complications from end-stage chronic kidney disease are a major cause of death, whereas patients with type 2 diabetes are more likely to have macrovascular diseases leading to myocardial infarction and stroke as the main causes of death. Cigarette use adds significantly to the risk of both microvascular and macrovascular complications in diabetic patients.

A. Ocular Complications

1. Diabetic cataracts—Premature cataracts occur in diabetic patients and seem to correlate with both the duration of diabetes and the severity of chronic hyperglycemia. Non-enzymatic glycosylation of lens protein is twice as high in diabetic patients as in age-matched nondiabetic persons and may contribute to the premature occurrence of cataracts.

2. Diabetic retinopathy—Three main categories exist: background, or “simple,” retinopathy, consisting of microaneurysms, hemorrhages, exudates, and retinal edema; preproliferative retinopathy with arteriolar ischemia manifested as cotton-wool spots (small infarcted areas of retina); and proliferative, or “malignant,” retinopathy, consisting of newly formed vessels. Proliferative retinopathy is a leading cause of blindness in the United States, particularly since it increases the risk of retinal detachment. Vision-threatening retinopathy virtually never appears in type 1 patients in the first 3–5 years of diabetes or before puberty. Up to 20% of patients with type 2 diabetes have retinopathy at the time of diagnosis. Annual consultation with an ophthalmologist should be arranged for patients who have had type 1 diabetes for more than 3–5 years and for all patients with type 2 diabetes, because many were probably diabetic for an extensive period of time before diagnosis. Patients with any macular edema, severe nonproliferative retinopathy, or any proliferative retinopathy require the care of an ophthalmologist. Extensive “scatter” xenon or argon photocoagulation and focal treatment of new vessels reduce severe visual loss in those cases in which proliferative retinopathy is associated with recent vitreous hemorrhages or in which extensive new vessels are located on or near the optic disk. Macular edema, which is more common than proliferative retinopathy in patients with type 2 diabetes (up to 20% prevalence), has a guarded prognosis, but it has also responded to scatter therapy with improvement in visual acuity if detected early. Injection of bevacizumab (Avastin), an anti-vascular endothelial growth factor (anti-VEGF), into the eye has been shown to stop the growth of the new blood vessels in diabetic eye disease. Avoiding tobacco use and correction of associated hypertension are important therapeutic measures in the management of diabetic retinopathy. There is no contraindication to using aspirin in patients with proliferative retinopathy.

3. Glaucoma—Glaucoma occurs in approximately 6% of persons with diabetes. It is responsive to the usual therapy for open-angle disease. Neovascularization of the iris in diabetics can predispose to closed-angle glaucoma, but this is relatively uncommon except after cataract extraction, when growth of new vessels has been known to progress rapidly, involving the angle of the iris and obstructing outflow.

B. Diabetic Nephropathy

As many as 4000 cases of end-stage chronic kidney disease occur each year among diabetic people in the United States. This is about one-third of all patients being treated for end-stage chronic kidney disease and represents a considerable national health expense.

The cumulative incidence of nephropathy differs between the two major types of diabetes. Patients with type 1 diabetes have a 30–40% chance of having nephropathy after 20 years—in contrast to the much lower frequency in type 2 diabetes patients, in whom only about 15–20% develop clinical kidney disease. However, since there are many more individuals affected with type 2 diabetes, end-stage chronic kidney disease is much more prevalent in type 2 than in type 1 diabetes in the United States and especially

throughout the rest of the world. Improved glycemic control and more effective therapeutic measures to correct hypertension—and with the beneficial effects of ACE inhibitors—can reduce the development of end-stage chronic kidney disease among diabetics.

Diabetic nephropathy is initially manifested by proteinuria; subsequently, as kidney function declines, urea and creatinine accumulate in the blood.

1. Microalbuminuria—Sensitive radioimmunoassay methods of detecting small amounts of urinary albumin have permitted detection of microgram concentrations—in contrast to the less sensitive dipstick strips, whose minimal detection limit is 0.3–0.5%. Conventional 24-hour urine collections, in addition to being inconvenient for patients, also show wide variability of albumin excretion, since several factors such as sustained erect posture, dietary protein, and exercise tend to increase albumin excretion rates. For these reasons, a timed overnight urine collection or albumin-creatinine ratio in an early morning spot urine collected upon awakening is preferable. Normal subjects excrete less than 15 mcg/min during overnight urine collections; values of 20 mcg/min or higher are considered to represent abnormal microalbuminuria. In the early morning spot urine, a ratio of albumin (mcg/L) to creatinine (mg/L) of < 30 mcg/mg creatinine is normal, and a ratio of 30–300 mcg/mg creatinine suggests abnormal microalbuminuria. At least two of three timed overnight or early morning spot urine collections over a 3- to 6-month period should be abnormal before a diagnosis of microalbuminuria is justified.

Subsequent end-stage chronic kidney disease can be predicted by persistent urinary albumin excretion rates exceeding 30 mcg/min. Increased microalbuminuria correlates with increased levels of blood pressure and increased LDL cholesterol, and this may explain why increased proteinuria in diabetic patients is associated with an increase in cardiovascular deaths even in the absence of end-stage chronic kidney disease. Glycemic control as well as a low-protein diet (0.8 g/kg/d) may reduce both the hyperfiltration and the elevated microalbuminuria in patients in the early stages of diabetes and those with incipient diabetic nephropathy. Antihypertensive therapy also decreases microalbuminuria. Evidence from some studies—but not the UKPDS—supports a specific role for ACE inhibitors in reducing intraglomerular pressure in addition to their lowering of systemic hypertension. An ACE inhibitor (captopril, 50 mg twice daily) in normotensive diabetics impedes progression to proteinuria and prevents the increase in albumin excretion rate. Since microalbuminuria has been shown to correlate with elevated *nocturnal* systolic blood pressure, it is possible that “normotensive” diabetic patients with microalbuminuria have slightly elevated systolic blood pressure during sleep, which is lowered during antihypertensive therapy. This action may contribute to the reported efficacy of ACE inhibitor drugs in reducing microalbuminuria in “normotensive” patients.

2. Progressive diabetic nephropathy—Progressive diabetic nephropathy consists of proteinuria of varying severity occasionally leading to nephrotic syndrome with hypoalbuminemia, edema, and an increase in circulating LDL cholest-

terol as well as progressive azotemia. In contrast to all other kidney disorders, the proteinuria associated with diabetic nephropathy does not diminish with progressive end-stage chronic kidney disease (patients continue to excrete 10–11 g daily as creatinine clearance diminishes). As end-stage chronic kidney disease progresses, there is an elevation in the renal threshold at which glycosuria appears.

Hypertension develops with progressive kidney involvement, and coronary and cerebral atherosclerosis seems to be accelerated. Approximately two-thirds of adult patients with diabetes have hypertension. Once diabetic nephropathy has progressed to the stage of hypertension, proteinuria, or early chronic kidney disease, glycemic control is not beneficial in influencing its course. In this circumstance, antihypertensive medications, including ACE inhibitors, and restriction of dietary protein to 0.8 g/kg body weight per day are recommended. ACE inhibitors have been shown to protect against deterioration in kidney function in type 1 diabetic patients with clinical nephropathy. This beneficial effect appears to be due to improved glomerular hemodynamics that cannot be explained only by the antihypertensive action of these drugs. Captopril (25 mg three times daily) has shown a 50% reduction in the risk of the combined end points of death, dialysis, and transplantation in type 1 subjects with diabetic nephropathy and clinical proteinuria. During initiation of ACE inhibitor therapy, an increment in serum creatinine greater than 2 mg/dL due to a rapid fall in intraglomerular pressure—or the occurrence of persistent hyperkalemia (above 6 mEq/L) due to hyporeninemic hypoaldosteronism—is an indication to stop this medication.

Dialysis has been of limited value in the long-term treatment of chronic kidney disease due to diabetic nephropathy. At present, experience in kidney transplantation—especially from related donors—is more promising and is the treatment of choice in cases where there are no contraindications such as severe cardiovascular disease.

C. Diabetic Neuropathy

Diabetic neuropathies are the most common complications of diabetes affecting up to 50% of older patients with type 2 diabetes.

1. Peripheral neuropathy

A. DISTAL SYMMETRIC POLYNEUROPATHY—This is the most common form of diabetic peripheral neuropathy where loss of function appears in a stocking-glove pattern and is due to an axonal neuropathic process. Longer nerves are especially vulnerable, hence the impact on the foot. Both motor and sensory nerve conduction is delayed in the peripheral nerves, and ankle jerks may be absent.

Sensory involvement usually occurs first and is generally bilateral, symmetric, and associated with dulled perception of vibration, pain, and temperature. The pain can range from mild discomfort to severe incapacitating symptoms (see below). The sensory deficit may eventually be of sufficient degree to prevent patients from feeling pain. Patients who have a sensory neuropathy should therefore be examined with a 5.07 Semmes Weinstein filament and

those who cannot feel the filament must be considered at risk for unperceived neuropathic injury.

The denervation of the small muscles of the foot result in clawing of the toes and displacement of the submetatarsal fat pads anteriorly. These changes, together with the joint and connective tissue changes, alter the biomechanics of the foot and increase plantar pressures. This combination of decreased pain threshold, abnormally high foot pressures, and repetitive stress (such as from walking) can lead to calluses and ulcerations in the high-pressure areas such as over the metatarsal heads (Plate 92). Peripheral neuropathy, autonomic neuropathy, and trauma also predisposes to the development of Charcot arthropathy. An acute case of Charcot foot arthropathy presents with pain and swelling, and if left untreated, leads to a “rocker bottom” deformity and ulceration. The early radiologic changes show joint subluxation and periarticular fractures. As the process progresses, there is frank osteoclastic destruction leading to deranged and unstable joints particularly in the midfoot. Not surprisingly, the key issue for the healing of neuropathic ulcers in a foot with good vascular supply is mechanical unloading. In addition, any infection should be treated with debridement and appropriate antibiotics; healing duration of 8–10 weeks is typical. Occasionally, when healing appears refractory, **platelet-derived growth factor** (becaplermin [Regranex]) should be considered for local application. A post-marketing epidemiologic study showed increased cancer deaths in patients who had used three or more tubes of becaplermin on their leg or feet ulcers, and there is now a “black box” warning on the drug label. Once ulcers are healed, therapeutic footwear is key to preventing recurrences. Custom molded shoes are reserved for patients with significant foot deformities. Other patients with neuropathy may require accommodative insoles that distribute the load over as wide an area as possible. Patients with foot deformities and loss of their protective threshold should get regular care from a podiatrist. Patients should be educated on appropriate footwear and those with loss of their protective threshold should be instructed to inspect their feet daily for reddened areas, blisters, abrasions, or lacerations.

B. ISOLATED PERIPHERAL NEUROPATHY—Involvement of the distribution of only one nerve (“mononeuropathy”) or of several nerves (“mononeuropathy multiplex”) is characterized by sudden onset with subsequent recovery of all or most of the function. This neuropathology has been attributed to vascular ischemia or traumatic damage. Cranial and femoral nerves are commonly involved, and motor abnormalities predominate. The patient with cranial nerve involvement usually has diplopia and single third, fourth, or sixth nerve weakness on examination but the pupil is spared. A full recovery of function occurs in 6–12 weeks. Diabetic amyotrophy presents with onset of severe pain in the front of the thigh. Within a few days or weeks of the onset of pain, weakness and wasting of the quadriceps develops. As the weakness appears, the pain tends to improve. Management includes analgesia and improved diabetes control. The symptoms improve over 6–18 months.

C. PAINFUL DIABETIC NEUROPATHY—Hypersensitivity to light touch and occasionally severe “burning” pain, particularly at night, can become physically and emotionally dis-

abling. Amitriptyline, 25–75 mg at bedtime, has been recommended for pain associated with diabetic neuropathy. Dramatic relief has often resulted within 48–72 hours. This rapid response is in contrast to the 2 or 3 weeks required for an antidepressive effect. Patients often attribute the benefit to having a full night's sleep. Mild to moderate morning drowsiness is a side effect that generally improves with time or can be lessened by giving the medication several hours before bedtime. This drug should not be continued if improvement has not occurred after 5 days of therapy. If amitriptyline's anticholinergic effects are too troublesome, then nortriptyline can be used. Desipramine in doses of 25–150 mg/d seems to have the same efficacy as amitriptyline. Tricyclic antidepressants, in combination with the phenothiazine, fluphenazine, have been shown in two studies to be efficacious in painful neuropathy, with benefits unrelated to relief of depression. Gabapentin (900–1800 mg/d in three divided doses) has also been shown to be effective in the treatment of painful neuropathy and should be tried if the tricyclic drugs prove ineffective. Pregabalin, a congener of gabapentin, has been shown in an 8-week study to be more effective than placebo in treating painful diabetic peripheral neuropathy. However, this drug was not compared with an active control. Also, because of its abuse potential, it has been categorized as a schedule V controlled substance. Duloxetine, a serotonin and norepinephrine reuptake inhibitor, has been approved for the treatment of painful diabetic neuropathy. In clinical trials, this drug reduced the pain sensitivity score by 40–50%. Capsaicin, a topical irritant, has been found to be effective in reducing local nerve pain; it is dispensed as a cream (Zostrix 0.025%, Zostrix-HP 0.075%) to be rubbed into the skin over the painful region two to four times daily. Gloves should be used for application since hand contamination could result in discomfort if the cream comes in contact with eyes or sensitive areas such as the genitalia.

Diabetic neuropathic cachexia is a syndrome characterized by a symmetric peripheral neuropathy associated with profound weight loss (up to 60% of total body weight) and painful dysesthesias affecting the proximal lower limbs, the hands, or the lower trunk. Treatment is usually with insulin and analgesics. The prognosis is generally good, and patients typically recover their baseline weight with resolution of the painful sensory symptoms within 1 year.

2. Autonomic neuropathy—With autonomic neuropathy, there is evidence of postural hypotension, decreased cardiovascular response to the Valsalva maneuver, gastroparesis, alternating bouts of diarrhea (particularly nocturnal) and constipation, inability to empty the bladder, and impotence. Gastroparesis should be considered in type 1 diabetic patients in whom unexpected fluctuations and variability in their blood glucose levels develops after meals. Impotence due to neuropathy differs from psychogenic impotence in that the latter may be intermittent (erections occur under special circumstances), whereas diabetic impotence is usually persistent; aortoiliac occlusive disease may contribute to this problem.

A. MANAGEMENT OF AUTONOMIC NEUROPATHY—There is no consistently effective treatment for diabetic autonomic

neuropathy. Metoclopramide has been of some help in treating diabetic gastroparesis over the short term, but its effectiveness seems to diminish over time. It is a dopamine antagonist that has central antiemetic effects as well as a cholinergic action to facilitate gastric emptying. It is given in a dose of 10 mg orally three or four times a day, 30 minutes before meals and at bedtime. Drowsiness, restlessness, fatigue, and lassitude are common adverse effects. Tardive dyskinesia and extrapyramidal effects also occur. Erythromycin appears to bind to motilin receptors in the stomach and has been found to improve gastric emptying in doses of 250 mg three times daily. Tegaserod (Zelnorm), the partial 5-HT₄ agonist, has been withdrawn from the US market by the FDA, so it is no longer used for this indication. In selected patients, injections of botulinum toxin into the pylorus can reduce pylorus sphincter resistance and enhance gastric emptying. Gastric electrical stimulation has been reported to improve symptoms and quality of life indices in patients with gastroparesis refractory to pharmacologic therapy. Diarrhea associated with autonomic neuropathy has occasionally responded to broad-spectrum antibiotic therapy, although it often undergoes spontaneous remission. Refractory diabetic diarrhea is often associated with impaired sphincter control and fecal incontinence. Therapy with loperamide, 4–8 mg daily, or diphenoxylate with atropine, two tablets up to four times a day, may provide relief. In more severe cases, tincture of paregoric or codeine (60-mg tablets) may be required to reduce the frequency of diarrhea and improve the consistency of the stools. Clonidine has been reported to lessen diabetic diarrhea; however, its usefulness is limited by its tendency to lower blood pressure in these patients who already have autonomic neuropathy, resulting in orthostatic hypotension. Constipation usually responds to stimulant laxatives such as senna. Bethanechol in doses of 10–50 mg three times a day has occasionally improved emptying of the atonic urinary bladder. Catheter decompression of the distended bladder has been reported to improve its function, and considerable benefit has been reported after surgical severing of the internal vesicle sphincter. Mineralocorticoid therapy with fludrocortisone, 0.2–0.3 mg/d, and elastic stockings or pressure suits have reportedly been of some help in patients with orthostatic hypotension occurring as a result of loss of postural reflexes.

B. MANAGEMENT OF ERECTILE DYSFUNCTION—There are medical, mechanical, and surgical treatments available for treatment of erectile dysfunction. Penile erection depends on relaxation of the smooth muscle in the arteries of the corpus cavernosum, and this is mediated by nitric oxide-induced cyclic 3',5'-guanosine monophosphate (cGMP) formation. cGMP-specific phosphodiesterase type 5 (PDE5) inhibitors impair the breakdown of cGMP and improve the ability to attain and maintain an erection. Sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis) have been shown in placebo-controlled clinical trials to improve erections in response to sexual stimulation. The recommended dose of sildenafil for most patients is one 50-mg tablet taken approximately 1 hour before sexual activity. The peak effect is at 1.5–2 hours, with some effect persisting for 4 hours.

Patients with diabetes mellitus using sildenafil reported 50–60% improvement in erectile function. The maximum recommended dose is 100 mg. The recommended dose of both vardenafil and tadalafil is 10 mg. The doses may be increased to 20 mg or decreased to 5 mg based on efficacy and side effects. Tadalafil has been shown to improve erectile function for up to 36 hours after dosing. In clinical trials, only a few adverse effects have been reported—transient mild headache, flushing, dyspepsia, and some altered color vision. Priapism can occur with these drugs and patients should be advised to seek immediate medical attention if an erection persists for longer than 4 hours. The PDE5 inhibitors potentiate the hypotensive effects of nitrates and their use is contraindicated in patients who are concurrently using organic nitrates in any form. Caution is advised for men who have suffered a heart attack, stroke, or life-threatening arrhythmia within the previous 6 months; men who have resting hypotension or hypertension; and men who have a history of cardiac failure or have unstable angina. Rarely, a decrease in vision or permanent visual loss has been reported after PDE5 inhibitor use.

Intracorporeal injection of vasoactive drugs causes penile engorgement and erection. Drugs most commonly used include papaverine alone, papaverine with phentolamine, and alprostadil (prostaglandin E₁). Alprostadil injections are relatively painless, but careful instruction is essential to prevent local trauma, priapism, and fibrosis. Intraurethral pellets of alprostadil avoid the problem of injection of the drug.

External vacuum therapy (Erec-Aid System) is a nonsurgical treatment consisting of a suction chamber operated by a hand pump that creates a vacuum around the penis. This draws blood into the penis to produce an erection which is maintained by a specially designed tension ring inserted around the base of the penis and which can be kept in place for up to 20–30 minutes. While this method is generally effective, its cumbersome nature limits its appeal.

In view of the recent development of nonsurgical approaches to therapy of erectile dysfunction, resort to surgical implants of penile prostheses is becoming less common.

D. Cardiovascular Complications

1. Heart disease—Microangiopathy occurs in the heart and may explain the etiology of congestive cardiomyopathies in diabetic patients who do not have demonstrable coronary artery disease. More commonly, however, heart disease in patients with diabetes is due to coronary atherosclerosis. Myocardial infarction is three to five times more common in diabetic patients and is the leading cause of death in patients with type 2 diabetes. Cardiovascular disease risk is increased in patients with type 1 diabetes as well, although the absolute risk is lower than in patients with type 2 diabetes. Premenopausal women who normally have lower rates of coronary artery disease lose this protection once diabetes develops. The increased risk in patients with type 2 diabetes reflects the combination of hyperglycemia, hyperlipidemia, abnormalities of platelet adhesiveness, coagulation factors, hypertension, oxidative stress, and inflammation. Large intervention studies of risk factor reduction in diabetes are lacking, but it

is reasonable to assume that reducing these risk factors would have a beneficial effect. Lowering LDL cholesterol reduces first events in patients without known coronary disease and secondary events in patients with known coronary disease. These intervention studies included some patients with diabetes, and the benefits of LDL cholesterol lowering was apparent in this group. The National Cholesterol Education Program clinical practice guidelines have designated diabetes as a coronary risk equivalent and have recommended that patients with diabetes should have an LDL cholesterol goal of < 100 mg/dL.

The ADA also recommends lowering blood pressure to 130/80 mm Hg or less. The Heart Outcomes Prevention Evaluation (HOPE) study randomized 9297 high-risk patients who had evidence of vascular disease or diabetes plus one other cardiovascular risk factor to receive ramipril or placebo for a mean of 5 years. Treatment with ramipril resulted in a 25% reduction of the risk of myocardial infarction, stroke, or death from cardiovascular disease. The mean difference between the placebo and ramipril group was 2.2 mm Hg systolic and 1.4 mm Hg diastolic blood pressure. The reduction in cardiovascular event rate remained significant after adjustment for this small difference in blood pressure. The mechanism underlying this protective effect of ramipril is unknown. Patients with type 2 diabetes who already have cardiovascular disease or microalbuminuria should therefore be considered for treatment with an ACE inhibitor. More clinical studies are needed to address the question of whether patients with type 2 diabetes who do not have cardiovascular disease or microalbuminuria would specifically benefit from ACE inhibitor treatment.

Aspirin at a dose of 81–325 mg daily has been shown to effectively inhibit thromboxane synthesis by platelets and reduce the risk of diabetic atherothrombosis without increasing risks of gastrointestinal hemorrhage. Use of low-dose enteric-coated aspirin is recommended in diabetic adults with evident macrovascular disease or in those with increased cardiovascular risk factors or those older than 30 years. Contraindications for aspirin therapy are patients with aspirin allergy, bleeding tendency, recent gastrointestinal bleeding, or active hepatic disease. The Early Treatment Diabetic Retinopathy Study (ETDRS) showed that aspirin does not influence the course of proliferative retinopathy. There was no statistically significant difference in the severity of vitreous/preretinal hemorrhages or their rate of resolution between the aspirin and placebo groups. Thus, it appears that there is no contraindication to aspirin use to achieve cardiovascular benefit in diabetic patients who have proliferative retinopathy.

2. Peripheral vascular disease—Atherosclerosis is markedly accelerated in the larger arteries. It is often diffuse, with localized enhancement in certain areas of turbulent blood flow, such as at the bifurcation of the aorta or other large vessels. Clinical manifestations of peripheral vascular disease include ischemia of the lower extremities, impotence, and intestinal angina.

The incidence of **gangrene of the feet** in diabetics is 30 times that in age-matched controls. The factors responsible for its development, in addition to peripheral vascular
